**Abstract**—Observations of the aerosol optical thickness (AOT) by the Moderate Resolution Imaging Spectroradiometer (MODIS) instruments aboard Terra and Aqua satellites are being used extensively for applications to climate and air quality studies. Data quality is essential for these studies. Here we investigate the effects of unresolved clouds on the MODIS measurements of the AOT. The main cloud effect is from residual cirrus that increases the AOT by  $0.015 \pm 0.003$  at  $0.55 \mu\text{m}$ . In addition, lower level clouds can add contamination. We examine the effect of lower clouds using the difference between simultaneously measured MODIS and AERONET AOT. The difference is positively correlated with the cloud fraction. However, interpretation of this difference is sensitive to the definition of cloud contamination versus aerosol growth. If we consider this consistent difference between MODIS and AERONET to be entirely due to cloud contamination we get a total cloud contamination of  $0.025 \pm 0.005$ , though a more likely estimate is closer to 0.020 after accounting for aerosol growth. This reduces the difference between MODIS-observed global aerosol optical thickness over the oceans and model simulations by half, from 0.04 to 0.02. However it is insignificant for studies of aerosol cloud interaction. We also examined how representative are the MODIS data of the diurnal average aerosol. Comparison to monthly averaged sunphotometer data confirms that either the Terra or Aqua estimate of global AOT is a valid representation of the daily average. Though in the vicinity of aerosol sources such as fires, we do not expect this to be true.

**Index Terms**—Aerosol, cirrus, cloud, Moderate Resolution Imaging Spectroradiometer (MODIS), remote sensing.

## I. INTRODUCTION

TWO Moderate-Resolution Imaging Spectroradiometers (MODIS) [1] were launched into polar orbit: aboard the Terra satellite in December 1999 and the Aqua satellite in May 2002. One of their primary missions is to observe the global aerosol system and its impact on climate and air quality. MODIS reports aerosol data at 10-km resolution, which is further aggregated to provide more condensed global data products at  $1^\circ$  resolution [2]. Surveys using internet-based search engines show that MODIS aerosol data were used in at least 28 papers published in 2004, alone. They show that MODIS data are used for the following:

- descriptions of the regional, seasonal, and global distribution of aerosols, and their relationship to other pollutants [3]–[15];
- studies of the effect of aerosol on atmospheric chemistry and local air pollution [16]–[18];
- measurements of the aerosol effect on distribution of solar radiation and consequent radiative forcing of climate [19]–[24];
- regional aerosol characterization [25]–[28];
- studies of the aerosol interaction with the meteorological field and with clouds [29], [30].

Each application has different requirements for data availability, and for absolute and relative accuracy. In this paper we shall concentrate on examination of the MODIS aerosol data over oceans. Extensive comparison of these data against ground-based measurements by the sunphotometers of the Aerosol Robotic Network (AERONET) [2], [31], [32] have been used to quantify and validate the MODIS aerosol data quality. They concluded that MODIS aerosol data over the ocean meet the expected accuracy [33], meaning that retrieved AOT errors are  $\Delta\tau = \pm 0.03 \pm 0.05\tau$ , where  $\tau$  is the aerosol optical thickness (AOT). Slightly higher errors were found for dust [34]. Since the MODIS-observed multiyear global averaged AOT over the ocean [35] is about  $\tau \sim 0.13$  an error of  $\pm 0.03$  may be quite significant.

In this paper we critically examine the MODIS aerosol data over oceans, looking for cloud contamination and diurnal sampling issues that may create biases in applications based on the long-term statistics from MODIS aerosol products. First we review the MODIS aerosol products in Section II and validation in Section III. Then, we study what portion of this uncertainty is a

bias due to contamination by cirrus clouds (Section IV), or due to lower level clouds (Sections V). Section VI discusses how a relationship between cloud and aerosol retrievals could either be physically real or an artifact. We end with an analysis of how representative the MODIS data are of the daily averaged aerosol (Section VII).

## II. MODIS AEROSOL PRODUCT

Above the oceans, the aerosol algorithm [33] derives the aerosol optical thickness and aerosol size distribution from MODIS spectral reflectance data, at a nominal resolution of 10 km (at nadir). Within this 10-km resolution, there are 400 MODIS data pixels at 0.5-km resolution, insuring good statistical representation of the  $10 \times 10 \text{ km}^2$  box. Aerosol products are retrieved providing that the target is at least  $40^\circ$  off the sunglint angle, and the scene is sufficiently free of clouds and surface inhomogeneities. Cloud screening is applied using combinations of spatial variability [37] tests in the visible channels and cirrus detection using the cirrus channel at  $1.38 \mu\text{m}$  [38]. The spatial variability mask also eliminates data points that are adjacent to the clouds. On average, the fraction of data points being eliminated by the screening mechanism is 80% higher than the fraction of cloudy pixels being analyzed in the cloud products [39]. The pixels remaining after cloud screening are used to derive the aerosol properties. Requiring a minimum of ten cloud-free pixels, the average of the 25th to 75th percentile (sorted by reflectance) of these pixels is assumed to be representative of the average cloud-free conditions. This average is a robust value that was expected to completely eliminate residual contamination by clouds and cloud shadows which may have remained after the cloud screening and occupy an area less than 25% of the 10-km grid box.

## III. MODIS AEROSOL VALIDATION

First we shall review the MODIS validation studies and their relevance to understanding measurement bias and errors. The MODIS aerosol data are compared against measurements from the surface based AERONET. Over each AERONET site, averages are calculated, such that the AERONET data are averaged in time ( $\pm 30$  min) and MODIS data are averaged in space ( $\pm 25$  km) [40]. This range of the MODIS spatial coverage and the AERONET temporal coverage was chosen as to minimize aerosol variability [41], and to maximize data availability in the presence of clouds. Winds that can shift the aerosol across the validation grid box generate a coupling between the aerosol spatial and temporal variability. Winds of 5–10 m/s during the 1 h of AERONET measurements shift the aerosol by 20–40 km.

AERONET has about 200 locations around the world that measure the spectral extinction of direct sunlight and spectral-angular properties of scattered sky radiances. Together they provide estimates of the spectral AOT as well as aerosol size distribution and optical properties. The coverage is best over continental Europe and North America, and less dense over the oceans, due to the need for either islands or sea-shores for instrument installation. However, given the now, nearly five years of both MODIS and AERONET observations, there are enough

colocated measurements to understand the statistics of the validation efforts [32], [42].

A valid comparison is considered when AERONET reports at least two values (out of the possible four to five measurements) during the hour and MODIS reports at least five measurements (over the ocean segment of the 25 measurements) in the grid box of 50 km. The AERONET data accuracy [43] is  $\delta\tau = \pm 0.015$  at airmass = 1, where airmass is cosine of the solar zenith angle. For all latitudes and seasons the uncertainty is reduced to 0.01.

This validation protocol requires that both MODIS and AERONET data are observed under sufficiently clear conditions, meaning that MODIS validation is biased toward low cloudiness conditions. In fact, we found that the cloud fraction over the ocean, averaged over the entire validation dataset, is 30%, which is about half the average cloud fraction otherwise observed by MODIS. We note that the cloud fraction is defined here as the fraction of the pixels that were rejected from analysis by the aerosol algorithm. For a broken cloud field it is larger than the actual cloud fraction since cloud-free pixels adjacent to the cloud are also rejected. This clear-sky bias to the validation set may imply biases to estimates of global AOT and other aerosol properties.

Is it possible, despite the rigorous cloud screening and the 25th to 75th percentile selection of data, that some cloud interference will remain in the aerosol data? The following are two main possible sources of cloud contamination.

- High concentrations of broken cloudiness may generate illumination of the aerosol field beyond the 500-m distance from the clouds [44].
- Although the cirrus screening eliminates cirrus cloud contamination above a threshold in cirrus reflectance at  $1.38 \mu\text{m}$  of 0.01, some residual cirrus contamination may remain. The threshold of 0.01 is used in order to avoid false elimination of high-altitude dust and to allow for sensor noise [38]

## IV. RESIDUAL THIN CIRRUS CONTAMINATION

To study the residual cirrus contamination, we divided the world into 13 geographic zones [35]: 12 zones are the products of three latitude regions ( $30^\circ$  to  $60^\circ\text{N}$ ;  $0^\circ$  to  $30^\circ\text{N}$ ;  $0^\circ$  to  $30^\circ\text{S}$ ) and four longitude belts ( $0^\circ$  to  $90^\circ\text{E}$ ;  $90^\circ$  to  $180^\circ\text{E}$ ;  $0^\circ$  to  $90^\circ\text{W}$ ;  $90^\circ$  to  $180^\circ\text{W}$ ); the 13th is the southern latitude belt ( $30^\circ$  to  $60^\circ\text{S}$ ). For each zone, a scatter plot was generated that plotted the AOT as a function of the cirrus reflection at  $1.38 \mu\text{m}$  calculated from the cirrus channel [45] [see Fig. 1 (bottom) for an example]. Each point in the scatter plots represents a grid box of 10 km. The average AOT is computed as a function of a given range of cirrus reflectance (i.e., first point is the average AOT for cirrus reflectance of 0–0.001, second for 0.001–0.002, etc.). Cirrus contamination is measured as the elevation of the AOT above its value for the lowest cirrus reflectance interval.

Assuming that there is no physical relationship between the AOT and cirrus reflectance, the systematic relationship between the AOT and cirrus indicates cirrus contamination. The process is repeated for every zone (ocean only) for the first nine months of 2004. The results are plotted in Fig. 2. Every point represents the results of the analysis of Fig. 1 for one zone and one

Fig. 1. Example of the analysis of cirrus contamination. (Top) Histogram of the cirrus reflectance measured by MODIS over the globe for one day (April 1, 2004). Each point is the average over a 10-km grid box. Note the logarithmic scale. (Bottom) Average aerosol optical thickness as a function of a given range of cirrus reflectance (i.e., first point is the average AOT for cirrus reflectance of 0–0.001, second for 0.001–0.002, etc.). Cirrus contamination is measured as the elevation of the AOT above its value for the lowest cirrus reflectance interval.

month. There is a significant variation among the zones. The variation can result from poor statistics, mainly in zones with small ocean cover, and meteorological coincidental correlation between the cirrus clouds and aerosols. It can also result from the cirrus channel detection of high-altitude dust in some of the zones. Dust located at 3–5 km, with little water vapor (<1 cm) left above it, will influence the cirrus observations. Therefore, to summarize the results, we combine two techniques. One is a simple average (dashed line) over the 13 zones, and the second is average of the 25th to 75th percentile among the 13 zones (solid line). The second method eliminates fluctuations that can be caused by errors in extreme zones in specific months. The difference between the two methods of average calculations is small, meaning that the average is robust. Using the second analysis as the bench mark, we estimate the average cirrus contamination of

$$\begin{aligned} \Delta\tau &= 0.012 \pm 0.0005 \text{ for Terra} \\ \Delta\tau &= 0.018 \pm 0.002 \text{ for Aqua.} \end{aligned} \quad (1)$$

The errors in (1) represent standard error due to variability among the 12 months for Terra and Aqua separately. The difference between the two satellites is larger and may result from small differences in their respective calibration.

The cirrus contamination in (1) was derived assuming that there is no interaction between the aerosol and the cirrus cloud and that any coincidental correlation will affect only some of the zones and will be canceled out in the 25th to 75th percentile average. In fact, since meteorological influence is expected to vary from month to month, the small standard error in (1) reflects their residual influence. To test the analysis further, we repeated the calculations of the cirrus contamination using only regions in the tropical Pacific (30° S to 30° N, 90° W to 90° E) and the Southern Ocean (30° S to 60° S) where most of the aerosol is low-level oceanic aerosol, less likely to interact with the cirrus. The results for Terra are that the cirrus contamination is  $\Delta\tau = 0.011$  for the Pacific Ocean and  $\Delta\tau = 0.012$  once the Southern Ocean was included, basically same as the bulk analysis.

## V. CONTAMINATION BY CLOUDS AND CLOUD ILLUMINATION

Broken clouds within or adjacent to the satellite field of view also may contaminate retrievals of aerosol properties. As cloud fraction increases within the scene, the potential for contamination increases. In Fig. 3, we plot the MODIS AOT, the AERONET AOT and the difference between them, as a function of the cloud fraction determined by MODIS in the 50-km grid box centered on the AERONET station. AERONET sunphotometers derive the AOT by observing the attenuation of sunlight through the atmosphere. Sunlight is three to six orders of magnitude brighter than the sky or clouds and therefore cloud illumination cannot affect the AERONET AOTs. AERONET also has an independent cloud screening procedure [46]. Though AERONET also may not be able to screen out very thin cirrus, the cirrus crystals' strong forward scattering of diffuse light into the AERONET sunphotometer field of view results in only ~50% of the cirrus optical depth being translated into an increase in apparent optical thickness [47].

Fig. 3 shows a correlation between MODIS AOT "error" and cloud fraction as defined by the MODIS aerosol algorithm. We note that this cloud fraction will always overestimate the true cloud fraction because the MODIS aerosol algorithm rejects both cloudy pixels and also those pixels adjacent to clouds. Thus, the global mean cloud fraction of ~60% corresponds in Fig. 3 to cloud fraction of ~80%, where the corresponding difference between MODIS and AERONET is  $0.010 \pm 0.002$  and  $0.025 \pm 0.005$  for Terra and Aqua respectively. Some of the discrepancy between MODIS and AERONET at high-cloud fractions is due to different treatment of cirrus contamination discussed in Section IV and quantified in (1). Though AERONET may have similar difficulties as MODIS to screen out thin cirrus, AERONET measurements are not affected as much by the presence of thin cirrus clouds; while the MODIS field of view is ~0.1° AERONET field of view is 1.2° allowing half of the scattering by the thin cirrus clouds to be detected still in the field of view. Therefore, we can expect AERONET to be affected only by 50% of the cirrus scattering and therefore only about half of the values in (1) (0.006 for Terra and 0.009 for Aqua) contribute to the discrepancy between MODIS and AERONET in Fig. 3. Thus, noncirrus effects, associated with clouds, are contributing

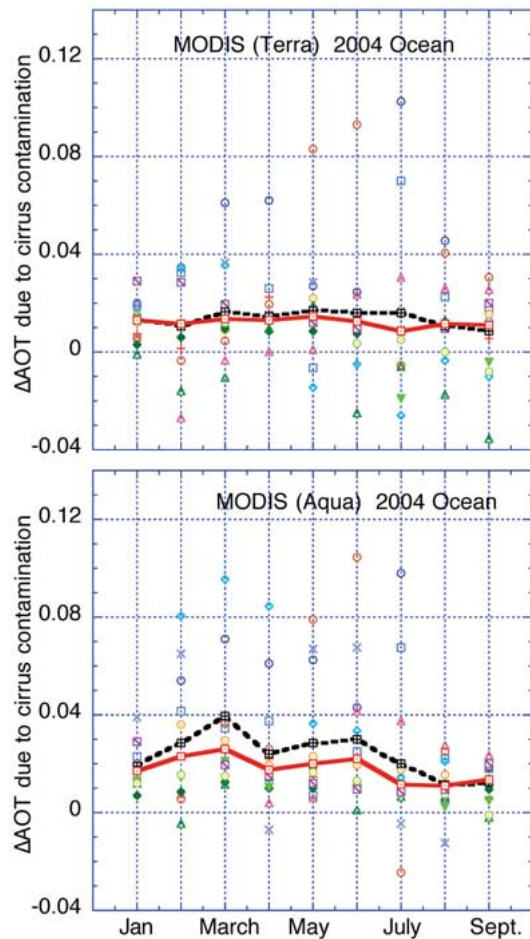

Fig. 2. Plot of the cirrus contamination calculated using scatter plots shown in Fig. 1. The earth was divided into 13 zones. For each, the average contamination over the ocean is plotted by symbols as a function of the month for 2004. The solid line is the median contamination calculated as the average of 25th to 75th percentile among the 13 zones. The dashed line is the simple average. Top is for Terra and bottom for Aqua.

to elevating the global MODIS AOT retrievals by  $0.004 \pm 0.002$  for Terra and  $0.016 \pm 0.005$  for Aqua.

What is the origin of the cloud fraction dependence of the difference of MODIS versus AERONET? One possibility is that when cloud fraction is high over ocean there is a gradient from land, where the sunphotometer is located to the ocean with different meteorological conditions. To investigate this possibility we analyzed separately the difference between MODIS and AERONET for island stations only. There is no significant difference between the results, decreasing the probability that a systematic gradient in cloudiness and aerosol conditions is the reason.

Another possibility to explain Fig. 3 is that, despite our best efforts, cloudy pixels are escaping our cloud mask and are being retrieved as aerosol. A third possibility related to the second is that clouds are brightening their surrounding pixels, even beyond the one pixel border that the MODIS algorithm imposes on the cloud mask. Cloud droplets are orders of magnitude larger than aerosol particles. Light scattering by large cloud droplets will be spectrally neutral. Therefore, cloud-contaminated retrieved spectral aerosol optical thickness will have less spectral dependence and be more neutral. We measure

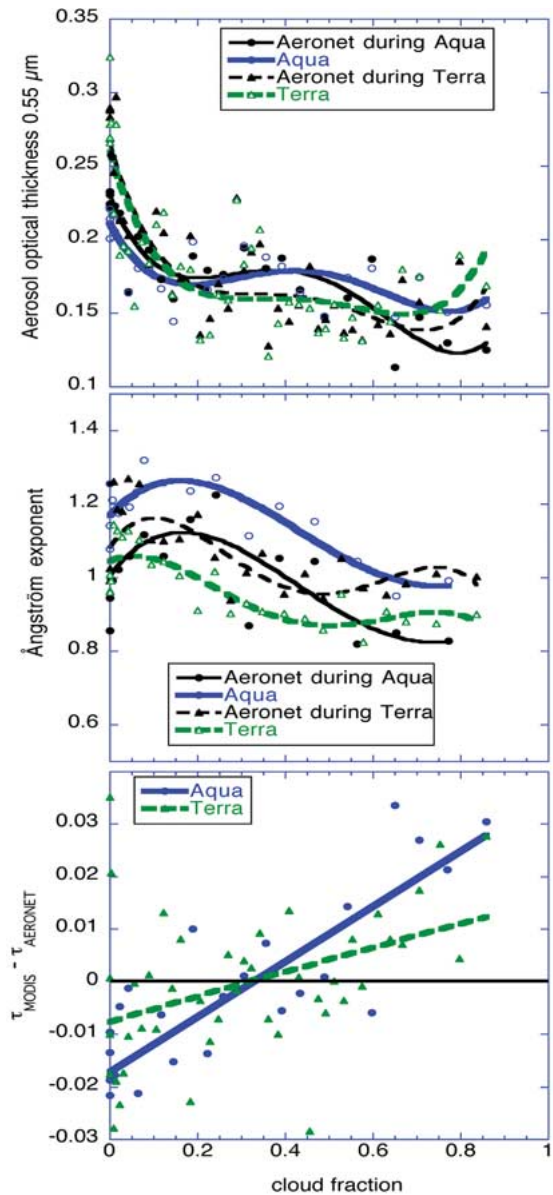

Fig. 3. (Top) Scatter plot of the MODIS aerosol optical thickness over the ocean and the AERONET-measured AOT as a function of the cloud fraction at 550 nm. The cloud fraction is defined here as the fraction of the points that were rejected from analysis by the aerosol algorithm. AERONET spectral measurements were interpolated to 550 nm using a parabolic fit in a logarithmic scale [43]. The 3500 points in the comparison were sorted as a function of the cloud fraction and averaged in groups of 50. (Middle) Same for the Ångström exponent for  $AOT \geq 0.1$ . (Bottom) The difference between the MODIS and AERONET measurements for Terra (green) and Aqua (blue). Data are taken from the MODIS validation over oceanic AERONET sites. The MODIS measurements are within 25 km of each AERONET station, and the AERONET data are within 30 min of the MODIS observations. The difference in the AOT, representing the error in the MODIS measurements, has a systematic dependence on the cloud fraction. The error dependence on the cloud fraction is  $\Delta\tau_{AQUA} = -0.017 + 0.052f_C$ , and  $\Delta\tau_{TERRA} = -0.008 + 0.023f_C$ .

spectral dependence with the Ångström exponent ( $\alpha$ ), which defines the slope of  $\ln(AOT)$  plotted against  $\ln(\text{wavelength})$ . A larger  $\alpha$  corresponds to a steeper slope, a greater spectral dependence and smaller particles. Thus, if cloud contamination is responsible for the differences in AOT between MODIS and AERONET in Fig. 3, then we expect two things: 1) as cloud fraction increases MODIS  $\alpha$  should decrease and 2) MODIS  $\alpha$

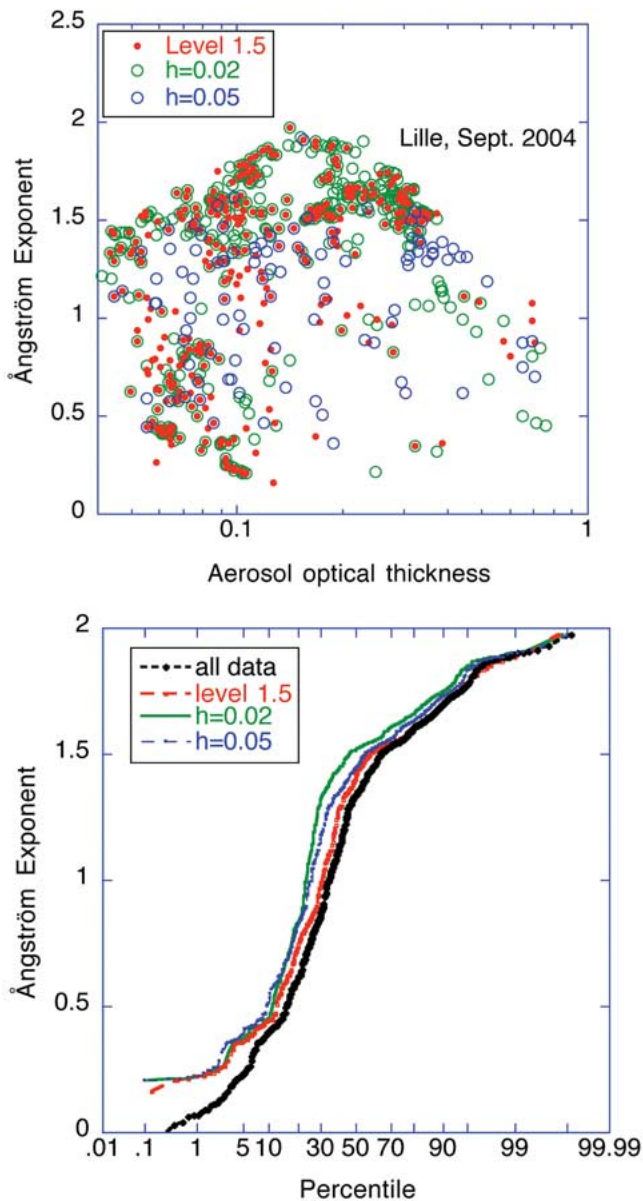

Fig. 4. Comparison of cloud rejection between two algorithms, the AERONET cloud screening (level 1.5 [46]) and a spectral sensitive cloud screening of (3) for the month of September 2004 in Lille, France. (Top) The Ångström exponent as a function of the aerosol optical thickness, for two application of the new algorithm with  $h = 0.02$  (green circles), additional points for  $h = 0.05$  [blue circles—see (4)], and for the AERONET level 1.5 data (red dots). (Bottom) Cumulative histograms of the Ångström exponent for the new algorithm (green— $h = 0.02$ ; blue— $h = 0.05$ ), for the AERONET level 1.5 cloud screened data (red), and for all the level 1.0 (before the level 1.5 cloud screening) data (black).

should decrease more sharply than AERONET. Fig. 3 (middle) shows the plot of Ångström exponent against cloud fraction for Terra, Aqua, and their associated AERONET measurements. The differences between Terra and Aqua can be explained by calibration differences in the two sensors. There certainly is a decrease of  $\alpha$  (increase in particle size) as cloud fraction increases. However, the differences between MODIS and AERONET Ångström exponent remain constant for the entire range of cloud fraction. With this consistency it becomes difficult to explain the difference between MODIS and AERONET AOT as simple cloud contamination.

Fig. 5. Scatter plot of the monthly independent average of MODIS (top) Terra and (bottom) Aqua aerosol optical thickness versus those of AERONET. At least five daily measurements were required for each sensor to generate the monthly average. The data are separated into Dust, marine aerosol, smoke, and urban aerosol. For each range of the AOT, the data are averaged and presented by the + sign with standard deviation. The data are summarized in Table I.

## VI. CLOUD CONTAMINATION VERSUS AEROSOL GROWTH

To understand the relationships between MODIS and AERONET optical thickness and Ångström exponent, we need to address the fundamental problem of how to differentiate between cloud contamination and variability of the aerosol optical thickness due to aerosol growth by cloud processes and humidification. The AERONET and MODIS cloud screening algorithms may separate cloud contamination from cloud growth differently. Are the differences in Fig. 3 due to stronger

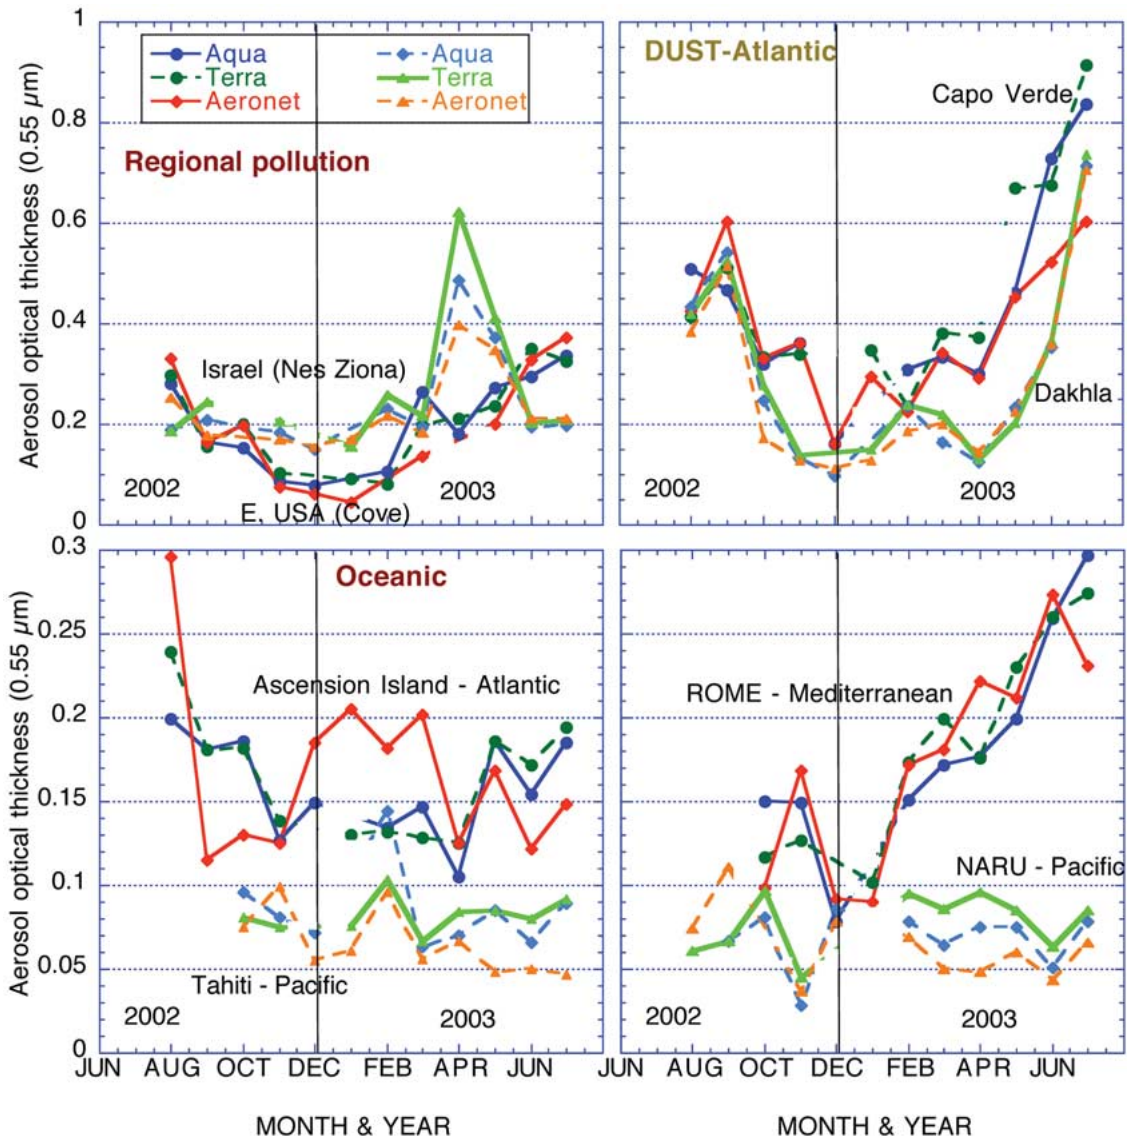

Fig. 6. Monthly average aerosol optical thickness values from MODIS Terra (green), Aqua (blue), and AERONET (red and orange), plotted for eight individual sites as a function of the month of observation. At least five measurements were required to generate each monthly average. Months with smaller number of points were skipped.

cloud contamination of the MODIS retrievals or more allowance for aerosol growth? We use the AERONET data to study this issue.

The main tool for AERONET cloud screening [46] is rejection of AOT variability in two time scales: fast variability of the AOT in between the three measurements taken 30 s apart (triplets) at each wavelength separately, and slower variability among measurements taken 15 min apart. The fast variability is the main criteria. The algorithm requires that the difference between the maximum and minimum aerosol optical thickness among the triplet measurements is smaller than 0.02 for every wavelength. For high optical thicknesses ( $AOT > 0.7$ ) the threshold is  $0.03\tau$ . This algorithm is applied globally to all aerosol types. For the purpose of this study we design a modified cloud screening algorithm, that applies to pollution or smoke aerosol only, by taking advantage of their strong spectral dependence, and quantifies cloud contamination and aerosol growth effects.

Assuming that the cloud optical depth is wavelength independent and that the aerosol optical depth has a wavelength dependence, we can calculate the contribution of cloud contamination to variations in the aerosol field separately from variations of the “true” aerosol. The measured spectral AOT,  $\tau_\lambda$ , with possible cloud contamination can be written as

$$\tau_\lambda = \langle \tau_\lambda \rangle + \Delta\tau_\lambda \quad (2)$$

where  $\Delta\tau_\lambda$  is the variability between the triplet measurements or the 15-min measurements of the aerosol optical thickness, and  $\langle \tau_\lambda \rangle$  is the spectral AOT of the bulk of the aerosol.

The cloud contamination is the difference between the measured aerosol variability at  $0.87 \mu\text{m}$  and the variability that corresponds to the bulk aerosol spectral dependence

$$\delta\tau_{\text{cloud}} = [\Delta\tau_{0.87} - \Delta\tau_{0.44}(\langle \tau_{0.87} \rangle / \langle \tau_{0.44} \rangle)] \quad (3)$$

restricted for Ångström exponent  $> 0$ .  $\Delta\tau_{\text{cloud}}$  is the residual spectrally neutral variability of the AOT measurements. What

(3) represents is that if the spectral dependence of  $\Delta\tau_\lambda$  is similar to that of  $\langle\tau_\lambda\rangle$  then the measurement is not cloud contaminated for any magnitude of the variability  $\Delta\tau_\lambda$ . In such case  $\Delta\tau_{\text{cloud}} = 0$ .

The new proposed cloud screening allows aerosol variability not to be rejected as cloud, as long as it has similar spectral properties to the bulk of the aerosol. However, aerosol growth can also reduce the aerosol wavelength dependence and generate a positive  $\Delta\tau_{\text{cloud}}$ . Analysis of sunphotometer data in the eastern U.S. humid and polluted summer environment [48] showed that changes in the relative humidity can change the Ångström exponent by up to 0.2, corresponding to  $\Delta\tau_{\text{cloud}}/\tau_{\text{aerosol}} = 20\%$ . Therefore, cloud contamination needs to be defined above a given threshold of  $\Delta\tau_{\text{cloud}}$

$$\Delta\tau_{\text{cloud}} > n + h\tau_{\text{aerosol}} \quad \text{for } 0.55 \mu\text{m}. \quad (4)$$

In Fig. 4, we compare the AERONET original cloud screening with the new concept for  $n = 0.005$  and  $h = 0.02$  or  $0.05$ , for measurements in Lille, France during September 2004. The value of “ $n$ ” means that we allow for noise in the data of  $\Delta\tau < n$  not to be called a cloud, and “ $h$ ” means that we allow variability of 100 h% in the wavelength-independent component of the AOT to be associated with aerosol growth rather than cloud contamination. In Fig. 4, we also show the cloud-screened level 1.5 AERONET AOT data and application of the new algorithm to the level 1.0 data. The new algorithm included additional points in the variable portion of the day. On average, for the month of September the new algorithm had 15% additional points for  $h = 0.02$  and 44% more points for  $h = 0.05$ , both possible result of aerosol growth. The corresponding change in the monthly average of AOT and Ångström exponent (at  $0.67 \mu\text{m}$ ) is from (0.145 and 1.22) for the AERONET algorithm to (0.170 and 1.32) for  $h = 0.02$  and (0.174 and 1.28) for  $h = 0.05$ . Note that the new algorithm, while adding data, also increased the Ångström exponent, by screening small residual clouds with a finer threshold. Therefore, differences in the AOT of  $\sim 0.02 \pm 0.01$  between MODIS and AERONET (from Fig. 3) as a function of the cloud fraction can be equally associated with aerosol growth as with cloud contamination. However, application of the new algorithm to dust and dust mixed with smoke or pollution is more complex and beyond the scope of the present paper.

## VII. EFFECT OF THE DIURNAL CYCLE

The MODIS observations take place at a narrow interval of the diurnal cycle, where Terra crosses the equator southward about 10:30 local solar time, whereas Aqua crosses northward about 13:30. Because of the difference in direction, midlatitude time differences between Terra and Aqua are approximately 1.5 h in the Northern Hemisphere and 4.5 h in the Southern Hemisphere. The use of MODIS data to represent regional aerosol burden requires understanding of the diurnal representation of these two times of the day. A previous analysis of AERONET data [49] found that there is no statistically significant difference between the AOT monthly averages, whether they were taken only around 10:30 or 1:30, or averaged throughout the day, although a diurnal cycle can exist [50] near aerosol sources

TABLE I  
COMPARISON OF TERRA AND AQUA MODIS AEROSOL OPTICAL THICKNESSES AT 550 nm TO AERONET FOR ALL OCEANIC STATIONS DURING ONE YEAR 2002–2003. EACH DATASET OVER EACH STATION IS AVERAGED MONTHLY INDEPENDENTLY OF THE OTHERS. THE DATA ARE THEN SORTED BY THE AERONET AOT AND AVERAGED IN GROUPS OF 8–30. SYSTEMATIC DEVIATIONS IN THE DIURNAL CYCLE WOULD AFFECT THE DIFFERENCE BETWEEN THE SATELLITE AND AERONET DATA

that have a strong diurnal cycle like smoke from fires, both prescribed fires in the tropics that are lit in the afternoon and wild fires that emits more during the day in the presence of strong winds. Over the oceans, far from aerosol sources [51], we would expect that either Terra or Aqua aerosol measurements would be representative of the daily averaged AERONET AOT [49].

In Fig. 5, we test the validity of this hypothesis using the actual MODIS data from Terra and Aqua on a  $1^\circ$  latitude and longitude resolution, over several AERONET stations in oceanic regions. The monthly average value was calculated if there were at least five days of reported data for each instrument. These are not collocated data, meaning that the AERONET data contain information from all daylight hours, not just at the time of overpass. Note the possibility that, in high cloudy conditions, data observed by AERONET, Terra, and Aqua are taken from different days of the month.

The plots in Fig. 5 distinguish among four aerosol types: dust, smoke, marine, and urban aerosol, based on their location/season. The average differences between the MODIS measurements and AERONET are also given in Table I, for all available AERONET oceanic data during one year in 2002–2003 (Level 2.0 data). On average Terra and Aqua AOTs are higher than those of AERONET by  $0.01 \pm 0.005$ . Thus, despite different sampling strategies, MODIS can represent AERONET’s long-term statistics to within the measurement uncertainties of both instruments.

However, there are differences for both small and large optical thickness conditions. For optical thickness  $\tau < 0.2$  the difference is  $\Delta\tau \sim 0.02$  both for Terra and Aqua. However, for high AOTs the MODIS results are lower for smoke and pollution, apparently due to higher aerosol absorption [52], [53], than that assumed in the MODIS inversion process. For dust the AOT is slightly higher probably due to the effect of dust nonsphericity that is not included presently in the aerosol algorithm. Depending on the scattering angles in the dataset, nonsphericity can increase or decrease the dust AOT.

In Fig. 6, the comparison of Terra, Aqua, and AERONET measurements is shown for eight stations as a function of the month. Differences between Terra and Aqua can either indicate strong diurnal cycle or low density of data. Nes-Ziona in Israel and COVE in the eastern U.S. represent locations influenced by pollution aerosols. Stations influenced by desert dust

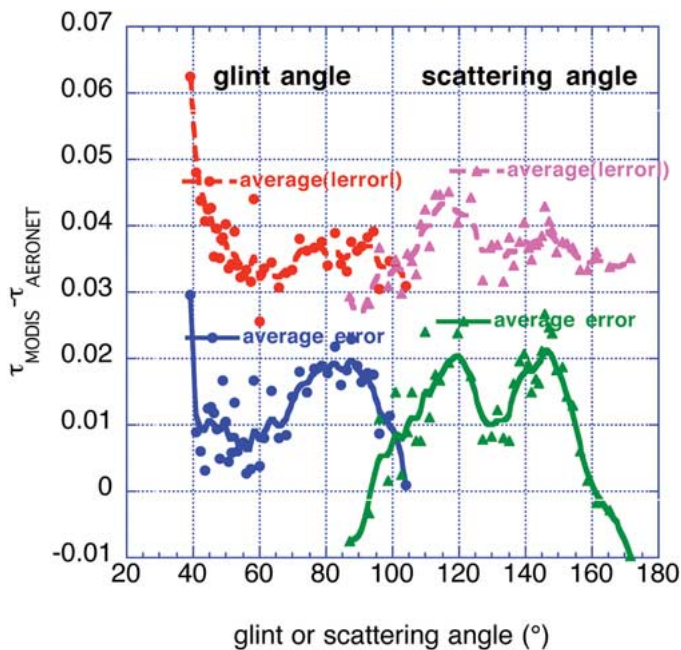

Fig. 7. Average difference between MODIS- (Terra and Aqua) and AERONET-derived aerosol optical thickness as a function of the glint angle and the scattering angle. The averaging is on 200 points with similar glint or scattering angle. Both averages of the absolute errors (red and pink dashed lines) and of the actual errors (blue and green solid lines) are shown.

(Capo Verde and Dakhla) show very good agreement between the measurements, except during the summer months at Capo Verde where Terra and Aqua report higher values. Tahiti and Ascension Island are both remote ocean sites; however, the agreement in Tahiti is better than that in Ascension Island where the satellite data rate is lower in December–March. It is during this period when biomass burning from Africa affects Ascension Island. Very good agreement is observed over Rome.

### VIII. GLINT AND SCATTERING ANGLES

The validation dataset that was used to observe the effect of cloud on the MODIS aerosol measurements can be also used to observe the effect of the different glint and scattering angles on the measurements. In Fig. 7, we plot the average error in the AOT measurements from MODIS on Terra and Aqua and the average of the absolute errors as a function of the glint angle and separately as a function of the scattering angle. The results show that the glint angle, on average, has no significant effect on the accuracy. The errors tend to be higher, and therefore the average of the absolute errors higher as we approach the glint for glint angle  $< 50^\circ$ . The dependence on the scattering angle shows also little dependence with some improvement of the accuracy for scattering angles  $< 110^\circ$  as suggested by Chylek *et al.* [54], though the density of the data for small scattering angles is very low. The errors are also lower around a scattering angle of  $160^\circ$ , which may be due to lower impact of aerosol nonsphericity.

### IX. IMPLICATIONS TO THE USE OF THE MODIS AEROSOL DATA

The accuracy of the MODIS aerosol data has different implications depending on the application for which they

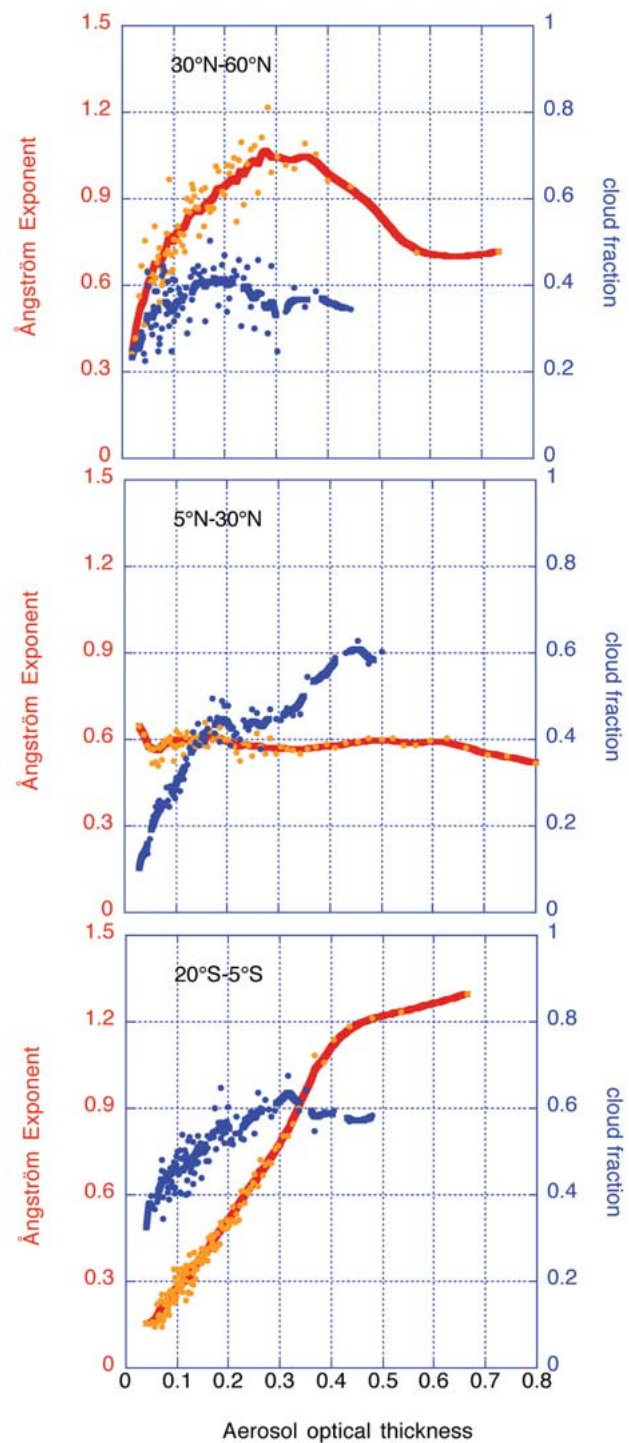

Fig. 8. Aerosol Ångström exponent [a measure of (solid red line) the aerosol size] and (dashed blue line) cloud fraction, as a function of the aerosol optical thickness. Cloud fraction is plotted only for AOT  $< 0.5$  to avoid effects of aerosol on the cloud fraction [39].

are used. MODIS estimates of regional and global average aerosol optical thicknesses are sensitive to cloud contamination. For 2001–2003 the MODIS average AOT over the ocean [35] weighted by the cloud-free area is  $\sim 0.13 \pm 0.01$  (the unweighted value is 0.14), while several chemical transport models [55]–[57] estimate  $0.090 \pm 0.005$ , where 0.005 is the deviation among the three models. The present analysis shows

cloud contamination of  $0.015 \pm 0.003$  for cirrus. The difference between MODIS measurements and AERONET shows dependence of the AOT on the cloud fraction that may indicate additional cloud contamination of AOT of  $\delta\tau \sim 0.01 \pm 0.005$  or can indicate different sampling of the effects of aerosol growth by the two algorithms. Therefore, the total cloud contamination is estimated to be at most  $0.025 \pm 0.005$ , with a more likely estimate closer to 0.020 after accounting for the probability of aerosol growth issues. This reduces the difference between the MODIS global measurements over the oceans and the transport models from 0.04–0.05 to  $\sim 0.02$ .

Another range of applications is the observations of aerosol influence on other atmospheric constituents, e.g., on the cloud microphysics and cloud development [29], [58], [59]. In such studies the cloud parameter is plotted as a function of the AOT, assuming that the change in the AOT represents the true increase in the aerosol load. In Fig. 3 we analyzed the dependence of possible cloud contamination on the cloud fraction. For example, an increase in cloud fraction of 0.25 can cause a maximum increase in the observed AOT of 0.01, independent of the values of the AOT.

Here we test this conclusion by using an additional measure of aerosol derived by MODIS, namely the change in the Ångström exponent as a function of the AOT. Cloud contamination is expected to have neutral spectral reflectance due to the large size of cloud droplets, thus reducing the Ångström exponent. If cloud contamination is an important factor in variation of the aerosol AOT, then we can expect the Ångström exponent to decline as a function of the increase in AOT. In Fig. 8, we plot the Ångström exponent and the cloud fraction as a function of the AOT, for three latitude zones of the Atlantic ocean analyzed for June–August 2002. Each point represents average on 50 daily values, with similar AOT in  $1^\circ$  resolution. This analysis differs from the previous analysis in Section V and Fig. 3(b) in that the previous analysis was confined to points collocated with AERONET stations, and here we use all available midocean data of the Atlantic basin for the period indicated. Before we were looking for discrepancies from AERONET as cloudiness increased. Here we are looking for relationships between aerosol size and aerosol optical thickness. In all cases for  $\text{AOT} < 0.3$ , as AOT increases the Ångström exponent increases or remains constant (for dust). The increase is due to transition from pure marine aerosol with Ångström exponent around 0.3 to smoke, or pollution with Ångström exponent of 1.0 or higher. Therefore, the increase of AOT cannot be explained by increase of cloud contamination or contamination from illumination from cloud sides. For the pollution zone ( $30^\circ$  to  $60^\circ$ ) for  $\text{AOT} > 0.3$  the Ångström exponent decreases. However, the cloud fraction is constant or decreases also. Therefore, this cannot be explained by cloud contamination but rather aerosol growth.

## X. CONCLUSION

We found a residual cloud contamination, in particular very thin cirrus on the MODIS aerosol optical thickness (AOT), de-

spite the MODIS unique cirrus detection channel, and vigorous spatial-spectral cloud rejection. Unresolved cirrus contributes  $0.015 \pm 0.003$  to the global aerosol average aerosol optical thickness over cloud-free oceans. An additional  $0.010 \pm 0.005$  of excess optical thickness is associated with cloudy conditions; however, it is difficult to distinguish with present data between broken-cloud contamination and aerosol growth. Though the total contamination of  $0.020 \pm 0.005$  is essential in using the satellite data to evaluate aerosol simulated by global chemical transport models, it is not detrimental in addressing aerosol effect on cloud microphysics, albedo, and precipitation. We also found the aerosol to show overall a weak diurnal cycle, though a strong diurnal cycle is expected in the vicinity of sources with a strong diurnal variability.

## ACKNOWLEDGMENT

Part of the work was performed while Y. J. Kaufman was a visiting professor in the Laboratory for Atmospheric Optics directed by D. Tanré. The author would like to thank J. Coakley (Oregon State University) for provocative questions that stimulated some of the analysis.

**Yoram J. Kaufman** received the B.S. and M.S. degrees in physics from the Technion—Israel Institute of Technology, Haifa, and the Ph.D. degree from Tel-Aviv University, Tel-Aviv, Israel.

He came to NASA Goddard Space Flight Center (GSFC), Greenbelt, MD, in 1979 on an NRC Fellowship Award. He is currently a Senior Fellow and Atmospheric Scientist at GSFC. He has served as the Project Scientist of the Earth Observing System first satellite EOS-Terra, from 1996 through its launch in December 1999, and was a Member of the MODIS Science Team (1988–2003). His present work includes theoretical and experimental research in atmospheric radiative transfer and remote sensing, including remote sensing of aerosol, their interaction with clouds and radiation, and impact on climate. He conducted the Smoke/Sulfate, Clouds And Radiation (SCAR) field experiments in Brazil and the U.S., to characterize smoke aerosol properties, their emissions from fires, and their effect on clouds and radiation. He has over 170 refereed publications.

Dr. Kaufman is the seventh recipient of the NASA/GSFC Nordberg Award for Earth Sciences and was awarded the NASA Medal for Exceptional Scientific Achievement. He is a Fellow of the American Meteorological Society and is listed among the ISI highly cited scientists in Geophysics.

**Lorraine A. Remer** received the B.S. degree in atmospheric science from the University of California, Davis, the M.S. degree in oceanography from the Scripps Institution of Oceanography, San Diego, CA, and the Ph.D. degree in atmospheric science from the University of California, Davis.

She has been with the National Aeronautics and Space Administration, Goddard Space Flight Center (GSFC), Greenbelt, MD, since 1991, employed by Science Systems and Applications, Inc., Lanham, MD, until 1998, when she became a civil servant.

She is currently a Physical Scientist with the Climate and Radiation Branch, Laboratory for Atmospheres, GSFC. She is a Member of the EOS-MODIS science team and was a member of the Global Aerosol Climatology Project science team. Her current research interests are the climatic effects and remote sensing of atmospheric aerosol. She has been involved in several field campaigns including the Smoke/Sulfate, Cloud And Radiation (SCAR) experiments, the Tropospheric Aerosol Radiative Forcing Observational Experiment (TARFOX), the Israeli Desert Transition Zone experiment, the Puerto Rico Dust Experiment (PRiDE), and the Chesapeake Lighthouse Airborne Measurements for Satellites (CLAMS).

**Didier Tanré** received the M.Sc. degree in physics in 1975 and the Thèse de 3ème Cycle and Doctorat d'Etat in atmospheric physics in 1977 and 1982, respectively, all from the Université des Sciences et Technologies de Lille, Lille, France.

He is an atmospheric scientist in the Centre National de la Recherche Scientifique (CNRS), collocated with the Laboratoire d'Optique Atmosphérique at the Université des Sciences et Technologies de Lille, France, where he has been a Research Scientist since 1982. In addition to these

positions, he was an NRC Resident Research Associate at NASA Goddard Space Flight Center from 1989 through 1991. He is a member of the MODIS Science Team, where he has primary responsibility for remote sensing of tropospheric aerosol over the ocean. He is a member of the Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observation (CALIPSO) science team and is the Principal Investigator of the Polarization and Anisotropy of Reflectances for Atmospheric Science coupled with Observations from a Lidar (PARASOL) mission. He has around 100 peer-reviewed papers in the field of remote sensing of aerosols and clouds. He is currently the Director of the Laboratoire d'Optique Atmosphérique at the Université des Sciences et Technologies de Lille.

**Rong-Rong Li** received the B.S. degree in optical physics from Nankai University, Tianjin, China, in 1982, and the M.S. and Ph.D. degrees in physics from the University of Cincinnati, Cincinnati, OH, in 1989 and 1995, respectively.

She is currently with the Goddard Earth Sciences and Technology Center, University of Maryland Baltimore County, Baltimore and the NASA Goddard Space Flight Center, Greenbelt, MD. Her research experiences in remote sensing include atmospheric aerosols, water vapor, clouds, vegetation indexes, fire, and coastal waters using multispectral and hyperspectral data acquired from both the aircraft and satellite platforms.

**Richard Kleidman** received the B.S. degree in environmental toxicology in 1980, the M.S. degree in plant protection and pest management in 1985, and several teaching credentials from the University of California, Davis.

After a brief career teaching elementary, middle, and high school students, he joined the MODIS aerosol group in 1992. He has participated in various field experiments including SCAR-A, SCAR-B, TARFOX, PRIDE, and CLAMS. He is involved in MODIS algorithm validation and analysis.

**Shana Mattoo** received the B.Sc. degree in mathematics and physics from the University of Srinagar, Srinagar, India, in 1965, and the M.S. degree in science teaching from the University of Agra, Agra, India, in 1968.

She taught mathematics and physics to high school students for almost ten years in India. After coming to the U.S. in 1982, she has been working as a Programmer/Analyst with different companies supporting projects at the Goddard Space Flight Center. She is currently the Lead Programmer/Analyst

responsible for the MODIS aerosol algorithm code. She is working with Science System and Applications, Inc. (SSAI), Lanham, MD, at the Climate and Radiation Branch at NASA Goddard Space Flight Center, Greenbelt, MD.

**Robert C. Levy** received the B.A. degree in mathematics from Oberlin College, Oberlin, OH, in 1994, and the M.S. degree in atmospheric science from Colorado State University, Fort Collins, in 1996. He is currently pursuing the Ph.D. degree in meteorology at the University of Maryland, College Park.

Since 1998, he has been with Science Systems and Applications, Inc., Lanham, MD, working on-site within the Climate and Radiation Branch, Goddard Space Flight Center, Greenbelt, MD. He supports the EOS-MODIS science team and focuses on

validation and development of the MODIS aerosol retrieval algorithms. He is currently working to improve the retrieval of aerosol over the land, globally, as well as specifically over the U.S. east coast region. He has been involved in major field campaigns including the Puerto Rico Dust Experiment (PRiDE) and the Chesapeake Lighthouse Airborne Measurements for Satellites (CLAMS).

**Thomas F. Eck** received the B.S. degree in meteorology from Rutgers University, Piscataway, NJ, in 1977, and the M.S. degree in meteorology from the University of Maryland, College Park, in 1982, where his major interests were in micrometeorology and aerosol remote sensing.

In 1981, he began work at the NASA Goddard Space Flight Center, Greenbelt, MD, and has continued through to the present. He is currently a Research Scientist affiliated with the GEST Center, University of Maryland Baltimore County, where he carries out instrument calibration and deployment, field experimentation, data analysis, and scientific research within the global Aerosol Robotic Network (AERONET) project. He has authored and coauthored over 75 papers with recent emphasis on studies of the optical properties of atmospheric aerosols, especially from biomass burning and fossil fuel combustion, and the attenuation of solar flux by aerosols.

**Brent N. Holben** received the M.S. degree from Colorado State University, Fort Collins, in 1976, specializing in biometeorology and remote sensing.

He is currently a Research Scientist at the NASA Goddard Space Flight Center (GSFC), Greenbelt, MD. He was a Staff Scientist with the University of Puerto Rico/Puerto Rico Nuclear Center investigating mesoscale radiation balance in the Luquillo Experimental Forest until 1978 when he joined the NASA GSFC. He has published on remote sensing of vegetation dynamics, atmospheric corrections to remotely sensed data, and more recently, aerosol optical properties. He is the Project Leader of the ground-based aerosol characterization program AERONET, initiating and guiding its development since 1992.

**Charles Ichoku** (M'01) received the B.Sc. and M.Sc. degrees in the surveying sciences from the University of Nigeria, Enugu, Nigeria, and the Diplôme d'Etudes Supérieures Spécialisées degree in remote sensing and the Ph.D. degree in earth sciences from the Université Pierre et Marie Curie, Paris, France, in 1982, 1987, 1989, and 1993, respectively.

He was a Research Fellow/Visiting Scientist at the Jacob Blaustein Institute for Desert Research, Ben-Gurion University of the Negev, Sede Boker Campus, Israel, from 1993 to 1997, then at the Max-Planck Institute for Chemistry, Mainz, Germany, from 1997 to 1998. His research activities included developing remote sensing applications in various branches of the earth sciences, including geology, hydrology, and atmospheric studies. He joined Science Systems and Applications, Inc., Lanham, MD, in November 1998, as a Research Scientist working at the NASA Goddard Space Flight Center, Greenbelt, MD. His research interests have been in remote sensing of aerosols and fires, their global distribution, and their impacts on the human population, the environment, and climate. He has been actively involved in the validation and applications of the aerosol and fire products derived from the Moderate-Resolution Imaging Spectroradiometer sensor aboard the EOS Terra and Aqua satellites.

Dr. Ichoku is a member of the American Geophysical Union.

**J. Vanderlei Martins** received the B.Sc., M.Sc., and Ph.D. degrees in physics from the Institute of Physics, University of Sao Paulo (USP), Sao Paulo, Brazil.

He joined the Group of Studies of Air Pollution, Institute of Physics (USP) in 1990 and conducted research in environmental and atmospheric applied physics, developing nuclear analytical techniques using particle accelerators for material analysis, including aerosols and tree rings. He has participated in several ground-based and aircraft field experiments studying properties of aerosols from biomass burning, urban, and biogenic emissions, as well as their effects on clouds and radiation. In 2000, he joined the MODIS aerosol group at the NASA Goddard Space Flight Center, Greenbelt, MD, through the Joint Center for Earth Systems Technology (JCET-UMBC), and in 2001 he was elected as a representative member of the International Radiation Commission where he serves to this date.
