During the peak year of preoperations, fewer than 5 people would be expected to in-migrate into the ROI, leading to essentially no increase over ROI-forecasted baseline revenues and expenditures (Table E.13). In the first year of operations, 190 in-migrants would be expected, leading to an increase of 0.1% in local revenues and expenditures.

E.3.5.3.2 Impacts from a Cylinder Transfer Facility

During the peak year of construction of a cylinder transfer facility, 130 direct jobs would be created at the site and 160 additional jobs indirectly in the ROI (Table E.13) as a result of the spending of employee wages and salaries and procurement-related expenditures. Overall, 290 jobs would be created. Construction activity would also produce direct and indirect income in the ROI surrounding the site, with $9 million of total income produced during the peak year. During the first year of operations of the cylinder transfer facility, 510 direct and indirect jobs would be created. Direct and indirect income would also be produced in the ROI, with $13 million in total income produced. Construction and operation of the transfer facility would result in an increase in the projected baseline compound annual average growth rate in ROI employment of 0.01 percentage points from 1999 through 2028.

Construction of the cylinder transfer facility would be expected to generate direct in-migration of 170 in the peak year (Table E.13). Additional indirect job in-migration would also be expected, bringing the total number of in-migrants to 220 in the peak year. Operation of the cylinder transfer facility would be expected to generate direct and indirect job in-migration of 240 in the first year of operations. Construction and operation of the transfer facility would result in an increase in the projected baseline compound annual average growth rate in ROI population of 0.004 percentage points from 1999 through 2028.

The cylinder transfer facility would generate a demand for 80 additional rental housing units during the peak year of construction, representing an impact of 1.5% on the projected number of vacant rental housing units in the ROI (Table E.13). A demand for 90 additional owner-occupied housing units would be expected in the first year of operations, representing an impact of 0.8% on the number of vacant owner-occupied housing units in the ROI.

During the peak year of construction, 220 people would be expected to in-migrate into the ROI, leading to an increase of 0.04% over ROI-forecasted baseline revenues and expenditures (Table E.13). In the first year of operations, 240 in-migrants would be expected, leading to an increase of 0.04% in local revenues and expenditures.

E.3.5.3.3 Impacts from Standard Cylinder Preparation

During the peak year of preoperational activities for standard cylinder preparation, fewer than 5 direct jobs would be created at the site and fewer than 5 additional jobs indirectly in the ROI (Table E.13) as a result of the spending of employee wages and salaries and procurement-related expenditures. Overall, fewer than 5 jobs would be created. Preoperational activities would also produce direct and indirect income in the ROI surrounding the site, with $0.1 million of total income produced during the peak year. During the first year of operations for standard cylinder preparation, 100 direct and indirect jobs would be created. Direct and indirect income would also be produced in the ROI, with $3 million in total income produced. Preoperational and operational activities for standard cylinder preparation would result in an increase in the projected baseline compound annual average growth rate in ROI employment of 0.01 percentage points from 1999 through 2028.

Preoperational activities for standard cylinder preparation would be expected to generate direct in-migration of fewer than 5 in the peak year (Table E.13). Additional indirect job in-migration would also be expected, bringing the total number of in-migrants to fewer than 5 in the peak year. Operational activities for cylinder preparation would be expected to generate direct and indirect job in-migration of 80 in the first year of operations. Preoperational and operational activities would result in an increase in the projected baseline compound annual average growth rate in ROI population of 0.001 percentage points from 1999 through 2028.

Standard cylinder preparation activities would generate a demand for fewer than 5 additional rental housing unit during the peak year of preoperations, representing essentially no impact on the projected number of vacant rental housing units in the ROI (Table E.13). A demand for 30 additional owner-occupied housing units would be expected in the first year of operations, representing an impact of 0.3% on the number of vacant owner-occupied housing units in the ROI.

During the peak year of preoperations, fewer than 5 people would be expected to in-migrate into the ROI, leading to essentially no increase over ROI-forecasted baseline revenues and expenditures (Table E.13). In the first year of operations, 80 in-migrants would be expected, leading to an increase of 0.01% in local revenues and expenditures.

E.3.6 Ecology

Predicted concentrations of contaminants in environmental media were compared with benchmark values of toxic and radiological effects to assess impacts to terrestrial and aquatic biota. Discussion of assessment methodology is presented in Appendix C.

No ecological impacts would be expected during preparation of standard cylinders. Under the cylinder overcontainer option, no site preparation or construction would occur. Normal operations would not result in impacts to surface water, groundwater, or soil (Section E.3.4). Atmospheric releases of contaminants would include only criteria pollutants, and emission levels

would be expected to be extremely low (Section E.3.3). Therefore, impacts of the cylinder overcontainer option to ecological resources would be negligible.

Impacts to ecological resources could result from construction of a cylinder transfer facility. Impacts could include mortality of individual organisms, habitat loss, or changes in biotic communities. Impacts due to operation of a cylinder transfer facility could result from exposure to airborne contaminants or contaminants released to soils, groundwater, or surface waters or changes in surface water or groundwater quality or flow rates.

E.3.6.1 Paducah Site

Site preparation for the construction of a cylinder transfer facility at the Paducah site would require the disturbance of approximately 21 acres (9 ha), including the permanent replacement of approximately 15 acres (6 ha), primarily with structures and paved areas. Existing vegetation would be destroyed during land clearing activities. Determination of the vegetation communities that would be eliminated by site preparation would depend on the exact location of the facility. Communities occurring on undeveloped land at the site are relatively common and well represented in the vicinity of the site; however, impacts to high quality native plant communities might occur if facility construction required disturbance to vegetation communities outside of the currently fenced site area (see Section E.3.9 for a discussion of land use). Construction of the transfer facility would not be expected to threaten the local population of any species. The loss of up to 21 acres (9 ha) of undeveloped land would constitute a moderate adverse impact to vegetation. Erosion of exposed soil at the construction site could reduce the effectiveness of restoration efforts and create sedimentation downgradient of the site. The implementation of standard erosion control measures, installation of storm-water retention ponds, and immediate replanting of disturbed areas with native species would help minimize impacts to vegetation. Impacts due to facility construction are shown in Table E.14.

TABLE E.14 Potential Impacts to Ecological Resources from Construction of the Cylinder Transfer Facility at the Paducah Site

Resource	Type of Impact	Degree of Impact
Vegetation	Loss of 21 acres	Moderate adverse impact
Wildlife	Loss of 15 to 21 acres	Moderate adverse impact
Wetlands	Loss, degradation	Potential adverse impact
Aquatic species	Water quality, habitat reduction	Negligible impact
Protected species	Destruction, habitat loss	Potential adverse impact

Wildlife would be disturbed by land clearing, noise, and human presence. Wildlife with restricted mobility, such as burrowing species or juveniles of nesting species, would be destroyed during land-clearing activities. More mobile individuals would relocate to adjacent available areas with suitable habitat. Population densities and competition would increase in these areas, potentially reducing the chances of survival or reproductive capacity of displaced individuals. Some wildlife species would be expected to quickly recolonize replanted areas near the facility following completion of construction. The permanent loss of 15 to 21 acres (6 to 9 ha) of habitat would not be expected to threaten the local population of any wildlife species because similar habitat would be available in the vicinity of the site. Construction of a cylinder transfer facility would be considered a moderate adverse impact to wildlife.

Impacts to surface water and groundwater quality during construction are expected to be negligible (Section E.3.4). Thus, construction-derived impacts to aquatic biota would also be expected to be negligible. Wetlands could potentially be impacted by filling or draining during construction. In addition, impacts to wetlands due to alteration of surface water runoff patterns, soil compaction, or groundwater flow could occur if the facility were located immediately adjacent to wetland areas. However, impacts to wetlands would be minimized by maintaining a buffer area around wetlands during construction of the facility. Unavoidable impacts to wetlands would require a *Clean Air Act* Section 404 permit, which might stipulate mitigative measures. Additional permitting might be required by state agencies.

Critical habitat has not been designated for any federal- or state-listed threatened or endangered species at the Paducah site. Prior to construction of the transfer facility, a survey would be conducted for federal- and state-listed threatened, endangered, or candidate species, or species of special concern. Impacts to these species could thus be avoided or, when impacts were unavoidable, appropriate mitigation could be developed.

Water withdrawal from surface waters or groundwater, as well as wastewater discharge, during facility construction and operation could potentially alter water levels. The changes in water levels could in turn affect aquatic ecosystems, including wetlands, such as those located along the periphery of these surface water bodies. However, water-level changes due to water withdrawal and wastewater discharge would be negligible (Section E.3.4). Therefore, impacts to wetlands and aquatic communities would be expected to be negligible.

Ecological resources in the vicinity of the transfer facility would be exposed to atmospheric emissions from the boiler stack and process stack; however, emission levels would be expected to be extremely low (Section E.3.3.1), well below concentrations known to adversely affect biota. Resulting impacts to biota would be expected to be negligible. Impacts due to facility operation are shown in Table E.15.

TABLE E.15 Potential Impacts to Ecological Resources from Operation of the Cylinder Transfer Facility at the Paducah Site

Contaminant	Biota	Maximum Exposure	Impact
HF	Wildlife	3.1×10^{-5} µg/m^3	Negligible
UO_2F_2 in air	Wildlife	2.1×10^{-6} µg/m^3	Negligible
Uranium in surface water	Aquatic	112 µg/L	Negligible

Effluent discharges to surface waters could contain a number of chemical contaminants. Facility wastewater would have a uranium concentration of about 112 µg/L in the undiluted effluent (Section E.3.4.1). Dilution of the discharge in the receiving stream by a factor in excess of 150,000 would result in negligible concentrations (Section E.3.4.1). Thus, impacts to aquatic biota in the vicinity of the outfall would be negligible.

Facility accidents, as discussed in Section E.3.2, could result in adverse impacts to ecological resources. The affected species and degree of impact would depend on a number of factors such as location of the accident, season, and meteorological conditions.

E.3.6.2 Portsmouth Site

Construction of a cylinder transfer facility at the Portsmouth site would result in the types of impacts associated with the Paducah facility. However, a smaller area would be required. Facility construction would disturb approximately 14 acres (6 ha), including the permanent replacement of 10 acres (4 ha), primarily with structures and paved areas. Construction of the transfer facility would not be expected to threaten the local population of any species. In addition to site-specific surveys for protected species, avoidance of wooded areas would reduce the potential for impacts to the sharp-shinned hawk (state-listed as endangered) and Indiana bat (federal- and state-listed as endangered). The loss of up to 14 acres (6 ha) of undeveloped land and 10 to 14 acres (4 to 6 ha) of habitat would constitute a moderate adverse impact to vegetation and wildlife.

Operation of a cylinder transfer facility at the Portsmouth site would result in lower atmospheric emissions of contaminants than predicted for the Paducah facility. Resulting impacts to biota would, therefore, also be negligible. Uranium concentrations in discharges to surface water would be slightly lower than predicted for the Paducah facility. Resulting impacts to aquatic biota would also be negligible.

E.3.6.3 K-25 Site

Construction of a cylinder transfer facility at the K-25 site would result in the types of impacts associated with the Paducah and Portsmouth facilities. However, a smaller area would be required. Facility construction would disturb approximately 12 acres (5 ha), including the permanent replacement of 8 acres (3 ha), primarily with structures and paved areas. Construction of the transfer facility would not be expected to threaten the local population of any species. The loss of up to 12 acres (5 ha) of undeveloped land and 9 to 12 acres (4 to 5 ha) of habitat would constitute a moderate adverse impact to vegetation and wildlife.

Operation of a cylinder transfer facility at the K-25 site would result in lower atmospheric emissions of contaminants than predicted for the Paducah or Portsmouth facilities. Resulting impacts to biota would, therefore, also be negligible. Uranium concentrations in discharges to surface water would be slightly lower than predicted for the Paducah or Portsmouth facilities. Resulting impacts to aquatic biota would also be negligible.

E.3.7 Waste Management

Estimates of waste generation were based on the total number of cylinders at each site. No liquid wastes would be expected at the sites as a result of cylinder shipment activities from either standard cylinders or cylinders in overcontainers. The only solid waste generated in these activities would be personal protective equipment and wipes and rags that would be used to remove surface contamination on the cylinders. These wastes are categorized as combustible solid low-level radioactive waste (LLW) and are shown in Table E.16 for each of the three sites. It was assumed that the LLW would be generated during removal of surface contamination and would be independent of the cylinders being standard or substandard. Thus, the amount of waste in this operation would be proportional to the total number of cylinders at the site. It was assumed that no cylinder breaches would occur inside the overcontainers during transportation.

The waste input resulting from the cylinder overcontainer operations would have minimal impact on radioactive waste management capabilities at any of the three sites or on a national level. The impact on site nonradiological waste management would also be negligible.

The estimated total quantities of solid and liquid wastes generated from activities associated with the construction of the cylinder transfer facility are shown in Table E.17. The type and quantity of solid and liquid waste expected to be generated from the operation of the cylinder transfer facility are shown in Table E.18, based on a throughput cylinder capacity of 5% of the total cylinder inventory at each site. The different types of waste generated during the operation of this facility would include LLW, low-level mixed waste (LLMW), hazardous waste, and nonhazardous waste.

TABLE E.16 Waste Generated with Activities for Cylinder Overcontainers or Standard Cylinder Preparation[a]

	Waste Generated		
Site	Waste Type[b]	Annual Volume (m^3/yr)	Uranium Form
Paducah	LLW (combustible solids)	12.7	UO_2F_2
Portsmouth	LLW (combustible solids)	7.0	UO_2F_2
K-25	LLW (combustible solids)	2.8	UO_2F_2

[a] Decontamination of the overcontainer surfaces was assumed to be performed at the conversion/storage facility prior to the overcontainer being sent back to the site for reuse.

[b] It was assumed that the low-level waste would be generated during removal of surface contamination and would be independent of the cylinder being standard or substandard.

TABLE E.17 Total Wastes Generated during Construction of the Cylinder Transfer Facility: Base Case

Waste Category	Quantity
Hazardous solids	38 m^3
Hazardous liquids	20,000 gal
Nonhazardous solids	
Concrete	76 m^3
Steel	30 tons
Other	612 m^3
Nonhazardous liquids	
Sanitary	3 million gal
Other	1 million gal

TABLE E.18 Estimated Annual Radioactive, Hazardous, and Nonhazardous Wastes Generated during Operation of the Cylinder Transfer Facility at the Three Sites

Type of Waste	Description of Waste	Annual Volume (m^3)			Contaminants
		Paducah	Portsmouth	K-25	
Low-Level Waste					
Combustible solids	Gloves, wipes, clothing, etc.	91	43	15	17 lb UO_2F_2
Metal, surface-contaminated	Failed equipment	12	5.3	2.2	16 lb UO_2F_2
Noncombustible compactible solids	HEPA filters	46	11	8.0	54 lb UO_2F_2
	Grouted waste	2.8	1.3	0.44	135 lb $UO_2(OH)_2$
Other	Lab packs (chemicals)	0.5	0.27	0.11	0.75 lb UO_2F_2
Low-Level Mixed Waste					
Lab packs	Chemicals	0.3	0.13	0.04	0.37 lb UO_2F_2
Inorganic process debris	Failed equipment	0.3	0.13	0.04	0.37 lb UO_2F_2
Combustible debris	Wipes, etc.	0.3	0.13	0.04	0.07 lb UO_2F_2
Hazardous Waste					
Organic liquids	Solvents, oil, paint, thinner	0.8	0.35	0.18	
Inorganic process debris	Failed equipment	1.2	0.6	0.26	1.5 lb HF, 2 lb NaOH
Combustible debris	Wipes, etc.	1.2	0.6	0.26	0.75 lb HF, 1 lb NaOH
Nonhazardous Waste					
Nonhazardous solid waste	Nonhazardous solid waste	87	46	20	
Nonhazardous liquid waste	Cooling tower blowdown process water, etc.	460	220	76	
Recyclable waste	Recyclable waste	180	85	30	

Notation: HEPA = high-efficiency particulate air (filters); HF = hydrogen fluoride; NaOH = sodium hydroxide; UO_2F_2 = uranyl fluoride; $UO_2(OH)_2$ = uranyl hydroxide.

The primary waste produced in the transfer process would be empty UF_6 cylinders and grouted waste drums. Radioactive or hazardous liquid materials would include decontamination liquids, laboratory liquid wastes, contaminated cleaning solution, lubricants, and paints. Radioactive or hazardous solid wastes would include failed process equipment, HEPA filters, laboratory wastes, wipes, rags, and operator-contaminated clothing. The LLW would be shipped off-site for disposal, and the LLMW and hazardous waste would be shipped off-site for both treatment and disposal. The total volume of crushed, empty UF_6 cylinders would be about 125,000 m^3. For the PEIS analysis, it was assumed that the treated cylinders would become part of the DOE scrap metal inventory. If a disposal decision were made, the treated cylinders could be disposed of as LLW, representing a 3% addition to the total projected DOE complex-wide LLW disposal volume.

Overall, the waste input resulting from construction and operation of a transfer facility would add about 7% to the Paducah site LLW generation and less at the Portsmouth and K-25 sites

(see Appendix C, Table C.3), based on the different-sized treatment facilities at each site. The input of LLMW and nonhazardous wastes from the transfer facility would represent less than 1% of each site's LLMW or nonhazardous waste loads.

The waste input resulting from the construction and operation of the transfer facility would have minimal impact on radioactive waste management capabilities at any of the three sites. The impact on nonradiological site waste management would also be negligible. The impacts of waste resulting from the operation of the depleted UF_6 transfer facility on national waste management capabilities would be negligible.

E.3.8 Resource Requirements

Cylinder overcontainers would be constructed primarily from steel purchased from existing steel vendors. The preliminary overcontainer design requires approximately 8,000 lb (3,600 kg) of steel per overcontainer (LLNL 1997). Resources would be required only for the construction of overcontainers. No substantial resources would be required for the use of the overcontainers. Because the overcontainers would be reusable, it is estimated that the total number of overcontainers required would be approximately 581 (LLNL 1997). This total assumes a 10% contingency for spares, unforeseen delays, and the few overcontainers that might be needed at the cylinder treatment facility. The total amount of steel required for the overcontainers would be about 4,640,000 lb (2,110,000 kg). Based upon the total steel required for construction of overcontainers, no impact on local or national steel availability or production would be expected (Standard & Poor's 1996; U.S. Bureau of the Census 1996). No other materials of significant quantity would be required.

Resource needs for the cylinder transfer facility are presented in Table E.19 as utilities consumed during construction and operations at the three sites. The facility was assumed to operate 24 hours per day, 7 days per week, and 292 days per year for an 80% plant availability during operations.

The process equipment would be purchased from equipment vendors. The total quantities of commonly used construction material (i.e., steel) for equipment would be minor as compared to the quantities for construction. The primary specialty material used for equipment fabrication is at most approximately 7 tons of Monel. The material quantities required for construction and operation of the cylinder transfer facility would be minor compared to local and national supplies.

E.3.9 Land Use

No impacts to land use from cylinder overcontainer operations at any of the current cylinder storage sites would be expected. No additional land would be required, and no new construction

TABLE E.19 Resource Requirements for Construction and Operation of the Cylinder Transfer Facility

Material/Resource	Unit	Total Requirement		
		Paducah	Portsmouth	K-25
Construction				
Utilities				
Electricity	GWh	40	35	25
Solids				
Concrete	yd^3	23,000	20,000	16,000
Steel	tons	9,000	8,000	6,000
Liquids				
Fuel	million gal	1.8	1.5	1.2
Gases				
Industrial gases	gal	5,000	4,400	3,500
Specialty material (Monel)	tons	7	5	4
Operations				
Utilities				
Electricity	GWh/yr	14.6	10.8	7.1
Solids				
Cement	lb	2,700	1,600	530
Potassium hydroxide	lb	4,600	2,700	930
Liquids				
Sulfuric acid	lb/yr	2,400	1,400	470
Hydrochloric acid	lb/yr	1,900	1,300	970
Sodium hydroxide	lb/yr	1,500	1,100	770
Liquid fuel	gal/yr	6,000	5,500	4,800
Gases				
Natural gas	million scf/yr	48.5	35	26

would be necessary. Existing handling and support equipment would be utilized with no modifications required (LLNL 1997). No off-site traffic impacts would be encountered during operations because the required labor force would not appreciably affect local traffic patterns or flows.

Impacts to land use from the construction and operation of a cylinder transfer facility would be negligible and limited to temporary disruptions to contiguous land parcels and potential minor traffic disruptions from peak year construction activities. Areal requirements would be small (approximately 21 acres or less), regardless of whether or not the facility were located at one or all of the current cylinder storage sites.

The peak construction labor force for the cylinder transfer facility could result in potential off-site traffic impacts in the vicinity of the three sites, although such impacts would be negligible and would ease as construction neared completion.

E.3.10 Cultural Resources

No impacts to cultural resources would be expected at the Paducah, Portsmouth, and K-25 sites as a result of the cylinder overcontainer option for cylinder preparation. Impacts could result from the cylinder transfer option during construction of the transfer facility at one of the sites. Specific impacts cannot be determined at this time and would depend on the exact location of a facility within each site and whether eligible cultural resources existed on or near that location. Operation of the transfer facility would not affect cultural resources.

E.3.11 Environmental Justice

The analysis of human health and environmental impacts associated with the cylinder overcontainer operations (Sections E.3.1 through E.3.9) indicates that no high and adverse human health effects would be expected at any of the current cylinder storage sites during normal operations. Consequently, no particular segment of the population, including minority and low-income persons, would be disproportionately affected. The results of accident analyses for cylinder preparation did not identify high and adverse impacts to the general public (i.e., the risk of accidents, consequence times probability, was less than 1).

The construction and operation of a cylinder transfer facility at any or all of the three storage sites would not result in disproportionate effects on minority or low-income populations. The analysis of human health effects and environmental impacts associated with a cylinder transfer facility (Sections E.3.1 through E.3.9) indicates that no high and adverse human health effects or environmental impacts would be expected.

E.3.12 Other Impacts Considered But Not Analyzed in Detail

Other impacts that could potentially occur if the cylinder preparation options considered in this PEIS were implemented include impacts to the visual environment (e.g., aesthetics), recreational resources, and noise levels, as well as impacts associated with decontamination and decommissioning of the cylinder transfer facilities. These impacts, although considered, were not analyzed in detail for one or more of the following reasons:

- Consideration of these impacts would not contribute to differentiation among the alternatives and, therefore, would not affect the decisions to be made in the Record of Decision to be issued following publication of this PEIS; or

- Impacts to the visual environment, recreational resources, and noise levels would be expected to stay the same as they are because cylinder preparation activities would be similar to the cylinder management activities currently ongoing at the three sites.

NOTATION (APPENDIX F)

The following is a list of acronyms and abbreviations, including units of measure, used in this document. Some acronyms used only in tables are defined in those tables.

ACRONYMS AND ABBREVIATIONS

General

CFR	*Code of Federal Regulations*
DOE	U.S. Department of Energy
EPA	U.S. Environmental Protection Agency
LCF	latent cancer fatality
LLMW	low-level mixed waste
LLNL	Lawrence Livermore National Laboratory
LLW	low-level radioactive waste
MEI	maximally exposed individual
NEPA	*National Environmental Policy Act*
NPDES	National Pollutant Discharge Elimination System
NRC	U.S. Nuclear Regulatory Commission
PEIS	programmatic environmental impact statement
PM_{10}	particulate matter with a mean diameter of 10 μm or less
ROI	region of influence

Chemicals

AlF_3	aluminum trifluoride
CaF_2	calcium fluoride
CO	carbon monoxide
Fe	iron
HC	hydrocarbons
HF	hydrogen fluoride
HNO_3	nitric acid
Mg	magnesium
MgF_2	magnesium fluoride
NO_2	nitrogen dioxide
NO_x	nitrogen oxides
TCE	trichloroethylene
SO_2	sulfur dioxide
UF_4	uranium tetrafluoride
UF_6	uranium hexafluoride

UO_2	uranium dioxide
UO_2F_2	uranyl fluoride
U_3O_8	triuranium octaoxide (uranyl uranate)

UNITS OF MEASURE

°F	degree(s) Fahrenheit	µg	microgram(s)
Ci	curie(s)	m	meter(s)
cm	centimeter(s)	m^3	cubic meter(s)
cm^3	cubic centimeter(s)	mg	milligram(s)
d	day(s)	min	minute(s)
ft	foot (feet)	mrem	millirem(s)
ft^2	square foot (feet)	MW	megawatt(s)
g	gram(s)	MWh	megawatt hour(s)
gal	gallon(s)	pCi	picocurie(s)
gpm	gallon(s) per minute	ppm	part(s) per million
GWh	gigawatt hour(s)	psia	pound(s) per square inch absolute
ha	hectare(s)	rad	radiation absorbed dose(s)
in.	inch(es)	rem	roentgen equivalent man
kg	kilogram(s)	s	second(s)
km	kilometer(s)	scf	standard cubic foot (feet)
L	liter(s)	ton(s)	short ton(s)
lb	pound(s)	yr	year(s)

APPENDIX F:

ENVIRONMENTAL IMPACTS OF OPTIONS FOR CONVERSION OF UF_6 TO OXIDE OR METAL

The U.S. Department of Energy (DOE) is proposing to develop a strategy for long-term management of the depleted uranium hexafluoride (UF_6) inventory currently stored at three DOE sites in Paducah, Kentucky; Portsmouth, Ohio; and Oak Ridge, Tennessee. This programmatic environmental impact statement (PEIS) describes alternative strategies that could be used for the long-term management of this material and analyzes the potential environmental consequences of implementing each strategy for the period 1999 through 2039. This appendix provides detailed information describing the conversion options considered in the PEIS. The discussion provides background information for the conversion options, as well as a summary of the estimated environmental impacts associated with each option.

Conversion Options

Conversion of depleted UF_6 to another chemical form is required for a number of storage, use, and disposal management alternatives. The principal conversion options considered in the PEIS are as follows:

Conversion to U_3O_8. This chemical form is a stable, low-solubility oxide considered for storage and disposal. Two different technologies were considered for conversion to U_3O_8.

Conversion to UO_2. This stable, low-solubility oxide is considered for storage, disposal, and potential use as shielding material. Three different technologies were considered for conversion to UO_2.

Conversion to Metal. Metallic depleted uranium is considered for use as shielding material. Two different technologies were considered for conversion to metal.

Conversion of depleted UF_6 to another chemical form is required for most alternative management strategies. Three different conversion options have been considered in the PEIS: (1) conversion to triuranium octaoxide (U_3O_8), (2) conversion to uranium dioxide (UO_2), and (3) conversion to uranium metal. The specific conversion option considered under each of the alternatives is shown in Table F.1. Because of their high chemical stability and low solubility, uranium oxides (i.e., U_3O_8 and UO_2) are considered for the storage and disposal alternatives. High-density UO_2 and uranium metal are considered for the use alternatives (e.g., spent nuclear fuel radiation shielding applications). Other details concerning the characteristics of the different chemical forms of uranium are given in Appendix A.

Conversion of depleted UF_6 to another chemical form would take place at a stand-alone industrial plant dedicated to the conversion process. A representative conversion plant layout is shown in Figure F.1; the actual plant layout would depend on the specific conversion option and technology selected, as well as on certain site characteristics. In general, the plant would be capable of receiving depleted UF_6 cylinders on trucks or railcars, temporarily storing a small inventory of

TABLE F.1 Summary of the Conversion Options Considered for Each Programmatic Management Alternative

	Option Considered for Management Alternative[a]					
		Long-Term Storage		Use		
Option	No Action	UF_6	Oxide	Uranium Oxide	Uranium Metal	Disposal
Conversion to U_3O_8	–	–	X	–	–	X
Conversion to UO_2	–	–	X	X	–	X
Conversion to metal	–	–	–	–	X	–

[a] X = option considered; – = option not considered.

full cylinders, processing the depleted UF_6 to another chemical form, and storing the converted uranium product and any other products until shipment off-site. The empty cylinders would be stored until transfer to a cylinder treatment facility, which is assumed to be located at the conversion plant site. It is estimated that a typical conversion plant would cover an area of approximately 20 acres (8 ha) (Lawrence Livermore National Laboratory [LLNL] 1997).

In general, potential environmental impacts would occur (1) during construction of a conversion facility, (2) during operations of the facility, and (3) during postulated accidents. The potential impacts associated with facility construction would result from typical land-clearing and construction activities. Potential impacts during operations would occur primarily to workers during handling operations and to the public as a result of routine releases of small amounts of contaminants through exhaust stacks and treated liquid effluent discharges. In addition, potential impacts to workers and the public from processing or storage might occur as a result of accidents that release hazardous materials.

The environmental impacts from the conversion options were evaluated based on the information described in the engineering analysis report (LLNL 1997). For each of the three conversion options (conversion to U_3O_8, UO_2, or metal), the engineering analysis report provides preconceptual facility design data, including descriptions of facility layouts; resource requirements; estimates of effluents, wastes, and emissions; and estimates of potential accident scenarios. Within each conversion option, several technologies or chemical processes that could be used to produce the same uranium end product are described (two are considered for conversion to U_3O_8, three for conversion to UO_2, and two for conversion to metal). Some of these technologies have not been demonstrated on a commercial scale but were considered to provide an estimate of the range of the

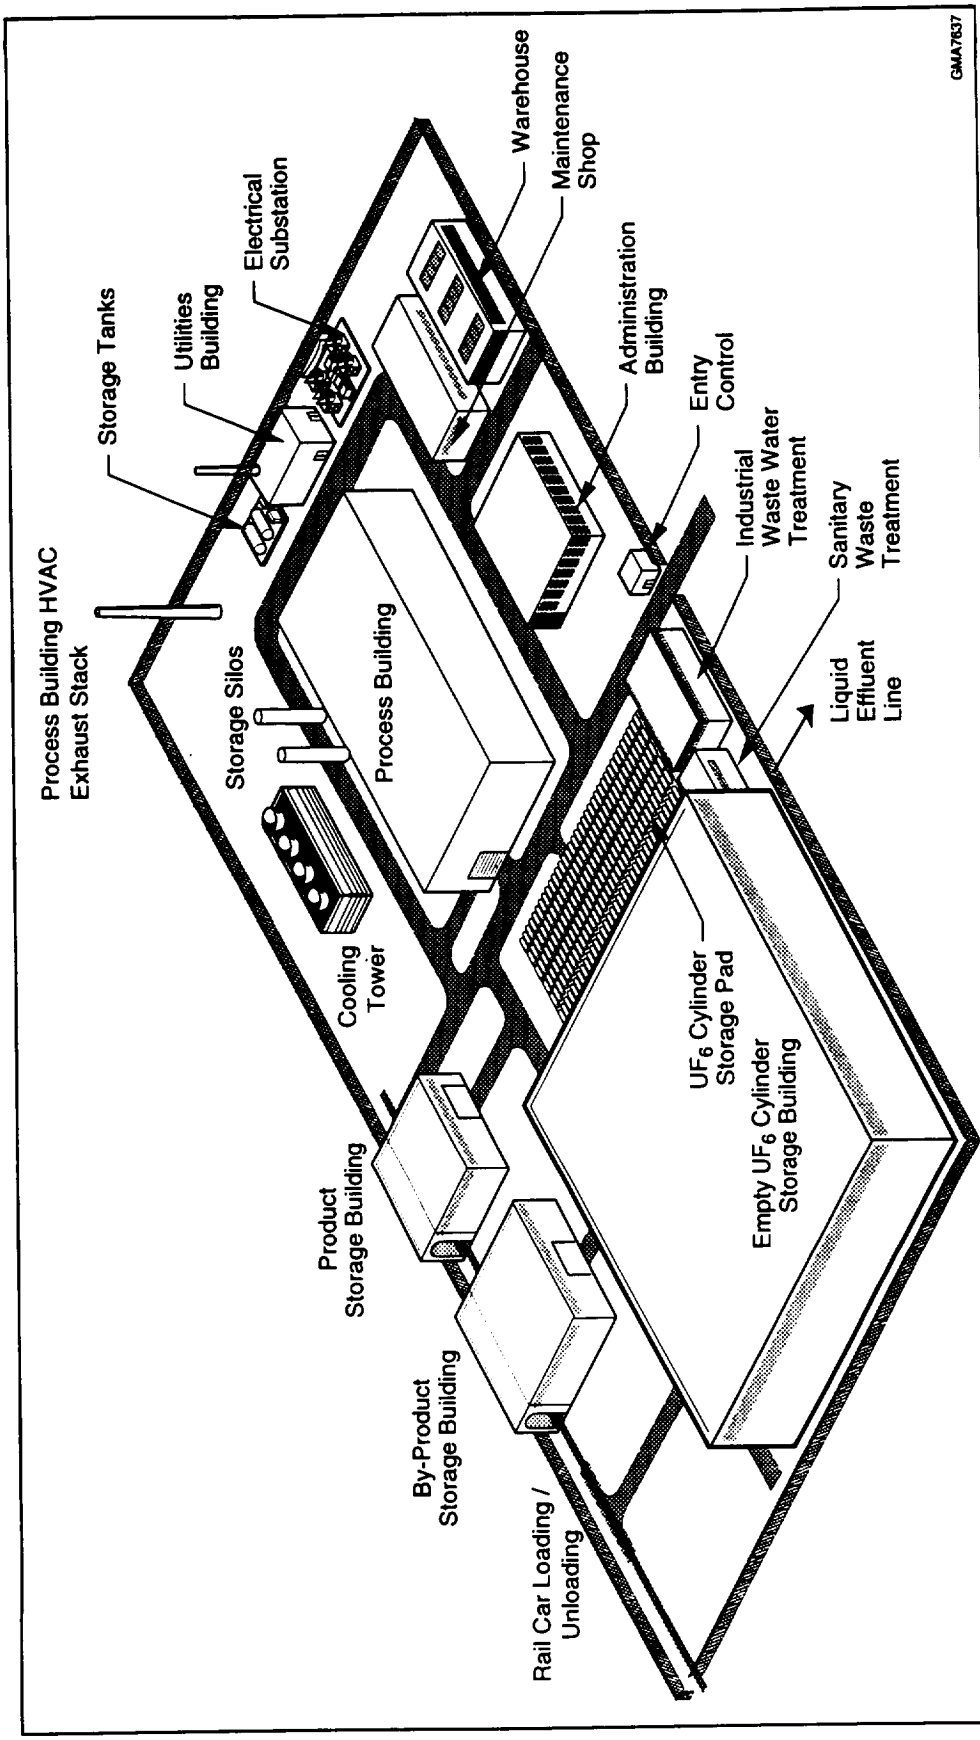

FIGURE F.1 Representative Site Layout for a Conversion Facility

862

environmental impacts that might be associated with each of the conversion options. All facility designs were based on a single plant sized to process the entire inventory of DOE-generated depleted UF_6 cylinders over a 20-year period (approximately 2,300 cylinders per year).

F.1 SUMMARY OF CONVERSION OPTION IMPACTS

A summary of the potential environmental impacts associated with the conversion options is provided in this section. These potential impacts are not site-specific because the location of a conversion facility, if required at all, would not be decided until some time in the future. For assessment purposes, the environmental impacts were determined for a range of environmental conditions represented by those at the three current depleted UF_6 storage sites.

The potential environmental impacts for the three conversion options are compared in Table F.2. For each conversion option, the potential environmental impacts are presented as a range within each area of impact. This range is intended to provide a reasonable estimate of the magnitude of impacts, taking into account the uncertainty relative to the specific technologies and sites that could ultimately be selected for conversion. The range of impacts results from two factors: (1) fundamental differences among the technologies within each conversion option; and (2) differences in the conditions at the three representative sites that were evaluated. A more detailed assessment of specific technologies and site conditions will be conducted, as appropriate, as part of the second phase (tier) of the programmatic *National Environmental Policy Act* (NEPA) approach. Additional discussion and details related to the assessment methodologies and results for individual areas of impact are provided in the remaining sections of this appendix.

F.2 DESCRIPTION OF OPTIONS

This section provides a brief summary of the different conversion options considered in the assessment of conversion impacts (Table F.3). The information is based on preconceptual design data provided in the engineering analysis report (LLNL 1997). The engineering analysis report includes much more detailed information, such as descriptions of facility layouts; resource requirements; estimates of effluents, wastes, and emissions; and estimates of potential accident scenarios.

All of the conversion options would involve the removal of depleted UF_6 from the storage cylinders, resulting in a large number of empty cylinders. These empty cylinders would contain approximately 22 lb (10 kg) of depleted UF_6 (Charles et al. 1991), called "heels." For assessment purposes, it has been assumed that a cylinder treatment facility would be constructed to wash the empty cylinders. This facility has been assumed to be an independent, or "stand-alone," facility, although it could be integrated directly into the design of the conversion plant. The facility would be co-located with the conversion plant.

[a] These impacts must be added to those for each of the conversion options.

[b] Land-use acreages given as maximum for a single site or facility. Conversion facilities would also need to establish protective action distances encompassing about 960 acres around the facility.

Notation: CO = carbon monoxide; LCF = latent cancer fatality; MEI = maximally exposed individual; PM_{10} = particulate matter with a mean diameter of 10 μm or less; ROI = region of influence.

TABLE F.3 Summary of Technologies Considered under Each Conversion Option

Conversion Option	Technologies
Conversion to U_3O_8	- Defluorination with anhydrous HF production - Defluorination with HF neutralization
Conversion to UO_2	- Dry process with anhydrous HF production - Dry process with HF neutralization - Gelation process
Conversion to metal	- Batch metallothermic reduction - Continuous metallothermic reduction

Following removal of the depleted UF_6, the emptied cylinders containing "heels" would be stored for about 3 months to allow the level of radioactivity associated with the decay products of uranium that remained after UF_6 withdrawal to decrease to acceptable levels. Subsequently, in the proposed cylinder treatment facility, the emptied cylinders are first washed with water and the resulting aqueous wash solution is evaporated and converted to solid U_3O_8 and hydrogen fluoride (HF). The U_3O_8 would be packaged and sent either for disposal or storage. The HF would be neutralized to calcium fluoride (CaF_2) and separately packaged for disposal or sale.

It was assumed that the treated cylinders with a very low residual radiation level would become part of the DOE scrap metal inventory. A report by Nieves et al. (1997) analyzed the potential health and cost impacts associated with various options for the empty cylinders after treatment, including recycle into low-level radioactive waste (LLW) disposal containers, reuse as LLW containers, free release for remelting, and disposal (i.e., burial) as LLW. Health endpoints assessed included chemical risks, radiation risks, and trauma risks. The estimated total health risks over 20 years of processing ranged from 0.1 to 0.8 total fatality for the various options. The potential health impacts were similar for each of the options; however, the disposal option was considered to have the greatest adverse environmental impacts because it would require land allocations and removal of the metal mass from any further usefulness.

F.2.1 Conversion to U_3O_8

A "dry" process, referred to as defluorination, is well established and currently used by industry. It is also practiced on a large-scale industrial basis by Cogema in France. In this process, UF_6 is chemically decomposed with steam and heat to produce U_3O_8 and concentrated HF. The

U_3O_8 would then be compacted to achieve a bulk density of about 3 g/cm^3 prior to storage or disposal.

Two technologies were considered for management of the HF following conversion of UF_6 to U_3O_8. The first process would upgrade the concentrated HF to anhydrous HF for sale. Anhydrous HF is a valuable product; one potential use for HF is in the production of UF_6 from natural uranium ore for feedstock to the gaseous diffusion process. The second process would neutralize the HF to CaF_2 for disposal or sale, depending on whether the CaF_2 with trace amounts of uranium could be marketed.

Because of the considerable market for anhydrous HF, the technology of defluorination with anhydrous HF production would minimize waste and increase product value. However, the handling, storage, and transportation of large quantities of anhydrous HF pose a potential hazard to both workers and the public. During the conversion process, the HF would be upgraded to anhydrous HF by distillation, a common industrial process. Based on historical experience, it is anticipated that the anhydrous HF would contain only trace amounts of depleted uranium (less than 1 ppm, or 0.4 pCi/g) (LLNL 1997). Thus, it was assumed that the anhydrous HF could be sold commercially for unrestricted use.

The process of HF neutralization with lime would convert the concentrated HF to CaF_2 for disposal or possible sale. This step would avoid the potential hazards associated with the processing, general handling, storage, and transportation of large quantities of anhydrous HF. However, the value of CaF_2 is significantly less than that of anhydrous HF, and large quantities of lime are required for neutralization, which would add to the cost of the neutralization option. It is also unknown whether the CaF_2 produced would be sold, disposed of as nonhazardous solid waste, or disposed of as LLW. If disposal were required, there could be moderate impacts to waste management (see Section F.3.7).

F.2.2 Conversion to UO_2

The conversion of UF_6 to UO_2 is used in the nuclear fuel fabrication industry. The UF_6 is converted to a low-density UO_2 powder by either a "wet" or "dry" process. "Wet" processes are based upon separation of solid UO_2 from an aqueous solution, whereas "dry" processes are based upon decomposing and reducing the UF_6. The resulting powder is pressed into a pellet under high pressure, and the pellet is sintered (agglomerated) at high temperatures to yield a dense solid. Depending on the shape, size, and size distribution, the bulk density of UO_2 will generally be 6 to 9 g/cm^3.

Three technologies were considered for the conversion of UF_6 to UO_2. A generic industrial dry process with conversion to produce centimeter-sized pellets is the basis for the first two technologies. The first process would upgrade the concentrated HF to anhydrous HF for sale, similar to the U_3O_8 process. The second process would neutralize the HF to CaF_2 for disposal or sale. The third process is a "wet" process, based on pilot-scale studies, and is referred to as the gelation process.

871

In the dry process, gaseous UF_6 would be chemically reacted with steam to produce solid uranyl fluoride (UO_2F_2) and HF. The UO_2F_2 would then be converted to UO_2 powder through a combination of chemical reactions. Using standard physical treatment operations (milling, compacting, and screening) and the addition of a dry lubricant, the UO_2 powder would be pressed into dense pellets with a bulk density of about 6 g/cm^3. The HF would be upgraded to anhydrous HF for commercial resale, as described in Section F.2.1. In the other dry process, the HF would be neutralized to CaF_2 rather than upgraded to anhydrous HF.

In the gelation process, small, dense spheres of UO_2 would be produced through a combination of chemical processes beginning with the conversion of UF_6 to UO_2F_2 and anhydrous HF. The solid UO_2F_2 would then be reacted with steam to produce U_3O_8 and additional anhydrous HF. The U_3O_8 would be dissolved in nitric acid, mixed with other chemicals, and chilled to form a feed broth. This broth would be formed into droplets and fed into a column of hot chlorinated hydrocarbon liquid. Once these droplets formed into spheres, they would be removed from the hot liquid and washed. The droplets would then be dried and converted by heating to dense uranium oxide. The final sintered uranium dioxide spheres are expected to have a density of about 95% or greater of the theoretical maximum density of uranium dioxide, resulting in a bulk density of about 9 g/cm^3. The gelation process has not been demonstrated on a commercial scale.

F.2.3 Conversion to Metal

The conversion of UF_6 to uranium metal would use a commercial process called metallothermic reduction. During this process, UF_6 would react with both hydrogen and magnesium metal to produce uranium metal, anhydrous HF, and magnesium fluoride ($MgFl_2$; slag). Two technologies were considered: a batch reduction process, which is the method used to date, and a continuous reduction process, which is under development and has not been demonstrated on a commercial scale.

In the batch metallothermic reduction process, the UF_6 would be mixed with hydrogen gas in a vertical reaction vessel to form uranium tetrafluoride (UF_4) and HF. The anhydrous HF would be recovered and stored for sale. The UF_4 powder and an excess of magnesium would be contained in a sealed metal vessel and preheated. Once initiated, the reaction would produce molten uranium metal (collecting at the bottom of the reactor) and less dense molten MgF_2 slag. The cycle time per batch (about 12 hours total) would be dominated by the heating and cooling periods. A large number of reactors would be required because of the long cycle time. The slag would be ground, screened, and prepared for disposal. Any metal pellets would be recovered for recycle.

In the continuous metallothermic reduction process, the UF_6 would be mixed with hydrogen gas in a vertical reaction vessel to form UF_4 and HF. The anhydrous HF would be recovered and stored for sale. A mixture of UF_4, magnesium (Mg), iron (Fe), and salt would be continuously fed into the top of a heated reactor. The more dense molten uranium/iron compound would settle to the bottom of the reactor where it would be continuously withdrawn. The lower density MgF_2/salt

mixture would float on top and be separately withdrawn. The molten uranium/iron compound would then be cast into ingots or the end-product form if the manufacturing function was integrated into the conversion facility. The molten salt mixture would be cooled and ground and the water-soluble salt dissolved. After evaporation and drying, the salt would be recycled to the reactor. The insoluble MgF_2 would be drummed for disposal. The annual throughput of the continuous metallothermic reduction reactor would be greater than a batch reactor, requiring fewer reactors.

Neutralization of HF to CaF_2 was not explicitly analyzed in the engineering analysis report for the conversion to metal options (LLNL 1997). However, the process could be implemented and would produce approximately one-third as much CaF_2 as would be produced under the conversion to oxide with neutralization options.

F.2.4 Conversion Technologies and Chemical Forms Considered But Not Analyzed in Detail

The conversion technologies analyzed in the engineering analysis report (LLNL 1997) and the PEIS are those with a sufficient technical basis to carry out preconceptual designs. A number of other promising conversion technologies were considered, but, with minor exceptions, these are in the early stages of conceptualization or development. These options are also discussed in the engineering analysis report (LLNL 1997).

For conversion to an oxide form, technologies considered but not analyzed in detail include a molten metal catalyzed process; the Cameco process (patent pending), which uses a different chemical process than steam hydrolysis/pyrolysis; a conversion process that produces a by-product of aluminum trifluoride (AlF_3); and a defluorination process that results in the production of hydrofluorocarbons. For conversion to metal, a plasma dissociation process was considered but not analyzed in detail.

F.3 IMPACTS OF OPTIONS

This section provides a summary of the potential environmental impacts associated with the conversion options, including impacts from construction and facility operations. For each area of impact, a description of the assessment methodology (including models) is provided in Appendix C.

The environmental impacts from the conversion options were evaluated based on the information described in the engineering analysis report (LLNL 1997). The following general assumptions apply to all conversion facility operations:

- All facility designs were based on a single conversion plant sized to process the entire inventory of DOE-generated depleted UF_6 cylinders over a 20-year period (approximately 2,300 cylinders per year).
- The conversion plant was assumed to operate 24 hours per day, 7 days per week, 52 weeks per year, with 20% down-time.
- A "stand-alone" cylinder treatment facility (for empty cylinders) is collocated with the conversion plant.

The location of a conversion facility at one of the three current storage sites, if required at all, would not be decided until some time in the future. Instead, for each conversion option, the environmental impacts were calculated separately for a single hypothetical facility located at each of the three current depleted UF_6 storage sites. The three current storage sites were used to provide a reasonable range of environmental conditions. A more detailed assessment of site considerations would be addressed, as appropriate, as part of the second phase (tier) of the programmatic NEPA approach.

For each conversion option, the potential environmental impacts are presented as a range within each area of impact. This range is intended to provide a reasonable estimate of the magnitude of impacts, taking into account the uncertainty relative to the specific technologies and sites that would ultimately be selected for conversion. The range of impacts results from two factors: (1) fundamental differences among the technologies within each conversion option and (2) differences in the site conditions.

F.3.1 Human Health — Normal Operations

F.3.1.1 Radiological Impacts

Radiological impacts to involved workers during normal operations at conversion facilities would result primarily from external radiation from the handling of depleted uranium materials. Impacts to noninvolved workers and members of the public would result primarily from trace amounts of uranium compounds released to the environment. Detailed discussions of the methodologies used in radiological impact analysis are provided in Appendix C and in Cheng et al. (1997).

F.3.1.1.1 Conversion to U_3O_8

Conversion to U_3O_8 would result in average radiation exposure of about 300 mrem/yr to involved workers and less than 0.01 mrem/yr to noninvolved workers and members of the public. Radiation doses and cancer risks associated with normal operations of the U_3O_8 conversion facilities are listed in Tables F.4 and F.5, respectively. The two conversion technologies evaluated are described in Section F.2.1. Due to the similarity of the conversion processes, the airborne emission rates of uranium compounds and the material handling activities are expected to vary only slightly from each other, resulting in similar radiological impacts.

Involved Workers. Radiation exposures for the involved workers are estimated according to the descriptions of material handling activities provided in the engineering analysis report (LLNL 1997). Due to the preliminary nature of each facility design, the estimated radiation doses are subject to a large degree of uncertainty. The results presented in this appendix should be used only for purposes of comparison among different technologies. Radiation exposure of involved workers would be monitored by a dosimetry program and maintained below regulatory limits.

The collective dose for involved workers is estimated to be about 41 person-rem/yr for 135 workers for the U_3O_8 conversion processes. This would result in about 0.02 excess latent cancer fatalities (LCFs) per year (or about 2 LCFs over a 100-year period) among the involved workers. If evenly distributed among involved workers, the average individual dose would be approximately 300 mrem/yr, well below the regulatory limit of 5,000 mrem/yr for workers (10 *Code of Federal Regulations* [CFR] Part 835). This corresponds to an average cancer risk of about 1×10^{-4} per year (1 chance in 10,000 of developing 1 LCF per year).

Noninvolved Workers. Estimated doses and health risks are much lower for noninvolved workers than for involved workers. Inhalation of U_3O_8 particulates accounts for more than 99.9% of the radiological exposures for noninvolved workers. The radiation dose (risk of an LCF) to a maximally exposed noninvolved worker would range from 1.6×10^{-3} mrem/yr (6×10^{-10} per year) to 5.8×10^{-3} mrem/yr (2×10^{-9} per year), which is a very small fraction (less than 1 in 1,000) of the maximally allowable dose limit (10 mrem/yr) from airborne emissions (40 CFR Part 61). The population of noninvolved workers would vary from site to site. For representative noninvolved worker population sizes ranging from 2,000 to 3,500, the resulting collective dose would range from 0.0021 to 0.0045 person-rem/yr.

General Public. The locations of the maximally exposed individual (MEI) for the general public are either at or near the site boundary. Although other exposure pathways are also considered, inhalation exposure accounts for more than 95% of the total dose. The radiation dose for the MEI would be negligible, ranging from 0.0049 to 0.0088 mrem/yr, compared with the dose limit of 10 mrem/yr from airborne emissions. The potential radiation dose resulting from drinking

TABLE F.4 Radiological Doses from Conversion/Treatment Options under Normal Operations[a]

Option	Dose to Receptor					
	Involved Workers[b]		Noninvolved Workers[c]		General Public	
	Average Dose (mrem/yr)	Collective Dose (person-rem/yr)	MEI Dose[d] (mrem/yr)	Collective Dose (person-rem/yr)	MEI Dose[e] (mrem/yr)	Collective Dose[f] (person-rem/yr)
Conversion to U_3O_8	300	41	1.6×10^{-3} – 5.8×10^{-3}	2.1×10^{-3} – 4.5×10^{-3}	4.9×10^{-3} – 8.8×10^{-3}	3.9×10^{-2} – 1.4×10^{-1}
Conversion to UO_2	180 – 340	49 – 54	3.2×10^{-3} – 2.2×10^{-2}	4.2×10^{-3} – 1.7×10^{-2}	9.7×10^{-3} – 3.3×10^{-2}	7.8×10^{-2} – 5.1×10^{-1}
Conversion to metal	230 – 240	33 – 67	6.8×10^{-4} – 1.7×10^{-2}	9.0×10^{-4} – 1.3×10^{-2}	2.1×10^{-3} – 2.6×10^{-2}	1.7×10^{-2} – 4.0×10^{-1}
Cylinder treatment	160	16	4.9×10^{-6} – 1.8×10^{-5}	6.5×10^{-6} – 1.4×10^{-5}	1.5×10^{-5} – 2.7×10^{-5}	1.2×10^{-4} – 4.1×10^{-4}

[a] Impacts are reported as ranges, which result from variations in the three representative facility locations and the different conversion technologies within each option.

[b] Involved workers are those workers directly involved with the handling of radioactive materials. Calculation results are presented as average individual dose and collective dose for the worker population. Radiation doses to individual workers would be monitored by a dosimetry program and maintained below applicable standards, such as the DOE administrative control limit of 2,000 mrem/yr.

[c] Noninvolved workers include individuals who work at the facility but are not directly involved in handling materials and individuals who work on-site but not within the facility. The population size of noninvolved workers ranges from 2,000 to 3,500 for all options.

[d] The MEI for the noninvolved workers was assumed to be located on-site 100 m or more from the release point at the location that would result in the largest dose, which includes doses from inhalation, external radiation, and incidental soil ingestion.

[e] The MEI for the general public was assumed to be located off-site at the point that would result in the largest dose from exposures through inhalation, external radiation, and ingestion of plant foods, meat, milk, soil, and drinking water.

[f] Collective dose was estimated for the populations (ranging from 500,000 to 880,000 persons) within a radius of 50 miles (80 km) around the three representative sites. The exposure pathways considered are inhalation, external radiation, and ingestion of plant foods, meat, milk, and soil.

876

TABLE F.5 Latent Cancer Risks from Conversion/Treatment Options under Normal Operations[a]

Option	Latent Cancer Risk to Receptor					
	Involved Workers[b]		Noninvolved Workers[c]		General Public	
	Average Risk (risk/yr)	Collective Risk (fatalities/yr)	MEI Risk[d] (risk/yr)	Collective Risk (fatalities/yr)	MEI Risk[e] (risk/yr)	Collective Risk[f] (fatalities/yr)
Conversion to U_3O_8	1×10^{-4}	2×10^{-2}	6×10^{-10} – 2×10^{-9}	9×10^{-7} – 2×10^{-6}	2×10^{-9} – 4×10^{-9}	2×10^{-5} – 7×10^{-5}
Conversion to UO_2	7×10^{-5} – 1×10^{-4}	2×10^{-2}	1×10^{-9} – 9×10^{-9}	2×10^{-6} – 7×10^{-6}	5×10^{-9} – 2×10^{-8}	4×10^{-5} – 3×10^{-4}
Conversion to metal	9×10^{-5} – 1×10^{-4}	1×10^{-2} – 3×10^{-2}	3×10^{-10} – 7×10^{-9}	4×10^{-7} – 5×10^{-6}	1×10^{-9} – 1×10^{-8}	9×10^{-6} – 2×10^{-4}
Cylinder treatment	6×10^{-5}	6×10^{-3}	2×10^{-12} – 7×10^{-12}	3×10^{-9} – 5×10^{-9}	8×10^{-12} – 1×10^{-11}	6×10^{-8} – 2×10^{-7}

[a] Impacts are reported as ranges, which result from variations in the three representative facility locations and the different conversion technologies within each option.

[b] Involved workers are those workers directly involved with the handling of radioactive materials. Calculation results are presented as average individual risk and collective risk for the worker population.

[c] Noninvolved workers include individuals who work at the facility but are not directly involved in handling materials and individuals who work on-site but not within the facility. The population size of noninvolved workers ranges from 2,000 to 3,500 for all options.

[d] The MEI for the noninvolved workers was assumed to be located on-site 100 m or more from the release point at the location that would result in the largest risk, which includes risks from inhalation, external radiation, and incidental soil ingestion.

[e] The MEI for the general public was assumed to be located off-site at the point that would result in the largest risk from exposures through inhalation, external radiation, and ingestion of plant foods, meat, milk, soil, and drinking water.

[f] Collective risk was estimated for the populations (ranging from 500,000 to 880,000 persons) within a radius of 50 miles (80 km) around the three representative sites. The exposure pathways considered are inhalation, external radiation, and ingestion of plant foods, meat, milk, and soil.

contaminated surface water would be two orders of magnitude less than that from exposure to airborne emissions.

For a location with an off-site population ranging from 500,000 to 880,000 persons within a 50-mile (80-km) distance from the site boundary, the collective dose would range from 0.039 to 0.14 person-rem/yr, which corresponds to about 2×10^{-5} to 7×10^{-5} LCF per year (less than 1 chance in 10,000 of 1 LCF per year in the population).

F.3.1.1.2 Conversion to UO_2

Conversion to UO_2 would result in average radiation exposure of less than 340 mrem/yr to involved workers and less than 0.04 mrem/yr to noninvolved workers and members of the public, similar to those for conversion to U_3O_8. The radiation doses and cancer risks associated with normal operations of the UO_2 conversion facilities are listed in Tables F.4 and F.5, respectively.

Involved Workers. The estimated collective dose for involved workers ranges from 49 to 54 person-rem/yr, slightly greater than conversion to U_3O_8. This would result in approximately 0.02 excess cancer fatality per year (2 LCFs over a 100-year period). If evenly distributed among involved workers (about 160 to 270 workers), the average individual dose would range from about 180 to 340 mrem/yr, well below the annual worker dose limit of 5,000 mrem/yr. This corresponds to an average cancer risk of 7×10^{-5} to 1×10^{-4} per year (less than 1 chance in 10,000 of developing 1 LCF per year).

Noninvolved Workers. The doses to noninvolved workers are similar to but slightly higher than those for conversion to U_3O_8. The dose to the MEI would range from 0.0032 to 0.022 mrem/yr, which is negligible compared with the dose limit of 10 mrem/yr for airborne emissions. For representative population sizes ranging from 2,000 to 3,500, the collective dose would range from 0.0042 to 0.017 person-rem/yr. The estimated number of potential LCFs would be less than 0.00001 per year.

General Public. The estimated radiation dose to the MEI for the general public would be slightly higher than that from conversion to U_3O_8, ranging from 0.0097 to 0.033 mrem/yr. These values are well below the radiation dose limit of 10 mrem/yr set for airborne emissions. The radiation dose from drinking contaminated surface water would be very small compared with the dose from airborne emissions. The collective dose for a population of 500,000 to 880,000 persons would range from 0.078 to 0.51 person-rem/yr. This would correspond to 4×10^{-5} to 3×10^{-4} LCF per year among the population (less than 1 chance in 3,000 of 1 LCF per year).

F.3.1.1.3 Conversion to Metal

Conversion to uranium metal would result in average exposure of less than 240 mrem/yr to involved workers and less than 0.03 mrem/yr to noninvolved workers and members of the public. The radiological impacts and cancer risks from operations of the metal conversion facilities are shown in Tables F.4 and F.5, respectively.

Involved Workers. The collective dose to involved workers would range from 33 to 67 person-rem/yr, similar to conversion to U_3O_8 and conversion to UO_2. The corresponding number of LCFs would range from 0.01 to 0.03 per year (1 to 3 LCFs over a 100-year period) among a worker population of approximately 140 to 270. If evenly distributed among workers, the average annual worker dose would be about 240 mrem/yr, which is well below the regulatory limit of 5,000 mrem/yr. The corresponding cancer risk is 0.0001 per year (less than 1 chance in 10,000 of developing 1 LCF per year).

Noninvolved Workers. The radiation dose to noninvolved workers would be similar to those for conversion to U_3O_8 and conversion to UO_2 and would be negligible compared with the regulatory dose limit of 10 mrem/yr. The collective dose would range from 0.0009 to 0.013 person-rem/yr for 2,000 to 3,500 workers.

General Public. The radiation dose for the MEI of the general public would range from 0.0021 to 0.026 mrem/yr, which corresponds to a cancer risk of 1×10^{-9} to 1×10^{-8} per year (less than 1 chance in 100 million of developing 1 LCF per year). The radiation dose from drinking contaminated surface water would be very small compared with the dose from airborne emissions. The collective dose for the population of 500,000 to 880,000 people living within 50 miles (80 km) of the site would range from 0.017 to 0.4 person-rem/yr. This corresponds to about 9×10^{-6} to 2×10^{-4} LCF per year within the exposed population.

F.3.1.1.4 Cylinder Treatment Facility

The empty UF_6 cylinders from the conversion facilities would be decontaminated at a cylinder treatment facility before reuse or final disposal. Average radiological exposure incurred by involved workers would be less than 200 mrem/yr, and maximum exposures incurred by noninvolved workers and the off-site public would be less than 3×10^{-5} mrem/yr. The estimated radiological impacts and cancer risks from cylinder treatment operations are presented in Tables F.4 and F.5, respectively.

Involved Workers. The average annual dose received by involved workers would be approximately 160 mrem/yr, which was calculated by evenly distributing the estimated collective dose of 16 person-rem/yr to a worker population of approximately 100. The average dose is a small fraction of the dose limit of 5,000 mrem/yr and corresponds to a cancer risk of 6×10^{-5} per year (1 chance in 16,000 of developing 1 LCF per year). The collective number of LCFs among the involved workers would be 6×10^{-3} per year.

Noninvolved Workers. Only a small amount of U_3O_8 (0.01 lb/yr) would be released to the atmosphere from the cylinder treatment facility. Radiological exposure to the noninvolved worker MEI would be negligible (less than 1.8×10^{-5} mrem/yr). The collective dose would range from 6.5×10^{-6} to 1.4×10^{-5} person-rem/yr for a population of 2,000 to 3,500.

General Public. The radiation exposure of the general public MEI from normal operations at the treatment facility would be negligible (less than 2.7×10^{-5} mrem/yr). The collective dose to the off-site population of 500,000 to 880,000 people would be less than 4.1×10^{-4} person-rem/yr.

F.3.1.2 Chemical Impacts

Potential chemical impacts to human health from normal operations at the conversion facilities would result primarily from exposure to trace amounts of insoluble uranium compounds (i.e., UO_2, U_3O_8, and UF_4) and HF released from process exhaust stacks. Risks from normal operations were quantified on the basis of calculated hazard indices. Information on the exposure assumptions, health effects assumptions, reference doses used for uranium compounds and HF, and calculational methods used in the chemical impact analysis are provided in Appendix C and Cheng et al. (1997).

Conversion to U_3O_8, UO_2, or metal would result in very low-level exposures to hazardous chemicals. No adverse health effects would be expected during normal operations. Hazardous chemical human health impacts resulting from normal operations of the conversion facilities are summarized in Table F.6. The hazard indices for all conversion processes are more than 5,000 times lower than the hazard index of 1, which is the level at which adverse health effects might be expected to occur in some exposed individuals. The range of chemical exposures to the noninvolved workers and general public results primarily from the assumed locations of the representative conversion facilities.

One of the UO_2 conversion options, the gelation process, would also generate emissions of the chemical trichloroethylene from the process stack. The estimated increased lifetime carcinogenic risk of cancer incidence for noninvolved workers and members of the general public from exposure to trichloroethylene would be less than 1×10^{-8}, a very small increased risk that would not be considered an adverse impact.

880

TABLE F.6 Chemical Impacts to Human Health for Conversion/Treatment Options under Normal Operations[a]

Option	Impacts to Receptor			
	Noninvolved Workers[b]		General Public	
	Hazard Index for MEI[c,d]	Population Risk[e] (persons at risk/yr)	Hazard Index for MEI[c,f]	Population Risk[e] (persons at risk/yr)
Conversion to U_3O_8	3.9×10^{-7} – 1.5×10^{-6}	–	3.4×10^{-5} – 1.2×10^{-4}	–
Conversion to UO_2	7.5×10^{-7} – 3.1×10^{-6}	–	6.2×10^{-5} – 1.9×10^{-4}	–
Conversion to metal	4.8×10^{-7} – 3.0×10^{-6}	–	4.1×10^{-5} – 1.5×10^{-4}	–
Cylinder treatment	4.2×10^{-10} – 1.5×10^{-9}	–	3.5×10^{-8} – 7.1×10^{-8}	–

[a] Impacts are reported as ranges, which result from variations in the three representative facility locations and the different conversion technologies within each option.

[b] Noninvolved workers include individuals who work at the facility but are not directly involved in handling hazardous materials and individuals who work on-site but not within the facility.

[c] The hazard index is an indicator for potential adverse health effects other than cancer; a hazard index greater than 1 indicates a potential for adverse health effects and a need for further evaluation. Hazard indices were calculated for combined exposures to uranium compounds and HF.

[d] The MEI for the noninvolved workers was assumed to be located on-site 100 m or more from the release point at the location that would result in the largest exposure from airborne emissions, including inhalation and incidental ingestion of contaminated soil.

[e] Calculation of population risk is not applicable when the corresponding hazard index for the MEI is less than 1.

[f] The MEI for the general public was assumed to be located off-site at the location that would result in the largest exposures through inhalation and ingestion of soil and drinking water.

The empty UF_6 cylinders from the conversion facilities would be decontaminated at a cylinder treatment facility prior to final disposal. Estimates of the hazardous chemical impacts to human health resulting from cylinder treatment operations are also summarized in Table F.6. The hazard indices from the cylinder treatment facility would be hundreds of times lower than those predicted for the conversion options, for which no adverse human health impacts were predicted.

F.3.2 Human Health — Accident Conditions

A range of accidents covering the spectrum from high-frequency/low-consequence accidents to low-frequency/high-consequence accidents has been presented in the engineering analysis report (LLNL 1997). These accidents are listed in Table F.7. The following sections present the results for radiological and chemical health impacts of the highest-consequence accident in each frequency category. Results for all accidents listed in Table F.7 are presented in Policastro et al. (1997). A detailed description of the methodology and assumptions used in the calculations is also provided in Appendix C and Policastro et al. (1997).

F.3.2.1 Radiological Impacts

Table F.8 lists the radiological doses to various receptors for the accidents that give the highest dose from each frequency category. The LCF risks for these accidents are given in Table F.9. The doses and the risks are presented as ranges (maximum and minimum) because two different meteorological conditions, three representative sites, and two or three technologies were considered for each conversion option (see Appendix C). The doses and risks presented here were obtained by assuming that the accidents would occur. The probability of occurrence for each accident is indicated by the frequency category to which it belongs. For example, accidents in the extremely unlikely category have a probability of occurrence of between 1 in 10,000 and 1 in 1 million per year. The following conclusions may be drawn from the radiological health impact results:

- No cancer fatalities would be predicted from any of the accidents.

- The maximum radiological dose to noninvolved worker and general public MEIs (assuming that an accident occurred) would be 9.2 rem. This dose is less than the 25-rem dose recommended for assessing the adequacy of protection of public health and safety from potential accidents by the U.S. Nuclear Regulatory Commission (NRC 1994).

- The overall radiological risk to noninvolved worker and general public MEI receptors (estimated by multiplying the risk per occurrence [Table F.9] by the annual probability of occurrence by the number of years of operations) would be less than 1 for all of the conversion facility accidents.

F.3.2.2 Chemical Impacts

The accidents considered in this section are listed in Table F.7. The results of the accident consequence modeling in terms of chemical impacts are presented in Tables F.10 and F.11. The results are presented as (1) number of people with potential for adverse effects and (2) number of

TABLE F.7 Accidents Considered for the Conversion Options

Option/Accident Scenario	Accident Description	Chemical Form	Amount (lb)	Duration (min)	Release Level[a]
Conversion to U_3O_8					
Likely Accidents (frequency: 1 or more times in 100 years)					
Corroded cylinder spill, dry conditions	A 1-ft hole results during handling, with solid UF_6 forming a 4-ft^2 area on the dry ground.	UF_6	24	60 (continuous)	Ground
Cylinder valve shear	A single UF_6 cylinder is mishandled, etc., resulting in the shearing of the cylinder valve and loss of solid UF_6 from the valve onto the ground.	UF_6	0.25	120 (continuous)	Ground
HF system leak during upgrading of HF to anhydrous HF	An HF absorber column line leaks 5% of its flowing contents due to potential vessel, pump, or pipe leakage.	HF	216	15	Stack
HF system leak during HF neutralization	An HF distillation column line leaks 5% of its flowing contents due to potential vessel, pump, or pipe leakage.	HF	10	15	Stack
Loss of cooling water during upgrading of HF to anhydrous HF	Cooling water is lost to the HF distillation column condenser, and HF vapor is removed by a limestone bed before reaching the environment.	HF	22	2	Stack
Loss of cooling water during HF neutralization	Cooling water is lost to the absorption column coolers, and HF vapor is released to the atmosphere.	HF	19	2	Stack
Loss of off-site electrical power	Off-site electrical power is lost, which halts facility operations but does not result in significant releases to the environment.	No release	NA[b]	NA	NA
U_3O_8 drum spill	A single U_3O_8 drum is damaged by a forklift and spills its contents onto the floor inside the storage facility.	U_3O_8	0.00014	30	Stack
Unlikely Accidents (frequency: 1 in 100 years to 1 in 10,000 years)					
Ammonia release	An ammonia fill line is momentarily disconnected, and ammonia is released at grade.	Ammonia	255	1	Ground
Corroded cylinder spill, wet conditions – rain	A 1-ft hole results during handling, with solid UF_6 forming a 4-ft^2 area on the wet ground.	HF	96	60 (continuous)	Ground
HF pipeline rupture	An earthquake ruptures an underground pipeline transporting HFs, releasing it to the ground.	HF	500	10	Soil
HF storage tank overflow	An HF storage tank overflows during filling, spilling onto the floor; the pool of HF evaporates and is released through the building stack.	HF	45	15	Stack

TABLE F.7 (Cont.)

Accident Scenario	Accident Description	Chemical Form	Amount (lb)	Duration (min)	Release Level[a]
Conversion to U_3O_8 (Cont.)					
Extremely Unlikely Accidents (frequency: 1 in 10,000 years to 1 in 1 million years)					
Corroded cylinder spill, wet conditions – water pool	A 1-ft hole results during handling, with solid UF_6 forming a 4-ft^2 area into a 0.25-in.-deep water pool.	HF	150	60 (continuous)	Ground
Earthquake	The U_3O_8 storage building is damaged during a design-basis earthquake, and 10% of the stored drums are breached.	U_3O_8	41	30	Ground
Hydrogen explosion	Due to equipment malfunction, hydrogen that accumulated in the conversion reactor ignites and causes the reactor to rupture.	U_3O_8 HF	0.27 7	30	Stack
Tornado	A windblown missile from a design-basis tornado pierces a single U_3O_8 drum in the U_3O_8 storage building.	U_3O_8	69	0.5	Ground
Vehicle-induced fire, 3 full 48G cylinders	Three full 48G UF_6 cylinders hydraulically rupture during a fire resulting from the ignition of fuel and/or hydraulic fluid from the transport vehicle, etc.	UF_6	0 11,500 8,930 3,580	0 to 12 12 12 to 30 30 to 121	Ground
Incredible Accidents (frequency: less than 1 in 1 million years)					
Anhydrous HF tank rupture	Large seismic or beyond-design-basis event causes rupture of a filled anhydrous HF storage tank.	HF	7,920	120	Ground
Ammonia tank rupture	Large seismic or beyond-design-basis event causes rupture of a filled ammonia storage tank.	Ammonia	118,000	20	Ground
Flood	The facility would be located at a site that would preclude severe flooding.	No release	NA	NA	NA
Small plane crash, 2 full 48G cylinders	A small plane crash affects two full 48G UF_6 cylinders. One cylinder hydraulically ruptures during a fire resulting from the ignition of aviation fuel.	UF_6	0 3,840 2,980 1,190	0 to 12 12 12 to 30 30 to 121	Ground
	The second cylinder is initially breached due to impact with aircraft debris, followed by sublimation due to fire.	UF_6	4,240 1,190	0 to 30 30 to 121	Ground

TABLE F.7 (Cont.)

Accident Scenario	Accident Description	Chemical Form	Amount (lb)	Duration (min)	Release Level[a]
Conversion to UO_2					
Likely Accidents (frequency: 1 or more times in 100 years)					
Ammonia stripper overpressure	Cooling water is lost to the ammonia stripping column, and ammonia vapor is released to the atmosphere.	Ammonia	15	1	Ground
Corroded cylinder spill, dry conditions	A 1-ft hole results during handling, with solid UF_6 forming a 4-ft^2 area on the dry ground.	UF_6	24	60 (continuous)	Ground
Cylinder valve shear	A single UF_6 cylinder is mishandled, etc., resulting in shearing of the cylinder valve and loss of solid UF_6 from the valve onto the ground.	UF_6	0.25	120 (continuous)	Ground
HF system leak during upgrading of HF to anhydrous HF	An HF absorber line leaks 5% of its flowing contents due to potential vessel, pump, or pipe leakage.	HF	216	15	Stack
HF system leak during HF neutralization	An HF distillation column line leaks 5% of its flowing contents due to potential vessel, pump, or pipe leakage.	HF	10	15	Stack
Loss of cooling water during upgrading of HF to anhydrous HF	Cooling water is lost to the HF distillation column condenser, and HF vapor is removed by a limestone bed before reaching the environment.	HF	22	2	Stack
Loss of cooling water during HF neutralization	Cooling water is lost to the absorption column coolers, and HF vapor is released to the atmosphere.	HF	19	2	Stack
Loss of off-site electrical power	Off-site electrical power is lost, which halts facility operations but does not result in significant releases to the environment.	No release	NA	NA	NA
Trichloroethylene (TCE) spill	A TCE storage tank spills onto the floor during operations, and the pool of TCE evaporates and is released to the environment.	TCE	120	120	Stack
Trichloroethylene vapor leak	The exhaust line from the gel sphere dryers leaks 5% of its flowing contents due to potential pipe leakage.	TCE	20	60	Stack
UO_2 drum spill	A single UO_2 drum is damaged by a forklift and spills its contents onto the floor inside the storage facility.	UO_2	0.000056	30	Stack

Small plane crash, 2 full 48G cylinders	A small plane crash affects two full 48G UF_6 cylinders. One cylinder hydraulically ruptures during a fire resulting from the ignition of aviation fuel.	UF_6	0 3,840 2,980 1,190	0 to 12 12 12 to 30 30 to 121	Ground
	The second cylinder is initially breached due to impact with aircraft debris, followed by sublimation due to fire.	UF_6	4,240 1,190	0 to 30 30 to 121	Ground
Cylinder Treatment Facility					
Likely Accidents (frequency: 1 or more times in 100 years)					
Loss of off-site electrical power	Off-site electrical power is lost, which halts facility operations but does not result in significant releases to the environment.	No release	NA	NA	NA
U_3O_8 drum spill	A single U_3O_8 drum is damaged by a forklift and spills its contents onto the ground outside the storage facility.	U_3O_8	0.138	30	Ground
Unlikely Accidents (frequency: 1 in 100 years to 1 in 10,000 years)					
Loss of scrubber water	Water is lost to both HF scrubbers, and HF is released with the off gas.	HF	26	30	Stack
Extremely Unlikely Accidents (frequency: 1 in 10,000 years to 1 in 1 million years)					
Depleted UF_6 cylinder rupture	A truck crashes into the depleted UF_6 heel storage pad, damaging two cylinders; the fuel from the truck ignites and releases all of the depleted UF_6.	UO_2F_2 HF	38.5 10	30	Ground
Earthquake	The solids product building is damaged during a design-basis earthquake, and 50% of the stored drums are breached.	U_3O_8	1.9	30	Ground
HF aqueous tank rupture	The evaporator tank fails, releasing its entire contents of HF to the floor; the pool of aqueous HF evaporates and is released to the indoor air of the process building.	HF	3.4	60	Stack
Tornado	A windblown missile from a design-basis tornado pierces a single U_3O_8 drum in the solids product building.	U_3O_8	69	0.5	Ground
Incredible Accidents (frequency: less than 1 in 1 million years)					
Flood	The facility would be located at a site that would preclude severe flooding.	No release	NA	NA	NA

[a] Ground-level releases were assumed to occur outdoors on concrete pads in the cylinder storage yards. To prevent contaminant migration, cleanup of residuals was assumed to begin immediately after the release was stopped.

[b] NA = not applicable.

[a] The bounding accident chosen to represent each frequency category is the one that would result in the highest dose to the general public MEI. Health impacts in that row represent that accident only and not the range of impacts among accidents in that category. Absence of an accident in a certain frequency category indicates that the accident would not result in a release of radioactive material.

[b] Accident frequencies: likely (L), estimated to occur one or more times in 100 years of facility operations ($> 10^{-2}$/yr); unlikely (U), estimated to occur between once in 100 years and once in 10,000 years of facility operations ($10^{-2} - 10^{-4}$/yr); extremely unlikely (EU), estimated to occur between once in 10,000 years and once in 1 million years of facility operations ($10^{-4} - 10^{-6}$/yr); incredible (I), estimated to occur less than one time in 1 million years of facility operations ($< 10^{-6}$/yr).

[c] Maximum and minimum doses reflect differences in assumed sites, technologies, and meteorological conditions at the time of the accident. In general, maximum doses would occur under meteorological conditions of F stability with 1 m/s wind speed, whereas minimum doses would occur under D stability with 4 m/s wind speed.

[d] Meteorological conditions analyzed for the tornado were D stability with 20 m/s wind speed.

[a] Values shown are the consequences if the accident did occur. The risk of an accident is the consequence (LCFs) times the estimated frequency times 20 years of operations. The estimated frequencies are as follows: likely (L), 0.1; unlikely (U), 0.001; extremely unlikely (EU), 0.00001; incredible (I), 0.000001.

[b] The bounding accident chosen to represent each frequency category is the one that would result in the highest risks to the general public MEI. Health impacts in that row represent that accident only and not the range of impacts among accidents in that category. Absence of an accident in a certain frequency category indicates that the accident would not result in a release of radioactive material.

[c] Accident frequencies: likely (L), estimated to occur one or more times in 100 years of facility operations ($> 10^{-2}$/yr); unlikely (U), estimated to occur between once in 100 years and once in 10,000 years of facility operations ($10^{-2} - 10^{-4}$/yr); extremely unlikely (EU), estimated to occur between once in 10,000 years and once in 1 million years of facility operations ($10^{-4} - 10^{-6}$/yr); incredible (I), estimated to occur less than one time in 1 million years of facility operations ($< 10^{-6}$/yr).

[d] Maximum and minimum risks reflect differences in assumed sites, technologies, and meteorological conditions at the time of the accident. In general, maximum risks would occur under meteorological conditions of F stability with 1 m/s wind speed, whereas minimum risks would occur under D stability with 4 m/s wind speed.

[e] Meteorological conditions analyzed for the tornado were D stability with 20 m/s wind speed.

Tornado[h]	EU	Yes	1	No	0	NA[i]	NA	NA	NA

[a] Values shown are the consequences if the accident did occur. The risk of an accident is the consequence (number of persons) times the estimated frequency times 20 years of operations. The estimated frequencies are as follows: likely (L), 0.1; unlikely (U), 0.001; extremely unlikely (EU), 0.00001; incredible (I), 0.000001.

[b] The bounding accident chosen to represent each frequency category is the one in which the largest number of people (workers plus off-site population) would be affected. Health impacts in that row represent that accident only and not the range of impacts among accidents in that category.

[c] Accident frequencies: likely (L), estimated to occur one or more times in 100 years of facility operations ($> 10^{-2}$/yr); unlikely (U), estimated to occur between once in 100 years and once in 10,000 years of facility operations ($10^{-2} - 10^{-4}$/yr); extremely unlikely (EU), estimated to occur between once in 10,000 years and once in 1 million years of facility operations ($10^{-4} - 10^{-6}$/yr); incredible (I), estimated to occur less than one time in 1 million years of facility operations ($< 10^{-6}$/yr).

[d] Maximum and minimum values reflect differences in assumed meteorological conditions at the time of the accident. In general, the maximum risks would occur under meteorological conditions of F stability with 1 m/s wind speed, whereas the minimum risks would occur under D stability with 4 m/s wind speed.

[e] At the MEI location, the determination is either "Yes" or "No" for potential adverse effects to an individual.

[f] MEI locations were evaluated at 100 m from ground-level releases for workers and at the location of highest off-site concentration for members of the general public; the population risks are 0 because the worker and general public population distributions for the representative sites were used, which did not show receptors at the MEI locations.

[g] These accidents would result in the largest plume sizes, although no people would be affected.

[h] Meteorological conditions analyzed for the tornado were D stability with 20 m/s wind speed.

[i] NA = not applicable.

[a] Values shown are the consequences if the accident did occur. The risk of an accident is the consequence (number of persons) times the estimated frequency times 20 years of operations. The estimated frequencies are as follows: likely (L), 0.1; unlikely (U), 0.001; extremely unlikely (EU), 0.00001; incredible (I), 0.000001.

[b] The bounding accident chosen to represent each frequency category is the one in which the largest number of people (workers plus off-site population) would be affected. Health impacts in that row represent that accident only and not the range of impacts among accidents in that category.

[c] Accident frequencies: likely (L), estimated to occur one or more times in 100 years of facility operations ($> 10^{-2}$/yr); unlikely (U), estimated to occur between once in 100 years and once in 10,000 years of facility operations ($10^{-2} - 10^{-4}$/yr); extremely unlikely (EU), estimated to occur between once in 10,000 years and once in 1 million years of facility operations ($10^{-4} - 10^{-6}$/yr); incredible (I), estimated to occur less than one time in 1 million years of facility operations ($< 10^{-6}$/yr).

[d] Maximum and minimum values reflect different meteorological conditions at the time of the accident. In general, the maximum risks would occur under meteorological conditions of F stability with 1 m/s wind speed, whereas the minimum risks would occur under D stability with 4 m/s wind speed. An exception is worker impacts for the ammonia tank rupture, for which maximum risks would occur under D stability with 4 m/s wind speed.

[e] At the MEI location, the determination is either "Yes" or "No" for potential irreversible adverse affects to an individual.

[f] MEI locations were evaluated at 100 m from ground-level releases for workers and at the location of highest off-site concentration for members of the general public; the population risks are 0 because the worker and general public population distributions for the representative sites were used, which did not show receptors at the MEI locations.

[g] These accidents would result in the largest plume sizes, although no people would be affected.

[h] Meteorological conditions analyzed for the tornado were D stability with 20 m/s wind speed.

[i] NA = not applicable.

people with potential for irreversible adverse effects. The tables present the results for the accident within each frequency category that would affect the largest number of people (total of workers and off-site population) (Policastro et al. 1997). The numbers of noninvolved workers and members of the off-site public represent the impacts if the associated accident was assumed to occur. The accidents listed in Tables F.10 and F.11 are not identical because an accident with the largest impacts for adverse effects might not lead to the largest impacts for irreversible adverse effects. The impacts may be summarized as follows:

- If the accidents identified in Tables F.10 and F.11 did occur, the number of persons in the off-site population with potential for adverse effects would range from 0 to 41,000 (maximum corresponding to HF tank rupture), and the number of off-site persons with potential for irreversible adverse effects would range from 0 to 1,700 (maximum corresponding to ammonia tank rupture).

- If the accidents identified in Tables F.10 and F.11 were to occur, the number of noninvolved workers with potential for adverse effects would range from 0 to 1,100 (maximum corresponding to HF tank rupture), and the number of noninvolved workers with potential for irreversible adverse effects would range from 0 to 440 (maximum corresponding to corroded cylinder spill, wet conditions — water pool).

- The largest impacts would be caused by HF tank rupture; corroded cylinder spill, wet conditions – rain; ammonia tank rupture; and vehicle-induced fire involving three full 48G cylinders. Accidents involving stack emissions would have very small impacts compared with accidents involving releases at ground level due to the large dilution (and lower source terms due to filtration and deposition) involved with the stack emissions.

- The bounding accidents for the conversion options (conversion to U_3O_8, UO_2, and metal) would have nearly identical impacts.

- For the most severe accidents in each frequency category, the noninvolved worker MEI and the public MEI would have the potential for both adverse effects and irreversible adverse effects. The likely accidents for each conversion option (frequency of more than one chance in 100 per year) would result in no potential adverse or irreversible adverse effects for the general public. The generally reduced impacts to the public MEI compared with the noninvolved worker MEI are related to dispersion of the chemical release with downwind distance (except for UF_6 cylinder fire with plume rise).

- The maximum risk was computed as the product of the consequence (number of people) times the frequency of occurrence (per year) times the number of years of operations (20 years, 2009 through 2028). The results indicate that the

maximum risk values would be less than 1 for all accidents except the following:

- *Potential Adverse Effects:*

  Corroded cylinder spill, dry conditions (L, likely): Workers
  Corroded cylinder spill, wet conditions – rain (U, unlikely): Workers

- *Potential Irreversible Adverse Effects:*

  Corroded cylinder spill, dry conditions (L, likely): Workers
  Ammonia stripper overpressure (L, likely): Workers
  Corroded cylinder spill, wet conditions – rain (U, unlikely): Workers

These risk values are conservative because the numbers of people affected were based on assuming (1) meteorological conditions that would result in the maximum reasonably foreseeable plume size (i.e., F stability and 1 m/s wind speed) and (2) wind in the direction that would lead to maximum numbers of individuals exposed for noninvolved workers or for the general population.

To aid in the interpretation of accident analysis results, the number of fatalities potentially associated with the estimated irreversible adverse effects was calculated. For the worker and general public accidents involving UF_6 releases shown in Table F.10, exposure to HF and uranium compounds could be high enough to result in death for 1% or less of the persons experiencing irreversible adverse effects (Policastro et al. 1997). Thus, for the corroded cylinder spill accidents having a range of 0 to 440 irreversible adverse effects for noninvolved workers, approximately 0 to 4 worker deaths would be expected; no deaths would be expected for members of the general public from such accidents. For the ammonia tank rupture accident caused by an earthquake, exposure to ammonia would result in death for about 2% of the persons experiencing irreversible adverse effects. This would correspond to about 4 to 8 deaths among noninvolved workers and 0 to 34 deaths for the general public. These are the maximum potential consequences of the accidents; the upper ends of the ranges result from assuming worst-case weather conditions, with the wind blowing in the direction where the highest number of people would be exposed.

F.3.2.3 Physical Hazards

The risk of on-the-job fatalities and injuries to all conversion facility workers was calculated using industry-specific statistics from the U.S. Bureau of Labor Statistics, as reported by the National Safety Council (1995). Annual fatality and injury rates for construction and manufacturing, respectively, were used for the construction and operational phases of the conversion facility lifetime.

No on-the-job fatalities are predicted for any of the options analyzed, but a range of about 300 to 500 injuries is predicted during the conversion facility lifetimes. Overall, the largest impacts are predicted for conversion to UO_2 through gelation and for conversion to metal through batch reduction because these options require larger numbers of employees. All other conversion options would result in similar impacts; fewer impacts are predicted for the cylinder treatment facility (i.e., approximately 170 injuries).

Because the conversion technologies analyzed for conversion of U_3O_8 would employ almost the same number of workers, there are essentially no differences between them. There would be a probability of about 0.35 of an on-the-job fatality (sum of 0.18 for the construction phase and 0.17 for the operations phase) for the U_3O_8 conversion options (Table F.12). The predicted injury incidence would be about 285 injuries over the lifetime of the facility.

The predicted probability of worker fatalities for conversion to UO_2 ranges from 0.4 to 0.59 (Table F.12). The predicted injury incidence ranges from about 320 to 492 injuries over the lifetime of the UO_2 conversion facility. The upper ends of the ranges result from the larger number of workers required for operation of the gelation facility.

The predicted probability of worker fatalities for conversion to metal ranges from about 0.4 to 0.55 (Table F.12). The predicted injury incidence ranges from about 300 to 490 injuries over the lifetime of the metal conversion facility. The upper ends of the ranges result from the larger number of workers required for operation of the batch reduction facility.

For the cylinder treatment facility option, the probability of an on-the-job fatality is about 0.19 (sum of 0.08 for the construction phase and 0.11 for the operations phase) (Table F.12). The estimated injury incidence would be about 170 over the lifetime of the facility.

F.3.3 Air Quality

Additional details regarding the analysis of air quality impacts for the conversion option are presented in Tschanz (1997).

F.3.3.1 Construction

The annual emissions of sulfur dioxide (SO_2), nitrogen dioxide (NO_2), hydrocarbons (HC), carbon monoxide (CO), and particulate matter (PM_{10}) expected during conversion plant construction are listed in Table F.13. The estimated 1-hour maximum pollutant concentrations at the facility boundary during construction are shown in Table F.14. Additional estimates were made for the conversion technology that had the highest estimated 1-hour maximum pollutant concentrations (i.e., gelation); these estimated concentrations are given in Table F.15). Although all of these pollutant concentrations would be much higher than those for plant operations, they remain below

TABLE F.12 Potential Impacts to Human Health from Physical Hazards under Accident Conditions for the Conversion Options[a]

	Impacts to Conversion Facility Workers[b]			
	Incidence of Fatalities		Incidence of Injuries	
Option	Construction	Operations	Construction	Operations
Conversion to U_3O_8	0.18	0.16–0.17	66	215–219
Conversion to UO_2	0.22–0.30	0.18–0.29	79–108	243–384
Conversion to metal	0.22–0.25	0.17–0.30	79–92	222–395
Cylinder treatment	0.08	0.11	30	140

[a] Impacts are reported as ranges, which result from variations in the employment requirements for the different conversion technologies for each option.

[b] Potential hazards were estimated for all conversion facility workers.

ambient air quality standards. One possible exception is PM_{10}, for which concentrations were estimated to be 90% of the 24-hour standard of 150 $\mu g/m^3$. Some fugitive dust control measures would be necessary to mitigate this potentially high concentration. Construction of the conversion plant in a region of already high, even if compliant, ambient pollutant concentrations might require consideration of changes and/or controls for the emission of the other pollutants as well.

Estimated emissions from the cylinder treatment facility for all aspects of construction and operations are of the same order of magnitude (generally about 0.4 to 0.7 times as large) as those associated with the baseline cylinder transfer facility (see Appendix E), and the cylinder treatment facility area would be about half as large as the baseline cylinder transfer facility area. Except for the

TABLE F.14 Maximum 1-Hour Average Pollutant Concentrations at the Nearest Point on the Facility Boundary from Construction of a Conversion Facility[a]

Option	Pollutant ($\mu g/m^3$)				
	SO_2	NO_2	HC	CO	PM_{10}
Conversion to U_3O_8	26	360	100	2,400	520
Conversion to UO_2	25–37	380–570	100–160	2,400–3,900	620–740
Conversion to metal	25–36	360–480	100–140	2,500–3,200	610–720

[a] The ranges shown for some pollutants include results from the various technologies used for the conversion option and the differences in representative sites used for analysis.

TABLE F.15 Maximum Air Quality Impacts from Conversion Facility Construction[a]

Pollutant	Estimated Pollutant Emissions[b]							
	1-Hour Average		8-Hour Average		24-Hour Average		Annual Average	
	Concentration[c] ($\mu g/m^3$)	Fraction of Standard[d]	Concentration[c] ($\mu g/m^3$)	Fraction of Standard[d]	Concentration[c] ($\mu g/m^3$)	Fraction of Standard[d]	Concentration[c] ($\mu g/m^3$)	Fraction of Standard[d]
CO	3,810	0.1	3,100	0.30	–	–	–	–
NO_x	–	–	–	–	–	–	16	0.17
SO_2	–	–	–	–	5.8	0.02	0.9	0.01
PM_{10}	–	–	–	–	136	0.90	21	0.42

[a] Estimated pollutant emissions are given for the conversion to UO_2 gelation option, which would have the highest emissions.

[b] Values are listed only for pollutant/averaging time period combinations that have applicable air quality standards.

[c] Concentrations are the second highest values estimated for one entire year. Short-term standards are not to be exceeded more than once per year.

[d] Ratio of the concentration to the respective air quality standard. A ratio of less than 1 indicates that the standard would not be exceeded.

1-hour average results, the analytical results shown in Table F.16 for the cylinder treatment facility are about 0.2 to 0.4 times as large as those shown in Appendix E, Tables E.9-E.11, for the cylinder transfer facility. The 1-hour average impacts of construction of a cylinder treatment facility would be essentially the same as those for cylinder transfer facility construction.

F.3.3.2 Operations

Hourly emission rates during operations were determined from annual emission rates given in the engineering analysis report (LLNL 1997); these rates are shown in Table F.17. The methods used to analyze the impacts of pollutant emissions are described in Appendix C. All air pollutant concentrations during operations would be well below applicable ambient air quality standards for all conversion options. The maximum ground-level atmospheric concentrations at the representative facility boundaries from the boiler stack's emissions are listed in Tables F.18 through F.20. At the upper ends of the ranges, the nearest any of the criteria pollutant concentrations would come to a corresponding air quality standard is the annual nitrogen oxides (NO_x) concentration, which would be between 0.0007 and 0.002 of the annual NO_x standard.

Maximum air quality impacts from the process stacks are also listed in Tables F.18 through F.20. State HF standards in Tennessee and Kentucky have been used for comparative purposes. The estimated 24-hour maximum HF concentrations at representative facility boundaries for the conversion to U_3O_8 with anhydrous HF are about 2% of the respective state standards. The batch conversion to uranium metal is the only case for which NO_2 would be emitted from the process stack, and the NO_2 emission rate from the process stack in that case would be about eight times larger than from the boiler stack. Nevertheless, the estimated maximum annual NO_2 concentrations at the representative facility boundaries are less than 1% of the respective state standards.

TABLE F.16 Air Quality Impacts from Construction of the Cylinder Treatment Facility

	Estimated Pollutant Emissions							
	1-Hour Average		8-Hour Average		24-Hour Average		Annual Average	
Pollutant	Range[a] ($\mu g/m^3$)	Fraction of Standard[b]	Range[a] ($\mu g/m^3$)	Fraction of Standard[b]	Range[a] ($\mu g/m^3$)	Fraction of Standard[b]	Range[a] ($\mu g/m^3$)	Fraction of Standard[b]
CO	1,800 – 3,500	0.088	310 – 450	0.045	120 – 180	–	7.2 – 13	–
NO_x	280 – 520	–	47 – 69	–	19 – 27	–	1.1 – 2.0	0.02
PM_{10}	390 – 720	–	65 – 95	–	26 – 37	0.25	1.5 – 2.6	0.052

[a] Concentrations are the second highest values estimated for one entire year. Short-term standards are not to be exceeded more than once per year.

[b] Ratio of the upper end of the concentration range to the respective air quality standard. A ratio of less than 1 indicates that the standard is not exceeded. Pollutant/averaging time period combinations for which no air quality standard exists are noted with a dash (–).

TABLE F.17 Emissions to the Atmosphere from Operation of a Depleted UF_6 Conversion Plant

Source: LLNL (1997).

Each emergency generator would operate for 300 hours or less during 1 year. When it was operating, however, an emergency generator would produce higher concentrations of criteria pollutants at the facility boundaries than would the boiler. The estimated pollutant concentrations from the generator are listed in Tables F.18 through F.20. Compared with the air quality standards, the estimated concentrations are no more than 5% of allowed values.

The boiler stack parameters are identical for the cylinder treatment facility and the baseline cylinder transfer facility (see Appendix E). Given the similarities in the input data, the results of the air quality analyses for the two facilities should be expected to be comparable. Although not presented explicitly here, the same can be said of the impacts for operations. In summary, all of the criteria pollutant impacts of the cylinder treatment facility would not differ substantially from those of the cylinder transfer facility; all of the impacts not explicitly noted here are considered to be negligible. The only pollutant of concern emitted by the cylinder treatment facility process stack would be HF, and it, too, would be comparable for the two facilities. The cylinder treatment facility process stack would produce maximum annual average HF concentrations of 1.6×10^{-6} µg/m^3. This concentration is several orders of magnitude smaller than any applicable HF air quality standard.

No quantitative estimate was made of the impacts on the criterion pollutant ozone. Ozone formation is a regional issue that would be affected by emissions data for the entire area around a proposed conversion site. The pollutants most related to ozone formation that would result from the

conversion of depleted UF_6 are HC and NO_x. In later Phase II studies, when specific technologies and sites would be selected, the potential effects on ozone of these pollutants at a proposed site could be put in perspective by comparing them with the total emissions of HC and NO_x in the surrounding area. Small additional contributions to the totals would be unlikely to alter the ozone attainment status of the region.

F.3.4 Water and Soil

This section discusses impacts of the conversion options on surface water, groundwater, and soils. The impacts are evaluated over a range of conditions present at the representative sites and are also relevant for a similarly sized generic site located in the vicinity of a river that could be used to supply water for construction and normal operations and to receive liquid waste discharges. The major conversion option parameters are summarized in Table F.21.

F.3.4.1 Surface Water

The methodology used to determine potential impacts to surface water for each conversion technology is described in Appendix C and Tomasko (1997).

F.3.4.1.1 Conversion to U_3O_8

Construction. Construction of a U_3O_8 conversion facility would produce increased runoff to nearby surface waters because of replacing soil and vegetation with either buildings or paved areas, approximately 13 acres (5.3 ha) (LLNL 1997). The amount of increased runoff would be negligible compared with the assumed existing area for runoff (0.3 to 0.8% of the representative site areas). None of the construction activities would measurably affect floodplains.

Table F.21 shows the quantity of water that would be used during construction of the U_3O_8 conversion facility (about 8 million gal/yr). This water would be withdrawn from nearby rivers or pumped from underlying aquifers. If the rate of water consumption were constant, the average rate of withdrawal would be about 15 gpm. This rate of withdrawal would be negligible compared to average flows in the adjacent rivers (less than 0.0001%). If the water were obtained from aquifers, there would be no impacts to the surface waters. Construction impacts would, therefore, range from none to negligible.

For construction, the net volume of water disposed of would be about 4 million gal/yr (7.6 gpm) (Table F.21). The primary contaminants of concern would be construction chemicals, organics, and some suspended solids. The wastewater would be discharged to nearby surface waters under a National Pollutant Discharge Elimination System (NPDES) permit, or to an appropriate

TABLE F.21 Summary of Conversion Option Parameters Affecting Water Quality and Soil[a]

Option	Disturbed Land Area (acres)	Operations Area (acres)	Construction Water (million gal/yr)	Operations Water (million gal/yr)
Conversion to U_3O_8	20	13	Raw = 8 Waste = 4	Raw = 34 – 47 Waste = 15 – 23 Sanitary = 1.2
Conversion to UO_2	22 – 31	14 – 20	Raw = 4 – 12 Waste = 5 – 6	Raw = 41 – 285 Waste = 9.7 – 135 Sanitary = 0.7 – 2.3
Conversion to metal	23 – 26	15 – 16	Raw = 10 – 12 Waste = 5 – 6	Raw = 55 Waste = 25 – 26 Sanitary = 1.4 – 2.3

Option	Accident Scenario	Radioactive Release to Surface Water[a] (Ci/yr)	Radioactive Effluent Concentration[b] (pCi/L)	Dilution Factor[c]	Surface Water Concentration (pCi/L)
Conversion to U_3O_8	HF pipeline break	0.001	12 – 17	47,000 – 4,200,000	4.1×10^{-6} – 2.6×10^{-4}
Conversion to UO_2	HF pipeline break	0.002 – 0.003	6 – 21	42,000 – 500,000	1.2×10^{-5} – 5.0×10^{-4}
Conversion to metal	HF pipeline break	0.001 – 0.002	10 – 21	42,000 – 2,600,000	4.0×10^{-6} – 4.9×10^{-4}

[a] Data from engineering analysis report (LLNL 1997).

[b] Concentration derived from estimated annual radioactive release and annual wastewater discharge.

[c] Dilution factor based on average flow conditions in receiving rivers.

wastewater sewer. By following good engineering practices (e.g., stockpiling materials away from surface water drainages, covering construction piles with tarps to prevent erosion by precipitation, and cleaning up small chemical spills as soon as they occur), concentrations in the wastewater would be small (well below any drinking water criteria).

Once in the surface water, mixing and dilution of the pollutants would occur. This dilution would be greater than 270,000:1 for average flow conditions in nearby rivers. This amount of dilution would reduce any contamination present to concentrations well below regulatory standards. Because the concentration of contamination in the water would be very low, impacts to sediment in the streams would also be negligible.

Operations. For normal operations, no impacts would occur to surface runoff, and there would be no measurable impacts on floodplains (effluent discharges to surface waters less than 0.001% of the average flows). As indicated in Table F.21, normal operation of the U_3O_8 conversion facility would require at most 47 million gal/yr (approximately 89 gpm) of raw water. If this water were obtained from nearby rivers, impacts would be negligible, less than 0.004% of the average flows. If the raw water were obtained from wells, there would be no impacts to surface waters.

A maximum of 23 million gal/yr of wastewater would be generated during operations, including cooling tower blowdown, process water, and industrial waste water. Another 1.2 million gal/yr of sanitary wastewater would be produced (Table F.21). For constant rates of discharge, about 44 gpm of wastewater and 2.3 gpm of sanitary water would be released to the environment at approved NPDES locations.

The primary contaminants of concern for the wastewater would be uranium and chemicals used to inhibit rust, reduce friction, and enhance heat exchange (e.g., copolymers, phosphates, phosphonates, calcium, magnesium, nitrates, sodium, and potassium). As discussed in the engineering analysis report (LLNL 1997), approximately 0.001 Ci/yr of uranium with an activity of 4×10^{-7} Ci/g would be released in the discharge water. For a waste volume of 23 million gal/yr (Table F.21), the uranium concentration in the effluent would be about 30 µg/L. After dilution in nearby surface water, the concentration would be much less than the proposed U.S. Environmental Protection Agency (EPA) drinking water standard for uranium of 20 µg/L, used here for comparison. Concentrations of the other chemicals released would also be expected to be very low and within the guidelines of an NPDES permit.

Accident Scenarios. Most of the accidents analyzed would involve outdoor releases on impermeable concrete pads in the cylinder yards; such releases could be cleaned up with little loss of the contaminated material to the soil. The only postulated accident that would release contaminated water to the environment is an HF pipeline break produced by an earthquake (Table F.21). Anhydrous HF would be pumped from the process building to the HF storage building through an underground pipeline that would carry liquid HF at a rate of 10 gpm (0.63 L/s) through 200 ft (61 m) of 1-in. (2.5-cm) pipe. For this accident scenario, 100% of the HF would drain into the ground at a point 3 ft (0.91 m) below grade during a 10-minute period. Approximately 500 lb (227 kg) of liquid HF (60 gal [227 L]) would be released. After 48 hours, the contaminated soil was assumed to be removed. Because of the rapid response to the accident, the HF would have little time to travel into the soil. For a silty sand, the travel distance would be about 2 ft (6.1 m) (Tomasko 1997). Removal of the contaminated soil and soil water would prevent any contamination problems to the groundwater and would prevent any cross contamination with surface waters. Therefore, there would be no net impact from this accident. Because this accident scenario would not affect surface runoff or existing floodplains, impacts to these parameters would also be nonexistent.

F.3.4.1.2 Conversion to UO_2

The environmental parameters associated with the UO_2 conversion alternatives are similar to those for U_3O_8 conversion (Table F.21), except for raw water use, which would be about five times larger for normal operations. If water were withdrawn from a nearby river, impacts would be negligible and would be less than 0.03% of the average flows. If it were withdrawn from wells, there would be no surface water impacts. Because of this option's similarities to the U_3O_8 conversion option, impacts to surface water produced by UO_2 conversion would be essentially the same as those for U_3O_8 conversion (i.e., none to negligible).

As was the case for the conversion to U_3O_8 option, discharge waters would receive from 0.002 to 0.003 Ci/yr. For the water discharges listed in Table F.21, the equivalent concentrations would range from 6 to 76 pCi/L (30 to 400 µg/L). After dilution in nearby surface waters, concentrations would be much less than the EPA proposed drinking water standard for uranium, used here for comparison.

F.3.4.1.3 Conversion to Metal

The environmental parameters associated with conversion to metal are very similar to those for U_3O_8 conversion (Table F.21); however, raw water usage for construction and normal operation would be about 50% higher. If the construction water was obtained from a nearby river, the rate of withdrawal would be negligible compared to average flows (less than 0.001%). For normal operations, the increased rate of withdrawal would produce an impact less than 0.005% of the average flows. If the construction water and water for normal operations were obtained from wells, there would be no impacts on surface water.

As was the case for the conversion to U_3O_8 and UO_2 options, discharge waters would receive either 0.001 or 0.002 Ci/yr. For the water discharges listed in Table F.21, the equivalent concentrations would range from 25 to 53 µg/L. After dilution in nearby surface waters, the concentrations would be much less than the EPA proposed drinking water standard for uranium, used here for comparison.

F.3.4.1.4 Cylinder Treatment

Construction and operation of the cylinder treatment facility would use less land and water and produce less wastewater than the construction and operation of conversion facilities, as shown in Table F.22. Thus, potential impacts would be smaller. There are no postulated accidents that would directly release contaminants to surface water (LLNL 1997).

TABLE F.22 Summary of Environmental Parameters for the Cylinder Treatment Facility

Parameter	Unit	Construction	Operations	Accidents
Land area	acres	8.7	–	None
Disturbed land	acres	4.5	–	None
Water	million gal/yr	3.6	3.4	None
Wastewater[a]	million gal/yr	1.3	2.3	None

[a] Includes sanitary wastewater, cooling tower blowdown, industrial water, and process water.

F.3.4.2 Groundwater

The methodology for assessing impacts to groundwater for each conversion technology is described in detail in Appendix C and Tomasko (1997).

F.3.4.2.1 Conversion to U_3O_8

Potential impacts to groundwater could occur during construction, normal operations, and postulated accident scenarios. These impacts include the following: changes in effective recharge to underlying aquifers; changes in the depth to groundwater; changes in the direction of groundwater flow; and changes in groundwater quality.

If construction water were supplied from underlying aquifers, approximately 15 gpm would be withdrawn. This withdrawal represents a maximum 0.1% increase in extraction over that at representative facilities and would produce a negligible impact on the groundwater system. If the construction water were obtained from surface water, there would be no groundwater impacts. Groundwater quality could also be impacted by construction activities. For example, exposed chemicals could be mobilized by precipitation and infiltrate the surficial aquifers. By following good engineering and construction practices (e.g., covering chemicals to prevent interaction with rainfall, promptly cleaning up any chemical spills, and providing retention basins to catch and hold any contaminated runoff), groundwater concentrations would be less than the EPA guidelines.

Normal operations of the conversion facility would require about 65 gpm of raw water (Table F.21). If pumped from wells in the surficial aquifers, the impact would be negligible (0.5% increase in extraction). If withdrawn from nearby surface water, there would be no impact on groundwater. Because discharges to groundwater are not planned for normal operations, there would

be no direct impacts to groundwater quality. Potential impacts could be derived from interaction with surface water; however, because impacts to surface water are negligible, impacts to groundwater via a surface water pathway would be even less.

As discussed in Section F.3.4.1.1, only one accident scenario, the HF pipeline break, would potentially release contaminants to the groundwater (Table F.21). Because of rapid mitigation and the small volume of HF in the release, this scenario would have a negligible impact on groundwater quality and would not affect recharge, depth to groundwater, or direction of flow.

F.3.4.2.2 Conversion to UO_2

The environmental parameters associated with the UO_2 conversion alternatives are very similar to those for U_3O_8 conversion (Table F.21), except for raw water use during normal operations (about five times larger). If water were obtained from underlying aquifers, pumping would represent an increase of about 5% of the current groundwater use. These impacts would be negligible.

F.3.4.2.3 Conversion to Metal

The environmental parameters associated with the metal conversion alternatives are very similar to those for U_3O_8 conversion (Table F.21), except for a 50% increase in raw water use during construction and normal operations. If the water for construction and normal operations was obtained from underlying aquifers, pumping would increase by 0.15% above current usage during construction, and by 0.8% of the current use for normal operations. These impacts would be negligible. If the water needed for construction and operations was obtained from surface water, there would be no impacts to groundwater.

During construction, groundwater concentrations would be kept below EPA guidelines (EPA 1996) by following good engineering practices. During normal operations, there would be no impacts to groundwater quality because direct discharges to groundwater are not planned.

F.3.4.2.4 Cylinder Treatment Facility

For the cylinder treatment facility, there would be no direct impacts to groundwater during normal operations because groundwater would not be used to supply the water required (Table F.22) and there would be no discharges of wastewater to the ground. Impacts to groundwater during construction of the cylinder treatment facility include changes in effective recharge, changes in the depth to the water table, changes in the direction of groundwater flow, and changes in quality.

Construction of the cylinder treatment facility would decrease the permeability of about 4.5 acres (1.8 ha) of land because of paving and building. This loss of permeable land would reduce recharge, increase the depth to the water table, and change the direction of groundwater flow; however, because the area affected would be small (about 0.1 to 0.3% of the land area available), these impacts would be negligible and limited to small, local regions in the immediate vicinity of the paved lots and building footprints.

During construction, groundwater quality would also be impacted. For example, stockpiled chemicals could be mobilized by precipitation and infiltrate the surficial aquifers. By following good engineering and construction practices (e.g., covering chemicals to prevent interaction with rain, promptly cleaning up any chemical spills, and providing retention basins to catch and hold any contaminated runoff), groundwater concentrations would be less than the EPA guidelines.

F.3.4.3 Soil

The methodology for estimating potential impacts to soil is described in detail in Appendix C and Tomasko (1997).

F.3.4.3.1 Conversion to U_3O_8

Potential impacts to soil could occur during construction, normal operations, and postulated accident scenarios. These impacts include changes in topography, permeability, quality, and erosion potential. The impacts are evaluated over a range of conditions present at the representative sites and are also applicable for a similarly sized generic site located in the vicinity of a major river.

Paving and construction would alter about 13 acres (5.3 ha) and potentially disturb up to 20 acres (8.1 ha) (LLNL 1997). Soil beneath the buildings and paved areas may be altered permanently. Although the alteration of these lands might be permanent, the net impact would be negligible in comparison to the representative land areas involved (ranging from 0.3 to 0.8% of the land area available). A larger range of values is associated with the potential land area disturbed (ranging from 0.5 to 1.2% of the land area available). These impacts could include increased permeability, modification of the local topography, changes in the soil chemistry, and increases in the potential for soil erosion. These impacts would, however, be insignificant on a sitewide scale. In addition, impacts to these areas would be mitigated with time (e.g., disturbed soil would be regraded to natural contours and seeded with natural vegetation, thereby returning the soils to their original condition).

By following good engineering practices (e.g., disturbing as little soil as possible, contouring and reseeding disturbed lands, scheduling construction activities to minimize land disturbance, controlling runoff, using tarps to prevent chemical/precipitation interactions, and cleaning up any spills as soon as they occurred), negligible impacts to soils should occur.

Because normal operations would not affect soil, there would be no soil impacts. The only accident identified that could potentially impact the soil is an HF pipeline rupture (Table F.21), discussed in Section F.3.4.1.1. Because of rapid mitigation (any contaminated soil would be cleaned up within 48 hours of the rupture) and the small release volume (60 gal of HF), impacts to the soil would be negligible.

F.3.4.3.2 Conversion to UO_2

The environmental parameters associated with the UO_2 conversion alternatives are very similar to those for U_3O_8 conversion (Table F.21). Because of these similarities, impacts to soil for UO_2 conversion would be negligible.

F.3.4.3.3 Conversion to Metal

The environmental parameters associated with the metal conversion alternatives are very similar to those for U_3O_8 conversion (Table F.21). Because of these similarities, impacts to soils would be essentially the same as those previously presented, i.e., none to negligible.

F.3.4.3.4 Cylinder Treatment Facility

For the cylinder treatment facility, the only impacts would occur during construction. There would be no discharges to the ground under normal operations, and there are no accidents identified in LLNL (1997) that would lead to direct contamination of the soil. Impacts from construction would include changes in topography, permeability, quality, and erosion potential. By following good engineering and construction practices (e.g., covering chemicals with tarps, cleaning up chemical spills as soon as they occur, and providing retention basins to catch and hold any contaminated surface runoff), impacts to soil quality would be negligible.

F.3.5 Socioeconomics

The impact of each conversion option on socioeconomic activity was estimated for a region of influence (ROI) at the three representative sites. The assessment methodology is discussed in Appendix C and Allison and Folga (1997).

Each of the conversion options is likely to have a small impact on socioeconomic conditions in the ROIs surrounding the three representative sites described in Chapter 3, Sections 3.1.8, 3.2.8, and 3.3.8. This is largely because a major proportion of the expenditures associated with procurement for the construction and operation of each technology option flows

outside the ROI to other locations in the United States, reducing the concentration of local economic effects of each conversion option.

Slight changes in employment and income would occur in each ROI as a result of local spending of personal consumption expenditures derived from employee wages and salaries, local procurement of goods and services required to construct and operate each conversion option, and other local investment associated with construction and operation. In addition to creating new (direct) jobs at each site, each conversion option would also create indirect employment and income in the ROI as a result of jobs and procurement expenditures at each site. Jobs and income created directly by each conversion option, together with indirect activity in the ROI, would contribute slightly to reduction in unemployment in the ROI surrounding each site. Minimal impacts are expected on local population growth, and consequently on local housing markets and local fiscal conditions.

The effects of constructing and operating each conversion technology on regional economic activity (measured in terms of employment and personal income) and on population, housing, and local public revenues and expenditures are described in Sections F.3.5.1 through F.3.5.4. Impacts are presented as ranges to include impacts that would occur with each conversion option and for the cylinder treatment facility at each of the representative sites. Impacts for the three sites are presented for the peak year of construction (assumed to be 2006) and the first year of operations (assumed to be 2009). The potential impacts for each conversion option and for the cylinder treatment facility are presented in Table F.23.

F.3.5.1 Conversion to U_3O_8

During the peak year of construction of a U_3O_8 conversion facility, between 240 and 250 direct jobs would be created at the site and 170 to 330 additional jobs would be created indirectly in the site ROI (Table F.23) as a result of the spending of employee wages and salaries and procurement-related expenditures. Overall, 410 to 580 jobs would be created. Construction activity would also produce direct and indirect income in the ROI surrounding the site, with total income ranging from $14 million to $17 million during the peak year. During the first year of operations of the U_3O_8 conversion facility, 440 to 510 direct and indirect jobs would be created. Direct and indirect income would also be produced in the ROIs, with total income ranging from $14 million to $15 million. Construction and operation of the conversion facility would result in an increase in the projected baseline compound annual average growth rate in ROI employment of 0.01 to 0.05 percentage points from 1999 through 2028.

Construction of the U_3O_8 conversion facility would be expected to generate direct in-migration of 330 to 340 people in the peak year of construction at the site. Additional indirect job in-migration would also be expected in the site ROIs, bringing the total number of in-migrants to between 410 and 470 in the peak year (Table F.23). Operation of the U_3O_8 conversion facility would be expected to generate direct and indirect job in-migration of 220 to 340 in the first year of

TABLE F.23 Potential Socioeconomic Impacts of the Conversion Options

	Conversion to U_3O_8		Conversion to UO_2	
	Construction[a]	Operations[b]	Construction[a]	Operations[b]
Economic activity in the ROI				
Direct jobs	240 – 250	200 – 210	330 – 630	230 – 360
Indirect jobs	170 – 330	240 – 300	230 – 730	310 – 920

[a] Impacts are for the peak year of construction, 2007. Socioeconomic impacts were assessed for 1999 through 2008.

[b] Impacts are the annual averages for operations for the period 2009 through 2028.

operations. Construction and operation of the facility would result in an increase in the projected baseline compound annual average growth rate in ROI population of less than 0.01 to 0.04 percentage points from 1998 through 2028.

A U_3O_8 conversion facility would generate a demand for 150 to 170 additional rental housing units during the peak year of construction (Table F.23), representing an impact of 2.7-11% on the projected number of vacant rental housing units in the representative site ROIs. A demand for 80 to 130 additional owner-occupied housing units would be expected in the first year of operations, representing an impact of 0.7 to 2.7% on the number of vacant owner-occupied housing units in the ROIs.

During the peak year of construction, 410 to 470 people would be expected to in-migrate into the ROI at the site, leading to increases of between 0.1 and 0.3% over forecasted baseline revenues and expenditures in the representative site ROI (Table F.23). In the first year of operations, 220 to 340 in-migrants would be expected, leading to increases of less than 0.1 to 0.2% in local revenues and expenditures.

F.3.5.2 Conversion to UO_2

During the peak year of construction of a UO_2 conversion facility, 330 to 630 direct jobs would be created at the site and 230 to 730 additional jobs indirectly in the site ROI (Table F.23) as a result of the spending of employee wages and salaries and procurement-related expenditures. Overall, 560 to 1,400 jobs would be created. Construction activity would also produce direct and indirect income in the ROI surrounding the site, with total income ranging from $19 million to $42 million during the peak year. During the first year of operations of the UO_2 conversion facility, 540 to 1,200 direct and indirect jobs would be created. Direct and indirect income would also be produced in the ROI, with total income ranging from $16 million to $28 million. Construction and operation of the conversion facility would result in an increase in the projected baseline compound annual average growth rate in ROI employment of 0.01 to 0.1 percentage points from 1999 through 2028.

Construction of the UO_2 conversion facility would be expected to generate direct in-migration of 460 to 860 people in the peak year of construction at the site. Additional indirect job in-migration would also be expected in the site ROIs, bringing the total number of in-migrants to between 570 and 1,200 in the peak year (Table F.23). Operation of the UO_2 conversion facility would be expected to generate direct and indirect job in-migration of 210 to 1,100 in the first year of operations. Construction and operation of the facility would result in an increase in the projected baseline compound annual average growth rate in ROI population of less than 0.01 to 0.06 percentage points from 1999 through 2028.

The UO_2 conversion facility would generate a demand for 210 to 440 additional rental housing units during the peak year of construction, representing an impact of 3.8 to 28% on the

projected number of vacant rental housing units in the representative site ROIs (Table F.23). A demand for 80 to 390 additional owner-occupied housing units would be expected in the first year of operations, representing an impact of 0.7 to 8.2% on the number of vacant owner-occupied housing units in the ROIs.

During the peak year of construction, 570 to 1,200 people would be expected to in-migrate into the ROI at the site, leading to increases of 0.1 to 0.7% over forecasted baseline revenues and expenditures in the representative site ROIs (Table F.23). In the first year of operations, 210 to 1,100 in-migrants would be expected, leading to increases of less than 0.1 to 0.6% in local revenues and expenditures.

F.3.5.3 Conversion to Metal

During the peak year of construction of a metal conversion facility, 380 to 440 direct jobs would be created at the site and 230 to 470 additional jobs indirectly in the site ROI (Table F.23) as a result of the spending of employee wages and salaries and procurement-related expenditures. Overall, 610 to 910 jobs would be created. Construction activity would also produce direct and indirect income in the ROI surrounding the site, with total income ranging from $15 million to $25 million during the peak year. During the first year of operations of the metal conversion facility, 520 to 890 direct and indirect jobs would be created. Direct and indirect income would also be produced in the ROI, with total income ranging from $15 million to $27 million. Construction and operation of the conversion facility would result in an increase in the projected baseline compound annual average growth rate in ROI employment of 0.01 to 0.09 percentage points from 1999 through 2028.

Construction of the metal conversion facility would be expected to generate direct in-migration of 520 to 600 people in the peak year of construction at the site. Additional indirect job in-migration would also be expected in the site ROI, bringing the total number of in-migrants to between 650 and 790 in the peak year (Table F.23). Operation of the metal conversion facility would be expected to generate direct and indirect job in-migration of 240 to 630 in the first year of operations. Construction and operation of the facility would result in an increase in the projected baseline compound annual average growth rate in ROI population of 0.01 to 0.08 percentage points from 1999 through 2028.

The metal conversion facility would generate a demand for 240 to 290 additional rental housing units during the peak year of construction, representing an impact of 4.3 to 18.5% on the projected number of vacant rental housing units in the representative site ROIs (Table F.23). A demand for 90 to 230 additional owner-occupied housing units would be expected in the first year of operations, representing an impact of 0.8 to 4.9% on the number of vacant owner-occupied housing units in the ROI.

During the peak year of construction, 650 to 790 people would be expected to in-migrate into the ROI surrounding the site, leading to increases of 0.1 to 0.5% over forecasted baseline revenues and expenditures in the representative site ROIs (Table F.23). In the first year of operations, 240 to 630 in-migrants would be expected, leading to increases of less than 0.1 to 0.4% in local revenues and expenditures.

F.3.5.4 Cylinder Treatment Facility

During the peak year of construction of a cylinder treatment facility, approximately 100 direct jobs would be created at the site and 40 to 80 additional jobs indirectly in the site ROI (Table F.23) as a result of the spending of employee wages and salaries and procurement-related expenditures. Overall, 150 to 180 jobs would be created. Construction activity would also produce direct and indirect income in the ROI surrounding the site, with total income ranging from $5 million to $6 million during the peak year. During the first year of operations of the cylinder treatment facility, 260 to 310 direct and indirect jobs would be created. Direct and indirect income would also be produced in the ROI, with total income ranging from $13 million to $14 million. Construction and operation of the facility would result in an increase in the projected baseline compound annual average growth rate in ROI employment of 0.01 to 0.03 percentage points from 1999 through 2028.

Construction of the cylinder treatment facility would be expected to generate direct in-migration of 140 people in the peak year of construction at the site. Additional indirect job in-migration would also be expected in the site ROI, bringing the total number of in-migrants to between 160 and 180 in the peak year (Table F.23). Operation of the cylinder treatment facility would be expected to generate direct and indirect job in-migration of 240 to 300 in the first year of operations. Construction and operation of the facility would result in an increase in the projected baseline compound annual average growth rate in ROI population of less than 0.01 to 0.02 percentage points from 1999 through 2028.

The cylinder treatment facility would generate a demand for 60 to 70 additional rental housing units during the peak year of construction, representing an impact of 1.1 to 4.4% on the projected number of vacant rental housing units in the representative site ROIs (Table F.23). A demand for 90 to 110 additional owner-occupied housing units would be expected in the first year of operations, representing an impact of 0.8 to 2.3% on the number of vacant owner-occupied housing units in the ROI.

During the peak year of construction, 160 to 180 people would be expected to in-migrate into the ROI surrounding the site, leading to increases of 0.0 to 0.1% over forecasted baseline revenues and expenditures in the representative site ROIs (Table F.23). In the first year of operations, 240 to 300 in-migrants would be expected, leading to increases of less than 0.1 to 0.2% in local revenues and expenditures.

F.3.6 Ecology

Moderate impacts to ecological resources could result from construction of a conversion facility. Impacts could include mortality of individual organisms, habitat loss, or changes in biotic communities. Impacts due to operation of a conversion facility would be negligible. Potential impacts to vegetation, wildlife, wetlands, and threatened and endangered species were assessed. The methodology used in the ecological impact analysis is discussed in Appendix C.

F.3.6.1 Conversion to U_3O_8

Site preparation for the construction of a facility to convert UF_6 to U_3O_8 would require the disturbance of approximately 20 acres (8 ha), including the permanent replacement of approximately 13 acres (5.3 ha) with structures and paved areas. Existing vegetation would be destroyed during land clearing activities. Determination of the vegetation communities that would be eliminated by site preparation would depend on the future location of the facility. Communities occurring on undeveloped land at the three representative sites are relatively common and well represented in the vicinity of the sites. Impacts to high-quality native plant communities may occur if facility construction requires disturbance to vegetation communities outside of the currently fenced areas (see Section F.3.9 for a discussion of land use). Construction of the conversion facility would not be expected to threaten the local population of any species. The loss of up to 20 acres (8 ha) of undeveloped land would constitute a moderate adverse impact. Erosion of exposed soil at construction sites could reduce the effectiveness of restoration efforts and create sedimentation downgradient of the site. The implementation of standard erosion control measures, installation of storm-water retention ponds, and immediate replanting of disturbed areas with native species would help minimize impacts to vegetation. Impacts due to facility construction are shown in Table F.24.

Wildlife would be disturbed by land clearing, noise, and human presence. Wildlife with restricted mobility, such as burrowing species or juveniles of nesting species, would be destroyed during land clearing activities. More mobile individuals would relocate to adjacent available areas with suitable habitat. Population densities, and thus competition for food and nesting sites, would increase in these areas, potentially reducing the survivability or reproductive capacity of displaced individuals. Many wildlife species would be expected to quickly recolonize replanted areas near the conversion facility following completion of construction. The permanent loss of up to 13 acres (5.3 ha) of habitat would not be expected to threaten the local population of any wildlife species because similar habitat would be available in the vicinity of the sites. Therefore, construction of a conversion facility for U_3O_8 production would be considered a moderate adverse impact to wildlife.

Impacts to surface water and groundwater quality during construction are expected to be negligible (Section F.3.4). Thus, construction-derived impacts to aquatic biota would also be expected to be negligible. Wetlands could potentially be impacted by filling or draining during construction. Impacts to wetlands due to alteration of surface water runoff patterns, soil compaction, or groundwater flow could occur if the conversion facility were located immediately adjacent to

TABLE F.24 Impacts to Ecological Resources from Construction of a Conversion Facility and Cylinder Treatment Facility

Option/Resource	Type of Impact	Degree of Impact
Conversion to U_3O_8		
Vegetation	Loss of 20 acres	Moderate adverse impact
Wildlife	Loss of 13 to 20 acres	Minor to moderate adverse impact
Wetlands	Loss, degradation	Potential adverse impact
Aquatic species	Water quality, habitat reduction	Negligible impact
Protected species	Destruction, habitat loss	Potential adverse impact
Conversion to UO_2		
Vegetation	Loss of 22 to 31 acres	Moderate adverse impact
Wildlife	Loss of 14 to 31 acres	Moderate adverse impact
Wetlands	Loss, degradation	Potential adverse impact
Aquatic species	Water quality, habitat reduction	Negligible impact
Protected species	Destruction, habitat loss	Potential adverse impact
Conversion to metal		
Vegetation	Loss of 23 to 26 acres	Moderate adverse impact
Wildlife	Loss of 15 to 26 acres	Moderate adverse impact
Wetlands	Loss, degradation	Potential adverse impact
Aquatic species	Water quality, habitat reduction	Negligible impact
Protected species	Destruction, habitat loss	Potential adverse impact
Cylinder treatment facility		
Vegetation	Loss of 9 acres	Moderate adverse impact
Wildlife	Loss of 5 to 9 acres	Moderate adverse impact
Wetlands	Loss, degradation	Potential adverse impact
Aquatic species	Water quality, habitat reduction	Negligible impact
Protected species	Destruction, habitat loss	Potential adverse impact

wetland areas. However, impacts to wetlands would be minimized by maintaining a buffer area around wetlands during construction of the facility. Unavoidable impacts to wetlands would require a *Clean Water Act* Section 404 permit, which might stipulate mitigative measures. Additional permitting might be required by state agencies.

Critical habitat has not been designated for any state or federally listed threatened or endangered species at any of the representative sites. Prior to construction of a conversion facility, a site-specific survey for federal- and state-listed threatened, endangered, or candidate species or

species of special concern would be conducted. Impacts to these species could thus be avoided or, where impacts were unavoidable, appropriate mitigation could be developed.

During operations, ecological resources in the vicinity of the conversion facility would be exposed to atmospheric emissions from the boiler stack and process stack; however, emission levels would be expected to be extremely low (Section F.3.3.2). The highest annual average air concentration of U_3O_8 at a representative site boundary would be less than 2.6×10^{-5} $\mu g/m^3$. This would result in a radiation exposure to the general public (nearly 100% due to inhalation) of less than 0.009 mrem/yr (Section F.3.1.1), well below the DOE guidelines of 100 mrem/yr (0.00027 rad/d). Wildlife species are less sensitive to radiation than humans (proposed DOE guidelines would require an absorbed dose limit to terrestrial animals of 0.1 rad/d). Therefore, impacts to wildlife due to radiation effects would be expected to be negligible. Toxic effects of chronic inhalation of U_3O_8 are minor at a concentration of 17 mg/m^3 for tested animal species. This is many orders of magnitude greater than expected emissions. Therefore, toxic effects to wildlife due to U_3O_8 inhalation would also be expected to be negligible. See Appendix C for further discussion.

The maximum annual average air concentration of hydrogen fluoride at a site boundary, due to operation of a conversion facility, would be less than 0.0073 $\mu g/m^3$ (Section F.3.3.2). Chronic exposure to HF gas produces only mild effects in tested animal species at concentrations as high as 7 mg/m^3, considerably higher than expected emissions. Therefore, toxic effects to wildlife from HF emissions would be expected to be negligible.

A portion of the U_3O_8 released from the process stack of a conversion facility would become deposited on the soils surrounding the site. Uptake of uranium-containing compounds can cause adverse effects to vegetation. Deposition of U_3O_8 on soils, resulting from atmospheric emissions, would result in soil uranium concentrations considerably below the lowest concentration known to produce toxic effects in plants. Therefore, toxic effects on vegetation due to U_3O_8 uptake would be expected to be negligible.

Effluent discharges to surface waters would result in a uranium concentration of about 12 pCi/L (0.03 mg/L) as uranyl nitrate (Section F.3.4.1). Resulting dose rates to maximally exposed organisms would be considerably lower than the dose limit of 1 rad/d for aquatic organisms, which is required by DOE Order 5400.5. Uranyl nitrate concentrations in the effluent also would be considerably lower than 0.15 mg/L, the lowest concentration known to cause toxic effects in aquatic biota. Mixing of the effluent with surface water downstream of the outfall would result in a dilution factor of more than 50,000. Therefore, impacts to aquatic biota would be considered to be negligible.

For the U_3O_8 conversion process, water withdrawal from surface waters or groundwater, as well as wastewater discharge, could potentially alter water levels which could in turn affect aquatic ecosystems including wetlands (including wetlands located along the periphery of these surface water bodies). However, water level changes due to process water withdrawal and wastewater discharge would be negligible (Section F.3.4.1). Therefore, impacts to wetlands would be expected to be negligible.

A potential release of contaminants due to the occurrence of an earthquake was analyzed. The subsequent rupture of an HF pipeline would potentially release anhydrous HF into the surrounding soil, surface water, or groundwater. Due to the brief duration of the release, the small volume involved, and rapid mitigation, the expected impacts to surface water, groundwater, and soil would be negligible (Section F.3.4). Therefore, impacts to ecological resources from such an accident would also be expected to be negligible. Facility accidents, as discussed in Section F.3.2, could result in adverse impacts to ecological resources. The affected species and the degree of impact would depend on a number of factors such as location of the accident, season, and meteorological conditions.

F.3.6.2 Conversion to UO_2

The construction of a facility to convert depleted UF_6 to UO_2 would generally result in the types of impacts associated with conversion to U_3O_8. Site preparation for the construction of a facility to convert depleted UF_6 to UO_2 would require the disturbance of approximately 22 to 31 acres (8.9 to 12.5 ha), including the permanent replacement of approximately 14 to 19 acres (5.5 to 7.8 ha) with structures and paved areas. The loss of 22 to 31 acres (8.9 to 12.5 ha) of undeveloped land would constitute a moderate adverse impact to vegetation. The permanent loss of up to 19 acres (7.8 ha) of habitat would not be expected to threaten the local population of any wildlife species because similar habitat would be available in the vicinity of the representative sites. However, habitat use in the vicinity of the facility might be greatly reduced for many species due to the construction of a perimeter fence. Consequently, the construction of a conversion facility for UO_2 production is considered a moderate adverse impact to wildlife.

Impacts to surface water and groundwater quality during construction would be expected to be negligible (Section F.3.4). Thus, construction-derived impacts to aquatic biota would also be expected to be negligible. Impacts to wetlands and protected species due to facility construction would be similar to impacts associated with conversion to U_3O_8.

During operations, exposures to contaminants from conversion to UO_2 would generally be slightly larger than for conversion to U_3O_8, but all exposures would be well below levels that might produce adverse effects. All impacts would therefore be negligible. Impacts to ecological resources from accident scenarios would be as discussed for conversion to U_3O_8 (Section F.3.6.1).

F.3.6.3 Conversion to Metal

Construction of a facility to convert depleted UF_6 to uranium metal would generally result in the types of impacts associated with conversion to U_3O_8. Site preparation would require the disturbance of approximately 23 to 26 acres (9.4 to 11 ha), including the permanent replacement of about 15 to 16 acres (6.2 to 6.5 ha) with structures and paved areas. The loss of 23 to 26 acres (9.4

to 11 ha) of undeveloped land would constitute a moderate adverse impact to vegetation and wildlife. Impacts due to facility construction are shown in Table F.24.

During operation of the metal conversion facility, exposure to contaminants would be considerably below levels known to cause toxic effects in biota. The resulting impacts would therefore be negligible. Impacts to ecological resources from accidents would be as discussed for conversion to U_3O_8 (Section F.3.6.1).

Construction of a cylinder treatment facility would generally result in the types of impacts associated with construction of a conversion facility; however, the area affected would be smaller (Table F.24). Site preparation for constructing a cylinder treatment facility would require the disturbance of approximately 9 acres (4 ha). About 5 acres (2 ha) would be permanently replaced with structures, paved areas, and landscaping. The loss of 9 acres (4 ha) of undeveloped land would constitute a moderate adverse impact to vegetation and wildlife. Exposure to contaminants resulting from operation of a cylinder treatment facility would be considerably below levels known to result in toxic effects to biota. The resulting impacts would therefore be negligible.

F.3.7 Waste Management

Impacts on waste management from wastes generated during construction and normal operations at the depleted UF_6 conversion facilities would be caused by the potential overload of waste treatment and/or disposal capabilities either at a site or on a regional/national scale. The types of wastes that are expected to be generated by the depleted UF_6 conversion include low-level radioactive waste (LLW), low-level mixed waste (LLMW), hazardous waste, nonhazardous solid waste, and nonhazardous wastewater. Currently, there are numerous DOE and commercial facilities that treat and/or dispose of LLW, hazardous waste, nonhazardous solid waste, and wastewaters. The treatment/disposal of LLMW is limited by regulatory and technological restrictions.

F.3.7.1 Conversion to U_3O_8

Construction of a facility to convert UF_6 into U_3O_8 would generate both hazardous and nonhazardous wastes. Approximately 115 m^3 of hazardous waste, 700 m^3 of nonhazardous solid waste, and 15,000 m^3 of wastewater would be generated during construction (see Table F.25). This compares with existing contributions for hazardous waste ranging from approximately 80 m^3/yr to 1,000 m^3/yr, solid waste loads for the representative sites of 2,100 to 28,000 m^3/yr, and wastewater loads of 500,000 to 880,000 m^3 annually for the representative sites (see Appendix C, Table C.3). No radioactive waste would be generated during the construction phase of the facility. Overall, only minimal waste management impacts would result from construction-generated wastes.

Operations at the facility to convert UF_6 into U_3O_8 would generate radioactive, hazardous, and nonhazardous wastes (Table F.25). The conversion facility would generate 140 to 600 m^3/yr of

TABLE F.25 Wastes Generated from Construction and Operations Activities for Depleted UF_6 Conversion[a]

Activity/ Waste Category	Volume Ranges for the Options		
	Conversion to U_3O_8	Conversion to UO_2	Conversion to Metal
Construction[a] (m^3)			
Low-level waste	–	–	–
Low-level mixed waste	–	–	–
Hazardous waste	115	140 – 200	140 – 180
Nonhazardous waste			
Solids	700	1,300	860 – 1,130
Wastewater	3,800	7,600	5,700 – 7,580
Sanitary wastewater	11,400	17,000	13,200 – 15,200
Operations (m^3/yr)			
Low-level waste			
Combustible waste	76.5	88.0 – 136	76.5 – 420
Noncombustible	62 – 68.2	82.0 – 140	112 – 470
Grouted	0 – 466	0 – 466	0 – 997
Total	140 – 600	170 – 740	190 – 1,890
Low-level mixed waste	1.1	1.1 – 8.8	1.1
Hazardous waste	7.32	7.32 – 17	7.32 – 9.5
Nonhazardous waste			
Solids	380 – 11,000[b]	520 – 30,600[b]	6,580 – 6,840[c]
Wastewater	58,000 – 87,100	74,900 – 510,000	94,000 – 96,500
Sanitary wastewater	4,540 – 4,920	5,680 – 8,700	5,300 – 8,700

[a] Total waste generated during construction period of 4 years.

[b] Includes 240 to 10,630 m^3 of CaF_2.

[c] Includes 67 m^3 of CaF_2 and 5,850 to 6,110 m^3 of MgF_2.

LLW, which, at the upper end, represents approximately 7 to 27% of the representative site LLW loads (see Appendix C, Table C.3). The U_3O_8 conversion facility waste input would represent less than 1% of DOE LLW generation. The U_3O_8 conversion facility would generate approximately 1.1 m^3/yr of LLMW, which is less than 1% of the LLMW generation at the representative sites (ranging from 100 to 5,000 m^3/yr LLMW) (see Appendix C, Table C.3). The U_3O_8 conversion facility would generate approximately 7 m^3/yr of hazardous waste, which would result in an increase of about 1 to 10% of the hazardous waste loads at the representative sites; and about 60,000 to

90,000 m^3/yr of wastewater, representing between 9 and 17% of the current loads for wastewater at the representative sites.

The CaF_2 potentially produced in the U_3O_8 conversion process was assumed to have a uranium content of less than 1 ppm (LLNL 1997). It is currently unknown whether this CaF_2 could be sold (e.g., as feedstock for commercial production of anhydrous HF) or whether the low uranium content would require disposal as either a nonhazardous solid waste or as LLW. The nonhazardous solid waste generation estimates for conversion to U_3O_8 and UO_2, as shown in Table F.25, are based on the assumption that CaF_2 would be disposed of as nonhazardous solid waste, generating approximately 380 to 11,000 m^3/yr of nonhazardous solid waste (from 18 to 500% of the current nonhazardous solid waste loads at the representative sites, depending on the conversion technology chosen). If CaF_2 were considered to be LLW, it would represent an additional 3 to 480% of the current LLW loads at the representative sites. The upper end of the range of nonhazardous and LLW volume increases (which correspond to the HF neutralization process) would constitute a potentially large impact to either nonhazardous or LLW management activities at an actual site. Disposal as LLW might require the CaF_2 to be grouted, generating up to 21,300 m^3/yr of grouted waste. The maximum volume of LLW generated would still represent less than 10.4% of the projected DOE complexwide LLW disposal volume, constituting a moderate impact with respect to complexwide LLW management. It is also unknown whether CaF_2 LLW would be considered DOE waste if the conversion were conducted by a private commercial enterprise. If CaF_2 could be sold, the nonhazardous solid waste or LLW management impacts would be reduced to a low level for U_3O_8 conversion technologies.

The impacts from normal operation of the U_3O_8 conversion facility would range from negligible to large, depending upon the choice of technology and the ultimate generation volumes and disposition of CaF_2 for the facility. Overall, the waste input resulting from normal operations at the U_3O_8 conversion facility would be expected to have a moderate impact on waste management. If CaF_2 were disposed of as nonhazardous solid waste, the increased input could be managed by expanding the capacity of the nonhazardous solid waste disposal facilities at the actual site.

F.3.7.2 Conversion to UO_2

Construction of a facility to convert UF_6 into UO_2 would generate approximately the same quantity of hazardous wastes as conversion to U_3O_8. Construction would generate approximately 1,300 m^3 of solid nonhazardous wastes and up to 24,000 m^3 of wastewater (see Table F.25). These waste loads are well below the representative site waste inputs for comparable wastes. No radioactive waste would be generated during the construction phase of the facility. Overall, only minimal waste management impacts would result from construction-generated wastes.

Operations at the facility to convert UF_6 into UO_2 would generate radioactive, hazardous, and nonhazardous wastes (Table F.25). The conversion facility would generate about 9 to 33% of the representative site LLW loads (see Appendix C, Table C.3). The UO_2 conversion facility would

generate up to 465 m^3/yr of a solid, grouted LLW that would require off-site disposal. The conversion facility LLW input would represent less than 1% of the projected annual DOE LLW treatment volume. The UO_2 conversion facility would generate from 1 to 9% of the LLMW generation for the representative sites (see Appendix C, Table C.3). The UO_2 conversion facility would generate 7 to 17 m^3/yr of hazardous waste, which would result in a minor increase to the hazardous waste load from routine operations at the representative site. The UO_2 conversion facility would add 520 to 30,600 m^3/yr of nonhazardous solid waste and about 80,000 to 500,000 m^3/yr of wastewater (see Table F.25).

As in the U_3O_8 conversion option, it is currently unknown whether CaF_2 generated in the conversion to UO_2 option could be sold or whether the low uranium content (less than 1 ppm) would require disposal as either a nonhazardous solid waste or as LLW. The nonhazardous solid waste generation estimates for conversion to UO_2 shown in Table F.25 are based on the assumption that CaF_2 would be disposed of as nonhazardous solid waste, generating about 240 to 11,000 m^3/yr of nonhazardous solid waste (up to 500% of the current nonhazardous solid waste loads at the representative sites, depending on the conversion technology chosen). If CaF_2 were considered to be LLW, it would represent up to 480% of the current LLW loads at the representative sites. The upper end of the range of nonhazardous and LLW volume increases (which correspond to the HF neutralization process) would constitute a potentially large impact to either nonhazardous or LLW management activities at an actual site. Disposal as a LLW might require the CaF_2 to be grouted, generating up to 21,300 m^3/yr of grouted waste. However, the maximum volume of LLW generated would still represent less than 10.4% of the projected DOE complexwide LLW disposal volume, constituting a moderate impact with respect to complexwide LLW management, if the CAF_2 were considered DOE waste. If CaF_2 could be sold, the nonhazardous solid waste or LLW management impacts would be reduced to a low level for UO_2 conversion technologies.

The large range in the expected volume of nonhazardous solid waste and wastewater is also a result of differences in UO_2 conversion technologies. The gelation technology would result in the highest nonhazardous waste generation volumes. The range of 520 to 30,600 m^3/yr for nonhazardous solid wastes represents an approximate range of 2 to 1,500% (15 times) the annual nonhazardous solid waste production at the representative sites. The estimated range for wastewater generation represents a range of about 13 to 115% of the annual wastewater generation at the representative sites.

The impacts from normal operation of the UO_2 conversion facility would range from negligible to large, depending upon the choice of technology for this facility. Overall, the waste input resulting from normal operations at the UO_2 conversion facility would be expected to have a moderate impact on waste management. The increased solid waste input could be managed by expanding the capacity of the solid nonhazardous waste disposal facilities at the sites. The increased wastewater input would be handled by existing site wastewater capabilities of the representative sites.

F.3.7.3 Conversion to Metal

Construction of the facility to convert UF_6 into uranium metal would generate approximately the same quantity of hazardous and nonhazardous wastes as conversion to U_3O_8 or UO_2 (Table F.25). No radioactive waste would be generated during the construction phase of the facility. Overall, only minimal waste management impacts would result from construction-generated wastes.

Operations at the facility to convert UF_6 into uranium metal would generate radioactive, hazardous, and nonhazardous wastes (Table F.25). The conversion facility would generate about 23 to 85% of the representative site LLW loads (see Appendix C, Table C.3). A metal conversion facility LLW input would represent less than 3% of the projected annual DOE LLW treatment volume. The metal conversion facility would generate less than 1% of the LLMW generation at the representative sites (see Appendix C, Table C.3) and less than 12% of the hazardous waste load from routine operations at the three representative sites. The metal conversion facility would add from 25 to 325% of the existing representative site solid waste load and from 12 to 20% of the load for wastewater. The increased solid waste input could be managed by expanding the disposal capacity of the solid nonhazardous waste disposal facilities at the actual site.

It is possible that the MgF_2 waste generated in the conversion to metal option would be sufficiently contaminated with uranium to require disposal as LLW rather than as solid nonhazardous waste. The uranium level in the MgF_2 is estimated to be about 90 ppm (LLNL 1997). Such disposal might require the MgF_2 waste to be grouted, generating about 6,150 to 12,300 m^3/yr of grouted waste for LLW disposal. This volume range represents about 72 to 560% of the current LLW generation for the representative three sites (see Appendix C, Table C.3). However, it would represent less than 6% of the projected DOE complexwide LLW disposal volume, constituting a low impact with respect to complexwide LLW management, if the MgF_2 were considered a DOE waste.

Neutralization of HF to CaF_2 was not explicitly analyzed in the engineering analysis report for the conversion to metal options (LLNL 1997). However, the process could be implemented and would produce approximately one-third as much CaF_2 as would be produced under the conversion to oxide with neutralization options (i.e., approximately 3,500 m^3/yr of CaF_2). If this CaF_2 waste were disposed of as LLW, it would constitute less than 3% of the DOE complexwide LLW disposal volume, representing a low impact with respect to complexwide LLW management.

Overall, the waste input resulting from normal operations at the uranium metal conversion facility would have a moderate impact on waste management.

F.3.7.4 Cylinder Treatment Facility

All of the conversion options would require the removal of depleted UF_6 from the storage cylinders, resulting in a large number of empty cylinders. These empty UF_6 cylinders from the conversion facility would be decontaminated at the cylinder treatment facility and then prepared for

disposal as scrap metal. It was assumed for this assessment that the cylinder treatment facility would be washing the empty cylinders with water to remove the "heels" of depleted UF_6. The resulting aqueous wash solution would be evaporated and converted to solid U_3O_8 and HF. The U_3O_8 would be packaged and sent for disposal. The HF would be neutralized to CaF_2 and separately packaged for either disposal or sale.

Construction of the cylinder treatment facility would generate both hazardous and nonhazardous wastes. These waste quantities — hazardous, 18 m^3; solid nonhazardous, 300 m^3; and sanitary and other nonhazardous liquids, 28,000 m^3 — all represent only minimal waste management impacts at any of the three potential sites. No radioactive waste would be generated during construction of this facility.

The amounts of waste generated annually during operation of the cylinder treatment facility are given in Table F.26. Included are crushed old cylinders and wastes obtained (U_3O_8 and CaF_2) from disposal of the "heels." All of these wastes, except the crushed old cylinders, represent only negligible impacts to the waste management system. Over 20 years of operations, the crushed old cylinders (2,322 cylinders/yr) would generate about 125,000 m^3 (6,190 m^3/yr × 20 years) of waste volume for disposal. It was assumed that the treated cylinders with a very low residual radiation level

TABLE F.26 Annual Waste Generation during Operation of the Cylinder Treatment Facility

Waste Category	Volume (m^3/yr)
Low-level waste	
Combustible solids	31
Contaminated metal and other noncombustible solids	11
U_3O_8	6.3
Low-level mixed waste	0.2
Hazardous waste	2
Nonhazardous waste	
Solids	100
Wastewater	6,400
CaF_2	14
Sanitary waste	2,300
Crushed cylinders	6,190

would become part of the DOE scrap metal inventory. If a disposal decision were made, the treated cylinders would be disposed of as LLW, representing a 3% addition to the projected DOE complexwide LLW disposal volume.

F.3.7.5 Summary

The impacts from the uranium metal conversion facility would be greater than the waste management impacts resulting from operations of U_3O_8 conversion, unless CaF_2 required disposal as a waste. In the latter case, the impacts to waste management facilities for U_3O_8 conversion would probably exceed those for uranium metal conversion. The largest waste volumes would result from conversion to UO_2.

F.3.8 Resource Requirements

Utilities and materials required for constructing the conversion facility for UF_6 to U_3O_8, UO_2, or uranium metal are listed in Table F.27. The equipment for conversion processes would be purchased from equipment vendors. The total quantities of commonly used materials of construction (e.g, carbon steel, stainless steel) for equipment would be minor compared to the quantities required for facility construction, as listed in Table F.27. The primary specialty materials required for fabricating process equipment include Monel and Inconel (LLNL 1997). Utilities and materials required for operating the three conversion facilities are shown in Table F.28.

F.3.9 Land Use

F.3.9.1 Conversion to U_3O_8

Impacts to land use from the construction and operation of a U_3O_8 conversion facility would be negligible. Such impacts would be limited to the clearing of required land, minor and temporary disruptions to contiguous land parcels, and a slight increase in vehicular traffic. Under this conversion option, a conversion facility would require approximately 20 acres (8 ha) for construction and about 13 acres (5 ha) for operation (see Table F.29). The construction phase requires more land because space is needed for material excavation storage, equipment staging, and construction material laydown areas.

The amount of land required for this conversion option would not be great enough to require major land modification. However, it should be noted that siting a conversion facility at a location that is already dedicated to similar use could result in fewer land-use impacts because immediate access to infrastructure and utility support would be possible with only minor disturbances to existing land use.

TABLE F.27 Resource Requirements for Constructing a Conversion Facility

Utilities/Materials	Unit	Total Consumption: Conversion to U_3O_8	Total Consumption: Conversion to UO_2	Total Consumption: Conversion to Metal
Utilities				
Electricity[a]	MWh	30,000	35,000	35,000 – 45,000
Solids				
Concrete	yd^3	15,000 – 18,000	21,000 – 44,300	20,000 – 23,000
Steel (carbon or mild)	ton	6,000 – 7,000	8,000 – 8,800	9,000 – 10,000
Liquids				
Diesel fuel	million gal	0.75	0.45 – 0.80	0.80 – 1.0
Gasoline	million gal	0.75	0.40 – 0.80	0.80 – 1.0
Gases				
Industrial gases (propane)	gal	4,000	4,400	4,400 – 5,500
Specialty materials				
Monel	ton	15 – 30	25 – 88	20 – 100
Inconel	ton	10	10 – 88	0 – 4
Titanium	ton	NA[b]	0 – 33	0 – 10

[a] The peak electricity demand during any hour would be as follows: conversion to U_3O_8, about 1.5 MW; conversion to UO_2, about 1.5 MW; conversion to metal, from 1.5 to 2.5 MW.

[b] NA = not applicable.

Source: LLNL (1997).

Impacts to land use outside the boundaries of a conversion facility would include negligible and temporary traffic impacts associated with project construction peaks. Also, because of the handling of UF_6 at the facility, NUREG-1140 (McGuire 1985) suggests that a 1-mile protective action distance be established around such a facility, which would cover an area of about 960 acres. The protective action distance is the recommended distance for which emergency planning would be appropriate to mitigate off-site exposure to accidental releases.

F.3.9.2 Conversion to UO_2

Impacts to land use from the UO_2 conversion option would be only slightly greater than those associated with other conversion options. The areal requirements for this option range from

928

TABLE F.28 Resource Requirements for Operating a Conversion Facility

Utilities/Materials	Unit	Average Annual Requirement		
		Conversion to U_3O_8	Conversion to UO_2	Conversion to Metal
Utilities				
Electricity[a]	GWh	11.0	24 – 29	25 – 44
Liquid fuel	gal	6,000	3,040 – 7,000	6,500 – 9,500
Natural gas	million scf[b]	102 – 118	38 – 116	100 – 167
Solids				
Calcium hydroxide (hydrated lime)	million lb	0.388 – 1.27	0.388 – 1.27	0.247
Calcium oxide (quicklime)	million lb	0 – 29	0 – 29	NA[c]
Cement	lb	0 – 862,000	0 – 862,000	0 – 940,000
Detergent	lb	500	600	600 – 700
Iron	million lb	NA	NA	0 – 1.3
Magnesium	million lb	NA	NA	8.4 – 8.6
Sodium chloride	lb	NA	NA	0 – 514,000
Pelletizing lubricant	lb	NA	236,000	NA
Liquids				
Ammonia	million lb	0 – 0.662	2.9	2.4
Hydrochloric acid	lb	11,100 – 18,200	8,900 – 13,600	5,300 – 9,500
Nitric acid	lb	NA	NA	0 – 230,000
Sodium hydroxide	lb	8,800 – 14,400	7,000 – 10,700	4,200 – 7,500

[a] Peak electricity demand during any hour would be as follows: conversion to U_3O_8, about 1.5 MW; conversion to UO_2, from 3.2 to 4.0 MW; conversion to metal, from 3.3 to 6.0 MW.

[b] scf = standard cubic feet measured at 14.7 psia and 60°F.

[c] NA = not applicable.

Source: LLNL (1997).

22 to 31 acres (9 to 13 ha) for construction and from 14 to 20 acres (5.5 to 8 ha) for operations (Table F.29). Siting a conversion facility at a location that is already dedicated to similar use could result in fewer land-use impacts because immediate access to infrastructure and utility support would be possible with only minor disturbances to existing land use.

Impacts to local traffic patterns outside potential UO_2 conversion plant sites could be greater than those expected under the conversion to U_3O_8 option due to the potential for increased traffic volume associated with greater construction workforce demands. However, such impacts would be temporary and would be expected to diminish during the operations phase. The protective

TABLE F.29 Land Requirements for the Conversion Options

Option	Land Requirement (acres)[a] Construction	Operation
Conversion to U_3O_8	20	13
Conversion UO_2	22 – 31	14 – 20
Conversion to metal	23 – 26	15 – 16

[a] NUREG-1140 (McGuire 1985) suggests that each conversion facility establish a protective action distance for emergency planning, which would incorporate an area of about 960 acres around each facility.

Source: LLNL (1997).

action distance described in Section F.3.9.1 would be applicable to an area of about 960 acres around the facility.

F.3.9.3 Conversion to Metal

Land-use impacts from the conversion to uranium metal option would be minimal. Land requirements (Table F.29) would be similar to those discussed for the conversion to UO_2 option, and impacts related to construction traffic outside the conversion plant sites would be negligible. The protective action distance would be applicable to an area of about 960 acres around the facility.

F.3.9.4 Cylinder Treatment Facility

Impacts to land use from the construction and operation of a cylinder treatment facility would be negligible and of a lesser magnitude than those generated under any of the conversion options. Although the cylinder treatment facility could be a stand-alone facility, it is likely to be integrated into a depleted UF_6 conversion facility. If the cylinder treatment facility were incorporated into a conversion facility, it would require less than 1 acre (0.4 ha) of land, regardless of the conversion option. Such a small areal requirement would account for much less than 1% of the land available for development at the representative sites. If construction of a cylinder treatment facility and conversion facility occurred simultaneously, the peak construction labor force of 230 for the

cylinder treatment facility could slightly increase the magnitude (expected to be negligible) of off-site traffic impacts associated with the conversion facility construction.

As a stand-alone facility, the cylinder treatment facility would require 8.7 acres (3.5 ha) of land for construction and 4.5 acres (2 ha) for operations. The areal requirement would probably not be large enough to result in land-use impacts, particularly if the facility were sited at a location already dedicated to a similar industrial-type use.

F.3.10 Other Impacts Considered But Not Analyzed in Detail

Other impacts that could potentially occur if the conversion options considered in this PEIS were implemented include impacts to cultural resources and environmental justice, as well as impacts to the visual environment (e.g., aesthetics), recreational resources, and noise levels, and impacts associated with decontamination and decommissioning of the conversion facilities. These impacts, although considered, were not analyzed in detail for one or both of the following reasons:

- The impacts could not be determined at the programmatic level without consideration of specific sites (e.g., impacts on cultural resources, threatened and endangered species, wetlands, and environmental justice). These impacts would be more appropriately addressed in the second-tier NEPA documentation when specific sites are considered.

- Consideration of these impacts would not contribute to differentiation among the alternatives and, therefore, would not affect the decisions to be made in the Record of Decision to be issued following publication of this PEIS.

NOTATION (APPENDIX G)

The following is a list of acronyms and abbreviations, including units of measure, used in this document. Some acronyms used only in tables are defined in those tables.

ACRONYMS AND ABBREVIATIONS

General

ALARA	as low as reasonably achievable
CFR	*Code of Federal Regulations*
DOE	U.S. Department of Energy
EPA	U.S. Environmental Protection Agency
LCF	latent cancer fatality
LLNL	Lawrence Livermore National Laboratory
LLMW	low-level mixed waste
LLW	low-level radioactive waste
MEI	maximally exposed individual
NEPA	*National Environmental Policy Act*
NPDES	National Pollutant Discharge Elimination System
NRC	U.S. Nuclear Regulatory Commission
PEIS	programmatic environmental impact statement
PM_{10}	particulate matter with a mean diameter of 10 μm or less
ROI	region of influence

Chemicals

CaF_2	calcium fluoride
CO	carbon monoxide
HC	hydrocarbons
HF	hydrogen fluoride
NO_x	nitrogen oxides
SO_x	sulfur oxides
UF_6	uranium hexafluoride
UO_2	uranium dioxide
UO_2F_2	uranyl fluoride
U_3O_8	triuranium octaoxide (uranyl uranate)

UNITS OF MEASURE

cm	centimeter(s)	µg	microgram(s)
cm^3	cubic centimeter(s)	m	meter(s)
ft	foot (feet)	m^3	cubic meter(s)
ft^2	square foot (feet)	min	minute(s)
g	gram(s)	mrem	millirem(s)
gal	gallon(s)	MWh	megawatt hour(s)
gpm	gallon(s) per minute	MWyr	megawatt year(s)
ha	hectare(s)	rem	roentgen equivalent man
in.	inch(es)	s	second(s)
kg	kilogram(s)	scm	standard cubic meter(s)
km	kilometer(s)	yd^3	cubic yard(s)
L	liter(s)	yr	year(s)
lb	pound(s)		

APPENDIX G:

ENVIRONMENTAL IMPACTS OF OPTIONS FOR LONG-TERM STORAGE AS UF_6 AND URANIUM OXIDE

The U.S. Department of Energy (DOE) is proposing to develop a strategy for long-term management of the depleted uranium hexafluoride (UF_6) inventory currently stored at three DOE sites near Paducah, Kentucky; Portsmouth, Ohio; and Oak Ridge, Tennessee. This programmatic environmental impact statement (PEIS) describes alternative strategies that could be used for the long-term management of this material and analyzes the potential environmental consequences of implementing each strategy for the period 1999 through 2039. This appendix provides detailed information describing the long-term storage options for DOE-generated UF_6 cylinders and uranium oxide considered in the PEIS. The discussion provides background information for these options, as well as a summary of the estimated environmental impacts associated with each option.

Storage is defined as holding material for a temporary period, after which the material is either converted to another chemical form, used, disposed of, or stored elsewhere. Storage options would preserve access to the depleted uranium for use at a later date by storing it in a retrievable form in a facility designed for indefinite, low-maintenance operation.

Storage Options

Depleted uranium could be stored until use at a later date. Storage options are defined by the chemical form of the uranium and the type of storage facility. The following storage options are considered in the PEIS:

Storage as UF_6. Storage of UF_6 could take place in cylinders similar to those currently used. Storage facilities considered include yards, buildings, and an underground mine.

Storage as U_3O_8. Depleted uranium could be stored in drums as U_3O_8 following conversion. Storage facilities considered for U_3O_8 include buildings, belowground vaults, and an underground mine.

Storage as UO_2. Similar to options for U_3O_8, depleted uranium could be stored in drums as UO_2 in buildings, belowground vaults, and an underground mine.

The storage options in the PEIS are defined by the chemical form of the depleted uranium stored and the type of storage facility. Depleted uranium could be stored as UF_6, or, following chemical conversion, as triuranium octaoxide (U_3O_8) or uranium dioxide (UO_2). Storage as UF_6 would take place in cylinders similar to those currently used, whereas U_3O_8 or UO_2 would be stored in drums. Several different types of storage facilities are considered for each chemical form (summarized in Table G.1). For storage of UF_6 cylinders, the storage options considered include outdoor yards, aboveground buildings, and an underground mine. For storage of U_3O_8 and UO_2 in drums, the storage options include aboveground buildings, belowground vaults, and an underground mine. Each type of storage facility is described in Section G.3.

TABLE G.1 Summary of Depleted Uranium Chemical Forms and Storage Options Considered

	Storage Option Considered			
Chemical Form	Yards	Buildings	Vaults	Mines
UF_6	Yes	Yes	No	Yes
U_3O_8	No	Yes	Yes	Yes
UO_2	No	Yes	Yes	Yes

The choice of the chemical form of the depleted uranium for storage would depend in part on the desired end use or disposition of the material. For instance, storage in the form of UF_6 would provide maximum flexibility for future uses; however, UF_6 is not as chemically stable as other chemical forms because it becomes a gas at relatively low temperatures and is soluble in water. Storage in the form of UO_2 or U_3O_8 is attractive in view of their long-term stability, and may be the form of the material preferred for use as shielding or for disposal.

All storage facilities would be stand-alone, single-purpose facilities consisting of a central receiving building/warehouse surrounded by storage areas, all within a security fence. The storage facility would be capable of receiving containers of depleted uranium by truck or railcar, inspecting the containers, repackaging the material if necessary, and placing the containers into storage. Depending on the option, containers would be stored in a series of yards, buildings, vaults, or underground mine tunnels (called drifts). Once placed in storage, the containers of depleted uranium would require only routine monitoring and maintenance activities. The containers would be routinely inspected for damage or corrosion, the air would be monitored for indications of releases that would signify the presence of damaged containers, and any damaged containers would be repaired or replaced. The storage facilities would be designed to protect the stored material from the environment and prevent potential releases of material to the environment.

In general, potential environmental impacts would occur during (1) construction of a storage facility, (2) routine storage facility operations, and (3) potential storage accidents. The potential impacts during construction are generally limited to the duration of the construction period and result from typical land-clearing and construction activities. Potential impacts during operations would result primarily from the handling and inspection of containers. Impacts could also occur from potential accidents that release hazardous materials to the environment.

In general, the environmental impacts from the storage options were evaluated on the basis of information described in the engineering analysis report (Lawrence Livermore National Laboratory [LLNL] 1997). For each storage option except storage as UF_6 in yards, the engineering analysis report provides preconceptual facility design data, including descriptions of facility layouts,

resource requirements, estimates of effluents, wastes, and emissions, and estimates of potential accident scenarios. The design of facilities required for UF_6 storage in yards was partially based on current yard storage practices (Parks 1997), as well as the designs for building and mine storage of UF_6 presented in the engineering analysis report (LLNL 1997). The assessment considers storage of depleted uranium through the year 2039. Storage facilities were assumed to receive containers of DOE-generated depleted uranium over a 20-year period beginning in 2009 and store the material for a period of 11 years after receipt of the last container.

G.1 SUMMARY OF STORAGE OPTION IMPACTS

Potential environmental impacts for the storage options are summarized in Table G.2. The potential environmental impacts from the storage options are not site-specific because the location of a storage facility will not be decided until sometime in the future (see Chapter 3). Instead, for assessment purposes, the environmental impacts were determined for a storage facility at representative sites. A more detailed assessment of specific storage technologies and site conditions will be conducted as appropriate as part of the second tier of the *National Environmental Policy Act* (NEPA) process.

The following general conclusions can be drawn from the summary table:

- The environmental impacts from storage tend to be small for all chemical forms and types of storage facilities.
- For storage as UF_6, yard storage has slightly greater environmental impacts than storage in buildings or a mine.
- For storage as U_3O_8, the environmental impacts tend to be similar among buildings, vaults, and a mine.
- For storage as UO_2, the environmental impacts tend to be similar among buildings, vaults, and a mine.
- The differences in impacts among chemical forms are partially related to differences in material bulk densities, with denser material, such as UO_2, requiring less storage space. UF_6 storage impacts also consider the greater reactivity of this form and the small potential for release of HF gas. However, differences in environmental impacts among the forms tend to be small.

TABLE G.2 Summary of Long-Term Storage Option Impacts

G.2 DESCRIPTION OF OPTIONS

This section provides a brief summary of the different storage options considered in the assessment of storage impacts. The information is based on preconceptual design data provided in the engineering analysis report (LLNL 1997). That report includes detailed information, such as descriptions of facility layouts, resource requirements, estimates of effluents, wastes, and emissions, and descriptions of potential accident scenarios.

The chemical form of the depleted uranium (i.e., whether it is UF_6, U_3O_8, or UO_2) determines the type of storage container, the total number of containers required, and the storage configuration (the way containers would be stacked). For storage of UF_6, U_3O_8, and UO_2, the following assumptions would apply to all storage facilities:

- The analysis of storage impacts for UF_6 was based on the assumption that UF_6 would be stored in cylinders meeting all applicable storage requirements, either the current cylinders or new cylinders. Cylinder preparation for transportation to a long-term storage site would require thorough inspection of the cylinders to determine that they meet transportation requirements; cylinders not meeting these requirements would be placed in overcontainers for shipment or would have their contents transferred to new cylinders. Cylinder preparation activities were assumed to be carried out so that the cylinders could be delivered to the long-term storage site and placed into storage without further preparation. However, a certain number of cylinders were assumed to be damaged during transport and handling, and the contents of these cylinders were assumed to be transferred to new cylinders at the long-term storage site.

- Depleted UF_6 cylinders would be stacked two high, as is the current practice for outside storage of these cylinders, in rows 1.2 m (4 ft) apart.

- U_3O_8 would be stored in powdered form in 55-gal (210-L) drums, consistent with current practice. Based on a bulk density of about 3 g/cm^3, the weight of a filled drum would be about 700 kg (1,600 lb). Approximately 714,000 55-gal drums would be required. The drums would be stored in rows of four-drum pallets, two pallets high. The width of each row would be about 1.2 m (4 ft), with 1 m (3 ft) between rows to allow for drum inspections.

- UO_2 would be stored in a sintered form in 30-gal (110-L) drums. Based on a bulk density of sintered UO_2 of about 9 g/cm^3, a filled 30-gal drum weighs about 1,100 kg (2,400 lb). Approximately 420,000 30-gal drums would be required. As with U_3O_8, the drums would be stored in rows of four-drum pallets, two pallets high. The width of each row would be about 1 m (3 ft), with 1 m (3 ft) between rows, to allow for drum inspections.

- For UF_6 cylinders and U_3O_8 and UO_2 drums, the contents of containers damaged during handling and storage would be transferred to new containers (0.7% of the drums containers received annually were assumed to require replacement [LLNL 1997]).

In these configurations, the total area required for storage would range from 96 to 144 acres (39 to 58 ha) for UF_6, from 124 to 212 acres (50 to 86 ha) for U_3O_8, and from 74 to 114 acres (30 to 46 ha) for UO_2. The storage areas differ primarily because the bulk densities differ between the chemical forms. Although the total storage area required differs among chemical forms, the basic designs of the storage facilities — buildings, vaults, and mines — would be similar for each. For instance, buildings of similar type would be used for the storage of UF_6, U_3O_8, and UO_2; however, 17 buildings would be required for storage of UF_6 cylinders, 20 buildings for storage of U_3O_8 drums, and only 9 buildings for storage of UO_2 drums. Because UF_6 is currently stored in cylinder yards at the three storage sites, long-term storage of UF_6 in cylinder yards at a single, centralized location was also examined.

The following sections provide a summary description of each of the storage options. Note that in addition to the primary storage units, each facility also would have an administration building, a receiving warehouse, a repackaging building (attached to the receiving warehouse), and a workshop. Storage facilities for UF_6 would require a cylinder washing facility to recover the heels from damaged cylinders after the removal of the UF_6.

G.2.1 Storage in Yards

Only depleted UF_6 would be stored in outdoor yards. Yard construction would be similar to current practice; the yards would consist of an 8-in. (20-cm) stabilized base under a 12-in. (30-cm) nonreinforced concrete pad. Twenty pads with dimensions of approximately 160 m × 80 m would be required. Additional facilities required for yard storage include a receiving warehouse and repackaging building, a cylinder washing building, and an administration building. Maintenance activities assessed for long-term yard storage are similar to those associated with the continued storage strategy (Parks 1997), and include routine inspections, ultrasonic inspections, valve monitoring and maintenance, and regular painting of the cylinders. The contents of any of the cylinders damaged during handling or storage would be subsequently transferred to new cylinders; the old cylinders would be washed and sent for further disposition.

G.2.2 Storage in Buildings

Storage in buildings is considered for UF_6, U_3O_8, and UO_2. Aboveground buildings would be built on-grade and consist of a concrete slab covered by a steel, preengineered, single-span structure. This type of building is commonly called a "Butler" building. Each building would be approximately 840 ft (260 m) long and 160 ft (50 m) wide, with a height of approximately 20 ft

(6 m). The number of buildings required for storage of UF_6, U_3O_8, and UO_2 would be 17, 20, and 9, respectively. Construction would follow generally accepted practices. Additional facilities are provided which combine receiving/inspection operations with administration, shipping/unloading capabilities, and permanent monitoring capabilities (to ensure the integrity of the stored containers).

G.2.3 Storage in Vaults

Storage in vaults is considered for U_3O_8 and UO_2. Belowground vaults are subsurface reinforced concrete structures, 131 ft (40 m) wide × 266 ft (81 m) long, with a height of approximately 20 ft (6 m). The concrete walls are 1 ft (0.3 m) thick, with a floor slab thickness of 2 ft (0.6 m). The majority of the structure is located underground, with only the roof area above grade. A steel roof supported by trusses is used which can be removed to allow access to the vault by a mobile crane outside the structure. A total of 79 vaults would be required for storage of U_3O_8, and 35 for storage of UO_2.

G.2.4 Storage in a Mine

Storage in a mine is considered for UF_6 (dry mine only), U_3O_8, and UO_2. A belowground mine facility consists of surface buildings where the depleted uranium is inspected and prepared for storage, access shafts from the surface to the belowground drifts, and mined storage drifts. Storage drifts are lateral extensions of belowground tunnels in which depleted uranium can be stored. The dimensions of the drifts are 35 ft (11 m) wide × 330 ft (100 m) long and 18 ft (5 m) high. Each drift would contain two rows of UF_6 cylinders stored side-by-side, five rows of 30-gal UO_2 drums on pallets, or four rows of 55-gal U_3O_8 drums on pallets. The number of drifts required for storage of UF_6, U_3O_8, and UO_2 would be 180, 215, and 105, respectively.

G.2.5 Storage Technologies and Chemical Forms Considered But Not Analyzed

Storage of UF_6 in the potentially moist environment of a belowground vault or a mine was not considered due to potential accelerated corrosion of the steel cylinders. In addition, storage as depleted uranium metal was not considered because uranium metal is not as stable as U_3O_8 or UO_2, it is subject to surface oxidation.

G.3 IMPACTS OF OPTIONS

This section provides a summary of the potential environmental impacts associated with the storage options, including impacts from construction and facility operations. Information related to the assessment methodologies for each area of impact is provided in Appendix C.

The environmental impacts from the storage options were evaluated based primarily on the information described in the engineering analysis report (LLNL 1997). The following general assumptions apply to storage facility operations:

- The assessment considers storage of depleted uranium through the year 2039.
- Two phases of facility operations are considered. Phase I beginning in 2009 corresponds to the first 20 years, when the facilities would receive UF_6 cylinders or UO_2 or U_3O_8 drums from off-site and place them into storage. Phase II corresponds to the next 11 years, when passive storage of cylinders or drums would take place.
- Construction of support buildings and initial storage facilities would begin about 2007, and additional storage facilities would be built as needed throughout Phase I.
- All storage containers would be routinely inspected, and any damaged containers would be replaced.
- UF_6 cylinder content transfers and empty cylinder washing activities would be the only sources of emissions associated with normal (nonaccident) operations. All U_3O_8 and UO_2 drum content transfers would be enclosed mechanical operations that would not involve material releases.

As described in Chapter 3, the potential environmental impacts from the storage options were not determined on a site-specific basis because the location of a storage facility would not be decided until sometime in the future. Instead, for yards, buildings, and vaults, the environmental impacts were calculated using the site conditions at the three current depleted UF_6 storage sites. These three representative sites were used to provide a reasonable range of environmental conditions. For assessment of mine storage, a representative dry location was assumed (storage in a wet mine environment was not considered reasonable due to potential corrosion of containers). A more detailed assessment of site considerations would be addressed, as appropriate, as part of the second phase (tier) of the programmatic NEPA approach.

G.3.1 Human Health — Normal Operations

G.3.1.1 Radiological Impacts

Radiation doses and the associated cancer risks were estimated for exposed individuals and collective populations. Radiation doses to the involved workers would result mainly from external radiation during handling of containers of uranium and during routine inspection activities. Radiation

doses to noninvolved workers and the general public would result from release of uranium compounds to the environment. According to the engineering analysis report (LLNL 1997), airborne emissions of depleted uranium would be negligible during normal operations of the storage facilities. Results from water quality analyses (Section G.3.4) also showed that potential impacts to surface water would be negligible. Therefore, radiological impacts to noninvolved workers and the off-site general public would be negligible for all storage options.

Discussion of the methodologies used in radiological impact analysis is provided in Appendix C and Cheng et al. (1997). The estimated results for involved workers are presented in Table G.3 and G.4 for all storage options. The results indicate that average radiation exposure to involved workers would be less than 1,200 mrem/yr.

G.3.1.1.1 Storage as UF_6

Radiation exposures for involved workers from storage as UF_6 would result mainly from cylinder handling, painting (for storage in yards), repackaging, and surveillance activities. Collective radiological impacts from storage in yards would be more than twice that from storage in buildings and mines. Compared with buildings and mines, storage in yards would require more cylinder inspection and cylinder maintenance (painting) activities to control corrosion in an outdoor environment. Radiological impacts would be similar for storage in buildings and storage in a mine. The collective dose would range from about 7.6 to 22 person-rem/yr (considering Phase I and Phase II) for a worker population of 19 to 26 individuals. The corresponding number of latent cancer fatalities (LCFs) among the involved workers would range from 0.003 to 0.009 per year (1 to 3 LCFs over a 300-year period).

The average annual individual doses were obtained by dividing the collective dose by the number of workers. To provide a conservative estimate of doses, the calculations did not consider the implementation of as low as reasonably achievable (ALARA) practices to minimize exposures. Because the exact number of workers required to conduct all types of activities is uncertain at this preliminary stage, the estimated average individual doses also involve a large degree of uncertainty. The estimated average individual dose ranges from 290 to 920 mrem/yr for the storage options, with a corresponding individual risk of a latent cancer fatality of 0.0001 to 0.0004 per year (a chance of about 1 to 4 in 10,000 per year). The average individual dose would be well below the regulatory limit of 5,000 mrem/yr (10 *Code of Federal Regulations* [CFR] Part 835) and would be smaller than the DOE administrative control limit of 2,000 mrem/yr (DOE 1992).

G.3.1.1.2 Storage as U_3O_8

For storage as U_3O_8, the worker activities would be expected to be similar among the three storage options — buildings, vaults, and mines. Therefore, radiological impacts to involved workers would be similar among these options. For all three options, the estimated collective dose is about

TABLE G.3 Radiological Doses from Long-Term Storage Options under Normal Operations

Option	Dose to Receptor: Involved Worker[a] Average Dose (mrem/yr)	Involved Worker[a] Collective Dose (person-rem/yr)	Noninvolved Worker[b] MEI Dose (mrem/yr)	Noninvolved Worker[b] Collective Dose (person-rem/yr)	General Public[c] MEI Dose (mrem/yr)	General Public[c] Collective Dose (person-rem/yr)
Storage as UF_6						
Yards	920	22	~0	~0	~0	~0
Buildings	290	7.6	~0	~0	~0	~0
Mine	420	7.6	~0	~0	~0	~0
Storage as U_3O_8						
Buildings	880	30	~0	~0	~0	~0
Vaults	910	30	~0	~0	~0	~0
Mine	1,200	30	~0	~0	~0	~0
Storage as UO_2						
Buildings	810	17	~0	~0	~0	~0
Vaults	670	17	~0	~0	~0	~0
Mine	920	17	~0	~0	~0	~0

[a] Involved workers are those workers directly involved with the handling of materials. Impacts are presented as average individual dose and collective dose for the worker population. Radiation doses to individual workers would be monitored by a dosimetry program and maintained below applicable standards, such as the DOE administrative control limit of 2,000 mrem/yr.

[b] Noninvolved workers are individuals who do not participate in material handling activities and individuals who work on-site but not within the facility. Because negligible airborne emission of radioactive materials would be expected from the storage facility (LLNL 1997), radiation doses to noninvolved workers would be negligible.

[c] The off-site general public is defined as residents who live within a radius of 50 miles (80 km) around the storage site. Radiation doses to the off-site public would be negligible because airborne emission of radioactive materials (LLNL 1997) and impacts to surface water quality would be negligible (Section G.3.4).

TABLE G.4 Latent Cancer Risks from Long-Term Storage Options under Normal Operations

Option	Latent Cancer Risk to Receptor

Storage as U_3O_8						
Buildings	4×10^{-4}	1×10^{-2}	~ 0	~ 0	~ 0	~ 0
Vaults	4×10^{-4}	1×10^{-2}	~ 0	~ 0	~ 0	~ 0
Mine	5×10^{-4}	1×10^{-2}	~ 0	~ 0	~ 0	~ 0
Storage as UO_2						
Buildings	3×10^{-4}	7×10^{-3}	~ 0	~ 0	~ 0	~ 0
Vaults	3×10^{-4}	7×10^{-3}	~ 0	~ 0	~ 0	~ 0
Mine	4×10^{-4}	7×10^{-3}	~ 0	~ 0	~ 0	~ 0

[a] Involved workers are those workers directly involved with the handling of materials. Impacts are presented as average individual risk and collective risk for the worker population.

[b] Noninvolved workers are individuals who do not participate in material handling activities and individuals who work on-site but not within the facility. Because negligible airborne emission of radioactive materials would be expected from the storage facility (LLNL 1997), cancer risks to noninvolved workers would be negligible.

[c] The off-site general public is defined as residents who live within a radius of 50 miles (80 km) around the storage site. Cancer risks to the off-site public would be negligible because airborne emission of radioactive materials (LLNL 1997) and impacts to surface water quality would be negligible (Section G.3.4).

960

30 person-rem/yr for 25 to 34 workers. The corresponding number of LCFs among workers would be about 0.01 per year (about 1 LCF over a 100-year period).

The estimated average individual dose ranges from about 880 to 1,200 mrem/yr for the U_3O_8 storage options, with a corresponding individual risk of a latent cancer fatality of 0.0004 to 0.0005 per year (a chance of about 1 in 2,000). The average dose would be well below the regulatory dose limit of 5,000 mrem/yr.

Storage as U_3O_8 would result in greater collective exposures for involved workers than storage as UF_6 or UO_2 because a larger number of containers would be needed for U_3O_8 than for UF_6 and UO_2. Consequently, the number of operations for transferring containers, retrieving damaged containers, and surveying the stored inventory would be the greatest for U_3O_8 among the three chemical forms for depleted uranium.

G.3.1.1.3 Storage as UO_2

The storage practices for UO_2 drums would be similar to those for U_3O_8 drums; however, the total number of UO_2 drums would be less than the number of U_3O_8 drums. As a result, the estimated collective exposures to involved workers from drum handling and inspection activities would be less for UO_2 than for U_3O_8. On the other hand, the number of UO_2 drums would be greater than the number of UF_6 cylinders. Therefore, collective exposures for storage in buildings and in a mine would be greater for UO_2 than for UF_6.

Radiological impacts to workers would be similar among the UO_2 storage options. The collective dose to involved workers would be about 17 person-rem/yr for 19 to 26 workers. The corresponding number of latent cancer fatalities among workers would be about 0.007 per year (about 1 LCF over a 140-year period).

The estimated average individual dose ranges from 800 to 920 mrem/yr, with a corresponding individual risk of an LCF of about 0.0003 to 0.0004 per year (a chance of about 1 in 2,500). The average dose would be well below the regulatory dose limit.

G.3.1.2 Chemical Impacts

Chemical impacts to the maximally exposed individual (MEI) were assessed for noninvolved workers and the public. However, according to the engineering analysis report (LLNL 1997), no airborne emissions of uranium would be expected for long-term storage facilities and only small quantities of hydrogen fluoride (HF) would be emitted under the UF_6 storage option. Therefore, the only potential chemical exposures for noninvolved workers and the public that were considered are those that would result from airborne emissions of HF emitted from the cylinder transfer and washing operations. In addition, potential chemical exposures resulting from the storage

facilities wastewater emissions were considered for the off-site general public; however, results from water quality analyses (Section G.3.4.1) showed that potential impacts to surface water bodies would be negligible. Information on the methodologies used for the chemical impact analysis is provided in Appendix C and Cheng et al. (1997).

The results of the analysis of hazardous chemical human health impacts from long-term storage options are summarized in Table G.5. No impacts on human health from chemical exposures would be expected during normal operations of storage facilities.

For the long-term storage option, the engineering analysis report (LLNL 1997) assumed that a low percentage of cylinders and drums would require repackaging annually due to handling or

TABLE G.5 Chemical Impacts to Human Health for Long-Term Storage Options under Normal Operations[a]

		Impacts to Receptor			
		Noninvolved Workers[a]		General Public[b]	
Option	Type	Hazard Index for MEI[c]	Collective Risk[d] (ind. at risk/yr)	Hazard Index for MEI[c]	Collective Risk[d] (ind. at risk/yr)
Storage as UF_6	Yards	~ 0	–	~ 0	–
	Buildings	~ 0	–	~ 0	–
	Mines	~ 0	–	~ 0	–
Storage as U_3O_8	Buildings	~ 0	–	~ 0	–
	Vaults	~ 0	–	~ 0	–
	Mines	~ 0	–	~ 0	–
Storage as UO_2	Buildings	~ 0	–	~ 0	–
	Vaults	~ 0	–	~ 0	–
	Mines	~ 0	–	~ 0	–

[a] Noninvolved workers include individuals who work at the facility but are not involved in hands-on activities and individuals who work on-site but not within the facility. Because no airborne emission of uranium and/or very low levels of HF are expected from the storage facility, there would essentially be no noncarcinogenic health impacts to the noninvolved workers.

[b] The off-site general public is defined as residents who live with a radius of 50 miles (80 km) around the storage site. There would essentially be no noncarcinogenic health impacts to the general public because no airborne emission of uranium and/or very low levels of HF are expected from the storage facility, there would essentially be no noncarcinogenic health impacts to the noninvolved workers.

[c] The hazard index is an indicator for potential health effects other than cancer; a hazard index greater than 1 indicates a potential for adverse health effects and a need for further evaluation.

[d] Calculation of population risk is not applicable when the corresponding hazard index for the MEI is less than 1.

corrosion damage. These repackaging operations would result in the only potential releases and exposures to uranium and fluoride compounds for the storage options. For drum repackaging, electrically powered transfer equipment would pour the contents of the damaged drums into new drums, minimizing involved worker contact with the drum contents. The transfer equipment would operate in such a way as to keep the operation enclosed and eliminate dust generation for the U_3O_8 and UO_2 storage forms.

For storage as UF_6, repackaging would require heating the cylinder in an autoclave and transferring the contents to a new cylinder. A small "heel" of UF_6 (approximately 22 lb [10 kg]) would remain in the emptied cylinder; this material would be removed in the cylinder washing building, converted to uranyl fluoride (UO_2F_2) and calcium fluoride (CaF_2), and disposed of. Small amounts of HF would be released from the cylinder washing building stack from the conversion of the UF_6 heels to UO_2F_2. The maximum annual emission of HF for the Phase I and Phase II operational periods of long-term UF_6 storage would be about 0.10 kg/yr (in yards). In comparison, the maximum estimated annual emission of HF for any of the depleted UF_6 conversion options would be 408 kg/yr. Therefore, the maximum estimated annual emission of HF from any of the UF_6 storage facilities would be more than 4,000 times lower than the maximum annual emission of HF from conversion facilities. Because the results of the conversion analyses (Appendix F) did not indicate any human health impacts and the atmospheric release and transport of HF would occur under similar conditions, the small quantities of HF present in the storage facility emissions would also not result in human health impacts.

For storage as UF_6, it should also be noted that emissions due to breaches were not assumed because all cylinders would be inspected once every 4 years and would be repackaged immediately if any handling or corrosion damage was identified. Additionally, yard storage assumes that rigorous maintenance would take place, such as ultrasonic test inspections, valve monitoring, and regular painting.

Airborne emissions of depleted uranium are not expected during normal operations of the storage facilities, according to data provided in the engineering analysis report (LLNL 1997). Therefore, no matter which chemical form of depleted uranium is selected, chemical impacts to noninvolved workers and the off-site general public would be negligible.

G.3.2 Human Health — Accident Conditions

For long-term storage as U_3O_8 and UO_2, a range of accidents covering the spectrum of high-frequency/low-consequence accidents to low-frequency/high-consequence accidents was presented in the engineering analysis report (LLNL 1997). Accidents analyzed for long-term storage in yards were consistent with those analyzed for continued cylinder storage (Appendix D), as given in the safety analysis reports (LMES 1997a-c). These accidents are listed in Table G.6. The following sections present the results for radiological and chemical health impacts of the highest consequence

TABLE G.6 Accidents Considered for the Long-Term Storage Options

Option/Accident Scenario	Accident Description	Chemical Form	Amount (lb)	Duration (min)	Release Level[a]
Storage as UF_6					
Likely Accidents (frequency: 1 or more times in 100 years)					
Corroded cylinder spill, dry conditions	A 1-ft hole results during handling, with solid UF_6 forming a 4-ft^2 area on the dry ground.	UF_6	24	60 (continuous)	Ground
Unlikely Accidents (frequency: 1 in 100 years to 1 in 10,000 years)					
Corroded cylinder spill, wet conditions – rain	A 1-ft hole results during handling, with solid UF_6 forming a 4-ft^2 area on the wet ground.	HF	96	60 (continuous)	Ground
Extremely Unlikely Accidents (frequency: 1 in 10,000 years to 1 in 1 million years)					
Corroded cylinder spill, wet conditions – water pool	A 1-ft hole results during handling, with solid UF_6 forming a 4-ft^2 area into a 0.25-in. deep water pool.	HF	150	60 (continuous)	Ground
Vehicle-induced fire, 3 full 48G cylinders	Three full 48G UF_6 cylinders hydraulically rupture during a fire resulting from the ignition of fuel and/or hydraulic fluid from the transport vehicle, etc.	UF_6	0 11,500 8,930 3,580	0 to 12 12 12 to 30 30 to 121	Ground
Incredible Accidents (frequency: less than 1 in 1 million years)					
Small plane crash, 2 full 48G cylinders	A small plane crash affects two full 48G UF_6 cylinders. One cylinder hydraulically ruptures during a fire resulting from the ignition of aviation fuel.	UF_6	0 3,840 2,980 1,190	0 to 12 12 12 to 30 30 to 121	Ground
	The second cylinder is initially breached due to impact with aircraft debris, followed by sublimation due to fire.	UF_6	4,240 1,190	0 to 30 30 to 121	Ground
Flood	The facility would be located at a site that would preclude severe flooding.	No release	NA	NA	NA
Storage as U_3O_8					
Likely Accidents (frequency: 1 or more times in 100 years)					
Mishandling/drop of drum/ billet inside the repackaging building	A single U_3O_8 drum is damaged by a forklift and spills its contents onto the ground inside the repackaging building.	U_3O_8	0.00028	Puff	Stack
Unlikely Accidents (frequency: 1 in 100 years to 1 in 10,000 years)					
Earthquake	The repackaging building is damaged during a design-basis earthquake, resulting in failure of the structure and confinement systems.	U_3O_8	33	30	Ground
Tornado	A major tornado and associated tornado missiles result in failure of the repackaging building structure and its confinement systems.	U_3O_8	33	0.5	Ground

TABLE G.6 (Cont.)

Option/Accident Scenario	Accident Description	Chemical Form	Amount (lb)	Duration (min)	Release Level[a]
Storage as U_3O_8 (Cont.)					
Extremely Unlikely Accidents (frequency: 1 in 10,000 years to 1 in 1 million years)					
Fire or explosion inside the repackaging building	A fire or explosion within the repackaging facility affects the contents of a single pallet of drums.	U_3O_8	0.0011	Puff	Stack
Incredible Accidents (frequency: less than 1 in 1 million years)					
Flood	The facility would be located at a site that would preclude severe flooding.	No release	NA	NA	NA
Storage as UO_2					
Likely Accidents (frequency: 1 or more times in 100 years)					
Mishandling/drop of drum/ billet inside the repackaging building	A single UO_2 drum is damaged by a forklift and spills its contents onto the ground inside the repackaging building.	UO_2	0.00011	Puff	Stack
Unlikely Accidents (frequency: 1 in 100 years to 1 in 10,000 years)					
Earthquake	The repackaging building is damaged during a design-basis earthquake, resulting in failure of the structure and confinement systems.	UO_2	33	30	Ground
Tornado	A major tornado and associated tornado missiles result in failure of the repackaging building structure and its confinement systems.	UO_2	33	0.5	Ground
Extremely Unlikely Accidents (frequency: 1 in 10,000 years to 1 in 1 million years)					
Fire or explosion inside the repackaging building	A fire or explosion within the repackaging facility affects the contents of a single pallet of drums.	UO_2	0.00045	Puff	Stack
Incredible Accidents (frequency: less than 1 in 1 million years)					
Flood	The facility would be located at a site that would preclude severe flooding.	No release	NA	NA	NA

[a] Ground-level releases were assumed to occur outdoors on concrete pads in the cylinder storage yards. To prevent contaminant migration, cleanup of residuals was assumed to begin immediately after the release was stopped.

accident in each frequency category. Results for all accidents listed in Table G.6 are presented in Policastro et al. (1997). Detailed descriptions of the methodology and assumptions used in these calculations are also provided in Appendix C and Policastro et al. (1997).

G.3.2.1 Radiological Impacts

The radiological doses to various receptors for the accidents that would result in the highest dose from each frequency category are listed in Table G.7. The LCF risks for these accidents are given in Table G.8. The doses and the risks are presented as ranges (maximum and minimum) because two different meteorological conditions and three representative sites were considered for each long-term storage option (see Appendix C). The doses and risks presented here were obtained by assuming that the accidents would occur. The probability of occurrence for each accident is indicated by the frequency category to which it belongs. For example, accidents in the extremely unlikely category have a probability of occurrence between 1 in 10,000 and 1 in 1 million in any 1 year. The following conclusions may be drawn from the radiological health impact results:

- No cancer fatalities would be predicted from any of the accidents.

- The maximum radiological dose to noninvolved worker and general public MEIs (assuming an accident occurred) would be 7.7 rem. This dose is less than the 25 rem dose recommended for assessing the adequacy of protection of public health and safety from potential accidents by the U.S. Nuclear Regulatory Commission (NRC 1994).

- The overall radiological risk to noninvolved worker and general public MEI receptors (estimated by multiplying the risk per occurrence [Table G.8] by the annual probability of occurrence by the number of years of operations) would be less than 1 for all accidents.

G.3.2.2 Chemical Impacts

The accidents considered in this section are listed in Table G.6. The results of the accident consequence modeling in terms of chemical impacts are presented in Tables G.9 and G.10. The results are presented as (1) number of people with potential for adverse effects and (2) number of people with potential for irreversible adverse effects. The tables present the results for the accident within the frequency category that would affect the largest number of people (total of noninvolved workers and off-site population) (Policastro et al. 1997). The numbers of noninvolved workers and

Fire or explosion inside the repackaging building	EU	1.5×10^{-8}	4.8×10^{-6}	1.5×10^{-8}	2.8×10^{-6}	4.4×10^{-12}	1.3×10^{-24}	7.5×10^{-10}	8.3×10^{-8}

[a] The bounding accident chosen to represent each frequency category is the one that would result in the highest dose to the general public MEI. Health impacts in that row represent that accident only and not the range of accidents in that category. Absence of an accident in a certain frequency category indicates that the accident would not result in a release of radioactive material.

[b] Accident frequencies: likely (L), estimated to occur one or more times in 100 years of facility operations ($> 10^{-2}$/yr); unlikely (U), estimated to occur between once in 100 years and once in 10,000 years of facility operations ($10^{-2} - 10^{-4}$/yr); extremely unlikely (EU), estimated to occur between once in 10,000 years and once in 1 million years of facility operations ($10^{-4} - 10^{-6}$/yr); incredible (I), estimated to occur less than one time in 1 million years of facility operations ($< 10^{-6}$/yr).

[c] Maximum and minimum doses reflect differences in assumed sites, technologies, and meteorological conditions at the time of the accident. In general, maximum doses would occur under meteorological conditions of F stability with 1 m/s wind speed, whereas minimum doses would occur under D stability with 4 m/s wind speed.

Earthquake	EU	3×10^{-3}	3×10^{-1}	1×10^{-4}	9×10^{-3}	1×10^{-4}	3×10^{-3}	4×10^{-6}	3×10^{-4}
Fire or explosion inside the repackaging building	I	6×10^{-12}	2×10^{-9}	8×10^{-12}	1×10^{-9}	2×10^{-15}	5×10^{-28}	4×10^{-13}	4×10^{-11}

a Values shown are the consequences if the accident did occur. The risk of an accident is the consequence (LCFs) times the estimated frequency times 20 years of operations. The estimated frequencies are as follows: likely (L), 0.1; unlikely (U), 0.001; extremely unlikely (EU), 0.00001; incredible (I), 0.000001.

b The bounding accident chosen to represent each frequency category is the one that would result in the highest risk to the general public MEI. Health impacts in that row represent that accident only and not the range of accidents in that category. Absence of an accident in a certain frequency category indicates that the accident would not result in a release of radioactive material.

c Accident frequencies: likely (L), estimated to occur one or more times in 100 years of facility operations ($> 10^{-2}$/yr); unlikely (U), estimated to occur between once in 100 years and once in 10,000 years of facility operations ($10^{-2} - 10^{-4}$/yr); extremely unlikely (EU), estimated to occur between once in 10,000 years and once in 1 million years of facility operations ($10^{-4} - 10^{-6}$/yr); incredible (I), estimated to occur less than one time in 1 million years of facility operations ($< 10^{-6}$/yr).

d Maximum and minimum risks reflect differences in assumed sites, technologies, and meteorological conditions at the time of the accident. In general, maximum risks would occur under meteorological conditions of F stability with 1 m/s wind speed, whereas minimum risks would occur under D stability with 4 m/s wind speed.

TABLE G.9 Number of Persons with Potential for Adverse Effects from Accidents under the Long-Term Storage Options[a]

Option/Accident[b]	Frequency Category[c]	Maximum Number of Persons[d]				Minimum Number of Persons[d]

[a] Values shown are the consequences if the accident did occur. The risk of an accident is the consequence (number of persons) times the estimated frequency times 31 years of operations. The estimated frequencies are as follows: likely (L), 0.1; unlikely (U), 0.001; extremely unlikely (EU), 0.00001; incredible (I), 0.000001.

[b] The bounding accident chosen to represent each frequency category is the one in which the largest number of people (workers plus off-site people) would be affected. Health impacts in that row represent that accident only and not the range of impacts among accidents in that category.

[c] Accident frequencies: likely (L), estimated to occur one or more times in 100 years of facility operations ($> 10^{-2}$/yr); unlikely (U), estimated to occur between once in 100 years and once in 10,000 years of facility operations ($10^{-2} - 10^{-4}$/yr); extremely unlikely (EU), estimated to occur between once in 10,000 years and once in 1 million years of facility operations ($10^{-4} - 10^{-6}$/yr); incredible (I), estimated to occur less than one time in 1 million years of facility operations ($< 10^{-6}$/yr).

[d] Maximum and minimum values reflect different meteorological conditions at the time of the accident. In general, maximum risks would occur under meteorological conditions of F stability with 1 m/s wind speed, whereas minimum risks would occur under D stability with 4 m/s wind speed.

[e] At the MEI location, the determination is either "Yes" or "No" for potential adverse effects to an individual.

[f] MEI locations were evaluated at 100 m from ground-level releases for workers and at the location of highest off-site concentration for members of the general public; the population risks are 0 because the worker and general public population distributions for the representative sites were used, which did not show receptors at the MEI locations.

[g] These accidents would result in the largest plume sizes, although no people would be affected.

[a] Values shown are the consequences if the accident did occur. The risk of an accident is the consequence (number of persons) times the estimated frequency times 20 years of operations. The estimated frequencies are as follows: likely (L), 0.1; unlikely (U), 0.001; extremely unlikely (EU), 0.00001; incredible (I), 0.000001.

[b] The bounding accident chosen to represent each frequency category is the one in which the largest number of people (workers plus off-site people) would be affected. Health impacts in that row represent that accident only and not the range of impacts among accidents in that category.

[c] Accident frequencies: likely (L), estimated to occur one or more times in 100 years of facility operations ($> 10^{-2}$/yr); unlikely (U), estimated to occur between once in 100 years and once in 10,000 years of facility operations ($10^{-2} - 10^{-4}$/yr); extremely unlikely (EU), estimated to occur between once in 10,000 years and once in 1 million years of facility operations ($10^{-4} - 10^{-6}$/yr); incredible (I), estimated to occur less than one time in 1 million years of facility operations ($< 10^{-6}$/yr).

[d] Maximum and minimum values reflect different meteorological conditions at the time of the accident. In general, maximum risks would occur under meteorological conditions of F stability with 1 m/s wind speed, whereas minimum risks would occur under D stability with 4 m/s wind speed.

[e] At the MEI location, the determination is either "Yes" or "No" for potential irreversible adverse effects to an individual.

[f] MEI locations were evaluated at 100 m from ground-level releases for workers and at the location of highest off-site concentration for members of the general public; the population risks are 0 because the worker and general public population distributions for the representative sites were used, which did not show receptors at the MEI locations.

[g] These accidents would result in the largest plume sizes, although no people would be affected.

members of the off-site public represent the impacts if the associated accident was assumed to occur. The accidents listed in Tables G.9 and G.10 are not identical because an accident with the largest impacts for the adverse effects endpoint might not lead to the largest impacts for the irreversible adverse effects endpoint. The results of the chemical impacts analysis may be summarized as follows:

- If the accidents identified in Tables G.9 and G.10 did occur, the number of persons in the off-site population with potential for adverse effects would range from 0 to 2,500 (maximum corresponding to vehicle-induced fire accident involving three full 48G cylinders), and the number of off-site persons with potential for irreversible adverse effects was estimated to be 0.

- If the accidents identified in Tables G.9 and G.10 did occur, the number of noninvolved workers with potential for adverse effects would range from 0 to 520 (maximum corresponding to the corroded cylinder spill accident with rain conditions), and the number of noninvolved workers with potential for irreversible adverse effects would range from 0 to 440 (maximum corresponding to corroded cylinder spill accident with pooling).

- The noninvolved worker population would receive the majority of the severe impacts and the off-site population much less, except for the vehicle-induced fire accident involving three full 48G cylinders. In such case, the plume would rise and hit the ground at distances downwind. The overall risk (frequency times consequence), however, is very low due to the low frequency of occurrence.

- The impacts resulting from the vehicle-induced fire involving three full 48G UF_6 cylinders would be large for members of the general public in terms of potential adverse effects because of the considerable source terms associated with such an accident.

- The overall impact for accidents associated with long-term storage as UF_6 in buildings/mines would be about the same as that associated with storage in a yard. Storage as U_3O_8 would have almost the same impacts as storage as UO_2, with both options having very small impacts compared with the potential impacts for storage as UF_6.

- Stack releases would have much lower impacts than ground-level releases.

- The maximum risk was computed as the product of the consequence (number of people) times the frequency of occurrence (per year) times the number of years in operations (31 years, 2009 through 2039). The results indicated that

the maximum risk values would be less than 1 for all accidents except the following:

- *Potential Adverse Effects:*

  Corroded cylinder spill, dry conditions (L, likely): Workers
  Corroded cylinder spill, wet conditions – rain (U, unlikely): Workers

- *Potential Irreversible Adverse Effects:*

  Corroded cylinder spill, dry conditions (L, likely): Workers
  Corroded cylinder spill, wet conditions – rain (U, unlikely): Workers

These risk values are conservative because the numbers of people affected were based on assuming (1) meteorological conditions that would result in the maximum reasonably foreseeable plume size (i.e., F stability and 1 m/s wind speed) and (2) wind in the direction that would lead to maximum numbers of individuals exposed for noninvolved workers or for the general population.

To aid in the interpretation of accident analysis results, the number of fatalities potentially associated with the estimated potential irreversible adverse effects was estimated. All the bounding case accidents shown in Table G.10 would involve releases of UF_6 and potential exposure to HF and uranium compounds. These exposures would likely be high enough to result in death for 1% or less of the persons experiencing irreversible adverse effects (Policastro et al. 1997). This would mean that for noninvolved workers experiencing a range of 0 to 440 irreversible adverse effects, 0 to about 4 deaths would be expected. No deaths would be expected among the general public. These are the maximum potential consequences of the accidents, the upper ends of the ranges assume worst-case weather conditions and that the wind would be blowing in the direction where the highest numbers of people would be exposed.

G.3.2.3 Physical Hazards

The risk of on-the-job fatalities and injuries to all long-term storage facility workers is calculated using industry-specific statistics from the Bureau of Labor Statistics, as reported by the National Safety Council (1995). Construction and manufacturing annual fatality and injury rates were used respectively for the duration of the construction and operational phases of the facility.

No on-the-job fatalities are predicted for any of the storage options analyzed (range of 0.10 for UF_6 yard storage to 0.43 for U_3O_8 mine storage, for the total construction, Phase I operations, and Phase II operations). The range of predicted injuries is about 92 to 222 for the entire facility lifetimes. Physical hazard risks of fatality and injury are presented in Table G.11 by construction, Phase I, and Phase II components. The largest component of physical hazard risks generally results

TABLE G.11 Potential Impacts to Human Health from Physical Hazards under Accident Conditions for the Long-Term Storage Options

	Impacts to All Long-Term Storage Facility Workers[a]					
	Incidence of Fatalities[b]			Incidence of Injuries[b]		
Option	Construction	Phase I Operations	Phase II Operations	Construction	Phase I Operations	Phase II Operations
Storage as UF_6	0.04 – 0.30	0.04	0.02	16 – 110	48 – 53	24 – 29
Storage as U_3O_8	0.20 – 0.36	0.04 – 0.05	0.02	83 – 132	55 – 64	25 – 27
Storage as UO_2	0.09 – 0.18	0.04	0.02	33 – 66	50 – 53	22 – 24

[a] Impacts are reported as ranges, which result from variations in the employment requirements for the different long-term storage chemical forms and facility types. All construction and operational workers at the storage facilities are included in physical hazard risk calculations.

[b] Fatality and injury incidence rates used in the calculations were taken from National Safety Council (1995).

from construction; except for UF_6 yard storage, construction physical hazard risks are 3 to 4 times greater than risks from Phase I and II operations combined. The maximum impacts are predicted for storage as U_3O_8 in mines; the differences in predicted impacts result from the increased work effort required to construct mines and to inspect the greater number of U_3O_8 containers during the operational phases. However, the overall differences in ranges of physical hazard risks between chemical forms and storage types are fairly small.

For storage as UF_6, the probability of an on-the-job fatality ranges from 0.10 for storage in yards to 0.36 for storage in mines — including construction, Phase I, and Phase II of storage. The predicted injury incidence ranges from about 92 to 187 injuries over the lifetime of the facility.

For storage as U_3O_8, the probability of an on-the-job fatality ranges from 0.29 for storage in vaults to 0.43 for storage in mines — including construction, Phase I, and Phase II of storage. The predicted injury incidence ranges from about 151 to 222 injuries over the lifetime of the facility.

For storage as UO_2, the probability of an on-the-job fatality ranges from 0.16 for storage in buildings to 0.24 for storage in mines — including construction, Phase I, and Phase II of storage. The predicted injury incidence ranges from about 104 to 143 injuries over the lifetime of the facility.

G.3.3 Air Quality

The methodology used to analyze impacts of the long-term storage options is described in Appendix C and Tschanz (1997). The storage site was assumed to be centered within a larger facility, and pollutant concentrations — carbon monoxide (CO), hydrocarbons (HC), nitrogen oxides

(NO_x), sulfur oxides (SO_x), and PM_{10} (particulate matter with a mean diameter of 10 μm or less) — were estimated for the boundaries of that facility. Screening modeling of construction emissions was used to estimate hourly pollutant concentrations under very conservative meteorological conditions at the boundary point that would be the shortest distance from the center of the facility. The maximum 1-hour concentrations for the representative facilities examined are shown in Table G.12. These impacts would occur when construction was under way at the corner of the storage site nearest the chosen boundary point. Concentrations from construction at the center of the storage site would be 1.5 to 2 times smaller than the ones listed in the table. Among the listed results, the PM_{10} values might require close consideration in actual construction of any sites similar to the assumed preconceptual ones. Based on the size of the estimated 1-hour concentrations, it is possible that, under particularly unfavorable conditions, concentrations could exceed the 24-hour PM_{10} standard of 150 $\mu g/m^3$.

Air quality impacts associated with storage in a mine were not analyzed in detail because the potential emissions associated with mine storage would be smaller than those for the other storage options considered. For example, during construction of facilities for long-term storage of U_3O_8, CO emissions for mine construction would be about 30% of those for aboveground buildings and only about 10% of those for belowground vaults. Similar ratios would apply for comparisons of emissions during operations associated with placing the uranium compounds in the storage facilities.

The maximum impacts of CO and NO_x at the facility boundaries during operations to place depleted uranium in storage are shown in Table G.13 for the averaging periods for which standards

TABLE G.12 Maximum 1-Hour Pollutant Concentrations at Long-Term Storage Facility Boundaries as a Result of Construction Emissions under Worst-Case Meteorological Conditions

	Maximum 1-Hour Concentration ($\mu g/m^3$)				
	Aboveground Building Storage			Belowground Vault Storage	
Pollutant	UF_6	U_3O_8	UO_2	U_3O_8	UO_2
CO	77	94	54	280	140
HC	34	38	21	110	55
NO_x	390	450	250	1,300	670
SO_x	26	30	17	85	44
PM_{10}[a]	370	420	240	460	250

[a] Fugitive dust emissions from land disturbance have been included with PM_{10} emissions from construction equipment to estimate total PM_{10} concentrations.

TABLE G.13 Maximum Pollutant Concentrations at Facility Boundaries from Operations Emissions during Long-Term Storage

	CO				NO_x	
	1-Hour Average		8-Hour Average		Annual Average	
Option	Pollutant Concentration ($\mu g/m^3$)	Percent of Standard at Maximum	Pollutant Concentration ($\mu g/m^3$)	Percent of Standard at Maximum	Pollutant Concentration ($\mu g/m^3$)	Percent of Standard at Maximum
Aboveground Buildings						
Storage as UF_6	6.2 – 7.9	0.02	1.6 – 1.9	0.02	0.18 – 0.48	0.5
Storage as U_3O_8	6.8 – 7.5	0.02	1.8 – 2.3	0.02	0.24 – 0.57	0.6
Storage as UO_2	5.4 – 6.9	0.02	1.1 – 1.7	0.02	0.13 – 0.39	0.4
Belowground Vaults						
Storage as U_3O_8	9.3 – 12.9	0.03	2.6 – 3.2	0.03	0.40 – 0.95	1.0
Storage as UO_2	10.0 – 10.7	0.03	2.1 – 3.1	0.03	0.27 – 0.82	0.8

exist. In all cases, the concentrations due to the storage operations are 1% or less of the standards. Although not shown, the comparisons between SO_x concentrations and the corresponding standards are similar to those for CO.

The results of comparing the impacts from CO and NO_x emissions for simultaneously conducted construction and operations activities are shown in Table G.14. The maximum construction impacts would result when construction took place at the corner of the storage site nearest the facility boundary point closest to the facility center. The operations emissions were assumed to be distributed uniformly over the entire storage site. Although the annual construction emissions are comparable to the corresponding operations emissions for both buildings and vaults, the construction impacts shown are considerably larger. Basically, this is the effect of concentrating the construction emissions in a small area closer to the boundary receptor point than is the average distance for the operations emissions. During most years, the construction would be farther from the boundary and have less impact. Even for the results shown in Table G.14, the combined construction and operations impacts are less than the applicable air quality standards.

The emissions from routine monitoring and maintenance following completion of the storage operations in all cases would be less than 25% as large as the operations emissions. Thus, in all cases, the maintenance air quality impacts would be less than 25% of the operations impacts alone.

Some of the estimated criteria pollutant impacts during the operations phase of long-term storage of UF_6 in yards, when both construction and operations would occur simultaneously, are shown in Table G.15. Construction would be the dominant contributor to most of the impacts, accounting for between 85% of the total for CO to nearly 100% for PM_{10}. The combined impacts

TABLE G.14 Maximum Air Quality Impacts from Construction Emissions for Long-Term Aboveground Building and Belowground Vault Storage of U_3O_8 Compared with Impacts from Operations Emissions

Pollutant/ Storage Option	Averaging Period	Maximum Concentration from Construction Emissions ($\mu g/m^3$)	Operations Concentration as Percent of Construction Concentration
CO			
Building	1-hour average	49	15
	8-hour average	8.1	22
Vault	1-hour average	170	8
	8-hour average	37	7
NO_x			
Building	Annual average	2.2	21
Vault	Annual average	12.4	7

TABLE G.15 Maximum Pollutant Concentrations at Facility Boundaries during Operations for the Long-Term Storage of Depleted UF_6 in Yards

Pollutant	Averaging Time	Pollutant Concentration ($\mu g/m^3$)		Maximum of Construction and Operations as Percent of Standard
		Construction	Operations	
CO	1 hour	8.2 –36	3.1 – 6.2	0.1
	8 hours	1.4 – 5.1	1.0 – 1.2	0.06
NO_x	Annual	0.14 – 1.4	0.014 – 0.026	1.4
PM_{10}	24 hours	7.5 – 31	0.012 – 0.013	21
	Annual	0.42 – 4.1	0.0014 – 0.0026	8

of construction and operations would be below the relevant standards, although closer examination of the likely PM_{10} impacts might be required if this option were to be implemented.

In the maintenance phase of UF_6 storage in yards, the impacts would be similar to those of operations without construction. The maintenance impacts for CO, NO_x, and PM_{10} would be 0.71, 0.76, and 0.77, respectively, of those listed for operations in Table G.15.

Only small quantities of HF would be released from the process stack, averaging 0.06 kg/yr during the operations phase and 0.012 kg/yr during the maintenance phase. The estimated maximum average annual HF concentration is about 3×10^{-6} $\mu g/m^3$.

No quantitative estimate was made of the impacts on the criterion pollutant ozone. Ozone formation is a regional issue that would be affected by emissions data for the entire area around a proposed long-term storage site. The pollutants most related to ozone formation that would result from the long-term storage of depleted UF_6 are HC and NO_x. In later Phase II studies, when specific technologies and sites would be selected, the potential effects on ozone of these pollutants at a proposed site could be put in perspective by comparing them with the total emissions of HC and NO_x in the surrounding area. Small additional contributions to the totals would be unlikely to alter the ozone attainment status of the region.

G.3.4 Water and Soil

The methodology used to determine water and soil impacts is presented in Appendix C and Tomasko (1997).

G.3.4.1 Surface Water

To evaluate construction impacts, it was conservatively assumed that construction would be completed in 1 year. Essentially negligible impacts to surface water would be expected for all long-term storage options.

G.3.4.1.1 Buildings

The total land requirements for aboveground storage in buildings would be greatest for storing depleted uranium as U_3O_8 (148 acres [60 ha]) (Table G.16). Of this area, about 70 acres (29 ha) would be disturbed, and 6 acres (2.4 ha) would be paved. This alteration of soil would impact surface waters by increasing the amount of runoff. On a sitewide scale, however, this amount of increased impermeable land would have a negligible impact on nearby rivers (0.1 to 0.4% of the and representative site areas available for runoff). In addition, there would be no measurable impacts to the existing floodplains.

TABLE G.16 Summary of Environmental Parameters for Long-Term Storage in Buildings

Option	Unit	Requirements		
		Storage as UF_6	Storage as U_3O_8	Storage as UO_2
Total land area	acres	131	148	79
Total disturbed land	acres	62	72	35
Total paved area	acres	5	6	4
Construction water	million gal/yr	0.5	0.6	0.3
Excavation	yd^3	157,000	183,000	81,000
Water	million gal/yr			
Phase I		1.2	1.4	1.1
Phase II		1.0	1.0	0.9
Wastewater	million gal/yr			
Construction		0.05	0.06	0.03
Phase I		1.1	1.2	1.1
Phase II		0.9	0.9	0.8

Water would be needed for constructing the storage buildings. As indicated in Table G.16, the total quantity of water ranges from about 0.3 million gal/yr (0.6 gpm) for the UO_2 storage option to about 0.6 million gal/yr (1.1 gpm) for storing depleted uranium as U_3O_8. If this water were obtained from a nearby river, the impact would be negligible (less than 0.00005% of the average flow).

During construction, wastewater would be discharged to nearby surface waters. About 0.05 million gal/yr (0.1 gpm) of water would be discharged for the U_3O_8 option (see Table G.16). The primary contaminants of concern would be construction chemicals, organics, and some suspended solids. By following good engineering practices (e.g., stockpiling materials away from surface water drainages, covering construction piles with tarps, and cleaning small chemical spills as soon as they occurred), concentrations in the wastewater would be expected to be very small and well within any regulatory standards. In addition, once in the nearby surface water, dilution would occur in excess of 20 million:1 for average flows. Because the levels of contamination from construction would be very low, impacts to sediment would also be negligible.

During Phase I, annual water use would range from 1.1 to 1.4 million gal/yr for the three storage forms (UF_6, UO_2, and U_3O_8) (Table G.16). For a constant rate of use, the maximum withdrawal from nearby surface water would be about 55 gpm. This amount of withdrawal

corresponds to less than 0.0001% of the average river flows. The impact of this increase in withdrawal on the flow system (particularly floodplains) would be negligible.

Impacts to surface water quality could also occur during Phase I and II. These impacts would result from releasing water containing chemicals or radionuclides. The maximum wastewater release of 1.2 million gal/yr (2.3 gpm) would occur during Phase I (Table G.16). This wastewater would contain low concentrations of pollutants that would be within National Pollutant Discharge Elimination System (NPDES) guidelines. Additional large dilution would occur in the receiving water.

Impacts to surface waters during Phase II would be even less than the impacts produced by Phase I operations because of smaller volumes of raw water used and wastewater released (Table G.16). Impacts to surface water would, therefore, be negligible.

None of the accident scenarios presented in LLNL (1997) would produce impacts to surface water. Accidents occurring within the concrete-bottomed buildings would be contained and isolated from surface water, and accidents in which the building fails would primarily produce potential impacts via the air pathway.

G.3.4.1.2 Vaults

The total land requirements for vault storage would be roughly similar to the requirements for building storage (Table G.17). The amount of increased impermeable land would have a negligible impact on nearby rivers. In addition, there would be no measurable impacts to floodplains.

The quantity of water needed for construction would be similar to that for constructing buildings (Table G.17). If this water were obtained from a nearby river, the impact would be negligible for any of the storage forms (less than 0.00001% of the average flows). During construction, wastewater volumes similar to the building option would be discharged to surface waters (U_3O_8 option; see Table G.17), and the impacts to surface waters would also be negligible.

During Phase I and Phase II operations, annual water use would be about two times greater than for the building option (Table G.17). The impact of this withdrawal on the flow system (particularly floodplains) would be negligible, as would the impacts to surface water.

None of the accident scenarios presented in LLNL (1997) would produce impacts to surface water. If an accident occurred within the vault it would be contained and isolated from surface water.

TABLE G.17 Summary of Environmental Parameters for Long-Term Storage in Vaults

Option	Unit	Physical Needs: Storage as U_3O_8	Physical Needs: Storage as UO_2
Total land area	acres	212	114
Total disturbed area	acres	86	40
Total paved area	acres	21	10
Excavation	million yd^3	1.7	0.75
Water			
Phase I	million gal/yr	1.1	1.2
Phase II	million gal/yr	0.8	0.9
Wastewater			
Construction	million gal/yr	0.8	0.4
Phase I	million gal/yr	1.1	1.0
Phase II	million gal/yr	0.9	0.8
Construction water	million gal/yr	0.8	0.4

G.3.4.1.3 Mine

Requirements for long-term storage in a mine are listed in Table G.18. These parameters are all similar to those for vault storage, and all potential impacts would be similar.

G.3.4.1.4 Yards

For long-term storage of depleted uranium as UF_6 in yards, 144 acres (58 ha) of land would be disturbed and 13 acres (5.3 ha) would be paved. This alteration of soil would impact local surface waters by increasing the amount of runoff. The amount of increased runoff, however, would be negligible on a sitewide scale because the land area affected would range from 0.25 to 1.5% of the representative site land areas available. In addition there would be no measurable impacts to the existing floodplains.

Water would be needed for constructing the long-term storage yards. Approximately 6.4 million gal/yr of water would be required. This amount of withdrawal would represent less than 0.000033% of average flows. The impact of this increase in withdrawal on the flow system (particularly floodplains) would be negligible.

TABLE G.18 Summary of Environmental Parameters for Long-Term Storage in a Mine

Option	Unit	Physical Needs		
		Storage as UF_6	Storage as U_3O_8	Storage as UO_2
Total land area	acres	96	124	74
Total disturbed area	acres	32	54	25
Total paved area	acres	3	3	3
Excavation	million yd^3	1.8	2.2	1.2
Water				
Phase I	million gal/yr	1.2	1.3	1.2
Phase II	million gal/yr	0.9	1.0	0.9
Wastewater				
Construction	million gal/yr	0.1	0.1	0.07
Phase I	million gal/yr	1.1	1.3	1.1
Phase II	million gal/yr	0.9	0.9	0.8
Underground area	acres	114	138	77
Construction water	million gal/yr	1.1	1.3	0.7

During construction of the storage yard, surface water quality could be impacted. The primary contaminants of concern would be chemicals used in construction, organic compounds, and some suspended solids. By following good engineering practices, concentrations in the wastewater would be expected to be very small and less than applicable U.S. Environmental Protection Agency (EPA) guidelines. Once the construction water mixed with surface water, dilution would occur. Depending on the volumetric release of water during construction, dilution would be about 1 million:1.

During normal operations, there would be no emissions that would impact surface water because all cylinders are assumed to be new at the start of the storage option, they would be inspected once every 4 years, and they would be replaced if any handling damage occurred. In addition, no impacts to surface water would result from accidents because no accidents are identified in LLNL (1997) that would produce emissions that would interact directly or indirectly with surface water.

G.3.4.2 Groundwater

The only groundwater impacts for long-term storage in buildings, vaults, or mines would occur during construction. Phase I and Phase II operations would produce no impacts because groundwater would not be used as a source for operations and there would be no direct discharges of wastewater to the aquifers. For vault construction, drains would be provided on the upgradient side of the facility to prevent groundwater from entering the facility and mobilizing any spilled contaminants. Accident sequences described in LLNL (1997) would also have no impacts on groundwater because the building, vault, or mine would isolate contaminants and eliminate any direct pathways to the underlying aquifers.

At any site, groundwater quality could be impacted by construction. For example, chemicals stored on the ground could be mobilized by precipitation and infiltrate to the underlying aquifers. By adopting good engineering and construction practices (e.g., covering material to prevent interaction with rain, promptly cleaning any chemical spills, and providing retention basins to catch and hold contaminated runoff), groundwater concentrations would be kept below EPA (1996) guidelines. Overall, impacts from construction would, therefore, be negligible. Phase I and Phase II operations would have no impacts because groundwater would not be used as a source for operations and there would be no direct discharges of wastewater to the aquifers.

The only groundwater impacts for long-term storage in yards would occur during construction. These impacts would primarily be to groundwater quality; impacts to the depth of groundwater, recharge, and flow direction would not be measurable on a sitewide scale because of the limited size of the facility. Impacts could, however, affect quality. For example, chemicals stored on the ground could be mobilized by precipitation and infiltrate to the underlying aquifers. By adopting good engineering and construction practices, impacts to quality would be minimized, and groundwater concentrations would be kept below EPA (1996) guidelines.

As with surface water, there would be no emissions that would impact groundwater during normal operations because all cylinders were assumed to be in good condition at the start of the storage option, they would be inspected once every 4 years, and they would be replaced if any handling damage occurred. In addition, no accident scenarios identified in LLNL (1997) would lead to direct or indirect groundwater contamination.

G.3.4.3 Soil

G.3.4.3.1 Buildings

The only impacts to soil from long-term storage in buildings would occur during construction. The maximum impact would occur for construction of the U_3O_8 building (Table G.16). Up to 148 acres (60 ha) of land (4.4 to 29% of the representative site land areas available) would be

disturbed, and 183,000 yd^3 (140,000 m^3) of soil would be excavated. These impacts would include modifications in the local topography, increased permeability and erosion potential in areas where the land surface is plowed, decreased permeability and erosion potential in areas where the soil is compacted by heavy equipment, and decreased soil quality in areas exposed to chemical alteration. On a sitewide scale, the impacts would be moderate; however, the impacts would be temporary. That is, with time the disturbed soil conditions would return to previous conditions everywhere except in paved lots. As discussed in Section G.3.4.1.1, this area would be about 6 acres (2.4 ha) (0.2 to 0.4% of the total land area available). On a sitewide scale, this impact would be negligible.

By following good engineering practices (e.g., disturbing as little soil as possible, contouring and reseeding disturbed land, scheduling activities to minimize land disturbance, controlling runoff, using tarps to prevent chemical/rainfall interaction, and cleaning any spills as soon as they occur), impacts to soils would be minimized.

G.3.4.3.2 Vaults

The only impacts to soil from long-term storage in vaults would occur during construction. The largest impact to soils would occur for construction of the U_3O_8 vault (Table G.16). Up to 212 acres (86 ha) of land (6 to 13% of the land area available) would be disturbed, and up to 1.7 million yd^3 (1.3 million m^3) of soil would be excavated. These impacts would include modifications in the local topography. If the excavated soil were spread evenly over the 212-acre (86-ha) facility, a mound 5 ft (1.5 m) deep would be created. This impact could be mitigated by trucking the soil off-site. Other impacts would include increased permeability and erosion potential in areas where the land surface is plowed or mounded, decreased permeability and erosion potential in areas where the soil is compacted by heavy equipment, and decreased soil quality in areas exposed to chemical alteration. On a sitewide scale, the impacts would be moderate; however, the impacts would, to a large extent, be temporary and readily mitigated. With time the disturbed soil conditions would be returned to existing conditions everywhere except in paved lots. As discussed in Section G.3.4.1.2, this area would be a maximum of 21 acres (8.5 ha) (0.6 to 1.2% of the total land area available). On a sitewide scale, this impact would be minor. By following good engineering practices, impacts to soils would be kept to a minimum.

G.3.4.3.3 Mine

The only impacts to soils from long-term storage in a mine would occur during construction. The maximum impact to soils would occur for construction of the U_3O_8 mine facility (Table G.16). Up to 124 acres (50 ha) of land (3.3 to 7.3% of the representative site land areas available) would be disturbed, and up to 2.4 million yd^3 (1.8 million m^3) of soil and rock would be excavated. These impacts would include modifications in topography (e.g., if the excavated material were spread evenly over the 124-acre (50-ha) facility, a mound 12 ft (3.7 m) high would be created; however, this impact could be mitigated by trucking the material off-site), increased permeability

and erosion potential in areas where the land surface is plowed or mounded, decreased permeability and erosion potential in areas where the soil is compacted by heavy equipment, and decreased soil quality in areas exposed to chemical alteration. Impacts would be moderate; however, the impacts would, to a large extent, be temporary and readily mitigated. That is, with time, the disturbed soil would be returned to previous conditions everywhere except in paved lots. This area would be about 3 acres (1.2 ha) (0.1 to 0.4% of the total land area available) and would result in a minor impact to soils. By following good engineering practices, impacts to soils would be kept to a minimum.

G.3.4.3.4 Yards

About 144 acres (58 ha) of land would be disturbed by construction of the long-term storage yard facility (3.8 to 8.5% of the land area available. Of this area, 13 acres (5.3 ha) would be paved (0.4 to 0.8% of the land area available). In addition, about 250,000 yd^3 (192,000 m^3) of soil would be excavated. Impacts from construction would include modifications in topography, increased permeability and erosion potential in areas where the soil would be broken, decreased permeability and erosion potential in areas where the soil would be compacted by heavy equipment or paving, and decreased soil quality in areas subjected to chemical loading. On a sitewide basis, the impacts would be moderate, but they would be mostly temporary. That is, with time, soil conditions would return to previous conditions everywhere except beneath paved lots, the 20 UF_6 storage pads, and associated buildings. By following good engineering practices, impacts to soils would be kept to a minimum.

There would be no emissions that would impact soils during normal operations because all cylinders would be inspected once every 4 years, and they would be replaced if any handling damage occurred. In addition, there are no identified accident scenarios that would lead to direct or indirect contamination.

G.3.5 Socioeconomics

Calculations for the analysis of socioeconomic impacts were based on detailed cost data developed for trial storage facilities, including the impacts of facility construction, operation and maintenance, emplacement and closure, and surveillance and monitoring activities. Impacts for each facility are presented for the peak year of construction and the first year of operations.

The potential socioeconomic impacts of long-term storage in yards, buildings, and vaults were estimated using the three representative sites. Because the sites that would be chosen for long-term storage in mines are not known, the analysis estimated the impacts of these facilities for a generic site. The impacts of long-term storage at the representative sites on regional economic activity was estimated for a region of influence (ROI): these impacts are presented in detail in Section G.3.5.1. The impacts of long-term storage at a generic site are presented in Section G.3.5.2. The methodology for assessing socioeconomic impacts is discussed in Appendix C.

Long-term storage would probably have a small impact on socioeconomic conditions in the ROIs surrounding the three sites described in Chapter 3, Sections 3.1.8, 3.2.8, and 3.3.8. This is partly because a major proportion of expenditures associated with procurement for the construction and operation of each technology option would flow outside of the ROI to other locations in the United States, reducing the concentration of local economic effects of the long-term storage yard.

Slight changes in employment and income would occur in each ROI as a result of local spending of personal consumption expenditures derived from employee wages and salaries, local procurement of goods and services required to construct and operate a long-term storage facility, and other local investment associated with construction and operation. In addition to creating new (direct) jobs at each site, the facility would also create indirect employment and income in the ROI as a result of jobs and procurement expenditures at each site. Jobs and income created directly by a long-term storage facility, together with indirect activity in the ROI, would contribute slightly to reduction in unemployment in the ROI surrounding each site. Minimal impacts are expected on local population growth and, consequently, on local housing markets and local fiscal conditions.

The effects of constructing and operating long-term storage facilities were assessed with regard to regional economic activity (measured in terms of employment and personal income) and population, housing, and local public revenues and expenditures. The results are presented as ranges to include impacts that would occur for a storage facility at each of the representative sites. Impacts for the three sites are presented for the peak year of construction and during the first year of operations. Table G.19 presents the potential range of impacts for long-term storage at the three representative sites.

G.3.5.1 Long-Term Storage as UF_6

During the peak year of construction of a UF_6 long-term storage yard or building, 100 to 200 direct jobs would be created at the site, and 80 to 310 additional jobs would be indirectly created in the ROI surrounding a representative site (Table G.19) as a result of the spending of employee wages and salaries and procurement-related expenditures. Overall, between 180 and 510 jobs would be created. Construction activity would also produce direct and indirect income in the ROI, with total income of $7 million to $15 million produced during the peak year. In the first year of operations of the facility, between 80 and 100 direct and indirect jobs would be created. Direct and indirect income would also be produced in the ROI surrounding each site, with total income of $4 million in the first year. Construction and operation of a UF_6 storage facility would result in an increase in the projected baseline compound annual average growth rate in employment in the representative site ROI of 0.001 to 0.006 percentage points from 2006 through 2039.

Construction of a UF_6 storage facility would be expected to generate direct in-migration of 130 to 280 in the peak year of construction. Additional indirect job in-migration would be expected into the site ROIs, bringing the total number of in-migrants to between 170 and 430 in the

TABLE G.19 Potential Socioeconomic Impacts of the Long-Term Storage Options for Yards, Buildings, and Vaults

Parameter	Long-Term Storage as UF_6		Long-Term Storage as UO_2		Long-Term Storage as U_3O_8	
	Construction[a]	Operations[b]	Construction[a]	Operations[b]	Construction[a]	Operations[b]
Economic activity in the ROI						
Direct jobs	100 – 200	50	120 – 140	70	170 – 210	60
Indirect jobs	80 – 310	30 – 50	100 – 190	30 – 60	140 – 280	40 – 70
Total jobs	180 – 510	80 – 100	220 –330	100 – 130	310 – 490	100 – 130
Income ($ million)						
Direct income	5 – 9	3	5 – 6	3	8 – 9	3 – 4
Total income	7 – 15	4	7 – 10	4	11 – 15	5 – 8
Population in-migration into the ROI	170 – 430	50 – 70	210 – 280	70 – 100	300 – 420	80 – 100
Housing demand						
Number of units in the ROI	60 – 160	20 – 30	80 – 100	30 – 40	110 – 150	30 – 40
Public finances						
Change in ROI fiscal balance (%)	<0.1 – 0.3	<0.01	0.1 – 0.2	<0.1 – 0.1	0.1 – 0.3	<0.1 – 0.1

[a] Impacts are for peak year of construction, either 2007 or 2008. Socioeconomic impacts from construction were assessed for 2007 through 2028.

[b] Impacts are the annual averages for the emplacement period (2009–2028). Annual averages for the surveillance and maintenance period (2029–2039) were estimated to be equal to or less than these values.

peak year (Table G.19). Operation of the facility would be expected to generate direct job in-migration of 40 in the first year. Additional indirect job in-migration into the ROI would also be expected, bringing the total number of in-migrants to between 50 and 70 in the first year of operations. Construction and operation of a UF_6 storage facility would result in an increase in the projected baseline compound annual average growth rate in representative site ROI populations of 0.001 to 0.01 percentage points from 2006 through 2039.

A UF_6 storage facility would generate a demand for 60 to 160 additional rental housing units during the peak year of construction (Table G.19), representing an impact of 3.5 to 8% on the projected number of vacant rental housing units at the representative sites. A demand for 20 to 30 additional owner-occupied housing units would be expected in the first year of operations, representing an impact of 0.2 to 0.5% on the number of vacant owner-occupied housing units at each site.

During the peak year of construction, between 170 and 430 persons would in-migrate into the ROI at each site, leading to an increase of less than 0.1 to 0.3% over ROI-forecasted baseline revenues and expenditures at the representative sites (Table G.19). In the first year of operations, 50 to 60 in-migrants would be expected, leading to an increase of less than 0.01% in local revenues and expenditures at the three sites.

G.3.5.2 Long-Term Storage as UO_2

During the peak year of construction of a UO_2 long-term storage building or vault, 120 to 140 direct jobs would be created at the site and 100 to 190 additional jobs indirectly in the ROI surrounding each site (Table G.19) as a result of the spending of employee wages and salaries and procurement-related expenditures. Overall, between 220 and 330 jobs would be created. Construction activity would also produce direct and indirect income in the ROI, with total income of $7 million to $10 million produced during the peak year. In the first year of operations of the facility, between 100 and 130 direct and indirect jobs would be created. Direct and indirect income would also be produced in the ROI surrounding the site, with total income of $4 million in the first year. Construction and operation of a UO_2 storage facility would result in an increase in the projected baseline compound annual average growth rate in employment in the ROI of 0.01 to 0.02 percentage points from 2006 to 2039.

Construction of a UO_2 storage facility would be expected to generate direct in-migration of 160 to 190 in the peak year of construction. Additional indirect job in-migration would be expected into the site ROIs, bringing the total number of in-migrants to between 210 and 280 in the peak year (Table G.19). Operation of the facility would be expected to generate direct job in-migration of between 11 and 70 in the first year. Additional indirect job in-migration into the ROI would also be expected, bringing the total number of in-migrants to between 70 and 100 in the first year of operations. Construction and operation of a UO_2 storage facility would result in an increase

in the projected baseline compound annual average growth rate in ROI population of 0.01 percentage points from 2006 to 2039.

A UO_2 storage facility would generate a demand for 80 to 100 additional rental housing units during the peak year of construction, representing an impact of 1.4 to 6.5% on the projected number of vacant rental housing units at the representative sites (Table G.19). A demand for 30 to 40 additional owner-occupied housing units would be expected in the first year of operations, representing an impact of 0.2 to 0.7% on the number of vacant owner-occupied housing units at each site.

During the peak year of construction, between 210 and 280 persons would in-migrate into the ROI for the site, leading to an increase of 0.1 to 0.2% over ROI-forecasted baseline revenues and expenditures at the representative sites (Table G.19). In the first year of operations, 70 to 100 in-migrants would be expected, leading to an increase of less than 0.1 to 0.1% in local revenues and expenditures at the sites.

G.3.5.3 Long-Term Storage as U_3O_8

During the peak year of construction of a U_3O_8 long-term storage building or vault, 170 to 210 direct jobs would be created at the site and 140 to 280 additional jobs indirectly in the ROI surrounding the site (Table G.19) as a result of the spending of employee wages and salaries and procurement-related expenditures. Overall, between 310 and 490 jobs would be created. Construction activity would also produce direct and indirect income in the ROI, with total income of $11 million to $15 million produced during the peak year. In the first year of operations of the facility, between 100 and 130 direct and indirect jobs would be created. Direct and indirect income would also be produced in the ROI surrounding the site, with total income of $5 million to $8 million in the first year. Construction and operation of a U_3O_8 storage facility would result in an increase in the projected baseline compound annual average growth rate in employment in the ROI of 0.001 to 0.003 percentage points from 2006 through 2039.

Construction of a U_3O_8 storage facility would be expected to generate direct in-migration of 230 to 290 in the peak year of construction. Additional indirect job in-migration would be expected into the site ROIs, bringing the total number of in-migrants to between 300 and 420 in the peak year (Table G.19). Operation of the facility would be expected to generate direct job in-migration of 60 to 70 in the first year. Additional indirect job in-migration into the ROI would also be expected, bringing the total number of in-migrants to between 80 and 100 in the first year of operations. Construction and operation of a U_3O_8 storage facility would result in an increase in the projected baseline compound annual average growth rate in ROI population of 0.001 to 0.005 percentage points from 2006 through 2039.

A U_3O_8 storage facility would generate a demand for 110 to 150 additional rental housing units during the peak year of construction, corresponding to an impact of 1.3 to 8.2% on the

projected number of vacant rental housing units at the representative sites (Table G.19). A demand for 30 to 40 additional owner-occupied housing units would be expected in the first year of operations, corresponding to an impact of 0.3 to 0.8% on the number of vacant owner-occupied housing units at the site.

During the peak year of construction, between 300 and 420 persons would in-migrate into the ROI at each site, leading to an increase of 0.1 to 0.3% over ROI-forecasted baseline revenues and expenditures at the representative sites (Table G.19). In the first year of operations, 80 to 100 in-migrants would be expected, leading to an increase of between less than 0.1 to 0.1% in local revenues and expenditures at the sites.

G.3.5.4 Long-Term Storage in a Mine

Construction-related impacts (engineering, construction, project management, and site preparation and restoration activities) and operations-related impacts (operation, emplacement and closure, and surveillance and maintenance activities) are shown in Table G.20 for storage in a mine. The location of a long-term storage mine has not yet been determined. The socioeconomic impacts of long-term storage in a mine were analyzed on a non-site-specific basis for a generic site. Impacts at the generic site are presented in terms of the impact of each storage option on direct (on-site) employment and income of construction and operation activities. Estimation of the indirect impacts that would occur off-site in the ROI around each facility would require site-specific information on

TABLE G.20 Potential Socioeconomic Impacts of Long-Term Storage in a Mine

Option/Parameter	Construction[a]	Operations[b]
Storage as UF_6		
Direct jobs	500	60
Direct income ($ million 1996)	29	3
Storage as U_3O_8		
Direct jobs	410	60
Direct income ($ million 1996)	19	3
Storage as UO_2		
Direct jobs	340	60
Direct income ($ million 1996)	20	4

[a] Impacts are for peak year of construction, 2007. Socioeconomic impacts from construction were assessed for 2007 through 2028.

[b] Impacts are the annual averages for the emplacement period (2009–2028). Annual averages for the surveillance and maintenance period (2029–2039) were estimated to be equal to or less than these values.

a variety of regional economic, demographic, housing, and jurisdictional characteristics and were therefore not included in the analysis. In addition, estimates of the relative impacts of direct employment and income at each facility compared with the local economic baseline are not provided (see Allison and Folga 1997).

G.3.6 Ecology

Moderate to large adverse impacts to ecological resources could result from construction of a facility for long-term storage as UF_6, U_3O_8, or UO_2. Impacts could include mortality of individual organisms, habitat loss, or changes in biotic communities. Impacts due to operation of a storage facility would be negligible.

G.3.6.1 Storage as UF_6

Site preparation for the construction of a facility to store UF_6 in buildings would require the disturbance of approximately 131 acres (53 ha), including the permanent replacement of about 62 acres (25 ha) of current land cover with structures and paved areas. Existing vegetation would be destroyed during land-clearing activities. The vegetation communities that would be eliminated by site preparation would depend on the location of the facility. Communities occurring on undeveloped land at the representative sites are relatively common and well represented in the vicinity of the sites; however, impacts to high-quality native plant communities might occur if facility construction required disturbance to vegetation communities outside of the currently fenced areas (see Section G.3.9 for a discussion of land use). Construction of the storage facility would not be expected to threaten the local population of any species. The loss of up to 131 acres (53 ha) of undeveloped land would constitute a large adverse impact to vegetation. Erosion of exposed soil at construction sites could reduce the effectiveness of restoration efforts and create sedimentation downgradient of the site. The implementation of standard erosion control measures, installation of storm-water retention ponds, and immediate replanting of disturbed areas with native species would help minimize impacts to vegetation. Impacts due to facility construction are shown in Table G.21.

Wildlife would be disturbed by land clearing, noise, and human presence. Wildlife with restricted mobility, such as burrowing species or juveniles of nesting species, would be destroyed during land clearing activities. More mobile individuals would relocate to adjacent available areas with suitable habitat. Population densities and competition would increase in these areas, potentially reducing the chances of survival or reproductive capacity of displaced individuals. Some wildlife species would be expected to quickly recolonize replanted areas near the storage facility following completion of construction. The permanent loss of 62 acres (25 ha) to 131 acres (53 ha) of habitat would not be expected to threaten the local population of any wildlife species since similar habitat would be available in the vicinity of the representative sites. However, habitat use in the vicinity of the facility may be reduced for some species due to the construction of a perimeter fence enclosing

TABLE G.21 Impacts to Ecological Resources from Construction of Long-Term Storage Facilities for Depleted Uranium

Option/Resource	Buildings	Vaults	Mine	Yards
Storage as UF_6

[a] Long-term storage as UF_6 in vaults and long-term storage as U_3O_8 or UO_2 in yards were not considered.

a 131-acre (53-ha) area. Overall, construction of a facility for UF_6 storage would be considered a moderate to large adverse impact to wildlife.

Impacts to surface water and groundwater quality during construction are expected to be negligible (Section G.3.4). Thus, construction derived impacts to aquatic biota would also be expected to be negligible. Wetlands could potentially be filled or drained during construction. In addition, impacts to wetlands due to alteration of surface water runoff patterns, soil compaction, or groundwater flow could occur if the storage facility were located immediately adjacent to wetland areas. However, impacts to wetlands would be minimized by maintaining a buffer area around wetlands during construction of the facility. Unavoidable impacts to wetlands would require a *Clean Water Act* Section 404 permit, which might stipulate mitigative measures. Additional permitting might be required by state agencies.

Critical habitat has not been designated for any state or federally listed threatened or endangered species at any of the representative sites. Prior to construction of a storage facility, a survey for state and federally listed threatened, endangered, or candidate species, or species of special concern would be conducted so that, if possible, impacts to these species could be avoided. Where impacts were unavoidable, appropriate mitigation could be developed.

Small releases of HF would be expected to occur during operation of the building storage facility. The air concentration of HF from facility operations would be 0.00031 to 0.00081 $\mu g/m^3$, well below levels injurious to wildlife. Resulting impacts to wildlife would be negligible.

Impacts due to construction of a facility to store UF_6 in a mine would be similar to impacts from storage in buildings, although a smaller area would be affected. Facility construction would require the disturbance of approximately 96 acres (39 ha), including the permanent replacement of approximately 32 acres (13 ha) of current land cover with structures and paved areas (including rock spoil). A larger proportion of the mine storage facility would be available for wildlife habitat in comparison with the building storage facility. Species diversity and abundance, however, would be expected to be low because of human presence, proximity of buildings, and the relatively poor habitat quality of landscaped areas. Construction of a facility to store UF_6 in a mine would constitute a moderate to large adverse impact to vegetation and a moderate adverse impact to wildlife. Impacts due to facility construction are shown in Table G.21. Releases of contaminants are not expected to occur during operation of the mine storage facility, therefore, impacts to wildlife due to facility operation would be negligible.

Impacts due to construction of a facility to store UF_6 in yards would be similar to impacts from storage in buildings, although a larger area would be affected. Facility construction would require the disturbance of approximately 144 acres (58 ha), including the permanent replacement of approximately 90 acres (37 ha) with buildings and paved areas. Compared with the building storage facility, a smaller proportion of the yard storage facility would be available for wildlife habitat. Construction of a facility to store UF_6 in yards would constitute a large adverse impact to vegetation and wildlife. Potential impacts associated with facility construction are shown in Table G.21.

Small releases of HF, UO_2F_2, and U_3O_8 would be expected to occur during operation of the yard storage facility due to transfers of UF_6 from defective cylinders. The maximum annual average air concentration at a storage site boundary from operation of a yard storage facility would be approximately 2.7×10^{-6} μg/m^3 for HF, 5.3×10^{-7} μg/m^3 for UO_2F_2, and 1.8×10^{-9} μg/m^3 for U_3O_8. Impacts to wildlife from these emissions are expected to be negligible.

Storage facility accidents, as discussed in Section G.3.2, could result in adverse impacts to ecological resources. The affected species and degree of impact would depend on such factors as location of the accident, season, and meteorological conditions.

G.3.6.2 Storage as U_3O_8

The construction of a facility to store U_3O_8 in buildings would generally result in the types of impacts associated with UF_6 building storage. Site preparation for the construction of a facility to store U_3O_8 in buildings would require the disturbance of approximately 148 acres (60 ha), including the permanent replacement of approximately 72 acres (29 ha) of current land cover with structures and paved areas. Construction of the storage facility would not be expected to threaten the local population of any species. The loss of up to 148 acres (60 ha) of undeveloped land would constitute a large adverse impact to vegetation. Releases of contaminants are not expected to occur during operation of the storage facility, therefore, impacts to biotic resources due to facility operation would be negligible. Impacts due to facility construction are shown in Table G.21.

The permanent loss of 72 to 148 acres (29 to 60 ha) of habitat would not be expected to threaten the local population of any wildlife species since similar habitat would be available in the vicinity of the representative sites. However, habitat use in the vicinity of the facility might be reduced for some species due to the construction of a perimeter fence enclosing a 148-acre (60-ha) area. Therefore, construction of a facility for U_3O_8 storage in buildings would be considered a large adverse impact to wildlife.

Impacts to surface water and groundwater quality during construction are expected to be negligible (Section G.3.4). Thus, construction derived impacts to aquatic biota would also be expected to be negligible.

Impacts due to construction of a facility to store U_3O_8 in vaults would be similar to impacts from storage in buildings, although a larger area would be affected. Facility construction would require the disturbance of approximately 212 acres (86 ha), including the permanent replacement of approximately 86 acres (35 ha) with structures and paved areas. A larger proportion of the vault storage facility would be available for wildlife habitat in comparison with the building storage facility. Species diversity and abundance, however, would be expected to be low because of human presence, proximity of buildings, and the relatively poor habitat quality of landscaped areas. Construction of a facility to store U_3O_8 in vaults would constitute a large adverse impact to vegetation and wildlife. The larger size of the facility also would increase the potential for

unavoidable direct and indirect impacts to wetlands due to facility location. Impacts due to facility construction are shown in Table G.21. Releases of contaminants are not expected to occur during operation of the vault storage facility, therefore, impacts to biotic resources due to facility operation would be negligible.

Impacts due to construction of a facility to store U_3O_8 in a mine would be similar to impacts from storage in buildings or vaults, although a smaller area would be affected. Facility construction would require the disturbance of approximately 124 acres (50 ha), including the permanent replacement of approximately 54 acres (22 ha) of current land cover with structures and paved areas (including rock spoil). A larger proportion of the mine storage facility would be available for wildlife habitat in comparison with the building storage facility. Species diversity and abundance, however, would be expected to be low because of human presence, proximity of buildings, and the relatively poor habitat quality of landscaped areas. Construction of a facility to store U_3O_8 in a mine would constitute a large adverse impact to vegetation and wildlife. Impacts due to facility construction are shown in Table G.21. Releases of contaminants are not expected to occur during operation of the mine storage facility, therefore, impacts to biotic resources due to facility operation would be negligible.

G.3.6.3 Storage as UO_2

The construction of a facility to store UO_2 in buildings would generally result in the types of impacts associated with UF_6 building storage. Site preparation for the construction of a facility to store UO_2 in buildings would require the disturbance of approximately 79 acres (32 ha), including the permanent replacement of approximately 35 acres (14 ha) with structures, including paved areas. Construction of the storage facility would not be expected to threaten the local population of any species. The loss of up to 79 acres (32 ha) of undeveloped land would constitute a moderate adverse impact to vegetation. Impacts due to facility construction are shown in Table G.21.

The permanent loss of 35 to 79 acres (14 to 32 ha) of habitat would not be expected to threaten the local population of any wildlife species because similar habitat would be available in the vicinity of the representative sites. However, habitat use in the vicinity of the facility might be reduced for some species due to the construction of a perimeter fence enclosing a 79-acre (32-ha) area. Therefore, construction of a facility for UO_2 storage would be considered a moderate adverse impact to wildlife.

Impacts to surface water and groundwater quality during construction are expected to be negligible (Section G.3.4). Thus, construction derived impacts to aquatic biota would also be expected to be negligible.

Impacts due to construction of a facility to store UO_2 in vaults would be similar to impacts from storage in buildings, although a larger area would be affected. Facility construction would require the disturbance of approximately 114 acres (46 ha), including the permanent replacement of

approximately 40 acres (16 ha) of current land cover with structures and paved areas. A larger proportion of the vault storage facility would be available for wildlife habitat in comparison with the building storage facility. However, species diversity and population densities would be expected to be low because of human presence, proximity of buildings, and the relatively low habitat quality of landscaped areas. Construction of a facility to store UO_2 in vaults would constitute a large adverse impact to vegetation and wildlife. The larger size of the facility would also increase the potential for unavoidable proximity to wetlands and consequent direct and indirect impacts. Impacts due to facility construction are shown in Table G.21. Releases of contaminants are not expected to occur during operation of the vault storage facility, therefore, impacts to biotic resources due to facility operation would be negligible.

Impacts due to construction of a facility to store UO_2 in a mine would be similar to impacts from storage in buildings or vaults, although a smaller area would be affected. Facility construction would require the disturbance of approximately 74 acres (30 ha), including the permanent replacement of approximately 25 acres (10 ha) of current land cover with structures and paved areas (including rock spoil). A larger proportion of the mine storage facility would be available for wildlife habitat in comparison with the building storage facility. Species diversity and abundance, however, would be expected to be low because of human presence, proximity of buildings, and the relatively poor habitat quality of landscaped areas. Construction of a facility to store UO_2 in a mine would constitute a moderate adverse impact to vegetation and wildlife. Impacts due to facility construction are shown in Table G.21. Releases of contaminants are not expected to occur during operation of the mine storage facility, therefore, impacts to biotic resources due to facility operation would be negligible.

G.3.7 Waste Management

Impacts on waste management from wastes generated during the long-term storage of depleted UF_6 would be caused by the potential overload of waste treatment and/or disposal capabilities either at a site or on a regional or national scale.

G.3.7.1 Storage of UF_6 in Yards, Buildings, and Mines

G.3.7.1.1 Yards

Construction of the storage pads and associated support facilities would generate nonhazardous solid waste and sanitary wastewater. Construction would generate about 3,500 yd^3 (2,700 m^3) of concrete and other solid wastes. Because solid waste disposal facilities can generally be expanded as required, the impact of the construction wastes would be minimal at any site.

The operations to maintain and store depleted UF_6 cylinders would consist of inspections, stripping and repainting of the external coating of cylinders, and disposal of scrap metal from old steel cylinders. These operations would generate three primary radioactive waste streams: uranium-contaminated scrap metal (low-level radioactive waste [LLW]) from replaced cylinders, UO_2F_2 from replaced cylinders (LLW), and solid process residue (low-level mixed waste [LLMW]) from cylinder painting. In addition, long-term yard storage operations would generate nonhazardous solid CaF_2 waste and sanitary wastewater. The amount of waste generated would depend upon the time when the activities occurred. For each waste type, the amount of waste generated annually would be larger during Phase I of the operations (see Table G.22). The waste totals from Phase I were generally used for comparison with the site waste loads.

The 109 yd^3/yr (83 m^3/yr) of scrap metal LLW and the 0.17 yd^3/yr (0.13 m^3/yr) of uranyl fluoride generated during Phase I would add from 1 to 3.8% to representative site LLW generation (Table G.22). The maximum amount of LLW generated annually during the continued storage of depleted UF_6 at all three sites would represent less than 1% of the projected annual DOE LLW generation. The 46 yd^3/yr (35 m^3/yr) of LLMW generated during long-term yard storage of depleted UF_6 would add from less than 1 to 35% to the LLMW loads at the representative sites, but UF_6 would be less than 1% of the total nationwide LLMW load.

TABLE G.22 Estimated Annual Waste Loads from Long-Term Storage of UF_6 in Yards

	Waste Load of Depleted UF_6		
	Annual Load (m^3/yr)		Total Load (m^3)
Waste Type	2009-2028	2029-2039	2009-2039
Low-level waste			
Scrap metal	83	44	2,144
UO_2F_2	0.13	0.07	3.37
Low-level mixed waste (inorganic process residue)	8.8	35	561
Nonhazardous waste (CaF_2)	0.08	0.05	2.15
Sanitary wastewater	6,500	6,700	204,000

[a] NA = not applicable; NR = not reported.

Source: DOE (1997).

The 0.11 yd^3/yr (0.08 m^3/yr) of solid nonhazardous waste generated during Phase I would represent less than 1% of the annual waste loads at the representative sites. The 8,700 yd^3/yr (6,700 m^3/yr) of sanitary wastewater would represent less than 1.5% of the annual wastewater load of the sites.

Overall, the waste input resulting from the long-term yard storage of depleted UF_6 would have negligible impact on radioactive waste management capabilities at the representative sites. The impact on nonradioactive site waste management would also be negligible. The impacts of waste resulting from the long-term yard storage of depleted UF_6 on national waste management capabilities would be negligible.

G.3.7.1.2 Buildings and Mines

The wastes generated during construction of any of the different types of storage facilities would be typical of a large construction project. The only wastes would be construction debris and the sanitary wastes of the labor force. Estimates for the wastewater generated during construction of the different types of UF_6 storage facilities are shown in Table G.23.

Operation of the UF_6 storage facility would be divided into two phases. Phase I (2009-2028) would involve the receipt, inspection, and repackaging of the depleted uranium containers and relocation of these containers to the storage facility. The wastes generated during this operation would be sanitary wastes of the labor force and the empty containers from the repacking process.

Phase II operations (2029-2039) would involve cylinder inspection, removal, repackaging and replacing of damaged containers. Damaged cylinders were assumed to be LLW. Waste generated during this phase of operations would be sanitary wastes of the labor force and the empty failed

TABLE G.23 Estimated Total Wastewater Volumes from Construction of Long-Term Storage Facilities for UF_6, U_3O_8, and UO_2

Uranium Compound	Wastewater Volume (million L)			
	Buildings	Vaults	Mine	Yards
UF_6	4.0	N/A[a]	8.5	24.0
U_3O_8	4.7	6.2	10	N/A
UO_2	2.1	2.7	5.0	N/A

[a] N/A = data not available.

cylinders. The conversion of "heels" of UF_6 in damaged cylinders would result in UO_2F_2 waste (LLW) and a CaF_2 waste. The wastes expected from the storage of UF_6 are listed in Table G.24.

G.3.7.2 Storage of U_3O_8 and UO_2 in Buildings, Mines, and Vaults

The discussion of waste generation during construction and operations given in Section G.3.7.1.2 on storage of depleted UF_6 also applies to the storage of U_3O_8 and UO_2. Estimates of wastewater generation during construction of U_3O_8 and UO_2 long-term storage facilities are given in Table G.23. Estimates of waste generation during storage of U_3O_8 and UO_2 are given in Table G.24. No UO_2F_2 or CaF_2 wastes would be generated in the storing of these waste forms.

G.3.7.3 Summary

Overall, the LLW generated annually during the operation of the different types of storage facilities (buildings and vaults) would be small (less than 1%) compared with the expected annual LLW generation at the representative sites. The waste input resulting from the long-term storage of any of the three types of uranium forms would have minimal impact on radioactive waste management capabilities at the representative sites. The impact on nonradioactive waste management would also be minimal. The impacts of waste resulting from the long-term storage of any of the final uranium forms on national waste management capabilities would be negligible.

The impacts of the LLW resulting from long-term storage of any of the final uranium waste forms in a mine would be negligible (less than 1%) compared with national DOE LLW management capabilities.

G.3.8 Resource Requirements

Resource requirements include all materials necessary to construct and operate the storage facilities. The requirements discussed in this section are for the storage of the three chemical forms of depleted uranium only and do not include resources required for conversion to U_3O_8 or UO_2, which would be required for storage as an uranium oxide. Resource requirements for the conversion options are presented in Appendix F, Section F.3.8.

In general, the amount of resources is directly related to the magnitude of construction, with the greatest resources required for the development of an underground mine, and the least required for UF_6 storage in yards. Materials required could include concrete, sand, cement, and steel. In general, none of the construction resources identified are in short supply, and any impacts on the local economies would be small. No strategic and critical materials are projected to be consumed for either construction or operations phases.

TABLE G.24 Annual Waste Loads from Long-Term Storage of UF_6, U_3O_8, and UO_2 in Buildings, Vaults, and Mines

Time Period	Low-Level Waste (m^3/yr)	UO_2F_2 (LLW) (kg/yr)	CaF_2 (Nonhazardous) (kg/yr)	Wastewater (million L/yr)
Storage as UF_6				
Phase I				
Buildings	2.95	140	71	4.2
Vaults	NA[a]	NA	NA	NA
Mine	2.95	140	70	4.25
Phase II				
Buildings	0.2	8.8	4.4	3.4
Vaults	NA	NA	NA	NA
Mine	0.185	9.0	4.45	3.2
Storage as U_3O_8				
Phase I				
Buildings	1.05	NA	NA	4.4
Vaults	1.1	NA	NA	4.3
Mine	1.05	NA	NA	4.75
Phase II				
Buildings	0.05	NA	NA	3.4
Vaults	0.05	NA	NA	3.3
Mine	0.05	NA	NA	3.55
Storage as UO_2				
Phase I				
Buildings	0.75	NA	NA	4.0
Vaults	0.8	NA	NA	3.9
Mine	0.75	NA	NA	4.25
Phase II				
Buildings	0.04	NA	NA	3.1
Vaults	0.04	NA	NA	2.9
Mine	0.037	NA	NA	3.15

[a] NA = not applicable.

Energy resources during construction and operations would include the consumption of diesel fuel and gasoline for construction equipment and transportation vehicles. The anticipated requirements would appear to be small and not impact local or national supplies.

Significant quantities of electrical energy are projected to be required during construction of the mine storage facility because the majority of the construction equipment utilized in the underground portion are powered by electricity to avoid polluting the air in the underground work area. Similarly, a relatively higher annual consumption of electricity is projected during underground operations, compared with the other storage facility options. The required electricity would presumably be purchased from commercial utilities.

During the operations phase, no chemicals are projected to be required. The amount of natural gas would be relatively small and would be expected to be readily available.

Estimated utilities and materials required for constructing storage facilities for UF_6, U_3O_8, and UO_2 are listed in Table G.25 for the storage options. Estimated utilities and materials required for operating the storage facilities for UF_6, U_3O_8, and UO_2 are shown in Table G.26. The resource requirements are presented separately for Phase I operations, which would be concurrent with the construction period, and for Phase II operations.

G.3.9 Land Use

Land area requirements for each uranium chemical form and relevant storage option are presented in Table G.27. These data do not include acreage required for the construction phase for any of the storage options because development of land would be incremental and space required for material excavation storage, equipment staging, and construction material laydown areas would be available on adjacent undeveloped parcels. Consequently, areal needs for construction would not be greater than that for operations.

Although no site has been chosen for the storage of UF_6, UO_2, or U_3O_8, selection of a storage facility site at or near a location that is already dedicated to similar use could result in reduced land use impacts because immediate access to infrastructure and utility support would be possible with only minor disturbances to existing land use.

G.3.9.1 Storage as UF_6

Except for potential impacts from disposal of rock spoil and excavated material in a mine, impacts to land use from the construction and operation of facilities dedicated to storage of depleted uranium in a UF_6 chemical form would be negligible and limited to clearing of required land, potential minor and temporary disruptions to contiguous land parcels, and a slight increase in vehicular traffic.

TABLE G.25 Resource Requirements for Constructing UF_6, U_3O_8, and UO_2 Storage Facilities

		Total Consumption		
Utilities/Material	Unit	Yards/ Vaults[a]	Buildings	Mines
UF_6 Storage Facility				
Utilities				
Electricity	MWyr	0.40	5.4	840
Solids				
Concrete	m^3	59,000	69,000	140,000
Cement	metric tons	12,000	14,000	29,000
Macadam	m^3	3,100	3,100	1,600
Steel	metric tons	1,000	29,000	50,000
Liquids				
Diesel fuel	million L	0.06	10	340
Gasoline	thousand L	53	8.6	11
U_3O_8 Storage Facility				
Utilities				
Electricity	MWyr	6.3	5.4	1,000
Solids				
Concrete	m^3	82,000	110,000	170,000
Cement	metric tons	16,000	22,000	34,000
Macadam	m^3	3,400	12,000	1,700
Steel	metric tons	34,000	37,000	59,000
Liquids				
Diesel fuel	million L	12	150	410
Gasoline	thousand L	11	11	15
UO_2 Storage Facility				
Utilities				
Electricity	MWyr	3.0	2.5	490

Source: LLNL (1997).

A storage building option would require 131 acres (53 ha) of land (see Table G.27). The storage yard option would require 144 acres (58 ha). The storage option utilizing a mine would require 96 acres (39 ha). The mine storage option would result in 1,990,000 yd^3 (1,520,000 m^3) of excavated material from the displacement of 114 underground acres (54 ha). Depending upon the location of the mine, disposal of such a large volume of material could result in land-use impacts ranging from changes in on-site topography to conflicts with existing local land-use plans. The amount of land required for the storage building option could result in potential land disturbance impacts, particularly if the site location featured land that was heavily wooded.

TABLE G.27 Land Requirements for the Long-Term Storage Options

	Land Requirement[a] (acres)				
				Mine	
Option	Yards	Buildings	Vaults	Aboveground	Underground
Storage as UF_6	144	131	N/A[b]	96	114
Storage as U_3O_8	N/A	148	212	124	138
Storage as UO_2	N/A	79	114	74	77

[a] There is no distinction between construction and operations because the storage areas would be cleared incrementally on the basis of need. Consequently, the acreage requirements listed here are the total number of acres required to meet the capabilities of the option.

[b] N/A = not applicable (option does not include this method of storage).

Source: LLNL (1997).

Road and rail access within a storage site, regardless of storage option, would be designed to minimize on-site traffic conflicts. For off-site traffic, potential impacts associated with construction vehicles could be encountered. The maximum labor force required for operation at a long-term storage facility, regardless of the storage option, would not be great enough to generate traffic impacts.

G.3.9.2 Storage as U_3O_8

Storage as U_3O_8 would require the greatest amount of land per option (see Table G.27) and would result in the greatest amount (2,350,000 yd^3 [1,800,000 m^3]) of excavated material and rock spoils. Disposal of the excavation material from a mine could result in minor land-use impacts that range from temporary disruptions of local traffic to minor land modification at the disposal site. Areal requirements for storage as U_3O_8 would range from 120 to 213 acres (48 to 86 ha). Consequently, the potential for land disturbance impacts would be greater than that expected for storage as either UF_6 or UO_2.

Road and rail access within a storage site, regardless of storage option, would be designed to minimize on-site traffic conflicts. For off-site traffic, only temporary minor impacts associated with construction vehicles could be encountered. The maximum labor force required for operation, regardless of the storage option, would not be great enough to generate traffic impacts.

G.3.9.3 Storage as UO_2

Storage as UO_2 would require the least amount of land per option (see Table G.27) and would result in the least amount (1,200,000 yd^3 [900,000 m^3]) of excavated material and rock spoils. Disposal of the excavation material from a mine could result in land-use impacts, but such impacts are expected to be negligible and of a lesser magnitude than would occur under storage as U_3O_8 or UF_6. Less land would have to be cleared for storage facilities (between 25 and 40 acres [10 and 16 ha]). Consequently, the potential for land disturbance impacts would be less than that expected for storage in either UF_6 or U_3O_8. The maximum labor force required for operations would not be great enough to generate off-site traffic impacts.

G.3.10 Other Impacts Considered But Not Analyzed in Detail

Other impacts that could potentially occur if the storage options considered in this PEIS were implemented include impacts to cultural resources and environmental justice, as well as impacts to the visual environment (e.g., aesthetics), recreational resources and noise levels, and impacts associated with decontamination and decommissioning of the storage facilities. These impacts, although considered, were not analyzed in detail for one or more of the following reasons:

- The impacts could not be determined at the programmatic level without consideration of specific sites. These impacts would be more appropriately addressed in the second-tier NEPA documentation when specific sites are considered.

- Consideration of these impacts would not contribute to differentiation among the alternatives and, therefore, would not affect the decisions to be made in the Record of Decision to be issued following publication of this PEIS.

NOTATION (APPENDIX H)

The following is a list of acronyms and abbreviations, including units of measure, used in this document. Some acronyms used only in tables are defined in those tables.

ACRONYMS AND ABBREVIATIONS

General

CFR	*Code of Federal Regulations*
DOE	U.S. Department of Energy
HEPA	high-efficiency particulate air (filter)
HLW	high-level radioactive waste
LCF	latent cancer fatality
LLNL	Lawrence Livermore National Laboratory
LLW	low-level radioactive waste
MEI	maximally exposed individual
NEPA	*National Environmental Policy Act*
NRC	U.S. Nuclear Regulatory Commission
PEIS	programmatic environmental impact statement
PM_{10}	particulate matter with a mean diameter of 10 µm or less

Chemicals

CO	carbon monoxide
HC	hydrocarbons
NO_x	nitrogen oxides
UF_6	uranium hexafluoride
UO_2	uranium dioxide
U_3O_8	triuranium octaoxide (uranyl uranate)

UNITS OF MEASURE

ft	foot (feet)	lb	pound(s)
g	gram(s)	µg	microgram(s)
gal	gallon(s)	µm	micrometer(s)
gpm	gallon(s) per minute	m	meter(s)

APPENDIX H:

ENVIRONMENTAL IMPACTS OF OPTIONS FOR THE MANUFACTURE AND USE OF URANIUM OXIDE AND URANIUM METAL

The U.S. Department of Energy (DOE) is proposing to develop a strategy for long-term management of the depleted uranium hexafluoride (UF_6) inventory currently stored at three DOE sites in Paducah, Kentucky; Portsmouth, Ohio; and Oak Ridge, Tennessee. This programmatic environmental impact statement (PEIS) describes alternative strategies that could be used for the long-term management of this material and analyzes the potential environmental consequences of implementing each strategy for the period 1999 through 2039. This appendix provides detailed information describing the manufacture and use options considered in the PEIS. The discussion provides background information for the manufacture and use of oxide and metal, as well as a summary of the estimated environmental impacts associated with each option.

Manufacture and Use Options

The representative manufacture and use options analyzed in detail in the PEIS consider using depleted uranium as radiation shielding material. Even though uranium is radioactive itself, it can be used effectively to shield gamma radiation from highly radioactive material — such as spent nuclear fuel — because it is very dense. Two representative options are considered:

Uranium Oxide Shielding Option. This option considers the manufacture and use of uranium oxide storage casks for spent nuclear fuel using a uranium concrete material similar to conventional concrete but containing high-density uranium oxide (UO_2) in place of normal aggregate (typically gravel).

Uranium Metal Shielding Option. This option considers the manufacture and use of uranium metal casks for the storage, transport, and disposal of spent nuclear fuel (sometimes called a multi-purpose unit).

Several current and potential uses exist for depleted uranium. Depleted uranium could be mixed with highly enriched uranium from retired nuclear weapons to produce nuclear reactor fuel. This process is called blending, and, to date, only natural uranium has been considered for this application. Depleted uranium is currently used as a counterweight in high-performance aircraft. Such uses can be expected in the future, and there are other potential uses as counterweights on forklifts and as flywheels. Military applications of depleted uranium include use as tank armor, armor piercing projectiles (antitank weapons), and counterweights in missiles.

The two use alternatives evaluated in detail in the PEIS, use as uranium oxide and use as uranium metal as radiation shielding, were selected as representative options for the purposes of comparing the potential environmental impacts of broad alternative management strategies. These options were selected in part because a recent market study suggests that the largest potential market for depleted uranium currently appears to be in shielding applications (Kaplan 1995). However, the

selection of these use options for analysis in the PEIS was not intended to imply that the PEIS will be used to select a specific end use or preclude other potential uses in the future. If a use strategy is selected in the Record of Decision, specific uses would be considered and evaluated in more detail in future planning and environmental analyses, as appropriate.

Shielding is any material that is placed between a source of radiation and people, equipment, or other objects, in order to absorb the radiation and thereby reduce radiation exposure. Common shielding materials include concrete, steel, water, and lead. For shielding gamma radiation sources, the more dense a material is, the more effective it is as a shield. Therefore, even though uranium is radioactive itself, it can be used effectively to shield more highly penetrating radiation because of its density. Uranium is one of the most dense materials known, being 1.6 times more dense than lead.

The PEIS evaluates two options for the manufacture and use of depleted uranium shielding: (1) the uranium oxide option, which is based on the use of dense uranium dioxide (UO_2); and (2) the uranium metal option, based on the use of uranium metal. Both options assume that the depleted uranium would be used as the primary shielding material in containers (called "casks") used to store spent nuclear fuel. Spent nuclear fuel is the highly radioactive "used" fuel produced in nuclear power plants. Although spent nuclear fuel is most commonly shielded by water in large storage pools, there is a growing need for heavily shielded storage casks. A typical storage cask is a cylindrical container about 15 ft (4.5 m) high and 5 ft (1.5 m) in diameter (see Figure H.1). For both options, the cask designs are based on existing designs, and assume that the uranium shielding material would be enclosed between stainless steel (or equivalent) shells (Lawrence Livermore National Laboratory [LLNL] 1997).

The uranium oxide option assumes that depleted uranium in the form of high density UO_2 would be used for the manufacture of depleted uranium concrete for shielding in spent nuclear fuel storage casks. This uranium concrete material, which substitutes dense UO_2 for the coarse aggregate (typically gravel) in conventional concrete, is known as DUCRETE. As a shielding material, DUCRETE offers size and weight advantages compared to conventional concrete. Shielding made of DUCRETE would typically require less than half the thickness of shielding made from concrete to obtain the same effect.

The uranium metal option assumes that depleted uranium in the form of metal would be used for the manufacture of shielding in a spent nuclear fuel cask that could be used not only for storage, but also for transportation and disposal. This type of cask is commonly called a multi-purpose unit. No assumptions were made regarding the fate of the uranium oxide or uranium metal casks after use. The empty casks could be recycled, stored, or disposed of as low-level radioactive waste (LLW).

For assessment purposes, the manufacture of depleted uranium shielded casks was assumed to take place at a stand-alone industrial plant dedicated to the cask fabrication process. In general,

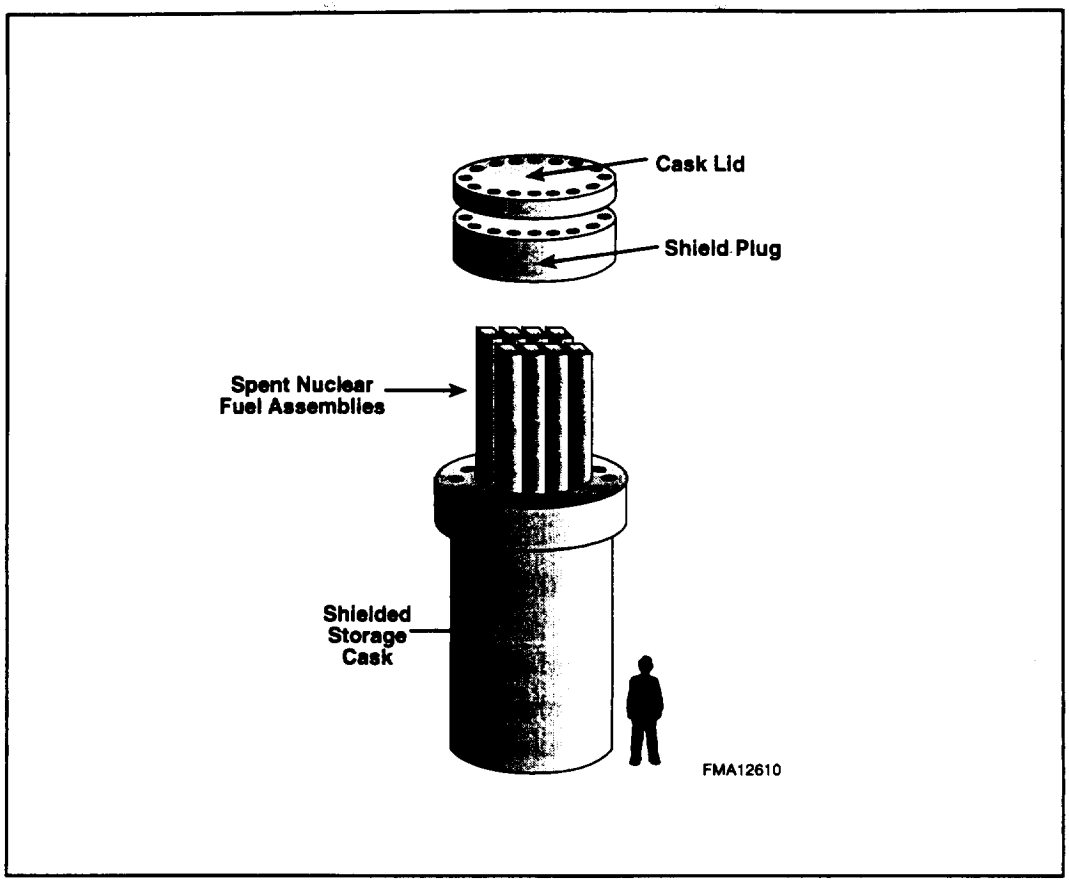

FIGURE H.1 Representative Spent Nuclear Fuel Storage Cask (Shielding is typically provided by concrete, DUCRETE [concrete with depleted UO_2], or uranium metal.)

the plant would be capable of receiving packages of depleted uranium (either UO_2 or metal) on trucks or railcars from a conversion facility, fabricating shielded casks, and storing the casks until shipment by rail to a user, such as a nuclear power plant. At the user facility, the casks would be used to store spent nuclear fuel.

The potential impacts from a manufacturing facility were analyzed for generic dry and wet environmental settings. The conditions at the dry environmental setting would be typical of a site in the western United States, and the conditions at the wet environmental setting would be typical of a site in the eastern United States.

In general, potential environmental impacts would occur (1) during construction of the cask manufacturing facility, (2) during routine operation of the cask manufacturing facility, and (3) as a result of potential manufacturing plant accidents. The potential impacts during construction would be generally limited to the duration of the construction period and would result from typical land-clearing and construction activities. Potential impacts during operations would result from handling the incoming containers of depleted uranium and from small emissions of uranium compounds to

the air and water. Impacts might also occur from potential manufacturing accidents that may result in the release of hazardous materials to the environment. Impacts during the use of depleted uranium shielded casks were not quantified in the PEIS. In general, the potential impacts associated with any structural components of a depleted uranium cask would be negligible compared with the potential impacts associated with the spent nuclear fuel stored within the casks during use. Excluding accidents, no release of depleted uranium material would occur during use.

The potential environmental impacts presented in this chapter were evaluated based on the information described in the engineering analysis report (LLNL 1997). For each manufacture and use option, the engineering analysis report provides preconceptual manufacturing facility design data, including descriptions of facility layouts; shielding cask design details; resource requirements; estimates of effluents, wastes, and emissions; and descriptions of potential accident scenarios.

H.1 SUMMARY OF MANUFACTURE AND USE OPTION IMPACTS

This section provides a summary of the potential environmental impacts associated with two manufacture and use options: (1) a uranium oxide shielding option and (2) a uranium metal shielding option. The assessment of impacts was limited to the potential impacts from construction and operation of cask manufacturing facilities. Additional discussion and details related to the assessment results for individual areas of impact are provided in Section H.3.

Potential environmental impacts from the two manufacture and use options are summarized in Table H.1. Based on the information in Table H.1 and Section H.3, the following conclusions can be drawn:

- For both manufacture and use options, potential human health and safety impacts to workers and the public would be small during construction and normal operations. The consequences of accidents involving release of radioactive or chemical materials would be low. About 1 fatality during construction and operations was estimated from an on-the-job occupational accident.

- For both options, potential impacts other than human health and safety tend to be small and similar between the options.

H.2 DESCRIPTION OF OPTIONS

This section provides a brief summary of the options considered in the assessment of manufacture and use impacts. The information is based on preconceptual design data provided in the engineering analysis report (LLNL 1997). The engineering analysis report contains much more

detailed information, including descriptions of manufacturing facility layouts; shielding cask design details; resource requirements; estimates of effluents, wastes, and emissions; and descriptions of potential accident scenarios. The manufacture and use options assume that depleted uranium in the form of UO_2 or metal would be shipped to the manufacturing plant from a conversion facility. The environmental impacts associated with the conversion process are provided in Appendix F.

H.2.1 Uranium Oxide Shielding Option

The uranium oxide shielding option would require a total site area of about 90 acres (37 ha), of which 32 acres (13 ha) would be disturbed or cleared. The manufacturing facility would receive high-density UO_2 from a conversion plant, and the partially fabricated stainless steel shells and other shielding cask components from a supplier. The steel cask shell would be fabricated using conventional industry practices, including welding, machining and final assembly. At the cask manufacturing facility, uranium oxide shielding would be prepared using high-shear mixing for evenly combining the high-density UO_2 and concrete components. The mixture would then be poured between an inner and outer steel cask shell. Final assembly of the shielding cask would be performed after the mixture cured. The oxide shielding composition would be nominally 74% UO_2, 11% sand, 10% cement and additives, and the remainder water. Each cask would contain about 50 tons (45 metric tons) of UO_2, with about 480 casks being manufactured each year. The casks would then be sent to a user, such as a nuclear power plant.

H.2.2 Uranium Metal Shielding Option

The metal shielding option would require a total site area of about 90 acres (37 ha), of which 36 acres (15 ha) would be disturbed or cleared. The manufacturing facility would receive uranium metal ingots (or alloy) from a conversion plant, and partially fabricated stainless steel or titanium alloy shells and other shielding cask components from a supplier. The inner and outer steel shells of the casks would be assembled using standard operations, such as welding, machining and final assembly. In a separate building, the uranium metal would be melted and directly cast between the inner and outer shells of the assembled cask. After cooling, final assembly of the shielding cask would be carried out. Each finished shielding cask would contain about 47 tons (43 metric tons) of uranium metal, with about 453 casks being manufactured each year.

H.2.3 Manufacture and Use Options Considered But Not Analyzed

Several manufacture and use options were not analyzed in depth in the engineering analysis report: (1) use of depleted uranium in light water reactor fuel, (2) use of depleted uranium as fuel in advanced breeder reactors, and (3) dense material applications other than radiation shielding. As discussed more fully in Section 2.3.2 of the PEIS, these uses are either too uncertain at this time for full analysis or are represented by the options analyzed in the PEIS.

H.3 IMPACTS OF OPTIONS

This section provides a summary of the potential environmental impacts associated with the manufacture and use options, including impacts from construction and facility operations. Information related to the assessment methodologies for each area of impact is provided in Appendix C.

The environmental impacts from the manufacture and use options were evaluated based on the information described in the engineering analysis report (LLNL 1997). The following general assumptions apply to the assessment of impacts:

- Shielding cask manufacturing facilities would operate over a 20-year period, from 2009 through 2028, using either depleted uranium oxide or metal from the DOE-generated inventory. Preoperation of manufacturing facilities would occur between 1999 and 2008, with actual construction requiring 7 years.

- The uranium oxide and uranium metal cask manufacturing plants would produce 480 and 453 casks per year, respectively, over the operational period.

- The cask manufacturing facilities were assumed to be stand-alone facilities built for the specific purpose of fabricating casks. The manufacturing facilities

would receive depleted uranium in the form of UO_2 or metal from a conversion facility.

- Potential impacts from a manufacturing facility were analyzed for generic dry and wet environmental settings and for generic rural and urban settings. The historical meteorological conditions for five actual "dry" locations in the southwestern United States and five actual "wet" locations in the central and southeastern United States were averaged to develop estimates for the generic settings. The generic rural setting was assumed to have a population density corresponding to 15 persons/mi^2 (6 persons/km^2); the generic urban setting was assumed to have a population density corresponding to 700 persons/mi^2 (275 persons/km^2).

- The assessment of impacts was limited to potential impacts from the construction and operation of a cask manufacturing facility. Impacts during the use of depleted uranium shielded casks have not been estimated in the PEIS because the impacts associated with the depleted uranium cask components would be negligible compared with the potential impacts associated with the spent nuclear fuel within a cask and because no release of depleted uranium material would occur during use. Use of spent nuclear fuel storage casks would be subject to DOE or U.S. Nuclear Regulatory Commission (NRC) review and approval.

- The impacts presented herein for manufacturing of oxide- and metal-shielded containers would be representative of any impacts associated with manufacture of other products that contain depleted uranium because none of the other potential uses would consume as much depleted UF_6 inventory as the oxide and metal container use.

- Because of existing regulations in the United States, it is highly unlikely that products containing depleted uranium would be available for unrestricted use at this time. Impacts to the general public from restricted use applications would be negligible. Impacts to the workers from uranium oxide or uranium metal casks at the user locations (e.g., commercial nuclear power generators) would depend largely on the particular application but would be less than those to workers at the manufacturing facilities. Any commercial use of depleted uranium would take place under an NRC license or a waiver from the NRC. Potential impacts from such use would have to be analyzed before a license or waiver could be obtained.

H.3.1 Human Health — Normal Operations

H.3.1.1 Radiological Impacts

Radiological impacts were assessed for involved workers, noninvolved workers, and the general public. Impacts to involved workers would result primarily from exposures to external radiation in the vicinity of uranium material for both options considered. The average radiation dose would be less than 110 mrem/yr. Impacts to noninvolved workers and the general public would result from release of uranium compounds to the environment. The maximum radiation dose would be very small, less than 0.002 mrem/yr. The estimated radiation doses and cancer risks are listed in Tables H.2 and H.3, respectively. Detailed discussions of the methodologies used in radiological impact analyses are provided in Appendix C and Cheng et al. (1997).

TABLE H.2 Radiological Doses from Manufacture and Use Options under Normal Operations

	Dose to Receptor[a]					
	Involved Worker[b]		Noninvolved Worker[c]		General Public	
Shielding Option	Average Dose (mrem/yr)	Collective Dose (person-rem/yr)	MEI Dose[d] (mrem/yr)	Collective Dose (person-rem/yr)	MEI Dose[e] (mrem/yr)	Collective Dose[f] (person-rem/yr)
Uranium oxide casks	110	23	6.1×10^{-5} – 2.8×10^{-4}	1.0×10^{-6} – 1.2×10^{-5}	1.9×10^{-4} – 8.7×10^{-4}	4.9×10^{-5} – 6.1×10^{-3}
Uranium metal casks	23	5.0	1.3×10^{-4} – 6.4×10^{-4}	6.2×10^{-6} – 7.5×10^{-5}	3.8×10^{-4} – 1.9×10^{-3}	3.0×10^{-4} – 3.7×10^{-2}

[a] Impacts are reported as ranges, which result from differences for five generic dry and wet environmental settings.

[b] Involved workers are those workers directly involved with the handling of materials. Results are presented as average individual dose and collective dose for the worker population. Radiation doses to individual workers would be monitored by a dosimetry program and maintained below applicable standards, such as the DOE administrative control limit of 2,000 mrem/yr.

[c] Noninvolved workers are individuals who do not participate in material-handling activities, such as managers and secretaries. The number of noninvolved workers would be about 200 for both uranium oxide casks and uranium metal casks.

[d] The MEI for the noninvolved workers was assumed to be located on-site at the location that would yield the largest dose from airborne emissions, including doses from inhalation, external radiation, and incidental ingestion of soil.

[e] The MEI for the general public was assumed to be located off-site at the point that would yield the largest dose from exposures through inhalation, external radiation, and ingestion of plant foods, meat, milk, soil, and drinking water.

[f] The collective dose was estimated for the off-site population within a 50-mile (80-km) radius around the facility. The range of collective doses results from differences in dry and wet locations surrounded by a rural (about 120,000 people) or urban (about 5,600,000 people) population. The exposure pathways considered were inhalation, external radiation, and ingestion of plant foods, meat, milk and soil.

TABLE H.3 Latent Cancer Risks from Manufacture and Use Options under Normal Operations

	Risk to Receptor[a]					
	Involved Worker[b]		Noninvolved Worker[c]		General Public	
Shielding Option	Average Risk (risk/yr)	Collective Risk (fatalities/yr)	MEI Risk[d] (risk/yr)	Collective Risk (fatalities/yr)	MEI Risk[e] (risk/yr)	Collective Risk[f] (fatalities/yr)
Uranium oxide casks	4×10^{-5}	9×10^{-3}	2×10^{-11} – 1×10^{-10}	4×10^{-10} – 5×10^{-9}	1×10^{-10} – 4×10^{-10}	2×10^{-8} – 3×10^{-6}
Uranium metal casks	9×10^{-6}	2×10^{-3}	5×10^{-11} – 3×10^{-10}	2×10^{-9} – 3×10^{-8}	2×10^{-10} – 1×10^{-9}	2×10^{-7} – 2×10^{-5}

[a] Impacts are reported as ranges, which result from differences for five generic dry and wet environmental settings.

[b] Involved workers are those workers directly involved with the handling of materials. Results are presented as average individual risk and collective risk for the worker population.

[c] Noninvolved workers are individuals who do not participate in material-handling activities, such as managers and secretaries. The number of noninvolved workers is about 200 for both uranium oxide casks and uranium metal casks.

[d] The MEI for the noninvolved workers was assumed to be located on-site at the location that would yield the largest risk from airborne emissions, including risks from inhalation, external radiation, and incidental ingestion of soil.

[e] The MEI for the general public was assumed to be located off-site at the point that would yield the largest risk from exposures through inhalation, external radiation, and ingestion of plant foods, meat, milk, soil, and drinking water.

[f] The collective risk was estimated for the population within a 50-mile (80-km) radius around the facility. The range of collective risks results from differences in dry and wet locations surrounded by a rural (about 120,000 people) or urban (about 5,600,000 people) population. The exposure pathways considered were inhalation, external radiation, and ingestion of plant foods, meat, milk and soil.

H.3.1.1.1 Impacts from Manufacturing

Uranium Oxide. For the uranium oxide option, the collective dose to involved workers was estimated to be approximately 23 person-rem/yr for a total of 220 workers, which corresponds to about 0.009 additional latent cancer fatality (LCF) per year among workers (i.e., 1 LCF would be expected in 110 years of operation). The average involved worker dose was estimated to be about 110 mrem/yr, well below the regulatory limit of 5,000 mrem/yr specified for workers (10 *Code of Federal Regulations* [CFR] Part 835). The average risk to an involved worker of developing an LCF would be about 4×10^{-5} per year (one chance in 25,000 per year).

Radiation doses to noninvolved workers and members of the general public would depend on the location of the facility and would be very small because of the small amount of uranium released. The radiation dose to the maximally exposed individual (MEI) of noninvolved workers would be less than 2.8×10^{-4} mrem/yr, whereas the dose to the MEI of the general public would be less than 8.7×10^{-4} mrem/yr.

Uranium Metal. Because of the smaller volume handled and better self shielding characteristics of uranium metal (the density of uranium metal is about twice that of uranium oxide), the manufacturing of uranium metal casks would result in less radiation exposures to involved workers than the manufacturing of uranium oxide casks. The collective dose to involved workers was estimated to be about 5.0 person-rem/yr for approximately 220 workers. The average dose received by an involved worker would be about 23 mrem/yr, corresponding to an LCF risk of 9×10^{-6} per year (1 chance in 110,000 per year).

Radiation exposures to noninvolved workers and members of the general public from the uranium metal facility would be greater than those from the uranium oxide facility because of the higher emission rate of uranium. However, the radiation doses to the MEIs would be very small, less than 6.4×10^{-4} mrem/yr for noninvolved workers and less than 1.9×10^{-3} mrem/yr for the general public.

H.3.1.1.2 Impacts from Use

The spent nuclear fuel shielding casks made with uranium metal or uranium oxide would have the same shielding capability as conventional casks made with concrete, lead, or other shielding material. Although depleted uranium would be incorporated into the manufactured casks, the resulting exposure to personnel from the depleted uranium would be negligible when compared with the exposures from the spent nuclear fuel stored in the cask.

H.3.1.2 Chemical Impacts

Potential chemical impacts to human health from normal operations would result primarily from uranium releases from the manufacturing facilities. Risks from normal operations were quantified on the basis of calculated hazard indexes. Information on the exposure assumptions, health effects assumptions, reference doses used for uranium compounds, and calculational methods used in the chemical impact analysis is provided in Appendix C and Cheng et al. (1997).

H.3.1.2.1 Impacts from Manufacturing

Airborne emissions of uranium compounds from the metal facility would be more than 5 times greater than uranium emissions from the uranium oxide facility (LLNL 1997). Therefore, chemical exposures for the noninvolved workers and off-site general public would be higher due to releases from the metal facility. However, human health impacts would still be negligible for the noninvolved workers and off-site public for both manufacture and use options.

Uranium Oxide. Estimates of the impacts to human health from hazardous chemicals during operations at the uranium oxide facility are summarized in Table H.4. The overall hazard indices for chemical impacts to the noninvolved worker MEI were estimated to be less than

TABLE H.4 Chemical Impacts to Human Health from Manufacture and Use Options under Normal Operations

	Impacts to Receptor[a]			
	Noninvolved Workers[b]		General Public	
Shielding Option	Hazard Index for MEI[c,d]	Collective Risk[e] (ind. at risk/yr)	Hazard Index for MEI[c,f]	Collective Risk[e] (ind. at risk/yr)
Uranium oxide casks	$7.7 \times 10^{-9} - 3.4 \times 10^{-8}$	–	$6.2 \times 10^{-7} - 2.9 \times 10^{-6}$	–
Uranium metal casks	$1.6 \times 10^{-8} - 7.9 \times 10^{-8}$	–	$1.4 \times 10^{-6} - 6.7 \times 10^{-6}$	–

[a] Impacts are reported as ranges, which result from differences for five generic dry and wet environmental settings.

[b] Noninvolved workers are individuals who do not participate in material-handling activities, such as managers and secretaries.

[c] The hazard index is an indicator for potential health effects other than cancer; a hazard index greater than 1 indicates a potential for adverse health effects and a need for further evaluation.

[d] The MEI for the noninvolved workers was assumed to be located on-site at the location that would yield the largest exposure from airborne emissions, including exposures through inhalation and incidental ingestion of soil.

[e] Calculation of collective risk is not applicable when the corresponding hazard index for the MEI is less than 1.

[f] The MEI for the general public was assumed to be located off-site at the point that would yield the largest exposures through inhalation and ingestion of soil and drinking water.

3.4×10^{-8} for all dry and wet representative locations. Because these values are considerably below the threshold for adverse effects (i.e., the ratio of intake to reference dose is less than 1), no health effects would be expected. The overall hazard indices for chemical impacts to the general public MEI are estimated to be less than 2.9×10^{-6} for all dry and wet representative sites. These values are also considerably below the threshold for adverse effects.

Uranium Metal. Estimates of the hazardous chemical human health impacts resulting from operations at the uranium metal facility are summarized in Table H.4. Hazard indices are approximately 2 times higher for the uranium metal option than for the uranium oxide option but still many orders of magnitude below the threshold for adverse effects.

H.3.1.2.2 Impacts from Use

Only the operations of the two types of manufacturing facilities would result in airborne and waterborne emissions of uranium; the use of shielding casks made with uranium metal or uranium oxide would not be expected to release any materials and, therefore, would not result in any impacts to the noninvolved workers and general public.

H.3.2 Human Health — Accident Conditions

A range of accidents covering the spectrum of high-frequency/low-consequence accidents to low-frequency/high-consequence accidents has been presented in the engineering analysis report (LLNL 1997). These accidents are listed in Table H.5. The following sections present the results for the radiological and chemical health impacts of the highest consequence accident in each frequency category. Results for all accidents listed in Table H.5 are presented in Policastro et al. (1997). A detailed description of the methodology and assumptions used in the calculations is also provided in Appendix C and Policastro et al. (1997).

H.3.2.1 Radiological Impacts

The radiological doses to various receptors for the accidents that give the highest dose from each frequency category are listed in Table H.6. The LCF risks for these accidents are given in Table H.7. The doses and the risks are presented as ranges (maximum and minimum) because two different meteorological conditions (wet and dry) and two different population distributions (rural and urban) were considered for each manufacture and use option. The doses and risks presented here were obtained by assuming that the accidents would occur. The probability of occurrence for each accident is indicated by the frequency category to which it belongs. For example, accidents in the extremely unlikely category have a probability of occurrence between 1 in 10,000 and 1 in 1 million in any 1 year. The following conclusions may be drawn from the radiological health impact results:

- No cancer fatalities would be predicted from any of the accidents.

- The maximum radiological dose to noninvolved worker and general public MEIs (assuming an accident occurred) would be 230 mrem. This dose is less than the 25-rem dose recommended for assessing the adequacy of protection of public health and safety from potential accidents by the NRC (1994).

- The overall radiological risk to noninvolved worker and general public MEI receptors (estimated by multiplying the risk per occurrence [Table H.7] by the annual probability of occurrence by the number of years of operations) would be less than 1 for all of the manufacture and use accidents.

H.3.2.2 Chemical Impacts

The accidents considered in this section are listed in Table H.5. The results of the accident consequence modeling in terms of chemical impacts are presented in Tables H.8 and H.9. The results are expressed as (1) number of persons with potential for adverse effects and (2) number of persons with potential for irreversible adverse effects. The tables present the results for the accident within each frequency category that would affect the largest number of people (total of noninvolved workers and population) (Policastro et al. 1997). The numbers of noninvolved workers and members of the

TABLE H.5 Accidents Considered for the Manufacture and Use Options

Option/Accident Scenario	Accident Description	Chemical Form	Amount (lb)	Duration (min)	Release Level[a]
Manufacture and Use as Oxide Shielding					
Likely Accidents (frequency: 1 or more times in 100 years)					
Mishandling/drop of drum/ billet inside the plant	A single UO_2 drum is damaged by a forklift and spills its contents onto the ground inside the UO_2 cask manufacturing plant.	UO_2	7.3×10^{-7}	Puff	Stack
Mixer/melter charge accident	Mishandling of the input load to the oxide mixer results in an airborne release of the input drum contents.	UO_2	0.000073	Puff	Stack
Mixer/melter operational accident	Failure of the oxide mixer during operation results in an airborne release of the mixer contents.	UO_2	0.00015	Puff	Stack
Mixer/melter discharge accident	Failure during discharge of the oxide mixers results in an airborne release.	UO_2	0.00044	Puff	Stack
Shield failure after casting	After the cask annulus has been filled with depleted uranium, it fails due to rupture or chemical reactivity.	UO_2	9.7×10^{-6}	Puff	Stack
Unlikely Accidents (frequency: 1 in 100 years to 1 in 10,000 years)					
Earthquake	The UO_2 cask manufacturing plant is damaged during a design-basis earthquake, resulting in failure of the structure and confinement systems.	UO_2	0.33	30	Ground
Tornado	A major tornado and associated tornado missiles result in failure of the UO_2 cask manufacturing plant structure and confinement systems.	UO_2	1.6	0.5	Ground
Extremely Unlikely Accidents (frequency: 1 in 10,000 years to 1 in 1 million years)					
Fire/explosion/chemical reagent contact inside the mixers	A leak or rupture of the oxide mixers results in a fire and/or explosion, but the HEPA filtration system is not affected.	UO_2	0.00044	Puff	Stack
Incredible Accidents (frequency: less than 1 in 1 million years)					
Flood	The facility would be located at a site that would preclude severe flooding.	No release	NA	NA	NA

TABLE H.5 (Cont.)

Option/Accident Scenario	Accident Description	Chemical Form	Amount (lb)	Duration (min)	Release Level[a]
Manufacture and Use as Metal Shielding					
Likely Accidents (frequency: 1 or more times in 100 years)					
Mishandling/drop of drum/ billet inside the plant	A pallet of uranium metal billets is damaged by a forklift and spills its contents onto the ground inside the uranium metal cask manufacturing plant.	U_3O_8	0.0012	Puff	Stack
Mixer/melter charge accident	Mishandling of the input load to the uranium furnace results in an airborne release of the input billets.	U_3O_8	0.00009	Puff	Stack
Mixer/melter operational accident	Failure of the uranium furnace during operation results in an airborne release of the furnace contents.	U_3O_8	0.0004	Puff	Stack
Mixer/melter discharge accident	Failure during discharge of the uranium furnace results in an airborne release.	U_3O_8	0.0004	Puff	Stack
Shield failure after casting	After the cask annulus has been filled with molten depleted uranium it fails due to rupture or chemical reactivity.	U_3O_8	0.00059	Puff	Stack
Unlikely Accidents (frequency: 1 in 100 years to 1 in 10,000 years)					
Earthquake	The uranium metal cask manufacturing plant is damaged during a design-basis earthquake, resulting in failure of the structure and confinement systems.	U_3O_8	0.05	30	Ground
Tornado	A major tornado and associated tornado missiles result in failure of the uranium metal cask manufacturing plant structure and confinement systems.	U_3O_8	0.05	0.5	Ground
Extremely Unlikely Accidents (frequency: 1 in 10,000 years to 1 in 1 million years)					
Fire/explosion/chemical reagent contact inside the cask annulus	The molten uranium within a cask annulus is oxidized, resulting in a fire and/or explosion, but the HEPA filtration system is not affected.	U_3O_8	0.0059	Puff	Stack
Incredible Accidents (frequency: less than 1 in 1 million years)					
Flood	The facility would be located at a site that would preclude severe flooding.	No release	NA	NA	NA
Uranium metal furnace failure	A large seismic event or beyond-design-basis event causes failure of eight furnaces feeding one cask.	UO_2	35	Puff	Ground

[a] Ground-level releases were assumed to occur outdoors on concrete pads in the cylinder storage yards. To prevent contaminant migration, cleanup of residuals was assumed to begin immediately after the release was stopped.

Notation: HEPA = high-efficiency particulate air; NA = not applicable; UO_2 = uranium dioxide; U_3O_8 = triuranium octaoxide.

TABLE H.6 Estimated Radiological Doses per Accident Occurrence for the Manufacture and Use Options

Option/Accident[a]	Frequency Category[b]	Maximum Dose[c]				Minimum Dose[c]

Fire/explosion/chemical reagent contact inside the mixers	EU	1.5×10^{-8}	1.2×10^{-7}	1.5×10^{-8}	2.7×10^{-5}	4.4×10^{-12}	3.6×10^{-11}	7.5×10^{-10}	2.7×10^{-7}
Manufacture and Use as Metal Shielding									
Mishandling/drop of drum/billet inside	L	3.9×10^{-8}	3.3×10^{-7}	4.0×10^{-8}	7.0×10^{-5}	1.2×10^{-11}	9.4×10^{-11}	2.0×10^{-9}	7.1×10^{-7}
Earthquake	U	1.1×10^{-2}	4.3×10^{-3}	3.4×10^{-4}	4.6×10^{-2}	4.7×10^{-4}	1.8×10^{-4}	1.3×10^{-5}	1.6×10^{-4}
Fire/explosion/chemical reagent contact inside the cask annulus	EU	1.9×10^{-7}	1.6×10^{-6}	2.0×10^{-7}	3.5×10^{-4}	5.8×10^{-11}	4.7×10^{-10}	9.8×10^{-9}	3.5×10^{-6}
Uranium metal furnace failure	I	2.3×10^{-1}	8.7×10^{-2}	7.0×10^{-3}	1.9	2.3×10^{-1}	8.7×10^{-2}	5.5×10^{-3}	4.2×10^{-2}

[a] The bounding accident chosen to represent each frequency category is the one that would result in the highest dose to the general public MEI. Health impacts in that row represent that accident only and not the range of impacts among accidents in that category. Absence of an accident in a certain frequency category indicates that the accident would not result in a release of radioactive material.

[b] Accident frequencies: likely (L), estimated to occur one or more times in 100 years of facility operations ($>10^{-2}$/yr); unlikely (U), estimated to occur between once in 100 years and once in 10,000 years of facility operations ($10^{-2} - 10^{-4}$/yr); extremely unlikely (EU), estimated to occur between once in 10,000 years and once in 1 million years of facility operations ($10^{-4} - 10^{-6}$/yr); incredible (I), estimated to occur less than one time in 1 million years of facility operations ($<10^{-6}$/yr).

[c] Maximum and minimum doses reflect differences in assumed sites, technologies, and meteorological conditions at the time of the accident. In general, maximum doses would occur under meteorological conditions of F stability with 1 m/s wind speed, whereas minimum doses would occur under D stability with 4 m/s wind speed.

[a] Values shown are the consequences if the accident did occur. The risk of an accident is the consequence (number of persons) times the estimated frequency times 20 years of operations. The estimated frequencies are as follows: likely (L), 0.1; unlikely (U), 0.001; extremely unlikely (EU), 0.00001; incredible (I), 0.000001.

[b] The bounding accident chosen to represent each frequency category is the one in which the largest number of people (workers plus off-site people) would be affected. Health impacts in that row represent that accident only and not the range of impacts among accidents in that category.

[c] Accident frequencies: likely (L), estimated to occur one or more times in 100 years of facility operations ($> 10^{-2}$/yr); unlikely (U), estimated to occur between once in 100 years and once in 10,000 years of facility operations ($10^{-2} - 10^{-4}$/yr); extremely unlikely (EU), estimated to occur between once in 10,000 years and once in 1 million years of facility operations ($10^{-4} - 10^{-6}$/yr); incredible (I), estimated to occur less than one time in 1 million years of facility operations ($< 10^{-6}$/yr).

[d] Maximum and minimum values reflect different meteorological conditions at the time of the accidents. In general, maximum risks would occur under meteorological conditions of F stability and 1 m/s wind speed, whereas minimum risks would occur under D stability and 4 m/s wind speed. Results for the general public MEI are for rural/urban locations, respectively.

[e] At the MEI location, the determination is either "Yes" or "No" for potential irreversible adverse effects to an individual.

[f] These accidents would result in the largest plume sizes, although no people would be affected.

[g] Meteorological conditions for the tornado scenario were considered to be D stability with 20 m/s wind speed. NA = not applicable.

[h] MEI locations were evaluated at 100 m from ground-level releases for workers and at the location of highest off-site concentration for members of the general public; the population risks are 0 because generic worker and general public population distributions were used, which did not show receptors at the MEI locations.

off-site public represent the impacts if the associated accident was assumed to occur. These results of the chemical impact analysis may be summarized as follows:

- If the accidents identified in Tables H.8 and H.9 did occur, the number of persons in the off-site population with potential for adverse effects would range from 0 to 1, and the number of off-site persons with potential for irreversible adverse effects would range from 0 to 1 (maximums corresponding to failure of the uranium metal furnace).

- If the accidents identified in Tables H.8 and H.9 did occur, the number of noninvolved workers with potential for adverse effects would range from 0 to 4, and the number of nonvinvolved workers with potential for irreversible adverse effects would range from 0 to 2 (maximums corresponding to failure of the uranium metal furnace).

- The impacts for the uranium metal shielding option would be slightly higher than those for uranium oxide applications. However, the overall impacts for the manufacture and use options would be very small compared with other options.

- For the most severe accident (uranium metal furnace failure), the noninvolved worker MEI would experience potential adverse effects and potential irreversible adverse effects, whereas the general public MEI would experience no adverse impacts at the rural site. If an urban site were chosen for this activity, a small number of both the noninvolved worker and the public MEIs could be affected in terms of both health criteria. The reduced impacts to the public MEI compared with the worker MEI were based on dispersion of the chemical release with downwind distance. For the other accidents assessed, neither the worker nor the public MEI would experience adverse effects.

- The maximum risk was computed as the product of the consequence (number of people) times the frequency of occurrence (per year) times the number of years of operations (20 years, 2009–2028). The results indicated that the maximum risk values would be less than 1 for all accidents.

To aid in the interpretation of accident analysis results, the number of fatalities potentially associated with the estimated potential irreversible adverse effects was estimated. All the bounding case accidents shown in Table H.9 would involve small releases of uranium oxide and potential exposure to uranium compounds. If the accidents occurred, exposures are estimated to result in death for 1% or less of the persons experiencing irreversible adverse effects (Policastro et al. 1997). Thus, for workers and members of the general public experiencing ranges of 0 to 2 and 0 to 1 irreversible adverse effects, respectively, 0 deaths would be expected.

H.3.2.3 Physical Hazards

The risk of on-the-job fatalities and injuries to all manufacturing facility workers from the fabrication of uranium oxide and uranium metal shielding was calculated using industry-specific statistics from the U.S. Bureau of Labor Statistics, as reported by the National Safety Council (1995). Construction and manufacturing annual fatality and injury rates were used for the construction and operational phases, respectively, of the manufacturing facility lifetime.

Because manufacturing activities would be quite labor-intensive, relatively high injury incidence rates are predicted, with about one fatality expected over the lifetime of facility operations. There is little difference in impacts between the uranium oxide and metal shielding options, although the fatality and incidence rates for the metal option would be slightly higher.

The estimated number of worker fatalities for the uranium oxide shielding option is 0.76 for the construction and operational phases combined (Table H.10). The estimated number of injuries over the lifetime of the uranium oxide facility is about 640.

The estimated number of worker fatalities for the uranium metal shielding option is 0.85 for the construction and operational phases combined (Table H.10). The estimated number of injuries over the lifetime of the metal facility is about 670.

TABLE H.10 Potential Impacts to Human Health from Physical Hazards under Accident Conditions for the Manufacture and Use Options

	Impacts to All Manufacturing Facility Workers[a]			
	Incidence of Fatalities[b]		Incidence of Injuries[b]	
Shielding Option	Construction	Operations	Construction	Operations
Uranium oxide casks	0.38	0.38	140	500
Uranium metal casks	0.48	0.37	180	490

[a] All construction and operational workers at the manufacturing facilities were included in physical hazard risk calculations.

[b] The incidence of fatalities and incidence of injuries were calculated as the number of full-time-equivalent employees times the annual fatality rate times the number of years. Only injuries involving lost workdays were estimated. Injury and fatality incidence rates used in the calculations were taken from National Safety Council (1995).

H.3.3 Air Quality

The methodology used to analyze the air quality impacts from both uranium oxide and uranium metal manufacturing and use options is provided in Appendix C and Tschanz (1997). The pollutant concentrations at several distances from the center of the facility were estimated because of uncertainty regarding the size and location of the generic manufacturing facility. Estimates at 750 m from the center of the manufacturing facilities are comparable to estimates for options based on representative environmental settings (i.e., conversion and long-term storage options using the three current storage sites as representative of those settings).

For both options, by far the largest emissions, and hence impacts on air quality, would occur during construction of the manufacturing facility. Table H.11 presents a comparison of some of the pollutant impacts from construction of the two types of manufacturing facilities at a generic wet environmental setting. The estimated pollutant concentrations — carbon monoxide (CO), nitrogen oxides (NO_x), and PM_{10} (particulate matter with a mean diameter of 10 μm or less) — are all 9% or less of the applicable air quality standards, even at the closest distance from the emissions point. The ranges of impacts for the generic wet setting (as represented by the results in Table H.11) are greater than those estimated for a generic dry setting, and the uncertainties of the wet setting impacts are also greater.

The area source emissions during operation of the manufacturing facility for either option would be smaller than during construction. For both types of facility, operations would emit about 4% as much CO and NO_x and about 1.4% as much PM_{10} as would be emitted during construction. The impacts from these low emissions would be negligible.

The quantities of uranium oxide emitted during operation of either manufacturing facility are estimated to be quite small. The uranium oxide facility would emit only 8 g/yr of uranium as UO_2, which corresponds to an annual average concentration of about 1.6×10^{-7} μg/m^3 at a distance of 3,300 ft (1,000 m). The approximately 50 g/yr of uranium in triuranium octaoxide (U_3O_8) emitted by the uranium metal facility would produce an annual average uranium concentration of 9.9×10^{-7} μg/m^3 at 3,300 ft (1,000 m). Impacts on air quality would be negligible for both options.

No quantitative estimate was made of the impacts of operations on ozone conditions in the atmosphere. Ozone formation is a regional issue that would be affected by emissions for the entire area around a proposed manufacturing site. The pollutants most relevant to ozone formation that would result from the manufacturing options are hydrocarbons (HC) and NO_x. In later Phase II studies, when specific technologies and sites would be selected, the potential effects of these pollutants released from a proposed facility at a specific site could be evaluated relative to the total emissions of HC and NO_x in the surrounding area. Small additional contributions to the total regional emissions would be unlikely to alter the ozone attainment status of the region.

[a] Results for a generic wet setting bound the results for a generic dry setting.

[b] A hyphen (–) indicates that no standard is available for that averaging period.

[c] Ratio of the upper end of the concentration range divided by the respective air quality standard. A ratio of less than 1 indicates that the standard would not be exceeded.

H.3.4 Water and Soil

The methodology used to determine water and soil impacts is presented in Appendix C and Tomasko (1997).

The environmental resource needs for the manufacturing options are summarized in Table H.12. The resource requirements (in particular, the paved area, volume of excavated material, and water usage) would be greater for the uranium metal option than for the uranium oxide option. Because the manufacture and use option is based on a generic site without a specified location and description, impacts could not be assessed on a site-specific basis; however, the impacts to surface

TABLE H.12 Summary of Environmental Parameters for the Manufacture and Use Options

		Requirements	
Shielding Option	Unit	Construction	Operations[a]
Uranium oxide			
Land area	acres	90	–
Disturbed land	acres	54	–
Building area	acres	14	–
Paved area	acres	15	–

Hauled material	yd^3	88,000	–
Annual water	million gal/yr	43	7.4
Wastewater	million gal/yr	8.5	5.0

[a] A hyphen (–) indicates no environmental resource needs.

water, groundwater, and soil would be smaller for the uranium oxide option because of its smaller resource requirements.

If the manufacture and use facility were located on a site having an area that was large compared with the size of the facility, and if the facility was near a river having a minimum flow that was large compared with annual water use and wastewater discharge, impacts to surface water, groundwater, and soil would be negligible. Negligible impacts would occur because a large site and large river could provide sufficient resource buffering to mitigate the effects produced by construction and operation of the facility.

On the other hand, if the site or the minimum flow in the river were small relative to the resource requirements, impacts would be larger. For example, if the minimum flow in the river was 500 gpm, the net annual water withdrawal would be about 15% of the flow. The impact of this relative withdrawal could produce moderate to large impacts to existing floodplains.

Similarly, if the facility was located in an urban area, paving 18 acres (7 ha) and constructing buildings on another 15 acres (6 ha) could seriously impact the local carrying capacity of storm-water runoff and produce local flooding. In addition, the paving and construction of the facility on a 90-acre (36-ha) site would produce moderate to large impacts to local soil permeability and erosion potential.

No process water effluents would be anticipated from the manufacturing facility (LLNL 1997), so no impacts to surface water quality would be expected. There are no accidents identified in the engineering analysis report (LLNL 1997) that would directly impact surface water. Secondary impacts resulting from deposition of airborne contaminants would not be measurable because of the low concentrations of deposited material.

H.3.5 Socioeconomics

Because the location of a shielding manufacturing facility has not yet been determined, the socioeconomic impacts of the shielding manufacturing options were analyzed on a non-site-specific basis for a generic site. The potential impacts of each facility on direct employment and direct income in the peak year of construction and in first year of operations are shown in Table H.13. Discussion of the assessment methodology is presented in Appendix C and Allison and Folga (1997).

Construction of a UO_2 shielding manufacturing facility would create 160 direct jobs and $7 million in direct income during the peak year of construction. Operation of the facility would create 470 direct jobs and produce $33 million in direct income in each year of facility operations.

TABLE H.13 Potential Socioeconomic Impacts from Construction and Operation of the Shielding Manufacturing Facilities

Option/Parameter	Construction[a]	Operations[b]
Manufacture from UO_2		
Direct employment	160	470
Direct income ($ million 1996)	7	33
Manufacture from metal		
Direct employment	190	470
Direct income ($ million 1996)	9	33

[a] Impacts during the peak year of construction, 2007. Preoperations were assumed to occur from 1999 through 2008, with actual construction requiring 7 years.

[b] Impacts are the annual averages for operations for the period 2009 through 2028.

Construction of a metal shielding manufacturing facility would create 190 direct jobs and $9 million in direct income during the peak year of construction. Operation of the facility would create 470 direct jobs and produce $33 million in direct income in each year of facility operations.

H.3.6 Ecology

Moderate adverse impacts to ecological resources could result from construction of a shielding manufacturing facility. Impacts could include mortality of individual organisms, habitat loss, or changes in biotic communities. Impacts due to facility operation would be negligible. Discussion of the methodology used to assess ecological impacts is presented in Appendix C.

H.3.6.1 Uranium Oxide

Site preparation for the construction of a uranium oxide shielding manufacturing facility would require the disturbance of approximately 54 acres (22 ha), including the permanent replacement of approximately 32 acres (13 ha) with structures, paved areas, and a storm-water pond. Existing vegetation would be destroyed during land-clearing activities. The facility would be included within a 90-acre (36-ha) area consisting of buildings, roads, and landscaped areas, which would be maintained as a controlled access area. The specific vegetation communities that would be eliminated by site preparation would depend on the location selected for the facility. The loss of

54 acres (22 ha) of undeveloped land and limited vegetation community development on the remainder of the 90-acre site would constitute a moderate adverse impact to vegetation. Erosion of exposed soil at construction sites could reduce the effectiveness of restoration efforts and create sedimentation downgradient of the site. The implementation of standard erosion control measures, installation of storm-water retention ponds, and immediate replanting of disturbed areas with native species would help minimize impacts to vegetation. Impacts from facility construction are summarized in Table H.14.

Wildlife would be disturbed by land clearing, noise, and human presence. Wildlife with restricted mobility, such as burrowing species or juveniles of nesting species, would be destroyed during land clearing activities. Mobile individuals would relocate to adjacent available areas with suitable habitat. Population densities, and thus competition for food and nesting sites, would increase in these areas, potentially reducing the survivability or reproductive capacity of displaced individuals. Some wildlife species would be expected to recolonize replanted areas near the manufacturing facility following completion of construction. The permanent loss of 32 to 90 acres (13 to 36 ha) of habitat due to the construction of a facility for manufacture of uranium oxide shielding would be considered a moderate adverse impact to wildlife.

Wetlands could potentially be eliminated or otherwise impacted during construction. Impacts to wetlands and aquatic habitats due to alteration of surface water runoff patterns, soil compaction, or groundwater flow could occur. Unavoidable impacts to wetlands would require a

TABLE H.14 Impacts to Ecological Resources from Construction of the Manufacturing Facility

Option/Resource	Type of Impact	Degree of Impact
Uranium oxide		
Vegetation	Loss of 54 acres	Moderate adverse impact
Wildlife	Loss of 32 to 90 acres	Moderate adverse impact
Wetlands	Potential loss, degradation	Potential adverse impact
Aquatic species	Water quality, habitat reduction	Potential adverse impact
Protected species	Potential destruction, habitat loss	Potential adverse impact
Uranium metal		
Vegetation	Loss of 54 acres	Moderate adverse impact
Wildlife	Loss of 36 to 90 acres	Moderate adverse impact
Wetlands	Potential loss, degradation	Potential adverse impact
Aquatic species	Water quality, habitat reduction	Potential adverse impact
Protected species	Potential destruction, habitat loss	Potential adverse impact

Clean Water Act Section 404 permit, which might stipulate mitigative measures. Additional permitting might be required by state agencies.

Prior to construction of a manufacturing facility, a survey for state and federally listed threatened, endangered, or candidate species, or species of special concern would be conducted. Impacts to these species could thus be avoided, or, where impacts were unavoidable, mitigation could be developed.

Ecological resources in the vicinity of the manufacturing facility would be exposed to atmospheric emissions from the boiler stack and process stack; however, emission levels would be expected to be extremely low (Section H.3.3). The maximum annual air concentration of UO_2 would be approximately 1.6×10^{-7} $\mu g/m^3$. Consequent impacts to biota would be expected to be negligible.

The manufacturing process would require withdrawal of water from surface waters or groundwater, as well as discharge of wastewater. Depending on the facility location, such withdrawal and discharge could potentially alter water levels (Section H.3.4). The altered water levels could, in turn, impact aquatic ecosystems, including wetlands, especially those located along the periphery of the affected surface water bodies.

Facility accidents, as discussed in Section H.3.2, could result in adverse impacts to ecological resources. The affected species and degree of impact would depend on a number of factors, such as location of the accident, season, and meteorological conditions.

H.3.6.2 Uranium Metal

The construction of a facility for the manufacture of depleted uranium metal shielding would generally result in the types of impacts associated with the manufacture of uranium oxide shielding. However, site preparation for the construction of a metal shielding manufacturing facility would require the disturbance of approximately 54 acres (22 ha), including the permanent replacement of approximately 36 acres (15 ha) of current land cover with structures, paved areas, and a storm-water pond. The facility would be included within a 90-acre (36-ha) area consisting of buildings, roads, and landscaped areas, which would be maintained as a controlled access area. The loss of 54 acres (22 ha) of undeveloped land and limited vegetation community development on the remainder of the 90-acre (36-ha) site would constitute a moderate adverse impact to vegetation.

The permanent loss of 36 to 90 acres (15 to 36 ha) of habitat would be considered a moderate adverse impact to wildlife. Impacts to ecological resources from operation of the uranium metal manufacturing facility would be similar to those due to operation of the uranium oxide facility.

H.3.7 Waste Management

For both options, the construction and operation of a depleted uranium shielding manufacture facility would generate LLW, hazardous waste, and nonhazardous waste. The LLW would consist of surface contaminated metals; noncombustible, noncompactible solids; dry active wastes; spent high-efficiency particulate air (HEPA) filters; and incinerator ash. Hazardous wastes generated would include paints, thinners, solvents, phenol, mercury (lamps), sulfuric acid, naphtha, lead (batteries), and pesticides.

Because the uranium oxide or uranium metal facility was assumed to be constructed at a generic, uncontaminated site, no radioactive waste would be generated during construction. About 94 and 105 yd^3 (72 and 80 m^3) of hazardous waste would be generated during construction for the uranium oxide and metal shielding facilities, respectively. These wastes would be sent to existing commercial treatment and disposal facilities. Nonhazardous waste generated during construction would be expected to total about 78,000 and 92,000 yd^3 (60,000 and 70,000 m^3), respectively, for the two options.

All radioactive wastes generated during operation of the uranium oxide or uranium metal facility would be routed to the facility waste management station. This part of the facility would include a grouting station and an incinerator. Failed mixers from a uranium oxide facility would be sent directly to disposal; all other facility wastes would be grouted. Spent HEPA filters would be drummed for disposal, and dry active waste would be incinerated, with the resulting ash grouted for disposal. Table H.15 lists expected LLW generation. The annual generation of 165 and 850 yd^3 (126 and 650 m^3) of LLW requiring disposal represents about 600 and 3,200 drums, respectively, per year and would represent about 0.2 and 1% of the projected annual LLW treatment volume for all DOE facilities nationwide (see Appendix C, Section C.10). All of the radioactive waste would be categorized as Class A by the NRC and would be suitable for near-surface disposal. Unlike the uranium oxide option, solidified ash waste from the uranium metal facility might require disposal in a special cell or mine. Hazardous wastes generated during operations are expected to be about 4 times the volume generated during construction. About 275 to 330 tons (250 to 300 metric tons) of nonhazardous waste would be generated annually and would be sent to commercial landfills.

No assumptions were made regarding the fate of the oxide- and metal-shielded casks after use. The empty casks could be recycled, stored, or disposed of as LLW.

TABLE H.15 Summary of Waste Volumes from the Manufacture of Depleted Uranium Shielding

Waste Type	Unit	Waste Volume	
		Uranium Oxide	Uranium Metal
Construction[a]			
Hazardous	m^3	71.6	79.5
Nonhazardous	m^3	60,000	70,000
Operations[b]			
Low-level waste	m^3/yr	126	650
Hazardous	m^3/yr	286	318
Nonhazardous	metric tons/yr	250	300

[a] Total volumes generated during the entire 7-year construction period.

[b] Annual volumes generated over normal operating lifetime of 20 years.

H.3.8 Resource Requirements

Resource requirements for the two manufacture and use options are presented in this section. These resource requirements are for the manufacturing of depleted uranium shielding only and do not include resources required for conversion to uranium oxide or uranium metal. Resource requirements for conversion are presented in Appendix F, Section F.3.8.

Estimated utilities and materials required for constructing a shielding manufacturing facility are listed in Table H.16 for the uranium oxide and uranium metal options (LLNL 1997). These required materials and chemicals are readily available and are not considered rare or unique. The total quantities of commonly used construction materials is not expected to be significant. No strategic and critical materials (e.g., Monel or Inconel) are projected to be consumed during construction. Energy resources used during construction would include diesel fuel and gasoline for construction equipment and transportation vehicles. The required electricity would presumably be purchased from commercial utilities.

Energy resources required for operating the two types of shielding manufacturing facilities are shown in Table H.17. No strategic and critical materials (e.g., Monel or Inconel) are projected to be consumed for either construction or operations phases. Energy resources during operations would include the consumption of diesel fuel for operations equipment (including backup electrical generators) and natural gas for space heating. Small amounts of diesel fuel and natural gas are

TABLE H.16 Resource Requirements for Construction of Shielding Manufacturing Facilities

		Requirements	
Utility/Resource	Unit	Uranium Oxide	Uranium Metal
Utilities			
Electricity	MW-yr	4.7	4.9

Diesel fuel	gal	2,000	2,000
Natural gas	million scf	20	32

Source: LLNL (1997).

projected to be used. The required electricity would presumably be purchased from commercial utilities.

H.3.9 Land Use

The assessment of potential land-use impacts for the manufacturing and use options was based on a determination of areal requirements for each option and the potential for incompatibility. The uranium oxide and uranium metal options would result in similar moderate land-use impacts. Both facilities would have a total site requirement of 90 acres (36 ha), of which 54 acres (22 ha) would be disturbed or cleared (LLNL 1997). Although the uranium oxide facility would produce a slightly smaller volume of excavated material than the uranium metal facility, topographical modifications of on-site land could result under both options.

No site has been chosen for a uranium oxide or uranium metal facility, but selection of a site at or near a location that is already dedicated to or zoned for similar use could result in reduced land-use impacts because immediate access to infrastructure and utility support would be possible with only minor disturbances to existing land. Traffic patterns could experience potentially moderate level-of-service impacts from the peak year construction labor force. Any such traffic impacts, however, would be greatly reduced once post-construction operations begin.

H.3.10 Other Impacts Considered But Not Analyzed in Detail

Other impacts that could potentially occur if the manufacture and use options considered in this PEIS were implemented include impacts to cultural resources and environmental justice, as well as the visual environment (e.g., aesthetics), recreational resources, and noise levels, and impacts associated with decontamination and decommissioning of the manufacturing facilities. These impacts, although considered, were not analyzed in detail for one or more of the following reasons:

- The impacts could not be determined at the programmatic level without consideration of specific sites. These impacts would be more appropriately addressed in the second-tier *National Environmental Policy Act* (NEPA) documentation when specific sites are considered;

- Consideration of these impacts would not contribute to differentiation among the alternatives and, therefore, would not affect the decisions to be made in the Record of Decision to be issued following publication of this PEIS.

NOTATION (APPENDIX I)

The following is a list of acronyms and abbreviations, including units of measure, used in this document. Some acronyms used only in tables are defined in those tables.

ACRONYMS AND ABBREVIATIONS

General

BEMR	*The 1996 Baseline Environmental Management Report*
CFR	*Code of Federal Regulations*
DOE	U.S. Department of Energy
EPA	U.S. Environmental Protection Agency
HEPA	high-efficiency particulate air (filter)
LCF	latent cancer fatality
LLMW	low-level mixed waste
LLNL	Lawrence Livermore National Laboratory
LLW	low-level radioactive waste
MCL	maximum contaminant level
MEI	maximally exposed individual
NEPA	*National Environmental Policy Act*
NRC	U.S. Nuclear Regulatory Commission
PEIS	programmatic environmental impact statement
PM_{10}	particulate matter with a mean diameter of 10 μm or less
Rf	retardation factor
WM PEIS	*Waste Management Programmatic Environmental Impact Statement for Managing Treatment, Storage, and Disposal of Radioactive and Hazardous Waste*

Chemicals

CO	carbon monoxide
HC	hydrocarbons
NO_x	nitrogen oxides
SO_x	sulfur oxides
UF_6	uranium hexafluoride
UO_2	uranium dioxide
$UO_3 \cdot H_2O$	schoepite (hydrous uranium oxide)
U_3O_8	triuranium octaoxide (uranyl uranate)

1058

UNITS OF MEASURE

cm	centimeter(s)
d	day(s)
ft	foot (feet)
ft^3	cubic foot (feet)
g	gram(s)
gal	gallon(s)
gpm	gallon(s) per minute
ha	hectare(s)
in.	inch(es)
kg	kilogram(s)
km	kilometer(s)
km^2	square kilometer(s)
L	liter(s)
lb	pound(s)
µg	microgram(s)
µm	micrometer(s)
m	meter(s)
m^3	cubic meter(s)
mi^2	square mile(s)
min	minute(s)
mrem	millirem(s)
MWh	megawatt-hour(s)
pCi	picocurie(s)
ppm	part(s) per million
rad	radiation absorbed dose(s)
rem	roentgen equivalent man
s	second(s)
scf	standard cubic foot (feet)
ton(s)	short ton(s)
yd^3	cubic yard(s)
yr	year(s)

APPENDIX I:

ENVIRONMENTAL IMPACTS OF OPTIONS FOR DISPOSAL OF OXIDE

The U.S. Department of Energy (DOE) is proposing to develop a strategy for long-term management of the depleted uranium hexafluoride (UF_6) inventory currently stored at three DOE sites in Paducah, Kentucky; Portsmouth, Ohio; and Oak Ridge, Tennessee. This programmatic environmental impact statement (PEIS) describes alternative strategies that could be used for the long-term management of this material and analyzes the potential environmental consequences of implementing each strategy for the period 1999 through 2039. This appendix provides detailed information describing the disposal options considered in the PEIS. The discussion provides background information for these options, as well as a summary of the estimated environmental impacts associated with each option.

Disposal Options

Depleted uranium material would be disposed of as low-level radioactive waste. The disposal options assessed in the PEIS were defined on the basis of the chemical form of the uranium and the type of disposal facility. The following disposal options were considered:

Disposal as U_3O_8. Depleted uranium could be disposed of as U_3O_8, either ungrouted (bulk) or grouted U_3O_8, following conversion. The disposal facilities considered included shallow earthen structures, belowground vaults, and an underground mine.

Disposal as UO_2. Similar to U_3O_8, depleted uranium could be disposed of as UO_2 following conversion, either in ungrouted or grouted form. The disposal facilities considered were the same as those considered for U_3O_8: shallow earthen structures, belowground vaults, and an underground mine.

Disposal is defined as the emplacement of material in a manner designed to ensure its isolation for the foreseeable future. For the PEIS disposal options, depleted uranium was assumed to be disposed of belowground as low-level radioactive waste beginning in 2009. Compared with long-term storage, disposal is considered permanent, with no intent to retrieve the material for future use. In fact, considerable and deliberate effort would be required to regain access to the material following disposal. Low-level radioactive waste disposal in burial facilities has been practiced in the United States for over 50 years.

The disposal options considered in the PEIS are defined by the chemical form of the depleted uranium to be disposed of and by the type of disposal facility. Two chemical forms of uranium oxides were evaluated: triuranium octaoxide (U_3O_8) and uranium dioxide (UO_2). These forms were considered because of their chemical stability; UF_6 and uranium metal are not considered acceptable forms because they are chemically reactive (Lawrence Livermore National Laboratory [LLNL] 1997). Three types of disposal facilities were considered for each chemical form: (1) shallow earthen structures (engineered "trenches"), (2) vaults, and (3) an underground mine. The chemical

forms and disposal options are summarized in Table I.1. Each type of disposal facility is described in Section I.2.

For each of the uranium oxides, two physical waste forms were considered in the PEIS, ungrouted and grouted. Ungrouted waste refers to U_3O_8 or UO_2 in the powder or pellet form produced during the conversion process. This bulk material would be disposed of in either 55-gal (208-L) drums for U_3O_8 or 30-gal (110-L) drums for UO_2. Grouted waste refers to the solid material obtained by mixing the uranium oxides with cement and repackaging it in drums. Grouting is intended to increase structural strength and stability of the waste, and reduce the leaching rate of the waste in water. However, because cement is added to the uranium oxide, grouting would increase the total volume requiring disposal. Grouting of waste was assumed to occur at the disposal facility.

In general, disposal facilities would be stand-alone, single-purpose facilities consisting of a central receiving building/warehouse (called the wasteform facility) and several disposal units. Depending on the option, the disposal units would be a series of shallow earthen structures, vaults, or underground mine tunnels (called drifts). Activities at the disposal facility would include receipt of containers of depleted uranium oxide by truck or railcar, inspection of the containers, grouting the material if necessary, and placement of the containers into the disposal units. The disposal unit would then be backfilled with soil, sand, gravel, or other material and covered with multiple layers of natural material (such as clay) designed to minimize infiltration of water for long periods of time. The disposal facilities would be designed to protect the waste from the environment and prevent potential releases of material to the environment. Following disposal of the last containers, the disposal facility would be closed and then monitored and maintained for a period of time consistent with regulatory and license requirements.

The potential environmental impacts from the disposal options were evaluated on the basis of information provided in the engineering analysis report (LLNL 1997). For each disposal option, the engineering analysis report provides preconceptual facility design data, including descriptions of facility layouts, resource requirements, estimates of effluents, wastes, and emissions, and

TABLE I.1 Summary of Depleted Uranium Chemical Forms and Disposal Options Considered

	Disposal Option Considered		
Physical/ Chemical Form	Shallow Earthen Structure	Vault	Mine
Grouted U_3O_8	Yes	Yes	Yes
Ungrouted U_3O_8	Yes	Yes	Yes
Grouted UO_2	Yes	Yes	Yes
Ungrouted UO_2	Yes	Yes	Yes

descriptions of potential accident scenarios. This report also contains additional discussion of issues related to low-level radioactive waste (LLW) disposal and discusses the results of previous assessments of the long-term impacts of uranium disposal.

The potential environmental impacts from disposal would differ from those for the other options considered in the PEIS. Whereas the impacts from the other options would generally occur during the operational period of the facilities considered (40 years or less), the impacts from disposal might occur hundreds to thousands of years after the facility had ceased operating. Thus, disposal impacts were estimated for two phases: (1) the operational phase, which includes construction of the facility and the period in which waste would be actively placed into disposal units, and (2) the post-closure phase, which considers hundreds of years in the future, beyond the time that any engineered disposal facilities would be expected to function as designed. The environmental impacts for the operational phase are presented in Section I.3, and those for the post-closure phase are presented in Section I.4.

Potential impacts during the operational phase, which would include construction activities and the handling of waste containers as they were placed into disposal units, would primarily affect workers. In addition, some potential impacts to the public would occur from air emissions during grouting of the waste. The potential impacts during the post-closure phase would affect only the public and would follow the eventual release of material from the disposal facility to the environment. For assessment purposes, all disposal facilities were assumed to fail, or release waste to the environment, at the end of an institutional control period (failure was assumed to occur around the year 2140, 100 years after site closure). Because of the infiltration of water, uranium would ultimately migrate through the soil, eventually contaminating the groundwater and potentially exposing members of the public. Post-closure impacts were estimated at 1,000 years after the disposal facilities were assumed to fail.

The potential environmental impacts from the disposal options were not determined on a site-specific basis because the location of a disposal facility would not be decided until sometime in the future. Instead, for assessment purposes, two generic environmental settings were defined, a generic dry setting and a generic wet setting. The conditions of the dry setting would be typical of a site in the arid western United States, and the conditions of the wet setting would be typical of a site in the eastern United States.

The estimated impacts associated with the disposal options are subject to a great deal of uncertainty, especially for the post-closure period. The degree of uncertainty in the disposal impacts is greater than that for the other categories of options in the PEIS, because disposal impacts consider an extremely long period of time and depend on predicting the behavior of the waste material as it interacts with soil and water in a complex and changing environment. Consequently, the estimated disposal impacts are very dependent on the assumptions made for the assessment, including such key factors as soil characteristics, water infiltration rates, depth to underlying groundwater table, chemistry of different uranium compounds, and locations of future human receptors. These factors

could vary widely depending on site-specific conditions. Therefore, a range of these factors was selected for analysis to represent the range of actual conditions that could occur.

I.1 SUMMARY OF DISPOSAL OPTION IMPACTS

This section provides a summary of the potential environmental impacts associated with the disposal of depleted uranium oxides in shallow earthen structures, vaults, and a mine during two distinct phases: (1) the operational phase and (2) the post-closure phase. Analysis of the operational phase included facility construction and the time during which waste would be actively placed in disposal units (2009 through 2028). Analysis of the post-closure phase considered potential impacts 1,000 years after the disposal units fail (i.e., release uranium material to the environment). For each phase, impacts were estimated for both generic wet and dry environmental settings. Additional discussion and details related to the assessment methodologies and results for each area of impact are provided in Section I.3 for the operational phase and Section I.4 for the post-closure phase.

For the operational phase, the potential environmental impacts for disposal of U_3O_8 and UO_2 are summarized in Tables I.2 and I.3, respectively. Within each table, the potential impacts are presented first for the grouted form and then for the ungrouted form. The following is a general summary of potential environmental impacts during the operational phase:

- ***Potential Adverse Impacts.*** Potential adverse impacts during the operational phase would be small and generally similar for all options. Minor to moderate impacts would occur during construction activities, although these impacts would be temporary and easily mitigated by common engineering and construction practices. Impacts during waste emplacement activities also would be small and limited to involved and noninvolved workers.

- ***Wet or Dry Environmental Setting.*** In general, potential impacts would be similar for generic wet and dry environmental settings during the operational phase.

- ***U_3O_8 or UO_2.*** The potential disposal impacts tend to be slightly larger for U_3O_8 than for UO_2 because the volume of U_3O_8 would be greater and most environmental impacts tend to be proportional to the volume.

- ***Grouted or Ungrouted Waste.*** For both U_3O_8 and UO_2, the disposal of grouted waste would result in larger impacts than disposal of ungrouted waste during the operational phase for two reasons: (1) grouting increases the volume of waste requiring disposal (by about 50%) and (2) grouting operations result in small emissions of uranium material to the air and water.

Construction and Operations: **All Workers:** Less than 1 (0.13) fatality, approximately 90 injuries	**Construction and Operations:** **All Workers:** Less than 1 (0.22) fatality, approximately 140 injuries	**Construction and Operations:** **All Workers:** Less than 1 (0.53) fatality, approximately 240 injuries
Air Quality		
Construction: Annual NO_x concentration potentially as large as 1.3% of standard; all other criteria pollutant concentrations between 0.07 and 0.6% of respective standards	**Construction:** Annual NO_x concentration potentially as large as 3.5% of standard; all other criteria pollutant concentrations between 0.1 and 1% of respective standards	**Construction:** All pollutant concentrations below 0.1% of respective standards
Operations: Annual NO_x concentration potentially as large as 2.3% of standard; all other criteria pollutant concentrations between 0.1 and 1% of respective standards	**Operations:** Annual NO_x concentration potentially as large as 10% of standard; all other criteria pollutant concentrations between 0.3 and 3% of respective standards	**Operations:** All pollutant concentrations below 0.02% of respective standards
Water[b]		
Construction: Negligible impacts to surface water and groundwater	**Construction:** Negligible impacts to surface water and groundwater	**Construction:** Negligible impacts to surface water and groundwater
Operations: None to negligible impacts to surface water and groundwater	**Operations:** None to negligible impacts to surface water and groundwater	**Operations:** None to negligible impacts to surface water and groundwater
Soil[b]		
Construction: Negligible, but temporary, impacts	**Construction:** Moderate to large, but temporary, impacts	**Construction:** Moderate to large, but temporary, impacts
Operations: No impacts	**Operations:** No impacts	**Operations:** No impacts
Socioeconomics		
Construction: Potential moderate impacts on employment and income	**Construction:** Potential moderate impacts on employment and income	**Construction:** Potential moderate impacts on employment and income
Operations: Potential moderate impacts on employment and income	**Operations:** Potential moderate impacts on employment and income	**Operations:** Potential moderate impacts on employment and income

TABLE I.2 (Cont.)

Impacts from Disposal as Ungrouted U_3O_8 in Shallow Earthen Structures	Impacts from Disposal as Ungrouted U_3O_8 in Vaults	Impacts from Disposal as Ungrouted U_3O_8 in a Mine
	Ecology	
Construction: Potential moderate impacts to vegetation and wildlife	**Construction:** Potential moderate impacts to vegetation and wildlife	**Construction:** Potential large impacts to vegetation and wildlife
Operations: Negligible impacts	**Operations:** Negligible impacts	**Operations:** Negligible impacts
	Waste Management	
Negligible to low impacts on national waste management operations	Negligible to low impacts on national waste management operations	Negligible to low impacts on national waste management operations
	Resource Requirements	
No impacts from resource requirements (such as electricity or materials) on the local or national scale are expected	No impacts from resource requirements (such as electricity or materials) on the local or national scale are expected	No impacts from resource requirements on the local or national scale are expected; impacts of electrical requirements for mine excavation depend on site location
	Land Use	
Use of approximately 46 acres; negligible impacts	Use of approximately 75 acres; potential moderate impacts	Use of approximately 232 acres; potential large impacts, including impacts from disposal of excavated material and potential off-site traffic impacts during construction

[a] Impacts presented in the table are for a generic wet setting (typical of the eastern United States). Potential impacts during the operational phase would be similar for a generic dry setting (typical of the western United States).

[b] Impacts are based on a site that would be large compared to the area of the facility, with a nearby river having a minimum flow that would be large compared to water use and discharge requirements.

Notation: LCF = latent cancer fatality; MEI = maximally exposed individual; NO_x = nitrogen oxides; ROI = region of influence.

TABLE I.3 (Cont.)

Impacts from Disposal as Ungrouted UO_2 in Shallow Earthen Structures	Impacts from Disposal as Ungrouted UO_2 in Vaults	Impacts from Disposal as Ungrouted UO_2 in a Mine
	Waste Management	
Negligible to low impacts on national waste management operations	Negligible to low impacts on national waste management operations	Negligible to low impacts on national waste management operations
	Resource Requirements	
No impacts from resource requirements (such as electricity or materials) on the local or national scale are expected	No impacts from resource requirements (such as electricity or materials) on the local or national scale are expected	No impacts from resource requirements on the local or national scale are expected; impacts of electrical requirements for mine excavation depend on site location
	Land Use	
Use of approximately 28 acres; negligible impacts	Use of approximately 28 acres; negligible impacts	Use of approximately 102 acres; potential moderate impacts, including impacts from disposal of excavated material and potential off-site traffic impacts during construction

[a] Impacts presented in the table are for a generic wet setting (typical of the eastern United States). Potential impacts during the operational phase would be similar for a generic dry setting (typical of the western United States).

[b] Impacts are based on a site that would be large compared to the area of the facility, with a nearby river having a minimum flow that would be large compared to water use and discharge requirements.

Notation: LCF = latent cancer fatality; MEI = maximally exposed individual; NO_x = nitrogen oxides; ROI = region of influence.

- ***Shallow Earthen Structure, Vault, or Mine.*** The potential impacts are essentially similar for disposal in a shallow earthen structure, vault, or mine. However, disposal in a mine could create slightly larger potential impacts if excavation of the mine was required (use of an existing mine would minimize impacts).

For the post-closure phase, the potential environmental impacts for disposal of U_3O_8 and UO_2 are summarized in Tables I.4 and I.5, respectively. Impacts were calculated for a post-failure time of 1,000 years. The potential impacts estimated for the post-closure phase are subject to a great deal of uncertainty because of the extremely long time period considered and the dependence of predictions on the behavior of the waste material as it interacts with soil and water in a distant future environment. The post-closure impacts would depend greatly on the specific disposal facility design and site-specific characteristics. Because of these uncertainties, the assessment assumptions are generally selected to produce conservative estimates of impact, that is, they tend to overestimate the expected impact. Changes in key disposal assumptions could yield significantly different results (see Section I.4).

The following is presented as a general summary of potential environmental impacts during the post-closure phase (from information in Tables I.4 and I.5 and Section I.4):

- ***Potential Adverse Impacts.*** For all disposal options, potentially large impacts to human health and groundwater quality could occur within 1,000 years after failure of a facility in a wet setting, whereas essentially no impacts would occur for a dry setting in the same time frame. Potential impacts would result primarily from the contamination of groundwater. The maximum dose to an individual assumed to live at the edge of the disposal site and use the contaminated water was estimated to be about 110 mrem/yr, which would exceed the 25-mrem/yr limit specified in 10 *Code of Federal Regulations* [CFR] Part 61 and DOE Order 5820.2A. (For comparison, the average dose to an individual from background radiation is about 360 mrem/yr.) Possible exposures (on the order of 10 rem/yr) could occur for shallow earthen structures and vaults if the cover material were to erode and expose the uranium material; however, this would not occur until several thousand years later, and the exposure could be eliminated by adding new cover material to the top of the waste area.

- ***Wet or Dry Environmental Setting.*** The potential impacts would be significantly greater in a wet setting than a dry setting. Essentially no impacts would be expected in a dry setting for more than 1,000 years because of the low water infiltration rate and greater depth to the water table.

TABLE I.4 Summary of Disposal Option Impacts for U_3O_8 during the Post-Closure Phase[a,b]

A. Grouted

Impacts from Disposal as Grouted U_3O_8 in Shallow Earthen Structures	Impacts from Disposal as Grouted U_3O_8 in Vaults	Impacts from Disposal as Grouted U_3O_8 in a Mine

Potential large impact to groundwater quality from uranium contamination	Potential large impact to groundwater quality from uranium contamination	Potential large impact to groundwater quality from uranium contamination
	Ecology	
Potential moderate impacts to wetlands and aquatic biota from surface water and groundwater contamination	Potential moderate impacts to wetlands and aquatic biota from surface water and groundwater contamination	Potential moderate impacts to wetlands and aquatic biota from surface water and groundwater contamination

[a] Impacts for the post-closure phase were calculated for a time 1,000 years after each disposal facility was assumed to fail. Impacts are presented for a generic wet setting; no impacts would be expected within 1,000 years in a dry setting.

[b] All disposal facilities would be designed to contain the waste material for at least hundreds of years. Shallow earthen structures would be expected to last several hundred years before failure; vaults and mines would be expected to last several hundreds to thousands of years before failure.

Notation: LCF = latent cancer fatality; MEI = maximally exposed individual.

[a] Impacts for the post-closure phase were calculated for a time 1,000 years after each disposal facility was assumed to fail. Impacts are presented for a generic wet setting; no impacts would be expected within 1,000 years in a dry setting.

[b] All disposal facilities would be designed to contain the waste material for at least hundreds of years. Shallow earthen structures would be expected to last several hundred years before failure; vaults and mines would be expected to last several hundreds to thousands of years before failure.

Notation: LCF = latent cancer fatality; MEI = maximally exposed individual.

- ***U_3O_8 or UO_2.*** Overall, the potential environmental impacts tend to be slightly larger for U_3O_8 than for UO_2 because the volume of U_3O_8 requiring disposal would be greater than that for UO_2. A larger volume essentially exposes a greater area of waste to infiltrating water.

- ***Grouted or Ungrouted Waste.*** For both U_3O_8 and UO_2, the disposal of grouted waste would have larger environmental impacts than disposal of ungrouted waste once the waste was exposed to the environment because grouting would increase the waste volume. However, further studies using site-specific soil characteristics are necessary to determine the effect of grouting on long-term waste mobility. Grouting might reduce the dissolution rate of the waste and subsequent leaching of uranium into the groundwater in the first several hundred years after failure. However, over longer periods the grouted form would be expected to deteriorate and, because of the long half-life of uranium, the performance of grouted and ungrouted waste would be essentially the same. Depending on soil properties and characteristics of the grout material, it is also possible that grouting could increase the solubility of the uranium material by providing a carbonate-rich environment.

- ***Shallow Earthen Structure, Vault, or Mine.*** Because of the long time periods considered and the fact that the calculations were performed for a time of 1,000 years *after* each facility was assumed to fail, the potential impacts are very similar for disposal in a shallow earthen structure, vault, or mine. However, shallow earthen structures would be expected to contain the waste material for a period of at least several hundred years before failure, whereas vaults and a mine would be expected to last even longer — from several hundred years to a thousand years or more. Therefore, vault and mine disposal would provide greater protection of waste in a wet environment. In addition, a vault and a mine would be expected to provide additional protection against erosion of the cover material (and possible surface exposure of the waste material) compared to shallow earthen structures. The exact time that any disposal facility would perform as designed would depend on the specific facility design and site characteristics.

I.2 DESCRIPTION OF OPTIONS

This section provides a brief summary of the different disposal options considered in the assessment of disposal impacts. The information is based on preconceptual design data provided in the engineering analysis report (LLNL 1997). The engineering analysis report includes much more detailed information, such as descriptions of facility layouts, resource requirements, estimates of effluents, wastes, and emissions, and descriptions of potential accident scenarios.

The three disposal options considered are (1) shallow earthen structures (engineered "trenches"), (2) vaults, and (3) an underground mine. For each option, the U_3O_8 and UO_2 would be packaged for disposal as follows:

- U_3O_8 would be disposed of in 55-gal (208-L) drums. If ungrouted, approximately 714,000 drums would be required; if grouted, approximately 1,500,000 drums would be required.

- UO_2 would be disposed of in 30-gal (110-L) drums. These small drums would be used because of the greater density of UO_2 — a filled 30-gal (110-L) drum would weigh about 2,350 lb (1,070 kg). If ungrouted, approximately 420,000 drums would be required; if grouted, approximately 630,000 drums would be required.

All disposal options would include a central wasteform facility where drums of uranium oxide would be received from the conversion facility and prepared for disposal. The wasteform facility would include an administration building, a receiving warehouse, and cementing/curing/short-term storage buildings (if necessary). Grouting of waste would be performed by mechanically mixing the uranium oxide with cement in large tanks and then pouring the mixture into drums. Once prepared for disposal (if necessary), drums would be moved into disposal units. For the grouted U_3O_8 option, the area of the wasteform facility would be approximately 9 acres (3.6 ha); for the grouted UO_2 option, the area would be about 6 acres (2.4 ha). For ungrouted disposal options, only about 4 acres (1.6 ha) would be required because the facilities for grouting, curing, and additional short-term storage would not be needed. The unique features of each disposal option are described in Sections I.2.1 through I.2.3.

I.2.1 Disposal in Shallow Earthen Structures

Shallow earthen structures, commonly referred to as engineered trenches, are among the most commonly used forms of low-level waste disposal, especially in dry climates. Shallow earthen structures would be excavated to a depth of about 26 ft (8 m), with the length and width determined by site conditions and the annual volume of waste to be disposed of. Disposal in shallow earthen structures would consist of placing waste on a stable structural pad with barrier walls constructed of compacted clay. Clay would be used because it prevents the walls from collapsing or caving in, and it presents a relatively impermeable barrier to waste migration. The waste containers (i.e., drums) would be tightly stacked three pallets high in the bottom of the structure with forklifts. Any open space between containers would be filled with earth, sand, gravel, or other similar material as each layer of drums was placed. After the structure was filled, a 6 ft (2 m) thick cap composed of engineered fill dirt and clay would be placed on top and compacted. The cap would be mounded at least 3 ft (1 m) above the local grade and sloped to minimize the potential for water infiltration. Disposal of ungrouted and grouted U_3O_8 would require about 42 acres (17 ha) and 76 acres (31 ha),

respectively. Disposal of ungrouted and grouted UO_2 would require about 24 acres (10 ha) and 33 acres (14 ha), respectively.

I.2.2 Disposal in Vaults

Vaults for disposal would be similar to those described previously for the storage options (Appendix G, Section G.2.3), except that each vault would be divided into five sections, each section approximately 66 ft (20 m) long by 26 ft (8 m) wide and 13 ft (4 m) tall. As opposed to shallow earthen structures, the walls and floor of a vault would be constructed of reinforced concrete. A crane would be used to place drums within each section. Once a vault was full, any open space between containers would be filled with earth, sand, gravel, or other similar material. A permanent roof slab of reinforced concrete that completely covers the vault would be installed after all five sections were filled. A cap of engineered fill dirt and clay would be placed on top of the concrete cover and compacted. The cap would be mounded above the local grade and sloped to minimize the potential for water infiltration. Disposal of ungrouted and grouted U_3O_8 would require about 71 and 140 acres (28 and 56 ha), respectively. Disposal of ungrouted and grouted UO_2 would require about 24 and 35 acres (10 and 15 ha), respectively.

I.2.3 Disposal in a Mine

An underground mine disposal facility would be a repository for permanent deep geological disposal. A mined disposal facility could possibly use a previously existing mine, or be constructed for the sole purpose of waste disposal. For purposes of comparing alternatives, the conservative assumption of constructing a new mine was assessed for this PEIS. A mine disposal facility would consist of surface facilities that provide space for waste receiving and inspection (the wasteform facility), and shafts and ramps for access to and ventilation of the underground portion of the repository. The underground portion would consist of tunnels (called "drifts") for the transport and disposal of waste underground. The dimensions of the drifts would be similar to those described previously for the storage options (Section G.2.4), except that each drift would have a width of 21 ft (6.5 m). Waste containers would be placed in drifts and backfilled. Disposal of ungrouted and grouted U_3O_8 would require about 228 acres (91 ha) and 462 acres (185 ha) of underground disposal space, respectively. Disposal of ungrouted and grouted UO_2 would require about 98 acres (39 ha) and 143 acres (57 ha), respectively.

I.2.4 Disposal Technologies and Chemical Forms Considered But Not Analyzed

Disposal of depleted uranium metal was not considered because uranium metal is not as chemically stable as U_3O_8 or UO_2. Uranium metal is subject to surface oxidation. Similarly, disposal of UF_6 and UF_4 were not considered because they react with water to form HF, which is a hazardous

and corrosive chemical that would degrade the containment for the waste material. These characteristics are considered unacceptable for disposal.

I.3 IMPACTS OF OPTIONS — OPERATIONAL PHASE

Potential impacts analyzed for the operational phase of the disposal options included impacts occurring during facility construction and during the 20-year period when the waste material would be actively placed into disposal units. (The potential environmental impacts for the post-closure period, after the disposal facility ceased operations, are presented in Section I.4). The estimated impacts are discussed for each area of impact. Information related to the assessment methodologies is provided in Appendix C.

The environmental impacts from the operational phase were evaluated based on the information described in the engineering analysis report (LLNL 1997). The following general assumptions apply to the assessment of impacts:

- Impacts during the operational phase include those from preliminary facility construction and the 20-year period (2008 to 2028) when waste material (i.e., depleted uranium oxide from the DOE-generated inventory) would be actively placed into disposal units. Construction of disposal units would continue over the 20-year period while waste material was being received.

- Ungrouted U_3O_8 and ungrouted UO_2 would be disposed of directly without additional processing at the disposal facility. Consequently, no air or water emissions would be associated with normal (nonaccident) operations, except for exhaust emissions from equipment used during disposal.

- Grouting of U_3O_8 and UO_2 would occur at the disposal facility and consist of mixing the uranium material with cement and pouring it into drums. Grouting operations would result in the release of small amounts of uranium material to the air and water during normal operations.

- The potential impacts from disposal were analyzed for generic dry and wet environmental settings. The historical meteorological conditions for five actual "dry" locations in the southwestern United States and five actual "wet" locations in the central and southeastern United States were used to develop estimates for the generic sites. It was assumed that a disposal facility would not be located in an urban area. Therefore, analyses for both dry and wet environmental settings assumed a rural population density corresponding to 15 persons/mi^2 (6 persons/km^2).

The potential environmental impacts from the disposal options were not evaluated on a site-specific basis because the location of a disposal facility would not be chosen until sometime in the future (see Chapter 3). A more detailed assessment of site considerations would be addressed, as appropriate, as part of the Phase II reviews of the programmatic *National Environmental Policy Act* (NEPA) approach.

I.3.1 Human Health — Normal Operations

I.3.1.1 Radiological Impacts

Radiological impacts during normal operations of the facility were estimated for involved workers, noninvolved workers, and members of the general public. External radiation resulting from the handling and shipping of uranium materials would be the major source of exposure for involved workers. Because grouted waste would increase the total volume of waste substantially, thereby increasing the number of waste containers for handling and shipping, impacts to involved workers would be greater from grouted waste than ungrouted waste. Variations in exposures for the three disposal types considered (shallow earthen structures, vaults, or mine) would be caused by different practices for different technologies. Disposal in a mine would require transport of waste containers from the ground surface to the underground cavities, whereas disposal in shallow earthen structures and vaults would require filling and capping efforts to cover the waste containers with dirt, cement, and/or other engineering materials. In general, average radiation exposure of involved workers would be less than 630 mrem/yr.

Exposures for noninvolved workers and the general public would result from releases of uranium compounds from the grouting facility. Radiation doses from both airborne and waterborne pathways would be less than 0.05 mrem/yr and would tend to be similar between dry and wet environmental settings.

The estimated results for different disposal options are listed in Tables I.6 and I.7. Detailed discussions of the methodology used in the radiological impact analyses are provided in Appendix C and Cheng et al. (1997).

I.3.1.1.1 Disposal as U_3O_8

The total collective doses to involved workers from grouted waste would be nearly twice those from ungrouted waste, ranging from approximately 24 person-rem/yr for 85 workers for shallow earthen structures to 36 person-rem/yr for 87 workers for a mine. The corresponding collective cancer risks for grouted waste would be about 1×10^{-2} fatalities per year (1 additional latent cancer fatality [LCF] in 100 years). The estimated average individual doses to involved workers range from 210 mrem/yr (disposal in vaults) to 410 mrem/yr (disposal in a mine) for grouted

[a] Two generic environmental settings were considered for each option, corresponding to a dry environment and wet environment, respectively.

[b] Involved workers are those workers directly involved with the handling of materials. Impacts are presented as average individual dose and collective dose for the worker population. Radiation doses to individual workers would be monitored by a dosimetry program and maintained below applicable standards, such as the DOE administrative control limit of 2,000 mrem/yr.

[c] Noninvolved workers are individuals who do not participate in material-handing activities, such as employees in the administration building. The number of noninvolved workers would be approximately 44.

[d] The off-site general public is defined as residents who live within a radius of 50 miles (80 km) around the disposal site. A rural environment with a population density of 6 persons/km^2 and a total population of 120,000 was assumed. Impacts to the MEI were assessed from both airborne and waterborne emissions; impacts to the total population were assessed from airborne emissions only.

[a] Two generic environmental settings were considered for each option, corresponding to a dry environment and wet environment, respectively.

[b] Involved workers are those workers directly involved with the handling of materials. Impacts are presented as average individual risk and collective risk for the worker population.

[c] Noninvolved workers are individuals who do not participate in material-handling activities, such as employees in the administration building. The number of noninvolved workers would be approximately 44.

[d] The off-site general public is defined as residents who live within a radius of 50 miles (80 km) around the disposal site. A rural environment with a population density of 6 persons/km^2 and a total population of 120,000 was assumed. Impacts to the MEI were assessed from both airborne and waterborne emissions; impacts to the total population were assessed from airborne emissions only.

waste. Average worker doses for ungrouted waste range from 330 to 630 mrem/yr. Potential exposures of involved workers would be well below the radiation dose limit of 5,000 mrem/yr (10 CFR Part 835).

Radiation exposures of noninvolved workers would occur only for disposal of grouted waste. The radiation dose to the maximally exposed individual (MEI) would be less than 0.0088 mrem/yr, a small fraction of the dose limit of 10 mrem/yr from airborne emissions (10 CFR Part 61). The collective dose for noninvolved workers would be less than 0.0002 person-rem/yr for a total of approximately 43 workers.

The estimated maximum individual dose to the off-site general public is less than 0.026 mrem/yr for grouted waste, which corresponds to a cancer risk of 1 in 80 million per year. For a collective population of 120,000 persons within 50 miles (80 km) of the site, the estimated number of LCFs is less than 3×10^{-6} per year (1 fatality in 300,000 years).

I.3.1.1.2 Disposal as UO_2

Compared with the disposal of U_3O_8, disposal of UO_2 would result in less collective exposures of involved workers because of the smaller volume of waste involved. Grouted UO_2 would result in larger collective worker doses than ungrouted UO_2, with the collective dose ranging from 21 to 24 person-rem/yr for approximately 72 workers. The average individual dose to involved workers for grouted waste ranges from 300 to 330 mrem/yr. Although ungrouted waste would result in less collective exposure, the number of involved workers (about 25) would also be less. As a result, the average worker dose would be greater for ungrouted waste than grouted waste. The estimated average individual worker dose ranges from 360 mrem/yr to 470 mrem/yr. For all disposal types considered, the average radiation doses to involved workers would be well below the dose limit of 5,000 mrem/yr. The estimated maximum individual dose to noninvolved workers is less than 0.017 mrem/yr, and the estimated collective dose is less than 0.0002 person-rem/yr. The number of noninvolved workers would be approximately 44.

The maximum individual dose to the off-site general public would be less than 0.050 mrem/yr, which corresponds to a cancer risk of 1 in 40 million per year. For the assumed rural collective population of 120,000 persons within 50 miles (80 km) of the site, the number of LCFs would be less than 5×10^{-6} per year (1 fatality in 200,000 years of operation).

I.3.1.2 Chemical Impacts

Potential chemical impacts to human health from normal operations at the disposal facilities would result primarily from exposure to the insoluble uranium compounds, UO_2 and U_3O_8. Risks from normal operations were quantified on the basis of calculated hazard indices. Additional information on the exposure assumptions, health effects assumptions, reference doses used for

uranium compounds, and calculational methods used in the chemical impact analysis are provided in Appendix C and Cheng et al. (1997).

Chemical impacts during the operational phase of the disposal facilities were calculated for noninvolved workers and the general public. Exposures of noninvolved workers and the general public to low levels of airborne emissions could occur from mixing uranium with cement and other grouting materials in the wasteform facility. Three disposal types (shallow earthen structures, vaults, and mines) were considered for U_3O_8 and UO_2 as both grouted and ungrouted wastes in generic dry and wet environmental settings.

Human health impacts from exposures to hazardous chemicals during normal operations of the U_3O_8 or UO_2 disposal facilities are summarized in Table I.8. Two waste forms were evaluated for U_3O_8 and UO_2: grouted and ungrouted. For grouted wastes, the range of chemical exposures to the noninvolved workers and general public would result primarily from differences between the locations and types of disposal facilities. The hazard indices for all disposal options are four orders of magnitude less than 1, the level for which potential adverse health effects could occur from normal operations. No impacts would occur for disposal of ungrouted U_3O_8 or UO_2 because airborne emissions would not be expected (LLNL 1997).

I.3.2 Human Health — Accident Conditions

A range of accidents covering the spectrum of high-frequency/low-consequence accidents to low-frequency/high-consequence accidents has been presented in the engineering analysis report (LLNL 1997). These accidents are listed in Table I.9. The following sections present the results for radiological and chemical health impacts of the highest consequence accident in each frequency category. Results for all accidents listed in Table I.9 are presented in Policastro et al. (1997). Detailed descriptions of the methodology and assumptions used in these calculations are also provided in Appendix C and Policastro et al. (1997).

I.3.2.1 Radiological Impacts

The radiological doses to various receptors for the accidents that give the highest dose from each frequency category are listed in Table I.10. The LCF risks for these accidents are given in Table I.11. The doses and the risks are presented as ranges (maximum and minimum) because two different meteorological conditions (wet and dry) were evaluated for each disposal option (see Appendix C). The doses and risks presented here were obtained by assuming that the accidents would occur. The probability of occurrence for each accident is indicated by the frequency category to which it belongs. For example, accidents in the extremely unlikely category have a probability of

[a] The range of impacts represent variations in meteorological conditions at the generic wet and dry environmental settings.

[b] Noninvolved workers are individuals who do not participate in material-handling activities, such as employees in the administration building.

[c] The hazard index is an indicator for potential health effects other than cancer; a hazard index greater than 1 indicates a potential for adverse health effects and a need for further evaluation.

[d] Calculation of population risk is not applicable when the corresponding hazard index for the MEI is less than 1.

TABLE I.9 Accidents Considered for the Disposal Options

Option/Accident Scenario	Accident Description	Chemical Form	Amount (lb)	Duration (min)	Release Level[a]
Disposal as Grouted U_3O_8					
Likely Accidents (frequency: 1 or more times in 100 years)					
Mishandling/drop of drum/ billet inside the product receiving area	A single U_3O_8 drum is damaged by a forklift and spills its contents onto the ground inside the product receiving area.	U_3O_8	0.00028	Puff	Stack
Mishandling/drop of drum/ billet outside	A single U_3O_8 drum is damaged by a forklift and spills its contents outside without HEPA filtration.	U_3O_8	0.000066	Puff	Ground
Unlikely Accidents (frequency: 1 in 100 years to 1 in 10,000 years)					
Earthquake	The product receiving area and cement mixing area are damaged during a design-basis earthquake, resulting in failure of the structure and confinement systems.	U_3O_8	400	Puff	Ground
Tornado	A major tornado and associated tornado missiles result in failure of the product receiving area and cement mixing area structures and confinement systems.	U_3O_8	770	Puff	Ground
Extremely Unlikely Accidents (frequency: 1 in 10,000 years to 1 in 1 million years)					
Fire/explosion inside the product mixing area	A fire or explosion within the product mixing area affects the contents of a single pallet of drums.	U_3O_8	0.0017	Puff	Stack
Incredible Accidents (frequency: less than 1 in 1 million years)					
Flood	The facility would be located at a site that would preclude severe flooding.	No release	NA	NA	NA
Disposal as Ungrouted U_3O_8					
Likely Accidents (frequency: 1 or more times in 100 years)					
Mishandling/drop of drum/ billet inside the product receiving area	A single U_3O_8 drum is damaged by a forklift and spills its contents onto the ground inside the product receiving area.	U_3O_8	0.00028	Puff	Stack
Unlikely Accidents (frequency: 1 in 100 years to 1 in 10,000 years)					
Earthquake	The product receiving area is damaged during a design-basis earthquake, resulting in failure of the structure and confinement systems.	U_3O_8	370	Puff	Ground
Tornado	A major tornado and associated tornado missiles result in failure of the product receiving structure and confinement systems.	U_3O_8	740	Puff	Ground
Incredible Accidents (frequency: less than 1 in 1 million years)					
Flood	The facility would be located at a site that would preclude severe flooding.	No release	NA	NA	NA

TABLE I.9 (Cont.)

Option/Accident Scenario	Accident Description	Chemical Form	Amount (lb)	Duration (min)	Release Level[a]
Disposal as Grouted UO_2					
Likely Accidents (frequency: 1 or more times in 100 years)					
Mishandling/drop of drum/ billet inside the product receiving area	A single UO_2 drum is damaged by a forklift and spills its contents onto the ground inside the product receiving area.	UO_2	0.00011	Puff	Stack
Mishandling/drop of drum/ billet outside	A single UO_2 drum is damaged by a forklift and spills its contents outside without HEPA filtration.	UO_2	0.00015	Puff	Stack
Unlikely Accidents (frequency: 1 in 100 years to 1 in 10,000 years)					
Earthquake	The product receiving area and cement mixing area are damaged during a design-basis earthquake, resulting in failure of the structure and confinement systems.	UO_2	0.73	Puff	Ground
Tornado	A major tornado and associated tornado missiles result in failure of the product receiving area and cement mixing area structures and confinement systems.	UO_2	2.1	Puff	Ground
Extremely Unlikely Accidents (frequency: 1 in 10,000 years to 1 in 1 million years)					
Fire/explosion inside the product mixing area	A fire or explosion within the product mixing area affects the contents of a single pallet of drums.	UO_2	0.00068	Puff	Stack
Incredible Accidents (frequency: less than 1 in 1 million years)					
Flood	The facility would be located at a site that would preclude severe flooding.	No release	NA	NA	NA
Disposal as Ungrouted UO_2					
Likely Accidents (frequency: 1 or more times in 100 years)					
Mishandling/drop of drum/ billet inside product receiving area	A single UO_2 drum is damaged by a forklift and spills its contents onto the ground inside the product receiving area.	UO_2	0.00011	Puff	Stack
Unlikely Accidents (frequency: 1 in 100 years to 1 in 10,000 years)					
Earthquake	The product receiving area is damaged during a design-basis earthquake, resulting in failure of the structure and confinement systems.	UO_2	0.59	Puff	Ground
Tornado	A major tornado and associated tornado missiles result in failure of the product receiving structure and confinement systems.	UO_2	1.2	Puff	Ground
Incredible Accidents (frequency: less than 1 in 1 million years)					
Flood	The facility would be located at a site that would preclude severe flooding.	No release	NA	NA	NA

[a] Ground-level releases were assumed to occur outdoors on concrete pads in the cylinder storage yards. To prevent contaminant migration, cleanup of residuals was assumed to begin immediately after the release was stopped.

Notation: HEPA = high-efficiency particulate air; NA = not applicable; UO_2 = uranium dioxide; U_3O_8 = triuranium octaoxide.

Earthquake	U	2.2×10^{-1}	9.3×10^{-3}	1.7×10^{-3}	2.2×10^{-3}	1.9×10^{-2}	1.6×10^{-3}	4.4×10^{-4}	1.3×10^{-3}

[a] The bounding accident chosen to represent each frequency category is the one that would result in the highest dose to the general public MEI. Health impacts in that row represent that accident only and not the range of impacts among accidents in that category. Absence of an accident in a certain frequency category indicates that the accident would not result in a release of radioactive material.

[b] Accident frequencies: likely (L), estimated to occur one or more times in 100 years of facility operations ($> 10^{-2}$/yr); unlikely (U), estimated to occur between once in 100 years and once in 10,000 years of facility operations ($10^{-2} - 10^{-4}$/yr); extremely unlikely (EU), estimated to occur between once in 10,000 years and once in 1 million years of facility operations ($10^{-4} - 10^{-6}$/yr).

[c] Maximum and minimum doses reflect differences in assumed sites, technologies, and meteorological conditions at the time of the accident. In general, maximum doses would occur under meteorological conditions of F stability with 1 m/s wind speed, whereas minimum doses would occur under D stability with 4 m/s wind speed.

[a] Values shown are the consequences if the accident did occur. The risk of an accident is the consequence (LCF) times the estimated frequency times 20 years of operations. The estimated frequencies are as follows: likely (L), 0.1; unlikely (U), 0.001; extremely unlikely (EU), 0.00001; incredible (I), 0.000001.

[b] The bounding accident chosen to represent each frequency category is the one that would result in the highest risk to the general public MEI. Health impacts in that row represent that accident only and not the range of impacts among accidents in that category. Absence of an accident in a certain frequency category indicates that the accident would not result in a release of radioactive material.

[c] Accident frequencies: likely (L), estimated to occur one or more times in 100 years of facility operations ($> 10^{-2}$/yr); unlikely (U), estimated to occur between once in 100 years and once in 10,000 years of facility operations ($10^{-2} - 10^{-4}$/yr); extremely unlikely (EU), estimated to occur between once in 10,000 years and once in 1 million years of facility operations ($10^{-4} - 10^{-6}$/yr).

[d] Maximum and minimum risks reflect differences in assumed sites, technologies, and meteorological conditions at the time of the accident. In general, maximum risks would occur under meteorological conditions of F stability with 1 m/s wind speed, whereas minimum risks would occur under D stability with 4 m/s wind speed.

1099

occurrence between 1 in 10,000 and 1 in 1 million in any 1 year. The following conclusions may be drawn from the radiological health impact results:

- No cancer fatalities would be predicted from any of the accidents.

- Except for the impacts to a noninvolved worker MEI from an earthquake accident, the maximum radiological dose to noninvolved worker and general public MEIs (assuming an accident occurred) would be 1.1 rem. This dose is less than the 25-rem dose recommended for assessing the adequacy of protection of public health and safety from potential accidents by the U.S. Nuclear Regulatory Commission (NRC 1994).

- For an earthquake accident, the potential dose to the noninvolved worker MEI would range from 0.22 to 140 rem, depending on the option implemented for uranium disposal. The NRC recommendations are not directly applicable to workers but are used in this instance as a guideline to indicate potential for health effects. A dose of 140 rem could result in temporary adverse health effects to the MEI worker.

- The overall radiological risk to worker and general public MEI receptors (estimated by multiplying the risk per occurrence [Table I.11] by the annual probability of occurrence by the number of years of operations) would be less than 1 for all of the disposal accidents.

I.3.2.2 Chemical Impacts

The accidents assessed in this section are listed in Table I.9. The results of the accident consequence modeling in terms of chemical impacts are presented in Tables I.12 and I.13. Results are presented as (1) number of people with the potential for adverse effects and (2) number of people with the potential for irreversible adverse effects. The tables present the results for the accident within each frequency category that would affect the largest number of people (total of noninvolved workers and off-site population) (Policastro et al. 1997). The number of workers and members of the off-site public represent the impacts if the associated accident was assumed to occur. These impacts may be summarized as follows:

- If the accidents identified in Tables I.12 and I.13 did occur, the number of persons in the off-site population with potential for adverse effects and irreversible adverse effects would range from 0 to 1 (MEI), the maximum corresponding to an earthquake accident. The number of workers with potential for adverse effects and irreversible adverse effects would range from 0 to 1, the maximum also corresponding to the earthquake accident.

TABLE I.12 Number of Persons with Potential for Adverse Effects from Accidents under the Disposal Options[a]

Option/Accident[b]	Frequency Category[c]	Maximum Number of Persons[d]				Minimum Number of Persons[d]			
		Noninvolved Workers		General Public		Noninvolved Workers		General Public	
		MEI[e]	Population	MEI[e]	Population	MEI[e]	Population	MEI[e]	Population
Disposal as Grouted U_3O_8									
Mishandle/drop of drum/billet outside[f]	L	No	0	No	0	No	0	No	0
Earthquake	U	Yes	1	Yes[g]	0	Yes	1	No	0
Fire/explosion inside[f]	EU	No	0	No	0	No	0	No	0
Disposal as Grouted UO_2									
Mishandle/drop of drum/billet outside[f]	L	No	0	No	0	No	0	No	0
Earthquake[f]	U	No	0	No	0	No	0	No	0
Fire/explosion inside[f]	EU	No	0	No	0	No	0	No	0

[a] Values shown are the consequences if the accident did occur. The risk of an accident is the consequence (number of persons) times the estimated frequency times 20 years of operations. The estimated frequencies are as follows: likely (L), 0.1; unlikely (U), 0.001; extremely unlikely (EU), 0.00001; incredible (I), 0.000001.

[b] The bounding accident chosen to represent each frequency category is the one in which the largest number of people (noninvolved workers plus off-site people) would be affected. Health impacts in that row represent that accident only and not the range of impacts among accidents in that category.

[c] Accident frequencies: likely (L), estimated to occur one or more times in 100 years of facility operations ($> 10^{-2}$/yr); unlikely (U), estimated to occur between once in 100 years and once in 10,000 years of facility operations ($10^{-2} - 10^{-4}$/yr); extremely unlikely (EU), estimated to occur between once in 10,000 years and once in 1 million years of facility operations ($10^{-4} - 10^{-6}$/yr); incredible (I), estimated to occur less than one time in 1 million years of facility operations ($< 10^{-6}$/yr).

[d] Maximum and minimum risks reflect different meteorological conditions at the time of the accident. In general, maximum risks would occur under meteorological conditions of F stability with 1 m/s wind speed, whereas minimum risks would occur under D stability with 4 m/s wind speed.

[e] At the MEI location, the determination is either "Yes" or "No" for potential adverse effects to an individual.

[f] These accidents would result in the largest plume sizes, although no people would be affected.

[g] MEI locations were evaluated at 100 m from ground-level releases for noninvolved workers and at the location of highest off-site concentration for members of the general public; the population risks are 0 because generic worker and general public population distributions were used, which did not show receptors at the MEI locations.

TABLE I.13 Number of Persons with Potential for Irreversible Adverse Effects from Accidents under the Disposal Options[a]

Option/Accident[b]	Frequency Category[c]	Maximum Number of Persons[d]				Minimum Number of Persons[d]			
		Noninvolved Workers		General Public		Noninvolved Workers		General Public	
		MEI[e]	Population	MEI[e]	Population	MEI[e]	Population	MEI[e]	Population
Disposal as Grouted U_3O_8

Earthquake[f]	U	No	0	No	0	No	0	No	0
Fire/explosion inside[f]	EU	No	0	No	0	No	0	No	0

[a] Values shown are the consequences if the accident did occur. The risk of an accident is the consequence (number of persons) times the estimated frequency times 20 years of operations. The estimated frequencies are as follows: likely (L), 0.1; unlikely (U), 0.001; extremely unlikely (EU), 0.00001; incredible (I), 0.000001.

[b] The bounding accident chosen to represent each frequency category is the one in which the largest number of people (noninvolved workers plus off-site people) would be affected. Health impacts in that row represent that accident only and not the range of impacts among accidents in that category.

[c] Accident frequencies: likely (L), estimated to occur one or more times in 100 years of facility operations ($> 10^{-2}$/yr); unlikely (U), estimated to occur between once in 100 years and once in 10,000 years of facility operations ($10^{-2} - 10^{-4}$/yr); extremely unlikely (EU), estimated to occur between once in 10,000 years and once in 1 million years of facility operations ($10^{-4} - 10^{-6}$/yr); incredible (I), estimated to occur less than one time in 1 million years of facility operations ($< 10^{-6}$/yr).

[d] Maximum and minimum risks reflect different meteorological conditions at the time of the accident. In general, maximum risks would occur under meteorological conditions of F stability with 1 m/s wind speed, whereas minimum risks would occur under D stability with 4 m/s wind speed.

[e] At the MEI location, the determination is either "Yes" or "No" for potential irreversible adverse effects to an individual.

[f] These accidents would result in the largest plume sizes, although no people would be affected.

[g] MEI locations were evaluated at 100 m from ground-level releases for noninvolved workers and at the location of highest off-site concentration for members of the general public; the population risks are 0 because generic worker and general public population distributions were used, which did not show receptors at the MEI locations.

1/102

- There would be no difference in accident consequences for disposal as UO_2 or U_3O_8 in shallow earthen structures, vaults, or a mine.

- The largest impacts would be caused by an earthquake in the product receiving and cement mixing areas. Accidents involving stack emissions would have very small impacts compared with accidents involving releases at ground level due to the large dilution (and lower source terms) involved with the stack emissions.

- For the earthquake accident, the noninvolved worker and the public MEIs could experience potential for both adverse effects and irreversible adverse effects. For all other accidents, the worker and general public MEIs would experience neither potential adverse effects nor potential irreversible adverse effects.

- The maximum risk was computed as the product of the consequence (number of people) times the frequency of occurrence (per year) times the number of years of operations (20 years, 2009 through 2028). The results indicated that the maximum risk values would be less than 1 for all accidents. These risk values are conservative because the numbers of people affected were based on assuming (1) meteorological conditions that would result in the maximum reasonably foreseeable plume size (i.e., F stability and 1 m/s wind speed) and (2) wind in the direction that would lead to maximum numbers of individuals exposed for workers or for the general population.

To aid in the interpretation of accident analysis results, the number of fatalities potentially associated with the estimated potential irreversible adverse effects was estimated. The bounding case accidents shown in Table I.13 would involve releases of uranium oxide and potential exposure to uranium compounds. If the accident occurred, exposures are estimated to result in death for 1% or fewer of the persons experiencing irreversible adverse effects (Policastro et al. 1997). Thus, for noninvolved workers and members of the general public experiencing a range of 0 to 1 irreversible adverse effects, 0 deaths would be expected.

I.3.2.3 Physical Hazards

The risk of on-the-job fatalities and injuries to all disposal facility workers is calculated using industry-specific statistics from the Bureau of Labor Statistics, as reported by the National Safety Council (1995). Construction and manufacturing annual fatality and injury rates were used, respectively, for the construction and operational components of the disposal facility activities.

One fatality due to accidental physical trauma would be predicted under the grouted U_3O_8 mine disposal option. The risk of a fatality for this option is almost twice as great as the risk for the

other options; this difference is due mainly to the increased risk associated with construction of the large mine that would be needed for the entire inventory of grouted U_3O_8. Mitigation of risks from construction, loading, and closure of mines can be accomplished to a certain extent by instituting safety measures and by conducting thorough safety training programs for personnel.

Estimated fatalities range from 0.13 to 0.94, and injury incidences range from 90 to 450 (see Table I.14). Except for the grouted U_3O_8 mine disposal option discussed above, the other options are fairly comparable with respect to predicted fatalities and injuries due to physical trauma.

I.3.3 Air Quality

The methodology used to analyze air quality impacts from disposal options is provided in Appendix C and Tschanz (1997). The pollutant concentrations at several distances from the center of the facility were estimated because of uncertainty regarding the size and location of the generic disposal facility. Estimates at 2,460 ft (750 m) from the center of the disposal facilities are comparable to the estimates for options based on representative environmental settings (i.e., conversion and long-term storage options using the three current storage sites as representative of those settings). The shortest distances from the centers of the representative sites to their boundaries range from 2,300 to 2,600 ft (700 to 800 m).

Pollutant emissions would result from construction of the wasteform facility and construction of the disposal areas/facilities. The annual emissions of carbon monoxide (CO), hydrocarbons (HC), nitrogen oxides (NO_x), sulfur oxides (SO_x), and particulate matter (PM_{10}), with a mean diameter of 10 μm or less) resulting from construction of the wasteform facility and from construction of disposal areas/facilities are shown in Table I.15 for disposal of grouted U_3O_8 in either shallow earthen structures or vaults. The criteria pollutant emissions from construction of facilities for the other disposal options and for operation of the facilities are related to those in Table I.15 by the scaling factors listed in Table I.16. For example, the CO emissions from operations for disposal of grouted UO_2 in shallow earthen structures would be 0.74 × 1.55 tons/yr, or 1.14 tons/yr (1.05 metric tons/yr). Operation of the wasteform facility would also produce 1.08 and 0.59 lb/yr (0.50 and 0.27 kg/yr) of uranium emissions for the grouted UO_2 and grouted U_3O_8 options, respectively.

The largest pollutant concentrations would result from the operation of vaults for disposal of grouted U_3O_8. The estimated NO_x concentrations for operation of this option are shown in the bottom half of Table I.17. The concentrations of CO, HC, SO_x, and PM_{10} are 0.21, 0.075, 0.065, and 0.070 times as large, respectively, as those for NO_x. The results show that the ranges of impacts would be larger for a wet environmental setting than for a dry setting, and in fact the ranges of dry setting impacts fall within those for the wet setting. At 2,460 ft (750 m), the maximum annual NO_x concentration during operations might be as large as 37% of the 100 $\mu g/m^3$ standard. The other

TABLE I.14 Potential Impacts to Human Health from Physical Hazards under Accident Conditions for the Disposal Options

Option	Impacts to All Disposal Facility Workers[a]					
	Fatality Incidence[b]			Injury Incidence[b]		
	Wasteform Facility	Disposal Facility	Total	Wasteform Facility	Disposal Facility	Total
Disposal as Grouted U_3O_8						
Shallow earthen structure	0.15	0.11	0.26	130	80	210
Vault	0.15	0.29	0.44	130	170	300
Mine	0.15	0.78	0.94	130	320	450
Disposal as Ungrouted U_3O_8						
Shallow earthen structure	0.06	0.08	0.13	50	40	90
Vault	0.06	0.17	0.22	50	90	140
Mine	0.06	0.47	0.53	50	190	240
Disposal as Grouted UO_2						
Shallow earthen structure	0.15	0.08	0.23	120	50	180
Vault	0.15	0.11	0.26	120	70	190
Mine	0.15	0.36	0.50	120	160	280
Disposal as Ungrouted UO_2						
Shallow earthen structure	0.06	0.07	0.13	50	40	90
Vault	0.06	0.10	0.15	50	60	110
Mine	0.06	0.27	0.33	50	120	170

[a] Values are rounded to two significant figures. All construction and operations workers at the disposal facilities were included in the physical hazard risk calculations.

[b] Fatality incidence and injury incidence were calculated as the number of full-time-equivalent employees times the annual fatality rate times the number of years. Only injuries involving lost workdays were included. Injury and fatality incidence rates used in the calculations were taken from National Safety Council (1995).

criteria pollutant concentrations are smaller fractions of their standards than is NO_x relative to its standard.

The NO_x concentrations for construction of the grouted U_3O_8 vault disposal option would be 0.35 times those for operation of the vaults and approximately the same as the estimated NO_x concentrations during operations for the disposal of grouted U_3O_8 in shallow earthen structures, shown in Table I.18. During operations for shallow earthen structure disposal of grouted U_3O_8, the CO, HC, SO_x, and PM_{10} impacts would be 0.22, 0.075, 0.066, and 0.070 times as large, respectively, as those for NO_x. The impacts of all of these other pollutants relative to their standards would be less than that of NO_x.

TABLE I.15 Pollutant Emissions from Construction Activities Associated with Disposal Facilities for Grouted U_3O_8[a]

Pollutant	Pollutant Emissions from Construction Activities (tons/yr)		
	Wasteform Facility	Shallow Earthen Structure	Vault
CO	2.11	1.55	2.62
HC	0.739	0.543	0.918
NO_x	9.79	7.18	12.2
SO_x	0.644	0.473	0.799
PM_{10}	0.688	0.505	0.854

[a] Represents emissions from construction of wasteform facility and from construction of either shallow earthen structures or vaults.

The NO_x concentrations from construction of the wasteform facility for grouted U_3O_8 disposal, shown in the upper half of Table I.17, would be slightly smaller than the NO_x concentrations for construction of vaults for grouted U_3O_8 disposal. However, construction of the wasteform facility would result in smaller ranges of impacts because the construction would take place only on a centrally located area; the ranges in this case reflect only the variability due to the different meteorological data sets used. For construction of the wasteform facility, the CO, HC, SO_x, and PM_{10} impacts relative to the NO_x impacts would be the same as those discussed for operation of the shallow earthen structure disposal of grouted U_3O_8.

Construction and operation would occur simultaneously for most of the operational phase. The combined construction and operations emissions might result in annual NO_x concentrations as large as 45 $\mu g/m^3$ at 2,460 ft (750 m) for the vault disposal of grouted U_3O_8, approaching 50% of the standard.

Operation of the wasteform facility would produce 0.6 lb/yr and 1.1 lb/yr of uranium emissions from the process stack for grouted U_3O_8 and grouted UO_2 suboptions, respectively, but no uranium emissions for the ungrouted suboptions. The impacts of uranium oxides emitted during operation of the wasteform facility for grouted disposal options are shown in Table I.19. Comparing the ranges of concentrations for the wet and dry settings indicates that the uranium emissions from the central point source would produce a slightly wider range of impacts for the dry setting than for the wet setting, in contrast to the wider wet setting impact ranges that would result for criteria pollutants from all the construction and operations area sources.

TABLE I.16 Scaling Factors for Criteria Pollutant Emissions from Construction and Operations for Disposal Options Relative to Emissions from Construction Activities Associated with Disposal Facilities for Grouted U_3O_8

	Scaling Factors	
Disposal Facility	Construction	Operations
Wasteform facility		
Grouted U_3O_8	1.00	0.62
Ungrouted U_3O_8	0.28	0.0041
Grouted UO_2	0.51	0.17
Ungrouted UO_2	0.17	0.0041
Shallow earthen structure		
Grouted U_3O_8	1.00	1.85
Ungrouted U_3O_8	0.51	0.87
Grouted UO_2	0.35	0.74
Ungrouted UO_2	0.26	0.56
Vault		
Grouted U_3O_8	1.00	2.87
Ungrouted U_3O_8	0.48	1.38
Grouted UO_2	0.21	1.12
Ungrouted UO_2	0.14	0.75

No quantitative estimate was made of the impacts on the ozone conditions. Ozone formation is a regional issue that would be affected by emissions for the entire area around a proposed disposal site. The pollutants most relevant to ozone formation that would result from the disposal of depleted uranium oxide are HC and NO_x. In later Phase II studies, when specific technologies and sites would be selected, the potential effects on ozone of releases of these pollutants at a proposed site could be evaluated by comparing those releases with the total emissions of HC and NO_x in the surrounding area. Small additional contributions to the regional totals would be unlikely to alter the ozone attainment status of the region.

I.3.4 Water and Soil

Tables I.20 through I.23 summarize the resource requirements for construction and operation of the wasteform facility, shallow earthen structure disposal facility, vault disposal facility, and mine disposal facility, respectively. Examination of these data indicates that the ranking of

TABLE I.17 Maximum NO_x Concentrations at Three Receptor Distances from Construction of the Wasteform Facility and Operation of Vaults for Disposal of Grouted U_3O_8

1,500 m	310 – 690	110 – 280	48 – 160	19 – 67	1.3 – 5.2

facilities (largest to smallest) on the basis of resource requirements would be as follows: mine, vault, shallow earthen structure, and wasteform facility. For each facility, a secondary ranking indicates that the resource requirements would be consistently larger for disposal of U_3O_8, and grouted forms would require more resources than ungrouted.

Because the disposal option is based on a generic site without a specified location and detailed description, impacts could not be assessed on a site-specific basis; however, the impacts to surface water, groundwater, and soil would follow the same ranking as that for resource needs. For example, construction and operation of a mine disposal facility for U_3O_8 in a grouted form would produce the greatest impacts to the environment; the least impacts would result from construction and operation of the shallow earthen structure for disposal of ungrouted UO_2.

1108

1,500 m	97 – 220	37 – 100	17 – 55	6.6 – 22	0.35 – 1.3

If the disposal facility was located on a site having an area that was large compared with the size of the facility, and if it was near a river having a minimum flow that was large compared with annual water use and wastewater discharge, impacts to surface water, groundwater, and soil would be negligible. Negligible impacts would occur because a large site and large river could provide sufficient resource buffering to mitigate the effects produced by construction and operation of the facility.

On the other hand, if the site or the minimum flow in the river were small relative to the resource requirements, impacts would be larger. For example, if the minimum flow in the river was 500 gpm, the net annual water withdrawal for operation of the wasteform facility for disposing of grouted U_3O_8 would be about 10% of the flow. The impact of this relative withdrawal could produce moderate impacts to existing floodplains. Similarly, if the mine disposal facility were located on a 500-acre (200-ha) site, paving 94 acres (38 ha) for disposing of depleted uranium as grouted U_3O_8 would permanently alter the soil structure of almost 20% of the land available. This disruption could produce moderate to large impacts to runoff at the site and moderate to large impacts to soil permeability and erosion potential.

More detailed calculations would be performed in the next tier of analyses if a disposal facility option were selected. In general, impacts could be minimized by constructing and operating a facility that would have the smallest resource requirements.

TABLE I.19 Maximum Annual Average Uranium Concentrations in Air during Operation of the Wasteform Facility for Disposal of Grouted Uranium Oxide

Site Environment/ Receptor Distance	Maximum Annual Average Uranium Concentration ($\mu g/m^3$)
Disposal as Grouted UO_2	
Dry setting	
750 m	$1.7 \times 10^{-5} - 3.0 \times 10^{-5}$
1,000 m	$1.2 \times 10^{-5} - 2.1 \times 10^{-5}$
1,500 m	$0.71 \times 10^{-5} - 1.3 \times 10^{-5}$
Wet setting	
750 m	$1.8 \times 10^{-5} - 2.7 \times 10^{-5}$
1,000 m	$1.2 \times 10^{-5} - 2.0 \times 10^{-5}$
1,500 m	$0.76 \times 10^{-5} - 1.3 \times 10^{-5}$
Disposal as Grouted U_3O_8	
Dry setting	
750 m	$0.94 \times 10^{-5} - 1.6 \times 10^{-5}$
1,000 m	$0.66 \times 10^{-5} - 1.2 \times 10^{-5}$
1,500 m	$0.39 \times 10^{-5} - 0.72 \times 10^{-5}$
Wet setting	
750 m	$0.96 \times 10^{-5} - 1.5 \times 10^{-5}$
1,000 m	$0.68 \times 10^{-5} - 1.1 \times 10^{-5}$
1,500 m	$0.42 \times 10^{-5} - 0.70 \times 10^{-5}$

I.3.5 Socioeconomics

The socioeconomic impacts of each disposal option were assessed for a generic site because the location of a disposal facility has not yet been determined. Impacts for each facility are presented for the peak construction year and the first year of operations. Discussion of the assessment methodology is presented in Appendix C and Allison and Folga (1997). Table I.24 shows construction-related impacts (engineering, construction, project management, and site preparation and restoration activities), and operations-related impacts (operation, emplacement and closure, surveillance, and maintenance activities). Impacts for each facility are presented separately. Because the wasteform facility would be utilized to process waste at the disposal site for each disposal option,

the total impact of each option would be the summation of the impacts of the wasteform facility and the impact of each separate option.

I.3.5.1 Disposal as U_3O_8

The impacts of U_3O_8 disposal options in both grouted and ungrouted form on direct employment and income are shown in Table I.24. Construction of a wasteform facility for grouted U_3O_8 would create 360 direct jobs and $15 million in direct income during the peak year of construction in 2006. Operation of the grouted U_3O_8 wasteform facility would create 90 direct jobs and produce $13 million in direct income with the beginning of facility operations in 2009. Construction of a wasteform facility for ungrouted U_3O_8 would create 110 direct jobs and $4 million in direct income during the peak year of construction in 2006. Operation of the ungrouted U_3O_8 wasteform facility would create 40 direct jobs and produce $5 million in direct income annually with the beginning of facility operations in 2009.

Construction of a shallow earthen structure for grouted U_3O_8 would create 10 direct jobs and $1 million in direct income during the peak year of construction in 2008. Waste placement operations for a shallow earthen structure for grouted U_3O_8 would create 50 direct jobs and produce $3 million in direct income annually with the beginning of facility operations in 2009. Construction of a shallow earthen structure for ungrouted U_3O_8 would create less than 5 direct jobs and less than $500,000 in direct income during the peak year of construction in 2008. Operation of a shallow earthen structure for ungrouted U_3O_8 would create 30 direct jobs and produce $2 million in direct income annually with the beginning of facility operations in 2009.

Construction of a vault facility for grouted U_3O_8 would create 180 direct jobs and $8 million in direct income during the peak year of construction in 2008. Waste placement operations for a vault facility for grouted U_3O_8 would create 190 direct jobs and produce $5 million in direct income annually with the beginning of facility operations in 2009. Construction of a vault facility for ungrouted U_3O_8 would create 90 direct jobs and $4 million in direct income during the peak year of construction in 2008. Operation of a vault facility for ungrouted U_3O_8 would create 40 direct jobs and produce $3 million in direct income annually with the beginning of facility operations in 2009.

Construction of a mine facility for grouted U_3O_8 would create 410 direct jobs and $27 million in direct income during the peak year of construction in 2005. Waste placement operations for a mine facility for grouted U_3O_8 would create 190 direct jobs and produce $3 million in direct income annually with the beginning of facility operations in 2009. Construction of a mine facility for ungrouted U_3O_8 would create 300 direct jobs and $20 million in direct income during the peak year of construction in 2005. Operation of a mine facility for ungrouted U_3O_8 would create 30 direct jobs and produce $2 million in direct income with the beginning of facility operations in 2009.

[a] Impacts in the peak year of construction: 2007 for the wasteform facility; 2009 for the shallow earthen structure and the vault; and 2006 for the mine. Preoperations were assumed to occur from 1999 through 2008, with construction continuing concurrently with waste placement through 2028.

[b] Impacts are the annual average for operations for the period 2009–2028 (20 years).

I.3.5.2 Disposal as UO_2

The impacts of UO_2 disposal options in both grouted and ungrouted form on direct employment and income are shown in Table I.24. Construction of a wasteform facility for grouted UO_2 would create 220 direct jobs and $9 million in direct income during the peak year of construction in 2006. Operation of the grouted UO_2 wasteform facility would create 90 direct jobs and produce $12 million in direct income annually with the beginning of facility operations in 2009. Construction of a wasteform facility for ungrouted UO_2 would create 60 direct jobs and $3 million in direct income during the peak year of construction in 2006. Operation of the ungrouted UO_2 wasteform facility would create 40 direct jobs and produce $5 million in direct income annually with the beginning of facility operations in 2009.

Construction of a shallow earthen structure for grouted UO_2 would create less than 5 direct jobs and less than $500,000 in direct income during the peak year of construction in 2008. Waste placement operations for a shallow earthen structure for grouted UO_2 would create 30 direct jobs and produce $1 million in direct income annually with the beginning of facility operations in 2009. Construction of a shallow earthen structure for ungrouted UO_2 would create less than 5 direct jobs and less than $500,000 in direct income during the peak year of construction in 2008. Operation of a shallow earthen structure for ungrouted UO_2 would create 20 direct jobs and produce $1 million in direct income annually with the beginning of facility operations in 2009.

Construction of a vault facility for grouted UO_2 would create 50 direct jobs and $2 million in direct income during the peak year of construction in 2005. Waste placement operations for a vault facility for grouted UO_2 would create 40 direct jobs and produce $2 million in direct income annually with the beginning of facility operations in 2009. Construction of a vault facility for ungrouted UO_2 would create 30 direct jobs and $1 million in direct income during the peak year of construction in 2005. Operation of a vault facility for ungrouted UO_2 would create 30 direct jobs and produce $2 million in direct income with the beginning of facility operations in 2009.

Construction of a mine facility for grouted UO_2 would create 270 direct jobs and $18 million in direct income during the peak year of construction in 2005. Waste placement operations for a mine facility for grouted UO_2 would create 40 direct jobs and produce $2 million in direct income annually with the beginning of operations in 2009. Construction of a mine facility for ungrouted UO_2 would create 250 direct jobs and $16 million in direct income during the peak year of construction in 2005. Operation of a mine facility for ungrouted UO_2 would create 30 direct jobs and produce $2 million in direct income annually with the beginning of facility operations in 2009.

I.3.6 Ecology

Moderate to large impacts to ecological resources could result from construction of a facility for disposal of U_3O_8 or UO_2. Impacts could include mortality of individual organisms,

habitat loss, or changes in biotic communities. Discussion of the methodology used to assess ecological impacts is presented in Appendix C.

I.3.6.1 Disposal as U_3O_8

I.3.6.1.1 Shallow Earthen Structure

Site preparation for the construction of a facility for the disposal of U_3O_8 in shallow earthen structures would require the elimination of approximately 46 acres (18 ha) of habitat for ungrouted U_3O_8 and 85 acres (34 ha) for grouted U_3O_8, including 3 acres (1.1 ha) that would be paved — including the areas required for construction of the wasteform facility, primarily structures and paved areas. Existing vegetation would be destroyed during land clearing activities. The vegetative communities that would be eliminated by site preparation would depend on the actual location of the facility. Although herbaceous vegetation could be reestablished relatively rapidly in a wet setting (with at least 40 in./yr [100 cm/yr] precipitation), such as in the eastern United States, a considerable period of time might be required in a dry setting (less than 10 in./yr [25 cm/yr] precipitation), such as in the western United States. The loss of 46 to 85 acres (18 to 34 ha) of undeveloped land would constitute a moderate adverse impact to vegetation. Erosion of exposed soil at construction sites could reduce the effectiveness of restoration efforts and create sedimentation downgradient of the site. The implementation of standard erosion control measures, installation of storm-water retention ponds, and immediate replanting of disturbed areas with native species would help minimize impacts to vegetation. Impacts due to facility construction are shown in Table I.25.

Wildlife would be disturbed by land clearing, noise, and human presence. Wildlife with restricted mobility, such as burrowing species or juveniles of nesting species, would be destroyed during land clearing activities. Mobile individuals would relocate to adjacent available areas with suitable habitat. Population densities and competition would increase in these areas, potentially reducing the chances of survival or reproductive capacity of displaced individuals. Some wildlife species would be expected to recolonize replanted areas near the disposal facility following completion of construction. However, habitat use in the vicinity of the facility might be reduced for some species due to the construction of a perimeter fence. Therefore, the loss of 85 acres (34 ha) of habitat for the construction of a facility for U_3O_8 disposal in shallow earthen structures would be considered a moderate adverse impact to wildlife.

Wetlands could potentially be impacted by filling or draining during construction. In addition, impacts to wetlands and aquatic habitats due to alteration of surface water runoff patterns, soil compaction, or groundwater flow could occur if the disposal facility was located adjacent to wetland or aquatic areas. However, impacts would be minimized by maintaining a buffer area around wetlands and aquatic habitats during construction of the facility. Unavoidable impacts to wetlands would require a *Clean Water Act* Section 404 permit, which might stipulate mitigative measures. Additional permitting might be required by state agencies. Depending on the facility location, water

TABLE I.25 Impacts to Ecological Resources from Disposal Facility Construction

Option/ Resource	Impacts from Disposal Facility Construction[a]		
	Shallow Earthen Structure	Vault	Mine
Disposal as U_3O_8			
Vegetation	Loss of 46 to 85 acres Moderate adverse impact	Loss of 75 to 149 acres Moderate to large adverse impact	Loss of 232 to 471 acres Large adverse impact

Protected species	Potential destruction, habitat loss	Potential destruction, habitat loss	Potential destruction, habitat loss

[a] All acreages include the wasteform facility.

withdrawal from surface waters or groundwater, as well as wastewater discharge, could potentially alter water levels (Section I.3.4), which could in turn affect aquatic ecosystems, including wetlands, especially those located along the periphery of these surface water bodies.

Prior to construction of a disposal facility, a survey for state and federally listed threatened, endangered, or candidate species, or species of special concern would be conducted so that, if possible, impacts to these species could be avoided. Where impacts were unavoidable, appropriate mitigation could be developed.

Ecological resources in the vicinity of the wasteform facility would be exposed to atmospheric emissions from facility operation; however, emission levels would be expected to be extremely low (Section I.3.3). At 230 ft (750 m) away, the highest annual average air concentration of U_3O_8 due to operation of the facility would be 1.6×10^{-5} µg/m^3. Resulting impacts to biota would be negligible.

Facility accidents, as discussed in Section I.3.2, could result in adverse impacts to ecological resources. The affected species and degree of impact would depend on a number of factors, such as location of the accident, season, and meteorological conditions.

I.3.6.1.2 Vault

The construction and operation of a facility for the disposal of U_3O_8 in vaults would generally result in impacts similar to those associated with shallow earthen structures. However, the size of the facility and area of disturbance for vault disposal would be larger. Disposal in vaults would require the disturbance of approximately 75 to 149 acres (30 to 60 ha) of habitat and 19 acres (8 ha) for paved areas, including the wasteform facility for grouted U_3O_8. This disposal option would also result in elevation of the soil surface by placement of excavated material and in reduction in soil permeability. The consequent decrease in soil moisture would make reestablishment of vegetation difficult and delay the establishment of native plant communities. This disposal option would result in a moderate to large adverse impact to existing vegetation and wildlife. Reestablishment of native vegetation over such a large area would be especially difficult in a dry environmental setting, and a considerable period of time might be required.

I.3.6.1.3 Mine

The construction and operation of a facility for the disposal of U_3O_8 in a mine would generally result in impacts similar to those associated with vaults. However, the mine option would require the disturbance of approximately 232 to 471 acres (93 to 188 ha), including 104 acres (42 ha) for buildings, paved areas, and the wasteform facility for grouted U_3O_8. This disposal option would result in elevation of the soil surface and in reduction in soil permeability. The excavated material would primarily consist of rock removed from the drifts and ramps. The consequent decrease in surface soil moisture would make reestablishment of vegetation difficult and delay the establishment of native plant communities. This disposal option would result in a large adverse impact to existing vegetation and wildlife. Reestablishment of native vegetation over such a large area would be especially difficult in a generic dry western environmental setting, and a considerable period of time might be required.

I.3.6.2 Disposal as UO_2

The construction and operation of a facility for the disposal of UO_2 would generally result in the types of impacts associated with the disposal of U_3O_8; however, the facility sizes would be smaller. A facility for disposal of UO_2 in shallow earthen structures would eliminate approximately 28 to 39 acres (11 to 16 ha) of habitat, including the wasteform facility for grouted UO_2. This habitat loss would result in a moderate adverse impact to vegetation and wildlife. A facility for the disposal of UO_2 in vaults would eliminate approximately 28 to 41 acres (11 to 16 ha) of habitat, including the wasteform facility for grouted UO_2. This loss would result in a moderate adverse impact to vegetation and wildlife. A mine disposal facility for UO_2 would result in disturbance of approximately 102 to 149 acres (41 to 60 ha) of habitat, including the wasteform facility for grouted UO_2. This habitat disturbance would constitute a large adverse impact to vegetation and wildlife.

Atmospheric emissions from wasteform facility operations would be expected to be slightly lower for grouted UO_2 disposal than for grouted U_3O_8 disposal (Section I.3.3). Emissions would be similar for ungrouted UO_2 and U_3O_8 disposal. The highest annual average air concentration of UO_2, due to operation of the facility, would be 0.00003 $\mu g/m^3$ at a distance of 230 ft (750 m) away from the facility. Resulting impacts to biota would be negligible.

I.3.7 Waste Management

Wastes would be generated during the construction of the wasteform facility. This facility would be used for the receipt of waste, grouting of the uranium oxide (if necessary), and storage of both the input and output from the facility. Waste generation would also occur during the construction of any of the three types of disposal facilities. No radioactive wastes would be generated during construction of the wasteform facility or any of the three possible disposal facilities because no radioactive materials would be used and the site would be uncontaminated. Table I.26 lists the various hazardous materials that would be generated in construction of the different types of disposal facilities. Only small differences are expected for the generation of waste for these different disposal options. The waste generated in the construction of any of these disposal facilities represents a negligible impact to DOE's waste management capabilities.

In grouting the converted uranium oxide, operation of the wasteform facility would generate two waste streams: the product (final form of uranium oxide grout) and minor amounts of secondary waste associated with making the final grout product of uranium. Table I.27 lists the volume throughputs of this facility as a function of the four different final form options for uranium. For the ungrouted wasteforms of U_3O_8 and UO_2, this facility would be used only as temporary storage between the conversion and disposal facilities. Consequently, no secondary waste streams would be generated at this facility for the ungrouted U_3O_8 and UO_2 final form options. Table I.28 lists the annual operational wastes from the wasteform facility for each of the four final waste form options (product waste) as well as the secondary waste streams expected from the two grouted waste options. The initial volumes of U_3O_8 and UO_2 listed under facility waste in Table I.28 are equivalent to the

Ungrouted UO_2	47,600	420,000	30-gal

final waste volumes expected for the two ungrouted wasteforms because no waste processing would take place in this facility for these two options.

Estimates of the amount of LLW to be disposed of at DOE waste management disposal facilities depend critically upon the time frame under consideration and the types of waste to be included. The *Waste Management Programmatic Environmental Impact Statement* (WM PEIS) estimates that 1,060,000 m^3 of LLW will be disposed of during the time frame 1995-2014 (DOE 1997). This estimate does not include any LLW from environmental restoration activities or facility stabilization activities. A more appropriate value is reported in *The 1996 Baseline Environmental Management Report* (BEMR) (DOE 1996), which estimates the total amount of LLW for treatment at waste management facilities to be 3,400,000 m^3. This estimate is for the next 75 years and includes contributions from environmental restoration and facility stabilization programs.

The majority of environmental restoration wastes are expected to be generated between 2003 and 2033, approximately the correct time frame to compare with the depleted UF_6 program. For this reason, the BEMR estimate was used for comparison with the depleted UF_6 wastes. Adjustments must be made to the BEMR estimate to convert treatment volumes into disposal volumes. Both volume reductions and expansions would occur during waste treatment and grouting, depending on the relative amounts of the different types of waste. On the basis of the WM PEIS analysis (DOE 1997), the BEMR estimate was adjusted to 4,250,000 m^3 for the estimated disposal volume. The total LLW disposal volumes from disposal of depleted uranium, as either UO_2 or U_3O_8 (grouted or ungrouted), were compared with the total estimated disposal volume for LLW for all DOE waste management activities (including environmental restoration waste). Disposal volumes were compared as total volume (m^3) because disposal facilities would typically have no throughput limitations but rather would be limited by the total volume of waste that could be accepted.

For the case of grouted U_3O_8 with a waste volume of 15,600 m^3/yr, the total disposal volume would be [(15,600) x 20 years operation] = 312,000 m^3. This would add about 7.3% to the estimated total DOE LLW disposal volume of about 4,250,000 m^3. Using a similar approach for the other cases would add about 1.7% for grouted UO_2, 3.5% for ungrouted U_3O_8, and 1.1% for

TABLE I.28 Estimated Annual Radioactive Waste Streams from Wasteform Facility Operations

Waste Stream	Treatment	Initial Volume (m^3/yr)		Final Volume (m^3/yr)		Uranium Content (kg)	Treatability Category
		Ungrouted U_3O_8	Ungrouted UO_2	Grouted U_3O_8	Grouted UO_2

[b] Determined by analogy to production facilities.

[c] Final volume based on bulk density of 40 lb/ft^3.

1/22

ungrouted UO_2 to the total volume. The amount of low-level mixed waste (LLMW) from depleted UF_6 disposal added to total nationwide LLMW load would be negligible (less than 1%).

Although more secondary wastes would be generated in producing either of the grouted wasteforms of U_3O_8 and UO_2, compared with the ungrouted wasteforms, the differences are not significant. The choice of which wasteform would be used should be based on other factors such as long-term stability of the wasteform, leach rates of the radioactive contaminants, and cost.

Waste generation for the different disposal options is not expected to vary with wet or dry environments. The choice of which disposal option would be used in a wet or dry environment is based on considerations other than waste generation.

Overall, the disposal options would generate appreciable amounts of waste for disposal in DOE facilities. Within the context of the total amount of LLW undergoing disposal in DOE facilities, these wastes would have a low impact on DOE's total waste management disposal capabilities.

I.3.8 Resource Requirements

Resource requirements for the disposal options were estimated for construction and operations. The materials required for monitoring of the groundwater and disposal cell performance would be expected to be minor.

Materials and utilities required for construction and operation of the shallow earthen structure, vault, and mine options are presented in Table I.29. In general, the amount of resources is directly related to the volume of waste to be disposed, with the greatest resources required for the grouted U_3O_8 waste form and least with the ungrouted UO_2 waste form. A fixed facility for solidification is required for the two grouted waste forms, which results in greater construction requirements. During the operations phase, cement and sand are required for solidification of the uranium oxides. The total quantities of commonly used construction materials are not expected to be significant and would be comparable to construction of a multistory building. No specialty materials (e.g., Monel or Inconel) are projected to be needed for either construction or operations phases.

Significant quantities of electrical energy could be required during construction of the mine option because most of the construction equipment utilized in underground mines is powered by electricity to avoid polluting the air in the underground work area. Similarly, a relatively higher annual consumption of electricity is projected during underground operations, compared with the other disposal facility options.

TABLE I.29 Resource Requirements for Construction and Operation of Disposal Facilities

[a] For the mine disposal facility, the unit of electricity is million MWh compared with MWh for the other disposal options.

I.3.9 Land Use

Land area requirements for each disposal option are presented in Table I.30. These data do not include acreage required for the construction phase for any of the disposal options because development of land would be incremental and space required for material excavation storage, equipment staging, and construction material laydown areas would be available on adjacent undeveloped parcels. Consequently, areal needs for construction would not be greater than those for operations.

Although no site has been chosen for facilities under each disposal option, selection of a site at or near a location that is already dedicated to similar use could result in reduced land-use impacts because immediate access to infrastructure and utility support would be possible with only minor disturbances to existing land use.

All disposal options would include a central wasteform facility where drums of uranium oxide would be received from the conversion facility and prepared for disposal. The facility would

TABLE I.30 Land Requirements and Excavated Material Volumes for Disposal Facilities

	Land Requirement[a] (acres)			
	Disposal as U_3O_8		Disposal as UO_2	
Facility	Grouted	Ungrouted	Grouted	Ungrouted
Shallow earthen structure	85	46	39	28

Mine	471	232	149	102

[a] Values include the wasteform facility areas, as follows: grouted U_3O_8 options, 9 acres, ungrouted U_3O_8 options, 4 acres; grouted UO_2 options, 6 acres; ungrouted UO_2 options, 4 acres.

Source: LLNL (1997).

include a grouting/cementing building, if necessary, which could affect the number of buildings erected for the wasteform facility. Impacts to land use from the wasteform facility would be very small and limited to clearing of required land, as well as potential minor and temporary disruptions to contiguous land parcels. No off-site impacts would be expected.

Land-use impacts resulting from the shallow earthen structure disposal option would be negligible to moderate and limited to clearing of required land and a potential slight increase in off-site vehicular traffic associated with construction activities. The shallow earthen structure option would require from 28 to 85 acres (11 to 34 ha) of land (including the wasteform facility) that would be cleared and developed incrementally. The rate of development would be determined by the selection of the wasteform. Up to 2.62 million yd^3 (2.0 million m^3) would be excavated. The large volume of excavated material that would remain on-site could, over time, result in topographical modifications of the site. Impacts of off-site disposal would be determined during the site-specific tier of NEPA documentation. Other than minor, temporary impacts associated with construction traffic, no other off-site impacts would be expected.

The vault option would require from 28 to 149 acres (11 to 60 ha) of land and would result in up to 1.62 million yd^3 (1.27 million m^3) of excavated material. Because the vault facility would be constructed incrementally (10 vault blocks per year), the amount of land disturbed during a given year would be limited. Impacts of off-site disposal would be determined during the site-specific tier of NEPA documentation.

Of all the disposal options, a mine would have the greatest potential for land-use impacts. A mine would require the largest amount of land, 102 to 471 acres (41 to 188 ha) (see Table I.30).

The construction associated with this option could result in potential land disturbance impacts for adjacent parcels. The large volume of excavated material (1.96 million yd^3 [1.5 million m^3]) would be disposed of on-site, probably resulting in topographical modifications of the site. The peak construction labor force could result in off-site land-use impacts, particularly if a remote site were chosen. Impacts could include pressure on existing commercial land and traffic congestion on local access roads and intersections.

I.3.10 Other Impacts Considered But Not Analyzed in Detail

Other impacts that could potentially occur if the disposal options considered in this PEIS were implemented include impacts to cultural resources and environmental justice, as well as impacts to the visual environment (e.g., aesthetics), recreational resources, and noise levels, and impacts associated with decontamination and decommissioning of the disposal facilities. These impacts, although considered, were not analyzed in detail for one or more of the following reasons:

- The impacts could not be determined at the programmatic level without consideration of specific sites. These impacts would be more appropriately addressed in the second-tier NEPA documentation when specific sites are considered.

- Consideration of these impacts would not contribute to differentiation among the alternatives and, therefore, would not affect the decisions to be made in the Record of Decision to be issued following publication of this PEIS.

I.4 IMPACTS OF OPTIONS — POST-CLOSURE PHASE

This section provides a summary of the potential environmental impacts associated with the post-closure phase of the disposal options. The post-closure phase considers the potential environmental impacts that could occur in the future, well beyond the time that any engineered disposal facility would be expected to function as designed. Post-closure impacts are evaluated because, no matter how well designed, all disposal facilities would be expected to release material to the environment eventually, a condition referred to as "failure."

Disposal facility failure would generally occur hundreds to thousands of years in the future (assuming no sustained effort to maintain the facility). This failure would be caused by natural degradation of the disposal structures over time, primarily from physical processes such as the intrusion of water. Following failure, the release of uranium from the facility would occur very slowly as water moved through the disposed material. This water would carry dissolved uranium through the soil under the facility, eventually contaminating the groundwater. This process could continue for thousands to millions of years because of the large amount of uranium in the disposal facility and low solubility of that uranium.

1127

In general, shallow earthen structures would be expected to contain the waste material for a period of at least several hundred years before failure. Vaults and a mine would be expected to last even longer, from many hundreds to thousands of years before failure. However, the exact time that a disposal facility would be expected to fail is extremely difficult to predict and would depend on the detailed facility design and site-specific conditions. Because of this difficulty, failure was assumed to occur at the end of a period of institutional control, 100 years after closure. The post-closure impacts were evaluated at 1,000 years after failure for all three disposal facility options.

Post-closure impacts were evaluated in three areas: (1) potential impacts to groundwater, (2) potential impacts to human health and safety, and (3) potential impacts to ecological resources. Impacts in other areas would be expected to be negligible. The following general assumptions apply to the assessment of post-closure impacts:

- All disposal facilities would fail at some time in the future. Failure is defined as the release of uranium material from the disposal facility to the surrounding soil. For consistency, failure was assumed to occur at the end of institutional control, 100 years after closure.

- The post-closure phase primarily considers impacts from the potential contamination of groundwater and surface water. Potential impacts from contamination of air and soil due to erosion of the disposal facility surface are also discussed.

- Impacts were evaluated at a time of 1,000 years after the facility failed and started to release uranium.

- Two generic environmental settings were assumed for the disposal facilities: a dry setting and a wet setting (see Section 3.4.4 for details).

- For analysis of groundwater impacts, assumptions were varied to assess a broad range of possibilities with respect to movement of the uranium through the soil to the groundwater aquifer.

The estimated impacts associated with the post-closure phase are subject to a great deal of uncertainty because the assessment considers an extremely long period of time and depends on predicting the behavior of the waste material as it interacts with soil and water in a complex and changing environment. Consequently, the estimated impacts are very dependent on the assessment assumptions. Key assumptions include such factors as soil characteristics, water infiltration rates, depth to the underlying groundwater table, chemistry of different uranium compounds, and the locations of future human receptors. These factors can vary widely depending on site-specific conditions. Because of these uncertainties, the assumptions were generally selected in a manner intended to produce conservative estimates of impact, that is, the assumptions tend to overestimate

the expected impact. Changes in key disposal assumptions could yield significantly different estimates of impact.

I.4.1 Human Health — Normal Operations

I.4.1.1 Radiological Impacts

Radiation doses and cancer risks for the post-closure phase were assessed for a hypothetical individual who would live at or near the disposal site after the institutional control period of the site ended. This individual was assumed to drill a well at the edge of the disposal site and use the well water for drinking, household purposes, irrigating plant foods and fodder, and watering livestock. Because of leaching of uranium from the disposal area to the groundwater table, the hypothetical resident could be exposed to radiation through use of contaminated well water. Detailed discussions of the methodologies used in radiological impact analyses are provided in Cheng et al. (1997). Additional information on the methodology and assumptions used in the groundwater analyses is provided in Section I.4.2.

The estimated groundwater concentrations involve large degrees of uncertainty because of the preliminary nature of facility design and the various soil properties that depend on the location of the facility. The radiological impacts estimated by using the groundwater concentrations are subject to a large degree of uncertainty as well. The groundwater contamination would persist for millions of years once it occurred because of the large inventory of U_3O_8 and UO_2 in the disposal area. Because of the long decay half-lives of uranium isotopes and the continuous generation of decay products, the maximum radiation dose, which could be greater than 1 rem/yr from using contaminated groundwater, would not be observed until sometime after 10,000 years, a time frame well beyond that considered in this analysis. Table I.31 lists the calculated radiation doses and cancer risks for the maximally exposed individual (MEI) 1,000 years after the failure of engineering barriers and waste containers. Although impacts from using the contaminated groundwater at that time could reach 110 mrem/yr, they could be either minimized by treating the groundwater or eliminated by switching to a clean water source.

In addition to the possible exposures resulting from use of contaminated groundwater, radiological impacts could be caused by external radiation and inhalation of contaminated dust particles if all the cover materials above the disposal site were removed and if containers of U_3O_8 or UO_2 disintegrated. This scenario could be caused by natural forces of erosion over long periods of time or by human intervention (i.e., digging) to bring the waste to the surface. The associated external radiation dose could be as high as 10 rem/yr for an individual living on the disposal site. However, the exposure would not occur until several thousand years after closure of the shallow earthen structure or vault disposal facility and would be quite unlikely for mine disposal because a mine would be located at a depth of several hundred feet below the ground surface. Detailed analyses for this exposure scenario were not conducted because it is beyond the time frame considered in this

TABLE I.31 Human Health Impacts for the MEI from Disposal Options: Post-Closure Phase

Option/ Location[a]	Radiological Impacts at 1,000 Years[b,c]				Chemical Impacts at 1,000 Years[b,c]

Wet	0.64 – 84	0.59 – 77	3×10^{-7} – 4×10^{-5}	2×10^{-7} – 4×10^{-5}	0.1 – 10	0.1 – 9.3

[a] Two generic environmental settings were considered for each option, corresponding to dry and wet environments, respectively.

[b] Impacts are reported as ranges, which result from different transport speeds of radionuclides in the unsaturated and saturated zones. Retardation factors of 5 and 50 were used to represent relatively mobile and immobile transport situations, respectively. Values correspond to estimated impacts 1,000 years after failure of the engineering barriers and containers.

[c] The maximally exposed individual was assumed to live at the edge of the disposal site and use contaminated groundwater for drinking, irrigating plant foods and fodder, and feeding livestock. The exposure pathways considered were ingestion of drinking water, plant foods, meat, and milk; and, for radiological exposures, inhalation of radon emanating from household water.

[d] The hazard index is an indicator for potential adverse health effects other than cancer; a hazard index of greater than 1 indicates a potential for adverse health effects and a need for further evaluation.

analysis. If any exposure occurred, the radiation dose could be eliminated by adding new cover materials to the top of the waste area.

I.4.1.1.1 Disposal as U_3O_8

Radiological impacts are presented in Table I.31 for a scenario in which an individual uses contaminated groundwater. In a dry setting, it would take more than 10,000 years for uranium and its decay products to reach the groundwater because of the low water infiltration rate. Therefore, no radiation exposure would occur before 1,000 years in a dry environment, the time frame considered in this analysis.

In a wet setting, the required time for uranium and decay products to reach the groundwater table could be less than 1,000 years after the failure of the disposal facility. The groundwater concentrations would vary from site to site, depending on the specific soil properties (which determine whether the uranium and decay products travel rapidly or slowly in soil). As a result, at 1,000 years after failure of the disposal facility, the radiation dose from using groundwater could range from 41 to 72 mrem/yr for disposal in shallow earthen structures, 48 to 84 mrem/yr for disposal in vaults, and 0.72 to 110 mrem/yr for disposal in a mine. With no remediation effort, the radiation dose could exceed the dose limit of 25 mrem/yr set for low-level waste disposal (10 CFR Part 61). Variation of radiation doses among different disposal types is related to the size of the disposal facility. More discussions are provided in Section I.4.2 regarding the effect of facility dimensions on groundwater concentrations.

I.4.1.1.2 Disposal as UO_2

Variations in disposal settings and disposal types have the same effects on the groundwater concentrations for UO_2 disposal as they do on the groundwater concentrations for U_3O_8 disposal. The time required for uranium and decay products to reach the groundwater table would be greater than 10,000 years for a dry setting, so no impacts would be expected within 1,000 years. The radiation doses estimated for a wet setting for disposal of UO_2 tend to be smaller than those for disposal of U_3O_8 because the waste volume of UO_2 would be less than the volume of U_3O_8 and would require a smaller disposal facility. The doses estimated for use of groundwater range from 34 to 54 mrem/yr for disposal in shallow earthen structures, 34 to 56 mrem/yr for disposal in vaults, and 0.59 to 84 mrem/yr for disposal in a mine at 1,000 years after failure of the disposal facility. With no remediation effort, the exposure could exceed the dose limit of 25 mrem/yr set for low-level waste disposal.

I.4.1.2 Chemical Impacts

Chemical impacts during the post-closure phase are assessed for a hypothetical individual who lives at the border of the disposal site after the institutional control period is over. As for the radiological assessment, potential chemical impacts to human health were evaluated for a scenario involving a hypothetical individual who drills a well at the edge of the disposal site and uses the well water for drinking, irrigating plant foods and fodder, and watering livestock. Leaching of uranium from the disposal area to the groundwater table could potentially result in the hypothetical resident being exposed to uranium from ingestion of drinking water, plant foods, meat, and milk. Risks are estimated on the basis of calculated hazard indices. Information on the exposure assumptions, health effects assumptions, reference doses used for uranium compounds, and calculational methods used in the chemical impact analysis are provided in Appendix C and Cheng et al. (1997).

I.4.1.2.1 Disposal as U_3O_8

Potential health impacts to the general public MEI from exposures to hazardous chemicals due to use of groundwater are presented in Table I.31. Two disposal options are evaluated: disposal as grouted U_3O_8 and ungrouted U_3O_8. The hazard indices for chemical impacts in a dry environment are always zero because the time required for the uranium to reach the groundwater would be greater than 10,000 years due to the low water infiltration rate. In a wet environmental setting, the time to reach groundwater would be less than 1,000 years, but would be dependent on the soil properties (i.e., retardation factor). A retardation factor of 5 results in the uranium reaching the groundwater more quickly and consequently producing greater chemical exposures at 1,000 years than would occur with a retardation factor of 50.

The range of hazard indices for all types of disposal facilities in a wet setting is about 0.1 to 14, exceeding the threshold of 1 for potential adverse health effects. The highest values are for mines, which would require the largest disposal area; and the lowest values are for shallow earthen structures, which would require the smallest disposal area. On the basis of maximum hazard indices, potential chemical impacts are greater for disposal as grouted waste than as ungrouted waste because of the larger waste volume that would be required. Among the groundwater-related exposure pathways that were analyzed, ingestion of drinking water is responsible for more than 80% of the total uranium exposure.

I.4.1.2.2 Disposal as UO_2

Potential human health impacts to the general public MEI from exposures to hazardous chemicals due to groundwater use are presented in Table I.31. Two disposal options were evaluated: disposal as grouted UO_2 and ungrouted UO_2. Differences in environmental settings and types of disposal facilities result in the same variations in groundwater concentrations for UO_2 disposal as they do in the groundwater concentrations for U_3O_8 disposal. Because the waste volume of UO_2

would be less than the volume of U_3O_8, the estimated maximum chemical exposures for UO_2 disposal are consistently less than those for U_3O_8 disposal.

The range of hazard indices for all types of UO_2 disposal facilities in a wet setting is about 0.1 to 10, exceeding the threshold of 1 for potential adverse health effects. The highest values are for mines, which would require the largest disposal area; and the lowest values are for shallow earthen structures, which would require the smallest disposal area. Based on maximum hazard indices, potential chemical impacts are greater for disposal as grouted waste because of the larger waste volume that would be required compared with disposal as ungrouted waste.

I.4.2 Groundwater

Potential impacts to groundwater for the three disposal options during the post-closure phase only include changes in groundwater quality. There would be no impacts to effective recharge, depth to groundwater, or the direction of groundwater flow.

I.4.2.1 Shallow Earthen Structure

During the post-closure period, the only potential impacts to groundwater would be to water quality. With time, the roof material would and allow water to infiltrate the disposal facility. This water could corrode the drums and permit leaching of their contents. Although both forms of the disposed material (U_3O_8 and UO_2) are essentially insoluble in water (LLNL 1997), a conservative estimate of dissolution was obtained by assuming that schoepite ($UO_3 \cdot H_2O$) would form under the aerobic conditions present in the structure.

With additional time (several hundred to thousands of years), the facility would fail completely, and dissolved schoepite would infiltrate the soil beneath the structure and interact with soil water present in the unsaturated zone. For the shallow earthen structure, this soil water would have a nearly neutral pH (about 7). For the ungrouted case, this interaction would have no impact, and the dissolved schoepite would move vertically downward toward the water table. Transport of the schoepite would be influenced by advection, dispersion, adsorption, and decay (Tomasko 1997).

For the grouted wastes, schoepite was again assumed to form at a concentration equal to its equilibrium value, although carbonates might also form, depending on the type of grout used and site-specific conditions. Because schoepite is about two million times more soluble under the high pH conditions that would occur for the grouted forms of the waste (pH between 10 and 12), the disposed material would dissolve at greatly different rates. However, once the schoepite reached the groundwater, its concentration would be oversaturated relative to the soil water, and it would precipitate and then slowly redissolve. After redissolving, it would be transported vertically downward through the unsaturated zone in the same way that transport would occur for the ungrouted case (Tomasko 1997).

At the water table, schoepite would mix with initially clean water in the uppermost groundwater aquifer and be diluted. After mixing and dilution, the contaminants would be transported in a direction consistent with natural flow. Advection, dispersion, adsorption, and decay would again influence the transport process (Tomasko 1997).

Uranium concentrations and activities at the water table for a wet environmental setting are summarized in Table I.32 for 1,000 years after failure. Values are shown for lateral distances of 0 and 1,000 ft (300 m) downgradient of the facility. For a dry setting, the concentrations would be very small (nearly zero) and are not shown. Additional details on the calculations for the dry location are presented in Tomasko (1997).

The highest uranium groundwater concentrations (270 pCi/L; 1,100 µg/L) would result from a grouted U_3O_8 wasteform; the lowest concentrations (188 pCi/L; 760 µg/L) would result from ungrouted UO_2 (see Table I.32). All of the predicted concentrations would exceed the U.S. Environmental Protection Agency (EPA) proposed maximum contaminant level (MCL) of 20 µg/L (EPA 1996) used for comparison. In all cases, concentrations from grouted wasteforms would be higher than those from ungrouted forms over the long term. This result occurs because a larger facility would be required for the grouted wastes, which would, in turn, reduce the amount of subsequent dilution when the leachate mixes with water in the underlying aquifer. Impacts to groundwater quality could be reduced by decreasing the size of the facility in a direction parallel to the direction of groundwater flow, thereby increasing dilution. The relative concentrations for the decay products formed during transport are reported in Tomasko (1997).

Varying the distance to the receptor from 0 to 1,000 ft (300 m) would have no effect on concentrations if the uranium was relatively mobile in the soil (a retardation of 5 [Table I.32]). This result occurs because of hydrological conditions present in the soil beneath the facility in the wet environment (Tomasko 1997). If the uranium was less mobile and had a retardation coefficient of 50, the concentration at 1,000 years at a lateral distance of 1,000 ft (300 m) would be about 100 times less than the concentration directly below the edge of the facility (0 ft) (Table I.32).

I.4.2.2 Vault

The disposal vault would be located in a dry or wet environment. Because of the design of the facility with a concrete slab roof and other engineered barriers (LLNL 1997), the vault would be expected to have an effective life ranging from several hundred years to tens of thousands of years. Failure of this facility would parallel the failure process described for the shallow earthen structure, and the only impacts to groundwater would be changes in quality once the facility failed completely.

Uranium concentrations in groundwater at 1,000 years for distances of 0 and 1,000 ft (300 m) from the edge of the vault are given in Table I.32. As for the shallow earthen structure, concentrations in the dry environment would be nearly zero, and are not presented here. At 1,000 years, uranium concentrations for a relatively mobile uranium species (retardation coefficient

TABLE I.32 Uranium Activity and Schoepite Concentration in Groundwater for the Disposal Options at 1,000 Years in a Wet Environmental Setting: Retardation Factor = 5 or 50[a]

Ungrouted U_3O_8	1,400	11	1,400	0
Grouted UO_2	1,300	9.7	1,300	0
Ungrouted UO_2	1,200	8.9	1,200	0

[a] The retardation factor (Rf) describes how readily a contaminant such as uranium moves through the soil to the groundwater. An Rf of 5 represents a case in which the uranium moves relatively rapidly through the soil, whereas an Rf of 50 represents a case in which the uranium moves very slowly through the soil.

of 5) would be the same at 0 and 1,000 ft (300 m) downstream of the facility because of the hydrological characteristics of the saturated zone (Tomasko 1997). The maximum concentration of uranium would be 315 pCi/L (1,300 µg/L) for grouted U_3O_8, and the minimum concentration (189 pCi/L; 760 µg/L) would occur for ungrouted UO_2 (Table I.32). These values would exceed the proposed EPA MCL of 20 µg/L (EPA 1996) used for comparison. The differences in concentrations between the different wasteforms primarily results from differences in the size of the facility. That is, the larger the facility, the greater the concentration because of decreased dilution. Impacts to groundwater quality could be reduced by decreasing the size of the facility in a direction parallel to the direction of groundwater flow, thereby increasing dilution (Tomasko 1997).

If the uranium were less mobile in the saturated zone and had a retardation coefficient of 50, uranium concentrations at 1,000 ft (300 m) would be about 100 times less than the concentration directly below the edge of the facility. Because of design considerations (size of the facility), the concentrations from the vault would be greater than those from the shallow earthen structure by about a factor of 1.2 (Tomasko 1997).

I.4.2.3 Mine

For disposal in a mine, waste would be placed in a mine hundreds of feet below the ground surface to minimize intrusion and potential erosion of a surface cap. The effective life of the mine would be expected to be thousands of years. As with the shallow earthen structure and vault, the only impacts to groundwater would be to quality once the facility failed completely.

If the disposal site were located in a dry environment, all of the resulting uranium concentrations at 1,000 years would be nearly zero (Tomasko 1997). In a wet climate, the uranium concentrations would all greatly exceed the proposed EPA MCL if the uranium was mobile (retardation coefficient of 5) (Table I.32) because the distance from the bottom of the mine to the top of the next lower aquifer was assumed to be small (100 ft). If the schoepite was less mobile (retardation coefficient of 50), uranium concentrations in groundwater after 1,000 years would be much less than the EPA proposed MCL and would be the smallest of all the disposal options considered (Table I.32) because the mine was assumed to be located at a distance of 100 ft (30 m) from the water table, whereas the shallow earthen structure and vault were assumed to be 30 ft (9.1 m) from the underlying aquifer. Impacts to groundwater quality could be reduced by decreasing the size of the facility in a direction parallel to the direction of groundwater flow, thereby increasing dilution (Tomasko 1997).

I.4.3 Ecology

Predicted concentrations of contaminants in groundwater were compared to benchmark values of toxic and radiological effects to assess impacts to biota. Discussion of assessment methodology is presented in Appendix C.

I.4.3.1 Disposal as U_3O_8

The disposal facilities considered would be expected to adequately prevent the release of their contents for considerable periods of time. Impacts to ecological resources due to the presence of the facility would not be expected to occur prior to facility failure. Failure of facility integrity would result in contamination of groundwater if the facility was located in a wet environmental setting (typical of the eastern United States, with at least 40 in./yr [100 cm/yr] precipitation). Groundwater could discharge to the surface (such as in wetland areas) near the facility, thus exposing biota to contaminants. Groundwater concentrations of schoepite ($UO_3 \cdot 2H_2O$) were calculated for 1,000 years after facility failure (Section I.4.2). Schoepite concentrations would be nearly zero throughout the time period analyzed for a disposal facility located in a dry environmental setting (typical of the western United States, with less than 10 in./yr [25 cm/yr] precipitation). Ecological impacts are summarized in Table I.33.

Failure of a shallow earthen structure disposal facility would result in groundwater concentrations of schoepite near the facility ranging from 3.1×10^{-6} to 1.1×10^{-3} g/L (0.003 to 1.5 ppm). Soluble uranium compounds can produce toxic effects in aquatic biota at concentrations as low as 1.5×10^{-4} g/L (0.15 ppm). An organism continuously exposed to the undiluted groundwater could therefore be adversely impacted by the toxic effects of uranium. Uranium activity would range from 2.0 to 270 pCi/L (Section I.4.2). Resulting dose rates to maximally exposed organisms would be less than 0.015 rad/d, less than 2% of the dose limit of 1 rad/d for aquatic organisms specified in DOE Order 5400.5.

Failure of a facility for disposal in vaults would result in groundwater concentrations of schoepite ranging from 9.7×10^{-6} to 1.3×10^{-3} g/L (0.01 to 1.3 ppm). Therefore an organism continuously exposed to this undiluted groundwater could be adversely impacted by the toxic effects of uranium. Uranium activity would range from 2.4 to 315 pCi/L (Section I.4.2). Resulting dose rates to maximally exposed organisms would be less than 0.015 rad/d, less than 2% of the dose limit of 1 rad/d.

Failure of a mine disposal facility would result in groundwater concentrations ranging from 0 to 1.7×10^{-3} g/L (1.7 ppm). Adverse impacts to aquatic biota could result from exposure to soluble uranium compounds within this concentration range. Uranium activity would range from 0 to 425 pCi/L (Section I.4.2). Resulting dose rates to maximally exposed organisms would be less than 0.015 rad/d, less than 2% of the dose limit of 1 rad/d.

I.4.3.2 Disposal as UO_2

Groundwater schoepite concentrations resulting from the failure of a facility for disposal of UO_2 would also be nearly zero at 1,000 years for a facility in a dry environmental setting. Groundwater concentrations for disposal of UO_2 in a wet environmental setting would be similar to those for disposal of U_3O_8.

TABLE I.33 Potential Radiological and Chemical Impacts to Aquatic Biota due to Failure of a Disposal Facility

Option/Contaminant	Maximum Exposure	Effect
Disposal as U_3O_8		
Shallow earthen structure		
Uranium in groundwater	2.0 to 270 pCi/L	Negligible
Uranium in groundwater	3.1×10^{-6} to 1.1×10^{-3} g/L	Moderate
Vault		
Uranium in groundwater	2.4 to 315 pCi/L	Negligible
Uranium in groundwater	9.7×10^{-6} to 1.3×10^{-3} g/L	Moderate
Mine		
Uranium in groundwater	0 to 425 pCi/L	Negligible
Uranium in groundwater	0 to 1.7×10^{-3} g/L	Negligible to moderate
Disposal as UO_2		
Shallow earthen structure		
Uranium in groundwater	1.7 to 204 pCi/L	Negligible
Uranium in groundwater	6.9×10^{-6} to 8.2×10^{-4} g/L	Moderate
Vault		
Uranium in groundwater	1.7 to 209 pCi/L	Negligible
Uranium in groundwater	6.9×10^{-6} to 8.4×10^{-4} g/L	Moderate
Mine		
Uranium in groundwater	0 to 316 pCi/L	Negligible
Uranium in groundwater	0 to 1.3×10^{-3} g/L	Negligible to moderate

Failure of a shallow earthen structure facility would result in groundwater concentrations of schoepite near the facility ranging from 6.9×10^{-6} to 8.2×10^{-4} g/L (0.007 to 0.82 ppm). Soluble uranium compounds can produce toxic effects in aquatic biota at concentrations as low as 1.5×10^{-4} g/L (0.15 ppm). An organism continuously exposed to the undiluted groundwater could be adversely impacted by the toxic effects of uranium. Uranium activity would range from 1.7 to 204 pCi/L (Section I.4.2). Resulting dose rates to maximally exposed organisms would be less than 0.015 rad/d, less than 2% of the dose limit of 1 rad/d.

Failure of a facility for disposal in vaults would result in groundwater concentrations of schoepite ranging from 6.9×10^{-6} to 8.4×10^{-4} g/L (0.007 to 0.84 ppm). Therefore, an organism

continuously exposed to this undiluted groundwater could be adversely impacted by the toxic effects of uranium. Uranium activity would range from 1.7 to 209 pCi/L (Section I.4.2). Resulting dose rates to maximally exposed organisms would be less than 0.015 rad/d, less than 2% of the dose limit of 1 rad/d.

Failure of a mined cavity disposal facility would result in groundwater schoepite concentrations ranging from 0 to 1.3×10^{-3} g/L (1.3 ppm). Adverse impacts to aquatic biota could result from exposure to soluble uranium compounds within this concentration range. Uranium activity would range from 0 to 316 pCi/L (Section I.4.2). Resulting dose rates to maximally exposed organisms would be considerably lower than the dose limit of 1 rad/d.

NOTATION (APPENDIX J)

The following is a list of acronyms and abbreviations, including units of measure, used in this document. Some acronyms used only in tables are defined in those tables.

ACRONYMS AND ABBREVIATIONS

General

CFR	*Code of Federal Regulations*
DOE	U.S. Department of Energy
DOT	U.S. Department of Transportation
ICRP	International Commission on Radiological Protection
LCF	latent cancer fatality
LLNL	Lawrence Livermore National Laboratory
LLMW	low-level mixed waste
LLW	low-level radioactive waste
MEI	maximally exposed individual
NEPA	*National Environmental Policy Act*
PEIS	programmatic environmental impact statement

Chemicals

CaF_2	calcium fluoride
HF	hydrogen fluoride; hydrofluoric acid
MgF_2	magnesium fluoride
NH_3	ammonia
UF_6	uranium hexafluoride
UO_2	uranium dioxide
U_3O_8	triuranium octaoxide (uranyl uranate)

UNITS OF MEASURE

ft	foot (feet)
h	hour(s)
kg	kilogram(s)
km	kilometer(s)
lb	pound(s)
m	meter(s)
mrem	millirem(s)

APPENDIX J:

ENVIRONMENTAL IMPACTS OF TRANSPORTATION OF UF_6 CYLINDERS, URANIUM OXIDE, URANIUM METAL, AND ASSOCIATED MATERIALS

The U.S. Department of Energy (DOE) is proposing to develop a strategy for long-term management of the depleted uranium hexafluoride (UF_6) inventory currently stored at three DOE sites in Paducah, Kentucky; Portsmouth, Ohio; and Oak Ridge, Tennessee. This programmatic environmental impact statement (PEIS) describes alternative strategies that could be used for the long-term management of this material and analyzes the potential environmental consequences of implementing each strategy for the period from 1999 through 2039. This appendix provides detailed information describing the transportation of radioactive and other hazardous materials associated with the options considered in the PEIS. The discussion provides background information, as well as a summary of the estimated environmental impacts associated with transportation.

Transportation

The transportation of hazardous and radioactive materials was assessed for all alternative strategies considered in the PEIS for management of the depleted UF_6 inventory currently stored at three DOE sites. For purposes of analysis, it was assumed that all long-term storage, conversion, disposal, and manufacture and use facilities would be located at different sites, thus requiring the transportation of materials between sites. The PEIS transportation assessment considered the impacts from all shipments associated with each category of the options that make up the alternatives. The materials considered include depleted UF_6 cylinders, uranium conversion products, chemicals required for or produced during processing (such as hydrogen fluoride and hydrochloric acid), as well as any low-level radioactive, low-level mixed radioactive, and hazardous waste generated during operations. The analysis considered both truck and rail shipment options.

All of the PEIS alternatives would involve some transportation of radioactive and hazardous materials. For purposes of the PEIS analysis, it was assumed that all long-term storage, conversion, disposal, and manufacture and use facilities would be located at different locations. Thus, transportation would form the links between the options that make up each of the PEIS alternatives, as shown graphically in Chapter 2, Figures 2.2 through 2.6. In reality, the transportation activities actually required by an alternative would depend on the locations of the facilities involved — if facilities were colocated, the transportation of materials, and any associated impacts, would be minimized or eliminated.

The transportation assessment considered all shipments associated with the categories of options that make up each of the PEIS alternatives. The primary uranium materials transported under these alternatives include depleted UF_6 cylinders, uranium oxide (uranium dioxide [UO_2] or triuranium octaoxide [U_3O_8]), uranium metal, and uranium oxide and uranium metal storage casks (see Table J.1). Also, each alternative would involve transportation of chemicals required for or

TABLE J.1 Primary Uranium Materials Transported under Each Management Alternative

PEIS Alternative	Primary Material Transported[a]				
	Depleted UF_6 Cylinders	Oxide (UO_2 or U_3O_8)	Uranium Metal	Uranium Oxide Casks	Uranium Metal Casks
No action	–	–	–	–	–
Long-term storage as UF_6	X[b]	–	–	–	–
Long-term storage as oxide	X	X	–	–	–
Use as uranium oxide	X	X	–	X	–
Use as uranium metal	X	–	X	–	X
Disposal	X	X	–	–	–

[a] In addition to the uranium materials listed, each alternative would also involve the transportation of chemicals required for or produced during processing, as well as LLW and LLMW.

[b] X indicates that the material was assumed to be transported under that PEIS alternative.

produced during processing (such as hydrogen fluoride [HF]), as well as any low-level radioactive waste (LLW), low-level mixed waste (LLMW), and hazardous chemical waste generated during operations.

Impacts from the on-site transportation of the various materials at the different facilities (conversion, storage, manufacture, and disposal) were not computed. On-site transportation impacts are expected to be negligible when compared with the impacts associated with the off-site transportation between facilities. On-site shipments of over 19 miles (30 km) were assessed for the Hanford site for comparison with off-site shipments analyzed in the *Waste Management Programmatic Environmental Impact Statement* (DOE 1997). The on-site impacts were found to be more than 100 times smaller than the off-site impacts, primarily because of the much shorter shipment distances involved (Biwer et al. 1996). For the depleted UF_6 PEIS, shorter on-site distances are likely; therefore, the on-site transportation impacts are also expected to be more than 100 times smaller than the off-site impacts. The decisions to be made based on this PEIS would not be affected by on-site transportation impacts. In addition, transportation impacts would be much smaller for on-site shipments than off-site shipments and would also be smaller than the impacts associated with loading and unloading shipments for off-site shipments, which were included in the involved worker doses estimated for facility operations.

Additional details regarding the methodology used to assess transportation impacts are provided in Biwer et al. (1997).

J.1 SUMMARY OF TRANSPORTATION OPTION IMPACTS

The potential environmental impacts associated with transportation activities for the PEIS alternatives are summarized in Table J.2. For purposes of comparison in Table J.2, the analysis was based on the assumption that all shipments would be transported a distance of 620 miles (1,000 km), regardless of the type of material. (Transportation impacts were evaluated for distances ranging from 155 to 3,100 mi [250 to 5,000 km] in Section J.3.) The assessment considered impacts on human health that would result from the radioactive and hazardous chemical characteristics of the materials shipped, as well as the impacts that would result from operation of the transportation vehicles. Additional discussion and details related to the results for individual areas of impact are provided in Section J.3.

Various options were considered for each alternative, including the following transportation-related steps:

- ***No Action Alternative.*** No off-site transportation is expected under the no action alternative, except for a few LLW and LLMW shipments. Minor amounts of LLW and LLMW may be generated during monitoring and maintenance activities associated with the storage of the depleted UF_6 cylinders at their current locations. Fewer than one shipment per year to a disposal site would be expected for the waste generated, and no fatalities would be anticipated from waste shipments. Shipment impacts are expected to be negligible, similar to LLW and LLMW shipments from the cylinder treatment facility or the cylinder transfer facility as considered under other alternatives.

- ***Long-Term Storage as UF_6.*** Long-term storage as UF_6 would involve transportation of the depleted UF_6 cylinders from the three existing storage sites to a long-term storage facility. The cylinders might be shipped in overcontainers. If a transfer facility were used to alleviate the problem of substandard cylinders before shipment of the UF_6, shipment of LLW and LLMW from the transfer facility would be required.

- ***Long-Term Storage as Oxide.*** Long-term storage as oxide (UO_2 or U_3O_8) would involve transportation of the depleted UF_6 cylinders to an oxide conversion plant. The conversion facility would also require inbound shipments of ammonia and outbound shipments of HF and waste. Cleaning of the empty cylinders at a cylinder treatment facility colocated with the conversion facility would require outbound shipments of U_3O_8 and waste. The final transportation step would be shipment of the oxide to the long-term storage facility.

TABLE J.2 Summary of Transportation Impacts by Alternative[a]

Impacts from Long-Term Storage as UF_6	Impacts from Long-Term Storage as Oxide	Impacts from Use as Uranium Oxide Cask	Impacts from Use as Uranium Metal Cask	Impacts from Disposal

[a] Shipping distance of 621 miles (1,000 km) for all materials; vehicle-related impacts were based on round-trip distance. The no action alternative is not included in this table (see Table J.1). Fewer than one off-site shipment per year to a disposal site would be expected for the minor amounts of LLW and LLMW generated during monitoring and maintenance activities under this alternative.

[b] Radiological LCFs were estimated from the calculated dose using dose-to-risk conversion factors of 0.0005 and 0.0004 fatalities per person-rem for members of the general public and occupational workers, respectively, as recommended in Publication 60 of the International Commission on Radiological Protection (ICRP 1991). The approximate corresponding dose for each of the radiological fatality risks listed in this table may be obtained by multiplying the fatality risk by 2,500 (i.e., $1 \div 0.0004$).

Notation: CaF_2 = calcium fluoride; HF = hydrogen fluoride; LCF = latent cancer fatality; LLW = low-level radioactive waste; LLMW = low-level mixed waste; MEI = maximally exposed individual; MgF_2 = magnesium fluoride; NH_3 = ammonia; UF_6 = uranium hexafluoride; UO_2 = uranium dioxide.

1153

- ***Use as Uranium Oxide Casks.*** Use as uranium oxide casks would involve transportation of the depleted UF_6 cylinders to a UO_2 conversion plant. The conversion facility would also require inbound shipments of ammonia and outbound shipments of HF and waste. Cleaning of the empty cylinders at a cylinder treatment facility colocated with the conversion facility would require outbound shipments of U_3O_8 and waste. The UO_2 would be transported to a cask manufacturing facility, which would also generate some waste for shipment to disposal. Finally, the casks would be shipped to an end user.

- ***Use as Uranium Metal Casks.*** Use as uranium metal casks would involve transportation of the depleted UF_6 cylinders to a metal conversion plant. The conversion facility would also require inbound shipments of ammonia and outbound shipments of HF and waste. Cleaning of the empty cylinders at a cylinder treatment facility colocated with the conversion facility would require outbound shipments of U_3O_8 and waste. The metal would be transported to a cask manufacturing facility, which would also generate some waste for shipment to disposal. Finally, the casks would be shipped to an end user.

- ***Disposal.*** The disposal option would involve the same transportation steps required for long-term storage as oxide, except that the final shipments of oxide would be sent to a disposal facility rather than a storage facility.

The transportation impacts in Table J.2 are presented as ranges of values. The ranges reflect differences in risk between truck and rail modes and differences in the types and quantities of materials required within a given option. The following is a general summary of potential impacts from transportation activities (based on information in Table J.2 and additional detailed information in Section J.3):

- The analysis of transportation risks presented in Table J.2 was based on the assumption that all shipments would travel a distance of 620 miles (1,000 km) and that essentially the entire inventory of DOE-generated depleted uranium would be shipped between long-term storage, conversion, manufacture and use, and disposal facilities. Transportation risks would be reduced or eliminated by colocating facilities or minimizing shipment distances between facilities.

- In general, the greatest risk from transportation would result from vehicle-related physical hazards, that is, potential fatalities caused by the physical trauma received during transportation accidents, independent of the material transported. This risk would increase directly with the number of shipments and shipment distance.

- The overall transportation risk resulting from the radioactive characteristics of the transported material would be small, generally less than one-tenth of the risk from vehicle-related causes for a given shipment.

- The overall transportation risk resulting from the hazardous chemical characteristics of the transported material would also be small, generally less than one-tenth of the risk from vehicle-related causes for most shipments.

- There is potential for low-probability, severe transportation accidents that could have large consequences. The accidents with the largest potential consequences would be rail accidents involving a tank car containing HF. Under unfavorable weather conditions, the HF released from these accidents could result in approximately 10 irreversible adverse effects in a rural environment or approximately 30,000 irreversible adverse effects in an urban environment. These impacts are discussed in Section J.3.4.2.

- Within each material category, the total transportation risk would be dominated by shipments of depleted UF_6 cylinders, U_3O_8, UO_2, uranium metal, and uranium oxide and uranium metal casks because of the large number of shipments required for these materials. Shipments of waste and process chemicals would not contribute significantly to the overall risk, except for potential shipments of the ammonia required for some conversion options and the HF by-product associated with some conversion options.

- In general, rail transportation would result in a slightly lower overall risk than truck transportation for the same amount of material, due primarily to higher rail shipment capacities and therefore fewer shipments.

J.2 TRANSPORTATION MODES

This assessment of transportation impacts was based on data provided in the engineering analysis report (Lawrence Livermore National Laboratory [LLNL 1997]). For each category of option assessed in the PEIS, the engineering analysis report provides estimates of the types, characteristics, and quantities of each material that would require transportation.

J.2.1 Truck Transportation

Truck transportation was considered for all materials shipped, except for some bulk shipments of HF, ammonia, and spent nuclear fuel casks (which are too large for road transport). Truck shipments would generally be in legal-weight semitrailer trucks, consistent with current practices. The maximum gross vehicle weight for truck shipments is limited by the U.S. Department of

Transportation (DOT) to 80,000 lb (36,400 kg). Truck shipments of depleted UF_6 were assumed to consist of a single cylinder per trailer. Shipments of conversion products and waste materials would generally be near the maximum allowed by weight limitations.

J.2.2 Rail Transportation

Rail transportation was considered as an option to truck transportation for the shipment of bulk materials where the amount of material shipped would justify the use of full railcars. These materials would include depleted UF_6 cylinders and conversion products. For rail transportation, the average payload weights for boxcars range from 100,000 to 150,000 lb (45,000 to 68,000 kg). Rail shipments of depleted UF_6 were assumed to consist of four cylinders per railcar, with transport by regular freight train service. In general, rail transportation was not considered for shipments of waste materials and most chemicals generated or used during processing because the annual volumes of these materials would be much less than typical railcar capacities.

J.2.3 Transportation Options Considered But Not Analyzed in Detail

Air and barge transportation options were considered but not analyzed in detail. Air transportation would be prohibitively expensive and is not practical for shipping waste and large amounts of material. The use of barge transportation for the depleted UF_6 cylinders, conversion products, or manufactured products was considered but not examined in detail because sites for the proposed facilities under consideration in the PEIS have not yet been determined. Generic input parameters to estimate the risks associated with barge transport are not as readily applicable as they are for truck or rail transport because of the fixed and limited nature of the inland and coastal waterways.

The use of barge transport for bulk shipments of depleted uranium materials would be a viable alternative if both the shipping and receiving sites were located near the U.S. inland or coastal waterway systems. In general, the risk per shipment would be approximately the same as for a truck or rail (one railcar) shipment, but fewer shipments would be necessary and the costs per ton-mile much lower. The primary risks to workers would occur during loading and unloading operations. Risks to the public could occur in the vicinity of locks when the barges were stopped during their passage through the locks and from accidents that might result in potential releases to the environment. Barge transport of the depleted UF_6 cylinders from the existing storage sites would first require truck or rail transport to the nearest river port, approximately 20 to 25 miles (32 to 40 km) for the Portsmouth and Paducah sites and approximately 1 mile (1.6 km) for the K-25 site.

J.3 IMPACTS OF OPTIONS

The potential environmental impacts associated with transportation activities are summarized in this section. Additional information related to the assessment methodologies for each area of impact is provided in Appendix C.

J.3.1 General Assumptions

The environmental impacts from transportation were evaluated for each category of option (i.e., cylinder preparation, conversion, long-term storage, manufacture and use, and disposal) on the basis of information described in the engineering analysis report (LLNL 1997). The materials transported for each option category are summarized in Table J.3, along with the origin and destination sites for each material and an indication of whether the material poses a radiological, chemical, or vehicle-related risk. The following general assumptions apply to the assessment of impacts:

- Because sites for long-term storage, conversion, disposal, and manufacture and use will not be selected or known until some time in the future, transportation impacts for each material were estimated as the risk per kilometer traveled, using representative national average route statistics. For comparison, total transportation impacts are presented for shipment distances of 155, 620, and 3,100 miles (250, 1,000, and 5,000 km).

- The assessment of total transportation impacts was based on the assumption that the entire inventory of depleted uranium would be shipped between long-term storage, conversion, manufacture and use, and disposal facilities.

- National average accident occurrence rates (accidents per million miles) and fatality rates (accident fatalities per million miles) were used for accident calculations for truck and rail shipments.

- Transportation impacts were estimated for all shipments of depleted UF_6 cylinders, uranium conversion products, chemicals required for or produced during processing (such as HF and ammonia), as well as any LLW and LLMW generated during operations. Some conversion options would produce large quantities of calcium fluoride (CaF_2) or magnesium fluoride (MgF_2). CaF_2 can be used or disposed of as either sanitary waste or LLW, depending on the residual uranium concentration and applicable regulatory release limits at the time of disposal. Similarly, MgF_2 can be disposed of as sanitary waste or LLW.

TABLE J.3 Summary of Materials Transported for Each Transportation Option

Option Category	Material Transported	Risk			Origin Site	Destination Site
		Radiological	Chemical	Vehicular		
Cylinder preparation	LLW	X	X	X	UF_6 current locations	LLW disposal site
	LLMW	X	X	X	UF_6 current locations	LLMW treatment/disposal site
	Hazardous waste	X	X	X	UF_6 current locations	Hazardous waste disposal site
Conversion	Depleted UF_6	X	X	X	Current locations	Conversion site
	LLW	X	X	X	Conversion site	LLW disposal site
	LLMW	X	X	X	Conversion site	LLMW treatment/disposal site
	Hazardous waste	–	X	X	Conversion site	Hazardous waste disposal site
	U_3O_8	X	X	X	Cylinder treatment facility	Storage or disposal site
	LLW	X	X	X	Cylinder treatment facility	LLW disposal site
	LLMW	X	X	X	Cylinder treatment facility	LLMW treatment/disposal
	Hazardous waste	–	X	X	Cylinder treatment facility	Hazardous waste disposal
	HF and NH_3 (various combinations, depending on conversion option)	–	X	X	Chemical manufacturer or conversion site	Conversion or disposal site
	CaF_2	–	–	X	Conversion site	LLW disposal site
	MgF_2	–	–	X	Conversion site	LLW disposal site
Long-term storage	Depleted UF_6	X	X	X	Current locations	Long-term storage site
	UO_2 or U_3O_8	X	X	X	Conversion site	Long-term storage site
Manufacture and use	Uranium metal or UO_2	X	X	X	Conversion site	Manufacturing site
	LLW	X	X	X	Manufacturing site	LLW disposal site
	LLMW	X	X	X	Manufacturing site	LLMW treatment/disposal site
	Uranium oxide or uranium metal casks	X	–	X	Manufacturing site	End user
Disposal	UO_2 or U_3O_8	X	X	X	Conversion or storage site	Disposal site (shallow earthen structure, vault, or mine)

- For the various options, the transportation risk for a number of shipments listed in the engineering analysis report (LLNL 1997) are not included in this PEIS because they would not pose a radiological risk or a chemical fatality risk. Such shipments include chemicals used for processing (hydrochloric acid, sodium hydroxide, and nitric acid) and output hazardous waste for most facilities. The acids would not be in concentrated form, and sodium hydroxide is not an inhalation hazard. Relatively few drums of hazardous waste would be generated with minor amounts per drum, typically less than 1 or 2 kg of hazardous material, some of which would not be an inhalation hazard.

- In general, transportation activities were assumed to take place over a 20-year period, consistent with the operational period of the facilities considered.

J.3.2 Impacts Considered

The transportation of depleted uranium and associated materials would pose potential risks to human health and the environment. These risks would result from both the radioactive and chemical nature of the materials transported, as well as from operation of the transportation vehicles. The potential risks are discussed in this section. Additional details are given in Appendix C. The collective risks are presented in terms of the expected number of fatalities (or potentially life-threatening effects for chemical impacts) among the general public from all shipments for per-shipment distances ranging from 155 to 3,100 miles (250 to 5,000 km). The risks are presented for both truck and rail options, where appropriate.

J.3.2.1 Human Health — Normal Operations

J.3.2.1.1 Radiological Impacts

Radiological risk associated with routine transportation would result from the potential exposure of people to low levels of external radiation near a radioactive shipment. External exposures could occur as shipments moved past members of the public along routes or while the shipment was stopped along the route. No radioactive materials would be released during routine operations. Collective risks were estimated for the transportation crew members and for members of the public living and working along the transportation routes, sharing the routes, and present at stops along the routes.

In addition to assessing the routine collective population risk, risks to the maximally exposed individual (MEI) were estimated for a number of hypothetical exposure scenarios; these risks are listed in Table J.4. The scenarios include exposure of persons living next to a shipment route or being next to a shipment while stopped in traffic. The scenarios were chosen to provide a

TABLE J.4 Definition of Maximally Exposed Individuals for Assessment of Routine Transportation Risk

Maximally Exposed Individual	Assumptions	Distance (m)	Exposure Duration
Inspector (truck and rail)	Federal or state vehicle inspector, not covered by a dosimetry program	3	30 minutes
Resident (truck and rail)	Person living near a site shipment entrance, not protected by shielding	30	Shipments pass at average speed of 24 km/h
Person at traffic obstruction (truck and rail)	Person stopped next to a radioactive material shipment due to traffic or other causes, not protected by shielding	1	30 minutes
Person at truck service station	Worker at a truck stop	20	2 hours
Resident near a rail stop	Resident living near a rail classification yard, not protected by shielding	200	20 hours

range of exposure conditions; they were not intended to be all inclusive. For the transportation-related radiological impacts assessed in this PEIS, all those resulting from external radiation during routine transport would be very small because the highest level of radiation from any one shipment would be less than 1 mrem/h at a distance of 3.3 ft (1 m) from the transport vehicle. This dose rate is more than 10 times less than the regulatory limit of 10 mrem/h at 6.6 ft (2 m) from the transport vehicle, as directed by the DOT (49 *Code of Federal Regulations* [CFR] Part 173) and the U.S. Nuclear Regulatory Commission (10 CFR Part 71).

J.3.2.1.2 Chemical Impacts

The analysis assumed that no leaks would occur in the shipping packages during normal transport. Therefore, no impacts on human health would be related directly to the hazardous nature of chemical shipments during routine operations.

J.3.2.1.3 Vehicle-Related Impacts (Chemical Hazards)

Vehicle-related health risks are independent of the nature of the cargo and would be incurred for similar shipments of any commodity. The routine risks assessed might be caused by potential exposure to increased levels of airborne particulates from vehicular exhaust emissions and

from fugitive dust raised from the roadbed by the transport vehicle. The health endpoint assessed was the excess (additional) latent mortality caused by inhalation of these particulates in urban areas where ambient particulate air concentrations already exceed threshold values thought to be necessary before adverse effects are observed. It was assumed that a latent mortality is equivalent to a latent cancer fatality.

J.3.2.2 Human Health — Accident Conditions

J.3.2.2.1 Radiological Impacts

Radiological impacts from transportation-related accidents could result from the potential release and dispersal of radioactive material into the environment during an accident and the subsequent exposure of people through multiple pathways, such as exposure to contaminated soil, inhalation, or ingestion of contaminated food. The radiological impacts are expressed in terms of latent cancer fatalities (LCFs). No acute effects would be expected for the materials relevant to the action under consideration in this PEIS.

The collective accident risks from radiological causes over the life of the project have been estimated for all radioactive material shipments for each option category (see Table J.3 for a list of shipments). The accident risk estimates were based not only on the consequences of potential accidents but also on the probabilities that accidents would occur.

Although the overall radiological accident risk would be small for all shipments, there would be potential for low-probability, severe transportation accidents that could have relatively large consequences. Population and MEI impacts were estimated for such accidents.

J.3.2.2.2 Chemical Impacts

Chemical impacts from transportation-related accidents could result from the potential release and dispersal of hazardous chemicals into the environment during an accident and the subsequent exposure of people through the inhalation pathway. None of the hazardous chemicals involved in the action under consideration are suspected carcinogens, and any acute effects from ingestion or dermal absorption of the contaminants would be expected to be dominated by inhalation effects. The collective accident risks from chemical causes were estimated in the same manner as the radiological risks, taking into account accident probability, the spectrum of accident severities, and accident consequences. The health endpoints presented are potential irreversible adverse effects and expected fatalities, which are discussed in detail in Appendix C and Policastro et al. (1997). Population and MEI consequences from potentially severe accidents are presented.

J.3.2.2.3 Vehicle-Related Impacts (Physical Hazards)

Accident risks from physical hazards are vehicle-related risks that result from the physical trauma created by accidents; such risks are not related to the shipment's cargo. Physical hazard risks represent fatalities from mechanical causes and were determined from fatality rates based on national average statistics maintained by the DOT for truck and rail transportation (Saricks and Kvitek 1994).

J.3.3 Cylinder Preparation Options

Two options were evaluated for preparing nonconforming cylinders for off-site transportation to either a conversion facility or a long-term storage site (see Appendix E). These problem cylinders were classified into three types: (1) overfilled cylinders, (2) overpressurized cylinders, and (3) substandard cylinders. Each of the two cylinder preparation options would prepare all three types of cylinders to meet all DOT requirements for off-site shipment.

J.3.3.1 Cylinder Overcontainers

An overcontainer would be suitable to contain, transport, and store the cylinder contents, regardless of cylinder condition, and could be designed as a pressure vessel enabling liquefaction of the depleted UF_6 for transfer out of the cylinder. Because only minimal cylinder handling operations would be required to load substandard cylinders into an overcontainer, no chemical transportation risks would be associated with this option. Potential risks associated with the transportation of depleted UF_6 cylinders in protective overcontainers are presented in Sections J.3.4.1 and J.3.5.1 for the conversion options and long-term storage options, respectively.

J.3.3.2 Cylinder Transfer Facility

The alternative to placing nonconforming cylinders into overcontainers would be to transfer the depleted UF_6 to new cylinders. A facility necessary to effect such a transfer was assumed to be colocated at each of the three existing sites where the cylinders are currently stored. Therefore, the only transportation risks would be from minor amounts of chemicals used at the facility and small amounts of LLW and LLMW generated at the facility.

The total collective radiological risks (i.e., the total risk to all workers and members of the general public potentially exposed) for shipments associated with the cylinder transfer option are summarized in Tables J.5 and J.6 for routine and accident risks, respectively. Routine risks to MEIs are summarized in Table J.7, whereas potential severe accident consequences to local populations from radiological and chemical hazards are summarized in Tables J.8 and J.9, respectively. Accident consequences to MEIs are summarized in Table J.10.

[a] Risks for rail transport were estimated on a railcar basis; therefore, the number of railcars was used for the total number of rail shipments.

[b] Radiological LCFs were estimated from the calculated doses using dose-to-risk conversion factors of 0.0005 and 0.0004 fatality per person-rem for members of the general public and occupational workers, respectively, as recommended in ICRP Publication 60 (ICRP 1991). The approximate corresponding dose received for each radiological fatality risk listed in this table may be obtained by multiplying the fatality risk by 2,500 (i.e., 1 ÷ 0.0004).

[c] Potential for irreversible adverse effects from chemical exposures. Exposure to HF or uranium compounds was estimated to result in fatality for approximately 1% or less of those persons experiencing irreversible adverse effects (Policastro et al. 1997). Exposure to ammonia was estimated to result in fatality for approximately 2% or less of those persons experiencing irreversible adverse effects.

[d] Includes the estimate for additional cylinders required to handle the depleted uranium in overfilled containers.

[a] Risks for rail transport were estimated on a railcar basis; therefore, the number of railcars was used for the total number of rail shipments.

[b] Radiological LCFs were estimated from the calculated doses using dose-to-risk conversion factors of 0.0005 and 0.0004 fatality per person-rem for members of the general public and occupational workers, respectively, as recommended in ICRP Publication 60 (ICRP 1991). The approximate corresponding dose received for each radiological fatality risk listed in this table may be obtained by multiplying the fatality risk by 2,500 (i.e., $1 \div 0.0004$).

[c] Potential for irreversible adverse effects from chemical exposures. Exposure to HF or uranium compounds was estimated to result in fatality for approximately 1% or less of those persons experiencing irreversible adverse effects (Policastro et al. 1997). Exposure to ammonia was estimated to result in fatality for approximately 2% or less of those persons experiencing irreversible adverse effects.

[d] Includes the estimate for additional cylinders required to handle the depleted uranium in overfilled containers.

[a] Lifetime risk of LCF for an individual was estimated from the calculated dose using the dose-to-risk conversion factor of 0.0005 fatalities per person-rem for members of the general public, as recommended in ICRP Publication 60 (ICRP 1991). The corresponding dose received for each radiological fatality risk listed in this table may be obtained by multiplying the risk of LCF by 2,000 (i.e., $1 \div 0.0005$).

[a] Lifetime risk of LCF for an individual was estimated from the calculated doses using a dose-to-risk conversion factor of 5×10^{-4} fatality per person-rem for members of the general public, as recommended in ICRP Publication 60 (ICRP 1991). The approximate corresponding dose received for each radiological fatality risk listed in this table may be obtained by multiplying the fatality risk by 2,000 (i.e., $1 \div 0.0005$).

[b] Yes or No applies to the effect of chemical exposure on the MEI. There is no probability estimate; either there would or would not be an irreversible adverse effect. Exposure to HF or uranium compounds was estimated to result in fatality for approximately 1% or less of those persons experiencing irreversible adverse effects (Policastro et al. 1997). Exposure to ammonia was estimated to result in fatality for approximately 2% or less of those persons experiencing irreversible adverse effects.

Transportation impacts associated with the cylinder transfer facility would be very small. No vehicle-related fatalities would be expected (< 1), and the vehicle-related risks would be about 10 times higher than the radiological risks. No radiological fatalities or irreversible adverse chemical effects would be expected as a result of a potential severe accident. The highest potential routine radiological exposure to an MEI, with a latent cancer fatality risk of 6×10^{-9}, would occur for a person stopped in traffic near a shipment for 30 minutes at a distance of 3.3 ft (1 m). Such an exposure would be about 100 times less than the exposure a person receives from natural sources in the course of 1 day.

J.3.4 Conversion Options

The conversion options would involve transportation of the depleted UF_6 cylinders from their current locations at the three storage sites to a conversion facility, transportation of any chemicals required by the conversion process, and transportation of the waste materials to a disposal site. Transportation of the conversion products is included in the discussion of the long-term storage, manufacture and use, and disposal options in Appendices G, H, and I of this PEIS.

The total collective radiological risks (i.e., the total risks to all workers and members of the public potentially exposed) associated with transportation of the depleted UF_6 cylinders; conversion to U_3O_8, UO_2, and metal; and the cylinder treatment facility are summarized in Tables J.5 and J.6 for routine and accident risks, respectively. Table J.7 summarizes the routine risks to MEIs, and Tables J.8 and J.9 summarize the potential severe accident consequences to local populations from radiological and chemical hazards, respectively. Table J.10 summarizes the accident consequences to MEIs.

J.3.4.1 Transportation of Depleted UF_6

The initial step in the conversion process would be to deliver the depleted UF_6 from the three storage sites to the conversion facility. The cylinders would be prepared for transport at each site, as discussed in Section J.3.3, and shipped to the conversion facility location. Shipment of all cylinders by both truck or rail has been assessed. Rail shipments would consist of four cylinders per railcar, whereas truck shipments would involve only one cylinder per truck. Because the number of cylinders that might require overcontainers is uncertain at this time, impacts were assessed for two bounding cases: under the first case, the depleted UF_6 would be transferred from nonconforming cylinders to new cylinders before transport; under the second case, all cylinders would be shipped in protective overcontainers. Risks for a given combination of cylinder shipments with and without overcontainers can be obtained by a linear interpolation between the two cases.

Protective overcontainers would reduce the external radiation emanating from the shipments by a factor of almost two. Because the radiological risk would be dominated by exposure during routine transport, the radiological risk from shipments with overcontainers would also be

about half the value for shipments without overcontainers. On the other hand, shipment of the depleted UF_6 cylinders in overcontainers is not expected to provide additional protection under severe accident conditions. Therefore, the risks from shipment of cylinders with and without overcontainers would be expected to be the same for severe accidents.

The chemical risk associated with cylinder transport would be much less than the radiological risk; however, the total risks would be dominated by vehicle-related risks, which would be about 10 times larger than the radiological and chemical risks combined. Thus, risks from transport by rail appear to be slightly less than the truck risks because of higher shipment capacities and therefore fewer shipments.

Impacts from a potential severe accident could lead to fatalities from both radiological and chemical effects. Up to 60 potential latent cancer fatalities from radiological hazards are estimated for a rail accident occurring in an urban population zone under stable weather conditions. On the basis of chemical toxicity effects for the same conditions, up to 4 persons could be affected by irreversible adverse effects.

The highest potential routine radiological exposure to an MEI, with a latent cancer fatality risk of 1×10^{-7}, would be for a person stopped in traffic near a shipment for 30 minutes at a distance of 3.3 ft (1 m). Such an exposure would be approximately 5 times less than the exposure a person receives from natural sources in the course of 1 day.

J.3.4.2 Conversion to U_3O_8, UO_2, or Metal

Conversion of the depleted UF_6 to the U_3O_8 or UO_2 oxide forms was assessed for both long-term storage (Appendix G) and disposal (Appendix I); conversion to UO_2 or metal was also assessed for use in cask manufacture (Appendix H). Transportation of other materials related to the conversion process would include the ammonia used in the conversion processes and the LLW, LLMW, and HF by-products of the conversion processes.

The total transportation risks associated with the conversion process would be low for all three conversion processes. The LLW and LLMW shipments to disposal would pose no irreversible adverse chemical effects, and the radiological risks would be about 100 times less than the vehicle-related risks. The largest risks would be associated with the chemical hazards associated with transportation of the HF by-product. These risks would be about 100 times the vehicle-related risks.

No radiological fatalities would be expected as a result of a potential severe accident. A severe accident involving ammonia or HF could result in fatalities, with a potential for approximately 30,000 persons to experience irreversible adverse effects from an accident involving HF under stable conditions in an urban area. However, the overall probability of an anhydrous HF accident occurring would depend on the total number of shipments and the actual locations of the

origin and destination sites. The probability of an accident would increase with the number of shipments and distance between sites. Approximately 5,000 railcars of anhydrous HF would be produced if the entire UF_6 inventory were converted to oxide. Assuming the distance traveled per shipment is 620 miles (1,000 km) and based on national average accident statistics for railcars, the overall probability for such an accident in an urban area would be about 3×10^{-5} (about 1 chance in 30,000) over the duration of the program. The resulting overall risk to the public (defined as the product of the accident consequence and the probability) would be 1 irreversible adverse effect (i.e, about 1 person would be expected to experience irreversible adverse effects) due to HF-related transportation accidents. This calculation assumes that the accident would occur in an urban area under weather conditions that result in maximum consequences. Further discussion on potential severe anhydrous HF accidents is presented in Chapter 5, Section 5.2.2.2.

The risk of latent cancer fatality to an MEI from a single routine radiological exposure to a given shipment would be negligible. The highest potential exposure, with an LCF risk of 6×10^{-9}, would occur for a person stopped in traffic near a shipment for 30 minutes at a distance of 3.3 ft (1 m). Such an exposure would be approximately 100 times less than the exposure a person receives from natural sources in the course of 1 day.

J.3.4.3 Cylinder Treatment Facility

After the depleted UF_6 cylinders were "emptied" at the conversion facility, they would still retain approximately 22 lb (10 kg) of UF_6, which corresponds to the amount remaining in the cylinder in the vapor phase at autoclave pressure and temperature (Charles et al. 1991). A cylinder treatment facility was assumed to be colocated with the conversion facility to clean and decontaminate the cylinders once they had been emptied. Therefore, the only chemical or radioactive material transportation risks would be from small amounts of U_3O_8, LLW, and LLMW generated at the facility. It was assumed that the cleaned cylinders would be placed in the scrap metal pile at the conversion site.

No fatalities would be expected due to transportation of materials from the cylinder treatment facility. The highest potential routine radiological exposure, with a latent cancer fatality risk of 2×10^{-7}, would occur for a person stopped in traffic near a shipment of U_3O_8 for 30 minutes at a distance of 3.3 ft (1 m) if it were shipped to a disposal site. Such an exposure would be less than half the radiological exposure that a person receives from natural sources in the course of 1 day.

Less than one radiological latent cancer fatality might be expected as a result of a potential severe accident involving shipment of U_3O_8 under stable weather conditions. Because of the chemical toxicity of the uranium oxide, approximately 8 persons could experience irreversible adverse effects in an urban area under stable weather conditions.

J.3.5 Long-Term Storage Options

Three options were assessed for long-term storage of depleted uranium compounds at a single location. The depleted uranium could be stored in its current form as depleted UF_6 or converted to an oxide form (UO_2 or U_3O_8) and then stored. Transportation impacts related to conversion of the depleted UF_6 to the oxide forms are discussed in Section J.3.4.2. Potential impacts from transportation of the depleted uranium material in its final form to a long-term storage site are discussed in this section.

Small amounts of waste could be generated due to container failure during the surveillance phase of the long-term storage options. The impacts of transporting this waste to a disposal site was not considered because the number of associated shipments would be less than one per year (LLNL 1997).

The estimated impacts associated with transportation for the long-term storage options are presented in Tables J.11 through J.14. The total collective radiological risks (i.e., the total risk to all workers and members of the public potentially exposed) are summarized in Tables J.11 and J.12 for routine and accident risks, respectively. Table J.7 summarizes the routine risks to MEIs, and Tables J.13 and J.14 summarize the potential severe accident consequences to local populations and MEIs, respectively.

J.3.5.1 Storage as Depleted UF_6

Long-term storage of depleted UF_6 at a single storage site would involve shipping the depleted UF_6 cylinders from their current locations at the three existing storage sites. The potential transportation impacts from shipping these depleted UF_6 cylinders to a storage facility would be the same as for shipping to a conversion facility (Section J.3.4.1).

J.3.5.2 Storage as U_3O_8 or UO_2

Long-term storage of depleted uranium as U_3O_8 or UO_2 would involve shipping the oxide from a single conversion facility to the storage site. The same impacts would also be incurred from shipping the oxide from a conversion facility or storage site to a disposal site (Section J.3.7) or to a cask manufacturing facility (Section J.3.6).

The radiological risk associated with shipping all of the U_3O_8 or UO_2 to a storage site from a conversion facility would be larger than the chemical risk, but the total risks would still be dominated by vehicle-related risks, which would be about 10 times larger than the radiological risks. Therefore, risks from rail transport would be less than risks from truck transport because of higher shipment capacities and therefore fewer shipments.

	Rail	8,480 – 8,800	0.01	0	0.006 – 0.007	0.02	0	0.03	0.06	0	0.1

[a] Risks for rail transport were estimated on a railcar basis; therefore, the number of railcars was used for the total number of rail shipments.

[b] Radiological LCFs were estimated from the calculated doses using dose-to-risk conversion factors of 0.0005 and 0.0004 fatality per person-rem for members of the general public and occupational workers, respectively, as recommended in ICRP Publication 60 (ICRP 1991). The approximate corresponding dose received for each radiological fatality risk listed in this table may be obtained by multiplying the fatality risk by 2,500 (i.e., 1 ÷ 0.0004).

[c] Potential for irreversible adverse effects from chemical exposures. Exposure to HF or uranium compounds was estimated to result in fatality for approximately 1% or less of those persons experiencing irreversible adverse effects (Policastro et al. 1997).

[d] Includes the estimate for additional cylinders required to handle the depleted uranium in overfilled containers.

	Rail	0	1	1	0	10	20
UO_2	Truck	0	0	0	0	1	2
	Rail	0	0	0	0	3	8

[a] Radiological LCFs were estimated from the calculated doses using dose-to-risk conversion factors of 0.0005 and 0.0004 fatality per person-rem for members of the general public and occupational workers, respectively, as recommended in ICRP Publication 60 (ICRP 1991). The approximate corresponding dose received for each radiological fatality risk listed in this table may be obtained by multiplying the fatality risk by 2,500 (i.e., $1 \div 0.0004$).

[b] Exposure to HF or uranium compounds was estimated to result in fatality for approximately 1% or less of those persons experiencing irreversible adverse effects (Policastro et al. 1997).

TABLE J.14 Potential Consequences to the MEI from Severe Accidents Involving Shipment of Materials for Long-Term Storage

		Accident Risk			
		Neutral Weather Conditions		Stable Weather Conditions	
Material	Mode	Radiological Risk of LCF[a]	Chemical Effects[b]	Radiological Risk of LCF[a]	Chemical Effects[b]
Depleted UF_6	Truck	0.0002	Yes	0.0005	Yes
	Rail	0.0009	Yes	0.002	Yes
UF_6 with overcontainer	Truck	0.0002	Yes	0.0005	Yes
	Rail	0.0009	Yes	0.002	Yes
U_3O_8	Truck	0.004	No	0.07	Yes
	Rail	0.01	Yes	0.2	Yes
UO_2	Truck	0.004	No	0.06	Yes
	Rail	0.01	No	0.2	Yes

[a] Lifetime risk of LCF for an individual was estimated from the calculated doses using a dose-to-risk conversion factor of 5×10^{-4} fatality per person-rem for members of the general public, as recommended in ICRP Publication 60 (ICRP 1991). The approximate corresponding dose received for each radiological fatality risk listed in this table may be obtained by multiplying the fatality risk by 2,000 (i.e., $1 \div 0.0005$).

[b] Yes or No applies to the effect of chemical exposure on the MEI. There is no probability estimate; either there would or would not be an irreversible adverse effect. Exposure to HF or uranium compounds was estimated to result in fatality for approximately 1% or less of those persons experiencing irreversible adverse effects (Policastro et al. 1997).

The risk of latent cancer fatality to an MEI for a single exposure to a given shipment would be small. The highest potential exposure, with a latent cancer fatality risk of 2×10^{-7}, would occur for a person stopped in traffic near a shipment for 30 minutes at a distance of 3.3 ft (1 m). Such an exposure would be less than half the radiological exposure that a person receives from natural sources in the course of 1 day.

Impacts from a potential severe accident could lead to fatalities from both radiological and chemical effects. Approximately 2 potential latent cancer fatalities from radiological hazards are estimated for a rail accident occurring in an urban population zone under stable weather conditions. Because of the chemical hazard of uranium, an estimated 20 people could experience irreversible adverse effects from chemical toxicity under the same conditions.

J.3.6 Manufacture and Use Options

Two alternative uses of depleted uranium were assessed: manufacture of casks using concrete made with cement and UO_2 and manufacture of casks using uranium metal. Potential impacts would be incurred from transport of the feed material (UO_2 or uranium metal) from a conversion facility to the manufacturing plant, transport of the manufactured cask to an end user, and transport of the small amount of LLW and LLMW expected to be generated at the manufacturing facility to a disposal site. Because of the size of the manufactured casks, cask shipment was assumed to occur by rail only. The shipment risks would be approximately the same for both cask options.

The collective population risks associated with the two manufacture and use options are summarized in Tables J.15 and J.16 for routine and accident risks, respectively. The routine risks to MEIs are summarized in Table J.7, and the accident consequences to MEIs and the population are summarized in Tables J.17 and J.18, respectively.

J.3.6.1 Uranium Oxide Casks

The uranium oxide cask option would involve the use of depleted uranium in the form of high-density UO_2 for the manufacture of depleted uranium concrete for shielding in spent nuclear fuel storage casks. The transportation risks associated with transport of the UO_2 to the cask manufacturing facility would be the same as the risks associated with transport of the UO_2 to a storage site (see Section J.3.5.2). Shipment of the uranium oxide casks to an end user would result in approximately the same overall risks as the UO_2 shipments. No chemical risks would be anticipated for transportation of the fabricated casks, and no radiological fatalities would be expected under severe accident conditions.

J.3.6.2 Uranium Metal Casks

The uranium metal cask option would involve the conversion of depleted UF_6 to uranium metal that would then be fabricated into a cask. Transportation impacts were analyzed for shipment of the uranium metal from a conversion facility to a cask manufacturing facility and shipment of the fabricated cask to an end user. No chemical transportation risks would be expected for this option.

The total radiological risk associated with uranium metal transport would be about a factor of 30 or more less than the vehicle-related risks. Shipment risks for the cask would be about the same as for rail transport of the uranium metal feed material. Risks for the generated waste shipments would be negligible compared with the shipment of uranium metal and casks.

The risk of latent cancer fatality to an MEI for a single exposure to a given shipment would be small. The highest potential routine radiological exposure, with a latent cancer fatality risk of 4×10^{-8}, would occur for a person stopped in traffic near a uranium metal or cask shipment for

TABLE J.15 Total Routine Shipment Risks for the Transportation of Materials for Manufacture and Use

Use/Material	Mode	Total Shipments[a]	Risks over 250 km			Risks over 1,000 km			Risks over 5,000 km

Cask	Rail	0.0004	No	0.006	No

[a] Lifetime risk of LCF for an individual was estimated from the calculated doses using a dose-to-risk conversion factor of 0.0005 fatality per person-rem for members of the general public, as recommended in ICRP Publication 60 (ICRP 1991). The approximate corresponding dose received for each radiological fatality risk listed in this table may be obtained by multiplying the fatality risk by 2,000 (i.e., $1 \div 0.0005$).

[b] Yes or No applies to the effect of chemical exposure on the MEI. There is no probability estimate; either there would or would not be an irreversible adverse effect. Exposure to HF or uranium compounds was estimated to result in fatality for approximately 1% or less of those persons experiencing irreversible adverse effects (Policastro et al. 1997).

30 minutes at a distance of 3.3 ft (1 m). Such an exposure would be approximately 10 times less than the exposure a person receives from natural sources in the course of 1 day.

No fatalities from severe accidents would be expected. The transportation risks associated with the transport of the uranium metal cask would be approximately the same as those for the uranium oxide cask.

J.3.7 Disposal Options

Two options were identified for potential disposal of the depleted uranium: disposal as U_3O_8 or disposal as UO_2. In each case, the uranium oxide form would be transported from a single site, either a conversion facility or a storage site, to a disposal site. The impacts associated with

[a] Radiological LCFs were estimated from the calculated doses using a dose-to-risk conversion factor of 0.0005 fatality per person-rem for members of the general public, as recommended in ICRP Publication 60 (ICRP 1991). The approximate corresponding dose received for each radiological fatality risk listed in this table may be obtained by multiplying the fatality risk by 2,000 (i.e., $1 \div 0.0005$).

[b] Exposure to HF or uranium compounds was estimated to result in fatality for approximately 1% or less of those persons experiencing irreversible adverse effects (Policastro et al. 1997).

transport to a disposal site would be the same as those for transport to a storage site (see Section J.3.5.2). Comparison of the transportation impacts associated with the two disposal options shows no significant difference between the two.

J.3.8 Other Impacts Considered But Not Analyzed in Detail

Other impacts could potentially occur if the transportation options considered in this PEIS were implemented, including impacts to air quality, water quality, ecology, socioeconomics, cultural resources, visual environment (e.g., aesthetics), recreational resources, wetlands, noise levels, and environmental justice issues. These impacts, although considered, were not analyzed in detail for one or more of the following reasons:

- Consideration of the impacts would not contribute to differentiation among the alternatives and therefore would not affect the decisions to be made in the Record of Decision that will be issued following this PEIS.

- The impacts could not be determined at the programmatic level without consideration of specific routes between specific sites. Potential impacts would be more appropriately addressed in the second-tier *National Environmental Policy Act* (NEPA) documentation when specific sites are considered.

NOTATION (APPENDIX K)

The following is a list of acronyms and abbreviations, including units of measure, used in this document. Some acronyms used only in tables are defined in those tables.

ACRONYMS AND ABBREVIATIONS

General

CFR	*Code of Federal Regulations*
DOE	U.S. Department of Energy
EPA	U.S. Environmental Protection Agency
LCF	latent cancer fatality
LLNL	Lawrence Livermore National Laboratory
LLMW	low-level mixed waste
LLW	low-level radioactive waste
MEI	maximally exposed individual
NEPA	*National Environmental Policy Act*
PEIS	programmatic environmental impact statement
ROI	region of influence

Chemicals

HF	hydrogen fluoride
MgF_2	magnesium fluoride
NO_x	nitrogen oxides
UF_6	uranium hexafluoride
UO_2	uranium dioxide
U_3O_8	triuranium octaoxide (uranyl uranate)

UNITS OF MEASURE

d	day(s)	mrem	millirem(s)
ft	foot (feet)	MWh	megawatt-hour(s)
ha	hectare(s)	pCi	picocurie(s)
km	kilometer(s)	rad	radiation absorbed dose(s)
L	liter(s)	rem	roentgen equivalent man
µg	microgram(s)	yd^3	cubic yard(s)
m	meter(s)	yr	year(s)
m^3	cubic meter(s)		

APPENDIX K:

PARAMETRIC ANALYSIS: ENVIRONMENTAL IMPACTS OF CONVERSION, LONG-TERM STORAGE, MANUFACTURE AND USE, AND DISPOSAL OPTIONS FOR PROCESSING LESS THAN THE TOTAL DEPLETED UF_6 INVENTORY

The U.S. Department of Energy (DOE) is proposing to develop a strategy for long-term management of the depleted uranium hexafluoride (UF_6) inventory currently stored at three DOE sites near Paducah, Kentucky; Portsmouth, Ohio; and Oak Ridge, Tennessee. This programmatic environmental impact statement (PEIS) describes alternative strategies that could be used for the long-term management of this material and analyzes the potential environmental consequences of implementing each strategy for the period from 1999 through 2039. This appendix provides detailed information describing the parametric analysis used to assess potential environmental impacts of conversion, long-term storage, manufacture and use, and disposal options considered in the PEIS for processing less than the total depleted UF_6 inventory.

The environmental impacts presented in Chapter 5 of the PEIS are based on the assumption that all facilities would be designed to either convert, store, manufacture and use, or dispose of all of the depleted UF_6 in the DOE inventory. This approach provided a conservative estimate of the impacts that could result from each of the alternatives considered. Detailed discussions of the estimated environmental impacts from processing the entire depleted UF_6 inventory are presented for cylinder preparation, conversion, long-term storage, manufacture and use, disposal, and transportation options in Appendices E through J, respectively. The results of these evaluations are referred to as "100%" cases because they are based on the assumption that all of the depleted UF_6 would be processed (i.e., converted, stored, manufactured and used, disposed of, or transported).

In contrast to the 100% cases, the parametric analysis cases presented in this appendix considered the environmental impacts of each option category if the facilities were designed to process or accommodate only a fraction of the depleted UF_6 inventory (in the event that DOE would select a combination of alternatives to manage the entire inventory; see below). The intent of the parametric analysis was to show how the environmental impacts calculated for the 100% cases would be affected by reductions in facility size and throughput. "Throughput" is a general term that refers to the amount of material handled or processed by a facility in a year. Sections K.2-K.6 of this parametric appendix present the environmental impacts for the conversion, long-term storage, manufacture and use, disposal, and transportation options for facilities designed to process between 25% and 100% of the depleted UF_6 inventory. (The impacts of the cylinder preparation options for various throughputs are addressed in Appendix E.)

The results of the parametric analyses for the individual management components presented in Sections K.2-K.6 can be compiled to estimate the environmental impacts of combinations of alternatives; for example, use of 50% of the inventory as metal and use of 50% of the inventory as oxide. An example calculation of impacts for such a combination of alternatives is provided in

Section K.7. Any combination of alternatives selected would result in management of 100% of the depleted UF_6 inventory. The results of the parametric analyses can also be used to estimate the impacts for situations in which more than one site would be used (e.g., conversion to oxide at two locations).

For assessment purposes, the parametric analysis assumed that all facilities would be designed to operate over a 20-year time period (i.e., the period required to process the DOE-generated cylinders, similar to the 100% cases presented in Appendices E through J). Thus, it was assumed that the processing of only a fraction of the DOE depleted UF_6 inventory would be accomplished by building and operating smaller facilities than those required for the 100% cases. In practice, it would be possible to process a fraction of the inventory by operating facilities designed to process 100% of the inventory over 20 years for a reduced time period, such as 10 years, or by operating the facility at a reduced level. In addition, changes in operating schedule could be used to accommodate small changes in the DOE inventory. For example, a 10% increase in the total DOE inventory could be accommodated by operating a full-scale facility for 22 years instead of 20.

For a given option, the environmental impacts resulting from the parametric analysis cases would tend to be less than or equal to those presented for the 100% cases. Thus, if the impacts were negligible for the 100% case, the impacts for the parametric cases would also be negligible. For most areas considered — such as human health and safety during normal operations, water, ecology, resource requirements, waste management, land use, and socioeconomics — the impacts would decrease as the facility size or throughput decreased. However, the reduction in impacts would not always be proportional to the reduction in throughput. For example, a facility designed to process 500 cylinders per year would generally have smaller impacts than a facility designed to process 1,000 cylinders per year, although the impacts would not necessarily be half of those of the larger facility. For accidents producing the greatest consequences, impacts would tend to be the same for the parametric analysis cases and the 100% case, primarily because these types of accidents would involve only a limited amount of material that would be at risk under accident conditions regardless of the facility size or throughput.

The following sections summarize the approach and results of the parametric analysis. Section K.1 presents a short summary of the assessment approach. The results are presented for the conversion options in Section K.2, for long-term storage options in Section K.3, for manufacture and use options in Section K.4, for disposal options in Section K.5, and for transportation options in Section K.6; parametric assessment results for the cylinder preparation options are provided in Appendix E. Section K.7 presents an example of the calculation of impacts for a specific combination alternative and the summary of impacts for several example combination alternatives.

The discussion in this appendix (Appendix K) does not include details of the assessment methodologies or definitions of the options considered in the PEIS. A detailed description of methodologies is presented in Appendix C, and definitions and descriptions of the option categories are provided in Appendices F through J. Finally, in cases where the impacts from the parametric analysis do not differ significantly from the 100% case, readers are referred to Appendices F through J for additional discussion.

K.1 PARAMETRIC ANALYSIS ASSESSMENT APPROACH

Two parametric cases were analyzed for conversion, long-term storage as oxide, manufacture and use, and disposal options: (1) facilities designed to process or accommodate 50% of the depleted UF_6 inventory; and (2) facilities designed to process or accommodate 25% of the inventory. To simplify the analysis, the parametric cases were analyzed in detail for a subset of options within each option category, as summarized in Table K.1. A subset of options was selected because the relationships among the options within each category could be determined from the detailed analyses conducted for the 100% cases. Therefore, the results for the options analyzed in detail were used to estimate the impacts for all options within each category by comparison with the 100% cases.

The basic assessment approach, areas of impact, and methodologies used to evaluate the parametric cases were the same as those used to evaluate the 100% cases. The environmental impacts for the 100% cases were evaluated using information provided in the engineering analysis report (Lawrence Livermore National Laboratory [LLNL 1997a]), including descriptions of facility layouts; resource requirements; estimates of effluents, wastes, and emissions; and descriptions of potential accident scenarios. To support the parametric assessment, similar design information was used for facilities sized to process or accommodate 25% and 50% of the depleted UF_6 inventory (LLNL 1997a).

The results of the parametric analysis are presented, where appropriate, as curves that show the environmental impacts as a function of facility throughput. The curves were constructed using the results for the 25%, 50%, and 100% cases. These curves can be used to estimate the environmental impacts for throughputs ranging between 25% and 100% of the depleted UF_6 inventory. In addition, the curves can also be used to provide rough estimates of the impacts for throughputs slightly below 25% and slightly above 100%. In cases where the impacts for the 100% case were negligible, the parametric analysis was conducted to confirm that the impacts were also negligible, and only a brief discussion is provided. (The terms used in this PEIS to describe impacts, such as "negligible," are defined in Chapter 4, Table 4.2.)

K.2 CONVERSION OPTIONS

The parametric analysis of the conversion options considered the environmental impacts of converting 25% and 50% of the depleted UF_6 inventory to triuranium octaoxide (U_3O_8), uranium dioxide (UO_2), or uranium metal over a 20-year period. The assessment considered the environmental impacts that would occur during (1) construction of a conversion facility, (2) routine conversion facility operations, and (3) potential conversion facility accidents. The areas of impact and the methodologies used to evaluate the parametric cases were the same as those used to evaluate the 100% cases, the results of which are discussed in Appendix F. The supporting data for the 25% and 50% parametric conversion cases are provided in the engineering analysis report (LLNL 1997a).

TABLE K.1 Specific Options and Parametric Cases Analyzed in Detail

Option Category/ Options Analyzed in Detail	Parametric Cases Analyzed for Each Option
Conversion	Conversion to U_3O_8, UO_2, and metal:
	100% case: Conversion of 100% of the inventory over 20 years
	50% case: Conversion of 50% of the inventory over 20 years
	25% case: Conversion of 25% of the inventory over 20 years
Long-term storage	
Storage as UF_6 in buildings	Storage as UF_6:
	100% case: Storage of 46,422 cylinders
	50% case: Storage of 23,211 cylinders
	25% case: Storage of 11,606 cylinders
Storage as UO_2 in buildings	Storage as UO_2:
	100% case: Storage of 420,000 drums
	50% case: Storage of 210,000 drums
	25% case: Storage of 105,000 drums
Manufacture and use	
Use as uranium oxide	Use as UO_2:
	100% case: Use of 100% of the inventory as oxide shielding
	50% case: Use of 50% of the inventory as oxide shielding
	25% case: Use of 25% of the inventory as oxide shielding
Use as uranium metal	Use as metal:
	100% case: Use of 100% of the inventory as metal shielding
	50% case: Use of 50% of the inventory as metal shielding
	25% case: Use of 25% of the inventory as metal shielding
Disposal	
Disposal as ungrouted U_3O_8 in a mine	100% case: Disposal of 100% of the inventory over 20 years
	50% case: Disposal of 50% of the inventory over 20 years
	25% case: Disposal of 25% of the inventory over 20 years

In general, the impacts for the 100% cases are presented in Appendix F as ranges, resulting from differences in technologies within each option and site differences. For the purposes of the parametric analysis, one technology from each option was considered and evaluated in detail at a representative site. A single technology and a representative site were evaluated for each option to simplify the parametric analysis. This simplification was possible because all technologies were evaluated at all representative sites for the 100% base case. The specific technologies considered were defluorination with anhydrous hydrogen fluoride (HF) production for conversion to U_3O_8; dry defluorination with anhydrous HF production for conversion to UO_2; and continuous metallothermic reduction for conversion to uranium metal. The resulting relationships between the technologies and sites that were identified for the 100% case were used to infer ranges of impacts for the parametric cases examined in detail.

K.2.1 Human Health — Normal Operations

K.2.1.1 Radiological Impacts

The estimated radiological impacts — radiation doses and latent cancer fatalities (LCFs) — from the normal operation of a full-scale (100%) facility for converting depleted UF_6 to U_3O_8 are described in Appendix F, Section F.3.1.1. Similar impacts were calculated for the 50% and 25% conversion facilities for the parametric analysis. The radiological impacts estimated for the 100%, 50%, and 25% case are shown in Figures K.1 through K.6 as the radiation doses for the six receptor scenarios considered in the PEIS:

- Members of the general public
  - Annual collective dose
  - Annual dose to the maximally exposed individual (MEI)

- Noninvolved workers
  - Annual collective dose
  - Annual dose to the MEI

- Involved workers
  - Annual collective dose
  - Annual average individual dose

The ranges of impacts resulting from site and technology differences for each option are represented by dashed lines in the figures. The results for the technology selected for detailed analysis are shown in the figures as solid points, with a curve drawn between the points to indicate how the impacts vary as a function of the percent of depleted UF_6 processed. The upper and lower bounds for impacts for the 25% and 50% cases were estimated on the basis of the range determined for the 100% case. The

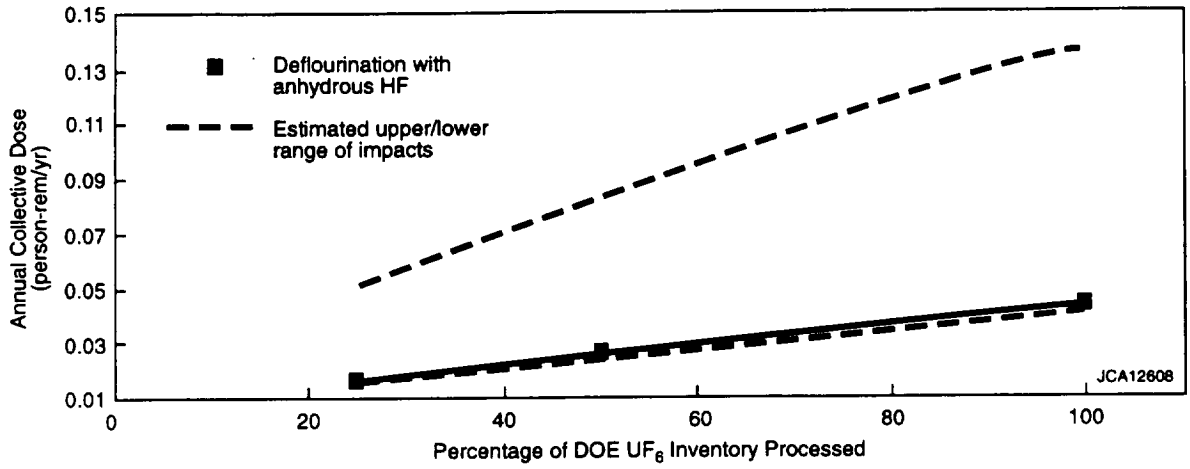

FIGURE K.1 Estimated Annual Collective Dose to Members of the Public from the Conversion of UF_6 to U_3O_8 (The upper and lower ranges reflect differences in both conversion technologies and representative site characteristics.)

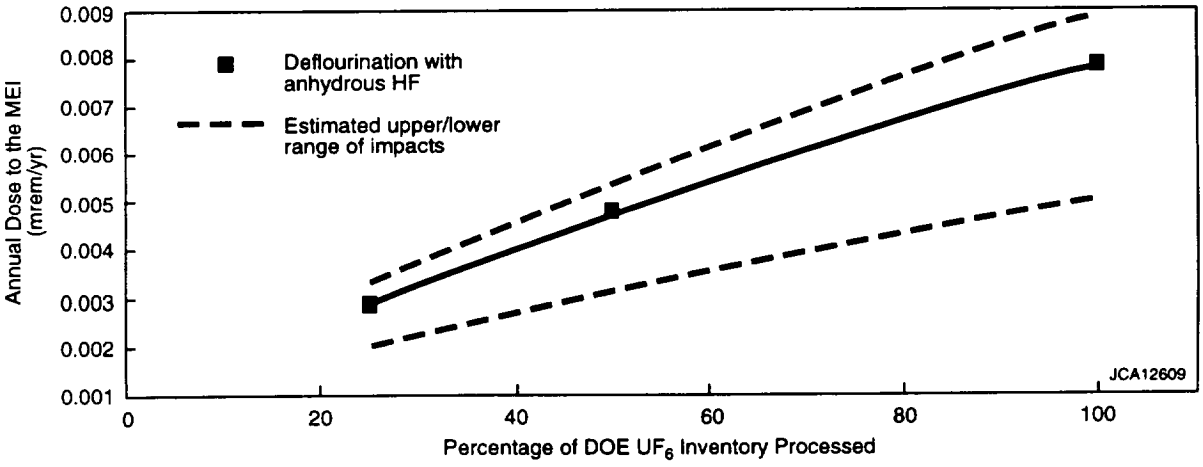

FIGURE K.2 Estimated Annual Dose to the General Public MEI from the Conversion of UF_6 to U_3O_8 (The upper and lower ranges reflect differences in both conversion technologies and representative site characteristics.)

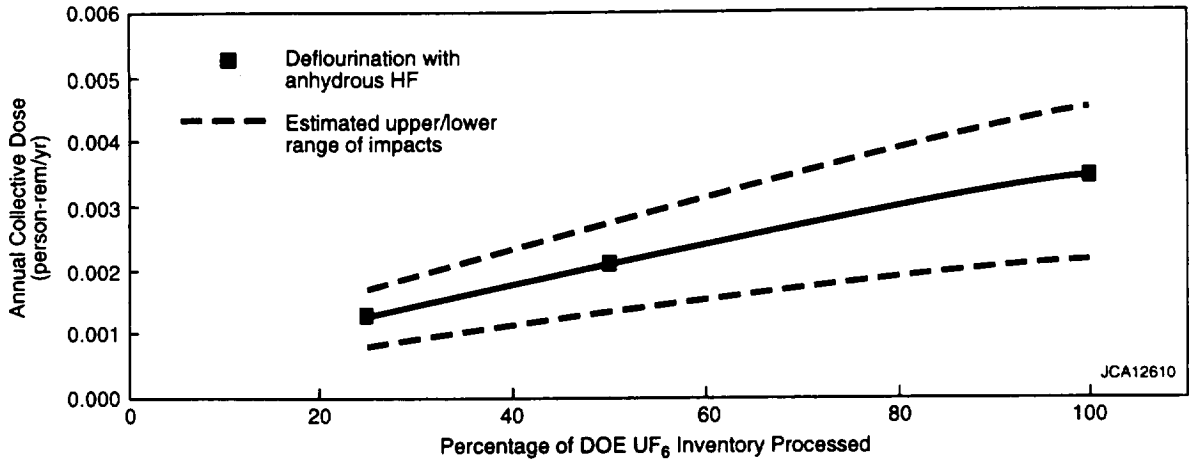

FIGURE K.3 Estimated Annual Collective Dose to Noninvolved Workers from the Conversion of UF_6 to U_3O_8 (The upper and lower ranges reflect differences in both conversion technologies and representative site characteristics.)

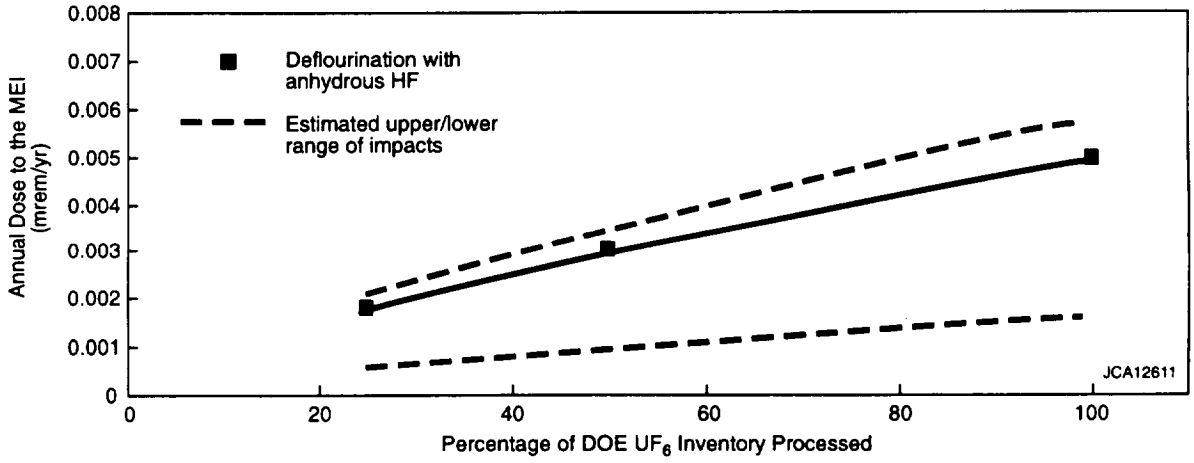

FIGURE K.4 Estimated Annual Dose to the Noninvolved Worker MEI from the Conversion of UF_6 to U_3O_8 (The upper and lower ranges reflect differences in both conversion technologies and representative site characteristics.)

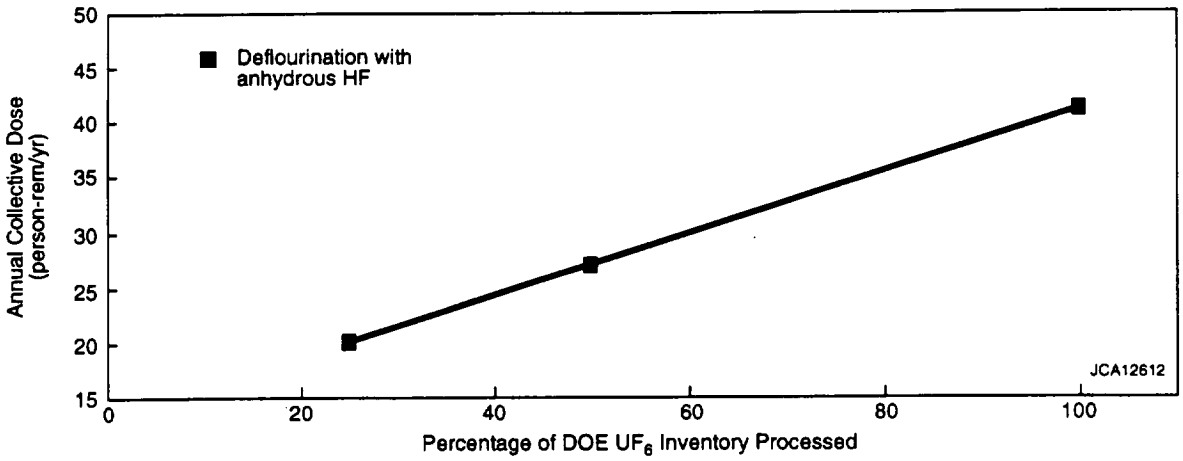

FIGURE K.5 Estimated Annual Collective Dose to Involved Workers from the Conversion of UF_6 to U_3O_8 (No range is presented because the estimated collective doses to involved workers were almost identical between conversion technologies.)

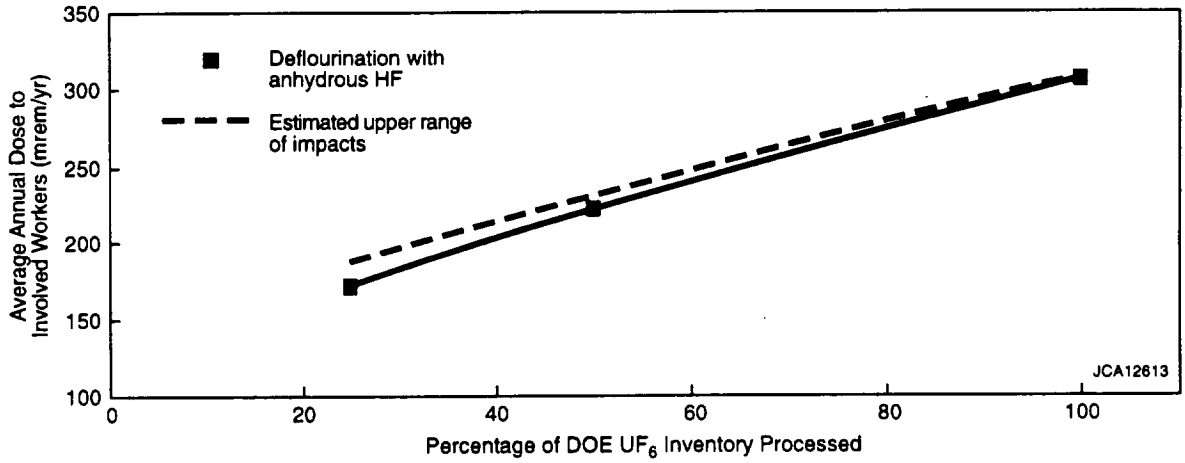

FIGURE K.6 Estimated Annual Average Individual Dose to Involved Workers from the Conversion of UF_6 to U_3O_8 (The upper and lower ranges reflect differences in conversion technologies.)

area enclosed by the lines in each figure indicates the range of impacts expected for throughputs between 25% and 100%, taking into account both technology and site differences.

The results of the parametric analysis for conversion to U_3O_8 (as shown in Figures K.1 through K.6) indicate that the radiological impacts would scale relatively linearly with the quantity of depleted UF_6 processed annually. The impacts of the 25% and 50% cases would be smaller than those for the 100% case, although the decrease would not be proportional to the reduction in throughput (i.e., the impacts for the 50% case would be greater than half of the impacts for the 100% case). The radiation doses to the general public would be greater than those to noninvolved workers because of longer exposure times and, for the collective dose, larger population size. The doses shown in the figures can be converted to the number (or risk) of LCFs by multiplying the doses (in rem or person-rem) by 0.0005 LCF/person-rem for members of the public and 0.0004 LCF/person-rem for workers. Additional discussion of the significance of the estimated doses is provided in Appendix F.

For conversion to UO_2, the estimated radiation doses for the 100%, 50%, and 25% throughput cases are presented in Figures K.7 through K.12 for each of the six receptor scenarios considered in the PEIS. The results are presented in a manner similar to the results discussed previously for conversion to U_3O_8. The general relationship between radiological impacts and throughput for conversion to UO_2 is similar to that for conversion to U_3O_8; that is, the radiological impacts would decrease with decreasing throughput. The estimated radiological impacts (doses and LCFs) from normal operation of a full-scale (100%) facility for converting depleted UF_6 to UO_2 are described in Appendix F, Section F.3.1.1.

For conversion to metal, the estimated radiation doses for the 100%, 50%, and 25% throughput cases are presented in Figures K.13 through K.18 for each of the six receptor scenarios considered in the PEIS. Similar to conversion to U_3O_8 and UO_2, the radiological impacts from conversion to metal would decrease with decreasing throughput. The estimated radiological impacts (doses and LCFs) from the normal operation of a full-scale (100%) facility for converting depleted UF_6 to uranium metal are described in Appendix F, Section F.3.1.1.

The estimated radiological impacts from operation of the cylinder treatment facility are less than the impacts from the operations of the conversion facilities. Low-level exposures would be expected for involved workers and negligible exposures for noninvolved workers and the general public. The estimated radiation doses for the 100%, 50%, and 25% throughput cases are presented in Figures K.19 through K.24 for each of the six receptor scenarios considered in the PEIS.

K.2.1.2 Chemical Impacts

The estimated impacts from chemical exposures during the normal operation of full-scale (100%) facilities for converting depleted UF_6 to U_3O_8, UO_2, and uranium metal are described in Appendix F, Section F.3.1.2. The results of the 100% case analyses indicated that noninvolved

FIGURE K.23 Estimated Annual Collective Dose to Involved Workers from the Cylinder Treatment Facility

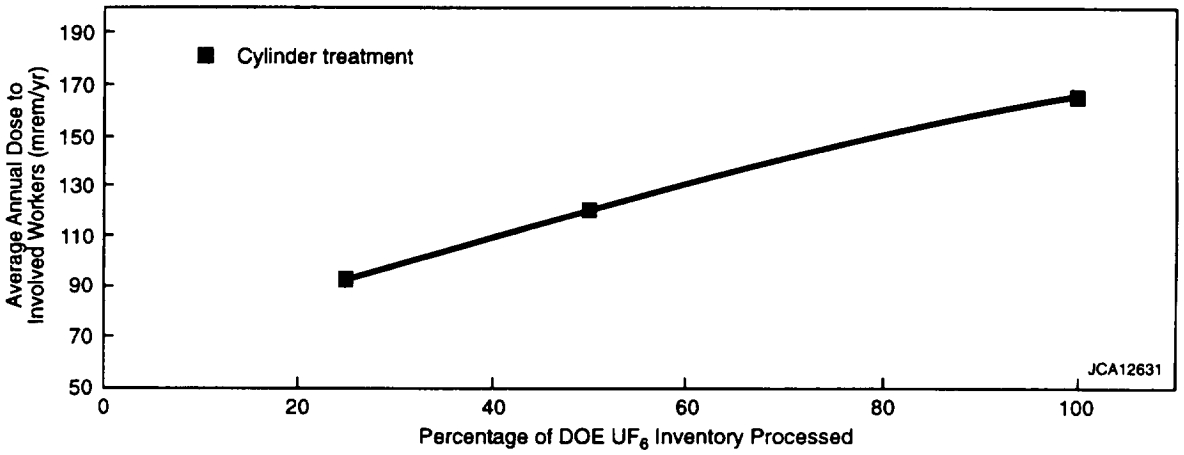

FIGURE K.24 Estimated Annual Average Individual Dose to Involved Workers from the Cylinder Treatment Facility

workers and members of the general public would receive very low exposures to chemicals from operation of the conversion facilities and that no adverse health impacts would be expected. For the 100% cases, the calculated hazard indices were much less than 1 for all three conversion options (a hazard index of greater than 1 indicates the potential for health impacts). For the parametric analysis of the 25% and 50% throughput cases, calculated hazard indices for noninvolved workers and members of the general public were proportionally smaller than those for the 100% cases. Therefore, because the hazard indices are much less than 1, no adverse health impacts from chemical exposures would be expected for throughput rates between 25% and 100%.

The chemical impacts from operations of the cylinder treatment facility were estimated to be less than the impacts from operations of the conversion facilities, therefore resulting in no adverse health impacts to noninvolved workers and the general public for the 25%, 50%, and 100% cases.

K.2.2 Human Health — Accident Conditions

K.2.2.1 Radiological Impacts

The estimated radiological impacts (radiation doses and LCFs) from potential accidents during operation of the full-scale (100%) conversion facilities are presented in Appendix F, Section F.3.2.1. Analysis of the 100% cases considered a range of accidents in four frequency categories; results are presented only for those accidents in each category that would have the greatest consequences (bounding accidents). Similar sets of accidents covering the same four frequency categories are defined in the engineering analysis report (LLNL 1997a) for the 25% and 50% throughput cases.

On the basis of the assessment of the 25% and 50% conversion cases, the radiological accident impacts associated with each of the parametric cases would be the same as those presented for the 100% cases in Appendix F. The impacts would be the same because the bounding accidents within each frequency category (those producing the greatest consequences) would be the same for all cases (100%, 50%, and 25%). The bounding accidents would be the same because they would involve only a limited amount of material that would be at risk under accident conditions regardless of the facility size or throughput. Some of the impacts from other accidents considered for the 25% and 50% cases (nonbounding) would be different than those for the 100% cases. In general, the impacts of these nonbounding accidents for the 50% and 25% cases would be less than those for the 100% cases because of the reduced throughput.

All accidents associated with the cylinder treatment facilities discussed in Appendix F would be the same for the parametric analysis (LLNL 1997a). The frequencies of some accidents, such as drum spills, might decrease as the number of drums handled decreased with facility throughput. However, it is not expected that the small changes in frequencies for specific accidents

would change the overall frequency category for those accidents. As a result, the accident impacts associated with the cylinder treatment facility would be the same for all parametric cases.

K.2.2.2 Chemical Impacts

The estimated chemical impacts from potential accidents during the operation of full-scale (100%) conversion facilities are presented in Appendix F, Section F.3.2.2. The analysis of the 100% cases considered a range of accidents in four frequency categories; results are presented only for those accidents in each category that would have the greatest consequences (bounding accidents). Similar sets of accidents covering the same four frequency categories are defined in the engineering analysis report (LLNL 1997a) for the 25% and 50% throughput cases.

As for the radiological accident impacts, the chemical accidents producing the greatest consequences for the 25% and 50% parametric cases would be the same as those assessed for the 100% cases in Appendix F. The impacts would be similar because the bounding accidents within most frequency categories would be the same for the 100%, 50%, and 25% cases, and in those cases where the accidents were different, no adverse chemical impacts were estimated. The bounding accidents would be the same because they would involve only a limited amount of material that would be at risk under accident conditions regardless of the facility size or throughput. Some of the impacts from other accidents considered for the 25% and 50% cases (nonbounding accidents) would be different than those for the 100% cases. In general, the impacts of these other accidents for the 50% and 25% cases would be less than those for the 100% cases because of the reduced throughput.

All accidents associated with the cylinder treatment facilities discussed in Appendix F would be the same for the parametric analysis (LLNL 1997a). The frequencies of some accidents, such as drum spills, might decrease as the number of drums handled decreased with facility throughput. However, it is not expected that the small changes in frequencies for specific accidents would change the overall frequency category for those accidents. As a result, the overall chemical accident impacts associated with cylinder treatment would be the same for all parametric cases.

K.2.2.3 Physical Hazards

The estimated health impacts, such as on-the-job injuries and fatalities, from potential physical accidents during the construction and operation of full-scale (100%) conversion facilities are presented in Appendix F, Section F.3.2.3. The impacts of the 25% and 50% cases would be smaller than those for the 100% cases, although the decrease would not be proportional to the reduction in throughput (i.e., the impacts for the 50% case would be greater than half of the impacts for the 100% case).

The estimated total fatalities over the entire period of construction and operations for the U_3O_8 conversion options for the 25%, 50%, and 100% cases would be 0.29, 0.32, and 0.35,

respectively (both conversion options analyzed resulted in the same fatality estimates). For the UO_2 conversion options, the estimated total fatalities for the 25%, 50%, and 100% cases would range from 0.35 to 0.49, 0.38 to 0.54, and 0.40 to 0.59, respectively. For the metal conversion options, total fatalities for the 25%, 50%, and 100% cases would range from 0.33 to 0.49, 0.36 to 0.52, and 0.4 to 0.55, respectively.

The total numbers of injuries over the entire period of construction and operation of the specific U_3O_8, UO_2, and metal conversion options analyzed parametrically are illustrated by the solid black line in Figures K.25 through K.27. The estimated upper ranges of impacts for all options examined in the PEIS are illustrated by the dotted lines in the figures (because both U_3O_8 options analyzed resulted in the same number of estimated injuries, only one line is shown in Figure K.25). The ranges of predicted injury incidence for the conversion options would be roughly comparable, reflecting the generally similar requirements for constructing and operating the three types of conversion facilities.

The estimated fatalities for the 25%, 50%, and 100% cases of construction and operation of a cylinder treatment facility would be 0.13, 0.16, and 0.19, respectively. The estimated number of injuries over the entire period of construction and operations would range from 122 to 170. The impacts are shown in Figure K.28 for throughputs ranging from 25% to 100%.

K.2.3 Air Quality

The estimated impacts on air quality during construction and operation of full-scale (100%) conversion facilities are presented in detail in Appendix F, Section F.3.3. All of the pollutant concentrations produced by the 100% capacity version of the conversion facilities would be well below their respective air quality standards, with the possible exception of dust emissions during construction. During construction, short-term particulate concentrations were estimated to potentially approach the applicable air quality standards for all options, although the condition would be temporary and minimized by good construction practices. The air quality impacts calculated for the 25% and 50% parametric cases, based on information provided in the engineering analysis report (LLNL 1997a), were found to be less than those for the 100% cases. During construction, short-term impacts for the parametric cases would be less than those for the 100% cases, and impacts during operations would also be negligible. However, the air quality impacts from operations would not scale proportionally with facility capacities. The impacts from a 25% capacity plant would be from about 45% to 100% of those from the full-capacity plant, depending on the specific source of the emissions.

All of the pollutant concentrations produced by the 100% capacity version of the cylinder treatment facility would be well below the respective air quality standards (see Appendix F, Section F.3.3). The air quality impacts calculated for the 25% and 50% parametric cases, based on information provided in the engineering analysis report (LLNL 1997a), were found to be less than those for the 100% cases, and thus would also be negligible.

FIGURE K.27 Estimated Number of On-the-Job Injuries (for entire construction and operational periods) for the Conversion of UF_6 to Uranium Metal (The ranges reflect differences in uranium metal conversion technologies.)

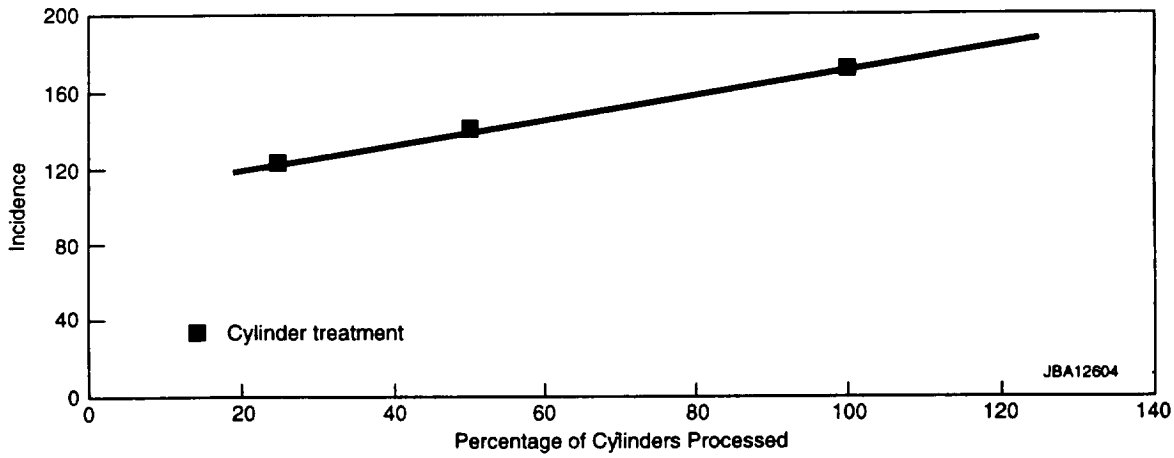

FIGURE K.28 Estimated Number of On-the-Job Injuries (for entire construction and operational periods) for the Cylinder Treatment Facility

K.2.4 Water and Soil

K.2.4.1 Surface Water

The estimated impacts on surface water during construction, operation, and potential accidents for full-scale (100%) conversion facilities and the cylinder treatment facility are presented in detail in Appendix F, Section F.3.4.1. The potential impacts evaluated included changes in runoff, changes in quality, and floodplain encroachment. The impacts to surface water from the 100% cases were found to be negligible for all three conversion options. The impacts to surface water estimated for the 25% and 50% parametric cases, based on information provided in the engineering analysis report (LLNL 1997a), were found to be less than those for the 100% cases, and thus would also be negligible.

K.2.4.2 Groundwater

The estimated impacts on groundwater during construction, operation, and potential accidents for full-scale (100%) conversion facilities and the cylinder treatment facility are presented in detail in Appendix F, Section F.3.4.2. The potential impacts evaluated included changes in the depth to groundwater, the direction of groundwater flow, recharge, and quality. The impacts to groundwater from the 100% cases were found to be negligible for all three conversion options. The impacts calculated for the 25% and 50% parametric cases, based on information provided in the engineering analysis report (LLNL 1997a), were found to be less than those for the 100% cases, and thus would also be negligible.

K.2.4.3 Soil

The estimated impacts to soil during construction, operation, and potential accidents for full-scale (100%) conversion facilities and the cylinder treatment facility are presented in detail in Appendix F, Section F.3.4.3. The potential impacts evaluated included changes in topography, permeability, quality, and erosion potential. The impacts to soil from the 100% cases were found to be negligible for all three conversion options. The impacts calculated for the 25% and 50% parametric cases, based on information provided in the engineering analysis report (LLNL 1997a), were found to be less than those for the 100% cases, and thus would also be negligible.

K.2.5 Socioeconomics

The socioeconomic impacts of U_3O_8, UO_2, and metal conversion and cylinder treatment facilities for the 50% and 25% parametric cases would be less than the impacts of the base-case facility sizes. Cost information was not available in sufficient detail to allow an analysis of impacts

using the same methodology that was used for the base cases. The impacts of parametric cases were therefore assessed qualitatively, based on the assumption that changes in the cost of equipment, materials, and labor between cases would be proportional to changes in total life-cycle cost. Compared with base-case facility sizes, smaller conversion and cylinder treatment facilities would result in the following: less direct and indirect employment and income would be created in the region of influence (ROI) at each representative site; fewer people would migrate into the ROI with fewer total jobs created, meaning fewer rental and owner-occupied houses would be needed; and the impact on local jurisdictional revenues and expenditures would be smaller.

K.2.6 Ecology

Site preparation for the construction of conversion and cylinder treatment facilities would result in the disturbance of biotic communities, including the permanent replacement of habitat with structures, paved areas, and landscaping (see Section K.2.9). Existing vegetation would be destroyed during land-clearing activities. Wildlife would be disturbed by land clearing, noise, and human presence.

Normal operations of the conversion facility would generate minor atmospheric emissions of criteria pollutants, HF, and uranium compounds. However, resulting air concentrations would be expected to be negligible under all three cases analyzed, resulting in negligible impacts to ecological resources.

Effluent discharges to surface water would contain low levels of contaminants, including uranium. However, under all three cases, contaminant concentrations in the undiluted effluent would be below levels that adversely affect aquatic biota.

Depending on the exact location of the conversion facility, the loss of approximately 10 to 30 acres (4 to 12 ha) of undeveloped land and habitat, representing the rounded 25-100% capacity range for oxide and metal conversion facilities, might constitute a minor to moderate adverse impact to vegetation and wildlife. For the cylinder treatment facility, the loss of 6.8 to 8.7 acres (2.8 to 3.5 ha) of undeveloped land and the permanent loss of 3.2 to 4.5 acres (1.3 to 1.8 ha) of habitat would constitute a negligible to low adverse impact. (See Section K.2.9 for details on land use assumptions.) When these facilities would be sited, all appropriate measures would be taken to preclude or minimize such impacts.

Impacts to wetlands and state and federally protected species due to facility construction would depend on facility location. Avoidance of wetland areas would be included during facility planning. Impacts to air quality, surface water, groundwater, and soil during construction and operations would be expected to be negligible, as would the resulting derived impacts to ecological resources.

K.2.7 Waste Management

The estimated impacts from waste management operations for construction and operation of full-scale (100%) conversion facilities are presented in detail in Appendix F, Section F.3.7. Potential moderate impacts to site, regional, and national waste management operations were found for all 100% throughput conversion option cases. On the basis of information provided in the engineering analysis report (LLNL 1997a), the impacts resulting from construction and operation of the conversion facility for the 25% and 50% parametric cases would be roughly linear for throughput ranges of between 25% and 100%. Minimal waste management impacts would result from construction-generated wastes. The annual amounts of waste generated during facility operations are shown in Table K.2. Overall, the waste input resulting from normal operations at the conversion facilities would have a low to moderate impact on waste management capacities locally or across the DOE complex.

There is a significant possibility that the magnesium fluoride (MgF_2) waste generated in the conversion to metal option would be sufficiently contaminated with uranium to require disposal as low-level radioactive waste (LLW) rather than as solid nonhazardous waste. Such disposal might require the MgF_2 waste to be grouted, generating up to 12,300 m^3/yr of grouted waste for LLW disposal. This volume represents a low (5.8%) impact to the DOE complexwide LLW disposal capacity for the 100% throughput case (scales linearly for the three throughput cases).

K.2.8 Resource Requirements

The estimated impacts from resource requirements during construction and operation of full-scale (100%) conversion facilities are presented in detail in Appendix F, Section F.3.8. The impacts on resources would be expected to be small for the 100% capacity conversion case. Although the resource requirements for the two conversion parametric analyses would be less than the 100% case, the reduction in requirements would not be linearly proportional to the decrease in throughput. For example, the amount of material required to construct a conversion facility for the 25% throughput case would be only about 10% to 20% less than the amount required for the 100% throughput facility due to "economies-of-scale."

Construction and operation of the proposed conversion options would consume irretrievable amounts of electricity, fuel, concrete, steel and other metals, water, and miscellaneous chemicals. The total quantities of commonly used materials would not be expected to be significant. No strategic and critical materials (e.g., Monel or Inconel) in significant quantities are projected to be consumed during construction or operation. The conversion options are not considered resource-intensive, and the resources required are generally not considered rare or unique. Furthermore, committing any of these resources would not be expected to cause a negative impact on the availability of these resources within local areas or nationally for the 100%, 50%, and 25% cases.

TABLE K.2 Waste Generation from Conversion Facilities for 100%, 50%, and 25% Throughput Cases

Waste Category	Waste Generated (m^3/yr) by Conversion to U_3O_8, UO_2, or Uranium Metal for Three Throughput Cases								
	U_3O_8			UO_2			Uranium Metal		
	100%	50%	25%	100%	50%	25%	100%	50%	25%
Low-level radioactive waste									
Combustible	77	73	70	88	84	82	77	71	69
Noncombustible	62	45	33	82	63	45	112	88	69
Grouted	466	233	116	466	233	116	37	26	18
Low-level mixed waste	1.1	1.1	1.1	1.1	1.1	1.1	1.1	1.1	1.1
Hazardous waste	7.3	6.7	6.1	7.3	6.7	6.1	7.3	6.7	6.1
Nonhazardous waste									
Solids	535	512	490	612	585	566	6,680[a]	3,590[a]	2,040[a]
Wastewater	58,000	36,300	24,600	74,900	47,300	31,000	96,500	57,500	37,500
Sanitary waste	4,920	4,730	4,540	5,680	5,380	5,220	5,300	4,950	4,800

[a] Includes the following volumes of MgF_2 waste: 6,120 m^3/yr for the 100% case; 3,060 m^3/yr for the 50% case, and 1,530 m^3/yr for the 25% case.

1228

Construction and operation of a cylinder treatment facility would also consume irretrievable amounts of electricity, fuel, concrete, steel, water, and miscellaneous gases and chemicals. Similar to the conversion facilities, the cylinder treatment facility option would not be expected to result in negative impacts relative to its resource requirements.

K.2.9 Land Use

K.2.9.1 Conversion to U_3O_8

Potential impacts to land use from the construction and operation of a U_3O_8 conversion facility would include the acquisition and clearing of required land, minor and temporary disruptions to contiguous land parcels, and increases in vehicular traffic. Site preparation for the construction of a facility to convert 25%, 50%, and 100% of the depleted UF_6 inventory to U_3O_8 by defluorination with anhydrous HF would require the disturbance of approximately 14, 16, and 20 acres (5.5, 6.4, and 8.1 ha), respectively. Within this disturbed area, the facility would require the permanent replacement of approximately 9, 11, and 13 acres (3.6, 4.2, and 5.3 ha) with structures, paved areas, and landscaping. The amount of land required for the other U_3O_8 conversion technologies would be roughly similar. Even the highest areal requirement would not be great enough to generate other than negligible, temporary disturbance impacts, particularly if the facility was sited in a location already dedicated to similar use with immediate access to infrastructure and utility support.

Impacts to land use outside the boundaries of a U_3O_8 conversion facility at 25%, 50%, or 100% of throughput would be limited to negligible, temporary traffic impacts associated with project construction.

K.2.9.2 Conversion to UO_2

Impacts to land use from the construction and operation of a UO_2 conversion facility, regardless of throughput capacity case, would be negligible and limited to minor and temporary disruptions to contiguous land parcels and increases in vehicular traffic associated with construction activities. Site preparation for the construction of a facility to convert 25%, 50%, and 100% of the depleted UF_6 inventory to UO_2 by the dry process with anhydrous HF would require the disturbance of approximately 16, 19, and 24 acres (6.4, 7.9, and 9.7 ha), respectively. Within this disturbed area, the facility would require the permanent replacement of approximately 10, 13, and 15 acres (4.0, 5.2, and 5.9 ha) with structures, paved areas, and landscaping. The amount of land required for the other UO_2 conversion technologies would be roughly similar, except for gelation, which would require a slightly greater amount of land. Even the highest areal requirement would not be great enough to generate other than negligible, temporary disturbance impacts associated with construction.

Impacts to land use outside the boundaries of a UO_2 conversion facility at 25%, 50%, or 100% of throughput would be limited to minor, temporary traffic impacts associated with project construction.

K.2.9.3 Conversion to Uranium Metal

Impacts to land use from the construction and operation of a facility for uranium metal conversion, regardless of throughput capacity case, would be negligible and limited to minor and temporary disruptions to contiguous land parcels and increases in vehicular traffic associated with construction activities. Site preparation for the construction of a facility to convert 25%, 50%, and 100% of the depleted UF_6 inventory to uranium metal by the continuous metallothermic production technology would require the disturbance of approximately 17, 21, and 26 acres (6.8, 8.6, and 10.6 ha), respectively. Within this disturbed area, the facility would require the permanent replacement of approximately 12, 14, and 15 acres (4.8, 5.5, and 6.2 ha) with structures, paved areas, and landscaping. The amount of land required for the other uranium metal conversion technology would be roughly similar. Even the highest areal requirement would not be great enough to generate other than negligible, temporary disturbance impacts associated with construction.

Impacts to land use outside the boundaries of a conversion-to-metal facility at 25%, 50%, or 100% of throughput would be limited to minor, temporary traffic impacts associated with project construction.

K.2.9.4 Cylinder Treatment Facility

Other than negligible and temporary disruptions to contiguous land parcels, and slight increases in vehicular traffic, virtually no impacts would be expected from a cylinder treatment facility at 25%, 50%, or 100% of throughput capacity. Site preparation for construction of a stand-alone cylinder treatment facility for 25%, 50%, and 100% of the depleted UF_6 inventory would require the disturbance of approximately 6.8, 7.5, and 8.7 acres (2.8, 3.0, and 3.5 ha), respectively. Within this disturbed area, the facility would require the permanent replacement of approximately 3.2, 3.7, and 4.5 acres (1.3, 1.5, and 1.8 ha) with structures and paved areas.

Potential impacts to land use outside the boundaries of a site containing a cylinder treatment facility at 25%, 50%, or 100% of throughput capacity would be limited to negligible, temporary traffic impacts associated with project construction.

K.2.10 Other Impacts Considered But Not Analyzed in Detail

Other impacts could potentially occur if the conversion options considered in this PEIS were implemented — including impacts to cultural resources and environmental justice, as well as

to aesthetics (e.g., visual environment), recreational resources, and noise levels, and impacts associated with decontamination and decommissioning of conversion facilities. These impacts, although considered, were not analyzed in detail for one or both of the following reasons:

- The impacts could not be determined at the programmatic level without consideration of specific sites. These impacts would be more appropriately addressed in the second-tier *National Environmental Policy Act* (NEPA) documentation when specific sites are considered.

- Consideration of the impacts would not contribute to differentiation among the alternatives; therefore, it would not affect the decisions to be made in the Record of Decision that will be issued following publication of this PEIS.

K.3 LONG-TERM STORAGE OPTIONS

The parametric analysis of the long-term storage options considered the environmental impacts of storing 25% and 50% of the depleted UF_6 inventory as UF_6 or as an oxide form. In both cases, it was assumed that the uranium material would be actively placed into storage over a 20-year period (from 2009 through 2028), and then stored for an additional 11-year period (from 2029 through 2039) with only routine monitoring and maintenance. The assessment considered the environmental impacts that would occur during (1) construction of a storage facility, (2) routine operations, and (3) potential storage facility accidents. The areas of impact and the methodologies used to evaluate the parametric cases were the same as those used to evaluate the 100% cases discussed in detail in Appendix G. The supporting engineering data for the 25% and 50% parametric storage cases are provided in the engineering analysis report (LLNL 1997a).

The environmental impacts for the 100% case are presented in Appendix G for (1) storage as UF_6 in yards, buildings, and an underground mine; (2) storage as U_3O_8 in buildings, vaults, and a mine; and (3) storage as UO_2 in buildings, vaults, and a mine. For the purposes of the parametric analysis, storage as UF_6 in buildings and storage as UO_2 in buildings were considered in detail. These options were chosen to simplify the parametric analysis because all options were evaluated in detail for the 100% base case. The relationships between the options that were identified for the 100% case were used to infer the impacts for all of the long-term storage options for the parametric analysis.

K.3.1 Human Health — Normal Operations

K.3.1.1 Radiological Impacts

The estimated radiological impacts (radiation doses and LCFs) from the normal operation of full-scale (100%) storage facilities for depleted UF_6 cylinders, UO_2 drums, and U_3O_8 drums are described in Appendix G, Section G.3.1.1. Similar impacts were calculated for the 50% and 25% storage facilities for the parametric analysis. Radiological impacts from the storage as UF_6, UO_2, and U_3O_8 would be limited to involved workers because emissions of uranium to the air and water would be expected to be negligible during normal operations. The radiological impacts for involved workers for the 100%, 50%, and 25% cases are shown in Figures K.29 through K.34. The range of impacts resulting from technology differences (i.e., differences between building, vault, and mine storage facilities) are represented by dashed lines in the figures. The results for the two parametric cases for storage in buildings are shown in the figures as solid points, with a curve drawn between the points to indicate how the impacts would vary as a function of the percent of depleted UF_6 processed. The upper and lower bounds of impacts for the 25% and 50% cases were estimated on the basis of the range determined for the different technologies for the 100% case. The area enclosed by the lines in the figures indicates the range of impacts expected for throughputs between 25% and 100%.

The results of the parametric analysis (as shown in Figures K.29 and K.34) indicate that the collective radiological impacts would scale relatively linearly with the total quantity of depleted UF_6 processed. The impacts of the 25% and 50% cases would be smaller than those for the 100% case, although the decrease would not be proportional to the reduction in throughput (i.e., the impacts for the 50% case would be greater than half of the impacts for the 100% case). The doses shown in the figures can be converted to the number (or risk) of LCFs by multiplying the doses (in rem or person-rem) by 0.0004 LCF/person-rem for workers. Additional discussion of the significance of the estimated doses is provided in Appendix G, Section G.3.1.1.

K.3.1.2 Chemical Impacts

The estimated impacts from chemical exposures during the normal operation of full-scale (100%) storage facilities are described in Appendix G, Section G.3.1.2. The results of the 100% case analyses indicated that noninvolved workers and members of the general public would receive very low exposures to chemicals from operation of all storage facilities and that no adverse health impacts would be expected. For the 100% cases, the calculated hazard indices were much less than 1 for all long-term storage options (a hazard index of greater than 1 indicates the potential for health impacts). For the parametric analysis of the 25% and 50% throughput cases, airborne emissions of depleted uranium and HF during normal operations would be less than the 100% cases and extremely small (LLNL 1997a). Therefore, by comparison with the 100% case results, no adverse health

FIGURE K.30 Estimated Annual Average Individual Dose to Involved Workers from Storage as UF_6 (The upper and lower ranges reflect differences in storage technologies, i.e., buildings, yards, and mine.)

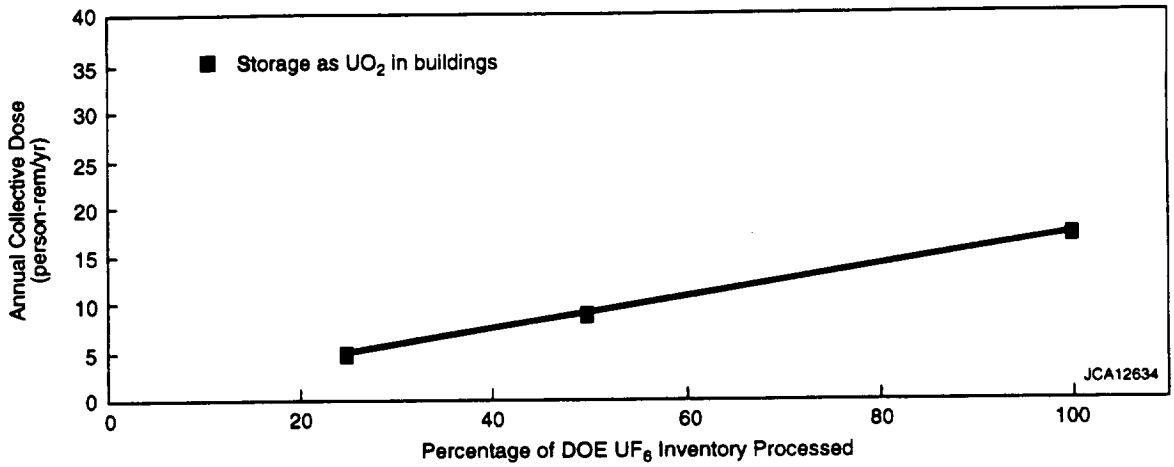

FIGURE K.31 Estimated Annual Collective Dose to Involved Workers from Storage as UO_2 (The collective doses for the different storage technologies would be essentially the same.)

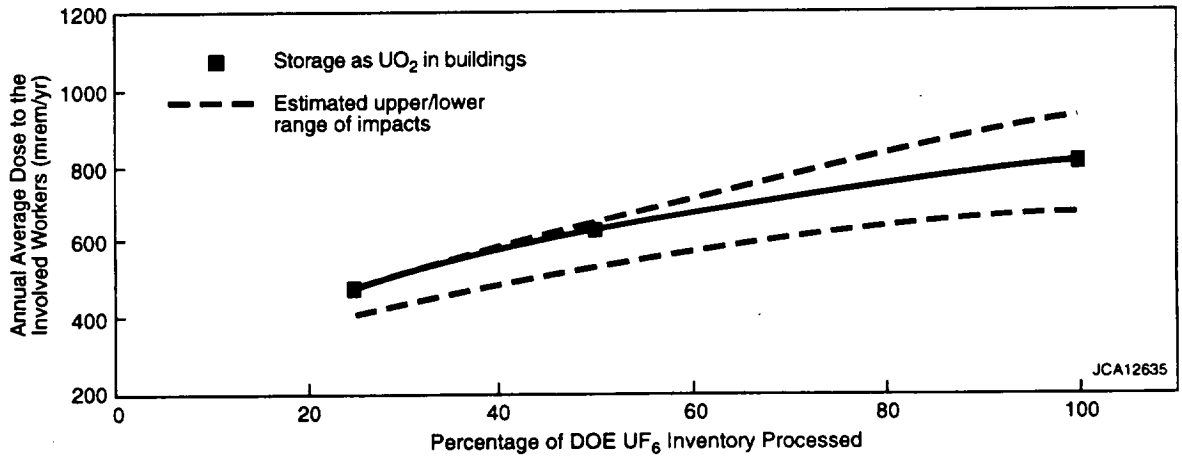

FIGURE K.32 Estimated Annual Average Individual Dose to Involved Workers from Storage as UO_2 (The upper and lower ranges reflect differences in storage technologies, i.e., buildings, vaults, and mine.)

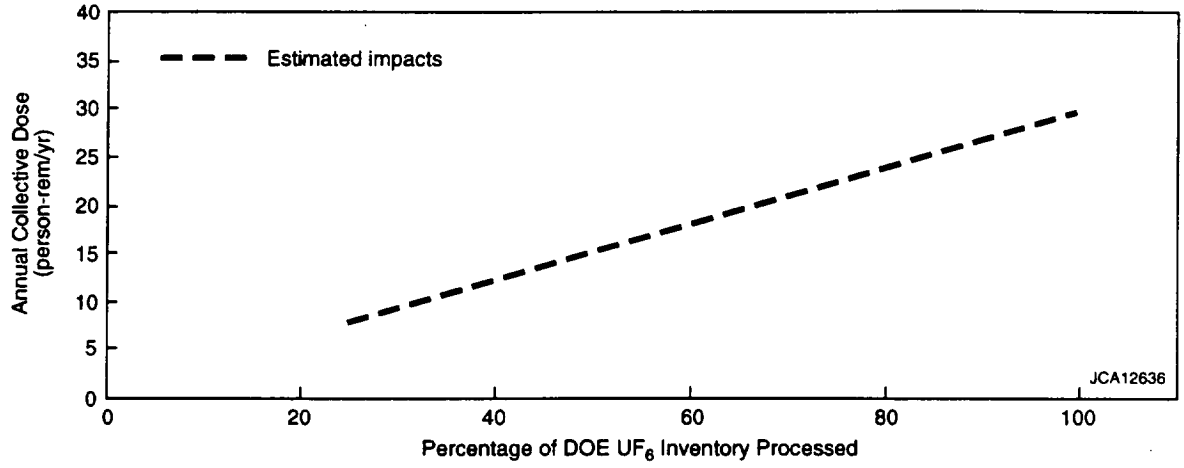

FIGURE K.33 Estimated Annual Collective Dose to Involved Workers from Storage as U_3O_8

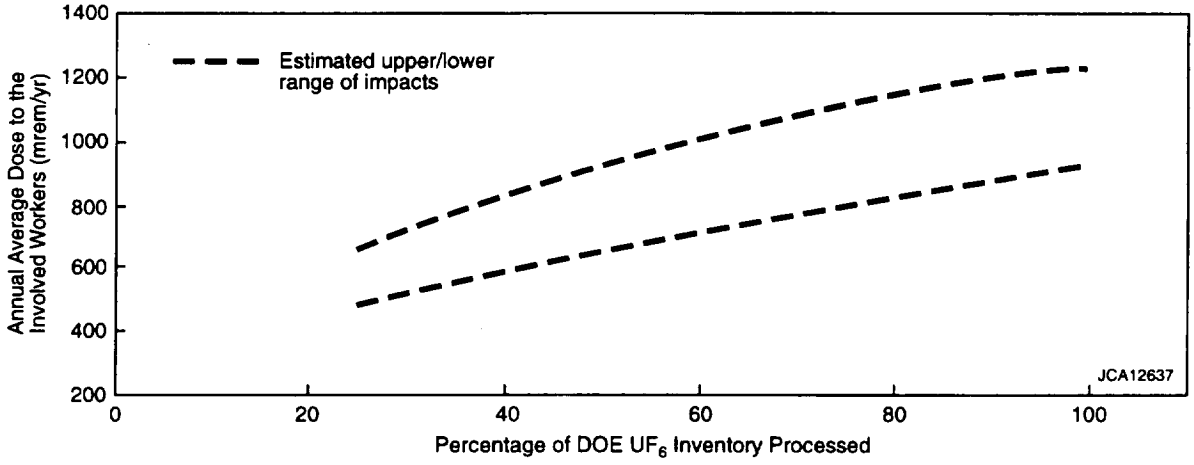

FIGURE K.34 Estimated Annual Average Individual Dose to Involved Workers from Storage as U_3O_8 (The upper and lower ranges reflect differences in storage technologies, i.e., buildings, vaults, and mine.)

impacts from chemical exposures would be expected for throughput rates between 25% and 100% for all long-term storage options.

K.3.2 Human Health — Accident Conditions

K.3.2.1 Radiological Impacts

The estimated radiological impacts (radiation doses and LCFs) from potential accidents during the operation of full-scale (100%) storage facilities for depleted UF_6, U_3O_8, and UO_2 are presented in Appendix G, Section G.3.2.1. The analysis of the 100% cases considered a range of accidents in four frequency categories; results are presented for only those accidents in each category that would have the greatest consequences (bounding accidents). Similar sets of accidents covering the same four frequency categories are defined in the engineering analysis report (LLNL 1997a) for the 25% and 50% throughput cases.

Based on the assessment of the 25% and 50% long-term storage cases, the radiological accident impacts associated with each of the parametric cases would be the same as those presented for the 100% case in Appendix G, Section G.3.2.1. The impacts would be identical because the bounding accidents within each frequency category would be the same for the 100%, 50%, and 25% cases. The bounding accidents would be the same because they would involve only a limited amount of material that would be at risk under accident conditions regardless of the facility size or throughput. However, as a result of the reduced throughput rates, the actual frequencies of some accidents that were related to handling operations (i.e., the "mishandle/drop of drum" accident) would decrease as the number of containers handled decreased. The resulting risk of these accidents would also decrease as their frequencies decreased. However, none of the accident frequencies would change enough to cause the accident to be considered in a different frequency category. Therefore, the overall impacts associated with the long-term storage options would be the same for all parametric cases.

K.3.2.2 Chemical Impacts

The estimated chemical impacts from potential accidents during the operation of full-scale (100%) storage facilities for UF_6 and oxide are presented in Appendix G, Section G.3.2.2. The analysis of the 100% cases considered a range of accidents in four frequency categories; results are presented for only those accidents in each category that would have the greatest consequences (bounding accidents). Similar sets of accidents covering the same four frequency categories are defined in the engineering analysis report (LLNL 1997a) for the 25% and 50% throughput cases.

Based on the assessment of the 25% and 50% long-term storage cases, the chemical accident impacts associated with each of the parametric cases would be the same as those presented

for the 100% case in Appendix G, Section G.3.2.2. As for radiological accidents, the impacts would be the same because the bounding accidents within each frequency category would be the same for the 100%, 50%, and 25% cases. The bounding accidents would be the same because they would involve only a limited amount of material that would be at risk under accident conditions regardless of the facility size or throughput. However, as a result of the reduced throughput rates, the actual frequencies of some accidents related to handling operations (i.e., the "mishandle/drop of drum" accident) would decrease as the number of containers handled decreased. The resulting risk of these accidents would also decrease as their frequencies decreased. However, none of the accident frequencies would change enough to cause the accident to be considered in a different frequency category. Therefore, the overall impacts associated with the long-term storage options would be the same for all parametric cases.

K.3.2.3 Physical Hazards

The estimated health impacts, such as on-the-job injuries and fatalities, from potential physical accidents during the construction and operation of full-scale (100%) storage facilities are presented in Appendix G, Section G.3.2.3. For the 100% storage cases, worker fatalities ranged from about 0.10 to 0.36 for storage as UF_6, 0.16 to 0.24 for storage as UO_2, and 0.29 to 0.43 for storage as U_3O_8 (see Table G.11 in Section G.3.2.3). On-the-job worker injuries for the 100% cases ranged from about 90 to 190 for storage as UF_6, from 150 to 220 for storage as U_3O_8, and from 100 to 140 for storage as UO_2. For the two options analyzed in detail in the parametric analysis, the impacts of the 25% and 50% cases would be smaller than those for the 100% cases, although the decrease would not be proportional to the reduction in throughput (i.e., the impacts for the 50% case would be greater than 50% of the impacts for the 100% case).

For parametric cases, the number of on-the-job worker fatalities for storage as UF_6 would range from 0.05 to 0.23 at 25% capacity and from about 0.10 to 0.29 at 50% capacity. For storage as UO_2, fatalities would range from 0.07 to 0.15 at 25% capacity and from about 0.10 to 0.19 at 50% capacity. The number of on-the-job worker injuries for storage as UF_6 would range from about 50 to 125 at 25% capacity and from about 60 to 150 at 50% capacity. For storage as UO_2, injuries would range from about 50 to 90 at 25% capacity and from about 75 to 110 at 50% capacity. The predicted number of injuries for UF_6 and UO_2 are shown as a function of throughput in Figures K.35 and K.36, respectively.

Although parametric cases for the U_3O_8 storage options were not explicitly analyzed, if it is assumed that the relative difference in magnitude of impacts for U_3O_8 and UO_2 is similar to that for the 100% cases, then the number of on-the-job fatalities for storage as U_3O_8 would range from about 0.12 to 0.26 for 25% capacity and from about 0.19 to 0.36 at 50% capacity. Estimated injuries for parametric cases of storage as U_3O_8 would range from about 75 to 135 for 25% capacity and from about 113 to 176 for 50% capacity.

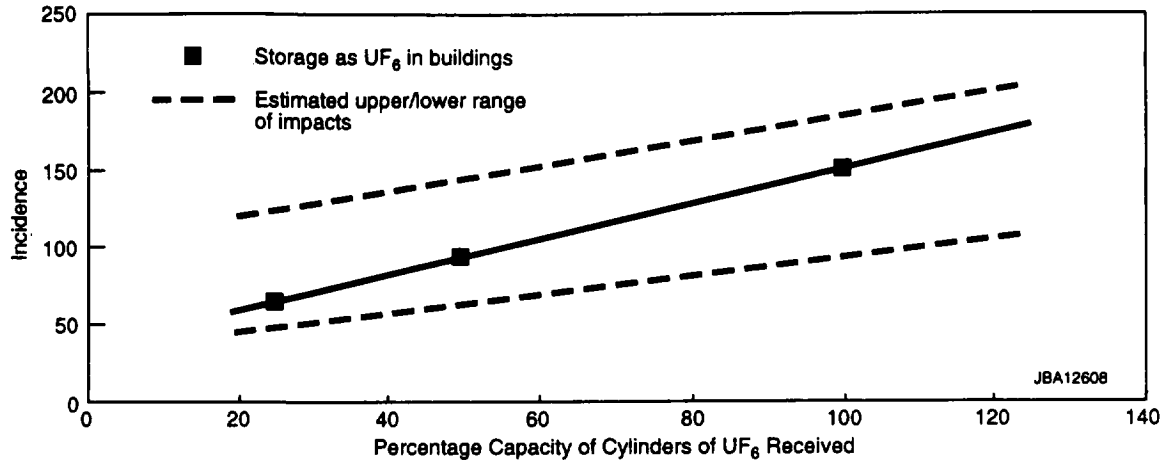

FIGURE K.35 Estimated Number of On-the-Job Injuries (for entire construction and operational periods) for Storage as UF_6 (The ranges reflect differences in storage technologies, i.e., buildings, yards, and mine.)

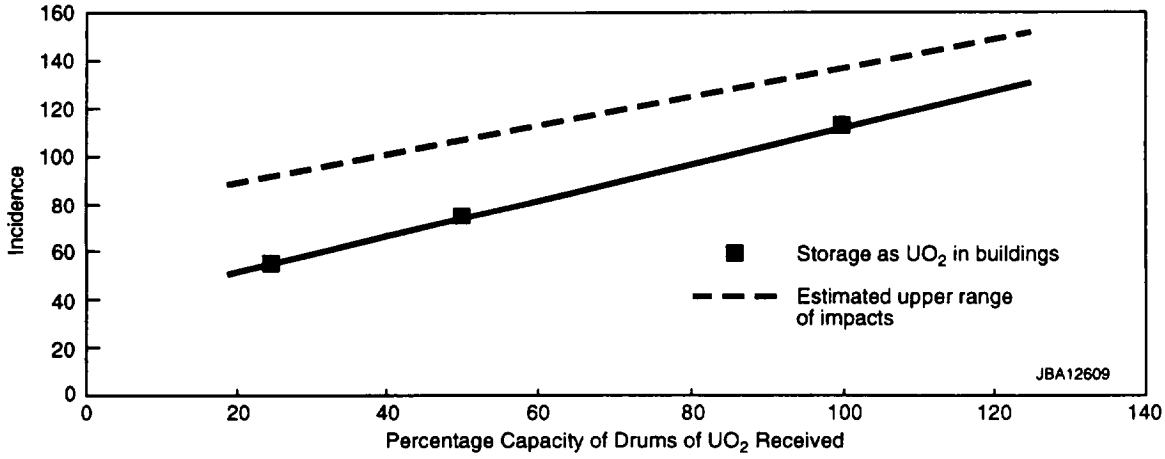

FIGURE K.36 Estimated Number of On-the-Job Injuries (for entire construction and operational periods) for Storage as UO_2 (The ranges reflect differences in storage technologies, i.e., buildings, vaults, and mine.)

K.3.3 Air Quality

The estimated impacts on air quality during construction and operation of full-scale (100%) long-term storage facilities for UF_6 and oxide are presented in detail in Appendix G, Section G.3.3. All of the pollutant concentrations resulting from 100% throughput would be below the respective air quality standards. During construction, short-term particulate concentrations would potentially approach the applicable air quality standards for all options, although the condition would be temporary and minimized by good construction practices. During operations, the pollutant concentrations would be less than 0.1% of the corresponding air quality standards, resulting in negligible impacts.

The air quality impacts calculated for the 25% and 50% parametric cases, based on information provided in the engineering analysis report (LLNL 1997a), were found to be less than those for the 100% cases. During construction, short-term impacts for the parametric cases would be less than those for the 100% cases; impacts during operations would also be negligible. The air quality impacts from storage were found to scale roughly proportionally with throughput. The impacts from the 50% case for both construction and operations would be about 0.6 of those from the 100% case for both UF_6 and UO_2; the impacts for construction for the 25% case would be 0.25 and 0.32 times the 100% case for UF_6 and UO_2, respectively; and the impacts for operations for the 25% case would be only about 0.2 times the 100% case for both UF_6 and UO_2.

K.3.4 Water and Soil

K.3.4.1 Surface Water

The estimated impacts on surface water during construction, operation, and potential accidents for full-scale (100%) storage facilities for UF_6 and oxide are presented in detail in Appendix G, Section G.3.4.1. The potential impacts evaluated included changes in runoff, changes in quality, and floodplain encroachment. The impacts to surface water from the 100% cases were found to be negligible for all storage options for both UF_6 and oxide (including storage of U_3O_8). The impacts calculated for the 25% and 50% parametric cases, based on information provided in the engineering analysis report (LLNL 1997a), were found to be less than those for the 100% cases, and thus would also be negligible.

K.3.4.2 Groundwater

The estimated impacts on groundwater during construction, operation, and potential accidents for full-scale (100%) storage facilities for UF_6 and oxide are presented in detail in Appendix G, Section G.3.4.2. The potential impacts evaluated included changes in depth to groundwater, direction of groundwater flow, recharge, and groundwater quality. The impacts to

groundwater from the 100% cases were found to be negligible for all storage options for both UF_6 and oxide (including storage of U_3O_8). The impacts calculated for the 25% and 50% parametric cases, based on information provided in the engineering analysis report (LLNL 1997a), were found to be less than those for the 100% cases, and thus would also be negligible.

K.3.4.3 Soil

The estimated impacts to soil during construction, operation, and potential accidents for full-scale (100%) long-term storage facilities for UF_6 and oxide are presented in detail in Appendix G, Section G.3.4.3. The potential impacts evaluated included changes in topography, permeability, quality, and erosion potential. The impacts to soil from the 100% cases were found to have potentially moderate, but temporary, impacts for all storage options. These moderate impacts would result from material excavated during construction that would be left on-site. In the long term, contouring and reseeding would return soil conditions back to their former state, and the impacts would be negligible. The impacts calculated for the 25% and 50% parametric cases for storage of UF_6 and UO_2 in buildings, based on information provided in the engineering analysis report (LLNL 1997a), were also found to have moderate, but temporary, impacts on soil, similar to the 100% cases. In the long term, impacts on soil would be negligible for all storage options.

K.3.5 Socioeconomics

The socioeconomic impacts of UF_6 and UO_2 long-term storage facilities for the 50% and 25% parametric cases would be less than the impacts of the base-case facility sizes. Cost information was not available in sufficient detail to allow an analysis of impacts using the same methodology that was used for the base cases. The impacts of parametric cases were therefore assessed qualitatively, based on the assumption that changes in the cost of equipment, materials, and labor would be proportional to changes in total life-cycle cost. Compared with base-case facility sizes, smaller UF_6 and UO_2 long-term storage facilities would result in the following: less direct and indirect employment and income in the ROI would be created at each representative site; fewer people would migrate into the ROI with fewer total jobs created, meaning fewer rental and owner-occupied houses would be needed; and the impact on local jurisdictional revenues and expenditures would be smaller.

K.3.6 Ecology

Impacts to ecological resources could occur during construction of UF_6 storage facilities for all options, although impacts during operations would be negligible. Impacts due to construction and operation of a facility to store UO_2 in buildings would be similar to impacts from storage of UF_6. Site preparation activities would result in the disturbance of biotic communities, including the permanent replacement of habitat with structures and paved areas (see Section K.3.9). Existing

vegetation would be destroyed during land-clearing activities. Wildlife would be disturbed by land clearing, noise, and human presence.

Depending on the exact location of the UF_6 facility, the loss of 40 to 130 acres (16 to 53 ha) of undeveloped land and habitat might constitute a moderate to large adverse impact to vegetation and wildlife. (See Section K.3.9 for details on land use assumptions.) Depending on the exact location of the UO_2 facility, the loss of 40 to 80 acres (16 to 32 ha) of undeveloped land and habitat might constitute a moderate adverse impact. However, when these facilities were sited, all appropriate measures would be taken to preclude or minimize such impacts.

Impacts to wetlands and state and federally protected species due to facility construction would depend on facility location. Avoidance of wetland areas and site-specific surveys for protected species would be included during facility planning.

K.3.7 Waste Management

The estimated impacts from waste management operations from the construction and operation of full-scale (100%) long-term storage facilities for UF_6 and oxide are presented in detail in Appendix G, Section G.3.7. On the basis of information provided in the engineering analysis report (LLNL 1997a), the impacts resulting from construction and operation of the long-term storage facility for the 25% and 50% parametric cases would be roughly linear for throughput ranges of between 25% and 100%. Minimal to moderate, but temporary, waste management impacts would result from construction wastes. Negligible impacts would be associated with all waste forms generated during operations. Overall, the waste input resulting from storage facilities would have negligible impact on waste management capacities locally or across the DOE complex.

K.3.8 Resource Requirements

The estimated impacts from resource requirements during construction and operation of full-scale (100%) long-term storage facilities for UF_6 and oxide are presented in detail in Appendix G, Section G.3.8. The impacts on resources would be expected to be small for the 100% capacity storage case for all options. Resource requirements for the two parametric cases considered would be less than those for the 100% case (LLNL 1997a). In general, the amounts of construction materials would be roughly proportional to the storage capacity because the majority of the construction materials would be for the actual storage buildings and the number of storage buildings required would be linearly related to the required storage capacity.

Construction and operation of the proposed storage facilities would consume irretrievable amounts of electricity, fuel, concrete, steel and other metals, water, and miscellaneous chemicals. The total quantities of commonly used materials would not be expected to be significant. No strategic and critical materials (e.g., Monel or Inconel) in significant quantities are projected to be

consumed during construction or operation for all long-term storage options. The storage options are not considered resource-intensive, and the resources required are generally not considered rare or unique. Furthermore, committing any of these resources would not be expected to cause a negative impact on the availability of these resources within local areas or nationally for the 100%, 50%, and 25% cases.

K.3.9 Land Use

Impacts to land use from the construction and operation of UF_6 storage buildings would be limited to the clearing of required land, potential minor and temporary disruptions to contiguous land parcels, and a slight increase in vehicular traffic. Site preparation for construction of a facility to store 25%, 50%, and 100% of the depleted UF_6 inventory in buildings would require the disturbance of approximately 42, 72, and 131 acres (17, 29, and 53 ha), respectively. Within this disturbed area, the facility would require the permanent replacement of approximately 16, 30, and 62 acres (6.5, 12, and 25 ha) with structures and paved areas. The amount of land required for the other UF_6 storage options would be generally similar.

Land for storage buildings would be cleared incrementally over the projected 20-year construction project, thereby reducing the potential for land disturbance and consequential land disruption impacts. Such potential impacts, however, would be greatest at 100% of throughput capacity. Also, the areal requirement of 131 acres (53 ha) for the 100% capacity case could result in land-use changes if an existing site with limited open space were chosen.

Road and rail access within a storage site would be designed to minimize on-site traffic conflicts. For off-site traffic, only temporary, minor impacts associated with construction vehicles would be expected.

Storage as UO_2 would be expected to generate only negligible impacts to land use and would result in a lower areal requirement and less land disturbance compared with storage as UF_6. Site preparation for the construction of a facility to store 25%, 50%, and 100% of the depleted UF_6 inventory as UO_2 in buildings would require the disturbance of approximately 37, 49, and 79 acres (15, 20, and 32 ha), respectively. Within this disturbed area, the facility would require the permanent replacement of approximately 13, 20, and 35 acres (5.1, 8.1, and 14 ha) with structures and paved areas. The amount of land required for the other uranium oxide storage options would be generally similar.

Land for storage buildings would be cleared incrementally over the projected 20-year construction project, thereby reducing the potential for land disturbance and consequential land disruption impacts. Such potential impacts, however, would be greatest at 100% of throughput capacity. The peak labor force during the 20-year construction period, regardless of throughput capacity, would not be large enough to generate other than negligible off-site traffic impacts.

K.3.10 Other Impacts Considered But Not Analyzed in Detail

Other impacts could potentially occur if the long-term storage options considered in this PEIS were implemented — including impacts to cultural resources and environmental justice, as well as to aesthetics (e.g., visual environment), recreational resources, and noise levels, and impacts associated with decontamination and decommissioning of storage facilities. These impacts, although considered, were not analyzed in detail for one or both of the following reasons:

- The impacts could not be determined at the programmatic level without consideration of specific sites. These impacts would be more appropriately addressed in the second-tier NEPA documentation when specific sites are considered.

- Consideration of the impacts would not contribute to differentiation among the alternatives; therefore, it would not affect the decisions to be made in the Record of Decision that will be issued following publication of this PEIS.

K.4 MANUFACTURE AND USE OPTIONS

The parametric analysis of the manufacture and use options considered the environmental impacts of using 25% and 50% of the depleted UF_6 inventory in the form of either uranium metal or dense UO_2 to manufacture uranium-shielded casks. The analysis of both options (uranium metal or dense UO_2) was based on the assumption that depleted uranium would be used as the primary shielding material in containers, called "casks," used to store spent nuclear fuel. The assessment considered the environmental impacts that would occur during (1) construction of a cask manufacturing facility, (2) routine operation of the cask manufacturing facility, and (3) potential manufacturing plant accidents. The manufacturing of casks was assumed to take place over a 20-year period, from 2009 through 2028. Impacts during use of depleted uranium shielded casks were not estimated in the PEIS.

The areas of impact and the methodologies used to evaluate the parametric cases for the manufacture and use options were the same as those used to evaluate the 100% cases. The evaluation of the 100% cases is presented in detail in Appendix H. The supporting engineering data for the 25% and 50% parametric cases are provided in the engineering analysis report (LLNL 1997a).

K.4.1 Human Health — Normal Operations

K.4.1.1 Radiological Impacts

The estimated radiological impacts (radiation doses and LCFs) from normal operation of a full-scale (100%) UO_2 cask manufacturing facility are described in Appendix H, Section H.3.1.1. Similar impacts were calculated for the manufacture of casks using 50% and 25% of the depleted UF_6 inventory. The radiological impacts estimated for the 100%, 50%, and 25% case are shown in Figures K.37 through K.42 as radiation doses to each of the six receptor scenarios considered in the PEIS: members of the general public — annual collective dose and annual dose to the MEI; noninvolved workers — annual collective dose and annual dose to the MEI; and involved workers — annual collective dose and annual average individual dose. Because the radiological impacts to involved workers (Figures K.41 and K.42) would not depend on the location of the manufacturing facility, no ranges of impact are presented. Ranges of impacts are presented for noninvolved workers and the general public in Figures K.37 through K.40. The range of impacts for noninvolved workers would be related only to possible differences in site meteorological conditions. The impact range for members of the general public would be related to differences in both meteorological conditions and population density (i.e., from rural to urban areas).

The results of the parametric analysis (as shown in Figures K.37 through K.42) indicate that the collective radiological impacts would scale relatively linearly with the total quantity of depleted UF_6 used to manufacture the casks. The impacts of the 25% and 50% cases would be smaller than those for the 100% case, although the decrease would not be proportional to the reduction in throughput (i.e., the impacts for the 50% case would be greater than half of the impacts for the 100% case). The doses shown in the figures can be converted to the number (or risk) of LCFs by multiplying the doses (in rem or person-rem) by 0.0005 LCF/person-rem for members of the public and 0.0004 LCF/person-rem for workers. Additional discussion of the significance of the estimated doses is provided in Appendix H, Section H.3.1.1.

The estimated radiation doses from the manufacture of uranium metal casks for the 100%, 50%, and 25% throughput cases are presented in Figures K.43 through K.48. The general relationship between radiological impacts and throughput would be similar to that for UO_2 casks; that is, the radiological impacts would decrease with decreasing throughput, although at a rate not proportional to the reduction in throughput.

K.4.1.2 Chemical Impacts

The estimated impacts from chemical exposures during the normal operation of full-scale (100%) cask manufacturing facilities for UO_2 and uranium metal are described in Appendix H, Section H.3.1.2. The results of the 100% case analyses indicated that noninvolved workers and members of the general public would receive very low exposures to chemicals from the normal

FIGURE K.45 Estimated Annual Collective Dose to Noninvolved Workers from the Manufacture of Casks Using Uranium Metal (The upper and lower ranges reflect differences in site characteristics, primarily meteorological conditions.)

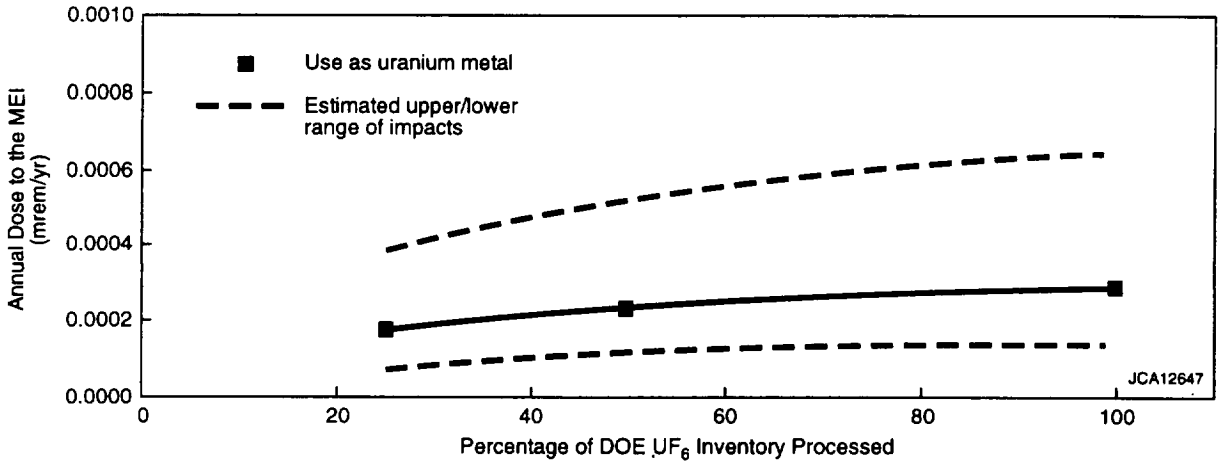

FIGURE K.46 Estimated Annual Dose to the Noninvolved Worker MEI from the Manufacture of Casks Using Uranium Metal (The upper and lower ranges reflect differences in site characteristics, primarily meteorological conditions.)

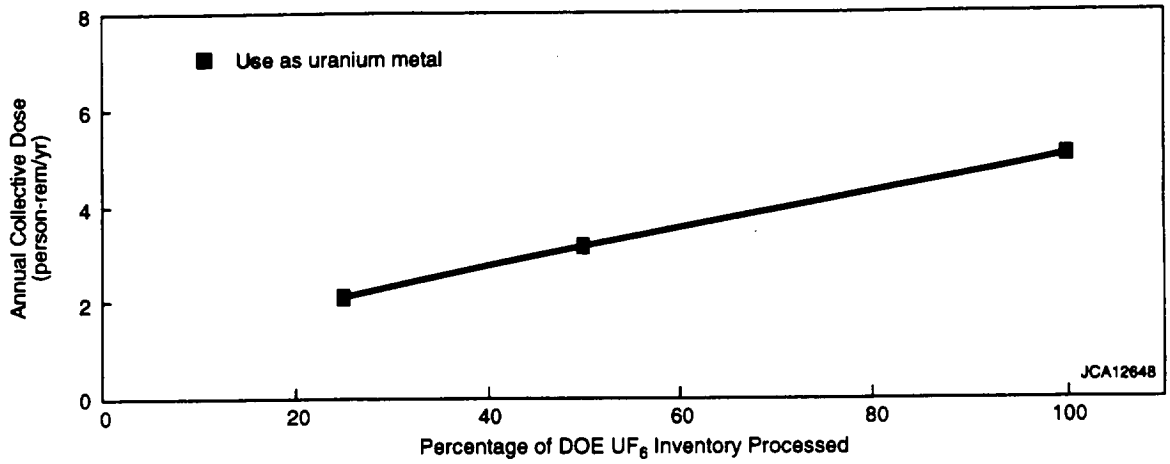

FIGURE K.47 Estimated Annual Collective Dose to Involved Workers from the Manufacture of Casks Using Uranium Metal

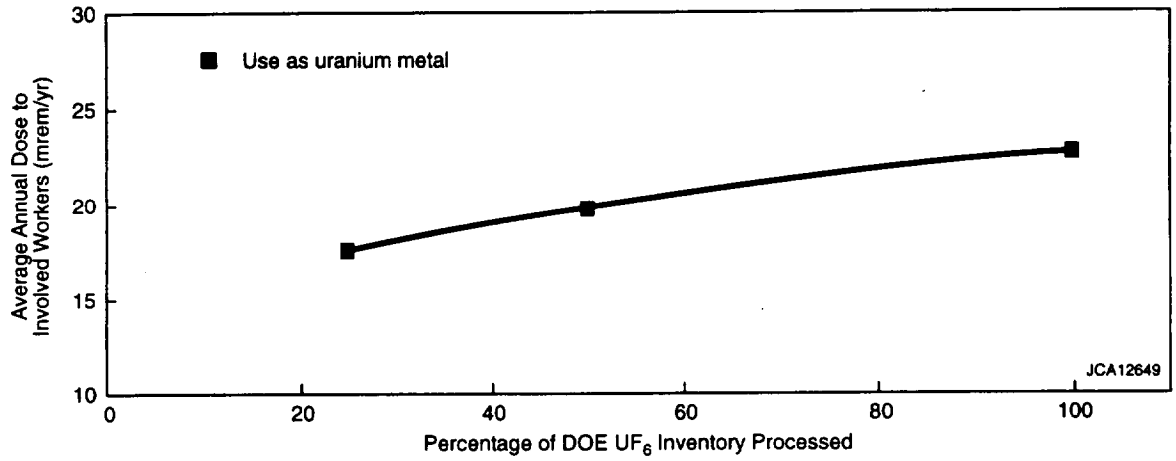

FIGURE K.48 Estimated Annual Average Individual Dose to Involved Workers from the Manufacture of Casks Using Uranium Metal

operation of manufacturing facilities and that no adverse health impacts would be expected. For the 100% cases, the calculated hazard indices were much less than 1 during normal operations (a hazard index of greater than 1 indicates the potential for health impacts). For the parametric analysis of the 25% and 50% throughput cases, airborne emissions during normal operations would be less than the 100% cases and extremely small (LLNL 1997a). Therefore, by comparison with the 100% case results, no adverse health impacts from chemical exposures would be expected for throughput rates between 25% and 100% for the manufacture of UO_2 and uranium metal shielded casks.

K.4.2 Human Health — Accident Conditions

K.4.2.1 Radiological Impacts

The estimated radiological impacts (radiation doses and LCFs) from potential accidents during the operation of full-scale (100%) cask manufacturing facilities are presented in Appendix H, Section H.3.2.1. The analysis of the 100% cases considered a range of accidents in four frequency categories; results are presented only for those accidents in each category that would have the greatest consequences (bounding accidents). Similar sets of accidents covering the same four frequency categories are defined in the engineering analysis report (LLNL 1997a) for the 25% and 50% throughput cases.

The impacts from bounding accidents for the 25% and 50% throughput cases would be the same as those presented in Appendix H, Section H.3.2.1 for the 100% case, with two exceptions. For the manufacture of both uranium oxide and uranium metal shielded casks, the bounding accident impacts for the "unlikely" frequency category would be less for the 25% and 50% cases than for the 100% case. The radiological impacts for these accident categories are presented in Tables K.3 and K.4 for the 100%, 50%, and 25% cases.

K.4.2.2 Chemical Impacts

The estimated chemical impacts from potential accidents during the operation of full-scale (100%) cask manufacturing facilities using uranium oxide and uranium metal are presented in Appendix H, Section H.3.2.2. The analysis of the 100% cases considered a range of accidents in four frequency categories; results are presented only for those accidents in each category that would have the greatest consequences (bounding accidents). Similar sets of accidents covering the same four frequency categories are defined in the engineering analysis report (LLNL 1997a) for the 25% and 50% throughput cases.

The bounding chemical accidents associated with the 25% and 50% throughput cases would be the same as those presented for the 100% cases in Appendix H. The impacts would be similar because the bounding accidents within most frequency categories would be the same as the 100%,

TABLE K.3 Estimated Radiological Doses per Accident Occurrence for the Manufacture and Use Options

Option/ Accident[a]	Frequency Category[b]	Capacity (%)	Maximum Dose[c]				Minimum Dose[c]			
			Noninvolved Workers		General Public		Noninvolved Workers		General Public

1253

50%, and 25% cases, and in those cases where these accidents were different, no adverse chemical impacts were estimated to occur. The bounding accidents would be the same because they would involve only a limited amount of material that would be at risk under accident conditions regardless of the facility size or throughput. Some of the impacts from other accidents considered for the 25% and 50% cases (nonbounding) would be different from those for the 100% cases. In general, the impacts of these nonbounding accidents for the 50% and 25% cases would be less than those for the 100% cases because of the reduced throughput.

K.4.2.3 Physical Hazards

The estimated health impacts, such as on-the-job injuries and fatalities, from potential physical accidents during the construction and operation of full-scale (100%) cask manufacturing facilities are presented in Appendix H, Section H.3.2.3. For the 100% analysis, up to 1 on-the-job fatality was predicted for the manufacture of both uranium oxide and uranium metal shielded casks. The predicted number of on-the-job worker injuries for the 100% case was 640 for manufacturing uranium oxide shielded casks and 670 for uranium metal shielded casks. For the two options analyzed in detail in the parametric analysis, the impacts of the 25% and 50% cases would be smaller than those for the 100% cases, although the decrease would not be proportional to the reduction in throughput (i.e., the impacts for the 50% case would be greater than 50% of the impacts for the 100% case).

The predicted number of on-the-job worker fatalities over the entire 20 years of the manufacture of uranium oxide or uranium metal shielded casks is about 1 (including construction and operations). For uranium oxide shielded casks, the number would range from 0.6 for the 25% case to 0.76 for the 100% case; whereas for uranium metal shielded casks, the number would range from 0.7 for the 25% case to 0.85 for the 100% case. The predicted number of on-the-job injuries (including construction and operations) would range from 480 to 640 for uranium oxide casks and from 510 to 670 for uranium metal casks. The estimated numbers of fatalities and injuries for uranium oxide and uranium metal shielded casks are shown as a function of throughput in Figures K.49 and K.50, respectively.

K.4.3 Air Quality

The estimated impacts on air quality during construction and operation of full-scale (100%) cask manufacturing facilities are presented in detail in Appendix H, Section H.3.3. All of the pollutant concentrations produced by the 100% capacity version of the storage facilities would be below their respective air quality standards. During construction, the largest impacts relative to air quality standards would occur for nitrogen oxides (NO_x). During construction, all pollutant concentrations would be less than 10% of the corresponding standards. During operations, all pollutant concentrations would also be less than 10% of the standards.

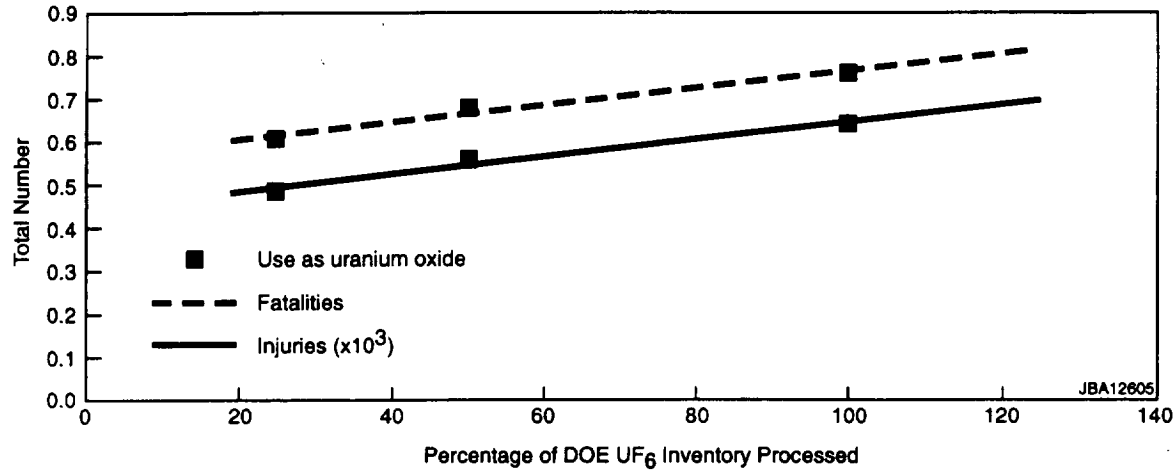

FIGURE K.49 Estimated Number of On-the-Job Fatalities and Injuries (for entire construction and operational periods) from the Manufacture of Uranium Oxide Shielded Casks

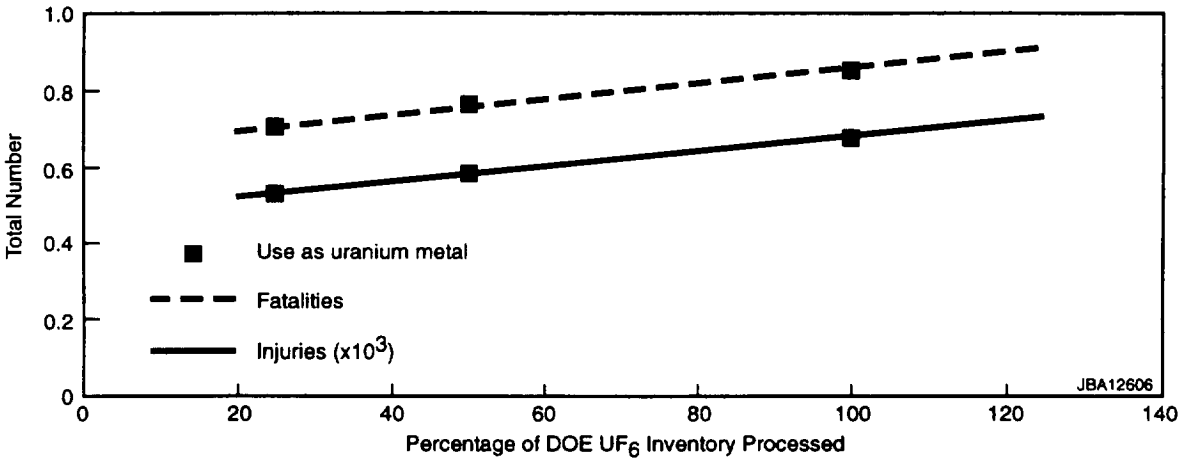

FIGURE K.50 Estimated Number of On-the-Job Fatalities and Injuries (for entire construction and operational periods) from the Manufacture of Uranium Metal Shielded Casks

The air quality impacts calculated for the 25% and 50% parametric cases, based on the information provided in the engineering analysis report (LLNL 1997a), were found to be less than those for the 100% cases. During construction, short-term impacts for the parametric cases would be less than those for the 100% cases, and impacts during operations would also be less. The 25% case impacts would not be much smaller than the 50% case impacts, and the operations impacts in all cases would be less than 10% of the corresponding construction impacts.

K.4.4 Water and Soil

K.4.4.1 Surface Water

The estimated impacts on surface water during construction, operation, and potential accidents for full-scale (100%) cask manufacturing facilities are presented in detail in Appendix H, Section H.3.4. The potential impacts evaluated included changes in runoff, changes in quality, and floodplain encroachment. The impacts to surface water from the 100% cases were found to be negligible for manufacturing both uranium oxide and uranium metal shielded casks. The impacts estimated for the 25% and 50% parametric cases, based on information provided in the engineering analysis report (LLNL 1997a), were found to be less than those for the 100% cases, and thus would also be negligible.

K.4.4.2 Groundwater

The estimated impacts on groundwater during construction, operation, and potential accidents for full-scale (100%) cask manufacturing facilities are presented in detail in Appendix H, Section H.3.4. The potential impacts evaluated included changes in the depth to groundwater, the direction of groundwater flow, recharge, and quality. The impacts to groundwater from the 100% cases were found to be negligible for manufacturing both uranium oxide and uranium metal shielded casks. The impacts calculated for the 25% and 50% parametric cases, based on information provided in the engineering analysis report (LLNL 1997a), were found to be less than those for the 100% cases, and thus would also be negligible.

K.4.4.3 Soil

The estimated impacts to soil during construction, operation, and potential accidents for full-scale (100%) cask manufacturing facilities are presented in detail in Appendix H, Section H.3.4. The potential impacts evaluated included changes in topography, permeability, quality, and erosion potential. The impacts to soil from the 100% cases were found to be negligible for manufacturing both uranium oxide and uranium metal shielded casks. The impacts calculated for the 25% and 50%

parametric cases, based on information provided in the engineering analysis report (LLNL 1997a), were found to be less than those for the 100% cases, and thus would also be negligible.

K.4.5 Socioeconomics

The socioeconomic impacts of UO_2 and metal manufacturing facilities for the 25% and 50% parametric cases would be less than the impacts of the base-case facility sizes. Cost information was not available in sufficient detail to allow an analysis of impacts using the same methodology that was used for the base cases. The impacts of parametric cases were therefore assessed qualitatively, based on the assumption that changes in the cost of equipment, materials, and labor would be proportional to changes in total life-cycle cost. Compared with base-case facility sizes, smaller UO_2 and metal manufacturing facilities would create less direct employment and income at the site.

K.4.6 Ecology

For both uranium oxide and uranium metal shielded cask manufacturing facilities, impacts to air quality, surface water, groundwater, and soil during construction and operations would be expected to be well below levels harmful to biota for the 25%, 50%, and 100% cases. Resulting contaminant-derived impacts to ecological resources would be expected to be negligible. Potential impacts to wetlands and state and federally protected species due to facility construction would depend on facility location. Avoidance of wetland areas would be included during facility planning. Site-specific surveys for protected species would be conducted prior to finalization of facility siting plans.

Site preparation for the construction of cask manufacturing facilities would result in the disturbance of biotic communities, including the permanent replacement of habitat with structures and paved areas (see Section K.4.9). Existing vegetation would be destroyed during land-clearing activities. Wildlife would be disturbed by land clearing, noise, and human presence. Depending on the exact location of the uranium oxide or uranium metal cask manufacturing facility, the loss of 27 to 90 acres (11 to 36 ha) of undeveloped land and habitat might constitute a moderate impact to vegetation and wildlife. However, when the uranium oxide and uranium metal cask manufacturing facilities were sited, all appropriate measures would be taken to preclude or minimize such impacts to ecological resources.

K.4.7 Waste Management

The estimated impacts from waste management operations from the construction and operation of full-scale (100%) cask manufacturing facilities are presented in detail in Appendix H, Section H.3.7. The impacts on regional and national waste management operations from construction and operation of manufacturing facilities were found to be negligible for the 100% throughput case.

On the basis of information provided in the engineering analysis report (LLNL 1997a), the impacts resulting from construction and operation for the 25% and 50% parametric cases would be roughly linear for throughput ranges of between 25% and 100%. Minimal waste management impacts would result from wastes generated during either construction or operations. Overall, the waste input resulting from normal operations at the manufacturing facilities would have negligible impact on waste management capacities locally or across the DOE complex. No assumptions were made regarding the fate of the oxide- and metal-shielded casks after use.

K.4.8 Resource Requirements

The estimated impacts from resource requirements during construction and operation of full-scale (100%) cask manufacturing facilities are presented in detail in Appendix H, Section H.3.8. The impacts on resources would be expected to be small for the 100% capacity case. Resource requirements for the two parametric cases considered would be less than those for the 100% case (LLNL 1997a).

Construction and operation of the cask manufacturing facilities would consume irretrievable amounts of electricity, fuel, concrete, steel and other metals, water, and miscellaneous chemicals. The total quantities of commonly used materials would not be expected to be significant. No strategic and critical materials (e.g., Monel or Inconel) in significant quantities are projected to be consumed during construction or operation of the facilities. Although high-grade graphite would be required for the metal shielded cask (as a lining for the crucibles containing molten uranium), the amounts required would not be significant. The manufacturing facility requirements would not be resource-intensive, and the resources required are generally not considered rare or unique. Furthermore, committing any of these resources would not be expected to cause a negative impact on the availability of these resources within local areas or nationally for the 100%, 50%, and 25% cases.

K.4.9 Land Use

Impacts to land use from the construction and operation of a uranium oxide shielded cask manufacturing facility, regardless of throughput capacity case, would be potentially moderate but limited to temporary disruptions to contiguous land parcels and increases in vehicular traffic associated with construction activities. Site preparation for the construction of a uranium oxide shielded cask manufacturing facility for 25%, 50%, and 100% of the depleted UF_6 inventory would require approximately 79, 84, and 90 acres (32, 34, and 36 ha), respectively. Within this area, the facility would require the permanent replacement of approximately 27, 28, and 31 acres (11, 11, and 13 ha) with structures and paved areas. Off-site impacts could occur from peak-year construction force vehicles, especially if the site had limited access from existing roadways.

Impacts to land use from the uranium metal shielded cask manufacturing facility would be the same as those discussed for the construction and operation of a uranium oxide shielded cask

manufacturing facility, with no difference in the magnitude of impacts when the three throughput capacity cases are compared. For off-site impacts, traffic patterns could experience potentially adverse level-of-service impacts during the 7-year construction period from the peak-year construction labor force.

K.4.10 Other Impacts Considered But Not Analyzed in Detail

Other impacts could potentially occur if the manufacture and use options considered in this PEIS were implemented — including impacts to cultural resources and environmental justice, as well as to aesthetics (e.g., visual environment), recreational resources, and noise levels, and impacts associated with decontamination and decommissioning of manufacturing facilities. These impacts, although considered, were not analyzed in detail for one or both of the following reasons:

- The impacts could not be determined at the programmatic level without consideration of specific sites. These impacts would be more appropriately addressed in the second-tier NEPA documentation when specific sites are considered.

- Consideration of the impacts would not contribute to differentiation among the alternatives; therefore, it would not affect the decisions to be made in the Record of Decision that will be issued following publication of this PEIS.

K.5 DISPOSAL OPTIONS

The parametric analysis of the disposal options considered the environmental impacts of disposing of 25% and 50% of the depleted UF_6 inventory as an oxide form. It was assumed that the uranium material would be actively placed into disposal units over a 20-year period (from 2009 through 2028). The assessment considered the environmental impacts that would occur during (1) construction of a disposal facility, (2) routine disposal facility operations, (3) potential disposal facility accidents, and (4) the post-closure phase, defined as 1,000 years in the future after the disposal facility had failed. The areas of impact and the methodologies used to evaluate the parametric cases were the same as those used to evaluate the 100% cases discussed in Appendix I. The supporting engineering data for the 25% and 50% parametric cases are provided in the engineering analysis report (LLNL 1997a).

The environmental impacts for the 100% disposal case are presented in Appendix I for (1) disposal of grouted and ungrouted U_3O_8 in shallow earthen structures, vaults, and a mine; and (2) disposal of grouted and ungrouted UO_2 in shallow earthen structures, vaults, and a mine. Two representative locations, described in Chapter 3 of the PEIS, were considered for each option: a "dry" location and a "wet" location. For purposes of the parametric analysis, disposal of ungrouted U_3O_8 in a mine at both wet and dry locations was considered in detail. This option was chosen to simplify

the parametric analysis because all options were evaluated in detail for the 100% base case. Impacts for the other disposal options, such as disposal of UO_2 and disposal in shallow earthen structures and vaults, were inferred from the relationships among the options identified from the 100% case analysis and from the additional relationships identified by the detailed parametric analysis conducted for the disposal of grouted U_3O_8 in a mine.

K.5.1 Human Health — Normal Operations

K.5.1.1 Radiological Impacts

The estimated radiological impacts (radiation doses and LCFs) from the normal operation of a full-scale (100%) disposal facility are described in Appendix I, Section I.3.1.1. Similar impacts were calculated for the 50% and 25% disposal facilities for the parametric analysis. Radiological impacts were calculated for the operational phase, during which time material would be disposed of, and for the post-closure phase, assumed to be 1,000 years in the future after the disposal facility had failed.

K.5.1.1.1 Operational Phase

The radiological impacts estimated for the 100%, 50%, and 25% cases during the operational phase are shown in Figures K.51 through K.66 for all disposal options. The impacts have been presented for the disposal of both grouted and ungrouted U_3O_8 and UO_2 as a function of the amount of material requiring disposal. The disposal of ungrouted U_3O_8 or UO_2 would not result in any airborne or waterborne emissions during operations because the material would be delivered to the disposal facility in packages that would be disposed of without being opened. Therefore, for the disposal of ungrouted waste, no impacts would be expected to the noninvolved workers and the off-site general public. The range of impacts resulting from technology and site differences are presented by dashed lines in the figures. The results for the disposal of ungrouted U_3O_8 in a mine, the case selected for detailed analysis, are shown in Figures K.63 and K.64 as solid points, with a curve drawn between the points to indicate how the impacts would vary as a function of the percent of material requiring disposal. The area enclosed by the dashed lines in Figures K.51 through K.66 indicates the range of impacts expected for throughputs between 25% and 100%, taking into account both technology and site differences.

FIGURE K.61 Estimated Annual Collective Dose to Involved Workers from the Disposal of Grouted UO_2 (The ranges reflect differences in disposal technologies, i.e., shallow earthen structures, vaults, and mine.)

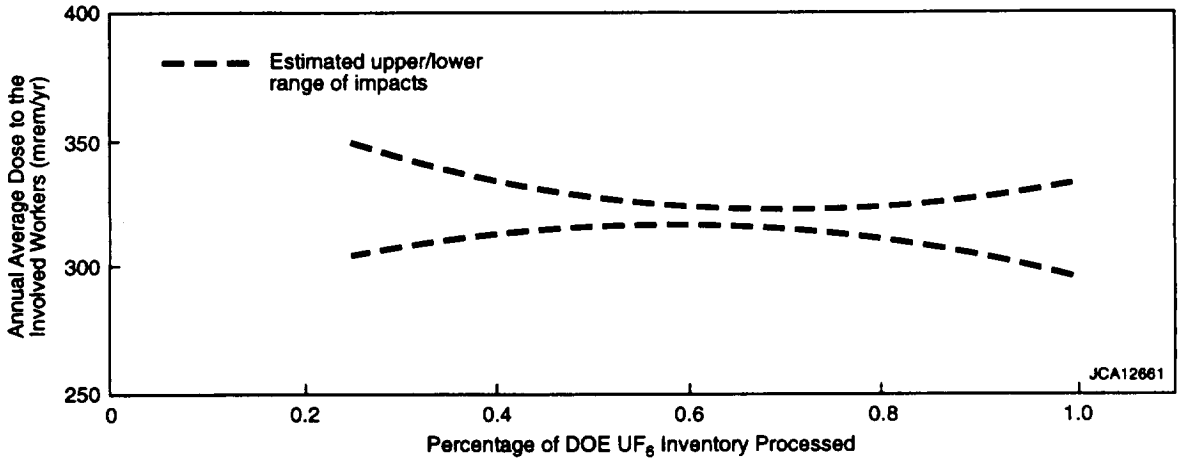

FIGURE K.62 Estimated Annual Average Individual Dose to Involved Workers from the Disposal of Grouted UO_2 (The ranges reflect differences in disposal technologies, i.e., shallow earthen structures, vaults, and mine.)

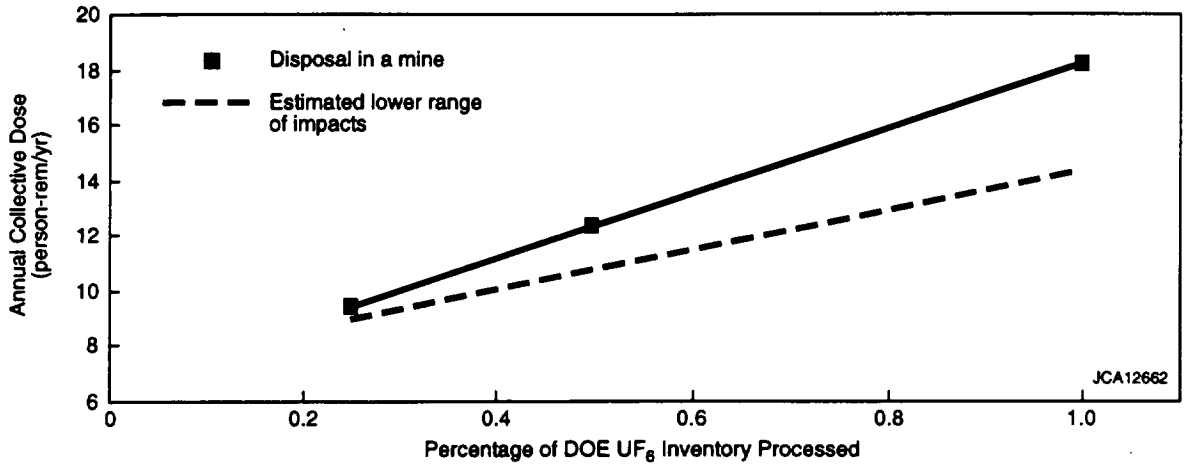

FIGURE K.63 Estimated Annual Collective Dose to Involved Workers from the Disposal of Ungrouted U_3O_8 (The ranges reflect differences in disposal technologies, i.e., shallow earthen structures, vaults, and mine.)

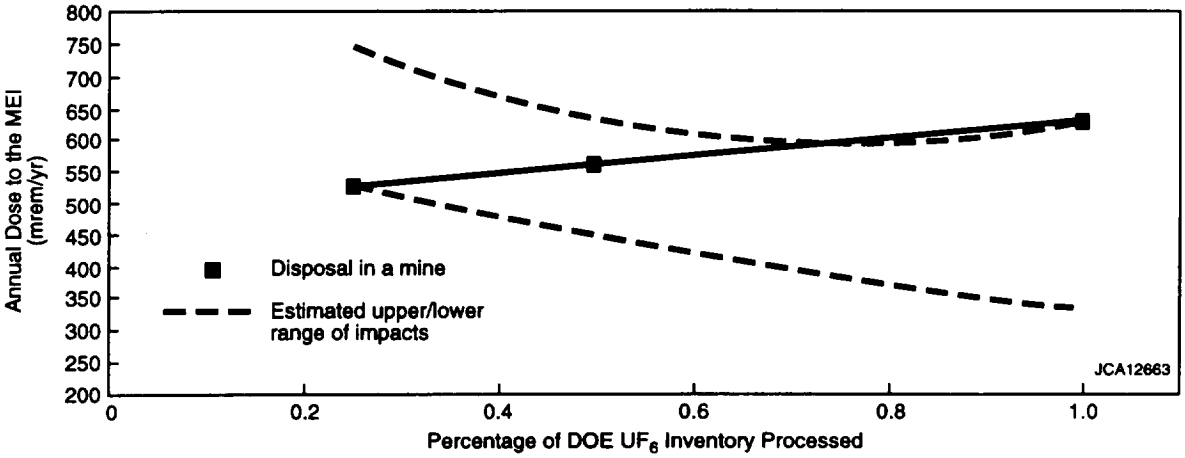

FIGURE K.64 Estimated Annual Average Individual Dose to Involved Workers from the Disposal of Ungrouted U_3O_8 (The ranges reflect differences in disposal technologies, i.e., shallow earthen structures, vaults, and mine.)

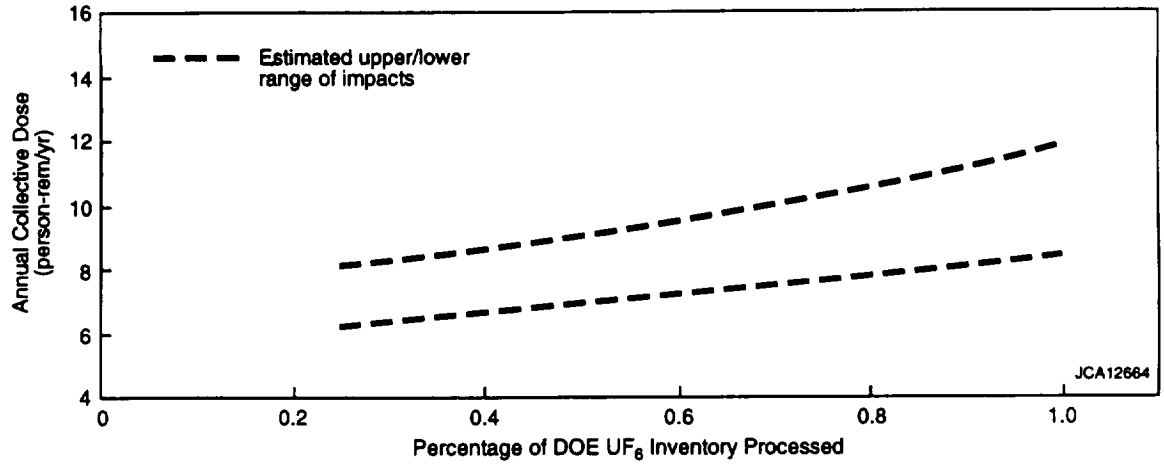

FIGURE K.65 Estimated Annual Collective Dose to Involved Workers from the Disposal of Ungrouted UO_2 (The ranges reflect differences in disposal technologies, i.e., shallow earthen structures, vaults, and mine.)

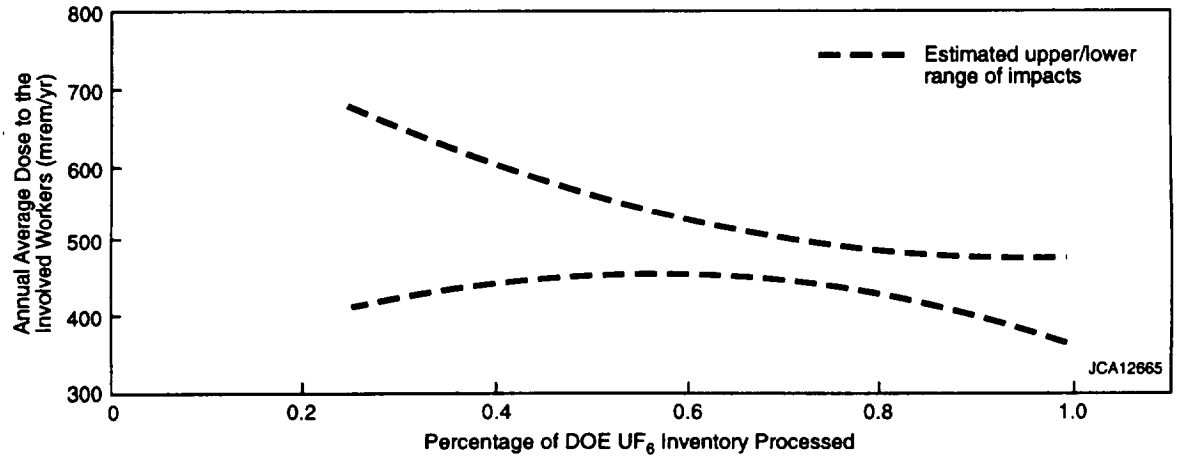

FIGURE K.66 Estimated Annual Average Individual Dose to Involved Workers from the Disposal of Ungrouted UO_2 (The ranges reflect differences in disposal technologies, i.e., shallow earthen structures, vaults, and mine.)

In general, the results of the parametric analysis (as shown in Figures K.51 through K.66) indicate that the collective radiological impacts during the operational phase would decrease with the total quantity of depleted uranium disposed of. The impacts of the 25% and 50% cases would be smaller than those for the 100% case, although the decrease would not be proportional to the reduction in throughput (i.e., the impacts for the 50% case would be greater than half of the impacts for the 100% case). Overall, radiation doses would be larger for the disposal of grouted waste compared with ungrouted waste because of the additional activities required and the small emissions resulting from the grouting process. In some cases, the average individual worker dose might increase or decrease as the throughput increased, primarily because the number of workers required would not increase at the same rate as the collective dose. The doses shown in the figures can be converted to the number (or risk) of LCFs by multiplying the doses (in rem or person-rem) by 0.0005 LCF/person-rem for members of the general public and 0.0004 LCF/person-rem for workers. Additional discussion of the significance of the estimated doses is provided in Appendix I.

K.5.1.1.2 Post-Closure Phase

At some time in the future after the closure of the disposal facility, potential impacts could occur to the public through the use of contaminated groundwater and from external radiation if the cover materials eroded away. In general, the complete erosion of the cover material, especially for a vault or mine, would not occur until thousands of years after the facility had been closed. Therefore, external radiation exposures would not be expected within the time frame considered (i.e., 1,000 years). Even if complete erosion occurred, the radiation exposure could be reduced by adding new cover material. Groundwater contamination would not be expected to occur until hundreds to thousands of years after the disposal facility had been closed. The estimated groundwater concentrations and associated uncertainty are discussed in Appendix I. For assessment purposes, the MEI was assumed to live at the edge of the disposal site and to use groundwater for drinking, irrigating plant foods and fodder, and feeding livestock. The potential radiation doses from using contaminated groundwater were based on groundwater concentrations calculated in the groundwater analysis that is discussed in detail in Section K.5.4.2.

The results of the groundwater analysis for a representative dry location indicate that measurable groundwater contamination would not occur until over 10,000 years after failure of the disposal facility. Therefore, no radiation exposures of the public would be expected for thousands of years following disposal in a dry environment.

Potential radiation exposures of the general public would be much greater if the disposal site was located in a wet environment. The results of the analysis indicate that the radiation dose to an individual using contaminated groundwater could reach about 80 mrem/yr for the 25% case, 96 mrem/yr for the 50% case, and 110 mrem/yr for the 100% case (considering both grouted and ungrouted wastes and different disposal technologies); these impacts could occur 1,000 years after failure of the containers and engineering barriers if the soil properties were such that uranium was transported rapidly toward the groundwater (mobile situation). If the depleted uranium was classified

as LLW, the radiation doses from using contaminated groundwater would exceed the dose limit of 25 mrem/yr specified in the *Code of Federal Regulations* (10 CFR Part 61) and DOE Order 5820.2a. However, radiation doses from contaminated groundwater could be reduced or eliminated by treating the water or by using an alternative source of water.

K.5.1.2 Chemical Impacts

K.5.1.2.1 Operational Phase

The estimated impacts from chemical exposures during the normal operation of full-scale (100%) disposal facilities are described in Appendix I, Section I.3.1.2. The results of the 100% case analyses for the operational phase indicated that noninvolved workers and members of the general public would receive essentially no exposures to chemicals for the disposal of ungrouted uranium material and very low exposures from disposal of grouted uranium material for all disposal facilities. No adverse health impacts would be expected for any of the disposal facilities considered. For the 100% cases, the calculated hazard indices were much less than 1 for all disposal options (a hazard index of greater than 1 indicates the potential for health impacts). For the parametric analysis of the 25% and 50% throughput cases, airborne emissions would be less than the 100% cases and extremely small (LLNL 1997a). Therefore, by comparison with the 100% case results, no adverse health impacts from chemical exposures would be expected for throughput rates between 25% and 100% for all disposal options.

K.5.1.2.2 Post-Closure Phase

As for radiological impacts, potential chemical impacts could occur to the general public at sometime in the future through use of contaminated groundwater. The potential chemical impacts to an MEI resulting from use of contaminated groundwater were determined on the basis of the same assumptions discussed in Section K.5.1.1 for radiological exposures. Chemical exposures were calculated for a time 1,000 years after the disposal facility was assumed to fail. The potential chemical impacts from using contaminated groundwater were based on the groundwater concentrations calculated in the groundwater analysis (see Section K.5.4.2).

Because of the low precipitation rate in a dry location, it would take more than 10,000 years for the uranium compounds to reach the groundwater after the first contact with infiltration water. Therefore, no chemical exposures would occur to an individual living next to the disposal site in a dry environment within 10,000 years.

Chemical exposures to the MEI could potentially be much greater if the disposal site was located in a wet environment. The concentrations of uranium in groundwater at 1,000 years after failure of the disposal facility would be such that potential adverse health impacts from chemical

exposures could result to an individual using contaminated groundwater for all cases. Risks from chemical exposures were quantified on the basis of calculated hazard indices. Assuming that the soil properties were such that uranium compounds could be transported rapidly toward the groundwater following failure of the containers and engineering barriers (at 1,000 years), the maximum hazard indices were estimated to be greater than 1, indicating a potential for adverse health effects. The hazard indices were calculated to be 8 for the 25% case, 10 for the 50% case, and 11 for the 100% case. However, chemical exposures from contaminated groundwater could be reduced or eliminated by treating the water or by using an alternative source of water.

K.5.2 Human Health — Accident Conditions

K.5.2.1 Radiological Impacts

The estimated radiological impacts (radiation doses and LCFs) from potential accidents during operation of full-scale (100%) disposal facilities are presented in Appendix I, Section I.3.2.1. The analysis of the 100% cases considered a range of accidents in four frequency categories; results are presented only for those accidents in each category that would have the greatest consequences (bounding accidents). Similar sets of accidents covering the same four frequency categories are defined in the engineering analysis report (LLNL 1997a) for the 25% and 50% throughput cases.

Based on the assessment of the 25% and 50% disposal cases, the radiological accident impacts associated with each of the parametric cases would be the same as those presented for the 100% case in Appendix I. The impacts would be identical because the bounding accidents producing the greatest consequences within each frequency category would be the same for the 100%, 50%, and 25% cases. The bounding accidents would be the same because they would involve only a limited amount of material that would be at-risk under accident conditions regardless of the facility size or throughput. However, as a result of the reduced throughput rates, the actual frequencies of some accidents related to handling operations (i.e., the "mishandle/drop of drum" accident) would decrease as the number of containers handled decreased. The resulting risk of these accidents would also decrease as their frequencies decreased. However, none of the accident frequencies would change enough to cause the accident to be considered in a different frequency category. Therefore, the overall impacts associated with the disposal options would be the same for all parametric cases.

K.5.2.2 Chemical Impacts

The estimated chemical impacts from potential accidents during full-scale (100%) operation of disposal as grouted or ungrouted UO_2 or U_3O_8 in shallow earthen structures, vaults, or a mine are presented in Appendix I, Section I.3.2.2. The analysis of 100% cases considered a range of accidents in four frequency categories; results are presented for only those accidents in each category that would have the greatest consequences (bounding accidents). Similar sets of accidents covering the

same four frequency categories are defined in the engineering analysis report (LLNL 1997a) for the 25% and 50% throughput cases.

The bounding chemical accidents associated with the 25% and 50% throughput cases that would produce the greatest consequences would be the same as those presented for the 100% case. The impacts would be similar because the accidents within most frequency categories would be the same for the 100%, 50%, and 25% cases, and in those cases where these accidents were different, no adverse chemical impacts were estimated to occur. The bounding accidents would be the same because they would involve only a limited amount of material that would be at risk under accident conditions regardless of the facility size or throughput. However, some of the impacts for other accidents (nonbounding) considered for the 25% and 50% cases would be different from those for the 100% cases. In general, the impacts of the nonbounding accidents for the 50% and 25% cases would be less than those for the 100% cases because of the reduced throughput.

K.5.2.3 Physical Hazards

The estimated health impacts, such as on-the-job injuries and fatalities, from potential physical accidents during the construction and operation of full-scale (100%) disposal facilities are presented in Appendix I, Section I.3.2.3. For the 100% analysis, no on-the-job fatalities were estimated during construction and operation of a mine disposal facility (for ungrouted U_3O_8). The predicted number of on-the-job worker injuries for the 100% case is about 240. The impacts of the 25% and 50% cases would be smaller than those for the 100% case, although the decrease would not be proportional to the reduction in throughput (i.e., the impacts for the 50% case would be greater than 50% of the impacts for the 100% case).

The predicted number of on-the-job worker fatalities over the duration of disposal operations is less than 1, ranging from 0.4 for the 25% case to 0.53 for the 100% case (including construction and operations). The predicted number of on-the-job injuries (including construction and operations) ranges from 160 to 240. The number of injuries is shown as a function of throughput in Figure K.67.

K.5.3 Air Quality

The estimated impacts on air quality during construction and operation of full-scale (100%) disposal facilities are presented in detail in Appendix I, Section I.3.3. All of the pollutant concentrations produced by the 100% capacity version of the disposal facilities would be below their respective air quality standards. The annual average concentrations of NO_x might be as high as one-third of the air quality standards during operation of vault disposal facilities for grouted U_3O_8 in a wet environmental setting. During operations, all pollutant concentrations would be much less than the corresponding standards.

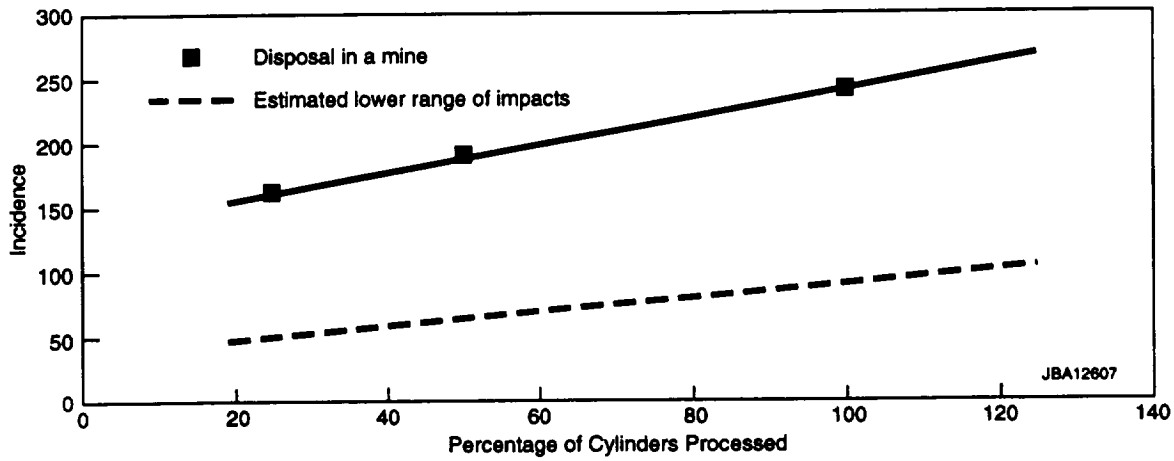

FIGURE K.67 Estimated Number of On-the-Job Injuries (for entire construction and operational periods) from the Disposal of Ungrouted U_3O_8 (The ranges reflect differences in disposal technologies, i.e., shallow earthen structures, vaults, or mine.)

The air quality impacts calculated for the 25% and 50% parametric cases, based on information provided in the engineering analysis report (LLNL 1997a), were found to be less than those for the 100% case. During construction, short-term impacts for the parametric cases would be less than those for the 100% case, and impacts during operations would also be less. Annual pollutant concentrations from construction of 50% and 25% capacity disposal facilities would be about 0.7 and 0.5 times as large as the full-capacity facility, respectively. For all the other disposal options, criteria pollutant levels would be lower percentages of their respective standards during both construction and operations.

K.5.4 Water and Soil

K.5.4.1 Surface Water

The estimated impacts on surface water during construction, operation, and potential accidents for full-scale (100%) disposal facilities are discussed in Appendix I, Section I.3.4. The actual impacts to surface water would depend on the ultimate site selected for disposal. However, for the generic sites considered in the PEIS, the impacts to surface water from the 100% case were found to be negligible for all disposal options for both the operational and post-closure phases. The impacts calculated for the 25% and 50% parametric cases, based on information provided in the engineering analysis report (LLNL 1997a), were found to be less than those for the 100% case, and thus would also be negligible.

K.5.4.2 Groundwater

The estimated impacts on groundwater during construction, operation, and potential accidents for full-scale (100%) disposal facilities are presented in detail in Appendix I, Section I.3.4. The actual impacts to groundwater would depend on the ultimate site selected for disposal. However, during the operational phase, which would include construction and disposal activities, negligible impacts to groundwater would be expected. As described in Appendix I, the impacts to groundwater from the 100% case were expected to be negligible for the operational phase of all disposal options. The impacts calculated for the 25% and 50% parametric cases, based on information provided in the engineering analysis report (LLNL 1997a), were found to be less than those for the 100% case, and thus would also be negligible.

Impacts to groundwater during the post-closure phase are discussed in Section I.4.2. Groundwater impacts during the post-closure phase would be limited to changes in quality caused by contamination migrating from the disposal facility hundreds to thousands of years in the future after failure of the engineered barriers. There would be no impacts to effective recharge, depth to groundwater, or flow direction once the facility was constructed.

Disposal facility failure would generally occur hundreds to thousands of years in the future (assuming no sustained effort to maintain the facility). This failure would be caused by natural degradation of the disposal structures over time, primarily from physical processes such as the intrusion of water. Following failure, the release of uranium from the facility would occur very slowly as water moved through the disposed material. The amount of groundwater contamination, as well as the length of time it would take for the groundwater to become contaminated, would depend on the integrity of the drums and the engineering barriers, as well as the site-specific properties of the soil surrounding the disposal facility. Without more precise information concerning the expected lifetimes of the containers and engineering barriers in the specific disposal facility environment, as well as site-specific soil and hydrological properties, the groundwater concentrations estimated for the analysis presented in this appendix using generic assumptions are subject to a large degree of uncertainty. Nevertheless, if no remedial actions were taken, once the release of uranium from the disposal facility began, it could last for millions of years for all three cases (25%, 50%, and 100%).

If the disposal site were located in a dry environment, all of the resulting uranium concentrations in groundwater would be essentially zero for at least 1,000 years in the future (Tomasko 1997) for disposal of 25%, 50%, and 100% of the uranium material. In a wet climate, however, the uranium concentrations in the groundwater beneath a mined facility for ungrouted U_3O_8 would range from about 260 pCi/L (1,000 µg/L) for the 25% capacity case to 350 pCi/L (1,400 µg/L) for 100% capacity if the soil properties were such that the uranium moved rapidly through the soil (a retardation factor of 5). These uranium concentrations would exceed the U.S. Environmental Protection Agency (EPA) proposed maximum contaminant level of 20 µg/L (EPA 1996) used as a guideline in this PEIS. If the uranium were less mobile in the soil surrounding the disposal facility (retardation coefficient of 50), uranium concentrations in the groundwater beneath the facility after

1,000 years for disposal of 25%, 50%, and 100% would be less than 20 µg/L. However, the concentrations would increase with time, ultimately approaching the concentrations that would occur under the mobile situation and exceeding 20 µg/L.

Post-closure impacts to groundwater quality resulting from disposal in an underground mine could be reduced by decreasing the size of the facility in a direction parallel to the direction of groundwater flow, thereby increasing dilution (Tomasko 1997).

K.5.4.3 Soil

The estimated impacts to soil during construction, operation, and potential accidents for full-scale (100%) disposal facilities are presented in Appendix I, Section I.3.4. The potential impacts evaluated included changes in topography (land elevation), permeability (ability to let water enter the ground), quality, and erosion potential for a dry and wet location. Although impacts were evaluated for dry and wet conditions, the impacts would be essentially the same for both locations.

As discussed in Appendix I, the impacts to soil from the 100% cases were found to have potentially moderate to large, but temporary, impacts for the disposal options. These impacts would result from material excavated during disposal facility construction that would be left on-site. For example, construction of a mine for ungrouted U_3O_8 disposal would require excavating about 1.2 million yd^3 (920,000 m^3) of consolidated material. In the short term, this amount of material would cause changes in site topography. In the long term, contouring and reseeding would return soil conditions to their former state, and the impacts would be minor. The impacts calculated for the 25% and 50% parametric cases, based on information provided in the engineering analysis report (LLNL 1997a), were also found to have potentially large, but temporary, impacts on soil, similar to the 100% cases. In the long term, impacts on soil would be minor for all disposal options.

K.5.5 Socioeconomics

The socioeconomic impacts of ungrouted U_3O_8 mine disposal facilities for the 50% and 25% parametric cases would be less than the impacts of the base-case facility sizes. Cost information was not available in sufficient detail to allow an analysis of impacts using the same methodology that was used for the base cases. The impacts of parametric cases were therefore assessed qualitatively, based on the assumption that changes in the cost of equipment, materials, and labor would be proportional to changes in total life-cycle cost. Compared with base-case facility sizes, smaller U_3O_8 mine disposal facilities would create less direct employment and income at the site.

K.5.6 Ecology

Site preparation for the construction of a facility for the disposal of ungrouted U_3O_8 in a mine would result in the disturbance of biotic communities, including the permanent replacement of habitat with structures and paved areas. Existing vegetation would be destroyed during land-clearing activities. Wildlife would be disturbed by land clearing, noise, and human presence.

This disposal option would result in elevation of the soil surface by approximately 2.8 to 4.1 ft (0.85 to 1.2 m) and a reduction in soil permeability. The excavated material would primarily consist of rock removed from the drifts and ramps. The consequent decrease in surface soil moisture would make reestablishment of vegetation difficult and delay the establishment of native plant communities. Construction of a disposal facility for ungrouted U_3O_8 in a mine would result in a large adverse impact to existing vegetation and wildlife.

Impacts to wetlands and state and federally protected species due to facility construction would depend on facility location. Avoidance of wetland areas would be included during facility planning. Site-specific surveys for protected species would be conducted prior to finalization of facility siting plans.

Impacts to air, surface water, groundwater, and soil quality during construction are expected to be negligible for the 25%, 50%, and 100% cases (Sections K.5.3 and K.5.4). Resulting construction-derived impacts to ecological resources would also be expected to be negligible. Impacts to ecological resources from air and water emissions would also be negligible during the operational phase of the disposal options.

During the post-closure phase, failure of facility integrity could result in contamination of groundwater (see Section K.5.4.2). Groundwater could discharge to the surface (such as in wetland areas) near the facility, thus exposing biota to contaminants. Groundwater concentrations of uranium calculated for 1,000 years after failure of a mined facility for ungrouted U_3O_8 would range from about 260 to 350 pCi/L for the 25% and 100% cases, respectively. Similarly, groundwater concentrations for a mined facility for grouted U_3O_8 would range from about 310 to 425 pCi/L for the 25% and 100% cases, respectively. Adverse impacts to aquatic biota could result from exposure to soluble uranium compounds within this concentration range. Resulting dose rates to maximally exposed organisms would be less than 2% of the dose limit of 1 rad/d, for aquatic organisms, as specified in DOE Order 5400.5.

K.5.7 Waste Management

The estimated impacts from waste management operations from the construction and operation of full-scale (100%) disposal facilities are presented in detail in Appendix I, Section I.3.7. The impacts on national waste management operations from construction of disposal facilities were found to be negligible for the 100% throughput case. The impacts that would result from construction for the 25% and 50% parametric cases, based on information provided in the

engineering analysis report (LLNL 1997a), would be less than those for the 100% case, and thus would also be negligible.

Operation of a disposal facility would generate radioactive, hazardous, and nonhazardous wastes (Section I.3.7). All of the secondary wastes listed would have a negligible impact on waste management capacities across the DOE complex. However, the product waste would represent a significant volume when compared with the complexwide total of LLW for disposal. Disposal of 100% of the depleted uranium inventory could represent from 1.1 to 7.3% of the total DOE LLW generated over roughly the same time period. Overall, the waste input resulting from the normal operation of the U_3O_8 disposal facility would have a negligible to low impact on DOE's complexwide waste management activities.

The parametric analysis of operational waste loads was conducted for throughput values of 25%, 50%, and 100% (Table K.5). Some of these analyses showed nonlinear effects, but the estimated impacts would be very small. The volume of product waste was shown to be linear with throughput. Thus, it was assumed that a linear interpolation could be used to estimate waste loads for throughput values other than 25%, 50%, and 100%.

K.5.8 Resource Requirements

The estimated impacts from resource requirements during construction and operation of full-scale (100%) disposal facilities are presented in detail in Appendix I, Section I.3.8. The impacts on resources, except for electrical consumption for a mine disposal facility, would be expected to

TABLE K.5 Wastes Generated during Facility Operations from the Disposal of Ungrouted U_3O_8

	Annual Waste Generated for Three Throughput Cases		
Waste Type	100%	50%	25%
Waste (m^3/yr)			
Solid LLW	81	57	40
Mixed liquid LLW	0.31	0.22	0.15
Nonhazardous waste (million L/yr)			
Solids	0.64	0.45	0.32
Wastewater	0.92	0.68	0.48
Product waste volume (m^3/yr)			
Ungrouted U_3O_8	7,440	3,720	1,860

be small for the 100% capacity case. Resource requirements for the 25% and 50% parametric cases considered would be less than those for the 100% case (LLNL 1997a).

Construction and operation of the disposal facilities would consume irretrievable amounts of electricity, fuel, concrete, steel and other metals, water, and miscellaneous chemicals. The total quantities of commonly used materials would not be expected to be significant. However, for a mine disposal facility, significant quantities of electrical energy would be required during construction (up to 1,100 MW-yr, orders of magnitude greater than that required for other disposal facility types) because the majority of the construction equipment used in the underground portion would be powered by electricity to avoid polluting the air in the underground work area. Similarly, compared with the other options, a relatively higher annual amount of electricity would be needed during underground operations. No strategic and critical materials would be expected to be consumed during construction or operation of the facilities. The disposal facility operations requirements would generally not be resource-intensive, and the resources required are not considered rare or unique. Furthermore, committing any of these resources (except for electrical consumption) would not be expected to cause a negative impact on the availability of these resources within local areas or nationally for the 100%, 50%, and 25% cases. The magnitude of impact of the high electrical requirement for a mine disposal facility on local energy resource usage would be dependent on the extent of existing site infrastructure.

K.5.9 Land Use

Potential moderate to large impacts from the construction and operation of a mined disposal facility would be expected from on-site disposal of excavated material. Potential traffic volume impacts would be associated with the construction labor force. Site preparation for the construction of a facility for the disposal of ungrouted U_3O_8 in a mine for 25%, 50%, and 100% of the depleted UF_6 inventory would require the disturbance of approximately 97, 165, and 232 acres (39, 66, and 93 ha), respectively. On-site topographical modifications associated with disposition of the excavated material could potentially affect future on-site land use, although such impacts would be small. Land use impacts from shallow earthen structure and vault options would range from negligible to moderate.

Impacts to land use outside the boundaries of a disposal facility would consist of temporary traffic impacts associated with project construction. The actual impacts would depend on the specific site chosen.

K.5.10 Other Impacts Considered But Not Analyzed in Detail

There are other impacts that can potentially occur if the disposal options considered in this PEIS are implemented. They include impacts to cultural resources and environmental justice, as well as to aesthetics (e.g., visual environment), recreational resources, and noise levels, and impacts

associated with decontamination and decommissioning of surface disposal facilities. These impacts, although considered, were not analyzed in detail for one or both of the following reasons:

- The impacts could not be determined at the programmatic level without consideration of specific sites. These impacts would be more appropriately addressed in the second-tier NEPA documentation when specific sites are considered.

- Consideration of the impacts would not contribute to differentiation among the alternatives; therefore, it would not affect the decisions to be made in the Record of Decision that will be issued following publication of this PEIS.

K.6 TRANSPORTATION

The estimated environmental impacts were presented in Appendix J for transportation of materials associated with the 100% cases considered for the depleted uranium inventory options. Because the locations of the various facilities are not determined, impacts for three shipment distances (250, 1,000, and 5,000 km) were presented to give the reader a basis for understanding the ramifications of shipment distance on the impacts. In this appendix, all transportation impacts are presented for a single shipment distance of 1,000 km because the objective here is the comparison among the three cases of throughput (25%, 50%, and 100%) associated with the depleted uranium.

The transportation impacts are presented in the form of line graphs in terms of risk (estimated fatalities) as a function of the number of total shipments over the 20-year life of the project. Each graph pertains to a single type of shipment either by truck or rail mode. As in Appendix J, estimated fatality risks from radiological (routine and accident), chemical (accident), and vehicle (routine and accident) causes are presented in each graph. The 25%, 50%, and 100% throughput cases are denoted with vertical lines on each graph.

K.6.1 Conversion Options

The conversion of the depleted UF_6 to an oxide or a metal form might require shipment of the depleted uranium to an off-site facility. Impacts for the 100% case are presented in Appendix J, Section J.3.4. Figures K.68 and K.69 present the results for shipping the depleted uranium cylinders either by truck or rail, respectively, for the three parametric cases. The 100% case risks for cylinder shipment are presented in Tables J.5 and J.6 in Section J.3.4.1. The impacts from routine external radiation if overcontainers were to be used are also presented. The radiological and chemical risks from accidents are not presented because these risks would be at least 100 times less than the other estimated risks.

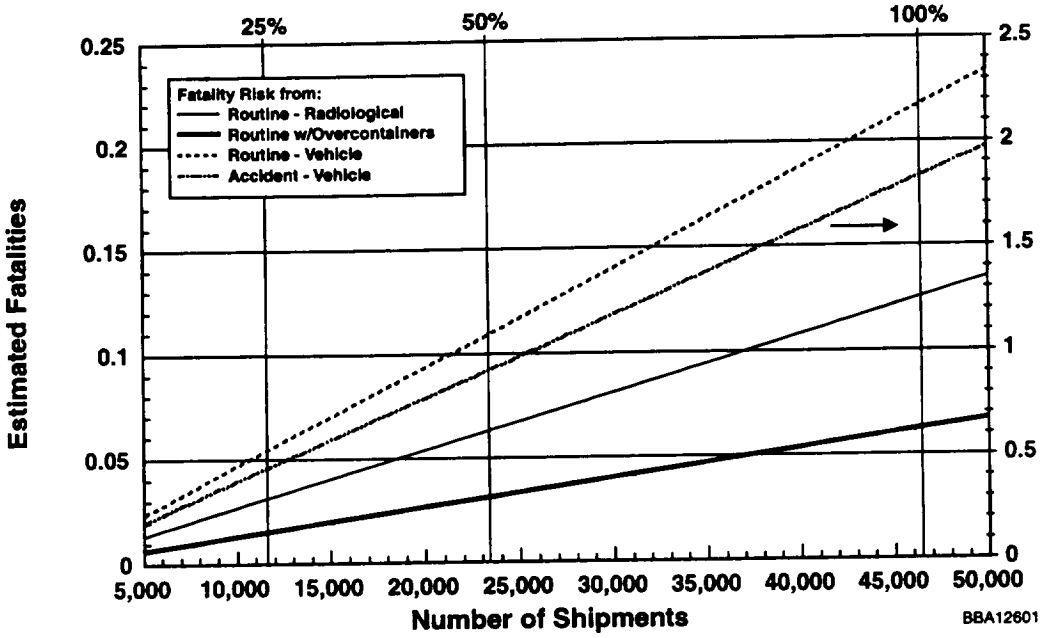

FIGURE K.68 Estimated Truck Transportation Risks for Depleted UF_6 Cylinders

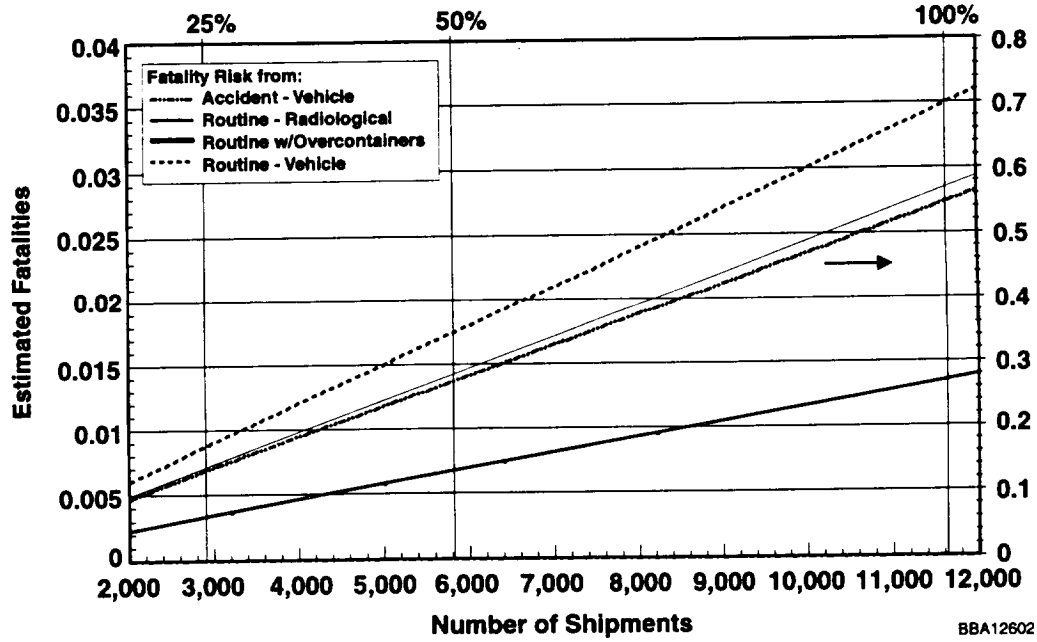

FIGURE K.69 Estimated Rail Transportation Risks for Depleted UF_6 Cylinders

Conversion of the depleted UF_6 to an oxide or uranium metal would involve transportation of input materials and output waste forms, as discussed in Appendix J, Section J.3.4. Ammonia might be used as an input material for oxide and metal conversion; Figure K.70 presents the chemical and vehicle risks from transportation of ammonia for shipment by rail for UO_2 or metal conversion. Anhydrous HF is a common product of the three conversion technologies studied for the parametric analysis. The two oxide technologies would produce about the same amount of HF for the same amount of depleted UF_6 input, an amount that is about three times the amount of HF produced in the conversion to metal. Figure K.71 presents the parametric risks for HF transport. The conversion-to-metal process would produce a large quantity of nonhazardous MgF_2 as another by-product. The vehicle-related parametric risks for transport of MgF_2 by truck and rail are shown in Figures K.72 and K.73, respectively.

Both LLW and low-level mixed waste (LLMW) would be produced at a conversion facility and would require transport for disposal, as discussed in Appendix J, Section J.3.4.2. The number of shipments required for LLMW disposal in all three options is not expected to change with the throughput case (25%, 50%, or 100%) because a minimal amount would be generated by the conversion process. The estimated transportation risks for the LLW generated at the three different conversion facilities shipped to a disposal site are presented in Figures K.74 through K.76.

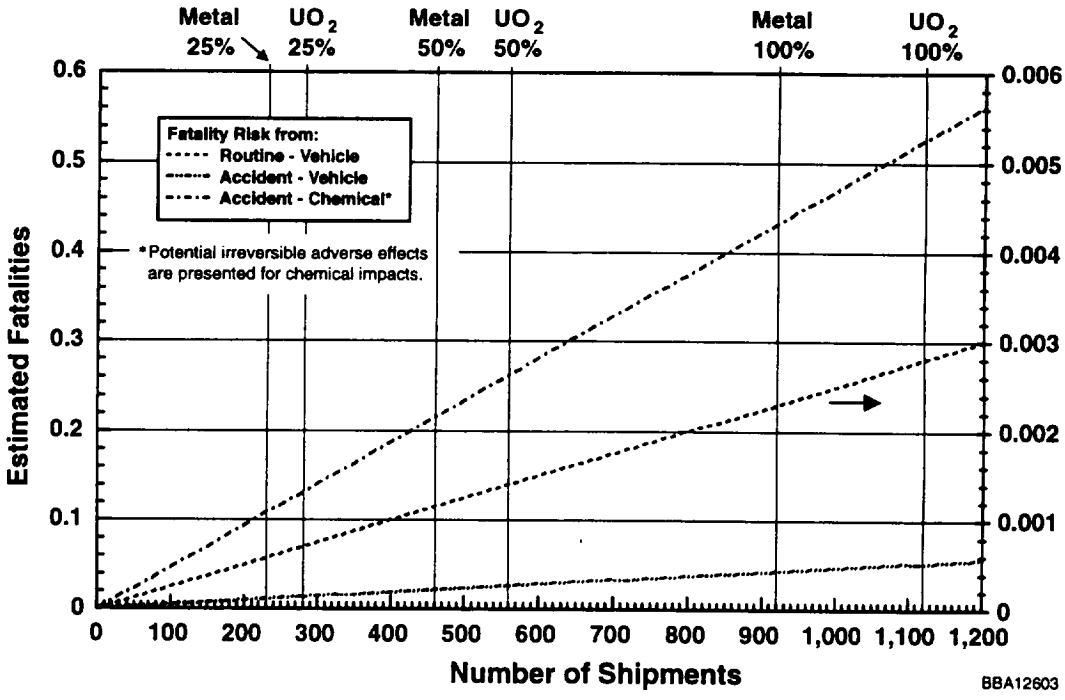

FIGURE K.70 Estimated Rail Transportation Risks for the Ammonia Used in the Conversion of Depleted UF_6 to UO_2 or Uranium Metal

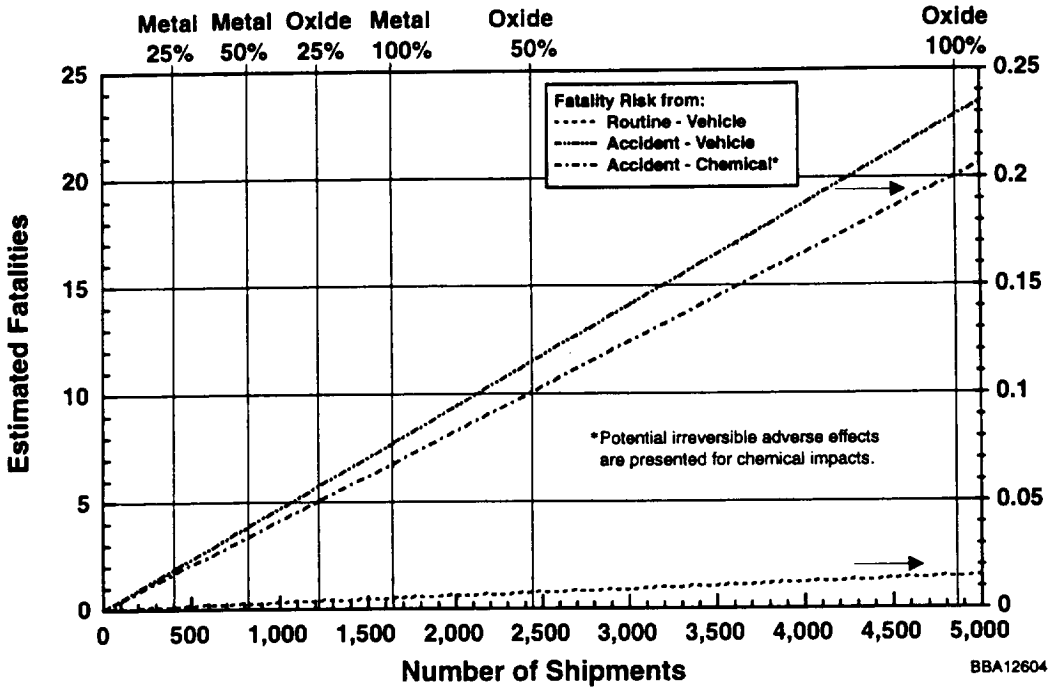

FIGURE K.71 Estimated Rail Transportation Risks for the HF Produced in the Conversion of Depleted UF_6 to U_3O_8, UO_2, or Uranium Metal

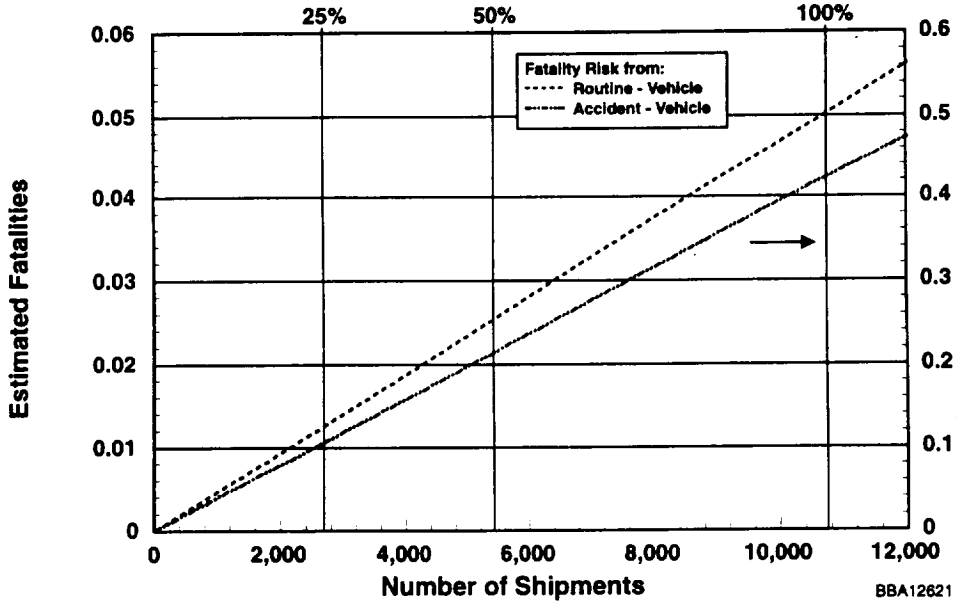

FIGURE K.72 Estimated Truck Transportation Fatality Risks for the MgF_2 Generated in the Conversion of Depleted UF_6 to Uranium Metal

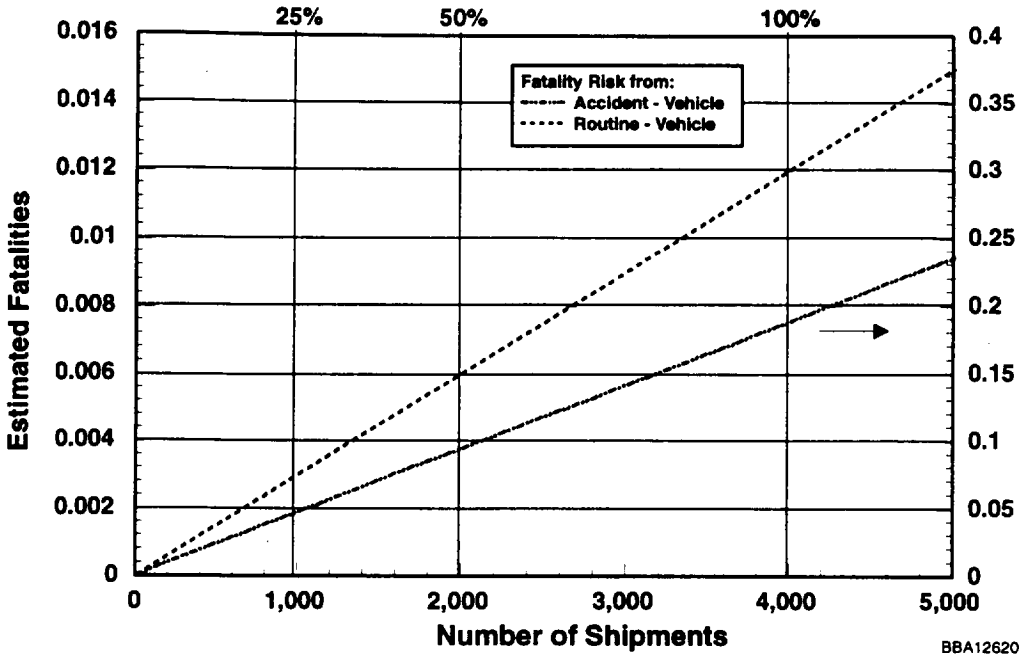

FIGURE K.73 Estimated Rail Transportation Fatality Risks for the MgF_2 Generated in the Conversion of Depleted UF_6 to Uranium Metal

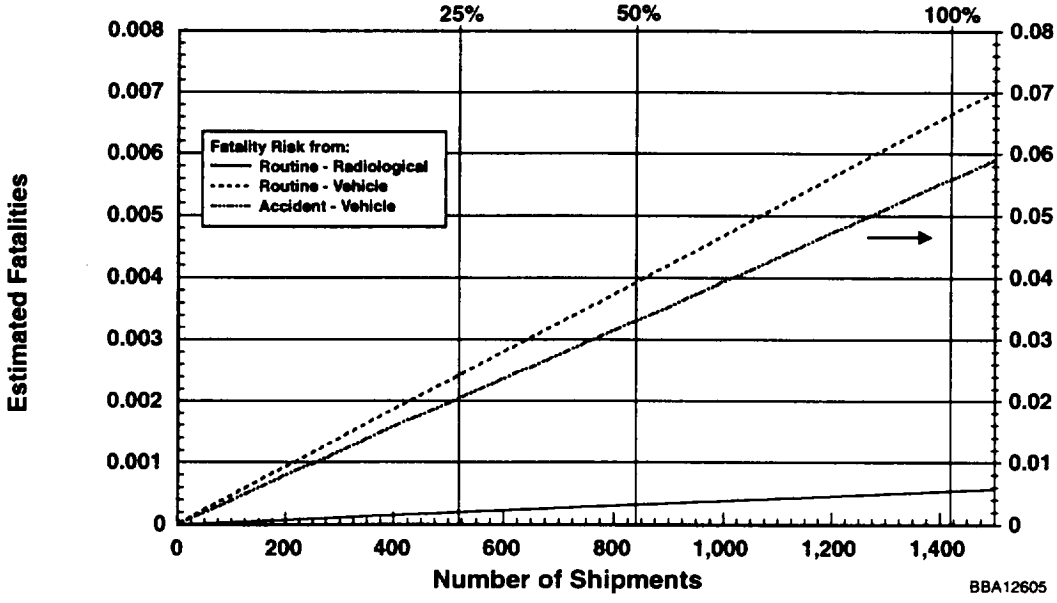

FIGURE K.74 Estimated Truck Transportation Risks for the LLW Generated in the Conversion of Depleted UF_6 to U_3O_8

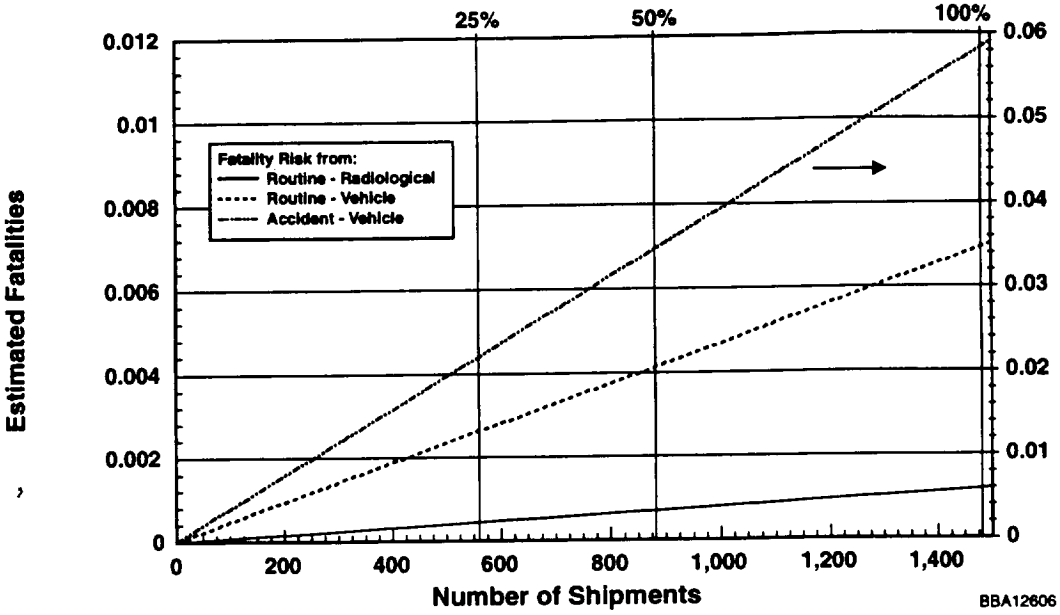

FIGURE K.75 Estimated Truck Transportation Risks for the LLW Generated in the Conversion of Depleted UF_6 to UO_2

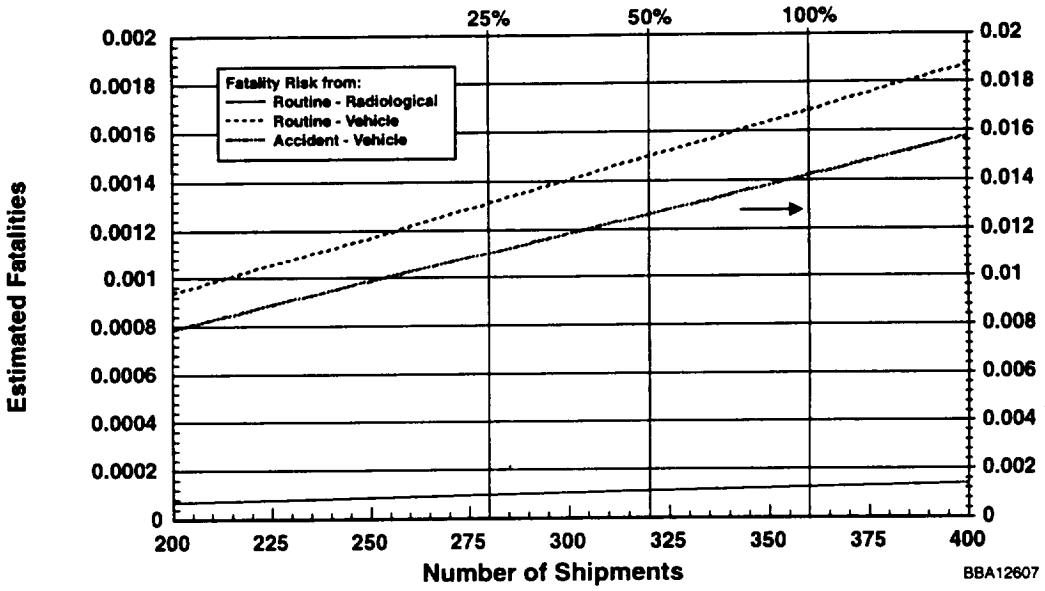

FIGURE K.76 Estimated Truck Transportation Risks for the LLW Generated in the Conversion of Depleted UF_6 to Uranium Metal

Radiological and chemical risks from accidents are not presented because they would be at least 100 times less than the other estimated risks.

Parametric transportation risks for the shipment of U_3O_8 are provided in Section K.6.4 under the U_3O_8 disposal option. Parametric transportation risks for the UO_2 conversion product are discussed in Section K.6.2 under the UO_2 long-term storage option, and the risks for the metal conversion product are discussed in Section K.6.3 for the manufacture and use option.

Each conversion option would require cleaning of the empty depleted UF_6 cylinders at the cylinder treatment facility, as discussed in Appendix J, Section J.3.4.3. The parametric transportation risks for the resulting LLW and U_3O_8 are presented in Figures K.77 and K.78, respectively. For the LLW shipments, the radiological and chemical risks are not presented because they are at least 100 times less than the vehicle emission risks, as shown in Appendix J, Section J.3.4.3. The number of shipments required for the LLMW generated at the cylinder treatment facility is not expected to change appreciably with the throughput case (25%, 50%, or 100%) because a minimal amount would be generated by the cleaning process.

K.6.2 Long-Term Storage Options

Storage as UF_6 in buildings assumes transportation of the depleted UF_6 cylinders to a storage site. Parametric risks from transportation of the depleted UF_6 cylinders is discussed in Section K.6.1. A very small amount of LLW and LLMW would be generated from occasional cylinder failure during the surveillance phase of this option. The type of waste generated would be similar to that generated at the cylinder treatment facility and would have similar single shipment risks. As discussed in Appendix J, Section J.3.5, less than one shipment per year is expected for the 100% case, with slightly fewer shipments necessary for the 50% and 25% cases.

Transportation of UO_2 from a conversion facility might be required for long-term storage as oxide, as discussed in Appendix J, Section J.3.5. Figures K.79 and K.80 present the results for shipping the UO_2 conversion product exclusively by truck or rail, respectively, for the three parametric cases. The chemical accident risks for UO_2 are not presented because they would be more than 100 times less than the routine radiological risks shown in Tables J.11 and J.12 for the 100% case.

K.6.3 Manufacture and Use Options

K.6.3.1 Use as Uranium Oxide

The estimated transportation risks for shipment of all the UO_2 from a conversion facility to a manufacturing site for uranium oxide cask production are presented in Appendix J,

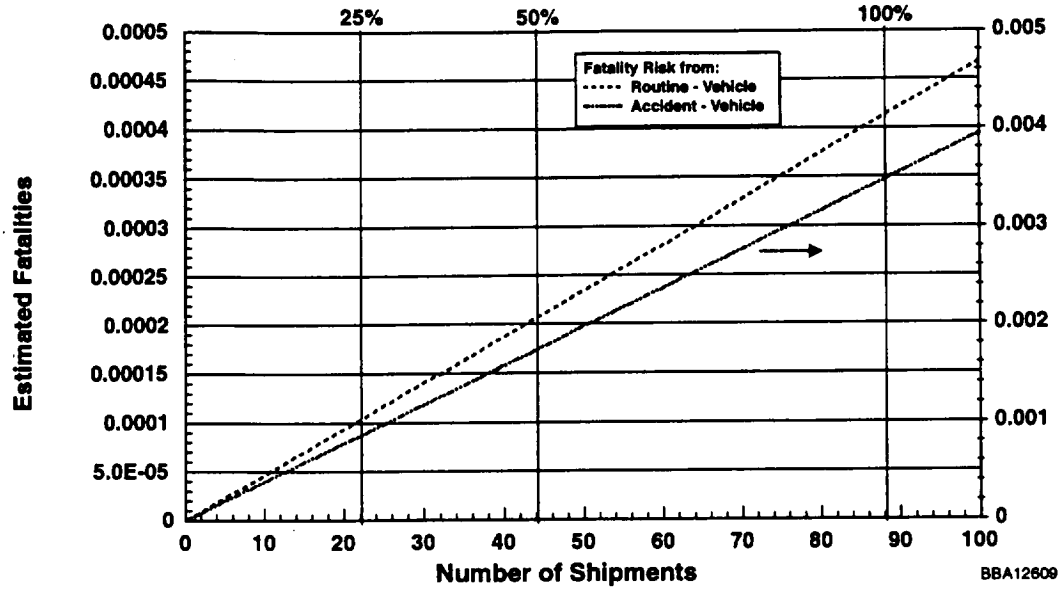

FIGURE K.77 Estimated Truck Transportation Risks for the LLW Generated at the Cylinder Treatment Facility

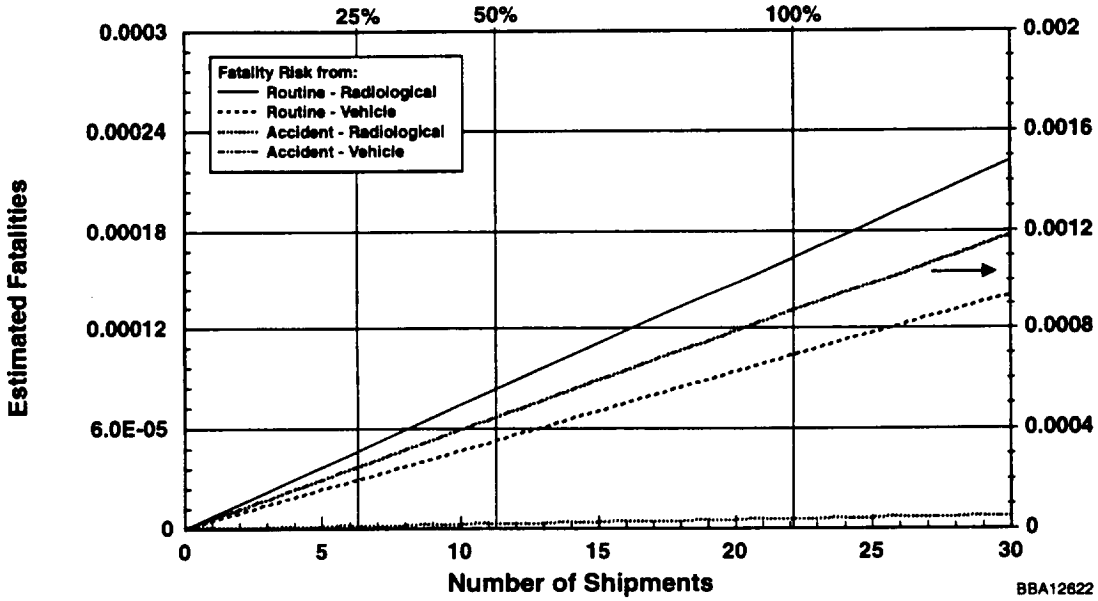

FIGURE K.78 Estimated Truck Transportation Risks for the U_3O_8 Generated at the Cylinder Treatment Facility

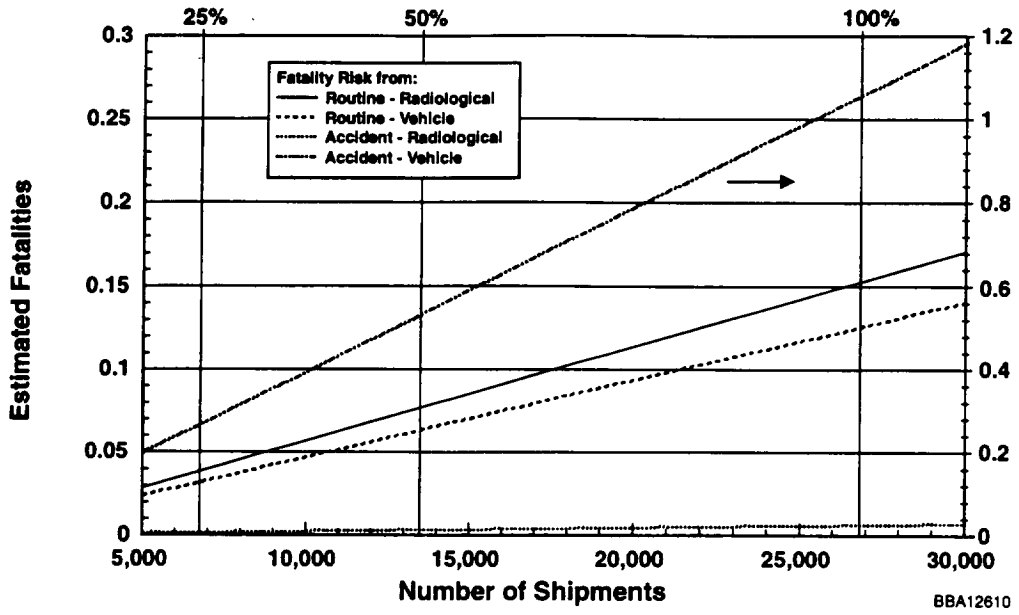

FIGURE K.79 Estimated Truck Transportation Risks for UO_2 Shipped from the Conversion Facility to Long-Term Storage or Oxide Cask Manufacture

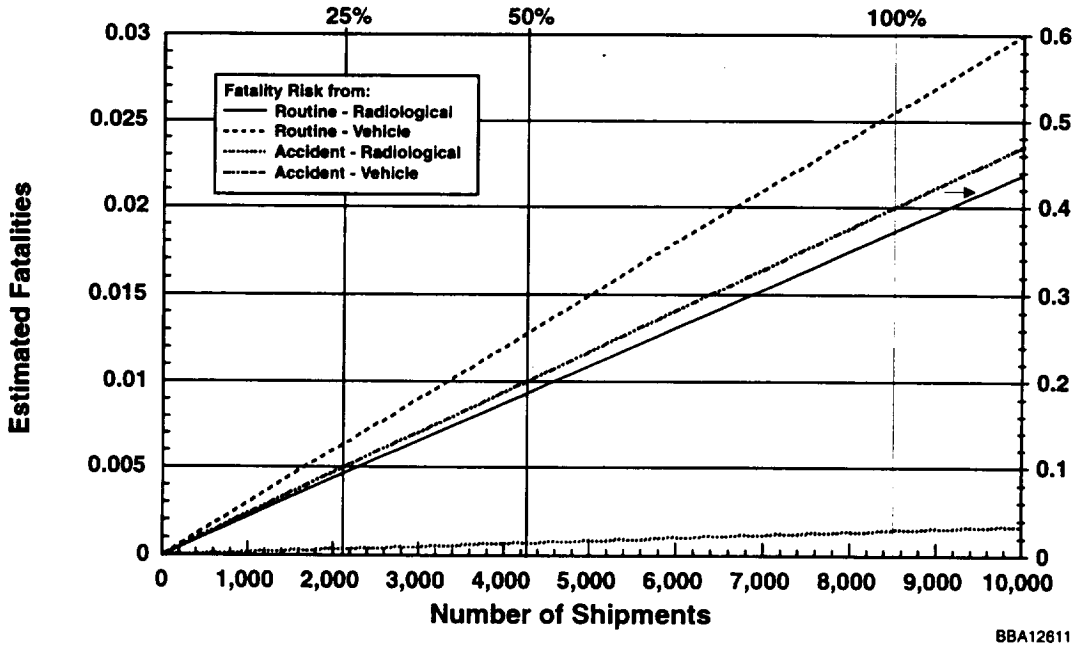

FIGURE K.80 Estimated Rail Transportation Risks for UO_2 Shipped from the Conversion Facility to Long-Term Storage or Oxide Cask Manufacture

Section J.3.6.1. The parametric risks for UO_2 are shown in Figures K.79 and K.80 for shipment by truck and rail, respectively.

Uranium oxide cask production would result in the generation of some LLW and LLMW, as discussed in Appendix J, Section J.3.6. The parametric results for the shipment of the LLW by truck to a disposal site are shown in Figure K.81. Radiological and chemical accident risks are not presented because they are more than 1 million times less than the other results shown in Tables J.15 and J.16 for the 100% case. The number of shipments required for LLMW disposal is not expected to change appreciably with the throughput case (25%, 50%, or 100%) because a minimal amount would be generated by the manufacturing process.

The transportation risks for shipment of the uranium oxide cask by rail from the manufacturing facility to an end-user are given in Appendix J, Section J.3.6.1. Figure K.82 shows the risks associated with rail shipments of the uranium oxide casks for the three parametric cases. Radiological and chemical accident risks are not presented because they are approximately 1 million times less than the other results shown in Tables J.15 and J.16 for the 100% case.

K.6.3.2 Use as Uranium Metal

The estimated transportation risks for shipment of all of the uranium metal from a conversion facility to a manufacturing site for metal cask production are presented in Appendix J, Section J.3.6.2. The parametric risks for the metal shipments are presented in Figures K.83 and K.84 for shipment by truck or rail, respectively. Radiological and chemical accident risks are not presented because they would be more than 1 million times less than the other results shown in Tables J.15 and J.16 for the 100% case.

The metal cask production would result in the generation of some LLW and LLMW, as discussed in Appendix J, Section J.3.6.2. The parametric results for the shipment of the LLW by truck to a disposal site are shown in Figure K.85. Radiological and chemical accident risks are not presented because they would be more than 100 times less than the other risks shown. The number of shipments required for LLMW disposal is not expected to change appreciably with the throughput case (25%, 50%, or 100%) because a minimal amount is generated by the manufacturing process.

The transportation risks for shipment of the metal cask by rail from the manufacturing facility to an end-user are given in Appendix J, Section J.3.6.2. Figure K.86 shows the risks associated with rail shipment of the metal casks for the three parametric cases. Routine radiological risks are not presented because these risks would be about 100 times less than the risks for the 100% case; radiological and chemical accident risks are also not presented because they would be approximately 100 million times less than the other risks for the 100% case, as shown in Tables J.15 and J.16.

FIGURE K.85 Estimated Truck Transportation Risks for Shipment of LLW from the Metal Cask Manufacturing Facility to a Disposal Site

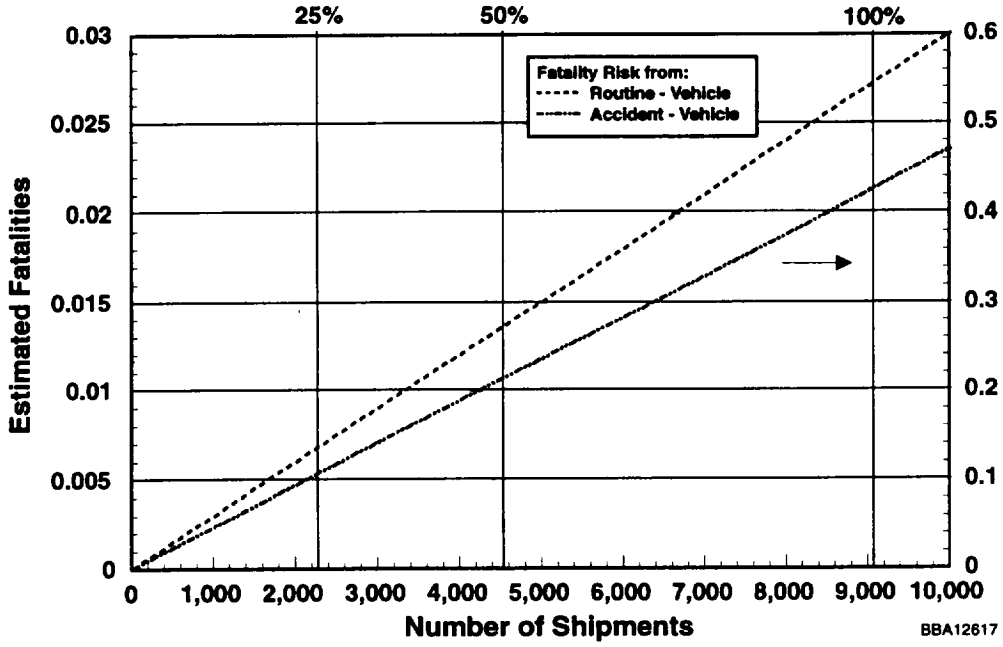

FIGURE K.86 Estimated Rail Transportation Risks for Shipment of Metal Casks from the Cask Manufacturing Facility to an End-User Site

K.6.4 Disposal as Ungrouted U_3O_8

The estimated transportation risks for shipment of all the U_3O_8 from a conversion facility to a disposal site are presented in Appendix J, Section J.3.7. The parametric risks for the oxide shipments are presented in Figures K.87 and K.88 for shipment by truck or rail, respectively.

K.7 IMPACTS OF COMBINATIONS OF ALTERNATIVES

The alternatives evaluated in detail in the PEIS are no action, long-term storage as UF_6, long-term storage as uranium oxide, use as uranium oxide, use as uranium metal, and disposal. DOE's preferred alternative is also considered in the PEIS. This section provides examples of how the impacts of parametric cases for continued storage, cylinder preparation, conversion, long-term storage, manufacture and use, disposal, and transportation activities (as presented in Appendixes D and E and Sections K.2-K.6 of Appendix K) can be added together to assess the impacts of strategies that combine one or more of the alternatives evaluated in the PEIS. Six example combinations of use as oxide, use as metal, and continued storage as UF_6 are evaluated (cases 1 through 6); an additional combination of 50% use as oxide, 50% use as metal (case 7) is also evaluated. Although these combinations were chosen as examples, the methods to calculate potential environmental impacts for them can be used to calculate impacts for other combinations as well (e.g., 50% disposal, 50% long-term storage).

The example combinations assessed (Table K.6) were selected to provide a reasonable range of possible combinations that might occur in the future as uses are identified. A summary of potential environmental consequences associated with these cases is presented in Tables K.9 and K.10 (tables follow Section K.7.2 of this appendix).

K.7.1 Example Calculation of Impacts for a Combination of Alternatives

The results of a sample calculation for Case 1 are presented in Sections K.7.1.1 through K.7.1.11. Under Case 1, 50% of the depleted UF_6 inventory would continue to be stored as UF_6, 25% would be converted and used as uranium oxide, and the remaining 25% would be converted and used as uranium metal. This sample is intended to illustrate how the impacts can be estimated for any combination of alternatives.

The impacts for this sample combination include impacts during continued cylinder storage, preparation of cylinders for shipment, conversion of UF_6 to uranium oxide and metal, treatment of empty cylinders, manufacture of uranium oxide and uranium metal casks, and transportation of cylinders, conversion products (oxide, metal, HF, ammonia, and waste), and casks. The potential impacts of Case 1 were calculated by adding the impacts from each of the individual components, as appropriate. Certain impacts, such as the dose to MEIs, are not additive because the MEI at each

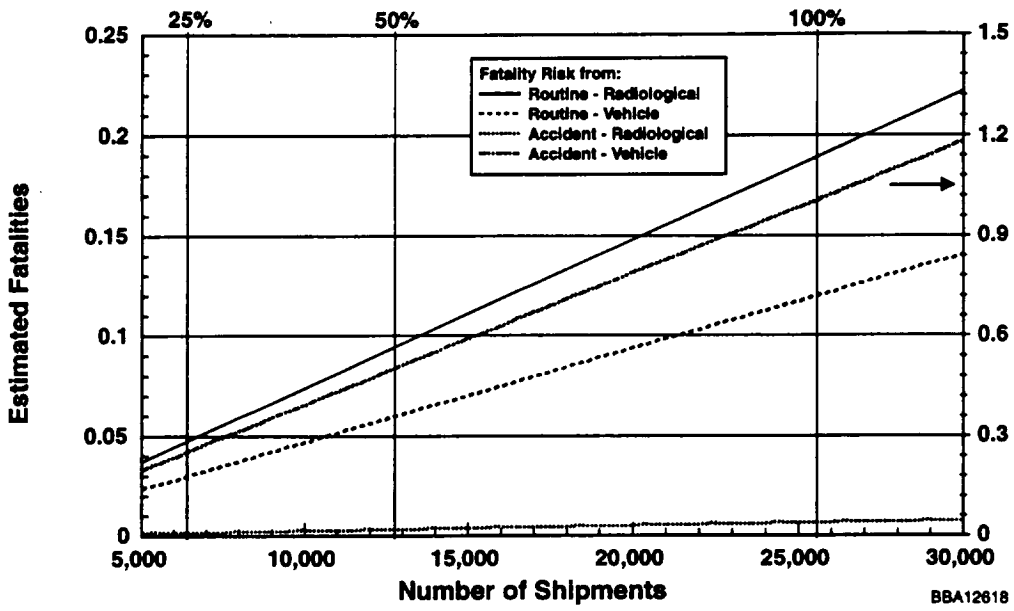

FIGURE K.87 Estimated Truck Transportation Risks for U_3O_8 Shipped from the Conversion Facility to Disposal

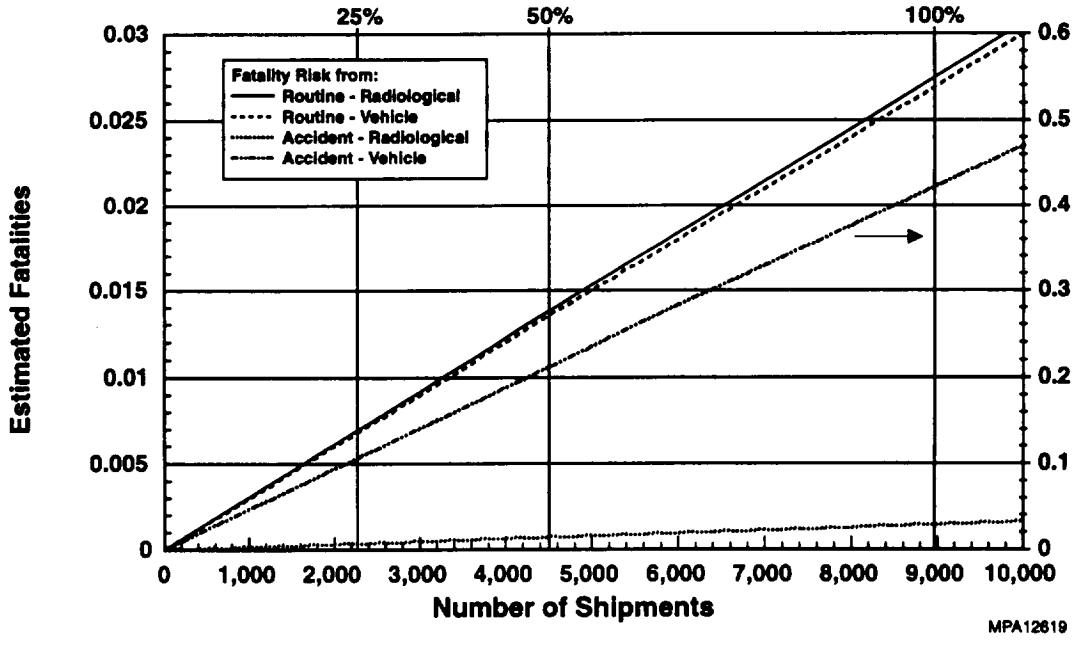

FIGURE K.88 Estimated Rail Transportation Risks for U_3O_8 Shipped from the Conversion Facility to Disposal

TABLE K.6 Example Combinations of Alternatives (Cases) for Which Environmental Impacts Were Evaluated

	Fraction of Inventory		
Case	Use as Uranium Oxide	Use as Uranium Metal	Continued Storage as UF_6 (No Action Alternative)
1	0.25	0.25	0.5
2	0.33	0.33	0.33
3	0.5	0	0.5
4	0	0.5	0.5
5	0.5	0.25	0.25
6	0.25	0.5	0.25
7	0.5	0.5	0

site would be different and the future facilities were assumed to be built at separate sites (except for the continued storage and cylinder preparation activities, which were assumed to occur at the current storage sites; and the conversion and cylinder treatment activities, which would likely occur at the same sites). The potential impacts from continued cylinder storage and cylinder preparation are provided in Appendices D and E, respectively; impacts from the other components are provided in Sections K.1 through K.6.

K.7.1.1 Human Health — Normal Operations

K.7.1.1.1 Radiological Impacts

Involved Workers. The collective radiation dose to involved workers was estimated by summing the radiation dose from each of the components comprising Case 1. The calculation of radiological impacts to involved workers is outlined below. The impacts are first presented for each of the individual components and then summed, as appropriate, to provide an estimate of the total radiological impact.

Continued Cylinder Storage. Potential radiological impacts during continued cylinder storage at the three current storage sites include impacts during storage of 100% of the inventory for a period of 10 years, removal of 50% of the cylinder inventory over a period assumed to be 20 years,

and storage of 50% of the inventory for the remaining 10 years considered during the assessment period (1999 through 2039).

The total dose to involved workers was calculated as follows:

Annual dose to involved workers from storage of the entire cylinder inventory (from Table D.2) = 36 person-rem/yr

Average annual dose from storage of 50% of the entire inventory = 0.5 × 36 person-rem/yr = 18 person-rem/yr

Average annual dose during the cylinder removal period for removal of 50% of the inventory = 0.5 × (36 person-rem/yr + 18 person-rem/yr) = 27 person-rem/yr

The total worker dose from continued cylinder storage of 50% of the inventory was then calculated as:

Total worker dose = 10 years × 36 person-rem/yr + 20 years × 27 person-rem/yr + 10 years × 18 person-rem/yr

Total worker dose = 1,080 person-rem

Cylinder Preparation. For purposes of assessing Case 1, it was assumed that the 50% of the cylinder inventory converted for use would be transported to a conversion site from the three current storage sites and that all of the cylinders transported would require preparation by either placement in overcontainers or transfer to new cylinders. Shipment of 50% of the cylinder inventory over a 20-year period corresponds to annual rates of 709 cylinders per year at the Paducah site, 335 cylinders per year at the Portsmouth site, and 117 cylinders per year at the K-25 site.

The annual collective dose to workers for a range of shipment rates at each site are provided in Appendix E, Figure E.3, for the overcontainer option and in Figure E.4 for the transfer facility option. The doses corresponding to the above shipment rates are as follows:

Annual dose to workers using overcontainer option = 14 person-rem/yr (Paducah) + 6 person-rem/yr (Portsmouth) + 2 person-rem/yr (K-25) = 22 person-rem/yr

Total dose over 20 years using overcontainer option = 22 person-rem/yr × 20 years = 440 person-rem

Annual dose to workers using cylinder transfer option = 35 person-rem/yr (Paducah) + 25 person-rem/yr (Portsmouth) + 20 person-rem/yr (K-25) = 80 person-rem/yr

Total dose over 20 years using cylinder transfer option = 80 person-rem/yr × 20 years = 1,600 person-rem

Total range of worker dose from cylinder preparation = 440 to 1,600 person-rem

Conversion. The doses to workers from conversion for various throughput rates are provided in Figure K.11 for conversion to uranium oxide (UO_2) and in Figure K.17 for conversion to uranium metal. From these data, the estimated collective worker doses for conversion of 25% of the inventory to oxide and 25% to uranium metal are as follows:

Annual dose to workers from conversion of 25% of the inventory to oxide = 22 to 31 person-rem/yr

Total worker dose from conversion to oxide = (22 to 31) person-rem/yr × 20 years = 440 to 620 person-rem

Annual dose to workers from conversion of 25% of the inventory to metal = 18 to 50 person-rem/yr

Total worker dose from conversion to metal = (18 to 50) person-rem/yr × 20 years = 360 to 1,000 person-rem

Cylinder Treatment. The collective dose to workers from the treatment of empty cylinders for a range in the number of cylinders treated is provided in Figure K.23. It was assumed that two treatment facilities would be required, one for each conversion facility. On this basis, the estimated doses to workers are as follows:

Annual dose to workers from treatment of 25% of the cylinder inventory = 6 person-rem/yr

Total worker dose from cylinder treatment = 2 × 6 person-rem/yr × 20 years = 240 person-rem

Manufacture and Use. The doses to workers from manufacture and use for various throughput rates are provided in Figure K.41 for manufacture of uranium oxide (UO_2) shielded casks

and in Figure K.47 for manufacture of uranium metal shielded casks. From these data, the estimated worker doses for manufacture of 25% of the inventory to oxide shielded casks and 25% to uranium metal shielded casks are as follows:

Annual dose to workers from manufacture of 25% of the inventory to oxide casks
= 10 person-rem/yr

Total worker dose from manufacture of oxide casks
= 10 person-rem/yr × 20 years = 200 person-rem

Annual dose to workers from manufacture of 25% of the inventory to metal casks
= 2 person-rem/yr

Total worker dose from manufacture of metal casks
= 2 person-rem/yr × 20 years = 40 person-rem

Total Radiological Impacts to Workers. The total collective radiation dose to involved workers was calculated by summing the collective doses from the individual components. The individual contributions, as well as the total dose, are summarized in Table K.7. In addition, the number of radiation-induced health effects was estimated by multiplying the collective dose by a health risk conversion factor of 4×10^{-4} LCF/person-rem for involved workers. The total LCFs among workers were estimated to range from 1 to 2 over the duration of the program. The radiological impacts to noninvolved workers would be negligible compared to those for involved workers (based on total doses for individual component activities two or more orders of magnitude lower than those for involved workers).

General Public. The collective radiation dose to members of the general public was calculated in a manner similar to that outlined above for workers. However, because the collective dose to members of the public in the vicinity of all sites was found to be well below levels expected to cause adverse health effects for all individual components, a conservative approach was taken to estimate the total impacts. The total impacts to members of the general public were conservatively estimated by summing the maximum dose estimates (100% cases) for each component, as follows:

Maximum collective dose to public from continued cylinder storage (Table D.1)
= 1.1 person-rem

Maximum collective dose to public from cylinder preparation (Table E.1)
= 0.006 person-rem

TABLE K.7 Range of Radiological Doses and Latent Cancer Fatalities among Involved Workers for Case 1: 50% Continued Storage, 25% Use as Oxide, and 25% Use as Metal

Component	Collective Dose (person-rem)
Continued cylinder storage	1,080
Cylinder preparation	440 - 1,600
Oxide conversion	440 - 620
Metal conversion	360 - 1,000
Cylinder treatment	240
Manufacture of oxide casks	200
Manufacture of metal casks	40
Total dose	2,800 - 4,780
Latent cancer fatalities[a]	1 - 2

[a] The number of latent cancer fatalities was calculated using a health risk conversion factor of 4×10^{-4} LCF/person-rem for workers.

Maximum collective dose to public from conversion to oxide (Table F.2)
= 10 person-rem

Maximum collective dose to public from conversion to metal (Table F.2)
= 8 person-rem

Maximum collective dose to public from cylinder treatment (Table F.2)
= 0.008 person-rem

Maximum collective dose to public from manufacture of oxide casks (Table H.1)
= 0.1 person-rem

Maximum collective dose to public from manufacture of metal casks (Table H.1)
= 0.7 person-rem

The maximum total collective dose to the public is estimated to be approximately 20 person-rem, much less than levels expected to cause adverse health effects.

Because individual activities would occur at separate sites and the results of the parametric analyses indicate that impacts decrease with a decrease in the amount processed, the dose to general public MEIs from Case 1 (as well as any of the other combinations analyzed) would be less than the estimates presented for each of the individual components. Therefore, all doses to individual members of the general public would be well below regulatory limits and well below levels expected to cause adverse health effects.

K.7.1.1.2 Chemical Impacts

Chemical impacts from components comprising Case 1 are generally nonadditive because these impacts were estimated for MEIs at each site and future facilities were assumed to be built at separate sites. The two exceptions are (1) continued storage and cylinder preparation activities, which would take place at the current storage sites; and (2) conversion and cylinder treatment activities, which would likely occur at the same site.

Estimated hazard indices for MEIs for all management options are much less than 1 (a hazard index of greater than 1 indicates the potential for health impacts). To provide a conservative estimate of potential hazards from activities occurring at the same sites, the maximum hazard index for both workers and the general public from continued cylinder storage activities for 1999 through 2039 (0.065; Tables D.5 and D.25) was added to the maximum hazard index from cylinder preparation activities (6.1×10^{-6}; Section E.3.1.2). Similarly, the maximum hazard index from conversion options (1.5×10^{-4}; Table F.6) was added to the maximum hazard index from cylinder treatment (7.1×10^{-8}; Table F.6). The results in both cases are still much lower than 1, so adverse chemical impacts from normal operations would not be associated with Case 1 (or any of the other combinations analyzed).

K.7.1.2 Human Health — Accident Conditions

K.7.1.2.1 Radiological and Chemical Impacts

For any combination involving continued cylinder storage and use as oxide and metal, the bounding impacts from accidents involving radiological or chemical releases would be the largest of the impacts estimated for the no action (continued storage) alternative, the use as oxide alternative, or the use as metal alternative. The consequences of bounding accidents for combination alternatives would be the same as the largest consequences of accidents under these alternatives because only a limited amount of material would be at risk of release under accident conditions, regardless of the facility size or throughput. Although the frequencies of some accidents (for example, cylinder-handling accidents) would decrease somewhat as the facility throughput

decreased, the overall frequency category for those accidents would remain the same despite these small changes in frequencies.

K.7.1.2.2 Physical Hazards

Physical hazards to involved and noninvolved workers were estimated by summing the injury and fatality hazards from each of the components comprising the combination, similar to the method described for estimating collective worker radiation dose in Section K.7.1.1.1. For Case 1, the calculations to estimate physical hazards are outlined below.

Continued Cylinder Storage. The numbers of fatalities and injuries during continued cylinder storage at the three current storage sites were estimated by summing the numbers estimated for 10 years of storage of the entire inventory, 20 years for removal of 50% of the cylinder inventory, and 10 additional years for storage of the remaining 50% of the inventory (covering the assessment period 1999 through 2039). The total number of fatalities and injuries to workers was calculated as follows:

Annual fatalities during storage of 100% of the inventory (no action) (from Table D.1)
= 0.11/40 years = 0.0028 fatalities per year

Annual injuries during storage of 100% of the inventory (from Table D.1)
= 143/40 years = 3.6 injuries per year

Annual fatalities during storage of 50% of the inventory
= 0.5 × 0.0028 = 0.0014 fatalities per year

Annual injuries during storage of 50% of the inventory
= 0.5 × 3.6 = 1.8 injuries per year

Average annual fatalities during the removal of 50% of the inventory
= 0.5 × (0.0028 fatalities per year + 0.0014 fatalities per year)
= 0.0021 fatalities per year

Average annual injuries during the removal of 50% of the inventory
= 0.5 × (3.6 injuries per year + 1.8 injuries per year)
= 2.7 injuries per year

The total number of fatalities and injuries from continued storage of 50% of the inventory was calculated as follows:

Total fatalities = 10 years × 0.0028 fatalities per year + 20 years × 0.0021 fatalities per year + 10 years × 0.0014 fatalities per year = 0.08 fatalities

Total injuries = 10 years × 3.6 injuries per year + 20 years × 2.7 injuries per year + 10 years × 1.8 injuries per year = 108 injuries

Cylinder Preparation. For purposes of assessing Case 1, it was assumed that the 50% of the cylinder inventory converted for use would be transported to a conversion site from the three current storage sites and that all of the cylinders transported would require preparation by either placement in overcontainers or transfer to new cylinders. Shipment of 50% of the cylinder inventory over a 20-year period corresponds to annual rates of 709 cylinders per year at the Paducah site, 335 cylinders per year at the Portsmouth site, and 117 cylinders per year at the K-25 site.

The fatalities and injuries for workers conducting overcontainer operations are provided in Appendix E, Figure E.10; the fatalities and injuries for workers conducting transfer operations are provided in Figures E.11 and E.12. These data are estimates of the total fatalities and injuries over the entire 20-year period that cylinder preparation activities were assumed to be ongoing. The estimated number of fatalities and injuries corresponding to shipment of 50% of the inventory at each site are as follows:

Fatalities among workers conducting overcontainer operations = 0.043 (Paducah) + 0.02 (Portsmouth) + 0.007 (K-25) = 0.07 fatalities

Injuries among workers conducting overcontainer operations = 57 (Paducah) + 27 (Portsmouth) + 9 (K-25) = 93 injuries

Fatalities among workers conducting cylinder transfer operations = 0.32 (Paducah) + 0.27 (Portsmouth) + 0.15 (K-25) = 0.74 fatalities

Injuries among workers conducting cylinder transfer operations = 218 (Paducah) + 159 (Portsmouth) + 100 (K-25) = 477 injuries

Total range of fatalities from cylinder preparation option = 0.07 to 0.74 fatalities

Total range of injuries from cylinder preparation option = 93 to 477 injuries

Conversion. The estimated numbers of fatalities and injuries for conversion of various throughput rates are provided in Section K.2.2.3. The estimated numbers of fatalities and injuries from conversion for Case 1 are as follows:

Fatalities among workers from conversion of 25% of the inventory to oxide
= 0.35 to 0.49 fatalities

Injuries among workers from conversion of 25% of the inventory to oxide
= 290 to 430 injuries

Fatalities among workers from conversion of 25% of the inventory to metal
= 0.33 to 0.49 fatalities

Injuries among workers from conversion of 25% of the inventory to metal
= 270 to 450 injuries

Cylinder Treatment. The estimated numbers of fatalities and injuries from the treatment of empty cylinders for a range in the number of cylinders treated is provided in Section K.2.2.3. In the case of conversion to both metal and oxide, two separate conversion facilities with separate cylinder treatment facilities would likely be constructed, so the impacts would be two times the 25% impacts, rather than the impacts for a single 50% capacity treatment facility. The estimated numbers of fatalities and injuries from cylinder treatment for Case 1 are as follows:

Fatalities among workers from treatment of 25% of the cylinder inventory = 0.13 fatalities

Injuries among workers from treatment of 25% of the cylinder inventory = 121 injuries

Total fatalities = 2 × 0.13 = 0.26 fatalities

Total injuries = 2 × 121 = 242 injuries

Manufacture and Use. Fatalities and injuries for manufacture of uranium oxide (UO_2) shielded casks are presented in Figure K.49; values for manufacture of uranium metal shielded casks are presented in Figure K.50. The estimated numbers of fatalities and injuries for Case 1 are as follows:

Fatalities among workers from manufacture of 25% of the inventory to oxide casks
= 0.61 fatalities

Injuries among workers from manufacture of 25% of the inventory to oxide casks
= 490 injuries

Fatalities among workers from manufacture of 25% of the inventory to metal casks
= 0.68 fatalities

Injuries among workers from manufacture of 25% of the inventory to metal casks
= 520 injuries

Total Physical Hazards. The total fatalities and injuries were calculated by summing the values for the individual components and then rounding to the nearest whole number. The individual contributions and total fatalities and injuries are summarized in Table K.8.

K.7.1.3 Transportation

The transportation impacts for normal operations and traffic accident fatalities were determined by the number of shipments required for each combination alternative, assuming a travel distance of 620 miles (1,000 km) per shipment. For Case 1, these impacts would be the sum of the number of shipments if 25% of the inventory was converted for use as oxide and 25% of the inventory was converted for use as metal (no off-site transportation of cylinders would be required

TABLE K.8 Range of On-the-Job Fatalities and Injuries among All Workers for Case 1: 50% Continued Storage, 25% Use as Oxide, and 25% Use as Metal[a]

Component	Fatalities	Injuries
Continued cylinder storage	0.08	110
Cylinder preparation	0.07 – 0.74	93 – 480
Oxide conversion	0.35 – 0.49	290 – 430
Metal conversion	0.33 – 0.49	270 – 450
Cylinder treatment	0.26	240
Manufacture of oxide casks	0.61	490
Manufacture of metal casks	0.68	520
Total	2 – 3	2,000 – 2,700

[a] Represents impacts to involved and noninvolved workers from construction and operation of facilities. Values rounded to two significant figures.

for continued cylinder storage). The impacts of the various combinations examined would be essentially the same for exposures from normal operations because these exposures would generally be expected to result in 1 or fewer adverse health effects among workers and members of the general public combined. As would be expected, traffic accident fatalities for Case 1, which would involve transportation of 50% of the cylinder inventory and the resulting conversion products, are estimated to be about half of those expected under the use as oxide and use as metal alternatives (Table K.9, which follows Section K.7.2 of this appendix).

For any combination involving continued cylinder storage and use as oxide and metal, the bounding impacts for accidents involving releases from cylinders or releases of other materials would be the larger of the impacts estimated for either the use as oxide alternative or the use as metal alternative. The consequences of bounding accidents for combination alternatives would be the same as the largest consequences of these alternatives because the same amount of material would be at risk under accident conditions, regardless of the number of shipments. The overall probability of accidents occurring would decrease in direct proportion to the number of shipments and the distance per shipment; in Case 1, the overall probability would be about half that estimated for the use as oxide alternative.

K.7.1.4 Air Quality

Air quality impacts from construction at the current storage sites would be the same as those predicted for the no action alternative because all construction activities are planned to take place prior to about 2003, during which time all cylinders would remain at the current storage locations under all alternatives and combination alternatives examined.

Air quality impacts from operations at the current storage sites for combination alternatives involving varying percentages of continued storage would depend on whether a certain percentage of cylinders was removed from each site or whether cylinders were preferentially removed from one or two of the sites. For 100% continued storage (no action alternative), a potential impact that could occur if cylinder maintenance and painting activities do not reduce cylinder corrosion rates would be exceedance of the HF standard at the K-25 site in about the year 2020 (see Appendix D, Section D.3, for further discussion).

In examining the potential air quality impacts of combination alternatives, the case where cylinders at the Paducah and Portsmouth sites would be preferentially removed for use was assumed as the bounding case, leaving all cylinders in place at the K-25 site. (The number of cylinders stored at the K-25 site constitutes only about 10% of the entire inventory, so that the combination alternatives that consider from 25 to 75% use of the inventory could all have the entire K-25 inventory remaining in place). Therefore, the bounding air quality impacts from operations at the current storage sites for combination alternatives (including Case 1) would be the same as the

impacts from the no action alternative. If the cylinders at K-25 were preferentially removed or part of the inventory was removed, then air quality impacts at the K-25 site would decrease accordingly. Also, if continued maintenance and painting are effective in controlling cylinder corrosion, as expected, concentrations of HF would be kept within regulatory standards at all sites under all combination alternatives.

Pollutant emissions during construction and operation of conversion and manufacturing facilities designed to process the entire inventory would remain within standards. Emissions under the combination alternatives also would remain within standards because emissions were estimated to be within applicable standards for full-scale (100%) facilities and emissions would be somewhat reduced for facilities with lower throughput rates because different sites were assumed for new facilities.

K.7.1.5 Water and Soil

As discussed for air quality impacts, impacts to groundwater at the current storage sites for combination alternatives involving varying percentages of continued storage would depend on whether a certain percentage of cylinders was removed from each site or whether cylinders were preferentially removed from one or two of the sites. For the no action alternative, a potential impact that could occur if cylinder maintenance and painting activities do not reduce cylinder corrosion rates would be that the groundwater uranium concentration at all three sites could exceed 20 µg/L in about the year 2100 or later (see Appendix D, Section D.3, for further discussion). For combination alternatives, the case where cylinders at the Paducah and Portsmouth sites would be preferentially removed for use was assumed as the bounding case, leaving all cylinders in place at the K-25 site. Therefore, the bounding groundwater quality impacts at the current storage sites for combination alternatives could include exceedance of the 20 µg/L guideline level at one or more of the current storage sites at some time after the year 2100. However, if cylinder maintenance and painting are effective in controlling cylinder corrosion, as expected, groundwater uranium concentrations would remain below 20 µg/L at all sites.

Potential surface water, groundwater and soil quality impacts at conversion and manufacturing facilities could be kept within applicable standards or guidelines by following good engineering practices.

K.7.1.6 Socioeconomics

Socioeconomic impacts for each component of the combination alternatives are summarized in Tables K.9 and K.10 (which follow Section K.7.2). Methods of estimating these impacts are discussed in Sections K.7.1.6.1 and K.7.1.6.2.

K.7.1.6.1 Continued Cylinder Storage

Socioeconomic impacts from construction activities at the current storage sites would be the same as those predicted for the no action alternative because all construction activities are planned to take place prior to about 2003, during which time all cylinders would remain at the current storage locations under all alternatives and combination alternatives examined.

The socioeconomic analysis evaluated direct income and jobs for the first year of operations. These values may be interpreted as annual averages over the operational periods because annual operations would generally be uniform. Continued storage impacts for combination alternatives need to be normalized to a standard number of years because continued storage would be ongoing for about 40 years (1999 through 2039), whereas use options were assumed to be ongoing for only 20 years (2009 through 2028). For continued storage operations, the totals for direct jobs and direct income were calculated as follows:

Direct jobs during storage (no action), three-site total (from Table D.18)
= 110 jobs per year

Direct income during storage, three-site total (from Table D.18)
= $5.1 million per year

Direct jobs during cylinder removal (action alternatives), three-site total (from Table D.30)
= 120 jobs per year

Direct income during cylinder removal, three-site total (from Table D.30)
= $6 million per year

Average jobs during the removal of 50% of the inventory = 0.5 × (110 jobs per year + 120 jobs per year) = 115 jobs per year

Average income during the removal of 50% of the inventory = 0.5 × ($5.1 million/yr + $6 million per year) = $5.55 million per year

The total jobs and income from continued storage of 50% of the inventory was calculated as follows:

Total jobs = 10 years × 110 jobs per year + 20 years × 115 jobs per year + 10 years × 55 jobs per year = 3,950 job-years

Total income = 10 years × $5.1 million per year + 20 years × $5.55 million per year + 10 years × $2.55 million per year) = $187.5 million

To facilitate comparison with the no action alternative, the total jobs and income were distributed over 40 years, resulting in a value of 99 jobs per year and $4.7 million income per year over 40 years (see Table K.9). To compare with use alternatives, the values should be converted to total jobs, assuming 40 years for no action and combination alternatives involving continued storage, and assuming 20 years for alternatives involving use only.

K.7.1.6.2 Cylinder Preparation, Conversion, and Manufacturing

Parametric socioeconomic impacts for the cylinder preparation, conversion, and manufacturing options were assessed qualitatively (see Sections E.3.5, K.2.5, and K.4.5), based on preliminary cost data for the 100% cases (LLNL 1996) and socioeconomic data for parametric cases provided in the cost analysis report (LLNL 1997b). The estimated direct jobs and direct employment values for combination alternatives calculated using the above-described data are presented in Tables K.9 and K.10.

K.7.1.7 Ecology

The principal differences in ecological impacts between the combination alternatives would be associated with habitat loss. Potential habitat loss at the current storage sites is the sum of habitat loss that would occur under the no action alternative (7 acres [2.8 ha]), which would be applicable for all alternatives because construction would occur prior to 2003) and loss that would occur from cylinder preparation activities. If overcontainers were used, no additional habitat loss would occur. Transfer facilities would range in areal site requirements from about 12 acres (4.9 ha) for a facility to process the inventory at the K-25 site (10% of the entire inventory), to 14 acres (5.7 ha) for a facility to process the inventory at the Portsmouth site (30% of the entire inventory), to 21 acres (8.5 ha) for a facility to process the inventory at the Paducah site (60% of the entire inventory) (see Section E.3.6). For alternatives involving 100% use, the maximum habitat loss at any site would be 28 acres (21 + 7) (11 ha). To estimate habitat loss for alternatives involving 50 to 75% use, it was assumed that all cylinders would be taken from a single facility until the entire inventory at a single site was used. Therefore, maximum habitat loss at any site for a 50% use facility would be estimated at 21 acres (8.5 ha) (Paducah site value) + 7 acres (2.8 ha), or 28 acres (11 ha). Similarly, maximum habitat loss at any site for alternatives involving 75% use would also be 28 acres (11 ha).

Potential habitat loss for conversion facilities was calculated on the basis of data provided in Sections K.2.9.2, K.2.9.3, and K.2.9.4. The habitat losses corresponding to 25%, 50% and 100% capacity uranium oxide (UO_2) conversion facilities would be 16, 19, and 24 acres (6.5, 7.7, and 9.7 ha), respectively. Similarly, the habitat losses corresponding to 25%, 50% and 100% capacity metal conversion facilities would be 17, 21, and 26 acres (6.9, 8.5, and 10.5 ha), respectively. Finally, for 25%, 50%, and 100% cylinder treatment facilities, the habitat losses would be 7, 8, and

9 acres (2.8, 3.2, and 3.6 ha), respectively. Although these parametric values were calculated for specific conversion options (e.g., conversion to UO_2 by the dry process, with anhydrous HF production), the amount of land required for the other conversion technologies would be roughly similar. For combination options involving both oxide and metal conversion, two cylinder treatment facilities would be required, one for each conversion facility. The habitat loss for conversion for Case 1 (25% use as oxide, 25% use as metal) was calculated as follows:

Habitat loss for conversion to oxide = 16 acres (6.5 ha)

Habitat loss for conversion to metal = 17 acres (6.9 ha)

Habitat loss for a treatment facility = 7 acres (2.8 ha)

Habitat loss for each conversion facility = 23 to 24 acres (9.3 to 9.7 ha) (total of 47 acres)

Potential habitat loss for manufacturing facilities was calculated on the basis of data given in Section K.4.9. For an oxide cask manufacturing facility, the land areas corresponding to 25%, 50%, and 100% capacity would be 79, 84, and 90 acres (32, 34, and 36 ha), respectively; the land areas for 25%, 50% and 100% capacity at a metal cask manufacturing facility are assumed to be the same. For Case 1, two 25% capacity manufacturing facilities would be required, so the total land area would be about 79 acres (32 ha) at either manufacturing facility (total of 158 acres).

K.7.1.8 Waste Management

For waste management at the current storage sites, impacts for all combination alternatives would be similar to those estimated for the no action alternative. Although waste generation amounts would vary somewhat on the basis of the numbers of cylinders being stored and maintained, overall impacts to nationwide waste generation would be negligible. Waste generation impacts associated with waste management capabilities at the Portsmouth and K-25 sites would be negligible. Due to large amounts of cylinder painting assumed at the Paducah site in the earlier years of continued storage, impacts to LLMW management at the Paducah site would be moderate for all combination alternatives.

The use as oxide and use as metal alternatives have potential moderate impacts to nationwide LLW generation on the basis of a possible requirement to dispose of CaF_2 and/or MgF_2 as LLW, if the CaF_2 or MgF_2 were considered DOE waste. If such disposal were required, these alternatives could generate a volume of LLW equal to about 10% of the projected DOE complexwide disposal volume. Moderate impacts to nationwide waste management are defined as additional volumes in excess of 10% of the DOE complexwide disposal volume; negligible to low impacts generate less than 10%. Assuming a linear decrease in potential LLW production, combination

alternatives involving 50% or more conversion to oxide or metal could have low to moderate impacts on nationwide LLW waste management.

K.7.1.9 Resource Requirements

Under the combination alternatives, adverse effects on local, regional, or national availability of materials would not be expected.

K.7.1.10 Land Use

Land use corresponds to habitat loss. See Section K.7.1.7 for an explanation of the values calculated for the combination alternatives.

K.7.1.11 Other Areas of Impact

Impacts to cultural resources at the current storage sites would depend on the selected locations for construction activities but are considered unlikely. Cultural resource activities at other facilities would depend on the locations and will be examined in detail at the next stage of the program when facilities are actually sited. Adverse environmental justice impacts for activities occurring under the example combination alternatives are not expected. The occurrence of severe transportation accidents involving a release is unlikely, and accidents occur at random locations along transportation corridors; therefore, significant and disproportionate high and adverse impacts to minority or low-income populations are unlikely.

K.7.2 Summary of Impacts for Example Combination Alternatives

The method used to estimate the impacts for combination alternatives described in Section K.7.1 was used to evaluate the impacts for the example cases listed in Table K.6. The results for the first six cases analyzed are presented in detail in Table K.9. The results for an additional 50% use as oxide, 50% use as metal combination strategy are presented in Table K.10. In general, the impacts for these combination alternatives tend to be very similar to the impacts estimated for the primary alternatives evaluated in the PEIS (as summarized in Chapter 2, Table 2.2).

TABLE K.9 Summary Comparison of Environmental Consequences of Example Combinations of Use as Oxide, Use as Metal, and Continued Storage as UF_6 Alternatives

Environmental Consequence	Case 1: 25% Use as Oxide; 25% Use as Metal; 50% Continued Storage	Case 2: 33% Use as Oxide; 33% Use as Metal; 33% Continued Storage	Case 3: 50% Use as Oxide; 50% Continued Storage	Case 4: 50% Use as Metal; 50% Continued Storage	Case 5: 50% Use as Oxide; 25% Use as Metal; 25% Continued Storage	Case 6: 25% Use as Oxide; 50% Use as Metal; 25% Continued Storage
Human Health and Safety — Normal Facility Operations[a]						
Radiation Exposure						
Involved workers						
Annual dose to individual workers	Monitored to be maintained within maximum regulatory limit of 5 rem/yr or lower	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1
Total health effects among involved workers (1999-2039)	1 to 2 additional LCFs	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1
Noninvolved workers						
Annual dose to noninvolved worker MEI (all facilities)	Well within public health standards (i.e., less than maximum dose limit of 100 mrem/yr)	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1
Total health effects among noninvolved workers (1999-2039)	0 additional LCFs from routine site emissions	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1
General public						
Annual dose to general public MEI (all facilities)	Well within public health standards (i.e., less than maximum dose limit of 100 mrem/yr)	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1
Total health effects among members of the public (1999-2039)	0 additional LCFs from routine site emissions	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1
Chemical Exposure of Concern (Concern = hazard index > 1)						
Noninvolved worker MEI[b]	No (Hazard Index <1)	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1
General public MEI	No (Hazard Index <1)	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1

TABLE K.9 (Cont.)

Environmental Consequence	Case 1: 25% Use as Oxide; 25% Use as Metal; 50% Continued Storage	Case 2: 33% Use as Oxide; 33% Use as Metal; 33% Continued Storage	Case 3: 50% Use as Oxide; 50% Continued Storage	Case 4: 50% Use as Metal; 50% Continued Storage	Case 5: 50% Use as Oxide; 25% Use as Metal; 25% Continued Storage	Case 6: 25% Use as Oxide; 50% Use as Metal; 25% Continued Storage
			Human Health and Safety — Facility Accidents[a]			
Physical Hazards from Construction and Operations (involved and noninvolved workers)						
On-the-job fatalities and injuries (1999-2039)	2-3 fatalities; 2,000-2,700 injuries.	2-3 fatalities; 2,100-2,800 injuries	1-2 fatalities; 1,200-1,700 injuries	1-2 fatalities; 1,200-1,800 injuries	3-4 fatalities; 2,200-2,900 injuries	3-4 fatalities; 2,100-2,900 injuries
Accidents Involving Releases of Chemicals or Radiation: Cylinder Accidents at Current Storage Sites						
Likely Cylinder Accidents[c]						
Accident[d]	Corroded cylinder spill, dry conditions	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1
Release	Uranium, HF	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1
Estimated frequency	~ 1 in 10 years	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1
Accident probability (1999-2039)	3-4 potential accidents	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1
Consequences (per accident)						
Chemical exposure – public	No adverse effects	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1
Chemical exposure – noninvolved workers[e]						
Adverse effects	70	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1
Irreversible adverse effects	3	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1
Fatalities	0	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1
Radiation exposure – public						
Dose to MEI	3 mrem	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1
Risk of LCF	1 in 1 million	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1
Total dose to population	0.4 person-rem	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1
Total LCFs	0	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1
Radiation exposure – noninvolved workers[e]						
Dose to MEI	77 mrem	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1
Risk of LCF	3 in 100,000	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1
Total dose to workers	2.2 person-rem	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1
Total LCFs	0	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1
Accident risk (consequence times probability)						
General public	0 fatalities	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1
Workers	0 fatalities	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1

			Environmental Justice			
All Sites	No disproportionately high and adverse impacts to minority or low-income populations in the general public during normal operations or from accidents; severe transportation accidents are unlikely and occur at random locations along routes; therefore, high and adverse disproportionate impacts to minority or low-income populations are unlikely	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1	Same as Case 1

[a] For purposes of comparison, estimates of human health effects (e.g., LCFs) have been rounded to the nearest whole number. Accident probabilities are the estimated frequencies multiplied by the number of years of operations.

[b] Chemical exposures for involved workers during normal operations would depend in part on facility designs. The workplace environment would be monitored to ensure that airborne chemical concentrations were below applicable exposure limits.

[c] Accidents with probabilities of occurrence greater than 0.01 per year.

[d] On the basis of calculations performed for the PEIS, the accidents that are listed in this table have been found to have the highest consequences of all the accidents analyzed for the given frequency range. In general, accidents that have lower probabilities have higher consequences.

[e] In addition to noninvolved worker impacts, chemical and radiological exposures for involved workers under accident conditions (workers within 100 m of a release) would depend in part on facility designs and other factors (see Section 4.3.2.1).

[f] Accidents with probabilities of occurrence from 0.0001 per year to less than 0.000001 per year.

[g] Other facilities are facilities for conversion, long-term storage, manufacturing, and disposal.

[h] The guideline concentration used for comparison with estimated surface water and groundwater uranium concentrations is the proposed EPA maximum contaminant level of 20 μg/L; this value is an applicable standard for water "at the tap" of the user, and is not a directly applicable standard for surface water or groundwater (no such standard exists). The guideline concentration used for comparison with estimated soil uranium concentrations is a health-based guideline value for residential settings of 230 μg/g.

Footnotes continue on next page

TABLE K.9 (Cont.)

Footnotes (Cont.)

[i] Other parameters evaluated include changes in runoff, floodplain encroachment, groundwater recharge, depth to groundwater, direction of groundwater flow, soil permeability, and erosion potential.

[j] For construction, direct jobs and direct income are reported for the peak construction year. For operations, direct jobs and income are presented as annual averages, except for continued storage, which is reported for the peak year of operations.

[k] Habitat losses and land-use acreages given as maximum for a single site or facility, conversion facilities would also need to establish protective action distances encompassing 960 acres around the facility.

[l] Resources evaluated include construction materials (e.g., concrete, steel, special coatings), fuel, electricity, process chemicals, and containers (e.g., drums and cylinders).

Notation: CaF_2 = calcium fluoride; HF = hydrogen fluoride; LCF = latent cancer fatality; LLW = low-level radioactive waste; LLMW = low-level mixed waste; MEI = maximally exposed individual; MgF_2 = magnesium fluoride; NH_3 = ammonia; UF_6 = uranium hexafluoride.

TABLE K.10 Summary of Potential Environmental Consequences of Example 50% Use as Oxide, 50% Use as Metal Combination Alternative

Environmental Consequence	Case 7: 50% Use as Uranium Oxide; 50% Use as Metal
Human Health and Safety — Normal Facility Operations[a]	
Radiation Exposure	
Involved workers	
Annual dose to individual workers	Monitored to be maintained within maximum regulatory limit of 5 rem/yr or lower
Total health effects among involved workers (1999–2039)	1 to 2 additional LCFs
Noninvolved workers	
Annual dose to noninvolved worker MEI (all facilities)	Well within public health standards (i.e., less than maximum dose limit of 100 mrem/yr)
Total health effects among noninvolved workers (1999–2039)	0 additional LCFs from routine site emissions
General public	
Annual dose to general public MEI (all facilities)	Well within public health standards (i.e., less than maximum dose limit of 100 mrem/yr)
Total health effects among members of the public (1999–2039)	0 additional LCFs from routine site emissions
Chemical Exposure of Concern (concern = hazard index > 1)	
Noninvolved worker MEI[b]	No (Hazard Index <1)
General public MEI	No (Hazard Index <1)
Human Health and Safety — Facility Accidents[a]	
Physical Hazards from Construction and Operations (involved and noninvolved workers)	
On-the-job fatalities and injuries (1999–2039)	3–4 fatalities; 2,300–3,100 injuries
Accidents Involving Releases of Chemicals or Radiation: Cylinder Accidents at Current Storage Sites	
Likely Cylinder Accidents[c]	
Accident[d]	Corroded cylinder spill, dry conditions
Release	Uranium, HF
Estimated frequency	~ 1 in 10 years
Accident probability (1999–2039)	3 potential accidents

TABLE K.10 (Cont.)

Environmental Consequence	Case 7: 50% Use as Uranium Oxide; 50% Use as Metal
Human Health and Safety — Facility Accidents[a] (Cont.)	
Consequences (per accident)	
Chemical exposure – public	No adverse effects
Chemical exposure – Noninvolved workers[e]	
Adverse effects	70
Irreversible adverse effects	3
Fatalities	0
Radiation exposure – public	
Dose to MEI	3 mrem
Risk of LCF	1 in 1 million
Total dose to population	0.4 person-rem
Total LCFs	0
Radiation exposure – Noninvolved workers[e]	
Dose to MEI	77 mrem
Risk of LCF	3 in 100,000
Total dose to workers	2.2 person-rem
Total LCFs	0
Accident risk (consequence times probability)	
General public	0 fatalities
Noninvolved workers	0 fatalities
Low Frequency-High Consequence Cylinder Accidents[f]	
Accident[d]	Vehicle-induced fire, 3 full cylinders (high for adverse effects); corroded cylinder spill, wet conditions (high for irreversible adverse effects)
Release	Uranium, HF
Estimated frequency	~ 1 in 100,000 years
Accident probability (1999–2039)	~ 1 chance in 2,500
Consequences (per accident)	
Chemical exposure – public	
Adverse effects	1,900
Irreversible adverse effects	1
Fatalities	0
Chemical exposure – noninvolved workers[e]	
Adverse effects	1,000
Irreversible adverse effects	300
Fatalities	3
Radiation exposure – public	
Dose to MEI	15 mrem
Risk of LCF	7 in 1 million
Total dose to population	1 person-rem
Total LCFs	0

TABLE K.10 (Cont.)

Environmental Consequence	Case 7: 50% Use as Uranium Oxide; 50% Use as Metal
Human Health and Safety — Facility Accidents[a] (Cont.)	
Radiation exposure – noninvolved workers[e]	
Dose to MEI	20 mrem
Risk of LCF	8 in 1 million
Total dose to workers	16 person-rem
Total LCFs	0
Accident risk (consequence times probability)	
General public	0 fatalities
Noninvolved workers	0 fatalities
Accidents Involving Releases of Chemicals or Radiation: Low Frequency-High Consequence Accidents at All Facilities[f]	
Chemical accident[d]	HF or NH_3 tank rupture
Release	HF, NH_3
Accident location	Conversion site
Estimated frequency	< 1 in 1 million years
Accident probability (1999–2039)	1 chance in 50,000 (over 20 years)
Consequences (per accident)	
Chemical exposure – public	
Adverse effects	41,000
Irreversible adverse effects	1,700
Fatalities	30
Chemical exposure – noninvolved workers[e]	
Adverse effects	1,100
Irreversible adverse effects	440
Fatalities	4
Accident risk (consequence times probability)	
General public	0 fatalities
Noninvolved workers	0 fatalities
Radiological accident	Earthquake damage to storage building at conversion site
Release	Uranium (UO_2)
Accident location	Conversion site
Estimated frequency	1 in 100,000 years
Accident probability (1999–2039)	1 chance in 5,000 (over 20 years)

TABLE K.10 (Cont.)

Environmental Consequence	Case 7: 50% Use as Uranium Oxide; 50% Use as Metal
Human Health and Safety — Facility Accidents[a] (Cont.)	
Consequences (per accident)	
Radiation exposure – public	
Dose to MEI	68 mrem
Risk of LCF	3 in 100,000
Total dose to population	5 person-rem
Total LCFs	0
Radiation exposure – noninvolved workers[e]	
Dose to MEI	2,300 mrem
Risk of LCF	9 in 10,000
Total dose to workers	210 person-rem
Total LCFs	0
Accident risk (consequence times probability)	
General public	0 LCFs
Noninvolved workers	0 LCFs
Human Health and Safety — Transportation[a]	
Major Materials Assumed to Be Transported between Sites	UF_6 cylinders Uranium oxide Uranium metal HF (if produced) CaF_2 (if produced) NH_3 MgF_2 LLW/LLMW Casks
Normal Operations	
Fatalities from exposure to vehicle exhaust and external radiation	0 to 1
Maximum radiation exposure to a person along a route (MEI)	Less than 0.1 mrem
Traffic Accident Fatalities (1999–2039) (physical hazards, unrelated to cargo)	
Maximum use of trucks	4 fatalities
Maximum use of rail	1 fatality

TABLE K.10 (Cont.)

Environmental Consequence	Case 7: 50% Use as Uranium Oxide; 50% Use as Metal
Human Health and Safety — Transportation[a] (Cont.)	
Traffic Accidents Involving Releases of Radiation or Chemicals	
Low Frequeny-High Consequence Cylinder Accidents	
Accident	Urban rail accident involving 4 cylinders
Release	Uranium, HF
Accident probability (1999–2039)	1 chance in 10,000
Consequences (per accident)	
Chemical exposure –All workers and members of general public	
Irreversible adverse effects	4
Fatalities	0
Radiation exposure – All workers and members of general public	
Total LCFs	60
Accident Risk (consequence times probability)	
Workers and general public	0 fatalities
Low Frequency-High Consequence Accidents with All Other Materials	
Accident	Urban rail accident involving anhydrous HF
Release	Anhydrous HF
Accident probability (1999–2039)	1 chance in 30,000
Consequences (per accident)	
Chemical exposure – workers and members of general public	
Irreversible adverse effects	30,000
Fatalities	300
Accident risk (consequence times probability)	
Irreversible adverse effects	1
Fatalities	0

TABLE K.10 (Cont.)

Environmental Consequence	Case 7: 50% Use as Uranium Oxide; 50% Use as Metal
Air Quality	
Current Storage Sites	
Pollutant emissions during construction	Maximum 24-hour PM_{10} concentration up to 95% of standard; other criteria pollutants well within standards
Pollutant emissions during operations	Maximum 24-hour HF concentration up to 93% of standard at K-25; HF concentrations well within standards at other sites; criteria pollutants well within standards at all sites
Other Facilities[g]	
Pollutant emissions during construction and operations	Maximum 24-hour PM_{10} concentration up to 90% of standard; other pollutant emissions well within standards (all less than 30% of standards)
Water and Soil[h]	
Current Storage Sites	
Surface water, groundwater, and soil quality	Uranium concentrations would remain within guideline levels
Other parameters[i]	No change
Other Facilities[g]	
Surface water, groundwater, and soil quality	Site-dependent; contaminant concentrations could be kept within guideline levels
Other parameters[i]	Site-dependent; none to moderate impacts
Socioeconomics[j]	
Current Storage Sites	
Continued storage	**Jobs:** 30 peak year, construction; 120 per year over 20 years operations **Income:** $1.4 million peak year, construction; $6 million per year over 20 years operations

TABLE K.10 (Cont.)

Environmental Consequence	Case 7: 50% Use as Uranium Oxide; 50% Use as Metal
	Socioeconomics*[j] *(Cont.)
Cylinder preparation	**Jobs:** 0–580 peak year, preoperations; 300–490 per year over 20 years operations **Income:** $0–26 million peak year, preoperations; $19–25 million per year over 20 years operations
Other Facilities[g]	
Conversion	**Jobs:** 710–1,100 peak year, construction; 520–770 per year over 20 years operations **Income:** $29–47 million peak year, construction; $31–44 million per year over 20 years operations
Manufacturing	**Jobs:** 300 peak year, construction; 540 per year over 20 years operations **Income:** $14 million peak year, construction; $38 million per year over 20 years operations
	Ecology
Current Storage Sites	
Habitat loss[k]	Up to 28 acres; negligible to potential moderate impacts
Concentrations of chemical or radioactive materials	Below harmful levels; potential site-specific effects from facility or transportation accidents
Wetlands and threatened or endangered species	None to negligible impacts
Other Facilities[g]	
Habitat loss[k]	**Conversion:** Up to 29 acres at a single site; total of 56 acres; potential moderate impacts to vegetation and wildlife **Manufacturing:** Up to 84 acres at a single site; total of 170 acres; potential moderate to large impacts to vegetation and wildlife

TABLE K.10 (Cont.)

Environmental Consequence	Case 7: 50% Use as Uranium Oxide; 50% Use as Metal
	Ecology (Cont.)
Concentrations of chemical or radioactive materials	Below harmful levels; potential site-specific effects from facility or transportation accidents
Wetlands and threatened or endangered species	Site-dependent; avoid or mitigate
	Waste Management
Current Storage Sites	**LLW:** no impacts **LLMW:** potential moderate impacts with respect to current waste generation at Paducah (> 20%); negligible impacts with respect to Portsmouth, K-25, or nationwide waste generation
Other Facilities[g]	
Conversion	Potential moderate impacts to current nationwide LLW generation for CaF_2 (if produced and not used) and MgF_2 as LLW (if required); potential moderate impact to site waste generation for CaF_2 and MgF_2 as nonhazardous solid waste
Manufacturing	Negligible impacts with respect to current regional or nationwide waste generation
	Resource Requirements[l]
All Sites	No effects on local, regional, or national availability of materials are expected
	Land Use
Current Storage Sites	Up to 28 acres; less than 1% of available land; negligible impacts
Other Facilities[g]	
Conversion	Up to 29 acres at a single site; total of up to 56 acres; potential moderate impacts
Manufacturing	Up to 84 acres at a single site; total of 170 acres; potential moderate impacts

TABLE K.10 (Cont.)

Environmental Consequence	Case 7: 50% Use as Uranium Oxide; 50% Use as Metal
Cultural Resources	
Current Storage Sites	Impacts unlikely
Other Facilities[g]	Impacts dependent on location; avoid and mitigate
Environmental Justice	
All Sites	No disproportionately high and adverse impacts to minority or low-income populations in the general public during normal operations or from accidents; severe transportation accidents are unlikely and occur randomly along routes; therefore, high and adverse impacts to minority or low-income populations are unlikely

[a] For purposes of comparison, estimates of human health effects (e.g., LCFs) have been rounded to the nearest whole number. Accident probabilities are the estimated frequencies multiplied by the number of years of operation.

[b] Chemical exposures for involved workers during normal operations would depend in part on of facility designs. The workplace environment would be monitored to ensure that airborne chemical concentrations were below applicable exposure limits.

[c] Accidents with probabilities of occurrence greater than 0.01 per year.

[d] On the basis of calculations performed for the PEIS, the accidents that are listed in this table have been found to have the highest consequences of all the accidents analyzed for the given frequency range. In general, accidents that have lower probabilities have higher consequences.

[e] In addition to noninvolved worker impacts, chemical and radiological exposures for involved workers (workers within 100 m of a release) under accident conditions would depend in part on facility designs and other factors (see Section 4.3.2.1).

[f] Accidents with probabilities of occurrence from 0.0001 per year to less than 0.000001 per year.

[g] Other facilities are facilities for conversion and manufacturing.

[h] The guideline concentration used for comparison with estimated surface water and groundwater uranium concentrations is the proposed U.S. Environmental Protection Agency (EPA) maximum contaminant level of 20 μg/L (EPA 1996); this value is an applicable standard for water "at the tap" of the user and is not a directly applicable standard for surface water or groundwater (no such standard exists). The guideline concentration used for comparison with estimated soil uranium concentrations is a health-based guideline value for residential settings of 230 μg/g.

[i] Other parameters evaluated include changes in runoff, floodplain encroachment, groundwater recharge, depth to groundwater, direction of groundwater flow, soil permeability, and erosion potential.

NOTATION (APPENDIX L)

The following is a list of acronyms and abbreviations used in this appendix.

ACRONYMS AND ABBREVIATIONS

General

CEQ	Council on Environmental Quality
DOE	U.S. Department of Energy
EPA	U.S. Environmental Protection Agency
FR	*Federal Register*
HEU	highly enriched uranium
LEU	low-enriched uranium
MOX	mixed oxide (fuel)
NEPA	*National Environmental Policy Act*
NOI	Notice of Intent
NRC	U.S. Nuclear Regulatory Commission
PEIS	programmatic environmental impact statement
USEC	United States Enrichment Corporation

Chemicals

UF_4	uranium tetrafluoride
UF_6	uranium hexafluoride
UO_2	uranium dioxide
U_3O_8	triuranium octaoxide (uranyl uranate)

APPENDIX L:

RESPONSES TO COMMENTS RECEIVED DURING THE SCOPING PROCESS FOR THE PROGRAMMATIC ENVIRONMENTAL IMPACT STATEMENT FOR ALTERNATIVE STRATEGIES FOR THE LONG-TERM MANAGEMENT AND USE OF DEPLETED URANIUM HEXAFLUORIDE

L.1 SCOPING PROCESS

The U.S. Department of Energy (DOE) issued a Notice of Intent (NOI) to prepare a programmatic environmental impact statement (PEIS) for depleted uranium hexafluoride (UF_6) on January 25, 1996, in the *Federal Register* (61 FR 2239). In addition, a letter from the project manager, copies of the NOI, a scoping comment form, and a fact sheet entitled "Overview of the Programmatic Environmental Impact Statement" were mailed to 3,800 individuals. These individuals were identified by personnel at the three DOE sites currently used for storage of depleted UF_6 and through the DOE stakeholder mailing list. Two public scoping meetings were held in the vicinity of each current storage site — Paducah, Kentucky (February 13, 1996); Oak Ridge, Tennessee (February 15, 1996); and Portsmouth, Ohio (February 20, 1996).

Information relevant to both the project and the *National Environmental Policy Act* (NEPA) process was provided through development of an Internet Home Page that includes an overview of the project, fact sheets, NEPA and Council on Environmental Quality (CEQ) regulations, access to an Internet Environmental Law Library, and links to DOE's NEPA Web and CEQ's NEPA Net. Provision for commenting on the scope of the PEIS was provided in the overview presentation on the Home Page. The computer-based overview presentation is available on CD-ROM and was available on computers at the scoping meetings. The public was also provided with a mechanism for commenting directly while viewing the computer program.

Approximately 300 persons attended the scoping meetings. DOE staff were present at information tables to receive comments directly from the attendees. In addition, the public was able to provide comments on the scope of the PEIS by filling out the scoping comment form (hardcopy or via the CD-ROM program); by mailing or faxing comments to the program office; and/or by sending an electronic mail message via the Internet. The majority of the 235 individual comments received during the scoping period were received at the scoping meetings.

The public comments are discussed in detail in the next section. All comments received at the scoping meetings, both written and oral, have been categorized as to subject and made available over the World Wide Web at the following address: http://www.ead.anl.gov/uranium.html.

L.2 ENVIRONMENTAL IMPACT ISSUES IDENTIFIED IN SCOPING

The purpose of the scoping process is to determine the range of actions, alternatives, and significant impacts to be considered in the PEIS. The comments provided by the public during this scoping process were reviewed and organized into several groups on the basis of the issues raised. The majority of comments focused on the range of technical options to be considered by DOE in constructing alternative strategies. The issues and their disposition are summarized below.

L.2.1 Environment

General environmental issues relate to the need to consider a broad range of impacts to human health and safety, water, air, land, wildlife, and socioeconomics. More specific comments relate to the need to consider radioactive decay products, health effects of specific chemicals, and trace elements.

- **Comment**: The PEIS should evaluate in detail a broad range of impacts to water, air, land, wildlife, and socioeconomic resources from all options for storage, use, disposal, or conversion of depleted UF_6.

  Response: The PEIS will cover these technical areas at a level of detail appropriate for the programmatic analysis. Site-specific details related to potential locations for facilities will be provided in follow-on NEPA documents that will be prepared prior to any future siting decisions.

- **Comment**: The PEIS should use the TRIAD model developed by the National Oceanic and Atmosphere Administration for analyzing atmospheric dispersion and releases of depleted UF_6.

  Response: The TRIAD model was evaluated by the project team, who selected a more advanced model called HGSYSTEM for use in the PEIS.

- **Comment**: The PEIS should analyze the "worst-case scenarios" for health impacts to the public and workers from all options for storage, use, disposal, or conversion of depleted UF_6.

  Response: The PEIS will consider various accident scenarios based on preconceptual designs, including reasonably foreseeable low-probability, but potentially high-consequence, events. Accidents evaluated will include those with a probability of occurrence of 1 in 1 million (10^{-6}) to 1 in 10 million (10^{-7}).

- **Comment**: The PEIS should evaluate the risks to the public from unrestricted use of depleted uranium or fluoride materials.

  Response: Due to U.S. Nuclear Regulatory Commission (NRC) radioactive material licensing requirements, among other things, commercial depleted uranium applications with limited public access are envisioned. The PEIS will evaluate the use of depleted uranium as shielding for radioactive materials for which public access is controlled. In the future, it may be possible to get an exemption from the NRC for certain depleted uranium applications. The PEIS will evaluate risks to the general public from conversion of depleted UF_6, including production of hydrogen fluoride, which would be sold.

- **Comment**: The PEIS should compare and contrast health and safety risks from all options for depleted UF_6.

  Response: The PEIS will compare and contrast health and safety risks from representative options that encompass the types of health and safety impacts related to depleted UF_6 management. The range of parameters considered in the PEIS will encompass many specific technologies and commercial processes.

- **Comment**: The PEIS should address the trace elements and contaminants in depleted UF_6 and their potential impacts upon the environment.

  Response: Depleted UF_6 is a very pure material. Decay products of uranium, which are in trace quantities, will be included in the analysis.

- **Comment**: The PEIS should evaluate the cumulative impacts upon the likely locations for all options for depleted UF_6.

  Response: Cumulative impacts for "no action" and for cylinder preparation at the three storage sites will be considered in the PEIS, as appropriate. Cumulative impacts at locations for use, conversion, storage, or disposal will be discussed qualitatively, with references to tiered NEPA reviews. Site-specific analyses of cumulative impacts at specific use, conversion, storage, or disposal locations will be presented in follow-on NEPA analyses prior to any future specific siting decisions for these activities.

- **Comment**: The PEIS should evaluate the impacts upon the DOE waste management system for all depleted UF_6 options.

  Response: The PEIS will address disposal of depleted uranium as an oxide form at a low-level-waste facility. For options involving use or storage of

depleted uranium, waste management will be analyzed for disposal or recycle of empty cylinders or by-products, as appropriate. This discussion will be based, in part, on DOE's *Final Waste Management Programmatic Environmental Impact Statement for Managing Treatment, Storage, and Disposal of Radioactive and Hazardous Waste* (DOE/EIS-0200-F).

- **Comment**: The PEIS should evaluate the long-term impacts from the changing chemistry and radioactive decay of uranium under the disposal options.

  Response: The PEIS analysis of disposal will include the decay products of uranium. It will be assumed that these products have a geochemical behavior similar to uranium.

L.2.2 Current Management of Depleted UF_6

Numerous comments were made regarding current management of cylinders at the Paducah site, the Portsmouth site, and the K-25 site on the Oak Ridge Reservation. These comments are summarized as follows:

- **Comment**: The PEIS should explain and evaluate current management of the cylinders at all three locations (Portsmouth, Paducah, and Oak Ridge).

  Response: The PEIS will provide a general discussion of cylinder management at the three sites and will consider the environmental impacts of "no action," which is continued cylinder management at the three sites.

- **Comment**: The PEIS should discuss the risks of current storage of the cylinders at all three locations.

  Response: The risks of current cylinder storage will be included in the PEIS.

L.2.3 Storage

A number of comments were received about alternative storage options, such as using old uranium mines or military installations. These comments are summarized below:

- **Comment**: The PEIS should evaluate a wide range of storage options, including storage in zinc mines in eastern Tennessee, transportation to a central location for consolidation, storage at retired military installations,

stringent monitoring processes, smaller size or different containers, and buildings and low-maintenance storage arrangements.

Response: The PEIS will consider a range of storage options, including storage in a mine, in yards, in buildings, and in vaults. The impacts associated with consolidating all the material at one location compared with dispersing the material at several locations will also be evaluated. The impacts of storage at specific sites, such as a retired military base, will be evaluated in follow-on NEPA analyses conducted prior to any future siting decisions.

- **Comment**: The PEIS should clarify how storage in a mine would work.

  Response: Storage in a mine will be described at the level of a preconceptual design.

- **Comment**: The PEIS should clarify how building storage would work, particularly in terms of ventilation and air controls.

  Response: The PEIS will consider a generic design for building storage. General assumptions about building performance will be made for the purpose of health and safety analysis. Particular designs for climate control and ventilation will be considered in follow-on NEPA analysis conducted prior to a decision on facility design.

- **Comment**: The PEIS should explain how the cylinders will be stored for all options.

  Response: The PEIS will explain cylinder storage for each alternative, as appropriate.

L.2.4 Conversion

A number of suggestions for conversion were made for consideration in the PEIS, which are summarized as follows:

- **Comment**: The PEIS should consider technology-specific options for conversion, such as the Quantum-Catalytic Extraction Process™.

  Response: The PEIS will conduct analyses of representative technologies in determining the impacts of various management strategy alternatives. The conversion technology options analyzed will have a sufficient technical basis to develop meaningful preconceptual designs and estimates of the

environmental data required for the PEIS analysis. After the decision is made on the long-term management strategy, specific technologies and sites will be considered in the second tier of the NEPA review process.

In response to the November 10, 1994, Request for Recommendations, a large number of promising conversion technologies were recommended that are in the early stages of design development or contain key aspects that are proprietary. In general, the proponents of these technologies believe that they offer process improvements and/or cost reductions compared with the more traditional processes. The Quantum-Catalytic Extraction Process™ is included in this category.

- **Comment**: The PEIS should consider other chemical forms for storage, such as metal, tetrafluoride, uranotile, and soddyite.

  Response: The PEIS will consider storage of depleted uranium as UF_6 and as the oxides triuranium octaoxide (U_3O_8) and uranium dioxide (UO_2). The rationale for selection of these chemical forms for analysis will be presented in the PEIS. In general, storage as metal would require substantially less storage space than the other chemical forms under consideration. This advantage must be weighed against disadvantages such as higher conversion cost, lower stability, and the uncertainty of the suitability of the metal form for eventual disposal. Uranium tetrafluoride (UF_4), or greensalt, is an intermediate form in the process of converting UF_6 to metal or converting oxide to UF_6. It is significantly more chemically reactive than uranium oxides, and no use has been identified for UF_4. Conversion into uranium-bearing minerals such as soddyite and uranotile for subsequent storage or disposal would require development of the chemical conversion process as well as examination of the suitability of such forms for storage or disposal.

- **Comment**: The PEIS should evaluate only conversion options at existing facilities, not at new facilities.

  Response: The PEIS is a programmatic-level document and will analyze conversion at representative facilities. The siting issues associated with building and operating conversion facilities at specific locations will be included in follow-on NEPA analyses conducted prior to any future siting decisions. The use of existing facilities would be evaluated when future siting decisions were made after the Record of Decision for this PEIS.

- **Comment**: The PEIS should consider shipping depleted UF_6 to Britain or France for processing.

Response: This PEIS addresses depleted UF_6 located in the continental United States and evaluates the transportation of all uranium products on a per-mile basis using U.S. national statistics. This could be applied to transport of the material to any port in the 48 contiguous states for shipment overseas. A decision as to vendors or processes for conversion of depleted UF_6 would be made after the Record of Decision for this strategic PEIS. At that time, NEPA analysis of international vendors or processes might be appropriate.

L.2.5 Use of Depleted UF_6

Many comments and suggestions were made about the use of depleted UF_6 after conversion, which are summarized as follows:

- **Comment**: The PEIS should consider the recovery (reenrichment) of uranium-235 from depleted UF_6.

  Response: Recovery of uranium-235 is a potential reason for storing depleted uranium. Long-term storage is a management option that would preserve some or all of the inventory of depleted UF_6 for use. The viability of refeeding depleted UF_6 is a function of the isotopic assay of depleted UF_6 and many uncertain factors in the future, such as uranium ore price, separative work cost, and demand. The PEIS will briefly discuss these factors.

- **Comment**: The PEIS should evaluate recycling cylinders as scrap steel.

  Response: The PEIS will address the issue of including empty cylinders in ongoing studies related to DOE's Recycle 2000 initiative for recycle of scrap metals.

- **Comment**: The PEIS should include use of depleted uranium in concrete as aggregate, including use in Hanford reactors.

  Response: Use of depleted uranium oxide in concrete for shielding purposes will be analyzed in the PEIS. The analysis of this technology at specific facilities will be addressed in follow-on NEPA analyses prior to any siting decisions.

- **Comment**: The PEIS should include use of depleted uranium for backfill material in spent nuclear fuel packages.

  Response: The PEIS will evaluate the use of depleted uranium for spent nuclear fuel shielding applications.

- **Comment**: The PEIS should include use of depleted uranium for blending highly enriched uranium (HEU) to produce low-enriched uranium (LEU) or for use in mixed-oxide (MOX) fuels.

  Response: The no action alternative and long-term storage alternatives preserve these options for later use of depleted uranium for blending HEU into LEU or in MOX nuclear fuels (see *Storage and Disposition of Weapons-Usable Fissile Materials, Final Programmatic Environmental Impact Statement*, DOE/EIS-0229, December 1996). The quantity of depleted uranium potentially used for these applications would be very small compared with the representative uses that will be considered in the Depleted UF_6 PEIS.

- **Comment**: The PEIS should evaluate separate uses for depleted uranium and fluorine.

  Response: The PEIS will analyze representative uses for the depleted uranium from depleted UF_6 and will assume that the fluorine from depleted UF_6 has commercial value as anhydrous hydrogen fluoride and would be sold.

- **Comment**: The PEIS should evaluate only feasible and attainable uses.

  Response: The representative options to be evaluated in the PEIS were selected because they are feasible and attainable in a reasonable time frame.

- **Comment**: The extent of uses in the general population and demands for such uses should be analyzed in the PEIS.

  Response: The demand for depleted UF_6 is an economic issue that is outside the scope of the PEIS because the need for management of depleted UF_6 is based on prudent management, not on demand. Such issues as the demand for depleted uranium — including existing data on potential uses, percent of inventory for current or future uses, and optimal form of depleted uranium for use — are discussed in the engineering and cost analysis reports, which will also support the decision on management strategy.

- **Comment**: The PEIS should consider the assay level (e.g., 0.2% uranium-235 compared with 0.4% uranium-235) as a discriminator for uses.

  Response: A homogeneous assay level is being assumed for this programmatic-level analysis. At a later time, when disposition of individual cylinders is decided, assay level will become an important consideration.

L.2.6 Cost

A number of issues were expressed with regard to costs. Some indicated that DOE should not spend a lot of money on the problem of depleted UF_6 management, whereas others indicated that costs and benefits of the options should be considered. Specific comments were grouped into the following major issues:

- **Comment**: The PEIS should present and evaluate costs for all depleted UF_6 management options. Costs should be kept to a minimum by using proven processing procedures, selling by-products, and using competitive bid processes.

  Response: A separate cost analysis report is being prepared, which will be considered in preparing the Record of Decision. The PEIS will discuss costs as they relate to socioeconomic impacts.

- **Comment**: The PEIS should explain the value of the materials in economic terms.

  Response: The value of the materials is being addressed separately in a cost analysis report.

L.2.7 Disposal

The disposal options for depleted UF_6 elicited comments regarding waste definitions and waste disposal options, as follows:

- **Comment**: The PEIS needs to evaluate the impacts of disposal in the event that depleted UF_6 were to be classified as a transuranic waste.

  Response: Depleted UF_6 is a source material. For purposes of the disposal options, it is being assumed that depleted UF_6 will be converted into an oxide and, in oxide form, will be treated as a low-level waste. The PEIS will evaluate the health and environmental impacts of such disposal.

- **Comment**: The PEIS should consider additional options for disposal, such as disposal in sedimentary formations on the ocean floor, vitrification with the molten glass or other techniques, disposal in old missile silos, or returning UF_6 to its original state and to its original source (i.e., uranium mines).

  Response: The PEIS will analyze a set of options that are anticipated to bound most possibilities for disposal. However, some options are subject to

institutional constraints, are speculative in nature, are in an unknown state of technical development, or have exorbitant costs. The PEIS will describe why certain options were considered in less detail or were judged to be unreasonable.

L.2.8 Transportation

It was suggested that barge transportation be considered in the PEIS:

- **Comment**: The PEIS should fully evaluate the transportation impacts from all options for depleted UF_6, especially barge transport (including shipping standards and emergency preparedness).

  Response: Transportation impacts will be discussed generally in the PEIS for representative routes and representative sites. Decisions on the locations of potential conversion, manufacturing, storage, or disposal facilities would be made after the Record of Decision for this PEIS. At that future time, barge transportation might be appropriate and would be analyzed in any accompanying NEPA documentation. This PEIS will include a qualitative discussion of the results of analyses conducted for other NEPA documents that compare barge transport to truck and rail transport, and a statement that future studies or NEPA analyses supporting siting decisions for conversion, manufacturing, storage, or disposal facilities will consider the transport of depleted UF_6 by barge, as appropriate.

L.2.9 Policy

Policy issues are higher level issues that could affect the whole PEIS structure and content. A number of these issues were included in the public comments, as follows:

- **Comment**: The PEIS should explain how its decisions fit within the context of other DOE decisions on materials.

  Response: The PEIS will explain how the programmatic depleted UF_6 decision (how best to manage depleted UF_6 in the future) fits with other related DOE decisions and programs currently under consideration.

- **Comment**: The PEIS should evaluate treatment, storage, and disposal of depleted UF_6 as a waste material.

Response: Depleted UF_6 is a source material. The disposal options considered in the PEIS assume conversion of depleted UF_6 to an oxide, with subsequent disposal. Uranium oxides are generally suitable forms for storage (and disposal). The impacts associated with both storage and disposal of U_3O_8 and UO_2 will be examined.

- **Comment**: The PEIS should explain the time frames for the options and provide some support for those time frames.

  Response: Time frames for the various phases of the options will be discussed in general terms within the PEIS.

- **Comment**: The PEIS should evaluate all depleted UF_6 materials in the United States, both existing stocks and those for the foreseeable future.

  Response: The PEIS will analyze a depleted UF_6 inventory accumulated by DOE and its predecessor agencies at Paducah, Kentucky; Portsmouth, Ohio; and Oak Ridge, Tennessee. The analysis will cover the period from 1945 through July 1, 1993, at which time the United States Enrichment Corporation (USEC), a government-owned corporation, was created to operate the Paducah and Portsmouth gaseous diffusion plants. Discussions between the Office of Management and Budget, USEC, and DOE are continuing regarding a Memorandum of Agreement, as provided in Section 3109(a)(2) of the USEC Privatization Act. This Memorandum of Agreement will allocate liabilities that arise from USEC's operations prior to privatization among DOE, USEC, the United States Government, and the new private corporation, including those liabilities arising from the disposal of depleted uranium, currently stored as UF_6, that was generated by USEC. The draft PEIS will address DOE's role in the management of this depleted uranium consistent with the terms of the Memorandum of Agreement. Because the new corporation will be responsible for the management of depleted UF_6 that it generates after privatization, DOE's role in the future disposal of this material is uncertain and speculative at this time. DOE will fulfill its NEPA responsibilities, as appropriate, when decisions are made in the future regarding the disposition of depleted UF_6 generated by the private corporation.

- **Comment**: DOE should include the NRC, the U.S. Environmental Protection Agency (EPA), and the Nevada Test Site in the discussions of disposal options for depleted UF_6.

  Response: Other federal agencies, including NRC and EPA, will be consulted during the PEIS comment process. The Nevada Test Site, a DOE site, will be asked for comments.

- **Comment**: The PEIS should analyze options for privatizing all facilities considered in the options for depleted UF_6.

  Response: The privatization of facilities will be considered qualitatively in the PEIS.

- **Comment**: DOE needs to identify the sources of funds that will be used for this program.

  Response: The issue of program funding is outside the scope of this NEPA analysis, which addresses impacts to the natural and human environment.

L.2.10 Other Issues

Other issues are not easily categorized and therefore have been placed at the end of the discussion of topics brought up during public scoping. These issues are summarized as follows:

- **Comment**: The PEIS should consider what other nations such as Japan and France have done with regard to depleted UF_6.

  Response: Part of the engineering development for options considered technologies in other countries.

- **Comment**: The PEIS should fully explain the need for taking any actions for depleted UF_6.

  Response: The PEIS will explain the purpose and need for the action.

- **Comment**: The PEIS should have a smaller list of alternatives so that the decisions and impacts can be clearly understood.

  Response: The PEIS will attempt to minimize the list of options and alternatives in order to clearly lay out the environmental effects for the decision makers and the public.

APPENDIX M:

CONTRACTOR DISCLOSURE STATEMENT

APPENDIX M:

CONTRACTOR DISCLOSURE STATEMENT

Argonne National Laboratory (ANL) is the contractor assisting DOE in preparing the PEIS for depleted UF_6. DOE is responsible for reviewing and evaluating the information and determining the appropriateness and adequacy of incorporating any data, analyses, or results in the PEIS. DOE determines the scope and content of the PEIS and supporting documents and will furnish direction to ANL, as appropriate, in preparing these documents.

The Council on Environmental Quality's Regulations (40 CFR 1506.5(c)), which have been adopted by the U.S. Department of Energy (10 CFR Part 1021), require contractors who will prepare an Environmental Impact Statement to execute a disclosure specifying that they have no financial or other interest in the outcome of the project. The term "financial interest or other interest in the outcome of the project" for the purposes of this disclosure is defined in the March 23, 1981, "Forty Most Asked Questions Concerning CEQ's National Environmental Policy Act Regulations," 46 *Federal Register* 18026-18028 at Questions 17a and 17b. Financial or other interest in the outcome of the project includes "any financial benefit such as promise of future construction or design work on the project, as well as indirect benefits the consultant is aware of (e.g., if the project would aid proposals sponsored by the firm's other clients"), 46 *Federal Register* 18026-18038 at 10831.

In accordance with these regulations, Argonne National Laboratory hereby certifies that it has no financial or other interest in the outcome of the project.

PUBLIC LAW 105-204

Public Law 105–204
105th Congress

An Act

To require the Secretary of Energy to submit to Congress a plan to ensure that all amounts accrued on the books of the United States Enrichment Corporation for the disposition of depleted uranium hexafluoride will be used to treat and recycle depleted uranium hexafluoride.

July 21, 1998
[S. 2316]

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled,

SECTION 1. UNITED STATES ENRICHMENT CORPORATION.

President.

Ohio.

(a) PLAN.—The Secretary of Energy shall prepare, and the President shall include in the budget request for fiscal year 2000, a plan and proposed legislation to ensure that all amounts accrued on the books of the United States Enrichment Corporation for the disposition of depleted uranium hexafluoride will be used to commence construction of, not later than January 31, 2004, and to operate, an onsite facility at each of the gaseous diffusion plants at Paducah, Kentucky, and Portsmouth, Ohio, to treat and recycle depleted uranium hexafluoride consistent with the National Environmental Policy Act.

(b) LIMITATION.—Notwithstanding the privatization of the United States Enrichment Corporation and notwithstanding any other provision of law (including the repeal of chapters 22 through 26 of the Atomic Energy Act of 1954 (42 U.S.C. 2297 et seq.) made by section 3116(a)(1) of the United States Enrichment Corporation Privatization Act (104 Stat. 1321–349), no amounts described in subsection (a) shall be withdrawn from the United States Enrichment Corporation Fund established by section 1308 of the Atomic Energy Act of 1954 (42 U.S.C. 2297b–7) or the Working Capital Account established under section 1316 of the Atomic Energy Act of 1954 (42 U.S.C. 2297b–15) until the date that is 1 year after the date on which the President submits to Congress the budget request for fiscal year 2000.

APPENDIX O:

SUMMARY OF THE ENGINEERING ANALYSIS REPORT*

*Please note that this entire Appendix O has been added after the public comment period.

UCRL-ID-124080

Depleted Uranium Hexafluoride Management Program

Summary of the ENGINEERING ANALYSIS REPORT for the Long-term Management of Depleted Uranium Hexafluoride

Prepared for the Department of Energy by
Lawrence Livermore National Laboratory

September 1997

1364

Work performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract W-7405-ENG-48.

Summary of the ENGINEERING ANALYSIS REPORT for the Long-Term Management of Depleted Uranium Hexafluoride

Note: This summary condenses and simplifies a number of technical issues and ideas. To obtain a fuller understanding of particular issues and ideas, the reader is urged to consult the complete *Engineering Analysis Report.*

1. Introduction

The Department of Energy is reviewing ideas for the long-term management and use of its depleted uranium hexafluoride.

The Department of Energy (DOE) owns about 560,000 metric tons (over a billion pounds) of depleted uranium hexafluoride (UF_6). This material is contained in steel cylinders located in storage yards near Paducah, Kentucky, and Portsmouth, Ohio, and at the East Tennessee Technology Park (formerly the K-25 Site) in Oak Ridge, Tennessee.

Uranium hexafluoride (UF_6) is a compound of one part uranium to six parts fluorine. At room temperature, it is a white solid similar to rock salt. It is usually measured in metric tons (MT). One MT equals about 2200 pounds.

On November 10, 1994, DOE issued a Request for Recommendations and an Advance Notice of Intent in the *Federal Register* (59 FR 56324 and 56325) to initiate the consideration of alternative strategies for the long-term management and use of depleted UF_6. The first part of the Depleted UF_6 Management Program consists of engineering, cost, and environmental impact studies. Part one will conclude with the selection of a long-term management plan, or strategy. Part two will carry out the selected strategy.

1.1 Background—What Is Depleted Uranium Hexafluoride?

Uranium is made up of several different types of atoms. One of these, uranium-235 (U-235), can be made to split apart and release a large amount of energy. As found in nature, uranium contains only a very small amount of U-235. In order for uranium to produce significant amounts of energy, the percentage of U-235 must be increased. For example, uranium fuel for powerplants usually contains between three and five percent U-235, while natural uranium contains only about 0.71 percent U-235. Uranium with more than 0.71 percent U-235 is called "enriched" uranium.

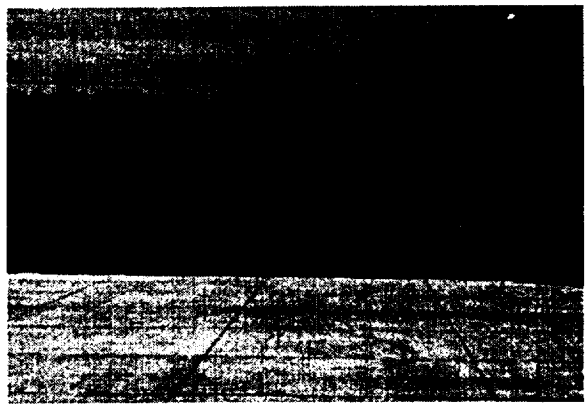
The enrichment process used in the United States is gaseous diffusion. It was first used on a large scale in the 1940s as part of the Manhattan Project in Oak Ridge, Tennessee. Later, plants were also built at Paducah, Kentucky, and Portsmouth, Ohio. On July 1, 1993, DOE leased these two plants to the United States Enrichment Corporation, as required by the Energy Policy Act of 1992. Oak Ridge had stopped enriching uranium in 1985.

The first step in gaseous diffusion is to heat solid natural UF_6 until it becomes a gas. The UF_6 gas is repeatedly separated into two streams. Gradually, one stream gains U-235, while the other loses U-235. When the U-235 in this second stream has been reduced to between 0.2 and 0.4 percent, the depleted UF_6 is removed from processing and placed in storage. Between 1945 and July 1, 1993, about 560,000 MT of depleted UF_6 was stored at the three gaseous diffusion plant sites.

Why is there so much depleted UF_6? For every pound of enriched uranium, between eight and nine pounds of depleted uranium are produced.

DOE's depleted UF_6 is stored in a partial vacuum inside steel cylinders. Most cylinders are about twelve feet long and 48 inches in diameter and hold between 9 and 12 MT of solid depleted UF_6. In all, there are 46,422 cylinders:

28,351 at Paducah
13,388 at Portsmouth
4,683 at Oak Ridge.



Depleted UF_6 is stored in cylinder yards like this one at Portsmouth.

1.2 Selecting a Management Strategy

The current management strategy is to continue safe storage of the depleted UF_6 cylinders in the existing storage yards. Activities in this strategy include inspection, handling, monitoring, and maintenance, as needed, to keep the cylinders in good condition. Other possible management strategies could involve use of the depleted uranium, long-term storage, disposal, or some combination of these. A complete management strategy may include a number of different activities. Examples are transportation or conversion of the depleted UF_6 to another chemical form, such as an oxide or metal.

The *Draft Programmatic Environmental Impact Statement* (Draft PEIS) looks at alternative strategies for the long-term management of depleted UF_6. They include the current management strategy (the "No Action alternative"), two alternatives for long-term storage, two alternatives for use, and one for disposal. DOE's preferred alternative is to use 100 percent of the depleted uranium, either as uranium oxide or uranium metal, or a combination of both. The fluorine in the depleted UF_6 would also be used.

The *Engineering Analysis Report* contains the technical data on which the Draft PEIS and the cost analysis are based. The PEIS, the *Cost Analysis Report*, and the *Engineering Analysis Report* will help DOE select a management strategy. The Record of Decision is expected in 1998.

2. The Engineering Analysis Project

Data from the engineering analysis will help DOE compare the environmental impacts and costs of management strategy alternatives.

In November 1994, DOE asked members of the public, industry, and other government agencies to submit recommendations for the use or long-term management of depleted UF_6. Fifty-seven replies were received and reviewed by independent technical experts. The results were published in the *Technology Assessment Report* in June 1995. Most of the recommendations were judged to be feasible, or capable of being carried out now or in the near future. These ideas and technologies were analyzed in more detail.

The main part of the Engineering Analysis Project developed engineering data for the feasible technology options. The data include general layouts for facilities, descriptions of processes, and analysis of hazards.

2.1 Work Breakdown Structure

A work breakdown structure shows the work that will need to be done on a project, moving from a general level to more and more detailed levels. It provides an orderly way to analyze and compare complex management strategies. Figure 1 shows the first three levels of the work breakdown structure for depleted UF_6 management.

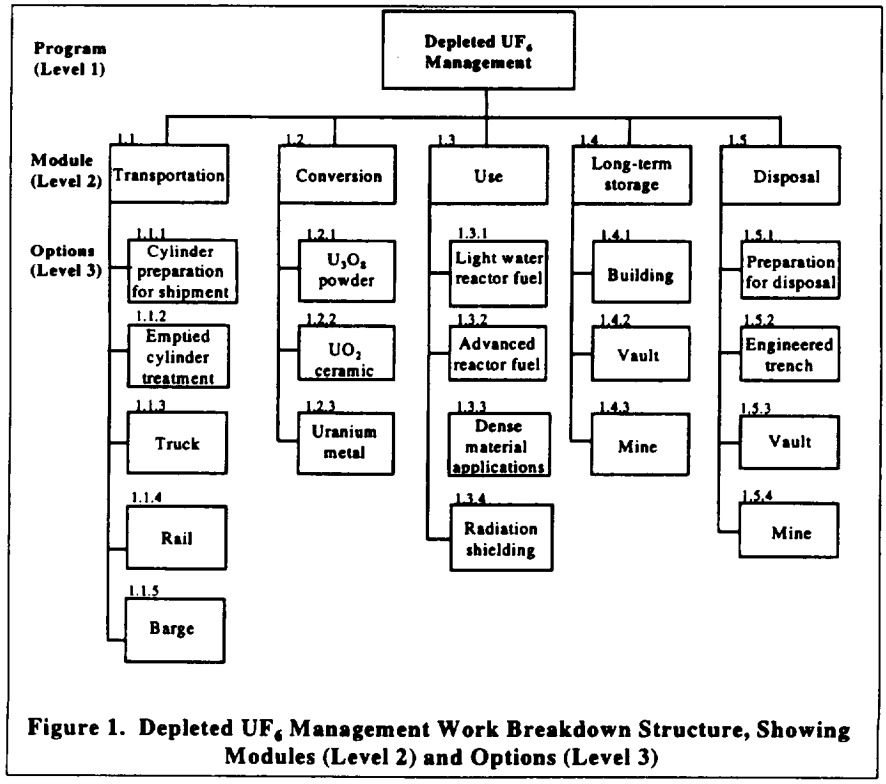


Figure 1. Depleted UF_6 Management Work Breakdown Structure, Showing Modules (Level 2) and Options (Level 3)

The recommendations received early in the Engineering Analysis Project fell into several general categories. These general categories are called modules because they are the most basic building blocks for management strategies (see Level 2 in Figure 1). The modules are transportation, conversion, use, long-term storage, and disposal. Most management strategy alternatives combine two or more of these five modules. For example, conversion of the depleted UF_6 to another chemical form is involved in the use and disposal alternatives and in one of the long-term storage alternatives. Transportation of materials occurs in all strategies except the No Action alternative.

In each module, there are various options (Level 3 in Figure 1), or different ways of doing things. For example, in the long-term storage module there are three different options for the type of facility in which the depleted uranium could be stored: building, vault, and mine.

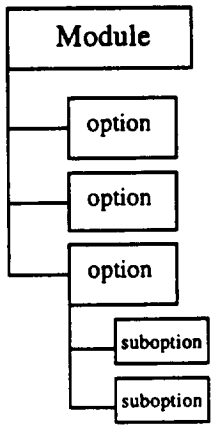

Figure 2. Modules are broken down into options. Options are broken down into suboptions.

The next level of detail after options is called suboptions. For example, the long-term storage facility types are further broken down by the forms of depleted uranium which might be stored in each. Figure 2 shows the general relationship among modules, options, and suboptions.

The *Engineering Analysis Report* focuses on technology options and suboptions. Data for the options and suboptions can be combined to provide overall data for alternatives. To get a better idea of how options and suboptions were linked together to form management strategy alternatives, see Figure 3, which appears at the end of this Summary.

2.2 Methodology

The *Engineering Analysis Report* contains 13 Engineering Data Input Reports, covering the specific options and suboptions named in the unshaded boxes in Table 1. These are the options and suboptions which were analyzed in depth. Options and suboptions which were analyzed in less detail are discussed in Chapter 4 of the *Engineering Analysis Report.*

Each Data Input Report includes layouts for facilities, descriptions of processes, estimates of wastes and emissions, estimates of resources and workers needed, hazard assessments, accident scenarios, and transportation information. The data are estimates based on an early stage of design. More detailed data for specific technologies will be developed in the second part of the Program.

Table 1. Options and Suboptions for the Various Modules

(Note: shaded boxes are principal options and suboptions analyzed in less detail)

Transportation Module		Conversion Module		Use Module		Long-Term Storage Module		Disposal Module	
Options	Suboptions	Options	Suboptions	Options	Suboptions	Options	Suboptions	Options	Suboptions
Cylinder preparation for shipment	• Current cylinders • Over-container • Transfer facility	U_3O_8 powder	• Dry process with AHF* • Dry process with HF neutralization	Light water reactor fuel	• Re-enrichment	Building	• UF_6 • U_3O_8 • UO_2	Preparation for disposal	• U_3O_8 cemented • UO_2 cemented • U_3O_8 bulk • UO_2 bulk
Emptied cylinder treatment	• Cylinder treatment facility	UO_2 ceramic	• Dry process with AHF* • Dry process with HF neutralization • Wet process (gelation) with AHF*	Advanced reactor fuel	• Breeder and other fast reactors			Engineered trench	• U_3O_8 cemented • UO_2 cemented • U_3O_8 bulk • UO_2 bulk
Truck	• UF_6 in current or new cylinders or over-container • Depleted uranium conversion products • Metal or oxide shields • By-products, chemicals, and wastes			Dense material applications	• Existing applications: munitions, armor, counter-weights, ballasts • New applications	Vault	• U_3O_8 • UO_2		
Rail		U metal	• Batch reduction					Vault	• U_3O_8 cemented • UO_2 cemented • U_3O_8 bulk • UO_2 bulk
Barge	• UF_6 in current or new cylinders or over-container		• Continuous reduction	Radiation shielding	• UO_2 • U metal	Mine	• UF_6 • U_3O_8 • UO_2	Mine	• U_3O_8 cemented • UO_2 cemented • U_3O_8 bulk • UO_2 bulk

* Anhydrous hydrogen fluoride (HF)

Examples of assumptions used in the engineering analysis:

- Total time for project: 20 years.
- Processing rate: 28,000 MT (60 million pounds) of depleted UF_6 per year.
- Each of the different forms of depleted uranium would always have the same bulk density and the same type of packaging for transportation.
- Facilities are newly built on previously unused sites.

To make it easier to compare the different options and suboptions, data were based on certain common assumptions.

Estimates based on different processing rates (50 percent and 25 percent of the assumed rate) were made for several technologies and are included in Chapter 8 of the *Engineering Analysis Report.*

Each Engineering Data Input Report includes its own analysis of reasonably foreseeable accidents involving radiological or hazardous materials. There is also an accident analysis in Chapter 7 which discusses two particular types of accidents: (1) accidents associated with depleted UF_6 cylinder handling and storage and (2) accidents which would have significant hazardous and/or radiological material releases but have a very low probability. In general, the higher the consequences of an accident, the less frequently such an accident is likely to occur. The accidents discussed in Chapter 7 are what are called "incredible" accidents, which means that their likelihood of occurrence is between once in one million years and once in ten million years.

The *Engineering Analysis Report* also includes discussions of license, permit, and regulatory requirements and changes in regulations for the transportation of depleted UF_6 cylinders.

3. Summary of Options Analyzed in Depth

Feasible technologies for which data could be developed were analyzed in depth.

Options which were judged to be feasible in the *Technology Assessment Report* were analyzed in depth. These are general types of technologies, but they have enough technical basis to allow engineers to develop the data needed for estimates of environmental impacts and costs. Additional options, most of which are at an earlier stage of development, were also considered. These are described in the *Engineering Analysis Report* but are analyzed in less detail.

This section describes the technology options and suboptions which were analyzed in depth. They are grouped into the five modules in the work breakdown structure. The modules are printed in boldface type and the options are underlined. Table 1 gives an overall summary of the information.

3.1 Transportation Module

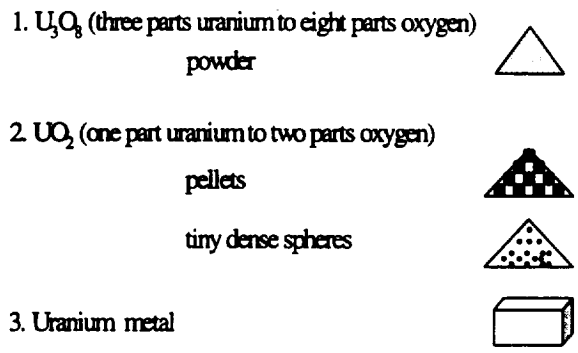
All of the Engineering Data Input Reports include a discussion of transportation of materials by both truck and rail. Materials which would be transported would include depleted UF_6, depleted uranium in other chemical forms (after conversion), manufactured products for use, and other materials such as by-products and wastes.

Two transportation options, preparation of depleted UF_6 cylinders for shipment and treatment of emptied cylinders, are analyzed in their own individual Data Input Reports.

Cylinder Preparation for Shipment. All alternatives in the Draft PEIS, except for the No Action alternative, assume that depleted UF_6 cylinders will be moved from their current locations. Transportation of cylinders is regulated by the Department of Transportation (DOT). These regulations involve (1) the amount of depleted UF_6 inside the cylinder, (2) the pressure inside the cylinder, and (3) the condition of the cylinder, especially the thickness of the steel walls. Some cylinders meet the DOT requirements and would require minimal preparation; however, some would require additional work to meet DOT regulations.

There are two suboptions for preparing these nonconforming cylinders. In the overcontainer suboption, the cylinder would be placed inside a container which meets DOT regulations. In the transfer facility suboption, the depleted UF_6 would be transferred to a new cylinder. Using the overcontainer would require less handling and produce less waste. It would also avoid the construction of a special facility. A transfer facility would be expected to have greater impacts, but it could be used in developing an alternative for long-term storage of depleted UF_6 in new cylinders.

Emptied Cylinder Treatment. In most of the management strategies, the depleted UF_6 would be taken out of the cylinders and converted to another chemical form. Any depleted UF_6 left in the emptied cylinder (called the "heel") would be washed out with water. After the water evaporates, the mixture of depleted uranium and fluorine would be converted to solid uranium oxide and hydrogen fluoride



UF_6 Conversion Products

(HF) gas. Hydrogen fluoride gas is corrosive. To neutralize it, or make it harmless, lime would be added, forming calcium fluoride (CaF_2). The analysis assumes that the cleaned, emptied cylinders will be stored as scrap metal.

3.2 Conversion Module

Most management strategy alternatives require converting the depleted UF_6 to another chemical form. Three other chemical forms of depleted uranium are analyzed in depth: triuranium octaoxide (U_3O_8) powder, uranium dioxide (UO_2) ceramic, and uranium metal. The oxides are compounds of uranium and oxygen. Because the oxides are very stable and slow to dissolve in water, they are presently the preferred forms for long-term storage and disposal. Very dense depleted UO_2 and depleted uranium metal are preferred for use in shielding for spent nuclear fuel because they are good at absorbing the kind of radiation called gamma rays. Depleted uranium metal is preferred for most dense material applications, which need high density and mass.

Conversion starts by heating solid depleted UF_6 to produce a gas. All the conversion processes being analyzed in depth produce large quantities of hydrogen fluoride (HF). Uranium hexafluoride and HF are the most significant chemical hazards to the environment and workers during conversion. The designs for the conversion process buildings and the HF storage buildings use reinforced concrete for added safety. Temperatures in the HF storage buildings would be kept between 45° and 55° Fahrenheit. This would prevent the HF from becoming a gas that a worker might inhale in case of a spill.

The conversion facilities would be expected to operate about 7000 hours per year. They would have enough outdoor storage for one month's supply of full depleted UF_6 cylinders. There would also be enough indoor storage space for three months' supply of nearly empty cylinders. This would allow time for short-lived radioactive products in the heel to decay before the cylinders are treated or shipped off site. The facilities would include storage for one month's production of the new depleted uranium form and one month's production of HF.

<u>U_3O_8 Option.</u> Two suboptions are analyzed for converting depleted UF_6 to depleted U_3O_8. (The conversion of UF_6 to an oxide is referred to as "defluorination" because fluorine atoms are removed.) Both suboptions use a two-step process in which depleted UF_6 reacts with steam at high temperatures. This is called a "dry" process, as opposed to "wet" processes, in which the main reactions occur in water. The process produces depleted U_3O_8 in fluffy powder form and concentrated HF, which is about 70 percent HF and about 30 percent water. After the depleted U_3O_8 is compacted, it would have a bulk or packing density of about 3 grams per cubic centimeter (about 1 3/4 ounces per cubic inch).

The first U_3O_8 suboption uses distillation to reduce the water content in the concentrated HF to one percent or less. The resulting HF vapor is called anhydrous HF (AHF), meaning that it has very little water. It is expected that the uranium content will be low enough that the AHF can be sold for use. The second U_3O_8 suboption would neutralize the HF to produce CaF_2 for sale or disposal.

UO_2 Option. Uranium dioxide in the ceramic form is very dense. Depending on the shape and size of its particles, the UO_2 will generally be two to three times denser than compacted U_3O_8 powder. The denser product would require less space for storage or disposal. The denser form could also be used in depleted uranium concrete for radiation shielding.

There are three suboptions for converting depleted UF_6 to depleted UO_2. Two of them use a dry process (similar to the one described above for U_3O_8) to make UO_2 powder. The UO_2 powder is pressed into pellets about 2 centimeters (3/4 inch) in diameter. To increase their density, the pellets are then heated at about 1700° centigrade (about 3092° Fahrenheit). The furnaces are expected to be larger than those currently used in nuclear fuel manufacturing plants. One of the dry process suboptions provides an AHF by-product and the other neutralizes the HF.

The third technology suboption is based on a "wet" process which produces dense depleted UO_2 in the form of very small spheres of a millimeter (about 1/20 inches) or less in diameter. These tiny particles can be packed very close. The process, called "gelation," dissolves U_3O_8 in an acid. Various chemicals are added and the solution is fed through nozzles which break it into small droplets. These droplets are then decomposed into jelly-like spheres of depleted uranium oxide. These are further processed and finally heated at high temperatures. Gelation has yet to be proven as an industrial process; therefore, the technological uncertainties with the wet process are greater than with the more developed dry processes.

Uranium Metal Option. The analysis considers two suboptions, a batch process and a continuous process, for converting depleted UF_6 to depleted uranium metal. Both processes start by combining depleted UF_6 with hydrogen to make depleted uranium tetrafluoride (UF_4) and AHF. In the second step, magnesium (Mg) is used to remove the fluorine from the UF_4 (known as "reduction"). Because it uses a metal, Mg, and takes place at high temperatures, this process is called "metallothermic reduction."

The batch process is the standard industrial process. A mixture of depleted UF_4 and Mg metal is heated in a sealed steel container until it forms liquid depleted uranium metal and a magnesium fluoride (MgF_2) by-product. The denser uranium metal settles to the bottom and the MgF_2 collects on top. After the container has cooled, the solid depleted uranium metal and MgF_2 are removed and separated from each other. The by-product contains some uranium. Without further treatment, it would have to be disposed of as a radioactive low-level waste. The design for the batch process includes a step for removing uranium from the MgF_2. It is assumed that, after this step, the MgF_2 could be disposed of as a nonradioactive, nonhazardous solid waste.

The other suboption analyzed in depth is the continuous process, which is currently being developed. In this process, depleted UF_4 and Mg are continuously fed into a heated container. The dense liquid uranium metal settles to the bottom and is removed. The liquid MgF_2 forms a middle layer and is separately removed. The liquid Mg floats on the top.

The continuous process has three possible advantages over the batch process: (1) a higher processing rate, (2) a lower level of uranium in the by-product, and (3) a liquid depleted uranium product which could be directly formed into an end product. The early design assumes that the amount of uranium in the by-product will be small enough that a decontamination step would be unnecessary. Based on the design, the continuous process would have a lower cost than the batch process. However, since the continuous process is still being developed, the technological uncertainties are greater.

3.3 Use Module

The use option analyzed in depth is to make depleted uranium into a shielding material to put around spent nuclear fuel. The fuel in nuclear powerplants has to be replaced every so often. The used-up, or spent, nuclear fuel (SNF) is still radioactive and must be shielded. The *Engineering Analysis Report* analyzes two suboptions for use as radiation shielding, but this is only one of several possible uses for depleted uranium. Other uses include fuel for light (regular) water reactors or advanced reactors and dense material applications. Section 4.3 discusses use options which were analyzed in less detail. The two radiation shielding suboptions analyzed in depth are examples of possible uses.

Radiation Shielding Option - UO_2 Suboption. This suboption would use depleted uranium in the form of UO_2 pellets. These dense pellets can be used instead of gravel to make concrete shielding for SNF storage containers. Depleted uranium concrete, also known as DUCRETE™, provides shielding with less weight and bulk than regular concrete. It might also be usable in overcontainers for SNF disposal, but this use has yet to be developed.

In the designs for storage containers, the depleted uranium concrete is enclosed inside stainless steel. The shielding manufacturer receives partly finished steel shells and other parts and puts the containers together in one building. In another building, where radiological materials can be handled, depleted UO_2 pellets from a conversion plant are combined with sand, cement, and water, and the depleted uranium concrete is poured between the stainless steel shells. After the cement hardens, the container is completed.

Radiation Shielding Option - Uranium Metal Suboption. This suboption would manufacture depleted uranium metal into shields for use inside a multi-purpose unit system. A multi-purpose unit is a container that would provide confinement of SNF during storage, transportation, and disposal.

In this design, the manufacturer receives depleted uranium metal (or alloy), partly completed stainless steel or metal alloy shells, and other pieces to enclose the uranium metal. The containers are put together in one building. In a separate building, where radiological materials can be handled, the depleted uranium metal is melted and poured between the steel or alloy shells. After the depleted uranium metal cools, the container is completed.

3.4 Long-Term Storage Module

Long-term storage means that the depleted uranium could be used at some later date. Three long-term storage options are analyzed in depth: (1) storage in a building, (2) storage in a below ground vault, and (3) storage in a mine. The suboptions are the chemical forms in which the depleted uranium is stored. Three forms are considered for storage in buildings or mines: UF_6, U_3O_8, and UO_2. Two forms are considered for storage in vaults: U_3O_8 and UO_2. These chemical forms have very different bulk densities. A denser product takes up less space and could therefore cost less to store. This analysis assumes that the tiny, dense UO_2 spheres produced by the gelation process would need the least storage space and U_3O_8 powder would need the most storage space.

The building option uses metal framed buildings for storage. The below ground vault would be made of reinforced concrete with a steel roof supported by trusses. Storage in a mine would use underground tunnels.

3.5 Disposal Module

The engineering analysis for this module considers three options for disposal: (1) disposal in an engineered trench, (2) disposal in a below ground vault, and (3) disposal in a mine. The engineered trench is an 8-meter (26-foot) deep trench covered with a sloping cap of closely packed clay and other barriers. This option would work best in drier areas.

A form which is stable and slow to dissolve is preferred for disposal. Therefore, the chemical forms analyzed for disposal are the oxides, U_3O_8 and UO_2. In addition, the depleted uranium oxide powder or pellets may either be mixed with cement before disposal or disposed of in bulk form inside drums. Altogether, there are four waste form suboptions: (1) cemented U_3O_8, (2) cemented UO_2, (3) bulk U_3O_8, and (4) bulk UO_2. Each disposal facility option is analyzed for all four waste forms.

The analysis covers a wide range of conditions, including variations in the climate and geology of possible disposal locations and variations in the amount of disposal space needed. Cemented U_3O_8 requires the most space because U_3O_8 is less dense than UO_2 and because the cement adds to the mass. The form requiring the least space for disposal is bulk UO_2.

All the disposal facility designs include a waste form facility (preparation for disposal option). This is where the depleted uranium oxide is received from the conversion plant. For cemented waste forms, preparation would include mixing the oxide with cement, repackaging it in new or recycled drums, and allowing it to harden. Bulk waste forms would require less preparation.

4. Summary of Principal Options and Technologies Analyzed in Less Detail

Technologies analyzed in less detail in this part of the Program are preserved for the second part of the Program.

Most of the options considered in the engineering analysis were replies to DOE's Request for Recommendations. The technologies discussed in Section 3 are general types, but they have enough technical basis to allow engineers to develop data which can be used to estimate environmental impacts and costs. A number of other technologies were also recommended. These options are promising but are analyzed in less detail for one or more of the following reasons: they are in earlier stages of design or development; they would take more time than the 20-year schedule assumed in this analysis; they are proprietary; they involve uses of depleted uranium which are already in practice.

Technologies analyzed in less detail during the first part of the Depleted Uranium Hexafluoride Program are still available for consideration for the next part of the Program. These technologies are briefly described below. The options and suboptions analyzed in depth are general enough that the estimates made could cover a variety of specific technologies.

4.1 Transportation Module

Transport by barge was considered. However, at this time the locations for most activities are unknown and the possibility of using barge transportation is uncertain. All three gaseous diffusion plant sites mainly use ground transportation. Except for the East Tennessee Technology Park, facilities for using barges would have to be developed.

4.2 Conversion Module

Many good ideas for conversion technologies were submitted. In general, they are in the early stages of design or development. Some of them are also proprietary. When more fully developed, these processes might offer such advantages as more flexibility, fewer processing steps, reduced environmental impacts, lower costs, and higher profits.

Uranium Oxide Suboptions. A number of responses recommended using the well-known dry process for converting UF_6 to an oxide with an AHF by-product. There were also several recommendations for newer technologies with important features. One example uses a wet process to convert depleted UF_6 to an intermediate compound which is then heated and converted to depleted U_3O_8. Anhydrous hydrogen fluoride is directly produced. Another technology uses a liquid metal such as iron to speed up the decomposition of depleted UF_6. Afterwards, uranium oxides and AHF are formed in a single step.

Two general processes were recommended which have a by-product other than AHF. One makes a depleted uranium oxide and a solid aluminum and fluoride compound which is used in the

production of aluminum metal. The other technology uses depleted UF_6 as a source of fluorine for making hydrofluorocarbons. Hydrofluorocarbons can be used instead of chlorofluorocarbons, which are believed to reduce ozone in the atmosphere.

Uranium Metal Suboptions. As discussed earlier, the more familiar processes for producing depleted uranium metal also produce large amounts of MgF_2 waste. A different type of technology called plasma dissociation avoids the MgF_2 waste stream. In this one-step process, a gas such as argon is heated to more than 5000° centigrade or 9032° Fahrenheit, using electrical energy. At these very high temperatures, depleted UF_6 is broken down into uranium and fluorine atoms. After the gas cools, the fluorine atoms react with added hydrogen to produce AHF, and the uranium atoms combine with each other to form depleted uranium metal.

This process would avoid the uncertainties about the disposal of MgF_2. It would also bring in more money from the sale of AHF, because all the fluorine in the depleted UF_6 is recovered. This process is in the early stage of development.

Several other recommendations contained improved ideas for removing uranium from MgF_2. These recommendations also had suggestions for the recovery and possible use of by-products (for example, converting the MgF_2 to AHF). These advanced treatment technologies could reduce waste and be more economical.

4.3 Use Module

Three use options are analyzed in less detail. These are (1) use as fuel for a light (regular) water power reactor, (2) use as fuel for an advanced power reactor, and (3) use in dense material applications. A number of people recommended these uses. The fuel options are analyzed in less detail because they would take a long time to use up significant amounts of depleted UF_6. The long-term storage options discussed in the *Engineering Analysis Report* and the preferred alternative in the Draft PEIS would allow these, and other, uses to be reconsidered in the future. The environmental impacts of existing or new dense material applications are expected to be similar to those of the uranium metal radiation shielding option which is analyzed in depth.

Light Water Reactor Fuel Option. The main suboption for this use would involve re-enriching the depleted UF_6, that is, increasing the percentage of U-235. The technologies that are used for enriching natural uranium could also be used to enrich depleted uranium. If all the U-235 in DOE's depleted UF_6 were recovered, it could provide fuel for the equivalent of about 100 power reactors operating for 10 years apiece. Re-enriching depleted uranium would save natural uranium resources and avoid the impacts of uranium mining and milling. However, only a small amount of the depleted uranium would actually be converted into enriched uranium. Most of the depleted uranium (over 90 percent) would remain after processing, and would still require management.

It is uncertain when re-enrichment would be economical. Continued storage preserves the possibility for the future, particularly for depleted uranium which has more than 0.3 percent U-235.

Another possible use of depleted uranium in light water reactors could involve converting the depleted UF_6 to UO_2. The depleted UO_2 could then be mixed with plutonium oxide to produce mixed oxide fuel. However, this suboption would use up only a very small amount of the depleted UF_6.

Advanced Reactor Fuel Option. One reason why DOE considered the depleted UF_6 a valuable resource was its potential use in advanced reactors of the future. One such type of reactor, called a fast breeder reactor, actually produces additional fuel. Used in an advanced reactor, the depleted uranium could provide hundreds of years of electrical power at the present U.S. production rate. However, this option would require a change in national policy, which is based on a once-through fuel cycle. In addition, since the advanced reactors are very fuel efficient, they would use up only a small amount of depleted uranium.

Dense Material Applications Option. Dense material applications include some ways in which depleted uranium metal is already being used, such as armor-piercing munitions, vehicle armor, ballasts in aircraft, and weights for stabilizing machinery. Other new uses were suggested in responses to the Request for Recommendations. These include energy storage flywheels (heavy metal wheels that store energy and make shafts rotate evenly), drill collars to keep oil well drill shafts centered, and explosives for the petroleum industry to open up the earth around natural gas and oil wells. Future dense material applications are uncertain at this time. The long-term storage options discussed in the *Engineering Analysis Report* and the preferred alternative in the Draft PEIS would allow these, and other, uses to be considered in the future.

4.4 Long-Term Storage Module

Storage as depleted uranium metal and storage as depleted uranium tetrafluoride (UF_4) were considered but analyzed in less detail. Uranium metal bars would require much less space than oxides or UF_6, but it costs much more to convert depleted UF_6 to metal than to U_3O_8. In addition, there are safety issues with storage as metal. Unless it is protected, bulk uranium metal slowly corrodes. In air, the metal flakes can catch fire and release energy rapidly. The reaction between moisture and uranium metal creates hydrogen, which could explode if it collected in closed storage containers. For these reasons, storage as metal would require special packaging and more supervision.

Depleted uranium in the form of UF_4 was considered for long-term storage or disposal but was analyzed in less detail. Conversion to UF_4 is fairly simple and inexpensive, but another conversion step would probably be required before the material could be used. Depleted UF_4 is less chemically reactive than depleted UF_6 but more reactive than the oxides and it would take up about the same amount of storage or disposal space as depleted U_3O_8. Other forms are more generally recommended for disposal.

4.5 Disposal Module

Disposal as depleted UF_6, depleted uranium metal, and depleted UF_4 were considered but analyzed in less detail. Regulations restrict the chemical forms that can be used for disposal. Reactive waste forms such as the fluorides and metal are specifically excluded by the Nevada Test Site and Hanford and by DOE Orders.

The *Engineering Analysis Report* analyzes bulk and cemented waste forms in detail. Another possible suboption is vitrification, in which depleted uranium oxide would be enclosed in glass. The basic technology is developed (for disposal of high-level radioactive waste), but other types of waste preparation are generally preferred for depleted uranium. Vitrified waste would require more space for disposal. In addition, a vitrification facility would be more complicated and costly to build and operate than a cementing facility.

5. Roadmap for Integration of Engineering Data Input Reports into Long-Term Management Strategy Alternatives

Figure 3 shows how complete management strategy alternatives can be put together from the options and suboptions analyzed in the *Engineering Analysis Report*. Depleted UF_6 stored in the cylinder yards at Paducah, Portsmouth, and Oak Ridge (the current management strategy) is shown at the left of the figure. Moving from left to right are the transportation, conversion, use, long-term storage, and disposal modules (work breakdown structure Level 2).

The options and suboptions which are analyzed in depth are shown as blocks below the module names. The arrows on the chart indicate the flow of material for the various management strategies. Offsite transportation may be required between one option or suboption and another. This is shown by the small boxes marked "T." Activities such as construction of facilities, transportation of other materials and by-products, and transportation and disposal of wastes are also included in the assessments of the management strategies.

5 INDICES BY COMMENTOR AND BY DOCUMENT NUMBER 5-1

1 OVERVIEW OF PUBLIC PARTICIPATION AND COMMENT PROCESS

On December 24, 1997, the Department of Energy (DOE) published a Notice of Availability (63 FR 7771) in the *Federal Register* for the *Draft Programmatic Environmental Impact Statement (PEIS) for Alternative Strategies for the Long-Term Management and Use of Depleted Uranium Hexafluoride* (DOE/EIS-0269). In accordance with the Council on Environmental Quality (CEQ) and DOE National Environmental Policy Act (NEPA) regulations, the notice invited interested agencies, organizations, and the general public to provide oral and written comments on the Draft PEIS.

This volume of the Final PEIS contains the comments and DOE's responses to comments received during the comment period. Chapter 2 contains photocopies of written submissions received by DOE on the Draft PEIS; DOE's responses to those comments are listed in Chapter 3. Chapter 4 provides the oral comments received at the public hearings and DOE's responses. Chapter 5 provides indices to comments and responses arranged by commentor name and by comment number.

1.1 TECHNOLOGY ASSESSMENT

On November 10, 1994, DOE published a Request for Recommendations (59 FR 56324) and an Advance Notice of Intent (59 FR 56325) in the *Federal Register* to prepare a PEIS for alternative strategies for the long-term management and use of depleted uranium hexafluoride (UF_6). The Request for Recommendations asked interested persons, industry and government agencies to submit suggestions for potential uses for the depleted UF_6 as well as technologies that could facilitate the long-term management of this material.

By publishing the Request for Recommendations, DOE offered a unique opportunity for the public to become involved in the Depleted Uranium Hexafluoride Management Program and provide input early in the decision-making process. In keeping with the DOE's intent to foster candid information exchange and ongoing two-way communication with stakeholders, two sets of information exchange forums/workshops were held at Oak Ridge, Tennessee; Paducah, Kentucky; and Portsmouth, Ohio: one in November/December 1994, after the release of the Request for Recommendations/Advance Notice of Intent, and one in July 1995, at the conclusion of the Technology Assessment phase of the Program. The purpose of these sessions was to explain the Depleted Uranium Hexafluoride Management Program and the Technology Assessment component, provide updates, solicit questions and comments, and foster awareness of the various opportunities for public participation.

A 60-day public comment period was announced; however, all responses, including those submitted after the end of the comment period, were evaluated. In all, 57 responses containing

approximately 70 recommendations were received and evaluated, including five options under consideration by DOE. The *Technology Assessment Report for the Long-Term Management of Depleted Uranium Hexafluoride* (UCLR-AR-120372, June 30, 1995) provides a summary of the responses to the Request for Recommendations, the verbatim assessments of the Independent Technical Reviewers, and a summary of the evaluation results. The feasibility analysis in the report was used by DOE in developing alternative strategies for the long-term management of depleted UF_6.

1.2 SCOPING

The DOE published a Notice of Intent (61 FR 2239) to prepare a PEIS in the *Federal Register* on January 25, 1996. The notice invited interested agencies, organizations, and the general public to provide oral and written comments to determine the scope of the PEIS. After publication of the Notice of Intent, stakeholders were sent a letter announcing the schedule for the scoping meetings, a copy of the Notice of Intent, a comment form, and a fact sheet titled "Proposed Scope of Environmental Issues."

Rather than the traditional hearing format, a more interactive workshop format was used for the scoping meetings which were held in February 1996 near the three DOE storage sites in Paducah, Kentucky; Portsmouth, Ohio; and Oak Ridge, Tennessee.

During the 60-day public scoping period, comments were submitted in a variety of ways: through comment forms available at meetings and in mailings, by making an oral comment to a Program representative at a meeting, by mailing or faxing DOE, by calling the toll-free information line, by sending an e-mail or by using the CD ROM program at the meetings. All comments received were entered into a database and were considered in determining the scope of the PEIS.

A summary report, consisting of a compilation of the comments from the scoping period and their disposition/responses, is included in Appendix L to the PEIS. The issues raised during the scoping period were used in developing the details of the draft outline PEIS.

1.3 DRAFT PEIS HEARINGS

During the 120-day public comment period for the Draft PEIS, DOE held four public hearings to discuss issues and to receive oral and written comments. The hearings were held near the three DOE storage sites in Paducah, Kentucky; Portsmouth, Ohio; and Oak Ridge, Tennessee; as well as in Washington, D.C. The Draft PEIS was made available to the public at the hearings, through mailings, the Depleted UF_6 website, and DOE public reading rooms.

The hearings on the Draft PEIS were an important component of the Program's continuing efforts to provide the public with opportunities to participate in DOE's decision-making process. In keeping with DOE's intent to foster candid information exchange and ongoing two-way communication with the public, an informal, interactive meeting format was chosen. An independent facilitator conducted the hearings that included an information exchange session and a question and answer period. As demonstrated during the scoping phase of the Program, interactive sessions were particularly effective for soliciting comments and gaining participation from the public.

To facilitate public involvement, there were a variety of ways to submit comments on the Draft PEIS. Written comments were accepted by mail, fax, Internet and e-mail. In addition, a toll-free telephone line was available. These methods augmented comments received from the public at the four public hearings. As during the scoping meetings, the public was able to submit both written and oral comments at the Draft PEIS hearings. Court reporters and note takers collected the oral comments offered by the public at each of the hearings. Chapter 4 contains the oral comments from each hearing with DOE's response to those comments.

1.4 COMMENTS ON THE DRAFT PEIS

DOE received approximately 600 comments contained within approximately 90 submissions on the Draft PEIS. The comments addressed a wide range of issues, encompassing technical, environmental, local, economic, and DOE policies. Comments were received from individuals, Federal and State agencies, local governments, foreign entities, and non-government organizations such as businesses, environmental and public interest groups.

Chapter 2 of this document (Volume III) contains photocopies of written submissions received by DOE on the Draft PEIS. Each document was assigned a commentor number. For those documents containing comments, each individual comment was delineated and assigned a unique identification number. This ensured that the comment tracking system tracked each comment, not just the document itself. It also provided DOE with greater detail as to the number of comments submitted in addition to the number of documents received.

After comments were delineated and numbered, each comment was assigned to one of five general categories based on the nature of the comment. In addition, key words were assigned within each category. The use of general categories and keywords facilitated the development of responses to comments and provided DOE with information concerning major issues raised by commentors. DOE's responses to comments are provided in Chapter 3. Where applicable, the responses identify specific chapters, sections, or appendices in the Final PEIS that address the issue(s) raised in the comments.

1.5 MAJOR ISSUES RAISED BY COMMENTORS

As discussed in the previous section, the use of general categories and keywords identified major issues raised by commentors. These issues are presented below with DOE's general response to these comments. The approximate percentage of commentors that addressed each major issue is provided and indicates the importance of that issue to those stakeholders who submitted comments.

Comment

Approximately 45% of the commentors raised the issue of the suitability of the Paducah site for continued cylinder storage and conversion actions due to its proximity to several fault zones, particularly the New Madrid Fault. The largest recorded earthquake in the region (magnitude of 7.3 on the Richter scale) occurred in 1812 and was centered in the New Madrid fault zone; the epicenter was 60 miles southwest of the Paducah site.

General Response

The PEIS addresses the potential for seismic activity at each of the three storage sites in Sections 3.1.4.1, 3.2.4.1, and 3.3.4.1. Of the three storage sites, an earthquake which could cause more than slight damage is considered credible (though highly unlikely) only for the Paducah site.

The analysis of accident scenarios for continued cylinder storage (Section D.2.2 of the PEIS) was based on the range of potential accident scenarios considered in the safety analysis reports (SARs) for each of the three storage sites (LMES 1997f-h; the full citations are provided in Chapter 8 of the PEIS). The SARs were issued in February 1997 by the DOE's management and operating contractor, and were subsequently reviewed and approved by DOE in March 1997.

The SARs considered a range of potential accident scenarios that could be associated with current storage activities, including natural phenomena events such as earthquakes. The accidents considered in the PEIS for current depleted UF_6 cylinder storage were extracted from those evaluated in the safety analysis reports. The accidents selected for the PEIS analysis were those accident scenarios in the SARs that resulted in the greatest potential consequences at each of the three storage sites. These accidents did not include earthquake scenarios, which were found in the SAR analyses to have lesser consequences than the accident scenarios discussed in the PEIS. The text in Section D.2.2 of the PEIS has been modified to clarify this point. If the safety analysis reports are revised in the future, DOE will modify its cylinder management program to ensure that the safety of the cylinders is maintained.

Comment

Approximately 45% of the commentors expressed doubt about any widespread uses for the depleted UF_6.

General Response

DOE expects that in the future, uses will be available for some portion of the depleted UF_6 inventory. Potential depleted uranium uses include radiation-shielding applications. Uses for the fluorine products exist now in the aluminum, chemical, steel, and glass industries.

The DOE provided its initial plan for the conversion of depleted uranium hexafluoride, as required by Public Law 105-204, to Congress on March 12, 1999. In addition, the Department issued a "Request for Expressions of Interest for a Depleted Uranium Hexafluoride Integrated Solution Conversion Contract and Near-Term Demonstrations" on March 4, 1999. Responses to the request for expressions of interest will provide information to develop the Department's detailed procurement strategy for an integrated approach to the management of its depleted UF_6 inventory. A final plan, incorporating information from the private sector and other stakeholders, is expected to be issued in 1999.

DOE plans to continue its support for the development of government applications for depleted uranium products. The two representative use options described in Section 2.2 and Appendix H of the PEIS, use as uranium oxide and use as uranium metal as radiation shielding, were selected to provide a basis for comparing the potential environmental impacts of broad, programmatic management strategies. The selection of these use options for analysis in the PEIS was not intended to imply that the PEIS will be used to select a specific end-use or preclude other potential uses in the future. If a use strategy is selected in the Record of Decision, specific uses would be considered and evaluated in more detail in future planning and environmental analyses as appropriate.

Comment

Approximately 40% of the commentors favored rapid conversion of the depleted UF_6 materials instead of storage. Of those, approximately 85% favored conversion to U_3O_8 for either storage or ultimate disposition.

General Response

Based on the comments received on the Draft PEIS, DOE has modified its preferred alternative for the final PEIS (see PEIS, Section 2.5). DOE's revised preferred alternative is to begin conversion of the depleted UF_6 inventory as soon as possible, either to uranium oxide, uranium metal, or a combination of both, while allowing for use of as much of this inventory as possible. This would be accomplished through continuing the safe, effective management of the cylinder inventory; beginning prompt conversion of the depleted UF_6 into uranium oxide and HF or CaF_2; interim storage of the uranium oxide pending use; converting depleted UF_6 into depleted uranium metal and HF or CaF_2 as uses for depleted uranium metal products become available; and/or fabrication of depleted uranium oxide and/or metal products for use.

Comment

Approximately 25% of the commentors requested the PEIS to address site-specific impacts for any proposed facility.

General Response

The PEIS evaluates broad programmatic strategies for the long-term management of the depleted UF_6 cylinder inventory, including strategies of long-term storage, use, and disposal. The evaluation of potential environmental impacts in the PEIS includes all of the activities that would be necessary to implement each of the alternatives (see Sections 2.1 and 2.2 of the PEIS). However, as a programmatic EIS, it does not propose any site-specific projects. Consequently, the impacts of some management activities, such as conversion, long-term storage, manufacture and use, and disposal, were evaluated using representative facility designs and environmental setting information. The characteristics of these representative designs and settings were selected to provide as substantive an assessment as possible and to allow for a comprehensive comparison of the strategy alternatives. The potential impacts from construction and operation of such representative facilities is included in the PEIS. Upon implementation of the strategy to be selected in the Record of Decision for the PEIS, additional NEPA reviews for any site-specific proposals would be prepared identifying the environmental impacts of site-specific projects and a range of alternative actions, including a "no action" alternative.

Comment

Approximately 45% of the commentors raised questions and concerns about the safety and adequacy of current management of the cylinders at the three DOE locations. Many of these concerns stemmed from cylinder inspection data showing that corrosion has occurred on numerous cylinders in the 50 years or so since cylinder storage at the three sites began.

General Response

DOE's current cylinder management program provides for safe storage of the depleted UF_6 cylinders. DOE is committed to the safe storage of the cylinders at each site during the decision making period and also through the implementation of the decision made in the Record of Decision. DOE has an active cylinder management program that involves upgrading of cylinder storage yards, constructing new yards, repainting cylinders to arrest corrosion, and regular inspection and surveillance of the cylinder and storage yard conditions.

Comment

Approximately 15% of the commentors opposed any unrestricted uses of the converted UF_6 products and questioned the process for radioactive release limits of such products as hydrogen fluoride (HF) or calcium flouride (CaF_2).

General Response

As described in Section 2.2 and Appendix H of the PEIS, the two use options evaluated in the PEIS, use as depleted uranium oxide and use as depleted uranium metal as radiation shielding, are representative and were selected to provide a basis for comparing the potential environmental impacts of broad, programmatic management strategies. The selection of these use options for analysis in the PEIS was not intended to imply that the PEIS will be used to select a specific end use or preclude other potential uses in the future. If a use strategy is selected in the Record of Decision, specific uses would be considered and evaluated in more detail in future planning and environmental analyses as appropriate. Careful consideration would be given to whether the benefits of any proposed use outweigh the potential risks. Use of depleted uranium products, HF, and CaF_2 would be subject to DOE and/or NRC review and approval, depending on the specific use.

The ultimate decision concerning HF or CaF_2 production will depend on the conversion process selected, the residual uranium concentrations, market demand, and both public acceptance and regulatory considerations. In response to this uncertainty, the potential environmental impacts of options for both production and sale of HF, and production and sale or disposal of CaF_2 are considered throughout the PEIS.

Comment

Approximately 5% of the commentors favored conversion to uranium metal, followed by long-term storage, use, or disposal.

General Response

The PEIS analyzes two options for radiation shielding applications using depleted uranium. The uranium metal option would result in a spent nuclear fuel disposal package, primarily as part of a Multi-Purpose Unit (MPU).

The reasons that long-term storage and disposal options for uranium metal were considered but not analyzed in detail are provided in Sections 2.3.3 and 2.3.4 of the PEIS. Disadvantages associated with long-term storage or disposal of uranium metal include higher conversion cost, lower chemical stability than uranium oxides, and regulatory restrictions on the disposal of the metal form.

Comment

Approximately 5% of the commentors provided information and raised questions about the health effects of depleted uranium exposures.

General Response

The analyses of potential health impacts conducted for the PEIS addressed both the chemical and the radioactive toxicity of uranium as several different compounds: UF_6, UO_2F_2, UO_2, U_3O_8, UF_4, and uranium metal. For normal operations, the chemical toxicity was addressed

by comparing potential exposure amounts with the U.S. Environmental Protection Agency's reference dose for uranium. For accidents, the chemical toxicity was addressed by comparing potential intakes with: 1) the intake of 30 mg given as the threshold for potential irreversible kidney damage under U.S. Nuclear Regulatory Commission (NRC) guidance for certification of gaseous diffusion plants (NRC 1994a; the full citation is provided in Chapter 8 of the PEIS); and 2) the intake of 10 mg, which NRC publications give as the threshold for potential adverse chemical effects (generally temporary, reversible effects occur in the range from 10 to 30 mg of intake). The methodology for chemical toxicity analyses for uranium exposure is summarized in Sections 4.3.1.2.2 and 4.3.2 of the PEIS and discussed in greater detail in Sections C.5.1.2 and C.5.2.1.1. The methodology for radiological toxicity analyses is summarized in Sections 4.3.1.1.2 and 4.3.2 and discussed in greater detail in Sections C.4.1 and C.4.2. Chemical toxicity was assessed for each alternative, and the results of the accident analyses show that the largest potential impacts from accidental uranium releases would be chemical impacts. Please see text in Section 2.4.2.2 of the PEIS, which states "chemical effects (kidney damage) occur at lower exposure levels than radiological effects," and elaborates on the numbers of workers and members of the general public estimated to experience these adverse chemical effects under the various accident scenarios analyzed.

1.6 CHANGES MADE TO THE DRAFT PEIS

DOE has revised the Draft PEIS in response to the comments received. In general, the responses to comments provided in Chapters 3 and 4 of this volume indicate whether or not a change was made to the text of the PEIS in response to the comment and the nature of the change. The revisions to the PEIS generally consisted of the following types: (1) editorial revisions, consisting mostly of corrections of typographical errors; (2) consistency revisions, in which inconsistencies between sections or tables were corrected; (3) clarifications, in which additional information was provided to clarify or provide further details about information provided; and (4) additions to the PEIS of information in response to changes in the overall scope of the PEIS analysis. The most significant revisions to the PEIS are summarized below.

Revision of the Preferred Alternative. After careful consideration of the comments received, DOE revised the preferred alternative for the PEIS. The revised preferred alternative, as described in detail in Section 2.5 of the PEIS, calls for prompt conversion of the depleted UF_6 inventory to U_3O_8 and long-term storage of that portion of the U_3O_8 that can not be put to immediate use. Under the revised preferred alternative, conversion to depleted uranium metal would take place only if uses for the metal product become available. The impacts of the revised preferred alternative are discussed in Sections 2.5, 5.7 and 6.3.7 of the PEIS.

Discussion of Potential Life-Cycle Impacts. In response to commentors' requests for life-cycle impact analysis, a new section has been added to the PEIS (Section 5.9) that discusses the

issues related to potential impacts of the long-term (beyond the year 2039) management of materials containing depleted uranium under all alternatives. However, because of the uncertainties associated with the events that would occur far into the future and with the regulatory atmosphere at that time, the discussion is limited to issues that would need to be considered and the options that would be available for managing the material beyond the year 2039.

Consideration of USEC-Generated Cylinders. In May and June of 1998, management responsibility for approximately 11,400 depleted UF_6 cylinders (approximately 137,000 metric tons) was transferred from the United States Enrichment Corporation (USEC) to DOE by the signing of two Memoranda of Agreement. The Memorandum of Agreement between DOE and USEC relating to depleted uranium generated prior to the privatization date was signed in May 1998 (DOE and USEC 1998a; the full citation is provided in Chapter 8 of the PEIS). It transferred management responsibility for approximately 9,400 cylinders (about 6,600 cylinders stored at Paducah and about 2,800 stored at Portsmouth) from USEC to DOE. A second Memorandum of Agreement between DOE and USEC relating to depleted uranium, signed in June 1998, transfers a total of about 2,000 depleted UF_6 cylinders from USEC to DOE between 1999 and 2004 (DOE and USEC 1998b). (The locations of these cylinders are not specified in this second agreement.)

To account for uncertainties related to the management of depleted UF_6 generated by USEC in the future, the analysis in the PEIS was expanded to consider management of up to 15,000 USEC-generated cylinders (approximately 180,000 metric tons). For the purposes of analysis, it was assumed that 12,000 of the USEC-generated cylinders would be managed at Paducah and 3,000 would be managed at Portsmouth. Chapter 6 has been added to the PEIS, and Chapter 2 and the Summary have been revised so the PEIS includes the impacts associated with the management of these additional USEC-generated cylinders.

COMMENTOR NO. 1: HOLLINGER, WADE
OAK RIDGE, TENNESSEE

Depleted Uranium Hexafluoride Management Program

Comment Form

The Department of Energy is interested in your comments on the *Draft Programmatic Environmental Impact Statement for Alternative Strategies for the Long-Term Management and Use of Depleted Uranium Hexafluoride.*

There are several ways to provide comments on this document and these include:

- ✓ attending public hearings and giving your comments directly to DOE officials
- ✓ returning this comment form to the registration desk at the hearing
- ✓ returning this comment form or other written comments to the address on the back
- ✓ faxing your comments to 301/428-0145
- ✓ commenting via the Depleted UF_6 World Wide Web site, http://www.sal.sal.gov/uranium.html
- ✓ calling toll-free and leaving your comments via voice mail, 1-800-517-3191
- ✓ commenting via electronic mail depleted_uf6@ecmail.gmt.saic.com

Comments

Make a reasonable risk based, economical decision, hire a team of lawyers and set on with getting rid of the stuff! Just take it for granted someone is going to sue DOE because they want you to make it so that it was never here in the first place (impossible) and put your lawyers to work, by the time it gets out of court you'll have the stuff gone. MAKE THE DECISION AND DO IT! I'm tired of supporting all you do nothing bureaucrats! A NEPA review and going out to the public was not necessary for this. You know what has to be

Document Ref.: PEIS: S.4 SUMMARY AND COMPARISON OF IMPACTS FOR ALTERNATIVEMANAGEMENT STRATEGIES

----- COMMENT -----

What is the basis for the consequences stated? In other words, if the no-action alternative creates 110 jobs over 40 years, that is as compared to what? Compare it to continuation of the present situation? But continuation of the present situation is not an option. The PEIS states its impacts relative to an inconceivable baseline. According to DOE's "Recommendations for the Preparation of Environmental Assessments and Environmental Impact Statements, "the no-action alternative provides an environmental baseline against which impacts of the proposed action (and alternatives) can be compared." Therefore, the consequences should be stated as deviations from the no action alternative. For example, as compared to the No Action alternative, for operations, Long-Term Storage creates 10 jobs per year over 20 years. Then there are 110 federal jobs from 20 to 40 years. For construction, no jobs are created relative to No Action. Comparisons like this should be made explicit by stating all consequences as deviations from the No Action alternative. This comment applies to all types of enviromental consequences, not just socioeconomic impacts.

Depleted Uranium Hexafluoride Management Program

Comment Form

The Department of Energy is interested in your comments on the *Draft Programmatic Environmental Impact Statement for Alternative Strategies for the Long-Term Management and Use of Depleted Uranium Hexafluoride.*

There are several ways to provide comments on this document and these include:

- ✓ attending public hearings and giving your comments directly to DOE officials
- ✓ returning this comment form to the registration desk at the hearing
- ✓ returning this comment form or other written comments to the address on the back
- ✓ faxing your comments to 301/428-0145
- ✓ commenting via the Depleted UF$_6$ World Wide Web site: http://www.ead.anl.gov/uranium.html
- ✓ calling toll-free and leaving your comments via voice mail, 1-800-517-3191
- ✓ commenting via electronic mail: depleted_uf6@ccmail.gmt.saic.com

Comments

I briefly Reviewed the UF$_6$ Draft PEIS. It appears to be a well developed and documented effort. One area that you may wish to improve is the hazardous analysis of the HF and UF$_6$ leak rupture. Other events including tornado induced missiles may wish to be addressed. These events may have been covered but I was unable to locate data on the Results of Analyses

Phil Ellison

Dear Friends and Former Associates,

I was happy to see that you are getting better at meeting schedules, only six months late in getting out the two volume Draft PEIS for the alternative strategies for the future of the few cylinders of depleted that are stored around.

I have spent some time reading it and thinking about the way it is presented, both from the my own point of view as one who knows what the stuff is and also from the point of view of one whose only knowledge of depleted UF_6 is from these writings. As you can see by my comments, I think you missed your opportunity to inform the unknowing and get them on your side once you make the long term management strategy.

4-1

I am interested in your reaction to my comments, and maybe we can work together to improve the document.

Comments as a Result of Reviewing the PEIS for
Alternative Strategies for the
Long-Term Management and Use of
Depleted Uranium Hexafluoride

As a result of several days of pouring through the two volumes of the referenced document, I have the following comments and suggestions to make. I believe that I am qualified to review the work because I have had 53 years of experience in the operation and design of the gaseous diffusion process in Oak Ridge while working 35 years for the operating contractor followed by 15 years for DOE . I have seen the depleted cylinders at all three of the plants, I actually filled some of them in Oak Ridge, I know the chemistry and physical properties of UF_6, I was on the committee to investigate the cause and effect of the wall failures of the two Portsmouth cylinders, and I am a voting member of the ANSI N14.1, *Uranium Hexafluoride - Packaging for Transport* standards committee that establishes cylinder design and fabrication criteria. Twice, I have presented my training course "Fundamentals of Gaseous Diffusion Plant Operations" to members of the Argonne National Laboratory staff who have prepared this report.

I will start with some general comments and proceed to some specific ones.

4-1 (Con't.)

UF_6 Storage Cylinder Description

Let me quote some of the words in the box on Page S-1 in Volume 1. "*Sufficient information must be included in the EIS for reviewers to evaluate the relative merits of each alternative.*"

It seems to me that you have to describe the problem in order for reviewers to see the merits of any of the possible solutions, including continued long term storage. In this case, the problem is what to do with the large quantity of depleted uranium hexafluoride that has accumulated at the gaseous diffusion plants in Oak Ridge, TN, Paducah KY, and Portsmouth, OH. I think you have to accept the fact that UF_6 is not a commodity that is familiar to the general public, especially those living

4-2

1409

COMMENTOR NO. 4: DYER, ROBERT (CONT'D.)
HARRIMAN, TENNESSEE

in the vicinity of the plants. Therefore, the description of depleted UF_6 in the storage cylinders on page S-2 is grossly understated "*Depleted UF6 is stored as a solid at all three sites in steel cylinders. Each cylinder holds approximately 10 to 14 tons (9 to 12 metric tons) of material.*"

The next mention of stored cylinders of UF_6 that I found was on page B1 in Volume 2. "*Depleted UF_6 has been stored in steel cylinders in outdoor yards at the three DOE storage sites since the 1950s. Most cylinders have either a 10- or 4- tons (9- or 12- metric tons) capacity and a nominal wall thickness of 5/16 in. (0.79 cm or 312.5 mil).*" It is a little more correct, in stating the cylinder capacity as 10 or 14 tons but is still oversimplified:

I, as a reviewer, know the details of the design criteria and methods of fabrication for the storage cylinders, and know that the UF_6 is being safely stored at the plants. I do not think the smidgen of information you have included will sufficiently inform and convince the farmer working the fields next to the plant, or the housewife in Wakefield, Ohio, or the new tenant in one of the K-25 buildings that they have nothing to worry about. These people should not forced to imagine what is in those somewhat rusted cylinders they see stored in the yards. I think you should at least use some of the pictures and descriptions of the cylinders from the ORO 651 series of documents. I can give you copies of ORO 651 Rev 5 and ORO 651 Rev 6, but you will have to buy the successor document USEC 651 Rev 7 from the USEC for which they charge $5.00. Also, and more importantly, you should point out that there is an American National Standard, ANSI N 14.1, *Uranium Hexafluoride - Packaging for Transport* which governs the quality of the material in and fabrication of these cylinders. You should be sure to point out that the cylinder has only one valve for filling and emptying. This valve is located at the 12 o'clock position on one of the ends.

4-2 (Con't.)

Assuming you expand your description of the cylinders, then you need to tell the people what is in them. You need to tell them that the ^{235}U isotope concentration has been reduced from the naturally occuring 0.711% to 0.2 - 0.3 % resulting in a proportional increase the concentration of ^{238}U.

You need to tell them that UF_6 is a chemical compound that has one atom of uranium combined with six atoms of fluorine. It can be either a solid, a liquid or a gas depending on its temperature. In the storage yards it is a solid in the bottom of the cylinders and a gas at subatmospheric pressure in the top. If a cylinder is heated, the solid will melt to a boiling

COMMENTOR NO. 4: DYER, ROBERT (CONT'D.)
HARRIMAN, TENNESSEE

liquid at 147°F. You need to tell them that it is a greater chemical hazard than a radioactive one.

You need to tell them how UF_6 reacts with the iron on the inner surfaces of the steel cylinder to form a corrosion inhibiting, protective surface layer of iron fluoride. This protective coating insures the UF_6 inside the cylinder will not react with and corrode the cylinder wall, i.e. if you protect the outside of the cylinder, and prevent it from rusting away, the UF_6 can stay in storage in the cylinders forever.

4-2 (Con't.)

Cylinder Fill Limits

There are long standing specific requirements that have been used to determine the quantity of UF_6 that can be safely stored in an approved design cylinder. The fundamental concepts of the approach to assuring the safety of the many cylinders of depleted UF_6 stored at Paducah, Portsmouth, and Oak Ridge are ***certified minimum volume*** and ***5% ullage***, in particular, my comment concerns the UF_6 fill-limit and heating temperature limit for 48G cylinders, although the same rationale applies to the other sizes of UF_6 cylinders.

The crucial concept is the ***certified minimum volume*** of the cylinder. UF_6 cylinders are fabricated in strict accordance with the drawings and criteria in the American National Standards Institute standard ANSI N14.1, ***Uranium Hexafluoride - Packaging for Transport***. One of the code requirements is that upon final fabrication, in order to determine its exact internal volume, the cylinder will be completely filled with 60°F water and weighed on a scale accurate to 0.1%. The actual water weight obtained is recorded for the individual cylinder certification data and stamped on the cylinder nameplate to conclusively demonstrate that the requirement has been met. For a cylinder to be acceptable, the quotient of the certified full cylinder water weight divided by 62.37(the weight in pounds of 1 ft^3 of water at 60°F) shall not be less than the published minimum volume. For a 48G cylinder, the minimum volume is 139 ft^3, equivalent to a water weight of 8669 lbs. Using this method of measurement, the actual internal volume of a cylinder can be determined and if it is not greater than the ***minimum volume***, the cylinder is destroyed.

4-3

1410

COMMENTOR NO. 4: DYER, ROBERT (CONT'D.)
HARRIMAN, TENNESSEE

The density, or weight of a cubic foot of UF_6 has to be known in order to use the ***certified minimum volume*** to determine a safe-fill quantity of UF_6 for the cylinder. During the first 20 years of the atomic age, much research work was done to determine the physical properties of UF_6. R. DeWitt of the Goodyear Atomic Corporation made an extensive literature search and compiled the results in a document, GAT 280, ***Uranium Hexafluoride: A Survey of the Physico-Chemical Properties January 29,1960.*** Data from this source has been used to produce Figures 1 and 2. Solid UF_6 undergoes a significant expansion as it is heated and melts from a solid to a liquid. This is illustrated in Figure 1, Density of Solid UF_6, and Figure 2, Density of Liquid UF_6 235 - 300°F.

Knowing that all cylinders are larger than the ***certified minimum volume*** allows the establishment of a safe UF_6 fill limit for them. This weight is obtained by using the density of liquid UF_6 at the 250°F design temperature of the cylinder and determining how much of this 250°F liquid UF_6 will fill 95% of the cylinder's ***certified minimum volume***. Because all cylinder volumes are certified to be greater than the minimum, this guarantees that there will be at least 5% of the ***certified minimum cylinder volume*** as ullage(space above the liquid in the cylinder) when the full cylinder is heated to its design temperature of 250°F, and thus there will be no possibility of hydraulic forces developing in the liquid to cause cylinder rupture.

4-3 (Con't.)

From ANSI N14.1, the minimum volume for a 48G cylinder is 139 ft^3 and from Figure 2, the density of liquid UF_6 at 250°F is 203.7 lbs/ft^3. For a 48G cylinder the calculation of the fill limit is:

95%(139 ft^3) (203.3lbs/ft^3 of UF_6) = 26840 lbs of UF_6

COMMENTOR NO. 4: DYER, ROBERT (CONT'D.)
HARRIMAN, TENNESSEE

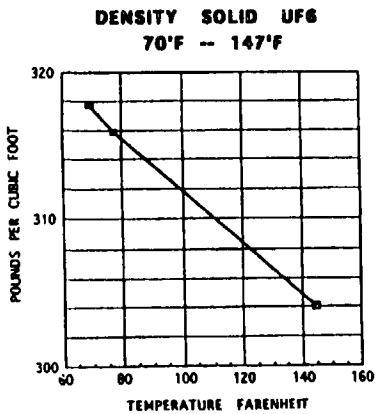

Figure 1

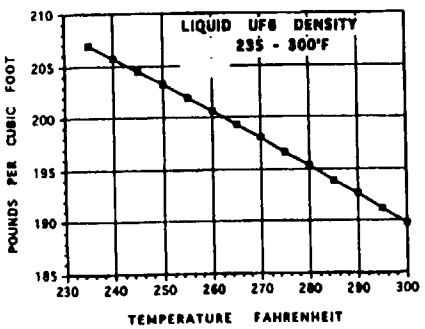

Figure 2

4-3 (Con't.)

COMMENTOR NO. 4: DYER, ROBERT (CONT'D.)
HARRIMAN, TENNESSEE

Keep in mind that because all cylinders are required to prove that they have greater than a minimum volume, there will always be at least, if not more than, a 5% ullage to prevent hydraulic rupture at the design temperature. At lower than design temperatures, because the density of liquid UF_6 expressed in lbs/ft³ increases as the temperature is lowered to the freeze point of147°F, the percentage of the cylinder volume occupied by gaseous UF_6 will increase and be larger than 5%. For example, prior to going to the storage yards, after all the air was evacuated from inside them, the depleted UF_6 cylinders were filled to the fill limit with liquid UF_6 at a temperature of 160°F with a density of 224 lbs/ft³. The ullage in this case is at least 14%. There can be no hydraulic rupture as long as gas in the ullage provides a cushion.

This fill-limit calculation assures safety if the cylinder is heated to the design temperature and before any material is removed from it. In diffusion plant practice, the cylinder is never heated above 100°F. As UF_6 gas is withdrawn, there is a smaller mass of liquid UF_6 in the cylinder so the ullage increases. Any volatile impurities that may have been in the cylinder will be expelled when feeding is first started so the pressure of the system will correspond to the vapor pressure of UF_6 for the temperature.

When the cylinder is filled with liquid UF_6 to its proper fill limit, and has cooled to room temperature, based on the data in Figure 1, showing the density at 68°F to be 317.8 lbs/ft³, the solid UF_6 will occupy 26,840 lbs/317.8 lbs/ft³ = 84.45 ft³/139 ft³ = 61% of the ***certified minimum volume***. The remaining 39% of the volume will be filled with UF_6 gas at subatmospheric pressure or vacuum.

4-3 (Con't.)

Minimum Cylinder Wall Thickness

The 0.25" minimum wall thickness specified in ANSI N14.1 and the ORO 651 series for the 48G, 48H, 48 HX, 48 O, and 48 OM cylinders is for a pressure vessel rated at 100 PSIG. However, this pressure is only achieved if the cylinder of solid is heated 147°F to liquefy the UF_6 and the heating of the liquid continued until the temperature of the liquid is increased to 200°F, as is done in gaseous diffusion plant operations requiring rapid emptying of the cylinder's contents. However, if by strict administrative control, the cylinder is only heated to a skin temperature of 133°F, 14°F below the liquefaction temperature, the UF_6 gas pressure in the cylinder will be atmospheric pressure(14.7 psia), and the UF_6 can be changed directly from solid to gas without going through the liquid phase

4-4

1411

COMMENTOR NO. 4: DYER, ROBERT (CONT'D.)
HARRIMAN, TENNESSEE

in order to remove it from the cylinder at a slow rate. (This is the way the French feed their diffusion plant, and is what you have heard referred to as "cold feeding". *4-4 (Con't.)*

Radiation Emanating from a Depleted Cylinder of UF_6

There is another aspect of the filled cylinders that I do not think has been adequately covered. There should be a statement concerning how many, or few, curies or sieverts of radiation emminates from one cylinder. Depleted UF_6 is by definition ^{238}U. The handbooks show ^{238}U to have a half life of 4.47 billion years (about as long as the earth has been around). The thorium and protactinium daughter products have melting points in the range of 1650-1850°F. This means that any daughter products that may be in a cylinder of normal assay UF_6 being fed into the cascade will not be vaporized and expelled from the cylinder with the UF_6 gas at 200°F. In essence, since no uranium daughter products are fed to the cascade, the only ones in depleted UF_6 are the ones that have grown in the past 50 years. With ^{238}U's half life, there can't be more than a handfull!

I know from experience that it is very difficult to measure any gamma radiation when scanning the outer surface of a full cylinder in storage with a radiation meter. However, after a cylinder has been heated, liquefied, emptied, and cooled, the scan will show a small amount of gamma radiation on the bottom of the cylinder. Keep in mind that the purpose for which the diffusion plants were built was to prepare uranium for fission, either in a weapon or a nuclear reactor. The diffusion process removes 70% of the fissionable isotope found in naturally occurring uranium. The stored depleted uranium has never been used as fuel in a nuclear reactor where fission products occur in great abundance. There are very few gamma emitting fission products in the depleted UF_6. The gamma radiation in the depleted uranium is coming from uranium decay daughter products. These non-volatile daughter product form extremely slowly throughout the cake of solid UF_6 as uranium decays. They are homogeneously mixed with the solid UF_6 resulting in their gamma rays being shielded by the uranium atoms. Because the daughters are chemically different than UF_6, they will not vaporize and be removed from the cylinder as a gas. They concentrate in an ever diminishing pool of liquid until they are all that is left on the bottom. In this location, their radiation is directed downward away from people working with the cylinders. If you sit on top of a cylinder, your butt is at least four feet from the emitters. *4-5*

1412

COMMENTOR NO. 4: DYER, ROBERT (CONT'D.)
HARRIMAN, TENNESSEE

I make no pretense of being a Health Physicist, so I find it hard to understand how you can estimate the exposures that people will get, if you don't state the intensity of the radiation at the source. Just one of many examples, Table D.1 page D-6 states as an impact during Storage(1999 - 2039), the *total collective dose to population within 50 miles (3 sites)* will be 0.38 person-rems. How can you be accurate to two decimal points when you don't know how much radiation, if any, is coming from a cylinder of depleted UF_6? Here is an area where you could do a lot of good in taking the hocus pocus out of Health Physics and educating the public about radiation and its effects! Don't let them learn it from the Simpsons on the anti-nuke Fox Network! *4-5 (Con't.)*

Specific Comments VOLUME 1

- Table S.3 Page S-46 What are the quantities of uranium compounds and HF considered to be released from a "*Corroded cylinder spill, dry conditions*," and "*Corroded cylinder spill, wet conditions*"? Without these numbers, it is difficult to understand the postulated consequences. The rest of the table has the same problem of not stating how much UF_6 or HF or UO_2 is released in the accidents *4-6*
- .PAGE 1-1 SECTION 1.1 BACKGROUND INFORMATION The statement is made: "*At atmospheric pressure, UF_6 is a solid material below a temperature of 134°F and a gas at temperatures above 134°F (additional information about the characteristics of the chemical UF_6 is provided in Appendix A).*" When I go to the Appendix A, I was amazed at the paucity of information presented not only for UF_6 but also for the other uranium compounds and HF. I thought at least, I would find the phase diagram of UF_6 that clearly shows the inaccuracy of the above statement but, alas, it wasn't there! UF_6 can be a gas below 134°F as well as above 134°F, and a solid all the way up to 147°F. *4-7*
- PAGE 3-50 TABLE 3.13 FOOTNOTE c The footnote states "*Radiation dose could result from drinking 365 L of K-25 site water(0.3 mrem/yr) and ingesting the maximally contaminated fish (1.6 mrem/yr)* " Do you have to drink all 96.5 gallons(365 L) of water and eat the fish at one sitting? If you do, this is nonsense and serves no purpose. If you don't, what is the time period? *4-8*

COMMENTOR NO. 4: DYER, ROBERT (CONT'D.)
HARRIMAN, TENNESSEE

- PAGE 4-14 DEFINITIONS *"Involved Worker - Might be exposed to direct gamma radiation emitted from radioactivematerials such as depleted UF_6 or other uranium compounds"* Here again, the question has to be asked, "How much radiation does depleted UF_6 or other uranium compounds emit/unit quantity of the substance?" Is the UF_6 still in the cylinder? Do you take credit for the shielding of the uranium in the UF_6 in the cylinder? The way this is written does absolutely nothing to allay the fears of the uninformed. — 4-9
- PAGE 8-18 DEFINITION OF TRANSURANIC WASTE The word "transuranic" means "beyond uranium" i.e. elements that have a greater than the 92 atomic weight of uranium. like plutonium, neptunium, americium, etc. They probably do have half-lives greater than 20 years. Plutonium is deliberately made in nuclear reactors and extracted from spent reactor fuel. In the late '70s, a very small quantity of uranium recovered from spent reactor fuel was refined, converted to UF_6, and fed into the diffusion plant complex. They do not exist in sufficient quantity in depleted UF_6 to be a problem. Here again is a place where you could do good in educating. — 4-10

Volume 2

- PAGE A-2 TABLE A-1 It seems incredulous that the particle and bulk density of UF_6 are each 4.6 g/cm³, and neither one of them is the generally accepted 5.1 g/cm³ at 68°F. — 4-11
- IBID. A.1.2 I think you should mention that uranyl fluoride picks up water of hydration from humid air and in doing so changes color from brilliant orange to yellow. If a cylinder should break open in the storage yard, this color change would probably be observed. — 4-12
- PAGE A-4 A.2.1 UF_6 is essentially inert to copper, witness all the copper tubing instrument lines in the plants. Also don't forget Teflon that was developed specially for the Manhattan Project. — 4-13
- PAGE B-7 4TH FULL PARAGRAPH, LAST SENTENCE *"It was assumed that uranium would be released as solid uranyl fluoride (UO_2F_2),which would be deposited on the ground."* You should do more than say it lays on the ground. Uranyl fluoride (UO_2F_2) has a characteristic of being very soluble in water, so as soon as it rains, its will go into solution which, because of the HF, will be acidic and be neutralized by the cement or limestone construction materials of the storage yard. The resulting calcium salts will — 4-14

1413

COMMENTOR NO. 4: DYER, ROBERT (CONT'D.)
HARRIMAN, TENNESSEE

probably be insoluble in water and lay where they have been formed.

- PAGE C-3 C.2.1 CONTINUED CYLINDER STORAGE 1ST PARAGRAPH 3RD SENTENCE *"Because of their age, potential direct contact with the ground, and skirted ends, many of the cylinders show signs of corrosion."* Unless you include the ORO 651 series of documents, how is the reviewer to know what you are talking about when you suddenly introduce "skirted ends"? — 4-15
- PAGE E-20 FIGURE E.1 The design of the Horizontal "Clamshell" Overcontainer looks interesting, and since you will have to use it at all three plant sites, while you are at it, why don't you design to be a 100 PSIG pressure vessel and use the steam heated autoclaves that you have at the plants to empty the defective cylinders? Otherwise you have to come up with an autoclave designed for hot air heating which will require different than your presently approved safety systems to avoid gross overheating with hot air. — 4-16
- PAGE E-21 E.2.2 CYLINDER TRANSFER You will have some damaged cylinders at all three sites, and if you can't get a DOT permit to ship them off the plant site, how would one of these expensive cylinder transfer facilities at each site be of value to the enterprise? — 4-17
- PAGE F-3 SITE LAYOUT FOR A CONVERSION FACILITY Why do you store the full cylinders outside, and build the biggest building on the site for the empties to be under cover? — 4-18
- PAGE F-11 1ST PARAGRAPH Why wash the empty cylinders with water when a nitric acid solution would do a better cleaning job? The used solution could also be evaporated to dryness for disposal. — 4-19
- PAGE F-13 F.2.3 CONVERSION TO METAL. 3RD PARAGRAPH, 4TH SENTENCE *"The more dense molten uranium/iron would settle to the bottom of the reactor where it would be continuously withdrawn"* What kind of material are you going to use for the reactor and liquid uranium/iron draw off piping? I have always been told that liquid uranium at 2100°F, and uranium alloys at lower temperatures are the universal solvents. Nothing, even yttrium lined equipment will contain them for very long. — 4-20

  If you go with the Fe/U alloy just to lower the molten metal temperature, how good a radiation shield will your alloy be as compared to pure uranium?
- PAGE F-14 IMPACTS OF OPTIONS The amount of HF produced from any of the conversion options should be expressed because it is the big safety hazard. The design rate of 2300 48G cylinders of UF_6 a year equates to 6.3*26,840 lbs or169,100 lbs UF_6 a day. Using a molecular — 4-21

COMMENTOR NO. 4: DYER, ROBERT (CONT'D.)
HARRIMAN, TENNESSEE

weight of 352 for UF_6, these 6.3 cylinders contain 480 lb/mols of UF_6. Each lb/mol of UF_6 that reacts with water will create six lb/mols of HF. Thus 480 lb/mols * 6 = 2880 lb/mols HF/day. Using a molecular weight of 20 for HF, this equates to 57,000 lbs or 6600 gallons of anhydrous HF/day produced. Remembering that HF boils at 60°F, this is a lot of HF to handle day in and day out in plastic pipes and tanks. You are buying a much bigger safety problem than I think you are portraying in these tomes. You should know that a drop of this liquid will burn a hole through your unprotected hand and the fumes can kill as happened at Kerr McGhee in Gore OK! *4-21 (Con't.)*

- PAGE F-23 TABLE F.7 In the Conversion to U_3O_8 section, the last accident is a U_3O_8 drum spilling its contents onto the floor after an accident with a forklift. These drums contain 1600 lbs of U_3O_8 powders, and you are asking the reviewer to believe that the spill quantity will only be 63 <u>milligrams</u>! This tends to lose your creditability for the whole study! Later on in the Table, you show a 2400 lb drum of UO_2 in a similar accident only spilling 25 <u>milligrams</u>, but you have an extremely unlikely 3, UF_6 cylinders bursting from some kind of fire and dumping 24,000 lbs in 30 minutes. I believe you lose integrity when you ignore the historical fact that this cylinder rupture scenario has not occurred, or even come close, in the past 50 years of cylinder storage. On the other hand, you seem to completely accept speculation about future accidents in plants that have not been built. It sure looks like you are trying to make people think this UF_6 stuff is the most hazardous thing there ever was? *4-22*
- PAGE F-29 CYLINDER TREATMENT FACILITY EXTREMELY UNLIKELY ACCIDENTS Why is the amount released in an earthquake where 50% of the stored drums are breached only 1.9 lbs, whereas in a Tornado that pierces only one drum of U_3O_8 the quantity released is 69 lbs? You need to cross check all these tables you publish. I am sure that I have not found all the inconsistencies. *4-23*
- IBID. The 3.4 lbs of HF released when the evaporator tank fails and the pool of HF evaporates into the building is just plain wrong. I can tell that none of you ever worked at Fernald! If the temperature is above 60°F, 3.4 lbs of anhydrous HF will become 61 standard cubic feet of extremely toxic and obnoxious gas.
- PAGE G-16 SECTION G.2.2 I don't find recognition of the cylinder sweating problem in any of the inside storage options. During the winter, the 10 or 14 ton cake of UF_6 in each cylinder cools approaching the temperature of the coldest day. When spring comes and the warm *4-24*

1414

COMMENTOR NO. 4: DYER, ROBERT (CONT'D.)
HARRIMAN, TENNESSEE

humid days return, the outer surface of the cylinders becomes a condenser for the water in the air, not unlike the sweating on your evening rum and coke glass. Unless you air condition the buildings, vaults, and mines, the cylinder wall corrosion will continue especially in the spring. *4-24 (Con't.)*

- PAGE H-16 TABLE H-5 Why is that the drop of a single 2400 lb drum of UO_2 only releases $7.3X10^{-7}$ pounds (3.3 mg) of UO_2 in this accident whereas the same accident in Table G.6 page G-26 releases $1.1X10^{-4}$ lbs (50 mg)of UO_2? Once again, what you got don't make no sense! *4-25*
- PAGE J-28 SECTION J.3.4.3 CYLINDER TREATMENT FACILITY I question the assumption that emptied UF_6 cylinders will retain a 22 lb heel. Why not use dry air to purge the UF_6 gas from the emptied cylinder in the autoclave and let these purge gases go directly to your conversion apparatus. If you do this you should get your heels to be around 10 ppm UF_6. However, even if you do this, you will still have to wash the cylinders to get the daughter products out *4-26*

Comments

I am writing concerning the Draft PEIS Summary, Vol I and Vol II. Thankyou for the opportunity to provide comments. I have been having this problem (w/ lack of fee in the the higher priority sites with the Gaseous Tanks and Metal Wells Storage Tanks at ORNL) since 1992 at Oak Ridge (K-25, PGDP and PORTS.

Please add me to your mailing list as individual below.

Thankyou again

Comments

NO COMMENT AT THIS TIME. THE PUBLIC MTG SHOULD ELICIT VARIOUS COMMENTS WHICH EITHER WILL ENHANCE OR DISTRACT FROM THE DECISION MAKING PROCESS.

QUESTION – I DIDN'T THINK "ECONOMICS" WAS A CONSIDERATION OF THE NEPA PROCESS. IF IT'S NOT, WHY IS IT PRESENTED IN THE PEIS?? IT'S BEING PRESENTED COULD ADVERSELY INFLUENCE ULTIMATE DECISIONS FOR THE PROJECT – PEOPLE WILL LOOK @ THE $$ INSTEAD OF THE BEST PROJECT OPTION

Comments

In discussing possible future uses of depleted uranium, you prominently mention radiation shielding. True for x-rays and gamma rays, and neutrons true for neutrons (fast or slow (slow associated with some simple minded experiments 40 yrs ago that made the point dramatically.) The neutrons produce fissions, and the (subcritical) multiplication ruins the shield.

Uranium pellets will ruin concrete blocks, if enough neutrons are around. So for any application involving around an accelerator, an analysis would have to be made.

So, qualify the statements to apply only to X-rays or X-ray shields. 7-1

Name: Dr Lee Plansky

Date Sent: 1/28/98

Document Ref.: PEIS: APPENDIX I: ENVIRONMENTAL IMPACTS OF OPTIONS FOR DISPOSAL OF OXIDE

----- COMMENT -----

A re: Disposal Options U- minerals are deposited in reducing environments. It would seem that you would chose a "grout" that would tend to be chemically neutral or also reducing, perhaps a glass or synroc. The oxidizing environment implied in the present scenario (cement grouts, implies rapidly rusting metal drum, and oxidation of U to U ++++++ (+6, or +5) and we mobilize what we don't want to. 8-1

B. The PEIS downplays the importance of U-toxicity as a metal. Refer to any simple MDSDS on U METAL and you and the public will all be shocked. 8-2

C. The way I understand it, the new proposed 20 micrograms/liter EPA MCL on U-238 is inviolable. Depleted uranium material would be disposed of as low-level radioactive waste. The disposal options assessed in the PEIS were defined on the basis of the chemical form of the uranium and the type of disposal facility. The following disposal options were considered: Disposal as U3O8. Depleted uranium could be disposed of as U3O8, either ungrouted (bulk) or grouted U3O8, following conversion. The disp al facilities considered included shallow earthen structures, belowground vaults, and an underground mine. Disposal as UO2. Similar to U3O8, depleted uranium could be disposed of as UO2 following conversion, either in ungrouted or grouted form. The disposal facilities considered were the same as those considered U3O8: shallow earthen structures, belowground vaults, and an underground mine. 8-3

Germantown, MD 20874

Dear Mr. Bradley

Secretary Pena recently held a press conference in Washington D.C. to tout his Openness Initiative. We hope that this willingness to be open includes efforts to be more inclusive in DoE's outreach to impacted, or potentially impacted communities.

Specifically of concern to the Military Toxics Project and the Indigenous Environmental Network is the **Draft Programmatic Environmental Impact Statement For Alternative Strategies For The Long-Term Management And Use Of Depleted Uranium Hexafluoride.**

We believe that all of the strategies that proposed have serious environmental justice concerns and potential impacts to communities that you have not adequately reached with the draft PEIS. We also believe that the meetings that the DoE has held in the past, as well as the ones that are beginning on February 19, 1998 in Paducah, are not properly reaching people who are or may be impacted by decisions that your agency will be making regarding the long-term plan for the use of this dangerous material. 9-1

Keeping with the spirit and intent of President Clinton's Executive Order on Environmental Justice, and Secretary Pena's Openess Initiative, we feel that it would be reasonable to request that the DoE initiate roundtable meetings, much like the Federal Facilities Restoration Dialogue meetings. We beleive that it is necessary and just to bring in grassroots leaders from community, labor and environmental justice groups to further discuss the implications of strategies that have been proposed. 9-2

We further request that the comment period be extended to six months to give these folks the opportunity to meet with you, in addition to the hearings that are taken place now, as well as the opportunity to obtain expert technical advice regarding the impact of the various different strategies. 9-3

Please respond to our request in writing. We will be happy to suggest participants for a roundtable discussion.

Sincerely,

Cathy Lemar

Comments One long-term alternative which has not been considered to date for long-term storage of the converted uranium (i.e., UO2, U3O8, etc.) is the placement in a uranium mill tailings impoundment for long-term retrievable storage. Mill tailings impoundments are designed for 1,000 year stability and the long-term care and maintenance is legally the responsibility of the Department of Energy. Quivira Mining Company's mill tailings site in New Mexico, for example, is presently licensed to dispose of 5,000,000 tons of byproduct materials even though the structural stability of the site was designed for an additional 43,000,000 tons.

The primary advantages of using a mill tailings site are (1) the inventory would be consolidated and isolated from the environment; (2) placement in a tailings impoundment would be relatively simple and with minimum personnel exposure; (3) it would remain in the custody of the US Government for long-term monitoring and care; and, (4) it could be retrieved at any time in the future should the need arise.

----- COMMENT -----

Appendix D, pg. 5, 1st Para. - The assumption that any further breaches would be a result of handling damage vs. corrosion is very valid, however the follow on assumption that this breach or damage would go undetected for 4 years is not a valid assumption. The same detailed Inspection of a cylinder is required each and every time it is handled as it is Quadrennially or Annually, the Inspections in fact almost identical, the same procedures and checklists are used regardless of the type of inspection or frequency. Any damage that might occur under the current regimented and proceduralized handling activities whether during painting, cylinder relocation to improved storage, or just normal storage yard operations, would be immediately noted and dealt with at the occurrence. Therefore there would be no release and no "Environmental Impact" whatsoever, furthermore the one handling damage induced breach (the Paducah cracked cylinder) was caused by handling damage in 1987; since that time this Site has handled thousands of cylinders without breaching a cylinder due to handling damage, the current Project alone has handled over 30,000 cylinder relocations since 1992 without causing damage to a cylinder sufficient to cause a breach. The facts do not support the conclusions of the predicted number of cylinder breaches portrayed in the "No Action Alternative": the estimate of 444 at Paducah over the next 40 years with only one under old handling practices (even disregarding that those practices have been improved) is sensationalistic.

Dear Mr. Bradley:

We are writing to you to request that you extend by six months the period for comment on the *Draft Programmatic Environmental Impact Statement for Alternative Strategies for the Long-Term Management and Use of Depleted Uranium Hexafluoride*. The material in the draft is very technical and complex, and many people concerned with the management of the hexafluoride have only recently received copies of it. 13-1

We should also like to recommend that people in the affected communities be invited to roundtable meetings like those for the Federal Facilities Restoration Dialogue. The affected communities should include those likely to be at risk if transportation of uranium hexafluoride on a large scale takes place. 13-2

Sincerely,

Mary B. Davis

WE URGE DOE TO DETERMINE ALL LEAKING CYLINDERS AT PGDP. TRANSFER THE CONTENTS OF LEAKING CYLINDERS INTO HEAVY GUAGE 48Y CONTAINERS. STORE IN A EARTHQUAKE PROOF CONCRETE STRUCTURE OFF THE FLOOR SO THEY CAN BE MONITORED FOR LEAKS. NO MAJOR EFFORTS TO TRANSFER CONTENTS AND WASH OUT CONTAINERS IN A PROCESS TO CHANGE TO URANIUM OXIDE SHOULD BE AT THE PADUCAH FACILITY. DOE HAS KNOWN DETAILS OF SEVERE SEISMIC POTENTIAL SINCE THE LATE 1970'S AND HAS TAKEN LITTLE OR NO ACTION TO PROTECT THE WORKERS OR THE COMMUNITY. NEGLIGENCE IS NOT AN "ACT OF GOD" IF ACUTE DAMAGE IS DONE TO THE FACILITY OR THE COMMUNITY DURING SEISMIC EVENTS. WE URGE A COMPREHENSIVE ENVIRONMENTAL IMPACT STUDY BE MADE ITS FULL REPORT TO THE PUBLIC. WE URGE ATTENTION TO DAMAGE AND HAZARD REDUCTION RE: THE EARTHQUAKE POTENTIAL UTILIZING NATIONAL & INTERNATIONAL EARTHQUAKE ENGINEERING AND SEISMIC SCIENTISTS, WHO ARE RESPECTED IN THEIR FIELD. WE EXPLORE THE USE OF DEPLETED URANIUM IN MILITARY EQUIPMENT

Cmnt No.	Page and Location [Revised Location]	Comment	Comment Disposition
1.	Page S-1; Para. 2; Sent. 4; and Page S-4; Sect. S.1.2; Sent. 2	Text states: "Additional NEPA analyses, as appropriate, will be prepared once a long-term management strategy has been selected..." "This PEIS examines the environmental consequences of alternative strategies of long-term storage, use, and disposal of the depleted UF_6 inventory." This document does not appear to analyze completely the use and disposal of the depleted UF_6 inventory when it defers the analysis of future siting, design, and construction to possible separate NEPA analyses (as appropriate) in the future when, in effect, they appear to be "connected actions" and/or "cumulative actions" and should be evaluated thoroughly in this PEIS.

DOCUMENT REVIEW RECORD

Document Title: *Proposed Remedial Action Plan for Solid Waste Management Unit 91 at the Paducah Gaseous Diffusion Plant, Paducah, Kentucky*

Date: February 13, 1998

Cmnt No.	Page and Location [Revised Location]	Comment	Comment Disposition
2.	Page S-42; Sect. S.4.13; Sent. 1	Text states: "All depleted UF_6 management alternatives would result in environmental impacts that, even when combined with other activities that could occur at the three current storage sites, would be expected to be relatively minor." This statement does not adequately address cumulative impacts from all alternatives considered in this draft PEIS. This statement conflicts with the statement on page 4-27 that states: "The cumulative impact analysis was conducted by examining those impacts resulting from depleted UF_6 management activities that would occur at the three current storage sites (Paducah, Portsmouth, and K-25). The impacts from these activities - including continued cylinder storage and cylinder preparation - were then added to the impacts of other past, present, and reasonable foreseeable future actions at these sites to assess potential cumulative UF_6 impacts." What past, present, and reasonable foreseeable future actions at these sites (specifically) were assessed, and where is the methodology discussing such assessment?	
3.	Page 3-12; Sect. 3.3.6.3; Sent. 1	Text states. "No wetlands were identified on the Paducah site by the National Wetlands Inventory (ANL 1991a)." This may be a true statement; however, jurisdictional wetlands were delineated by a wetlands survey performed in 1995 and confirmed by the U.S. Army Corps of Engineers in 1996 in some of the drainage ditches on the Paducah site. So the text stated above may be true, but it is inaccurate as far as the current wetland scenario on the Paducah site. Is it possible old information has been quoted?

DOCUMENT REVIEW RECORD

Document Title: *Proposed Remedial Action Plan for Solid Waste Management Unit 91 at the Paducah Gaseous Diffusion Plant, Paducah, Kentucky*

Date: February 13, 1998

Cmnt. No.	Page and Location [Revised Location]	Comments	Comment Disposition	
4.	General	Cumulative impacts are not analyzed thoroughly throughout this document. The storage and management scenarios are well known and scoped; however, the unknowns (siting, design, and construction) are described in enough detail (with enough siting criteria described) to narrow the likely locations at which of these facilities possibly will be sited and constructed to be evaluated for cumulative impacts in this document. These "Phase II actions" appear to be "connected actions" and should be analyzed in this PEIS. Phase II is described as "... implementation of the strategy selected."(page S-5, 1st paragraph, 1st sentence). It would be difficult to implement efficiently a strategy of this magnitude that has "connected actions" that are not fully described, planned, and evaluated in this document.		15-4
5.	Pages S-2, S-18, S-55, S-66, S-78, and S-94	No cumulative impacts discussions were included for each of these alternative discussions even though Figure 4.1 on page 4-7 shows "Areas of Potential Impact Evaluated in the PEIS for Each Alternative." The "Cumulative Impacts " box appears in the center at the bottom of this figure.		15-5
6.	Page S-104; Sect. S.8; Sent. 4	Text states: "No non-DOE actions have been identified that would have potential cumulative impacts at the three sites." How was this conclusion reached? What "non-DOE" entities were contacted and what past, present, and reasonably foreseeable actions were analyzed that considered these "non-DOE" entities' actions? Were local governments, municipalities, regional planning agencies, federal agencies, state agencies, local industries, and other non-DOE entities directly communicated with in this PEIS? Are they referenced in this document?		15-6
7.	Appendix E; Page E-72, Sect. E.3.12; Bullet 2	Text states: "The impacts would be negligible." What methodology and analysis deem these impacts to be "negligible?" Where is a cumulative impacts analysis performed to make this decision?		15-7

Comt No.	Page and Location (Revised Location)	Comment	Comment Disposition	
14.	General	Throughout the PEIS, at the Paducah site, Bayou Creek is referenced as "Big Bayou Creek." This is in error, as the 1978 USGS topographic map for Heath, KY, shows the creek as Bayou Creek not Big Bayou Creek.		15-11
15.	General	Is there any correlation between this PEIS and the "Department of the Navy Final Environmental Impact Statement for a Container System for the Management of Naval Spent Nuclear Fuel," DOE/EIS-0251, Nov., 1996, specifically with concern to interim consolidated storage of spent nuclear material at some location such as Yucca Mountain or another site?		15-12
16.	General	The preferred alternative is not one of the alternatives described and compared in the body of this PEIS but is a combination of alternatives 4 and 5. Why wasn't there another alternative (say # 7) that described and compared the use of the entire UF$_6$ inventory as the preferred alternative? It seems a little difficult to the reader to see that the preferred alternative isn't one of the decribed and compared alternatives in the body of the PEIS. In combining alternatives 4 and 5, were additive, countervailing, and synergistic effects evaluated? If so, where is this covered in the PEIS?		15-13
17.	Pages 5-109, 5-111, 5-113; Tables 5.12, 5.13, and 5.14	Tables are titled: "Maximum Cumulative Impacts of Depleted UF$_6$ Activities, Existing Operations, and Other Reasonably Foreseeable Future Actions at the ..." The reader does not agree that these tables should be titled "Maximum Cumulative Impacts ..." because cumulative impacts have not been analyzed in detail and appear to be based on a limited cumulative impacts methodology and evaluation. In addition, the "Impact Categories" are incomplete and do not include other potential impact areas.		15-14
18.	General	Has this action been correlated with the Vortec Vitrification proposed action for the Paducah Site?		15-15

COMMENTOR NO. 18: JANASKIE, MARK
OAK RIDGE, TENNESSEE

Question/Information Request Card

If you have questions that were not addressed or need additional information, please fill out this form and bring it to the registration table. DOE will address your concern to extent possible.

Name: MARK JANASKIE
Address: 151 LAFAYETTE DRIVE, SUITE 210 | OAK RIDGE 37830
Phone: 482-0400 Fax: 482-7690
E-mail: MJanaskie@DPRA.com

DEPLETED

Question/Request: Is there a [redacted] considered by DOE to measure the corrosion rates, and if [redacted] the corrosion rate is slow or benign, [redacted] is there a chance that DOE will do no coating and simply wait until the [redacted] conversion (2006+)? If the corrosion rate is slow [redacted] could DOE consider the risk to cylinders low, and thus simply wait until conversion begins. 18-1

Is this one of DOE's current options?

COMMENTOR NO. 19: PARROTT, ROBERT C.
OAK RIDGE, TENNESSEE

Question/Information Request Card

If you have questions that were not addressed or need additional information, please fill out this form and bring it to the registration table. DOE will address your concern to extent possible.

DUPLICATED

Question/Request: 1) What does DOE plan to do with the cylinders after conversion occurs? Disposal as is, decon + sale as scrap or reuse? 2) Does DOE have a predictive technology to convert the DUF6? Is it realistic that DOE can convert the material by 2028? 3) The current painting program seems inadequate to control corrosion. Does DOE plan to increase the rate of coating? 4) How will DOE decide whether to transport cylinders in overpacks or transfer the contents to new cylinders?

COMMENTOR NO. 20: RADCLIFFE, DONALD W.
ADDRESS UNKNOWN

TO: depleted UF6 at SAIC_BM2
Subject: Unable to comment on DUF6

When I tried to send a commet through the e-mail link on the website, AOL could not deliver to that address. My comment on the PEIS is:

The cost of enrichment services is much lower and thus the viability of refeeding the DUF6 at higher assays is much improved at some locations outside the U.S. The PEIS should address the issues of overseas shipping and disposal.

COMMENTOR NO. 21: UNITED STATES DEPARTMENT OF THE INTERIOR
WASHINGTON, D.C.

United States Department of the Interior

OFFICE OF THE SECRETARY
Washington, D.C. 20240

In Reply Refer to:
ER 97/732

MAR 5 1998

Mr. Charles E. Bradley, Jr.
Office of Facilities (NF-40)
Office of Nuclear Energy, Science and Technology
U.S. Department of Energy
19901 Germantown Road
Germantown, MD 20874-1290

Dear Mr. Bradley:

The Department of the Interior has reviewed the draft " Programmatic Environmental Impact Statement (PEIS) for Alternative Strategies for the Long-Term Management and Use of Depleted Uranium Hexafluoride" and offers the following comments:

The Paducah site's proximity to the Reelfoot Rift and New Madrid fault zones would seem to indicate that an earthquake caused accident could be considerably greater at Paducah than at either the Portsmouth site or the Oak Ridge site. This area has experienced seismic activity within the last two to three months. This should be factored into the analysis. 21-1

§ 1.3 Under Proposed action-Contaminants leaking into groundwater may not be detected for several hundred years. The rate of movement of contaminants in groundwater is variable. Because of the long period of time during which the radiation would still be potentially harmful, monitoring of ground-water contamination should continue as long as a risk exists and should cover a large enough area to capture the full geographic extent of possible contamination. The McNairy-Nacatoch aquifer is a very important source of drinking and domestic water for a number of towns in Missouri and Arkansas. Monitoring should be extensive enough to capture any incidence of contamination in these important water sources following a contamination event. 21-2

§ 4.5-It is important to note that the Paducah site should be considered a "wet site." A disposal facility failure in this wet environment would impact the ground-water system with uranium concentrations in groundwater greater than 20 mg/l. within 1,000 years after the failure. 21-3

The Paducah site is also vulnerable to changes in the biological and chemical composition of surface water caused by ground-water discharges into surface water streams. If contamination from such a discharge were to occur, it could affect the ecological stability of the surface water environment. 21-4

1425

COMMENTOR NO. 21: UNITED STATES DEPARTMENT OF THE INTERIOR (CONT'D.)
WASHINGTON, D.C.

There is not sufficient information presented in the PEIS to permit an analysis or assessment of the validity of the models; therefore, we cannot confirm that the worst-case accident or other scenarios are reasonable simulations. 21-5

Most of the strategies for disposing of the inventory of uranium would require construction of processing plants to convert UF6 to other chemical forms, however, locations of these plants are not identified. The use of generic data for the proposed plant seems to be a weak link in the analysis because of uncertainty about site location and lack of specific data. Therefore, we cannot confirm the validity of the potential environmental impacts that might be caused by this conversion process. 21-6

The units for measuring contaminant concentrations are reported differently in different parts of the document (e.g., mg/g, ug/mg, etc.). The same is true of hydraulic conductivity (cm/s, ft/d). Consistent units of measure should be used throughout the PEIS. 21-7

On page 3-28, the assertion that the high thallium concentrations may be caused by a problem in the laboratory analysis should be confirmed or denied, and explained if levels are confirmed to be as high as suggested. 21-8

Program Manager, Facilities Office, ONEST
19901 Germantown Rd.
Germantown, MD 20874

Dear Mr. Bradley:

It was a pleasure to meet you, last night, at the DOE public meeting in Oak Ridge. Heather and I both feel that the preferred program to convert the stockpiled UF6 to uranium oxide and uranium metal for future use is the most worthwhile alternative.

Eco-Pak Specialty Packaging is very interested in assisting in the transport of this material to the future conversion facilities. I am enclosing a brochure on both Eco-Pak Specialty Packaging (ESP) and our parent company, The Columbiana Boiler Company (CBC).

ESP is a division of The Columbiana Boiler Company (CBC) and part of the Columbiana network of companies, which encompasses more than 100 employees and 200,000 square feet of manufacturing area. ESP and CBC offer the knowledge and manufacturing experience of both the UF6 cylinders (30B & 48" series) and the UF6 cylinder overpacks. Additionally, ESP has experience in packaging for the transportation of uranium oxide materials, plutonium products, and waste products. ESP has a comprehensive quality assurance program in place, which is approved by the U.S. Nuclear Regulatory Commission under Quality Assurance Program Approval for Radioactive Material Packages No. 0179, Revision 6. NCI has on staff a core group of project engineers with a wide range of experience, a strong management team, regulation specialists, a certified core of welders, AWS Certified Welding Inspectors also certified in accordance with ASNT-TC-1A for nondestructive inspection, and excellent production personnel. 23-1

I hope some of this information helps in the decision making for this project. I look forward to working and meeting with you, again.

If you have any questions about our company or need any further information regarding our capabilities, please contact myself or Heather Little at (800) 221-2465

Best regards,

William M. Arnold
President

Dear Mr Bradley:

Enclosed is a copy of the Depleted Uranium Case Narrative about the health and environmental consequences of depleted uranium munitions. I hope that you will carefully review the information presented here as part of your effort to determine the fate of uranium hexaflouride stockpiles.

24-1

Depleted uranium should be stored in safe containers away from humans, water supplies, and the food chain. The use of depleted uranium in ammunition is an unwise use for chemically toxic and radioactive waste.

If I can be of further assistance, please do not hesitate to contact me.

Respectfully,

Dan Fahey

DEPLETED URANIUM CASE NARRATIVE
QUOTES SHEET

I. Pre-Desert Storm Reports:

1974: "In combat situations involving the widespread use of DU munitions, the potential for inhalation, ingestion, or implantation of DU compounds may be locally significant."
Medical and Environmental Evaluation of Depleted Uranium; Ad Hoc Working Group on Depleted Uranium of the Joint Technical Coordinating Group for Munitions Effectiveness; April, 1974; p. ix.

1974: "The use of DU in certain RDT&E [Research, Development, Training and Evaluation] and combat activities results in the redistribution of uranium in the environment, thereby providing a potential for adverse effects. Adherence to safety procedures and use of protective clothing minimize the potential for human exposure during RDT&E activities."
Medical and Environmental Evaluation of Depleted Uranium; April, 1974; p. viii.

July, 1990: "Aerosol DU exposures to soldiers on the battlefield could be significant with potential radiological and toxicological effects."
Kinetic Energy Penetrator Environmental and Health Considerations; Science Applications International Corporation (SAIC); July 1990. Vol. 1, 4-5.

July, 1990: "Under combat conditions, the MEI's [most exposed individuals] are probably the ground troops that re-enter a battlefield following the exchange of armor-piercing munitions, either on foot or motorized transports."
Kinetic Energy Penetrator Environmental and Health Considerations; SAIC; July 1990, Vol. 2, 3-4.

July, 1990: "We are simply highlighting the potential for levels of [DU] exposure to military personnel during combat that would be unacceptable during peacetime operations."
Kinetic Energy Penetrator Environmental and Health Considerations; SAIC; July 1990; Vol. 1, 4-5.

July, 1990: "Following combat, however, the condition of the battlefield, and the long-term health risks to natives and combat veterans may become issues in the acceptability of the continued use of DU kinetic energy penetrators for military applications."
Kinetic Energy Penetrator Environmental and Health Considerations; SAIC; July 1990, Vol. 2, 3-4.

July, 1990: "Depleted uranium: low level alpha radiation emitter which is linked to cancer when exposures are internal, [and] chemical toxicity causing kidney damage."
Kinetic Energy Penetrator Environmental and Health Considerations; SAIC; July 1990; Vol. 1, 2-2.

July, 1990: "Assuming US regulatory standards and health physics practices are followed, it is likely that some form of remedial action will be required in a DU post-combat environment."
Kinetic Energy Penetrator Environmental and Health Considerations; SAIC; July 1990; Vol. 1, 4-6.

October, 1990: "Bioassay procedures will be performed when radioactive materials are used in such a manner that they could be inhaled, ingested, or absorbed into the body."
Preventative Medicine; US Army Regulation 40-5; October 15, 1990; Chapter 9, 9-6 a(2).

September, 1990: "If ingestion or inhalation of radioactive materials is suspected, bioassays should be performed."
Guidelines for Safe Response to Handling, Storage, and Transportation Accidents Involving Army Tank Munitions and Armor Which Contain Depleted Uranium; TB 9-1300-278; Headquarters, Department of the Army, September, 1990; p. 7-3.

II. Post-Desert Storm Reports:

March, 1991: "There has been and continues to be a concern regarding the impact of dU on the environment. Therefore, if no one makes a case for the effectiveness of dU on the battlefield, dU rounds may become politically unacceptable and thus, be deleted from the arsenal . . . I believe we should keep this sensitive issue at mind when after action reports are written."
"The Effectiveness of Depleted Uranium Penetrators;" Los Alamos National Laboratory memorandum; Lt Col M V Ziehm; March 1, 1991.

March, 1991: "As Explosive Ordnance Disposal (EOD), ground combat units, and the civil populations of Saudi Arabia, Kuwait, and Iraq come increasingly into contact with DU ordnance, we must prepare to deal with the potential problems. Toxic war souvenirs, political furor, and post conflict clean-up (host nation agreement) are only some of the issues that must be addressed."
"Depleted Uranium (DU) Ammunition;" Lt. Col. Gregory Lyle; Defense Nuclear Agency; March, 1991.

1995: "When DU is indicted as a causative agent for Desert Storm illness, the Army must have sufficient data to separate fiction from reality. Without forethought and data, the financial implications of long-term disability payments and health-care costs would be excessive."
Health and Environmental Consequences of Depleted Uranium Use in the US Army: Technical Report; US Army Environmental Policy Institute (AEPI); June, 1995; p. 4.

1996: "US service personnel also could have been exposed to DU if they inhaled or ingested DU dust particles during incidental contact with vehicles destroyed by DU munitions, or if they lived or worked in areas contaminated with DU dust from accidental munitions fires. Thus, unnecessary exposure of many individuals could have occurred."
Presidential Advisory Committee on Gulf War Veterans' Illnesses Final Report; December, 1996; p. 99.

1993: "Army officials believe that DU protective methods can be ignored during battle and other life-threatening situations because DU-related health risks are greatly outweighed by the risks of combat."
Operation Desert Storm: Army Not Adequately Prepared to Deal With Depleted Uranium Contamination; US General Accounting Office; GAO/NSIAD-93-90; January, 1993; p. 4.

1995: "Combat in Desert Storm has shown us that all soldiers anytime during battle may come across depleted uranium and depleted uranium contamination."
Development of Depleted Uranium Support Package: Tier I - General Audience; US Army Chemical School; October, 1995; p. 25.

1995: "The person most likely to be contaminated is breathing without protection when DU munitions hit and penetrate his AHA [DU armored] M1 tank and the DU aerosolizes into the tank turret. He will inhale large amounts of DU dust. Next is the person in an AHA M1 tank hit and penetrated by non-DU munitions. The DU in the armor would aerosolize into the turret. Other persons include crew members in Bradleys struck by DU ammunition. Last are individuals moving

Statement of Jerry Wheat
Gulf War Veteran
4/7 Cav, 3rd Armored Division
March 2, 1998

My name is Jerry Wheat, and I served in the Army from 1987 until 1991 as a cavalry scout. During the Gulf War, I was assigned to the 3rd Armored Division in Germany and was sent to the Gulf on December 24, 1990. We were deployed near the Iraqi border, where we practiced manuvers before the invasion in February 1991. I left the Gulf in March 1991.

Our unit was engaged in heavy fighting on February 26, 1991. I was injured in a friendly fire incident involing depleted uranium ammunition. Our Bradley Fighting Vehicle was struck twice by DU rounds fired by US tanks, and I was awarded a Purple Heart for my shrapnel wounds.

In October 1991, I became ill. I began having abdominal pains that would drop me to the floor, and I could barely eat. This went on for several weeks even though I was seeing a doctor at an Air Force hospital in Albuquerque, NM. I left the military shortly after falling ill, and I could no longer seek medical care from the military. I contemplated suicide because there were no answers and there was no treatment. At that time, I was not informed nor was I aware of the fact I could go to the Department of Veterans Affairs for medical care. The pain is still with me today.

Later on, I visited the VA in Albuquerque, and I was told that the illnesses are not real, but that it is psychological -- that it is in my head. After seven years, the VA won't say if my physical ailments are related to DU exposure.

In March 1992, my father, an industrial hygenist technician at Los Alamos Laboratory, called me and informed me that the shrapnel taken from my gear and skin were radioactive. This was a tremendous surprise to me, since the Army never bothered to tell me I was hit with radioactive and toxic ammunition.

I am now part of a VA medical review following the health of veterans exposed to DU. This program only follows a handful of those with known heavy doses of DU exposure. By 1993, I had lost 60 pounds, and the VA has yet to explain this to me.

I am speaking out today because so many people are affected by Gulf War illnesses. Our government should stop using depleted uranium. If it won't do that, then the least it can do is provide training and health care for those exposed to the toxic waste.

Remember, this sad legacy of government mistakes is not new. About 50 years ago, veterans were used as human test subjects for atomic bomb blasts. Then the government tested LSD drugs on others. Then there was the use of Agent Orange more than 30 years ago.

The government should conduct more research into the health effects of DU. The government should admit that many, many more were exposed to DU dust and begin to provide health care as soon as possible -- before it is too late. Thank you.

March 10, 1998

I. INTRODUCTION AND BACKGROUND

Good afternoon, my name is William Quapp, from Starmet Corporation. I have been actively involved in evaluating the management issues associated with depleted uranium hexafluoride since May 1993. At that time and until June 1996, I was employed at the Idaho National Engineering Laboratory. My investigations were performed for DOE Environmental Management Program (EM50). Over these three years, we identified various management options and costs of their deployment. One of the major things we learned is that the management of the depleted uranium inventory must be considered as a system in context with other DOE materials and waste management responsibilities. While the depleted uranium hexafluoride can be processed and useful fluorine byproducts extracted for the recycle value, the residual uranium material – oxide or metal – must be managed as a radioactive material. The fluorine product value will not pay for the total conversion and byproduct management costs. Consequently, DOE must either plan on disposal of the residual uranium materials or identify products that can consume the material and be manufactured at reasonable costs. Additionally, there must be customers for those products. The alternative to products and customers is to manage the depleted uranium as waste.

25-1

The INEL program developed and patented one technology – *DUCRETE Shielding: A Depleted Uranium Concrete* -- which has been considered in the DOE PEIS as a potential use for depleted uranium. However, as will be pointed out later, because of the radioactive nature of depleted uranium, certain policies with respect to eventual disposal must be put in place to remove obstacles and encourage the use of depleted uranium in products.

25-2

As has been shown in studies supported by DOE EM, the current quantity of depleted uranium reasonably matches the required quantity if some of the storage applications were to be implemented. No other economic use has been identified that uses large quantities of material.

COMMENTOR NO. 25: QUAPP, WILLIAM J., P.E. (CONT'D.)
IDAHO FALLS, IDAHO

My remarks today will provide a summary of the INEL findings and provide my recommendations for DOE policies and actions needed to support the depleted uranium recycle applications envisioned in the PEIS for the preferred alternative.

2. DISPOSAL AS WASTE

The INEL studies addressed this issue in a parametric sense using published costs of conversion of UF_6 to oxide and the then current cost of disposal at the Nevada Test Site and Hanford. The studies showed that the potential cost range was somewhere between $3 to $11 billion assuming that either the Nevada Test Site or Hanford could accept the material and dispose of it in shallow land burial. Parameters considered included 1.) disposal as a compacted oxide and as stabilized oxide, 2.) disposal site locations and costs, and 3.) disposal as LLW versus Mixed LLW (RCRA controlled material).

25-3

3. RECYCLE USES

We evaluated recycle uses with the recognition that the depleted uranium is a radioactive material and must be controlled, used, and ultimately disposed of in appropriate nuclear waste repositories. We did not consider uses that would allow unrestricted use and disposal.

25-4

After evaluating numerous concepts (nuclear shielding, flywheels, drill rods, blast shielding, etc.), we concluded nuclear shielding was the only viable use for depleted uranium since it was a controlled nuclear material and will be slightly radioactive forever. Additionally, because of the lower cost of competitive materials, depleted uranium was not an economic alternative for most other applications. Depleted uranium metal makes economic sense when the benefit of its very high density enables a solution that is otherwise not possible with traditional materials (steel, lead, concrete, etc.).

Depleted uranium has been used as metallic shielding in the past for various shipping casks and as shielding for radiation sources. In these applications, depleted uranium was selected because of its higher efficiency for gamma attenuation would allow cask weight limitations and/or size constraints to be met.

We found that one of the biggest impediments to the use of depleted uranium as metal in storage cask shielding applications is the high cost of converting from UF_6 to uranium metal. In a survey performed for DOE by Technics Corporation, the cost was identified to be about $11.70 per kg-U ($5.30 per lb-U) for conversion of UF_6 to metal and casting into a shape. Any forming or machining was additional and was priced at $4.40 to $22 per kg-U. Some cost reductions could be forecast through larger conversion facilities but these would not be expected to be sufficient to dramatically reduce the costs below those cited. Consequently, since casks could be made with conventional materials at lower total cost, we believed that there was no economic application for depleted uranium metal in storage casks.

25-5

This economic reality spawned the invention of DUCRETE Concrete as a potentially economic alternative for using depleted uranium and avoiding the near term investment in disposal. This concept, while not directly cost competitive with conventional concrete, is much cheaper than

14 30

COMMENTOR NO. 25: QUAPP, WILLIAM J., P.E. (CONT'D.)
IDAHO FALLS, IDAHO

using depleted uranium metal and has some performance values that can make it economically competitive to traditional materials on a life cycle cost basis. And, by recycling the material, DOE can avoid declaring the material waste.

4. DUCRETE SPENT FUEL AND HIGH-LEVEL WASTE STORAGE CASKS

1.) DUCRETE Concrete is a technically viable material for spent fuel and high-level waste dry storage casks. Smaller, lighter weight, and more versatile casks can be designed and fabricated. DUCRETE casks can be factory fabricated and shipped to the user facility and re-shipped to the interim storage site or the geologic repository as required.
2.) DUCRETE Storage casks can be developed and deployed at DOE sites, commercial utility sites, the DOE Interim Spent Fuel Storage Site, and for shielding in Yucca Mountain. However, there is no industry incentive to independently finance DUCRETE cask demonstrations. Consequently, DOE must support such demonstration.
3.) DUCRETE Casks are competitive with traditional concrete IF DOE pays for conversion of the UF_6 into the depleted uranium aggregate (UF_6 to UO_2 to aggregate). DUCRETE concrete is not a competitive cask material if the cost for conversion from UF_6 to aggregate must be born by the cask fabricator.
4.) DUCRETE Casks will be acceptable to utilities and other users IF DOE agrees to accept them at end of life in a DOE disposal facility such as the NTS or the Spent Fuel Geologic Repository. Without a predefined disposal option, no commercial utility will accept ownership.
5.) DUCRETE concrete is a stable chemical form of material that meets the disposal criteria of the Nevada Test Site as-is. No further processing would be required for disposal.
6.) When used as shielding in casks or other radioactive material containers, DUCRETE concrete is managed by organizations already licensed to hold nuclear materials. Thus, the institutional control required for handling of depleted uranium is in place.

25-5 (Con't.)

4. TIMELY ACTIONS REQUIRED

Driven by the need for spent fuel storage in the country, many fuel storage actions are underway by both DOE OCRWM and utility organizations. Since a cask demonstration and licensing program could take up to 4 years, if DOE NE is to be successful in its goal to recycle the depleted uranium into nuclear storage products, prompt funding of demonstration cask projects need to be undertaken. If prompt initiation of such programs is not undertaken, the window of opportunity for the deployment of depleted uranium in spent fuel storage casks will have passed. To take advantages of the unique characteristics of DUCRETE cask systems, the cask design must be compatible with other transportation systems being developed. This necessitates early integration of cask design with other parts of the transportation systems.

25-6

5. POLICIES THAT DOE SHOULD ESTABLISH TO ENCOURAGE DEPLETED URANIUM RECYCLING

1. Any product manufactured from depleted uranium after the PEIS ROD should be accepted at the NTS or other DOE site for disposal, provided that,

25-7

COMMENTOR NO. 25: QUAPP, WILLIAM J., P.E. (CONT'D.)
IDAHO FALLS, IDAHO

a) All depleted uranium products submitted to DOE for future disposal be in a chemical and physical which form meets the current Waste Acceptance Criteria at that DOE disposal site, or,
b) DOE shall retain title to the depleted uranium material and, at end of product life, DOE will accept the product for disposal at the NTS provided that the depleted uranium product meets the NTS Waste Acceptance Criteria. *25-7 (Con't.)*

1. The Nuclear Waste Policy Act should be modified to allow disposal of depleted uranium casks or other depleted uranium materials in empty drift space between or other locations within the geologic repository. Presently, the Act restricts disposal of all materials other than spent fuel or high level waste. *25-8*
2. Empty depleted uranium storage casks in sound physical condition should be accepted at the NTS for re-use and at no cost to the owner. DUCRETE spent fuel or high-level waste casks would be very suitable as high integrity containers for the subsequent disposal of various Greater-than-Class C wastes from reactor decommissioning. DOE has responsibility for receiving such future wastes. *25-9*

6. OTHER DOE ACTIONS THAT WILL FACILITATE THE RECYCLE OF DEPLETED URANIUM

1. DOE should stimulate the demonstration of low cost UF_6 conversion technologies to lower the cost of management. Low cost processes to convert the UF_6 to metal or to an oxide are needed to reduce the management cost to DOE and to support any recycle objective. *25-10*
2. DOE should support the development and licensing of DUCRETE storage casks and mandate their use on DOE storage projects where the total system life cycle cost can be shown to be advantageous to DOE. *25-11*
3. DOE can consider the provision of DUCRETE storage casks to utilities for interim storage of spent fuel as partial compensation for being unable to receive spent fuel as required by law. *25-12*
4. DOE should objectively evaluate the use of DUCRETE shielded storage casks for shielding the spent fuel and high level waste packages in the geologic repository as an alternative to operating the repository as a remote handled facility for the 125 year period during emplacement and post-closure monitoring. *25-13*

7. CONCLUSIONS

Fifty years of nuclear activities in the US have left a large inventory of material with both unique and undesirable characteristics. To minimize the future cost of management in an environmentally and economically responsible manner, a system solution is needed to assure that the beneficial attributes of depleted uranium are recognized and used while the negative impacts of being a nuclear material are minimized. *25-14*

During the studies I managed for the DOE, we defined such a system solution where DUCRETE casks were used for spent fuel storage at reactor sites, at the interim storage facility, and for disposal containers in the geologic repository. That concept still appears to me to be the most environmentally responsible solution achievable at the least cost to the US taxpayers.

Subject: Comments requested on "Programmatic Environmental Impact Statement for Alternative Strategies for the Long-Term Management and Use of Depleted Uranium Hexafluoride"

Dear Mr. Bradley:

Remediation of the depleted uranium (DU) storage problem is an important and urgent task of Herculean proportions. My choice of the six options presented is No. 2: **Long-Term Storage as UF_6**—storage of UF_6 cylinders in yards, buildings, or a mine at a consolidated site. This choice has the least potential to pollute the environment with more DU. I suggest that each cylinder of DU hexafluoride should be placed in a permanent overcontainer filled with one atmosphere pressure of an inert gas such as argon to retard corrosion by preventing water vapor and oxygen from entering the containers. The overcontainers should be sealed hermetically and designed to last for 100 years or more. *26-1*

I believe that at this time we as a nation do not possess sufficient wisdom or foresight needed to decide on the final disposition of this enormous stockpile of waste uranium. It would be prudent to wait a few decades more before deciding on a final course of action.

Under no circumstance should DU be allowed in commercially-manufactured consumer goods or be made available to the general public as has been hinted at in a New York Times article by Mathew Wald.[1] He mentions industrial use of DU flywheels to store energy and use as a substitute for lead weights. Elsewhere it has been suggested that DU should be used as ballast in the keels of sailboats. Imagine a long-forgotten sailboat sunk in a storm and unretrievable, its hulk polluting a deep freshwater lake with uranium that slowly becomes soluble and pollutes the water. I became even more convinced that DU should be banned from commercial use when I saw an advertisement for a new driver golf club that contains a sphere of DU metal in its head so that a golf ball can be driven farther. These suggested commercial uses of DU are irresponsible and reckless, and will be dangerous to public health if they are implemented. The average person knows nothing about the technical aspects of uranium or radioactivity and is totally unprepared to deal with this radioactive and pyrophoric material that is highly toxic both chemically and radiologically.[2] Uranium in any chemical form presents significant dangers to health and safety, if it is not handled with scrupulous care. *26-2*

Beginning on the next page, detailed reasons are given why I chose the second alternative.

I would appreciate it very much if you would please add my name to the Depleted UF_6 mailing list. Thank you.

Sincerely,

Leonard A. Dietz

Depleted Uranium Hexafluoride Management Program Office of Facilities
Office of Nuclear Energy, Science and Technology
Department of Energy
Germantown, MD 20874-1290

Dear Mr. Bradley,

We are interested in the Depleted Uranium Hexafluoride Management Program and the safe disposal of this material. Our major interest is in the utilization of the fluorine contained in the depleted uranium hexafluoride.

A number of proposals for the chemical conversion of the UF_6 have been made. At present, the conversion of UF_6 into elemental fluorine and uranium metal proposed by BNFL Inc. appears to be the most promising scheme. The preparation of high value fluorine (F_2) makes the most economic sense. We have had and continue to have discussions with BNFL Inc. about this process and our uses for the fluorine product. Although we do not anticipate any interest in the uranium coproduct this may also be its most desirable form for ultimate use or disposal by others.

27-1

We will continue our discussions and contacts with BNFL Inc. and the Department of Energy. Please do not hesitate to contact us if we be of any help to you in your work on the Depleted Uranium Hexafluoride Management Program.

Programmatic Environmental Impact Statement For Alternative Strategies For The Long-Term Management And Use Of Depleted Uranium Hexafluoride

The Tennessee Department of Environment and Conservation, DOE Oversight Division (TDEC/DOE-O) would like to request an extension on the comment period for the "Programmatic Environmental Impact Statement for Alternative Strategies for the Long-Term Management and Use of Depleted Uranium Hexafluoride." This is an important issue for the State of Tennessee, and we would like additional time to complete a thorough review of this document. An extension of the comment period to May 7, 1998, will be sufficient. Please let us know if this is acceptable.

The Honorable Frederico Pena
Secretary
The United States Department of Energy
1000 Independence Avenue, SW
Washington, DC 20585

Dear Secretary Pena:

We are writing to express our interest in the important work underway at the Department of Energy (DoE) to evaluate strategies for the long-term management and use of depleted uranium hexafluoride. As you know, there are over 1 billion pounds of this uranium enrichment by-product stored at the enrichment plants in Ohio and Kentucky, as well as in Oak Ridge, Tennessee. We are aware that the Department is currently soliciting public comments on a Draft Programmatic Environmental Impact Statement on various uranium hexafluoride management strategies. We commend you for moving to address this health, safety and environmental issue for the employees and neighbors of these facilities. 29-1

One of the options under the consideration by DoE is a technology which can convert uranium hexafluoride to a safe and stable form of uranium suitable for long-term storage, retrievable disposal, or further use. This process is essentially the reverse of the uranium conversion process performed by AlliedSignal in Metropolis, Illinois. The technology, which is being tested through a joint DoE - industry partnership in Metropolis, offers two key benefits.

First, it converts the uranium to a solid, or oxide state, making it safer to store and available for possible future use. Secondly, it captures the Hydrogen Fluoride contained in the uranium hexafluoride which can then be recycled for use in the ongoing uranium conversion process, and for other manufacturing processes such as the production of non-ozone depleting refrigerants. The benefit to DoE and the country is that the danger posed by the existing uranium hexafluoride containers can be removed and the government can be compensated for the value of the captured Hydrogen fluoride. 29-2

We realize that DoE will not make a final decision on a uranium hexafluoride management strategy until early next year. Our hope is that the time between now and then can be used productively to fully demonstrate this technology so its full costs and benefits can be determined. In order for this to happen, DoE funding needs to continue through fiscal year 1999. We hope that sufficient funding for the current fiscal year is available within the Department's FY 1998 appropriation. Please inform us of the current and future funding plans for this

Dear Charles:

I am interested to see that things are moving ahead much as you told us they would, when we were preparing our National Research Council Report, "Affordable Clean Up". [Dr. Fred Schneider and I wrote the chapter on "Disposition of the UF_6".

At the time we saw little to suggest that conversion to metal made any sense, but I see that mentioned as one of DOE's ambitions. I wonder if you are really serious about that.

In your PEIS (Summary version, page S-44) you indicated that DOE is "committed to continuing its support for the development of applications for depleted uranium products and, for as long as is necessary, to continue the safe management of its depleted UF_6 cylinder inventory". Now that position bothers me! We have had this material in storage for 50 years and have been studying options for using the stuff for a large number of those years. Continued storage and study is just a way of avoiding a decision in my opinion. Only DOE would consider such an option!

30-1

I read where the money allotted to DOE clean-up activities is well below that required for expeditious clean-up. But the UF_6 ought to be on the list somewhere, not just relegated perpetually to the future.

Sincerely,

Wesley G. May

Germantown, MD 20874

Subject: Programmatic Environmental Impact Statement for Alternative Strategies for the Long-Term Management and Use of Depleted Uranium Hexafluoride. Summary, DOE/EIS-0269, December 1997.

The Friends of Oak Ridge National Laboratory, an organization of retired and present employees and of others interested in the welfare of the Laboratory and the community, wishes to comment on the referenced PEIS.

Roughly 46,000 cylinders containing depleted UF_6 (not counting 8000 under management of the United State Enrichment Corporation) are stored at the three gaseous diffusion sites, about 4,700 of them in Oak Ridge. Each is partially filled with 10 to 14 tons, solid at ambient temperature, for a total in the neighborhood of 500,000 tons. DOE plans between 2009 and 2020 to convert the material to HF and a solid form of uranium, likely U_3O_8. There is an established market for HF, and the hope is to find beneficial uses for the uranium. Barring the breeding of nuclear fuel, not likely in the next few decades, prospects for use of a substantial fraction of it are dim.

31-1

There does not seem to be agreement in estimates of the costs of conversion, except that they will be large. If we assume for discussion, $3 a pound, net of HF value, a total of about $3 billion would be be required. Quoted current costs for management of the inventory range from fifteen to thirty million/year. If there were no significant risks involved and if the maintenance costs were to track inflation, there would be no particular urgency for getting on with conversion, because interest on the conversion investment would easily exceed present annual outlays. We have serious doubts about both premises.

31-2

COMMENTOR NO. 31: FRIENDS OF OAK RIDGE NATIONAL LABORATORY (CONT'D.)
OAK RIDGE, TENNESSEE

The cylinders are constructed of carbon steel, of nominal thickness 0.312 inches (older ones were of twice this thickness). Although internal corrosion from UF_6 appears small, so long as integrity of containment is maintained, there is abundant evidence of general external corrosion from exposure to the elements, particularly of those in Oak Ridge, which tend to be older. Of more concern, there is pitting and crevice corrosion. Seven of the cylinders are known to have developed cracks, five involving handling, but two from corrosion alone. In these cases, atmospheric moisture has hydrolyzed the uranium hexafluoride to UO_2F_2, which has acted as a seal. The HF produced has dissipated harmlessly, and the contamination of water with soluble uranium compounds has not yet caused serious embarrassment. The benign effects of these failures seem to have lulled policy makers about untoward events during the thirty years projected before completion of conversion to a form safe for indefinite storage. 31-3

However, even if events having serious consequences are discounted, steep rises in the annual costs of custodial care and in the eventual costs of conversion seem inevitable. As corrosion worsens, there will be increasing numbers of breaches requiring patches. The weakening of the cylinders will increase the costs and dangers of handling them in periodic painting or in removing the contents for conversion. If all are to be converted at a single site, more and more will have walls that do not meet the minimum 0.25-inch walls DOE specifies for safe transportation by highway or rail. 31-4

Confidence that there is small risk of more damaging events may be misplaced. The cylinders support about 250,000 pounds force from the atmosphere (25000 in^2 times 10 psi differential). In addition to this evenly distributed stress is that from resting on the surface and, for the bottom layer, from those stacked on top. Many of the cylinders are forty years old. The program to clean and paint the outer surfaces lags deterioration. 31-5

There are a number of conceivable scenarios for catastrophic failures of containment, beyond what uranyl fluoride could seal, from an earthquake or transportation accidents, for example. Over the interval before planned conversion, with the number involved, stacked as they are, collapse in place of some is hard to exclude. If such an event occurred in a wet situation, a dangerous plume of HF could be produced. In Table 6.3 on page 6-17 of the referenced Summary, it is estimated that such a failure might occur in 1 to 10 years under dry conditions; on the next page, the frequency of a more serious accident, involving three cylinders apparently being transported, is given as 1 in 100,000 years under wet conditions. Chemical exposure from the latter is projected to have adverse effects on 1900 of the public, and on 1000 non-involved workers (of which 300 would suffer irreversible effects). With the climate here and the difficulty of reaching cylinders in the middle of storage areas, the 1 to 10 year single-cylinder failure might well occur under wet 31-6

1435

COMMENTOR NO. 31: FRIENDS OF OAK RIDGE NATIONAL LABORATORY (CONT'D.)
OAK RIDGE, TENNESSEE

conditions, perhaps with less, but still unacceptable, effects.

There seems to be general agreement that conversion is eventually necessary. We advocate acceleration. We recommend that conversion begin in Oak Ridge as the pilot. The cylinders here are in the worst condition and are likely most risky to transport. We believe that work should not be delayed until a market for the uranium develops, a long shot at best. We encourage research to lower costs of conversion, but not at the expense of timely action. In the meantime a major overhaul of the cylinder storage situation at Oak Ridge should be a high priority. 31-7

As we understand it, the cylinders are not considered waste, and as a result conversion is not on the table when remediation priorities are set. If funding for conversion is not available in the appropriate category, we believe DOE should rise above administrative barriers and assess the possible problems from the cylinders in comparison with the risks from delays of other remediation projects. 31-8

Respectfully,

William Fulkerson, President

COMMENTOR NO. 26: DIETZ, LEONARD A. (CONT'D.) NISKAYUNA, NEW YORK

Detailed Reasons for Choosing the Second Alternative

Design of the DU Processing Plant and its Containment Efficiency

The processing of DU hexafluoride into uranium oxide or uranium metal requires extensive chemical processing, melting and casting operations. The pyrophoric nature of uranium makes it inevitable that significant quantities of uranium oxide aerosol particles will be formed. There does not have to be an accident at a DU processing plant for the public to be exposed to dangerous concentrations of aerosol micrometer particles of uranium oxide. Exposure can occur from DU aerosol particles released into the atmosphere during normal operations. To illustrate this, we assume that a well-designed and super-efficient processing plant can be built that would contain 99.99999% of all the uranium it processes. In such a plant only 1-gram in 10-million grams of DU would escape into the environment. We examine how this relates to the large amount of DU proposed to be processed from the years 2009 through 2028 and then compare it with an actual experience in New York State.

Using the data given on page S-2, Vol. I, The depleted UF_6 cylinders currently managed by DOE plus the cylinders produced by the United States Enrichment Corporation total approximately 54,422. They contain about 600,000 metric tons of DU hexafluoride. Continued operation of the Portsmouth and Paducah diffusion plants could double this amount by the year 2028. Therefore, the DU hexafluoride that must be processed each year for 20 years beginning in 2009 is approximately 60,000 metric tons, of which two thirds is the element uranium. Thus, it appears that up to 40,000 metric tons of DU will be processed per year.

Containment of DU within the processing facility or facilities will be a major problem, even with the very best technology available. For example, if as postulated, 99.99999% of the DU can be contained successfully, then in 40,000 metric tons of DU processed each year, 4,000-grams will escape at an average rate of 333-grams per month.

26-3

The New York State Experience with a DU Processing Plant

The estimated rate of 333-grams of DU escaping into the atmosphere per month must be compared with the New York State experience with National Lead Industries, a former DU processing plant near Albany, NY. At NL Industries DU was processed into DU metal penetrators for 30-mm cannon rounds and into airplane counterweights made of DU. In February 1980, a court order by NY State citing public health reasons shut down NL Industries for exceeding a NY State Department of Environmental Conservation monthly radioactivity limit of 150 microcuries (387-grams of DU) for airborne emissions. Recently the highly contaminated plant was razed and a large quantity of radioactively contaminated structural material and soil has been prepared for shipment to a disposal site.

The NL Industries plant caused massive contamination to the residential area and commercial properties outside the perimeter of the plant. In 1984, 1985 and 1988 a total of 950 cubic meters of radioactively contaminated soil were removed by DOE from 53 of 56 vicinity properties.[3] My hypothetical super-efficient plant would release 333-grams (129 microcuries) of DU airborne particles per month into the environment. This amount of DU is not significantly different from the 150 microcuries per month limit set by New York State. It is highly unlikely that a release rate of 150 microcuries of DU per month into the atmosphere will ever again be allowed by a local government or by citizens affected by the fallout. The containment efficiency of a DU processing plant would have to

[3]DOE Report No. DOE/OR/21950-888, "Engineering Evaluation/Cost Analysis (EE/CA) for the Colonie Interim Storage Site (CISS) Buildings," June 1993, p. ES-1.

14 36

COMMENTOR NO. 26: DIETZ, LEONARD A. (CONT'D.) NISKAYUNA, NEW YORK

be at least 10 times better than I have assumed, allowing less than 1-gram of DU in 100-million grams (100 metric tons) of DU to escape into the environment. This extremely high requirement may be impossible to meet. The control and containment of DU emissions inside the plant would have to be even more stringent. When processing such huge quantities of DU it will be extremely difficult if not impossible to keep workers inside the plant from becoming contaminated with it.

26-3 (Con't.)

Transport of DU Particles in the Atmosphere

Another serious issue is what happens to the uranium particles that escape into the atmosphere and become dispersed far and wide by wind action. In the fall of 1979 I worked at the Knolls Atomic Power Laboratory in Schenectady, NY. The laboratory was operated by the General Electric Company for the Department of Energy. While troubleshooting a problem for the radiological group, my colleagues and I accidentally discovered DU aerosols collected in environmental air filters exposed at the Knolls site. The source of the uranium contamination was the NL Industries plant in Colonie, 10 miles east of the Knolls site, outside Albany, NY. We also discovered DU in air filters exposed at the Kesselring site in West Milton, NY, where crews for the nuclear Navy are trained, 26 miles NW of the NL plant. This is by no means the maximum fallout distance for uranium aerosols. A radius of 26 miles encompassed an area of more than 2,000 square miles around Albany where this fallout occurred. In January, 1980 I wrote and issued an internal technical report that documents our mass spectrometer measurements.[4] Airborne uranium aerosol particles act like dust and can go everywhere that dust goes. The scientific explanation of how micrometer-size uranium particles can easily travel such large distances when airborne is given in a survey paper that is available on the Internet.[5]

26-4

Use of DU Metal in Large Commercial and Military Airplanes

The use of DU metal counterweights in commercial and military airplanes should be banned. Until about 1980 each Boeing 747 passenger jet contained 1,500 kilograms of DU metal counterweights used for dynamic flight control.[6] In a crash and ensuing intense fire DU metal will begin to oxidize rapidly and sustain slow combustion when it is heated in air at a temperature of 500° C.[6] This can cause DU oxide particles to be formed that can become airborne and poison large numbers of people and their surroundings.[7] This scenario has already happened. In 1977 two Boeing 747s crashed into each other and burned on a runway at Tenerife, Canary Is. In 1988 a Boeing 747, Pan Am Flight 103, crashed and burned at Lockerbie, Scotland. And in 1992 an El Al Isralei Boeing 747 crashed into an apartment building and burned in Amsterdam, Holland.

26-5

Fire and safety personnel exposed to the combustion products of DU are at risk. How many fire and safety emergency crews at airports or in cities have been trained and provided with equipment that will protect them from uranium particles that have been generated in intense fires?

Germantown, MD 20874-1290

Dear Mr. Bradley:

The Illinois Department of Nuclear Safety (IDNS) hereby submits its comments on the Department of Energy (DOE) Preliminary Environmental Impact Statement (PEIS) for Alternative Strategies for the Long-Term Management and Use of Depleted Uranium Hexafluoride (UF6). IDNS applauds DOE's early recognition of Illinois' unique situation relative to this issue and appreciates the opportunity to comment on the Draft. IDNS considers itself a stakeholder in this process for two reasons. Clearly, IDNS is interested in any environmental impacts from changes in the mission of the Paducah Gaseous Diffusion Plant (PGDP) facility because of its proximity to Illinois. However, IDNS is also interested for a reason not reflected in the PEIS; the close proximity to the subject facility of the Allied-Signal Metropolis Works in Illinois. *36-1*

Fundamentally, IDNS supports the general strategy of converting UF6 to more chemically stable forms such as U_3O_8 as soon as possible. We agree that DOE needs a longer-term plan for management of UF6 that goes beyond inspections and repairs of leaking cylinders in storage yards. We also agree with the general strategy of trying to find markets for the by-products of the conversion process, although we have some concerns about radioactive contaminants in these by-products which we will discuss below. *36-2*

The major shortcoming of the PEIS in our view, however, is its failure to recognize that the Allied-Signal Metropolis Works does exist and that there is a reasonably high probability that it will have an important role to play in DOE's UF6 management strategy. DOE must recognize that given Allied-Signal's *36-3*

1439

COMMENTOR NO. 36: STATE OF ILLINOIS, DEPARTMENT OF NUCLEAR SAFETY (CONT'D.) SPRINGFIELD, ILLINOIS

experience in the conversion business and the existing infrastructure at Metropolis, the Metropolis Works may be the only facility in the United States capable of handling the UF6 to oxide conversion at a reasonable cost. *36-3 (Con't.)*

IDNS understands that given the method that DOE generally employs to develop a PEIS, siting issues are not addressed until the second phase of the NEPA approach. However, we feel that the decision to recognize or ignore Allied-Signal, even at this early stage, has significant impact on evaluating the risks and benefits of DOE's management options. *36-4*

Page 2-5 - This section describes the option of long-term storage as depleted UF6. This option is the least desirable from IDNS' point of view. Associated with this option would be all the risks of transportation with none of the benefits of conversion to oxide. We suggest that this option be given no further serious consideration. *36-5*

Section 3.1.7 - The description of the affected environment surrounding the PGDP fails to recognize the presence of the Allied-Signal Metropolis Works as another major uranium processing facility in the immediate vicinity. Allied-Signal's effluent releases and impacts on the environment are thereby not considered in this review. *36-6*

Page 3-14 - The region of influence includes Massac County, Illinois (not Massaic). *36-7*

Page 3.4 - Check the map scale. 3000 km is not roughly equivalent to 2 miles. *36-8*

Table F.2 - If Allied Signal were considered as a site for a conversion facility, most of the health risks and potential benefits would need to be evaluated. Risks and benefits from construction activities would be particularly impacted. While on one hand, ecological and land use impacts would be smaller, economic benefits from increased employment would also be smaller. *36-9*

Page F-11 - Anhydrous HF may have been a valuable product at one time, however, given the glut of UF6 on the market, one questions the value of a product whose primary use is the production of more UF6 from ore. *36-10*

Page F-12 - IDNS is concerned about the depleted uranium content of the anhydrous HF that could be produced by a conversion process. IDNS would be interested in any uncertainties associated with the 1 ppm figure quoted. In any *36-11*

COMMENTOR NO. 36: STATE OF ILLINOIS, DEPARTMENT OF NUCLEAR SAFETY (CONT'D.) SPRINGFIELD, ILLINOIS

case, we do not believe it is certain that the material will have commercial value if it is known to be contaminated at any level.

Table F.25 - We assume that the source of the figures in this table are from (LLNL 1997) which is an estimate based on theoretical considerations. We suggest that actual historical low-level radioactive waste generation figures from Allied-Signal would be more useful. *36-12*

Page J-7 - The failure to consider existing facilities has led to inconsistencies in making assumptions. In Appendix J, the analysis of transportation risks is based on the assumption that the distance between the storage and conversion facilities is 1000 km. However, in Appendix F, it assumed that the facilities are co-located. *36-13*

Questions on our comments should be addressed to Richard Allen, Manager, Office of Environmental Safety at 217-782-1322.

Sincerely,

Thomas W. Ortciger
Director

Dear Mr. Bradley:

Re: Disposition of Depleted Uranium

The only responsible course for the Department of Energy to follow regarding the huge DU inventory is to establish safe, long-term storage of this material, which remains radioactive for what amounts to eternity. *37-1*

DU should definitely NOT be used for military purposes. We must not be responsible for blanketing battlefield areas with this long-lived radioactive material. *37-2*

Sincerely yours,

Lillian Nurmela

COMMENTOR NO. 38: OAK RIDGE NATIONAL LABORATORY (CONT'D.)
OAK RIDGE, TENNESSEE

1. **Retain adequate depleted UF_6 to support the Surplus Plutonium Disposition Program under the "No action alternative" long-term management strategy for depleted UF_6.**

One of the options for dispositioning the surplus weapons-grade plutonium is for use as mixed-oxide (MOX) fuel in light water reactors. A small portion, less than 0.3% of the available supply of the depleted UF_6 (ORNL/TM-13417 Rev. 1), should be set aside and reserved for use in the Surplus Plutonium Disposition Program. The required UF_6 to be removed from inventory is approximately 1400 MT as indicated in ORNL/TM-13466, Rev. 1, which is a Data Report to be released concurrently with the Surplus Plutonium Disposition Environmental Impact Statement.

The depleted UF_6 should be stored at the Portsmouth site since that is the only facility with operating transfer autoclaves for emptying the depleted UF_6 from the 12.7 MT (14 ton) storage cylinders into 2.28 MT (2.5 ton) feed cylinders. The smaller cylinders are required for transporting the depleted UF_6 by truck to commercial conversion facilities where the depleted UF_6 will be converted to uranium oxide and subsequently blended with oxide derived from surplus plutonium to make MOX fuel at a proposed government-owned fuel fabrication facility. The UF_6 cylinders will be selected based on a depleted uranium assay specified by the consortium selected to provide MOX fuel fabrication and reactor irradiation services. The feed requirement for the depleted uranium expected to be required by the Surplus Plutonium Disposition Program is approximately 0.25 wt % as indicated in ORNL/TM-13466, Rev. 1. *38-1*

The PEIS (Section S.5.1 and Section 1.6) acknowledges that other DOE programs, such as the Surplus Plutonium Disposition Program, have requirements for small amounts of depleted UF_6. It is stated that this small fractional requirement of the UF_6 inventory would not affect the selection of a long-term management strategy in the Record of Decision (ROD) to be issued following the publication of the final version of the PEIS. However, the comments under Item 1 above are relevant in that specific cylinders of excess depleted UF_6 should not be considered surplus to all government programs and will be requested to be stored at Portsmouth for potential use in the disposition of surplus plutonium.

COMMENTOR NO. 38: OAK RIDGE NATIONAL LABORATORY (CONT'D.) OAK RIDGE, TENNESSEE

2. **Consider the benefit of using the depleted uranium in geological disposal sites such as Yucca Mountain and the Waste Isolation Pilot Plant (WIPP) under the "Use as Uranium Oxide" long-term management strategy for depleted UF_6.**

Depleted uranium can be used to improve the performance of the repository for disposal of spent nuclear fuel (SNF). Depleted uranium reduces the radionuclide release rate from a SNF waste package and minimizes the potential for long-term nuclear criticality. In this context, the U.S. Nuclear Waste Technical Advisory Panel—the Congressionally-mandated scientific review panel for the DOE Yucca Mountain project— stated (U.S. Nuclear Waste Technical Review Board, *Report To The Congress And The Secretary of Energy: 1995 Findings and Recommendations*, Arlington, Virginia, April 1996):

"The Board suggests that DOE consider increasing the criticality control robustness of the EBS (Engineered Barrier System)... In particular, the use of depleted uranium in filler, invert, or backfill material, or in all three, is a concept the program has not yet explored adequately. Conceivably, increasing the criticality control robustness of the EBS could turn a potentially intractable analysis of external criticality into a comparatively easy one."

38-2

The recommendations of nationally recognized, congressionally-mandated scientific review boards on uses of depleted uranium should be explicitly considered in the PEIS. It is also noted that the Spanish repository program is investigating the use of depleted uranium to improve repository performance. This use of depleted uranium is receiving attention worldwide.

Additional information on this option can be found on pages 8-9 of the paper "Beneficial Uses Of Depleted Uranium," authored by Colette Brown of DOE and Allen Croff and M. Jonathan Haire of ORNL. The paper was prepared for the Beneficial Re-Use '97 Conference held in Knoxville, Tennessee, on August 5-7, 1997.

3. **Expand the discussion in the PEIS of potential "Use Options" of the depleted UF_6, either as Uranium Oxide or Uranium Metal.**

The primary use of the depleted UF_6 discussed in the PEIS, either as uranium oxide used to make high density concrete (Section 2.2.4) or as uranium metal (Section 2.2.5), is as

38-3

1442

COMMENTOR NO. 38: OAK RIDGE NATIONAL LABORATORY (CONT'D.) OAK RIDGE, TENNESSEE

shielding for spent nuclear fuel or high-level waste (HLW) storage containers. The detailed discussion should be expanded to include other options which could potentially use substantial amounts of the depleted UF_6, such as its use in industrial counterweights for forklift trucks. Another potential option would be the use of the depleted UF_6 in the manufacture of casks for low-level wastes (LLW), as recently proposed in a Technical Development Initiative for Fernald. The discussion of each "use option," including the use of the depleted UF_6 as shielding, should address the economic and technical viability of each option since these issues have been challenged in the public hearings for this PEIS held in Paducah and Oak Ridge. Additional information on these options can be found in the paper "Beneficial Uses of Depleted Uranium," referenced in Item 2.

38-3 (Con't.)

4. **Account for the end of life disposal requirement for any application under the "Use Options" for long-term management strategy for depleted UF_6.**

DOE is considering using depleted uranium in the manufacture of casks for spent nuclear fuel or high-level waste (HLW) storage containers. One application is to covert the depleted UF_6 to an oxide which in turn would be used as the aggregate to make depleted-uranium-concrete. The high density of the uranium allows the same shielding effectiveness with approximately half the thickness of conventional concrete. This concrete would then be used to manufacture oxide-shielded casks.

Another option would be to chemically-convert the depleted UF_6 to uranium metal which could be enclosed between the stainless steel shells making up the body of the casks. The uranium metal would be the primary shielding material in the casks which could be reduced in thickness relative to casks using only steel as the shielding material. The PEIS (pages 2-14 and 2-15) states that no assumptions were made regarding the fate of depleted-uranium-concrete casts or the uranium metal casks following use. However, the disposal requirements for depleted uranium at end of life have a major impact on "use options." When the depleted uranium is used for an application such as shielding, at the end-of-life it must be converted into an acceptable waste form. The end-of-life costs to convert depleted uranium into an acceptable form may far exceed manufacturing costs. The consequence of this requirement should be evaluated in the PEIS.

38-4

COMMENTOR NO. 38: OAK RIDGE NATIONAL LABORATORY (CONT'D.) OAK RIDGE, TENNESSEE

5. **Consider disposal of the depleted uranium at the Yucca Mountain repository for spent nuclear fuel and high-level waste under the "Disposal Alternative" long-term management strategy for depleted UF_6.**

The draft PEIS (Section 2.2.6) lists three options under the "Disposal Alternative": shallow-land earthen structures, below ground vaults, and mine disposal. At least two of these three options, shallow-land earthen structures and below ground vaults, do not meet regulatory requirements for protection of public health and safety according to the detailed analysis in Appendix I of the draft PEIS. The detailed analysis within the draft PEIS on page I-23 states:

"The maximum dose to an individual, assumed to live at the edge of the disposal site and use the contaminated water, was estimated to be about 110 mrem/yr, which would exceed the 25 mrem/yr limit specified in 10 Code of Federal Regulations Part 61. Possible exposures (on the order of 10 rem/yr) could occur for shallow earthen structures and vaults if the cover material were to erode and expose the uranium material..."

38-5

The detailed technical analysis within the draft PEIS Appendix I is consistent with the U.S. Nuclear Regulatory Commission (NRC) analysis that near surface disposal of large quantities of depleted uranium is not acceptable (J. W. N. Hickey, *Letter from J. Hickey, Chief Fuel Cycle Safety Branch, U.S. Nuclear Regulatory Commission To Louisiana Energy Services, L.P.*, Docket No 70-3070, U.S. Nuclear Regulatory Commission, Washington D.C., September 22, 1992). It is also consistent with DOE performance assessments for near-surface disposal at specific sites (Martin Marietta Energy Systems, Inc.; EG&G Idaho, Inc.; and Westinghouse Savannah River Co., *Radiological Performance Assessment for the E-Area Vaults Disposal Facility*, WSRC-RP-94-218, Oak Ridge National Laboratory, Grand Junction, CO., 1994). Additional analysis is necessary to determine the viability of mine disposal of the depleted uranium to meet regulatory requirements for protection of public health and safety.

1443

COMMENTOR NO. 38: OAK RIDGE NATIONAL LABORATORY (CONT'D.) OAK RIDGE, TENNESSEE

At the current time, the only facility being planned in the United States that would meet the requirements for disposal of this material is the proposed Yucca Mountain repository for spent nuclear fuel and high-level waste. Because this is the only current option that meets the regulatory requirements for safe disposal of this material, it should be included as a disposal option in the PEIS.

6. **Clarify the "no action alternative" long-term management strategy for depleted UF_6 in the PEIS with the preferred waste form for final disposition of depleted uranium favored by the U.S. NRC.**

The no action alternative as initially announced in the "Notice of Intent" to prepare this PEIS included eventual chemical conversion of the UF_6 to oxide followed by storage. However, after public scoping and internal DOE reviews, it was determined that the no action alternative should consider the continued storage of UF_6 cylinders indefinitely at the three current storage sites, as indicated on page 2-2 of the PEIS. The NRC stated that the preferred waste form for final disposition of depleted uranium is U_3O_8 (J. W. N. Hickey, *Letter from J. Hickey, Chief Fuel Cycle Safety Branch, U.S. Nuclear Regulatory Commission To Louisiana Energy Services, L.P.*, Docket No 70-3070, U.S. Nuclear Regulatory Commission, Washington D.C., September 22, 1992). The NRC, in the referenced license application for the private Louisiana Energy Services enrichment plant, further stated that conversion of the depleted UF_6 to uranium oxides should be done on a specific schedule.

38-6

It is ORNL's recommendation that the two points of view on the storage form of depleted UF_6 be reconciled between the DOE and NRC.

COMMENTOR NO. 39: CITY OF OAK RIDGE, ENVIRONMENTAL QUALITY ADVISORY BOARD OAK RIDGE, TENNESSEE

CITY OF
OAK RIDGE

ENVIRONMENTAL QUALITY ADVISORY BOARD

POST OFFICE BOX 1 • OAK RIDGE, TENNESSEE 37831-0001

April 9, 1998

Charles E. Bradley, Jr.
U S Department of Energy
Office of Nuclear Energy, Science and Technology
Office of Disposition Technologies
19901 Germantown Road
Germantown, MD 20874

Dear Mr. Bradley:

Members of the Environmental Quality Advisory Board (EQAB) have reviewed the Draft Programmatic Environmental Impact Statement for Alternative Strategies for the Long-Term Management of Depleted Uranium Hexafluoride (DOE/EIS-0269). The City of Oak Ridge has a strong interest in the future management of the DOE depleted uranium hexafluoride (UF_6) inventory, since about 10% of this inventory is stored at the East Tennessee Technology Park (ETTP, formerly K-25 Site) in Oak Ridge.

As explained in the draft programmatic environmental impact statement (PEIS), the continued storage of depleted hexafluoride in steel cylinders in outdoor storage yards does not pose an imminent threat to workers, public, or the environment. However, continued safe storage requires an ongoing program of surveillance and maintenance, and the job of assuring safe storage will become more difficult as time passes. Furthermore, the continued presence of this material at the ETTP may adversely affect ongoing site reuse initiatives, both by presenting a negative aesthetic image to prospective ETTP tenants and by preventing new uses of the areas occupied by cylinder storage yards. 39-1

EQAB members support the concept, embodied in most of the alternatives considered in the PEIS, of converting the depleted UF_6 to a more stable form (either uranium oxide or metal) that would be suitable for long-term storage, reuse, or disposal. However, we think the timetable for action that is presented in the PEIS is much too slow. Instead of waiting until 2009 to start converting this material (and finishing the job in about 2028), DOE should act now to start the conversion process as soon as feasible. (There appear to be no technical barriers to starting the conversion process.) The Oak Ridge Gaseous Diffusion Plant operated for about 40 years (1945 to 1985), the federal government owes it to this community not to wait an additional 43 years (1985 to 2028) to deal responsibly with the byproducts of gaseous diffusion. 39-2

Thank you for the opportunity to review and comment on this document.

Sincerely,
For the Board

Gerald L. Paleu

Gerald L. Paleu

COMMENTOR NO. 40: DORTCH, JOTILLEY PADUCAH, KENTUCKY

4205 Buckner Lane
Paducah, KY 42001
7 April 1998

Charles E. Bradley, Jr., Program Manager
Depleted Uranium Hexafluoride Mgmt. Program
Office of Facilities (NE-40)
Office of Nuclear Energy, Science and Technology
U.S. Department of Energy
19901 Germantown Road
Germantown, MD 20874-1290

Dear DOE Representatives:

A PEIS for UF_6 strategies and management must take all available information on the subject into consideration. This PEIS does not cite the following:

1. "Draft Preliminary Report - DOE Independent UF_6 Cylinder Assessment Team"; DOE draft; 25 Mar 1992.
2. "Integrity of Uranium Hexafluoride Cylinders" ONFSB Technical Report; 5 May 1995. 40-1
3. "Affordable Cleanup? — Opportunities for Cost Reduction in the Decontamination and Decommissioning of the Nation's Uranium Enrichment Facilities"; National Research Council; 1996.

Why weren't these studies used as a basis for addressing this problem and its solutions?

The above-ground cylinder storage is risky. There are many styles of containers of varying wall thicknesses. Rust, both visible and under the paint, has weakened many. Improper storage — too close to the ground, too close together to be inspected all around, stacking incompatible styles, damage to cylinders in transport all add to the danger. Leaky or degraded valves and cylinder ID tags missing or unreadable are a problem. 40-2

How full the cylinders are presents another problem. Many were filled before the current limits were 40-3

COMMENTOR NO. 40: DORTCH, JOTILLEY (CONT'D.) PADUCAH, KENTUCKY

established.

The geology of the area at PGDP includes high risk earthquake zones. It is not a stable place to store or reprocess UF_6. It is not a good place to store the product until a market opens up or a use is discovered". 40-4

A viable long-term solution is to convert the cylinder contents to U_3O_8, a more stable oxide that can be reconverted if the need arises. France does this very thing. 40-5

The problems that have surfaced since we have come off the "production-at-all-cost" mentality do not need bandaids. They need real and permanent solutions based on sound technology and upon sound geologic grounds. 40-6

Sincerely,
jotilley dortch

14th April 1998

Dear Ched,

Please find enclosed the BNFL response to the draft PEIS. The response document is an amalgamation of expert opinion within the Company from those with experience of various aspects of depleted hex tails processing, storage and disposition. The responses are presented as general comments or specific to the appendices of the PEIS.

You will note that one of the main concerns that we have is the omission of an option for depleted uranium metal as a medium for long-term storage/disposal. As you are aware the technology BNFL is currently developing to process our own tails has as products, uranium metal and fluorine gas. BNFL's view is that uranium metal is feasible for long-term storage and disposal and could have clear cost and environmental advantages. This has not been adequately recognised or assessed in the report. 41-1

If you have any queries about the BNFL comments, please contact me or Marilyn Meigs at BNFL Inc.

Yours sincerely

COMMENTOR NO. 41: BRITISH NUCLEAR FUELS PLC (CONT'D.)
RISLEY WARRINGTON CHESHIRE, UNITED KINGDOM

COMMENTS ON THE DRAFT PROGRAMMATIC ENVIRONMENTAL IMPACT STATEMENT FOR ALTERNATIVE STRATEGIES FOR THE LONG TERM MANAGEMENT AND USE OF DEPLETED URANIUM HEXAFLUORIDE

A Note by BNFL plc

GENERAL COMMENTS

1. BNFL supports the strategy of safe storage as UF_6 pending the development of suitable uses. These uses would be most likely within the nuclear fuel cycle. *41-2*

2. The Engineering Analysis has several significant omissions and inaccuracies which although unlikely to affect the overall environmental impact, could weaken the conclusions of the PEIS and the Cost Analysis. *41-3*

3. The approach taken for the assessment of the environmental impacts arising from the various management options is good and the methodologies are suitably transparent to scrutiny. However, there are a number of general areas where the assessment methodologies could be improved and these are detailed below. *41-4*

4. The methodologies used in the Cost Analysis are considered to be sound. However the report is based on the Engineering Analysis and the comments made for that report will also have cost implications and might alter the conclusions of the Cost Analysis. In particular, the basis for the revenues or credits for the sale of AlIF, CaF_2 and radiation shields require robust justification. *41-5*

5. Long-term storage as uranium metal has not been analysed even though it was a feasible recommendation in the Technology Assessment Report and there are significant volume and cost benefits which might make the economics of this route more attractive than U_3O_8 or UO_2. *41-6*

6. Disposal as uranium metal has not been analysed even though it was a feasible recommendation in the Technology Assessment Report and there are significant volume and cost benefits which might make the economics of this route more attractive than U_3O_8 or UO_2. The PEIS shows that reducing the volume of the material disposed significantly reduces the impacts on the environment, suggesting that uranium metal, which has the minimum volume, would minimise the environmental impacts. Although current DOE Orders restrict such disposal, there is no equivalent restriction at the commercial disposal sites. *41-7*

7. The environmental impacts of disposing of, or recycling, the products containing uranium metal or oxide at the end of their useful life should be analysed. *41-8*

Detailed comments are presented below.

1446

COMMENTOR NO. 41: BRITISH NUCLEAR FUELS PLC (CONT'D.)
RISLEY WARRINGTON CHESHIRE, UNITED KINGDOM

COMMENTS ON THE ENGINEERING ANALYSIS

General

The Engineering Analysis uses conservative assumptions resulting in excessive rather than realistic costs and tending to preclude meaningful comparison of the options. Examples are: taking 7 years to build a facility, not considering use of several existing facilities in the USA, and the high projected manning levels. *41-3 (Con't.)*

Transportation Module

Cylinder Preparation for Shipment

The suggestions for the Pre-transport Preparations of UF_6 Cylinders appear to be compliant with the recommendations in IAEA Safety Series 6, 7, 8, 37 and 80.

An overcontainer used for a cylinder which does not meet DOT requirements would need to contain any leakage from the cylinder. To achieve this, the overcontainer would need to meet the requirements of a Type A Package, as defined by the IAEA. An overcontainer "slightly bigger than the cylinder" which meets DOT regulations may not achieve this. It would be more prudent to plan for the transfer of the UF_6 to a new cylinder to cater for the instance of an over-pressure and damaged cylinder which could not be transported even in an overcontainer. *41-9*

The engineering required to deal with some of the severely degraded cylinders has been underestimated. It is not reasonable to assume that these cylinders can be placed into overcontainers nor that their contents can be transferred in the manner described. *41-10*

Accidents considered for the Cylinder Preparation Options involving cylinders of solid UF_6 assume releases of UF_6 in dry conditions and HF in wet conditions (rain). Accidents involving UF_6 vapour assume releases of UO_2F_2 and HF. Releases of any physical form of UF_6 result in reaction with water vapour in the air, producing UO_2F_2 and HF vapour. The PEIS therefore has underestimated the impacts of such accidents. *41-11*

COMMENTOR NO. 41: BRITISH NUCLEAR FUELS PLC (CONT'D.)
RISLEY WARRINGTON CHESHIRE, UNITED KINGDOM

Emptied Cylinder Treatment

The residue remaining after the cylinder has been washed out and the water has evaporated will be UO_2F_2, rather than a "mixture of uranium and fluorine".

The cleaned cylinders could be cleaned further and monitored for free-release, or could be recycled to fabricate other containers for use in the nuclear industry. *41-12*

Conversion Module

The vast majority of process and other buildings use reinforced concrete in their construction. The use of reinforced concrete for the conversion process buildings cannot in itself be considered a safety feature. *41-13*

Control of HF vapour by limiting the temperature of the building will not work. The vapour pressure of HF at 32°F is nearly half an atmosphere so even at this low temperature HF will vaporise quite quickly. Control of vapour in the manner described is analogous to saying that a cup of coffee does not give off water vapour because it is below the boiling point of water. *41-14*

Upgrading the concentrated HF as described in both the U_3O_8 and UO_2 options will produce approximately equal quantities of azeotropic HF, a highly corrosive liquid, and AHF. The azeotropic HF has relatively little value, and no disposal or use route is described. However, the reduction of UF_6 to UF_4 with hydrogen or cracked ammonia to produce metal does indeed produce just anhydrous HF as a by-product. *41-15*

U_3O_8 Option

A dry conversion process could produce dense U_3O_8 *41-16*

UO_2 Option

UO_2 is a metastable oxide which could react with oxygen or air to form U_3O_8 with an increase in volume. *41-17*

COMMENTOR NO. 41: BRITISH NUCLEAR FUELS PLC (CONT'D.)
RISLEY WARRINGTON CHESHIRE, UNITED KINGDOM

Sintering in a hydrogenous atmosphere is required to achieve the densities quoted (9 gm/cc). The hazards associated with hydrogen have not been addressed. *41-17 (Con't.)*

Uranium Metal Option

A continuous metallothermic reduction process produces a uranium/iron compound with a lower melting point than that of pure uranium, allowing the operating temperature of the process to be lower. This is necessary to control the magnesium evaporation rate since magnesium has a significant vapour pressure at temperatures well below the melting point of pure uranium. The uranium/iron compound is much less dense than uranium metal and would be a relatively inefficient gamma radiation shielding material. The two metallothermic reduction processes are not therefore equivalent for the production of metal for use and should not be compared. *41-18*

The Unlikely Accident during Conversion to Metal "Uranium metal fire" would be better described as a conventional fire causing some oxidation of the adjacent uranium derbies. The large size of the uranium derbies would prevent them from catching fire. *41-19*

Pressurisation of the metallothermic reduction vessel caused by vaporisation of excessive magnesium has not been considered. This should be a "Likely Accident". *41-20*

The estimated quantity of uranium released to atmosphere from the conversion facility is very small given the throughput of the facility. *41-21*

Use Module

For shielding gamma radiation, it is not only the material's density which makes it an effective shield, but, as in the case of uranium, a high atomic number is also significant. There are alternative dense metals such as tungsten for applications which need solely high density and mass: in such applications, uranium is usually preferred only when particular mechanical properties are required in addition to density. *41-22*

The number of UO_2 shielded casks and the number of uranium metal shielded casks seem to be derived by dividing the weight of uranium in the tails UF_6 by the weight of uranium in each cask. This number should be compared with the number of casks needed by the US nuclear power program for the storage/disposal of irradiated fuel.

Uranium metal is a much more effective gamma shield than UO_2, and so more spent fuel could be loaded into each metal-shielded cask, thereby reducing the transport and final disposal costs of the spent fuel. *41-23*

COMMENTOR NO. 41: BRITISH NUCLEAR FUELS PLC (CONT'D.)
RISLEY WARRINGTON CHESHIRE, UNITED KINGDOM

The proposed method of fabricating the casks with uranium metal shielding is not practicable and is hazardous. Molten uranium forms low melting point eutectics with Fe, Cr and Ni, therefore the molten uranium will dissolve the steel shells, liberating large quantities of heat and resulting in a major spillage of uranium. There are, however, other, methods available to fabricate casks from depleted uranium that do not have these safety problems

41-24

No reason is given why solidified ash waste from the facility producing uranium metal shielding components should require disposal in a special cell or mine.

41-25

The estimated quantity of uranium released to atmosphere from the manufacturing facility is very small given the throughput of the facility.

41-26

The release from accidental mishandling/drop of drum/billet inside the plant should be more for the oxide case than the metal case since the oxide is at this stage a loose and powdery material and the metal is in massive billet form.

41-27

The chemical form of a release due to failure of a uranium metal furnace should be U_3O_8 and not UO_2.

One factor which limits the useful market for uranium is its radioactivity which means that at the end of life it cannot be disposed of by the user in a straightforward manner. The Engineering Analysis considers the manufacture and use of the depleted uranium in both oxide and metal forms for the shielding of spent nuclear fuel. However there is only a disposal route defined for the oxide form since uranium metal is not considered suitable for disposal. The environmental impacts of disposing of, or recycling, the products containing uranium metal or oxide at the end of their useful life should be analysed, including impacts from disposal of the shielding with the spent fuel still in it.

41-28

Long-Term Storage Module

Recommendations from the Technology Assessment Report to store the uranium as metal have not been analysed even though they were considered feasible. Storage of bulk metal does not produce metal flakes so the pyrophoricity issue is not relevant. Corrosion of uranium metal by moisture can produce hydrides in the metal, but these are only a hazard if oxygen (or air) are excluded. The possibility of an explosion if the hydrogen from corrosion is collected in closed containers only arises when the containers are opened and air is admitted. Storage of bulk uranium metal in a building in air, as opposed to closed containers, is entirely practicable and safe. Should the consequent slow corrosion be

41-29

1448

COMMENTOR NO. 41: BRITISH NUCLEAR FUELS PLC (CONT'D.)
RISLEY WARRINGTON CHESHIRE, UNITED KINGDOM

unacceptable, it is feasible to consider development and application of a protective coating.

In a response to a comment on the storage of uranium in forms other than oxide, received during the scoping process for the PEIS, it was stated that "the rationale for the selection of these chemical forms for analysis will be presented in the PEIS". The same response questions the suitability of uranium metal, as opposed to uranium oxide, for storage on the grounds of "higher conversion cost, lower stability and uncertainty of the suitability of the metal form for eventual disposal". The Engineering Analysis, Cost Analysis and PEIS fail to justify any of these assertions. No account is taken of the introduction of new technologies which would produce uranium metal at significantly lower cost.

41-30

Disposal Module

Using 30 gal drums for UO_2 disposal is not an optimum solution. There are no real reasons why 55 gal drums (about 2,000kg weight) cannot be used and handled efficiently. This would reduce the number of drums to be disposed with consequential lower environmental impacts.

41-31

Recommendations from the Technology Assessment Report to dispose of the uranium as metal have not been analysed even though they were considered feasible. Uranium metal is accepted at commercial disposal sites in the USA, and there are no NRC regulations which would prevent such disposal. The DOE Orders which specifically exclude fluorides and metal from the Nevada Test Site and Hanford should be comprehensively reviewed to identify the adverse consequences/impacts, if any, which lead to the dismissal of U metal as a suitable form for disposal.

41-32

The U oxides are stated to be the preferred forms for disposal because of their stability and slow dissolution rates in water. Uranium metal is slow to dissolve in water, and therefore should be considered for disposal especially when the much smaller volume of metal is taken into consideration.

41-33

The reduced volume of the uranium metal would significantly reduce the impacts on the environment as the PEIS shows that most environmental impacts tend to be proportional to volume. The observations that impacts for the denser UO_2 are less than for U_3O_8, and the impacts for ungrouted wasteforms are less than for grouted wasteforms because the volumes are lower (about 50%) should enhance the case for disposal as U metal because metal volumes will be even lower. Disposal as U metal blocks would not involve grouting and would therefore also have lower environmental impacts through the avoidance of the long term effects of grouting.

41-34

COMMENTOR NO. 41: BRITISH NUCLEAR FUELS PLC (CONT'D.)
RISLEY WARRINGTON CHESHIRE, UNITED KINGDOM

It is not correct to describe surface oxidation of U metal as "similar" to HF formation from reaction of uranium fluorides with water. The consequences of the two are very different. *41-35*

COMMENTS ON THE PEIS METHODOLOGY

Areas where the Assessment Methodologies could be improved

The treatment of uncertainty in any kind of assessment methodology is a vital issue, especially where generic (non site specific) settings have been used. The uncertainties in the input parameters and assumptions in conceptual models, and their effect on the predicted consequences, need to be determined, usually by a sensitivity analysis technique. Measures can then be taken to reduce the uncertainties.

Uncertainty has been recognised as important in the PEIS but little has been done to analyse the issue. Instead, assumptions have been made with the intention that the various anticipated environmental impacts result in conservative rather than realistic estimates. As it turns out, in most cases (except groundwater contamination in the disposal option) the impacts are still low enough to be acceptable. However, this approach tends to obscure meaningful comparison between the alternatives and is not always appropriate. When a management option and suitable site are chosen, the environmental impacts for that site should be assessed on a realistic basis. *41-4*

One exception to this conservative approach is the assumption that manufacture of shielded containers would bound any impacts associated with other products. In this case, the shielded containers are as large a product as can be reasonably imagined. Smaller products would require more operators per unit weight of uranium processed, and would be less self-shielded, giving much larger total involved worker doses.

Radiation and chemical effects are analysed by considering the maximally exposed individual (MEI) in three groups, "involved workers", "noninvolved workers" and "members of the general public". However, no account seems to have been taken for cumulative exposures between groups (the MEI in the involved worker group could also be the MEI in the general public group if he/she lives near the site). This approach has resulted in some anomalies, such as in the case of the manufacturing facility where the MEI radiation dose and hazard index of a member of the general public are predicted to *41-36*

1449

COMMENTOR NO. 41: BRITISH NUCLEAR FUELS PLC (CONT'D.)
RISLEY WARRINGTON CHESHIRE, UNITED KINGDOM

be greater than those for a noninvolved worker, under normal operating and certain accident conditions. A preferable approach would be to use a larger number of critical exposed groups, chosen to be mutually exclusive.

The chemical and radiation risk to the MEI for the involved worker group during normal operations has not been quantified. The reason given is that worker activities are uncertain at this stage. However, uncertainties such as this have not stopped the authors from making conservative assumptions in order to quantify environmental impacts in many other areas of the PEIS. The PEIS approach must be consistent. *41-36 (Con't.)*

The impacts to the involved workers of clearing up from the assumed accidents have not been considered. The amount of material released inside the plant which the involved workers would have to clean up is likely to be significantly more than the amounts quoted in the PEIS, which are presumably the amounts released to the environment outside the process buildings. *41-37*

The environmental impacts due to human intervention (deliberate and inadvertent) do not appear to have been addressed. While human intervention is most applicable for the disposal option (post-closure phase), where mining and construction activities could bring material back to the surface, there are also human intervention scenarios plausible for all of the other options. No mention is made of any institutional controls likely to be in place to help prevent such occurrences. Assessment of the risks resulting from human intervention is usually carried out by an expert elicitation process to determine the probability and consequences of various human actions. *41-38*

The environmental impacts due to the disposal of secondary wastes such as MgF_2 from the conversion options have not been fully addressed. The only impact addressed is the extra burden on the capacity of the disposal sites and the environmental impacts due to the construction of new disposal sites to cope with the increase in demand. The post-closure impacts of such sites are not addressed in the PEIS. *41-39*

The prediction of groundwater contamination is highly site specific. Most of the calculations in the PEIS connected with this issue have to make large assumptions over the geochemical and hydrological characteristics of generic sites and the value of environmental impacts calculated in this way is questionable. Only site-specific data should be used when calculating risks from a groundwater pathway. *41-40*

Specific Comments on the Storage Option

COMMENTOR NO. 41: BRITISH NUCLEAR FUELS PLC (CONT'D.)
RISLEY WARRINGTON CHESHIRE, UNITED KINGDOM

Cylinder yard doses do not seem consistent with a strict care, maintenance and inspection regime. Portsmouth at 2mSv (196mRem/yr) is most realistic. (probably plausible if a large number of personnel are used, and/or remote inspection equipment or shielding is implemented) *41-41*

Assumption of 0.0041 breaches per cylinder move (Appendix B Section B3) would result in 2 x(28351+13388+4683)X0.0041 = 380 breaches if all containers were moved for painting. This does not seem consistent with number of breaches quoted in Table B1. *41-42*

Comprehensive wall thickness testing at time of refurbishment would aid future decision making. However corrosion rates will be difficult to estimate if initial wall thickness is unknown. *41-43*

Thorough inspection, testing and painting will result in high doses potentially. *41-44*

In the event of aircraft crash on any of the UF_6 storage areas, the environmental impact would be far greater than for any storage option e.g. UO_2. *41-45*

Uranic oxide powders stored in 200 litre drums expose operators to higher dose rates than UF6 cylinders. Thin drums are stored indoors to prevent corrosion but periodic inspection is required. *41-46*

Specific Comments on the Disposal Option

There is no description of the methodology used for estimating post-closure risks for the UF_6 disposal option in the PEIS. *41-47*

The term "indefinite period" needs to be defined in the context of monitoring and maintaining a disposal facility post-closure. Monitoring and maintenance in perpetuity is not a realistic scenario. *41-48*

The impact of post-closure peak doses from uranium daughters at 1,000 years is not sufficiently long since peak doses from uranium daughters occur much later. A more reasonable assumption would be 10^6 years. *41-49*

The PEIS finds that groundwater contamination in the post-closure phase of a disposal site in a wet location could lead to both the radiation dose to the public exceeding *41-50*

/450

COMMENTOR NO. 41: BRITISH NUCLEAR FUELS PLC (CONT'D.)
RISLEY WARRINGTON CHESHIRE, UNITED KINGDOM

regulatory limits and the concentration of uranium causing adverse health effects. These effects are dismissed by stating that the water could be treated or an alternative source used. Given that this is one of the few instances in the PEIS that such limits are exceeded, this is neither a scientific nor a publicly-reassuring stance and does not fit in well with the general environmental impact assessment approach used in the PEIS. This is an example where the PEIS would have benefited from utilising a full treatment of uncertainty/sensitivity analysis to give realistic rather than conservative estimates. *41-50 (Con't.)*

Vaults appear to perform less well than shallow trenches in terms of human health impacts. Does this imply that vaults should be dismissed in favour of shallow earthen structures? Some clarification is needed as to the reasons why "...the concentrations from the vault would be greater than those from shallow earthen structure by a factor of 1.2". *41-51*

General Comments

In summary, I agree with the DOE's position that depleted UF_6 can and should be reprocessed into either a uranium oxide or uranium metal form for use in commercial or industrial settings. The American public, whether they cared to or not, has spent significant funds during the last 50 years on the mining, milling, processing, and enrichment of uranium. It would be economically negligent to reprocess and dispose of depleted UF_6 into a form and location, respectively, that can no longer be of use or benefit to American citizens or industry. Such a process would also be in contrast with America's recognition of the value of recycling valuable raw materials. 42-1

The Draft PEIS is relatively complete and informative. I do have several specific comments as noted below:

Comments related to Volume II, Appendix E

1 Why not ship all casks in clamshell cases? 42-2

- A. No UF_6 transfer facility would be needed, which would reduce potential environmental impact and permitting activities.
- B. The use of clamshell cases could possibly reduce the number and cost of ultra-sonic wall thickness tests
- C. Clamshell case costs would not go up if a local facility is used to process UF_6 (i.e. it may be more economical to build 2 or 3 facilities near each gaseous diffusion plant.)
- D Public perception would be more favorable toward the DOE if the DOE shows demonstrated caution by using clamshell cases. The DOE's decision tree would be reduced by one layer, and one area of judgment/opinion would be eliminated
- E. Accident scenarios would decrease with regard to potential environmental and health impacts.

1451

COMMENTOR NO. 42: KARPIN, TIMOTHY L., CHMM (CONT'D.)
DAVIS, CALIFORNIA

- F. Consider modifying nearby runways and flying MD-17s in and out with clamshell cases (MD-17s are civilian versions of the new C-17 military transport). Of course, an economic study would be required to validate this concept.
- G. The costs and energy/resource consumption of a transfer facility would be very high in comparison to clamshell case use.
- H. One important issue was not directly discussed. You would need a separate facility or partitioned area at the UF_6 processing facility to decontaminate the clamshell cases (if necessary).

42-2 (Con't.)

Thank you for allowing me the opportunity to comment on this document. Good luck on the final version.

Sincerely,

Timothy L. Karpin

COMMENTOR NO. 43: VERSGROVE, TOM
POMONA, ILLINOIS

Charles Bradley
US DOE (NE-40)
19901 Germantown Rd
Germantown, MD 20874

April 13, 1998

Dear Mr. Bradley,

These are the comments of the undersigned on the Depleted Uranium cylinders DPEIS. There are some 50,000 plus cylinders of the DUF6 containing from 10 to 14 tons of material apiece currently stored in the three sites, Paducah, Portsmouth, and Oak Ridge.

The scope of the DPEIS is inadequate to cover the activities required to deal with the cylinders. Implementing either of the conversion alternatives will trigger a series of events which will have to take place in order to complete the conversion. These include building factories to do the conversion and for cleaning the highly radioactive residues out of the emptied cylinders. The DUF6 will have to be defluorinated, which is a highly dangerous activity. The converted material and the empty cylinders will have to disposed or stored, as will the hydrogen fluoride which is separated from the DUF6. 43-1

These activities are all connected actions which require a hard look in combination with the ongoing cleanup activities at the three facilities where the cylinders are stored - Paducah, Portsmouth, and Oak Ridge. There are clearly cumulative effects from these proposals and projects which are not adequately addressed in the draft. 43-2

Although the largest majority of cylinders, some 40,000, are at Paducah, they are inadequately stacked and stored presently. These are vulnerable to the high seismic risk at Paducah from the New Madrid fault. Because it will be decades or longer before this material can be converted, the risks from earthquake damage go greater as time goes on. Any conversion facilities planned for Paducah have to fully consider the earthquake potential at Paducah, and any construction of conversion facilities at Paducah would have to be made to an earthquake standard. The extra costs of this need to be disclosed. 43-3

If cylinders are going to be transported for conversion, then the risks transportation needs to be considered carefully. This would require many thousands of shipments. Many of the older cylinders may not be capable of being lifted or loaded for transportation. Some may not be able to be heated to be emptied. All of these problems could significantly increase the cost. The DOE needs to be more up-front about the real dollar costs of this problem. 43-4

Although it appears that the best alternative is converting the material from the reactive UF 6 form to the more stable uranium oxide form, the DPEIS doesn't give enough information for the commentors to decide where the best place for conversion would be and the best methods. 43-5

Finally, it seems ill-advised to continue to fill more cylinders daily with more DUF6 while this huge problem of disposal continues to accumulate. If the nuclear industry cannot manufacture its product without creating such huge amounts of toxic waste, it should strongly consider ceasing production. 43-6

Thank you for considering these comments.

Sincerely,

Tom Versgrove

COMMENTOR NO. 45: DONHAM, MARK & HANSON, KRISTI BROOKPORT, ILLINOIS

.harles Bradley
Office of Facilities (NE-40)
US Dept. Of Energy
19901 Germantown Rd.
Germantown, MD 20874

April 5, 1998

Dear Mr. Bradley,

These are the comments of the undersigned on the Depleted UF6 Draft PEIS.

(1) We are concerned about the failure of DOE to reference or mention the 3 studies and/or reports which specifically address the cylinder problem. These are "Draft Preliminary Report - DOE Independent UF6 Cylinder Assessment Team", from the Oak Ridge Field Office, Mark 25, 1992; "Integrity of Uranium Hexafluoride Cylinders" and "Affordable Cleanup? - Opportunities for Cost Reduction in the Decontamination and Decommissioning of the Nation's Uranium Enrichment Facilities", National Research Council, National Academy Press, 1996. 45-1

(2) One of the first key issues which must be addressed is the earthquake risk at Paducah from the New Madrid fault/rift zone. Any strategy for dealing with the cylinders has to address this problem, as well over half the cylinders are in Paducah. Most of these cylinders are stored on soils with liquefaction potential. Due to the close stacking of the cylinders, and the configuration of the stacks, breach of cylinders due to puncturing from other cylinders in the event of a seismic event strong enough to move he cylinders is probable. Any punctures in the cylinders would result in .he slow release of hydrogen fluoride and uranium and other radionuclides, which would then accelerate the further corrosion of the cylinders. 45-2

Because the tens of thousands of cylinders are stacked in a configuration which makes it virtually impossible to access cylinders in the center of the stacks in a timely fashion. These factors are why the seismic risk at Paducah has to be considered in any long term strategy to deal with the cylinders.

(3) In considering the long term seismic risk at Paducah and its effect on cylinder management, the first question to ask is, will any future conversion/storage take place at Paducah. If the answer is yes, and if the plans are to bring cylinders in from Portsmouth and Oak Ridge, then these facilities have to be built to highest earthquake standards available. In addition, transportation risks from Portsmouth and Oak Ridge to Paducah must be considered.

If the answer is yes, but only for the Paducah cylinders, then either three conversion facilities will have to built or the facility will have to be mobile, which means it will have to be transported contaminated or will have to be completely decontaminated. None of these alternatives is looked at in the PEIS. 45-3

If the answer is no, there will not be conversion/storage at Paducah, then the massive transportation burden to get the 40,000 cylinders at Paducah, some of which it is doubtful could be moved, from Paducah to wherever the conversion/storage would take place. This is not considered properly in the .EIS.

Connected Actions/Cumulative effects

(4) To determine the scope of environmental impact statements, agencies shall consider 3 types of actions, 3 types of alternatives, and 3 types of 45-4

1453

COMMENTOR NO. 45: DONHAM, MARK & HANSON, KRISTI (CONT'D.) BROOKPORT, ILLINOIS

impacts. They include: (a) Actions (other than unconnected single actions) which may be: (1)Connected actions, which means that they are closely related and therefore should be discussed in the same impact statement. Actions are connected if they: (i) Automatically trigger other actions which may require environmental impact statements. (ii) Cannot or will .otproceed unless other actions are taken previously or simultaneously. (iii) re interdependent parts of a larger action and depend on the larger action for their justification. (2) Cumulative actions, which when viewed with other proposed actions have cumulatively significant impacts and should therefore be discussed in the same impact statement. (3) Similar actions, which when viewed with other reasonably foreseeable or proposed agency actions, have similarities that provide a basis for evaluating their environmental consequences together, such as common timing or geography An agency may wish to analyze these actions in the same impact statement. It should do SO when the best way to assess adequately the combined impacts of similar actions or reasonable alternatives to such actions is to treat them in a single impact statement.

It is clear that the UF6 DPEIS is inadequate in both its scope and its cumulative effects analysis, and that this flaw is serious.

Certain alternatives for dealing with the DUF6 cylinders are provided in the DEIS. Those alternatives include conversion to Uranium oxide, conversion to uranium metal, and long term storage. 45-4 (Con't.)

In order to convert to either uranium metal or uranium oxide, several unavoidable, connected steps must be undertaken. These include (1) building the facilities which will empty the cylinders and convert the DUF6; (2) the ylinders will have to be moved to the facility; (3) the material will have .o be defluorinated; (4) the emptied cylinders will have to be washed and dealt with, and a wastewater treatment plant will need to be built to treat the effluent, which will contain small amounts of transuranics; (5) the hydrogen fluoride will have to be placed into cylinders and stored or disposed, which will require facilities; (6) the empty DUF6 cylinders will have to be dealt with; (7) the converted material will have to be disposed or stored.

If one of the conversion alternatives is chosen as the preferred alternatives, there is no avoiding any of the above steps. These are all clearly "connected actions" as described above. Yet, the DEIS defers analysis of the effects of the conversion process until a future NEPA document. This future NEPA analysis would come at a time when a decision has already been made committing to one of these alternatives. NEPA requires that information be made available to decision makers and the public before decisions are made and actions taken.

In addition, at all of the facilities involved (Paducah, Portsmouth, and Oak Ridge) there are other cleanup activities ongoing, either under the WM or ER programs of DOE. These activities are clearly "proposals" and could have cumulative effects in regard to releases of radionuclides and other hazardous substances. The cumulative effects analysis of this DEIS (and the segmented NEPA analysis of the other cleanup projects ongoing at the sites) needs to be looked at in combination. The DEIS fails to make this important analysis.

Incorporation by Reference

(5) As is true is most DOE NEPA documents, there are sweeping impact assumptions based upon referenced material, mostly internal DOE information. .EPA requires that agencies which incorporate by reference material in an EIS make that material readily available to the public for review. Yet there is no mention where such referenced material (such as the GENII model) could be reviewed or obtained. This is a serious and blatant flaw in the 45-5

COMMENTOR NO. 45: DONHAM, MARK & HANSON, KRISTI (CONT'D.) BROOKPORT, ILLINOIS

DEIS
(6) NEPA does not allow conclusory assertions of no impact to suffice for a hard look. Assumptions in an EIS must be supported by objective or espirical data. By DOE making sweeping, conclusory statements of no impact (for example, of the environmental impact of the release of radiation from the activities associated with DEIS) based upon internal studies, which are not explained or described and which are not readily available to the public, DOE is violating one of the main tenants of NEPA - to inform the public of their proposed actions. 45-6

Thank you for considering these comments.

Sincerely

Mark Donham
Kristi Hanson

Germantown, MD 20874

April 13, 1998

Dear Mr. Bradley,

These are the comments of the undersigned on the Depleted Uranium cylinders DPEIS. There are some 50,000 plus cylinders of the DUF6 containing from 10 to 14 tons of material apiece currently stored in the three sites, Paducah, Portsmouth, and Oak Ridge.

The scope of the DPEIS is inadequate to cover the activities required to deal with the cylinders. Implementing either of the conversion alternatives will trigger a series of events which will have to take place in order to complete the conversion. These include building factories to do the conversion and for cleaning the highly radioactive residues out of the emptied cylinders. The DUF6 will have to be defluorinated, which is a highly dangerous activity. The converted material and the empty cylinders will have to disposed or stored, as will the hydrogen fluoride which is separated from the DUF6. 46-1

These activities are all connected actions which require a hard look in combination with the ongoing cleanup activities at the three facilities where the cylinders are stored - Paducah, Portsmouth, and Oak Ridge. There are clearly cumulative effects from these proposals and projects which are not adequately addressed in the draft. 46-2

Although the largest majority of cylinders, some 40,000, are at Paducah, they are inadequately stacked and stored presently. These are vulnerable to the high seismic risk at Paducah from the New Madrid fault. Because it will be decades or longer before this material can be converted, the risks from earthquake damage go greater as time goes on. Any conversion facilities planned for Paducah have to fully consider the earthquake potential at Paducah, and any construction of conversion facilities at Paducah would have to be made to an earthquake standard. The extra costs of this need to be disclosed. 46-3

If cylinders are going to be transported for conversion, then the risks transportation needs to be considered carefully. This would require many thousands of shipments. Many of the older cylinders may not be capable of being lifted or loaded for transportation. Some may not be able to be heated to be emptied. All of these problems could significantly increase the cost. The DOE needs to be more up-front about the real dollar costs of this problem. 46-4

Although it appears that the best alternative is converting the material from the reactive UF 6 form to the more stable uranium oxide form, the DPEIS doesn't give enough information for the commentors to decide where the best place for conversion would be and the best methods. 46-5

Finally, it seems ill-advised to continue to fill more cylinders daily with more DUF6 while this huge problem of disposal continues to accumulate. If the nuclear industry cannot manufacture its product without creating such huge amounts of toxic waste, it should strongly consider ceasing production. 46-6

Thank you for considering these comments.

Sincerely,

Carlene Barnwell

COMMENTOR NO. 47: WESTERMAN JONES, CAROL & JONES, ANTHONY E.
CARBONDALE, ILLINOIS

Charles Bradley
US DOE (NE-40)
19901 Germantown Rd.
Germantown, MD 20874

April 13, 1998

Dear Mr. Bradley,

These are the comments of the undersigned on the Depleted Uranium cylinders DPEIS. There are some 50,000 plus cylinders of the DUF6 containing from 10 to 14 tons of material apiece currently stored in the three sites, Paducah, Portsmouth, and Oak Ridge.

The scope of the DPEIS is inadequate to cover the activities required to deal with the cylinders. Implementing either of the conversion alternatives will trigger a series of events which will have to take place in order to complete the conversion. These include building factories to do the conversion and for cleaning the highly radioactive residues out of the emptied cylinders. The DUF6 will have to be defluorinated, which is a highly dangerous activity. The converted material and the empty cylinders will have to disposed or stored, as will the hydrogen fluoride which is separated from the DUF6. 47-1

These activities are all connected actions which require a hard look in combination with the ongoing cleanup activities at the three facilities where the cylinders are stored - Paducah, Portsmouth, and Oak Ridge. There are clearly cumulative effects from these proposals and projects which are not adequately addressed in the draft. 47-2

Although the largest majority of cylinders, some 40,000, are at Paducah, they are inadequately stacked and stored presently. These are vulnerable to the high seismic risk at Paducah from the New Madrid fault. Because it will be decades or longer before this material can be converted, the risks from earthquake damage go greater as time goes on. Any conversion facilities planned for Paducah have to fully consider the earthquake potential at Paducah, and any construction of conversion facilities at Paducah would have to be made to an earthquake standard. The extra costs of this need to be disclosed. 47-3

If cylinders are going to be transported for conversion, then the risks transportation needs to be considered carefully. This would require many thousands of shipments. Many of the older cylinders may not be capable of being lifted or loaded for transportation. Some may not be able to be heated to be emptied. All of these problems could significantly increase the cost. The DOE needs to be more up-front about the real dollar costs of this problem. 47-4

Although it appears that the best alternative is converting the material from the reactive UF 6 form to the more stable uranium oxide form, the DPEIS doesn't give enough information for the commentors to decide where the best place for conversion would be and the best methods. 47-5

Finally, it seems ill-advised to continue to fill more cylinders daily with more DUF6 while this huge problem of disposal continues to accumulate. If the nuclear industry cannot manufacture its product without creating such huge amounts of toxic waste, it should strongly consider ceasing production. 47-6

COMMENTOR NO. 49: MOBLEY, E.V.
IDAHO FALLS, IDAHO

File A:\uf-6..wpd UF-6 Comments Rev 1, 03-26-98

I have reviewed DOE/EIS-0269, PEIS for UF-6 Management, 12/97. I have the following comments:

1. I agree with and support the DOE preferred alternative i.e, use rather than disposal of the UF-6. 49-1

2. Vol. 1, S.5.1, contains an informative summary of possible uses for converted UF-6 in addition to cask shielding, but its location in the document makes it a surprise. I suggest that other possible uses be mentioned in paragraph S.2. 49-2

3. The radiation effects calculations are based on the linear-no-threshold (LNT) hypothesis (Vol 1, S.4.3.1.1.2 and Vol.2, C.4.2.2). A number of studies, for example those cited in The Scientist, March 3, 1997 and in Nuclear News, June 1997, indicate the LNT hypothesis is excessively conservative and in some cases is detrimental. I suggest an improved analysis practice that includes evaluating the magnitude of the conservatism instead of merely stating that the result is conservative. Data are available for derivation of best-estimate or most-probable health effects. A more realistic presentation in the UF-6 PEIS would result if there were a comparison of best-estimate and conservative health effects. 49-3

4. In Volume 2, paragraphs C.4.1.5, C.4.2.2, and C.4.2.3, it appears that four different dose to health effects conversion standards were used. I suggest some additional explanation to avoid the appearance of confusion. 49-4

Depleted Uranium Hexafluoride Management Program

Comment Form

The Department of Energy is interested in your comments on the *Draft Programmatic Environmental Impact Statement for Alternative Strategies for the Long-Term Management and Use of Depleted Uranium Hexafluoride.*

There are several ways to provide comments on this document and these include:

- ✓ attending public hearings and giving your comments directly to DOE officials
- ✓ returning this comment form to the registration desk at the hearing
- ✓ returning this comment form or other written comments to the address on the back
- ✓ faxing your comments to 301/428-0145
- ✓ commenting via the Depleted UF6 World Wide Web site: http://www.ead.anl.gov/uranium.html
- ✓ calling toll-free and leaving your comments via voice mail, 1-800-517-3191
- ✓ commenting via electronic mail: depleted_uf6@comail.gmt.saic.com

Apr 14, 1998

Comments: My comments (4 pages, 9 comments) are given in the attachment. If any of my comments or questions are not clear, I would appreciate being contacted. — 53-1

How will comments on the draft PEIS be documented by DOE? What is the status of the sale of the enrichment plants to USEC? Please call me at your convenience. — 53-2

Sincerely,
Gene Hoffman

Thank you for your input. Please use additional sheets if necessary and attach them to this form.

COMMENTOR NO. 53: HOFFMAN, EUGENE (CONT'D.)
KNOXVILLE, TENNESSEE

COMMENTS BY EUGENE E. HOFFMAN (DOE-RETIRED) TO THE U.S. DEPARTMENT OF ENERGY ON THE DRAFT PEIS ON MANAGEMENT AND USE OF DEPLETED URANIUM HEXAFLUORIDE, DOE/EIS-0269, DECEMBER, 1997

1. **The DOE "preferred alternative" (see PEIS, pp. S-42, -44) is to "use the entire inventory of material" based on market demand for uranium oxide (UO_2), uranium metal and fluorine products. "Safe management of the cylinder inventory would continue until 100% of the inventory had been converted for use." - - - This DOE preferred alternative would be supported by everyone if the DOE assumed use potential had any basis in fact. Every documented evaluation of potential use of the DUF6 by independent investigators, DOE contractors, and commercial firms in the uranium business during the past ten years has concluded that future use of only a small fraction of the 1,200,000,000 plus pounds of the depleted UF6 can be projected.** — 53-3

   In the PEIS, DOE evaluated six alternative management strategies (see page S-6). However, an option to continue storage of a reasonable (small) fraction of the DUF6 (only the best cylinders, under shelter) for future use and begin conversion of the most degraded cylinders to the safe, stable form (U_3O_8) was not considered. WHY?? — 53-4

COMMENTOR NO. 53: HOFFMAN, EUGENE (CONT'D.)
KNOXVILLE, TENNESSEE

Comments by E. E. Hoffman (cont'd) - 2 -

2. The 1100-page draft PEIS did not cite or reference the three independent reports that directly relate to the subject of the PEIS. These are listed below:
   a) *"Draft Preliminary Report - DOE Independent UF6 Cylinder Assessment Team", DOE Oak Ridge Field Office, dated March 25, 1992 (never published).*
   b) *"Integrity of Uranium Hexafluoride Cylinders", Defense Nuclear Facilities Safety Board Technical Report DNFSB/TECH-4, May 5, 1995.*
   c) *"Affordable Cleanup? - Opportunities For Cost Reduction in the Decontamination and Decommissioning of the Nation's Uranium Enrichment Facilities", National Research Council, National Academy Press, 1996*
      Chapter 7. Disposition of the DUF6

53-5

3. The draft PEIS presents brief and totally inaccurate statements regarding the New Madrid earthquake safety issue, which is of particular importance to the Paducah plant site which has in excess of 28,000 of the DUF6 cylinders. (PEIS reference - page 3 -7)

53-6

4. The French have been converting hundreds of millions of pounds of their depleted UF6 to the safe, stable oxide and stored it in steel containers in metal framed, earthquake resistant buildings since 1977 to avoid the hazards associated with storing UF6.

53-7

1459

COMMENTOR NO. 53: HOFFMAN, EUGENE (CONT'D.)
KNOXVILLE, TENNESSEE

Comments by E. E. Hoffman (cont'd) - 3 -

5. At least 17,475 of the DUF6 cylinders exhibit accelerated corrosion (Reference: DOE/ORO Work Agreement document, dated 10/30/96). The current DOE schedule for cleaning, inspecting, and re-painting of the cylinders will require at least 30 years, especially when the fact is considered that many of the cylinders will have to be re-cleaned and re-painted at least three times during that period. Each handling operation risks rupture. (Reference: Letter, S. J. Pawel to M. S. Taylor, Feb. 10, 1997, ORNL/CST-SP-021097-05, *Update on Development Activities, page 4, "The life of the paint system presently in use is not analytically known, but current estimates suggests that a 12-year life (on average) prior to significant maintenance or re-painting is reasonable".*

53-8

6. The DUF6 safety and accident concerns presented in the Defense Nuclear Facilities Safety Board report (DNFSB/TECH-4, May 5, 1995) are not cited in the draft PEIS.

53-9

7. On February 18, 1998 a USAF B-1 supersonic bomber weighing in excess of 200,000 pounds crashed and burned approximately 40 miles from the Paducah cylinder storage yards. The Barkely Regional Airport is located approximately 2 miles from these storage yards. Has the accident scenario of a large plane crash into the cylinder yards on a rainy day been analyzed? Under such circumstances a number of cylinders would be ruptured and large quantities of hydrofloric acid gas would be generated which could caused additional ruptures and make control of the accident very difficult.

Excerpt from "Integrity of Uranium Hexafluoride Cylinders", Defense Nuclear Facilities Board (DNFSB) Report DNFSB/TECH-4, May 5, 1995

page 6. The review conducted by the DOE Independent UF6 Cylinder Assessment Team (*Reference: "Draft Preliminary Report: DOE Independent UF6 Cylinder Assessment Team", DOE Oak Ridge Field Office, March 25, 1992)* was a comprehensive assessment of the entire cylinder program. The team reviewed the design, fabrication, transportation, filling, storage, handling, inspection, legal considerations, safety and health considerations, environmental considerations and ultimate disposition of the cylinders

Unfortunately, this report is still considered "draft" after three years.

Reports on DUF6 Cylinders by Independent Investigating Teams

"Draft Preliminary Report - DOE Independent UF6 Cylinder Assessment Team", DOE Oak Ridge Field Office, dated March 25, 1992

This report resulted from a DOE Memorandum "Uranium Hexafluoride Feed and Tails Cylinder Program Review" dated January 29, 1992 to P.Gross, et al., from Joe LaGrone, Manager, DOE Oak Ridge Field Office. The charter to the review team included the following statement:

You should assess the design, fabrication, transportation, filling, storing, handling, inspection, legal considerations, safety and health considerations, environmental considerations, and ultimate disposition of the cylinders.

Status of this report: Contrary to normal investigations of this type by DOE, this report was never formally issued and made available to the public.

"Integrity of Uranium Hexafluoride Cylinders", Defense Nuclear Facilities Safety Board Technical Report DNFSB/TECH-4, May 5, 1995.

Status of this report: This comprehensive report was issued and made available to DOE/HQ and the public and resulted in DNFSB Recommendation 95-1 to DOE/HQ. (Not cited in the Draft PEIS on DUF6, December, 1997)

"Affordable Cleanup? - Opportunities For Cost Reduction in the Decontamination and Decommissioning of the Nation's Uranium Enrichment Facilities", National Research Council, National Academy Press, 1996.

Status of this report: Available to the public. Contains much information on the depleted uranium hexafluoride situation in the U.S., including recommendations. (Not cited in the Draft PEIS on DUF6, December, 1997)

KNOXVILLE, TENNESSEE

Seismic Risk-Paducah Site

Depleted UF6 Draft PEIS, December, 1997, Vol. 1 - Page 3-7

The largest recorded earthquake in the region occurred in 1812 and was centered in the New Madrid fault zone. This earthquake had a magnitude of 7.3 on the Richter scale, and the epicenter was 60 miles (96 km) southwest of the site (ANL) 1991 a). The estimated 1,000-year return period peak ground acceleration is 0.45 of the acceleration of gravity (DOE 1995c).

"The Coming Quake" by T. A. Heppenheimer, Times Books,1988 - References to the New Madrid Earthquake

p.238 The December 16, 1811 quake had been of magnitude 8.5 or 8.6 making it up to twice as powerful as the worst in California. Its largest aftershock had rated at 8.2, very close to the 8.3 of California's earthquakes of 1857 and 1906. The shock of January 23, 1812, had been less powerful, at 8.4. But the main quake of February 7 went all the way up to 8.7 or 8.8-- as much as three times the force of the California shakings.

p.244 Nuttli (Otto) estimates that at present (1973), enough stress has built up along the faults to produce a quake of magnitude 7.6. That is the tremor worth fearing; and it has the potential to strike this very day.

COMMENTOR NO. 53: HOFFMAN, EUGENE (CONT'D.)

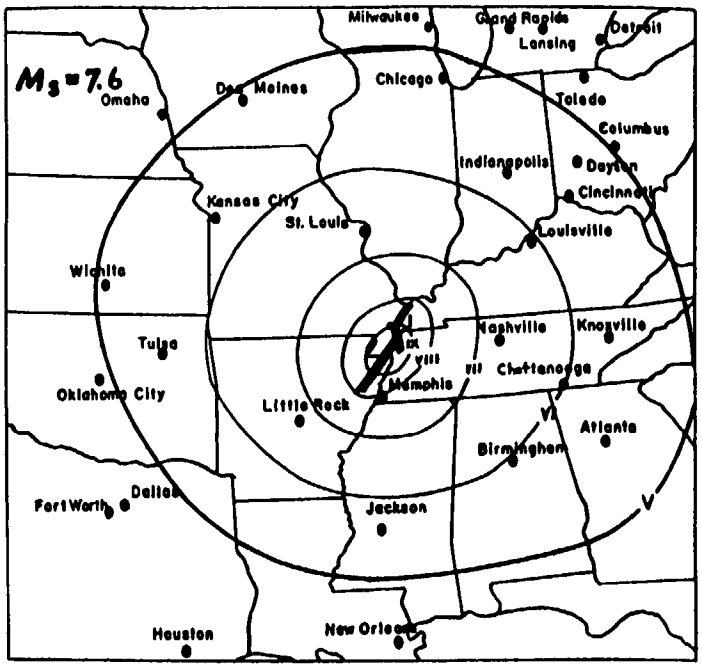
COMMENTOR NO. 53: HOFFMAN, EUGENE (CONT'D.)
KNOXVILLE, TENNESSEE



Map by Otto Nuttli showing damage areas, as indicated by zones of various Modified Mercalli intensity, that must be expected from a magnitude-7.6 earthquake on the New Madrid faults. Such a quake could occur today. The zigzag mark at the center is the trace of the New Madrid faults. (Courtesy U.S. Geological Survey)

"The Coming Quake," T.A. Heppenheimer, 1988, p 24b

THE CRUST OF THE EARTH
Chapter 13 - The Greatest Quake
by Chet Raymo

The New Madrid earthquake was rated XII on the modified Mercalli scale of intensity. XII is the highest rating on that scale. The scale describes a level XII quake in this way; "Super panic. Damage total. Waves seen on ground surfaces. Lines of sight distorted. Objects thrown upward into the air."

It was the greatest earthquake to shake the United States in historic times, and possibly one of the greatest ever to rock the crust of the earth.

Inventory of Thin-wall UF6 Cylinders at Three DOE Sites

- May 3, 1990 Inventory List Given to DOE-ORO Investigating Team by Martin-Maretta staff in February, 1992

10-Ton Cylinders	4,230	Model T
14-Ton Cylinders	1,000	Model 48 HX
	3,640	Model 48 H
	6,602	Model O
	16,602	Model OM* (*4450 not codeable)
	23,806	Model 48 G

Total 14-Ton Cylinders 51,419
Total Thin-wall Cylinders 55,649

- Number of UF6 Cylinders in Long-Term Storage in Table given to DOE/ORO Investigating Team by D.L.Mason (Martin-Marietta, 1/92) 54,000

- Number in DOE/ORO Report, March 25, 1992 - 54, 768
- Number in DNFSB Report, May 5, 1995 - 55, 649
- Number in Draft PEIS, December, 1997 - 46,422

DOE INDEPENDENT UF_6 CYLINDER ASSESSMENT TEAM

DRAFT PRELIMINARY REPORT

DOE OAK RIDGE FIELD OFFICE

March 25, 1992

TABLE 2
POTENTIAL DEFICIENCIES IDENTIFIED WITH LONG-TERM STORAGE UF_6 CYLINDERS

CONDITION	PGDP	PORTS	K-25	TOTAL
Total in long-term storage	35,339	13,359	6,070	54,768
Channel type stiffener (Type O)	5,313	83	163	5,559
Thin-wall skirted (Types T, H, and HX)	2,576	3,282	2,397	8,255
Bottom longitudinal weld		2,095 (Type T)		
In/near ground contact	2,818	0	949	3,767
Inaccessible plug end	10,162	10,259	810	21,231
Improper support upper tier	1,620		390	2,010+
Stacking incompatible designs		83	166	249+
Shell to lug contact	3,644	352	450	4,446
Other handling damage		4	285	289+
Valve leakage	Assessing	2	Assessing	Assessing
In poor drainage yard	12,153	0	100	12,253
Deficient saddles	19,994	0	12	20,006
Substandard bonnet nut/port cap	60/3	526/17	47/36	633/56
Valve replaced with plug			5	5+

UF_6 LONG-TERM STORAGE CYLINDER INTEGRITY MANAGEMENT PLAN K/ETO-114 September 1992

Table 2. Long-term storage inventory potential deficiencies

	Identified Potential Deficiency	Number of Cylinders
A.0	Direct Container Integrity Concerns	
A.1	breached cylinders- cylinders with holes in the cylinder shell	6
A.2	corroded cylinders- cylinders with visible pitting and/or scaling rust	15,000
A.3	leaking valves- valves and plugs that have recurring contamination	10*
B.0	Storage Facility Concerns	
B.1	substandard facilities- sinking or poorly drained load-bearing surfaces	12,000
B.2	improper support- upper tier cylinders supported by unsound points of contact	3,000
C.0	Uranium Control Issues	
C.1	non-depleted material- Normal or enriched material located in DU storage facilities	8
C.2	ID plates- loose or detached identification plates	200*
D.0	UF, Transfer Issues	
D.1	fill-limit consideration- cylinders without certified internal volumes or cylinders filled above the current maximum allowable limit established in ORO-651[15]	15,000
D.2	substandard valves- valves with missing or cracked parts, teflon tape on threads, bent stem, and/or improper engagement	3,000
D.3	plug replacing valves- plugs in place of valves	1,000*
D.4	defective cylinders- cylinders that do not pass the inspection criteria established in ORO-651 for liquid transfer	100*
D.5	non-conforming cylinders- cylinders that will not fit into currently designed autoclaves	140
E.0	Best Storage Practice Issues	
E.1	inaccessible cylinder- cylinders that cannot be accessed at both heads for a visual inspection	22,000
E.2	above internal vacuum- cylinders with internal pressure above the ideal vacuum conditions	1,000
E.3	uncoated cylinder- cylinders with no or little rust protective coating	23,000*

* Improved estimates are to be determined from the baseline inspection.

DELIVERABLES/MILESTONES/DATES OF COMPLETION (continued)

S. By September 30, 1996, remove all full depleted uranium cylinders from ground contact at Paducah.

T. Complete the required inspection of 12,340 cylinders as part of the triennial inspection program by September 30, 1996.

U. Complete annual inspection of 17,475 cylinders exhibiting accelerated corrosion and other problems (as defined in ETO-114) by September 30, 1996.

V. Continue the Biological Monitoring effort at Paducah and issue the annual report by April 30, 1996.

W. Complete the milestones and markers as defined in the FY 1996 baseline program plan.

Excerpts from "Investigation of Breached Depleted UF6 Cylinders", POEF-2068, ORNL/TM-11988, E.J.Barber, et al., September, 1991

page 4. Because the green salt deposit closely matches the color of the paint covering the cylinder, very careful inspection was required to spot the hole when viewed from the front of the cylinder.

page 29. An additional design fault in the UF6 storage cylinders is the protective coating applied to these cylinders. The color of the paint is so similar to that of UF4 that it hinders visual identification of reaction products from a breached cylinder. When a patch of rust forms under the paint, it has the same appearance as UF4 concealing a breach. It should also be mentioned that the quality of paint is highly variable and, in many cases, it offers little long-term surface protection.

COMMENTOR NO. 53: HOFFMAN, EUGENE (CONT'D.)
KNOXVILLE, TENNESSEE

Excerpts From Report KY/EM-187, "Lessons Learned From Paducah Site Pilot UF6 Cylinder Painting Project", R.I.Reynolds,et al. Nov.26,1996

page 1. "1231 cylinders have been painted with painting operations continuing."

page 2. "The cylinders are placed on their stiffening rings on wood timbers asnd chocks which supports the cylinder approximately 14 inches off the floor. The paint utilized is a one-coat system and consists of a Carboline inorganic zinc coating approximatelly three-to-five mils in thickness."

page 8. "Currently, the results indicate the following:

1. Most of the cylinders have relativelly loose and wispy rust but approximately 1,000 cylinders at Paducah have an underlayer of rust that is quite adherent and brittle. These cylinders are generally cylinders that have been in ground contact which accelerates rusting and pitting.
2. Although many cylinders manufactured after the late 1970's have some degree of painted surfaces, the paint is generally poorly adherent and brittle. Only the 6,000 DOE cylinders painted since 1990 have paint which provides some significant corrosion protection.
3. ---Bottom row cylinders vary according to storage conditions with most ground contact cylinders varying between 200 to 220 mils with the worst cylinder idenfied at about 177 mils. ---

U.S. Department of Energy Memorandum, February 20, 1992, "Plans for Ultimate Disposition of Depleted Uranium". To: Leo P.Duffy, Director, Office of Environmental Restoration and Waste Management, EM-1. From: Philip S. Sewell, Deputy Assistant Secretary for Uranium Enrichment, Office of Nuclear Energy

page 4. It is assumed that, beginning in 2020, 5,000 cylinders of depleted UF6 are emptied each year and the UF6 is converted to U3O8. Based on a schedule where conversion of UF6 begins in 2020, all the cylinders containing UF6 would be emptied by about 2065.

page 7. Summary. - - If alternate uses for the depleted uranium are not found to be feasible by approximately 2010, then steps will be taken to convert the UF6 to an oxide of uranium, U3O8, as the most appropriate form for ultimate storage and ultimate disposition. The U3O8 will be stored until it is determined that all or a portion of the depleted uranium is no longer needed. At that point, the U3O8 will be disposed as low-level waste.

COMMENTOR NO. 53: HOFFMAN, EUGENE (CONT'D.)
KNOXVILLE, TENNESSEE

Excerpts from "Depleted Uranium Hexafluoride Management Program", UCRL-AR-120372, June 30, 1995

Information Package 1, page 4

In 1977, French officials determined that storage of depleted UF6 from enrichment operations should be limited in time and quantity. License conditions were established for the enrichment facilities, which resulted in Cogema implementing a project for converting the depleted UF6 inventory to U3O8 on an industrial scale. Currently, Cogema packs and stores the U3O8 in 3-cubic-meter metal containers. Each container has a capacity of 9 tons. The containers are placed on concrete pads and are housed in metal framed, seismic resistant modular sheds. Each shed can hold 2,600 containers. With 12 sheds located onsite, Cogema estimates a U3O8 storage capacity of roughly 20 years (Cogema 1989)

(Gene Hoffman Note: One of the principal potential long-term uses of DUF6 cited by DOE is for application in future U.S. breeder reactors. If the U.S. persues breeders ever this application is many decades away. In addition it should be noted that the French are far ahead of the U.S. in breeder reactor demonstration and yet they still chose to convert their DUF6 to U3O8 for storage over 20 years ago.)

Excerpt from "An Integrated Solution For UF6 Tails Management", S. L. Rock, Allied Signal, Inc. and L. G. Davis, General Atomics, Proceedings of the Third International UF6 Conference, Paducah, Ky, November, 1995

"Storage in a Stable Form. Thirdly, the tails can be converted to a usable or uranium-retrieveable form such as metal or oxide. It should be noted that uranium metal cannot be stored simply, but must be protected from corrosion. U3O8 is the end product of all uranium decomposition. Also the production of metal from UF6 is relatively expensive compared to conversion to U3O8 and historically has created a significant hazardous material waste stream. -- Both the Department of Energy and the Nuaclear Regulatoriy Commission have gone on record as favoring conversion to U3O8 as the most desirable and sensible approach."

Excerpts from letter Allied Signal, Inc (M.D. Kosmider, plant manager) to Martin Marietta (Joe Russell), Subject: Critique of ORNL Report Entitled "Investigation of Breached Depleted UF6 Cylinders", dated February 7, 1992

"The only thing that disturbed me about the report was the lack of any mention of the long-term solutions to this problem. - - There are already 40,000 tails cylinders in storage; many are already dented from contact with surrounding cylinders lifting lugs; the number of tails cylinders is increasing by several thousands per year; and the report indicated that even a cylinder which is not dented has a storage life which probably does not exceed 50 - 60 years. In other words there exists a large potential for future problems which will not be resolved by improving painting, handling, inspecting, and stacking practices. Improving these practices will probably only delay the inevitable. - - - it must at least be mentioned that de-conversion of the tails to a relatively non-hazardous oxide form is the only way to eventually solve the problem."

1469

COMMENTOR NO. 53: HOFFMAN, EUGENE (CONT'D.)
KNOXVILLE, TENNESSEE

Conversion of DUF6 To Safe (U-metal), Safer (UO2) and Safest (U3O8) Forms

--- 4,683 cylinders at Oak Ridge (oldest and most heavily corroded)

--- 13,388 cylinders at Portsmouth

--- 28,351 cylinders at Paducah

- o Transportation of degraded cylinders is a problem on-site and a much more challenging and expensive off-site transportation problem.
- o Conversion of Paducah cylinders on-site would eliminate off-site transportation problem.
- o Conversion of Oak Ridge and Portsmouth cylinders at a second conversion facility should be considered, this would -
  - expedite more timely conversion of the most hazardous cylinders and
  - provide technical and cost competion which would benefit the taxpayers

KNOXVILLE, TENNESSEE

Excerpt from "Affordable Cleanup?", Report of the Committee on Decontamination and Decommissioning of Uranium Enrichment Facilities, National Research Council, D.F. Stein, Chairman, National Academy of Science, *National Academy Press, 1996*

Executive Summary - DUF6

A DOE study has found that past practices for storage of DUF6 have been inadequate in several respects (see reference below). There have been no serious consequences, however, and there is a vigorous program to correct past deficiencies.

There is general agreement, however, that DUF6 is an unsuitable chemical form for long-term storage; it is to reactive and volatile. Eventually it needs to be converted to the more suitable form of uranium oxide (U3O8). No large-scale uses have been identified, and the most promising potential uses do not preclude conversion to oxide.

> Recommendation. The committee recommends that, if consistent with the prioritized cost-and risk-reduction process, the DUF6 should be converted to the more stable chemical form, U3O8, for storage or disposal.

COMMENTOR NO. 53: HOFFMAN, EUGENE (CONT'D.)
KNOXVILLE, TENNESSEE

Excerpt from Draft PEIS, December, 1997

"In nearly 40 years of cylinder handling activities, no accidents involving releases from cylinders containing uranium hexafluoride have occurred that have caused diagnosed irreversible adverse effects among workers."

Excerpt from U. S. Nuclear Regulatory Report NUREG-1198, dated June, 1986, Executive Summary

"On January 4, 1986, at 11:30 a.m., a Model 48Y cylinder filled with uranium hexafluoride (UF6) ruptured while it was being heated in a steam chest at the Sequoyah Fuels Corporation facility near Gore, Oklahoma. The incident resulted in the death of one plant worker and injuries to several others as a result of exposure to hydrofluoric acid, a reaction product of UF6 and airborne moisture."

COMMENTOR NO. 53: HOFFMAN, EUGENE (CONT'D.)
KNOXVILLE, TENNESSEE

Excerpt from CONF-9110117, Second International Conference, Uranium Handling Conference, 1991, *"UF6 Overfilling Prevention at Urodif Production, Georges Besse Plant, p.65*

" On January 4th, 1986, a 48 Y model cylinder of uranium hexafluoride opened up while it was being heated in an oven at the uranium fluorination plant located near Gore, Oklahoma (USA) and operated by the Sequoyah Fuels Corporation. This accident caused the death of a plant employee and intoxication of several other people subsequent to exposure to the vapors produced by the released uranium hexafluoride (UF6), especially the hydrogen fluoride. Emission of toxic vapors lasted roughly 40 minutes. Carried by winds blowing at 40 km/hr, the cloud was visible more the 1.5 km away from the site of the accident. " (Accident reported in NUREG-1179, Vol. 1, February, 1986)

"The accident is one of the most serious accidents known yet involving uranium hexafluoride (UF6), given both the human consequences as well as the amount of UF6 released: approximately 13 tons of natural UF6."

KNOXVILLE, TENNESSEE

FILL LIMIT PROBLEM

Excerpts from "A Review of UF6 Cylinder Practices and Criteria", C. W. Walter, KY/L - 1522, March, 1989

page 3. The determination of a maximum fill limit involves concern for system safety and efficiency. During much of the past 40 years of filling Model - 48 cylinders, a uniform safety factor was not established and even today discussions and changes are being made as concerns are raised and evaluated. - The physical property of UF6 to expand in volume as much as 40 percent when heated from a solid state at ambient temperature to a liquid at working temperature can create substantial containment problems. A cylinder, when completely filled with liquid at 175 degrees F and then heated above that temperature, will rupture due to hydraulic forces generated by the expanding liquid, thereby spilling the contents of the cylinder.

page 5. However, there are cylinders in storage yards that are filled to earlier fill limits which assumed greater minimum volumes than presently assumed and based on 100 percent fill. These cylinders cannot be shipped unless the excess material is removed and the cylinder meets the current shipping limits.

COMMENTOR NO. 53: HOFFMAN, EUGENE (CONT'D.)
KNOXVILLE, TENNESSEE

Corroded DUF6 Cylinders (less than 0.25-in. wall thickness) Unloaded By Improper Process

Reference: Occurrence Report No. ORO-MMES-PGDPOPERD-1992-0018, dated March 10, 1992

Excerpts from Item 15. Description of Occurrence:

Two cylinders of non-enriched uranium hexafluoride (normally called "feed") were not fed by the precautionary method (normally called "cold feed") because hold tags had not been attached to them. -- Information that these steel cylinders had thin areas in parts of their surfaces was not properly communicated nor responded to. The "cold feed" method eliminates the possibility of surface rupture of cylinders with thin surface areas. "Cold feeding" is a plant practice whereby cylinders with surface thickness less than .250 inches are fed at reduced temperature, keeping cylinder pressure below atmospheric pressure. - -The two cylinders in question had areas of .245 inches and .223 inches respectively.

Item 23. Evaluation : (By Facility Manager/Designee

There appears to be deficiencies in both clearly defined procedures and formality in communication in this area. The lack of clearly established roles and responsibilities led to this occurrence.

COMMENTOR NO. 53: HOFFMAN, EUGENE (CONT'D.)
KNOXVILLE, TENNESSEE

Excerpts from "Integrity of Uranium Hexafluoride Cylinders, Defense Nuclear Facilities Safety Board, DNFSB/TECH-4, May 5, 1995, p. 16

"A paper entitled *Investigation of Breached Depleted UF6 Cylinders*, presented at the Second International Conference on Uranium Hexafluoride Handling, proposed experimental effort directed at examining the effect of a hole near the top of the cylinder that remains undetected. Scenarios had been proposed that could lead to a steam-driven expulsion of contaminmated liquid and HF from the cylinder due to the accumulation of water in the vapor space (due to rain and condensation) and subsequent chemical reactions. Further examination of this potential accident would appear warranted, based on the information available to-date."

"Consequences of seismic events in the storage yards are not addressed."

(Gene Hoffman Note: The hole-in- top of a cylinder safety concern cited above is justified by the possibility of cracks or holes resulting from transportation accidents or seismic events. The consequences of seismic events are very important when one considers that all options evaluated by DOE in the PEIS involve storage of degraded DUF6 cylinders for many, many years. This is especially true in view of the documents produced by many New Madrid experts, including Otto Nuttli. In 1973 Nuttli estimated that a 7.6 earthquake could occur in the Paducah region <u>today.</u>)

COMMENTOR NO. 53: HOFFMAN, EUGENE (CONT'D.)
KNOXVILLE, TENNESSEE

Excerpts from "Integrity of Uranium Hexafluoride Cylinders" Defense Nuclear Facilities Board (DNFSB) Report DNFSB/TECH-4, May 5, 1995

page 5. The report (*The Ultimate Disposition of Depleted Uranium, T. R. Lemons, et al., K/ETO-44, December, 1990)* discussed possible options for ultimate disposition, such as transfer or sales to other government programs or to the private sector, but recognized that commercial and government sectors would use only a small fraction of the depleted uranium in the foreseeable future. The report recommended that: UF6 cylinders be inspected on a semi-annual basis; cylinder maintenance and storage yards be up-graded; and depleted uranium be converted to U3O8 for long-term storage or disposal. Contrary to the last recommendation, the present plan established by DOE provides for long-term storage of the depleted uranium stockpile as UF6 until conversion to uranium oxide begins in fiscal year 2020.

1474

COMMENTOR NO. 53: HOFFMAN, EUGENE (CONT'D.)
KNOXVILLE, TENNESSEE

Excerpts from "UF6 Long-Term Storage Cylinder Integrity Management Plan, K/ETO-114, September, 1992

page 2. With the growing inventory of depleted UF6, a study of the ultimate disposition of DU was conducted by Energy Systems in 1990. This study reviewed the actual and potential used for DU and provided recommendations toward the ultimate disposition. The study concluded that there are currently few alternative uses of this material.

page 3. In the past two years, significant substandard conditions have been identified. For example, cylinders in and near ground contact have been observed with accelerated corrosion; accelerated corrosion at the skirt-to-head connection has been reported, and improper stacking of these cylinders has been identfied. All of these conditions can affect the life expectancy of the containment vessels.

COMMENTOR NO. 53: HOFFMAN, EUGENE (CONT'D.)
KNOXVILLE, TENNESSEE

Uses for Depleted Uranium (Reference: "Affordable Cleanup?", National Research Council, 1996, pp. 158-163.

Shielding Applications

" The UO2 suggested for Ducrete represents a very high density oxide but is not the thermodynamically stable form; U3O8 (uranium oxide) has a lower density but is the stable form and would probably be the preferred form for any Ducrete planned for long-term use. Consequently, proposals for the use of Ducrete would not conflict with a decision to convert DUF6 to a more stable oxide."

Use as a Fluorination Agent

"An inherent disadvantage of these fluorination schemes using UF6 is the need to introduce uranium into otherwise nonradioactive chemical plants, with the resulting complications of licensing, radiation protection,and low-level waste generation."

Re-enrichment or Dilution

DUF6 Enrichment by AVLIS - "AVLIS requires uranium metal feed, so the DUF6 must be converted to metal; this conversion is an expensive process. - - Final decisions on AVLIS. in praticular the use of DUF6 feed, are probably several years in the future. In the meantime, significant quantities of low 235U assay UF6 (less than 0.21 percent 235U) could be converted to U3O8 without affecting the potential use as AVLIS feed."

Blending Agent - "The volumes of material required for blending are not large. Thus a blending agent would have little effect on a decision to proceed with conversion of the DUF6 to U3O8."

Potential Energy Resource for Reactors - "The deployment of the breeder reactor in the United States is uncertain. Based on an economic analysis, a recent NRC report notes the advanced liquid-metal reactors may become competitive with advanced light-water reactors sometime in the latter part of the 21st century (NRC, 1996). Hence, the potential use of DUF6 as a resource for breeder reactors is relatively far in the future."

COMMENTOR NO. 54: HANSON, KRISTI & DONHAM, MARK
BROOKPORT, ILLINOIS

Charles Bradley
US DOE (NE-40)
19901 Germantown Rd.
Germantown, MD 20874

April 13, 1998

Dear Mr. Bradley,

These are the comments of the undersigned on the Depleted Uranium cylinders DPEIS. There are some 50,000 plus cylinders of the DUF6 containing from 10 to 14 tons of material apiece currently stored in the three sites, Paducah, Portsmouth, and Oak Ridge.

The scope of the DPEIS is inadequate to cover the activities required to deal with the cylinders. Implementing either of the conversion alternatives will trigger a series of events which will have to take place in order to complete the conversion. These include building factories to do the conversion and for cleaning the highly radioactive residues out of the emptied cylinders. The DUF6 will have to be defluorinated, which is a highly dangerous activity. The converted material and the empty cylinders will have to disposed or stored, as will the hydrogen fluoride which is separated from the DUF6. 54-1

These activities are all connected actions which require a hard look in combination with the ongoing cleanup activities at the three facilities where the cylinders are stored - Paducah, Portsmouth, and Oak Ridge. There are clearly cumulative effects from these proposals and projects which are not adequately addressed in the draft. 54-2

Although the largest majority of cylinders, some 40,000, are at Paducah, they are inadequately stacked and stored presently. These are vulnerable to the high seismic risk at Paducah from the New Madrid fault. Because it will be decades or longer before this material can be converted, the risks from earthquake damage go greater as time goes on. Any conversion facilities planned for Paducah have to fully consider the earthquake potential at Paducah, and any construction of conversion facilities at Paducah would have to be made to an earthquake standard. The extra costs of this need to be disclosed. 54-3

If cylinders are going to be transported for conversion, then the risks transportation needs to be considered carefully. This would require many thousands of shipments. Many of the older cylinders may not be capable of being lifted or loaded for transportation. Some may not be able to be heated to be emptied. All of these problems could significantly increase the cost. The DOE needs to be more up-front about the real dollar costs of this problem. 54-4

Although it appears that the best alternative is converting the material from the reactive UF 6 form to the more stable uranium oxide form, the DPEIS doesn't give enough information for the commentors to decide where the best place for conversion would be and the best methods. 54-5

Finally, it seems ill-advised to continue to fill more cylinders daily with more DUF6 while this huge problem of disposal continues to accumulate. If the nuclear industry cannot manufacture its product without creating such huge amounts of toxic waste, it should strongly consider ceasing production. 54-6

Thank you for considering these comments.

Sincerely,

Kristi Hanson Kristi Hanson

Comment Form

The Department of Energy is interested in your comments on the *Draft Programmatic Environmental Impact Statement for Alternative Strategies for the Long-Term Management and Use of Depleted Uranium Hexafluoride.*

There are several ways to provide comments on this document and these include:

- ✓ attending public hearings and giving your comments directly to DOE officials
- ✓ returning this comment form to the registration desk at the hearing
- ✓ returning this comment form or other written comments to the address on the back
- ✓ faxing your comments to 301/428-0145
- ✓ commenting via the Depleted UF_6 World Wide Web site: http://www.ead.anl.gov/uranium.html
- ✓ calling toll-free and leaving your comments via voice mail, 1-800-517-3191
- ✓ commenting via electronic mail: depleted_uf6@comail.gnet.saic.com

Comments

(1) DOE must immediately move to convert the entire inventory of DU to the oxide for long term storage. — 55-1

(2) Conversion can not wait for ten years or any period of time. — 55-2

(3) DOE must conduct the conversion to the oxide at its present storage location. No transportation of DUF6 a conversion facility — 55-3

(4) all Cylenders must be checked for integrity prior to moving to the on-site conversion facility. All such must be stored on-site under cover. — 55-4

Thank you for your input. Please use additional sheets if necessary and attach them to this form.

Submitted Via Fax: (301) 428-0145

Subject: Draft Programmatic Environmental Impact Statement (PEIS) for Alternative Strategies for the Long-Term Management and Use of Depleted Uranium Hexafluoride (UF6)

Dear Mr. Bradley:

The Citizens' Advisory Panel (CAP) of the Oak Ridge Reservation (ORR) Local Oversight Committee (LOC) submits the following comments on the subject document. Several members of the CAP attended the February 24, 1998, public hearing on the PEIS and reviewed the available documentation. The LOC Board has not had the opportunity to review and approve the comments and thus these comments should be considered submitted by the CAP only.

The LOC is a non-profit regional organization funded by the State of Tennessee and established to provide local government and citizen input into the environmental management and operation of the DOE ORR. The Board of Directors of the LOC is composed of the County Executives of Anderson, Knox, Loudon, Meigs, Morgan, Rhea, and Roane Counties; the Mayor of the City of Oak Ridge; and the Chairs of the Roane County Environmental Review Board (RCERB), the City of Oak Ridge Environmental Quality Review Board (EQAB), and the LOC Citizens Advisory Panel (CAP). The CAP currently has 19 members with diverse backgrounds representing the greater ORR region.

The CAP concurs that the alternatives considered in the PEIS are appropriate, but the assumptions which delay action to 2009 with completion in 2028 are not acceptable. We understand that the continued storage of the UF6 cylinders does not pose an immediate health or environmental threat. However, as time passes, the task of assuring safe storage will become more demanding, with increasing cost for surveillance and maintenance of the deteriorating cylinders. — 56-1

The condition of the oldest cylinders at Oak Ridge and Paducah should be considered when planning for decontaminating and decommissioning (D&D). The toxicity of the fluorine component is the primary concern with regard to health risk, although release of depleted uranium to the environment could result in a costly public relations disaster. — 56-2

COMMENTOR NO. 56: OAK RIDGE RESERVATION LOCAL OVERSIGHT COMMITTEE (CONT'D.) OAK RIDGE, TENNESSEE

C. E. Bradley, Jr.
April 22, 1998
Page 2

As you may know East Tennessee Technology Park (ETTP, formerly K-25) has an active reindustrialization program underway. The continued presence of the UF6 cylinders might negatively impact the site reuse activities from an aesthetic viewpoint or as a perceived risk to co-located workers, as well as by the loss of the storage yard land to new uses. 56-3

DOE has a responsibility to begin reducing its stockpile of UF6. The CAP urges that an expedited conversion program be started immediately. We have reviewed the voluminous amount of information associated with this subject and the variety of suggestions on how to properly handle this situation. Our recommendations follow: 56-4

1. Increase and expedite the current maintenance program to clean and paint all cylinders starting with the most needy. 56-5
2. Improve the storage conditions so that all cylinders are accessible and safe.
3. Convert the UF6 to the more stable oxide (triuranium octaoxide) or metal form. There do not appear to be any technical barriers to beginning conversion. Begin the conversion process as soon as feasible. 56-6
4. Start conversion with the oldest cylinders and those in the worst physical condition.
5. Place the conversion products in interim storage until a decision is made for permanent storage, use, or disposal.

The Energy Policy Act of 1992 provides for payment of the costs of remedial actions at gaseous diffusion facilities from the Uranium Enrichment & Decommissioning Fund. Appropriations received to date have lagged behind the available funds by an approximate factor of two. We urge that this money be made available in a timely manner for the UF6 processing that is needed. 56-7

The LOC's CAP appreciates the opportunity to comment on the *Draft PEIS for Alternative Strategies for the Long-Term Management and Use of Depleted UF6*. If you have any questions, please call me at (423) 483-1333.

Sincerely,

Susan L. Gawarecki, Ph.D.
Executive Director

COMMENTS: DEPLETED URANIUM HEXAFLUORIDE MANAGEMENT PROGRAM

THE CYLINDERS SHOULD CONTINUE TO BE STORED. THE OLDER OR COMPROMISED CYLINDERS SHOULD BE PLACED IN OVER PAKS LIKE THOSE USED TO PROTECT DRUMMED WASTE. ALL CYLINDERS SHOULD BE STORED IN AN EARTHQUAKE SECURE FACILITY. 57-1

NO CONVERSION TO U308 SHOULD TAKE PLACE AT THE PADUCAH SITE DUE TO THE PROXIMITY OF THE NEW MADRID EARTHQUAKE FAULT AND THE CLOSE PROXIMITY OF THE PLANT NEIGHBORS 57-2

CONVERSION TO U308 WILL ADD TO THE WASTE INVENTORY BECAUSE OF THE LARGE VOLUME OF CYLINDERS. IF CONVERSION HAD BEEN CONSIDERED AT AN EARLIER TIME THE WASTE STREAMS COULD HAVE BEEN HANDLED EASIER. 57-3

QUESTIONS:

IF CYLINDERS SHOULD BUMP INTO EACH OTHER DURING A SEISMIC EPISODE AND BREAK OFF NUMEROUS FILL VALVES, ARE THERE PROCEDURES IN PLACE TO HANDLE A LARGE NUMBER OF VALVE REPLACEMENTS ? 57-4

HOW MANY BROKEN FILL VALVES IN THE 30,000 PLUS CYLINDERS WOULD CONSTITUTE A EMERGENCY ? 57-5

WOULD STACKING THE CYLINDERS TWO HIGH IN CLOSE ROWS ADD TO THE DAMAGE OF MORE FILL VALVES BEING BROKEN DURING A SEISMIC EPISODE ? 57-6

THANK YOU,

RONALD LAMB

The following catalog is for earthquakes in the New Madrid seismic zo
ano is produced by the Cooperative New Madrid Seismograph Network (CN
a member of the Council of the National Seismic System.  CNMSN suppor
comes from the United States Geological Survey and the State of Tenne

In the early 1800's, the New Madrid seismic zone was the site of what
are considered to be the largest earthquakes to have occurred in the
conterminous United States.  During the winter of 1811-1812, a series
of three earthquakes, estimated at magnitude 8 or larger, struck in a
period of three months.  There have been several magnitude 6-7 events
since that time and there is a continuing activity of small earthquak
that defines the present day seismic zone.  The principal seismic act
is found in western Tennessee, northeast Arkansas, and southeast Miss

Other catalogs for various regions of the United States can be obtain
using the finger mechanism 'finger quake@machine'.  The following lis
gives the machine names for different regions.

Comments of the Institute for Energy and Environmental Research on the draft of the Department of Energy Programmatic Environmental Impact Assessment for Alternative Strategies for the Long-Term Management and Use of Depleted Uranium Hexafluoride, December 1997

by

Annie Makhijani and Arjun Makhijani

March 1998

The Department of Energy's Draft Programmatic Environmental Impact Statement (PEIS)for Alternative Strategies for the Long-Term Management of Depleted Uranium Hexafluoride purports to analyze the impacts of the storage, use and/or disposal of the 560,000 metric tons of depleted uranium hexafluoride currently stored in 46,422 cylinders at three sites located near Portsmouth, Ohio; Oak Ridge, Tennessee; and Paducah, Kentucky. This long term management is for the depleted uranium generated prior to 1993.

In this report the DOE examines six alternatives:

- The "no action" alternative which would be a continuation of the current management program, that is storage on site in cylinders of the depleted uranium hexafluoride.
- Two storage alternatives based on retrievability
  - in UF_6 form in yards, buildings or an underground mine
  - in oxide form in buildings, below-ground vaults or an underground mine
- Two use alternatives
  - radiation shielding for casks for storage of spent fuel or high level wastes after conversion to metal
  - radiation shielding for casks for storage of spent fuel or high level wastes after conversion to oxide
- Disposal as low-level waste in the oxide form in drums placed in
  - shallow earthen structures
  - vaults
  - mines

The Draft also makes mention of other possible uses of depleted uranium as part of the use alternatives (see below).

COMMENTOR NO. 58: INSTITUTE FOR ENERGY AND ENVIRONMENTAL RESEARCH (CONT'D.) TAKOMA PARK, MARYLAND

One of these alternatives will be selected in the Record of Decision, which is scheduled for this year. DOE's preferred alternative is to use the entire inventory of depleted uranium after its conversion to a metal and/or oxide form.

The DOE's effort to address the long-term management of the country's depleted uranium hexafluoride, specifically the realization of the importance to convert this material into a stable form is long overdue. The draft PEIS is seriously deficient because it does not address the most environmentally appropriate option - specifically, the DOE did not include the alternative of disposing of depleted uranium according to the rules of 40 CFR 191 which govern the disposal of transuranic (TRU) wastes. IEER, in its comments (Mar 22, 1996) on DOE's Notice of Intent (Jan 25, 1996), had already noted that the proposed list of alternatives was incomplete since it did not include the option of disposal under 40 CFR 191. The DOE has rejected our comments without providing any technical or environmental explanation. Our comments of March 22, 1996 are attached . DOE should include this option in the Final PEIS.

58-1

IEER agrees with DOE that the no action alternative is inappropriate and should be rejected because of the dangers of UF_6 storage. For the same reason, long-term UF_6 storage in new containers should also be rejected. Overall, conversion to oxide would reduce risks. While conversion poses risks to workers and the off-site population, continued storage also poses serious risks.
However, the various alternatives the DOE has considered have not been properly assessed in this PEIS.

58-2

A. Conversion of uranium hexafluoride

Most of the alternatives considered involve the conversion of uranium hexafluoride. Three alternatives would convert uranium hexafluoride to an oxide and one alternative would convert uranium hexafluoride to a metal. This conversion would have the positive result of putting the depleted uranium in a more stable chemical form, therefore eliminating the chances of an hazardous releases of UF_6 and hydrofluoric acid from aging corroding cylinders. DOE's analysis is incomplete or deficient in regard to the

58-3

- fate of the empty cylinders,
- commercial use of contaminated anhydrous hydrogen fluoride (produced during the conversion process),
- the radiological effects on workers.

1. Fate of the empty cylinders

DOE admits that ".. the ultimate disposition of the empty cylinders was not analyzed in detail as part as the alternative management strategies." The empty cylinders would become part of the DOE scrap metal inventory. The options for disposition are: recycling

58-4

14480

COMMENTOR NO. 58: INSTITUTE FOR ENERGY AND ENVIRONMENTAL RESEARCH (CONT'D.) TAKOMA PARK, MARYLAND

"... into LLW disposal containers, reuse as LLW containers, free release for re-melting, and disposal as LLW." However DOE has not analyzed the environmental and health impacts of these proposals. This lack of analysis is a serious problem since the volume of contaminated metal involved is large and doses to the public and to workers may be significant.

58-4 (Con't.)

2. Commercial use of contaminated HF and CaF_2

The DOE has not properly assessed the management of both HF, a by-product of the conversion process, and calcium fluoride (CaF_2), a product of the neutralization of HF. Both these products will be slightly contaminated and in the Cost Analysis Report for the Long-Term Management of Depleted Uranium Hexafluoride concerns are expressed as to the public acceptance of the uranium contaminants. Regardless of this concern, the DOE, in its Draft PEIS, assumed that these products could be commercially sold for unrestricted use. It is unacceptable to release a non-labeled contaminated product which has not received public acceptance. The Cost Analysis Report also states that the demand for HF is "still very uncertain". An other option is to use the HF for the production of UF_6. For this option as well as the commercial use option, DOE has not addressed the fact that part of the UF_6 inventory is recycled UF_6 which is contaminated by radionuclides other than uranium-238, such as Tc-99 and U-236 which both have a long half life.

58-5

3. Radiological effects on workers

In their calculation of radioactive dose assessment, DOE does not take into account internal radiation doses that would be received by involved workers during the conversion process. This is a serious deficiency since involved workers are the most at risk. DOE claims that measures taken to prevent inhalation and ingestion of radioactive material would effectively protect the involved workers. The emphasis on prevention measures is not enough without a monitoring program installed for health purposes. DOE also claims use of respirators will reduce workers doses. But routine reliance on respirators is unacceptable as a radiological control practice. Moreover, some of the depleted uranium comes from the enrichment of UF_6 from recycled uranium from spent fuel. This UF_6 contains some radionuclides of concern such as technitium-99, a long lived beta emitter and uranium-236, a long lived alpha emitter. DOE does not seem to have analyzed the radiological impacts.

58-6

B. Uses of depleted uranium

1. Uses unalyzed

DOE's preferred alternative is to use the entire inventory of depleted uranium after its conversion to a metal or an oxide form for radiation shielding in storage casks for spent fuel. However since these casks would have to be licensed by the NRC (6.11-9-1 Engineering analysis report) this choice is premature. Even if the licensing is approved cask fabrication creates more problems than solutions. The problems are that

58-7

COMMENTOR NO. 58: INSTITUTE FOR ENERGY AND ENVIRONMENTAL RESEARCH (CONT'D.) TAKOMA PARK, MARYLAND

- it is not a final solution since the casks envisioned do not meet the criteria for deep repository disposal. Hence this is not a solution but a stop-gap storage method that would create more contamination and radioactive waste in the form of used casks. The DOE has not done the preliminary work ascertaining the license ability of the casks. DOE's choice of preferred option is premature and inappropriate.
- DOE doesn't say what will happen to the DU in the casks. It only states that: "No assumptions were made regarding the fate of the oxide- and metal-shielded casks after use. The empty casks could be recycled, stored, or disposed of as LLW." (p. H-32).

58-7 (Con't.)

For the manufacturing casks as with the conversion process, the contribution to the dose from internal radiation to involved workers has not been assessed.

2. *Other uses not analyzed in depth*

With the long-term storage options DOE preserves the possibility to pursue the use of depleted uranium in light water reactor fuel cycle, advanced reactor fuel cycles and, dense material applications. The light water reactor option has two sub-options: the re-enrichment of DU and the use of DU for MOX. Among these options, the fact that the use of depleted uranium in advanced reactors (that is fast neutron reactors, also known as breeder reactors) is at all considered is particularly disturbing. Depleted uranium being the raw material for plutonium production, by converting it into a material not only much more radioactive but also weapons usable would not only defeat the stated purpose of the PEIS which is to "achieve the safe and effective long-term management of depleted UF_6." It would also have serious proliferation consequences.

58-8

3. *Uses not analyzed*

The feasibility of using depleted uranium hexafluoride for the blending down of surplus highly enriched uranium was not considered in this PEIS. Although it would utilize only a small portion of the stock, this use would have several advantages, among them: the contribution to non-proliferation, a minimum of handling, and incorporation of depleted uranium into spent fuel. This use option could be made part of any of the alternatives except UF_6 storage.

58-9

C. IEER's recommendations

IEER recommends that:

- depleted uranium be classified as a waste equivalent to TRU waste for management purposes

58-1 (Con't.)

- UF_6 be converted to an oxide form and declared a waste to be handled on a par with repository-designated TRU waste, with the possible exception of a relatively small quantity to be used for the blending down of highly enriched uranium. This should be the preferred option in the Final PEIS

58-2 (Con't.)

1481

COMMENTOR NO. 58: INSTITUTE FOR ENERGY AND ENVIRONMENTAL RESEARCH (CONT'D.) TAKOMA PARK, MARYLAND

- The issue of internal radiation for involved workers during conversion and cask fabrication be addressed carefully along with an assessment of the effects of uranium-236 and technitium-99

58-6 (Con't.)

- the fate of the empty UF_6 cylinders and their proper disposition should be studied

58-4 (Con't.)

- the fate of the anhydrous hydrogen fluoride and calcium fluoride should be properly studied
- radioactive materials such as HF from UF_6 processing and steel from empty UF_6 cylinders not be circulated in the civilian economy.

58-5 (Con't.)

Comments of the Institute for Energy and Environment on the Department of Energy Notice of Intent addressing the Alternative Strategies for the Long-Term Management and Use of Depleted Uranium Hexafluoride, Federal Register, Thursday, January 25, 1996

by

Arjun Makhijani and Annie Makhijani

22 March 1996

The Department of Energy has announced its intent to prepare a programmatic environmental impact statement addressing the use and/or disposal of the 560,000 tonnes of depleted uranium hexafluoride currently stored in cylinders at three sites located near Portsmouth, Ohio; Oak Ridge, Tennessee; and Paducah, Kentucky.

The DOE plans to consider a set of six preliminary alternatives:

- The "no action" alternative which would be a continuation of the current management program, that is storage on site in cylinders of the depleted uranium hexafluoride.
- Two storage alternatives based on retrievability
  - in the UF_6 form
  - in the oxide form
- Two use alternatives
  - radiation shielding after conversion to metal
  - radiation shielding after conversion to oxide
- Disposal as low-level waste in the oxide form in drums placed in
  - engineered trenches
  - below-ground concrete vaults
  - mines

IEER welcomes the DOE's effort to address the long-term management of the country's depleted uranium hexafluoride. However the DOE list of alternatives does not include all reasonable alternatives. Specifically DOE should add another option to the above mentioned list. This option would be the disposal of depleted uranium according to the rules of 40 CFR 191 which govern the disposal of transuranic (TRU) wastes.

1482

Currently, uranium is still classified as a source material. In cases where it might be disposed of as a waste the Nuclear Regulatory Commission has put it by default into the category of class A low-level radioactive waste according to 10 CFR 61.55 (6). 10 CFR 61.55 allows near surface disposal. The inappropriateness of this default classification is demonstrated be the NRC's own assessment that shallow-land burial of depleted uranium could result in unacceptably high doses to future generations. [1] However in its notice of intent, the DOE has left the low-level category of depleted uranium ambiguous. In the three scenarios of the disposal alternative, the DOE does not specify in which low-level waste class it puts depleted uranium. The first one - disposal in engineered trenches - corresponds to a classification of depleted uranium as class A low-level radioactive waste. The last two - disposal below-ground in concrete vaults and disposal in mines - imply that the current classification is inadequate. DOE should clearly include waste classification as an issue as it relates to depleted uranium in its implementation plan and address it in detail in the PEIS.

We set forth below the scientific reasons why depleted uranium should be put in the same classification as transuranic wastes for the purpose of waste management and disposal. This would mean that depleted uranium would have to be placed in a deep geological repository.

The current definition of TRU waste according to 40 CFR 191.01 (i) is: ". . .waste containing more than 100 nanocuries of alpha-emitting transuranic isotopes, with half-lives greater than twenty years, per gram of waste . . . ."

What matters to health and environmental considerations is the specific activity of the radioactive wastes, the nature of the radiation being emitted during the radioactive decay (alpha or beta and whether the decay is accompanied by gamma radiation) and, the energy per radioactive decay. Depleted uranium is, in these essential respects, the same as the transuranic constituents of TRU waste. The specific ways in which uranium or the transuranic radionuclides in TRU waste might affect people will, of course, depend on the chemical form of the waste, the packaging, and the disposal method.

There is one nominal difference between TRU waste and depleted uranium. TRU waste consists of elements with atomic numbers greater than or equal to 93 -- that is of elements with atomic numbers greater than uranium, whose atomic number is 92. But this is a difference of nomenclature; it has no bearing upon health and environmental issues.

A. Properties of depleted uranium

1. *Specific Activity*

The radioactivity per unit weight (called specific activity) of depleted uranium metal is dominated by its principal constituent, uranium-238. It also depends somewhat on the exact extent to which uranium-235, and hence also uranium-234, have been separated and

[1] Final Environmental Impact Statement for the Construction and Operation of the Claiborne Enrichment Center, Homer Louisiana, NUREG-1484, Vol. 1, August 1994.

passed into the enriched uranium stream. It may vary from about 360 nanocuries/gram to about 450 nanocuries/gram. Even assuming that only uranium-238 remains, the specific activity would be still about 340 nanocuries/gram which is 3.4 times higher than that defining transuranic waste.

The specific activity of other chemical forms is somewhat lower than for uranium metal, because when radioactive uranium is chemically bound with non-radioactive isotopes of elements like oxygen and fluorine, its specific activity is correspondingly lower. Table 1 shows the specific activity of four forms of depleted uranium. For convenience we have assumed a single reference value of 360 nanocuries/gram for the specific activity of uranium metal which is the lowest practical value in the range cited above.

Table 1 also shows, for reference, the minimum specific activity of transuranic waste as defined by regulations and the radioactivity of ore containing 0.2 percent uranium.

Table 1
Specific Activities of various chemical forms of depleted uranium, TRU waste and 0.2% uranium ore

Chemical form	Specific activity, nCi/g
uranium metal (U)	360
uranium oxide (U_3O_8)	300
uranium tetrafluoride (UF_4)	270
uranium hexafluoride (UF_6)	240
transuranic activity in TRU waste	>100 (See note 2)
0.2 % uranium ore	4 (See note 3)

Notes for Table 1
1. Specific activities of the four forms of uranium have been rounded to two significant figures, and that of uranium ore to one significant figure.
2. The minimum limit of 100 nanocuries/gram of transuranic elements for waste to be classified as TRU waste includes only those isotopes of transuranic elements with half-lives greater than 20 years. The most common isotope in TRU waste that is eliminated from the counting in this way is plutonium-241, which has a half-life of 14.4 years. However the decay product of plutonium-241, americium-241 is included in TRU waste because it has a half-life of about 432 years. All these uranium isotopes we are dealing with in these comments have half-lives far longer than 20 years.
3. The specific activity of 0.2 percent uranium ore shown includes all decay products of uranium-238 up to and including radium-226, assuming they are in secular equilibrium with uranium-238. Radon-222, and its decay products are not included.

It is clear from Table 1 that depleted uranium is comparable in specific activity to transuranic waste. This conclusion is independent of the chemical form of the depleted uranium. Note that depleted uranium is far more radioactive than uranium ore because the ore is mixed with large quantities of non-radioactive materials. Thus, putting depleted uranium in mines is in no way like replacing the original material that was mined out of the ground. Rather it is analogous to putting TRU waste in the ground.

2. *Mode of decay, energy of decay, and half-life*

1483

COMMENTOR NO. 59: INSTITUTE FOR ENERGY AND ENVIRONMENTAL RESEARCH (CONT'D.)
TAKOMA PARK, MARYLAND

The main radionuclide of concern in most TRU waste is plutonium-239. Other radionuclides that are present in significant quantities are plutonium-240, plutonium-238, neptunium-237, and americium-241. The predominant mode of decay of all of these radionuclides is alpha decay. That is also the case with all three uranium isotopes (uranium-238, uranium-234, and uranium-235) present in depleted uranium. In all these cases, the emitted alpha particles have energies between 4 and 6 MeV, so that the total energy deposited in tissue per picocurie of radioactive material in the body is the same. Thus, once a unit of radioactivity of TRU waste or of depleted uranium is in the body, the amount of radiation dose per unit of time is approximately the same.

Table 2 shows the principal characteristics of concern of the main radionuclides in TRU waste and in depleted uranium. Note that the decay products of uranium-238 build up over hundreds of thousands of years, and we have ignored these for the sake of argument in these comments.[3]

Table 2
Properties of Uranium Isotopes and Selected Transuranium Elements

Isotope	Main decay mode	Alpha particle energy, MeV	Half-life, years	Comments
uranium-238	alpha	4.1	4.46 billion	
uranium-234	alpha	4.8	245,000	
neptunium-237	alpha	4.8	2.14 million	
plutonium-238	alpha	5.5	87.7	
plutonium-239	alpha	5.1	24,110	
plutonium-240	alpha	5.1	6,537	
plutonium-241	beta	see note 2	14.4	not included in TRU waste definition
americium-241	alpha	5.5	432	strong gamma emitter

Notes
1. All energies rounded to two significant figures. The alpha emitting radionuclides emit alpha particles with more than one characteristic energy, with each energy level being produced with a known probability. The alpha particle energy shown is an approximate average of these particles energies, weighted by the emission probability.
2. Plutonium-241 is not included in the definition of TRU waste since it has a half-life of less than 20 years. Its beta particle energy is 0.021 MeV.

B. Chemical forms of depleted uranium

As has been shown, regardless of its chemical form, depleted uranium is always more radioactive than the lowest specific activity defining TRU waste. However, some chemical forms are more reactive than others. For example UF_6 is very reactive. In the

[3] In general, the specific activity of wastes containing mainly plutonium-239 will decline as time progresses, but that of wastes containing mainly uranium-238 will increase as time progresses, due to the differences in half-lives of the decay products of these two radionuclides

COMMENTOR NO. 59: INSTITUTE FOR ENERGY AND ENVIRONMENTAL RESEARCH (CONT'D.)
TAKOMA PARK, MARYLAND

presence of moist air, UF_6 reacts with the water in the air to form uranyl fluoride particulates (UO_2F_2) and hydrogen fluoride fumes (HF) both of which are very toxic. In water hydrogen fluoride becomes a very corrosive acid. Anhydrous hydrogen fluoride is also corrosive. Other chemical forms are less reactive, the oxide forms of uranium being the most physically and chemically stable. DOE should consider disposal of depleted uranium as an oxide (U_3O_8 or UO_2) under 40 CFR 191 rules.

C. Conclusions

We recognize that in comparing uranium and plutonium on the basis of equal masses of these two elements in pure form, plutonium is far more radioactive than uranium. This is because the half-lives of the isotopes of plutonium shown in Table 2 are far shorter than those of uranium. This means that a given mass of uranium decays more slowly -- that is, it gives off fewer alpha particles per unit of time. However, the far lower specific activity of uranium isotopes in depleted uranium relative to pure plutonium is irrelevant to this discussion because we are examining the properties of materials on the basis of the radioactivity per unit mass of waste to be disposed of. TRU waste is defined as that containing more than 100 nanocuries/gram. By weight it consists mainly of non-radioactive materials mixed with small masses of transuranic elements. By contrast, depleted uranium would be disposed of in nearly pure form, with only the possible addition of and element such as oxygen. As a result, TRU waste is comparable to depleted uranium. DOE TRU waste is slated for disposal in a deep geological repository.

Therefore we believe that depleted uranium should be put in the same category as TRU waste so far as its characteristics for waste management and disposal are concerned. Therefore in the PEIS the DOE should:

- reexamine the waste classification of depleted uranium based on the explicit recognition of the scientific facts discussed above and,
- add one alternative consisting of converting depleted uranium to the oxide form (U_3O_8 or UO_2), and disposing it of in a geologic repository under 40 CFR 191 rules. The proposed PEIS would be fundamentally flawed and deficient if it omitted this option.

The implementation plan for the PEIS should include these two items.

COMMENTOR NO. 60: EDMONDS, ROBERT F., JR. OAK RIDGE, TENNESSEE

Author: Robert F Edmonds Jr

Subject: Comments on"Programmatic Environmental Impact Statement for

Following are the comments of Duke Engineering and Services Inc. (DE&S) on the draft PEIS dated December 1997.

1. Volume I, Page S-3: We agree that conversion of the UF6 to U3O8 is the safest next step. This step can and should be initiated soon. The PEIS provides no compelling reason not to proceed with this step. There are abundant safety and environmental reasons, as documented in the PEIS, why continued storage as DUF6 is not the best alternative. Further, conversion to U3O8 does not preclude reuse of the depleted Uranium in the event national defense needs dictate or reuse options are ultimately proven cost effective. *60-1*

2. Cost Analysis Report, Paragraph 4.1.2 Treatment of Emptied Cylinders: The PEIS Cost Report assumes that empty DUF6 cylinders are crushed and sent to DOE facilities for disposal. There is no cost associated wiht disposal. This appears to be a completely unsupported assumption. There will be a cost, possibly a substantial cost, associated with disposal of the empty cylinders. They could be contaminated and require special handling. *60-2*

3. Cost Analysis Report, Paragraph 2.4.2 Use as Uranium Dioxide in DUCRETE for Shielding Applications: Report discusses the conversion of DUF6 to UO2 which in turn would be used to make DUCRETE. It should be pointed out that conversion of DUF6 to U3O8 and then to DUCRETE is an equally acceptable option. *60-3*

4. Cost Analysis Report, Paragraph 4.2.2 Revenue from Sale of Byproduct AHF and CaF2: This paragraph, as well as the PEIS Volume I, speak about sale of AHF byproduct. It should be noted that there is also a market for Aqueous HF. It is an equally acceptable option to make and market Aqueous HF. *60-4*

Thank you for the opportunity to comment. Please adress any questions on these comments to Bob Edmonds at the below address.

COMMENTOR NO. 61: BARCLAY, MIKE & JANASKIE, MARK OAK RIDGE, TENNESSEE

Name: Mike Barclay, Mark Janaskie Organization: DPRA, Inc.

Date Sent: 4/23/98

Document Ref.: PEIS: DUF6 PEIS OVERALL CONTENTS

----- COMMENT -----

Comments on the UF6 PEIS QUESTION:

The preferred UF6 management scenario presented in the PEIS carries with it a huge price tag. As such, would funding availability create performance uncertainties for DOE that need to be acknowledged? Specifically, will the funds to begin conversion be available in the amounts needed to initiate large-scale conversion efforts by the year 2009? Will annual funding be available in sufficient amounts to support conversion of the entire inventory within the expected year conversion period? Both questions point to temporal uncertainties that have a bearing on DOE's strategy for interim storage and maintenance of UF6 cylinders. Lesser amounts of funding would require longer - potentially much longer - storage, and a much greater emphasis on the corrosion protection and reconditioning of UF6 cylinders. As best we can discern from the PEIS and from discussions at the public hearings, DOE's strategy for UF6 cylinder corrosion control s to paint the cylinders with the worst corrosion. Perhaps inherent in this strategy is the idea that conversion efforts will start soon enough (e.g. 2009) and will conclude quickly enough (e g. 2029) that a larger number of cylinders do not need reconditioning to prevent additional corrosion. Is this generally accurate as to DOE's underlying strategy? How many cylinders does DOE anticipate painting at the three sites? It is our understanding that corrosion coatings from paint will last about ten years. Other corrosion protection options, although slightly more costly initially, offer much longer corrosion protection. Specifically, thermal spray coatings provide 30+ years of corrosion control, and offer other significant advantage including dramatic cost savings potential when life cycle costing is factored into total cost considerations. Has DOE factored life cycle costing into its decision making regarding the choice of paint over other coating options? Why did DOE choose paint as a preferred coating choice? *61-1* *61-2*

QUESTION: As stated in the PEIS, DOE's preference is to convert the entire inventory of UF6 material into usable products. Given the large volume of UF6, it is unclear whether a correspondingly large market demand exists for products arising from the conversion effort. Has DOE conducted a thorough market analysis (applications, demand) for UF6 conversion products? If so, please describe the results of this analysis, and an estimate of the percentage of the inventory for which definable, cost-effective usages exist? *61-3*

QUESTION: Given that there appears to be a limited market for the converted uranium oxide *61-4*

COMMENTOR NO. 61: BARCLAY, MIKE (CONT'D.)
OAK RIDGE, TENNESSEE

(at least based on current information), what will happen to the remainder of the UF 6 stockpile? In terms of program management, it seems certain that the remainder of unconverted UF6 will become a waste (per U.S. EPA regulations), and therefore will likely be transferred to DOE's EM program. Given this scenario, is there an integration of efforts currently taking place between DOE programs to address this kind of future scenario? In addition, have there been any discussions between DOE programs as to how the waste would be formally transitioned into the EM program? Also, given the transition of UF6 as waste into the EM program, is there an existing remediation/cleanup fund established to manage UF6 as waste material? *61-4 (Con't.)*

QUESTION: The PEIS states that there is a very substantial cost associated with transferring the non-conforming cylinders to a central location for conversion. The actual reference case stated in the PEIS estimates this cost at more than $800 million. Of that $800 million, approx. $161 million is for what DOE terms "overcontainers". Given that reference case in the PEIS, we would appreciate responses to the following questions:

1.) Has DOE looked at other options to "re-engineer" the non-conforming cylinders for transport/shipping, so as to eliminate the need to employ overcontainers?
2.) Is there an actual U.S. Dept. of Transportation regulation/requirement to use overcontainers for the UF6 cylinders? If so, what is it?
3.) Has the DOE held discussions with the U.S. DOT to discuss the requirements for shipping non-conforming cylinders? If so, is this what DOE based its $161 million overcontainer estimate on in the PEIS?
4.) Using the DOE reference case of $161 million for overcontainers, what is the true unit cost per cylinder for transporting the non-conforming cylinders to a central location for conversion?
5.) Does the term "overcontainers" mean the same as "overpacking", as in waste operations? *61-5*

QUESTION: We understand at the Nevada Test Site (NTS) has recently changed its Waste Acceptance Criteria in the last year or so, so that it can receive more DOE waste for disposal. Given the scenario that DOE determines that UF6 conversion is not economically feasible or prudent, would anything prevent the DOE from sending the UF6 waste to the NTS for disposal, or even interim storage (retrievable storage) prior to DOE developing a better, more economically efficient method to convert theUF6? *61-5*

1486

COMMENTOR NO. 62: ROSS, WAYNE A., & HAASS, MATHEW, P.E.
RICHLAND, WASHINGTON

COMMENTS ON THE DRAFT PROGRAMMATIC ENVIRONMENTAL IMPACT STATEMENT FOR ALTERNATIVE STRATEGIES FOR THE LONG-TERM MANAGEMENT AND USE OF DEPLETED URANIUM HEXAFLUORIDE

BY
Wayne A. Ross, Staff Engineer
Pacific Northwest National Laboratory
And
Mathew Haass, P.E.
Geosafe Corporation, Richland, WA
04/23/98

The following comments represent those of the authors and are not official comments of Battelle PNNL or Geosafe. They result from our continuing interest in the adoption of a lower-cost, long-term management strategy for the depleted uranium hexafluoride (UF_6).

We have previously provided information on the Molten Glass Reactor (MGR) Process for the single step immobilization of the uranium hexafluoride. Attached is a copy of the material previous provided in 1995 and 1996 on this process. This process has a factor of at least two lower cost than those included in the EIS. It should also have less environmental impacts. This option was not identified or considered in the EIS and is not within the bounds of the EIS for cost or for impacts. Therefore the EIS failed to consider a reasonable, technically feasible, cost-effective and environmentally favorable alternative for the disposition of the deleted UF_6. *62-1*

We recognize that additional work will be needed to verify the process, but as was stated in the Summary of the Cost Analysis Report Section 3.0 "Most technologies would require significant engineering development." Thus the MGR process with the previous developments for high-level and mixed waste vitrification and the development of the In-situ-Vitrification Process (ISV) would make the state of development superior to many of the other proposed alternatives. Thus, the lower state of development of the MGR process is not a sufficient reason for omitting it from consideration. *62-2*

The MGR process would be generally consistent with the intent of the preferred alternatives "use of the material." The MGR process would place the uranium in a high concentration in a vitreous state near the earth's surface, thus providing the opportunity to retrieve and reprocess the material as a very high grade ore, if in the future there is a need for depleted uranium. At the same time, the uranium has very low availability to the environment, as the vitreous waste form provides very good containment of the uranium. *62-3*

The "disposition of other alternatives" in the engineering analysis documents (section 4.5) stated "Another possible suboption is vitrification, in which depleted uranium oxide would be enclosed in glass. The basic technology is developed (for disposal of high-level radioactive waste), but other types of waste preparation are generally preferred for depleted uranium. Vitrified waste would require more space for disposal. In addition, a vitrification facility would be more complicated and costly to build and operate than a cementing facility." These statements to dismiss the alternative, while possibly applicable to a stand alone vitrification processing facility that would incorporate the waste into glass in canisters for disposal, are not applicable to the MGR Process and therefore the MGR process does not qualify for exclusion based on it. The MGR would have lower disposal area requirements and lower capital and operating costs that any of the proposed facilities *62-4*

We are very interesting in developing additional information about the MGR Process. If you would like additional information please contact us.

The following are additional comments from our review of the document:

1 There does not appear to be a strong basis for the preferred option. All alternatives have similar impacts and costs. *62-5*

2 The PEIS Summary document should contain a discussion of the various life cycle cost of the alternatives. *62-6*

COMMENTOR NO. 62: ROSS, WAYNE A., & HAASS, MATHEW, P.E. (CONT'D.) RICHLAND, WASHINGTON

3. The use of discounted cash flow, while technically justifiable, obscures the actual costs for the various processes. I have not seen many DOE projects where the costs have decreased with time. They nearly always increased. Discounting at a rate of 7% makes major operating costs in the out years very small and meaningless. A constant dollar basis is more meaningful, but probably still optimistic. 62-7

4. The projection that all of the materials will be used seems highly speculative. I did not identify in the draft how all the uranium would be used. An accounting of the use of the materials should be included in the final EIS. The accounting could identify future uses currently unidentified. Some order of magnitude calculations give the following results. Page H-10 indicates that 933 casks would be produced for 20 years for a total of 18,660 casks. I don't think there is sufficient uranium to produce that many casks based on other information. The current forecast (DOE/RW-0006 Rev 12, page 23) indicates that there will be less than 90,000 MTU of commercial sent fuel. If one uses the Multiple Purpose Cask (MPC) as the model cask, then each cask will hold 11 MTU. Thus, if all the spent fuel was to be shipped in MPC, about 8200 shipments is all that would be needed. It seems unrealistic, however, that all of the fuel would be shipped to the repository in single use casks. It would be far more economical for reactor operators to use reusable casks that can be use for 100's of shipments. Thus the use of most of the inventory for casks seems unrealistic and the preferred alternatives basis that all materials can be used is high speculative. Your position would be greatly strengthen if you had some statements from DOE-RW that they were planning on using the uranium for this purpose. With respect to the Hanford SNF in K-Basins there has been serious concerns expressed about the present of uranium mental in the repository. Further, we anticipate that the use of uranium as counter weights would not be highly regarded by industry, when they found the needs for radiation monitoring and inventory control were necessary. This leads us to the conclusion that a significant fraction of the materials will need to be processed and disposed. The MGR being a modular process could accomplish this very effectively and could be implemented in a relatively short period of time. 62-8

5. It was interesting to note that one of the major hazards identified was the shipment of HF. The MGR process converts the fluoride to calcium fluoride and dissolves it in the glass structure thus eliminating the HF hazard. It also means that there is only one transportation operation in the MGR process further reducing transportation impacts.. 62-9

6. The concentrated form of the final waste form requires less land space that other options since all of the uranium could be disposed in an area about 1200 ft by 1200 ft (33 acres). Note this is less than the disturbed area for one cask manufacturing facility (36 acres). 62-10

TREATMENT AND DISPOSAL OF UF_6 BY A MOLTEN GLASS REACTOR

Wayne Ross, John Tixler, and Xiangdon Feng
Pacific Northwest Laboratory[1]

SUMMARY

An economical method for the treatment and disposal of uranium hexafluoride (UF_6) has been conceived and is described in this proposal. The method would react the UF_6 within a large molten glass reactor (MGR), which would leave the uranium in moderate concentration in a highly stable glass form in a disposal site. The large processing capacity, minimal need for processing chemicals, and low operational labor should make the process very cost-effective. Order-of-magnitude estimates indicate that it will cost less than one-half of previous estimates, which only included costs to convert the UF_6 to UO_2 without considering disposal costs. The process could be implemented in phases using the mobile equipment so large capital expenditures for treatment facilities are not needed. This enables processing of the most hazardous fraction of the current inventory in the near term, in concert with recent recommendations of the Defense Nuclear Facilities Safety Board. The needs of the associated development program are identified.

BACKGROUND

Uranium hexafluoride has been accumulating for 40 years at the nation's enrichment facilities. The national inventory is now of the order of 500,000,000 kilograms, with the largest inventories at Paducah and Portsmouth and a smaller inventory at Oak Ridge. The Defense Nuclear Facilities Safety Board has recently reviewed the situation and found increasing hazards for the continued storage of the tails as uranium hexafluoride and has recommended that DOE take several actions. Its recommendations include: 1) action to protect against the dispersal of large amounts of uranium to soil and groundwater in years to come, 2) an early start to remedial action should be planned and then instituted, and 3) a study be instituted to determine whether a more suitable chemical form should be selected for long-term storage of the depleted uranium. In doing this, the Board also recognized that it could be a massive problem with extraordinary financial costs.

A 1991 study done by Oak Ridge[2] on just the conversion of the material to UO_2 estimated that the cost would be about $1.3-3.1 billion. More recently, in a press release[3], M-4 Technologies estimated that the worldwide market for treatment of uranium hexafluoride tails would be about $6-10 billion. Thus, it is apparent that the costs for treatment and disposal of these materials could be a multi-billion dollar activity and opportunities to significantly reduce those costs should be vigorously pursed.

[1] Pacific Northwest Laboratory is operated for the U.S. Department of Energy by Battelle Memorial Institute under Contract DE-AC06-76RLO-1830.

CARBONDALE, ILLINOIS

Charles Bradley
US DOE (NE-40)
19901 Germantown Rd.
Germantown, MD 20874

April 13, 1998

Dear Mr. Bradley,

These are the comments of the undersigned on the Depleted Uranium cylinders DPEIS. There are some 50,000 plus cylinders of the DUF6 containing from 10 to 14 tons of material apiece currently stored in the three sites, Paducah, Portsmouth, and Oak Ridge.

The scope of the DPEIS is inadequate to cover the activities required to deal with the cylinders. Implementing either of the conversion alternatives will trigger a series of events which will have to take place in order to complete the conversion. These include building factories to do the conversion and for cleaning the highly radioactive residues out of the emptied cylinders. The DUF6 will have to be defluorinated, which is a highly dangerous activity. The converted material and the empty cylinders will have to disposed or stored, as will the hydrogen fluoride which is separated from the DUF6. 63-1

These activities are all connected actions which require a hard look in combination with the ongoing cleanup activities at the three facilities where the cylinders are stored - Paducah, Portsmouth, and Oak Ridge. There are clearly cumulative effects from these proposals and projects which are not adequately addressed in the draft. 63-2

Although the largest majority of cylinders, some 40,000, are at Paducah, they are inadequately stacked and stored presently. These are vulnerable to the high seismic risk at Paducah from the New Madrid fault. Because it will be decades or longer before this material can be converted, the risks from earthquake damage go greater as time goes on. Any conversion facilities planned for Paducah have to fully consider the earthquake potential at Paducah, and any construction of conversion facilities at Paducah would have to be made to an earthquake standard. The extra costs of this need to be disclosed. 62-3

If cylinders are going to be transported for conversion, then the risks transportation needs to be considered carefully. This would require many thousands of shipments. Many of the older cylinders may not be capable of being lifted or loaded for transportation. Some may not be able to be heated to be emptied. All of these problems could significantly increase the cost. The DOE needs to be more up-front about the real dollar costs of this problem. 62-4

Although it appears that the best alternative is converting the material from the reactive UF 6 form to the more stable uranium oxide form, the DPEIS doesn't give enough information for the commentors to decide where the best place for conversion would be and the best methods. 62-5

Finally, it seems ill-advised to continue to fill more cylinders daily with more DUF6 while this huge problem of disposal continues to accumulate. If the nuclear industry cannot manufacture its product without creating such huge amounts of toxic waste, it should strongly consider ceasing production. 62-6

Thank you for considering these comments.

Sincerely,

Bill Cronin
Melinda Harmon

RE: Depleted Uranium PEIS:
DOE/EIS-0269, "DRAFT PROGRAMMATIC ENVIRONMENTAL IMPACT STATEMENT FOR ALTERNATIVE STRATEGIES FOR THE LONG-TERM MANAGEMENT AND USE OF DEPLETED URANIUM HEXAFLUORIDE," (PEIS), dated December, 1997.

and its supporting documents:
UCRL-AR-124060, "DEPLETED URANIUM MANAGEMENT PROGRAM: THE ENGINEERING ANALYSIS REPORT FOR THE LONG-TERM MANAGEMENT OF DEPLETED URANIUM HEXAFLUORIDE," Rev. 2, Volumes 1 and 2, (EAR), dated May, 1997.

UCRL-AR-127850, "COST ANALYSIS REPORT FOR THE LONG-TERM MANAGEMENT OF DEPLETED URANIUM HEXAFLUORIDE," (CAR), dated May, 1997.

Dear Mr. Bradley,

Thank-you for the opportunity to review and comment on the Depleted Uranium Programmatic Environmental Impact Statement (DU PEIS). I find it to be interesting reading, having worked in and out of uranium-related programs for two decades. I find that the PEIS has over simplified and, in some cases, over-looked important facets of DU that have important implications for its management, and I feel compelled to comment on the subject for the record. My comments are attached. Summarizing, the comments are:

- Disposal and waste management are significant issues not well addressed in the PEIS. It is highly probable that a significant fraction of the DU - perhaps all of it - will end up as a radioactive waste, either as itself or in a reuse "product." It is not until well into the PEIS (Chapter 5) that the reader is informed that near surface disposal will significantly exceed 10 CFR Part 61 limits (for NRC/commercial facilities) and DOE limits for public doses. In other words, codified regulations will be broken. Also, mined cavity disposal, which may be a solution for DU, does not currently exist for LLW, and there are no current plans for mined cavity disposal of LLW in the U.S. 64-1

- Market demand does not and is not likely to exist for the reuse of DU, and the PEIS does not identify routes to build such a market. Currently, cost and liability are almost insurmountable hurdles for the "reuse" of DU, as its competitor for the (most likely) reuse scenarios (spent fuel shielding) is concrete. The use of DU shielding requires an integrated approach to minimize consumer, utility, and DOE costs, and DOE acceptance of DU liability (basically disposal). This implies that even for reuse scenarios, the DU form must be compatible with disposal. Myself and other authors have written on this extensively. 64-2

- No significant uses of DU currently exist in shielding applications. No licensed spent fuel casks use DU shielding, and there are no current plans or pending applications for spent fuel casks 64-3

COMMENTOR NO. 64: MURRAY, ALEXANDER P. (CONT'D.)
GAITHERSBURG, MARYLAND

using DU. DOE-RW has identified DU as a cost and machining disadvantage for spent fuel casks. The PEIS needs to openly state these points, and identify means to resolve them. Again, myself and others have written on this extensively.

- The analyses and alternatives are uneven and neither analyzed at comparable levels nor taken to equivalent endpoints. For example, all of the uranium oxides will perform differently. The gelation-produced uranium dioxide is equivalent to nuclear fuel in terms of high density and low porosity, and will have improved leach resistance, heat transfer, and sizing as compared to the other oxides (including the lower density uranium dioxide) - in short, it's a better material. Significant items have been left out of the analyses (e.g., disposition of shielding, rollup of disposal impacts, and protective action distance impacts on site sizes). There is no reconciliation between known technologies/impacts and those in the report - for example, the proposed uranium dioxide pellet furnaces used for analysis in the PEIS correspond to 100-200 teU/yr capacity, not the 7,000 teU/yr capacity claimed by the analysis. The same pellet technology also currently requires about 1 FTE/te/yr, not the 0.014 FTE/te/yr used in the PEIS. The conversion reactors (low number and large size) appear to be very optimistic. The gelation facility includes two plants (one to U3O8, and one to UO2), which is not consistent with the technology and explains why its impacts are slightly higher. The PEIS should recognize these shortcomings, limitations, and differences, and be more equivalent in its analyses. 64-4

- The limitations of the technologies should be recognized in the PEIS, and means identified to address them. Only the French conversion to U3O8 technology has been used on a scale approaching that needed for the PEIS, and it needed compactors to increase the density to circa 3 g/cc. To state that current pelletization technology is established for the throughputs and equipment used in the PEIS analyses is incorrect - the gelation route with VTF's has actually achieved higher equipment rates per unit floor area. 64-5

- Recent NRC positions in the area are not stated in the EIS, but are alluded to in the supporting documentation. The NRC (in a response to the FR notice and in a separate EIS) has clearly stated concerns about the lack of a use for the DU, the likely probability that a significant amount (if not all) of the DU will become waste, and the high probability that DU will require "deep disposal" because of unacceptably high MEI doserates from near surface disposal. Such significant conclusions by a regulator should be included and discussed in the PEIS. 64-6

- DU metal seems to receive a favorable treatment in the PEIS with impacts significantly below historical experience. This appears because some of the release fractions and impacts are underestimated significantly (beyond technological optimism). This should be corrected in the PEIS. 64-7

- Gelation technology appears to receive a less than favorable treatment in the PEIS, using TCE as a solvent instead of oil, tray instead of tube furnaces, and including a U3O8 production step, followed by nitric acid dissolution and UO2 production (the aforementioned two plants in one misrepresentation). While in the final analysis the difference is small, it is incorrect, and the PEIS should correct the misrepresentation. There are recent published articles (which you have copies of) that give a detailed description of gelation technology as applied to DU, and these should be used as references in the PEIS. 64-8

- Costs are not brought forward in the PEIS. Costs from the CAR and from published articles should be discussed and reconciled in the PEIS, as cost is likely to be a significant determinant in the DU disposition option selected. 64-9

1489

COMMENTOR NO. 64: MURRAY, ALEXANDER P. (CONT'D.)
GAITHERSBURG, MARYLAND

- DUSCOBS and PYRUC shielding materials are not discussed in the PEIS. DOE appears to have an interest in these materials, and they are likely to have better properties for disposal than either DU metal or uranium oxide in concrete. As such, they should be mentioned and discussed. 64-10

I hope you find these comments useful and incorporate them into the PEIS. If you have trouble finding any of the publically available articles, please let me know.

Sincerely Yours,
Alex Murray
Alexander P. Murray,
Private Consultant.

Attachment.

COMMENTOR NO. 64: MURRAY, ALEXANDER P. (CONT'D.)
GAITHERSBURG, MARYLAND

Comments:

a. Waste: In Section S.4.8 on page S-40, waste management impacts are discussed. DOE should consider briefly highlighting the potential uranium content of the secondary streams, along with a brief assessment of acceptability for either reuse/nonradioactive disposal or disposal as radioactive waste. DOE should expand the discussion in the last paragraph about uranium disposal as LLW. The DOE may wish to cite regulatory agency positions on the wastes, including the NRC position letter (from Benero) sent to DOE as part of this EIS process and the NRC LES EIS analysis. For example, the NRC documents provide analyses supporting DU disposal as a LLW, but note that its disposal could require a mine or another means of "deep" ("Non near-surface") disposal. Currently, no "deep" disposal sites exist, and all current LLW disposal sites (existing and planned) use near-surface facilities. Thus, it would seem that disposal of DU may have significant impacts and regulatory requirements beyond those listed in the PEIS. DOE should consider adding the cumulative impacts from DU oxide disposal to Section S.4.13 "Cumulative Impacts." 64-11

- Leach Rates - Page 2-22 briefly mentions leach rates and waste forms, and states that grouted wastes are representative of immobilized waste forms with low leach rates, with the implication that grouting is also representative of vitrification. DOE should clarify this text, as grouting may be representative for some parameters (e.g., facility size) but not representative in others (e.g., energy usage, emissions). Also, while grouting should provide for somewhat lower leach rates as compared to the ungrouted material, vitrification would be expected to provide for much lower leach rates than grouting (typically, 5-6 orders of magnitude less), and this may be an issue for some disposal options. Consequently, these items should be discussed. 64-12
- Empty Cylinders - The impacts from disposition of the empty cylinders are not included, although potential options are listed (page 2-23). It would seem reasonable to provide a brief discussion on these options and include impacts from cylinder disposition in the EIS. 64-13
- Water Impacts - The summary table of impacts (Table 2-2) and the supporting text for the water and soil section (page 2-50) note that the groundwater uranium concentrations will exceed drinking water guidelines. It is recommended that the expected concentrations are also expressed in terms of individual radiation doses. 64-14
- Waste - Pages 2-52 et seq present a summary of the waste management impacts from the impacts. Comparisons are primarily with the DOE waste management system, although these facilities could also be commercially operated under NRC or State regulations. Consequently, DOE should consider adding a comparison to commercial LLW generation rates and categorization per 10 CFR Part 61. The section mould also include estimated uranium levels for the magnesium fluoride waste (from DU metal production) and discuss the aspects of DU disposal, including the potential need for either a dedicated or a deep disposal facility. 64-15
- Dilution of Effluents - On page 5-51, the text indicates effluent levels exceeding EPA guidelines for uranium, but notes that the concentration would be much lower and below the guideline after dilution in nearby surface water. This should be clarified, and potential dose consequences of these effluents presented. 64-16
- Metal Waste - Page 5-76 of the PEIS presents waste management for the metal cask manufacturing route. Waste management appears to have overlooked secondary 64-17

1490

COMMENTOR NO. 64: MURRAY, ALEXANDER P. (CONT'D.)
GAITHERSBURG, MARYLAND

wastes related to manufacturing, which are unique to uranium metal. For example, induction furnaces for uranium metal are usually lined with graphite, which requires periodic removal and replacement (sometimes as frequently as every ten charges or so). Also, while the proposed approach appears to use primarily direct casting, some uranium metal machining operations may be required, and, historically, these generate significant wastes containing partially oxidized uranium metal. The PEIS should include these potential impacts that primarily affect only the metal route. 64-17

Doses from DU Disposal: Section 5.6 (pages 5-78 at seq) and Appendix I present the impacts from disposal of the DU, for both the operational phase and the post-closure period. The radiological impacts from the accidents seem unexpectedly high; for example, the analysis shows public doses of up to 1.1 rem and noninvolved worker doses as high as 140 rem, apparently due to earthquake initiated events, without explanation. The routine impacts also seem high for the postclosure phase and appear to follow the radiological order: mine impacts>vault impacts>trench impacts. Calculations appear to use an infiltration area effect and do not account for chemical form, solubility, and kinetic effects. Table I.31 contains zero values for the dry site doses fc. all three disposal approaches, and no collective dose estimates are included. These points are non-obvious and it is recommended that they are explained in more detail. 64-18

b. Unspecified Applications: On page S-11 and later in the summary (pages S-42 at seq), DOE identifies the preferred alternative strategy as use of 100% of the DU hexafluoride inventory, as either uranium oxide, uranium metal, or a combination of both, without specifying the use of the material and the potential impacts (positive and negative) from such DU use. The PEIS also does not provide information indicating a market demand capable of consuming 100% of the DU inventory, but the conversion of the DU hexafluoride would occur as "... uses for these [uranium oxide and metal] products become available" (page S-43). Without applications for significant quantities of DU oxides and metals, these DU materials may ultimately become a waste material. The discussion does not discuss regulatory and licensing requirements for these DU applications. It is recommended that (1) DOE identifies the likely market consumption of DU oxides and metals over the timeframe of the EIS, (2) DOE estimates the impacts from these potential DU uses, (3) DOE considers the potential of the converted DU materials becoming a waste, thus, requiring conversion into forms compatible with disposal, and (4) DOE evaluates the likely regulatory and licensing aspects. 64-19

c. DU as Cask Shielding: DOE appears to be relying upon the potential future use of DU as SNF cask shielding for a large consumption of its DU inventory (see page S-43 and 1-8, and Volume 2 of the EAR, which analyzes a DU cask manufacturing facility as the only use of DU). If this is indeed the case, DOE may wish to describe and discuss it in a little more detail in the PEIS summary and in Section 2.5 (pages 2-54 et seq), and it should be noted that no currently licensed or planned SNF cask uses DU. 64-20

d. Fate of DU Shielding: As currently written, the PEIS does not include a discussion of the eventual fate and potential impacts of the DU SNF cask after its use (e.g., see pages 2-14 and 64-21

COMMENTOR NO. 64: MURRAY, ALEXANDER P. (CONT'D.)
GAITHERSBURG, MARYLAND

2-15). Pages S-55 and S-65 also mention that DU cask disposition after use is excluded, and page S-65 notes that disposal would amount to an additional 180,000 cubic meters (6.4 million cubic feet) of waste requiring disposal, with a (calculated) average specific gravity of 2.2. This does not seem inconsequential, particularly if a dedicated disposal facility is required and the impacts are estimated to be similar to disposal (e.g., page S-83 et seq; exceeding 10 CFR Part 61.41 dose limits). Also, there are statements in the document that question if significant quantities of DU metal are suitable for disposal (e.g., last paragraph on page 2-21). Inclusion of a discussion about the disposition of the DU cask after use, and potential impacts, is recommended. *64-21*

e. "Uranium Oxides." The PEIS generally combines all uranium oxide compounds under the title "uranium oxides" for consideration in the alternatives and strategies (see page S-6 et seq). This seems too all inclusive, as uranium oxides have significantly different chemical and physical properties that produce a wide range of ES&H impacts. For example, uranium octaoxide is a high porosity powder, with a low density and a significant respirable fraction. Uranium dioxide powder is also porous, and can spontaneously ignite in air. On the other hand, sintered uranium dioxide has the highest density of the uranium oxides and is essentially pore free. The presence (or absence) of pores also has significant implications for the potential disposal of the material, either as a management option or as an end-use item; a denser, essentially pore free material would appear to be advantageous. Thus, a uranium dioxide material sintered to a lower density (say, 4-5 g/cc) would not be expected to perform as well in a disposal environment as a uranium dioxide sintered to a high density (say, 9-10 g/cc). It is recommended that more qualifiers are given to the term "uranium oxides," perhaps including low and high density as the principal discriminators. *64-22*

f. Equivalent Bases and Life-Cycle Effects: The text does not seem to incorporate a life-cycle approach to the different management alternatives and compare them on an equivalent basis (see pages S-7 et seq). For example, recycle (if a market exists) and disposal would seem to be the logical endpoints for all of the alternative branches shown in Figure S.2, and may influence the impacts and potential alternative(s) selected. However, disposal is only shown for the disposal as oxide alternative. It would seem that the "manufacture and use" alternatives will ultimately result in impacts from the DU component; for example, the material (perhaps as itself or in a product) could be shipped to a disposal facility. Such potential impacts do not appear to be included in the analysis, and may even preclude some options or require additional conversion and conditioning; for example, without supporting analyses, it is unlikely that significant quantities of DU metal can meet the regulatory requirements of disposal sites. Thus, pursuit of use as a metal option may require another conversion facility (with its impacts) to convert the DU metal into a form compatible with disposal. Other examples of the need for equivalent bases include the oxide conversion routes, due to fundamental differences in the uranium oxide forms. One of the specific oxide conversion routes (gelation) appears to be manufacturing uranium dioxide with properties comparable to high density nuclear fuel which would be anticipated to have improved stability and related properties as compared to the other oxides. The gelation route also appears to include two plants - one for uranium octaoxide production and one for dissolution/uranium dioxide production - which appears inconsistent with literature reports on the process (i.e., only one plant; no production of uranium octaoxide) and *64-23*

1491

COMMENTOR NO. 64: MURRAY, ALEXANDER P. (CONT'D.)
GAITHERSBURG, MARYLAND

the other oxide conversion routes. Long-term storage also appears to lack the realization of ultimate disposal in the future. The PEIS should consider and analyze the alternatives on an equivalent basis with the same/comparable endpoints and include life-cycle effects.

g. Results: Pages S-15 et seq summarize and compare the results of the impacts for the alternative management strategies. Some of these results seem inconsistent and are not intuitively obvious. For example, it is not clear why the use as uranium oxide results in higher impacts than the use as uranium metal (see pages S-20 and S-49) - the opposite would be anticipated. Land use impacts seem uneven; conversion and metal use plants would be anticipated to have larger land use because of facility size and require potentially larger setbacks for potential accident mitigation from uranium releases (see the NRC LES EIS). It is not clear if the disposal analyses include all of the potential long-term impacts and doses from uranium leaching from the disposal area. It is recommended that DOE consider greater consistency in the results and clarify the summary. *64-24*

h. Ranking: The summary of the results (page S-15 et seq) does not include a ranking of alternatives, and implies that all of the alternatives are acceptable. DOE may wish to rank or identify those alternative(s) that appear more favorable than others based upon the analysis. DOE may also want to consider if any of the proposed alternatives are precluded by the analysis; for example, page S-84 mentions individual (groundwater ingestion) doses of 100 mrem/yr from disposal, thus exceeding 10 CFR Part 61 standards of 25 mrem/yr. Page S-84 also mentions a scenario for a hypothetical future resident living on the disposal site and receiving radiation doses as high as 10 rem/yr. The PEIS summary also mentions an NOV on storage at the Portsmouth facility, which might imply that a no-action alternative is not a viable option for this site. *64-25*

i. Technology and Equipment Development: The PEIS encompasses numerous technologies that are at different stages of development, in terms of process, understanding, equipment, (potential) impacts, and uncertainties. For example, of the conversion, application, and disposal impacts discussed within the summary, none are practiced on any scale domestically, and only conversion to the octaoxide is practiced on a large scale internationally, producing a low density product. Thus, there is only one direct analogy. DOE should consider including a technology discussion, with status and assessment, perhaps with either a time schedule or probability of success, for some of these technologies. For example, it seems like a significant extension of existing uranium dioxide sintering technology to take pellets from 100 te(U)/yr/line to 7,000 te(U)/yr/line. From the uranium dioxide technology perspective, microspheres (e.g., from gelation) may be the more mature technology because of the (potential) use of tube furnaces and pilot plant tests with equipment processing rates an order of magnitude larger. Similarly, a uranium dioxide/concrete cask approach appears to be a significantly easier technology to understand and scale than casting a 40 te(U) metal shield. *64-26*

j. Existing Facilities and Experience: There are obvious analogies with existing, commercial fuel cycle facilities, which process uranium hexafluoride into uranium dioxide (for nuclear fuel) and

COMMENTOR NO. 64: MURRAY, ALEXANDER P. (CONT'D.)
GAITHERSBURG, MARYLAND

(to a lesser extent) uranium metal. These facilities are already licensed by the appropriate regulatory agencies. The PEIS does not mention these facilities, either as a source of experience or as a source of processing capacity, particularly during the development of uses for the DU materials and as a means for surge capacity. The PEIS also does not appear to draw upon the operating experience of these facilities, including waste generation and uranium content of byproducts. DOE may wish to include the experience of operating commercial facilities and comment upon their potential use (or non-use) during the development of applications and uses for the DU. 64-27

k. Regulatory Basis for Future Facilities: The PEIS indicates several facilities may be involved for the management alternatives, and may involve DOE, commercial, and/or both types of facilities. DOE should briefly discuss the regulatory bases for these facilities, potential differences (if any), and any impacts, and any effects from facilities transitioning from DOE to the NRC regulatory environment. 64-28

l. Economics: The PEIS mentions a separate Cost Analysis Report (CAR) as providing input to the PEIS (e.g., page 1-7). However, program costs do not appear to be included in the analyses. DOE should consider including the costs and other economic impacts in the PEIS, perhaps as part of the summary (e.g., in Table S-2). 64-29

m. DU Quantities: The insert on page S-2 identifies some 46,422 DU cylinders distributed between the three sites. While the total quantity is listed in the main text of the report, it would be helpful to have the approximate masses (as either MTU or MTUF6) for the three sites listed in the summary as well. The insert on page S-2 also notes that an additional 6,000 cylinders have been produced by USEC. It is suggested that this number is also divided between the sites and expressed in mass quantities. It is also recommended that a brief discussion about the USEC DU is included, perhaps as part of the first paragraph on page S-4. While the EIS excludes the USEC DU from its analysis, it also implies that there is a reasonable probability of it becoming DOE's responsibility. Consequently, DOE may want to consider that possibility in its impact analysis. 64-30

n. Other DU Uses: Page 2-21 mentions non-shield use of DU. No mention is made of quantities or relative percentages of the DU inventory. Also, it is not self-explanatory that DU cask manufacturing and uses bound all of the potential uses; for example, metal uses would appear to require a significant amount of alloying and/or machining, and involve handling and disposal concerns. DOE may wish to include a longer discussion and a better explanation. 64-31

o. Other Sites: Pages 3-56 et seq present information on the generic sites for wet and dry locations, and mention that the site data for each are derived from actual wet and dry sites. It is suggested that the actual sites which provide the basis for the generic locations are listed. 64-32

p. TimeFrame: Page 4-2 lists a 41 year time period for the EIS (through the year 2039), and

1492

COMMENTOR NO. 64: MURRAY, ALEXANDER P. (CONT'D.)
GAITHERSBURG, MARYLAND

indicates activities beyond 2039 would be subject to appropriate NEPA reviews and decisions in the future. This appears to truncate the analyses for some of the alternatives which might influence the selection of the preferred option; for example, impacts from wastes in a disposal cell are unlikely to occur by 2039, major cylinder/container replacements may be required for the storage option in the 10-20 years after 2039, significant applications may not have developed etc. DOE may wish to consider a time period consistent with the logical conclusion of the options or their "life-cycle," which may require a timeframe beyond 2039. 64-33

q. Failure Rates: Pages 5-3 and 5-19 discuss the estimated cylinder failure rates for the No Action and UF6 Storage alternative. These appear to use the opposite ends of the failure rate range - No Action uses the lowest failure rate, while Storage uses the highest failure rate - without explanation. Also, the existing cylinders may not have adequate wall thicknesses under either alternative due to corrosion over the years (see Appendix E), and the DU may have to be transferred to new cylinders within the timeframe covered by the EIS. DOE should consider presenting a discussion on these items in the text. Also, on page 5-40, Table 5.4 lists tank rupture accidents as "incredible" events. Usually, these are assigned a value corresponding to the "extremely unlikely" frequency bin. A brief discussion is recommended. 64-34

r. Site Sizes: Page 5-55 identifies land use requirements for the facilities. These seem small, particularly when compared to other proposed facilities performing similar operations (e.g., the LES EIS analyzes a generic conversion facility with a site area of 1,000 acres). The text also does not indicate if any major setbacks, protective action distances (PAD's), or planning zones are likely to be needed around the facility because of the handling of large quantities of DU, the hexafluoride, and/or the metal (including melting operations). DOE should consider a discussion in the text on these subject matters. 64-35

s. Accident Consequences: Pages 5-55 et seq discuss the use and impacts of uranium dioxide as shielding, and pages 5-66 et seq discuss the use and impacts of uranium metal as shielding. Some of the values imply non-intuitively obvious lower impacts from a metal route as compared to the oxide route; it is recommended that these are discussed and explained in more detail. For example, the text on page 5-71 estimates the highest consequences from an accident with the metal route as 15 mrem (from a fire involving three cylinders, an energetic accident with reactive materials), as compared to 270 mrem (from an earthquake during uranium dioxide storage, a low energy event with non-reactive materials) - there is no explanation for the difference. Also, the supporting information in Appendix H shows similar inconsistencies; the unlikely accidents for the oxide (Table H-5, page H-16) are significantly higher than the corresponding accidents for the metal (page H-17). Page H-17 also contains apparent inconsistencies and incongruances; the mishandling/dropping of solid DU metal accident releases a greater quantity of uranium than the molten uranium accidents. Upon further review, the source of these apparent anomalies goes back to Section 6.11 of the EAR, where different material at risk and release fractions were used. All of the metal cases examined used the least bounding values, and values inappropriately low for the phenomena being modelled per the DOE accident handbook. These errors should be corrected. 64-36

Comments on the Department of Energy's
Draft Programmatic Environmental Impact Statement for Alternative Strategies for the Long-Term Management and Use of Depleted Uranium Hexaflouride

The Department of Energy's (DOE) Draft Programmatic Environmental Impact Statement (D-PEIS) for Alternative Strategies for the Long-Term Management and Use of Depleted Uranium Hexaflouride (DU-HF) is lacking with respect to it's assessment of the long-term impacts of converting and using DU-HF. A review of the summary clearly depicts DOE's strong interest in utilizing this stockpile, but the supporting evidence does not adequately address the legitimate environmental concerns associated with DU use - concerns which are based on a growing body of scientific data. While the summary presents a clear picture of DOE's commitment to provide "support for the development of applications for depleted uranium products," it does not, and with our current knowledge probably cannot, adequately assess the current extent of environmental impacts at the three DU-HF sites. In turn, it cannot assess what impacts to the nearby communities and the local environment will result from future releases of the evaluated alternatives. Without better scientific knowledge of the toxicity of DU, it is impossible to provide even a guess of the potential impacts, which makes the risk projections provided within this summary of little value. As a result, we support the long-term storage of this material, with improved containment and monitoring, until we are better equipped to assess the toxicity and safe uses of the DU stockpile. 65-1

Up front, it should be noted that our limited resources only allowed us to review the summary and not the entire PEIS. Thus, we acknowledge that some discussion within the body of the PEIS itself may address a few of the concerns raised in the comments that follow. We believe that it is acceptable for us to comment based solely on the summary, as this is the main document likely to be reviewed by the commenting public. We hope that these comments are still useful for DOE and we request that these comments be considered with the utmost diligence.

Current Storage

Significant concerns exist with current storage conditions based on the fact that cylinders now show evidence of corrosion and that at least seven cylinders have developed breaches. While the management plan in place is to "continue safe storage," it seems to be in question whether safe storage is currently taking place. This is supported by community concerns that have been expressed from around the sites, and the Notice of Violation that has been issued by the Ohio Environmental Protection Agency. We assume that the Defense Nuclear Facilities Safety Board has suggested improving both inspection time tables and storage approaches. 65-2

While the summary explains that a dense plug is formed by the reaction of moist air with the exposed DU-HF, the summary does not address if any studies have been made to assess the adequacy of such a plug. Certainly, this plug may not be air tight, allowing additional moisture to enter the container thereby acting as a continued source of HF gas. It would seem prudent for DOE to develop a better storage system regardless of the decision to use or store these cylinders. Either way, many 65-3

1494

COMMENTOR NO. 65: UNIVERSITY OF MARYLAND (CONT'D.)
BALTIMORE, MARYLAND

of these containers will still house DU-HF for years or decades to come, and will require improved storage capabilities.

Assessment of Risks

While the summary lists various technical assessments that have been or are being conducted, none of these studies nor this PEIS really assess the potential environmental impacts from the current production and storage operations or the proposed alternatives. This flaw has been seen in PEISs produced for other purposes by DoD, where the PEIS selects a direction to focus development dollars, but does not consider the specific technologies that may be employed and does not consider the site-specific characteristics. In the end, such factors will strongly influence the extent of contamination and impacts from the general approach (i.e. use as oxide) selected. Once the process reaches the point where these specific factors are assessed, there will be serious pressures to make the approach work given the time and financial investments made. This limits the adequacy of the site-specific assessments when they are made. In turn, we strongly suggest that DOE take a serious look at the potential risks from converting DU-HF and its use an oxide or metal before one selects a programmatic alternative. Factors that should be considered in this evaluation are the migrating potential of DU that will be released, the cumulative impacts of such releases in conjunction with pre-existing contamination, and the potential impacts on costs of the selected approach when the toxicity of such compounds are elucidated. 65-4

Affected Environment

The summary sorely lacks a description of the environmental sampling that has been conducted at each site. In the case of Paducah, Kentucky, it is mentioned that the effluent discharges are regulated under Kentucky Pollutant Discharge Elimination System, but there is no discussion of whether radiological parameters and/or uranium metal are monitored in this system. While the specifics of such a monitoring program may be beyond the scope of this summary, whether or not environmental sampling from Big Bayou and Little Bayou Creeks has been considered in selecting the proposed alternative is relevant and critical. The extent of contamination in surface water and sediments is a significant issue, since future activity will add to the levels already present even if future emissions do not exceed the governing release limits of the time. There is no discussion of such sampling, and there clearly needs to be in order to determine the current baseline risk level at the site, both for human health and ecological receptors. The potential exposure pathways (see below) and current ambient levels are important for projecting future exposure scenarios. 65-5

As with the Paducah site, there is no mention of the current extent of contamination in local media at the Portsmouth site in Ohio. Assuming significant contamination is already present as suggested by the groundwater data that are referenced, would it affect the feasibility of the selected alternative if it were deemed necessary to conduct such operations at other sites? This question requires serious consideration, particularly since the conversion technology to be used to produce the oxide or metal is not assessed in the D-PEIS. If contamination is approaching environmental limits, then even the expected discharges may not be acceptable. As with any Brownfields site, the investor 65-6

COMMENTOR NO. 65: UNIVERSITY OF MARYLAND (CONT'D.)
BALTIMORE, MARYLAND

(DOE in this case) certainly should want to know whether they will be able to conduct operations at the site or nearby (as suggested on S-14), requiring adequate site characterization. From the description of environmental settings, it is unclear whether the environmental data on the natural environment are limited to climatic conditions or if the site specific environmental data includes current contamination levels. 65-6 (Con't.)

Exposure Pathway Assessment

In Table S-2, the chemical exposure of concern for both the non-involved worker and the general public is listed as falling below a hazard index of 1. Did the calculation of such risks include all the pertinent exposure pathways which may apply, including fish/game consumption, drinking water, inhalation, etc? It would be inappropriate to consider just the workplace exposure for the non-involved worker, if that person lived nearby and fished in the local stream. In predicting future impacts or risks, one must consider the individual's total exposure. This has been a serious flaw within risk assessments at Superfund sites, and improving this approach is not unreasonable to request given that 1) this is a "looking forward" assessment which allows us to be more protective since the contamination has not yet been produced, and 2) we are still unable to adequately assess other parameters, such as synergistic effects, which do reduce the conservativeness of the risk projections being made. 65-7

Toxicity of Uranium

Based on the limited research that has been completed on the toxicity of uranium metal, it seems quite premature to be selecting an alternative in this PEIS for the next 40 years. In light of the ignorance with which the Department of Defense exposed Gulf War soldiers to DU, DOE should strongly consider whether it wants to make the same short-sighted mistake. We have been intensively studying lead for decades and we are still learning more everyday about its toxicological effects and the low levels at which such effects are exerted. We are still trying to recover from the use of this metal in paint and gasoline, which is a direct result of our inability or disinterest in predicting environmental accumulation and the resulting impacts if the compound turned out to be toxic. As a society, we must not make the same mistake again by blindly pursuing commercial use of the DU-HF stock. 65-8

Given the extensive research currently underway regarding DU, it does not seem appropriate to be completing this PEIS at the present time. Research at the Armed Forces Radiobiology Research Institute suggests that DU may be more mutagenic than lead, and that this metal can reach the brain and fetuses of exposed animals. Additionally, work is currently being conducted on exposed Gulf War veterans at the VA Hospital in Baltimore, Maryland, which may provide valuable information on the distribution of DU within the body and possible impacts on specific organ systems in humans. It would seem logical to learn from our mistakes and select long-term storage until we are better able to assess potential human health impacts from its toxicity as well as its radiological emissions in localized lung tissue. 65-9

COMMENTOR NO. 65: UNIVERSITY OF MARYLAND (CONT'D.)
BALTIMORE, MARYLAND

Until the results of these various investigations are published and reviewed by the scientific community, we cannot know if the projections of adverse effects are accurate. The chemical toxicity of low level DU exposure does not seem to have been adequately considered. The monitoring of effects in soldiers is still in progress, so we question statements describing how "a few workers have been exposed to estimated amounts of uranium approximately three times the guideline levels used for assessing irreversible adverse effects, but none of these workers actually experienced such effects." The effects used to establish the guideline values do not include low level, chronic effects of DU just now being recognized. 65-9 (Con't.)

Release and Environmental Fate

Predicting the extent of release and long-term fate of the DU released during its conversion and subsequent use should be meticulously evaluated. On page S-42, the authors state the "potential uses that are capable of consuming a substantial fraction or all of the depleted uranium inventory are not yet fully developed, and it is entirely possible that the 100% use scenario may involve some of the material being converted to an oxide and used, with the remaining portion being converted to uranium metal and used." Without reviewing the specific industrial processes to be implemented in the conversion and use alternative, it is impossible to accurately assess how much DU would be released. This is a serious issue since other industrial sites have been closed down due to the excessive release and migration of DU. This quote also reveals that little is known about what commercial applications will exist for the converted material. Despite these unknowns, the PEIS clearly reflects an entrepreneurial eagerness by DOE to utilize the stock in this fashion. This assessment of the summary is further supported by a statement on the following page in which the authors indicate that "this preferred alternative allows flexibility in responding to changing market conditions and to the continued development of new uses for conversion products." We question whether this is appropriate, as the conversion process may be pushed forward without a clear plan and understanding of its eventual use. This, in turn, will evoke significant pressures to find a use for the oxide or metal and likely reduce the quality of the decision process used to determine acceptable use. 65-10

Ecological Impacts

The consideration of ecological impacts in the summary is limited. A full paragraph discusses the loss of habitat resulting from carrying out particular alternatives. However, no concrete information is provided regarding the chemical effects of elevated uranium concentrations on ecological receptors, although the potential for such effects is mentioned. While few data exist for specific ecological impacts, a study by Los Alamos on the long-term fate of DU found significant concentrations in various aquatic plant species as well as aquatic organisms such as tadpoles. Detritus, benthic diatoms and phytoplankton were predicted to contain the highest levels of DU in the environment, and the impacts of the conversion and use alternative on these important parameters of the food chain should be considered. In short, an adequate assessment of the data that do exist should be made, and critical data gaps should be pinpointed before we decide whether use of this stockpile is prudent. 65-11

COMMENTOR NO. 65: UNIVERSITY OF MARYLAND (CONT'D.)
BALTIMORE, MARYLAND

Miscellaneous Assessment Observations

Given the lack of discussion regarding the environmental assessments at the sites, a few observations are worth noting. For instance, radioactivity and/or uranium appear to have been found in groundwater at the Portsmouth and K-25 sites, but not at the Paducah site. As for the estimated maximum radiation dose to a member of the general public, the value presented for the Paducah site is 3 mrem/yr, but only 0.07 mrem/yr for the Portsmouth site. This is quite a difference for two similar sites which raises questions with regard to the adequacy of the assessment, or indicates that significant differences exist between the site estimations and/or quality of operations. Such observations within the summary suggest that DOE should take a closer look at the quality of the assessments conducted or the manner in which the assessment was presented in the summary. Even if it is the latter, this is a significant issue as many from the public who provide comments will only have the time or ability to review the summary. It is important for DOE to be as clear as possible and provide the public with the opportunity to constructively assess the PEIS without undue burden. 65-12

COMMENTOR NO. 66: GRABER, JEAN & DICK
GOLCONDA, ILLINOIS

Charles Bradley
US DOE (NE-40)
19901 Germantown Rd.
Germantown, MD 20874

April 13, 1998

Dear Mr. Bradley,

These are the comments of the undersigned on the Depleted Uranium cylinders DPEIS. There are some 50,000 plus cylinders of the DUF6 containing from 10 to 14 tons of material apiece currently stored in the three sites, Paducah, Portsmouth, and Oak Ridge.

The scope of the DPEIS is inadequate to cover the activities required to deal with the cylinders. Implementing either of the conversion alternatives will trigger a series of events which will have to take place in order to complete the conversion. These include building factories to do the conversion and for cleaning the highly radioactive residues out of the emptied cylinders. The DUF6 will have to be defluorinated, which is a highly dangerous activity. The converted material and the empty cylinders will have to disposed or stored, as will the hydrogen fluoride which is separated from the DUF6. 66-1

These activities are all connected actions which require a hard look in combination with the ongoing cleanup activities at the three facilities where the cylinders are stored : Paducah, Portsmouth, and Oak Ridge. There are clearly cumulative effects from these proposals and projects which are not adequately addressed in the draft. 66-2

Although the largest majority of cylinders, some 40,000, are at Paducah, they are inadequately stacked and stored presently. These are vulnerable to the high seismic risk at Paducah from the New Madrid fault. Because it will be decades or longer before this material can be converted, the risks from earthquake damage go greater as time goes on. Any conversion facilities planned for Paducah have to fully consider the earthquake potential at Paducah, and any construction of conversion facilities at Paducah would have to be made to an earthquake standard. The extra costs of this need to be disclosed. 66-3

If cylinders are going to be transported for conversion, then the risks transportation needs to be considered carefully. This would require many thousands of shipments. Many of the older cylinders may not be capable of being lifted or loaded for transportation. Some may not be able to be heated to be emptied. All of these problems could significantly increase the cost. The DOE needs to be more up-front about the real dollar costs of this problem. 66-4

Although it appears that the best alternative is converting the material from the reactive UF 6 form to the more stable uranium oxide form, the DPEIS doesn't give enough information for the commentors to decide where the best place for conversion would be and the best methods. 66-5

Finally, it seems ill-advised to continue to fill more cylinders daily with more DUF6 while this huge problem of disposal continues to accumulate. If the nuclear industry cannot manufacture its product without creating such huge amounts of toxic waste, it should strongly consider ceasing production. 66-6

Thank you for considering these comments.

Sincerely,

Jean & Dick Graber

Subject: Non-proprietary comments regarding the draft PEIS

Dear Mr. Bradley:

Thank you very much for talking with me and for requesting some opinions from me.

As we have discussed, Santa Fe Alloys (using Federal funding) and Los Alamos Consultants (using private funding) have devised and experimentally developed continuous metallothermic reduction procedures for production of uranium and other metals over a period of nearly 20 years. Most of the successful experiments on these procedures were carried out at the SFA/LAC laboratory in NM.

Comments on the Draft PEIS--This Writer's Opinions:

Overall High Quality: Your wise recommendation, as based on the material presented, is to convert the DUF_6 to metal or oxide and to use the DU for shielding of HLW. It was very much needed. That way the DU will be recoverable later while being protected for now.

To emphasize the need to save DU, the reader should recognize that many of the better uranium sources worldwide have already been destroyed to collect and use U-235, but leaving >99.5% of the natural U unused. Saving the remainder (mostly U-238) as breeder fuel would allow its use substantially fully as reactor fuel (as Pu-239) by future generations. Yet some people seriously recommend burying this fuel as waste! Wasting the DU would be an environmental atrocity.

(See "Management and Disposition of Excess Weapons Plutonium," National Academy Press, 1994, p.28, and DOE/NN-0007, Jan. 1997, p.39, showing that Pu fuel is now used in other countries.)

Avoidance of Too Strict Definitions of Processes to Be Used:
From a chemical and engineering view, this PEIS should be looked on as sketches of what sort of approach could be used to convert the DUF_6 to metal or oxide. As such these sketches allow realistic broad decisions such as saving the DU for future use, as just discussed.

However, the current overregulation from within and outside of DOE tends to turn such sketches into rigid models before experiment has shown what would be realistic. Consider, for example, the recent failures of numerous radwaste vitrification units--inadequately tested proposals rigidly specified what turned out to inadequate approaches.

71-2

Here the decision to use continuous metallothermic reductions for production of uranium for cask shielding is sound. However, as discussed below, the writer recommends versions of reductions that differ significantly from the version described, e.g., UCRL-AR-124080 Vols 1 and 2 Rev 2, Sec 8.10-4.

However, there is need to examine cost features.

Locations and Types of Facilities Needed for UF_6 Conversions to Metal or Alloy:

Alternative to Hydrogen Reduction of UF_6 to UF_4: Historically this reduction has been used before the continuous metallothermic reductions of UF_4 by Mg in molten salt as done by SFA prior to its work for AVLIS with ORNL (Lockheed Martin) and LLNL.

However, an alternative continuous metallothermic approach (description proprietary by LAC) by SFA would convert UF_6 to UF_4 in molten salt prior to continuous Mg reductions to metal or alloy.

71-3

Incorporating this LAC metallothermic reduction to UF_4 as a precursor to the U-metal production would (a) avoid the cost of separate hydrogen reduction facility and operations, (b) integrate well with the molten salt operations of the Mg-UF_4 reductions, and (c) avoid some shipping and handling.

Alternative to Aqueous Separation of MgF_2 By-product from NaCl Molten Salt Additive: Because of experimental flaws in ORNL pilot tests, which seemed to invalidate containers used by SFA for continuous metallothermic reductions, the separation of MgF_2 by-product continuously from molten salt was abandoned in the system of the PEIS--instead batch aqueous separations were incorporated into the DOE plans.

71-4

SANTA FE ALLOYS & LOS ALAMOS CONSULTANTS, (SFA/LAC)
4515 Stockbridge Ave., NW, Albuquerque, NM, 87120
(505) 899-2178, E-mail-elliotgrb@juno.com

However, SFA is eager to correct the ORNL flaws and demonstrate that continuous circulation of molten salt carrier with removal of solid, clean MgF_2 by-product can be maintained.

Alternative to Formation of U-3%Fe Alloy in UF_4-Mg Reductions: As described, the continuous metallothermic reductions lead to U-Fe alloy, which has the advantage of a lower melting point than pure U. However, the U-Fe alloy is brittle in castings and unwanted in breeding. Therefore, the production and casting of pure U should be evaluated also. 71-5

Location of U-Metal Production Facilities: To avoid the expenses and hassles of shipping radioactive materials by people's houses, it seems best to move the DUF_6 cylinders on-site at Paducah, ORNL, and Portsmouth to already HEPA-filtered buildings. Then, movable, also HEPA-filtered, UF_6-UF_4 units for continuous metallothermic reductions can be operated to produce U castings already suitable for use in casks. Then, with one radioactive shipment, the unshielded casks and the shielding castings could be assembled at the HLW site. 71-6

It seems reasonable, and in accord with many environmentalists' wishes, that the casks could be stored long-term in underground mausoleums, where they were available for remote monitoring and eventually for HLW recycle and DU reactor use.

Reduction of Costs for Operations and Maintenance in the Manufacture of Metallic Shielding: With some $800 million as the cost of Operations and Maintenance (Cost Analysis, UCRL-AR-127650, May 1997, p. 57) for manufacturing metallic shielding, it becomes very important to move the material rapidly through the processing, e.g., in ten years. 71-7

If an SFA continuous metallothermic reduction unit produced 1 cu ft of DU/hr full time for a year, the unit would produce 8760 cu ft of U. With 820,000 cu ft of U in cylinders, it would take 70.6 unit years to dispose of the DUF_6. With those assumptions, 10 SFA units could dispose of the DUF_6 within ten years.

ACTION:
With billions of dollars at stake, it seems urgent to get more

experimental work from SFA. With even three months work, SFA working in its licensed DU laboratory could (presumably) demonstrate, and revalidate, containment for its water-free operations of continuous metallothermic reductions.

Later, other work could be discussed.

Sincerely,

COMMENTOR NO. 72: GOVERNORS PATTON, PAUL E., VOINOVICH, GEORGE V., & SUNDQUIST, DON PADUCAH, KENTUCKY; PORTSMOUTH, OHIO; OAK RIDGE TENNESSEE

April 27, 1998

The Honorable Federico Peña, Secretary
U.S. Department of Energy
1000 Independence Avenue, SW
Washington, DC 30585

RE: "Draft PEIS for Alternative Strategies for the Long-Term Management and Use of Depleted Uranium Hexafluoride," DOE/EIS-0269 dated December 1997.

Dear Secretary Peña:

More than forty years ago the U.S. Department of Energy began the uranium enrichment initiative that created a common link between Ohio, Kentucky, and Tennessee. This commonality includes the U.S. Department of Energy's legacy of waste, a significant portion of which is made up of depleted uranium hexafluoride. Today, our three states are working together in order to recommend the selection of an appropriate and lawful alternative for the long-term management and use of depleted uranium hexafluoride. We believe that such an alternative must minimize impacts on human health and the environment, as well as benefit the overall mission of our states and the U.S. Department of Energy ("DOE"). 72-1

Ohio, Kentucky, and Tennessee have the following significant concerns regarding the above-referenced document:

- DOE should consider the immediate conversion of all depleted uranium hexafluoride (DUF6) to the less hazardous uranium oxide (U3O8) and provide above ground storage of the U3O8. We do not believe that waiting for possible market demands for the DUF6 is justification for delaying this project. It is incumbent upon DOE to immediately begin seeking funds from Congress for this conversion. We urge DOE to complete conversion by the year 2018 or earlier and reduce the mortgage of maintaining the cylinders. 72-2

- A long-term strategy for DUF6 must include DOE's entire cylinder inventory, including heel and small cylinders. The 10,000+ cylinders of DUF6 generated by the United States Enrichment Corporation (USEC), which will revert to DOE ownership upon privatization of USEC, must also be considered in any plans. 72-3

- An estimated $480 million has been accrued by USEC since 1993 in order to offset the cost of the future conversion of DUF6 generated by USEC. DOE should work with Congress now to ensure this fund is not diverted into the federal treasury for an unrelated use. In addition, DOE might consider partnering with the future owner of USEC in a long-term strategy for managing and converting DUF6, in order to avoid redundancy of efforts. Any partnering effort, however, must not slow progress toward conversion. 72-4

- Natural phenomena events or accidents may not have been adequately considered in the PEIS. DOE must identify the "worse-case" cylinder conditions and explicitly use this information in the hazard modeling descriptions. 72-5

1501

COMMENTOR NO. 72: GOVERNORS PATTON, PAUL E., VOINOVICH, GEORGE V., & SUNDQUIST, DON PADUCAH, KENTUCKY; PORTSMOUTH, OHIO; OAK RIDGE TENNESSEE (CONT'D.)

- In order for states to effectively evaluate the potential impacts of the preferred alternative, DOE must provide information on the location of the sites where conversion would occur and how wastes generated from this process will be managed. In order to avoid the undue risk of transporting deteriorating cylinders, we recommend that DOE evaluate the feasibility of on-site conversion plants. 72-6

- DOE must ensure that funding for safe storage and maintenance of DUF6 cylinders and storage yards is at an adequate level to protect human health and the environment. 72-7

The States welcome the opportunity to work closely with the Department of Energy in addressing these complex issues and moving rapidly toward an alternative that will well serve the public and the environment. In addition, we urge DOE to carefully consider the more detailed comments being submitted by each of our states' environmental regulatory agencies.

Sincerely,

Governor Paul E. Patton

Governor George V. Voinovich

Governor Don Sundquist

ALTO PASS, ILLINOIS

Charles Bradley
US DOE (NE-40)
19901 Germantown Rd.
Germantown, MD 20874 April 13, 1998

Dear Mr. Bradley,

These are the comments of the undersigned on the Depleted Uranium cylinders DPEIS. There are some 50,000 plus cylinders of the DUF6 containing from 10 to 14 tons of material apiece currently stored in the three sites, Paducah, Portsmouth, and Oak Ridge.

The scope of the DPEIS is inadequate to cover the activities required to deal with the cylinders. Implementing either of the conversion alternatives will trigger a series of events which will have to take place in order to complete the conversion. These include building factories to do the conversion and for cleaning the highly radioactive residues out of the emptied cylinders. The DUF6 will have to be defluorinated, which is a highly dangerous activity. The converted material and the empty cylinders will have to disposed or stored, as will the hydrogen fluoride which is separated from the DUF6. 73-1

These activities are all connected actions which require a hard look in combination with the ongoing cleanup activities at the three facilities where the cylinders are stored - Paducah, Portsmouth, and Oak Ridge. There are clearly cumulative effects from these proposals and projects which are not adequately addressed in the draft. 73-2

Although the largest majority of cylinders, some 40,000, are at Paducah, they are inadequately stacked and stored presently. These are vulnerable to the high seismic risk at Paducah from the New Madrid fault. Because it will be decades or longer before this material can be converted, the risks from earthquake damage go greater as time goes on. Any conversion facilities planned for Paducah have to fully consider the earthquake potential at Paducah, and any construction of conversion facilities at Paducah would have to be made to an earthquake standard. The extra costs of this need to be disclosed. 73-3

If cylinders are going to be transported for conversion, then the risks transportation needs to be considered carefully. This would require many thousands of shipments. Many of the older cylinders may not be capable of being lifted or loaded for transportation. Some may not be able to be heated to be emptied. All of these problems could significantly increase the cost. The DOE needs to be more up-front about the real dollar costs of this problem. 73-4

Although it appears that the best alternative is converting the material from the reactive UF 6 form to the more stable uranium oxide form, the DPEIS doesn't give enough information for the commentors to decide where the best place for conversion would be and the best methods. 73-5

Finally, it seems ill-advised to continue to fill more cylinders daily with more DUF6 while this huge problem of disposal continues to accumulate. If the nuclear industry cannot manufacture its product without creating such huge amounts of toxic waste, it should strongly consider ceasing production. 73-6

Thank you for considering these comments.

Sincerely,

Georgeann Hartzog

Re: U.S. Department of Energy's Draft Programmatic Environmental Impact Statement (PEIS) for Alternative Strategies for the Long-Term Management and Use of Depleted Uranium Hexafluoride (DOE/EIS-0269) dated December 18, 1997.

Gentlemen,

The Kentucky Division of Waste Management (Division) has reviewed the December 18, 1997 *U.S. Department of Energy's Draft Programmatic Environmental Impact Statement (PEIS) for Alternative Strategies for the Long-Term Management and Use of Depleted Uranium Hexafluoride* (DOE/EIS-0269). Since the Paducah Gaseous Diffusion Plant currently store and manage the largest volume of Depleted Uranium Hexafluoride (DUF6) in the nation, the Division is very interested in the decision making process for the long-term storage and management of the DUF6. Attached are the Division's general and specific concerns of DOE's proposed alternative and long-term strategy.

If you have any questions or require additional information, please contact me or Tuss Taylor at (502)-564-6716.

Sincerely,

Robert H. Daniell, Director
Division of Waste Management

COMMENTOR NO. 75: COMMONWEALTH OF KENTUCKY, DEPARTMENT FOR ENVIRONMENTAL PROTECTION (CONT'D.) FRANKFORT, KENTUCKY

Kentucky Division of Waste Management's General and Specific Comments on the DOE's Draft Programmatic Environmental Impact Statement (PEIS) for Alternative Strategies for the Long-Term Management and Use of Depleted Uranium Hexafluoride (DOE/EIS-0269) dated December 18, 1997.

General Comments:

1. DOE's Preferred Alternative: DOE's preferred alternative, as repeatedly mentioned in PEIS is to use the entire inventory of DUF_6 as metal or oxide. However, no evidence has been documented in the PEIS, which suggests that the market demand exists or will be found for all or even a significant part of DUF_6 inventory in the near future. Moreover, two independent studies (*"Integrity of Uranium Hexafluoride Cylinders", DNFSB/TECH-4, May 5, 1995, and "Affordable Cleanup?: Opportunities for Cost Reduction in the Decontaminating and Decommisstioning of the Nation's Uranium Enrichment Facilities", Board on Energy and Environmental Systems, Commission on Engineering and Technical Systems, National Research Council of the National Academy of Sciences, February 9, 1996*) also report that the market demand doesn't currently exist for the DUF_6 or its conversion products, nor is the demand anticipated in the near future. In light of the present uncertainties in the market demand, the Division therefore recommends that the DOE should consider converting the entire inventory immediately to the more stable form U_3O_8. The long-term storage of this material is much safer than the current storage of DUF_6, and it can also be retrieved if future demand is obtained. *75-1*

2. Time Frame: The PEIS doesn't justify the 40-year time frame considered. Justification is warranted for the same. The PEIS recommends storing the cylinders until 2010, after which 20 years would be required to convert the entire inventory of DUF_6 using DOE's preferred alternative. During these years, there is continued storage of DUF_6 required, which will also necessitate the continued monitoring activities. The Division therefore recommends that the process of conversion should be expedited in order to minimize the risk to the human health and the environment from continued storage of deteriorating cylinders. This would also help in cutting down the cost on the annual maintenance and surveillance activities. *75-2*

3. Management of USEC cylinders: The PEIS doesn't take into account the cylinders (~8000) produced by United States Enrichment Corporation (USEC) since its privatization. The ownership of these cylinders has yet to be determined. It is the Division's understanding that under the current agreement between DOE and USEC, the USEC will be able to return to DOE, any waste not easily disposed of commercially. In this scenario, if these cylinders are considered waste, there is a possibility that they could be returned to the DOE. This represents a significant *75-3*

1504

COMMENTOR NO. 75: COMMONWEALTH OF KENTUCKY, DEPARTMENT FOR ENVIRONMENTAL PROTECTION (CONT'D.) FRANKFORT, KENTUCKY

increase in the inventory. Hence the Division recommends that a contingency plan should be incorporated in the PEIS to address the USEC cylinders.

4. Conversion Facilities/Site Selection: It is the Division's understanding that the DOE has not yet come to the conclusion of final selection of the site, as is evident from the PEIS. The PEIS describes the impact on the environment, considering various generic settings. However, the Division believes that site specific impact is also necessary after final selection of the site. For example, it is clear from the PEIS that the DOE has not given enough attention to the earthquake prone regions, and the seismic activities at the sites proposed for storage of the waste. The Division believes that it is critical and the site-specific information should be included in the PEIS. If PGDP is selected as one of the conversion facilities for example, then new facts gathered about this should be considered. The summary of some recently gathered seismic data at Paducah site is given in the specific comments. *75-4*

5. Generation of Secondary Waste: Preliminary calculations performed by Division indicate that if DOE's preferred alternative were used, large amounts of secondary waste could be generated. More specifically, around 70% of the product stream will consist of Uranium (in the metal or oxide form) and 30% will be in the form of other products (anhydrous HF, CaF_2, or MgF_2). The Division believes that the potential exist that all the handling, transportation, and disposal for uranium left at the end of the treatment process will meet Low-Level Waste (LLW) requirements. Moreover, unless the specific technology is available to totally remove all the radioactive contamination from these secondary products (e.g. HF, CaF_2, MgF_2 etc.-), all the disposal, handling, and treatment activities for this waste must follow the (LLW) management guidelines. Please provide a description of all potential anticipated wastes that may be derived from the preferred alternative. *75-5*

Specific Comments:

1. One of the chemicals of potential concern (COPC) identified in the conversion (to oxide or metal) is ammonia. Provide a brief discussion regarding the generation of ammonia. *75-6*

2. DOE has proposed a 40-year time frame for the proposed alternatives. Please provide a detailed justification for the proposed 40-year time frame. *75-7*

3. Consideration of "no-action" alternative should include at a minimum, implementation of Recommendation 95-1 of the Defense Nuclear Facilities Safety Board. *75-8*

COMMENTOR NO. 75: COMMONWEALTH OF KENTUCKY, DEPARTMENT FOR ENVIRONMENTAL PROTECTION (CONT'D.) FRANKFORT, KENTUCKY

4. It is clear from the PEIS that DOE has not given enough attention to the earthquake prone regions, and seismic activities at the sites proposed for storage of the waste. The Division believes it is critical that site specific information is included within the PEIS.

   The following is a summary of new information discovered at the PGDP: Dr. Ronald Street of the University of Kentucky, Department of Geological Sciences commenced an investigation of earthquake related features in the vicinity of the PGDP (*Acquisition of Shear Wave Seismic Reflection and Refraction Data in the Area of the Northwestward Trending Contaminant Plume at the PGDP*). The purpose of this investigation is to map geologic contacts between the Mississippian limestone, the McNairy Formation, the lower Continental Deposits, and the upper Continental Deposits. It has been proposed that faulting has created horst and graben features in these units and that these features may affect groundwater flowpaths in the area on the Northwest and Northeast plumes. A pilot study conducted by Dr. Street located a small graben structure north of the PGDP. As part of the current project, Dr. Street has collected 17.3 km of six and twelve fold reflection and refraction data using a 24 bit floating point seismograph unit. Work on this project started in May of 1997 and a final report is due to AIP in May of 1998.

   Preliminary interpretations of the data collected in this study were presented to the AIP in February 1998. These interpretations, which are subject to change, indicate that the PGDP is underlain by a series of northeast trending fault zones exhibiting substantial vertical offset on the surface of the Mississippian Limestone as well as the upper surface of the McNairy formation. *75-9*

   In other work conducted by Dr. John Nelson of the Illinois Geological Survey northeast trending faulting was found in sediments north of the PGDP in Southern Illinois. Dr. Nelson identified faulting in road cuts and railroad cuts. He also identified a graben in the surface of the McNairy formation with a vertical offset of 200+ feet.

   Dr. Tom Hildenbrand (USGS, Menlo Park) compiled magnetic, seismic moment, and gravity maps for the Paducah region. An anomalous feature appeared approximately 5 miles northwest of the PDGP on all three maps, gravity high, a magnetic high, and a cluster of small earthquakes. This feature has been interpreted as a mafic intrusion located near the community of Needmore. Earthquakes in the vicinity of this possible intrusion are thought to be the result of the regional compressive stress field being deflected around the structure.

   This evaluation indicates that the probability of significant seismic activities within this region is high and that further consideration is needed within the PEIS.

5. The PEIS should describe clearly the criteria for choosing the sites for treatment/disposal. The Division believes that such information is crucial. It is the *75-10*

1505

COMMENTOR NO. 75: COMMONWEALTH OF KENTUCKY, DEPARTMENT FOR ENVIRONMENTAL PROTECTION (CONT'D.) FRANKFORT, KENTUCKY

   Division's understanding that several options will be available for the conversion process of UF_6 to either oxide or metal and production of anhydrous HF. Because there are varying chemical products and potential waste products generated with different conversion methods; DOE must provide a general description of waste products and waste which are anticipated to be generated. If a method has been selected, please state the method. *75-10 (Con't.)*

   Additionally, DOE must address the management and disposal of miscellaneous wastes that will be generated during the conversion process. This would include management and disposal of potentially large volumes of low-level wastes from the neutralization of HF; also various filters and filtered materials. *75-11*

   Finally, discussion is needed for the management of "cylinder heals" from the bottom of the DUF6 cylinder. This material contains a variety of radionuclides (i.e. daughter products and other contaminants) that are not suitable for conversion into uranium oxides or uranium metal. *75-12*

6. While evaluating the alternative "conversion of UF_6 to oxide or metal form", different steps have been delineated as is the case with the other alternatives. In this particular case, the facilities for conversion process, storage of converted uranium form, and the manufacturing of the casks (which is the end use for this alternative, and this is DOE's preferred alternative) are all planned to be located at separate locations. There will be transportation required between these locations. The PEIS should address the impacts of the transportation, including the potential impacts on the environment, human health. However, the transportation impacts could be minimized if DOE would integrate the conversion and manufacturing plants in one complex. This would reduce the amount of land required thereby decreasing possible habitat loss. It is not clear whether DOE has considered this alternative. If not, we recommend that this option be considered. *75-13*

7. A correction is needed on page 3-7, Section 3.1.4.1; the reference to the earthquake magnitude of 7.3 should have been referenced as the "Nuttly Scale" and not as the "Richter Scale". Although, the Nuttly Scale does converts to 8.0 on the Seismic Moment scale sometime referred to as the Richter scale. *75-14*

8. Section 3.1 Paducah Site; U.S. EPA has authorized the Commonwealth of Kentucky for the Resource Conservation and Recovery Act (RCRA) Program. Therefore, when references are made to the U.S. EPA RCRA program, the Kentucky Hazardous Waste should also be referenced. *75-15*

9. Pages2-60 and 2-61; 2-64 and 2-65; 2-68 and 2-69; 3-2 and 3-4; Figure 3.1 of Volume I of the Draft DUF6 PEIS are missing. A comprehensive review could not be performed due to the lack of these pages. Provide the missing pages. *75-16*

COMMENTOR NO. 75: COMMONWEALTH OF KENTUCKY, DEPARTMENT FOR ENVIRONMENTAL PROTECTION (CONT'D.) FRANKFORT, KENTUCKY

10. Page 5-108, Section 5.8.2.1 Paducah Site; the last paragraph states that 11 pollutants have been detected in the groundwater effecting quality. This statement is incorrect. Numerous pollutants have been detected at the PGDP. In fact, one of the most predominant contaminants at the site is omitted, Technetium 99. Other radionuclides and organic contaminants have been detected in groundwater throughout the PGDP.

The Honorable Federico Pena, Secretary
U.S. Department of Energy
1000 Independence Avenue, SW
Washington, DC 30585

RE: " Draft PEIS for Alternative Strategies for the Long-Term Management and Use of Depleted Uranium Hexafluoride," DOE/EIS-0269 dated December 1997.

Dear Secretary Pena:

Ohio EPA has long been interested in the management of depleted uranium hexafluoride (DUF6). Ohio's concerns result from the 13000+ cylinders of DUF6 which have been stored for decades at the Portsmouth Gaseous Diffusion Plant in southern Ohio. As you may know, management of DUF6 at the Portsmouth site was the subject of recent judicial and administrative consent orders signed by the U.S. Department of Energy ("DOE") and the State of Ohio. The State of Ohio is working to support an appropriate lawful alternative for the long term management and use of DUF6. We have reviewed the above-referenced document and offer the following comments:

1. **There is no evidence to suggest that market demand exists or will be found for all or even a large part of DOE's DUF6 inventory in the near term or the foreseeable future. Therefore, conversion should begin as soon as possible and be completed by 2018 or earlier. DOE should begin now to seek funds from Congress for conversion, and should consider the immediate conversion of all the DUF6 to U3O8, and long-term above-ground storage of this material.** According to the draft PEIS, the preferred alternative for long-term use of DUF6 is conversion of 100% of stockpiled DUF6 to oxide (i.e., U3O8 and/or UO2) and depleted uranium metals. Conversion would not begin until 2010, and would occur over a twenty year period on the basis of market demand. However, in the Draft PEIS, DOE states that "the actual percentage of depleted UF6 inventory for which uses will be identified within the time frame assessed in the PEIS (i.e., up to the year 2040) will be determined as uses develop and conversion begins." In other words, this market demand is uncertain.

76-1

The National Research Council of the National Academy of Sciences (NSF)[1] conducted

[1]"Affordable Cleanup?: Opportunities for Cost Reduction in the Decontaminating and Decommissioning of the Nation's Uranium Enrichment Facilities", Board on Energy and

COMMENTOR NO. 76: STATE OF OHIO ENVIRONMENTAL PROTECTION AGENCY (CONT'D.)
COLUMBUS, OHIO

a review in 1996 of possible uses for depleted uranium in shielding applications, as a fluorinating agent, and for re-enrichment by Atomic Vapor Laser Isotope Separation (AVLIS). According to the NSF, market demand does not currently exist for DUF6 or its conversion products, nor is demand anticipated in the near future. This is corroborated by the DNFSB who stated in a 1995 report[1] that according to DOE, only a "small fraction" of depleted uranium has a use in the "foreseeable future". *76-1 (Cont'd.)*

We recognize that market demand is, at best, uncertain. DUF6 can be stored more safely in a converted state. Therefore, rather than wait for market demand to drive conversion, DOE should begin now to seek funds from Congress for conversion, and should consider the immediate conversion of all the DUF6 to U3O8, and long-term above-ground storage of this material, which can be retrieved if demand is established. If a market exists for a small percentage of DUF6, only those cylinders in the best condition should remain unconverted for use by the market.

2. **The draft PEIS provides no assurance that DOE will fund and implement an adequate long-term program of inspecting and coating cylinders throughout the life of the DUF6 cylinders, prior to conversion.** Safe cylinder management requires an adequate inspection program combined with an aggressive cylinder coating program. Several times throughout the PEIS, it is indicated that funding for a cylinder coating program is "uncertain". However, DOE states in the PEIS that coating is expected to be successful and therefore, minimal releases of DUF6 from cylinders to air and groundwater are expected. It is unclear how DOE can assume coating will be successful if funding is uncertain and the success rate of coating cylinders is unknown. Even if funded, there is no assurance that coating will be adequately applied and renewed frequently enough to prevent or slow corrosion. DOE must comply with all DNFSB recommendations for management of cylinders and yards, and with the DUF6 management plan contained in Ohio orders. *76-2*

3 **DOE should ensure that the PEIS addresses the management of DUF6 in compliance with RCRA and state hazardous waste law. The February 28, 1998 Director's Findings and Orders reiterated Ohio EPA's view that DUF6 is a mixed waste regulated under RCRA and state hazardous waste law. These Findings and Orders provide an exemption from state hazardous waste requirements for a 10-year period to allow DOE to identify and implement an appropriate and lawful strategy for use, reuse, or conversion of this material. The Findings and Orders require compliance with a safe management plan for the DUF6 during the 10-year period. Ohio has also reserved legal rights to reassert state hazardous waste requirements. Thus, it is imperative that the PEIS address the management of** *76-3*

1507

COMMENTOR NO. 76: STATE OF OHIO ENVIRONMENTAL PROTECTION AGENCY (CONT'D.)
COLUMBUS, OHIO

DUF6 as a mixed waste under RCRA and state hazardous waste law.

4. **A variety of independent and DOE estimates regarding breached cylinders are available but not considered in the draft PEIS.** The draft PEIS estimates that 59 breaches and releases from cylinders could occur over the next forty years, assuming control of external corrosion by painting cylinders. Assuming no control of corrosion, the draft PEIS estimates that 731 breaches and releases could occur. However, according to the Defense Nuclear Facility Safety Board (DNFSB)[1], it has been stated by DOE and the former MMES that 200 cylinders are expected to breach if no corrosion control is undertaken, and more than 1000 cylinders have the potential to breach in storage within 22 years (by the year 2020). *76-4*

5. **DOE's estimate of three to four cylinder spill accidents from breaches due to corrosion appears unrealistically low.** The draft PEIS estimates that as a result of all activities associated with the preferred alternative, three to four spill accidents will occur by 2038 as a result of cylinders that will breach due to corrosion. However, DOE records show that from 1990 to 1992, seven cylinders stored at the DOE three gaseous diffusion plants have breached due to corrosion. In light of DOE's own predictions mentioned in comment #2 above, as well as the current age of the cylinders, unknown cylinder corrosion rates, and the uncertainty of a long-term, ongoing cylinder coating program, a more realistic estimate of cylinder spill accidents due to corrosion must be made. *76-5*

6. **If cylinder breaching rates have been underestimated, all other calculations made in the draft PEIS that were based on this breach rate, such as the impact of a release of DUF6 to soil, groundwater, human health, etc., have also been underestimated. These estimates should be revised accordingly.** *76-6*

7. **Conversion of DUF6 to U3O8 should be expedited in order to minimize the risk to human health and the environment from continued storage of deteriorating cylinders.** In order to implement the preferred alternative in the Draft PEIS, DOE recommends storing cylinders until 2010. Then, a period of twenty years, at a cost of $200 million per year, would be required to convert the entire DUF6 inventory to either depleted metals or oxide at one conversion plant, the site of which has not yet been determined. During conversion, aqueous HF would be generated and marketed. According to the National Research Council, a twenty year conversion rate and was chosen to reduce the cost of plant investment (spread the cost out over twenty years) and to render the HF production rate less disruptive to the market. The rate at which HF would be generated over twenty years is equal to approximately 2% of the estimated annual market in North America. It is recommended that conversion be completed by 2018 or earlier. Expediting conversion will minimize the risk of continued storage and defray the annual cost for cylinder maintenance and surveillance, which is estimated by DOE at $12 to 15 million. *76-7*

[1]Recommendation 95-1 to the Secretary of Energy pursuant to 42 USC 2286a(5) Atomic Energy Act of 1954, as amended.

COMMENTOR NO. 76: STATE OF OHIO ENVIRONMENTAL PROTECTION AGENCY (CONT'D.)
COLUMBUS, OHIO

8. **Rather than construct a conversion plant at a single location and transport all cylinders to the conversion site, DOE should evaluate the feasibility of on-site conversion of DUF6 to U3O8.** According to DOE, 50% to 95% of the DUF6 cylinders have corroded to the point that they are not capable of being handled and transported without undue risk. The draft PEIS states that cylinders would be over packed or their contents transferred into new containers prior to transporting them to an undetermined conversion plant. If cylinders can be converted onsite without transporting them, this will minimize the number of times they are handled, therefore, limiting the risks associated with transferring cylinder contents and transporting them to conversion sites. In addition, the time required for over packing, transferring contents, and transporting cylinders could be saved. The use of a mobile treatment unit that could be transported to each GDP site should be considered. In the alternative, DOE could construct a plant onsite at each GDP (if seismic conditions allow), within an existing, unused gaseous diffusion building. *76-8*

9. **Seismic and flooding concerns were not adequately discussed in the draft PEIS.** For example, Paducah, Kentucky is located approximately 60 miles from the New Madrid fault. Earthquakes of a magnitude of 8.4 to 8.8 on the Richter scale have been measured in the region. These have the potential to damage stored cylinders. The majority of cylinders are stored at Paducah. Seismic issues for Ohio, Kentucky and Tennessee must be adequately considered in the PEIS, especially in light of continued storage of cylinders until at least 2010, and conversion at an unknown site. *76-9*

10. **DOE should evaluate a long-term strategy for DUF6 that would include DOE's entire cylinder inventory including heel and small cylinders as well as the current inventory of 10,000+ cylinders of DUF6 generated by USEC since it's 1993 inception.** When privatization occurs, these USEC-generated cylinders will become the responsibility of DOE. Pursuant to the federal privatization legislation, funds have been accrued for each kilogram of DUF6 generated by USEC in order to pay for future treatment of tails. Currently, this fund may now hold as much as $480 million. When USEC is privatized, this fund will be turned over to the federal treasury. DOE should take steps to secure these funds to offset the cost of conversion of the DUF6 to be acquired from USEC, as well its existing inventory of DUF6. *76-10*

Ohio EPA is willing to work closely with DOE on this issue. We suggest forming a workgroup that includes representatives of Ohio, Kentucky and Tennessee that can work with DOE to find a solution that meets the needs of all three states as well as DOE. Please contact Donna Goodman of my staff at (740)385-8501 if you have any questions or wish to discuss this further.

Sincerely,

Donald R. Schregardus

COMMENTOR NO. 77: WATKIN, MARY ELLEN & MONTEITH, JERRY
COBDEN, ILLINOIS

Charles Bradley
US DOE (NE-40)
19901 Germantown Rd.
Germantown, MD 20874

April 13, 1998

Dear Mr. Bradley,

These are the comments of the undersigned on the Depleted Uranium cylinders DPEIS. There are some 50,000 plus cylinders of the DUF6 containing from 10 to 14 tons of material apiece currently stored in the three sites, Paducah, Portsmouth, and Oak Ridge.

The scope of the DPEIS is inadequate to cover the activities required to deal with the cylinders. Implementing either of the conversion alternatives will trigger a series of events which will have to take place in order to complete the conversion. These include building factories to do the conversion and for cleaning the highly radioactive residues out of the emptied cylinders. The DUF6 will have to be defluorinated, which is a highly dangerous activity. The converted material and the empty cylinders will have to disposed or stored, as will the hydrogen fluoride which is separated from the DUF6. *77-1*

These activities are all connected actions which require a hard look in combination with the ongoing cleanup activities at the three facilities where the cylinders are stored - Paducah, Portsmouth, and Oak Ridge. There are clearly cumulative effects from these proposals and projects which are not adequately addressed in the draft. *77-2*

Although the largest majority of cylinders, some 40,000, are at Paducah, they are inadequately stacked and stored presently. These are vulnerable to the high seismic risk at Paducah from the New Madrid fault. Because it will be decades or longer before this material can be converted, the risks from earthquake damage go greater as time goes on. Any conversion facilities planned for Paducah have to fully consider the earthquake potential at Paducah, and any construction of conversion facilities at Paducah would have to be made to an earthquake standard. The extra costs of this need to be disclosed. *77-3*

If cylinders are going to be transported for conversion, then the risks transportation needs to be considered carefully. This would require many thousands of shipments. Many of the older cylinders may not be capable of being lifted or loaded for transportation. Some may not be able to be heated to be emptied. All of these problems could significantly increase the cost. The DOE needs to be more up-front about the real dollar costs of this problem. *77-4*

Although it appears that the best alternative is converting the material from the reactive UF 6 form to the more stable uranium oxide form, the DPEIS doesn't give enough information for the commentors to decide where the best place for conversion would be and the best methods. *77-5*

Finally, it seems ill-advised to continue to fill more cylinders daily with more DUF6 while this huge problem of disposal continues to accumulate. If the nuclear industry cannot manufacture its product without creating such huge amounts of toxic waste, it should strongly consider ceasing production. *77-6*

Thank you for considering these comments.

Sincerely,

Mr. Mrs. Watkin

McDermott, Ohio 45652-8932
Telephone (614) 259-4688
Fax (614) 259-3912

Hello,

My name is Vina Colley a former worker who suffers form a disabling illnesses as the result of U235 in my lungs and toxic exposures from working at the Portsmouth /Piketon Uranium Enrichment plant located here in Piketon.

I am here today representing PRESS Portsmouth/Piketon Residents for Environmental Safety and Security. Press is am member group of several national organizations representing communities living in the shadows of the U.S. nuclear weapons complex such as the Alliance for Nuclear Accountability (formerly the Military Production Network),Military Toxic Project, Reclamation & Conversion Project, and Task Force on Radiation and Human Right.

Press doesn't represent the union body of the Piketon plant but workers like my myself that have been effect from this facility. PRESS represents the interests members of the directly affected.

We are her today to speak about one of the biggest problems facing the public from the DOE/DOD programs the Uranium Hexafluoride tails (UF6) DU cylinders. A hazardous materials specialist, David Kozlowski was quote as saying " Uranium Hexafluoride is highly corrosive ", its effect to those hydrochloric acid. Sites such as Piketon, he said are regarded as potential "general emergency" sites by the DOE, meaning if there were gas formation it could require evacuation of nearby areas. While in D.C. last year with the national groups we were told by another top person for the DOE that painting, these cylinders was like putting lipstick on a corpse. Slightly contaminated DU cylinders become a problem equal to high level radioactive waste as they age because of the decay daughter product to radium. — 80-1

I would like to remind you of the 1978 spill here at the plant when over 21 thousand LBS left this site by air, ground and water many workers where effected. In September of 1996 another airborne plume went off site in between the lithuim storage building and the national guards bulding. This airborne plume headed toward Wakefield. I have been told that workers were paid over time and told to stay inside, I also called a reporter when this was happening, he called the plant and they lied about the release and two days later put there own story in the paper. I would like someone to tell me why we have alarms and run through drills and when there is an actual potential — 80-2, 80-3, 80-4

15/10

COMMENTOR NO. 80: PORTSMOUTH-PIKETON RESIDENTS FOR ENVIRONMENTAL SAFETY AND SECURITY (CONT'D.) MCDERMOTT, OHIO

dangerous releases there is no sound of alarms to warn the citizens of the surrounding communities. Residents didn't know about the situation so therefore didn't know to stay inside. — 80-4 (Con't.)

Charles Bradley you didn't seen to believe me about the airborne plume from the DU cylinder could form,you though it would suck back inside the cylinder like the video that was show here. That video is misleading in ways. B Removed tape as update — 80-5

I would like to view another picture of children standing around DU cylinders, This should not be allowed with all the information about the hazard of this product,and the problems with on site hazards threat Piketo — 80-6

PRESS considers a decision that there is little effect to the public and it's worlore to be a serious environmental justice concern and and was not address adequately in the draft PEIS.

PRESS along with the Military Toxic Project is asking for the comment period be extended to six months to give folks the opportunity to meet with you in a roundtable meetings, much like the Federal Facilities Restoration Dialogue meetings. We need to have the opportunity to discuss the strategies that have been proposed. — 80-7

I am putting in records the letter form the Military Toxic Project.

PRESS an other viewer should see in writing all agreement between the states of all three facilities OakRidge, Paducah, and Piketon.

All agreements between CONGRESS the USEC,DOD, DOE, and any others involved. — 80-8

The EPA was to fine this facility I believe over the DU clinders, we would like to know how much, and why.

I would like to remind you that Piketon has never been licensed to accept or store Radioactive waste and we have broken many laws by doing so. You have consistenly withheld information from the citizens about radioactive release whether planned, routine, or accidently. PRESS feels that there is a number of cylinders no long inventory and would like to know who is hidding them or where they stolen,or is some one all ready doing conversion? — 80-9

PRESS is worried that a earthquake would create multiple cylinder failures at all the sites,also worried over the possibly of airoraft wrecking and hidding the cylinders. — 80-10

Press feels we need to look at some real problem that the National Research Council as put on the table. — 80-11

We feel that untill we find a safe way to handle these cylinders they should be put in earthquake proof containers or maybe find away to neat them up in the place where stored, then put then in new cylinder untill new safe technology comes along. — 80-12

I have a Report from Geore Hoffman To put in Record

COMMENTOR NO. 80: PORTSMOUTH-PIKETON RESIDENTS FOR ENVIRONMENTAL SAFETY AND SECURITY (CONT'D.) MCDERMOTT, OHIO

I would like to put in record a report from Gene Hoffman. At request, I will make a copy for people here that would like one. Also a letter sent to NY TIMES BUREAU from Leonard A. Dietz. [redacted] about the DU issue.
I would like to thank you for this time to speak.

Worker Radiation Dose Records Deeply Flawed

BY ARJUN MAKHIJANI AND BERND FRANKE

As part of its responsibility for the production and testing of nuclear weapons, the Department of Energy (DOE) and its predecessor agencies (the Atomic Energy Commission, 1947–1974; and the Energy Research and Development Administration, 1974–1977) have been responsible for ensuring that workers were not exposed to more than the allowable amounts of radiation. The DOE has also been responsible to adhere to what is called the "ALARA" principle—the idea that radiation exposures should be kept "As Low As Reasonably Achievable" with available technology.

The goal of using radiation dose limits and following the ALARA guideline is to protect worker health by limiting exposure. But if exposure is not properly measured, radiation exposure regulations cannot be enforced, nor can guidelines be followed. Health monitoring personnel may not be aware of instances when workers are overexposed. Diseases that workers may be at greater risk of contracting may go undetected, harming them and their families. Health studies based on worker dose data would produce misleading results because dose records would be incomplete and knowledge of them would be inaccurate.

A worker at the Plutonium Finishing Plant at Hanford, Washington receives a whole-body survey to detect potential radioactive contamination.

From the beginning of the nuclear era until 1989, *radiation doses from radioactive materials inhaled or ingested by workers were not calculated or included in worker dose records.* This was revealed by DOE in a background paper sent to IEER on April 7, 1997.[1] DOE and its predecessor agencies did make measurements of internal exposure to radioactive materials, though often sporadic (see below), mainly by taking urine samples. After the mid-to-late 1960s, there was also selection use of more sophisticated counters that

See Worker Doses, page 4

Editorial

Identify Groups of Workers at Risk

As noted in the accompanying article, the Department of Energy has stated that it did not calculate internal doses for workers, and therefore did not integrate them into dose records until 1989. This single fact means that historical worker dose records for 500,000 to 600,000 DOE workers are open to question and that a large number of them—those belonging to workers at risk of internal exposure—are flawed.

The DOE was not actively required to do such integration of internal and external doses, as we note in the article. Still, in the 1950s it was possible to crudely calculate internal worker doses and enter them into worker dose records (though such estimates would often have underestimated exposures). Relatively certain estimates were possible after the mid-1960s by matching up urine data with direct measurements of lung burdens, as IEER did in the case brought against

See Editorial, page 2

COMMENTOR NO. 80: PORTSMOUTH-PIKETON RESIDENTS FOR ENVIRONMENTAL SAFETY AND SECURITY (CONT'D.) MCDERMOTT, OHIO

Editorial, *from page 1*

National Lead of Ohio by workers at the Fernald Plant in 1991. (See SDA Vol. 5 No. 3) But the AEC, its successor agencies, and their contractors did not make the effort until 1989, when new regulations required it.

As the case of Iodine 131 in fallout out shows, (see article, p. 1) the nuclear weapons establishment chose not to properly inform the public about the risks and sacrifices that it was imposing upon them. The counterpart for workers of the public relations campaign that accompanied atmospheric testing was constant reassurances that doses were under allowable limits—and vigorous contestation of worker compensation claims even though the DOE and its predecessor agencies had failed to do their homework on what worker exposures actually were, and though relatively accurate estimates were possible after the mid-1960s.

Relatively precise estimates of internal doses were possible after the mid-1960s.

It is time for the DOE to straighten out the mess by commissioning an independent assessment of the state of internal and external dose data. Simultaneously, the DOE must expeditiously review workers' records to determine which *groups* of workers who labored to make and test this country's huge nuclear arsenal were at risk of high internal exposures and/or high lifetime exposures. The reconstruction of individual worker doses would be a very costly and difficult exercise, which would in many or most cases also be frustrating because huge uncertainties will inevitably remain. That is why we advocate the calculation of doses to groups of workers to determine at-risk groups for the purposes of medical monitoring and, if warranted, compensation. That way more resources can be devoted to workers rather than to legal studies.

It is also possible that the DOE and its contractors have used incomplete dose records to argue its case in compensation cases and other lawsuits. It is improper for the government to continue to fight workers' claims based on exposure data that systematically underestimated doses. A review should be conducted to determine if DOE or its contractors have presented any pre-1989 records as accurate data on internal worker doses.

Private industry failed to calculate internal worker doses until the 1991–1994 period. We have not examined any set of data relating to workers in the private sector of the nuclear industry. The industry's failure to measure internal doses needs to be reviewed and an assessment should be made of its impact on workers.

There are two rays of hope in this dismal picture. One is that DOE began in 1989 to incorporate internal dose estimates into worker dose records. The other is that DOE and its predecessor agencies appear to have taken sufficient measurements to enable group worker doses to be approximately calculated, at least in the one instance where IEER has had access to the raw data. Since its inception, the DOE has made some effort to track individual worker exposures, which has undoubtedly resulted in lower overall exposures than would have occurred if no effort were made. But these measures have been grossly inadequate. If the DOE can spend $4.5 billion a year on laboratory testing and computer simulation of nuclear weapons, which we have found to be essentially unnecessary for maintaining safety (See SDA Vol. 5 No. 2), it can find the resources to do justice to the people exposed to radiation while building nuclear weapons.

Let Them Drink Milk

Iodine-131 Doses from Nuclear Weapons Testing

BY PAT ORTMEYER

. . .it seems necessary to adopt a rather conservative attitude toward the involuntary exposure of the general populations. An error on the radical side will not be immediately apparent, but the chickens will inevitably come home to roost at some later date.

-Howard L. Andrews,
National Institutes of Health,
September 13, 1953[1]

The National Cancer Institute (NCI) recently released results of its 14-year study showing that fallout of Iodine-131 from atmospheric tests conducted in Nevada in the 1950s and early 1960s resulted in thyroid doses to virtually all of the 100 million people living in the United States at the time. The estimated 150 million curies of Iodine-131 released from the tests resulted in a cumulative average thyroid dose to the population of 2 rad.[2] Children were particularly affected: their doses averaged 6 to 14 rad, with some doses as high as 112 rad. Prior to this study, the most recent estimates of children's thyroid doses from Iodine-131 in fallout, reported to Congress in 1959 and cited as recently as 1997, gave a dose range for children of 0.2 to 0.4 rad—15 to 70 times less than the NCI dose estimates.[3] (Note: These are estimates of thyroid doses, not whole body doses. See Crutchfield table on dose.)

Some of the highest thyroid doses in the country were in areas far from the test site.

Thyroid irradiation increases the risk of cancer to children. A 1993 peer-reviewed publication says there is "convincing evidence" of increased thyroid cancer risk to children under age 15 whose thyroids are exposed to 10 rad or more.[4] This study mostly concerned individuals exposed to external radiation sources such as X-rays, but the effect on tissues from ionizing radiation from internal sources is essentially the same.[5] (See foot note for full explanation.)

Thyroid cancer is relatively rare, but the NCI estimates that 10,000 to 75,000 thyroid cancers can be expected as a result of these doses, roughly five to ten percent of which will be fatal. (The upper estimate of 75,000 is more plausible, since the lower estimate assumes that internal radiation doses from Iodine-131 are "as little as one-fifth as hazardous" as the same dose of external radiation.[6] This assumption is very dubious, not based on human data, and not protective of public health.) About 40 percent of thyroid cancers due to Iodine 131 fallout have yet to be diagnosed, according to the NCI,[7] and survivors of thyroid cancer require lifelong treatment with a synthetic thyroid hormone essential for metabolism and other physiological functions. Thyroid irradiation has also been linked to other thyroid disorders, such as autoimmune hypothyroidism, autoimmune thyroiditis, hyperthyroidism (nodular or Grave's disease), and thyroid nodules.[8] Estimates of the level of dose at which these effects occur vary considerably.

While NCI has not estimated the number of children who were put at risk due to fallout, simple demographics coupled with the published numbers indicate that millions of people who were under 15 during the period in question may have received over 10 rad. Doses to girls may be of particular significance, as the incidence of thyroid cancer among women is more than twice that of men.[9]

Iodine can be inhaled, or ingested through contaminated eggs, cottage cheese, or leafy plants and vegetables. But the main pathway of exposure was through ingestion of contaminated milk. As fallout settled on fields and pastures after each test, cows and goats would eat the grass and the Iodine would become concentrated in their milk. Children received higher doses because in general they consumed more milk than adults, and their thyroids were smaller and growing more rapidly. The estimated 20,000 people in the country at the time who drank goat's milk also received higher doses—up to 20 times greater than those drinking cow's milk—because goat's milk concentrates Iodine-131 more than cow's milk.[10] Doses to goat's milk drinkers could, in the most affected counties, have been as high as 180 to 316 rad.

High doses were not limited to those areas directly downwind of the tests. Local precipitation or wind patterns in areas far from the test site caused selective deposition of fallout, or "hot spots," a phenomenon understood by the Atomic Energy Commission (AEC) from the time of the first test, "Trinity," in 1945. As a result, some of the highest estimated thyroid doses in the country were in areas far from Nevada, such as in Meagher County, Montana, with an average dose of 15.8 rad, and Custer County, Idaho with 15.4 rad. Other high doses were estimated throughout the midwest: 8.6 rad in Lyman, South Dakota (26 to 60 rad for children), and 8.1 rad in Lewis County, Missouri (24 to 57 rad for children).[11]

The Atomic Energy Commission understood early on that locating the test site in the western part of the

Worker Doses *from page 1*

directly measure radionuclides in workers' bodies. The DOE was not required by regulations to calculate worker doses, but only to keep records of whether workers were internally exposed to more than certain amounts of radionuclides.

The lack of historical internal dose data in worker dose records has important consequences for public policy on health issues, for scientific investigations of radiation risk, and most of all for the more than half a million workers (and their families) who have been involved since the Manhattan Project in making and testing U.S. nuclear warheads. In 1989, DOE began to correct this historical problem by initiating a program of integrating internal and external worker doses.

Exposure Limits

Limits for allowable exposure have varied over the years, and have generally tended to decline as evolving knowledge about the cancer risks from radiation indicated that the dangers it posed were greater than previously thought. (See Gottlieb.) In order to ensure that workers are not overexposed, the most important routes of exposure must be properly monitored. Consideration must also be given to the fact that ionizing radiation affects people in various ways.

When only external radiation is involved, measurement of worker dose is accomplished by the use of film badges, small photographic plates sensitive to gamma and beta radiation, or thermoluminiscent dosimeters (reusable devices that measure external radiation—also referred to as TLDs). These devices can measure how much radiation a worker has been exposed to, but not the amount of radiation that may have been taken into the body through inhalation, ingestion or other means.

Internal radiation exposure occurs when radioactive materials get inside the body and decay, irradiating nearby tissues. Internal radiation is often more organ-specific than external radiation. If the radionuclides become lodged in particular parts of the body, such as the lungs or bones, for instance, those areas are irradiated far more than others. Risk of internal exposure is high in workplaces where the air becomes contaminated with radioactive materials or dust, as has frequently occurred in various kinds of uranium processing plants and in uranium mines. Workers can also be exposed internally through ingestion of radioactive materials (if the radioactive materials get into the mouth from the air, for example) or by absorption through wounds or cuts.

Internal exposure is less likely in situations where the radioactive materials are sealed or separated in some other way from the work environment, such as in glove boxes. However, if accidents occur in these situations, or if equipment such as a ventilating system or glove box is not efficient or in proper working order, then workers could be exposed internally as well.

For almost the entire period of nuclear weapons production, limits have been imposed on exposure from both internal and external modes. Some current limits apply to combined external and internal exposure, while past limits have applied specifically to particular organs, such as the lungs. For instance, the limit for lung exposure until 1958 was 15 rem per year for workers and off-site populations. It was lowered for off-site populations to 1.5 rem per year in 1959.

Monitoring Doses

Internal dose is monitored in various ways. One common way is to measure radionuclide concentrations in urine. If one knows the rates of excretion corresponding to various body burdens, then it is possible to calculate these body burdens and thereby infer the radiation dose.

Another method is to measure the gamma radiation being emitted by the radionuclide inside the body. Since a portion of gamma radiation penetrates the body, a fraction of the gamma rays emitted by radionuclides inside the body escape outside it. This is measured by putting the worker or part of his or her body into a "counter," which is a chamber that measures gamma radiation. Thus, we have "whole body counters," "lung counters," and so on. Care must be taken to exclude or adjust for other sources of environmental radioactivity in the measurement of internal body burdens, possibly radon and its decay products.

> *From the beginning of the nuclear era until 1989, internal radiation doses were not calculated or included in worker dose records.*

Internal doses can also be assessed indirectly by measuring the concentrations of radionuclides in the air in the plant. In areas where exposure is more likely, workers can wear portable air monitoring devices to measure concentrations of radionuclides in the "breathing zone"—that is, in the air very close to their faces. Internal worker doses can be estimated if breathing rates, efficiencies of protective devices worn by workers (if any), and other factors are known.

It is essential that radiation monitoring be carried out accurately and in sufficient detail. For instance, film badges and TLDs must be stored properly when not in use, so that they are not contaminated between worker exposure times. Also, workers at risk of internal exposures must be monitored frequently enough to accurately determine internal body burdens of radionuclides. This is because over time the body eliminates radionuclides

See **Worker Doses,** *page 5*

1/5/13

COMMENTOR NO. 80: PORTSMOUTH-PIKETON RESIDENTS FOR ENVIRONMENTAL SAFETY AND SECURITY (CONT'D.) MCDERMOTT, OHIO

Worker Doses *from page 4*

some are excreted in a very short time, while others are eliminated very slowly. (The amount of time it takes to eliminate half of the body burden of a radionuclide is called its biological half-life.) It is also important to know the chemical form of the inhaled or ingested radionuclide because the rate at which it is eliminated from the body depends on the solubility of the particular chemical compound.

Failure to Monitor

The April 7, 1993 background paper sent to IEER by the U.S. Department of Energy Office of Worker Protection Programs and Hazards Management clearly set forth what IEER had suspected for several years, that

> ... [d]uring 1989 to DOE, and 1991-1994 in the nuclear industry (NRC and Agreement States) external radiation doses were not calculated [or] for workers. Radiation activity (worker exposure or percent of body burden) was recorded in the DOE prior to 1989

Thus, while workers were being monitored for internal body burdens, these body burdens were not being translated into radiation dose estimates; nor were any radiation dose estimates corresponding to internal radionuclide body burdens entered into the dose records of workers.

While there was no regulatory requirement to actually calculate worker doses, the lack of internal radiation dose estimates in worker dose records means that the records of workers who were at risk of internal exposures are incomplete, misleading, and inaccurate. The degree of incompleteness and inaccuracy will vary from one worker to the next, from one historical period to the next, and from one facility to the next. But the overall result is that *large numbers of workers have received information about their radiation exposures which systematically understates their actual exposures.*

Another consequence of the incomplete internal dose records before 1989 is that in compensation cases involving workers who had internal exposures, the DOE and its contractors may have based their arguments on incomplete data that underestimated exposures. Many cases may therefore have been unjustly decided against workers. Whether the DOE or its predecessor agencies knowingly omitted internal dose information from some worker compensation cases is, at this time, an open question, but a reasonable one to pose.

While it is not possible to give an accurate estimate of the proportion of the 300,000 to 600,000 workers who have worked for the DOE that were at risk of exposure beyond allowable limits, we note that at the uranium processing plant in Ohio, commonly called the Fernald Plant, most workers were at risk in the early years. In fact, in 1955, the worst year for worker exposure, IEER estimates that almost 90 percent of workers were exposed to more than the allowable dose limit of 15 rem to the lung. (See SDA Vol. 5 No. 1.)

There are a number of other direct consequences of seriously incomplete dose records:

- Internal exposures of uranium workers may also have led in some cases to heavy metal poisoning, notably of the kidneys. Such cases could have been better detected had internal dose information been a part of dose records.
- Improper medical diagnoses may have resulted in some cases because dose records were inadequate.
- Corrective measures to improve working conditions were likely delayed or not implemented in many cases because dose records did not show overexposures.

The problem was most acute in the period before the mid-to-late 1960s for two reasons. First, evidence indicates that this was the period when workplace conditions were the dirtiest and when workers were at higher risk of exposure. This observation cannot be used to arrive at conclusions about specific workers or even specific plants. But to date, most of the evidence we have examined indicates that for various reasons, exposures were generally highest in this period.

Second, this period is prior to the availability of counting techniques that allowed for direct measurement of body burdens. Action levels were set for radionuclides in urine. So long as the content of specific radionuclides was below these action levels, body burdens and worker doses were assumed to be below the maximum allowable limits. After lung and body-counters became available in the early 1960s, there were delays in using them, even after they were brought into use, for example in 1968 at Fernald, urine measurements continued to be the main method for monitoring internal dose.

Unfortunately, the monitoring procedure adopted by the DOE and its contractors was flawed. IEER's analysis of Fernald dose records in 1985 revealed the following problems:

- The lung burden inferred from urine data was consistently underestimated because of improper assumptions about the ratio of urinary excretion per unit of uranium lodged in lung tissues.
- Other was not monitored for all radionuclides.
- Urine monitoring was generally too infrequent to allow for accurate determination of body burdens and their change with time. Since many chemical forms of radionuclides are excreted relatively rapidly, infrequent monitoring was likely to miss doses from accidents and other occasional but high exposures. Further, in many cases, urine measurements were so infrequent that even chemical forms with relatively long biological half-lives would not have been accurately detected. As a result, low urine concentrations may not have corresponded to low exposure, but merely to a long

See **Worker Doses,** *page 6*

COMMENTOR NO. 80: PORTSMOUTH-PIKETON RESIDENTS FOR ENVIRONMENTAL SAFETY AND SECURITY (CONT'D.) MCDERMOTT, OHIO

Worker Doses, *from page 5*

time lapse between the intake of the radionuclide and the taking of urine samples (or lung counts).

- The solubility of the compound inhaled or ingested was not determined or, if known, was not recorded.
- The relationship of urine sampling time to exposure was, in most cases, unknown.

As a result of all these factors, the assumption that the dose was below allowable limits if the concentration of a radionuclide in urine was below the action level was scientifically unsound. Even when the actual doses were below allowable limits, the internal doses should have been entered into worker dose records and added to external doses in appropriate ways.

Whole-Body and Organ-Specific Doses

Radiation standards limit dose both to specific organs as well as to the whole body. Consider, for example, doses to the lung. The lung may be exposed by external gamma radiation from sources outside the body, resulting in doses essentially equal to those for other organs in the body. It may also be exposed from inhaled radionuclides. In order to ensure compliance with the lung dose limit, which was 15 rem in the 1950s through 1980s, DOE and its contractors only had to consider internal body burdens of radionuclides. (However, as we have indicated, before 1989 internal doses were not calculated from these data.) In most cases, such as at the Fernald plant, lung doses were inferred from measurements of uranium in urine. If these were found to be below allowable concentrations, compliance with the 15 rem/year limit was assumed to have been demonstrated.

In the period since the late 1980s, the regulatory practice has been to use "committed effective dose equivalents."[2] In this model, "effective dose" is calculated by multiplying doses to individual organs or tissues, like the thyroid, bone tissue, or the lung, with a weighting factor that accounts for the relative likelihood of cancer mortality from exposure to a particular organ. This allows exposures to a single organ and exposure of the whole body to be considered together. Further, internal organ doses are calculated on the basis of a fifty-year "committed" dose—that is, the entire dose from a radionuclide to an organ over a fifty year period (in most cases, the majority of the dose is delivered in a few years or less). These two concepts, "effective dose equivalent" and "committed dose" are put together to arrive at "committed effective dose equivalent." For regulatory purposes, the entire committed dose is assigned to the year in which the radionuclide is incorporated into the body. But even in this new practice, the organ doses arising from internal radiation must be known, because without that data, the correct effective dose equivalent cannot be calculated. This change in regulations requiring calculation of effective dose equivalents caused DOE to begin to move to a policy of integrating internal and external radiation doses.

While the unavailability of precise scientific techniques before the mid-1990s would have precluded accurate internal dose assessment, the doses could have been inferred from urine data and integrated into dose records, but were not. After the mid-1990s, the AEC and its contractors could have made relatively accurate worker dose estimates, but still failed to do so. It would appear that the same institutional outlook that put weapons production before environmental protection also relegated sound worker dose records into second place until the Cold War began to wind down.

> *The same institutional outlook that put weapons production before environmental protection also relegated sound worker dose records into second place until after the Cold War.*

Consequences of Underestimating Dose

Underestimation of internal doses is not just poor practice for worker health protection. It also creates problems for epidemiological studies. Accurate epidemiological work is needed to estimate the health risk of radiation exposure, and this requires studies with sound data on doses to various groups of workers.

Cohort studies, for example, compare the health status of people with various degrees of exposure. Such studies are common among worker populations and help to assess the risk of exposure to radiation (or other disease-causing agents). But if worker dose records are distorted by omission of a crucial component of dose, highly exposed workers and workers with low exposures could be jumbled up in ways for which no statistical control is possible.

For instance, studies that consider external exposure only would group workers with low external doses together and those with high external doses in another group. If some or all of the low external exposure group workers had higher internal doses than the high external exposure group, the study would be comparing workers with high exposure to others also with high exposure![3] Such a study would be misleading and lead to underestimate risk estimates. By contrast, if the high external exposure group had even higher internal exposures, the study would also be misleading and would tend to overestimate radiation risk.

See **Worker Doses,** *page 7*

Worker Doses, *from page 6*

The April 1997 DOE background paper also points out that lifetime dose records have not been carefully maintained through the risk to workers is based on lifetime radiation dose. If dose records are not transferred from one contractor to the next at a plant, or from one plant to another when the worker changes jobs, worker health as well as public health is compromised because it becomes impossible to accurately track the health effects of occupational exposure. Of course, this is another complicating factor in doing epidemiological studies and assessing radiation risk.

External Exposure Data

The state of external dose data also needs to be carefully examined. The DOE has admitted the following problems[4]:

- External exposure data are often incomplete and unreliable.
- Raw dose data and electronic versions of the data (which are often used by researchers in studies) do not always agree.
- In some cases, worker dose records contain entries stating that the dose was zero, regardless of what the actual dosimeter reading may have been.

Finally, there were very few measurements made of worker exposure to non-radioactive hazardous materials. But we do know from the nature of work done at nuclear weapons plants that many workers were exposed to or were at risk of exposure to acids, organic solvents, beryllium, fluorine and fluorides, and heavy metals.

As a result of all of these problems we can conclude that knowledge of workplace exposure during nuclear weapons production and testing was poor, and the results of at least some epidemiological studies are likely to be misleading. At present, it is impossible to say what health effects might be revealed by properly conducted studies. But we can say with confidence that the radiation doses for large numbers of workers were higher than those that are apparent from their dose records because internal doses were omitted until 1989, and because there were many deficiencies in other dose records.

A CENTERFOLD FOR TECHNO-WEENIES

Exposure and Dose

This Centerfold provides information about dose in rad and how it relates to energy deposited in tissue, as well as a brief history of the evolution of radiation exposure standards and regulations. We also include additional information about Iodine-131 and thyroid doses received by the US public during the years of atmospheric testing.

A rad is defined as the deposition of 100 ergs of energy per gram of tissue. Since the measurement is *per gram*, then the same dose in rad can reflect very different radiation exposures, depending on the mass into which the energy is deposited:

If the dose is:	...and the total mass into which the energy is deposited is:	...then the total energy deposited is:
2 rad	2 grams (weight of an infant's thyroid)	400 ergs*
2 rad	20 grams (weight of an adult's thyroid)	4,000 ergs
2 rad	70,000 grams (the official definition of "standard man" in radiation protection practice; equal to about 154 lbs.)	14 million ergs

Conversely, the same amount of deposited energy can result in very different doses, depending on the mass into which the energy is deposited:

If the total energy deposited is:	...and the total mass into which the energy is deposited is:	...then the dose is:
4,000 ergs	2 grams (weight of an infant's thyroid)	20 rad
4,000 ergs	20 grams (weight of an adult's thyroid)	2 rad
4,000 ergs	70,000 grams (the official definition of "standard man" in radiation practice; equal to about 154 lbs.)	0.0006 rad

* To every day terms, an erg is a very small amount of energy. It takes about 1.3 million ergs to light a 60-watt bulb for one hour. But in the context of the way cells that make up living tissue work, 100 ergs is a large amount of energy. One erg is enough energy to disrupt tens of millions of the chemical bonds that hold molecules together.

For more on rad, rem and roentgen, see "Dear Arjun," page 13.

COMMENTOR NO. 80: PORTSMOUTH-PIKETON RESIDENTS FOR ENVIRONMENTAL SAFETY AND SECURITY (CONT'D.) MCDERMOTT, OHIO

Iodine-131

- **General:** its name is from the Greek word "iodeis," meaning "violet colored," after the violet color of iodine in a gas form. As a solid it is shiny, black and nonmetallic. In its non-radioactive form occurs on land and in sea in sodium and potassium compounds, and is necessary for proper functioning of the thyroid.
- **Half-life:** 8.01 days
- **Atomic number:** 53.
- **Decay mode:** beta radiation.
- **Sources:** Fission product created in nuclear reactors and in nuclear weapons explosions.
- **Release of Iodine-131 per kiloton of fission explosive power:** 125,000 curies.
- **National Cancer Institute estimate of Iodine-131 releases from the Nevada Tests:** 150 million curies.
- **Organ most affected:** thyroid.
- **Main pathway:** milk.
- **Other pathways:** ingestion of other dairy products, vegetables, fruits, and eggs; inhalation; and external irradiation.
- **Direct physical effects:** radioactive iodine damages or destroys thyroid cells.
- **Health effects:** Increased risk of thyroid tumors, notably in children. Likely increase of thyroid cancer risk in children exposed before the age of 15 years. Children under five at highest risk. Females have more than twice the risk of males. Linked to other thyroid disorders, such as autoimmune hypothyroidism, autoimmune thyroiditis, hypothyroidism incident to Grave's disease, and thyroid nodules.
- **NCI estimate of thyroid dose from Nevada Tests averaged over entire country:** 2 rad.
- **NCI estimate of thyroid dose to children aged 3 months to five years in high fallout areas:** 27 to 112 rad.
- **Official Iodine-131 release estimate from Chernobyl:** 7.3 million curies - decay-corrected to ten days after the start of the accident.
- **Iodine-131 inventory in the Chernobyl reactor on April 26, 1986, the day the accident started:** approximately 83 million curies.
- **IEER's rough estimate of actual releases from Chernobyl over the course of the ten-day fire:** 10 to 15 million curies (assuming the official estimate of a 20% release fraction is correct).

1931–34	US Advisory Committee on X-Ray and Radium Protection (precursor to the National Council on Radiation Protection and Measurements) adopts X-ray "tolerance dose" of 0.1 roentgen *per day*.
1940–41	US Advisory Committee proposes but does not implement, lowering the X-ray tolerance dose to 0.07 roentgen *per day*.
1942	U. of Chicago Metallurgical Laboratory adopts a "maximum permissible exposure" standard of 0.1 roentgen *per day*. Becomes standard for entire Manhattan Project.
1954	Atomic Energy Commission adopts National Bureau of Standards recommended dose limit of 5 rem *per year*. Sets additional limits for internal exposures at 1/5 rem per year for most organs.
1956	Dose limit for workers remains 5 rem per year. AEC also adopts dose limits for the public equal to one-tenth of those allowed for workers: 0.5 rem for external exposure and 1.5 rem for most organs for internal exposure.
late 1980s -1990	Department of Energy adopts dose limit for the public of 100 millirem (0.1 rem) per year; dose limit for workers remains 5 rem per year. A new model for calculation of internal doses in workers is adopted, the "committed effective dose equivalent." (See main article.)
1991	International Committee for Radiological Protection recommends worker dose limit be reduced to 2 rem per year. Recommendation is not adopted by DOE.

NOTE: [illegible]

IEER Releases New Report on "Clean-up" of Nuclear Weapons Complex

More than half a century of nuclear weapons production in the United States has created tens of millions of cubic meters of long-lived radioactive waste, decontaminating problems associated with thousands of contaminated facilities, and environmental problems involving contaminated land and water. The production of 70,000 nuclear warheads and bombs would have resulted in a problem of environmental remediation and waste management in any case. But the neglect and mismanagement of radioactive and toxic wastes have created problems that are far more costly than they might have been; some appear to be intractable with current technology.

IEER's newly released report, *Containing the Cold War Mess*, looks at the problem of environmental remediation and waste management of the nuclear weapons complex through case studies of three rather different problems, each important in its own way: a) transuranic waste management; b) high-level waste tank farms at Hanford; and c) radium- and thorium-contaminated wastes at Fernald. It also outlines alternatives that could be considered in reforming the environmental management program of DOE. The main findings of this report and a summary of recommendations are given below.

Main Findings

1. Nuclear weapons production and associated activities have created tens of millions of cubic meters of dangerous wastes and roughly two billion cubic meters of contaminated soil and water.

2. Since 1989, DOE has made considerable progress in characterizing many of the crucial problems of environmental remediation and waste management in the nuclear weapons complex, but much remains to be done.

3. DOE is proceeding with the most expensive environmental program in history without national remediation standards to govern and guide the process.

4. Despite about $40 billion dollars in expenditures since 1989, DOE does not have a sound direction, plan, priorities, or implementation strategy for dealing with remediation and waste management problems. Institutional factors are the single most crucial element in DOE's failure to achieve a sound direction.

The principal institutional problems that we have identified are:

- an attachment to Cold War technologies related to weapons research, development, testing, and production
- a tendency toward "environmentalization"—that is, rushing into big projects without proper preparatory scientific and engineering work (this tendency perhaps deriving from a desire to also maximize the flow of funds into the weapons complex)
- a lack of sound internal scientific and technical peer review that actually matters in decision-making, or in approval and implementation of large projects, and a corresponding tendency to ignore inconvenient extra-departmental advice
- a tendency to approve large budget increases for contractors without thorough engineering-based reviews of the problems that led to the budget changes
- a failure to learn lessons from past mistakes
- an attachment to the Yucca Mountain and Waste Isolation Pilot Project (WIPP) repository programs out of institutional, legal, political, and financial inertia even though these are compromising a much larger effort to remediate the weapons complex, manage long-lived highly-radioactive wastes, and develop a scientifically sound long-term high-level waste management program
- a lack of independent regulation of DOE's nuclear activities.

5. The U.S. waste classification system is on unsound basis for implementing waste management or environmental remediation decisions. (See NDA Vol. 6 No. 1.)

6. DOE is not holding contractors sufficiently accountable for project mismanagement and poor technical decisions.

7. A number of problems cannot be satisfactorily solved with presently available technology. Sound research and development and careful project planning will be needed over a long period.

Main Recommendations

The most important single reform that is needed is institutional in nature. DOE can make internal reforms at once. It should:

- create a project review structure for large projects that is both technical and financial in scope
- create a standing advisory committee to review projects from early stages through implementation both as regards their technical aspects and the reasonableness of budgets from an engineering standpoint. The majority of members on this committee should be free of conflicts of interest in regard to contracting with DOE or its contractors.
- reinstate the practice of issuing annual Baseline Environmental Management Reports, and make them more complete by including all sites, whether

See Report *page 10*

MILK *from page 1*

country would result in fallout spreading over most of the country. In a 1948 memo, an Air Force meteorologist advised the committee assigned to finding a test site that "Because the United States is predominantly under the influence of westerly winds, it seems obvious that the eastern coast areas of the United States may provide a suitable site."[12] But the site was located in the west, where the proximity to the weapons laboratories would allow for acceleration of the weapons program.

Doses Avoidable

Iodine 131 is a relatively short-lived radioisotope with a half life of 8 days. (See Centerfold for more information.) Therefore, radioactivity levels in contaminated milk would have decreased significantly several weeks after the time of detonation, making most of the iodine-131 doses to the public avoidable. Contaminated milk could have been dumped or diverted from the market and used for products such as dried milk, butter or cheese, which take longer to process and would allow time for the radioactivity to decay. But the government made no such provisions, though they were aware as early as 1953 of the "milk pathway," the primary source of exposure for iodine-131 in humans. Warnings about iodine-131 in milk were also issued at the 1955 United Nations Conference on Peaceful Uses of Atomic Energy, where researchers suggested that the then-allowable air concentration limits for iodine-131 were ten thousand times too high and should be lowered:

> This limit should be reduced by four orders of magnitude to provide protection solely for grazing animals. Approximately the same reduction is required for the safety of humans eating large quantities of fresh garden produce and drinking milk from cows grazing on some 10[3] contaminated pasture.[13]

An Oxford University delegation to the conference stressed that "human beings whose diet consists largely of milk, notably infants . . . become of their youth may be considered super-susceptible to the effects of radiation."[14] The advice of the UK delegates, while ignored by the AEC, was heeded by British officials in 1957 when, after a reactor accident that resulted in a release of 14,000 to 27,000 curies of iodine-131, ordered that milk within a 200-square mile area around the plant be dumped as a health precaution.

But even as the early 1960s, when the milk pathway was widely understood, the US government refused to acknowledge the risk of iodine-131 contamination or take measures to reduce it. In 1962 officials in Utah and Minnesota diverted possibly contaminated milk from the market when iodine levels exceeded radiation guidelines set by the Federal Radiation Council (FRC). In response, the FRC, whose members included the chairman of the AEC and the Secretary of Defense, declared that they did "not recommend such actions" and that such "countermeasures may have a net adverse rather than favorable effect on the public well-being."[15] Further, the FRC made the remarkable determination that their own radiation guidelines should not be applied to fallout without further detailed studies because "any possible health risk which may be associated with exposures even many times above the guide levels would not result in a *demonstrable* increase in the incidence of disease" (emphasis added). Since thyroid cancers can develop many years after radiation exposure and are therefore not immediately detectable, this reassurance was highly misleading.

While the public was not warned to refrain from milk consumption and was continually reassured that fallout posed no danger, the AEC was providing advance notice of tests, including "forecasts of contaminated areas based on meteorological data"[17] to the National Association of Photographic Manufacturers. This was done so that they could "anticipate local contamination and take preventive action"[18] to protect photographic film from being ruined by radiation exposure. The warning to the photographic industry began in 1951 – the first year of testing in Nevada – as a result of the Eastman Kodak Company's threat to sue the AEC over damaged film from nuclear fallout. The warnings continued throughout the atmospheric testing program but were not extended to the public.

Other Doses from Fallout

The United Nations Scientific Committee on the Effects of Atomic Radiation estimates that globally, iodine 131 doses comprise only about 2% of the overall radiation dose from weapons testing (dose integration time to the year 2000).[19] Ninety-eight percent of the dose is from other radionuclides. These calculations do not take hot spots into account, which may increase the relative share of iodine 131 dose. In addition, in areas of high precipitation both in the US and in other countries, hot spots probably resulted in high concentrations of other radionuclides besides iodine-131. Further work is needed to clarify which populations were most affected by testing throughout the world. So viet and Chinese testing could have affected populations in Alaska, for example, and there may be incidences of hot spots in the Pacific, including Hawaii, from French, British, and US Pacific area testing. There is also evidence from the NCI study that hot spots occurred in Canada and may have occurred in northern Mexico from Nevada tests.

A thorough assessment of the effects of all nuclear testing – not just US tests – is needed so that those at risk of high doses can receive proper screening. Soviet tests, for example,

15/16

COMMENTOR NO. 80: PORTSMOUTH-PIKETON RESIDENTS FOR ENVIRONMENTAL SAFETY AND SECURITY (CONT'D.) MCDERMOTT, OHIO

Milk, *from page 11*

had a larger total fission yield than US tests (110.9 megatons compared to 72.1 megatons), and the combined fission yield of Chinese, British and French tests was 34.2 megatons. IEER estimates that only a small fraction of the cesium-137 in the soil in the eastern United States is due to fallout from detonations at the Nevada Test Site. In light of the NCI findings, we make the following recommendations:

- An international study should be funded to carry out a global assessment of the effects of nuclear weapons testing and should follow a process that is open to the general public.
- France, Britain, China and the former Soviet Union should make public all their data on fallout.
- Further study should be conducted to assess the risk of cancer and other thyroid disorders from radiation doses.
- The US government should provide thyroid screening for those who were children at the time of atmospheric testing living in high fallout areas in the United States. The Agency for Toxic Substances and Disease Registry has suggested screening for those who received a cumulative dose of 10 rad or more while they were age 15 or younger.[9]
- The results of the NCI study should be made widely available to the public in a format that is accessible and understandable so that those who may be at risk can receive proper screening in a manner that reduces risk of disease.

This article is based on an article that appeared in the November-December issue of The Bulletin of the Atomic Scientists, *entitled "Worse Than We Knew." It is available on the web at "www.bullatomsci.org," and on IEER's webpage, "http://www.ieer.org/latestfindiant.html."*

The full text of NCI's study can be found on the web at "http://www.nci.nih.gov/newsroom/allout/fallout/contents.html."

Errata

In SDA Vol. 6 No. 1 (on radioactive waste management), the entry in the "Radioactivity" column of the "Uprated Uranium" row on the table appearing on pages 10-11 should read "31.2," to that same table, the entry in the "Rocketdyne States" column of the "Uranium Mill Tailings" row should read "UMTRA and Uranium Mill Tailings Radiation Control Act."

In SDA Vol. 5 No. 4 (on MOX), lines 9 and 10 of the middle column of page 2 should read, ". . . between 8 to 10 million gallons of liquid waste . . ." Our thanks to James C. Ward of Los Angeles, CA for pointing out this error. You win $25! This is a standing offer to SDA readers! IEER will award $25 to the first person sending in a correction of arithmetic errors appearing in SDA, as well as our gratitude for keeping us on our toes!

COMMENTOR NO. 80: PORTSMOUTH-PIKETON RESIDENTS FOR ENVIRONMENTAL SAFETY AND SECURITY (CONT'D.) MCDERMOTT, OHIO

Dear Arjun

Dear Arjun:

What's the difference between a rad, a rem, and a roentgen?

—Mixed-up in Margaritaville

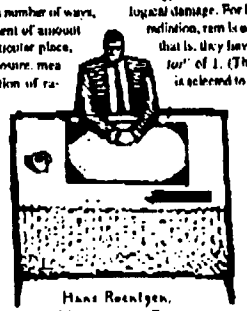
Dear Mixed-Up:

In the 1960s in the United States, individuals who were deeply involved with the so-called counter-culture were sometimes referred to as *radical*, or *"rad"* for short. There were also individuals who didn't want to rock the boat too much, but still liked to be associated with the counter-culture, who were called *"rem,"* short for "regularly enlightened mainstreamers." Everyone else was considered by the rad and rem to be part of the "rank and file," which was later shortened to *"roentgen* file," after a particularly mainstream leader of the time, Hans Roentgen.

But unbeknownst to these radicals, *rad, rem* and *roentgen* had already been used as units to express *doses* from radiation exposure. Radiation dose is calculated in a number of ways, including measurement of amount of radiation at a particular place, measurement of exposure, measurement of absorption of radioactivity, and of relative effect of that absorption on different organs or types of tissue. Dose calculations take into account the type of radiation involved (alpha, beta, gamma, or neutron). Radiation doses can also be expressed in standard international units, sieverts or grays (one sievert equals 100 rem, one gray equals 100 rad).

A *rad*, or "radiation absorbed dose," is a unit of *absorbed* dose equivalent to the deposition of 100 ergs of energy per gram of tissue. (See Clusterfold for more on rad and ergs.) Since a rad measures deposition of *energy per gram of tissue*, a 2-rad dose to a certain organ, like the thyroid (which weighs roughly 20 grams), reflects a very different total deposition of energy than does a 2-rad dose to the entire body (typical weights range from 40,000 to 100,000 grams).

A *rem*, or "radiation equivalent man," is a unit of absorbed dose that takes into account the relative biological damage caused by the various ways that ionizing radiation deposits its energy in tissue (known as the Relative Biological Effectiveness, or RBE). In general the larger the amount of energy absorbed, the larger the biological damage. For beta and gamma radiation, rem is equivalent to rad; that is, they have a *"quality factor"* of 1. (The quality factor is selected to approximate the RBE as it relates to overall risk, and is used in regulatory practice to convert radiation dose measured by energy deposited in radiation dose measured in terms of biological damage.)



Hans Roentgen, Mainstream Guy

For alpha radiation, which involves heavy particles, much more damage is done per unit of energy deposited. Increasing the ratio between damage to tissue and energy deposited. The currently accepted quality factor for alpha radiation is 20, but may change as more is learned about damage due to ionizing radiation. Neutron radiation has a varying quality factor between 5 and 20, depending on neutron energy. Rem is the unit used to express regulatory limits for radiation exposures.

A *roentgen* (abbreviated "R" and pronounced "rent-gen") measures gamma and beta radiation dose based on the amount of ionization in the air. It is the common form of calibration of radiation measuring instruments because the beta and gamma radiation broken up inside the instrument, creating electrically charged particles which can be measured by creating an electric current in the instrument. A roentgen is a unit of radiation dose that causes an ionization charge equal to 2.58×10^{-4} (0.000258) coulombs per kilogram of air.* Because it measures ionization in air and not in tissue, there is no exact, fixed correspondence between roentgen and rad, but an approximate equivalence is that one roentgen equals 0.93 rad for non-body biological tissue. Since the uncertainties in dose calculation are typically far larger than 7 percent, one roentgen is often considered about equal to one rad, for convenience.

* A coulomb is a unit of electrical charge. The charge of an electron is 1.6×10^{-19} coulomb.

It Pays to Increase Your Jargon Power

by Dr. Egghead

1. body burden

a. The strain felt by writers when they have written introductory and closing paragraphs, but still have to write the rest of an essay.

b. What diet pill companies want people to believe they have.

c. What you feel when you get the bill from the auto body shop.

d. The amount of a radioactive material deposited in the body at a given point in time (in units of mass or radioactivity).

2. whole body counter

a. A specially-designed surface in diners where customers can eat while lying down.

b. Someone not content to do just a headcount.

c. A hospital employee whose job it is to count how many whole bodies came out of the operating room.

d. A chamber equipped with instruments to measure gamma radiation being emitted from anywhere in the body.

3. ALARA

a. The younger, lesser-known sister of Evita.

b. Name of a failed apple harvesting company.

c. Acting in the manner of Ra.

d. Acronym for "As Low As Reasonable Achievable." Usually "ALARA Principle," which dictates that radioactivity released to the environment and radiation doses be not merely in compliance with regulations, but further reduced below the allowable limits, given the technological and financial resources available.

4. effective dose equivalent

a. The number of naps taken during the day by a nuclear plant operator working night shifts to effectively enable him or her to stay awake on the job.

b. The dose delivered by a placebo that works as intended.

c. What a swig of whiskey was back in the days before anesthesia.

d. A dose estimate that takes into account the combined effects of internal and external radiation, the selective uptake and distribution of radionuclides, and their varying effects on different organs. The effective dose equivalent is calculated by multiplying the dose to an individual organ, such as the lung, by a weighting factor which addresses the likelihood of a cancer mortality from radiation exposure to that particular organ.

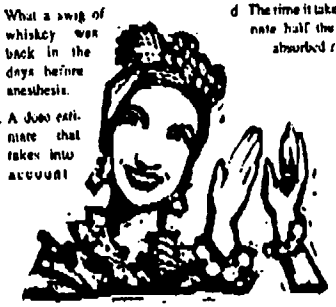
5. biological half-life

a. The time it takes for half a room of biology students to fall asleep.

b. The portion of a soccer player's life spent playing halfback.

c. The time it takes for half a log to decay.

d. The time it takes the body to eliminate half the mass of a given absorbed radionuclide.



ALARA

ATOMIC PUZZLER

Gamma dosing on the job...

Back in the late 1980s, when Dr. Egghead's trusty sleuthing dog Gamma was just a pup, the Department of Energy began using a method of worker dose calculation referred to as the "committed effective dose equivalent." Even then, Gamma was interested in such things and would entertain himself by calculating effective dose equivalents for workers (Always the workhound, that Gamma.) He recently fetched his old records and was hoping for some help in completing some unfinished dose estimates. Note that Gamma was at that time learning the Standard International units of becquerels and sieverts, and so was converting from rems and picocuries to sieverts and becquerels. His notes are reprinted below, paw prints, conversions, and all, except for the final dose calculation:

A worker is exposed to an annual average concentration of uranium 238 of 27 picocuries per cubic meter of air—or 1 becquerel per cubic meter of air.

The worker breathes 9.6 m^3 (cubic meters) of air on each working shift (8 hours) and works 200 shifts per year.

The dose conversion factor for the lung is 9.84×10^{-4} rem per picocurie—or 2.66×10^{-4} sieverts per becquerel. (Gamma converted rems to sieverts by dividing by 100. He then multiplied the result by 27 because there are 27 picocuries per becquerel. Try it!)

The weighting factor for the lung is 0.12.

Assuming no other organ is affected, what is this worker's dose in rem? (Note: This dose is called the "committed effective dose equivalent." See main article.) Round to 2 decimal points. What is the committed effective dose equivalent in sieverts?

Hint: The dose conversion factor is used to convert radiation intake into dose. The weighting factor converts the lung dose into the effective dose equivalent.

Gamma the puppy calculating worker doses.

Send us your answers via fax (301-270-3029), e-mail (ieer@ieer.org), or regular mail (IEER 6935 Laurel Ave., Suite 204, Takoma Park, MD 20912), postmarked by Dec. 19, 1997. IEER will award 25 prizes of $10 each to people who send in a solution to the puzzle (by the deadline), right or wrong. There is one $25 prize for a correct entry, to be drawn at random if more than one correct answer is submitted.

COMMENTOR NO. 80: PORTSMOUTH-PIKETON RESIDENTS FOR ENVIRONMENTAL SAFETY AND SECURITY (CONT'D.) MCDERMOTT, OHIO

Report *from page 10*

closed or operational.

Such internal reforms are unlikely to solve the entrenched problems that we have discussed above. We recommend that President Clinton appoint a commission on Institutional Reform of Environmental Remediation and Waste Management. The commission should hold hearings around the country and make definitive recommendations within a six- to twelve-month period.

Whatever the reform chosen, general technical principles will need to be adopted and reforms implemented to restructure the environmental management program. Specifically, the government should:

1. *Create a new, national, environmentally-protective system of radioactive waste classification* according to longevity and specific activity, so that comparable hazards are managed comparably.

2. *Coordinate waste management and environmental remediation* and make reduction of short-term risks compatible with minimizing long-term risks.

3. *Approach remediation with independently enforced, national, health-based cleanup and waste management standards*, including specific provisions to protect groundwater resources and mandatory guidelines to keep doses as low as reasonably achievable (ALARA) both for workers and for off-site populations. The ALARA guideline for releasing sites for unrestricted use should be to remediate to background levels, if reasonable, or else to keep doses to under 2 millirem per year (which is the British ALARA guideline).

4. *Suspend the politically expedient Yucca Mountain and WIPP repository programs and put in place a scientifically sound program of long term high level waste management*, including repository research, subseabed disposal research, and research on materials to contain radioactivity that are analogues to natural materials that can last for millions of years.

5. *Provide funds and technical support to communities that have residual contamination* so that they can monitor the environment and keep themselves informed. Such funds are needed to protect communities against future known risks and also against risks due to inadequate characterization or present incomplete understanding of risks. The size of the fund should depend on the size and character of the residual radioactive and non-radioactive hazardous contamination of land, remaining structures, surface waters, river beds, and groundwater, as well as the total amount of radioactivity and non-radioactive hazardous material left in disposal areas on site.

6. *Manage non-radioactive toxic components of wastes in ways that do not seriously compromise management of radioactive components.*

7. *Stabilize waste so as to greatly reduce or eliminate the most serious environmental and health threats* and store it on site while sound long-term management strategies are developed.

8. *Provide the states, Indian tribes, and the public (with special emphasis on the affected communities and workers) with timely information* so that they can participate effectively in decision making.

Cylinder plug damaged at Lockheed Martin plant

By Martin Poston
Times Staff Writer

The U.S. Department of Energy reported that there was a small release of material at Lockheed Martin Energy Systems in Piketon as a result of a damaged cylinder plug on a 14-ton cylinder, which contained about 18 pounds of uranium-238.

The cylinder plug was replaced, and a precautionary environmental sampling was taken.

Officials at the plant said that a worker was operating a vehicle to move cylinders in a storage yard, when he accidentally struck a cylinder plug on a cylinder that contained uranium hexafluoride. There were no injuries in the accident, and the cylinder contained no enriched uranium.

As a precautionary measure, traffic on the perimeter road of the plant was rerouted for a brief period between the north and west access roads.

MILITARY TOXICS PROJECT

[author block redacted]

February 4, 1998

Copy of this Letter into Records with support from PRESS.

Press is a member group of Military Toxics Project

Charles R. Bradley, Jr.
U.S. Department of Energy
Office of Nuclear Energy, Science and Technology
19901 Germantown Road
Germantown, MD 20874

Dear Mr. Bradley

Secretary Pena recently held a press conference in Washington D.C. to tout his Openness Initiative. We hope that this willingness to be open includes efforts to be more inclusive in DoE's outreach to impacted, or potentially impacted communities.

Specifically of concern to the Military Toxics Project and the Indigenous Environmental Network is the Draft Programmatic Environmental Impact Statement For Alternative Strategies For The Long-Term Management And Use Of Depleted Uranium Hexafluoride.

We believe that all of the strategies that presented have serious environmental justice concerns and potential impacts to communities that you have not adequately reacted with the draft PEIS. We also believe that the meetings that the DoE has held in the past, as well as the one that are scheduling on February 19, 1998 in Paducah, are not properly reaching people who are or may be impacted by decisions that your agency will be making regarding the long-term plan for the use of this dangerous material.

Keeping with the spirit and intent of President Clinton's Executive Order on Environmental Justice, and Secretary Pena's Openness Initiative, we feel that is would be reasonable to request that the DoE initiate roundtable meetings, much like the Federal Facilities Restoration Dialogue meetings. We believe that it is necessary and just to bring in grassroots leaders from community, labor and environmental justice groups to further discuss the implications of strategies that have been proposed.

We further request that the comment period be extended to six months to give these folks the opportunity to meet with you, in addition to the hearings that are taken place now, as well as the opportunity to obtain expert technical advice regarding the impact of the various different strategies.

Please respond to our request in writing. We will be happy to suggest participants for a roundtable discussion.

Sincerely,

Cathy Lemar

COMMENTOR NO. 80: PORTSMOUTH-PIKETON RESIDENTS FOR ENVIRONMENTAL SAFETY AND SECURITY (CONT'D.)
MCDERMOTT, OHIO

1144 Maingate Road
Niskayuna, NY 12309-1315
(518) 377-8203

June 29, 1997

NY Times Bureau
Attention: Mr. Matthew L. Wald
1627 I Street NW
Washington, DC 20006

Dear Mr. Wald:

I am writing to you regarding an article you published in the NY times on March 14, 1997. The title of the article is, "Danger From Uranium Waste Grows as Government Considers Its Fate." Midway through the article you say, "But there was never enough thought given to the final use of the uranium-238, and the leftovers have accumulated like raisin bran with all the raisins picked out. But this leftover is still slightly radioactive because a little of the uranium-235 remains." This statement that the depleted uranium in the storage cylinders at Piketon, Ohio is only slightly radioactive unfortunately is not true. Contrary to public perception, the uranium-235 isotope plays only a very minor role in the radioactivity of either natural uranium or depleted uranium.

I am a retired physicist who worked at the Knolls Atomic Power Laboratory from 1955 to 1983 in Schenectady, NY. On the 26th of June I testified before Congressman Christopher Shays' Sub-Committee on Human Resources concerning the use of depleted uranium munitions during the Gulf War and its potential as one of the causes of Gulf War Illness, also called Gulf War syndrome. On the panel with me was Dr. Asaf Durakovic, former Chief of Nuclear Medicine Service, Wilmington, DE, Veterans Affairs Medical Center. Dr. Durakovic is an internationally recognized expert on the internal contamination of radioisotopes. A copy of his testimony is attached, in which he states that "DU is still very radioactive..."

I would like to illustrate for you the physics reality underlying Durakovic's statement. In Table I I have listed the isotopic compositions of natural uranium and depleted uranium. Using these values I have computed the disintegrations per second of each isotope in one gram of uranium. The results are given in Table II.

Table I. Isotopic composition of natural and depleted uranium in atom percent. The isotopic compositions for uranium-234 (U-234), uranium-235 (U-235) and uranium-238 (U-238) were measured in highly sensitive and accurate mass spectrometers at the Knolls Atomic Power Laboratory, Schenectady, NY.

	U-234	U-235	U-238
Natural Uranium	0.0058	0.7196	99.2746
Depleted Uranium	0.0008	0.2018	99.7947

1521

COMMENTOR NO. 80: PORTSMOUTH-PIKETON RESIDENTS FOR ENVIRONMENTAL SAFETY AND SECURITY (CONT'D.)
MCDERMOTT, OHIO

Table II. The number of nuclear transformations (disintegrations) per second for each isotope in 1-gram of natural uranium and in 1-gram of depleted uranium. These are the alpha particle activities only.

	U-234	U-235	U-238
Natural Uranium	12380	568	12280
Depleted Uranium	1788	160	12325

Theoretically, the disintegration rates of U-234 and U-238 in natural uranium should be identical, because the U-234 is in secular equilibrium with its parent isotope, U-238, the first isotope in the long uranium decay chain. The slight difference results from using only two significant figures in reporting the 0.0055% and small errors in measuring its abundance by mass spectrometry. From Table II we see that the U-235 activity in natural uranium is 568/(12380 + 568 + 12280) = 0.022, or only 2.2% of the alpha particle activity in natural uranium. Similarly, the U-235 activity in depleted uranium is 160/(1788 + 160 + 12325) = 0.011, or only 1.1% of the alpha particle activity in depleted uranium. Clearly, U-235 contributes little to the total alpha particle radioactivity of each kind of uranium.

But this is not even half of the story about the radioactivity of depleted uranium. U-238 decays into thorium-234 (Th-234); thorium-234 decays into protactinium-234 (Pa-234); and protactinium-234 decays into U-234, etc. down the long uranium decay chain. The thorium and protactinium emit energetic beta particles and gamma rays both have short half lives and therefore are in secular equilibrium with U-238, i.e. all three isotopes are decaying at the same rate. See Table III.

Table III. Disintegrations per second in 1-gram of natural uranium and in 1-gram of depleted uranium for U-238, Th-234 and Pa-234 in secular equilibrium with each other. Half lives used: U-238 = 4.47 billion years; Th-234 = 24.10 days; Pa-234 = 1.17 minutes, 6.66 hours (two decay pathways).

	U-238 →	Th-234 →	Pa-234
Natural Uranium	12280	12280	12280
Depleted Uranium	12325	12325	12325

Note that in depleted uranium the U-238 and its decay progeny are decaying at slightly higher rates than the corresponding isotopes in natural uranium. This is because 0.5% of the U-235 in natural uranium has been removed, as is shown in Table I.

You could not have gotten your statement about the low radioactivity of depleted uranium in storage at Piketon, Ohio from any scientific publication, therefore I assume that someone told you this. Whoever it was, he or she did you a great disservice, because it is so far off the mark that it damages your credibility in the scientific community. Furthermore Dr. Durakovic's testimony indicates how easily micrometer aerosol particles of uranium can be inhaled and pass from the lung into the blood stream, from whence they can go anywhere in the body. This makes inhaled depleted uranium particles (or any other kind of uranium) extremely dangerous to health. Furthermore, it is well known that the 2.23 million electron volt beta particles (fast electrons) from

COMMENTOR NO. 80: PORTSMOUTH-PIKETON RESIDENTS FOR ENVIRONMENTAL SAFETY AND SECURITY (CONT'D.) MCDERMOTT, OHIO

Pa-234 have a range of 0.5-inch in water. Our bodies are at least 75% water and have an average density close to that of water, therefore one of these fast electrons can penetrate the same distance in body tissue. This means that each Pa-234 beta particle can traverse more than 500 body cells, potentially damaging DNA molecules in the nuclei of cells. A sufficient number of these hits eventually will cause cancer.

I urge you to show this letter to someone you trust, a person with a scientific background who understands the physics of radioactive decay chains and can make independent calculations of the results I show in Tables I through III.

For the latest background information available on the depleted uranium munitions issue and its possible link to Gulf War illnesses, obtain a copy of the recently published book, *Mind of Dishonor*. A copy can be obtained from the International Action Center (Sara Flounders/Frank Alexander Tel: 212-633-6646; Fax: 212-633-2889). It contains a chapter by me entitled, "DU Spread and Contamination of Gulf War Veterans and Others." I submitted it as my written testimony before the Congressional Sub-Committee on Human Resources. Dr. Durakovic can be reached at Tel: 301-681-8258; Fax: 302-633-5490.

A final comment: When are you folks at the New York Times going to stop letting Bill Mader at *The Nation* run circles around you, scooping you at every turn about the growing scandal surrounding depleted uranium and its use in the Gulf War, and how it is now suspected of causing some of the illnesses being experienced by sick veterans? For example, I testified to the Sub-Committee that in 1979 my colleagues and I at the Knolls Atomic Power Laboratory had measured depleted uranium emissions in air filters exposed at the Knolls site and documented the measurements in a 1980 report. The contamination was coming from the National Lead Industries plant outside Albany, NY, 10 miles east of the Knolls site. We also measured the airborne depleted uranium emissions at another site 26 miles NW of the NL plant. I stated that I had given a copy of my report to the Sub-Committee. Yet, after my testimony, an Army colonel testified that because uranium is dense and heavy, they had measured that it falls to the ground close to a struck vehicle. When Chairman Sheys challenged him about my 26 mile fallout statement, the colonel had no answer. At the conclusion of all the testimony, another Army colonel from the Armed Forces Radiobiology Research Institute (AFRRI) made the following statement, "I want to go on record that it is AFRRI's position that depleted uranium is not dangerous." Incredible!

Sincerely,

Leonard A. Dietz

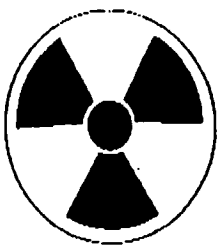
National Grassroots Networking Toward Pollution Prevention and Environmental Justice

How Depleted Uranium Effects Each of Us

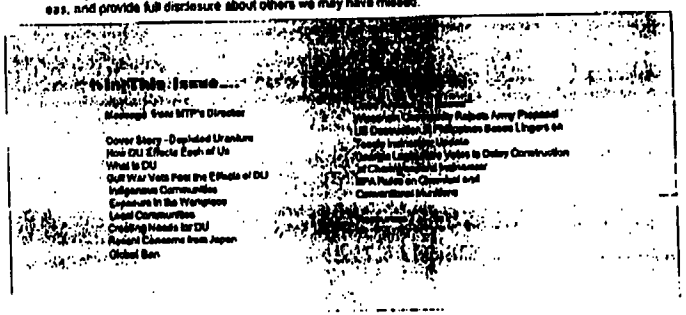
The Department of Defense (DoD) has known since at least 1980 that human exposure to depleted uranium (DU) could result in serious, long-term health disorders. Yet, it refuses to acknowledge publicly the growing list of maladies exhibited by veterans and public citizens alike who have come in contact with this substance.

As investigations heat up concerning Gulf War Syndrome and the many horrible chemicals to which soldiers were exposed in the Persian Gulf, DU is noticeably absent from public discussion. The US Government appears to be burying the story in the sands of the Middle East.



Some opponents of DU manufacturing have characterized the radioactive material as the "Agent Orange" of the 90's, citing the far-reaching, negative effects that DU has on human health and the environment throughout its entire life-cycle. DU harms not only troops and rescue workers on the battlefield, but also the communities near uranium mines, the workers who process uranium and manufacture DU weapons, the communities whose land is contaminated by DU weapons testing and warfare, and the communities who ultimately serve as DU waste repositories.

This issue of *TOUCHING BASES* describes many of the slices of the DU pie. It is MTP's hope that when the DoD finally admits to the severity of the DU crisis, it will address each of these important areas, and provide full disclosure about others we may have missed.



In This Issue....

A Message From MTP's Director

As we come into Spring, there is a lot of activity in the MTP office, as well as in MTP campaigns. We are glad that we have the opportunity to work with all of you and look forward to continuing that relationship.

This issue of *Touching Bases* is long overdue. All of us are excited about the new look and all the good news that is being reported by all of you. This issue is dedicated to the problems associated with Depleted Uranium (DU). What we hope to do is to show the *full picture* of DU -- from cradle to grave -- and the many lives it has affected. We hope that after you read the information provided, you will get as angry as we are that, thanks to Uncle Sam, these weapons still are being produced, tested, used and disposed of in this country and in others. The Pentagon would prefer that we all just go away and leave this particular subject alone. But, the continued production, testing and use of these weapons has the potential to affect the health of many generations to come. We are going to bring together each piece of the DU pie, so that readers will have the total picture. We hope that you get mad enough to let your Congressional Representatives know what you think of DU munitions.

MTP also is gearing up for Board Elections once again. This is the time to get in your nominations for at-large elections. For members of MTP network campaigns, it is time to start thinking of what member in your network you want to have representing your concerns on the MTP Board. Nomination ballots will be mailed out soon to all network members.

This summer, MTP will hold its annual Board Meeting, which will be open to all MTP members and allies. At this meeting, the Executive Committee will be elected. This will also be the first meeting that new board members will be attending.

Finally, we are so proud of those of you out on the front lines in communities, workplaces and veterans organizations that have done so much for so many. Keep up the good work!

Cathy Lerner
Executive Director

What is Depleted Uranium?

The *Handbook of Chemistry and Physics* states, "Uranium is a silvery metal, which is pyrophoric [i.e., capable of igniting spontaneously] when finely divided. It has fourteen isotopes, all of which are radioactive." Naturally existing uranium refined from ore is made up largely of U-238, a relatively stable isotope of the element, from which the highly fissionable isotope U-235 is extracted for nuclear weapons and power uses. After the U-235 is partially extracted (reduced from approximately .7% to .2% of the natural uranium), the remainder is misleadingly called "depleted uranium." It still can be used for nuclear weapons and energy programs by being transformed into plutonium in a breeder reactor, and it is still radioactive and toxic. Recent studies indicate there is no threshold level of radiation below which an exposed person is safe from radiation damage, and though DU is less radioactive than U-235 or plutonium, it remains an extremely harmful substance with the chemically toxic properties of many heavy metals.

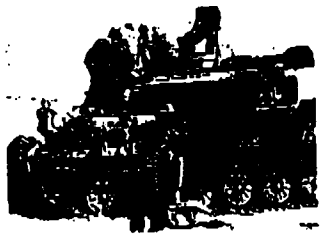
Because of uranium's extreme density, DU can be used to make munitions and armor of great density. The penetrators made with DU have great range and velocity -- velocity that gives them an ability to penetrate most kinds of armor (including otherwise virtually impenetrable DU armor, as Gulf War friendly fire casualties demonstrated).

DU burns on impact, spreading into the atmosphere and creating a small-scale fallout of aerosolized uranium particles which can be inhaled or ingested from the air or by contact with contaminated materials and sites. The particles can travel anywhere that dust goes.

Gulf War Vets Feel the Effects of DU

by Dan Fahey, Swords to Plowshares

Armor-piercing projectiles and tank armor made of DU proved highly effective in their first combat test during Operation Desert Storm. However, military commanders blatantly ignored the serious health and environmental impacts of shooting bullets made of radioactive waste. As a result, tens of thousands of soldiers and civilians were exposed to more than 600,000 pounds of DU contamination, which still remains on Gulf War battlefields. Though the proliferation of DU weapons since the Gulf War threatens to accelerate the spread of DU around the world, the impacts of DU weapons can be prevented if action is taken now.



FIRING TEST OF THE KOREAN [illegible] EXPOSED WITH PARTICLES

When a DU round strikes a target, up to 70% of the round burns, scattering radioactive and chemically toxic dust in and around the target. DU poses its greatest danger to human health when its dust is inhaled or ingested. An Army report on DU completed six months before Desert Storm noted that "aerosol DU exposures to soldiers on the battlefield could be significant with potential radiological and toxicological effects." The same report also stated that "short term effects of high doses can result in death, while long term effects of low doses have been implicated in cancer." Despite these warnings, military officials failed to inform soldiers about the use and dangers of DU weapons during Operation Desert Storm.

During and after the ground war, tens of thousands of soldiers climbed on and entered destroyed vehicles -- many of which were covered in uranium dust -- to look for hiding Iraqi soldiers, to remove any usable equipment, or just to examine the shattered tanks. It was not until a week after the cease-fire ending Desert Storm

COMMENTOR NO. 80: PORTSMOUTH-PIKETON RESIDENTS FOR ENVIRONMENTAL SAFETY AND SECURITY (CONT'D.)
MCDERMOTT, OHIO

that a message was sent to Army commanders warning that "any system struck by a DU penetrator can be assumed to be contaminated with DU." Yet, even after this message was sent, information about the presence and dangers of DU contamination was never passed on to soldiers in the field.

A 1993 General Accounting Office report, aptly titled *Army Not Adequately Prepared to Deal with Depleted Uranium Contamination*, revealed that even the soldiers of the 144th Supply Company of the National Guard, who were tasked with recovering DU vehicles contaminated by DU in friendly fire incidents, were never told of "the existence of DU contamination or radiation hazards," and that they worked on contaminated vehicles for several weeks "without any protective gear."

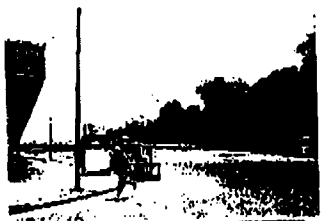
Mark Parsons, who served an active tour of duty for nine months with the 144th Supply Company, reported that more than twenty soldiers worked for five months at the King Khalid Military Camp in Saudi Arabia cleaning tanks contaminated with radioactive dust. For the first month and a half, the soldiers had no idea that they were dealing with radioactive dust.

In March 1991, the Pentagon sent civilians in the camp to take measurements of the radioactivity. Dressed in full protective gear with rubber gloves, respirators, dosimeters and Geiger counters, the civilians went about their work. After two weeks, they concluded that the soldiers had been exposed to hazardly radiation.

The soldiers got no relief, when their commanding officer ordered them back to work with no additional protective equipment.

When GAO investigators inquired about the widespread lack of awareness among US troops about the use and dangers of DU munitions, Army officials stated that "DU protective methods can be ignored during combat and other life-threatening situations because DU-related health risks are greatly outweighed by the risks of combat." The line of military logic was also used to justify exposing soldiers and civilians to poisonous herbicides such as Agent Orange and radiation from atomic testing and fallout.

In July 1991, a fire broke out at a US Army Base at Doha, Kuwait. Nearly $40 million in equipment and ammunition was destroyed, including 860 DU tank rounds and four fully loaded Abrams tanks. The 860 tank rounds destroyed represented more than 7,000 pounds of highly toxic, radioactive uranium that was spread around the Doha base and ejected into the atmosphere during more than 4 hours of explosions.



Explosion at the U.S. Army base at Doha, Kuwait on July 11, 1991. Photo courtesy of Michael Hines.

At the time of the fire, nearly 3,000 troops were at the base. After the fires burned themselves out, explosive safety personnel returned to identify and clear out unexploded ordnance, followed by other soldiers detailed to clean the area. Soldiers approached burned DU armored tanks, carried debris and shrapnel with their bare hands, inhaled the toxic DU dust -- and never knew it. Soldiers involved in the cleanup of the fire area were not provided any radiation protection equipment, and no contamination cleanup of areas was apparently done.

Several of the National Guardsmen exposed to DU in Saudi Arabia have developed serious health disorders since Desert Storm. Symptoms include headaches, cold sweats, hypertension, numbness in the extremities, diarrhea, insomnia, bronchitis and renal disorders. Some have had children with birth defects.

Because troops were exposed to many potentially hazardous substances in the Gulf War, it is difficult to determine how much of a role DU had to play in the cumulative health disorders of ailing soldiers. However, Dr. Asaf Durakovic, one of the military's top medical contamination experts, recently stated, "Every piece of evidence I have from my studies of amputees and autopsies has led me to the conclusion that DU is the cause."

MCDERMOTT, OHIO

Dr. Durakovic treated two dozen of the soldiers from the 144th Division who cleaned the DU-contaminated tanks in Saudi Arabia. He accuses the Department of Veterans Affairs of terminating his position with the VA, and harassing him "for pursuing the proper medical management of veterans exposed to depleted uranium." He also claims that medical records of the soldiers he had examined have mysteriously disappeared, an allegation the VA flatly denies.

Since the Gulf War, the Pentagon has downplayed the dangers of DU and the significance of DU exposures in the Gulf War because it does not want to draw negative attention to a prized weapon system. The Department of Veterans Affairs (VA) has accepted the Pentagon's assurances obediently, and denied testing and treatment to other veterans suffering from kidney problems and cancers which may be related to DU exposure. Both the Pentagon and VA have expressed, in writing, a desire to avoid the costs of medical care and disability payments for veterans who develop DU-related health problems.

Dan Fahey works closely with ailing Gulf War Veterans as the Legal Assistant for Swords to Plowshares, a San Francisco-based non-profit organization that helps war veterans meet their basic needs. He is also serving Veterans for Peace, Mr. Fahey also serves on MTP's Board of Directors. He recently released a report entitled The Silence is Deafening: A Report on Exposures of Persian Gulf War Veterans and Others to Depleted Uranium Munitions, *which is available from MTP headquarters. For more information about Gulf War Veterans' Illnesses, contact Swords to Plowshares at 995 Market Street, 3rd Floor, San Francisco, CA 94103. Phone: 415-247-8777.*

The Military Toxics Project organizes activities of the Depleted Uranium Citizens' Network. On November 12, 1994, in Jonesborough, Tennessee, the DU Citizens' Network adopted the following mission statement:

In response to the latest form of military radioactive pollution, the mission of the Depleted Uranium Citizen's Network is to provide outreach and unite people affected by the production, testing, and use of depleted uranium for military purposes; and to demand cleanup, health care, compensation and the end of depleted uranium munitions use worldwide to help ensure the survival of future generations.

For more information about DU weapons and efforts to help Gulf War veterans and civilians impacted by DU, contact:

Depleted Uranium Citizens' Network, Military Toxics Project, 411 Main Street, 2nd Floor, Lewiston, Maine 04240.

Going to the Source:
How Uranium Mining Destroys Indigenous Communities

By Philippa Winkler, Desert Concerns

Against the Rainbow Serpent, sleeper in the earth guarding those monumental powers that lie outside of mankind's control. Any attempt made to steal these underworld powers will disturb the serpent and bring destruction and death upon the Earth. -- An Indigenous People's Belief, Australia

When evaluating the need for different materials in modern-day life, it is imperative to go to the beginning of a product's life-cycle. For DU, the life-cycle begins with uranium mining, often on Indigenous lands.

Uranium is mined in many countries around the world, with Australia, Canada, Kazakhstan, Namibia, Niger, Russia, south Africa, the US, and Uzbekistan leading world production. US uranium mining began in earnest in New Mexico, right after World War II, when the US government realized the capabilities of the metal.

Uranium mining in the desert Southwest, has left open and permanent scars on the land, which many Indigenous communities hold sacred. Pollution from the mining has resulted in an epidemic of cancer cases.

Since the 1970s, tourism has exploded in the American Southwest. The rivers, washes and canyons, the sandstone and shale, the mesas and the spectacular red "cathedral" rocks are familiar to us from countless magazine photographs, advertisements, and films. But, no tourist brochure mentions the following scenarios:

> Since World War II, the Navajo Nation and developers of uranium mines have been engaged in a continuous power struggle. The Navajo Nation has called for an international ban on uranium mining, while the uranium industry has fought such resistance. A moratorium on uranium mining on Navajo lands has been in effect since 1983.
>
> Of more than 2000 Navajo uranium miners who worked in the Four Corners (Navajo) Area, Northwest New Mexico, Southeast Utah, and South-west Colorado) mines from 1947 to 1971, in all have died of lung cancer and other illnesses linked to radiation exposure. Yet, only fifty Navajo widows have been compensated under the 1990 Radiation Exposure Compensation Act.
>
> Cancer clusters have been found in Indigenous Navajo -- especially among children and the elderly -- living downwind and downstream of uranium mines.
>
> In one community, at Shiprock, New Mexico, the Special Olympics Games take place annually because of the high number of disabled children.
>
> Church Rock, New Mexico, part of the Checkerboard Area of the Eastern Navajo Agency, was the site of a 1979 radioactive waste spill, the largest in US history.
>
> Church Rock is one of the communities targeted by Hydro Resources, Inc., of Dallas, Texas, for involvement in the construction and operation of two uranium mines and related processing plants in the Checkerboard Area. This is the equivalent of recommissioning the nuclear power plant at Three Mile Island.
>
> From 1946 to 1968, more than 13 million tons of uranium ore were mined on the Navajo reservation to make atomic bombs. More than a thousand abandoned, yet highly radioactive, mines have not been cleaned up or reclaimed.
>
> Despite evidence that cancer is ravaging the Navajo communities, the US Government has routinely denied funding for a complete epidemiological study. According to Arizona Department of Health Physiologist Al Gossman, "the highest birth defect rate in the state -- equal to seven times the national average -- was in the Common-Gray Mountain area of the Navajo Reservation north of Flagstaff. The area is dominated by numerous open pit uranium mines."

In the mid-eighties, the Federal Government began efforts to remove Indigenous Peoples from their ancestral homes in the mineral-rich land of Northwest Arizona. The government intended to mine coal and uranium for further industrial and military uses.

In 1993, the World Uranium Hearings convened in Salzburg, Austria to call for worldwide protection of indigenous peoples and lands and the end to nuclear technology. Despite all these efforts, Navajo communities face continual threats. Yet the struggle of indigenous communities continues.

The Havasupai People, living at the bottom of the Grand Canyon in Colorado, are currently fighting uranium mine developments, while the Navajo are struggling against planned uranium mining operations in New Mexico.

COMMENTOR NO. 80: PORTSMOUTH-PIKETON RESIDENTS FOR ENVIRONMENTAL SAFETY AND SECURITY (CONT'D.) MCDERMOTT, OHIO

Philippa Winkler, works for Desert Concerns, a project of the World Survival Foundation. The group examines the health effects of uranium mines of the Southwestern US and uranium battlefields of the Middle East. Contact Desert Concerns at PO Box 1148, Clarkdale, Arizona, 86324. Phone 520-634-4327.

Activists Raising Funds For New Video on DU

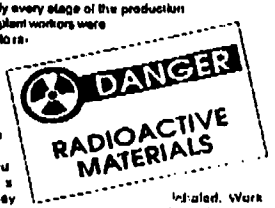
Three organizations, including Desert Concerns, World Survival Foundation, and Southwest Indigenous Uranium Forum, seek funding for a 30-minute documentary on the environmental and human health hazards of uranium mining and depleted uranium. The video will address the entire life-cycle of depleted uranium, and is provisionally titled, *Radioactive Mines -- Radioactive Bullets*. If you would like to contribute to this effort, or assist in fundraising for this important resource, please contact Daniel Robicheau or Philippa Winkler at Desert Concerns, PO Box 1145, Clarkdale, Arizona 86324. Phone: 520-634-4327.

DU Exposure in the Workplace

One of the manufacturers of DU is Aerojet, formerly TNS, Inc., located in Jonesborough, Tennessee. In 1991, employees walked out of their work place, in protest of hazardous working conditions.

The plant uses DU to produce armor-piercing projectiles, primarily for the US Air Force. Prior to the employee walk-out, the US Department of Energy had been sending a powdery substance known as *green salt* to the contractor in 55-gallon drums. The green salt was actually uranium tetrafluoride which was used to manufacture DU.

At virtually every stage of the production process, plant workers were exposed to radioactive substances, often in the form of contaminated dusts which they inhaled. Workers moved the drums from the warehouse to the plant foundry with a forklift. Often, the forklift pierced the drums, spilling green salt onto the plant floor. When the workers tried to clean up the mess with shovels and brooms, they dispersed it into the air. The weighing and blending stages further spread the hazardous substance around the plant, and onto employees. The exhaust system did little to vent the dust and fumes away from the workers who complained of having green salt in their ears, nostrils and mouths. Workers also described violent furnace blow-outs which expelled contaminated material into the workplace.



Many employees began to complain of discharging black mucus from their noses, having chronic nose bleeds, lower back pain and difficulty in urinating. TNS refused to acknowledge that DU was potentially responsible for the health problems, despite their own records indicating airborne contamination in the plant.

In 1980, more than 8% of the workforce sustained whole body doses of radiation ten times as great as the average exposure for workers in the nuclear industry nationwide.

After the workers' walkout, employee exposure to radiation declined significantly. The plant upgraded the blending and weighing equipment to remote-controlled devices, disposed of the old equipment in a landfill, and installed a new dust collector.

The Oil, Chemical & Atomic Workers International Union (OCAW) represented roughly 100 TNS employees in a 1994 legal suit in the United States Court of Appeals. Although the workers won their suit, the company challenged the ruling, and it was overturned. Since then, OCAW has appealed and is awaiting a final decision.

DU Weapons Threaten Local Communities

by Judy Scatchell

In 1994, the American public learned that the U.S. government had secretly exposed to radiation its own citizens including pregnant women, teenagers, sick people, atomic plant workers, military and civilian populations - all without their consent during a period from the 1940's to the early 1970's.

Now in the 1990's another involuntary human radiation experiment begun years ago during the Cold War era continues. It is the production, manufacture, development, testing and use of depleted uranium as a military weapon. In the Persian Gulf War the depleted uranium projectile, a weapon made from the nuclear fuel enrichment cycle, was used for the first time. Even though the uranium metal weapon is highly toxic, both chemically and radiologically, it is currently classified as a conventional weapon.

The Army Environmental Policy Institute (AEPI) "Health and Environmental Consequences of Depleted Uranium Use in the U.S. Army: Technical Report" of almost 200 pages does not really tell us much about the health and environmental consequences of DU use. There are no long-term health studies of DU production or manufacturing workers and their offspring. Nor are there health studies of residential populations that have been exposed to radiation from aerosol or ingested DU from DU production, manufacturing or testing. There are no health studies of Gulf War Veterans who were exposed to DU through inhalation or ingestion, and there are no studies of these veterans' children born after the Gulf War. How then can there be the following finding in the AEPI report Executive Summary:

> *"After an exhaustive review of weapons systems containing DU, AEPI concluded that the Army has done an excellent job attending to the environmental and health impact of these systems."*

The AEPI report reports specific action on the effects of DU on the environment consists of three paragraphs on pages 145 - 146. In these, only two sources are cited on the effects of DU on plant life. One, Hanson and Miera in 1978, (almost 30 years ago), concluded that in DU contaminated soil most injury occured in the roots of plants. In the other study at Eglin Air Force Base, Florida in 1980, 25 vegetation samples were collected and yucca roots were found to have "the highest apparent radiation concentrations." Is this a scientific basis for concluding what DU's impact is on plant life in the environment? In the report, there is very limited and superficial discussion of the effects of DU on animal life. An ongoing monitoring of plants and animals should be integral to assessing the effects of DU on the environment.

There are 50 different sites in the United States where DU has been produced, developed, manufactured tested and stored. A major shortcoming of the AEPI report is the lack of consideration given to the health and environmental consequences on the adults and children at the 50 sites.

In Concord, Massachusetts, near Nuclear Metals, Inc. (NMI), there are two middle schools and one elementary school. NMI has been a manufacturing site using uranium metals for 37 years. It is currently one of the two manufacturers in the U.S. of the DU penetrator.

Citizens' Research and Environmental Watch (CREW) has found DU contaminated soil as far away as nine-tenths of a mile from NMI. Among the contaminated areas on NMI's 40.4 acre site is an unlined pit that has 400,000 pounds of uranium wastes which are leaching and migrating.

The State of Massachusetts has designated the NMI property as a Superfund site.

A November 1984 internal memo from the Nuclear Regulatory Commission states, *"migration [of the uranium plume in the groundwater under NMI] might have already reached the site boundry, or at any rate will reach it soon at the projected rate of movement in [bedrock fissures]."*

NMI is but one example of contamination on and off site, caused by the U.S. Army's use of DU that is not revealed in the AEPI report. How many other examples similar to NMI can be found at the other 49 sites? And what about their nearby neighborhoods, schools, public lands and waterways?

And what of the health of all the people living near those sites? In August 1995, CREW researcher Bill Smith completed a statistical study of cancer in Concord. Using the Massachusetts Cancer Registry data available (1982-1990), Smith found that Concord had a higher incidence of six types of cancer relative to state averages. Concord had the second highest incidence of thyroid cancer in the state, nearly two and a half times the state average. The reason for this higher incidence of cancer is not known.

TOXIC SHOTS HEARD ROUND THE WORLD

Sunday, April 27, 1997
3:00 p.m.
First Parish Church
20 Lexington Road
Concord Center, MA

Radioactive Weapons and Waste in Concord

Panelists from Massachusetts, New York, Tennessee and Louisiana will discuss:

* The hazards of radioactive contamination from the manufacture of the depleted uranium penetrator at Nuclear Metals Inc. in Concord, MA and at other sites in the US.

* Clean-up of the toxic and radioactive wastes generated by DU.

* Gulf War veterans' exposure to DU contamination.

Co-sponsored by Grassroots Actions for Peace and the Social Action Council of First Parish Church. Supported in part by the Military Toxics Project Community Exchange Program.

Recent Concerns from Japan

The latest DU weapons incident to hit the news happened on an uninhabited island in Japan in late 1996 and early 1996. The US Marine Corps publicly stated that it accidentally fired 1,520 DU bullets on the island of Tori Shima near Okinawa. While the rounds had been labelled "armor-piercing," they were not specifically marked "depleted uranium."

While the Marine Corps apologized to Japan for firing the rounds and cleaned up 192 of the bullets, it downplayed the likihood that any health or environmental threat remained in the area.

Dan Boyd, a US Air Force spokesman in Japan told Reuter news service that the amount of radiation released on Tori Shima was "absolutely insignificant," and likened it to that of early television sets.

Yet, Japanese officials, citizens and local fishermen are skeptical. Last month, a staffer for a Japanese Parliament member contacted the MTP office asking for information on DU as they try to determine the extent of contamination [illegible]

While the incident on Tori Shima raises concerns about how US military use of DU threatens Japanese communities, it is important to keep the situation in perspective. During Operation Desert Storm, when DU bullets were first introduced, US forces fired 940,000 small-caliber and 4,000 large-caliber DU rounds in combat. Six years after the war, none of the more than 600,000 pounds of DU has been cleaned up, and no apologies have been issued to exposed Gulf War veterans or the populations of Kuwait and Iraq who live amidst this contamination. A classified United Kingdom Atomic Energy Authority report warned in 1991 that depleted uranium contamination on Gulf War battlefields could cause 500,000 deaths among soldiers and civilians.

COMMENTOR NO. 80: PORTSMOUTH-PIKETON RESIDENTS FOR ENVIRONMENTAL SAFETY AND SECURITY (CONT'D.) MCDERMOTT, OHIO

A Global Ban on DU The Only Solution

By Chris Larson, Patriots for Peace

The first international conference on DU was held at the United Nations (UN) in New York City on September 12, 1996. People from around the world crowded into the standing-room-only hall to learn about the complex DU issue and initiate a global ban on DU weapons through public education.

One conference participant raised the following question: "What would you do if you owned a portion of the US nuclear waste?" The answer, "Essentially, each of us does." Virtually all of us are taxpaying citizens on the grid (using electricity via nuclear power) and thereby own a portion of the waste created. As shareholders in the nuclear waste crisis, each of us has a responsibility to stop the use of waste uranium for further destruction, and to demand environmentally safe and renewable power supplies.

Conference keynote speaker and former US Attorney General Ramsey Clark stressed the need to create a worldwide ban against the use of DU, and many other speakers described their personal experiences with DU. Native Americans, war veterans, scientists and activists all agreed that DU has no place in modern society.

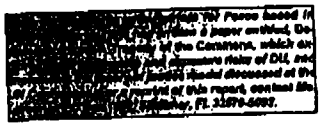
International efforts to curtail the DU problem were evident throughout the forum. Dr. Jay Gould, former Environmental Protection Agency Science Advisory Board member, announced a "tooth fairy" grant that he had received from the United Methodist Church to analyze New England children's baby teeth for proof of DU exposure. A London physician distributed DU fact sheets to the UN delegations. Kenk van der Kaur, a Dutch participant, presented information on LAKA, a data collection and research center in the Netherlands that gathers and shares information on nuclear energy issues internationally with interested parties. A film crew from Japan Broadcasting Corporation attended the conference and developed a 60 minute documentary on DU.

Conference participants pondered a Thomas Jefferson decree that citizens hold their government accountable for its actions, and considered a model for constructive, patriotic participation to address the DU problem. The model contains the following three levels of awareness: personal understanding and conviction; interpersonal cooperation, and omni-personal respect for the Commons, or the life-sustaining ecosystem we all share.

Many people at the conference characterized the mainstream media as a major obstacle to accurate information about the DU crisis, and agreed to develop alternative information sources for public education. Conference-goers stressed the importance of seeking alternative news and information sources, and encouraged others to join the Military Toxic Project's DU Citizen's Network, which works to ensure that prompt, accurate information about DU is disseminated by grassroots organizations. Participants gathered more than $1800 to begin a comprehensive DU book that will be written in lay terminology.

Nuclear physicist Dr. Michio Kaku, delivered perhaps the most inspiring statement of the conference when he proclaimed, "There is one power stronger than plutonium, the power of educated people."

MTP's DU Citizens' Network currently is developing a resolution for global action on DU. The Network seeks to strengthen an August 1996 UN resolution which urges all States to "curb production and spread of weapons of mass destruction or with indiscriminate effect, in particular nuclear weapons, chemical weapons, fuster bombs, napalm, cluster bombs, biological weaponry and weaponry containing depleted uranium." The stronger resolution would ban, not just curb, the production and spread of DU weapons.



Dan Fahey and Chris Larson at the September UN conference on DU

Metal of Dishonor: How the Pentagon Radiates Soldiers & Civilians With DU Weapons. Published by the International Action Center (IAC), with selections by Dr. Hosain Rahek, Dr. Helen Caldicott, Ramsey Clark, Dr. Leonard Dietz, Pat Brandy, Carol Picou, Dan Fahey, Dolores Lymburner, Dr. Michio Kaku, Manuel Pino, and Dr. Victor Sidel. Focuses on the environmental and health effects of depleted uranium. Book and companion video to be released in late April 1997. $12.95 plus $4.00 shipping and handling for the first copy. $1.00 for each additional copy. Available at discounted bulk rates for organizing, educational, or fundraising use by community organizations. The companion video - 45 minutes. $20.00 for individuals, $40.00 for institutions plus $4.00 shipping and handling for first copy. $1.00 for each additional copy. All mail orders must be pre-paid. Send check or money order to:

IAC, 39 West 14th Street, Room 206, New York, NY 10011. Phone: 212-633-6646. Fax: 212-633-2889.

Project CENSORED Honors MTP For DU Research

MTP's Depleted Uranium Citizen's Network report, "Radioactive Battlefields of the 1990s: A Response to the Army's Unreleased Report on Depleted Uranium Weaponry," took honors as the ninth most "censored" or "under-reported" story of 1996. Project Censored, based at Sonoma State University in California, identified twenty-five issues to be reviewed in the organization's annual yearbook. Of those issues, the top ten ranked stories will become the primary focus of public discussion on more than 125 radio and television talk shows during the spring and summer. MTP will receive a small cash award from Project Censored for its efforts in educate the public about the environmental and health threats of DU.

Creating Needs for DU

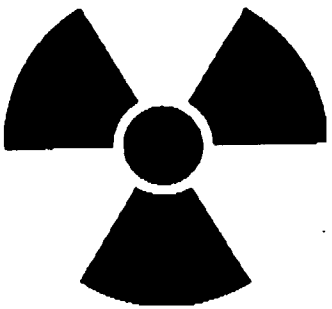
By Dolly Lymburner
National Organizer, MTP's DU Citizens' Network

Depleted uranium has been licensed for a new use by the Idaho National Engineering Laboratory (INEL) as containers for spent nuclear fuel.

The US Department of Energy currently has an estimated 555,000 metric tons of DU that it is trying to dispose of or use. The production of containers for spent nuclear fuel will use large quantities of DU. Originally, the plan was to convert DU into a metal, but this was considered very costly. A cheaper course evaluated by INEL was using a DU rock-like aggregate as an ingredient in concrete. This material is called "DUCRETETM". INEL has completed initial testing and Lockheed Martin Idaho Technologies Company is obtaining patents here in the U.S. and in other countries.

DUCRETETM will replace the concrete and steel casks currently being developed. According to INEL, DU, because of its density, will better shield radiation from spent fuel. They also state that these new casks will be thinner and lighter in weight, making handling and transportation at the storage sites easier.

Teton Technologies, Inc. has formed a partnership with Nuclear Metals, Inc (NMI) to further develop the process and marketing strategy. Initial production will be at NMI's facilities in Barnwell, South Carolina with production starting this year.



ONCE AROUND THE BASES

Wisconsin Community Rejects Army Base Conversion Plan

By Laura Olah, Citizens for Safe Water Around Badger

Environmentalists, local government officials, and regulatory agencies alike rejected a recent Army base conversion proposal in Wisconsin.

At issue is the Badger Army Ammunition Plant (BAAP), a defunct 7,400-acre facility which has been on stand-by since 1975. BAAP has become the focus of a county-wide battle to preserve the area's rural quality of life, its endangered natural resources, and its local economic health.

Opposition to the reindustrialization plan, spearheaded by Citizens for Safe Water Around Badger (CSWAB), arose in response to a September 18, 1996 announcement by Olin Corporation and the US Army to initiate an aggressive marketing scheme which would bring the pulp and paper industry; varnish, paint and lacquer manufacturers; ethanol and cosmetics industries; and nitrogenous fertilizer plants to BAAP by 1997.

BAAP identified the target industries in a Strategic Planning Process which excluded nearby communities, local town, village and county boards, planning and zoning authorities, and other stakeholders. Through a nine-month planning process -- costing 275,000 taxpayer dollars -- BAAP hosted no public meetings.

The reindustrialization proposal is the result of the 1992 Armament Retooling and Support Act (ARMS). The ARMS initiative encourages private firms to use Army ammunition facilities (specifically government-owned, contractor-operated facilities) for commercial purposes. The US Government authorized ARMS to create jobs at facilities like Virginia's Radford Army Ammunition Plant, where a recent lay-off resulted in the loss of thousands of positions. Opponents of the BAAP conversion proposal noted that, by contrast, BAAP had not had a significant job loss since the mid-1970s, and today employs only about 100 people.

Under the ARMS program, the Department of Defense makes contracts available to private industry for one or more years. Companies receive *Facilities Use Contracts* to develop and implement a reuse plan and, in return, receive part of the rent from new industries brought on-site. At BAAP, the operating contractor is Olin Corporation.

One of the objectives of the ARMS program is to perpetuate Badger and other Army ammunition plants as military facilities, avoiding closure and allowing deferral of cleanup efforts. This tactic contradicts a February 20, 1997 report from the Government Accounting Office which concludes that BAAP and three other military plants could be eliminated because alternative sources exist to provide the capabilities that these plants provide.

In the Community around Badger, there is a strong sentiment that the ARMS program is neither applicable nor appropriate for the BAAP facility and Sauk County. A flat labor market, housing shortages, overflowing schools, and other stressed infrastructure are all signs that additional development in the area is not warranted. Community members maintain that other possible uses for the site have not yet been evaluated. The other options may, in fact, provide much greater benefits to the Community than rendustrialization.

One of the assets cited by the Strategic Plan is open, currently undeveloped land. Local residents are very concerned that reindustrialization may promote uncontrolled development of agricultural lands within the plant for new industry. Contrary to statements in the Strategic Plan, there is a paucity of available farmland in Sauk County, which is reflected by local farmland preservation ordinances. Moreover, the value of farmland and small farms is highly prized in the area.

BAAP itself lies primarily on the terrain of the former Sauk Prairie, a bioregion which hosts remnants of many diverse ecosystems including prairie, oak savanna, dry forest, southern hardwood swamp and sandy meadow.

MCDERMOTT, OHIO

ONCE AROUND THE BASES

The base is also home to a wide variety of animal species including some that have been classified as rare, endangered and threatened. BAAP is surrounded by the Baraboo Range -- a National Natural Landmark. Composed of quartzite, the hardest rock on Earth, it covers 144,000 acres in parts of Sauk and Columbia counties. The 25-mile Range extends from Rock Springs in the West to just west of the interstate highway in adjoining Columbia County in the East. It stands as high as 799 feet above the Wisconsin River and is one of the largest and most ancient rock outcrops in North America.

The Range includes 55,300 acres of forest -- the largest tract of southern upland forest remaining in an ecoregion which covers 40,000,000 acres in parts of five states (central Minnesota through southern Wisconsin, northeastern Iowa, northern Illinois, and northwestern Indiana.) Although the Range covers less than 0.5% of this area, it supports 68% of all breeding bird species, 44% of all mammal species, and 37% of all reptile species found in the ecoregion. This ecoregion is home to more than 16,000 species of plants and animals, including 138 species of breeding birds alone. Seventy-seven of these plant and animal species are rare or imperiled in Wisconsin, and 25 are on the State or Federal lists of threatened or endangered species.

Reindustrialization of the region has met broad opposition at local, state, national and federal levels.

The Town of Merrimac, the Village of Merrimac, the Town of Sumpter, the Town of Honey Creek, the Town of Spring Green, and Sauk County all have passed resolutions opposing the proposed conversion plan. Local business organizations, including the Baraboo Economic Development Council, have drafted resolutions opposing BAAP's proposal citing unfair competition from new industries coming into the plant which would be exempt from real estate and property taxes. The Spirit Prairie School District Administration also has written to the Army objecting to the negative financial impact on the district.

At least sixteen environmental groups, including the Rural Alliance for Military Accountability, the Sierra Club, the Madison Audubon Society, the Aldo Leopold Chapter of the Society for Conservation Biology, the Baraboo Range Preservation Association, and several chapters of Physicians for Social Responsibility have co-signed a letter opposing the proposed reindustrialization.

The Wisconsin Department of Natural resources, the US Department of Interior, and the US Environmental Protection Agency all have written letters forewarning potentially negative primary and secondary impacts on the adjacent Baraboo Range ecosystem. The Ferry Bluff Eagle Council, a non-profit organization whose mission is to protect wintering American Bald Eagles, has documented serious concerns about the potential harm to this endangered species and its habitat.

In response to the proposed reindustrialization of BAAP, CSWAB hosted a series of four public meetings to encourage and solicit community input and consensus. Public meetings averaged 60 participants. CSWAB has collected more than 600 signatures from local residents opposing reindustrialization.

CSWAB has called for the closure of BAAP, citing that maintenance of the plant -- although out of operation since the 1970s -- costs taxpayers millions of dollars each year. In 1991 alone, maintenance costs exceeded $17 million. Built in 1942 in response to World War II, the BAAP production facilities are obsolete and would require more than $119 million in upgrades to meet current state and federal environmental standards. Environmental damage continues to plague the facility -- since 1975, there have been more than 56 chemical spills and incidents.

Environmental cleanup of the Badger plant, operating intermittently since 1942, is expected to exceed $250 million. Of the 40 contaminated military sites in Wisconsin, the Defense Environmental Restoration Agency has cited BAAP as the most contaminated -- 32 areas within the plant are polluted with high levels of solvents, toxic metals and explosive wastes. Groundwater beneath the plant is saturated with cancer-causing chemicals, including carbon tetrachloride, trichloroethylene and dinitrotoluenes. An area know as the Propellant Burning Grounds is the source of a three-mile long plume of contaminated groundwater that has migrated several miles offsite, polluting private drinking water wells in its path and dumping into the Wisconsin River.

CSWAB was organized in 1990 when the community learned that private drinking water wells near BAAP were polluted with high levels of cancer-causing chemicals. The founders believed that community involvement could have prevented this tragedy and consequently organized CSWAB both to empower and to protect nearby residents and plant workers from further harm. For more information, contact CSWAB at 212629 Weigand's Bay South, Merrimac, Wisconsin. Phone: (608) 643-3124; Fax: (608) 643-0005, Alternate Fax: (608) 643-2662; Email: olah@speagle.com.

PHILIPPINES

Toxic Threat at Former US Bases in the Philippines Lingers On

By Myrla Baldonado

Almost five years have passed since the US Military agreed to terminate operations at Subic and Clark Bases in the Philippines. Despite findings of a 1992 report from the US General Accounting Office which stated that "the costs for environmental cleanup and restoration could approach Superfund proportions," there has been no comprehensive investigation nor cleanup.

To date, the US Government's only act regarding the bases is the release of incomplete Drawdown Reports which were supposed to have been turned over to the Philippines Government prior to the pullout.

During President Clinton's official visit to the Philippines in 1994, base clean-up advocates managed to put the issue on the discussion agenda, despite the reluctance of both governments to touch the issue.

At a joint press conference of Presidents Ramos and Clinton at Malacanang, President Clinton was asked about the toxic contamination at the former Clark Air Base and Subic Naval Station, his Government's offer of financial and technical assistance, and his willingness to accept the moral and financial responsibility for any necessary cleanup.

President Clinton responded by stating that the U.S. was "continuing to work with the Philippine government on this and will continue to do so." He added, "it is very important not to let the general policy pronouncements or the rhetoric outrun the facts we have on the case, so we decided we should focus on finding the facts now, and when we find them, deal then with the facts as they are."

A few months later, the Philippine Health Department asked for a consultation from the US Center for Disease Control (CDC) to help test the drinking water of wells in an area inside Clark that used to be a motor pool. The official response was that the agency adhered to a US State Department policy of "no responsibility," and that they would send a technical person if the Philippine Government could pay for his transportation and per diem.

During the November APEC Summit in Manila, delegates of the 1996 International Forum on US Military Toxics and Bases Clean-up lobbied for the inclusion of the toxics problem in the bilateral talks between the two governments. As a result, former Secretary of State Warren Christopher and Philippine Foreign Affairs Secretary Domingo Siazon discussed the matter. Secretary Christopher assured US willingness to help with the clean-up, but a quick follow-up by supporters in Washington, DC revealed that the State Department would not confirm what Mr. Christopher said, nor admit knowing anything about it.

The current policy of the US Department of Defense (DoD) requires host countries to demonstrate "imminent and substantial danger" at former overseas bases used by the US Military before it provides further assistance. The People's Task Force for Bases Clean-up, with headquarters in Manila, is targeting DoD's reckless scheme, hoping to shift the burden of proof back to the entity that created the mess in the first place.

The requirement to technically demonstrate imminent and substantial threat is beyond the capacity of the Philippines and many other Third World countries. Thus, the US must responsibly assist its former host countries with the task of meeting this requirement.

Myrla Baldonado is the coordinator of the People's Task Force for Bases Clean-up in Manila. For more information about the ongoing campaign to fight US military pollution in the Philippines, contact the group at: Room 511, J & T Building, 3884 R. Magsaysay Boulevard, Sta. Mesa, Manila, PHILIPPINES. Phone/Fax: 632-716-1084. Email: mbaldonado@ibc.apc.org. The US Working Group for Philippine Bases Cleanup is assisting the Task Force, and can be reached at: PO box 5644, Hercules, CA 94547. Phone/Fax: 510-799-2551.

ONCE AROUND THE BASES

Chemical Weapons

Activists Call For Permanent Shutdown of Tooele Incinerator

The Kentucky based Chemical Weapons Working Group (CWWG), the Sierra Club and the Vietnam Veterans of America Foundation have joined forces and filed suit in federal Court to permanently close the chemical weapons incinerator in Tooele County, Utah.

The US Army owns the Tooele facility, while the defense contractor EG&G Defense Materials, Inc. operates it.

The controversial incinerator has suspended operations six times since it opened in August 1996. The latest shutdown occurred in late January, when lethal nerve agents leaked inside the plant to areas often occupied by unprotected workers and visitors.

According to an Army "Unusual Occurrence Report," air pressure adjustments being made to stabilize flame strength in the liquid agent incinerator resulted in agent leaking into two observation corridors. Personnel donned gas masks and evacuated the building. Utah state officials asked the Army to close the facility until they determined the cause of the problem and corrected it.

"Yet another dangerous incident illustrates this plant's defective design, poor operating procedures, and lack of safety culture," said Craig Williams, national spokesman for the CWWG. "Instead of suggesting that the plant should be closed for a couple of days, the State should protect the workers and local residents by suspending the Army's permit until a safe approach can be implemented."

Craig Williams, Sergeant Turnbo, Peter Hille of the Chemical Weapons Working Group

Since a leak-burn in July 1996, two former employees of the Tooele incinerator have come forward with evidence of numerous major safety and environmental problems at the plant. The new evidence supports charges made by Steve Jones, the plant's former chief Safety Officer who EG&G fired in 1994 for refusing to approve the plant's level of safety and environmental compliance.

Former General Plant Manager Gary Miller, also fired for raising concerns about incineration operations, likens the safety mind-set at the Tooele facility to that which preceded the Three Mile Island and Chernobyl disasters.

On January 8, 1997 former plant employee John R. Hall made similar accusations and filed a wrongful termination suit against EG&G with the Department of Labor. Mr. Hall claims retaliation and eventual termination due to raising concerns about the incinerator's safety and environmental compliance.

An estimated 180 million Americans live downwind of proposed chemical weapons incinerators, and face the risk of agent contamination.

The Pentagon admits that small amounts of the kinds of nerve agent that may have contributed to Gulf War illnesses are emitted in smokestack exhaust at the Tooele incinerator, yet it claims that the amounts are so low that citizens downwind should not be concerned.

Gulf War illnesses researcher, Howard Urnovitz, Ph.D., a leading researcher on immune system damage caused by low-level chemical agent exposure said, "Study after study indicates that there is a link between low-level exposure to chemical agents and chronic health problems. There is no proven acceptable level of exposure to these chemicals."

Due to public opposition to incineration, cost overruns, and technical problems at facilities in the Pacific and Utah, the Army announced its recommendation to abandon incineration in Maryland and Indiana to pursue non-incineration technologies. Through the 1997 Defense Appropriations Act, the US Congress has funded and mandated demonstration of safer, non-incineration technologies for assembled munitions, such as those stored in Utah.

"The CWWG advocates the use of alternative technologies," said Mr. Williams. "The Army has demonstrated effective use of such technologies in Maryland and Indiana, so there is no excuse not to do the same in Utah and at all chemicals weapons storage sites."

COMMENTOR NO. 80: PORTSMOUTH-PIKETON RESIDENTS FOR ENVIRONMENTAL SAFETY AND SECURITY (CONT'D.) MCDERMOTT, OHIO

As this issue of *Touching Bases* goes to press, the Toodle chemical weapons incinerator is back up and running, and the Oregon Environmental Quality Commission has issued a permit to begin construction of a similar facility in that state. The CWWG remains committed to shutting down all chemical weapons incinerators, and preventing the permitting of all new chemical weapons incineration facilities.

Georgia Legislators Stall Construction of Alabama Incinerator

In February, the Georgia House of Representatives passed a unanimous resolution calling for a federal hearing on Pentagon plans to build a chemical weapons incinerator in Anniston, Alabama. The proposed facility would be located less than two miles from a school in the community.

The resolution, H.R. 174, includes the following language, which other communities may wish to use when fighting permitting of chemical weapons incinerators:

> Urging the Georgia congressional delegation to urge Congress to request the Environmental Protection Agency to hold public hearings in northwest Georgia; and for other purposes.
>
> Whereas, the Alabama Department of Environmental Management, the United States Army, and Westinghouse plan to construct a chemical weapons incinerator in Anniston, Alabama; and
>
> Whereas, the operation of such a facility has the potential to affect the air quality, health, quality of life, and economy of the residents of northwest and west central Georgia; and
>
> Whereas, other states, including Maryland, Indiana, and Kentucky, have passed legislation precluding the construction of such a facility within their boundaries; and
>
> Whereas, nonincineration and chemical neutralization methods are being studied by the United States Army which may prove to be safer alternatives for the destruction of chemical weapons; and
>
> Whereas, Georgia residents have expressed concern about the construction of such a facility because of toxins that might be released into the air and harmful genetic repercussions:
>
> NOW, THEREFORE, BE IT RESOLVED BY THE GENERAL ASSEMBLY OF GEORGIA that the members of this body urge the Georgia congressional delegation to encourage Congress to take steps to initiate public hearings conducted by the Environmental Protection Agency in northwest Georgia prior to the construction and operation of the chemical weapons incinerator in Anniston, Alabama

> BE IT FURTHER RESOLVED that the Clerk of the House of Representatives is authorized and directed to issue one appropriate copy of this resolution to the members of the Georgia congressional delegation.

For more information about the incineration of U.S. chemical weapons, contact: Chemical Weapons Working Group, PO Box 467, Berea, Kentucky 40403. Phone: 606-986-7565. Fax: 606-986-2695.

MTP To Sue EPA Over Munitions Rule

On February 11, the US Environmental Protection Agency (EPA) released its final rule clarifying when conventional and chemical military munitions become a hazardous waste under the Resource Conservation and Recovery Act (RCRA). After reviewing the Rule, the Military Toxics Project (MTP) decided to sue EPA.

Attorney Rena Steinzor, with the University of Maryland Environmental Law Clinic in Baltimore, Maryland, is representing MTP.

Members of MTP's Conventional Munitions Network who reviewed the Rule were outraged by EPA's failure to promulgate legislation that "shall assure protection of human health and the environment," as the directive from Congress clearly states.

"The EPA has proposed that the DoD regulate itself," stated Laura Olah, MTP member and Director of Citizens for Safe Water Around Badger, in Wisconsin. "The EPA has failed to meet its obligation as defined by law, and has let down both communities and Congress by proposing self-regulation."

On December 3, 1996, the Conventional Munitions Network adopted a position on EPA's proposed rule. EPA failed to address most of the concerns that the Network raised more than two years ago.

While States and Tribal Governments will retain their right to adopt and enforce more stringent requirements than those adopted nationally, EPA's final rule:

allows the DoD to determine whether to do anything about the environmental damage caused by munitions scattered over hundreds of thousands of acres of active military ranges;

postpones action on unexploded ordnance and explosive wastes on closed and transferred ranges in part because the DoD has not yet issued its range rule currently under development; and

flagrantly disregards the environmental and cultural impact of military munitions activities on indigenous lands, communities of color, and poor rural communities.

In December, 1995, MTP testified before the National Environmental Justice Advisory Committee (NEJAC) on how the proposed rule did not follow the Presidential Executive Order on Environmental Justice in Minority Populations and Low-Income Populations.

"The review of problems associated with military facilities suggests that military munitions activities heavily impact many communities of color, other poor, rural communities, and particularly the lands of Native Americans, Native Alaskans, and Native Hawaiians," stated Al Larson, Sr. who represents the Indigenous Environmental Network (IEN) from Chickaloon Village, Alaska. "EPA Administrator Carol Browner signed the final document that fails to protect the health and way of life of my people."

In February, 1994, MTP filed a *Notice of Intent to File Suit of EPA Failure to Act*, and subsequently sued the EPA because it was in violation of the Federal Facilities Compliance Act, which amended the Solid Waste Disposal Act, in which Congress required that the EPA Administrator propose the Munitions Rule by April 1993. MTP brought legal action against the Administrator of the EPA for failure to perform a non-discretionary duty imposed by Congress. MTP filed a consent decree in the US Court of Appeals for the District of Columbia.

MTP has decided to do a special reprint of citizen testimonies submitted to EPA more than a year ago regarding the EPA's ruling on when conventional and chemical weapons become hazardous waste. In light of the recent ruling which allowed the Department of Defense to regulate itself, it is clear that EPA ignored the valid concerns of these and many other citizens. The testimonies reprinted below were originally submitted to the Environmental Protection Agency's Resource Conservation and Recovery Act (RCRA) Docket #F-94-MMP-FFFFF.

From Mary Grisco, Chair, Military Accountability Committee, Sierra Club, Alaska Chapter -- January 8, 1996

...We of the Alaska Chapter of the Sierra Club, 1300 Alaskans, add our voice of strong concern about the proposed rule on military munitions. We know that if adopted in its current form particularly with the options that allow increased self-regulation by the Department of Defense, our public health will be endangered and our environment more damaged...

...Ft. Richardson, within the Anchorage municipal area, has been "training" at Eagle River Flats for years -- exploding munitions that were killing migratory waterfowl and lowering water quality as recreational hunter safety. We spent many years forcing the US Fish and Wildlife Service to force the Army to comply with environmental standards. Only recently did the Army finally announce that it is working to protect our water and wildlife. Ft. Greely, outside of Fairbanks contains many unexploded ordnance as well as storage vaults of unmanned weapons. Neighbors complain of headaches and nausea and wildlife (their subsistence) testing "funny." Ft. Greely continues training while issuing statements that public health is not being threatened.

These two small examples of the way the Department of Defense conducts business throughout our state lead us to support the critique of the proposed rule adopted by the Military Toxics Project's Conventional Munitions Network. In the Federal Facilities Compliance Act, Congress clearly legislated that the military cannot be allowed to regulate itself. External oversight, including the constitutional right of states to set more stringent standards than those established nationally, are basic for protecting our health and environment. The growing partnership of regulatory agencies and public stakeholders that is emerging in the cleanup of federal facilities requires that the military not be allowed to continue its cold war "announce and defend" mentality. We are the owners of these facilities and expect a level playing field for decision making.

From Bruce K. Gagnon, State Coordinator, Florida Coalition for Peace & Justice -- December 14, 1996

...We write to express our deep concern and outrage that the EPA is even considering allowing the Pentagon to regulate themselves in your proposed rule on military munitions.

We have several munitions impact ranges and disposal sites in our state and know that the military has a poor record of maintaining the health and safety standards at these locations.

In Florida, where our water table is so vulnerable, we are sure that allowing the military to "do as they please" will endanger our drinking water quality as toxic wastes from munitions leaks into the aquafer.

The Pentagon should not be allowed to regulate itself under any circumstance. If the EPA won't stand up to protect the American people then who will?

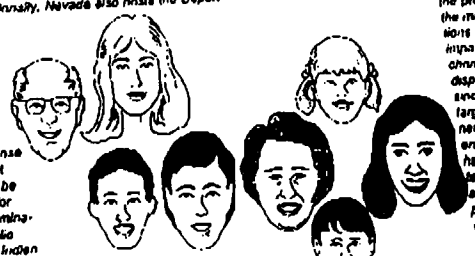
External oversight, from the EPA and the states must be strengthened, not eliminated.

COMMENTOR NO. 80: PORTSMOUTH-PIKETON RESIDENTS FOR ENVIRONMENTAL SAFETY AND SECURITY (CONT'D.) MCDERMOTT, OHIO

Please make it known that our organization demands that the final rule preserves the intent of Congress to fully protect our communities. EPA should not back down to the Pentagon for one moment...

From Grace Bukowski, Military Land and Airspace Program Director, Rural Alliance for Military Accountability (RAMA), Reno, Nevada -- January 12, 1996

Today, Nevada hosts 20% of our nations military lands (over 4 million acres) including the largest military installation in the western hemisphere, Nellis Air Force Base. The Hawthorne Army Weapons Depot is the site of our nation's largest munitions stockpile nationally. Nevada also hosts the Department of Energy Nevada Test Site, and Fallon Naval Air Station...



...The Defense Department should not be rewarded for their contamination of public lands and Indian lands. Nevada has experienced first hand the hazards associated with off-range bomb contamination of public and Indian lands. Currently, 25,000 acres of public lands surrounding bombing ranges at Naval Air Station Fallon are closed to the public. Five thousand six hundred acres of the Walker River Paiute Reservation are contaminated with live munitions. Instead of cleaning up the land, the Navy is trying to take it over and the proposed rule would allow it. We note that Naval officials knew of this contamination for over a decade and failed to notify the State of Nevada or the Walker River Paiute Tribe.

The Defense Department view that withdrawal is the only solution to their careless contamination of public lands, is a bygone concept. We consider rewarding mismanagement a very serious policy issue. The off-range ordnance problem is wholly the Defense Department's doing and the magnitude of the problem points to a record of decades of [illegible] of public lands. To [illegible] withdrawal of these lands from the public domain as the only solution to contamination exacerbates the known problem. The proposed rule would permit, with EPA blessing, the deliberate contamination of public lands. How will the Defense Department acquire lands in the future? The answer is simple: largely bereft the perspective lands they request a withdrawal for public health and safety protection...

From Suzanne Marshall, Chair, SAFE (Serving Alabama's Future Environment) -- January 2, 1996

I am writing as Chair of SAFE -- Serving Alabama's Future Environment, an organization of citizens in Alabama who work to end toxic pollution, especially the military toxics generated by Fort McClellan and the Anniston Army Depot. We are very concerned about the proposed rule on the military munitions and how it will impact the US chemical weapons disposal program since we are a site targeted for a nerve gas incinerator. We also have weapons testing ranges and non-stockpile chemical weapons at Fort McClellan, which was recently added to the base closure list. Our comment is:

States, such as Alabama, that have chemical weapons stockpiles must keep their right to make and enforce laws regarding chemical weapons disposal that are stricter than federal laws. The incineration of chemical weapons is not acceptable to people in Alabama because it is an unsafe, unproven, out-dated, dioxin-producing technology. The proposed rule could stop our state from passing the stringent, necessary laws to regulate the disposal of chemical weapons and protect the health and safety of our communities...

...We advocate the research and development of closed-loop treatment and disposal technologies for chemical weapons and other munitions. The DOD has agreed to look into some of the alternatives [illegible] The EPA rule should reflect the need for the development of innovative, [illegible] disposal technologies.

COMMENTOR NO. 80: PORTSMOUTH-PIKETON RESIDENTS FOR ENVIRONMENTAL SAFETY AND SECURITY (CONT'D.) MCDERMOTT, OHIO

We support cooperation among the DOD, the EPA, and the public in creating good solutions to military munitions disposal problems. We know that the best solutions come when all affected groups -- especially citizens near disposal sites -- take part in making decisions.

We wholeheartedly support the critique of the proposed rule adopted by the Military Toxics Project's Conventional Munitions Network of December 3, 1995. In the Federal Facilities Compliance Act, congress decided that the military should not be permitted to regulated itself -verynnvious,fair,and logical decision. We believe that external oversight, mandatory citizen participation, and state ability to pass tougher laws than those passed nationally, are crucially important if we are truly going to protect the health of people and the environment.

We hope that the final rule will coincide with the intent of Congress -- that the Army should not regulate itself -- and that we can all work together to clean up our world...

EIS Comments on Technology Development Needs for Depleted Uranium Metal Applications

Prepared by
W. J. Quapp
April 29, 1998

1. Introduction

These comments are prepared to identify the required research in depleted uranium production that must be funded by the DOE to reduce the production cost. Without such cost reduction, some applications, while technically feasible, will never be economic compared to alternative metal options such as steel, lead, and copper. As will be discussed later, the performance advantage of depleted uranium metal must be very high to overcome the high product cost of metallic uranium components. This paper identifies some opportunities and offers suggestions for reducing the economic penalty of using metallic depleted uranium.

81-1

2. Background

Depleted uranium metal is a unique material. It is slightly radioactive and, thus, possession and use are regulated for all but the smallest quantities. Depleted uranium and its alloys have the undesirable attribute of being easily oxidized at room temperature and machine turnings are pyrophoric. The property of depleted uranium which makes it use most desirable is its high density – 18.95 g/cm^3. The high-density characteristic can be used in selected applications such as radiation shielding and counterweights to provide superior product performance. But the radioactive baggage factor require management as a radioactive material.

In shielding applications, depleted uranium provides an efficient gamma shielding material and can allow designers to create smaller and frequently lighter shielded casks. This is particularly important in transportation casks where shipment weight or size restrictions cannot be met with alternative materials such as steel and lead. In counterweight applications, the high density allows for the manufacture of heavy components occupying a small volume. Depleted uranium aircraft counterweights have been used on military and commercial wide body jets for over thirty years but recently the industry has been shifting to tungsten because of the radioactive stigma of depleted uranium and the counterweight maintenance requirements.

The primary direct performance competitor to depleted uranium for both shielding and aircraft counter-weight applications is tungsten with a density of 19.3 g/cm^3. The main advantage of tungsten is its non-radioactive attribute. Its disadvantage is both cost and fabrication difficulties. However, there are also several other metallic alternatives to depleted uranium in applications where space is not a critical premium – industrial equipment such as forklifts and excavators. Most commonly, these alternatives are steel, lead, and, occasionally, copper with densities of 7.87, 11.35, 8.96 gm/cm^3, respectively. Heavy concrete with steel chips is used in excavator counterweights.

STARMET

3. Metallic Uranium Applications

2.1 Radiation Shielding Applications

Depleted uranium is an excellent gamma shield having 2.4 times the density of steel and 1.7 times the density of lead. Depleted uranium offers a significant advantage over lead in transportation casks during the postulated fire accident scenario due to its much higher melting point – 1135°C compared to 327°C. Depleted uranium offers advantages over steel in radiation attenuation in proportion to its density efficiency for spent fuel shielding applications. For some specific isotopes (specific photon energies), uranium is much more efficient than the density ratio alone would imply. However, depleted uranium alloys have never been established as an ASME code material so that no structural credit for depleted uranium is given by the NRC in cask applications regulated under 10CFR Part71. Consequently, the surrounding steel, which is also required to preclude oxygen from reaching the depleted uranium, must provide the structural requirements even though some depleted uranium alloys have very high strength and toughness.

81-2

Given that selected depleted uranium alloys have been used by the US Army for penetrators and tank armor, it appears that that there is ample precedent for using depleted uranium metal in high technology and demanding applications where corrosion protection can be assured.

3.2 Counterweight Applications

As stated previously, aircraft counterweights have been in use in wide-body aircraft for about 30 years. These counterweights are generally very small and are used to adjust the center of gravity and to balance loads on various aircraft components. Modern aircraft design techniques have reduced the need for counterweights. In addition, some aircraft owners are switching to tungsten to avoid issues associated with radioactive materiel. For example, Japan prohibits any aircraft using depleted uranium counterweights. Consequently, this market is relatively stagnant and little future use is projected.

81-3

Other potential counterweight applications include equipment such as fork lifts which require massive (several ton) counter weights to balance lifting loads. This market does not currently exist but if economic issues could be overcome (as well as regulatory and public acceptance issues), a large market might develop. One promoter of this application has sugested major warehouse cost savings and forklift safety improvements associated with forklifts using depleted uranium counterweights. The claimed cost savings come from more compact warehouses. The safety benefits come from a lower center of gravity. If all forklift production was converted to using depleted uranium counterweights, the entire inventory of depleted uranium could be consumed in a few years.

However, regulatory and public acceptance issues aside, the major barrier to commercial depleted uranium counterweight use is the cost of production. This is addressed in the next section.

STARMET

4. Depleted Uranium Metal Production Costs

3.1 Current Production Costs

The method used commercially for uranium metal production is the Ames process. In this process, UF_6 is reacted with hydrogen to produce UF_4 or "greensalt" and HF. In a separate step, the greensalt is mixed with magnesium metal chips and is ignited in a graphite lined retort (a high temperature chemical reactor) at about 800°C. The magnesium reduces the UF_4 to uranium metal and forms MgF_2. This solid phase reaction liberates tremendous heat and the entire mass of uranium and MgF_2 become molten. Due to density differences, the U metal liquid phase separates by gravity from the MgF_2 salt to form a "derby" which takes the shape of the crucible. After this material is cooled, the uranium metal derby is manually separated from the MgF_2 salt. The MgF_2 salt is disposed as a radioactive waste as it typically contains 1% to 2% uranium by weight. The metal is then cleaned and alloyed, as required, in a vacuum casting furnace. The metal is then shaped via extrusion, rolling or casting into its product form.

The Starmet CMI facility in Barnwell, SC, is the only remaining commercial US producer that manufactures uranium metal from UF_6. Some DOE conversion capability exists at the Y-12 and Los Alamos weapons facilities. Starmet CMI uses the Ames process. This facility has converted UF_4 to metal since 1983 for use by the US Army (as well as the British and French) for depleted uranium penetrators. The UF_6 to UF_4 capability was added in about 1987. These are the same processes that were employed at the DOE Fernald site prior to its shutdown.

81-4

Uranium derbies are shipped from Starmet CMI in South Carolina to the Starmet facility in Concord, MA, for alloying, casting and forming into products. After alloying, the uranium is cast into either ingots or slabs. Ingots to be used for penetrators are extruded into rods for subsequent machining operations. Starmet also casts slabs that are sent to the DOE INEEL facility in Idaho for use in fabricating armor for the Abrahms tank. These uranium slabs are fabricated at the Concord facility in vacuum melters from scrap uranium being recycled from prior operations at the INEEL facility.

The biggest non-regulatory impediment to the use of depleted uranium metal in commercial applications is the high cost of converting from UF_6 to uranium metal. In a survey performed for DOE in 1993 by Technics Corporation, the cost was identified to be about $11.70 per kg-U ($5.30 per lb-U) for conversion of UF_6 to metal and casting into a shape. Any forming or machining cost was additional and was priced at $4.40 to $22 per kg-U. Some cost reductions could be forecast through larger conversion facilities but these would not be expected to be sufficient to dramatically reduce the costs below those cited.

3.2 Market Production Cost Requirements

In a recent meeting between Starmet personnel and a Japanese forklift manufacturer, the manufacturer stated that the counterweight must not cost more than its steel equivalent. Thus,

15 33

STARMET

unless the performance advantage of forklifts designed with uranium counterweights justifies the higher costs, none will be sold unless the cost of uranium metal production is reduced.

3.3 Cost Reduction Opportunities

3.3.1 Continuous Metallothermic Reduction

This process was developed at Oak Ridge National Laboratory in support of the AVLIS Enrichment process that uses a uranium-iron eutectic as feed material. The process uses a bath of molten magnesium into which uranium tetrachloride is injected. The magnesium reduces the uranium tetrachloride and forms magnesium chloride that can be recycled to recover the magnesium. The molten uranium is alloyed with iron during this process to reduce the melting point from 1135 C to about 700 C. This reduces the uranium vapor pressure and simplifies subsequent operations. The potential cost reduction for this process, compared to the AMES process, is not known due to proprietary restrictions associated with the AVLIS technology. *81-5*

Conceptually, this process might be adapted to uranium hexafluoride however, the process has not yet been successfully demonstrated at production scale. Furthermore, the advantages of using the eutectic mixture for AVLIS would probably be unavailable for counterweight applications since the metallurgical properties of the uranium-iron alloy are very poor. During cooling, shrinkage cracks develop and the alloy is very brittle at room temperature. By casting the alloy in a steel sheath, these metallurgical property deficiencies might be made irrelevant.

3.3.2 Direct Plasma Conversion of UF_6 to Uranium Metal

Technology Description

This technology was conceived at the INEEL as a possible method for a lower cost production of uranium metal from UF_6. Conceptually, the process operates as shown in Figure 1. The UF_6 is injected as a gas into the center of a hydrogen-rich plasma operating at about 5000°C. At this temperature, the UF_6 dissociates to Umetal and elemental fluorine. The fluorine combines with the hydrogen to form HF. As the gas exits the plasma reactor, it must be cooled rapidly to avoid the back reaction of HF with U. At the exit of the reactor, the gas (HF and unreacted H_2) with the entrained Umetal vapor enters a cyclone where the cooled metal particles are separated from the gas stream. The system operates with excess hydrogen and to maximize conversion of the fluorine to HF. This excess hydrogen must be separated from the HF gas and recycled. *81-6*

Advantages of this direct conversion approach must be contrasted with the traditional method for uranium metal production – the Ames process. The INEEL plasma conversion process consumes only hydrogen and liberates only anhydrous HF and H_2 as byproducts. The H_2 is extracted from the HF and recycled. The HF gas is comparably easy to purify of uranium using filtration techniques. The metal formed from this process is nanometer sized particles that are very pyrophoric. A method must be developed to solidify the uranium particles into an ingot before exposure to air.

COMMENTOR NO. 81: STARMET (CONT'D.)
IDAHO FALLS, IDAHO

STARMET

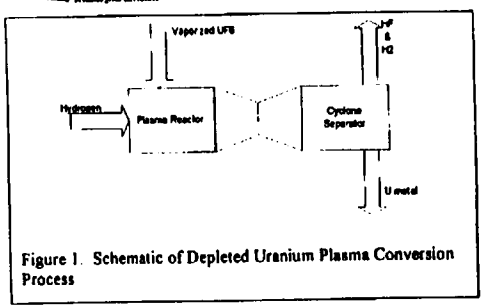

Figure 1. Schematic of Depleted Uranium Plasma Conversion Process

In all past uranium metal production operations, because of the relatively small production, the HF was captured in a scrubber to form aqueous HF that was subsequently reacted with CaOH to form CaF_2 and water. The water was evaporated and the CaF_2 was disposed as a radioactive waste. The greensalt reduction reaction to produce uranium metal consumes magnesium and produces MgF_2 as a radioactive by-product waste. Method to separate the uranium contamination from the MgF_2 have been considered but not deployed. *81-6 (Con't.)*

The INEEL process was successfully demonstrated at the small bench scale under a program funded by DOE EM 50 in 1994. The major challenge with the plasma reduction process is associated with the design and maintenance of a plasma reactor operating at such high temperature. INEEL researchers identified methods for designing such plasma reactors but further demonstration was beyond the scope of the funded program.

Estimated Cost Savings

After the proof-of-concept, bench scale test was successfully completed, an engineering conceptual design was performed for INEEL by Morrison Knudsen to estimate the total lifecycle cost of this approach. In summary, this report identified that a reasonably sized facility could produce uranium metal at about $3.00 per kg-U. This compares to estimated commercial costs from the Ames process of about $8.80 per kg-U.

To achieve this production cost reduction, substantial research support will be required and probably at least ten years of effort will be needed before large-scale production could be achieved.

5. Conclusions

Applications for depleted uranium metal have been identified. These applications include radiation shields and industrial counterweights.

Barriers to using radiation shielding applications are minimal as numerous precedents have been set for use in transportation casks. Barriers to industrial counterweight applications are institutional and economic. The institutional barriers are public acceptance and legal possession limits. Such regulatory barriers may be resolvable, as the real toxic health effects of depleted *81-7*

1534

COMMENTOR NO. 81: STARMET (CONT'D.)
IDAHO FALLS, IDAHO

STARMET

uranium are less than for lead. The radiation issues from depleted uranium are miniscule provided the material is not ingested into the lungs. Resolution of public acceptance issues are difficult to predict but in an industrial setting, but they must be solved.

Thus, the largest barrier to the use of depleted uranium metal is production costs. Unless the forklift industry can sell the concept of substantially increased performance for the depleted uranium counterweight forklift designs, then the counterweight must have a similar cost to a steel counterweight. With steel casting costing in the range of $1.54 per kg versus uranium casting costing over $12 per kg, it is clear that reduced manufacturing costs are needed for commercial applications.

The direct plasma conversion of UF_6 to uranium metal offers significant cost reduction potential but will require substantial research investment to demonstrate commercial feasibility. Even then, assuming success and that the economics are as predicted, the estimated costs are still over a factor of two greater than a cast steel counterweight. *81-7*

Consequently, wide scale application would be contingent upon either 1.) justifying to forklift buyers that the increased performance of a forklift with depleted uranium counterweights justifies a higher price, or 2.) alternatively, DOE could subsidize the conversion cost to neutralize the cost differential as a preferred action to managing the UF_6 for disposal. If the direct plasma conversion process were successful, the DOE subsidy would be less that the currently expected disposal costs – assuming the counterweights remained continuously in commerce and ultimately did not require disposal.

In summary, large scale industrial use of depleted uranium metal in applications such as counterweights will require development of a lower cost production technology for economic deployment. The INEEL process is one potential process which comes close to the needed production cost point.

1000 Independence Avenue, SW
Washington, DC 30585

RE: "Draft PEIS for Alternative Strategies for the Long-Term Management and Use of Depleted Uranium Hexafloride," DOE/EIS-0269 dated 12/97.

Dear Secretary Peña:

Thank you for the opportunity to comment upon the draft PEIS pertaining to future management plans for depleted uranium hexafloride (DUF6) being stored at the Portsmouth Gaseous Diffusion Plant in Southeastern Ohio. As a lifelong resident of Appalachian Ohio who has represented the area in a number of roles and as someone who has been closely involved with other issues regarding Portsmouth, my primary concerns are the safety, economy and environment of the region.

With this in mind, I support the near-term conversion of the significant stockpile of DUF6 to U308 at the Portsmouth plant. Under "normal" circumstances, one would wait until a market for a given product develops before engaging in such an activity. However, the DUF6 is stored in canisters of somewhat questionable integrity, and for which funding for long-term maintenance is noted in the PEIS as "uncertain." Thus, converting the DUF6 to a "safer" product as soon as possible is the more prudent option. *82-1*

Assuming that conversion is chosen as the preferred option, USDOE should carefully reassess the status of these cylinders and the practicality (safety) of transporting them through the region to a central conversion site. The deteriorating condition of the cylinders may make on-site conversion at each plant a safer, preferred alternative. On-site conversion may also serve to maintain employment in each region. *82-2*

DOE should work with Congress now to ensure that funds presently accrued by the US Enrichment Corporation to offset DUF6 conversion are maintained for that specific purpose, and to lay the groundwork for the on-site conversion efforts. *82-3*

COMMENTOR NO. 83: MILLER, JANE E. MURPHYSBORO, ILLINOIS

Charles Bradley
US DOE (NE-40)
19901 Germantown Rd.
Germantown, MD 20874 April 13, 1998

Dear Mr. Bradley,

These are the comments of the undersigned on the Depleted Uranium cylinders DPEIS. There are some 50,000 plus cylinders of the DUF6 containing from 10 to 14 tons of material apiece currently stored in the three sites, Paducah, Portsmouth, and Oak Ridge.

The scope of the DPEIS is inadequate to cover the activities required to deal with the cylinders. Implementing either of the conversion alternatives will trigger a series of events which will have to take place in order to complete the conversion. These include building factories to do the conversion and for cleaning the highly radioactive residues out of the emptied cylinders. The DUF6 will have to be defluorinated, which is a highly dangerous activity. The converted material and the empty cylinders will have to disposed or stored, as will the hydrogen fluoride which is separated from the DUF6. 83-1

These activities are all connected actions which require a hard look in combination with the ongoing cleanup activities at the three facilities where the cylinders are stored - Paducah, Portsmouth, and Oak Ridge. There are clearly cumulative effects from these proposals and projects which are not adequately addressed in the draft. 83-2

Although the largest majority of cylinders, some 40,000, are at Paducah, they are inadequately stacked and stored presently. These are vulnerable to the high seismic risk at Paducah from the New Madrid fault. Because it will be decades or longer before this material can be converted, the risks from earthquake damage go greater as time goes on. Any conversion facilities planned for Paducah have to fully consider the earthquake potential at Paducah, and any construction of conversion facilities at Paducah would have to be made to an earthquake standard. The extra costs of this need to be disclosed. 83-3

If cylinders are going to be transported for conversion, then the risks transportation needs to be considered carefully. This would require many thousands of shipments. Many of the older cylinders may not be capable of being lifted or loaded for transportation. Some may not be able to be heated to be emptied. All of these problems could significantly increase the cost. The DOE needs to be more up-front about the real dollar costs of this problem. 83-4

Although it appears that the best alternative is converting the material from the reactive UF 6 form to the more stable uranium oxide form, the DPEIS doesn't give enough information for the commentors to decide where the best place for conversion would be and the best methods. 83-5

Finally, it seems ill-advised to continue to fill more cylinders daily with more DUF6 while this huge problem of disposal continues to accumulate. If the nuclear industry cannot manufacture its product without creating such huge amounts of toxic waste, it should strongly consider ceasing production. 83-6

Thank you for considering these comments.

Sincerely,

Jane E. Miller

COMMENTOR NO. 84: BAILEY, SUSAN
NASHVILLE, TENNESSEE

Dear Mr Bradley
I sent deadline listed as Apr. 23 • April 27. Since Nashville's tornado really slowed me down, I hope April 27 was accurate.

Comments on PEIS for Alternative Strategies for the Long Term Management • Use of Depleted UF_6:

I am concerned that the draft PEIS does not include the alternative of disposing of depleted uranium per the rules of 40CFR191. Long-term storage of uranium poses serious risks which make the no action alternative • the new containers (for long term storage) option inappropriate • unacceptable. The waste classification of depleted uranium should be re-examined • should be put in the same category as transuranic waste. The scientific basis for this concern was well-documented in the comments of the Institute for Energy • Environmental Research. 84-1

COMMENTOR NO. 87: STATE OF TENNESSEE, GOVERNOR SUNDQUIST, DON
NASHVILLE, TENNESSEE

STATE OF TENNESSEE

DON SUNDQUIST
GOVERNOR

May 1, 1998

Mr. Charles E. Bradley, Jr., Program Manager
Depleted Uranium Hexafluoride Management Program
Office of Facilities (NE-40)
Office of Nuclear Energy, Science and Technology
US Department of Energy
19901 Germantown Road
Germantown MD 20874-1290

Dear Mr. Bradley:

As the Governor's Lead Contact for State of Tennessee's National Environmental Policy Act (NEPA) reviews, I am providing comments in response to the **"Programmatic Environmental Impact Statement (PEIS) for Alternative Strategies for the Long-Term Management and Use of Depleted Uranium Hexafluoride," DOE/EIS-0269**. The attached comments from state agencies represent the complete and official response of the State of Tennessee.

We prefer conversion of the entire inventory of stored Uranium Hexafluoride (UF_6) material which is recommended by the proposed alternative, however, the time line presented for the proposed alternative is unduly long considering the questionable condition of the stored inventory and potential health and environmental risks associated with leakage. As Governor Sundquist emphasized in his joint letter with the Governors of Kentucky and Ohio, the State of Tennessee urges the DOE to "consider the immediate conversion" of UF_6. The proposed alternative will provide the most rapid reduction of hazard to the environment and public if the time line for conversion is shortened . This recommendation applies only to the current scope of alternatives presented. 87-1

Up to this point the DOE has not fully funded the proper storage, inspection, testing and maintenance of stored cylinders of material nor does the PEIS address this pressing need for funding. Previous DOE documents have underscored its importance. Current inventories, however, remain in improper storage conditions and inspections of these inventories are limited Improperly stored cylinders are at risk to natural catastrophes such as earthquakes and tornadoes In order to fully assess the hazards associated with long-term storage versus conversion of UF_6, the DOE must address these funding concerns in the PEIS. 87-2

State Capitol, Nashville, Tennessee 37243-0001
Telephone No. (615) 741-2001

COMMENTOR NO. 87: STATE OF TENNESSEE, GOVERNOR SUNDQUIST, DON (CONT'D.) NASHVILLE, TENNESSEE

Beyond the condition of stored cylinders, issues concerning the handling of cylinders for transport have been insufficiently addressed or neglected in the PEIS. DOE's inspection of stored cylinders has been limited raising the concern that breaches in corroded cylinders may exist. Handling such corroded cylinders as well as cylinders that have been overfilled or cylinders containing "heel" materials—conditions which do not meet Department of Transportation's specifications for transport—will require costly training of personnel to repackage materials. The DOE cannot adequately assess alternatives for long-term management of stored inventory without realistically assessing these hazards and costs in the PEIS. *87-3*

We further request that the PEIS address the Inventory of the United States Enrichment Corporation (USEC) which may come into DOE possession. Omission of this significant inventory represents an incomplete analysis. *87-4*

In addition to these general comments, I request that the enclosed comments be given your full consideration. As always, your timely consideration of the interests of the State of Tennessee is appreciated. If you have any questions, please contact our staff policy analyst at (615)532-4968 (fax 615-532-0740).

Sincerely,

Justin P. Wilson
Deputy to the Governor for Policy

Charles E. Bradley, Jr., Program Manager
Depleted Uranium Hexafluoride Management Program
Office of Facilities (NE-40)
Office of Nuclear Energy, Science and Technology
US Department of Energy
19901 Germantown Road
Germantown, MD 20874-1290

Dear Mr. Bradley

Document Review: "Programmatic Environmental Impact Statement (PEIS) for Alternative Strategies for the Long-Term Management and Use of Depleted Uranium Hexafluoride," DOE/EIS-0269, December, 1997.

The Tennessee Department of Environment and Conservation, DOE Oversight Division (TDEC/DOE-O) has reviewed the subject PEIS in accordance with the requirements of the National Environmental Policy Act (NEPA) and associative regulations of 40 CFR 1500-1508 and 10 CFR 1021.

After review, the Division would like to express its support of the preferred alternative of converting uranium hexafluoride to oxide and/or metal. Tennessee has joined with Kentucky and Ohio in challenging DOE to begin the conversion immediately and complete the conversion by 2018. The PEIS has not properly addressed the need to provide adequate funding for the safe maintenance of the cylinder yards and implement requirements that protect the workers, public, and environment at and adjacent to the sites. *87-1 (Con't.)*

COMMENTOR NO. 87: STATE OF TENNESSEE, GOVERNOR SUNDQUIST, DON (CONT'D.) NASHVILLE, TENNESSEE

Charles E. Bradley, Jr.
April 21, 1998
Page Two

Additional comments, for DOE's consideration in preparation of the Final Programmatic Environmental Impact Statement, are attached.

If you have any questions regarding the Division's review, please contact John Owsley or Jim Harless at (423) 481-0995.

Sincerely

Earl C. Leming

COMMENTOR NO. 87: STATE OF TENNESSEE, GOVERNOR SUNDQUIST, DON (CONT'D.) NASHVILLE, TENNESSEE

Tennessee Department of Environment and Conservation /DOE Oversight Division

Comments on Programmatic Environmental Impact Statement for Alternative Strategies for the Long-Term Management and Use of Depleted Uranium Hexafluoride, DOE/EIS-0269, December, 1997

General Comments:

The State agrees with the preferred alternative as stated in Section 2.5, Page 2-54 of converting uranium hexafluoride to oxide and/or metal. Given, however, the numerous reports that cast doubts on the integrity of uranium hexafluoride cylinders and their environmental safety, the State, as shown in a recent letter from the Governors to Secretary Pena on the same subject, would prefer that fabrication and conversion facilities be sought as early as possible and not wait until the year 2005 as stated in the PEIS. *87-1 (Con't.)*

In order for Tennessee to effectively evaluate the potential impacts of the preferred alternative, the PEIS must provide information on the location of the sites where conversion might occur and how waste and materials generated from this process will be managed. *87-5*

More than 50% of the cylinders were not constructed to Department of Transportation (DOT) specifications. After thirty years in storage, a much higher percentage of the cylinders may not meet DOT specifications for transportation purposes and may need to be overpacked if they are moved for processing. Also, deteriorated cylinders may require cold extraction of the contents. The personnel needed to handle the cylinders will need to be trained for extreme conditions. The costs of recruiting and training appropriate personnel for the duration of the processing operations will have to be factored in the cost-benefit analysis. *87-3 (Con't.)*

Funding must be addressed in the PEIS to provide for regulatory compliance and the continued storage of cylinders, including the heel and smaller cylinders. The "Draft Preliminary Report-DOE Independent UF6 Cylinder Assessment Team" dated 03-25-92, still in draft form, states the primary issues with cylinder management is funding to properly store, inspect, and maintain. Site visits by the State in July 1997, confirmed that funding has not been fully appropriated to maintain the yards or the cylinders. *87-2 (Con't.)*

The Draft PEIS fails to address two major issues. The first is the treatment, recycling, or reuse of Uranium Hexafluoride (UF_6) in a timely manner. The second issue is the final safe disposition of the "heels" component of the UF_6 cylinders, containing a high energy (gamma emitting) RCRA mixed waste like material. The Division estimates there to be 120 million pounds of this material in cylinders stored on the Oak Ridge Reservation. Of paramount concern under the No Action or Long-Term Storage alternatives, is the slow migration of the "heel" material into the groundwater/surface water and the release of UF_6 into the air, due to the corrosion and failure of the cylinders. The Draft PEIS is unclear on the criteria used for hazard modeling. The PEIS must identify the "worst-case" cylinder conditions and explicitly use this information in the hazard modeling descriptions. The PEIS must describe the modeling parameters such as total wall area found to be less than minimum thickness, age of the cylinder, manufacturing requirements (ASME or other design/construction), denting/bulging, and if the cylinder is in an "overfilled" condition. *87-6*

COMMENTOR NO. 87: STATE OF TENNESSEE, GOVERNOR SUNDQUIST, DON (CONT'D.) NASHVILLE, TENNESSEE

These conditions then must be coupled with the natural phenomenon hazards in determining the risk. The PEIS must accurately identify the cylinder population with these conditions.

The PEIS does not address storage and maintenance of the overfilled cylinders. The K-25 site has determined there are approximately 2300 14-ton and two 10-ton cylinders that contain more UF6 than is allowed for off-site shipment by DOT regulations. Although the cylinders are determined to be overfilled for transportation, they also must be properly evaluated for long-term handling and storage. 87-7

The document does not address potential waste issues arising out of leaks (breach or rupture) in the cylinders and/or leaks caused by the handling of the cylinders. Prolonged storage of the UF_6 in outdoor yards can and has been shown to cause corrosion events. The products of corrosion include radioactive and hazardous wastes. In so far as the products of corrosion are not collected and recycled, they are wastes. With age, the probability of corrosion and external breach for the cylinders increases. Thus leakage from the long-term storage of Uranium Hexafluoride cylinders could result in hazardous waste violations and non-compliance with applicable DOE Orders. 87-8

The PEIS has not presented supporting evidence that mines, shallow earthen trenches, and other underground sites are suitable for long-term storage. The State cannot continue to rely on "later determinations," "future treatments," or other vague options for storage and/or disposal. DOE has failed to approve long-term storage and disposal sites for other materials/wastes thus the State could expect the same lengthy time period for decision making on UF6. Placing any of the UF6 material for long-term storage or disposal in shallow earthen structures, below ground vaults, and/or underground mines should not be an alternative consideration. 87-9

United States Enrichment Corporation (USEC) since its privatization, has produced about 8000 cylinders (now reported to be upwards of 10,000) and is estimated to be currently producing 2 to 4 cylinders daily. The exact number of cylinders in question must be identified in the PEIS. The ownership of these cylinders has yet to be determined. The decision regarding USEC's 8000 cylinders should be made now, not as described in a "future Memorandum of Agreement between the USEC and the Office of Management and Budget." If the 8000-10,000 cylinders were considered part of DOE's inventory, it would represent a significant increase in total cylinder inventory. 87-4 (Con't.)

A long-term strategy for DUF6 must include DOE's entire cylinder inventory, including heel and small cylinders as well as the 10,000+ cylinders of DUF6 generated by the USEC since 1993. The USEC cylinders will revert to DOE ownership upon privatization of USEC. DOE might consider partnering with the future owner of USEC in a long-term strategy for managing and converting DUF6 in order to avoid redundancy of efforts, so long as the partnering does not slow progress toward conversion. An estimated $480 million has been accrued by USEC since 1993 in order to offset the cost of future conversion of the DUF6 generated. DOE should take steps now to ensure that this fund is not diverted into the federal treasury for an unrelated use.

The PEIS must give a clear definition for "heel" and list the word in the definition section. 87-10

1541

COMMENTOR NO. 87: STATE OF TENNESSEE, GOVERNOR SUNDQUIST, DON (CONT'D.) NASHVILLE, TENNESSEE

Specific Comments:

Page S-3, Section S.1.1, Background
"Under the current management plan, if alternative uses for the depleted uranium have not been found to be feasible by approximately the year 2010, steps would then be taken to convert the UF_6 to triuranium octaoxide (U_3O_8) beginning in the year 2020." Conversion to an oxide should be completed by 2018 whether the material has a useful purpose or not. 87-1 (Con't.)

Page S-6, Section S.2, Description of Alternatives
This section describes an alternative for "long-term" management. DOE has defined long-term in previous NEPA documents as storage for up to 50 years. This document does not identify any time frame in its definitions. The continued storage of these cylinders under the No Action alternative has already reached the long-term storage definition. 87-11

Page S-8, Table S.1
The No Action and Long-Term Storage alternatives state *"...cylinders would be subject to a comprehensive monitoring and maintenance program..."* Describe how this program differs from those already proposed. The document *"Draft Preliminary Report-DOE Independent UF6 Cylinder Assessment Team,"* dated 03-25-92, made specific observations and recommendations for UF6 cylinder management, but is still in draft form. DOE has proposed many plans, but has failed to appropriate the funding to fully carry out those plans. The PEIS must take into consideration historical management plans and DOE's failure to fund or comply with its own requirements. 87-2 (Con't.)

DOE continues to state there is to be maintenance and monitoring plans, but the PEIS state that funding is questionable for some cylinder activities, such as coating. Current cylinder conditions leave no question that funding has been less than adequate. DOE must take aggressive action to ensure whatever alternative is selected and there will be no reduction or elimination of necessary maintenance and inspection activities due to lack of funding.

Page S-13, Section S.3.3, K-25 Site on the Oak Ridge Reservation
"Which consists of three major facilities..." The K-25 site contains more than three storage yards. 87-12

Page S-32, Section S.4.1
"...exposures of workers and members of the public to radiation and chemicals were estimated to be within applicable public health standards and regulations during normal facility operations." The K-25 facility is no longer in normal operation status, and yet poses a significant gamma exposure risk to members of the public and to "reindustrialization workers." The Division has recorded the annual radiation dose (by method of thermoluminescent dosimetry monitoring) at the fences of K-1066-K Yard to be 1240 mrem, B Yard to be 950 mrem, and J Yard to be 260 mrem. Members of the public have access to the fence line at the K-1066-K area. The Division questions the methods DOE used for the estimated radiation exposures of "workers and members of the public." 87-13

COMMENTOR NO. 87: STATE OF TENNESSEE, GOVERNOR SUNDQUIST, DON (CONT'D.) NASHVILLE, TENNESSEE

Page S-38, Section S.4.5, Water and Soil
"...(based on the U. S. Environmental Protection Agency (EPA) proposed maximum contaminant level (MCL) of 20 µg/l for drinking water, and on the EPA health-based guideline of 230 µg/g for residential soil)." This is not the spirit or the letter of environmental and nuclear regulatory limits and the laws that codify these regulations. The spirit or the letter of environmental and nuclear regulatory limits and the laws is to minimize contaminant migration at its earliest and most effective point. 87-14

Page S-42, Section S.5, DOE's Preferred Alternative
The State supports DOE's Preferred Alternative of simultaneously implementing both use as uranium oxide and use as uranium metal as described in this section. Disposal as Oxide should be retained as an option as these uses progress, since it may be necessary to pursue the disposal options for some of the material. 87-15

Page 1-5, paragraph 2, Section 1.1, Background Information
The Division concurs "The DOE has responsibility for continued management of the depleted UF_6 cylinders generated by DOE and stored at the Paducah, Portsmouth, and K-25 sites." However, the proposed time table does not adequately address the safety and environmental concerns of the State of Tennessee. It has been estimated that there are an additional 12 undiscovered breached cylinders in the inventory, in addition to 7 already identified, and that the number may be as high as 200. Since some cylinders (with approximately 3 curies per cylinder) have experienced a 1/3 to 1/2 wall thickness loss due to corrosion, the continued storage of cylinders does not seem prudent or reasonable. The timetable should be accelerated to convert the UF_6 to triuranium octaoxide (U_3O_8) as soon as possible. The U_3O_8 or metal form of depleted uranium represents "safe" storage of depleted uranium. 87-2 (Con't.)

Pages 2-54 and 2-55, Section 2.5, DOE's Preferred Alternative
"...(1) continuing the safe, effective management of the cylinders and (2) beginning conversion of the depleted UF_6 into depleted uranium oxide and/or metal products as uses for these products become available."

This document should address the safety concerns raised by the National Defense Facilities Nuclear Safety Board (DNFSB) in 1995 on the integrity of Uranium Hexafluoride Cylinders.

In its conclusions, DNFSB noted in 1995 *"DOE has stored depleted UF_6 in transportation cylinders for more than 40 years and may continue to store them for an additional 30 years. The analysis of the adequacy of the existing cylinders for use as storage systems over this extended time period has not been systematic and has not addressed all the pertinent concerns. Specifically, the following areas need further assessment:*
1. the potential for failure by accelerated corrosion mechanisms needs to be better characterized and then quantified;
2. the inspection program, used to characterize the condition of the cylinder population and monitor continued adequacy for storage, needs significant overhaul to achieve these purposes;
3. cylinder handling procedures need to be analyzed and then revised to incorporate precautions for handling degraded cylinders; and 87-16

1542

COMMENTOR NO. 87: STATE OF TENNESSEE, GOVERNOR SUNDQUIST, DON (CONT'D.) NASHVILLE, TENNESSEE

4. the safety analyses for the cylinder storage yards need to be upgraded to: include insights gained through the above reviews; investigate the unique problems presented by a breach in the vapor space; investigate the hazards associated with moving degraded cylinders; and incorporate structural analyses of the cylinders." 87-16 (Con't.)

The PEIS does not include the DFNSB report in its Reference section. In the absence of effective management reactions to these recommendations, storage of the cylinders in their present location and present condition may not be continued safely. Continued safety is questionable as the probability of loss of container integrity and external corrosion increase with time.

Also continued long-term storage of the cylinders is in conflict with the accelerated clean up program of DOE. The availability of skilled and trained workers for the extraction and treatment of UF_6 ten or twenty years beyond 2006 will be more expensive. If the present conditions of storage persist, a greater population of the containers will be structurally unsound and the risk of release by rupture will be compounded. 87-17

Page 3-42, Section 3.3.1, Cylinder Yards
"The four breached cylinders have been patched to restore their integrity, segregated from other cylinders in K- and E-yards, and placed under temporary awnings. No estimates of material loss are available for these cylinders."
Appendix B-2: Breached cylinders and material loss - conflicts with the statement above. The following information has been obtained from the *"Investigation of Breached Depleted UF6 Cylinders at the K-25 Site"* dated 10-94:

Cylinder Number	Hole Diameter	Total Weight of Material Collected External to the Cylinder	Uranium Content of Material
101244	6 inch	Not Available	0.160
114951	8-12 inch width by 15-17 inch length	11.8 Kg	1.8 Kg
7953	9 inch	9.8 Kg	2.2 kg
116797	2 inch	----	----

87-18

Breach of the Cylinder 116797 is presumed to be mechanically induced cylinder breach and the reason for the absence of Uranium containing deposits. Estimated amount of UF_6 lost is 0-4 pounds for cylinder 116797 versus 17 pounds to greater than 109 pounds of estimated loss for Cylinder 114951.

Page 3-46, Chapter 3, Section 3.3.5.1, Surface Water
Monthly sampling plan does not include a means to identify contamination of the storage yards and run-off from the UF_6 material. The timing of the sampling with that objective should be immediately after a precipitation event, since Uranyl fluoride is extremely soluble in water. Thus the discussion of the results of the monthly sampling and the analyses is not relevant to the storage of UF_6 cylinders. 87-19

COMMENTOR NO. 87: STATE OF TENNESSEE, GOVERNOR SUNDQUIST, DON (CONT'D.) NASHVILLE, TENNESSEE

Pages 4-2 through 4-5, Section 4.2, Major Assessment Assumptions And Parameters
The reports from the Oak Ridge and Paducah assessment teams on the UF_6 Cylinders, 1992 and 1994 respectively, have noted many deficiencies with regard to cylinder integrity and thinning of walls due to internal and external corrosion. Corrosion has occurred to the extent that special training is required for personnel engaged in the monitoring of the cylinders. Also, the safety analysis performed on the cylinders is incomplete and does not include effects due to high winds, tornadoes, earth movements, and etc. Some of the cylinders have been reported to have thinning of the walls in the middle. Handling of such cylinders may be cause for concern. Under these circumstances, the No Action alternative will be a potentially hazardous alternative. 87-20

In addition, the stated assessment period of forty years is in conflict with DOE's accelerated clean-up plan for K-25. While the cylinder storage yards have not been identified as hazardous waste sites, the fact that breached cylinders exist and have the potential to leak out toxic substances is of major concern to the State of Tennessee. While the release so far may not meet the reportable quantity requirements, DOE has a responsibility for any environmental impact due to the breaches. Also, there is the possibility that future leaks will be of a greater magnitude. In spite of known breached cylinders, DOE has not undertaken any action to determine the degree of contamination to the soil and to the water stemming from the breaches. 87-21

Page 5-69, Section 5.5.1.1.2, General Public
"*...the total dose would be about 1 mrem, and the resulting chance of dying from a radiation-induced latent cancer would be less than 1 in 1 million.*" The risk of dying from a radiation-induced latent cancer associated with a total dose of 1 mrem is closer to 1 in 30,000. Please provide a citation or reasoning to support a 1 in 1 million radiation induced latent cancer risk. 87-22

Page 5-72, Section 5.5.1.2.2, Accidents Involving Releases of Radiation or Chemicals
"*All doses would be considerably below the 25 rem maximum allowable dose specified in NRC regulations (10 CFR Part 76).*" The regulation with which 10 CFR 76 refers is 10 CFR 20, which is the regulation with the widest applicability "Standards for Protection Against Radiation." The 10 CFR 20 applies to all activities licensed by the NRC which encompasses all commercial uses of radioactive material. Part 20 provides extensive details on "subsets" of exposure such as hourly exposure and exposure of minors. For comparative purposes, Part 20 limits whole body dose to 5 rem for personnel in restricted areas and 0.5 rem for personnel in unrestricted areas. The term "unrestricted area" is usually interpreted to extend to the site boundary, but not beyond to the "environment." This interpretation keeps 10 CFR 20 from conflicting with 40 CFR 190. It also assumes that the licensee has at least some minimal control over the personnel exposed. 87-23

The 40 CFR 190 regulates doses received by members of the general public in the "general environment" resulting from the nuclear fuel cycle. This is a different scope than 10 CFR 20 since 40 CFR 190 includes all processes and facilities in the nuclear fuel cycle (excluded is any dose due to occupational exposure as part of the nuclear fuel cycle). The "general environment" means the environment outside the boundary of the facility covered by the regulation. This keeps 40 CFR 190 from conflicting with 10 CFR 20. The whole body exposure limit specified by 40 CFR 190 is 25 mrem. The 25 rem "maximum allowable dose" is not really a "maximum allowable dose" at all, but rather, the dose at which notification to the NRC must be made. Section 20.403 states that "*Each licensee shall immediately report any events involving byproduct, source, or special nuclear material possessed by the licensee that may have caused or threatens to cause: (1) Exposure of the whole body of any individual to 25 rems or more...*"

COMMENTOR NO. 87: STATE OF TENNESSEE, GOVERNOR SUNDQUIST, DON (CONT'D.) NASHVILLE, TENNESSEE

Page 5-76, Section 5.5.7, Waste Management
Generation of "1 m^3/yr of LLMW" seriously underestimates the "heels" component of the UF_6 cylinders containing a high energy (gamma emitting) RCRA mixed waste. The Division estimates there to be 120 million pounds of this material in cylinders stored on the Oak Ridge Reservation.. 87-24

Page 5-108, paragraph 3, Section 5.8.2.1, Paducah Site
The Clean Air Act contains a Particulate Matter $_{2.5}$ ($PM_{2.5}$) standard. 87-25

Page 5-108, paragraph 4, Section 5.8.2.1, Paducah Site
"*...cylinder breaches occurring at Paducah before the year 2020 could result in groundwater concentrations of uranium exceeding 20 μg/L*" is not provided for under the "Clean Water Act." 87-26

Page 5-110, paragraph 3, Section 5.8.2.2, Portsmouth Site
The Clean Air Act contains a Particulate Matter $_{2.5}$ ($PM_{2.5}$) standard. 87-25 (Con't.)

Page 5-110, paragraph 4, Section 5.8.2.2, Portsmouth Site
"*Uncontrolled corrosion until about 2050 before groundwater concentrations of uranium would approach 20 μg/L*" is not provided for under the Clean Water Act or Safe Drinking Water Act (SDWA). 87-26 (Con't.)

Page 5-112, Paragraph 3, Section 5.8.2.1, Oak Ridge Reservation: K-25 Site
The Clean Air Act contains a Particulate Matter $_{2.5}$ ($PM_{2.5}$) standard. 87-25 (Con't.)

Page 5-112, Paragraph 5, Section 5.8.2.3, Oak Ridge Reservation: K-25 Site
"*Uncontrolled corrosion until about 2025 before groundwater concentrations of uranium would approach 20 μg/L*" is not provided for under the Clean Water Act or SDWA. 87-26 (Con't.)

Page 5-115, First bullet, Section 5.9, Mitigation
The Clean Air Act contains a Particulate Matter $_{2.5}$ ($PM_{2.5}$) standard. 87-25 (Con't.)

Page 5-115, Third bullet, Section 5.9, Mitigation
"*Future impacts on groundwater from failure of a disposal facility could be minimized by selection of a site in a dry environmental setting*" should be highlighted and recognized as a major siting factor. The same argument could be made for the storage of "awaiting conversion" cylinders, that are currently deteriorating and corroding. 87-27

Page 5-119 and 5-120, Section 5.13, Pollution Protection And Waste Minimization
This section should address the "heels" component of the UF_6 cylinders. These heels contain a high energy (gamma emitting) RCRA like mixed waste. 87-6 (Con't.)

Page 6-1, Section 6, Environmental, Occupational Safety, And Health Permits And Compliance Requirements
The Clean Water Act/SDWA should also be included as a "potential requirement" 87-28

Re PEIS for DOE's Long-Term Management of Depleted Uranium Hexafluoride

Dear Mr Bradley

The Division of Radiological Health has the following comments

- The discussion of the statistical nature of the hazards posed by radiation exposure was a good addition to this report. — 87-29
- The PEIS document considers a number of different options for dealing with the Depleted Uranium Hexafluoride. Several of the options include the conversion of the material from UF_6 to either uranium oxide or uranium metal. In their analysis of this option, they always consider the conversion beginning in the year 2008 (PEIS 2-6, 2-9, 2-12, 2-15) This seems to be an unreasonably long time before starting conversion Even considering that it will take time to decide what to do with the material, and to build the facilities if conversion is the chosen option, it does not seem that 10 years should be necessary before conversion can begin. — 87-1 (Con't.)
- Chapter 5 of the PEIS discusses the environmental impacts of the various alternatives. As support for the discussion several graphs are included On page 5-20 a single graph compares the long term cancer risk (radiation risk) if the material is maintained as UF_6. Pages 5-37 and 5-39 compare the long term cancer risk (radiation risk) for conversion to an oxide and the probabilty of injury (non-radiation risk) if the material is converted to an oxide. While the report states that the chemical hazards of the material in its UF_6 form are greater than if it is converted to an oxide the omission of a graph showing the probability of injury if the material is maintained as UF_6 leads to an unbalanced representation of the hazards of these two options for the disposition of the material. Also, the combination of all non-radiation hazards as "risk of injury" is a misleading representation. — 87-30
- There are a number of questions about the characterization of the hazard from earthquakes at the Paducah, KY location These questions are outlined in an attached memo from a State geologist. — 87-35

1544

COMMENTOR NO. 87: STATE OF TENNESSEE, GOVERNOR SUNDQUIST, DON (CONT'D.) NASHVILLE, TENNESSEE

- References to the usefulness of the depleted uranium in either its oxide or metallic forms are unsupported. The document states that changing circumstances have made the specific uses mentioned unlikely for the future and yet no other possible uses are adequately addressed. (PEIS 2-20) This makes the position that this material is a resource as opposed to a waste tentative at best. If there are realistic scenarios for the future use of this material, they should be presented in the PEIS. If there are no realistic future uses, then the material should be treated and disposed of as waste. — 87-31
- Recommendation number 15 of the Draft Preliminary Report – DOE Independent UF_6 Cylinder Assessment Team dated March 25, 1992, states "All cylinders in or near ground contact should be removed from those conditions, ... and ultrasonic wall thickness examinations be performed of all cylinders with significant corrosion to determine the amount of residual thickness remaining." At the time of the PEIS, it is mentioned that ultrasonic testing is now part of the cylinder maintenance. (PEIS 2-56) It is also stated, however, that "Because the ultrasonic tests are time-consuming and costly only a small portion of the entire inventory has been measured." (PEIS B-2) This is a problem for two reasons First, it does not begin to meet the minimum of testing all cylinders with significant corrosion. Second, this brings doubt to statements such as "the cylinder breaches were assumed to go undetected for [at most] 4 years (the inspection interval for most cylinders)." (PEIS 2-5) The inspection for most of the cylinders consists only of a visual inspection. The visual inspection method, as described, does not appear to be adequate since many of the cylinders can not be seen on all sides and cylinders that are leaking may not be detected visually since the color of the paint matches the color of the leaking material exposed to air. — 87-32
- The PEIS states on page 4-3 that "While in storage at the three current storage sites, cylinders were assumed to be inspected and maintained in safe storage consistent with current management practices and plans." Based on the number of breaches detected, the rusting of the cylinders, the improper storage conditions and the documented lack of adequate surveillance of these cylinders, the assumption that material is in safe storage is only true when qualified by the phrase "consistent with current management practices and plans." Essentially DOE is defining their practices and procedures as safe This allows them to say that a process is safe simply because it meets the standards of the procedure, not because an unbiased safety analysis has been performed. — 87-33
- Appendix G of the PEIS, table G.6 compares accident consequences associated with the long term storage of the material in different chemical forms. Why are the accidents considered differently for the different forms. For example, an earthquake or a tornado are considered under unlikely accidents for the uranium oxide but neither scenario is considered for the UF_6. A comparison of this type would seem to be most useful if it compares the same types of accidents. Another difference is that "unlikely accidents" for UF_6 are described as having a possible frequency of "1 in 10,000 to 1 in 1 million years," while under the uranium oxide option the "unlikely accident" is described as having a frequency of "1 in 100 years to 1 in 10,000 years." It is not clear why an "unlikely accident" would have a different probability associated with it for a different chemical composition? — 87-34

MEMORANDUM

TO: Mike Mobley & Joelle Key, Div. of Rad. Health

FROM: Mike Hoyal, Asst. State Geologist

DATE: February 20, 1998

Subject: Draft DOE PEIS, Earthquake Hazard

Regarding the information you provided on the above referenced document, please refer to the attached information from the Center for Earthquake Research and Information (CERI), at Memphis University.

The draft PIES seems to not only down-play past seismic events but gives very little information on future potential events. By all accounts, the Paducah area is located in a high-risk area for major damage from earthquakes (see attached seismic risk map). In comparison, the Oak Ridge area is located in a moderate-risk area and experiences fewer and less severe earthquakes. The information presented by this document might be more accurate for the East Tennessee area but seems to be an understatement for the Paducah plant area.

87-35 (Con't.)

The article on earthquake intensity gives a good explanation for how we can determine the extent of damage a seismic event can cause to manmade and natural objects in a particular place. The Modified Mercalli Scale describes intensities in physical terms that can be related by personal or observable results, thus more subjective. By contrast, the Richter Scale is a specific measurement of magnitude or energy released during an earthquake and is determined at the time of the event. While every earthquake can have many intensities, depending on distance from the epicenter, it can only have one measurement of magnitude. While magnitude measurements provide useful data for scientific research, including accurate comparison of

earthquakes, they give no specific information about the damage or other effects caused by an earthquake.

For specific information on the probability or frequency of significant seismic events, please refer to the CERI attachment.

87-36 (Con't.)

Our Division has several publications available on earthquakes in Tennessee and both Ron Eurewski, Director, and Tom Hart, Geologist, are active in the Central U. S. Earthquake Consortium for this region.

If we can provide further service, please advise.

COMMENTOR NO. 87: STATE OF TENNESSEE, GOVERNOR SUNDQUIST, DON (CONT'D.) NASHVILLE, TENNESSEE

The New Madrid Fault System

The greatest earthquake risk east of the Rocky Mountains is along the New Madrid fault system. Damaging earthquakes are much less frequent than in California, but when they do occur, the damage can be far greater, due to the underlying geology.

The New Madrid fault system, or the New Madrid seismic zone, is a series of faults beneath the continental crust in a weak spot known as the Reelfoot Rift. It cannot be seen on the surface. The fault system extends 150 miles southward from Cairo, Illinois through New Madrid and Carruthersville, Missouri, down through Blytheville, Arkansas to Marked Tree, Arkansas. It dips into Kentucky near Fulton and into Tennessee near Reelfoot Lake, and extends southeast to Dyersburg, Tennessee. It crosses five state lines, and crosses the Mississippi River in at least three places.

The great New Madrid earthquake of 1811-12 was a series of quakes that happened over a three-month period. The main shocks, the three largest earthquakes, were estimated to be greater than magnitude 8.0 Aftershocks included two events around magnitude 8.0, five magnitude 7.7, ten magnitude 5.3, and eighty-nine estimated at magnitude 4.3. The entire fault system is believed to have ruptured in this series of earthquakes. Aftershocks were felt in the region for more than a year. This was the largest release of seismic energy in the continental United States. The only other larger event was the Great Alaska Earthquake, in 1964

Earthquakes of 5.0 or less are also possible in many other parts of the central and eastern U.S. In addition to the New Madrid seismic zone (NMSZ), earthquakes of magnitude 6.0 and above have occurred at Charleston, South Carolina, and recent research suggests that the Wabash Valley fault system in Illinois and Indiana has produced large earthquakes.

The possibility of a great earthquake happening soon in the New Madrid seismic zone is small. Scientists believe that catastrophic events like those of the 1811-12 happen in the New Madrid region every 550-1200 years. THis means there is roughly a 0.3-1.0% probability of an event greater than magnitude 8.0 within the next 15 years, and a 2.7-4.0% probability within 50 years. Even though the probabilities are small, there is no reason to be complacent, for there have been other damaging earthquakes in the region since 1811 and 1812.

A major earthquake, magnitude 7.0 or greater happens every 254-500 years and has a probability of five to nine percent within the next fifteen years, and a nineteen to twenty nine percent within the next fifty years. An earthquake of this size would be felt throughout much of the central and eastern United States. Damage could amount to several billion dollars.

A damaging earthquake in this area, magnitude 6.0 or greater, happens every seventy to ninety years and has a probability of 40-63% within the next fifteen years, and 86-97% within the next one hundred and fifty years. An earthquake of this size would cause damage to older structures, especially those of masonry construction. There could be serious damage to many schools in the region.

The fault system is active averaging more than 200 earthquakes per year. Of these, eight to ten are large enough to be felt. There are approximately forty six earthquakes in the magnitude 2.0 range, and seven in the magnitude 3.0 range per year. (If your browser does not support HTML Table Tags, please use this link.)

1546

Magnitude	Expected Rate (yr)
4.0	14 months
5.0	10-12 yr
6.0	70-90 yr
7.0	254-500 yr
8.0	550-1200 yr

Magnitudes are determined by various methods The one of which most people are familier, is the Richter Scale. The Richter Scale is a measure of energy released in an earthquake. It is determined by ground motion on seismograms. An earthquake has only one Richter magnitude.

What do the numbers on the Richter Scale tell us? Each unit of the Richter Scale is a tenfold increase in the relative size of an earthquake. A magnitude 6.0 is ten times the size of a magnitude 5.0, and one hundred times the size of a 4.0. But energy release is a different matter. Each unit up the Richter Scale is around a 32 times greater release of energy. A magnitude 6.0 releases 32 times more energy than a magnitude 5.0, and about one thousand times more energy than a magnitude 4.0

The amount of energy released in a small earthquake is not enough to prevent a large one from occurring. A million magnitude 2.0 earthquakes would release the same amount of energy as one magnitude 6.0 quake. 32,768 magnitude 2.0 earthquakes would release the same amount of energy as one magnitude 5.0

Of greatest concern in the near future, then , are the 6.0 to 6.5 events. Damaging earthquakes in this magnitude range are possible within the lifetimes of our children. Two have occurred since 1811-1812, one in 1843, and another in 1895.

Many things can be done to protect ourselves. Education, preparedness planning, and proper building construction are proven means to minimize the deaths, injuries, and economic losses due to earthquakes. Northern California and Armenia recently experienced 6.9-7.1 earthquakes.Northern California was prepared, Armenia was not. In northern California 62 people died and there were more than $6 billion in losses. In Armenia over 25,000 people died and losses were greater than $20 billion. The central United States is more prepared than Armenia, but not nearly as well prepared as northern California.

The choice is ours. We can get ready and reduce our losses, or we can do nothing, and suffer the full consequences of a damaging earthquake. We need to continue to plan, to build better buildings, and make sure that earthquake preparedness becomes a part of all our lives. We cannot prevent the coming of an earthquake, but we can reduce the effects.

2

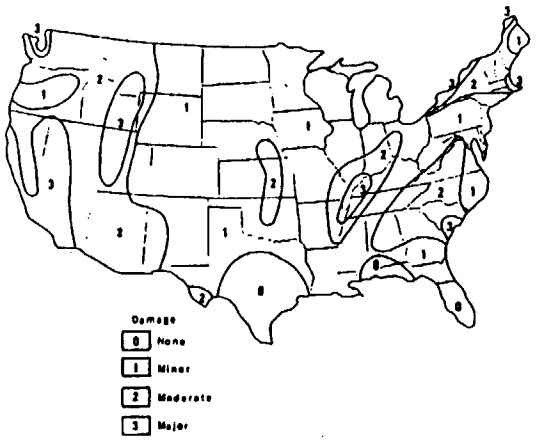

Figure 1. General seismic risk map of the United States. Note that much of Tennessee is in zone 2 or 3, where at least moderate damage is predicted. From Algermissen, Seismic risk studies in the U.S., Fourth world conference on earthquake engineering, January 14, 1969, Santiago, Chile.

CAUSES OF EARTHQUAKES

Most earthquakes are the result of shock waves created by the sudden release of slowly accumulated stress in rigid bedrock. This release of stress results in the rock's sliding along fractures, called *faults* by geologists. On either side of a fault the rock is offset. The sliding relieves the stress for a time, but continued stress accumulation often leads to recurrent sudden slippage on the fault, and more earthquakes are the result. It is for this reason that geologists are so concerned with accurately mapping fault locations, both old faults no longer active and those along which slippage has occurred in the recent geologic past. By studying the actual history of earthquakes along these faults, it may be possible to predict the likelihood of future earthquakes.

Throughout the world many earthquakes occur along precipitous sea coasts or actively rising mountains at the edges of continental plates. These plates are segments of the outer thin "shell", or crust, of the earth. The crust consists of several of these plates moving slowly apart, or sliding past, over, or under each other. It is along the boundaries of these plates that great amounts of energy are released in earthquakes and volcanic activity. It is not surprising, then, that quakes are so common in California and other places (e.g., Japan) at plate edges along the borders of the Pacific Ocean.

One might ask, "Why should earthquakes occur in and near Tennessee, since we are obviously far from

Charles E. Bradley, Jr.
U.S. Dept. of Energy
19901 Germantown Road
Germantown, MD. 20874-1290

Dear Mr. Bradley,

Thank you for your response to our letter, regarding the Department of Energy's draft Programmatic Environmental Impact Statement for Alternative Strategies for the Long-Term Management and Use of Depleted Uranium Hexaflouride. As per our phone conversation you agreed to meet with the Military Toxics Project and other interested parties to discuss the P.E.I.S., however DOE could not afford to foot the bill. The citizens and impacted communities we work with simply do not have the money to fly to Chicago or Washington, D.C. to meet. Therefore, I simply wish to have on record the Military Toxics Project's position regarding Depleted Uranium.

As you may know, the Military Toxics Project (MTP) is a non-profit grassroots organization. Our membership is made up of concerned citizens, community organizations, national organizations, physicians, scientists, veterans, environmental justice activists, labor and peace groups from around the country. MTP's mission is "to unite activists, organizations and communities in the struggle to clean up military pollution, safeguard the transportation of hazardous materials, and to advance the development and implementation of preventative-based solutions to the toxic and radioactive pollution caused by the United States military activities. MTP's mission is based on mutual respect and justice for all peoples, free from any form of discrimination or bias".

In 1992, the Military Toxic Project formed the Depleted Uranium Citizens Network. The Depleted Uranium Network provides outreach and education, uniting people affected by the mining, production, manufacturing, testing, sale and use of depleted uranium for military and commercial purposes; and to demand cleanup, health care, compensation and the end of depleted uranium munitions use worldwide to help ensure the survival of future generations.

COMMENTOR NO. 88: MILITARY TOXICS PROJECT (CONT'D.)
LEWISTON, MAINE

The Military Toxics Project adamantly opposes any use of the depleted uranium for military purposes such as in weaponry and munitions. First used in the Persian Gulf War in 1991, U.S. and British forces used depleted uranium as both armor piercing bullets and as tank armor. When uranium weapons burn, when they corrode, and when they are machined, uranium oxide dust is created. The U.S. Department of Defense estimates approximately 315 tons (630,000 pounds) of depleted uranium were fired in the Gulf. This firing resulted in the release of large amounts of DU dust which contaminated thousands of tanks, vehicles and land.

88-1 (Con't.)

Recently, the Military Toxics Project released a report with Swords to Plowshares and the National Gulf War Resource Center called the ***Depleted Uranium Case Narrative***. The report details how hundreds of thousands Gulf War Veterans may have been exposed to DU radioactive dust in the Gulf War. I have enclosed a copy for your review.

88-2

All too often we see industry and government with end of the pipe mentality, redefining waste as a product to be used. For example the paper industry's waste they call fertilizer and spread sludge on unsuspecting communities, further exposing citizens to toxics. Changing the medium doesn't necessarily reduce the risk. We hope the Department of Energy will start working towards more preventative based solutions in the future.

88-3

The task you are charged with now is to find the most safe and effective way to manage/use DU. When reviewing the comments for the Programmatic Environmental Impact Statement for Alternative Strategies for the Long-Term Management and Use of Depleted Uranium Hexaflouride, we hope you will weigh MTP's concerns on how DU is used. Dealing with the tremendous stockpiles of Depleted Uranium Hexaflouride is a monumental task. We wish you well and if you have any questions, please don't hesitate to call.

Sincerely,

Tara Thornton

DEPLETED URANIUM WEAPONS
Threaten Nuclear Non-Proliferation Treaty

A Briefing Paper To The Delegations to the 1998 Non Proliferation Treaty Preparatory Committee

Governments concerned about the future of nuclear weapons must be alerted to the dangerous proliferation of a new class of radioactive weapons first used in warfare by U.S. aircraft and U.S. and British tanks in the Gulf War. These weapons are made from Depleted uranium (DU).[1] Depleted Uranium is a radioactive and chemically toxic nuclear waste product that has been manufactured into an armor-piercing projectile known as the depleted uranium penetrator. At least fourteen countries including the U.S., the United Kingdom, France, Russia, Greece, Turkey, Israel, Saudi Arabia, Bahrain, Egypt, Kuwait, Pakistan, Thailand, and Taiwan now have DU penetrators in their arsenal.[2] Other sources assert that the weaponry has proliferated to Iraq, Oman, Jordan, Abu Dhabi and the United Arab Emirates.

The U.S. Department of Defense estimates approximately 315 tons (630,000 pounds) of depleted uranium were fired in the Gulf in 1991. This firing resulted in the release of large amounts of DU dust which contaminated thousands of tanks, vehicles and land. Depleted uranium dust can be transported by wind or water and can enter the human body via wound contamination or injection (as in fragments), inhalation or ingestion. Depleted uranium has a half life of 4 1/2 billion years.

Among the short and long term health effects of inhaled or ingested depleted uranium particles are kidney and liver problems, immune system disfunction, reproductive problems, birth defects and cancers. A March 2, 1998 report released by Swords to Plowshares, the Military Toxics Project, and the U.S. National Gulf War Resource Center details how hundreds of thousand Gulf War veterans may have been exposed to DU radioactive dust in the Gulf War. The Depleted Uranium Case Narrative is available on the Internet at www.miltoxproj.org.

Since the Gulf War battlefields remain contaminated with depleted uranium, the health of today's civilians, as well as that of future generations, is at risk. The United Nations Human Rights commission in Geneva has taken up the issue of depleted uranium weaponry through its Sub-Commission on Prevention of Discrimination and Protection of Minorities. The Sub-Commission adopted resolutions in 1996 and 1997 (resolution 1996/16 and 1997/36), which included depleted uranium weaponry among "weapons of mass or indiscriminate destruction", incompatible with international humanitarian or human rights law. In 1997 the U.N. appointed Mme. Clemencia Forero de Castellanos (Columbia) Rapporteur to take over the study of DU and other weapons of "mass or indiscriminate destruction". The report is due in the Sub-Commission 1998 summer session.

COMMENTOR NO. 88: MILITARY TOXICS PROJECT (CONT'D.)
LEWISTON, MAINE

Besides being a threat to human rights, DU weapons may impose on a nation a burden of health care costs and contamination of the environment that is expensive to address. In the United States, the price of clean up of 152,000 pounds of depleted uranium fragments and dust on 500 acres at Jefferson Proving Ground in Indiana has been estimated at $4 to $5 billion dollars.[3]

In addition to causing dire and costly health and environmental damage, depleted uranium can be modified to make an atomic bomb of plutonium 239. Depleted uranium penetrators purchased in sufficient quantities by any country could be disassembled and the DU diverted for breeding weapons grade plutonium in a nuclear power reactor that had been suitably adapted. Therefore, it is critical to the success of the Nuclear Non-Proliferation Treaty, that depleted uranium weapons be considered for their potential to become a plutonium bomb as well as their intrinsic capability of being "weapons of mass or indiscriminate destruction". Thus, depleted uranium weapons' development, production, stockpiling, testing, sale and or transfer, as well as use, must be banned.

---

1 During the process of making fuel for nuclear weapons and nuclear power plants, the fissionable isotope Uranium 235 is seperated from uranium. The remaining uranium, which is 99.8% uranium 238, is misleadingly called "depleted" uranium. As a result of more than fifty years of uranium enrichment, the U.S. Department of Energy currently maintains a stockpile in excess of 1.1 billion pounds radioactive uranium waste.

2 The Depleted Uranium Case Narrative, by Dan Fahey, Swords to Plowshare, March 1998, p. 67. The report is available on the Internet at www.miltoxproj.org, http://www.gulfweb.org/ngwrc, http://www.nsnn-us.org/ or http://www.globalidea.com/~borrelvw/. For copies call the Military Toxics Project in the USA at (207) 783-5091.

3 Depleted Uranium Case Narrative, p 50.

This paper has been prepared by the Military Toxics Project. MTP is a national network of groups working to clean up military pollution, safeguard the transportation of hazardous materials, and advance pollution prevention at US Dept. of Defense installations. Through its Depleted Uranium Campaign, MTP provides outreach and unites people affected by the production, testing, and use of DU for military purposes; and demands cleanup, health care, compensation and the end of DU munitions use worldwide to help ensure the survival of future generations. For more information contact MTP at 60 Pine Street, Suite 2, Lewiston, ME. 04240, USA. Phone: (207)783-5091, Fax: (207)783-5096, E-mail: miltoxpr@lme.net, Website: www.miltoxproj.org.

COMMENTOR NO. 88: MILITARY TOXICS PROJECT (CONT'D.)
LEWISTON, MAINE

International Declaration on Depleted Uranium

Developed at the International Forum on Depleted Uranium held in Washington, DC on November 14 ~ 16, 1997.

In the spirit of universal harmony, with regard for the integrity for all peoples and nations, and for the perpetuity of safe and healthy environments and workplaces for ourselves and future generations;

Mindful that depleted uranium is the largest radioactive/hazardous waste of the nuclear enrichment process, and has accumulated in enormous quantities since the dawn of the nuclear age;

Concerned that depleted uranium is highly toxic and radioactive, with a half life of four and a half billion years, causing cancer, damage to internal organs (especially lung, kidney and bone), and birth defects;

Deeply concerned for the many people who are experiencing illnesses and medical problems because they are or have been knowingly or unknowingly exposed to depleted uranium;

Knowing that depleted uranium weaponry has proliferated throughout the world and that its use is incompatible with international law;

In response to the latest form of military radioactive pollution, namely weaponry made from depleted uranium which was used for the first time in warfare in Operation Desert Storm, which poses a threat to veterans, civilians, and future generations, citizens from the world community hereby agree to:

- **provide outreach and education, uniting people affected by the production, manufacture, testing, sale, and use of depleted uranium for military and commercial purpose**
- **pursue providing information and training for workers and soldiers regarding the hazards of depleted uranium exposure**
- **pursue the establishment of an independent international scientific and medical commission**
- **demand cleanup, health care, and compensation**
- **demand the end of the production and use of depleted uranium munitions worldwide.**

"The mission of the Military Toxics Project is to unite activists, organizations, and communities in the struggle to clean up military pollution, safeguard the transportation of hazardous materials, and advance the development and implementation of preventative based solutions to the toxic and radioactive pollution caused by United States military activities. MTP's mission is based on mutual respect and justice for all peoples, free from any form of discrimination or bias."

COMMENTOR NO. 88: MILITARY TOXICS PROJECT (CONT'D.)
LEWISTON, MAINE

ABOUT THE PROBLEM.....

The Department of Defense(DoD) is the nation's worst polluter. Continuing production, testing, and disposal of weapons threatens communities daily, yet the DoD has managed for the most part to escape existing environmental regulations and reporting. The closing of dozens of bases and other military cutbacks creates the opportunity to make a transition from a polluting military-dominant economy to sustainable peacetime endeavors. Public awareness and involvement are critical at this time, to ensure that communities know the extent of local pollution, facilities are adequately cleaned up, disposal methods are safe, and new military and civilian industry is pollution prevention-oriented to protect the environment and public health.

ABOUT MTP.....

The Military Toxics Project(MTP) unites activists, organizations, and communities to remedy and prevent pollution created by the military. Over the last seven years, the MTP's effective combination of research and public awareness, organizing and technical assistance, and networking has led to a number of accomplishments.

These have included:

- ⇒ creation of a powerful grassroots force.
- ⇒ national issue networks involving over 130 groups from the U.S., Hawaii, and Alaska.
- ⇒ publication of several major research reports detailing the extent of the DoD's toxic burden.
- ⇒ substantive policy actions by the DoD and the U.S. Congress.

The MTP has increased its impact by forming strong working relationships with other groups, including both community and national environmental organizations, and constituencies concerned about military toxics such as physicians, veterans, environmental justice activists, labor and peace groups.

The MTP will continue its work to raise public awareness about the DoD's toxic legacy; increase the effectiveness of local groups working on military toxic issues; build a multi-racial staff, leadership and program; and network groups to advance practices and policies on the national level which increases public knowledge and participation, hold the military accountable and promote safe, sustainable industry.

Its activities will include:

- Organizing Assistance and Training - on-site and phone consultation with grassroots groups; training; distribution of newsletter and organizing material.
- Technical Assistance - - Distribution of reports and fact sheets and other information specific to individual communities.
- Networking - - Continued facilitation of issue networks on base closure, depleted uranium, public participation and conventional munitions; implementation of a collaborative campaign focusing on issues that affect all groups.
- Workshops, Conferences, and Meetings - - Continues to organize and facilitate workshops around the country.
- Multi-racial Effort - - Increasing racial diversity on staff, among groups, and in the program work. MTP has a leadership development program which promotes diversity.

These activities will result in greater public awareness, more effective local leaders and groups, changes by the DoD, and other government agencies and the U.S. Congress.

COMMENTOR NO. 89: UNITED STATES NUCLEAR REGULATORY COMMISSION (CONT'D.) WASHINGTON, D.C.

U. S. NUCLEAR REGULATORY COMMISSION COMMENTS ON DOE/EIS-026, DRAFT "PROGRAMMATIC ENVIRONMENTAL IMPACT STATEMENT FOR ALTERNATIVE STRATEGIES FOR THE LONG-TERM MANAGEMENT AND USE OF DEPLETED URANIUM HEXAFLUORIDE," (PEIS), dated December 1997.

Supporting Documents Reviewed:

UCRL-AR-124080, "DEPLETED URANIUM MANAGEMENT PROGRAM: THE ENGINEERING ANALYSIS REPORT FOR THE LONG-TERM MANAGEMENT OF DEPLETED URANIUM HEXAFLUORIDE," Rev. 2, Volumes 1 and 2, (EAR), dated May 1997.

UCRL-AR-127650, "COST ANALYSIS REPORT FOR THE LONG-TERM MANAGEMENT OF DEPLETED URANIUM HEXAFLUORIDE," (CAR), dated May 1997.

The purpose of the U.S. Department of Energy (DOE) programmatic environmental impact statement (PEIS) is to assess the potential impacts of alternative strategies for managing the depleted uranium hexafluoride at three DOE sites. DOE states that its preferred alternative is to use 100% of the uranium hexafluoride, either as uranium oxide, uranium metal, or both. The following are comments the Nuclear Regulatory Commission believes need to be addressed in the PEIS.

General Comments:

1. Assumption of Future Potential Use

While we agree that the use of UF_6 is desirable, we recommend that DOE include in the PEIS an alternative that addresses UF_6 for which no use can be found. The PEIS does not provide information indicating a market demand capable of consuming 100% of the depleted uranium (DU) inventory and notes that "potential uses that are capable of consuming a substantial fraction or all of the inventory . . . are not yet fully developed . . . ." In fact, very little of the material has been used in the decades over which it has been generated and it is not clear that all of it will be used in the future, as DOE has assumed in its preferred alternative. The existing management plan for depleted uranium described on page S-3 explicitly recognizes that future uses may not be found. In this regard, the Council on Environmental Quality (CEQ) recommends that an environmental impact statement (EIS) contain ". . .all reasonable alternatives. . . . Reasonable alternatives include those that are *practical or feasible* [emphasis in original text] from the technical and economic standpoint and using common sense, rather than simply *desirable* [emphasis in original text] from the standpoint of the applicant." ["Forty Most Frequently Asked Questions Concerning CEQ's NEPA Regulations," 46 FR 18027, March 23, 1981]. An alternative that recognizes that uses may not be found seems appropriate for the PEIS, given this CEQ guidance. 89-1

Furthermore, CEQ recommends that existing management plans be included as alternatives in EISs. One of the two CEQ interpretations of the "no action" alternative is "no change" from current management direction, i.e., continuing with the present course of action. Under the current DOE management plan for UF_6, if alternative uses have not been found to be feasible

ENCLOSURE

COMMENTOR NO. 89: UNITED STATES NUCLEAR REGULATORY COMMISSION (CONT'D.) WASHINGTON, D.C.

by approximately the year 2010, steps would be taken to convert the UF_6 to U_3O_8 beginning in the year 2020. The U_3O_8 would be safely stored until there was a determination that all or a portion of the depleted uranium was no longer needed. At that point, the U_3O_8 would be disposed of as low-level radioactive waste. Thus, our concern about future uses not developing as projected in the PEIS would be addressed by following this CEQ guidance.

Also, the discussion does not address regulatory and licensing requirements for the DU applications. It is recommended that (1) DOE identifies the likely market consumption of DU oxides and metals over the timeframe of the EIS, (2) DOE estimates the impacts from these potential DU uses, (3) DOE considers the potential of the converted DU materials becoming a waste, thus, requiring conversion into forms compatible with disposal, and (4) DOE evaluates the likely regulatory and licensing aspects of potential uses. 89-2

In addition, DOE's assumption that all of the depleted uranium can be used in the future appears to mean that the UF_6 would be stored onsite as it is stored now, until uses actually develop. The PEIS states that conversion to metal or oxide would not begin until uses for these products become available, and that safe management of the cylinder inventory in accordance with existing practices would continue until all of it had been converted for use. Thus, if no significant uses were to develop, the PEIS would in effect be endorsing an alternative that continues to spend resources indefinitely on maintaining and monitoring the steel containers, to expose workers to radiation in performing these functions, and to put off a long-term plan for disposal. 89-3

2. Additional Evaluation of Combination of Alternatives

While the combination of 50% use as uranium oxide and 50% use as uranium metal is evaluated in the PEIS, other combinations, assuming DU applications are not forthcoming, would be beneficial. One example would be to assume only 50% inventory use altogether, and the remaining 50% requiring conversion to a more stable form and disposal. Again, this seems appropriate due to the uncertainty of inventory use. 89-4

3. Ranking of the Alternatives

The summary of the results (page S-15 et seq) does not include a ranking of alternatives, and implies that all of the alternatives are acceptable, but that there is one "preferred alternative." DOE may wish to rank or identify those alternative(s) that appear more favorable than others based upon the analysis. DOE may also want to consider and mention if any of the proposed alternatives are precluded by the analysis. For example, page S-84 mentions individual doses from groundwater ingestion of 100 mrem/yr from disposal in shallow earthen structures, far in excess of 10 CFR Part 61 standards of 25 mrem/yr. Page S-84 also mentions a scenario for a hypothetical future resident living on the disposal site and receiving radiation doses as high as 10 rem/yr. These limitations should be included in the summary. 89-5

4. Use of the Term "Uranium Oxides"

The PEIS generally combines all uranium oxide compounds, U_3O_8 and UO_2, under the title "uranium oxides" for consideration in the alternatives and strategies (see page S-6 et seq). 89-6

1553

COMMENTOR NO. 89: UNITED STATES NUCLEAR REGULATORY COMMISSION (CONT'D.) WASHINGTON, D.C.

This seems too all inclusive, as uranium oxides have significantly different chemical and physical properties that produce a wide range of environmental health and safety impacts. For example, U_3O_8 is a high porosity powder, with a low density and a significant respirable fraction. UO_2 powder is also porous, and can spontaneously ignite in air. On the other hand, when UO_2 is sintered, a process involving high temperatures to reduce porosity, increase density, and decrease volume, it has the highest density of the uranium oxides and is essentially pore free. The presence (or absence) of pores also has significant implications for the potential disposal of the material, either as a management option or as an end-use item; a denser, essentially pore free material would appear to be advantageous due to lower leaching potential. Thus, a dioxide material sintered to a lower density (i.e. 4-5 g/cm^3) would not be expected to perform as well in a disposal environment as a uranium dioxide sintered to a high density (i.e. 9-10 g/cm^3). It is recommended that more qualifiers are given to the term "uranium oxides," perhaps including low and high density as the principal discriminator. 89-6 (Con't.)

5. Equivalent Bases and Life-Cycle Effects, the Cradle-to-Grave Approach

The text does not seem to incorporate a life-cycle approach to the different management alternatives and compare them on an equivalent basis (see pages S-7 et seq). For example, even if a market exists for potential uses of the depleted uranium (DU), at the end of the product's useful life it is still radioactive ($t_{1/2}$ = 4.5 x 10^9 years) and will require disposition. Thus, disposal would seem to be the logical endpoint for all of the alternative branches shown in Figure S.2, instead of only for the disposal as oxide alternative. Following the DU product from cradle to grave thereby influences the impacts and potentially the alternative(s) selected. It would seem that the "manufacture and use" alternatives will ultimately result in impacts from the DU component; for example, the material (perhaps as itself or in a product) could be shipped to a disposal facility. Such potential impacts do not appear to be included in the analysis, and may even preclude some options or require additional conversion and conditioning. For example, without supporting analyses, it is unlikely that significant quantities of DU metal can meet the regulatory requirements of disposal sites due to high solubility and the formation of hydrides. Thus, pursuit of use as a metal option may require another conversion facility to convert the DU metal into a form compatible with disposal. In addition, the long-term storage alternative also appears to lack the realization of ultimate disposal in the future. The PEIS should consider and analyze the alternatives on an equivalent basis with the same/comparable endpoints and include life-cycle effects. 89-7

Other examples of the need for equivalent bases include the oxide conversion routes, due to fundamental differences in the uranium oxide forms. One of the specific oxide conversion routes (gelation) appears to be manufacturing UO_2 with properties comparable to high density nuclear fuel. This process would be anticipated to have improved stability and related properties as compared to the other oxides. The gelation route detailed in the PEIS appears to include two plants - one for U_3O_8 production and one for dissolution/UO_2 production:

$$UF_6 \rightarrow U_3O_8 \rightarrow UO_2$$

COMMENTOR NO. 89: UNITED STATES NUCLEAR REGULATORY COMMISSION (CONT'D.) WASHINGTON, D.C.

This appears inconsistent with literature reports on the process which maintain that no production of U_3O_8 is necessary. The process described in the PEIS would cause double the impacts by performing a two step process when the same result is achievable in a one step conversion from $UF_6 \rightarrow UO_2$. 89-7 (Cont.)

6. Results of the Analyses

Pages 8-15 et seq summarize and compare the results of the impacts for the alternative management strategies. Some of these results seem inconsistent and are not intuitively obvious. For example, it is not clear why the use as uranium oxide results in higher impacts than the use as uranium metal (see pages S-20 and S-49) - the opposite would be anticipated. A more rigorous analysis of the assumptions made in the Engineering Analysis UCRL-AR-124080 is recommended (see specific comments #20). In V2, Section 8.11, Potential Shielding Applications, a large disparity is evident between the damage fractions assumed for uranium metal (1%) and those assumed for uranium dioxide(100%). Again, this seems questionable based on the pyrophoricity of uranium metal upon heating. Furthermore, the airborne release fractions are orders of magnitude lower than what is recommended in the DOE Accident Analysis Handbook 3010-94. These calculations should be examined more closely to confirm DOE's conclusion. 89-8

Furthermore, it is unclear whether or not the disposal analyses include all of the potential long-term impacts and doses from uranium leaching from the disposal area. It is recommended that DOE consider greater consistency in the results and clarify the summary.

7. Waste Management

In Section S.4.8 on page S-40, waste management impacts are discussed. DOE should consider briefly highlighting the potential uranium content of the secondary streams (i.e. CaF_2, MgF_2), along with a brief assessment of acceptability for either reuse/nonradioactive disposal or disposal as radioactive waste. The uses and demands for the by-products of conversion (HF, CaF_2) should be explored and discussed. DOE should expand the discussion in the last paragraph about uranium disposal as low-level waste (LLW). 89-9

Furthermore, the DOE may wish to cite the Louisiana Enrichment Services (LES) Final EIS (NUREG-1484) analysis. The NRC documents provide analyses supporting DU disposal as a LLW, but note that its disposal could require a mine or another means of "deep" (rather than near-surface) disposal. Similar to the conclusion drawn in the PEIS, the LES EIS determined near-surface disposal would cause exceedance of 10 CFR Part 61.41 requirements. Currently, no "deep" disposal sites exist, and all current LLW disposal sites (existing and planned) use near-surface facilities. 89-10

8. DU Use as Spent Nuclear Fuel (SNF) Cask Shielding

DOE appears to be relying upon the potential future use of DU as SNF cask shielding for a large consumption of its DU inventory (see page 8-43 and 1-8, and Volume 2 of the EAR, which 89-11

1554

COMMENTOR NO. 89: UNITED STATES NUCLEAR REGULATORY COMMISSION (CONT'D.) WASHINGTON, D.C.

analyzes a DU cask manufacturing facility as the only use of DU). If this is indeed the case, DOE may wish to discuss it in more detail in the PEIS summary, and it should be noted that no currently licensed or planned SNF cask uses of DU.

9. Fate of DU SNF Cask Shielding

As currently written, the PEIS does not include a discussion of the eventual fate and potential impacts of the DU SNF cask after use (pages 2-14 and 2-15). Pages 5-55 and 5-65 mention that "no assumptions are made regarding the fate of the cask after use," and page 5-65 notes that disposal would amount to an additional 160,000 cubic meters (6.4 million cubic feet) of waste requiring disposal, with a (calculated) average specific gravity of 2.2. This does not seem inconsequential, particularly if a dedicated disposal facility is required and the impacts are estimated to be similar to disposal (e.g., page 8-83 et seq; exceeding 10 CFR Part 61.41 dose limits). Also, there are statements in the document that question if significant quantities of DU metal are suitable for disposal (e.g., last paragraph on page 2-21). Inclusion of a discussion about the disposition of the DU cask after use, and potential impacts, is recommended. 89-12

10. Technology and Equipment Development

The PEIS encompasses numerous technologies that are at different stages of development, in terms of process, understanding, equipment, (potential) impacts, and uncertainties. For example, of the conversion, application, and disposal impacts discussed within the summary, none are practiced on any scale domestically, and only conversion to U_3O_8 is practiced on a large scale internationally, producing a low density product. Thus, there is only one direct analogy. DOE should consider including a technology discussion, with status and assessment, perhaps with either a time schedule or probability of success, for some of these technologies. For example, it seems like a significant extension of existing uranium dioxide sintering technology to take pellets from 100 te(U)/yr/line to 7,000 te(U)/yr/line. From the uranium dioxide technology perspective, microspheres (e.g., from gelation) may be the more mature technology because of the (potential) use of tube furnaces and pilot plant tests with equipment processing rates an order of magnitude larger. Similarly, a uranium dioxide/concrete cask approach appears to be a significantly easier technology to understand and scale than casting a 40 te(U) metal shield. 89-13

11. Existing Facilities and Experience

There are obvious analogies with existing, commercial fuel cycle facilities, which process uranium hexafluoride into uranium dioxide (for nuclear fuel) and (to a lesser extent) uranium metal. On an international scale, Cogema has been converting UF_6 to U_3O_8, compressing it in steel containers, and storing the containers in metal reinforced seismic buildings since 1977 to avoid the hazards of storing UF_6. These facilities are already licensed by the appropriate regulatory agencies. The PEIS does not mention these facilities, either as a source of experience or as a source of processing capacity, particularly during the development of uses for the DU materials and as a means for surge capacity. The PEIS also does not appear to draw upon the operating experience of these facilities, including waste generation and uranium content of byproducts. Reliance upon existing facilities may lessen environmental impacts associated with the construction of a new facility. Thus, DOE may wish to include the 89-14

COMMENTOR NO. 89: UNITED STATES NUCLEAR REGULATORY COMMISSION (CONT'D.) WASHINGTON, D.C.

experience of operating commercial facilities and comment upon their potential use (or non-use) during the development of applications for the DU.

12. Economic/ Socioeconomic Analyses

The PEIS mentions a separate Cost Analysis Report (CAR) as providing input to the PEIS (page 1-7). However, program costs do not appear to be included in the analyses. DOE should consider including a brief comparison of the costs and other economic impacts in the PEIS, perhaps as part of the summary (e.g., in Table S-2). Also, from a socioeconomic standpoint, all the alternatives considered will create jobs, DOE should address whether or not the areas chosen for construction can sustain the necessary development that will accompany the influx of workers. 89-15

Specific Comments:

1. Fuel Cycle Process

In the background section of the summary on pages S-1, S-2, DOE may want to briefly explain the fuel cycle process and point out the various forms of uranium at each stage. This would help elucidate the natural occurrence of U_3O_8 and substantiate its suitability for disposal alternatives. 89-16

2. Mass of DU

The insert on page S-2 identifies some 46,422 DU cylinders distributed between the three sites. While the total quantity is listed in the main text of the report, it would be helpful to have the approximate masses (as either MTU or $MTUF_6$) for the three sites listed in the summary as well. 89-17

3. United States Enrichment Corporation DU

The insert on page S-2 also notes that an additional 8,000 cylinders have been produced by USEC. It is suggested that this number is also divided between the sites and expressed in mass quantities. It is also recommended that a brief discussion about the USEC DU be included, perhaps as part of the first paragraph on page S-4. While the EIS excludes the USEC DU from its analysis, it also implies that there is a reasonable probability of it becoming DOE's responsibility. Consequently, DOE may want to consider that possibility in its impact analysis. 89-18

4. Summary Table S.2

On pages S-17 and S-18, irreversible adverse health effects as well as adverse effects are identified for cylinder accidents. This terminology should be defined and explained by a footnote in the table. A more quantitative measure of chemical effects should be included, as uranium toxicity is a major concern that needs to be addressed. In addition, the cylinder accident scenarios should indicate estimated quantities of the releases of uranium and HF 89-19

COMMENTOR NO. 89: UNITED STATES NUCLEAR REGULATORY COMMISSION (CONT'D.) WASHINGTON, D.C.

shown in the table including the time period of exposure and length of time of the release. Finally, DOE should indicate exposures to involved workers instead of only exposures to the public and non-involved workers.

5. New Madrid Seismic Zone

Page S-34 mentions "the conversion accidents estimated to have the largest potential consequences were...involving the rupture of tanks of anhydrous HF or ammonia" would be caused by a large earthquake which has an assumed frequency of less than 1 in 1 million per year of operations. DOE should mention that a facility built near the Paducah Gaseous Diffusion Plant would be located near the New Madrid seismic zone. Additional seismic analyses would need to be performed for such a facility as well as an accident analysis taking into account the seismicity of this area. 89-20

6. Non-Shield Use of DU

Page 2-21 mentions uses for DU such as developing penetrators, vehicle armor, and industrial ballasts. No mention is made of quantities or relative percentages of the DU inventor that these uses would require. Also, it is not self-explanatory that DU cask manufacturing and uses bound all of the potential uses. For example, metal uses would appear to require a significant amount of alloying and/or machining, and involve handling and disposal concerns. DOE may wish to include a longer discussion and a more comprehensive explanation. 89-21

7. Leach Rates for Disposal

Page 2-22 briefly mentions leach rates and waste forms, and states that grouted wastes are representative of immobilized waste forms with low leach rates, with the implication that grouting is also representative of vitrification. DOE should clarify this text, as grouting may be representative of vitrification for some parameters (e.g., facility size) but not representative in others (e.g., energy usage, emissions). Also, while grouting should provide for somewhat lower leach rates as compared to the ungrouted material, vitrification would be expected to provide 5 to 6 orders of magnitude lower leach rates than grouting. Furthermore, a quantitative mention of the values of the leach rates is beneficial, as each uranium form will exhibit different rates. These factors may be an issue for some disposal options and consequently should be discussed. 89-22

8. Disposition of Empty Cylinders

Often when a cylinder is processed, an amount of UF_6 (the heel, containing U^{235} daughter products) remains in the cylinder. DOE should describe how the cylinders will be cleaned and how the heels are going to be dealt with. Furthermore, though potential options for the disposition of empty DU cylinders are listed on page 2-23, the impacts are not included. It would seem reasonable to provide a brief discussion on these options and include impacts from cylinder disposition in the EIS. 89-23

1555

COMMENTOR NO. 89: UNITED STATES NUCLEAR REGULATORY COMMISSION (CONT'D.) WASHINGTON, D.C.

8

9. Water and Soil Impacts from DU Disposal

The summary table of impacts (Table 2-2) and the supporting text for the water and soil section (page 2-50) note that the groundwater uranium concentrations will exceed drinking water guidelines. It is recommended that the expected concentrations are also expressed in terms of individual radiation doses. 89-24

10. Waste Management

Pages 2-52 et seq present a summary of the waste management impacts from the alternatives. Comparisons of the amounts generated are primarily made relative to the DOE waste management system, however, these facilities could also be commercially operated under NRC or State regulations. Consequently, DOE should consider adding a comparison to commercial LLW generation rates. The section should also include estimated uranium levels for the magnesium fluoride waste (from DU metal production) and discuss the aspects of DU disposal, including the potential need for either a dedicated or a deep disposal facility. 89-25

11. DOE's Preferred Alternative

Section 2.5 (pages 2-54 et seq) present DOE's preferred alternative. This section would benefit from a greater discussion of the potential uses of DU, including the SNF storage casks. 89-26

12. Generic Sites

Pages 3-58 et seq present information on the generic sites for wet and dry locations for disposal, and mention that the site data for each are derived from actual wet and dry sites. It is suggested that the actual sites which provide the basis for the generic locations be listed. 89-27

13. PEIS Time Period

Page 4-2 lists a 41 year time period for the EIS (through the year 2039), and indicates activities beyond 2039 would be subject to appropriate NEPA reviews and decisions in the future. This appears to truncate the analyses for some of the alternatives which might influence the selection of the preferred option; for example, impacts from wastes in a disposal cell are unlikely to occur by 2039, major cylinder/container replacements may be required for the storage option in the 10-20 years after 2039, significant applications for use of the DU may not have developed etc. DOE may wish to consider a time period consistent with the logical conclusion of the options or their "life-cycle," which may require a timeframe beyond 2039. 89-28

14. Background Radiation

On page 4-15, the example with background radiation appears to have left "year" out of the units. 89-29

15. Waste Management Approach

1556

COMMENTOR NO. 89: UNITED STATES NUCLEAR REGULATORY COMMISSION (CONT'D.) WASHINGTON, D.C.

9

Page 4-25 lists the waste management approach. Inclusion of waste categorization methods and categories (e.g., per 10 CFR 61), and current commercial capabilities would be beneficial. DOE may also want to discuss if there are any waste management situations that require the development of additional waste management capabilities and/or capacity. 89-30

16. No Action and Storage Alternatives

Pages 5-3 and 5-19 discuss the estimated cylinder failure rates for the No Action and UF6 Storage alternative. These appear to use the opposite ends of the failure rate range - No Action uses the lowest failure rate, while Storage uses the highest failure rate - without explanation. Also, the existing cylinders may not have adequate wall thicknesses under either alternative due to both internal and external corrosion over the years (see Appendix E), and the DU may have to be transferred to new cylinders within the timeframe covered by the EIS. Furthermore, if the cylinder wall thicknesses deteriorate significantly, they may not meet American Society of Mechanical Engineering (ASME) code for processing. DOE should consider presenting a discussion on these items in the text. 89-31

17. Tank Rupture Frequencies

On page 5-40, Table 5.4 lists tank rupture accidents as "incredible" events, when typically they are assigned a value corresponding to the "extremely unlikely" frequency bin. A brief discussion of the basis for DOE's assessment is recommended. 89-32

18. Surface Water Dilution of Effluents

On page 5-51, the text indicates effluent levels greatly exceeding EPA guidelines for uranium, but notes that the concentration would be much lower and below the guideline after dilution in nearby surface water. This should be clarified, and potential dose consequences of these effluents presented. 89-33

19. Land Use Requirements

Page 5-55 identifies land use requirements for the facilities. Contrary to the small land requirements indicated in the PEIS, conversion and metal use plants would be anticipated to have larger land use because of facility size and require potentially larger setbacks for potential accident mitigation from uranium releases. The LES EIS maintains the amount of land required for a generic conversion facility is 1000 acres whereas the PEIS indicates only 30-40 acres are necessary. The text also does not indicate if any major setbacks, protective action distances (PADs), or planning zones are likely to be needed around the facility because of the handling of large quantities of DU, the hexafluoride, and/or the metal (including melting operations). DOE should consider a discussion in the text on these subject matters. 89-34

20. Oxide and Metal Accident Consequences

Pages 5-55 et seq discuss the use and impacts of uranium dioxide as shielding, and pages 5-66 et seq discuss the use and impacts of uranium metal as shielding. Some of the values imply non-intuitively obvious lower impacts from a metal route as compared to the oxide route; it is 89-35

COMMENTOR NO. 89: UNITED STATES NUCLEAR REGULATORY COMMISSION (CONT'D.) WASHINGTON, D.C.

recommended that these are discussed and explained in more detail. For example, the text on page 5-71 estimates the highest consequences from an accident with the metal route as 16 mrem (from a fire involving three cylinders, an energetic accident with reactive materials), as compared to 270 mrem (from an earthquake during uranium dioxide storage, a low energy event with non-reactive materials) - there is no explanation for the difference. Also, the supporting information in Appendix H shows similar inconsistencies; the unlikely accidents for the oxide (Table H-5, page H-18) are significantly higher than the corresponding accidents for the metal (page H-17). Page H-17 also contains apparent inconsistencies; the mishandling/dropping of solid DU metal accident releases a greater quantity of uranium than the molten uranium accidents. Upon further review, the source of these apparent anomalies goes back to Section 6.11 of the Engineering Analysis Report (EAR). These anomalies and inconsistencies include:

- Page 6.11-7-6 uses a damage fraction of 30% for the metal and 100% for the oxide; comparable or lower values would seem appropriate for the oxide.
- Page 6.11-7-7 uses a damage fraction of 1% with molten uranium metal and 100% for the oxide for a mixer/melter accident; these values for the damage fraction appear to be contradictory and may have been inadvertently reversed (i.e., they should be 100% for the metal and 1% for the oxide).
- A similar incongruity exists for the Mixer/Melter Discharging Accidents on pages 6.11-7-7 and 6.11-7-8, where the damage fraction for metal use is 1% while 100% is used for the oxide route.
- On page 6.11-7-8, the metal shield failure uses a damage fraction of 0.1% while the oxide shield failure damage fraction uses 100%; again, these appear to be reversed. Also, the failure modes may be completely different, and this does not appear to have been captured by the scenarios and calculations.
- The stated release fractions for the metal accidents on these pages appear to be unconservatively low; DOE-HDBK-3010-94 recommends 1E-02 as bounding for "disturbed molten metal surface with high turbulence" and 1.0 for "small molten metal drops hurled through air or explosion of entire metal mass." The melter failure and discharge accidents would appear to be in the latter category, and most of the other accidents would appear to be bimodal, with some portions of the release in both categories. These effects would increase the source terms for the analyses.
- The oxide and metal design basis events are analyzed with different bases; the high efficiency particulate air (HEPA) filters for the metal facility are assumed to keep functioning, while the oxide HEPA system does not function. This seems inconsistent.
- The oxide release fractions appear to be based upon fuel pellet data sintered from powders (i.e., submicron grain size), sintered too close to the theoretical density of uranium dioxide (11 g/cc). It is not clear how this data applies to the lower density

89-35 (Con't.)

1557

COMMENTOR NO. 89: UNITED STATES NUCLEAR REGULATORY COMMISSION (CONT'D.) WASHINGTON, D.C.

uranium dioxide pellets (i.e. 6 g/cc, expect a somewhat higher release fraction) and the density of the solution formed gelation particles (much larger grain sizes - expect a lower release fraction).

- Table H-5 of the PEIS categorizes a furnace failure as an "incredible" event while the EAR (page 6-11-7-6) implies 8E-5/yr.

89-35 (Con't.)

These points should be discussed and explained better in the PEIS, and values corrected as required.

21. Metal Cask Waste

Page 5-76 of the PEIS presents waste management for the metal cask manufacturing route. Waste management appears to have overlooked secondary wastes related to manufacturing, which are unique to uranium metal. For example, induction furnaces for uranium metal are usually lined with graphite, which requires periodic removal and replacement (sometimes as frequently as every ten charges). Also, while the proposed approach appears to use primarily direct casting, some uranium metal machining operations may be required, and, historically, these generate significant wastes containing partially oxidized uranium metal. The PEIS should include these potential impacts that primarily affect only the metal route.

89-36

22. Waste Disposal

Section 5.6 (pages 5-78 et seq) and Appendix I present the impacts from disposal of the DU, for both the operational phase and the post-closure period. The radiological impacts from the accidents seem unexpectedly high. For example, public doses of up to 1.1 rem and noninvolved worker doses as high as 140 rem are determined, apparently due to earthquake initiated events, without explanation. The routine impacts also seem high for the post-closure phase and appear to follow the radiological order: mine impacts > vault impacts > trench impacts. Calculations appear to use an infiltration area effect and do not account for chemical form, solubility, and kinetic effects. Table I.31 contains values of zero for the dry site doses for all three disposal approaches, and no collective dose estimates are included. These points are not obvious and it is recommended that they are explained in more detail.

89-37

23. Other Uranium Forms

The primary uses the PEIS focuses on are uranium in concrete and DU metal for the shielding material. Other uses exist such as vitrified pellets with UO_3 and UO_2 composite material in a SNF cask. These have been published in the open literature and should be mentioned and referenced.

89-38

24. Low Estimates of Staffing Levels

The estimated numbers of staff required for several of the alternatives in the PEIS seem low. For example, the UO_2 pellet approaches use similar technologies to existing fuel fabrication

89-39

COMMENTOR NO. 89: UNITED STATES NUCLEAR REGULATORY COMMISSION (CONT'D.) WASHINGTON, D.C.

facilities of 1,000 te/yr capacity which employ several hundred people. However, the PEIS estimates only 300 workers will be needed for a plant of 20,000 te/yr capacity. This seems low even considering economies of scale. | *89-39 (Con't.)*

Subject: DUF6 PEIS Comments

Please accept my comments below on the DUF6 PEIS. I did my best to get them to you as soon as possible. Thank you for the opportunity to comment.

Brian Bowers

****

1. General - The PEIS describes the preferred alternative as "to use the entire inventory of material." This is misleading. The goal is to use the material but since there is little demand at present, the actual action is continued storage indefinitely. Demand for use of the material, as stated in the PEIS, is quite limited at present. It is accurate to say that the material would be converted and reused as demand dictates but it is misleading to emphasize the speculative portion of the alternative when, in reality, it could be stored as UF6 for a long time. I agree that the best alternative is to continue the safe storage of the UF6 and convert/use it as demand dictates, but I think the PEIS needs to clearly present the preferred alternative in those terms rather than mislead the reader into focusing on uses that have yet to be identified. | *90-1*

2. General - The main conclusions of the cost analysis report should be included in the analysis of socioeconomics in the PEIS. It is misleading and irresponsible to analyse only the perceived benefits (employment, increased local revenues) and not consider the costs. Who is going to pay for these actions and how much is it going to cost? In this era of taxpayer dissatisfaction, consideration of costs must be included in any socioeconomic analysis as this is certainly a potential impact on the human environment. | *90-2*

3. General - The PEIS does not adequately evaluate the impacts associated with the empty steel cylinders that would be generated in the event of conversion and/or reuse of the material. What to do with over 46,000 14-ton, radioactively contaminated steel cylinders is an extremely important part of the long-term management strategy and must be appropriately analyzed and considered in any decision making. The PEIS does not demonstrate adequate analysis of this issue. | *90-3*

4. General - I understand the accident analysis methodology in terms of probability and consequence. However, I could not find in the PEIS where such "statistical" accidents were matched to real accident scenarios. From comments on other documents, it is clear this is what the public | *90-4*

COMMENTOR NO. 90: BOWERS, BRIAN (CONT'D.)
OAK RIDGE, TENNESSEE

wants to know. They want to know about the probability and consequences of a tornado and an earthquake. I could not tell if such scenarios were adequately represented in the PEIS.

5. General - There are still numerous places where the West Kentucky Wildlife Management Area is incorrectly referred to as the Western Kentucky Wildlife Management Area. — 90-5

6. p. S-3, para. 2 - I challenge the notion that the current management plan calls for conversion to triuranium octaoxide. Where is this written? How would conversion and disposal be paid for? This is not considered part of No Action. — 90-6

7. Section 3, general - Based on the text on page 3-1 and Figure 3.1, the PEIS describes the "Paducah site" as including all of the land owned by DOE including that licensed to the Commonwealth of Kentucky. The PEIS describes the "PGDP" as a 750-acre industrial area within the Paducah site. As there is a security fence around the 750-acre area (actually 748 acres) and the area outside this fence is primarily wooded, it is appropriate to discuss these separately, where necessary, to distinguish differences in the two environments. However, the PEIS makes numerous mistakes when describing various aspects of the two environments, apparently due to confusing the "Paducah site" with the "PGDP." For example, Section 3.1.6.3 states that there are no wetlands "identified on the Paducah site by the National Wetlands Inventory." This statement would be correct for PGDP but not the Paducah site. These errors are pointed out in the specific comments below. — 90-7

In addition, the PEIS often does not use the most current and accurate information readily available. For example, the National Wetlands Inventory does not provide very useful information for anyone wanting to know about wetlands that occur on the Paducah site. Two reports that should be used include:

<paraindent><param>left</param>U. S. Department of the Army, Corps of Engineers - Nashville District and Waterways Experiment Station, <italic>Environmental Investigations at the Paducah Gaseous Diffusion Plant and Surrouding Area McCracken County, Kentucky</italic>, Volumes I -V, May 1994

</paraindent> — 90-8

<paraindent><param>left</param>CDM Federal Programs Corporation, <italic>Investigation of Sensitive Ecological Resources Inside the Paducah Gaseous Diffusion Plant</italic>, August 19, 1994, Document Control Number 7916- 003-FR-BBRY

</paraindent>

The first document reports on wetlands, floodplains, cultural resources, and threatened/endangered species on and near the PGDP site, primarily outside of the plant security fence. The latter document reports on wetlands and threatened/endangered species inside the plant security fence. There have been some informal updates to these reports since they were issued.

1559

COMMENTOR NO. 90: BOWERS, BRIAN (CONT'D.)
OAK RIDGE, TENNESSEE

Two sensitive resources common to the DOE reservation at PGDP but not analyzed in the PEIS are 100-year floodplains and prime farmland. Granted, there would not be much analysis based on the PEIS approach of deferring site-specific evaluations to later NEPA documents. However, the PEIS should include these resources in site descriptions and evaluate for potential impacts at the appropriate time. Information on floodplains at PGDP is reported in the Corps of Engineers report referenced above. Prime farmland information is available from site personnel or local offices of the Natural Resources Conservation Service. — 90-9

Section 3 should be thoroughly reviewed and revised to accurately describe the affected environment. Consequently, analysis of potential impacts should be revised, where necessary. — 90-10

8. Sec. 3.1 - The PEIS does not provide an accurate portrayal of the size and location of the West Kentucky Wildlife Management Area (WKWMA). WKWMA totals about 6823 acres of which the state owns 3106, 1986 acres are licensed from DOE, and 1731 acres are licensed from the Tennessee Valley Authority. WKWMA completely surrounds PGDP. Much of the area referred to in the PEIS as the Paducah site is also part of WKWMA. This is not reflected in Figure 3.1 or in some of the analyses of impacts. — 90-11

9. Sec. 3.1.5.1 - DOE received a new KPDES permit on March 13, 1998. The PEIS should be revised accordingly to reflect the changes. — 90-12

10. Sec. 3.1.6.3 - The PEIS is incorrect - there are many wetlands on the Paducah site. In fact, some were filled in to build the latest cylinder storage yard. — 90-13

11. Sec. 3.1.6.4 - The information here with regards to threatened and endangered species is misleading. First, there is a lot of significant potential summer habitat for the federally endangered Indiana bat so it is quite likely it occurs on the Paducah site. Second, there is no state list with any enforceable protection standards. I applaud the PEIS for looking at these "state-listed" species but their legal status should be made clear. — 90-14

12. Sec. 3.1.10 - Overall, the description of cultural resources is current and well done. However, there is at least one cemetery on the Paducah site, just north of PGDP. — 90-15

13. Sec. 5.8 - The PEIS purports to include other past, present, and future actions, and non-DOE actions in its cumulative impacts analysis. However, no specific actions are identified. In order for the reader to assess if cumulative impacts were adequately assessed, the PEIS needs to include specific information on what other activities were considered. — 90-16

14. Pages D-3 to D-5 tell me all I really need to know regarding potential impacts. Continued storage (No Action Alternative) would result in an estimated worst case of 59 cylinder breaches through 2039. Impacts from these breaches would be minimal. On the other hand, the action alternatives would result in an estimated worst case of 731 breaches through 2039. On the basis of potential impacts alone, it is — 90-17

COMMENTOR NO. 90: BOWERS, BRIAN (CONT'D.)
OAK RIDGE, TENNESSEE

clear that No Action is environmentally preferrable. The PEIS needs to clearly state this in all summary text areas.

15. General (Overall Conclusion) - The PEIS clearly supports continued storage of the material as UF6 until viable uses are identified (called No Action in the PEIS). Continued storage, with the assumption of at least partial use by the year 2039, is shown to have the fewest environmental impacts. It is also, by far, the least costly alternative although the PEIS is deficient in showing this. Finally, continued storage for several more years with little adverse impact would allow for further demands for the material to be developed and speculative measures, such as conversion or consolidation, would not be necessary at this time. It is disappointing that all of DOE's effort did not result in any significant, realistic near-term uses for the material but at least the PEIS shows that continued storage as UF6 at the current sites would not present unmanageable problems. *90-18*

Re: Draft Programmatic Environmental Impact Statement for Alternatives Strategies for the Long-Term Management and Use of Depleted Uranium Hexaflouride

Dear Mr. Bradley:

Thank you for your letter dated December 18, 1997 and the Draft Programmatic Environmental Impact Statement for Alternatives Strategies for the Long-Term Management and Use of Depleted Uranium Hexaflouride which accompanied it. It is our agency's opinion that the depleted uranium hexaflouride (DUF_6) should be converted to a form that is more stable and less hazardous, such as uranium oxide (U_3O_8), for long term storage or until an alternate use can be found and we applaud your management program for proposing this alternative. In accordance with our responsibilities under the National Environmental Policy Act (NEPA) and Section 309 of the Clean Air Act, we have reviewed the information that you submitted. Based on the information provided, we have rated this DEIS EC-2. The EC portion of the rating indicates that we have environmental concerns and the 2 portion of the rating indicates additional information, data, analyses or discussion should be included in the final EIS. To satisfy these concerns, please provide additional discussion, data, and/or analysis to addresses the following: *91-1* *91-2*

1. A single location for a conversion pilot plant should be identified to evaluate the engineering and other demands of converting the material. After experience has been gained operating a stabilization process in a single location, consideration should be given to whether the single plant, or plants at multiple locations would be best suited to converting any remaining material. *91-3*

2. Until such time as the DUF_6 is converted to a more stable form, a long-term storage strategy should be developed to address issues surrounding deteriorating storage canisters. *91-4*

Recyclable/Recyclable - Printed with Vegetable Oil Based Inks on 50% Recycled Paper (20% Postconsumer)

COMMENTOR NO. 91: UNITED STATES ENVIRONMENTAL PROTECTION AGENCY (CONT'D.) CHICAGO, ILLINOIS

3. Before transporting DUF_6 in storage canisters with deteriorated or uncertain integrity, secondary containment or other engineering measures should be employed to ensure safety comparable to that provided by new canisters. *91-5*

4. U.S. Department of Energy (USDOE) and the United States Enrichment Corporation (USEC) should apply a single, compatible methodology to discharge their respective responsibilities for the materials. *91-6*

5. Conversion of this material should not be dependant on market demand. DOE should include plans to seek funds from Congress for conversion of all DUF_6. *91-7*

6. An appropriate budget should be submitted to adequately fund this process for the necessary time periods. Funding needs to be provided to insure the reduction of potential risks to the environment and to public health. *91-8*

Be advised that you may require a Section 404 permit from the U.S. Army Corps of Engineers if wetlands will be impacted during this project. You should be in contact with them to determine whether this project will require such a permit. In accordance with the Section 404(b) (1) guidelines of the Clean Water Act, wetland impacts must be avoided and/or minimized whenever possible, and satisfactory compensation for unavoidable impacts must be provided.

With respect to provision of compensatory wetlands, our Agency routinely finds that a minimum of 1.5 acres of compensatory wetlands are necessary to offset the loss of each acre of naturally occurring wetlands impacted by the project at issue. In addition, the compensatory wetlands should be designed to replicate as closely as possible the specific mix of types, functions and values provided by the project-impacted wetlands. The compensatory wetlands should be established via the process of restoration to the extent feasible, and they should be located in an area as close as practicable to the project-impacted wetlands. *91-9*

We trust that you will find these comments useful. If you should have any questions, please contact me at 312-886-7342.

Sincerely,

Michael W. MacMullen, Manager

Re: Draft Programmatic Impact Statement for Alternative Strategies for the Long-Term Management and Use of Depleted Uranium Hexafluoride.

Dear Mr. Bradley:

The Natural Resources and Environmental Protection Cabinet (NREPC) serves as the state clearinghouse for review of environmental documents generated pursuant to the National Environmental Policy Act (NEPA). Within the cabinet, the Commissioner's Office in the Department for Environmental Protection coordinates the review for Kentucky State Agencies.

We have just gotten response from one of the Kentucky State Agencies, the Division of Water, which has comments (attached) on the UF_6 Management Strategy that you may be able to use in your considerations for selecting alternative strategies. I am hopeful that you can still incorporate these comments. If, and/or when, a final environmental impact statement is published, please send 16 copies of the document, and I will coordinate responses from the Kentucky State Agencies.

If you should have any questions, please contact me at (502) 564-2150, ext. 112.

Sincerely,

Alex Barber

MEMORANDUM

TO: Alex Barber
State Environmental Review Officer
Department for Environmental Protection

FROM: Timothy Kuryla TK
EIS Coordinator
Division of Water

DATE: June 4, 1998

SUBJECT: PDEIS, Long Term Management of UF_6 (No Apparent Kentucky County), SERO 980114-02

The Division of Water has reviewed the Programmatic Draft Environmental Impact Statement, prepared by the U.S. Department of Energy, Office of Nuclear Energy, Science, and Technology, regarding the long term management and use of depleted Uranium Hexafloride (UF_6) (no apparent Kentucky county). The Division finds the current facility emergency response contingency plans appear to be adequate. If UF_6 were to be used or stored in Kentucky, then pursuant to 401 KAR 5:037, a groundwater protection plan would be required.

Subject: Comments for UF6 meeting on June 2, 1998

Dear Mr. Bradley:

I would like to submit the following comments for public use in your upcoming UF_6 meeting:

1. I believe that DOE offers reasonable evaluations and wise preferences among the alternative strategies, i.e., preferring 100% use of the UF_6 (i) for conversion to uranium as oxide or metal and (ii) using as much of the material as DOE can to leave it recoverable.

Roughly 99 times the potential energy of the bomb U-235 material remains with the U-238 (DU) residue--as some of your readers will know. This DU could all be used in breeder reactors to generate future electric power, and then it would have high economic value.

It would be an environmental tragedy to throw it away, yet many people urge discarding this "useless" metal.

I commend DOE's for trying its best to save the material and for how it has identified DU use for radiation shielding. This would leave the DU available and not wasted. Other uses are sought.

One of the saddest parts of this situation is that all the DU metal could be saved if we would--the DU volume from all UF_6 (and all that energy) could be stored in a cube less than 100 feet on edge. But such storage is probably not politically feasible at this time.

93-1

COMMENTOR NO. 93: SANTA FE ALLOYS (CONT'D.)
ALBUQUERQUE, NEW MEXICO

2. The draft PEIS serves well in justifying the DOE preference above, but care must be taken that postulated processes are reasonably justified experimentally before they are heavily funded. Sometimes, an overall process is not well evaluated to see if the pieces have been combined in ways that are not awkward. *93-2*

Specifically in the case of the selected CMR production of DU metal, there should be evaluations and experimental confirmation of whether the old hydrogen reduction of UF_6 should be a precursor of the metal production, or if other approaches are better. Also, features such as minimization of radioactive transport (which the public dislike) should also be considered carefully.

3. The people doing the postulated process writeups have done well, but further input is needed. Your public meetings may provide that input, especially as combined with private meetings from outside DOE. *93-3*

Thank you for this opportunity for input.

Sincerely,

Guy R. B Elliott

3.2 DOE RESPONSE TO COMMENTS

Commentor No. 1: Hollinger, Wade

Comment 1

Make a reasonable risk-based, economical decision, hire a team of lawyers and get on with getting rid of the stuff! Just take it for granted someone is going to sue DOE because they want you to make it so that it was never here in the first place (impossible) and put your lawyers to work, by the time it gets out of court you'll have the stuff gone. MAKE THE DECISION AND DO IT! I'm tired of supporting all you do nothing bureaucrats! A NEPA review and going out to the public was not necessary for this. You know what has to be done. DO IT!

Response 1

DOE has determined that the selection of a long-term management strategy for depleted uranium hexafluoride is a major Federal action with potentially significant environmental impacts. As such, the National Environmental Policy Act of 1969 requires DOE, as the responsible Federal agency, to prepare an environmental impact statement. The National Environmental Policy Act also requires DOE to include public involvement activities during EIS preparation. The results of the EIS will be used, together with economic and engineering analyses, to select a management strategy which will be announced in a Record of Decision.

Commentor No. 2: Ragan, Guy

Comment 1

PEIS: S.4 SUMMARY AND COMPARISON OF IMPACTS FOR ALTERNATIVE MANAGEMENT STRATEGIES: What is the basis for the consequences stated? In other words, if the no-action alternative creates 110 jobs over 40 years, that is as compared to what? Compare it to continuation of the present situation? But continuation of the present situation is not an option. The PEIS states its impacts relative to an inconceivable baseline. According to DOE's "Recommendations for the Preparation of Environmental Assessments and Environmental Impact Statements, "the no-action alternative provides an environmental baseline against which impacts of the proposed action (and alternatives) can be compared." Therefore, the consequences should be stated as deviations from the no action alternative. For example, as compared to the No Action alternative, for operations, Long-Term Storage creates 10 jobs per year over 20 years. Then there are 110 federal jobs from 20 to 40 years. For construction, no jobs are created relative to No Action. Comparisons like this should be made explicit by stating all consequences as deviations from the No Action alternative. This comment applies to all types of environmental consequences, not just socioeconomic impacts.

Response 1

In EISs for proposed new facilities or programs, the no action alternative does indeed represent an environmental baseline, often described as no change to the existing environment. However, DOE is currently managing existing depleted uranium hexafluoride cylinders in existing facilities; so that, even if DOE were to take no further programmatic action, cylinder storage would continue at the three sites. Continued cylinder management includes steps necessary to maintain the cylinders in a safe and environmentally protective condition, which means that in the future the no action alternative will also have impacts on the natural and human environment. Recognizing this fact, the PEIS evaluates the impacts of all alternatives, including the no action alternative. This allows comparison of the impacts of alternatives in a manner similar to other NEPA assessments and allows alternatives to be compared on equal footing. The impacts of all the alternatives, including the no action alternative, are presented in Chapter 5 and compared side-by-side in Sections 2.4 and 2.5 of the PEIS. Any differences among the alternatives can be discerned from Tables 2.2 and 2.4 and the accompanying text in Sections 2.4 and 2.5.

Commentor No. 3: Ellison, Phillip
Idaho National Engineering and Environmental Laboratory

Comment 1

I briefly reviewed the UF_6 Draft PEIS. It appears to be a well developed and documented effort. One area that you may wish to improve is the hazardous analyses of the HF and NH_3 tank farms. Other events, including tornado induced missiles may wish to be addressed. These events may have been covered but I was unable to locate data of the results of the analyses.

Response 1

Impacts associated with potential releases from HF and NH_3 tanks during both normal operations and postulated accidents are addressed in the PEIS. The impacts are summarized in Table 2.2, and discussed in detail in Appendix F, Section F.3, and in the backup report for the PEIS (Policastro et al. 1997; the full citation is provided in Chapter 8 of the PEIS).

The analysis of accident scenarios for continued cylinder storage (Section D.2.2 of the PEIS) was based on the range of potential accident scenarios considered in the safety analysis reports (SARs) recently prepared for each of the three storage sites (LMES 1997f-h; the full citations are provided in Chapter 8 of the PEIS). The SARs considered a range of potential accident scenarios that could be associated with current storage activities, including natural phenomena events such as tornadoes. The accidents considered in the PEIS for current depleted UF_6 cylinder storage were extracted from those evaluated in the SARs. The accidents selected for the PEIS analysis were those accident scenarios in the SARs that resulted in the greatest potential consequences at each of the three storage sites. These accidents did not include tornado scenarios,

which were found in the SAR analyses to have lesser consequences than the accident scenarios discussed in the PEIS. The text in Section D.2.2 of the PEIS has been modified to clarify this point.

For the other cylinder management options (i.e., cylinder preparation for shipment, conversion, long-term storage, manufacture and use, and disposal), analysis of adverse impacts associated with tornado-induced missiles were conducted, but for purposes of conciseness, the results were included in the PEIS only if the accident affected a greater number of people than any other accident in the frequency category (see Sections E.3.2, F.3.2, G.3.2., H.3.2, and I.3.2). Impact estimates for tornado-induced missile accidents are presented in the PEIS for some conversion options (see Tables F.8-F.11) and for some manufacture and use options (see Tables H.6-H.9). Tornado-induced missile accidents were not included in the appendices for cylinder preparation, long-term storage, or disposal because they affected fewer people than other accidents in the same frequency category. However, the results of impact analyses for all accidents considered (including tornado-induced missiles) are given in the backup report by Policastro et al. (1997) referenced in the PEIS. This report and other PEIS supporting documents are available for review at DOE public reading rooms near the three current storage sites and in Washington, DC (listed in the Notice of Availability), and can also be obtained by contacting the DOE program manager identified on the cover sheet of the PEIS.

Commentor No. 4: **Dyer, Robert**
Dyer Enterprises

Comment 1

I was happy to see that you are getting better at meeting schedules, only six months late in getting out the two volume Draft PEIS for the alternative strategies for the future of the few cylinders of depleted that are stored around.

I have spent some time reading it and thinking about the way it is presented, both from my own point of view as one who knows what the stuff is and also from the point of view of one whose knowledge of depleted UF_6 is from these writings. As you can see by my comments, I think you missed your opportunity to inform the unknowing and get them on your side once you make the long-term management strategy.

I am interested in your reaction to my comments, and maybe we can work together to improve the document.

As a result of several days of pouring through the two volumes of the referenced document, I have the following comments and suggestions to make. I believe that I am qualified to review the work because I have had 53 years of experience in the operation and design of the gaseous diffusion process in Oak Ridge while working 35 years for the operating contractor followed by 15 years for

DOE. I have seen the depleted cylinders at all three plants, I actually filled some of them in Oak Ridge, I know the chemistry and physical properties of UF_6, I was on the committee to investigate the cause and effect of the wall failures of the two Portsmouth cylinders and I am a voting member of the ANSI N14.1 Uranium Hexafluoride-Packaging for Transport standards committee that establishes cylinder design and fabrication criteria. Twice, I have presented my training course "Fundamentals of Gaseous Diffusion Plant Operations" to members of the Argonne National Laboratory staff who have prepared this report. I will start with some general comments and proceed to some specific ones.

Response 1

The commentor's qualifications and statement of accomplishments are noted.

Comment 2

UF_6 Storage Cylinder Description: Let me quote some of the words in the box on Page S-1 in Volume 1. "Sufficient information must be included in the EIS for reviewers to evaluate the relative merits of each alternative."

It seems to me that you have to describe the problem in order for reviewers to see the merits of any of the possible solutions, including continued long term storage. In this case, the problem is what to do with the large quantity of depleted uranium hexafluoride that has accumulated at the gaseous diffusion plants in Oak Ridge, TN, Paducah, KY and Portsmouth, OH. I think you have to accept the fact that UF_6 is not a commodity that is familiar to the general public, especially those living in the vicinity of the plants. Therefore the description of the depleted UF_6 in storage cylinders on page S-2 is grossly understated. "Depleted UF_6 is stored as a solid at all three sites in steel cylinders. Each cylinder holds approximately 10-14 tons (9 to 12 metric tons) of material."

The next mention of stored cylinders of UF_6 that I found was on page B1 in Volume 2. "Depleted UF_6 has been stored in steel cylinders in outdoor yards at the three DOE storage sites since the 1950s. Most cylinders have either a 10- or 14-tons (9 to 12 metric tons) capacity and a nominal wall thickness of 5/16 in. (0.79 com or 312.5 mil)." It is a little more correct, in stating the cylinder capacity as 10 or 14 tons but is still oversimplified:

I, as a reviewer, know the details of the design criteria and methods of fabrication for the storage cylinders, and know that the UF_6 is being safely stored at the plants. I do not think the smidgen of information you have included will sufficiently inform and convince the farmer working the fields next to the plant, or the housewife in Wakefield, Ohio, or the new tenant in one of the K-25 buildings that they have nothing to worry about. These people should not (be) forced to imagine what is in those somewhat rusted cylinders they see stored in the yards. I think you should at least use some of the pictures and descriptions of the cylinders form the ORO 651 series of documents. I can give you copies of ORO 651 Rev 5 and ORO 651 Rev 6, but you will have to buy the successor document USEC 651 Rev 7 from the USEC for which they charge $5.00. Also, and more

importantly, you should point out that there is an American National Standard, ANSI N 14.1, Uranium Hexafluoride-Packaging for Transport, which governs the quality of the material in and fabrication of these cylinders. You should be sure to point out that the cylinder has only one valve for filling and emptying. This valve is located at the 12 o'clock position on one of the ends.

Assuming you expand your description of the cylinders, then you need to tell the people what is in them. You need to tell them that the U-235 isotope concentration has been reduced from the naturally occurring 0.711% to 0.2-0.3%, resulting in a proportional increase (in) the concentration of U-238.

You need to tell them that UF_6 is a chemical compound that has one atom of uranium combined with six atoms of fluorine. It can be either a solid, a liquid, or a gas depending upon its temperature. In the storage yards it is a solid in the bottom of the cylinders and a gas at subatmospheric pressure in the top. If a cylinder is heated, the solid will melt to a boiling liquid at 147 degrees F. You need to tell them that it is a greater chemical hazard than a radioactive one.

You need to tell them how UF_6 reacts with the iron on the inner surfaces of the steel cylinder to form a corrosion inhibiting, protective surface layer of iron fluoride. This protective coating insures the UF_6 inside the cylinder will not react with and corrode the cylinder wall, i.e., if you protect the outside of the cylinder, and prevent it from rusting away, the UF_6 can stay in storage in the cylinders forever.

Response 2

In response to this comment, more detailed descriptions of the characteristics of both the storage cylinders and depleted UF_6 have been added to Section S.1.1 of the PEIS Summary and Section 1.1 of Chapter 1. Detailed information has been added which addresses the physical characteristics of the cylinders which are used for storage, as well as the physical and chemical characteristics of the depleted UF_6. Photographs have also been included which detail the cylinder and its associated parts which are referenced in the document, such as the cylinder skirt and stiffening rings.

Both the ORO-651 series of documents (DOE's own standard for handling UF_6) and the ANSI N14.1 Standard were reviewed during preparation of the PEIS. The ANSI standard is incorporated under Title 49, Code of Federal Regulations, Section 173.420, the federal regulations governing transport of depleted UF_6. Reference to the 49CFR173 has been added to Section 1.1 of the PEIS.

Comment 3

Cylinder Fill Limits: There are long standing specific requirements that have been used to determine the quantity of UF_6 that can be safely stored in an approved design cylinder. The fundamental concepts of the approach to assuring the safety of the many cylinders of depleted UF_6 stored at Paducah, Portsmouth, and Oak Ridge are certified minimum volume and 5% ullage. In particular, my comment concerns the UF_6 fill-limit and heating temperature limit for 48G cylinders, although the same rationale applies to the other sizes of UF_6 cylinders.

The crucial concept is the certified minimum volume of the cylinder. UF_6 cylinders are fabricated in strict accordance with the drawings and criteria in the American National Standards Institute standard ANSI N14.1, Uranium Hexafluoride-Packaging for Transport. One of the code requirements is that upon final fabrication, in order to determine its exact internal volume, the cylinder will be completely filled with 60°F water and weighed on a scale accurate to 0.1%. The actual water weight obtained is recorded for the individual cylinder certification data and stamped on the cylinder nameplate to conclusively demonstrate that the requirement has been met. For a cylinder to be acceptable, the quotient of the certified full cylinder water weight divided by 62.37 (the weight in pounds of 1 ft^3 of water at 60°F) shall not be less than the published minimum volume. For a 48G cylinder, the minimum volume is 139 ft^3, equivalent to a water weight of 8,669 lbs. Using this method of measurement, the actual internal volume of a cylinder can be determined and if it is not greater than the minimum volume, the cylinder is destroyed.

The density, or weight of a cubic foot of UF_6 has to be known in order to use the certified minimum volume to determine a safe-fill quantity of UF_6 for the cylinder. During the first 20 years of the atomic age, much research work was done to determine the physical properties of UF_6. R. DeWitt of the Goodyear Atomic Corporation made an extensive literature search and compiled the results in a document, GAT 280, "Uranium Hexafluoride: A Survey of the Physico-Chemical Properties January 29, 1960." Data from this source has been used to produce Figures 1 and 2. Solid UF_6 undergoes a significant expansion as it is heated and melts from a solid to a liquid. This is illustrated in Figure 1, Density of Solid UF_6, and Figure 2, Density of Liquid UF_6 235-300°F.

Knowing that all cylinders are larger than the certified minimum volume allows the establishment of a safe UF_6 fill limit for them. This weight is obtained by using the density of liquid UF_6 at the 250°F design temperature of the cylinder and determining how much of this 250°F liquid UF_6 will fill 95% of the cylinder's certified minimum volume. Because all cylinder volumes are certified to be greater than the minimum, this guarantees that there will be at least 5% of the certified minimum cylinder volume as ullage (space above the liquid in the cylinder) when the cylinder is heated to its design temperature of 250°F, and thus there will be no possibility of hydraulic forces developing in the liquid to cause cylinder rupture.

From ANSI N14.1, the minimum volume for a 48G cylinder is 139 ft^3 and from Figure 2, the density of liquid UF_6 at 250°F is 203.7 lbs/ft^3. For a 48G cylinder, the calculation of the fill limit is:

$$95\% \ (139 \ ft^3) \ (203.3 lbs/ft^3 \text{ of } UF_6) = 26{,}840 \text{ lbs of } UF_6$$

Keep in mind that because all cylinders are required to prove that they have greater than a minimum volume, there will always be at least, if not more than, a 5% ullage to prevent hydraulic rupture at the design temperature. At lower than design temperatures, because the density of liquid UF_6 in lbs/ft^3 increases as the temperature is lowered to the freeze point of 147°F, the percentage of the cylinder volume occupied by gaseous UF_6 will increase and be larger than 5%. For example, prior to going to the storage yards, after all the air was evacuated from inside them, the depleted UF_6 cylinders were filled to the fill limit with liquid UF_6 at a temperature of 160°F with a density of 224 lbs/ft^3. The ullage in this case is at least 14%. There can be no hydraulic rupture as long as gas in the ullage provides a cushion.

This fill-limit calculation assures safety if the cylinder is heated to the design temperature and before any material is removed from it. In diffusion plant practice, the cylinder is never heated above 100°F. As UF_6 gas is withdrawn, there is a smaller mass of liquid UF_6 in the cylinder so the ullage increases. Any volatile impurities that may have been in the cylinder will be expelled when feeding is first started so the pressure of the system will correspond to the vapor pressure of UF_6 for the temperature.

When the cylinder is filled with liquid UF_6 to its proper fill limit, and has cooled to room temperature, based on the data in Figure 1, showing the density of 68°F to be 317.8 lbs/ft^3, the solid UF_6 will occupy 26,840 $lbs/317.8 \ lbs/ft^3 = 84.45 \ ft^3/139 \ ft^3 = 61\%$ of the certified minimum volume. The remaining 39% of the volume will be filled with UF_6 gas at subatmospheric pressure or vacuum.

Response 3

Comment noted. However, it should also be pointed out that not all of the depleted cylinders in storage have an individual "certified volume" which allows the actual cylinder volume to be calculated and filled accordingly. Some of the older cylinders in storage must be assessed based on the published ANSI N14.1 minimum volume required and therefore will "appear" to be overfilled.

Comment 4

Minimum Cylinder Wall Thickness. The 0.25" minimum wall thickness specified in ANSI N14.1 and the ORO 651 series for the 48G, 48H, 48 HX, 48 O, and 48 OM cylinders is for a pressure vessel rated at 100 psig. However, this pressure is only achieved if the cylinder of solid is heated 147°F to liquefy the UF_6 and the heating of the liquid continued until the temperature of the liquid is increased to 200°F, as is done in gaseous diffusion plant operations requiring rapid emptying of

the cylinder's contents. However, if by strict administrative control, the cylinder is only heated to a skin temperature of 133°F, 14 degrees below the liquefaction temperature, the UF_6 gas pressure in the cylinder will be atmospheric pressure (14.7 psia), and the UF_6 can be changed directly from solid into gas without going through the liquid phase in order to remove it from the cylinder at a slow rate. (This is the way the French feed their diffusion plant, and is what you have heard referred to as "cold feeding.")

Response 4

The 0.25" minimum wall thickness indicated in the PEIS is specifically a measure by which the existing cylinder inventory at the three G.D.P. sites was assessed for off-site transportation. The criteria for offsite shipping is a minimum of 250 mils (1/4 inch) for thin-walled cylinders which had an original wall thickness of 312.5 mils (5/16-inch). The minimum acceptable cylinder wall thicknesses for the various depleted UF_6 cylinder models is provided in Table 4-3 of the engineering analysis report (LLNL 1997a; the full citation is provided in Chapter 8 of the PEIS), with a description of the requirements for offsite transportation of depleted UF_6 cylinders given in Section 4.0 (Identification and Comparison of Options) in the engineering analysis report.

Comment 5

Radiation Emanating from a Depleted Cylinder of UF_6. There is another aspect of the filled cylinders that I do not think has been adequately covered. There should be a statement concerning how many, or few, curies or sieverts of radiation emanates from one cylinder. Depleted UF_6 is by definition U-238. The handbooks show U-238 to have a half life of 4.47 billion years (about as long as the earth has been around). The thorium and protactinium daughter products have melting points in the range of 1650-1850°F. This means that any daughter products that may be in a cylinder of normal assay UF_6 being fed into the cascade will not be vaporized and expelled from the cylinder with the UF_6 gas at 200°F. In essence, since no uranium daughter products are fed to the cascade, the only ones in depleted UF_6 are the ones that have grown in the past 50 years. With U-238's half life, there can't be more than a handful!

I know from experience that it is very difficult to measure any gamma radiation when scanning the outer surface of a full cylinder in storage with a radiation meter. However, after a cylinder has been heated, liquefied, emptied, and cooled, the scan will show a small amount of gamma radiation on the bottom of the cylinder. Keep in mind that the purpose for which diffusion plants were built was to prepare uranium for fission, either in a weapon or a nuclear reactor. The diffusion process removes 70% of the fissionable isotope found in naturally occurring uranium. The stored depleted uranium has never been used as a fuel in a nuclear reactor where fission products occur in great abundance. There are very few gamma emitting fission products in the depleted UF_6. The gamma radiation in the depleted uranium is coming from uranium decay daughter products. These non-volatile daughter product form extremely slowly throughout the cake of solid UF_6 as uranium decays. They are homogeneously mixed with the solid UF_6 resulting in their gamma rays being shielded by the uranium atoms. Because the daughters are chemically different from the UF_6,

they will not vaporize and be removed from the cylinder as a gas. They concentrate in an ever diminishing pool of liquid until they are all that is left on the bottom. In this location, their radiation is directed downward away from people working with the cylinders. If you sit on top of a cylinder, your butt is at least four feet from the emitters.

I make no pretense of being a Health Physicist, so I find it hard to understand how you can estimate the exposures that people will get, if you don't state the intensity of the radiation at the source. Just one of many examples, Table D.1 page D-6 states as an impact during Storage (1999-2039) the total collective dose to a population within 50 miles (3 sites) will be 0.38 person-rems. How can you be accurate to two decimal points when you don't know how much radiation, if any, is coming from a cylinder of depleted UF_6? Here is an area where you could do a lot of good in taking the hocus pocus out of Health Physics and educating the public about radiation and its effects! Don't let them learn it from the Simpsons on the anti-nuke Fox Network.

Response 5

The radiation exposure of workers handling cylinders was estimated using computer models that calculate the external gamma dose rate in the vicinity of a cylinder. These models account for the ingrowth of gamma-emitting uranium decay products and shielding by both the cylinders walls and the depleted UF_6 itself. The results of the computer modeling were in good agreement with actual radiation measurement results provided by the cylinder storage sites that indicate that the external radiation level on the outside surface of a filled cylinder is typically about 2 to 3 mR/hr, decreasing to about 1 mR/hr at a distance of 1 ft. The methods used to calculate worker dose are summarized in Appendix C, with results provided in Appendix D of the PEIS. For purposes of conciseness, details related to these calculations are provided in the backup report by Cheng et al. (1997) referenced in Appendix C of the PEIS. A discussion of UF_6 cylinder hazards and dose rates has also been added to Sections S.1.1 and 1.1 of the PEIS to address this comment.

The population dose of 0.38 person-rem referred to by the commentor is the estimated radiation dose to the off-site public resulting from uranium potentially released from breached cylinders and transported to the off-site environment by air or water (see Section D.2.1.1 of the PEIS and Cheng et al. (1997) for additional details). The gamma radiation emitted by the cylinders does not contribute to the off-site public dose. Although a large degree of uncertainty is associated with such calculations, dose estimates were presented to two significant figures throughout the PEIS for purposes of comparison among alternatives.

Comment 6

Table S-3 Page S-46: What are the quantities of uranium compounds and HF considered to be released from a "Corroded cylinder spill, dry conditions," and "Corroded cylinder spill, wet conditions"? Without these numbers, it is difficult to understand the postulated consequences. The rest of the table has the same problem of not stating how much UF_6 or HF or UO_2 is released in the accidents.

Response 6

Table S.3 is a summary of potential environmental consequences of the preferred alternative. Data and methodologies used to arrive at the numbers presented in this table are given in the Appendices. The amount of UF_6 assumed released from a corroded cylinder spill under dry conditions was 24 lb. The amount of HF assumed released from a corroded cylinder spill under wet conditions (the solid UF_6 would be deposited on the ground and the HF subsequently generated) was 96 lb. This information, along with other details about the accident scenario, is provided in Table D.6 of Appendix D. Similar accident summary tables are provided in Appendix E (Cylinder Preparation), Appendix F (Conversion), Appendix G (Long-Term Storage), Appendix H (Manufacture and Use), and Appendix I (Disposal).

Comment 7

PAGE 1-1 SECTION 1.1 BACKGROUND INFORMATION: The statement is made: "At atmospheric pressure, UF_6 is a solid material below a temperature of 134°F and a gas at temperatures above 134°F (additional information about the characteristics of the chemical UF_6 is provided in Appendix A)." When I go to the Appendix A, I was amazed at the paucity of information presented not only for UF_6, but also for the other uranium compounds and HF. I thought at least, I would find the phase diagram of UF_6 that clearly shows the inaccuracy of the above statement but, alas, it wasn't there! UF_6 can be a gas below 134°F as well as above 134°F, and a solid all the way up to 147°F.

Response 7

The text on page 1-1 is correct, in that UF_6 is a solid material at atmospheric pressures below a temperature of 134°F and gas at temperatures above 134°F. The commentor is correct in stating that UF_6 can be a solid at a temperature of 147.3°F but this is at a pressure of 22.04 psia, higher than atmospheric pressure (14.696 psia).

Explanatory text and associated phase diagram for UF_6 have been added after the first paragraph of section A.1.1 on page A-1 of Appendix A, as suggested by the above comment.

Comment 8

PAGE 3-50 TABLE 3.13 FOOTNOTE c: The footnote states: "Radiation dose could result from drinking 365 L of K-25-site water (0.3 mrem/yr) and ingesting the maximally contaminated fish (1.6 mrem/yr)." Do you have to drink all 96.5 gallons (365 L) of water and eat the fish at one sitting? If you do, this is nonsense and serves no purpose. If you don't, what is the time period?

Response 8

The stated ingestion rates of water and fish are annual consumption rates. The footnote has been revised to make this point clear.

Comment 9

PAGE 4-14 DEFINITIONS: "Involved Worker — Might be exposed to direct gamma radiation emitted from radioactive materials such as depleted UF_6 or other uranium compounds." Here again, the question has to be asked, "How much radiation does depleted UF_6 or other uranium compounds emit/unit quantity of the substance?" Is the UF_6 still in the cylinder? Do you take credit for the shielding of the uranium in the UF_6 in the cylinder? The way this is written does absolutely nothing to allay the fears of the uninformed.

Response 9

The section of the PEIS referred to is intended to define the categories of workers considered in the radiological assessment. The sources of radiation exposure vary according to the category of worker being addressed and the option or alternative being considered in the PEIS. For example, the primary radiation source for involved workers during cylinder management activities is the uranium and decay products contained in the cylinders. However, during conversion, radiation exposures for involved workers considered both radiation from uranium contained in cylinders and from uranium in processing equipment and post-conversion containers. For purposes of conciseness, a description of the methods used to calculate the potential impacts to workers is summarized in Appendix C, with detailed information provided in the backup report by Cheng et al (1997), as referenced in Appendix C of the PEIS.

In response to the question concerning the dose rates associated with UF_6 cylinders, the radiation exposure of workers handling cylinders was estimated using computer models that calculate the external gamma dose rate in the vicinity of a cylinder. These models account for the ingrowth of gamma-emitting uranium decay products and shielding by both the cylinders walls and the depleted UF_6 itself. The results of the computer modeling were in good agreement with actual radiation measurement results provided by the cylinder storage sites that indicate that the external radiation level on the outside surface of a filled cylinder is typically about 2 to 3 mR/hr, decreasing to about 1 mR/hr at a distance of 1 ft. A discussion of UF_6 cylinder hazards and dose rates has been added to Sections S.1.1 and 1.1. of the PEIS to address this comment.

Comment 10

PAGE 9-18 DEFINITION OF TRANSURANIC WASTE: The word "transuranic" means "beyond uranium" i.e. elements that have a greater than the 92 atomic weight of uranium, like plutonium, neptunium, americium, etc. They probably do have half-lives greater than 20 years. Plutonium is deliberately made in nuclear reactors and extracted from spent reactor fuel. In the late '70s, a very small quantity of uranium recovered from spent reactor fuel was refined, converted to UF_6, and fed into the diffusion plant complex. They do not exist in sufficient quantity in depleted UF_6 to be a problem. Here again is a place where you could do good in educating.

Response 10

The definition shown on page 9-18 for transuranic waste has been revised to indicate transuranic waste to be "Waste contaminated by alpha-emitting transuranic radionuclides (i.e., radionuclides with atomic numbers greater than 92) with half-lives of more than 20 years and concentrations ...." As indicated by the commentor, the quantity of transuranic elements in the depleted UF_6 is very small. One reason is as given in the comment that there was very little UF_6 fed into the enrichment cascades that came from recycling operations. Another reason is that depleted UF_6 produced as the result of uranium recovered from spent nuclear fuel would not be expected to contain appreciable amounts of transuranic radionuclides. Among the various fluorides of plutonium, only plutonium hexafluoride (PuF_6) is volatile (and thus would be separated during the gaseous diffusion process of enriching uranium). Unlike the stable uranium hexafluoride, plutonium hexafluoride is thermodynamically unstable, dissociating into fluorine gas (F_2) and the relatively nonvolatile PuF_4 (plutonium tetrafluoride). Neptunium hexafluoride, like plutonium hexafluoride, is decomposed in the presence of light. Therefore, they would not end up in the UF_6 stream that was fed into the enrichment cascades.

Comment 11

PAGE A-2 TABLE A-1: It seem incredulous that the particle and bulk density of UF_6 are each 4.6 g/cm^3, and neither one of them is the generally accepted 5.1 g/cm^3 at 68°F.

Response 11

The document "Calculational Methods for Analysis of Postulated UF_6 Releases" by W.R. Williams (NUREG/CR-4360, Sept. 1985) provides the following correlation for the density of solid UF_6 in the cylinder:

$$[\text{Density, solid } UF_6 \text{ (lb/ft}^3)] = 330.0 - (0.18 \times [\text{Temperature of solid } UF_6 \text{ (degrees °F)}])$$

so that at 68 °F, the solid UF_6 density is approximately 318 lb/ft^3 or 5.1 g/cm^3. The value in the text has been revised accordingly.

Comment 12

PAGE A-2 TABLE A-1: A.1.2 I think you should mention that uranyl fluoride picks up water of hydration from humid air and in doing so changes color from brilliant orange to yellow. If a cylinder should break open in the storage yard, this color change would probably be observed.

Response 12

The text of Section A.1.2 has been revised to include a statement to indicate that uranyl fluoride is hygroscopic and changes in color from brilliant orange to yellow after reacting with water.

Comment 13

PAGE A-4 A.2.1: UF_6 is essentially inert to copper, witness all the copper tubing instrument lines in the plants. Also don't forget Teflon that was developed specially for the Manhattan Project.

Response 13

The text on page A-4 of the PEIS has been revised to indicate that UF_6 is essentially inert to clean aluminum, steel, Monel, nickel, aluminum, bronze, copper, and Teflon and that Teflon is commonly used in the packing and cap gasket for cylinders storing depleted UF_6.

In general, design considerations such as using copper for instrument lines in contact with gaseous UF_6 have been factored into the facility layouts provided in the engineering analysis report (EAR) (LLNL 1997a; the full citation is provided in Chapter 8 of the PEIS). The design sign basis and processing parameters for the various options are provided in the EAR, as well as any process considerations such as the material of construction of the various reactors and process equipment.

The engineering analysis report is available for review at DOE public reading rooms near the three current storage sites and in Washington, DC (listed in the Notice of Availability), and can also be obtained by contacting the DOE program manager identified on the cover sheet of the PEIS.

Comment 14

PAGE B-7, 4TH FULL PARAGRAPH, LAST SENTENCE: "It was assumed that uranium would be released as solid uranyl fluoride (UO_2F_2),which would be deposited on the ground." You should do more than say it lays on the ground. Uranyl fluoride (UO_2F_2) has a characteristic of being very soluble in water, so as soon as it rains, its will go into solution which, because of the HF, will be acidic and be neutralized by the cement or limestone construction materials of the storage yard. The resulting calcium salts will probably be insoluble in water and lay where they have been formed.

Response 14

It is true that uranyl fluoride would react further upon contact with water. The second paragraph of section C.2.1 of the PEIS indicates that the estimation of potential impacts to water resources from cylinder breaches assumed reaction of the uranyl fluoride laying on the ground with water to form hydrogen fluoride and various uranium compounds which could dissolve and infiltrate surface and shallow groundwater resources. Text has been added to Section B.3 to clarify this point.

Comment 15

PAGE C-3, C-2.1 CONTINUED CYLINDER STORAGE, 1ST PARAGRAPH 3RD SENTENCE: "Because of their age, potential direct contact with the ground, and skirted ends, many of the cylinders show signs of corrosion." Unless you include the ORO 651 series of documents, how is the reviewer to know what you are talking about when you suddenly introduce "skirted ends"?

Response 15

A definition of "skirted ends" has been added to the text referenced in the comment.

Comment 16

PAGE E-20, FIGURE E.1: The design of the Horizontal "Clamshell" Overcontainer looks interesting, and since you will have to use it at all three plant sites, while you are at it, why don't you design to be a 100 PSIG pressure vessel and use the steam-heated autoclaves that you have at the plants to empty the defective cylinders? Otherwise you have to come up with an autoclave designed for hot air heating which will require different than your presently approved safety systems to avoid gross overheating with hot air.

Response 16

Air-heated autoclaves were utilized in the design to assure safe vaporization of UF_6 from incoming cylinders that are substandard due to corrosion defects, overpressuring, or overfilling. It was assumed that the use of steam-heated units could result in a steam/UF_6 reaction due to in-leakage of steam in a substandard cylinder. This potential steam in-leakage would result in the formation of uranyl fluoride and hydrogen fluoride, which would be a potential health and safety hazard to the workers supervising cylinder withdrawal. In addition, the hydrogen fluoride produced during steam heating could lead to equipment failure and the potential large-scale release of UF_6 in the vapor state to the atmosphere, which would present an environmental hazard.

Comment 17

PAGE E-21, E.2.2 CYLINDER TRANSFER. You will have some damaged cylinders at all three sites, and if you can't get a DOT permit to ship them off the plant site, how would one of these expensive cylinder transfer facilities at each site be of value to the enterprise?

Response 17

The cylinder transfer facility, if deemed appropriate, would mainly be used to transfer the contents of intact cylinders that do not meet the requirements of the Department of Transportation (DOT) for off-site transport into cylinders that do meet those requirements, if it became necessary to transport the cylinders to another site, for example, for conversion to another chemical form. The damaged cylinders would be handled on a case by case basis.

Comment 18

PAGE F-3, SITE LAYOUT FOR A CONVERSION FACILITY: Why do you store the full cylinders outside, and build the biggest building on the site for the empties to be under cover?

Response 18

It is assumed that the "biggest building on the site" that the comment refers to is the Outgoing Empty Cylinder Storage Building. This building is primarily a warehouse which provides space for three months storage of emptied cylinders during radiological "cooling." Preliminary

estimates have indicated possible dose rates in the range of 1 rem/hr at the lower surface of UF_6 cylinders which have been emptied of their contents, due to the retention of a heel of radioactive daughter products of uranium in the cylinder after emptying. Analysis performed for the engineering analysis report (LLNL 1997a) indicated that a period of approximately three months of on-site storage is required to allow these daughter products to decay to acceptable levels for shipment off-site. The emptied cylinders would be stored inside of a metal-frame building, which would be a restricted area with limited personnel access, to reduce worker exposures. The functions of the Empty Cylinder Storage Building, as shown in Figure F.1, page F-3 of the PEIS, are explained in Section F.2 of the PEIS. There is also a section describing this building in each of the conversion reports in the engineering analysis report (LLNL 1997a; the full citation is provided in Chapter 8 of the PEIS) (see for example Section 2.1.3.4 in 6.4, U_3O_8: Defluorination/Anhydrous HF Facility).

The engineering analysis report is available for review at DOE public reading rooms near the three current storage sites and in Washington, DC (listed in the Notice of Availability), and can also be obtained by contacting the DOE program manager identified on the cover sheet of the PEIS.

Comment 19

PAGE F-11, 1st PARAGRAPH: Why wash the empty cylinders with water when a nitric acid solution would do a better cleaning job? The used solution could also be evaporated to dryness for disposal.

Response 19

The PEIS assumes that the empty cylinders would be treated only with water, and that contaminants not removable by simple wash and rinse procedures will remain in the cylinders prior to their disposition. Water would be used to remove the heels from the empty cylinders, as a heel as great as 50 pounds of UF_6 can be treated with 10 gallons of water without exceeding the solubility limit of UO_2F_2 (i.e., about 32%). The UO_2F_2 produced during cylinder washing could then be processed at a UF_6 conversion facility to generate U_3O_8 or UO_2, minimizing costs. Addition of nitric acid would produce uranyl nitrate hexahydrate, $UO_2(NO_3)_2*6H_2O$, which would require processing techniques different from those considered in the PEIS to produce either U_3O_8 or UO_2. The uranyl nitrate could be evaporated to dryness for disposal purposes, but this would generate a relatively large amount of uranium-bearing waste (on the order of 500 to 600 tons) that would require disposal as a low-level waste.

Comment 20

PAGE F-1 3, F.2.3 CONVERSION TO METAL, 3RD PARAGRAPH, 4TH SENTENCE: "The more dense molten uranium/iron would settle to the bottom of the reactor where it would be continuously withdrawn." What kind of material are you going to use for the reactor and liquid uranium/iron draw off piping? I have always been told that liquid uranium at 2100°F, and uranium

alloys at lower temperatures are the universal solvents. Nothing, even yttrium lined equipment will contain them for very long.

If you go with the Fe/U alloy just to lower the molten metal temperature, how good a radiation shield will your alloy be as compared to pure uranium?

Response 20

The reactor and associated piping would be both insulated and graphite-lined. The service life of the graphite liner is limited by erosion/corrosion, and is assumed in the PEIS to be on the order of 8 months.

Iron is added to produce an uranium alloy with 3% iron. This small percentage of iron should not significantly attenuate the radiation shielding potential of the uranium-iron alloy compared with pure uranium metal.

Comment 21

PAGE F-14, IMPACTS OF OPTIONS: The amount of HF produced from any of the conversion options should be expressed because it is the big safety hazard. The design rate of 2300 48G cylinders of UF_6 a year equates to 6.3*26,840 lbs or 169,100 lbs UF_6 a day. Using a molecular weight of 352 for UF_6, these 6.3 cylinders contain 480 lb/mols of UF_6. Each lb/mol of UF_6 that reacts with water will create six lb/mols of HF. Thus 480 lb/mols * 6 = 2880 lb/mols HF/day. Using a molecular weight of 20 for HF, this equates to 57,000 lbs or 6600 gallons of anhydrous HF/day produced. Remembering that HF boils at 60°F, this is a lot of HF to handle day in and day out in plastic pipes and tanks. You are buying a much bigger safety problem than I think you are portraying in these tomes. You should know that a drop of this liquid will burn a hole through your unprotected hand and the fumes can kill as happened at Kerr McGhee in Gore, OK!

Response 21

The amount of hydrofluoric acid that would be produced during UF_6 conversion would be on the order of 7,400 gallons per day, assuming complete conversion of DOE's depleted UF_6 inventory within a 20-year period. This daily production rate is equivalent to an annual production rate of about 9,200 MT/year, which is 5% or less of the estimated U.S. annual capacity for HF production. The safety issues associated with the production of hydrofluoric acid have been considered in the PEIS. As an example, the anhydrous HF produced during UF_6 conversion would be stored in tanks and a building cooled to about 50 °F to minimize the HF that vaporizes if a spill should occur. The storage tanks themselves would have high level alarms and interlocks that stop the transfer pump, and would be diked to contain spillage. The building itself would have HF air monitoring instruments and a water spray system that can be activated to absorb HF. Further information concerning the engineering aspects of the production and storage of HF is provided in the engineering analysis report (1997a; the full citation is provided in Chapter 8 of the PEIS).

Comment 22

PAGE F-23, TABLE F.7: In the conversion to U_3O_8 section, the last accident is a U_3O_8 drum spilling its contents onto the floor after an accident with a forklift. These drums contain 1600 lbs of U_3O_8 powders, and you are asking the reviewer to believe that the spill quantity will only be 63 milligrams! This tends to lose your credibility for the whole study! Later on in the Table, you show a 2400 lb drum of UO_2 in a similar accident only spilling 25 milligrams but you have an extremely unlikely 3, UF_6, cylinders bursting from some kind of fire and dumping 24,000 lbs in 30 minutes. I believe you lose integrity when you ignore the historical fact that this cylinder rupture scenario has not occurred, or even come close, in the past 50 years of cylinder storage. On the other hand, you seem to completely accept speculation about future accidents in plants that have not been built. It sure looks like you are trying to make people think this UF_6 stuff is the most hazardous thing there ever was?

Response 22

The accident analysis in the PEIS was performed using standard methodologies based on research and historical experience to determine the accident source terms. The difference in the amount assumed to be released for the accidents is primarily due to the physical form of the material involved (solid versus gas) and type of accident (simple drum spill versus fire-induced rupture of a UF_6 cylinder). The U_3O_8 drum spill accident for the conversion to U_3O_8 option assumed that 50% of the solid U_3O_8 would be released from the breached drum containing 1,380 lb U_3O_8, and that 0.02% of the released amount would be rendered airborne by the accident and contain powder in the respirable range. It should also be noted that the building filtration system would reduce the release by 99.9%, thus resulting in a release to the atmosphere of 0.00014 lb (1,380 lb × 0.5 × 0.0002 × .001).

The fire-induced UF_6 cylinder rupture accident scenario postulates that a vehicle with a large fuel inventory would crash into a UF_6 cylinder storage pad, and that the UF_6 cylinders would hydraulically rupture during heating, releasing UF_6 both as liquid and vapor. It should be noted that the total release of vapor UF_6 is respirable, unlike that of solid U_3O_8 for which a small portion is respirable.

Further information about the details of the source terms for the accident analysis performed in the PEIS can be found in the engineering analysis report (LLNL 1997a; the full citation is provided in Chapter 8 of the PEIS). This report is available for review at DOE public reading rooms near the three current storage sites and in Washington, DC (listed in the Notice of Availability), and can also be obtained by contacting the DOE program manager identified on the cover sheet of the PEIS.

Comment 23

PAGE F-29, CYLINDER TREATMENT FACILITY EXTREMELY UNLIKELY ACCIDENTS: Why is the amount released in an earthquake where 50% of the stored drums are

breached only 1.9 lbs, whereas in a Tornado that pierces only one drum of U_3O_8 the quantity released is 69 lbs? You need to cross check all these tables you publish. I am sure that I have not found all the inconsistencies.

IBID, PAGE F-29, CYLINDER TREATMENT FACILITY EXTREMELY UNLIKELY ACCIDENTS: The 3.4 lbs of HF released when the evaporator tank fails and the pool of HF evaporates into the building is just plain wrong. I can tell that none of you ever worked at Fernald! If the temperature is above 60°F, 3.4 lbs of anhydrous HF will become 61 standard cubic feet of extremely toxic and obnoxious gas.

Response 23

All the appendix tables summarizing accidents considered for the various options have been checked; there are no known errors. Background information and details on the rationale for the release amounts are given in the engineering analysis report (LLNL 1997a; the full citation is provided in Chapter 8 of the PEIS), which is available for review at DOE public reading rooms near the three current storage sites and in Washington, DC (listed in the Notice of Availability), and can also be obtained by contacting the DOE program manager identified on the cover sheet of the PEIS.

With respect to the specific questions raised in the comment, the difference in the release amounts for earthquakes and tornadoes is mainly due to the high winds which accompany a tornado. During a tornado, a wind-blown missile could impact a single U_3O_8 drum and release the 1,380 lb inventory of the drum, with 5% of the released amount rendered airborne outside the building and containing powder in the respirable range, resulting in a release of 69 lbs. For an earthquake, it was assumed that 50% of the 28 drums stored in the Solids Product Building would be damaged, 50% of the material in the drums released, and 0.02% of the released amount would be rendered airborne outside the building and contain powder in the respirable range, for a total of 1.9 lbs. An analogous situation would be dropping a bag of Portland cement onto a hard surface. The bag would rupture and a very small amount of fine dust particles would be emitted in the air. In the case of a tornado, the entire contents of the cement bag that had burst open would be entrained by the high winds.

With regards to the evaporator tank failure which was postulated to release 3.4 lb of hydrogen fluoride (HF), the evaporator would contain 154 gallons of 13.3% HF (equivalent to 176 lb. HF) at its boiling point. The accident scenario postulates that the evaporator tank would fail and the entire contents be spilled. Flash evaporation (due to HF being at its boiling point) of the tank contents would result in 1% being vaporized (1.8 lb HF flashed vaporized). Normal evaporation of the HF spill on the concrete floor over a 60-minute period would result in another 1.6 lb HF being released, for a total of 3.4 lb HF over a 60-minute duration.

Comment 24

PAGE G-16, SECTION G.2-2: I don't find recognition of the cylinder sweating problem in any of the inside storage options. During the winter, the 10 or 14 ton cake of UF_6 in each cylinder cools approaching the temperature of the coldest day. When spring comes and the warm humid days return, the outer surface of the cylinders becomes a condenser for the water in the air, not unlike the sweating on your evening rum and coke glass. Unless you air condition the buildings, vaults, and mines, the cylinder wall corrosion will continue especially in the spring.

Response 24

The PEIS assumed that designs for the three storage options would include heating, ventilation, and cooling (HVAC) in order to avoid the effects of temperature and humidity extremes mentioned in the comment. This should limit the potential for cylinder sweating.

Comment 25

PAGE H-16, TABLE H-5: Why is that the drop of a single 2400 lb drum of UO_2 only releases 7.3×10^{-7} pounds (3.3 mg) of UO_2 in this accident whereas the same accident in Table G.6 page G-26 releases 1.1×10^{-4} lbs (50 mg) of UO_2? Once again, what you got don't make no sense!

Response 25

The reason for the difference is the degree of filtration, which would reduce the amount of UO_2 that is released to the environment through the stack. Table G.6 indicates accidents that could occur during storage of UO_2 in a metal building with minimal filtration, while the building design for Manufacture and Use in Table H.5 would include a number of filtration units to reduce emissions.

It should be noted that the amount of released solid material such as UO_2 or U_3O_8 during an accident would be a function of the fraction of the material made airborne at the point of the accident, the fraction of the release in the respirable size range, and the fraction of the material that would be released from the building to the environment after being mitigated by air-treatment attenuation devices such as air filters. The fraction of the material made airborne at the point of the accident would be a function of the type of the material. During conversion of UF_6 to form UO_2, very dense and hard pellets are formed, similar to those used in nuclear reactor fuel. The UO_2 pellets would not be expected to release many airborne particles after simply being dropped, which explains why such a relatively small percentage of the drum contents would be released to the atmosphere.

Comment 26

PAGE J-28, SECTION J.3.4.3, CYLINDER TREATMENT FACILITY: I question the assumption that emptied UF_6 cylinders will retain a 22 lb heel. Why not use dry air to purge the UF_6 gas from the emptied cylinder in the autoclave and let these purge gases go directly to your

conversion apparatus. If you do this you should get your heels to be around 10 ppm UF_6. However, even if you do this, you will still have to wash the cylinders to get the daughter product out.

Response 26

The amount of UF_6 remaining as "heels" (22 lbs) was taken from the document "Cost Study for the D&D of the GDPs, Depleted Uranium Management and Conversion," K/D-5940-DF (Sept. 1991). This document presents a preliminary design developed by the Central Engineering Department at the Oak Ridge Site for conversion of the depleted UF_6 to form U_3O_8. This document also indicated that on the order of one pound of insoluble solids per cylinder would be removed during cylinder washing. Reference to this report has been added to Appendix F and Appendix J of the PEIS.

Mountain Technologies Network Group

Comment 1

I am currently reviewing the Draft PEIS Summary, Vol. I and Vol. II. Thank you for the opportunity to provide comment. I have been tracking this problem (which I feel is of the highest priority along with the Gunnite Tanks and Melton Valley Storage Tanks at ORNL) since 1992 at Oak Ridge (K-25), PGDP and PORTs.

Response 1

Comment noted.

Commentor No. 6: **Weigel, Rudy**

Comment 1

Question: I didn't think "economics" was a consideration of the NEPA process. If it's not, why is it presented in the PEIS? It's being presented could adversely influence ultimate decisions for the project-people will look at the dollars instead of the best project option.

Response 1

NEPA and its implementing regulations require that federal agencies address the impacts of proposed actions on the human environment. Consequently, the PEIS addresses socioeconomic impacts on human communities, including changes in employment, local housing demand, public finances, and population in-migration. The ultimate decision on a management strategy will be announced in a Record of Decision. The Record of Decision will consider the results of the PEIS, including socioeconomic impacts, along with other information, such as cost and engineering data,

to select a management strategy. The Record of Decision will document the strategy selected and describe how it was selected from among the different alternatives.

Commentor No. 7: Peelle, Bob

Comment 1

In discussing possible future uses of depleted uranium, you predominantly mention radiation shielding. True for x-rays and gamma rays, and sometimes true for electrons. Never true for neutrons! (fast or slow). (I was associated with some simple minded experiments 40 years ago that made the point dramatically.) The neutrons produce fissions, and the (subcritical) multiplication ruins the shield. Uranium pellets would ruin concrete blocks, if many neutrons are around. So for any application including around an accelerator, an analysis would have to be made. So, qualify the statements to apply only to x-rays or x-ray shields.

Response 1

Dense materials, such as uranium, are primarily used for shielding x-ray, gamma, and beta radiation. Qualifying statements have been added to the PEIS (Sections 1.5.3 and 2.2.4) to indicate that uranium would be used to shield these types of radiation.

Commentor No. 8: Plansky, Dr. Lee

Comment 1

A. re: Disposal Options U- minerals are deposited in reducing environments. It would seem that you would chose a *grout* that would tend to be chemically neutral or also reducing, perhaps a glass or synroc. The oxidizing environment implied in the present scenario (cement grouts, implies rapidly rusting metal drum, and oxidation of U to U ++++++ (+6, or +5) and we mobilize what we don't want to.

Response 1

The PEIS considers disposal of uranium in the form of uranium oxides such as U_3O_8. Uranium appears in nature as U_3O_8 and this is the generally recommended form for disposal due to its inertness and low solubility.

Grouting of waste materials is widely practiced in the disposal of radioactive waste. Most processes use a cementing or binding agent (for example Portland cement or asphalt). The resulting block of waste, with relatively low permeability, reduces the surface area across which the transfer of pollutants such as uranium can occur. Some versions of waste stabilization involve adjusting the pH and oxidation-reduction conditions in the waste to prevent waste solubilization in groundwater. This is not necessary with uranium oxides such as U_3O_8 due to their low solubility in groundwater.

Comment 2

B. The PEIS downplays the importance of U-toxicity as a metal. Refer to any simple MSDS on U METAL and you and the public will all be shocked.

Response 2

The analyses of potential health impacts conducted for the PEIS addressed both the chemical and the radioactive toxicity of uranium as several different compounds: UF_6, UO_2F_2, UO_2, U_3O_8, UF_4, and uranium metal. For normal operations, the chemical toxicity was addressed by comparing potential exposure amounts with the U.S. Environmental Protection Agency's reference dose for uranium. For accidents, the chemical toxicity was addressed by comparing potential intakes with: 1) the intake of 30 mg given as the threshold for potential irreversible kidney damage under U.S. Nuclear Regulatory Commission (NRC) guidelines for certification of gaseous diffusion plants (NRC 1994a; full citation is provided in Chapter 8 of the PEIS); and 2) the intake of 10 mg, which NRC publications give as the threshold for potential adverse chemical effects (generally temporary, reversible effects occur in the range from 10 to 30 mg of intake). The chemical toxicity analyses for uranium are summarized in Sections 4.3.1.2.2 and 4.3.2.1 of the PEIS, and discussed in greater detail in Sections C.5.1.2 and C.5.2.1.1. Chemical toxicity was assessed for each alternative, and the results of the accident analyses show that the largest potential impacts from accidental uranium releases would be chemical impacts. Please see text in Sections S.4.2.2 and 2.4.2.2, which states "chemical effects (kidney damage) occur at lower exposure levels than radiological effects," and elaborates on the numbers of workers and members of the general public estimated to experience these adverse chemical effects under the various accident scenarios analyzed.

Comment 3

C. The way I understand it, the new proposed 20 micrograms/liter EPA MCL on U-238 is inviolable. Depleted uranium material would be disposed of as low-level radioactive waste. The disposal options assessed in the PEIS were defined on the basis of the chemical form of the uranium and the type of disposal facility. The following disposal options were considered: Disposal as U_3O_8. Depleted uranium could be disposed of as U_3O_8, either ungrouted (bulk) or grouted U_3O_8, following conversion. The disposal facilities considered included shallow earthen structures, below ground vaults, and an underground mine. Disposal as UO_2. Similar to U_3O_8, depleted uranium could be disposed of as UO_2 following conversion, either in ungrouted or grouted form. The disposal facilities considered were the same as those considered U_3O_8: shallow earthen structures, below ground vaults, and an underground mine.

Response 3

The proposed maximum contaminant level (MCL) for uranium was used as a guideline in the PEIS to estimate the potential for adverse environmental impacts to groundwater and surface water of the various alternatives. The potential impacts of the options listed in the comment (e.g.,

disposal as grouted or ungrouted U_3O_8 or UO_2 in shallow earthen structures, below ground vaults, or a mine) were considered under the disposal alternative.

Comment 1

We believe that all of the strategies that proposed have serious environmental justice concerns and potential impacts to communities that you have not adequately reached with the Draft PEIS. We also believe that the meetings that DOE has held in the past, as well as the ones that are beginning on February 19,1998 in Paducah, are not properly reaching people who are or may be impacted by decisions that your agency will be making regarding the long-term plan for use of this dangerous material.

Response 1

The approach used in the PEIS to assess environmental justice concerns is consistent with guidelines in "Environmental Justice: Guidance Under the National Environmental Policy Act" (Council on Environmental Quality 1997; the full citation is provided in Chapter 8 of the PEIS). The approach taken involved a two-step process to identify impacts associated with environmental justice (see Section 4.3.12 of the PEIS). The first step concerns the presence of disproportionately high percentages of low-income or minority populations in those areas anticipated to experience high and adverse impacts. The second step concerns the presence of high and adverse impacts in general, and thus affecting the total population. Section C.8 of the PEIS provides a detailed discussion of the methods used to identify and assess potential environmental justice impacts.

Because one must know the economic and racial composition of an area potentially affected in order to assess environmental justice impacts, the assessment must be site-specific. In the PEIS, the only alternative components for which locations are known are continued cylinder storage (Appendix D) and cylinder preparation (Appendix E). For these components, environmental justice issues were examined thoroughly (see Sections D.2.11 and E.3.11 which discuss environmental justice impacts). As discussed in these Sections, no high and adverse human health effects or environmental impacts would be expected from continued storage of cylinders or cylinder preparation activities at the Paducah, Portsmouth, and K-25 sites. Because of this general lack of high and adverse impacts, and because minority and low-income populations would not be more prone than the general population to experience impacts from the two site-specific activities, no environmental justice impacts are anticipated. With regard to the remaining four alternative components (that is, conversion, long-term storage, manufacture and use, and disposal), because their locations currently are unknown no environmental justice evaluation could be conducted in the PEIS. If in its Record of Decision for this PEIS DOE selects an approach to the management

of its depleted uranium inventory that involves any of these alternative components, possible sites will be identified and those sites evaluated in subsequent NEPA documents, as described in Section 1.4 of the PEIS. One component of those evaluations would be an assessment of environmental justice impacts.

With regard to reaching people who are or may be affected by decisions on the management of the DOE depleted uranium inventory, the Department has made a substantial effort as part of the public outreach component of the PEIS to inform all interested parties of the document's preparation and various means of participating in the process of its preparation. DOE distributed PEIS documents and public hearing notices to about 2,400 individuals and organizations identified by the three current storage sites and through the DOE stakeholder mailing list as parties potentially interested in the PEIS. Those contacted included advisory boards, environmental groups, interest groups, local organizations, tribal organizations, and government representatives at the local, state, and federal levels. Publicity for the Draft PEIS and the four public hearings included Federal Register notices, newspaper display advertisements, site press releases and/or newsletters, public service radio announcements, postcard notices to local stakeholders, the Depleted UF_6 World Wide Web site (http://www.ead.anl.gov/uranium.html) and DOE's NEPA Web site (http://tis.eh.doe.gov/nepa). The entire PEIS is available for review on the Depleted UF_6 World Wide Web site. DOE believes all groups were provided adequate opportunity to comment on the Draft PEIS.

Comment 2

Keeping with the spirit and intent of President Clinton's Executive Order on Environmental Justice and Secretary Pena's Openness Initiative, we feel that it would be reasonable to request that the DOE initiate round table meetings, much like the Federal Facilities Restoration Dialogue meetings. We believe that it is necessary and just to bring in grassroots leaders from community, labor, and environmental justice groups to further discuss the implications of strategies that have been proposed.

Response 2

Openness and public outreach were important components of the process to prepare, distribute, and solicit comments on the Draft PEIS. DOE distributed PEIS documents and public hearing notices to about 2,400 stakeholders in December 1997. This distribution included many environmental groups, including environmental justice advocates. Public hearings were conducted in March and April 1998 in Paducah, Kentucky; Oak Ridge, Tennessee; Piketon, Ohio; and Washington, D.C. These hearings provided opportunities for community leaders, labor organizations, environmental groups, and other individuals and organizations to provide oral and written comments on the Draft PEIS and to discuss the Draft PEIS with representatives of DOE's depleted uranium hexafluoride management program. Publicity for the Draft PEIS and the public hearings included Federal Register notices, newspaper display advertisements, site press releases and/or newsletters, public service radio announcements, postcard notices to local stakeholders, the

Depleted UF_6 World Wide Web Site, and DOE's NEPA Web Site. DOE believes all groups were provided adequate opportunity to comment on the Draft PEIS during the 120-day comment period.

Comment 3

We further request that the comment period be extended to six months to give these folks the opportunity to meet with you, in addition to the hearings that are taken place now, as well as the opportunity to obtain expert technical advice regarding the impact of the various different strategies.

Response 3

DOE announced a 120-day public comment period upon publication of the Draft PEIS in December 1997. This comment period was much longer than the 45 days required by Council on Environmental Quality and DOE regulations implementing the National Environmental Policy Act. DOE believes this comment period was of sufficient duration to allow review of the Draft PEIS and submittal of comments by government agencies, potentially affected communities, and other individuals and organizations.

Commentor No. 11: Adkisson, Ron
Rio Algom Mining Corporation

Comment 1

One long-term alternative which has not been considered to date for long-term storage of the converted uranium (i.e., UO_2, U_3O_8, etc.) is the placement in a uranium mill tailings impoundment for long-term retrievable storage. Mill tailings impoundments are designed for 1,000 year stability and long-term care and maintenance is legally the responsibility of the Department of Energy. Quivira Mining Company's mill tailings site in New Mexico, for example, is presently licensed to dispose of 5,000,000 tons of byproduct materials even though the structural stability of the site was designed for an additional 43,000,000 tons. The primary advantages of using a mill tailings site are: (1) the inventory would be consolidated and isolated from the environment; (2) placement in a tailings impoundment would be relatively simple and with minimum personnel exposure; (3) it would remain in the custody of the US Government for long-term monitoring and care; and (4) it could be retrieved at any time in the future should the need arise.

Response 1

Uranium mill tailings are the residual wastes of milled ore that remain after uranium has been recovered. Uranium mill tailings are part of a broad category of radioactive wastes called by-product materials. The tailings contain about 0.004 to 0.01% U_3O_8.

Uranium mill tailings are to be disposed of in a tailings impoundment. This must have a cover designed to control radiological hazards for a minimum of 200 years. The Ambrosia Lake uranium mill tailings site operated by the Quivira Mining Company is authorized by the U.S. Nuclear Regulatory Commission to accept 11e.(2) material for disposal. The term "11e.(2)" material means by-product material produced by the extraction or concentration of uranium or thorium from any ore processed primarily for its source material content. The basis for the definition of this group of by-product materials is Section 11e(2) of the Atomic Energy Act of 1954. Depleted uranium would not be classified as 11e.(2) material, and as such, could not be disposed of at the Ambrosia Lake uranium mill tailings site (or any other mill tailings site) without relicensing to allow emplacement of depleted uranium. It would be highly speculative within the PEIS to consider amendment of legislation such as the Atomic Energy Act of 1954 to allow disposition of depleted uranium within a mill tailings impoundment.

Commentor No. 12: Balding, Andrew

Comment 1

Appendix D, pg. 5, 1st Para: The assumption that any further breaches would be a result of handling damage vs. corrosion is very valid, however the follow on assumption that this breach or damage would go undetected for 4 years is not a valid assumption. The same detailed Inspection of a cylinder is required each and every time it is handled as it is Quadrennially or Annually, the Inspections in fact almost identical, the same procedures and checklists are used regardless of the type of inspection or frequency. Any damage that might occur under the current regimented and proceduralized handling activities whether during painting, cylinder relocation to improved storage, or just normal storage yard operations, would be immediately noted and dealt with at the occurrence. Therefore there would be no release and no "Environmental Impact" whatsoever, furthermore the one handling damage induced breach (the Paducah cracked cylinder) was caused by handling damage in 1987; since that time this Site has handled thousands of cylinders without breaching a cylinder due to handling damage, the current Project alone has handled over 30,000 cylinder relocations since 1992 without causing damage to a cylinder sufficient to cause a breach. The facts do not support the conclusions of the predicted number of cylinder breaches portrayed in the "No Action Alternative": the estimate of 444 at Paducah over the next 40 years with only one under old handling practices (even disregarding that those practices have been improved) is sensationalistic.

Response 1

The commentor seems to be referring to the text of the Introduction to Appendix D, paragraphs 9 through 11 (found on pages D-3 and D-4 of the Draft PEIS). With regard to the number of breaches estimated to occur during the period of operations, two separate analyses were conducted. The first analysis took credit for the improved management program, and specifically assumed that the painting program would eliminate breaches caused by corrosion. Under these assumptions, the assumed breaches would be the result of mechanical damage occurring during

handling. The number of breaches assumed to occur from handling damage through 2039 were 36 for the Paducah site, 16 for the Portsmouth site, and 7 for the K-25 site (as stated in the text). These assumptions are quite reasonable based on the large numbers of annual cylinder relocations and/or paintings assumed for the three sites; these assumptions were used as the base case for the assessment of continued storage impacts, as presented in detail in Sections D.2.1 through D.2.11 of Appendix D.

Another reasonably foreseeable scenario for cylinder breaches would be the possibility that the painting program would not be effective in controlling further corrosion, or that the required painting schedule could not be maintained. In order to address this possible (but less likely) scenario, a second assessment based on the assumption that external corrosion was not halted by improved storage conditions and painting was also conducted. Based on these assumptions, the total numbers of breaches estimated through 2039 were 444 for the Paducah site, 74 for the Portsmouth site, and 213 for the K-25 site. The impacts based on these assumptions are presented in Section D.3 of Appendix D as a supplemental analysis.

With respect to the period of time before a breach would be detected (assumed to be 4 years), the PEIS analyses used a reasonable value based on available data. Since all of the cylinders must be inspected at least once every 4 years, this would be the maximum amount of time a breach could go undetected. This assumption was also used because data exist on how much of the cylinder content would be lost during that period of time; a breached cylinder at the Portsmouth site which had been in storage for 4 years prior to discovery of the breach was estimated to have lost 4 lb of uranium (see Section B.3 of Appendix B).

Commentor No. 13: Davis, Mary B., Ph.D.
Ygdrasil Institute

Comment 1

We are writing to you to request that you extend by six months the period for comment on the Draft Programmatic Environmental Impact Statement for Alternative Strategies for the Long-Term Management and Use of Depleted Uranium Hexafluoride. The material in the draft is very technical and complex, and many people concerned with the management of the hexafluoride have only recently received copies of it.

Response 1

DOE announced a 120-day public comment period upon publication of the Draft PEIS in December 1997. This comment period was much longer than the 45 days required by Council on Environmental Quality and DOE regulations implementing the National Environmental Policy Act. PEIS documents and public hearing notices were widely distributed and were publicized in Federal Register notices, newspaper display advertisements, site press releases and/or newsletters, public

service radio announcements, postcard notices to local stakeholders, the Depleted UF_6 World Wide Web Site, and DOE's NEPA Web Site. DOE believes the 120-day comment period was of sufficient duration to allow review of the Draft PEIS and submittal of comments by government agencies, potentially affected communities, and other individuals and organizations.

Comment 2

We should also like to recommend that people in the affected communities be invited to round table meetings like those for the Federal Facilities Restoration Dialogue. The affected communities should include those likely to be at risk if transportation of uranium hexafluoride on a large scale takes place.

Response 2

Openness and public outreach were important components of the process to prepare, distribute, and solicit comments on the Draft PEIS. DOE distributed PEIS documents and public hearing notices to about 2,400 stakeholders in December 1997. This distribution included the communities surrounding the current storage sites that could be affected if cylinders were to be transported from their current locations. Public hearings were conducted in March and April 1998 in Paducah, Kentucky; Oak Ridge, Tennessee; Piketon, Ohio; and Washington, D.C. These hearings provided opportunities for community leaders, labor organizations, environmental groups, and other individuals and organizations to provide oral and written comments on the Draft PEIS and to discuss the Draft PEIS with representatives of DOE's depleted uranium hexafluoride management program. Publicity for the Draft PEIS and the public hearings included Federal Register notices, newspaper display advertisements, site press releases and/or newsletters, public service radio announcements, postcard notices to local stakeholders, the Depleted UF_6 World Wide Web Site, and DOE's NEPA Web Site. DOE believes all groups were provided adequate opportunity to comment on the Draft PEIS during the 120-day comment period.

Comment 1

We urge DOE to determine all leaking cylinders at PGDP. Transfer the contents of leaking cylinders into heavy gauge new containers. Store in an earthquake proof concrete structure off the floor so they can be monitored for leaks. No major efforts to transfer contents and wash out containers in a process to change to uranium oxide should be at the Paducah facility.

Response 1

An intensive effort is ongoing to improve yard storage conditions at all three cylinder storage sites. New storage yards with stabilized concrete bases and monitored drainage have been constructed at the Paducah and Portsmouth sites. Cylinders are being relocated to allow space for

adequate visual inspections; relocated cylinders are being placed on concrete saddles to keep them out of ground contact. Each site has an intensive cylinder inspection program to allow identification of any damaged or breached cylinders as well as a radiological program to detect leakage from valves. At the Paducah site, for example, approximately 23% of the cylinders are inspected annually. Annual inspections are required for those cylinders that have previously been stored in substandard conditions and/or for those that show areas of heavy pitting or corrosion. All other cylinders must be inspected once every four years. Through these efforts, 7 breached cylinders were identified at the three sites before 1998 (one at the Paducah site). An additional breached cylinder was identified at the K-25 site in 1998; see Appendix B, Section B.2 of the PEIS for further details on this cylinder breach. Due to the improved storage conditions and frequent inspections, any breached cylinders identified in the future are expected to be recently breached with little material loss. Breached cylinders are either patched or have the contents transferred to new cylinders to prevent further material loss. See the introduction to Appendix D of the PEIS for more details on the current cylinder management program.

The proposed action of this PEIS is to select a long-term management strategy for the depleted UF_6 inventory. Options of storage in buildings, cylinder content transfer (including cylinder washing), and conversion to oxide or metal have been considered. The Department of Energy acknowledges the commentor's preference for storage as UF_6 in buildings, and the preference that cylinder content transfers and/or conversion should not take place at the Paducah facility. The selection of a long-term management strategy will be based on environmental analyses, technical and economic studies, national policy considerations, and public input. However, siting decisions are being deferred until after the selection of a long-term management strategy.

Comment 2

DOE has known details of severe seismic potential since the late 1970's and has taken little or no action to protect the workmen or the community. Negligence is not an "Act of God" if acute damage is done to the facility or the community during seismic events. We urge a comprehensive environmental impact study be made with full report to the public. We urge attention to damage and hazard reduction re: the earthquake potential utilizing national and international earthquake engineering and seismic scientists, who are respected in that field.

Response 2

The PEIS addresses the potential for seismic activity at each of the three storage sites in Sections 3.1.4.1, 3.2.4.1, and 3.3.4.1. Of the three storage sites, an earthquake which could cause more than slight damage is considered credible (though highly unlikely) only for the Paducah site.

The analysis of accident scenarios for continued cylinder storage (Section D.2.2 of the PEIS) was based on the range of potential accident scenarios considered in the safety analysis reports (SARs) for each of the three storage sites (LMES 1997f-h; the full citations are provided in

Chapter 8 of the PEIS). The SARs were issued in February 1997 by the DOE's management and operating contractor, and were subsequently reviewed and approved by DOE in March 1997.

The SARs considered a range of potential accident scenarios that could be associated with current storage activities, including natural phenomena events such as earthquakes. The accidents considered in the PEIS for current depleted UF_6 cylinder storage were extracted from those evaluated in the SARs. The accidents selected for the PEIS analysis were those accident scenarios in the SARs that resulted in the greatest potential consequences at each of the three storage sites. These accidents did not include earthquake scenarios, which were found in the SAR analyses to have lesser consequences than the accident scenarios discussed in the PEIS. The text in Section D.2.2 of the PEIS has been modified to clarify this point. If the SARs are revised in the future, DOE will modify its cylinder management program to ensure that the safety of the cylinders is maintained.

Comment 3

We deplore the use of depleted uranium in military equipment.

Response 3

The commentor's objection to the use of depleted uranium in military equipment is noted. DOE's PEIS for selecting a management strategy for its depleted UF_6 inventory does not establish policy or requirements for depleted uranium uses by the U.S. Department of Defense in munitions or other military equipment. As described in Section 2.2 and Appendix H of the PEIS, the two use options evaluated in the PEIS, use as depleted uranium oxide and use as depleted uranium metal as radiation shielding, are representative and were selected to provide a basis for comparing the potential environmental impacts of broad, programmatic management strategies. The selection of these use options for analysis in the PEIS was not intended to imply that the PEIS will be used to select a specific end use or preclude other potential uses in the future. If a use strategy is selected in the Record of Decision, specific uses would be considered and evaluated in more detail in future planning and environmental analyses as appropriate. Careful consideration would be given to whether the benefits of any proposed use outweigh the potential risks.

Comment 1

Page S-1; Para. 2; Sent.4 and Page S-4; Sect. S.1.2; Sent.2: Text states: "Additional NEPA analyses, as appropriate, will be prepared once a long-term management strategy has been selected ....This PEIS examines the environmental consequences of alternative strategies of long term storage, use, and disposal of the depleted UF_6 inventory." This document does not appear to analyze completely the use and disposal of the depleted UF_6 inventory when it defers the analysis of future siting, design, and construction to possible separate NEPA analyses (as appropriate) in the future

when, in effect, they appear to be "connected actions" and/or "cumulative actions" and should be evaluated thoroughly in this PEIS.

Response 1
