71 **EXECUTIVE SUMMARY**

72 The Center for Veterinary Medicine (CVM) is charged with the regulatory responsibility  
73 of ensuring that the use of antimicrobial drugs in food-producing animals does not result  
74 in adverse health consequences to humans. The selection of antimicrobial resistant  
75 bacterial populations is a consequence of exposure to antimicrobial agents and can occur  
76 from human, animal, and agricultural uses. Food animals are administered antimicrobial  
77 drugs for therapeutic, preventive, and production purposes. The use of antimicrobial  
78 drugs in food-producing animals is necessary to maintain their health and welfare.  
79 However, food-producing animals can become reservoirs of bacteria capable of being  
80 transferred in or on food. Food carrying resistant bacterial pathogens can cause illness in  
81 people consuming the food or contribute to the human reservoir of resistant bacteria. The  
82 use of antimicrobial drugs in food-producing animals may cause bacterial pathogens to  
83 become resistant to drugs that may also be used to treat human illness, potentially making  
84 human illness more difficult to treat.

85 CVM recognizes that minimizing the emergence of antimicrobial-resistant bacteria in  
86 animals and their subsequent spread to humans through the food supply is a complex  
87 problem requiring a coordinated multifaceted approach. Accordingly, CVM has  
88 expended considerable effort to identify and support those programs and activities that  
89 will reduce the risk to the public. Where mitigation strategies were identified that lie  
90 outside the regulatory authority of CVM, support has been enlisted from other Federal  
91 agencies, international agencies dedicated to public and animal health, and stakeholder  
92 organizations. CVM believes that, taken together, these steps will have a substantial  
93 impact in controlling the emergence and spread of resistant bacteria from animals to  
94 humans through the food supply.

95 Despite these preemptive measures, there may occur situations in which the approved use  
96 of an antimicrobial drug in animals gives rise to resistant bacteria that in turn pose a risk to  
97 human health. In these situations, and as an added measure of human health protection,  
98 CVM is considering the establishment of regulatory thresholds intended to arrest the  
99 further emergence of resistant foodborne pathogens. As required by the Federal Food,  
100 Drug, and Cosmetic Act (FFDCA), CVM has applied the reasonable certainty of no harm  
101 standard to human safety considerations associated with the use of antimicrobial drugs in  
102 food-producing animals. CVM believes that implementation of an approach as outlined in  
103 this paper could be consistent with this standard, but is exploring the impact of the  
104 approach under the current standard, whether modifications to the approach or an  
105 alternative approach could also meet the standard, or whether legislative change to the  
106 standard should be considered.

107 This discussion document describes a possible approach to the establishment and use of  
108 thresholds. The approach describes two types of thresholds, a human health threshold

109 and a resistance threshold. The human health threshold is the unacceptable prevalence of  
110 infections in humans that are treated with the antimicrobial drug of concern, are  
111 associated with bacteria resistant to the drug of concern, and for which the resistance is  
112 attributable to the use of an antimicrobial drug in animals. Based on the current safety  
113 standard, the "unacceptable prevalence" is considered that level at which there is no  
114 longer reasonable certainty that there is no harm to human health. The human health  
115 thresholds discussed in this document focus on enteric or systemic illness in humans.  
116 The resistance threshold is the maximum allowable prevalence of resistant bacteria  
117 isolated from animal-derived food, that is, the level of such resistant bacteria at which  
118 there would still be reasonable certainty that the human health threshold would not be  
119 crossed. The resistance threshold is derived through an epidemiology-based model that  
120 relates the prevalence of resistant bacteria in food to an impact on either enteric illness  
121 (EI) or systemic illness (SI) in humans. The scope and complexity of the implementation  
122 and use of thresholds is described with the intent to stimulate constructive discussion.

123 If this threshold approach is implemented, when post-approval surveillance indicates that  
124 bacterial susceptibility to specific antimicrobial drugs is decreasing, the prevalence of  
125 resistant bacteria is increasing, or that the prevalence of resistant bacteria has exceeded  
126 the resistance threshold level, a range of actions may be taken. For example, if changes  
127 are observed, but the resistance threshold has not been reached, voluntary mitigation  
128 strategies by groups such as the pharmaceutical industry, food animal production groups,  
129 and the veterinary community (e.g., education, labeling changes, use restrictions, etc.)  
130 may be implemented to curtail further loss of susceptibility. However, if surveillance  
131 data indicate that the resistance threshold has been exceeded, CVM would initiate  
132 procedures to withdraw from the label any animal species that has reached or exceeded  
133 its threshold.

**134 Introduction**

135 The Center for Veterinary Medicine (CVM) is charged with the regulatory responsibility  
136 of ensuring that the use of antimicrobial drugs in food-producing animals does not result  
137 in adverse health consequences to humans. Food animals are administered antimicrobial  
138 drugs for therapeutic, preventive, and production purposes. CVM recognizes that the use  
139 of antimicrobial drugs in food-producing animals is important in helping to promote  
140 animal health, welfare, and productivity. However, food-producing animals can serve as  
141 reservoirs of pathogenic bacteria that may be transferred to humans by consumption of  
142 contaminated food products. With the use of antimicrobial drugs in food-producing  
143 animals, these bacterial pathogens may become resistant to drugs that may also be used to  
144 treat human illness, potentially making human illnesses more difficult to treat. In  
145 addition, bacteria pathogenic to humans can acquire resistance traits from non-pathogenic  
146 bacteria originating in food animals by mechanisms that allow the exchange of their  
147 genetic material in the human gastrointestinal tract.

148 Antimicrobial resistance is a complex human health issue with multiple contributing  
149 factors. The selection of antimicrobial resistant bacterial populations is a consequence of  
150 exposure to antimicrobial drugs and can occur from human, animal, and agricultural uses.  
151 Recently implemented food safety monitoring programs are still developing in response to  
152 the evolving needs of agencies such as the FDA. As a consequence, the human health  
153 impact due to the use of antimicrobial drugs in food-producing animals can be difficult to  
154 assess. It requires the ability to attribute human health impacts (in whole or in part) to the  
155 domestic (i.e., U.S.) use of antimicrobial drugs in animals. This association is  
156 complicated by other sources of resistance, including the use of the same or similar  
157 antimicrobial drugs in human medicine, people contracting resistant bacterial infections  
158 while traveling outside of the United States, illness in people consuming imported foods  
159 or foods from imported animals, and epidemics of multi-drug resistant pathogens.  
160 Antimicrobial drug resistance has been linked to resistance against other antimicrobial  
161 drug classes, disinfectants, and other compounds such as heavy metals. The use of  
162 unrelated drugs can result in the co-selection of multiple drug resistance. Additionally,  
163 cross-drug resistance occurs from the use of a particular antimicrobial drug when the  
164 mechanism of resistance affects more than one class of antimicrobial drug.

165 CVM recognizes that minimizing the emergence of antimicrobial-resistant bacteria in  
166 animals and their subsequent spread to humans through the food supply is a complex  
167 problem requiring a coordinated multifaceted approach. Accordingly, CVM has expended  
168 considerable effort to identify and support those programs and activities that will reduce  
169 the risk to the public. Where mitigation strategies were identified that lie outside the  
170 regulatory authority of CVM, additional support has been enlisted from other Federal  
171 agencies, international agencies dedicated to public and animal health, and stakeholder  
172 organizations. The CVM strategy for addressing antimicrobial resistance is one

173 component of more broad reaching strategies being developed at the Agency level by the  
174 Food and Drug Administration and at the interagency level in the form of the Public  
175 Health Action Plan to Combat Antimicrobial Resistance.<sup>1</sup> Copies of this plan are  
176 available at <http://www.cdc.gov/drugresistance/actionplan/>.

177 It is important to understand the legal framework within which CVM must operate. For a  
178 new animal drug to be approved for use in food animals, the sponsor must demonstrate to  
179 CVM that there is reasonable certainty that no harm to human health will result from the  
180 proposed use of the drug. Therefore, since the standard to be met is reasonable certainty  
181 rather than absolute certainty, the sponsor does not have to demonstrate zero risk. CVM  
182 believes that the presence of antimicrobial resistant human pathogens in or on animal-  
183 derived food as a consequence of antimicrobial drug use in animals is a safety concern that  
184 is subject to the reasonable certainty of no harm standard.

185 This discussion document does not attempt to define the minimum criteria for what would  
186 constitute "harm". However, as described in this document, the relevant human health  
187 concern is considered to be an unacceptable increase in the prevalence of human  
188 infections that are treated with the antimicrobial drug of concern and that are caused by  
189 bacteria resistant to that drug due to the use of an antimicrobial drug in animals. Based on  
190 the current safety standard, an "unacceptable increase" is considered that level at which  
191 there is no longer reasonable certainty that there is no harm to human health.

192 CVM recognizes that meeting this standard is difficult, and may have significant impact on  
193 the availability of drugs to treat animal illness. CVM wishes to foster debate on the best  
194 policies and science to meet the reasonable certainty of no harm standard, as well as on the  
195 implications to animal health of meeting the statutorily-required standard. CVM  
196 recognizes that there are times in which the allowed use of an approved antimicrobial drug  
197 leads to the development of resistance in pathogens in food from animals treated with the  
198 drug. In those circumstances, the agency needs a way by which it and the sponsor know  
199 when a level of resistance has been reached that violates the standard of reasonable  
200 certainty of no harm, that is, when the use of the animal drug is no longer shown to be safe.  
201 That is the goal of the approach for establishing thresholds described in this document.

202 The CVM strategy that includes a number of contributing components, described in brief  
203 below, is a regulatory approach that CVM believes is protective of the human health. The  
204 threshold concept provides an added measure of human health protection by establishing a  
205 clearly defined point at which CVM would initiate procedures for withdrawing the  
206 approval of a particular antimicrobial drug use in animals. This action would be triggered  
207 in the event that the approved use of the drug in animals is found to give rise to resistant  
208 bacteria that in turn present an unacceptable risk to human health. As noted above, CVM is  
209 required by the FFDCFA to apply the reasonable certainty of no harm standard to human  
210 safety considerations associated with the use of antimicrobial drugs in food-producing  
211 animals. CVM believes that implementation of an approach as outlined in this paper could  
212 be consistent with this standard, but is exploring the impact of the approach under the  
213 current standard, whether modifications to the approach or an alternative approach could

214 also meet the standard, or whether legislative change to the standard should be considered.  
215 The threshold concept is but one component of a multifaceted approach for assuring that  
216 the use of antimicrobial drugs in food-producing animals is safe with regard to human  
217 health. The various components of this multifaceted strategy are briefly described below.

### 218 **National Antimicrobial Resistance Monitoring System (NARMS)**

219 CVM believes that the safety assessment of antimicrobial drugs must include monitoring  
220 for the development of resistance. Monitoring is done through the National Antimicrobial  
221 Resistance Monitoring System (NARMS).

222 NARMS was initiated in 1996 as a collaboration between the FDA, the Centers for Disease  
223 Control, National Center for Infectious Diseases (CDC), the United States Department of  
224 Agriculture Agricultural Research Service, and Food Safety and Inspection Service.  
225 NARMS monitors development of antimicrobial resistance of zoonotic enteric pathogens  
226 from human and animal clinical specimens, from healthy farm animals, and from carcasses  
227 of food-producing animals at slaughter.<sup>2</sup> NARMS current partners include 17 state and  
228 local public health laboratories and 8 veterinary sentinel sites. Its purpose is to  
229 prospectively monitor the antimicrobial resistance of human, animal, and animal product  
230 isolates of selected enteric bacteria.

231 Concerns associated with the approval of antibiotics important to human medical therapy  
232 for use in food animals was the driving force for the development of NARMS. Prior to  
233 NARMS there was no antibiotic resistance surveillance system that was national in scope,  
234 continuous, and that monitored within the same system resistance development among  
235 isolates from both humans in the community setting and from animals.

236 The goals of NARMS are to provide descriptive data on the extent and temporal trends of  
237 antimicrobial susceptibility in enteric organisms from the human and animal populations;  
238 provide timely information to veterinarians and physicians; prolong the life span of  
239 approved drugs by promoting the prudent use of antimicrobial agents; identify areas for  
240 more detailed investigation; and guide research on antimicrobial resistance. The majority  
241 of the animal isolates are obtained from raw product collected from federally inspected  
242 slaughter and processing plants. The human isolates are collected from state health  
243 department partners. The seventeen NARMS sites (CA, CT, CO, FL, GA, KS, Los  
244 Angeles County, MA, MD, MN, NJ, New York City, NY, OR, TN, WA, and WV)  
245 represent 100 million people, or approximately one-third of the U.S. population.

246 Since 1996, NARMS has conducted surveillance for antimicrobial resistance among  
247 isolates of non-typhoidal *Salmonella* and *Escherichia coli* O157:H7. In 1997, surveillance  
248 was expanded to include human isolates of *Campylobacter*. Currently, NARMS  
249 surveillance also includes *enterococci* isolated from human stool samples and animal  
250 products, *Campylobacter* isolated from animal products, as well as human isolates of  
251 *Shigella* and *Salmonella* Typhi.

252 Isolates are tested for susceptibility using minimum inhibitory concentrations, or MICs.  
253 *Salmonella*, *Shigella* and *E. coli* are tested with Sensititre (Trek Diagnostics, Westlake  
254 OH) a semi-automated system, for susceptibility to 17 antimicrobial agents.  
255 *Campylobacter* isolates are tested using the E-test system (AB Biodisk, Solna Sweden) for  
256 susceptibility to 8 antimicrobial agents. *Enterococci* isolates are identified to species level  
257 and tested by Sensititre and microbroth dilution for susceptibility to 27 antimicrobial  
258 agents. Results are entered into a SAS database for analysis.

259 Since 1996, NARMS has provided data that have been used to initiate field investigations  
260 of outbreaks of illness marked by a pathogen which displayed an unusual antimicrobial  
261 resistance pattern, provided the data for a risk assessment of the human health impact of  
262 fluoroquinolone use in poultry, stimulated research in molecular characteristics of  
263 resistance emergence and transfer, improved our knowledge of risk factors associated with  
264 the development of an antimicrobial-resistant infection, and triggered broader research  
265 projects of prudent antimicrobial use in animals and the role of the environment in the  
266 emergence and spread of antimicrobial resistance.

267 The NARMS program continues to expand by adding new test sites, bacterial pathogens and  
268 antimicrobial drugs for evaluation. Plans are currently underway to include the resistance  
269 profiles of enteric pathogens isolated from a wide variety of retail foods. This dynamic,  
270 national monitoring system will be an integral part of the threshold monitoring process.

## 271 **Pathogen Reduction Programs**

272 Recently implemented food safety programs such as USDA's pathogen reduction program  
273 are critical contributors to CVM's overall strategy for managing human health risks  
274 associated with resistant foodborne pathogens. The USDA program that is based on the  
275 principles of Hazard Analysis and Critical Control Point (HACCP) appears to be having a  
276 positive effect on reducing the overall incidence of foodborne pathogens. However,  
277 surveillance data indicate that pathogens continue to be present on animal-derived food  
278 products.<sup>3</sup> CVM recognizes the importance of this program in that reducing the incidence  
279 of pathogens on food will reduce human exposure and, in turn, reduce the incidence of  
280 foodborne related human illness. Any gains achieved in reducing the overall incidence of  
281 foodborne disease will serve to reduce the potential human health impact experienced as a  
282 consequence of foodborne disease that is associated with a resistant pathogen. CVM also  
283 recognizes that the USDA pathogen reduction program is essential in that it serves as a  
284 critical source of isolates for the NARMS program. This collaboration between agencies  
285 is critical to the success of the program.

## 286 **Framework Document**

287 CVM announced with the publication of Guidance for Industry #78, "Consideration of the  
288 Human Health Impact of the Microbial Effects of Antimicrobial New Animal Drugs  
289 Intended for Use in Food-Producing Animals", a regulatory change with regard to the  
290 safety evaluation of antimicrobial drugs.<sup>4</sup> Although CVM had previously considered such

291 effects for certain uses of antimicrobial drugs, the guidance stated CVM's intention to  
292 consider the potential human health impact of the microbial effects associated with all  
293 uses of all classes of antimicrobial new animal drugs intended for use in food-producing  
294 animals. The microbial effects of concern include the impact of antimicrobial drug use in  
295 animals on the rate and extent of resistance emergence and on the quantity of bacteria in  
296 animals that are pathogenic to humans.

297 Given that the regulatory approach then in use did not adequately address these concerns,  
298 CVM outlined in a 1998 discussion document titled, "Proposed Framework For  
299 Evaluating And Assuring The Human Safety Of The Microbial Effects Of Antimicrobial  
300 New Animal Drugs Intended For Use In Food-Producing Animals" (i.e., the Framework  
301 Document) several coordinated strategies to the management of risk associated with  
302 antimicrobial use in food-producing animals.<sup>5</sup> The Framework Document discussed both  
303 pre-approval and post-approval approaches. The strategies include: 1) revision of the pre-  
304 approval safety assessment for antimicrobial resistance for new animal drug applications  
305 to assess all uses for microbial safety; 2) categorization of antimicrobial drugs based upon  
306 the importance of the drug for human medicine; 3) post-approval monitoring for the  
307 development of antimicrobial drug resistance; 4) the collection of food animal drug use  
308 data; and 5) the establishment of regulatory thresholds.

309 *Drug categorization:* A key component of the Framework Document is the concept of  
310 categorizing antimicrobial drugs according to their importance for treating disease in  
311 humans. The Framework Document discusses three categories with the most important  
312 drugs being considered Category I. CVM believes that this categorization process is an  
313 integral part of a safety assessment in that it provides some initial indication of the  
314 potential human health impact resulting from treatment failure due to resistance. The  
315 categorization process also focuses the greatest level of attention on those antimicrobial  
316 drugs of greatest importance to human medical therapy. As outlined in the Framework  
317 Document, pre-approval and post-approval requirements would likely be greatest for those  
318 antimicrobial drugs that are highly important for treating disease in humans. As a  
319 consequence, greater emphasis would likely be placed on developing drugs for animal use  
320 that are of lower importance for human therapy.

321 *Pre-approval Assessment of antimicrobial drugs:* As noted previously, CVM announced  
322 with Guidance for Industry #78 its intentions to include in its safety evaluation of all  
323 antimicrobial drugs intended for use in food-producing animals a consideration of the  
324 potential human health impact associated with the emergence of antimicrobial resistance.  
325 CVM has held discussions on the subject of using pre-approval study information to  
326 characterize safety in terms of the rate and extent of resistance development in food-  
327 producing animals (i.e., public workshop held February 22-24, 2000). The transcripts of the  
328 February 22-24, 2000, public meeting and copies of the speaker presentations are available  
329 at <http://www.fda.gov/cvm/antimicrobial/oldmeet.htm>. Such studies would be used to  
330 provide CVM with information to assess whether antimicrobial susceptibility changes of  
331 human health concern would occur, or would occur at an unacceptable rate. The Center  
332 intends to issue further guidance on this aspect of a microbiological safety assessment in the

333 future. The current document discusses the type of data that may be provided as part of an  
334 assessment of the microbiological safety of an unapproved antimicrobial new animal drug.

335 During the evaluation of antimicrobial drugs prior to their approval, CVM considers all  
336 available relevant information pertaining to food safety including the potential of the drug  
337 to promote the emergence or spread of resistant food borne pathogens. Traditionally,  
338 where there was concern, CVM relied on restrictive measures as a means of managing  
339 risk. Such restrictions included limiting the sale and distribution to prescription only  
340 channels, specifying a dose or dose range sufficiently large to minimize the emergence of  
341 resistant pathogens, specifying the conditions under which the drug could be used, and  
342 prohibiting extra label use when deemed appropriate

343 CVM can only approve drugs for food animals which, in its best judgment, meet the  
344 standard of reasonable certainty of no harm. With respect to antimicrobial resistance,  
345 CVM would not approve a drug intended for use in food animals if it had reason to believe  
346 that the approval would lead in a relatively short period of time, to development of  
347 antimicrobial resistance at a level that would pose a risk to human health such that it would  
348 preclude a finding of reasonable certainty of no harm. Unfortunately, unlike chemical  
349 residues which are evaluated for their toxic properties using a battery of well-established  
350 animal and laboratory methods, CVM is aware of no such predictive models to estimate  
351 with precision the rate and extent of bacterial resistance that may emerge from the use of  
352 antimicrobial drugs in food animals.

353 *Thresholds:* FDA can only approve drugs for use in food animals for which the sponsor has  
354 established, among other things, that there is a reasonable certainty that no harm attributable  
355 to use of the drug will come to people from eating food from the animal species  
356 administered the drug according to approved label conditions. The agency recognizes that  
357 there can be no absolute certainty that use of the drugs will not ultimately lead to adverse  
358 human health effects. Therefore, as an added safeguard to protect human health in the event  
359 that resistance among bacterial isolates in humans results from the use of a drug in food  
360 animals, CVM is considering the establishment of resistance thresholds. Through the  
361 establishment of resistance thresholds, CVM hopes to define predetermined endpoints  
362 which, if reached, would indicate that the antimicrobial drug is no longer shown to be safe  
363 for use in a given food animal species. The threshold, therefore, would serve as the  
364 regulatory trigger for initiating immediate withdrawal from the label of the animal species  
365 that has reached its resistance threshold, recognizing that actually accomplishing such  
366 withdrawal takes time because of due process requirements, and that antimicrobial  
367 resistance may continue to increase during that time.

368 Although the overall concept is the same, it should be noted that the threshold approach  
369 outlined in this document differs from that initially proposed in the Framework Document.  
370 A description of how the approach discussed in this document differs from that in the  
371 Framework Document is provided later in the *Threshold Concept Background*.

372 *Drug use information:* CVM currently requires the submission of certain drug sales  
373 information as part of the annual drug experience report for approved drug products. The  
374 Framework Document identified the need for the pharmaceutical industry to submit more  
375 detailed antimicrobial drug sales information as part of its annual report. CVM believes  
376 that this additional information is needed to monitor drug use patterns in relation to the  
377 antimicrobial susceptibility data being monitored through the NARMS program. The  
378 ability to correlate use patterns with changing antimicrobial susceptibility would allow  
379 implementation and assessment of intervention or mitigation strategies. CVM is moving  
380 forward on developing new requirements for antimicrobial drug use information through a  
381 notice and comment rule-making process.

### 382 **Judicious Use of Antimicrobial Drugs**

383 Antimicrobial resistance is of concern when the same or related antimicrobial drugs are used  
384 in both animal agriculture and in human medicine. Guidelines for the judicious use of  
385 antimicrobial drugs have recently been prepared by the American Veterinary Medical  
386 Association (AVMA) and provide guidance to veterinary practitioners on ways to maximize  
387 the efficacy of antimicrobial drugs, while minimizing the development of antimicrobial  
388 resistance.<sup>6</sup> Initiatives are also underway in many producer associations to develop similar  
389 guidelines and / or recommendations. CVM has participated with a number of these  
390 organizations in developing these principles and has provided support for developing  
391 educational materials. CVM has also provided support for several ongoing studies to  
392 evaluate the impact of judicious use practices on the emergence of antimicrobial resistance.

### 393 **Research Initiatives**

394 CVM recognizes that additional research is needed on the relationship between  
395 antimicrobial use in food animals and the associated human health impact related to  
396 antimicrobial resistant bacteria. The importance of the issue and the need for interagency  
397 collaboration is highlighted in the Draft Public Health Action Plan to Combat  
398 Antimicrobial Resistance.<sup>1</sup> Copies of the draft are available at  
399 <http://www.cdc.gov/drugresistance/actionplan/>.

400 CVM has initiated its own intramural and collaborative research efforts to investigate  
401 factors associated with development, dissemination, and persistence of bacterial antibiotic  
402 resistance in both the animal production environment and food supply. Microbiologists  
403 from CVM's Office of Research are currently conducting or are participating in projects  
404 specifically targeted to gathering data on such issues as: (1) the current background level  
405 of bacterial antibiotic resistance in retail animal-derived food products; (2) the  
406 development and persistence of bacterial antibiotic resistance from aquaculture and animal  
407 production environments; (3) characterization of mechanisms of resistance dissemination  
408 and transfer among pathogenic and commensal bacteria associated with food-producing  
409 animals and aquaculture environments; (4) determining the roles that animal feeds and  
410 feed commodities play in the dissemination of antibiotic resistance and pathogen carriage;  
411 and (5) co-selection of antibiotic resistance phenotypes associated with the use of

412 sanitizers and other antimicrobial drugs in animals. In addition, CVM is a contributing  
413 laboratory to CDC's PulseNet molecular fingerprinting network involved in the molecular  
414 epidemiology of foodborne outbreaks. The CVM laboratory provides the only source of  
415 data on animal-associated bacterial pathogens into the PulseNet system.

416 In addition to the intramural research, CVM also collaborates in extramural research  
417 grants and funds extramural research activities through cooperative agreements. This  
418 extramural research is designed to complement and augment the intramural research  
419 program. Six of the projects are designed to elucidate the prevalence and risk factors  
420 associated with the dissemination of antibiotic resistant *Salmonella*, *E. coli* O157:H7, and  
421 enterococci within the animal production environment. Another study seeks to adapt and  
422 validate for use in the animal production environment microbial detection methods  
423 developed for human food.

#### 424 **Alternatives to antimicrobial drugs**

425 CVM is interested in evaluating products that may be considered alternatives to  
426 antimicrobial drugs. As an example, CVM approved the first competitive exclusion product  
427 in 1999 "for the early establishment of intestinal microflora in chickens to reduce  
428 *Salmonella* colonization." CVM would support the development of other products that  
429 would have a positive human health impact. In addition, CVM acknowledges the  
430 importance of continued advances in vaccine development and other management practices  
431 that may reduce reliance on the use of antimicrobial drugs in food-producing animals.

#### 432 **Threshold Concept Background**

433 This discussion document describes a possible approach for establishing thresholds as a  
434 means of assuring the safe use of antimicrobial drugs in food-producing animals  
435 complimentary to the approval process itself. Such thresholds are intended to provide an  
436 added measure of protection should the emergence of antimicrobial resistance as a  
437 consequence of antimicrobial drug use in food-producing animals pose an unacceptable  
438 risk to human health, that is, that there was no longer reasonable certainty that no human  
439 health harm would result from an approved use of the drug. This document provides a  
440 detailed technical description of the proposed methodology for the purpose of stimulating  
441 discussion at an upcoming scientific public meeting.

442 The current document provides a more detailed discussion of the threshold concept  
443 introduced in the Framework Document and describes a possible approach for establishing  
444 thresholds. It should be noted that the approach outlined in this document differs from  
445 that initially proposed in the Framework Document. The Framework Document discussed  
446 two thresholds, a resistance threshold and a monitoring threshold, that would be  
447 established prior to the approval of a new animal antimicrobial drug for use in food-  
448 producing animals. The resistance threshold was described as the upper limit for the level  
449 of resistant bacteria that can be transferred from animals to consumers and still be  
450 considered safe for the consumer. Exceeding the resistance threshold was considered to

451 represent an unacceptable human health risk. The monitoring threshold was described as  
452 a level of resistance for the food animal species that would allow industry to monitor the  
453 development of resistance to the antimicrobial and identify when intervention and  
454 mitigation programs should be implemented. Exceeding the monitoring threshold was  
455 considered to represent an early warning signal of resistance development.

456 The approach outlined in this document also proposes the establishment of two types of  
457 thresholds, a human health threshold and a resistance threshold. The human health  
458 threshold described in this document represents the unacceptable prevalence of infections  
459 in humans that are treated with the antimicrobial drug of concern, are associated with  
460 bacteria resistant to the drug of concern, and for which the resistance is attributable (in  
461 whole or in part) to the use of an antimicrobial drug in animals. Based on the current  
462 safety standard, the "unacceptable prevalence" is considered that level at which there is no  
463 longer reasonable certainty that there is no harm to human health.

464 The resistance threshold described in this document is the maximum allowable level of  
465 resistance prevalence in bacteria isolated from the food animal that does not pose an  
466 unacceptable risk to human health. This resistance threshold is derived through an  
467 epidemiology-based model that describes the relationship between the human health  
468 threshold and resistance levels in animals. Therefore, exceeding a resistance threshold  
469 would be considered a level of resistance at which there is no longer reasonable certainty  
470 that there is no harm to human health.

471 The approach described in this paper does not include the establishment of "monitoring  
472 thresholds" as an early warning system. However, given that the proposed resistance  
473 threshold is based on a measurable endpoint in animals, CVM believes that resistance  
474 thresholds will allow industry to monitor the development of resistance to the  
475 antimicrobial and identify when intervention and mitigation programs should be  
476 implemented. A monitoring system that utilizes thresholds, such as that described in this  
477 document, would provide a timely warning of the emergence of bacterial resistance among  
478 pathogens of human health concern. At this time, the approach included in this discussion  
479 paper addresses the establishment of thresholds for foodborne pathogens only. However,  
480 CVM intends to apply a similar risk-based approach to the establishment of resistance  
481 thresholds for non-pathogenic bacteria such as enterococci. CVM is in the process of  
482 developing a risk assessment on enterococci that should be helpful in further refining an  
483 approach to establishing thresholds for non-pathogenic bacteria.

484 CVM believes that resistance thresholds would need to be determined for certain  
485 antimicrobial products prior to approval. CVM envisions that resistance thresholds will 1)  
486 encourage industry participation in monitoring for the development of resistance to an  
487 antimicrobial product; 2) identify when intervention and mitigation programs might be  
488 implemented by the pharmaceutical industry, producer organizations, or CVM; 3) identify  
489 when procedures should be initiated by CVM to withdraw from the label the approval of a  
490 particular food animal species; and 4) assist in prolonging the effectiveness of  
491 antimicrobial drugs in humans and food animals. If it is determined that resistance

492 thresholds do not have to be established for certain drugs or drug classes, it may also help  
493 the pharmaceutical industry to target classes of drugs for development for animal use.

#### 494 **AN APPROACH FOR ESTABLISHING THRESHOLDS**

##### 495 **Overview**

496 The approach outlined in this document discusses the establishment of two types of  
497 thresholds for certain antimicrobial products intended for use in food-producing animals.  
498 The first type of threshold, referred to as the human health threshold ( $T(x)$ ), is the  
499 unacceptable prevalence of infections in humans that are treated with the antimicrobial  
500 drug of concern, are associated with bacteria resistant to the drug of concern, and for  
501 which the resistance is attributable (in whole or in part) to the use of an antimicrobial drug  
502 in animals. These human health thresholds specifically focus on the incremental effects  
503 on existing enteric illness or systemic illness in humans as a consequence of the causative  
504 bacteria being resistant to the antimicrobial drug the affected persons are expected to  
505 receive. Based on the current safety standard, the "unacceptable prevalence" is considered  
506 that level at which there is no longer reasonable certainty that there is no harm to human  
507 health.

508 The second type of threshold discussed is referred to as the resistance threshold. The  
509 resistance threshold ( $t(x)$ ) is the maximum allowable prevalence of resistant bacteria  
510 isolated from animal-derived food that does not pose an unacceptable risk to human  
511 health. The resistance threshold is derived through an epidemiology-based model that  
512 relates the prevalence of resistant bacteria in food to an impact (as described above) on  
513 either enteric illness (EI) or systemic illness (SI) in humans. Isolates are defined as  
514 resistant if their minimum inhibitory concentration (MIC) reaches or exceeds the  
515 resistance breakpoint established for the related drug used in human medicine. Therefore,  
516 a resistance threshold (i.e., prevalence of resistance in animals) would be established for a  
517 particular antimicrobial drug in animals that correlates to the human health threshold. If  
518 changes in susceptibility or changes in the prevalence of resistance among animal isolates  
519 are observed via monitoring, but a resistance threshold is not exceeded, voluntary  
520 mitigating actions may be implemented. However, if a resistance threshold were  
521 exceeded, this would be considered a level of resistance at which there is no longer  
522 reasonable certainty that there is no harm to human health. .

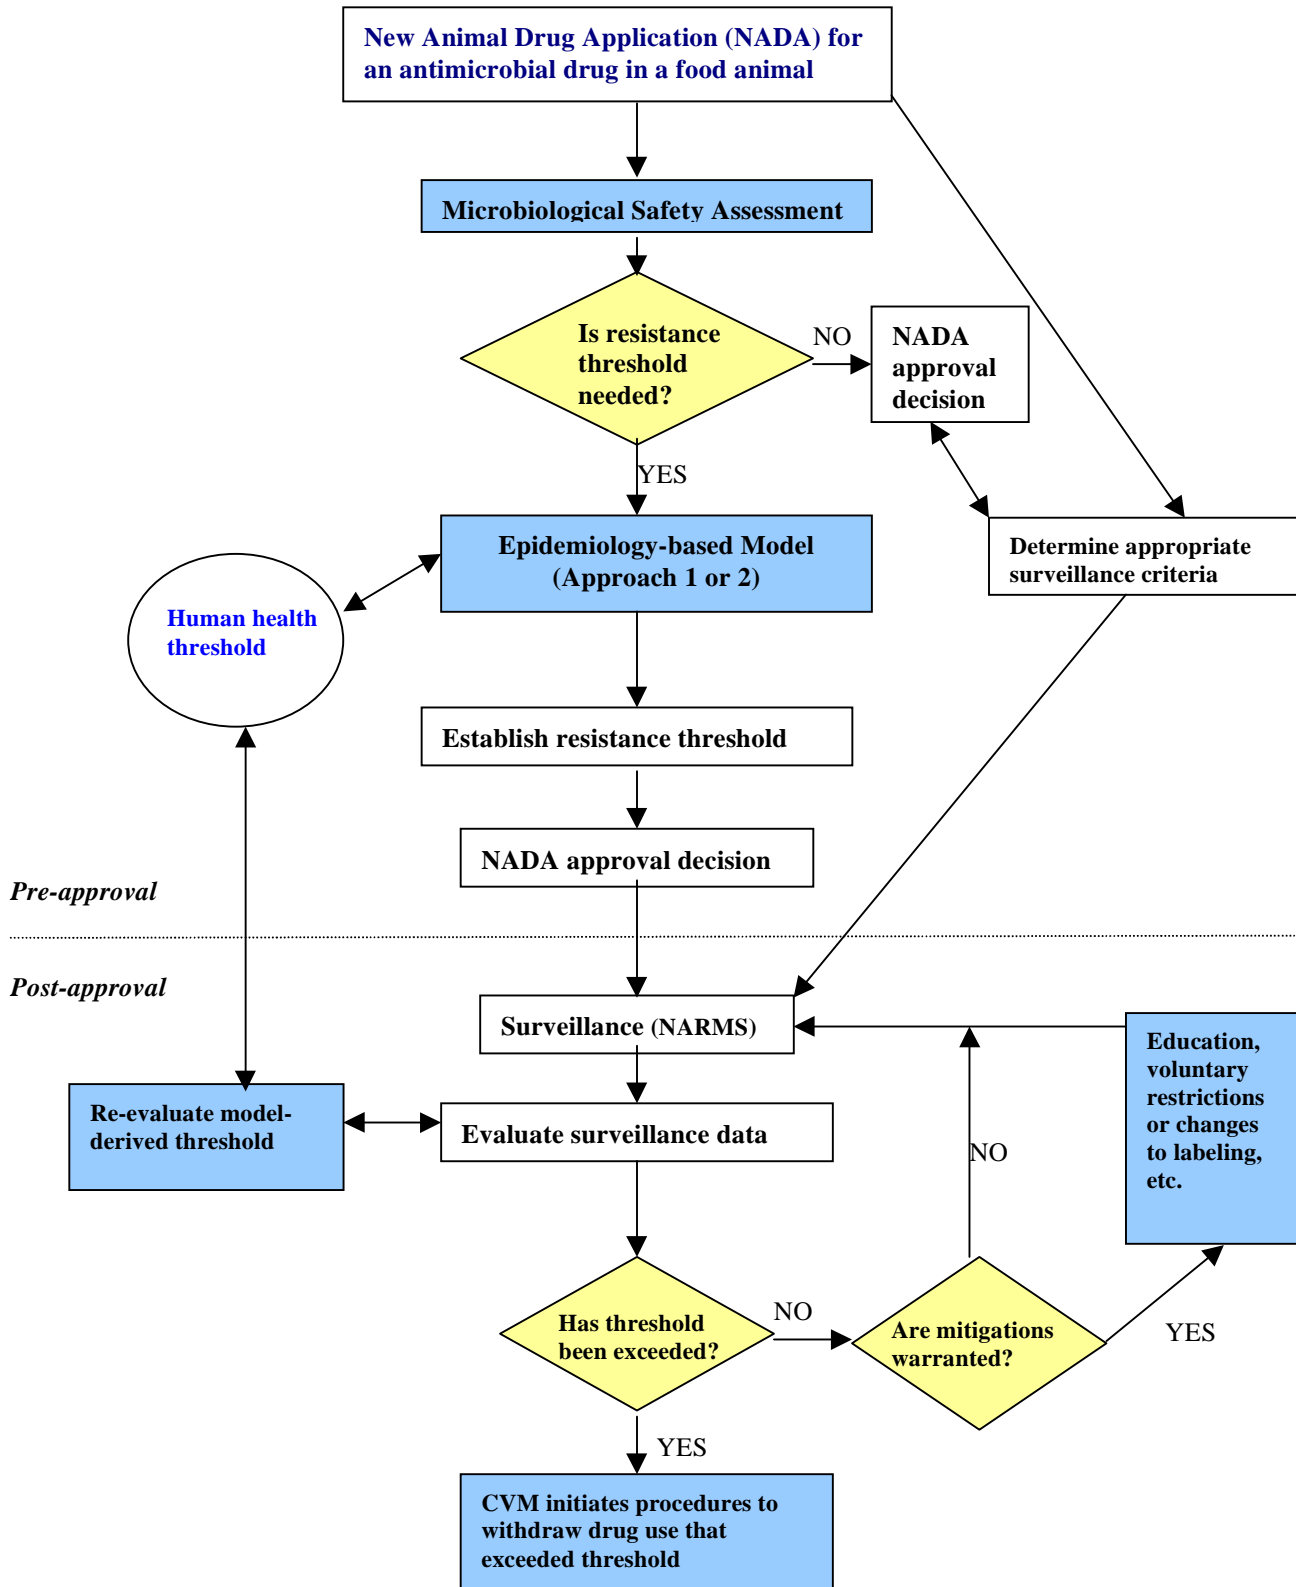

523 This document outlines an approach for assessing when the establishment of thresholds  
524 would be needed for the approval of an antimicrobial drug in animals. This determination  
525 could be made through the completion of a Microbiological Safety Assessment by the  
526 animal drug sponsor. Through this process, it may be determined that the proposed  
527 antimicrobial product does not pose a human health concern and, therefore, the  
528 establishment of resistance thresholds would not be needed prior to approval in a food-  
529 producing animal.

530 If the Microbiological Safety Assessment concludes that establishment of resistance  
531 thresholds are necessary for approval, this document describes an epidemiology-based  
532 model that could be used to derive such thresholds. The epidemiology-based model is  
533 intended to relate the prevalence of resistant bacteria in food to an impact on either enteric  
534 illness (EI) or systemic illness (SI) in humans. This document outlines two alternative  
535 methods by which the resistance thresholds could be derived. The determination of which  
536 method to use would be driven by data availability. Although the two methods presented  
537 are very similar in concept, one method uses an estimate of the maximum human health  
538 impact in its calculations (i.e., makes assumption that all human cases attributed to animal  
539 species were due to bacteria resistant to drug of concern), whereas, the second method  
540 uses current human health impact information (i.e., uses current data to determine  
541 proportion of animal-related human cases that were due to bacteria resistant to drug of  
542 concern). The advantage of using the maximum possible human health impact is that it  
543 permits calculation of the resistance threshold ( $t(x)$ ) without the data required for the  
544 second method.

545 Following the establishment of the resistance thresholds and subsequent approval of the  
546 antimicrobial new animal drug, the pertinent bacterial pathogen(s) (for which thresholds were  
547 established) would be monitored post-approval with regard to susceptibility to the related  
548 drug of importance to human medicine. As discussed above, observed shifts in susceptibility  
549 (that do not exceed the resistance threshold) may trigger certain voluntary actions. However,  
550 if the prevalence of resistance exceeds the threshold, CVM would initiate procedures to  
551 withdraw from the label any animal species that has reached or exceeded its threshold. An  
552 overall outline of this approach for establishing thresholds is presented in Figure 1.

553

**Figure 1:** Overview of the approach for establishing thresholds described in this document.

---

**555 Pre-approval Microbiological Safety Assessment**

556 As outlined in Guidance for Industry #78, "Consideration of the Human Health Impact of  
557 the Microbial Effects of Antimicrobial New Animal Drugs Intended for Use in Food-  
558 Producing Animals", CVM intends to consider the potential human health impact of the  
559 microbial effects associated with all uses of all classes of antimicrobial new animal drugs  
560 intended for use in food-producing animals.<sup>4</sup> CVM believes that consideration of this  
561 concern may be facilitated by a Microbiological Safety Assessment. Such an assessment  
562 would collect and organize all pertinent data and information relevant to the potential  
563 human health impact associated with the proposed antimicrobial drug use in animals.  
564 Data, provided by the drug sponsor, that may be necessary for this evaluation may include,  
565 but are not limited to:

- 566 • Information regarding the proposed conditions of use of the product that would help  
567 characterize the potential for human exposure to zoonotic enteric bacteria associated  
568 with the treated animal.
- 569 • Baseline prevalence of appropriate zoonotic enteric bacteria in the target animal  
570 species and in humans.
- 571 • Baseline susceptibility of appropriate zoonotic enteric bacteria to the relevant drug  
572 used in human medicine obtained from animal isolates and human community isolates.
- 573 • Information to determine the level of concern for the proposed animal drug use as it  
574 may impact human medicine.
- 575 • Antimicrobial susceptibility breakpoints for the relevant human drugs in the  
576 appropriate zoonotic enteric bacteria.
- 577 • Pharmacokinetic and pharmacodynamic information for the new animal drug in the  
578 food animal.
- 579 • Information regarding the mechanism of action and mechanism(s) of resistance.

580 The information included in the Microbiological Safety Assessment may be used to evaluate  
581 the potential human health impact associated with the proposed use and may be used to  
582 make a determination as to whether it was necessary to establish a resistance threshold at the  
583 time of approval. CVM anticipates that a resistance threshold would likely be required for  
584 those drugs considered highly important to human medicine. For those antibiotics that are  
585 not used in human medicine and are not cross-resistant to drugs used in human medicine, a  
586 resistance threshold may not be required. The extent to which thresholds should be  
587 established for the other drugs, and how those thresholds might be set, are issues that require  
588 further discussion.

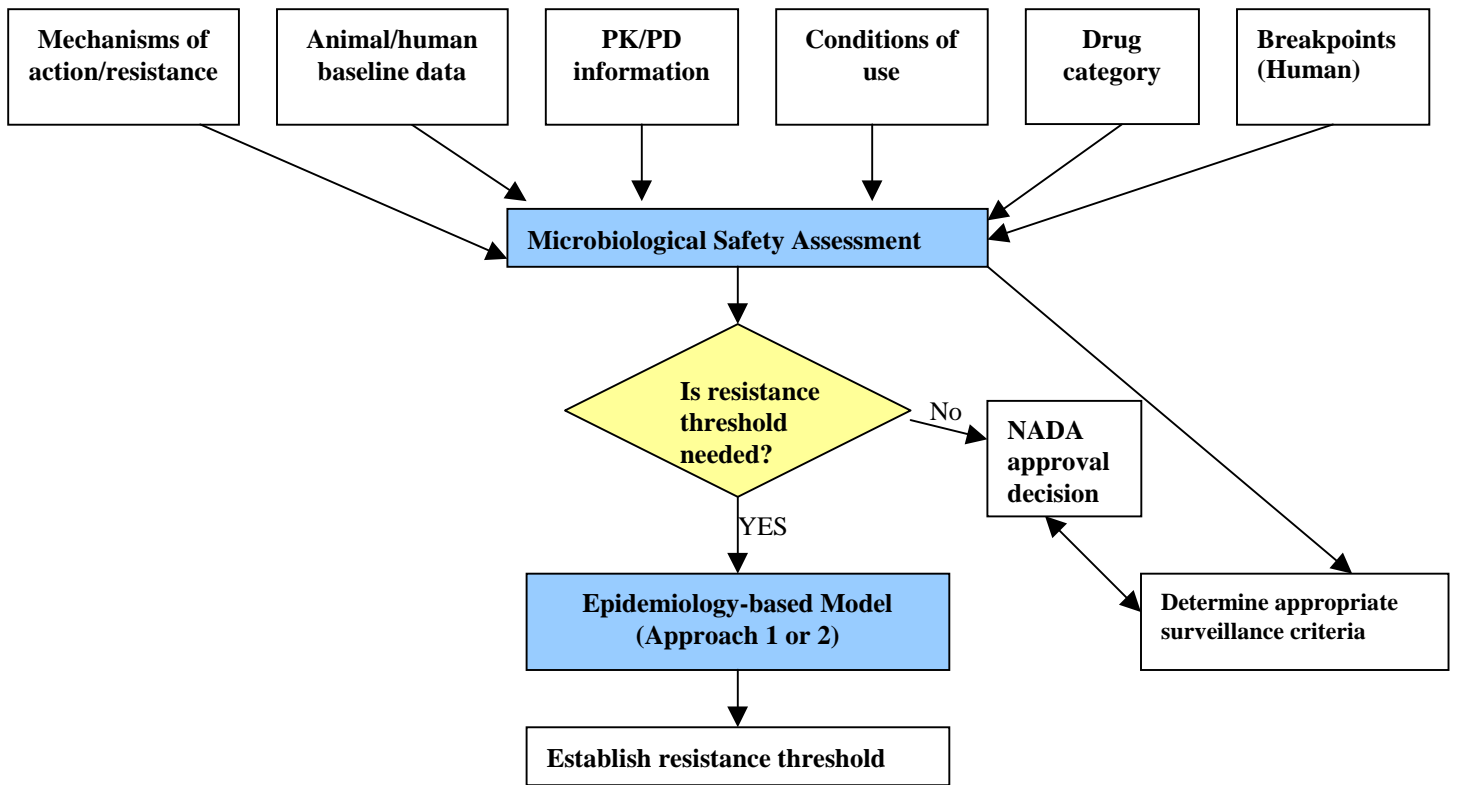

589 CVM also believes that the Microbiological Safety Assessment would help to guide the  
590 establishment of the appropriate post-approval surveillance criteria for the proposed

591 product. As noted above, CVM envisions that all proposed uses of antimicrobial drugs in  
592 food animals would be required to undergo this assessment. The information provided in  
593 this assessment may be used to make a determination as to whether post-approval  
594 surveillance is warranted, and if so, what should be the appropriate criteria for such  
595 surveillance.

596

597

**Pre-approval Microbiological Safety Assessment  
Data input**

**Figure 2:** Summary of type of data that may be included in a pre-approval Microbiological Safety Assessment.

## 598 **Establishment of Thresholds**

### 599 **Overview**

600 This section contains two subsections. The first subsection, Setting Human Health  
601 Thresholds, discusses the concept of setting human health thresholds. The human health  
602 threshold is defined as the unacceptable prevalence of infections in humans that are treated  
603 with the antimicrobial drug of concern, are associated with bacteria resistant to the drug of  
604 concern, and for which the resistance is attributable (in whole or in part) to the use of an  
605 antimicrobial drug in animals.

606 The second subsection, Establishing Resistance Thresholds, describes an epidemiology-  
607 based model that is used to derive resistance thresholds. The resistance threshold (referred  
608 to later in this document as  $t(x)$ ) is the maximum allowable prevalence of resistant bacteria  
609 isolated from animal-derived food that does not pose an unacceptable risk to human  
610 health. The resistance threshold is derived through an epidemiology-based model that  
611 relates the prevalence of resistant bacteria in food to a particular impact on either enteric  
612 illness (EI) or systemic illness (SI) in humans.

613 The association between the human health and the resistance thresholds is based on certain  
614 epidemiological information. In particular, an association is made between the annual  
615 prevalence of people affected by enteric or systemic foodborne-related illness and the  
616 quantity of food animal commodity containing resistant bacteria to which the population  
617 was exposed during the year. The calculations provided in the following sections  
618 demonstrate that the threshold of material can be reduced to an expression of the threshold  
619 prevalence of resistance among bacterial isolates from the food animal commodity. The  
620 resistance threshold is that prevalence associated with a particular preset human health  
621 threshold. A resistance threshold can be set to correspond to a measurable human health  
622 impact, or through safety factors (see Appendix 2) to avoid any human health impact.

### 623 **Setting Human Health Thresholds**

624 There is a wide spectrum of potential human health impacts associated with treatment  
625 failure due to antimicrobial resistance. This document focuses on foodborne-related enteric  
626 or systemic illness in humans and the potential associated incremental health impact  
627 experienced as a consequence of antimicrobial resistance in the causative bacteria. CVM  
628 considers that enteric and systemic illnesses are possible endpoints that could be used in the  
629 regulation of the antimicrobial animal drug.

- 630 1. **Threshold for impact on enteric illness:** In a given year, a certain proportion of the  
631 U.S. population will experience enteric foodborne illness and will be treated with an  
632 antimicrobial drug. Some cases may be due to bacteria that are resistant to the drug  
633 administered. Therefore, the threshold for impact on enteric illness is defined as the  
634 unacceptable prevalence of cases of enteric illness in the U.S. population that are  
635 treated with the antimicrobial drug of concern, are associated with bacteria resistant to

636 the drug of concern, and for which the resistance is attributable (in whole or in part) to  
637 the use of an antimicrobial drug in animals. Such cases would be expected to  
638 experience decreased or loss of effectiveness of their antimicrobial drug treatment.

639 2. **Threshold for impact on systemic illness:** In a given year, a certain proportion of the  
640 U.S. population will experience systemic foodborne illness and will be treated with an  
641 antimicrobial drug. Some cases may be due to bacteria that are resistant to the drug  
642 administered. Therefore, the threshold prevalence of cases of systemic illness impacted  
643 is defined as the unacceptable prevalence of cases of systemic illness in the U.S.  
644 population that are treated with the antimicrobial drug of concern, are associated with  
645 bacteria resistant to the drug of concern, and for which the resistance is attributable (in  
646 whole or in part) to the use of an antimicrobial drug in animals. Such cases would be  
647 expected to experience decreased or loss of effectiveness of their antimicrobial drug  
648 treatment.

649 The symbol T(EI) is used for the human health threshold for enteric illness. The symbol  
650 T(SI) is used for the human health threshold for systemic illness. A symbol of T(x) may  
651 be used to represent the human health threshold without specifying a particular end point  
652 such as enteric illness or systemic disease.

653 The threshold concept is one component of a multi-pronged strategy for managing  
654 antimicrobial resistance. As stated previously, CVM has issued guidance (Guidance for  
655 Industry #78) indicating that the safety evaluation of new animal drug applications for  
656 antimicrobial drugs for food-producing animals should include a consideration of the  
657 potential impact of antimicrobial resistance on human health. CVM believes that  
658 thresholds provide a mechanism for taking appropriate action should post-approval  
659 monitoring efforts indicate that an antimicrobial drug used in animals is no longer shown  
660 to be safe. Implementation of a threshold concept, such as that discussed in this  
661 document, necessitates that a certain human health impact(s) be identified as a means of  
662 monitoring the continued safety of antimicrobial drug use in animals. Based on current  
663 safety standards, such thresholds would be used to indicate the point at which there is no  
664 longer reasonable certainty that there is no harm to human health.

665 CVM anticipates considerable discussion regarding the selection of the appropriate human  
666 health impacts to measure and establishment of the unacceptable threshold prevalence for  
667 that human health impact. This document is intended to stimulate discussion on these  
668 points. CVM seeks further input on setting human health thresholds.

## 669 **Establishing Resistance Thresholds**

### 670 **Description of Model for Deriving Resistance Thresholds**

671 **Model proportionality factor (k-res):** The basis for determining a resistance threshold is  
672 a modeled rate or proportionality factor, k-res. This factor links a measurable level of  
673 human health impact (H(x)) to a quantity of animal-derived food (Q) containing bacteria

674 resistant to an antimicrobial drug of interest. The factor, k-res, is a key component of the  
 675 approach outlined for deriving resistance thresholds in that it is intended to approximate  
 676 the relationship between exposure to resistant bacteria (i.e., Q) and some effect on human  
 677 health (i.e., H). The ability to calculate k-res is dependent on the availability of data to  
 678 derive values for the parameters H and Q. If such data are not available (e.g., in the case  
 679 of a new drug where no resistance has been documented), some other means of  
 680 approximating k-res would be necessary. This may include applying the k-res factor  
 681 derived for other drug/bacteria situations.

682 As noted above, the factor, k-res, attempts to link drug-related human health effects to  
 683 exposure to animal-derived food containing bacteria resistant to that drug. Therefore,  
 684 when considering data to derive the factor, k-res, it should be noted that, based on current  
 685 safety standards, existing information relevant to drug-related human health effects must  
 686 not preclude a determination of reasonable certainty of no harm.

687 **Uncertainty distributions:** Point estimates of quantities will be discussed in the process  
 688 of explaining the data and the steps used to calculate resistance thresholds. It should be  
 689 noted, however, that the resistance thresholds derived from the model would have  
 690 attendant uncertainty distributions. The 95<sup>th</sup> percentile of the distribution of the estimated  
 691 number of people affected and the associated prevalence of resistance in animals could be  
 692 used rather than the mean of the distribution. Alternatively, the 5<sup>th</sup> percentile of the  
 693 distribution of the resistance threshold derived from the model could be used.

694 **Measurable human health impact (H(x)):** As discussed in this document, a measurable  
 695 human health impact (H(x)) represents the current measured prevalence of infections in  
 696 humans that are treated with the antimicrobial drug of concern, are associated with  
 697 bacteria resistant to the drug of concern, and for which the resistance is attributable (in  
 698 whole or in part) to the use of an antimicrobial drug in animals. Additionally, exposure is  
 699 associated with meat containing drug-resistant bacteria whose resistance was attributed to  
 700 the use of antimicrobial drugs in the food animal species that produced the meat.

701 One way to estimate the prevalence of people impacted (H(x)) is as follows:

702	H(x) = estimate of the total prevalence of cases of disease
703	×
704	proportion of total cases due to exposure to animal-derived food commodity
705	×
706	proportion of cases with resistance attributed to animal-derived food commodity
707	×
708	proportion of cases expected to be treated with the antimicrobial drug of interest

709 The estimated total prevalence of cases is determined annually for foodborne pathogens in  
 710 FoodNet, Foodborne Diseases Active Surveillance Network, by the CDC. Periodically, the  
 711 CDC also conducts case-control studies and surveys that provide more detailed  
 712 information. Such information includes the prevalence of people impacted by infections

713 caused by drug-resistant bacteria for which they sought care and received an antibiotic to  
 714 which the bacteria were resistant. In the case of antimicrobial drugs for which transmission  
 715 of resistance from animals to humans would primarily be expected to occur through  
 716 foodborne pathogens, resistance thresholds would be established only for a few bacteria,  
 717 perhaps *Campylobacter* and *Salmonella*. CDC provides annual estimates of the total  
 718 number of campylobacteriosis and salmonellosis cases in the U.S. With attention focused  
 719 mainly on a few foodborne pathogens, it will be possible to develop estimates of the  
 720 proportion of all cases and from this, the number of cases, attributable to various animal  
 721 species. Scientific panels may also be useful in determining estimates for parameters that  
 722 are difficult to measure directly. These estimates would need to be reviewed periodically.  
 723 Once in place, the estimates would be used during the pre-approval process in the  
 724 establishment of resistance thresholds using one of the approaches described in the  
 725 following sections.

726 It should be noted that the current measurable level of human health impact (H(x)) must be  
 727 lower than the human health threshold (T(x)) which, as stated earlier in this document, is  
 728 the level at which there is no longer a reasonable certainty of no harm to humans.

729 **Measurable level of exposure (Q):** This document describes a measurable level of  
 730 exposure as the number of pounds of a particular food animal commodity containing drug-  
 731 resistant bacteria.

732 While number of pounds of product containing resistant bacteria may be the most practical  
 733 way to discuss the measurable level of exposure, Table 1 illustrates that the quantity is not  
 734 measured directly. Instead, a measurable quantity to which the population is exposed (Q)  
 735 would typically be a product of several terms. The total number of pounds of food animal  
 736 commodity consumed is known from USDA records. The portion of the total number of  
 737 pounds containing any of the bacteria of interest is estimated from the USDA data. The  
 738 prevalence of antimicrobial resistance among bacterial isolates is determined through the  
 739 NARMS program.

740 Therefore, Q could be estimated as follows:

741	Q =	total pounds of product consumed
742		×
743		proportion of sampled pounds containing bacteria
744		×
745		proportion of samples from which resistant bacteria are isolated

#### 746 **Calculating Resistance Thresholds**

747 The proportionality relationship between the measurable human health impact (H(x)) and  
 748 the associated observable exposure (Q) is expressed,

749 
$$H(x) = [k\text{-res}] * Q. \quad (\text{Equation 1})$$

750 Now, assuming all underlying factors in the system modeled remain stable over the period  
 751 of interest, this relationship is considered stable over that period. During such a stable  
 752 period, the relationship allows a linear prediction of the prevalence of people impacted  
 753 from the quantity of food animal commodity containing resistant drug-resistant bacteria to  
 754 which the population is exposed. If the level of exposure associated with the human  
 755 health threshold,  $T(x)$ , is designated  $Q_t(x)$ , it is also true that for the specific threshold  
 756 values,  $T(x)$  and  $Q_t(x)$ ,

$$757 \quad T(x) = [k\text{-res}] * Q_t(x). \quad (\text{Equation 2})$$

758 Taking equations (1.) and (2.) in combination it follows that,

$$759 \quad [k\text{-res}] = \frac{H(x)}{Q} = \frac{T(x)}{Q_t(x)} \quad (\text{Equation 3})$$

760 This relationship permits solution for a resistance threshold  $t(x)$ , expressed as the  
 761 prevalence of resistance among isolates from samples of the food commodity containing  
 762 the bacteria of interest. A resistance threshold ( $t(x)$ ) is associated with a set human health  
 763 threshold value ( $T(x)$ ), given measurable values of impact  $H(x)$ , and proportion of all  
 764 isolates from food samples from which resistant isolates are obtained ( $h$ ). To illustrate as  
 765 in Equation 3 above, write:

$$766 \quad \frac{H(x)}{Q} = \frac{H(x)}{\text{total weight in pounds} * \text{proportion contaminated with bacteria} * h}$$

767 and

$$768 \quad \frac{T(x)}{Q_t(x)} = \frac{T(x)}{\text{total weight in pounds} * \text{proportion contaminated with bacteria} * t(x)}$$

769 Then when the total weight in pounds and proportion contaminated with bacteria are  
 770 cancelled from both sides in Equation 3, it can be seen that the solution for the resistance  
 771 threshold specified in terms of prevalence of resistance is:

$$772 \quad t(x) = \frac{T(x) \times h}{H(x)} \quad (\text{Equation 4})$$

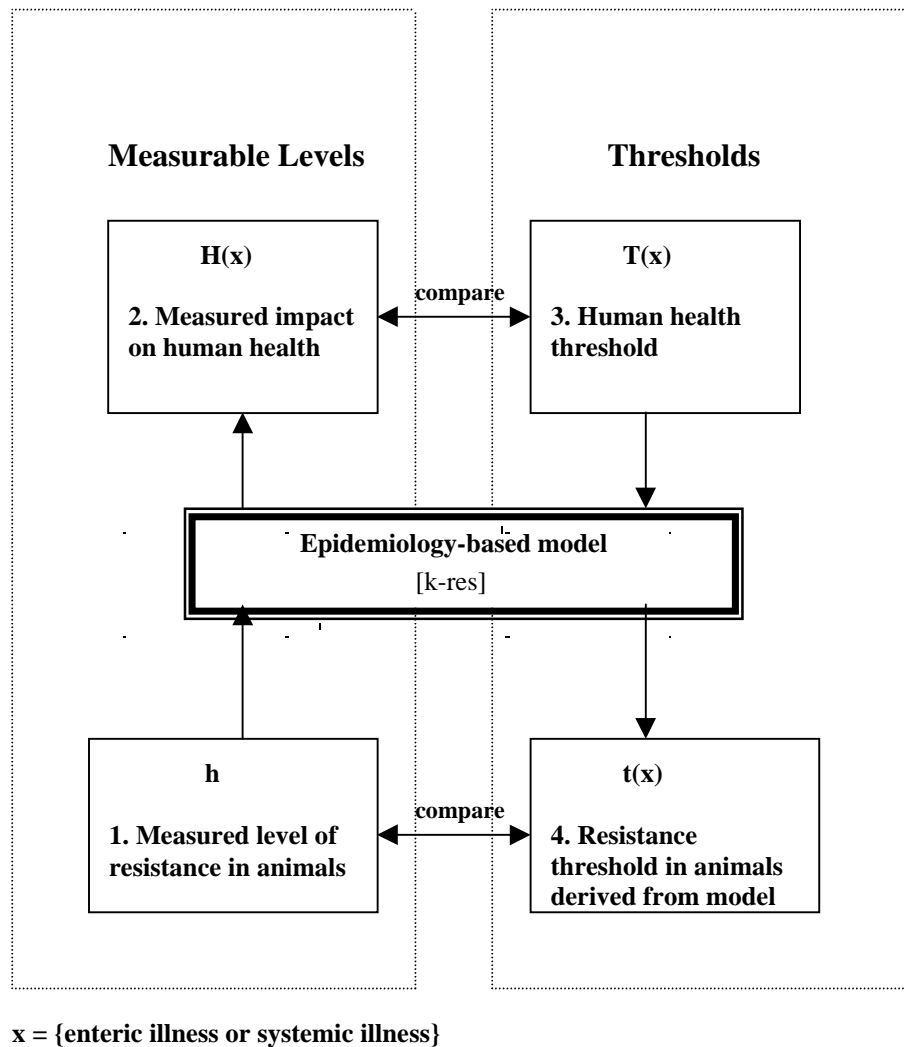

773 We would consider using the prevalence of carcasses from which resistant bacteria are  
 774 isolated at slaughter (or from products at retail for situations in which slaughter data will  
 775 not be collected).

776 The essential strategy of the proposed quantitative approach outlined above is illustrated  
 777 in Figure 3. There are four quantities represented here:

- 778 •  $H(x)$  – The current measured prevalence of infections in humans that are treated  
779 with the antimicrobial drug of concern, are associated with bacteria resistant to the  
780 drug of concern, and for which the resistance is attributable (in whole or in part) to  
781 the use of an antimicrobial drug in animals.
- 782 •  $h$  – A consistent measure of the current prevalence of animal-derived foods  
783 containing resistant bacteria.
- 784 •  $T(x)$  – The unacceptable prevalence of infections in humans that are treated with  
785 the antimicrobial drug of concern, are associated with bacteria resistant to the drug  
786 of concern, and for which the resistance is attributable (in whole or in part) to the  
787 use of an antimicrobial drug in animals.
- 788 •  $t(x)$  – The resistance threshold ( $t(x)$ ) is the maximum allowable prevalence of  
789 resistant bacteria isolated from animal-derived food that does not pose an  
790 unacceptable risk to the human health.

791

792 **Figure 3:** Diagram illustrating the relationship between human health thresholds, resistance  
 793 thresholds, measured levels of resistance in animals, and measured impacts in human health.  
 794 A measured level of resistance (1.) is linked to a measured human health impact (2.) by  
 795 Equation 1 through [k-res], based on an epidemiology-based model. The human health  
 796 health threshold (3.) is linked through [k-res] to the resistance threshold (4.). After approval the  
 797 measured prevalence of resistance (h) is compared to the resistance threshold [t(x)] set prior  
 798 to approval. The measurable human health impact [H(x)] is compared to the set human  
 799 health threshold [T(x)] level for confirmation. The relationship between observable human  
 800 health impact and observable prevalence of resistance is examined to determine if [k-res]  
 801 needs to be adjusted.

---

**802 Two Alternative Methods for Deriving Resistance Thresholds**

803 Two methods are described in the following sections for using the proposed  
804 epidemiology-based model for deriving resistance thresholds. The methods differ mainly  
805 in the amount of data required to perform the calculations to establish the resistance  
806 thresholds. Coincident differences in assumptions are required.

**807 Method 1: *Maximum Human Health Impact Method of Establishing  $t(x)$*** 

808 In the case of antimicrobial drugs for which transmission of resistance from animals to  
809 humans would primarily be expected to occur through food borne pathogens, resistance  
810 thresholds would likely be established for *Campylobacter* and *Salmonella*.

811 *Campylobacter* and *Salmonella* are commonly isolated from food animals at slaughter<sup>7-14</sup>  
812 and represent the predominant bacterial pathogens isolated from cases of enteric illness for  
813 those pathogens under surveillance in FoodNet<sup>15</sup>. CDC provides annual estimates of the  
814 total prevalence of cases of campylobacteriosis and salmonellosis in the U.S. in FoodNet  
815 reports. To use Method 1, it is necessary to know the total prevalence of cases of illness  
816 in humans attributable to the animal species of interest. The total prevalence of illness is  
817 multiplied by the attributable fraction to determine the prevalence of cases attributed to the  
818 animal species. The assumption is made that when there are no resistant bacterial isolates  
819 among isolates from a given animal species, no human cases with resistant bacteria are  
820 attributable to that animal species. Similarly, the assumption is made that when all  
821 isolates from an animal species are resistant; all human cases attributable to that animal  
822 species will be caused by resistant bacteria.

823 This maximum prevalence of cases with resistant infections is multiplied by the fraction of  
824 those cases expected to be treated with the antimicrobial drug of concern to yield the  
825 maximum human health impact that would be expected if 100 percent of the animal isolates  
826 are resistant. A line drawn between these two points, the zero value and the prevalence of  
827 cases attributable to the animal species who would be given the antimicrobial drug of  
828 interest, is a first approximation of the relationship between the human health impact and  
829 the prevalence of resistance among isolates from the food animal commodity of interest.  
830 The maximum prevalence of cases who were given the antimicrobial drug to which the  
831 bacteria causing their infections are resistant constitutes a measurable health impact ( $H(x)$ ),  
832 denoted  $H_{\max}(x)$ . Its associated value of prevalence of resistance among isolates in the  
833 animal species is  $h = 1$ . As mentioned in the previous section, these two values and the set  
834 value  $T(x)$  may now be used to solve for the resistance threshold ( $t(x)$ ) in the animal species:

835 
$$t(x) = \frac{T(x)}{H_{\max}(x)} \quad (\text{Equation 5})$$

836 Note that this method implies that the prevalence of resistance among isolates in the food  
837 animal commodity is the same as the prevalence of resistance among isolates from people  
838 with illness attributed to the food animal commodity. This method is quite simple to  
839 apply and beneficial in the situation where there are little data on resistance in the food

840 animal, such as when a novel animal drug is in the review process. This method assumes  
841 that the likelihood of the pathogen to cause an infection in humans is the same for  
842 susceptible and resistant strains. It also assumes that the distribution of the total numbers  
843 of bacteria that are found on units of a food-animal commodity is the same regardless of  
844 the prevalence of resistance among the bacteria. An example calculation using Method 1  
845 is provided in Appendix 1.

846 **Method 2: Current Human Health Impact Method of Establishing  $t(x)$**

847 Calculating  $t(x)$  by Method 2 requires data on the prevalence of cases with disease caused  
848 by resistant bacteria for which resistance is attributable to use of an antimicrobial drug in a  
849 food animal species, and on the prevalence of resistance among isolates from the food  
850 animal commodity of interest. This prevalence is not estimated under the current  
851 surveillance system, which estimates only the total prevalence of cases caused by each  
852 pathogen. The total prevalence must then be translated into the prevalence of cases caused  
853 by resistant bacteria attributable to the food animal commodity by applying an estimated  
854 proportion of resistant cases among all cases attributable to the food animal commodity.  
855 Until the prevalence of cases caused by resistant pathogens attributable to the food animal  
856 commodity is estimated directly, Method 2 requires the data required by Method 1 plus an  
857 estimate of the proportion of cases with resistant bacteria attributable to the food animal  
858 commodity. Despite the additional data requirements, Method 2 has an advantage over  
859 Method 1 because it assumes linearity only over a narrow range around the current estimate  
860 rather than over the entire range from 0 to 100% resistance prevalence in the isolates from  
861 the food animal commodity.

862 The current human health impact is an estimation of the prevalence in the U.S. population  
863 of some particular health effect in the current year. The two prevalences offered for  
864 consideration in this document are:

- 865 1. **Current impact on enteric illness:** In any given year, a certain proportion of the U.S.  
866 population will experience enteric foodborne illness and will be treated with an  
867 antimicrobial drug. Some cases may be due to bacteria that are resistant to the drug  
868 administered. The current impact on enteric illness is defined as the current  
869 prevalence of cases of enteric illness in the U.S. population that are treated with the  
870 antimicrobial drug of concern, are associated with bacteria resistant to the drug of  
871 concern, and for which the resistance is attributable (in whole or in part) to the use of  
872 an antimicrobial drug in animals. Such cases are expected to experience decreased or  
873 loss of effectiveness of their antimicrobial drug treatment.
- 874 2. **Current impact on systemic illness:** In any given year, a certain proportion of the  
875 U.S. population will experience systemic foodborne illness and will be treated with an  
876 antimicrobial drug. Some cases may be due to bacteria that are resistant to the drug  
877 administered. The current impact on systemic illness is defined as the current  
878 prevalence of cases of systemic illness in the U.S. population that are treated with the  
879 antimicrobial drug of concern, are associated with bacteria resistant to the drug of  
880 concern, and for which the resistance is attributable (in whole or in part) to the use of

881 an antimicrobial drug in animals. Such cases are expected to experience decreased or  
882 loss of effectiveness of their antimicrobial drug treatment.

883 Just as was the case for each threshold prevalence where there is an associated expected  
884 human health impact  $T(x)$ , there is a current human health impact estimate associated with  
885 each current prevalence. These are the values  $H(x)$  introduced in the section above  
886 entitled, **Description of Model for Deriving Resistance Thresholds**. Risk managers  
887 compare estimates of the current prevalences with the threshold prevalences, or the  
888 corresponding values of  $H(x)$  to  $T(x)$ , to determine whether an unacceptable human health  
889 risk has been or is about to be reached. The following offers some suggestions on how  
890 these values could be determined and then how the resistance threshold is calculated.

### 891 *Calculating Resistance Thresholds Using Current Impacts*

892 This measure of risk ( $H(x)$ ) will normally be the most easily estimated impact, since it will  
893 usually be the most frequent human health effect.

894	$H(x) =$	current total prevalence of people with illness ( $x = EI$ or $SI$ )
895		×
896		the attributable fraction for the food animal species
897		×
898		current prevalence of resistance in cases attributed to food animal commodity
899		×
900		proportion expected to receive antimicrobial drug of concern

901 Assuming the current prevalence of resistance in cases attributed to food animal  
902 commodity is known, the resistance threshold associated with the human health threshold  
903 is calculated as follows:

$$904 \quad t(x) = \frac{T(x) \times h}{H(x)} \quad (\text{Equation 6})$$

### 905 *Summary of Establishing Resistance Thresholds*

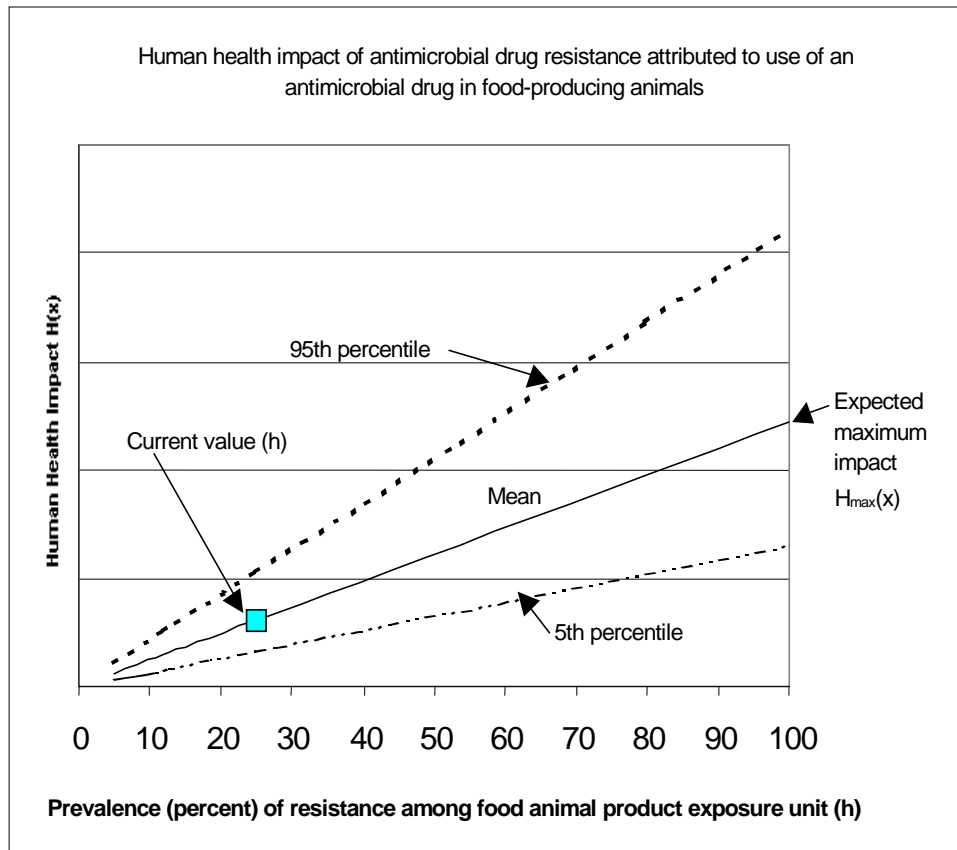

906 A resistance threshold set under the approach in this document would be established prior to  
907 the approval of certain antimicrobial products for use in food-producing animals. As  
908 discussed above, the resistance threshold would be linked to the human health threshold  
909 through a proportionality relationship between a measurable human health impact and the  
910 exposure to food animal product containing resistant bacteria associated with that human  
911 impact. The graph shown in Figure 4 illustrates that the maximum human health impact and  
912 the current human health impact are two conveniently understood points among the many  
913 possible points that comprise the relationship between human health impact and resistance  
914 among animal isolates.

915 This document describes two methods for using a model to derive resistance thresholds.  
916 The availability of data partially dictates how estimates for required quantities are derived.  
917 Table 1 lists the type of information used in the model and compares the information  
918 needed for the two methods described.

919 The benefit of using Method 1, the maximum health impact method, is that it permits  
920 calculation of  $t(x)$  without requiring data on the prevalence of resistance in cases attributed  
921 to the food animal commodity. This would be particularly useful in situations where a  
922 product is the first new animal drug in its class. In such situations, there presumably would  
923 be no data on the prevalence of resistance to the drug in the food animal commodity  
924 attributable to animal drug use at the time of the review of the new animal drug application.  
925 Method 1 derives the resistance threshold by making the assumption that all human cases of  
926 foodborne disease attributed to the food animal species would be due to bacteria resistant to  
927 the drug of concern. The advantage of using Method 2, the current health impact method, is  
928 that it allows CVM to adjust the calculation of  $k$ -res from that based on the assumptions in  
929 Method 1. That is, Method 2 uses current data to determine the proportion of animal-related  
930 human cases that would be due to bacteria resistant to the drug of concern. Of course, in  
931 such situations, approvals for new uses could only occur in circumstances in which the  
932 existence of animal-related human cases due to bacteria resistant to the drug of concern  
933 would not preclude approval of such drug for additional uses.

934 The 5<sup>th</sup> percentile of the uncertainty distributions for the modeled resistance threshold  
935 would be more protective of human health than would be the mean of the distribution.  
936 See Appendix 1 for example calculations of resistance thresholds for individual animal  
937 species and extensions to multiple species as discussed later in this document. The  
938 example calculations are not modeled values. They are presented to illustrate the logic  
939 used in modeling resistance thresholds.

952

953 **Figure 4:** Indicates the proportional relationship between human health impact  
954 ( $H(x)$ ) and resistance among animal isolates ( $h$ ) showing current and maximum  
955 human health impact ( $H_{\max}(x)$ ) estimates. The expected maximum impact used in  
956 Method 1 is the prevalence of infections in humans that are treated with the  
957 antimicrobial drug of concern, are associated with bacteria resistant to the drug of  
958 concern, and for which the resistance is attributable to the use of an antimicrobial  
959 drug in animals. It is called the maximum impact because it is calculated assuming  
960 all disease cases attributable to the animal species are resistant. A line connects  
961 the maximum to (0,0) and  $[k\text{-res}]$  is the slope of that line. Using Method 2, the  
962 ratio of the current human impact (y-axis) to the prevalence of resistance among  
963 food animal product associated with the current human impact (x-axis) is  $[k\text{-res}]$ .

964 **Table 1.** Types of data and information that may be needed in the epidemiology-based  
 965 model. Data and sources are listed for example purposes and are not intended to be an  
 966 exhaustive list.

<i>Data to support human health impact estimate</i>	<i>Method 1</i>	<i>Method 2</i>
U.S. population (denominator for determining prevalences)	Yes <sup>1</sup>	Yes
FoodNet (or other sample) population	No	Yes
Observed cases enteric/systemic disease in the sampled population	No	Yes
Prevalence of culture confirmed cases reportable to health department (enteric and systemic) in US	Yes	No <sup>2a</sup>
Prevalence of culture confirmed resistant cases reportable to health department (enteric and systemic) in U.S.	No	Yes <sup>3</sup>
Proportion of enteric/systemic disease cases attributable to the animal species	Yes	Yes
Proportion of enteric/systemic disease cases attributed to the animal species and resistant to the antimicrobial drug under study	No	Yes <sup>2b</sup>
Proportion of persons with enteric/systemic disease that seek care and are treated with the antimicrobial drug under study	Yes	Yes
<i>Data to support exposure estimate</i>		
Total prevalence of bacteria among the animal product samples	No	No
Prevalence of antibiotic resistant bacteria among bacteria collected from contaminated animal product samples	No	No
Estimated prevalence of antibiotic-resistant bacteria in animal product	No	Yes
Consumption of animal product from domestically reared animals, per capita (lbs.) in U.S. <sup>4</sup>	No	No
Total consumption of animal product from domestically reared animals in U.S. (lbs.) <sup>4</sup>	No	No
Total consumption of animal product from domestically reared animals contaminated with antibiotic resistant bacteria in U.S. (lbs.) <sup>4</sup>	No	No

- 967 1. "Yes" indicates the value is necessary for calculating a resistance threshold by the given  
 968 method.  
 969 2. Information estimated by the current surveillance system.  
 970 3. If this information were estimated by the surveillance system, this line would supplant the line  
 971 containing 2b.  
 972 4. Note: Although consumption data are not needed, changes in consumption will alter the value  
 973 of [k-res], as indicated between Equations 3 and 4.

**974 Risk Management Considerations**

975 After assessing the risk, there may be circumstances where additional factors need to be  
976 considered in order to make a decision as to how to manage the risk identified. Such  
977 factors may include a consideration of sub-populations that may be at greater risk than the  
978 general population. In addition, consideration may be given to the level of uncertainty  
979 inherent in the evaluation of the risk. Such uncertainty may be addressed through the  
980 application of various safety factors. Also, safety factors could be applied to the model in  
981 order that thresholds be set to correspond to a level to preclude a measurable human health  
982 impact. These examples of risk management considerations are described in Appendix 2  
983 of this document to stimulate further discussion.

**984 Setting thresholds for multiple food animal species**

985 The approach set out in the document would allow CVM to consider a number of options  
986 including the relative contribution to the human health impact from each animal  
987 commodity group. CVM believes that there needs to be significant discussion for setting  
988 thresholds when a particular antimicrobial drug is or potentially will be approved in more  
989 than one food animal species.

990 One possible approach is to set resistance thresholds based on the relative contribution to  
991 human health by each food animal commodity. If an antimicrobial is to be used in  
992 multiple species, it may be necessary to provide each animal industry with its own  
993 resistance threshold. CVM believes that the use of a specific antimicrobial in animals  
994 constitutes the decision option against which the human health risk should be measured.  
995 This means that whatever human health thresholds are determined, the risk should be  
996 shared among the animal species for which the antimicrobial has been approved such that  
997 the combined human health impact from all antimicrobial drug use in food animals will  
998 not exceed  $T(x)$ . This leads to the restriction that for number of species ( $n$ ),

$$999 \quad \sum_{i=1}^n a_i [t_i(x) * k - res_i] \leq T(x) \quad (\text{Equation 8})$$

1000 where  $a_i$  is the multiplier used to allocate a portion of the resistance threshold to species  $i$ .

1001 A readily calculable method for distributing the allowable risk among species would be to  
1002 allocate the risk in proportion to the weight of consumable food product contributed by  
1003 each animal species. The resistance thresholds derived for each animal species (based on  
1004 that species' contribution to the human health impact) would be divided by the number of  
1005 species. In this case  $a_i$  is  $1/n$ . See Appendix 1 for example calculations of resistance  
1006 thresholds for multiple species.

1007 Alternatives to this approach would be to share the human health impact equally among  
1008 all species or to allocate the resistance threshold in proportion to the species contribution  
1009 to human disease.

1010 Once these human health thresholds are set by species, one needs to determine a measure  
1011 that estimates the relative proportion of foodborne disease that each species contributes.  
1012 The model can then determine what the resistance threshold would be for that species to  
1013 match its human health threshold. If any commodity group exceeds the resistance  
1014 threshold, CVM would initiate procedures to withdraw from the label the animal species  
1015 that has reached or exceeded its threshold.

1016 Pharmaceutical companies may seek approval for a new antimicrobial one species at a time.  
1017 Following the above philosophy, seeking approval for a second, third, etc. species would  
1018 necessitate reducing the level of resistance allowed in those species already approved.

1019 In the event that it proves impossible to distinguish the proportion of foodborne disease  
1020 contributed by each species, it would be necessary to monitor the total human health  
1021 impact and relate that directly to the human thresholds, withdrawing the product globally  
1022 should the human health threshold be reached.

### 1023 **Reassessment of Thresholds**

1024 CVM anticipates that after the approval of a new antimicrobial drug for use in food-  
1025 producing animals, it will periodically reassess the established threshold to account for new  
1026 information and data. Data collected through the NARMS program and from other sources  
1027 after approval will allow a more accurate determination of a resistance threshold for a  
1028 particular use of an antimicrobial drug. Reconsideration of an established resistance  
1029 threshold would also be appropriate given changes in the use of the antimicrobial drug or  
1030 related antimicrobial drug in human medicine, changes in the pathogenicity or virulence of  
1031 resistant bacteria, changes in hygienic practices leading to greater or fewer foodborne  
1032 illnesses, changes in consumption patterns of animal-derived foods, and emergence of new  
1033 foodborne pathogens.

### 1034 **Regulatory Options for Approved Products**

1035 CVM envisions the codification of the resistance threshold as part of the approval of a  
1036 new animal drug application. If the resistance threshold was determined to have been  
1037 exceeded prior to approval, the new animal drug application would not be approved. The  
1038 basis for this codification is that the continued use of the new animal drug, when the  
1039 resistance threshold has been exceeded, contributes to the loss of effectiveness of  
1040 important human antimicrobial therapies and, as such, causes the use of the new animal  
1041 drug to be no longer shown to be safe.

1042 If, after antimicrobial drug approval, shifts in susceptibility are observed via the post-  
1043 approval monitoring program (and the resistance threshold has not been exceeded)

1044 voluntary action may be initiated to mitigate further loss of susceptibility. However, if the  
1045 resistance threshold was found to have been exceeded, CVM would initiate procedures to  
1046 withdraw from the label any animal species that has reached or exceeded its threshold.  
1047 This process would not preclude the agency from taking any regulatory steps at any time if  
1048 human health is at risk because of the use of a new animal drug.

1049

1050

1051

**GLOSSARY**

1052 **ADI** - Acceptable Daily Intake. Quantity of the new animal drug that may safely be  
1053 consumed in the human diet daily for a lifetime.

1054 **Breakpoints** - Specific values, expressed relative to terms such as Minimum Inhibitory  
1055 Concentrations (MICs), or zones of inhibition (which can be correlated with MICs using  
1056 appropriate statistical methods), which categorize bacteria as clinically susceptible,  
1057 intermediate or resistant.

1058 **Campylobacter Risk Assessment** - The first probabilistic risk assessment undertaken by  
1059 the Center for Veterinary Medicine which estimated the human health impact of drug  
1060 resistant Campylobacter resulting from fluoroquinolone use in poultry. Available at  
1061 [http://www.fda.gov/cvm/antimicrobial/Risk\\_asses.pdf](http://www.fda.gov/cvm/antimicrobial/Risk_asses.pdf).

1062 **Current impact on enteric illness:** In any given year, a certain proportion of the U.S.  
1063 population will experience enteric foodborne illness and will be treated with an antimicrobial  
1064 drug. Some cases may be due to bacteria that are resistant to the drug administered. The  
1065 current impact on enteric illness is defined as the current prevalence of cases of enteric illness  
1066 in the U.S. population that are treated with the antimicrobial drug of concern, are associated  
1067 with bacteria resistant to the drug of concern, and for which the resistance is attributable (in  
1068 whole or in part) to the use of an antimicrobial drug in animals. Such cases are expected to  
1069 experience decreased or loss of effectiveness of their antimicrobial drug treatment.

1070 **Current impact on systemic illness:** In any given year, a certain proportion of the U.S.  
1071 population will experience systemic foodborne illness and will be treated with an  
1072 antimicrobial drug. Some cases may be due to bacteria that are resistant to the drug  
1073 administered. The current impact on systemic illness is defined as the current prevalence  
1074 of cases of systemic illness in the U.S. population that are treated with the antimicrobial  
1075 drug of concern, are associated with bacteria resistant to the drug of concern, and for  
1076 which the resistance is attributable (in whole or in part) to the use of an antimicrobial drug  
1077 in animals. Such cases are expected to experience decreased or loss of effectiveness of  
1078 their antimicrobial drug treatment.

1079 **Drug characterization factor (DCF)** - An additional factor to multiply the estimated  
1080 human health impact of an antimicrobial drug to compensate for the loss of an important  
1081 human drug therapy. Criteria will be established.

1082 **Framework Document** - A December 1998 draft document by the Center for Veterinary  
1083 Medicine that outlines a range of potential regulatory issues affecting antimicrobial drugs  
1084 to be used in food-producing animals. These issues include pre- and post-approval  
1085 studies, the significance of the drug to human medicine and regulatory thresholds (See  
1086 page 1 onto 2). The document is issue oriented and has not resulted in Center guidance at  
1087 this time. . Available at <http://www.fda.gov/cvm/index/vmac/antimi18.html>.

- 1088 **Human Health Threshold** - The unacceptable prevalence of infections in humans that  
1089 are treated with the antimicrobial drug of concern, are associated with bacteria resistant to  
1090 the drug of concern, and for which the resistance is attributable (in whole or in part) to the  
1091 use of an antimicrobial drug in animals. Human health thresholds specifically focus on the  
1092 incremental effects on enteric illness or systemic illness in humans as a consequence of the  
1093 causative bacteria being resistant to the antimicrobial drug the affected persons are  
1094 expected to receive. Based on current safety standards, the "unacceptable prevalence" is  
1095 considered that level at which there is no longer reasonable certainty that there is no harm  
1096 to human health.
- 1097 **K-res** - A proportionality constant relating the nominal mean number of cases of illness  
1098 due to drug resistant bacteria attributable to a particular food-animal species to the  
1099 estimated amount of food product (derived from given food animal species) consumed  
1100 that contains drug-resistant bacteria.
- 1101 **h** - A consistent measure of the current prevalence of animal-derived foods containing  
1102 resistant bacteria.
- 1103 **H(EI)** - The current level of human health impact of enteric illness resulting from the  
1104 current level of material containing drug-resistant bacteria.
- 1105 **H<sub>max</sub>(x)** - The maximum level of human health impact resulting from the use of an  
1106 antimicrobial drug in food producing animals causing 100% resistance to a human  
1107 antimicrobial drug, given current prescription practices in human medicine.
- 1108 **H(SI)** - The current level of human health impact of systemic illness given the current  
1109 level of material containing drug resistant bacteria.
- 1110 **H(x)** - The current measured prevalence of infections in humans that are treated with the  
1111 antimicrobial drug of concern, are associated with bacteria resistant to the drug of concern,  
1112 and for which the resistance is attributable to the use of an antimicrobial drug in animals  
1113 (where x = EI or SI).
- 1114 **Minimum inhibitory concentration (MIC)** - The lowest concentration of an  
1115 antimicrobial drug, expressed in µg/ml or mg/L that, under defined *in-vitro* conditions  
1116 prevents the growth of bacteria within a defined period of time.
- 1117 **Minimum inhibitory concentration (MIC) distribution** - The range of MICs for a given  
1118 population of organisms when tested against a specific antimicrobial drug under defined  
1119 *in-vitro* conditions
- 1120 **Mitigation Programs** - Actions initiated by CVM, the sponsor, or other groups to  
1121 alleviate the concern for unacceptable human health impacts resulting from the use of the  
1122 antimicrobial drug in food animals. These actions may include a wide range of activities

- 1123 such as education, changes in animal production practices, changes to the animal drug  
1124 label, or initiation of procedures to withdraw the animal drug product.
- 1125 **Model Adjustment Factor (MAF)** - A factor to multiply risk estimates to compensate  
1126 for uncertainty in the model. This may be similar to the uncertainty multipliers commonly  
1127 used in unit risk estimates from laboratory animals to derive an acceptable daily intake.  
1128 Criteria and experience will be developed as the Center considers using such factors.
- 1129 **Monitoring** - The collection of specific data used for regulatory purposes
- 1130 **NADA** - New Animal Drug Application
- 1131 **NARMS** - National Antimicrobial Resistance Monitoring Program. Available at  
1132 <http://www.cdc.gov/ncidod/dbmd/narms/>
- 1133 **Q** - Quantity of product containing bacteria resistant to an antimicrobial of interest.
- 1134 **Resistance** - A characteristic of a bacterial strain in which it is not inhibited by the  
1135 usually achievable systemic concentrations of an antimicrobial agent with normal dosing  
1136 schedules and/or falls in the range where specific mechanisms are likely (e.g., beta-  
1137 lactamases), and clinical efficacy has not been reliable in treatment studies.
- 1138 **Resistance Threshold** - The resistance threshold ( $t(x)$ ) is the maximum allowable  
1139 prevalence of resistant bacteria isolated from animal-derived food that does not pose an  
1140 unacceptable risk to human health. The resistance threshold is derived through an  
1141 epidemiology-based model that relates the prevalence of resistant bacteria in food to an  
1142 impact on either enteric illness (EI) or systemic illness (SI) in humans.
- 1143 Exceeding a resistance threshold would be considered a level of resistance at which there  
1144 is no longer reasonable certainty that there is no harm to human health. For the purposes  
1145 of this definition, bacteria are considered resistant if their minimum inhibitory  
1146 concentration (MIC) reaches or exceeds the resistance breakpoint established for the  
1147 related drug used in human medicine.
- 1148 **Surveillance** - The close and vigilant review of data coming from a system used for  
1149 regulatory purposes.
- 1150 **Susceptible** - A characteristic of a bacterial strain in which it is inhibited by the usually  
1151 achievable systemic concentrations of an antimicrobial agent with normal dosing  
1152 schedules and/or falls in the range where specific mechanisms are not likely (e.g., beta-  
1153 lactamases), and clinical efficacy has been reliable in treatment studies.
- 1154 **Threshold for impact on enteric illness:** In a given year, a certain proportion of the U.S.  
1155 population will experience enteric foodborne illness and will be treated with an antimicrobial  
1156 drug. Some cases may be due to bacteria that are resistant to the drug administered.  
1157 Therefore, the threshold for impact on enteric illness is defined as the unacceptable

1158 prevalence of cases of enteric illness in the U.S. population that are treated with the  
1159 antimicrobial drug of concern, are associated with bacteria resistant to the drug of concern,  
1160 and for which the resistance is attributable (in whole or in part) to the use of an antimicrobial  
1161 drug in animals. Such cases are expected to experience decreased or loss of effectiveness of  
1162 their antimicrobial drug treatment.

1163 **Threshold for impact on systemic illness:** In a given year, a certain proportion of the  
1164 U.S. population will experience systemic foodborne illness and will be treated with an  
1165 antimicrobial drug. Some cases may be due to bacteria that are resistant to the drug  
1166 administered. Therefore, the threshold prevalence of cases of systemic illness impacted is  
1167 defined as the unacceptable prevalence of cases of systemic illness in the U.S. population  
1168 that are treated with the antimicrobial drug of concern, are associated with bacteria resistant  
1169 to the drug of concern, and for which the resistance is attributable (in whole or in part) to  
1170 the use of an antimicrobial drug in animals. Such cases are expected to experience  
1171 decreased or loss of effectiveness of their antimicrobial drug treatment.

1172 **t(EI)** - The resistance threshold for enteric illness. It is the maximum allowable  
1173 prevalence of resistant bacteria isolated from animal-derived food that does not cause an  
1174 unacceptable impact on enteric illness in humans.

1175 **t(SI)** - The resistance threshold for systemic illness in humans. It is the maximum  
1176 allowable prevalence of resistant bacteria isolated from animal-derived food that does not  
1177 cause an unacceptable impact on systemic illness in humans.

1178 **t(x)** - The generic resistance threshold (i.e., a resistance threshold derived in relation to a  
1179 human health impact, x (where x = EI or SI). See above for complete definition of  
1180 **Resistance Threshold**.

1181 **T(EI)** - The human health threshold for enteric illness.

1182 **T(SI)** - The human health threshold for systemic illness.

1183 **T(x)** - The generic form of the human health threshold, for  $x=\{EI \text{ or } SI\}$ .

1238

**Appendix 1**

1239

1240

**Example Calculation of Thresholds t(EI) by Method 1**

1241

1242

Assume that the current estimated prevalence of an enteric illness caused by animal-derived food is 6.67 cases per 1000 people in the U.S. annually.

1243

1244

Assume that 10 percent of the cases are treated with the antimicrobial drug of concern such that:

1245

$$H_{\max}(\text{EI}) = 6.67 * 10^{-3} * 0.10 = 6.67 * 10^{-4}$$

1246

1247

1248

1249

1250

Assume that the antimicrobial drug of concern is approved for use in four food animal species and that each species is responsible for causing a proportion of total enteric illness cases such that: Species *A* causes 60 percent of the cases, Species *B* causes 20 percent of the cases, Species *C* causes 15 percent of the cases, and Species *D* cause 5 percent of the cases.

1251

1252

1253

For any given human health threshold (T(EI) expressed as a prevalence), a resistance threshold (t(EI) expressed as percent) can be calculated for each species according to the formula:

1254

1255

$$t_i(\text{EI}) = \frac{T(\text{EI}) * a_i * 100\%}{H_{\max}(\text{EI}) * S_i}$$

1256

Where:

1257

1258

$a_i = 1/n$  where  $n$  is the number of food animal species for which the antimicrobial drug is approved. In this example,  $n=4$  such that  $a_i = 0.25$ .

1259

1260

$S_i$  is fraction of the total number of food borne cases caused by the food animal species of concern such that:

1261

$$S_A = 0.60$$

1262

$$S_B = 0.20$$

1263

$$S_C = 0.15$$

1264

$$S_D = 0.05$$

1265

1266

**Appendix 2**

1267

**Risk Management Considerations**

1268

**Consideration of sub-populations**

1269

1270

1271

1272

1273

1274

1275

1276

If an identifiable sub-population (e.g., certain immuno-compromised people) bears a significantly greater proportion of the risk than the general population it seems appropriate that they should be the focus of protective measures. However, this is provided that the defined sub-population is not able to avoid or manage the risk and receives no significant direct benefits from exposure to the risk that are greater than the population in general. One could argue that these people are shouldering the risk for the entire population and that they should not have to be exposed to any risk imposed on them by the population as a whole that is greater than the population accepts upon itself.

1277

1278

1279

In that case, the current prevalence estimates for enteric illness (EI) and systemic illness (SI) that will be compared with the threshold prevalences for these potential impacts would be modified as follows:

1280

1281

1282

**Sub-population current prevalence (EI)** = Expected cases of enteric illness in sub-population due to resistance in the year and treated with the antimicrobial drug of concern / Size of sub-population.

1283

1284

1285

**Sub-population current prevalence (SI)** = Expected cases of systemic illness in sub-population due to resistance in the year and treated with the antimicrobial drug of concern / Size of sub-population.

1286

1287

1288

1289

For any identified sub-populations, these threshold levels would replace the three population risk estimates (since they will always be more stringent), and used together to determine whether an unacceptable human health impact has or is likely to be reached by comparing them with the threshold prevalences for enteric illness (EI) and systemic illness (SI).

1290

**Adjusting the current risk estimate for statistical uncertainty and model uncertainty**

1291

***Compensating for statistical uncertainty***

1292

1293

1294

1295

1296

1297

Models used to estimate current levels of human health impact should account for statistical uncertainty. The resultant estimates therefore have uncertainty distributions that reflect the degree to which one cannot be sure about the true value because of the small amount of data. Picking the 95<sup>th</sup> percentile of these estimates, or any other appropriately high percentile, as the measure of the risk is a conservative action because it evaluates the risk at a value that we are 95% (for example) statistically certain the true value lies below.

1298

1299

This approach has the limitation that it only considers the uncertainty due to inference about some measure from a set of data. Any inference is based on a mathematical model.

1300 Statistical analysis cannot take into account any inaccuracies arising from a mismatch  
1301 between the model assumptions used to create the mathematics of the model and physical  
1302 reality. The model uncertainty can be separately accounted for by multiplying the risk  
1303 estimates by a 'model adjustment factor' described below.

1304 *Compensating for model uncertainty*

1305 CVM recognizes that the epidemiology-based model set out in this document may  
1306 overestimate or underestimate the impact of the animal drug on antimicrobial bacterial  
1307 resistance and changes in human health. A model adjustment factor (MAF) intended to be  
1308 applied to provide adjustments for unquantified factors may need to be applied to the  
1309 results of the model to address this concern. CVM will need to develop criteria for the  
1310 application of this uncertainty factor.

1311 *Compensating for potential loss of efficacy of an important drug*

1312 CVM recognizes that the epidemiology-based model set out in this document may not  
1313 address the importance of the drug in human medicine. A drug categorization factor  
1314 (DCF) may need to be applied to the results of the model to address this concern. CVM  
1315 will need to develop criteria for the application of this uncertainty factor.

1316 **Resistance Threshold Safety Factor**

1317 The resistance threshold described in this document is the maximum allowable level of  
1318 resistance prevalence in bacteria isolated from the food animal that does not pose an  
1319 unacceptable risk to human health. This resistance threshold is derived through an  
1320 epidemiology-based model that describes the relationship between the human health  
1321 threshold and resistance levels in animals, and presumably could contain some safety  
1322 factor to minimize the likelihood of the human health threshold ever being reached.  
1323 Further discussion is needed regarding the development and application of such a safety  
1324 factor.
