and

Rhoda D. Levin

Center for Chemical Physics, National Bureau of Standards, Gaithersburg, MD 20899

The available data on gas phase basicities and proton affinities of molecules are compiled and evaluated. Tables giving the molecules ordered (1) according to proton affinity and (2) according to empirical formula, sorted alphabetically are provided. The heats of formation of the molecules and the corresponding protonated species are also listed.

Key words: basicity, heats of formation, ion-molecule reaction, proton affinity, proton transfer.

1. Introduction

1.1. Definitions

The gas phase basicity and proton affinity of a molecule, M, are both defined in terms of the hypothetical reaction:

The gas phase basicity is the negative of the free energy change associated with this reaction, while the proton affinity is the negative of the corresponding enthalpy change.

1.2. Proton Affinities and Gas Phase Basicities: An Overview

Proton transfer reactions are of considerable importance in chemistry. Acid-base reactions have been studied extensively in solution for decades, but it is only in the past twenty years or so that experimental techniques have been devised to permit the quantitative study of the thermochemistry of proton transfer reactions in the gas phase. Particularly in the years since 1971, when the first gas phase ion-molecule equilibrium studies on proton transfer appeared, there has been a burgeoning of data in the literature, and consequently, a great interest in using information from such gas phase studies to distinguish between the chemical effects of solvation and the effects of intrinsic molecular properties. To date, although several excellent reviews of this active field of research have appeared¹⁻⁷, and two unevaluated compilations of data are available⁸⁻⁹, there was, until the current publication, no single reference which presented a comprehensive collection of data on gas phase proton affinities evaluated for internal consistency.

The vast majority of proton affinities presented here are based on measurements of the equilibrium constants of gas phase proton transfer reactions:

where:

$$-RT \ln K_{eq} = \Delta G_{Rn} = \Delta H_{Rn} - T\Delta S_{Rn} \quad (3)$$

and the equilibrium constant for reaction 2 is obtained from a mass spectrometric observation of the relative abundances of equilibrated ions, MH^+ and NH^+ , in a mixture of known composition of compounds M and N:

$$K_{eq} = [NH^+]/[MH^+][M]/[N] \quad (4)$$

The observed equilibrium constant of reaction 2 directly leads to a value for the Gibbs free energy

change of reaction, which represents the relative gas phase basicities of compounds M and N; if the entropy change of the reaction is determined, or can be reliably estimated, a value for the enthalpy change of reaction, or relative proton affinity, is obtained. Thus, the extensive scales of data presented here based on equilibrium constant measurements provide relative gas phase basicities and relative proton affinities, but do not directly give any information about absolute values of proton affinities, i.e., about the actual enthalpy changes of reaction 1 for the various compounds. Absolute values must be assigned based on some comparison standard incorporated in the thermochemical ladder for which heats of formation of both M and MH^+ are independently available. These species will necessarily be limited to those for which an MH^+ ion of known structure can be generated in a mass spectrometer, so that a reliable independent gas phase heat of formation will be known.

Thus, it must be emphasized that for data derived from equilibrium constant measurements, absolute values for proton affinities cited by authors depend on the proton affinity value selected for a comparison standard, and these may vary considerably from year to year, and from paper to paper. (For example, proton affinities varying from 202 kcal/mol to 210 kcal/mol have been cited for ammonia, which is often used as a comparison standard for scales of proton affinities). Although researchers working in the field are usually acutely aware of these arbitrary fluctuations in absolute values assigned to gas phase proton affinities, workers in related fields who seek to use these data often fall unwarily into the trap of using proton affinities from the literature without realizing that the experimental results actually lead only to relative thermochemical relationships, and that the absolute values assigned to proton affinities may have changed because of subsequent re-evaluations of the thermochemistry of a primary standard. The current publication seeks to provide a complete and internally-consistent set of gas phase proton affinity values based mainly on the vast body of data generated by equilibrium constant measurements, and to assign absolute values to the resulting proton affinity scale using the best current information about the thermochemistry of positive ions, imposing the requirement of internal consistency.

2. Types of Experiment Leading to Proton Affinity/Gas Basicity Data

In this compilation, as discussed above, most of the information is derived from scales of relative values for the gas basicities and proton affinities, based on (1) measurements of equilibrium constants of proton transfer reactions, or (2) use of the so-called "bracketing" technique. Absolute values are assigned to the scale using certain primary standards (discussed in

detail below), whose position in the proton affinity scale is known and for which well-established values of the heats of formation of both M and MH^+ are available.

2.1. Absolute Proton Affinity Values from Ionization Thresholds

Experiments in which the heat of formation of MH^+ is determined lead directly to values for the proton affinity when combined with a heat of formation of the corresponding neutral molecule, M. If MH is a sufficiently stable species that it can be introduced into a mass spectrometer or be generated in situ, or if MH^+ exists as a fragmentation product from some larger molecular species, absolute values for the heat of formation of MH^+ may be obtained through determinations of the ionization potential of MH :

or the appearance potential of MH^+ from a larger molecule:

Because the heats of formation of MH^+ are known from ionization potential or appearance potential determinations, such "absolute" proton affinity determinations are labelled "Threshold Value" in Table 1. Such absolute values for proton affinities are available for only a very few species of the 780 compounds on which data is reported here, largely because in most cases the neutral MH molecule does not exist, and the energetics of formation of an MH^+ ion of the required structure in ionic fragmentation processes is not reliably established.

2.2. Proton Affinity Values from Thermochemical Information Derived from Hydride Transfer Equilibrium Constant Determinations

Values for heats of formation of a number of carbonium ions, $C_nH_{2n+1}^+$, are known from measurements of hydride transfer equilibrium constants in alkane mixtures:

In systems for which the heats of formation of three reactant species have been independently established, the heat of formation of the fourth can be determined. Since a knowledge of the heat of formation of the $C_mH_{2m+1}^+$ carbonium ion can be used to calculate an absolute proton affinity value for the corresponding olefin, C_mH_{2m} , several values based on hydride transfer equilibria are also included in the compilation; the heats of formation of ions from such experiments are all related to the heat of formation of the tert-butyl ion as

a primary standard. (See below for a discussion of the heat of formation of this standard.)

2.3. Relative Gas Basicity Values from Proton Transfer Equilibrium Constants

During the past decade, there has been extensive use of gas phase ion-molecule equilibrium constant measurements to establish the relative basicities of chemical compounds in the absence of solvent effects. In these studies, carried out in a number of laboratories using mainly high pressure mass spectrometry, ion cyclotron resonance spectroscopy, and flowing afterglow experiments, the equilibrium constants associated with proton transfer reactions such as (2) are measured, yielding the relative gas basicities of M and N from the free energy change associated with the reaction at a given temperature (Eq. 3). If assumptions are made about the entropy changes associated with reaction 2, or if experimental determinations of the entropy change have been made (Sec. 3.1.1), values for relative gas phase basicities obtained in this way can be translated into scales of relative proton affinities. Although these equilibrium constants are determined mass spectrometrically at pressures of 10^{-6} torr to approximately 1 torr, there is abundant evidence¹⁻⁷ that thermodynamic equilibrium is achieved in this type of experiment.

2.4. Relative Gas Basicity/Proton Affinity Values from "Bracketing"

There are certain species for which measurements of equilibrium constants for proton transfer reactions are difficult or impossible. These include free radicals and species for which the MH^+ ion undergoes fast reactions with M or alternate reaction channels with N. In these cases, the basicity is usually estimated using the technique known as "bracketing". In this approach, one reacts MH^+ with a series of bases, observing whether or not proton transfer occurs:

The basicity of M is assumed to lie between those of B_1 and B_2 , and where these species have known gas basicity values, a value can be assigned to M. Results obtained through bracketing experiments are generally less reliable than those obtained through other methods because of numerous possible complications. For instance, exothermic proton transfer reactions sometimes do not occur when there is an energetically favorable alternate channel open to the reactants. Furthermore, endothermic proton transfer reactions can be observed if the reaction has a negative Gibbs free

energy change, or if the reaction is not endothermic by more than ~ 8 kJ/mol (~ 2 kcal/mol). Finally, if there are several isomeric structures of B_1H^+ , the observed proton transfer reaction may involve a rearrangement of the B_1 or B_1H^+ species in the reaction complex to a more stable structure, so that the observed "bracketing" does not necessarily reflect the thermochemistry of a straightforward or even unique proton transfer reaction.

2.5. Other Sources of Proton Affinity/Gas Basicity Data

The compilation includes a few pieces of data originating from measurements which do not fall into any of the above categories. Quantitative information about relative proton affinities has been obtained through the determination of the energy barrier associated with endothermic proton transfer reactions through an Arrhenius treatment of the temperature dependence of the rate constants. Also, determinations of the equilibrium constants of processes such as:

lead to values of heats of formation of the condensation or association ions, ABH^+ , if the heats of formation of AH^+ and B are known; this information can then be used to derive the proton affinity of AB .

Qualitative information about relative proton affinities has been derived from observations of the modes of dissociation of $(ABH)^+$ ions into $(AH^+ + B)$ or $(BH^+ + A)$; a semi-quantitative relationship between the ratios of the two product ions and relative proton affinities has been reported¹⁰.

3. Description of the Evaluation

3.1. Thermodynamic Ladders

In the compilation of gas phase basicity and proton affinity data presented here, the available thermodynamic ladders giving relative gas phase basicities of series of compounds were made the initial basis for the evaluation, using consistency between sets of data from different laboratories and matching of the intervals of the scale with those predicted from widely separated primary standards as the criteria for judgement. To minimize problems due to uncertainties in the temperature at which measurements were made, the thermodynamic ladders were related to as many local standards over the course of the scale as possible. Results obtained from "bracketing" experiments were then related to the evaluated scale. A specific example of this procedure and the mode of presentation in Table 1 is given in Sec. 5.1. Finally, the experimentally-determined scale of relative gas basicities was translated

into a scale of proton affinities by evaluating the entropy change associated with reaction 1.

3.1.1. Entropy Changes

For most polyatomic species, the entropy change of the half reaction ($M \rightarrow MH^+$) was estimated by making the usual simplifying assumption¹⁻⁷ that this quantity can be adequately approximated by the expression:

$$\Delta S = R \ln[\sigma(M)/\sigma(MH^+)] \quad (11)$$

(where $\sigma(M)$ and $\sigma(MH^+)$ are the rotational symmetry numbers of M and MH^+). The use of this expression is obviously inexact, in some cases enough so that a more exact calculation of the entropy change from the complete partition function is warranted. This is especially true for species in which internal rotations are lost or gained upon protonation, or in which there is a significant difference in the moments of inertia of the protonated and unprotonated species. In such cases, the entropy change was calculated from the complete partition function. In all cases for which experimental entropy change determinations of reaction 2 have been made, the experimental results were made the basis of the evaluation of the relevant entropy changes.

3.1.2. Temperature

Several of the data sets constituting the backbone thermodynamic ladder for Table 1 are very extensive, covering energy ranges of up to 300 kJ/mol (72 kcal/mol). Uncertainties of only a few percent in the operating temperature used in the original experiments may translate into differences of tens of kJ (or several kcal) in the absolute values assigned to gas basicities or proton affinities when applied across such an energy range relative to a single absolute standard. One must be particularly aware of this problem in dealing with data sets from ion cyclotron resonance experiments originally reported to have been carried out at "300 K". More recent work has shown that unless special precautions are taken, the operating temperature of an ICR cell at "ambient" temperature is higher than 300 K by 20 to 50 degrees. In such cases, the free energy changes originally calculated from the observed equilibrium constant (Eq. 3) have been corrected by multiplying by $T(\text{corrected})/300$. Where such changes in the original data have been made, the magnitude of the correction factor is indicated in the notes under the literature citation. A comparison of data from these sets with analogous results from experiments in which the temperature was measured generally confirms that the magnitudes of these corrections are at least approximately correct. (It is obvious that for the data sets considered here, the distinction between "300 K" and the temperature corresponding to STP conditions,

298.15 K, is essentially irrelevant; the two numbers, 298 and 300, will be used in this discussion and in the tables essentially interchangeably, depending mainly on which number was used in a particular paper.)

3.2. Assignment of Absolute Values to the Scale: Reference Standards

Although absolute values have been assigned to the relative proton affinity scale here, these values can be considered really well-established only for the lower part of the scale (i.e., for proton affinities lower than about 750 kJ/mol or 180 kcal/mol), which is based on numerous primary comparison standards. The upper part of the scale is based primarily on the proton affinity of isobutene, which in turn depends on the heat of formation of the tert-butyl ion; other standards, which appear to give a consistent assignment to the scale, are ketene and ammonia. However, none of these standards can be considered to have a firmly-enough established proton affinity that it can be stated with certainty that future variations in absolute assignments will not occur.

To minimize problems due to uncertainties in the temperature, long thermodynamic ladders have been related to as many local standards over the course of the scale as possible. In such cases, the same data are listed twice in Table 1, once as originally reported and a second time in evaluated form, as described in more detail in Sec. 5.1. Similarly, in the single thermodynamic ladder available for the low end of the scale (H_2 to C_2H_6), in agreement with an evaluation of these data from the laboratory where the original work was done¹¹, we have chosen to relate segments of the scale to well-established local standards, rather than accept the originally-reported relationships between widely separated portions of the scale.

In the following section, we present details of the evaluations of the proton affinities of the compounds which served as the primary standards for assigning absolute values to the gas basicity and proton affinity scales. In this process, for all but the lowest part of the scale (H_2 to C_2H_6), the greatest weight was given to the proton affinities of ethylene, propylene, and isobutene. The heats of formation of $C_2H_5^+$ and $CH_3C^+HCH_3$ have been carefully studied in numerous laboratories, and are now rather well established. The heat of formation of the tert-butyl ion is somewhat less well established, but recent evaluations of this heat of formation give a proton affinity value for isobutene which is in fairly good agreement with information from other comparison standards in the immediate vicinity in the scale (ketene and ammonia). The relevant heats of formation, and evaluated 300 K proton affinity values of the standard compounds are summarized in Sec. 3.3. It should be noted that the heats of formation of positive ions cited here are given using the so-called "stationary electron convention" commonly used by

mass spectrometrists¹², and described in detail below (Sec. 5.2.1).

3.2.1. Ammonia

For reasons which appear to have more to do with tradition than with science, the scale of gas phase proton affinities is often related to the proton affinity of ammonia as a standard. This proton affinity is defined by the reaction:

An experimental determination of the heat of formation of NH_4^+ based on its appearance energy from a $(NH_3)_2$ dimer¹³:

leads to a value of the proton affinity of ammonia of 846.3 kJ/mol (202.3 kcal/mol) at 0 K, and assuming that all rotational degrees of freedom are excited and that no vibrational degrees of freedom are excited at 298 K, this corresponds to a value of 852 kJ/mol (203.6 kcal/mol) for the proton affinity of ammonia at 298 K. Although the authors of that paper cite error limits of ± 5 kJ/mol (1.3 kcal/mol) for this value of the proton affinity, an examination of the error limits associated with the appearance energy measurement (± 2 kJ/mol or 0.5 kcal/mol), the heat of formation of NH_2 (± 12 kJ/mol or 3 kcal/mol) and the assumed well depth for formation of the $(NH_3)_2$ dimer (± 4 kJ/mol or 1 kcal/mol) leads one to assign error limits of at least ± 13 kJ/mol (3.2 kcal/mol) to this value. Substitution of the dimer well depth used in reference 13 (-14.6 kJ/mol or 3.5 kcal/mol) with a value from a more recent ab initio calculation¹⁴ (-7.9 kJ/mol or 1.9 kcal/mol) leads to a modification of the proton affinity derived from this experimental result to a value of 845 kJ/mol (202.0 kcal/mol). More direct ab initio calculations of the proton affinity of ammonia^{15,16} lead to values of 858 kJ/mol (205.0 kcal/mol) and 879 kJ/mol (210 kcal/mol), respectively.

In fact, the exact value for the proton affinity of ammonia is of less importance than it is usually accorded, since the position of ammonia in the scale of relative gas phase basicities is not well established. In fact results from various laboratories show considerable variation in measurements involving this molecule. For instance, relative to the proton affinity of isobutene, one would assign values for the proton affinity of ammonia ranging from 851 to 858 kJ/mol (203.5 to 205.0 kcal/mol), depending on which set of measurements one selected. (Although this range is not really large in terms of absolute quantities, the reproducibility of measurements of proton transfer equilibrium constants often allows one to assign error limits of < 0.4 kJ/mol (0.1 kcal/mol) to any particular directly-measured

interval in the free energy scale. The apparently poor quality of the measurements involving this compound is easy to rationalize, since ammonia tends to adsorb on surfaces making accurate pressure measurements difficult.) The selected value for the proton affinity of ammonia, 853.5 kJ/mol (204.0 kcal/mol), which is in good agreement with the experimental determination¹³ and one theoretical calculation¹⁵, is an intermediate value taken from the several thermochemical ladders which have been reported relating the proton affinity of ammonia to that of the primary standard isobutene. Because the agreement between the different thermochemical scales is generally good except for the position of ammonia, the exact value of the proton affinity of ammonia was given little weight in carrying out the evaluation reported here. This proton affinity was treated as a secondary standard, and, in fact, was allowed to "float" relative to the rest of the scale in evaluating different data sets, in order to maintain the overall agreement between the different experimentally-determined thermodynamic ladders.

The entropy change associated with the half reaction ($\text{NH}_3 \rightarrow \text{NH}_4^+$) is -7.5 J/mol K (-1.8 cal/mol K), calculated from the complete partition function. This leads to a value of 818 kJ/mol (195.6 kcal/mol) for the 300 K gas phase basicity.

3.2.2. Ketene

The proton affinity is defined by the reaction:

A recent determination¹⁷ of the heat of formation of CH_3CO^+ at 298 K led to a value of 657 kJ/mol (157 kcal/mol). Accepting a value of -47.7 kJ/mol (-11.4 kcal/mol) for the heat of formation of ketene¹⁸, this would correspond to a proton affinity of 825.5 kJ/mol (197.3 kcal/mol). A re-evaluation of the data of that reference by the present authors gives a heat of formation for CH_3CO^+ of 653 kJ/mol (156 kcal/mol) which corresponds to a proton affinity of 830 kJ/mol (198.3 kcal/mol). However, from the onset of 9.6035 eV determined¹⁹ for the occurrence of the reaction:

one calculates a slightly less negative heat of formation for CH_2CO , -36.4 kJ/mol (-8.7 kcal/mol), which would correspond to a proton affinity¹⁷ of 832 kJ/mol (198.8 kcal/mol), or 836 kJ/mol (199.8 kcal/mol), respectively.

The position of ketene in the thermochemical ladder of proton affinities has been established^{12,20}, and relative to the value chosen above for isobutene, leads to a proton affinity for ketene of 828 kJ/mol (198.0 kcal/mol).

3.2.3. Isobutene

The proton affinity of isobutene is defined by the reaction:

The heat of formation of the $\text{tert-C}_4\text{H}_9^+$ ion is less well established than those of the ethyl and sec-propyl ions discussed below. A recent analysis of the 298 K heat of formation of this ion as derived from appearance energy measurements led to a value of $<695 \pm 3 \text{ kJ/mol}$ ($166.2 \pm 0.8 \text{ kcal/mol}$)²¹. A value of 697 kJ/mol (166.5 kcal/mol) is obtained for this heat of formation taking a value of $50.2 \pm 4 \text{ kJ/mol}$ ($12.0 \pm 1. \text{ kcal/mol}$) for the heat of formation of the tert-butyl radical²² and a value of 6.7 eV for the ionization potential²³. However, the latter value can not be considered well-established without additional corroborating evidence, since experimentally-determined values for the heat of formation of the radical ranging from 44 to 35 kJ/mol (10.5 to 8.4 kcal/mol)²⁴⁻²⁷ have also been reported, and a value of 6.58 eV has been reported for the ionization potential²⁸. The corroborating evidence is derived from measurements²⁹⁻³¹ of the equilibrium constant of the reaction:

which give a value of -5.4 kJ/mol (-1.3 kcal/mol) for the enthalpy change at 300 K; from these data the heat of formation of the tert-butyl ion would be estimated to be 694 kJ/mol (165.8 kcal/mol) accepting a value of 899 kJ/mol (214.8 kcal/mol) for the heat of formation of the benzyl ion. This is based on a value for the heat of formation of the benzyl radical of 204 kJ/mol (48.8 kcal/mol)^{22,32} and an ionization potential of the radical of 7.20 eV³³. (The heat of formation of $(\text{CH}_3)_3\text{CCl}$ is taken as -182 kJ/mol or -43.5 kcal/mol ³⁴; the heat of formation of $\text{C}_6\text{H}_5\text{CH}_2\text{Cl}$ is derived from a liquid phase heat of formation³⁴ and a heat of vaporization³⁵ taken to be 4.1 kcal/mol.) Based on this result, the proton affinity of isobutene is 820 kJ/mol (195.9 kcal/mol).

Taking into account changes in external rotational symmetry numbers, the gain of an internal rotation upon protonation, and the change in the moments of inertia, the entropy change for the half reaction

is about $+3 \text{ J/mol K}$ ($+0.7 \text{ cal/mol K}$)³⁶. This leads to a value of 784 kJ/mol (187.3 kcal/mol) for the 298 K gas phase basicity.

3.2.4. Propylene

The proton affinity of propylene is defined by the reaction:

The heat of formation of the $\text{sec-C}_3\text{H}_7^+$ ion at 298 K has been determined to be 798 kJ/mol (190.8 kcal/mol)³⁷, 799 kJ/mol (190.9 kcal/mol)³⁸, or 802.5 kJ/mol (191.8 kcal/mol)²¹. Taking a value of 799 kJ/mol (191.0 kcal/mol) for this heat of formation, the proton affinity of propylene is 751 kJ/mol (179.5 kcal/mol).

A calculation of the rotational entropy change associated with changes in the moments of inertia and rotational symmetry numbers for the half reaction ($\text{CH}_3\text{CH}=\text{CH}_2 \rightarrow \text{sec-C}_3\text{H}_7^+$) leads to a value of -3.8 J/mol K (-0.9 cal/mol K); this estimate fails to take into account the predicted positive entropy change brought about by the loss of the double bond. (The methyl group in the ion can be taken to be essentially a free rotor³⁹.) In the evaluation of the gas basicity of propylene, it has been assumed that the entropy change of this half reaction is close to zero, as discussed before³⁶. On this basis, the gas basicity of propylene is taken to be 718 kJ/mol (171.7 kcal/mol).

The gas basicity of propylene has been related through thermochemical ladders to several of the other comparison standards listed here. If one estimates the proton affinity through such data using ethylene as the primary standard for the proton affinity scale (i.e. using the data from reference 40 for the interval $\text{C}_2\text{H}_4\text{-H}_2\text{O}$ and from reference 41 for the interval $\text{H}_2\text{O-C}_3\text{H}_6$), one obtains a value of 752 kJ/mol (179.7 kcal/mol) for the proton affinity of propylene, in excellent agreement with the conclusion presented above. On the other hand, the interval in the thermochemical ladder between isobutene and propylene appears to be somewhat constricted, an effect which may result from the fact that small inaccuracies in temperature measurement may cause noticeable errors in such a scale if the scale covers a wide energy range, as discussed above, or may possibly reflect uncertainties in the heat of formation of the tert-butyl ion, also discussed above.

3.2.5. Formaldehyde

Approximately following the recent discussion of Collyer and McMahon⁴⁰, an analysis of the proton affinity of formaldehyde is given. Although this compound was not used as a primary reference standard in the evaluation of the thermochemical ladder, this proton affinity provides an additional reference point to verify the assignment of absolute values to the proton affinity scale. Values for the heat of formation of CH_2OH^+ derived from the appearance energy of this ion from CH_3OH range from 711 kJ/mol (170.0 kcal/mol) to 714 kJ/mol (170.7 kcal/mol)⁴²⁻⁴⁴ corresponding to proton affinity values of 711-715 kJ/mol (170-171 kcal/mol). Since the proton affinity of formaldehyde is 22 kJ/mol (5.2 kcal/mol) above that of water⁴⁵, the value predicted from the evaluated proton affinity scale is 718 kJ/mol (171.7 kcal/mol), in

reasonably good agreement with that obtained from threshold measurements.

3.2.6. Water

A value for the heat of formation of H_3O^+ has been obtained from a measurement of the appearance energy of this ion from a hydrogen-bonded dimer⁴⁶:

From this experiment, one obtains a value for the proton affinity of H_2O of 694 kJ/mol (165.8 kcal/mol) at 0 K, and assuming that all rotational degrees of freedom are excited and that no vibrational degrees of freedom are excited at 298 K, this corresponds to a value of 697 kJ/mol (166.5 kcal/mol) for the proton affinity of water at 298 K. The error limits cited by the authors for this proton affinity are ± 7.5 kJ/mol (1.8 kcal/mol), with the major uncertainty being the well depth for formation of the water dimer. A recent state-of-the-art ab initio calculation⁴⁷, which included corrections for the change in the zero point energy upon protonation, correction to 298 K, and vibrational mode corrections, verifies the well depth of -17 kJ/mol (-4 kcal/mol) assumed in the interpretation of those results; these authors also calculate a value for the proton affinity of water of 689 kJ/mol (164.8 kcal/mol), in good agreement with the experimental result.

Recent equilibrium studies^{40,48} have tied the proton affinity of H_2O to that of ethylene. The experimental results from those studies indicate that the Gibbs free energy change of the reaction:

is -7.5 kJ/mol (-1.8 kcal/mol)⁴⁸ or -14 kJ/mol (-3.4 kcal/mol)⁴⁰. In one of these studies⁴⁸, the direct measurement of the free energy change of reaction 20 was complicated by clustering of H_3O^+ to C_2H_4 , and therefore, more weight is given to the latter result, which is based on a low pressure measurement of a thermodynamic ladder linking the gas basicities of the two compounds through several interlocking steps. Accepting a value for the proton affinity of C_2H_4 of 680 kJ/mol (162.6 kcal/mol) (see Discussion below) this result leads to a proton affinity of water of 697 kJ/mol (166.7 kcal/mol) if one calculates the entropy change for reaction 20 taking into account only the changes in the rotational symmetry numbers of the reactants and products; a more complete calculation of the entropy change for this reaction leads to a value of 696 kJ/mol (166.3 kcal/mol). Both estimates of the entropy change give proton affinity values which are in agreement with the value derived from the threshold determination of the heat of formation of H_3O^+ ⁴⁶ and with the ab initio calculation⁴⁷.

The entropy change associated with the half

reaction ($\text{H}_2\text{O} \rightarrow \text{H}_3\text{O}^+$) is 4.3 J/mol K (1.03 cal/mol K)⁴⁹. The evaluated proton affinity of water, 697 kJ/mol (166.5 kcal/mol), thus corresponds to a gas phase basicity of 665 kJ/mol (159.0 kcal/mol).

3.2.7. Ethylene

The proton affinity of ethylene is defined by the reaction:

The heat of formation of C_2H_5^+ at 298 K has been determined from photoion-photoelectron coincidence experiments to be 901 ± 4 kJ/mol (215.3 ± 1.0 kcal/mol)³⁷, or 903 ± 2 kJ/mol (215.9 ± 0.5 kcal/mol)³⁸, and from photoionization mass spectrometric appearance potentials, to be 904 ± 2 kJ/mol (216.0 ± 0.5 kcal/mol)²¹. In agreement with recent analyses of these data^{40,48}, we take an average value of 902 kJ/mol (215.6 kcal/mol) for this heat of formation, and on that basis, take a value for the proton affinity of ethylene of 680 kJ/mol (162.6 kcal/mol).

Assuming the C_2H_5^+ ion to have a non-classical bridged structure of C_{2v} symmetry¹⁶ (which has been calculated⁵⁰ to be 21.6 kJ/mol or 5.2 kcal/mol lower in energy than the classical structure), the entropy change calculated from the complete partition function for the half reaction ($\text{C}_2\text{H}_4 \rightarrow \text{C}_2\text{H}_5^+$) is -10 J/mol K (-2.4 cal/mol K). The gas basicity of this compound is 651 kJ/mol (155.6 kcal/mol).

3.2.8. Carbon monoxide

The heat of formation of HCO^+ derived from appearance potential measurements in formaldehyde is 824 kJ/mol (196.9 kcal/mol) corresponding to a proton affinity of 596 kJ/mol (142.4 kcal/mol)⁵¹, or 827 kJ/mol (197.6 kcal/mol) corresponding to a proton affinity of 593 kJ/mol (141.7 kcal/mol)⁵². The selected value is the average of these two and some other values from appearance potential measurements⁵³, or 594 kJ/mol (141.9 kcal/mol). Accepting a recent recommended value for the heat of formation of HCO^+ of 37 ± 5 kJ/mol (8.9 ± 1.2 kcal/mol), an ionization potential determination⁵³ for this radical of 8.27 ± 0.01 eV leads to a heat of formation of the HCO^+ ion of 835 kJ/mol (199.6 kcal/mol), and a corresponding proton affinity of 584.5 ± 6 kJ/mol (139.7 ± 1.4 kcal/mol), in good agreement with the values derived above.

Following the recommendation of Bohme et al.¹¹, the entropy change associated with the half reaction ($\text{CO} \rightarrow \text{HCO}^+$) is taken as 3 J/mol K (0.8 cal/mol K).

3.2.9. Carbon dioxide

From the appearance potential of HCO_2^+ in formic acid (12.29 eV)⁵⁴, one can derive a heat of formation of the ion of 589 kJ/mol (140.8 kcal/mol), which corresponds to a proton affinity of 548 kJ/mol (130.9 kcal/mol).

Following the recommendation of Bohme et al.¹¹, the entropy change associated with the half reaction ($\text{CO}_2 \rightarrow \text{HCO}_2^+$) is taken as 19 J/mol K (4.5 cal/mol K).

3.2.10. Oxygen atom

The heat of formation of the OH^+ ion has been determined from its appearance potential in H_2O (18.115 ± 0.008 eV) to be 1293 kJ/mol (308.96 kcal/mol)⁵⁵. A value for the ionization potential of the OH radical has been derived from appearance energy measurements in HOF to be 12.88 eV⁵⁶ in good agreement with the value of 13.01 eV⁵⁷ obtained from a direct experimental measurement. These values correspond to heats of formation of the OH^+ ion of 1281.5 or 1294 kJ/mol (306.3 or 309.3 kcal/mol), respectively. Accepting the value of 1293 kJ/mol (308.96 kcal/mol)⁵⁵, the proton affinity of the O atom is taken as 487 kJ/mol (116.3 kcal/mol).

Bohme et al.¹¹ recommend a value of 27 J/mol K (6.5 cal/mol K) for the entropy change associated with the half reaction ($\text{O} \rightarrow \text{OH}^+$). On this basis, the gas basicity of the O atom at 298 K is taken as 463 kJ/mol (110.7 kcal/mol).

3.2.11. Molecular Oxygen

The ionization potential of O_2H has been determined to be 11.35 ± 0.01 eV⁵⁸. Accepting values for the heat of formation of O_2H of 13 kJ/mol (3.2 kcal/mol) at 0 K, or 10.5 kJ/mol (2.5 kcal/mol) at 298 K⁵⁹, one obtains a value for the heat of formation of O_2H^+ ion of 1108 or 1098 kJ/mol (264.9 or 262.4 kcal/mol) at 0 or 298 K, respectively, leading to a value for the proton affinity of oxygen of 420 kJ/mol (100.5 kcal/mol). This result is in good agreement with a value of 422 kJ/mol (100.9 kcal/mol) which has been cited⁶⁰ for this proton affinity, based on the appearance potential of O_2H^+ in H_2O_2 .

The entropy change associated with the half reaction ($\text{O}_2 \rightarrow \text{O}_2\text{H}^+$) is taken to be 27 J/mol K (6.5 cal/mol K)¹¹. The gas basicity of O_2 is taken as 397 kJ/mol (95.0 kcal/mol).

3.3. Summary of Thermochemical Data on Comparison Standards for Proton Affinity Scale

Standard(M)	$\Delta_f H(M)(298\text{ K})$		$\Delta_f H(MH^+)^b$			Proton Affinity ^c

*Selected value.

^aSee Sec. 3.2 for detailed discussion and error limits.^bHeats of formation using "stationary electron convention" (described in Sec. 5.2.1)^c298 K heat of formation of H⁺ (Eq. 1) in "stationary electron convention" = 365.7 kcal/mol, 1530.0 kJ/mol.

4. Experimental Error Limits

As shown in Sec. 3.3, the heats of formation of the MH^+ ions used for establishing absolute values for the proton affinity scale have error limits which are larger than ± 4 kJ/mol (± 1 kcal/mol), sometimes considerably larger (e.g., NH_4^+). In general, absolute values assigned to the proton affinities of species determined through equilibrium measurements can be considered to be known to within ± 8 kJ/mol (± 2 kcal/mol) if the proton affinity lies in the region of the scale between water and ammonia (i.e. if the proton affinity is in the range 700–850 kJ/mol). In the region of the scale below water (proton affinities less than about 700 kJ/mol), the absolute values of proton affinities can be assumed to be known to within 4–6 kJ/mol for species determined through equilibrium measurements. In the region of the scale above ammonia (proton affinities greater than 850 kJ/mol), the absence of reliable absolute standards makes it impossible to check on the reliability of assigned proton affinity values. In particular, if the temperatures at which measurements were made were not well known, the thermochemical ladders generated from equilibrium constant determinations could be too long or too short, causing proton affinity values at the top end of the scale to vary considerably from their correct absolute values. Some confidence in the assigned values is gained from the general agreement observed in the reported thermochemical ladders generated in different laboratories. However, the lack of reference proton affinities in the upper part of the scale necessitates the assignment of relatively large error limits in this region, ± 16 kJ/mol. Throughout the scale, relative values derived from equilibrium constant measurements can be considered to be known to within ± 1 kJ/mol (0.2 kcal/mol) or less when ΔG is small (≤ 4 –6 kJ/mol). Since the experimentally measured free energy changes are given in Table 1, users of this compilation can identify for themselves species for which larger or smaller error limits on relative gas basicities are warranted. Proton affinities derived from bracketing measurements have error limits which are determined by the size of the bracket (given under the appropriate literature reference).

In Table 2, the values given for the heats of formation of the positive ions include, of course, the error limits associated with the assignment of absolute

values to the proton affinity scale (described above in Sec. 3.2) as well as the error limits associated with the heat of formation of the neutral molecule.

Nearly all of the data compiled here were originally reported in units of kcal/mol; the cited values in these units are given to tenths of a kcal/mol, in order to preserve the originally-reported information about relative ordering. On the other hand, in order to emphasize the large absolute uncertainties in cited proton affinity values, the columns giving data in kJ/mol show values only to within the nearest kilojoule per mole.

5. Explanation of the Tables

5.1. Explanation of Table 1

Table 1 presents a summary of the data from the literature, an evaluation of those data, and evaluated values for the gas basicities at 300 K and the proton affinities, in units of both kcal/mol and kJ/mol (where one kcal/mol is defined as 4.184 kJ/mol). The data in Table 1 are presented in order of descending proton affinity. Data from proton transfer equilibrium measurements are given in considerable detail, with (as described below) reference bases and temperatures specifically noted in most cases. The bracketing experiments, denoted by (br), have been related to the evaluated thermodynamic ladders from equilibrium constant measurements. Details of bracketing and hydride transfer experiments are provided in annotations under the appropriate literature references, as is information about equilibrium measurements related to reference bases not included in the standard list given below in Sec. 5.1.1; these latter experiments are identified in Table 1 by the notation (Key) appearing in the column usually used to identify the reference base.

In order to understand the structure of Table 1 (as well as the thought processes which went into the evaluation) it is best to consider specific examples of data sets, and illustrate how they are presented in Table 1. Table A represents a small portion of an extensive set of data originally published in J. F. Wolf, R. H. Staley, I. Koppel, M. Taagepera, R. T. McIver, Jr., J. L. Beauchamp, and R. W. Taft, *J. Am. Chem. Soc.* **99**, 5417 (1977) (denoted by 77WOL/STA in Table 1).

TABLE A.

	ΔG kcal/mol	Reference
NH ₃	0.0	77WOL/STA
CH ₃ COCH ₃	-7.2	77WOL/STA
iso-C ₄ H ₈	-8.6	77WOL/STA
H ₂ S	-27.8	77WOL/STA
H ₂ O	-31.4	77WOL/STA

In Table A, ΔG represents the free energy changes (in kcal/mol) derived for the process $(MH^+ + NH_3 \rightarrow NH_4^+ + M)$ from interlocking series of equilibrium constant determinations at a temperature assumed to be 300 K. As one can find in the comments under 77WOL/STA in the annotated references, the authors of this paper subsequently found that the operating temperature at which the original measurements were made was actually approximately 320 K, and therefore, from Eq. (3), the experimentally determined values of ΔG were increased by a factor of 320/300. These data then would appear in Table 1 as shown in Table B with the temperature-corrected values of ΔG (these are surrounded by parentheses) in the column labelled "Relative gas basicity, kcal/mol". The "Relative gas basicity" is the negative of the Gibbs free energy change associated with the reaction:

where B(Ref) is the reference base corresponding to the one- or two- alphabetic character denoter given in the list in Sec. 5.1.1.

TABLE B.

	Reference base	Relative gas basicity kcal/mol	Gas basicity kcal/mol	Reference
NH ₃	A	(0.0)	195.6	77WOL/STA
CH ₃ COCH ₃	A	(-7.9)	187.9	77WOL/STA
iso-C ₄ H ₈	A	(-9.2)	186.4	77WOL/STA
H ₂ S	A	(-29.6)	167.0	77WOL/STA
H ₂ O	A	(-33.5)	163.1	77WOL/STA

The entry "A" in Table B in the column labelled "Reference base" identifies ammonia as the species to which the original authors referred their basicity data. The "Gas basicity" values displayed here next to the corresponding "Relative gas basicity" are taken relative to the absolute gas basicity of ammonia derived in Sec. 3.2.1 and obtained using the relative ΔG values cited here.

Since, as described in Secs. 3.2.3 and 3.2.6, the gas basicities of iso-C₄H₈ and water are taken to be, respectively, 187.3 and 159.0 kcal/mol, it appears that in this data set cumulative errors exist in the overall thermochemical ladder over the span of more than 30 kcal/mol. Therefore, the data from this paper are related to several local standards. In the example set shown here, iso-C₄H₈ and H₂O happen to be species for which well-established values for the gas basicity and proton affinity can be assigned (Sec. 3.2), and therefore, these are chosen as local standards. In Table 1, data from any given reference are always reproduced in their original form (or, as here, their original form corrected for temperature) in addition to appearing in their evaluated form (if the two differ); original thermochemical ladders have been preserved in the presentation so that users of the compilation can examine the information as it appeared in the literature and re-evaluate the data for themselves if future experimental results bring about changes in values assigned to particular reference gas basicities or proton affinities. Thus, any given piece of data from 77WOL/STA could appear twice, once as given above and once with the cited gas basicity value as derived in relation to the appropriate local standard. The example data would be given in Table 1 as shown in Table C.

TABLE C.

	Reference base	Relative gas basicity kcal/mol	Gas basicity kcal/mol	Reference
NH ₃	A	(0.0)	195.6	77WOL/STA
	H		196.6	
CH ₃ COCH ₃	A	(-7.9)	187.9	77WOL/STA
	H		188.9	
iso-C ₄ H ₈	A	(-9.2)	186.4	77WOL/STA
	H	(0.0)	187.3	
H ₂ S	A	(-29.6)	167.0	77WOL/STA
	N		162.9	
H ₂ O	A	(-33.5)	163.1	77WOL/STA
	N	(0.0)	159.0	

In Table C (see the list in Sec. 5.1.1) the symbols H and N identify iso-C₄H₈ and H₂O as respective local

standards; the gas basicity values taken relative to these standards are shown in the appropriate column. In Table 1, when two entries appear together without a repetition of the "Reference" identifier, the second entry represents the same data item as the first but, as in the example given here, the "Gas basicity" in the second instance is that relative to a local standard not used by the original authors. In cases where such dual entries occur, only the second "evaluated" gas basicities were taken into account in the final evaluation of the gas basicity of the particular compound. The local standards used for particular data sets are identified in the list in Sec. 5.1.1 and also can be located in Table 1 by the appearance of the entry "(0.0)" in the "Relative gas basicity" column.

The evaluation of the gas basicity and proton affinity of a particular compound and its reconstruction from the entries in Table 1, can be illustrated by considering a single molecule from our example data set, H_2S . All the entries from Table 1 relating to H_2S are reproduced in Table D. However, for clarity of presentation we want the gas basicity values taken into account in the final evaluation to stand out and therefore, all the entries of "unevaluated" gas basicities (e.g. the basicity of H_2S relative to that of ammonia in the example given above) are here replaced by a row of dots.

TABLE D.

T K	Reference base	Relative gas basicity kcal/mol	Gas basicity kcal/mol	Reference
H_2S				
340	Y	(0.0)	162.8	78FRE/HAR(2)
296	N	(4.6)	163.6	73HOP/BON
298	N	(3.8)	162.8	78TAN/MAC
320	A	(-29.6)	77WOL/STA
320	N		162.9	
550	N	(3.9)	162.7	77MAU/FIE
600	A	(-31.8)	79LAU
600	N		162.2	

In Table D, the absence of entries in the "Reference" column indicates that the particular experimental result comes from the reference cited immediately above; such a result has been related to a local standard (water, N, in this case) which is different from the comparison standard used by the original authors. In all such cases, it is the second entry which is taken into account in the final evaluation of the absolute gas basicity of the compound. Other entries shown here (73HOP/BON, 78TAN/MAC, 77MAU/FIE) are clearly results derived from studies in which the authors related their experimentally-determined thermochemical ladders to water. The first entry, with a Y in

the "Reference base" column and (0.0) under "Relative gas basicity" shows that in the paper 78FRE/HAR(2), the authors have related the gas basicities of some other compound(s) to that of H_2S (symbol, Y); the gas basicity given opposite this entry is the evaluated value, 162.8 kcal/mol, derived from the five determinations relative to an H_2O standard.

A final example will illustrate how results from bracketing experiments are evaluated and listed in Table 1. In J. J. Solomon and R. F. Porter, J. Am. Chem. Soc. **94**, 1443 (1972) (72SOL/POR) it was seen that H_3O^+ transfers a proton to B_3H_9 but H_3S^+ does not. Therefore, the gas basicity of B_3H_9 is assumed to lie between those of water and hydrogen sulfide. The entry for B_3H_9 is shown in Table E. The gas basicity given is the average of that of the two bracketing compounds; these are listed in the comments under the appropriate reference.

TABLE E.

T K	Reference base	Relative gas basicity kcal/mol	Gas basicity kcal/mol	Reference
B_3H_9	(br)		161	72SOL/POR

In many instances, investigators have determined proton transfer equilibrium constants of pairs which do not include any of the standards listed above in Secs. 3.2 and 3.3., nor even any of the more commonly-used secondary standards listed in Sec. 5.1.1. In such cases, the data have been tied in to the scale in the usual way by relating to evaluated thermochemical ladders, and the identities of the particular reference compounds are given in comments under the appropriate reference at the end of Table 1. Such cases are identified by the designation (Key) appearing in the "Reference base" column.

In some cases, "proton affinities" have been reported in the literature without any information about the details of the experiment leading to the cited value; such data are usually reported here as they originally appeared since evaluation is impossible. Unevaluated data are denoted by a double asterisk (**). Other papers have presented revisions by original authors of data published earlier; in such cases the details of the original experiments are available, but the nature of the revisions are not; these data also have not been evaluated, and are denoted by a single asterisk (*).

The entries in the column labelled "Gas basicity" are actual gas phase basicities only for measurements made at temperatures close to 300 K. The gas basicities listed for experiments at higher temperatures have been normalized to those at 300 K in order to make

intercomparison easier; that is, in the defining reaction, that part of the term $T\Delta S$ which is associated with the proton is taken as 32.6 kJ/mol (7.8 kcal/mol)⁶¹ in all cases, so that actual differences in the free energy change of the defining reaction due to entropy changes associated with the half reaction ($M \rightarrow MH^+$) may be discerned.

Literature references, identified by the eight-character identifier at the end of a data-containing line, are given at the end of the Table 1, sorted alphabetically according to the characters appearing in the identifying tag. The individual references contain annotations giving any special remarks pertaining to the particular paper.

5.1.1. Explanation of Symbols Used in Table 1

Symbol used in Table 1	Reference base	Evaluated gas basicity (300 K)		Evaluated proton affinity

(Key) — Identity of reference base or other experimental details (in the case of hydride transfer equilibrium constant determinations, for instance) are given in a comment under the appropriate literature citation. (In the case of proton transfer equilibria, usually used for small data sets which were experimentally related to unusual reference bases.)

(br) — Bracketing result.

* — Asterisk appearing after gas basicity value indicates that original authors reevaluated the original data in a subsequent publication, but without giving

sufficient information for relating the reevaluation to the present scale. Data as cited are the reevaluated values of the authors.

** — Double asterisks appearing after gas basicity or proton affinity values indicate that insufficient information is available to evaluate the data. Proton affinity values are given as reported by the original authors, and are not necessarily internally consistent with the evaluated proton affinity scale.

RN — CAS Registry Number.

5.2. Explanation of Table 2

Table 2 presents the evaluations from Table 1 sorted according to the empirical formula of the appropriate compound. The empirical formulas are given at the beginning of each new data item enclosed in square brackets; component atoms are listed alphabetically, with no concessions to chemical meaning (except that lower case letters are given a lower priority than upper case letters), and the compounds are given simply according to an alphabetical ordering of these empirical formulas. Table 2 also lists the heat of formation at 298 K of the compound, and a 298 K heat of formation of the protonated molecule derived from the evaluated proton affinity, using the "stationary electron convention".

5.2.1. Conventions Used

As mentioned above, the heats of formation of protonated molecules given in Table 2 are given according to the so-called "stationary electron" convention¹². According to this convention, the integrated heat capacity of the electron in eqs. (5) and (6) is taken as zero at all temperatures, and the thermal energy of the electron is not taken into account in calculating the heat of formation of the ion at temperatures other than zero kelvin. Obviously, since ionic species occur on both sides of equation (1), the absolute value for the proton affinity does not change with the convention, but one must take care to use consistent data in calculating a proton affinity from ionic heats of formation. If the heats of formation of ions given here are to be used in conjunction with heats of formation of ions taken from a compilation of thermodynamic data (such as "The NBS Tables of Chemical Thermodynamic Properties: Selected Values for Inorganic and C₁ and C₂ Organic Substances in SI Units"⁵⁹ or the "JANAF Thermochemical Tables"⁶¹) in which the electron is treated as a conventional chemical element, the 298 K values given here must be increased by 1.48 kcal/mol or 6.2 kJ/mol in order to achieve consistency. The existence of two different conventions does not matter for neutral species. For the defining eq. (1), the 298 K heat of formation of the proton using this convention is 1530.0 kJ/mol or 365.7 kcal/mol. Relevant heats of formation of reference ions used to standardize the scale were taken at 298 K in all cases where sufficient information was available that this was possible.

5.2.2. Heats of Formation of Neutral Molecules

Heats of formation of the neutral molecule, M, in eq. (1) are listed in Table 2. The experimental data in Table 1 lead to a value for the proton affinity of M, and if the heat of formation of M is known or, as described below, can be estimated, one can thereby obtain a value

for the heat of formation of the protonated molecule MH⁺. In a few cases, a reliable value for the heat of formation of MH⁺ was available from other sources, and the proton affinity determination led to a determination of the heat of formation of the neutral molecule or radical. No distinction is made between these cases in Table 2, but in the latter case, the cited reference will be to the paper describing the proton affinity determination.

Values for the heats of formation of neutral molecules were taken from the experimental literature wherever possible. If data for a particular compound could be obtained from an evaluated data compilation, this value was selected for inclusion. Such compilations included, for organic compounds:

(1) J. B. Pedley and J. Rylance, "Sussex-N. P. L. Computer Analysed Thermochemical Data: Organic and Organometallic Compounds," University of Sussex (1977)³⁴. The numerous data from this evaluated compilation of 300 K heats of formation of organic compounds are identified as [77PED/RYL]. Where condensed phase data from this reference have been used in conjunction with experimental or estimated heats of vaporization or sublimation, the source of the heat of formation is identified simply by an asterisk (*) in the first space of the reference identification.

and for inorganic compounds (in order of preference):

(2) D. D. Wagman, W. H. Evans, V. B. Parker, R. H. Schumm, I. Halow, S. M. Bailey, K. L. Churney, and R. L. Nuttall, "The NBS Tables of Chemical Thermodynamic Properties: Selected Values for Inorganic and C₁ and C₂ Organic Substances in SI Units," J. Phys. Chem. Ref. Data, Vol. 11, Suppl. 2 (1982), hereafter referred to as 82/TN270 from the original publication of this compilation as a series of NBS Technical Notes called the 270-series⁵⁹.

(3) (a) D. R. Stull and H. Prophet, "JANAF Thermochemical Tables," NSRDS-NBS 37 (1971); (b) M. W. Chase, J. L. Curnutt, H. Prophet, R. A. McDonald, and A. N. Syverud, "JANAF Thermochemical Tables, 1975 Supplement," J. Phys. Chem. Ref. Data 4, 1 (1975); (c) M. W. Chase, Jr., J. L. Curnutt, J. R. Downey, Jr., R. A. McDonald, A. N. Syverud, and E. A. Valenzuela, J. Chem. Phys. Ref. Data 11, 695 (1982). Information from these sources is hereafter referred to as JANAF⁶¹.

The preferential use of these compilations as sources of experimental data recognizes that these data have been evaluated for internal consistency insofar as possible. Experimental information about heats of formation of compounds not included in these sources was obtained

from scientific articles presenting relevant thermochemical determinations; when more than one such article was available for a given piece of data, the most recent value was usually arbitrarily chosen in the possibly naive hope that improved instrumentation and compound purity, as well as a greater awareness of the problems inherent in particular measurements or of the thermochemistry of particular classes of compounds, should contribute to improved values. In such cases, it should be noted, the cited references are not always the primary references for the determination, but may represent a choice by a subsequent author. Heats of formation of deuterated or partially deuterated molecules were assumed to be the same as the heats of formation of the non-deuterated analogues. Also, gas phase heats of formation of racemic mixtures are the same as the heats of formation of the optically pure enantiomers.

Implicitly, in assigning gas phase heats of formation to the neutral species, the compounds are assumed to be ideal gases at STP. Few of the species are, in fact, gases under these conditions — most are liquids or solids. Numerous methods exist for measuring and interpreting experimental heats of sublimation [$\Delta H(\text{solid} \rightarrow \text{gas})$] and of vaporization [$\Delta H(\text{liquid} \rightarrow \text{gas})$], and, so need not be discussed here. Where available, such measurements were used to translate condensed phase data into gas phase information. However, such measurements do not exist for many compounds of interest here, either because of lack of adequate volatility, purity, or thermal stability, or even, seemingly because of a lack of interest in the species in the gas phase. Estimation methods for heats of vaporization, and occasionally sublimation, have been described in the literature. Some require other experimental data (e.g., critical constants), while others are limited to well-defined, however large, classes of compounds. Some of these methods have been used to generate values of gas phase molecular heats of formation from corresponding liquid or solid phase data; although such heats of formation are based on an estimation of one parameter, comparisons indicate that the resulting gas phase data are usually within 4 kJ/mol (1 kcal/mol) of accepted values, at least for heats of vaporization. Therefore, these entries are not labelled "Est" for "Estimate" (see below), but are rather identified by a two-part reference, the first segment giving the source of the liquid or solid phase heat of formation of the compound (abbreviated to an asterisk (*) when that source is the often-referred to [77PED/RYL]), and the second segment, listing a reference describing the technique of determining the heat of vaporization or sublimation.

Heats of formation of compounds for which no experimental data were available were estimated, and are labelled "Est". Several estimation approaches were utilized. Only brief descriptions of these will be given here; a detailed discussion will be presented elsewhere⁶².

One approach utilizes experimental information

about isomerization processes for the formation of two or more isomeric species in a particular reaction. The assumption is made that $\Delta\Delta_f H = \Delta\Delta_f G$ for a pair of isomers (ΔS is assumed negligible) in the experimentally observed process, so that a heat of formation of an unknown species can be predicted from thermochemical information about isomeric molecules. This approach, which is not well characterized and so is less trustworthy than other approaches used here, utilizes various types of information including direct equilibration studies on isomers and the more casual observation that two isomers are formed in comparable quantities in a particular process, and so have comparable Gibbs free energies and enthalpies of formation.

A related approach to estimation is based on the assumption that $\Delta\Delta_f H$ can be equated with ΔE_{tot} for two isomers, where ΔE_{tot} is the total energy of the molecule calculated quantum chemically. For this assumption, as well as all other estimation approaches employing quantum chemical studies, only ab initio calculations were considered as opposed to any of the plethora of semi-empirical studies at a wide variety of levels and approximations to the correct Hamiltonian and wavefunction. In all cases, care was taken to compare isomeric species with the same basis set and degree of geometry optimization. Built into this last assumption that $\Delta\Delta_f H = \Delta E_{\text{tot}}$ are the requirements that the zero point energy and enthalpy function $H^0 - H_0^0$ are essentially equal for an arbitrary pair of isomers, and that conformational isomerism and relative energies hardly affect heats of formation. None of these assumptions is rigorously true, but experience indicates that they represent a good first guess as to molecular energetics.

There remain three related approaches which were employed to estimate heats of formation of molecules here. The first and best characterized is Benson's "group increment" approach^{63,64} in which the molecule of interest is defined as a collection of groups, and a "group", in turn, is defined as a polyvalent atom (ligancy ≥ 2) with all its ligands in a molecule. The heat of formation of the molecule is obtained by summing statistically-determined contributions from the heats of formation of the various "groups", and correcting for various higher order interaction and other "correction" terms. These corrections include such things as the presence of gauche configurations in substituted alkanes, and the presence of heterocyclic and/or non-six membered rings.

A related approach consists of formulating the molecule of interest as a substituted derivative of a well-characterized species. The unknown heat of formation is taken to be the sum of the known heat of formation and a suitable correction term associated with the exchange of the substituent and parent components. For example, the heat of formation of an arbitrary aliphatic azoxy compound may be determined⁶⁵ from the heat of formation of the related (E)-olefin by:

$$\Delta_f H(\text{R}-\text{NN}(\text{O})-\text{R}') = \Delta_f H(\text{R}-\text{CH}=\text{CH}-\text{R}') + 14.6 \text{ kcal/mol}, \quad (23)$$

where the 14.6 kcal/mol for the $[\Delta_f H(-\text{NN}(\text{O})-) - \Delta_f H(-\text{CH}=\text{CH}-)]$ correction term was obtained by averaging the difference of the heats of formation of $\text{R}-\text{NN}(\text{O})-\text{R}'$ and $(\text{E})\text{R}-\text{CH}=\text{CH}-\text{R}'$ for $\text{R}=\text{R}' = \text{tert-butyl}$ and $n\text{-propyl}$.

The final estimation approach, termed "macro-incrementation reactions"⁶⁶, assumes that "if for each of two sets of molecules the total number of bonds, atoms and structural types is the same, then the total heat of formation of each set of molecules is the same. Then, if all but one of the heats are available, the remaining one can be estimated by simple arithmetic. It deals with ring strain, resonance energy and other interactions much more explicitly but less universally by embedding these corrections in the heat of formation of the individual molecules which among them possess the desired bonding characteristics. Further, it maximizes the direct use of available experimental data."⁶⁶

Quite clearly, the last three approaches described here are interrelatable, and "were they flawless, they would agree with each other and with experiment"⁶⁷. Furthermore, macroincrementation considerations, when coupled with the earlier assumption, $\Delta\Delta_f H = \Delta E_{\text{tot}}$, result in "isodesmic reactions"⁶⁸ and "group separation reactions"⁶⁹, widely employed here and elsewhere.

5.2.3. References

The reference citations given in Table 2 refer to the sources of data on the heats of formation of the neutral molecules. The references having to do with proton affinity determinations are given at the end of Table 1. In the column labelled "Reference" in Table 2, the appropriate literature reference is given as an eight-character identifier showing the year the paper appeared and the first three letters of the names of the first two authors. In addition, as discussed above in part, the following specialized notations and abbreviations are used:

Notation	Definition
82/TN270	D. D. Wagman, W. H. Evans, V. B. Parker, R. H. Schumm, I. Halow, S. M. Bailey, K. L. Churney, and R. L. Nuttall, "The NBS Tables of Chemical Thermodynamic Properties: Selected Values for Inorganic and C ₁ and C ₂ Organic Substances in SI Units," <i>J. Phys. Chem. Ref. Data</i> 11 , Suppl. 2 (1982).
JANAF	(a) D. R. Stull and H. Prophet, "JANAF Thermochemical Tables," <i>NSRDS-NBS</i> 37 (1971). (b) M. W. Chase, J. L. Curnutt, H. Prophet, R. A. McDonald, and A. N. Syverud, "JANAF Thermochemical Tables," 1975 Supplement, <i>J. Phys. Chem. Ref. Data</i> 4 , 1 (1975); (c) M. W. Chase, Jr., J. L. Curnutt, J. R. Downey, Jr., R. A. McDonald, A. N. Syverud, and E. A. Valenzuela, <i>J. Phys. Chem. Ref. Data</i> 11 , 695 (1982).

Notation	Definition
*00ABC/DEF	A condensed phase heat of formation was obtained from 77PED/RYL (J. B. Pedley and J. Rylance, "Sussex-N. P. L. Computer Analysed Thermochemical Data: Organic and Organometallic Compounds," University of Sussex (1977)) and translated into a gas phase heat of formation using heat of vaporization or sublimation data from the reference 00ABC/DEF.
Est	The gas phase heat of formation was estimated using the approaches described in the previous section.
DEF	A defined heat of formation.
(E) or (Z)	In the absence of other information, the most stable isomeric configuration (usually E) has been assumed.

6. Literature Coverage

Data from literature which appeared before June 1983, are included. A number of researchers who were aware that this compilation was in progress made available to the authors preprints of work which was in press or in preparation, and these more recent data are also included. Older data, which have been superseded by newer, better, measurements have been omitted. These include primarily bracketing measurements which have been replaced by results from equilibrium studies. In some cases where an author has repeated his own measurements in a later study and obtained different results, both sets of data are included, with preference generally given to the more recent set in carrying out the evaluation. Exceptions to this policy are specifically mentioned under the description of the evaluation of a paper in the annotated reference. Particularly in laboratories which have been very active in determinations of proton affinities from ion-molecule equilibrium constant measurements, one sees that closely similar or identical results on a particular molecule or set of molecules often appear in various publications from the laboratory without specific reference to earlier appearances of the data in print. In these cases, we do not presume to try to judge who the "original" author was, but simply present all the reincarnations of the data set.

In a few cases, authors have bracketed the gas phase basicities of molecules between limits which are so widely spaced (i.e., ammonia and water) that the result is difficult to present in the more quantitative scale given here; in such cases, the paper is listed in the bibliography, but the result is not included in the Tables 1 and 2. Other authors have given only an upper or lower limit to a gas basicity; these results have not been included.

Acknowledgements

As specifically noted, Mahnaz Motevalli-Aliabadi collaborated in the preparation of Table 2, carrying out

estimates of the heats of formation of neutral molecules. In addition, the authors gratefully acknowledge the work of Carol Martin and Clairemarie Lanthier who critically proofread the Tables, and Ricardo Metz, Nathan Seidenman, Carlo Messina, and Dr. Thomas J. Buckley who carried out the computer processing leading to the production of the final manuscript.

We would also like to acknowledge those colleagues, notably Dr. Michael Mautner, who made available to the authors experimental data which was in various stages of preparation, so that the compilation could be as complete and up-to-date as possible.

One of us (J. F. L.) acknowledges partial support from the U. S. Department of Energy, Office of Health and Environmental Research.

High pressure mass spectrometer. $\Delta H[C_2H_5^+ + CH_4 \rightleftharpoons C_3H_7^+] = -6.6$ kcal/mol
- 76HIR/KEB K. Hiraoka and P. Kebarle, "Stabilities and Energetics of Pentacoordinated Carbonium Ions. The Isomeric $C_2H_7^+$ Ions and Some Higher Analogues: $C_3H_9^+$ and $C_4H_{11}^+$ ", *J. Am. Chem. Soc.* **98**, 6119 (1976).
High pressure mass spectrometer. A and B: The heat of formation of $C_2H_7^+$ was determined from the equilibrium constant for the process: $C_2H_5^+ + H_2 \rightarrow C_2H_7^+$. Different values were obtained at low and at high temperature regimes. The authors interpret this as evidence for two $C_2H_7^+$ structures.
The heat of formation of $C_3H_9^+$ was determined from the equilibrium constant for the process: $C_2H_5^+ + CH_4 \rightleftharpoons C_3H_9^+$ and that of $C_4H_{11}^+$, from the equilibrium constant for the process: $sec-C_3H_7^+ + CH_4 \rightleftharpoons C_4H_{11}^+$. Values reported in the paper have been modified slightly to take into account more recent values for heats of formation of relevant ions.

- TAFT**
 ICR. Unpublished compiled list of values of gas phase basicities measured by several workers, notably including R. W. Taft, R. McIver, W. J. Hehre, and co-workers. Here referred to as the "TAFT list". Most of the data given on the list have been published elsewhere, and are listed here with the appropriate reference. (See: 75ARN, 72ARN/JON, 76COO/KAT, 82DEF/HEH, 80DEF/MCI, 76DEV/WOL, 74HEH/MCI, 72HEN/TAA, 79LOC/HUN, 83MCI, 82PAU/HEH, 82PAU/HEH(2), 82PIE/HEH, 82PIE/HEH(2), 79PIE/POL, 77POL/DEV, 80POL/HEH, 81POL/RAI, 77POL/WOL, 77SUM/POL, 75TAF, 83TAF, 73TAF/TAA, 74WOL/ABB, 75WOL/HAR, 77WOL/STA). Values cited as "TAFT" either have not been published, or the publication has not been identified for the current compilation. All data from these various publications have been assumed to have been taken at 320 K, rather than the originally reported 300 K (R. W. Taft, private communication). As a result of the uncertainty in the actual temperature(s) at which measurements were made, and the great length of the free energy scale represented by these results, there may be some uncertainty in the length of the scale. To minimize this problem, sections of the scale have been related to local standards (i.e. H_2O , isobutene) wherever possible. Occasionally thermochemical scales from other laboratories have been related by the subsequent authors to this base scale; when this is the case, the notation given here is "Related to TAFT scale".
