out of 8740) showed a statistically significant change in expression levels, without inducing detectable morphological changes. Dose-dependent analysis of the transcript profile revealed the expression of a set of 56 genes significantly modified in the fetal testis by transplacental exposure to EE. Comparing the effect of EE exposure on the testis versus the uterus, EE induces changes in the expression of 19 transcripts exclusively in the developing testis, suggesting these transcripts represent male-specific estrogenic activity. The expression of several proteins was affected in a similar manner by EE as the gene expression profile. For example, steroidogenic acute regulatory protein (StAR) was significantly decreased in developing testes. Thus, our data demonstrate that transplacental exposure to a potent ER agonist changes the gene expression profile of estrogen-sensitive tissues of the male, and that these transcripts could be valuable markers of estrogen exposure. These studies have lead to the further investigation of additional compounds and the potential effects at very low doses.

## 925 MORPHOLOGY OF THE FETAL RAT TESTIS PRESERVED IN DIFFERENT FIXATIVES.

P. C. Howroyd<sup>2, 1</sup>, R. Hoyle-Thacker<sup>1</sup>, O. Lyght<sup>1</sup>, D. Williams<sup>1</sup> and E. Kleymenova<sup>1</sup>. <sup>1</sup>CIIT Centers for Health Research, Research Triangle Park, NC and <sup>2</sup>Experimental Pathology Laboratories, Inc., Research Triangle Park, NC. Sponsor: <u>E.</u> Gross.

Developmental toxicity studies play a significant part in risk assessment. Histopathological examination of the fetal and neonate testes is important for the detection of developmental effects. The rat is the preferred species for such studies. This study was conducted to compare the morphology of H&E or immunostained fetal rat testes after fixation in modified Davidson fluid (mDF), Bouin fluid or 10% neutral buffered formalin (NBF). Fetal testes with epididymides, fixed in situ, were removed from the abdomen, embedded in paraffin, and 5 micron sections cut. Sections were stained with H&E, for apoptotic cells by the TUNEL technique, or immunostained for BrdU. In 10% NBF-fixed testes, chromatin and nucleoli were not easily discernable in the nuclei of cells above the basal layer of the seminiferous epithelium. In Bouin-fixed testes, the clarity of nuclear detail especially in suprabasal cells was better than with 10% NBF, as nucleoli were visible as basophilic structures. In mDF-fixed testes, nuclear detail was even clearer in supra-basal cells with some gonocyte nucleoli clearly visible as eosinophilic structures, in contrast to cells in the basal layer and interstitium, in which nucleoli were basophilic. In 10% NBF-fixed testes, there was only mild shrinkage artifact affecting cells in the seminiferous epithelium. In BrdU-stained slides, clarity of nuclear counter-staining was better in Bouin or mDF-fixed testes than with 10% NBF, although the numbers of positive cells and the intensity of staining were similar regardless of the fixative used. In TUNEL-stained slides, nuclear detail was clearer with mDF compared to 10% NBF fixation. Bouin fixation gave far worse visualization of nuclear detail and TUNEL-stained nuclei, and high background staining. We concluded that fixation in mDF resulted in better nuclear detail in seminiferous epithelium of rat fetuses compared to fixation in 10% NBF or Bouin fluid. Use of Bouin fluid did not allow satisfactory detection of fluorescent TUNEL staining

926

DEVELOPMENTAL EXPOSURE TO DI-N-BUTYL PHTHALATE AFFECTS CORD ORGANIZATION AND SERTOLI CELL-GONOCYTE INTERACTIONS IN THE FETAL RAT TESTIS.

E. Kleymenova, E. Dei Rossi, K. Liu, C. Swanson, L. Pluta and <u>K. Gaido</u>. CIIT Centers for Health Research, Research Triangle Park, NC.

Impaired spermatogenesis in adults has been associated with abnormal development of Sertoli and Leydig cells during fetal life. We used rats in utero exposed to di-n-butyl phthalate (DBP) to gain insights into fetal abnormalities underlying impaired spermatogenesis. In earlier studies, exposure to 500 mg/kg/day DBP from gestation day (GD) 12 to 21 caused multinucleated gonocytes, Leydig cell hyperplasia, and incomplete spermatogenesis. We hypothesized that this outcome is linked to abnormal cell proliferation and apoptosis in the DBP-exposed fetal testis. Cell proliferation was assessed on tissue slides by histological methods and BrdU incorporation, and apoptosis was measured by TUNEL assay. Cadherins that may play a role in Sertoli cell-gonocyte interactions were analyzed by immunostaining. In rats exposed to 500 mg/kg/day from GD 12 to the termination day, the total number of cells and the number of tubular cells were significantly (two-way ANOVA) decreased starting on GD 17. BrdU incorporation and TUNEL assays suggest that this decrease is caused by altered proliferation of Sertoli and peritubular cells but not apoptosis. A pilot study revealed that at GD 19 this decrease appears to be dose-dependent in the range from 0.1 to 500 mg/kg/day but NOAEL was not determined due to small sample size. As early as GD 17, treated testes had fewer cords that were enlarged and less convoluted. Beginning on GD 20, Sertoli cells in treated testes exhibited hypertrophy. Multinucleated gonocytes, first detected at GD 19, appeared to be arrested in telophase/cytokinesis I phase of meosis.

Immunostaining for P- and N-cadherins suggested changes in Sertoli cell - gonocyte interactions in the DBP-treated testis. Our data indicate that *in utero* exposure to a high dose of DBP affects cords formation and development of Sertoli cells that may alter meiosis in gonocytes. These data support the hypothesis linking impaired spermatogenesis in the adults with failure of fetal Sertoli cells to proliferate and mature.

### 927 MODULATION OF HOST DEFENSES BY AIR POLLUTANTS.

M. D. Reed<sup>1</sup> and I. Gilmour<sup>2</sup>. <sup>1</sup>Toxicology, Lovelace Respiratory Research Institute, Albuquerque, NM and <sup>2</sup>Experimental Toxicology Division, National Health and Environmental Effects Research Laboratory, USEPA, Research Triangle Park, NC.

Epidemiological evidence links air pollutants with increases in morbidity and mortality in susceptible populations. Among the health effects of long term and episodic air pollution, parameters associated with respiratory infections in susceptible populations, especially small children and the elderly, may be of primary importance. The mechanistic work detailing the modulation of infection by air pollutants is a developing and exciting field of research that brings together cutting edge biology and mechanistic toxicology. For example, the role of toll-like receptors (tlr) in response to infection and airborne particulates has been recognized. This symposium will address the epidemiological evidence suggesting that ambient air pollutants may modulate the occurrence and/or severity of respiratory infection. Subsequently, the current state of experimental models of host defense mechanisms and pathogenesis will be presented in relation to both bacterial and viral respiratory infection as modulated by individual pollutants and pollutant mixtures. Speakers will detail susceptibility to, and lung clearance of gram positive and negative bacteria, and viruses such as RSV. Focus will be placed on infection models modulated by ambient particulates, source emissions (coal fly ash and diesel exhaust), and metals. Target Audience: This Symposia encompasses the fields of microbial pathogenesis, immunology, air pollution, mixtures and mechanistic toxicology.

#### **928** MECHANISMS OF HOST DEFENSE.

I. Gilmour and M. K. Selgrade. Experimental Toxicology Division, National Health and Environmental Effects Research Laboratory, USEPA, Research Triangle Park, NC.

The respiratory tract is maintained in a remarkably sterile condition by the combined anti-microbial activity of the mucociliary, phagocytic and immune systems. Epidemiological studies of smokers and others exposed to high levels of air pollutants have demonstrated that these individuals suffer from more frequent and severe respiratory infections. Experiments in animals have also shown that a wide range of airborne pollutants including cigarette smoke, oxidant gases, acid aerosols, metals, organic compounds, and combustion products can interfere with the normal defense processes of the lung to enhance susceptibility to respiratory infection. The mechanisms for these effects include decreases in mucociliary clearance and macrophage phagocytosis, as well as reduced specific immune responses such as antibody formation, and natural killer (NK) and T cell function. Although there is some evidence that similar effects occur in humans, the link to ambient air pollutants are not as strong because of incomplete individual exposure histories. Animal studies provide dosimetric information, which can be used to predict the relative health risk of simple and complex exposures, and also lend insight into the mechanisms of air pollution toxicity. This presentation will describe host defense processes in the respiratory tract and illustrate how these may be reduced by air pollutant exposure resulting in increased severity of lung disease. These data can then be applied to risk assessment through in vitro and in vivo comparisons of immune function in animals and humans. This abstract does not reflect EPA policy.

#### 929

## EPIDEMIOLOGY OF AMBIENT AIR POLLUTION AND PULMONARY INFECTION.

A. Pope. Department of Economics, Brigham Young University, Provo, UT. Sponsor: M. Reed.

Substantial epidemiological evidence suggests that air pollution common to many urban and industrial environments is a risk factor contributing to the exacerbation or development of pulmonary infection in susceptible populations including children and the elderly. Associations observed include an increased prevalence of respiratory symptoms consistent with chronic and acute pulmonary infection, and increased hospitalizations for bronchitis and pneumonia. These findings suggest that inhaling air pollutants may modulate host defenses and immunity. This presentation will review the current state of epidemiological associations of air pollutants, especially those of ambient air, with risk of pulmonary infection.

930 INCREASED LUNG PATHOGENESIS TO RESPIRATORY VIRAL INFECTION BY DIESEL ENGINE COMBUSTION COMPONENTS.

K. S. Harrod<sup>1</sup>, J. A. Berger<sup>1</sup>, J. D. McDonald<sup>2</sup> and M. D. Reed<sup>2</sup>. <sup>1</sup>Asthma and Pulmonary Immunology Program, Lovelace Respiratory Research Institute, Albuquerque, NM and <sup>2</sup>Toxicology, Lovelace Respiratory Research Institute, Albuquerque, NM.

Epidemiology studies clearly indicate a relationship between poor air quality and childhood illness, particularly respiratory infections. However, experimental evidence is lacking, leaving a poor understanding of the mechanisms by which air pollutants alter susceptibility to pulmonary infections and disease. Using an inhalation exposure system of diesel engine emissions (DEE), altered susceptibility to a common childhood pathogen, respiratory syncytial virus (RSV), was examined in an in vivo experimental model. At concentrations reflecting ambient exposures, RSV persistence was increased in the respiratory tract following exposure to inhaled DEE, and increased lung viral burdens were concordant with increased lung pathogenesis and disease. Following exposure to DEE, distinct lung epithelial cell populations exhibited altered remodeling and/or injury to RSV infection. Evidence shows that lung epithelial-specific mechanisms of host defense or immunomodulation were altered by prior exposure to DEE. Furthermore, adaptive and innate immune mechanisms were exacerbated by DEE following infection, suggesting a greater reliance on immune mechanisms for clearance of RSV from infected lungs. Collectively, these studies suggest a role for air pollutants from engine combustion sources in the increased susceptibility to respiratory infection and provide an experimental model for elucidation of mechanisms by which these pollutants contribute to respiratory disease in childhood.

#### 931

EFFECT OF WORKPLACE PARTICULATES ON THE SUSCEPTIBILITY TO BACTERIAL INFECTION AND THE SUPPRESSION OF LUNG DEFENSE RESPONSES IN RATS.

<u>I. M. Antonini</u>. Health Effects Laboratory Division, National Institutes of Occupational Safety and Health, Morgantown, WV.

Inhalation of increased levels of air pollutants generated in the workplace and environment may augment pulmonary infection and increase morbidity and mortality. The effect of exposure to different workplace particulates on lung defense responses was investigated using a rat bacterial infectivity model. Male Sprague-Dawley rats were pretreated by intratracheal instillation with 1.0 mg/100 g body wt of residual oil fly ash (ROFA), stainless steel welding fumes particulate matter (SS), or silica (Si) prior to bacterial inoculation with  $5 \times 10^3$  or  $5 \times 10^5$  Listeria monocytogenes. Particle-induced effects on pulmonary clearance of the bacteria, lung macrophage function (phagocytosis, oxidant production, and bacterial killing), and the secretion of lung cytokines, important in immune responses, were assessed. Pretreatment with ROFA and SS significantly slowed the lung clearance of bacteria, increased animal morbidity, suppressed macrophage function, and altered IL-2, IL-6, and IL-10 production after infection. The suppression observed for ROFA was due to soluble metals, whereas a combination of soluble and insoluble metals was responsible for the effect seen with SS. Conversely, Si pretreatment enhanced lung bacterial clearance and significantly upregulated non-specific lung defense responses (macrophage phagocytosis, oxidant production, and neutrophil activation) despite the presence of significant lung inflammation and fibrosis. In conclusion, inhalation of different workplace particulates may induce varied lung defense responses to infection. Chronic exposure to metal particles in the workplace may alter macrophage function and increase the susceptibility to lung infection in exposed

#### 932

EXACERBATION OF PULMONARY PNEUMONIA BY INHALED AMBIENT PARTICULATE MATTER AND ASSOCIATED METALS.

<u>J. T. Zelikoff</u>, Y. Li, K. Schermerhorn, M. D. Cohen and R. B. Schlesinger. Nelson Institute of Environmental, NYU School of Medicine, Tuxedo, NY.

Epidemiological studies demonstrate that pneumonia contributes to the increased morbidity among individuals following exposure to ambient particulate matter (PM). This suggests that inhaled PM can act as an immunosuppressant. A 5 hr exposure of Streptococcus pneumoniae-infected rats to concentrated PM 2.5  $_{\mu}$ m from N.Y City air exacerbates infection and depresses antimicrobial pulmonary defense mechanisms. Infected rats exposed to PM 48 hr following bacterial instillation have increased: pulmonary bacterial burdens; bacterial-associated lung lesions; and, bacteremia compared to sham. Exposure to CAPS also decreased lavageable neutrophils, cytokines, and bronchus associated lung tissue. To identity the possible constituents responsible for the worsening pneumonia, studies were undertaken to

correlate the physiochemical attributes of CAPS with *in vivo* immunotoxicity. Using a similar model, rats were exposed by inhalation to Fe, Cu, Mg, Ni, or Zn. Uninfected rats were assessed for pulmonary cytokine levels, markers of cell damage, and oxyradical production, or histopathology; effects on systemic immunity were determined by examining blood cell profiles and splenic lymphoproliferation. Results showed that while Mn or Cu had no effect on local or systemic immunity, Fe, Zn, and Ni either reduced or delayed pulmonary bacterial clearance in infected rats. Metal interractions were observed in infected animals exposed to metals in combination. Collectively, these results indicate that PM can worsen the outcome of an ongoing pulmonary infection and that associated Fe, and possibly Ni and/or Zn, play a role in this effect. EPA Center Grant No. R827351.

#### 933

### ROLE OF TOLL-LIKE RECEPTORS (TLRS) IN RESPONSES TO AIR POLLUTANTS AND INFECTIONS.

S. R. Kleeberger. Environmental Genetics Group, Laboratory of Pulmonary Pathobiology, National Institute of Environmental Health Sciences, Research Triangle Park. NC

The innate immune response is the first line of defense against infectious diseases. Unlike the adaptive immune system (i.e., T-cell receptor and B-cell antibody receptor), cells of the innate immune system such as macrophages and dendritic cells discriminate between 'self' and infectious 'non-self' via constitutive receptors that identify pattern ligands synthesized exclusively by pathogens (e.g., lipopolysaccharide, bacterial lipoproteins BLP, bacterial DNA), so called pattern recognition factors (PRFs). TLRs are emerging as key regulators of host responses to injury and infection. Recent studies with mice have shown that immune cell activation by the PRFs of Gram-negative bacteria requires a pattern recognition receptor, TLR4. TLR4 is known as a lipopolysaccharide (LPS) receptor in mice, and altered TLR4 function by the mutation in C3H/HeJ mice is believed to confer resistance to LPS in this strain. Moreover, studies with Tlr4-deficient mice (Tlr4null) strongly supported the role of murine TLR4 in LPS responsiveness. The mutation of Tlr4 limits the pulmonary hyperpermeability and inflammation induced by exposure to particulate matter and ozone in mice. In addition, decreased innate immune responses (i.e., natural killer cell trafficking, IL-12 expression) were observed in the lungs of Tlr4-deficient mice after respiratory syncytial virus infection. Considerable progress has been made to define the TLR signaling pathways, and it is becoming increasingly clear that multiple ligands bind each of the TLRs. A more clear understanding of the interactions between inhaled respiratory pollutants/pathogens and TLRs should enhance strategies to protect individuals against these agents.

#### 934

### THE PRESENT AND FUTURE OF TOXICOGENOMICS IN PRECLINICAL DRUG DEVELOPMENT.

<u>I. K. Leighton</u><sup>2</sup> and <u>K. L. Kolaja</u><sup>1</sup>. <sup>1</sup> Toxicology, Iconix Pharmaceuticals, Mountain View, CA and <sup>2</sup>Food and Drug Administration, Laurel, MD.

Toxicogenomics, the genome scale analyses of chemically induced changes in complex populations of mRNA to understand toxicity, has the potential to dramatically împrove predictive, mechanistic and descriptive insights into drug development candidates prior to human exposures. Currently, toxicogenomics and microarray research are used selectively in drug development, primarily to facilitate the generation of proto-type compound databases and/or mechanistic and assay development research on compounds dropped from development consideration. However, as regulatory guidance begins to crystallize regarding toxicogenomics, the opportunity to use transcription profiling to improve and broaden understanding of efficacy and safety of development candidate(s) early in the testing paradigm could become more and more common. This session will discuss the current implementation of toxicogenomics in pharmaceutical companies and delve into the not-so-distant future for this technology. The first speaker will outline some critical steps needed to allow the true value of genome wide expression analysis to be realized. In order to improve human health using transcription profiling, a number of technical, biological, and regulatory/procedural issues will need to be resolved. The remaining speakers will discuss focused hypothesis-driven research projects highlighting the strategic advantage(s) inherent to toxicogenomics.

#### 935

TECHNICAL, PROCEDURAL, AND BIOLOGICAL ISSUES IN THE INCORPORATION OF TOXICOGENOMICS INTO THE REGULATORY PROCESS.

J. K. Leighton. USFDA/CDER, Rockville, MD. Sponsor: F. Sistare.

Critical steps are needed to allow the true value of genome-wide expression data from nonclinical stages of pharmaceutical investigations to be realized. In order to improve human health using transcription profiling data from early phases of pharmaceutical development that are destined for regulatory review groups, a number of technical, biological, and regulatory/procedural issues need to be resolved. FDA has been working to address these issues and to enable the application of this technology by pharmaceutical developers in a way that maximizes confidence in the data, maximizes mutual biological understanding of compound actions, and promotes evolution of this new technology, while minimizing risks to adverse regulatory actions. Sets of gene expression data that have been submitted to FDA will be described and the regulatory value and limitations of these data, technical and biological lessons learned, and the procedural pathways forward that are being taken will be discussed.

#### 936

## GENE EXPRESSION PROFILING IN PHARMACEUTICAL TOXICOLOGY RESEARCH.

R. G. Ulrich. Molecular Profiling, Rosetta Inpharmatics-Merck Research Laboratories, Kirkland, WA. Sponsor: K. Kolaja.

Toxicogenomics, defined as the study of the structure and output of the genome as it relates and responds to adverse xenobiotic exposure, is impacting the way new drugs are discovered. Molecular profiling of cell or tissue gene expressional changes using DNA microarrays, when coupled with appropriate bioinformatics, generates compound-specific transcriptional fingerprints that reflect molecular phenotypes. Importantly, these fingerprints includes both on-target and off-target responses and thus illuminates pathways positively affected for a new drug candidate based on interactions with the intended target and adverse effects due to untoward downstream responses from the therapeutic target or to off-target interactions. Using unsupervised hierarchical clustering algorithms it has been found that compounds with similar putative toxic mechanisms form clusters based on similar effects on gene expression. Using a database of such gene expressional profiles, called a response compendium, it is possible to classify the effects of new or unknown compounds even in the absence of pathology. Thus, relative adverse effects can be identified using either unsupervised or supervised clustering approaches, and specific predictions can be made using classification approaches. Toxicogenomics is also used to describe potential biological consequences of exposure in great detail. Where sufficient annotations exist, discrete gene analysis can help identify specific affected metabolic pathways (both on- and off-target) and identify putative toxic mechanisms. While not currently used for risk assessment, molecular profiling approaches are quickly becoming part of the toxicology paradigm.

#### 937

## IDENTIFICATION AND EVALUATION OF GENOMIC BIOMARKERS OF TOXICITY.

F. M. Goodsaid. Genetic and Molecular Toxicology, Schering-Plough Research Institute, Lafayette, NJ. Sponsor: W. Choy.

The application of genomic biomarkers of toxicity in drug discovery and development requires several levels of evaluation. These levels include cross-species evaluation, evaluation across multiple toxic compounds, in silico evaluation in toxicogenomic databases, and pilot evaluation in discovery. We have developed quantitative RT-PCR assays for biomarker candidates previously published for rat hepatotoxicity and nephrotoxicity and tested them in non-rodent species. We have evaluated the sensitivity and specificity of these candidates in tissues from a rat tissue bank at Iconix Pharmaceuticals based on studies using a variety of toxic compounds, and we have also queried their databases for an in silico evaluation of these candidate biomarkers of toxicity. Through this process, we have assessed the performance of KIM1/HAVcr-1 and clusterin as predictive genomic biomarkers of nephrotoxicity and investigated the transfer of these tests across different platforms with the throughput required for drug discovery applications. This assessment has shown that induction of either the clusterin or KIM1/HAVcr-1 genes in rat kidney is a genomic indicator of nephrotoxicity for a test compound. We conclude that these genes are good candidates for further evaluation in drug discovery.

#### 938

IMPLEMENTATION OF STRATEGY TOWARD IMPACTING PRECLINICAL DEVELOPMENT WITH GENOMICS APPROACHES.

C. Afshari. Amgen Inc., Thousand Oaks, CA.

Studies in toxicology are conducted in order to facilitate identification of safety thresholds and potential health risks associated with new drug candidates in development. The rapid development and evolution of genomic, proteomic, and metabonomic based technologies has led to the development of the new field of toxicogenomics that will allow application of these technologies to improve the efficiency of safety and risk assessments by facilitating better understanding of the mechanisms by which compound induced injury occurs. The initial phase of development

opment of this program at Amgen is focused on using global gene expression technologies to explore mechanisms of toxicity and reveal early, sensitive candidate biomarkers of toxicity with a focus on liver and kidney toxicity. We are working to use these findings to develop new screens that will contribute early in the drug development process and to integrate these data to reveal mechanistic information about the underlying biology of the development of potential toxicities. This talk will highlight ongoing work being conducted at Amgen as well as work that is being conducted in collaboration with the International Life Sciences (ILSI) HESI-Genomics/Nephrotoxicity Subcommittee.

## APPLICATION OF TOXICOGENOMICS TO PHARMACEUTICAL DRUG DISCOVERY AND DEVELOPMENT.

Z. Jayyosi. eSafety-Drug Safety Evaluation, Aventis Inc., Bridgewater, NJ.

Kinase inhibitors are an important class of compounds being developed as pharmaceuticals for the treatment of diseases, such as asthma and cancer. Because of the numerous intracellular kinases, specificity of a selected kinase inhibitor is crucial for its pharmacological action, as well as, its potential toxicity. Within a class of kinase inhibitors, toxicities may be similar, but not likely identical. Toxicogenomics was used to evaluate alterations in gene expression in response to compound treatment to differentiate the mechanism(s) of toxicity from the mechanism(s) of action, and to determine the overall utility of toxicogenomics in drug discovery and development. Spleen kinase (syk) plays a central role in mast cell activation. Therefore, syk inhibitors may be useful in the treatment of inflammatory diseases. This presentation will review the exploratory toxicogenomic studies conducted in rats to evaluate the potential toxicity of a syk inhibitor. In a 14-day study in rats, target organ toxicities were observed in liver, kidney, nasal epithelium and immune-related organs, including spleen and lymph nodes. The expression profiles of approximately 8, 800 genes in the target organs were analyzed and evaluated against the biochemical toxicology, histopathology and clinical pathology data. Interpretation of gene expression data revealed a distinct separation between the pharmacological and toxicological effects of the subject syk inhibitor. This study provided a number of valuable clues as to the mechanism of toxicity of this compound in the liver, kidney and spleen including oxidative stress, effects on energy metabolism and potential for immune suppression. Overall, gene expression analysis was found to be a valuable tool for the elucidation of mechanisms of toxicities when complemented with other safety assessment tools, including histopathology and clinical pathology.

940

### USE OF A LARGE CHEMOGENOMIC DATABASE TO FACILITATE DRUG DEVELOPMENT.

K. L. Kolaja. Toxicology, Iconix Pharmaceuticals, Mountain View, CA.

Chemogenomics can broadly be considered the study of pharmacology and toxicology using genomic analysis. The key is to combine the benefits of the study an organism as a whole with genome-scale approach such as microarray analysis of gene expression and broad molecular pharmacology profiling. The knowledge gained from screening a wide range of drugs, chemicals, and toxicants across a broad spectrum of assays has helped uncover previously uncharacterized activities, both good and bad. This reference database, combined with a set of statistical predictive tools, can be used to help characterize drug candidates very early in the development process and optimize the selection process. This presentation will present examples of findings generated from this database, with a particular focus on the potential mechanisms of hepatotoxicity. One key example will discuss how a contextual reference dataset reveal a potential explaination for a multi-organ model of hepatotoxicity of non-steroidal anti-inflammatories (NSAIDS).

941

INTRODUCTION TO THE SYMPOSIUM ON "TISSUE AND SPECIES DIFFERENCES IN REGULATION OF CYTOCHROME P450S".

X. Ding<sup>1, 2</sup>. <sup>1</sup>Wadsworth Center, New York State Department of Health, Albany, NY and <sup>2</sup>School of Public Health, SUNY at Albany, Albany, NY.

Tissue differences in the expression and regulation of various xenobiotic-metabolizing cytochrome P450 genes are critical determinants of organ-selective chemical toxicity, and species differences in P450 expression and regulation will impact risk assessment. Although tremendous progress has been made in recent years on the identification and characterization of biotransformation enzymes involved in metabolic activation, we still know very little about the expression and regulation of these enzymes in various extrahepatic target tissues, in either humans or laboratory animals. The goal of this symposium is to provide a timely forum for the dissemi-

nation of recent progress in studying P450 regulation in several important extrahepatic organs, including the brain, the lung, the skin, and the nasal mucosa. The individual research topics to be discussed will be diverse, involving different tissues, different P450 genes, different modes of regulation, and different approaches. However, a common theme of tissue- and species differences will be emphasized, and the approaches used will likely benefit studies on gene regulation in other tissues.

942

TISSUE DIFFERENCES IN THE REGULATION OF THE CYP2A GENES.

X. Ding<sup>1, 2</sup>. <sup>1</sup>Wadsworth Center, New York State Department of Health, Albany, NY and <sup>2</sup>School of Public Health, SUNY at Albany, Albany, NY.

The CYP2A genes play important roles in the metabolic activation of many procarcinogens and toxicants. CYP2A3, and its mouse and human orthologs (CYP2A5 and CYP2A13, respectively), are expressed preferentially in the olfactory mucosa (OM). We previously found that a nuclear factor 1 (NFI)-related regulatory element (NPTA element) in the proximal promoter region of the CYP2A3 gene is critical for transcriptional activation in vitro. Recently, we used DNA-affinity purification to isolate the NPTA-binding proteins from rat OM. Mass spectral analysis showed that isoforms corresponding to each of the four NFI genes are present in the purified NPTA-binding fraction, with NFI-A being the most abundant. Further studies led to the identification of a novel NFI-A isoform (NFI-A-short), which has a truncated transactivation/repression domain. Transient transfection assays showed that NFI-A2, an OM-specific NFI, transactivated the CYP2A3 promoter, whereas NFI-A-short offset the activation. These data suggest that NFI may play important roles in the tissue-specific expression of the CYP2A3 gene. In another study, we examined tissue differences in the control of CYP2A5 expression by circadian rhythm in mice, which has been previously demonstrated in mouse liver. We found that, the circadian variation in CYP2A5 mRNA level occurred in the kidney, as well as in the liver, but not in the OM. Additionally, we and others have recently discovered a global induction of microsomal P450s, including CYP2A5, in the liver of mice with liver-specific deletion of the NADPH-cytochrome P450 reductase (Cpr) gene. This finding revealed novel regulatory pathways of CYP expression associated with altered cellular homeostasis. We are characterizing another mouse model, which exhibits down-regulation of the Cpr gene in all organs, to determine whether the loss-of-CPR associated P450 induction also occurs in the OM and other extrahepatic tissues. (Supported in part by NIH grant ES07462)

943

OLFACTORY MUCOSAL METABOLIC ENZYMES: MODULATION OF TOXIC ENDPOINTS BASED ON DISTRIBUTION, INDUCTION, AND AGE-AND SPECIES VARIABLES.

M. Genter. Department of Environmental Health and Center for Environmental Genetics, University of Cincinnati, Cincinnati, OH.

The olfactory mucosa (OM) is a common site of toxicant induced damage by inhaled and systemically-administered chemicals, often as a result of target tissue bioactivation. Alachlor (ALA), 2, 6-dimethylaniline (DMA), and naphthalene (NP) cause OM tumors in the rat, likely as a result of local bioactivation by cytochromes P450 (CYPs) 2A3 and 2f2. Because OM enzymes are clearly involved in the bioactivation of ALA and/or its intermediate metabolites, we have been studying a number of possible ALA bioactivation pathways, including N-hydroxylation of the intermediate metabolite 2, 6-diethylaniline, acetylation, and DNA adduct formation, to clarify its mechanism of action. Mice and rats display different carcinogenic outcomes following chronic administration of ALA or NP. The speciesrelated differences in response to these compounds may be due to differential pharmacokinetics or to differences in ratios of bioactivating:detoxification enzymes. OM metabolic enzymes can be induced, though generally not to the same degree as hepatic enzymes. For example, lidocaine metabolism was increased in OM microsomes from TCDD-treated rats, coincident with induction of CYPs 1A1/2, 2B1, 2C11 and microsomal epoxide hydrolase. Similarly, inhibition of Phase 1 and Phase 2 OM enzymes is associated with modulation of the toxic effects of compounds, e.g. vinyl acetate and dichlobenil. OM enzymes, including CYP2A13, superoxide dismutases, flavin containing monooxygenases, and glutathione-S-transferases, vary in expression with age, suggesting differing potential for toxicity depending on the age of the exposed individual. Given that the mechanism underlying the development of chemically-induced nasal cancers in humans (e.g. by wood dust or nickel) is poorly understood, the role of concomitant environmental exposures that could modify the effects of these compounds needs further investigation. Supported by NIH grant ES08799.

944 GENE REGULATION BY THE AHR IN HUMAN KERATINOCYTES.

H. I. Swanson, S. S. Ray, E. M. Hoagland, E. Thompson, D. Pupula and Z. M. Georgia. *Molecular and Biomedical Pharmacology, University of Kentucky, Lexington, KY.* 

While the mechanisms governing gene regulation by the AHR have been well characterized in hepatocytes, those that exist in epithelial cells are largely unexplored. Our recent findings indicate that as primary human keratinocytes undergo senescence/differentiation, both the expression of the AHR and its ability to transactivate genes such as CYP1A1 dramatically increases. In addition, the increase in intracellular calcium levels that typically accompany keratinocyte differentiation is sufficient to increase both TCDD-induced gene activation and DNA binding of the AHR/ARNT heterodimer. Using microarray analyses, we have identified novel TCDD responsive genes. In the differentiating keratinocytes, a number of gene products are upregulated by TCDD. This includes the previously identified TCDD target genes, CYP1B1, CYP1A1 and CYP1A2. In addition, several upregulated genes are those involved in retinoid signaling, including NADP-dependent retinol dehydrogenase, RXRB and RAR beta. Genes that have been identified to be downregulated by TCDD in an AHR dependent manner include tumor suppressors such as p16, p19 and p53. Alterations of these gene pathways may be a critical factor in the ability of TCDD and the AHR to alter epithelial cell fate.

945

NICOTINE INCREASES CYP2B IN THE BRAIN BUT NOT IN THE LIVER: CONTRASTING THE REGULATION IN RODENTS, NON-HUMAN PRIMATES AND PEOPLE.

R. F. Tyndale, A. Lee and S. Miksys. *Department of Pharmacology, Center for Addiction and Mental Health, University of Toronto, Toronto, ON, Canada.* Sponsor: X. Ding.

Approximately 25% of adult Americans smoke daily. Nicotine is consumed not only by smokers, but also by passive smokers and ex-smokers on nicotine replacement therapies (NRTs), and NRTs are in clinical trials for the treatment of a number of neurological diseases. The metabolism of drugs and toxins can be substantially altered by enzyme induction by constituents of tobacco smoke such as nicotine. We have found that in rat, low, behaviorally relevant doses of nicotine given for 7 days (s.c.) increase CYP2B in the brains but not in the livers. The induction by nicotine in the brain is specific for both cell-type and brain region. The elevation in brain CYP2B protein, determined by western blotting and immunocytochemistry, is dose-dependently related to increased CYP2B1 mRNA. These data suggest that the regulation of CNS CYP2B by nicotine involves transcriptional mechanisms. In human brain, we have found brain region- and cell type-specific distributions of CYP2B6. We also have found elevated levels of CYP2B6 in the brains from smokers, compared to non-smokers. The regional and cellular localization of brain CYP2B6 in smokers differs from the regional and cellular localization of nicotine-induced CYP2B in the rat brain. To investigate this further, we treated non-human primates (African Green Monkeys) with nicotine and are currently investigating the presence and induction by nicotine of CYP2B in liver and brain. As predicted from rat and human data, there is no elevation of CYP2B in monkey liver. Data derived from the monkey brain should help us to differentiate species effects (rodent versus primate) from inducer effects (nicotine versus cigarette smoking), and allow us to validate the African Green Monkey as a model for human smokers. Funded by CIHR MT 14173 and by a Canadian Research Chair in Pharmacogenetics to RFT.

MECHANISMS THAT CONTROL THE SELECTIVE EXPRESSION OF CYP2F1, CYP4B1, AND CYP3A5 IN HUMAN LUNG.

G. S. Yost<sup>1</sup> and R. N. Hines<sup>2</sup>. <sup>1</sup>Pharmacology and Toxicology, University of Utah, Salt Lake City, UT and <sup>2</sup>Department of Pediatrics, Medical College of Wisconsin, Milwaukee, WI.

The toxicity of many acute pneumotoxicants and carcinogens to lung tissues requires bioactivation by the CYP2F1, CYP4B1, or CYP3A5 enzymes. In many cases, toxicant-specificity to lung tissues is highly related to the selective expression of these P450 genes in specific cells in the lung. However, the mechanisms responsible for the selective expression of these genes has not been elucidated. In our work we have characterized the structures of the CYP2F1, CYP4B1, CYP3A4, and CYP3A5 genes, and have identified several novel regulatory elements in the proximal promoter regions of these genes. Specific promoter elements were identified within the first 200 bp of the CYP2F1, CYP4B1, and CYP3A4/5 genes. These elements were shown by functional reporter gene activation to regulate transcription in human lung cells, and a novel nuclear transcription factor was identified, that

formed protein/DNA transcriptional complexes with the CYP2F1 gene at the -152 to -182 bp motif [J. Biol. Chem. 278, 15473-15483 (2003)]. Four putative Sp1/3 binding sites were shown to coordinately regulate basal CYP2F1 transcription in A549 lung cells. Other proteins, belonging to the Sp1/3 (CYP4B1) or E-box families of transcriptional factors (CYP3A4/5), from human lung tissues or lung cells, formed specific binding complexes with the regulatory motifs of these other genes. Ten additional transcriptional factors were excluded (by competitive EMSA analyses) as candidates for the tissue-selective regulation of CYP4B1 expression. Inclusion of a double E-box "silencer" element (-127 to -70) from the CYP3A4 promoter region into the CYP3A5 promoter dramatically decreased reporter gene activation of CYP3A5 in A549 lung cells. Therefore, the results strongly support the hypothesis that promoter elements in these lung-selective genes control organ-specific transcription by recruiting transcription factors that are selectively expressed in lung cells. SYSTEMIC DRUG ALLERGY:FREQUENCY, CHALLENGES, MECHANISMS AND NEED FOR PREDICTIVE MODELS.

<u>I. Dean</u><sup>2</sup> and <u>R. Pieters</u><sup>1</sup>. <sup>1</sup> Immunotoxicology, IRAS/Utrecht University, Utrecht, Netherlands and <sup>2</sup> Sanofi-Synthelabo, Inc., Malvern, Philadelphia, PA.

A number of drugs induce hypersensitivity responses that may result in systemic allergy and/or autoimmune-like phenomena in susceptible individuals. These reactions can be very serious and even life-threatening. The susceptibility for immunemediated adverse drug reactions (ADRs) is dependent on a complex interplay of inherent idiosyncratic factors combined with poorly defined environmental factors. Due to the complexity of the mechanisms underlying these ADRs and the lack of predictive models, the potential for these reactions can be missed in routine toxicology testing and often remains undetected until the drug is already on the market. Therefore, a better understanding of the mechanisms of ADRs as well as the development and validation of predictive tests represent important issues for the pharmaceutical industry and for governmental agencies. Rat (in particular Brown Norway strain) as well as certain mouse models are in use to study mechanisms of ADRs by specific drugs, but these models are not applicable as general screening models. For screening for hazard identification two assays have been evaluated, the popliteal lymph node assay (PLNA) and a recently investigated modification of the Local Lymph Node Assay. These assays detect direct immunostimulatory effects of chemicals following subcutaneous administration, and PLNA data collected over the past 15-20 years correlated well with documented ADRs in man. As many drugs are administered by the oral route, an additional assay using the oral route of exposure is desirable. Recent efforts combining relevant routes of exposures with simple read-out systems such as the local lymph node assays have shown promise.

948

MECHANISMS OF ADVERSE EFFECTS OF LOW MOLECULAR WEIGHT CHEMICALS.

J. Uetrecht. Faculty of Pharmacy and Medicine, University of Toronto, Toronto, ON, Canada.

Idiosyncratic drug reactions are a major clinical problem as well as a major impediment to drug development. The characteristics of these reactions strongly suggest that most idiosyncratic reactions are immune-mediated, and there is also a large amount of circumstantial evidence that reactive metabolites are involved. The hypothesis that has been used to link these two concepts is the Hapten Hypothesis in which reactive metabolites bind to proteins and make them foreign. A more recent hypothesis, the Danger Hypothesis, proposes that it is cell damage, presumably caused by reactive metabolites, rather than foreignness that leads to an immune response. The P-I Hypothesis questions the need for reactive metabolites and proposes that a reversible pharmacological interaction between drug and the MHC II / T cell receptor complex is sufficient to initiate an immune response. A new animal model, i.e. nevirapine-induced skin rash in the rat, will be presented which can be used to test these hypotheses. The incidence of the rash varies with rat strain: 0% in Lewis rats, 20% in Sprague-Dawley rats and 100% in Brown Norway rats. The rash only affects female animals of the strains tested. Tolerance can be induced by treatment with a lower dose for 2 weeks. The onset takes 2-3 weeks on initial exposure but the ears turn red within 24 hours on reexposure in a sensitized animal. The rash is immune-mediated because this sensitization can be transferred to naive rats with spleen cells. It could also be prevented by the immunosuppressant tacrolimus. The characteristics of this rash are very similar to the rash that occurs in some humans who are treated with the drug. In order to design safer drugs we need a much better understanding of the mechanisms of idiosyncratic drug reactions, and such animal models, although exceedingly rare, represent a very powerful tool for mechanistic studies. This work was supported by grants form the Canadian Institutes of Health Research and Boehringer Ingelheim.

## POPLITEAL LYMPH NODE ASSAY AND RECENT MECHANISTIC STUDIES.

R. Pieters. Immunotoxicology, IRAS/Utrecht University, Utrecht, Netherlands. Sponsor: J. Dean.

Generally applicable animal models to predict drug hypersensitivity based on systemic or clinical effects do not exist, although some chemicals induce adverse immune-mediated effects in some animal strains. This unpredictibility is thought to be due to a complex interplay of predisposing idiosyncratic and environmental factors. Because drug hypersensitivity reactions often mimick graft-versus-host (GVH) reactions the popliteal lymph node assay (PLNA), originally used to measure GVH activity, was introduced to study chemical induced hypersensitivity. To date, around 140 different chemicals (drugs and homologues thereof as well as other compounds) have been tested in various isolated PLNA studies. When the lack of metabolism in the PLNA is taken into account the outcomes of this simple screening test correlated well with documented adverse effects in man. Modifications of the simple primary PLNA by including immunologically more relevant parameters than cell proliferation have allowed mechanism-based and therefore better assessment of sensitizing potential of chemicals. Recent studies, using KO-mice and specific blocking monoclonals have shown that costimulatory molecules (CD40L and CD86) are crucial for induction of PLNA responses by Th-2 sensitizing modeldrugs like D-penicillamine and DPH studies. The response to the Th-1 stimulating model compound streptozotocin however, particularly involves CD80, and is more or less independent of CD40L. This indicates that immunosensitization by drugs follows general immunological patterns, but also that expression of costimulation may be used as an alternative read-out parameter. In all, the PLNA appears not only suitable to screen for the sensitizing potential of series of drugs (including structural homologues) but also to study fundamental aspects of drug-induced hypersensitiv-

MODIFICATION OF THE LOCAL LYMPH NODE ASSAY TO EVALUATE THE POTENTIAL FOR ADVERSE IMMUNOLOGICALLY-MEDIATED DRUG REACTIONS.

B. J. Meade<sup>1</sup> and J. L. Weaver<sup>2</sup>. <sup>1</sup>NIOSH, Morgantown, WV and <sup>2</sup>CDER, USFDA, Laurel. MD.

There is no generally accepted preclinical method to predict the potential for drug allergy to systemically administered drugs. A collaborative research project, involving members of industry, government and academia, was initiated to evaluate an assay which uses the basic protocol of the Local Lymph Node Assay (LLNA, an assay accepted by regulatory agencies for hazard identification of skin sensitizers) modified by administration of test article by subcutaneous injections between the ears, rather than the prescribed topical exposure. Test compounds were selected from marketed drugs known to cause human drug allergy. Selection of active drugs was based on reports of adverse events found in at least two independent data sources including FDA postmarketing data, drug labeling, clinical trial data, and publications. The following drugs associated with adverse reactions were tested by at least three laboratories: streptozotocin, hydralazine, sulfamethoxazole, diphenhydramine, procainamide, clonidine, ofloxacin, chlorpromazine, nevirapine, abacavir, lamotrigine, and zomepirac. Clinically negative drugs tested were phenobarbital and metformin. The pure compound was used if available; otherwise the marketed drug formulation was used. Range finding studies in mice were performed to allow selection of the highest dose that did not produce systemic toxicity. Both clinically negative drugs tested negative in the assay. Six of the 12 clinically positive drugs were positive in the modified LLNA (mLLNA). For a limited set of drugs, a concurrent Popliteal Lymph Node Assay was performed and the results were comparable to those obtained in the mLLNA. Evaluation of the lymph node cell phenotypes by flow cytometry showed population changes in general agreement with the mLLNA data. These results suggest that the mLLNA holds promise as a screen for systemic hypersensitivity inducing drugs and the use of concurrent flow cytometry may provide insight into the underlying mechanisms.

THE USE OF THE PLNA IN RELATION TO ORAL ROUTE OF EXPOSURE TO LMWCS.

B. W. Gutting. Chemical Biological Systems Technology Division, Naval Surface Warfare Center, Dahlgren Division, Dahlgren, VA.

This work examined diclofenac (an NSAID) and oxazolone (a contact sensitizer) in the Direct- and RA-PLNAs in naive mice and mice that had been orally pretreated with the respective LMWC. Both caused T cell-mediated PLN reactions in naive mice. Oxazolone increased the percent of CD4+ PLN T cells and decreased the percent of CD8+ PLN T cells, with a significant increase in CD4+ T cells having an activated phenotype (highCD44, lowCD62L). With diclofenac the PLN reaction was significantly attenuated in T cell-deficient mice, while wild-type mice showed

an accumulation of CD4+ and CD8+ T cells with an activated phenotype. When co-injected with TNP-OVA, diclofenac also selectively induced IgG1 AFCs, IgE AFCs, and CD4+IL-4+INFg- T cells. Oral pretreatment with either compound appeared to affect the respective PLN reactions. Oral pretreatment with oxazolone (3 doses) rendered mice hypo-responsive to a footpad injection with oxazolone and the suppression could be adoptively transferred using CD8+ splenocytes. Oral pretreatment with diclofenac yielded a mixed effect on a subsequent diclofenac-induced PLN reaction. For example, mice gavaged a single time had augmented and accelerated diclofenac-induced PLN reactions both in the direct PLNA and when co-injected with TNP-Ficoll (increases of IgM, IgG1 and IgG3 AFCs). In contrast, 3 oral doses with diclofenac rendered mice hypo-responsive following footpad injection by an as of yet unidentified mechanism. These observations suggest the PLNA may be well suited to study the systemic immunomodulating effects of chemicals following oral priming and support further examination of the assays.

### 952 SCIENCE IN THE LEGISLATIVE PROCESS: A CONGRESSIONAL AND SCIENTIFIC VIEW.

W. J. Brock<sup>1</sup> and K. Olden<sup>2</sup>. <sup>1</sup>ENVIRON Health Sciences Institute, Arlington, VA and <sup>2</sup>National Institute of Environmental Health Sciences, Research Triangle Park, NC

A primary goal for the Society of Toxicology is to promote the use of sound toxicological science in regulatory and legislative practices and policies. To achieve this goal, the SOT focuses significant activity to support science-related functions in regulatory agencies and legislative bodies with the objective of achieving better working relationships with policy makers. In this session, representatives from Congress and experienced SOT members will explore those practices that have worked best in developing and promoting good science policy. Topics to be included in this session will be a Congressional view on the "rights" and the "wrongs" of working with Congressional committees or individual representatives. It is anticipated that a speaker from both the Senate and House of Representatives will provide special insights for the SOT membership on developing relationships with Congressional members and their staff. Also, SOT members with significant experience with presentations before Congress or have worked closely with Congressional members will present on the practices that work best for the scientific community. A general discussion between speakers will address the importance of strategy and effective communication between policy makers and scientists during those times when scientific topics are being addressed by Congress. A key outcome from this roundtable discussion will be to provide SOT members with greater perspective of how the process of legislation works and how scientists can be a part of that process.

THE ROLE OF ESTROGEN IN THE MAINTENANCE OF AH RECEPTOR EXPRESSION IN MCF-7 BREAST CANCER CELLS.

D. C. Spink, B. H. Katz and B. C. Spink. New York State Department of Health, Wadsworth Center, Albany, NY.

Numerous studies indicate cross-talk between estrogen receptor-alpha- and Ah receptor(AhR)-mediated signaling in breast and endometrial cells. In this study we examined the effects of long-term estrogen deprivation and estrogen re-exposure on Ah responsiveness in MCF-7 human breast cancer cells. Estrogen-deprived MCF-7 cells were obtained by long-term culture in medium prepared with 5% bovine calf serum, which contains minimal estrogen. These estrogen-deprived cells showed depressed levels of AhR mRNA and protein and reduced responsiveness for induction of CYP1A1 and CYP1B1 by dioxin. The reduced Ah-responsiveness was reversed by culture for four passages in medium supplemented with 1 nM estradiol (E2). Expression from a transiently transfected CYP1B1-promoter-luciferase reporter construct was reduced in the long-term estrogen-deprived cells, but was restored by co-transfection with an AhR expression construct, indicating that AhR expression was limiting in the estrogen-deprived cells. To determine whether the reduced AhR expression in estrogen-deprived cells involved alterations in transcription of the AhR, we investigated AhR promoter activity using a vector that contained 5.8 kb of the human AhR gene promoter cloned into the luciferase reporter vector, pGL3-Basic. A deletion construct containing 1.9 kb of the AhR proximal promoter was also used. Use of either promoter-reporter construct showed significantly lower AhR promoter activity in long-term estrogen-deprived MCF-7 cells compared with cells maintained in estrogen-containing medium. When estrogen- deprived cells were cultured for four passages in medium containing 1 nM E2, AhR promoter activity was restored, implicating E2 in the regulation of AhR expression. These studies indicate that the continued presence of estrogen is required to maintain high levels of AhR expression and inducibility of CYP1A1 and CYP1B1 in MCF-7 cells and that the reduced expression of AhR in long-term estrogen-deprived MCF-7 cells involves altered transcriptional regulation of the AhR. (Supported by NIH grant CA81243.)

A PROPOSED ROLE FOR THE ARYLHYDROCARBON RECEPTOR (AHR) IN NON-PHOTIC FEEDBACK TO THE MASTER CIRCADIAN CLOCK.

L. T. Frame<sup>1</sup>, W. Li<sup>1</sup>, J. D. Miller<sup>2</sup> and R. L. Dickerson<sup>1</sup>. <sup>1</sup>Pharmacology and Neuroscience, Texas Tech Health Sciences Center, Lubbock, TX and <sup>2</sup>Department of Cell and Neurobiology, Keck School of Medicine of USC, Los Angeles, CA.

The arylhydrocarbon receptor (AhR) is a ligand-activated transcription factor and PAS-domain protein, best known for its role in mediating the toxicity of dioxin. Despite a wealth of knowledge about the molecular biology of the AhR, its physiological role remains unknown. We propose a novel role for the AhR in non-photic feedback to circadian clocks. In this scheme, stimulation of the AhR pathway opposes behavior associated with the expression of clock-associated PAS-domain proteins in the suprachiasmatic nucleus (SCN) of the hypothalamus. According to this model, many natural AhR agonists are produced as a consequence of specific interactions with the environment (i.e. behavior). Under normal conditions, these chemical signals transiently stimulate the AhR pathway, and play a role in daily resetting of the circadian clock. More significant changes to the circadian program may occur with stress, when production of other relevant chemical signals may enhance stimulation of the receptor. In the extreme, persistent activation of the AhR pathway (i.e. TCDD) leads to total failure of circadian homeostasis. This hypothesis evolved from recent data in our C57B6 mouse model, which showed 1) TCDDassociated inhibition of the clock-associated protein, mPER, within pacemaker cells of the SCN; 2) low-dose TCDD phase-response curves similar to other non-photic stimuli, such as serotonin and neuropeptide Y; 3) behavioral splitting and arrhythmicity as a consequence of high-dose TCDD; and 4) behavior in AhR knockout animals that appears consistent with a non-functioning negative feedback pathway to the master circadian clock. This model provides a framework for understanding the role of the AhR in both regulation and dysregulation of the circadian system and sets the premise for mechanistic studies. It also puts PAS-domain proteins at every level of circadian control, with the possibility of cross-talk from the molecular to behavioral level.

## 955 LIGHT-INDUCED SIGNALING VIA THE ARYL HYDROCARBON RECEPTOR (AHR).

A. Rannug<sup>1</sup>, M. Oberg<sup>1</sup>, L. Bergander<sup>2</sup>, H. Hakansson<sup>1</sup> and University. Rannug<sup>2</sup>. <sup>1</sup>Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden and <sup>2</sup>Cellular and Genetic Toxicology, Stockholm University, Stockholm, Sweden.

The AHR is a ligand-activated transcription factor that is implicated in the mechanism of dioxin induced toxicity. The physiological roles of the AHR as well as the possible endogenous ligand(s) are still mostly unknown. We have introduced a new concept in dioxin research, suggesting that the AHR has a physiological function as a sensor of chemical signals for light. UV irradiation of the essential amino acid tryptophan gives rise to substances of the formylindolo[3, 2-b]carbazole type. These bind to the AHR with very high affinity and induce the AHR battery of genes. In accordance with hormone signaling, the presence of the photoproducts seems to be strictly regulated and the target cells degrade them via the upregulated biotransformation enzymes to terminate the signal. The aim of this project was to study and quantify the impact of light, in combination with different medium components, on the CYP1A1 activity in rat hepatoma cells. In addition, we aimed at identifying the active photoproduct(s). Cell culture media with or without tryptophan (16 mg/l) were exposed to visible light (60 W light bulb) for 24 hours and then fractionated to enable identification of the formed photoproduct(s). The light exposed medium was tested for CYP1A1 inducing activity. Several non-polar substances were formed in tryptophan containing medium and for the first time, one of the inducers was identified and found to be identical to the previously identified compound 6-formylindolo[3, 2-b]carbazol. This finding ultimately explains many reports in the literature, describing 1) increased CYP1A1 gene expression after change of medium; 2) high constitutive CYP1A1 mRNA levels and low responsiveness to induction by dioxin in cells that lack CYP1A1 enzyme activity; and 3) the resetting of circadian rhythms that has been observed in cells in culture after medium change. Also, the results clearly show that formation of AHR ligands from tryptophan, should be considered in mechanistic studies performed with cells grown in culture.

956 AH RECEPTOR-REGULATED CHROMATIN REMODELING AND TRANSCRIPTIONAL

ELONGATION: Sequential recruitment of transcription factors and differential phosphorylation of c-terminal domain of rna polymerase ii at cyp1a1 promoter.

Y. Tian and S. Ke. Vet. Physiology and Pharmacology, Texas A&M University, College Station, TX.

The expression of cytochrome P450 1A1 gene (*cyp1a1*) is regulated by the aryl hydrocarbon receptor (AhR), which is a ligand-activated transcription factor that mediates most toxic responses induced by 2, 3, 7, 8-tetrachlorodibenzo-p-dioxin

(TCDD). In the nucleus, ligand-activated AhR binds to the xenobiotic response elements, initiating chromatin remodeling and recruitment of coregulators, leading to the formation of preinitiation complex followed by elongation. Here, we report that ligand-activated AhR plays an active role in chromatin remodeling/histone modifications as well as control of transcriptional elongation. Using chromatin immunoprecipitation assay, we found that, in Hepa1c1c7 cells, TCDD treatment resulted in recruitment of histone methyltransferase (CARM1) which methylates argine 17 of histone H3 at cyp1a1 promoter. The recruitment of CARM1 is likely through direct ligand-dependent association between AhR and CARM1 as determined by the co-immunoprecipitation assay using Hepa1c1c7 cells as well as by the GST-pulldown assay. Furthermore, we found that AhR actively regulates *cyp1a1* transcriptional elongation. We found that AhR recruits the positive transcriptional elongation factor (P-TEFb) and RNA polymerase II (RNÂ P II) to cyp1a1 promoter with concomitant phosphorylation of RNA P II carboxyl domain (CTD). Inhibition of P-TEFb kinase activity by 5, 6-dichloro-1-β-D-ribofuranosyl-benzimidazole (DRB) suppressed CTD phosphorylation (especially serine 2 phosphorylaiton) and abolished processive elongation without disrupting the assembly of the preinitiation complex at cyp1a1 promoter, suggesting that the formation of the preinitiation complex and elongation are interconnected but distinct transcriptional processes. We showed that ligand-activated AhR associated with P-TEFb through the C-terminus of cyclin T1, suggesting that AhR recruit the P-TEFb to cyp1a1 promoter whereupon its kinase subunit phosphorylates the RNA P II

957

COREGULATOR DYNAMICS OF AHR-MEDIATED TRANSCRIPTIONAL ACTIVATION: RECRUITMENT OF ER $\alpha$  TO TCDD RESPONSIVE PROMOTERS.

J. Matthews<sup>1</sup>, B. Wihlen<sup>1</sup> and J. Gustafsson<sup>2, 1</sup>. <sup>1</sup>Biosciences, Karolinska Institutet, Huddinge, Sweden and <sup>2</sup>Medical Nutrition, Karolinska Institutet, Huddinge, Sweden. Sponsor: T. Zacharewski.

Using the chromatin immunoprecipitation (ChIP) assay we studied the TCDDmediated recruitment of the AhR and ARNT heterodimeric complex (AHRC) and several coregulators to the prototypic AhR target gene CYP1A1 in MCF-7 human breast cancer cells. AhR and ARNT displayed time-dependent recruitment to the CYP1A1 promoter, reaching a peak at 75 min and maintaining promoter occupancy for the remainder of the 165 min time course. Recruitment of AhR and ARNT was closely followed by AIB1/SRC3 and TIF2/SRC2, which preceded the accumulation of CBP and p300. The arrival of HATs coincided with that of the TRAP/SMCC/mediator complex, which was followed by histone H3 acetylation and the phosphorylation of RNAPII. Mutual recruitment of the AHRC to a DRE rich region approximately 1000 bp upstream from the promoter and the tata-box region suggests the formation of a larger transcriptionally active complex that bridges the proximal and distal promoter regions. No recruitment of AHRC was observed to a region within the CYP1A1 coding sequence, demonstrating the specific recruitment of AHRC to the promoter region. Interestingly, ERa displayed a TCDD and time-dependent recruitment to the CYP1A1 promoter region. Cotreatment experiments with TCDD and estradiol showed a significant increase in the recruitment of ERa to CYP1A1. Transient transfection experiments HuH7 liver and MDA-MB231 breast cancer cell lines confirmed previously reported ERa enhancement of AHRC gene activity. In contrast to other reports, TCDD did not induce the recruitment of ERa to the estrogen responsive pS2 promoter, and cotreatment experiments demonstrated a time-dependent reduction in the recruitment ERα to estrogen responsive promoters. Collectively, these data suggest that  $\text{ER}\alpha$  acts as a coregulator of AhR signaling cascades and the recruitment of  $\text{ER}\alpha$  by AHRC represents a further mechanism of AhR-ERα cross-talk.

958

AGONIST AND CHEMOPREVENTATIVE LIGANDS INDUCE DIFFERENTIAL TRANSCRIPTIONAL COFACTOR RECRUITMENT BY ARYL HYDROCARBON RECEPTOR.

E. Hestermann<sup>1, 2, 3</sup> and M. Brown<sup>2, 3</sup>. <sup>1</sup>Biology Department, Furman University, Greenville, SC, <sup>2</sup>Medical Oncology, Dana Farber Cancer Institute, Boston, MA and <sup>3</sup>Harvard Medical School, Boston, MA.

Aryl hydrocarbon receptor (AHR) is a transcription factor whose activity is regulated by environmental agents, including several carcinogenic agonists. We measured recruitment of AHR and associated proteins to the human cytochrome P4501A1 gene promoter *in vivo* by chromatin immunoprecipitation. Upon treatment with the agonist beta-naphthoflavone (BNF), AHR is rapidly associated with the promoter, and recruits the three members of the p160 family of coactivators as well as the p300 histone acetyltransferase, leading to recruitment of RNA polymerase II (Pol II) and induction of gene transcription. AHR, coactivators, and Pol II cycle on and off the promoter, with a period of ~60 minutes. In contrast, the chemopreventative AHR ligand 3, 3'-diindolylmethane (DIM) promotes AHR nu-

clear translocation and p160 coactivator recruitment, but, remarkably, fails to recruit Pol II or cause histone acetylation. This novel mechanism of receptor antagonism may account for the antitumor properties of chemopreventative compounds targeting the AHR.

959 PROTEIN KINASE C (PKC)-ELICITED PHOSPHORYLATION OF THE ARYL HYDROCARBON RECEPTOR (AHR) IS INHIBITED BY MUTATION OF AHR TYROSINE 9.

G. D. Minsavage<sup>1</sup>, G. S. Bedi<sup>2</sup> and <u>T. A. Gasiewicz</u><sup>1</sup>. <sup>1</sup> Toxicology Training Program, Department of Environmental Medicine, University of Rochester, NY and <sup>2</sup>Biochemistry and Biophysics Center for Oral Biology, University of Rochester, Rochester, NY.

The aryl hydrocarbon receptor (AhR) is a ligand-activated member of the bHLH-PAS transcription factor family which includes PER, AhR nuclear translocator (ARNT or Hypoxia Inducible Factor 1-beta), SIM, and HIF 1-alpha. Xenobiotics, such as TCDD, bind to the AhR and initiate pleiotropic responses. It has been reported that formation of the AhR/ARNT:DNA ternary complex is disrupted by a single mutation at AhR tyrosine 9 (Y9). We previously demonstrated a basic isoelectric point shift that was detected by two-dimensional gel electrophoresis of mouse ÅhRY9F. This suggests that AhR Y9 is either a phosphorylated residue and/or that Y9 contributes to maintaining normal posttranslational modification at other unidentified residues. Here, we address how Y9 may contribute to phosphorylation of other AhR residues. Kinase assays were performed using synthetic peptides corresponding to the wild-type (MSS GAN ITY ASR KRR KPV QKT VK) and mutant (Y9F or a phosphorylated Y9) mouse AhR residues 1-23. Protein kinase C (PKC)-elicited phosphate incorporation into the Y9F and phosphorylated Y9 peptides was 69% and 36% of the incorporation into the wild-type peptide. An AhR peptide corresponding to residues 383-406, containing two serines and two threonines, did not incorporate a significant amount of phosphate. In addition, compared to AhRY9F, partially purified full-length wild-type AhR was more rapidly phosphorylated specifically by PKC. Overall, these data indicate that Y9 may play a unique role in maintaining a DNA binding conformation of the full-length AhR by permitting proper phosphorylation of serine(s)/threonine(s) by PKC. Furthermore, these data implicate PKC in the regulation of AhR activity as we demonstrate for the first time that PKC can directly phosphorylate the AhR. (Funded in part by NIH Center Grant ES01247, Training Grant ES07026 and Grant ES02515.)

960 IMPACT OF NUCLEOCYTOPLASMIC SHUTTLING AND ACCESSORY PROTEINS ON THE DEGRADATION OF THE ARYL HYDROCARBON RECEPTOR (AHR).

J. Popat, R. Buzzeo and <u>R. S. Pollenz</u>. *Biology, University of South Florida, Tampa, FL.* 

The aryl hydrocarbon receptor is a member of the basic-helix-loop-helix/PAS (bHLH/PAS) family of transcription factors. The AHR is an orphan receptor and bind exogenous ligands typified by 2, 3, 7, 8-tetrachlorodibenzo-p-dioxin (TCDD). The unliganded AHR exists in the cell in a complex with hsp90, the immunophilin protein XAP2 and p23. Upon ligand binding, the AHR is localized to the nucleus where it binds with ARNT and DNA and then degraded via the 26S proteasome. Since the AHR contains both nuclear import and export signals, studies were initiated to determine how the location of the AHR impacted degradation events and whether the unliganded AHR exhibited dynamic shuttling between the nucleus and cytoplasm. Importantly, these studies investigated the endogenously expressed AHR in multiple cell culture models. Western blot and immunohistochemical studies showed that degradation events followed the nuclear accumulation of the AHR in rat smooth muscle (A7), mouse myoblast (C2C12), murine fibroblast (10T1/2) and murine Hepa-1 cells. In all cells, nuclear accumulation was complete within 30-45 minutes of ligand exposure, whereas significant degradation was not observed until 45-90 minutes. To determine whether the AHR was activity shuttling in the absence of exogenous ligand, cells were treated with the nuclear export inhibitor, leptomycin B (LMB). Results showed that treatment with LMB did not affect the cytoplasmic location of the AHR in various Hepa-1 lines, but resulted in the AHR becoming predominately nuclear in A7, C2C12 and 10T1/2 cells within 2 hours. To determine the contribution of hsp90, XAP2 and p23 to the dynamics of AHR location, IP studies were carried out. Results suggest that loss of hsp90, XAP2 and p23 from the core AHR complex is distinct in liganded vs. unliganded translocation events. These studies suggest that the AHR can actively shuttle between the nucleus and cytoplasm and indicate that ligand mediated 26S proteasome degradation can occur within the nuclear compartment. Supported by NIEHS 10991.

961 MOLECULAR MECHANISMS OF DIOXIN
INSENSITIVITY IN XENOPUS LAEVIS EMBRYOS AND
TADROLES

J. A. Lavine, B. H. Philips, T. C. Susman, A. J. Rowatt, A. J. Whitington, T. Klimova and W. H. Powell. *Biology, Kenyon College, Gambier, OH.* Sponsor: M. Hahn

2, 3, 7, 8 tetrachlorodibenzo-p-dioxin (TCDD) is a potent developmental toxicant in most vertebrates. However, several frog species are resistant to TCDD toxicity, especially during early life stages. We have used X. laevis as a model for investigating the molecular mechanisms of TCDD insensitivity in frogs. X. laevis tadpoles express two distinct transcripts encoding aryl hydrocarbon receptors (AHRs), AHR1 $\alpha$  and AHR1 $\beta$ . Biochemical analysis of each AHR indicated that while TCDD enabled sequence-specific DNA interactions, it bound the receptors with an affinity approximately twenty-fold lower than mouse AHR. Furthermore, the signaling activity of the AHRs is attenuated in early life stages. TCDD exposure induced the expression of CYP1A6 and CYP1A7 mRNAs in stage 54 tadpoles (-1 month), but did not alter their expression at stage 48 (~7.5 days) or earlier, despite the expression of both AHR mRNAs. Finally, like other frogs, *X. laevis* embryos eliminate TCDD very rapidly. Embryos (stage 42) exposed to [<sup>3</sup>H]TCDD eliminated their TCDD burden with a half-life less than one day. While older tadpoles (stage 54 and later) exhibited no TCDD elimination over several days, they were nonetheless remarkably insensitive to TCDD-induced lethality. Taken together, these studies suggest that multiple mechanisms combine to produce TCDD insensitivity in different stages of frog development. Rapid TCDD elimination and repressed AHR activity are likely important in embryos, while weak TCDD binding by AHRs allows insensitivity to persist into the later tadpole stages. Understanding the molecular mechanisms of TCDD insensitivity in different life stages is important for determining the human health relevance of frog embryo toxicity assays (e.g. FETAX). Moreover, the unique features of frog AHR function and expression may provide a novel perspective on the relationship between AHR expression, AHR activity, mechanisms of TCDD toxicity, and the endogenous functions of AHRs during vertebrate development. [NIH R15-ES11130]

962 FUNCTIONALITY OF HUMAN XRCC1 399 AND 194 VARIANT PROTEINS IN CELLS DETERMINED BY AN ULTRA-SENSITIVE AND REAL-TIME SSB ASSAY.

J. Nakamura<sup>1</sup>, T. Takanami<sup>2</sup>, J. A. Swenberg<sup>1</sup> and Y. Kubota<sup>2</sup>. <sup>1</sup>Department of Environmental Sciences and Engineering, University of North Carolina at Chapel Hill, Chapel Hill, NC and <sup>2</sup>Department of Biochemistry, Medical School of Medicine, Iwate Medical University, Morioka, Iwate, Japan.

Inherited polymorphisms in DNA repair genes have been suggested as risk factors for cancer susceptibility. The X-ray repair cross-complementing group 1 (XRCC1) has a pivotal role in the coordination of base excision repair (BER) by serving as an essential scaffold protein which interacts with proteins involved in the BER pathway. Although there are conflicting experimental observations, increasing evidence suggests that XRCC1 codon 399 genotype are associated with increased susceptibility to breast, head and neck, as well as lung cancer. However, the functionality of these polymorphisms has not been fully characterized. The goal of this study was to determine the functionality of XRCC1 variant proteins in cells using a newly established ultra-sensitive single strand break (SSB) assay. We evaluated SSB repair capacity in isogenic XRCC1-deficient Chinese hamster ovary cells expressing wildtype (wt) and two major human XRCC1 variant proteins under oxidative and alkylating conditions. XRCC1-truncated (EM9) cells harboring empty vector or expressing either XRCC1 wt protein, XRCC1 194 or 399 variant proteins were exposed to methyl methanesulfonate (MMS) or hydrogen peroxide (H2O2) and intracellular NAD(P)H in these cells was monitored in real time. EM9 cells harboring empty vector showed a significant depletion of intracellular NAD(P)H after either MMS or H<sub>2</sub>O<sub>2</sub> exposure. All EM9 cell lines expressing XRCC1 wild-type, 194, or 399 variant proteins after either MMS or H<sub>2</sub>O<sub>2</sub> exposure showed a greater resistance to the depletion of intracellular NAD(P)H levels compared to the EM9 cells harboring the empty vector, but there were no significant differences between cells expressing wt and variant proteins. These data strongly suggest that both human XRCC1 194 and 399 variant proteins are as functional as wt XRCC1 protein in facilitating repair of SSBs induced by either alkylation or oxidation.

963 STUDIES ON PROTEIN STABILITY AND METABOLIC ACTIVITY OFHUMAN CYTOCHROME P450 2A6 (CYP2A6) GENETIC VARIANTS.

K. George, X. He and J. Hong. Joint Graduate Program Toxicology, Rutgers University/UMDNJ and School of Public Health, Piscataway, NJ.

Human cytochrome P4502A6 (CYP2A6) is a major enzyme for the metabolism of nicotine and for the bioactivation of several tobacco-related carcinogens such as 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK). Functional genetic polymorphisms of CYP2A6 could be an important factor in determining an individual's

susceptibility to tobacco-related cancers. Our previous studies showed that the CYP2A6 natural missense variants CYP2A6\*2 (Leu160His), CYP2A6\*3b (Leu156Pro) and CYP2A6\*5 (Gly479Val) are enzymatically inactive. In addition, we observed CYP2A6\*2 had a lower protein expression level than the wild-type in a baculovirus/insect cell expression system. The aim of present study is to confirm these observations in mammalian cells. The cDNAs of CYP2A6\*2, CYP2A6\*3b, CYP2A6\*5 and wild-type CYP2A6 were transfected into Chinese hamster ovary (CHO) cells. Analysis of gene expression by reverse transcriptase polymerase chain reaction (RT-PCR) revealed that CYP2A6 mRNA were expressed in all the transfected CHO cells. However, the level of immunodetectable CYP2A6 proteins were significantly lower in the cells transfected with the variant cDNAs than the wildtype CYP2A6, suggesting decreased stability of these missense proteins. In order to analyze the metabolic activity of the variant proteins, the stable transfectants were challenged with NNK and cell viability was assessed by methyl tetrazolium salts (MTS) assay. Preliminary results show that the CHO cells expressing these variant CYP2A6 cDNAs have significantly lower cytotoxicity with NNK at 400-800 µg/µl than those expressing the wild-type CYP2A6. This result is consistent with the role of CYP2A6 in NNK metabolic activation and the reduced metabolic activity of the variant proteins. Further work with circular dichroism analysis of the wild-type and variant CYP2A6 proteins will be conducted to determine the structure-activity relationship.(Supported by NIH grant ES-07148-17 and ROI-ES-10048)

## 964 SINGLE AND COMBINED GENOTYPES ON LUNG CANCER SUSCEPTIBILITY IN CHILEAN PEOPLE.

L. Gil, V. Martinez and M. Adonis. *Cellular and Molecular Biology, Faculty of Medicine University of Chile, Santiago, Chile.* Sponsor: R. Yang.

It has been suggested that more than 80% of cancers (CA) are produced by chemical carcinogenic compounds. In the year 2000, 10 million of new cases of CA in the world were diagnosed and 6 million of them died. The same year in Chile the number of cases was 2, 174, of which 1, 900 died. The magnitude of lung CA mortality is related to the high rate of incidence and poor survival after the treatment. Although the advances in surgery and other therapies have been important, the 5 years survival rate for lung CA is still low. It is well established that one of the risk factors of CA is the smoking habit. However, the CA is not only related to smoking, suggesting other sources and factors in the CA incidence. Type and aggressiveness of lung CA and degree of response to a specific treatment might be determined by time and level of exposure to chemical carcinogenic agents as well as to genetic susceptibility. Our studies have shown in Santiago as well as in working places very high PM10 levels associated with high PAHs and nitro-PAHs levels and with high mutagenic activity. Additionally, our results have shown that the frequencies of CYP1A1 variant alleles for MspI (m2 or CYP1A1\*2A) and null genotype for GSTM1, were higher in lung CA patients than in Chilean healthy controls. The estimated relative risk for combined unfavourable genotypes was particulate high for null genotypes of GSTM1 and m2 variant allele (OR =2.51), especially when the sample was stratified by smoking habit (OR=2.98). If the codon 72 for p53 protein (Pro) polymorphism is included the risk was highly increased (m2+GŜTM1+Pro, OR=6.19). In conclusion, considering lung CA aggressiveness, the early detection might play a fundamental role in the rate of survival. If it is considered that the cost of each lung CA treatment is of approximately US\$23.000, studies to detect genetic polymorphisms in susceptible individuals would be highly profitable in terms of prevention and improvement in the efficiency of the treatment. F

## 965 N-ACETYLTRANSFERASE 2, EXPOSURE TO SMALL AMOUNTS OF AROMATIC AMINES, AND BLADDER CANCER.

K. Golka<sup>1</sup>, K. Farker<sup>2</sup>, W. Weistenhoefer<sup>1</sup>, T. Reckwitz<sup>3</sup>, V. Prior<sup>4</sup>, T. Seidel<sup>5</sup>, R. Thier<sup>1</sup>, M. Blaszkewicz<sup>1</sup> and H. M. Bolt<sup>1</sup>. <sup>1</sup>Institute for Occupational Physiology, University of Dortmund, Dortmund, Germany, <sup>2</sup>Institute of Clinical Pharmacology, Friedrich-Schiller-University Jena, Jena, Germany, <sup>3</sup>Department of Urology, Klinikum Leverkusen, Leverkusen, Germany, <sup>4</sup>Department of Urology, Klinikum Dortmund, Dortmund, Germany and <sup>5</sup>Department of Urology, Paul-Gerhard-Stiftung, Lutherstadt Wittenberg, Germany.

The slow NAT2 acetylation state is a risk factor for subjects exposed to aromatic amines at benzidine production sites. We investigated bladder cancer subjects occupationally exposed to aromatic amines at low levels (painters, who started with their apprenticeship decades ago), or non-occupationally exposed (smokers). Sixteen painters with bladder cancer and 26 healthy colleagues were matched for age (± 5 years), gender, and place of residence and investigated for their occupational histories and smoking habits. Additionally, 591 bladder cancer subjects from 3 different industrialized areas with known risk factors for bladder cancer and 196 bladder cancer subjects from the area of Jena without known risk factors were investigated for smoking habits. The NAT2 acetylation state was determined in all subjects. Fourteen of the 16 painters with bladder cancer (88%), but only 17 of the 26 painters without bladder cancer were slow acetylators. Smoking habits and age at

first exposure to colorants revealed no relevant differences. In the group of bladder cancer subjects from urological hospitals in areas with known risk factors for bladder cancer, subjects with a smoking history were over-represented, compared with non-smokers: 152 of 240 smokers (63%), but only 70 of 138 non-smokers (51%) were slow acetylators. In the area of Jena, 57% were slow acetylators; from those with known smoking habits (n=69), 65% of the smokers were slow acetylators. The slow acetylation state is a susceptibility factor for bladder cancer also in subjects exposed to low levels of carcinogenic aromatic amines in the past.

#### 966 CORRELATION BETWEEN CATECHOL-O-METHYLTRANSFERASE GENOTYPE AND PHENOTYPE.

A. E. Sullivan<sup>1</sup>, J. E. Goodman<sup>2</sup>, P. M. Silber<sup>3</sup> and J. D. Yager<sup>1</sup>. <sup>1</sup> Environmental Health Sciences, Johns Hopkins University, Baltimore, MD, <sup>2</sup> Laboratory of Human Carcinogenesis, NCI, NIH, Bethesda, MD and <sup>3</sup> In Vitro Technologies, Inc., Baltimore, MD.

A major detoxification pathway for the carcinogenic catechol estrogens is methylation by catechol-O-methyltransferase (COMT). A val108met polymorphism in the COMT gene has been associated with an increased risk for breast cancer. It had been hypothesized that the met allele (COMT<sup>L</sup>) codes for a protein with lower activity than that coded by the val allele (COMTH). Other laboratories have shown that the val108met polymorphism is associated with a 3-4-fold difference in COMT activity in homogenates of human erythrocytes, liver and kidney tissue. However, studies conducted in our laboratory using recombinant human COMT protein and the cytosolic fractions of COMT homozygous human breast cell lines revealed no differences between the kinetic parameters of COMT<sup>H</sup> and COMT<sup>L</sup>. Interestingly, the previous studies where differences in activity were found did not normalize COMT activity to COMT protein levels. In order to address this discrepancy we obtained hepatocytes from thirty-one Caucasian female donors and determined their COMT genotype, COMT activity and COMT protein levels. We found that cytosolic COMT activity levels directly correlate with COMT protein levels. Therefore, lower COMT activity seen in tissues and cells with COMT<sup>LL</sup> genotypes is due to lower COMT protein levels compared with tissues and cells from  $COMT^{HH}$  individuals. Protein turnover studies are currently being conducted to determine if  $COMT^{L}$  has a shorter half-life compared to  $COMT^{L}$ . Supported by grants R01CA77550 and T32ESO7141.

### 967 GLUTATHIONE-S-TRANSFERASE POLYMORPHISMS AND ASSOCIATIONS WITH T1DM.

L. M. Bekris<sup>1</sup>, C. Shephard<sup>1</sup>, F. Farin<sup>1</sup>, J. Graham<sup>2</sup>, B. Mcneney<sup>2</sup>, T. J. Kavanagh<sup>1</sup> and A. Lernmark<sup>1</sup>. <sup>T</sup>Environmental Health, University of Washington, Seattle, WA and <sup>2</sup>Statistics and Actuarial S, Simon Fraser University, Burnaby, BC, Canada.

Glutathione (GSH) is the major endogenous antioxidant produced by the cell. GSH participates directly in the neutralization of free radicals and maintains exogenous antioxidants such as vitamins C and E in their reduced forms. GSH plays a role in the immune response. Glutathione S-transferases (GSTs) conjugate GSH to free-radicals or xenobiotics. GST activity depletes GSH levels and may either detoxify or enhance the toxicity of a compound. Glutathione-s-transferase mu 1 (GSTM1) located at 1p13.3 and glutathione-s-transferase theta 1 (GSTT1) located at 22q11.2 have polymorphic homozygous deletion (null) genotypes resulting in complete absence of enzyme activity. GST null genotypes have been associated with susceptibility to cancer and protection against chronic pancreatitis. GSTM1 and GSTT1 null genotypes in Caucasian populations have frequencies of approximately 50% and 15-20%, respectively. Type 1 diabetes mellitus (T1DM) is an autoimmune disease characterized by pancreatic beta cell destruction involving autoreactive T-cells, pro-inflammatory cytokines, reactive oxygen species and loss of insulin. Monozygotic twin studies show only a 20-30% concordance with T1DM indicating strong environmental contributions to the disease. Genetic contributors associated with T1DM include HLA, insulin VNTR, and CTLA-4. The aim of this study was to investigate associations with GSTM1 and GSTT1 polymorphisms in a group of 200 T1DM patients and 200 control subjects who participated in the Combined Swedish Childhood Diabetes Registry and Diabetes Incidence Study. Results show that the GSTM1 null genotype (p=0.07, OR=0.69) but not the GSTT1 (p=0.34, OR=0.75) may protect against T1DM. Taken together, the GSTM1 and GSTT1 null genotypes showed a stronger and statistically significant association with T1DM (p=0.03, OR=0.64). These results suggest that GST null genotypes are negatively associated with T1DM and that susceptibility to T1DM involves GST conjugation and possibly GST mediated GSH depletion.

## 968 POLYMORPHISMS IN HUMAN SOLUBLE EPOXIDE HYDROALSE.

P. K. Srivastava and D. F. Grant. Pharmacy, University of Connecticut, Storrs, CT.

Human soluble epoxide hydrolase (hsEH) and its endogenous substrates have been suggested to play a role in several physiological processes including blood pressure regulation, inflammation, and cell proliferation. It may also play a role in the me-

tabolism of xenobiotics. HsEH consists of two domains, an N-terminus having phosphatase activity and a C-terminus having epoxide hydrolase activity. Recently, we found 6 SNPs in the hsEH gene (EPHX2) in humans. Studies showed that some of these SNPs are associated with changes in epoxide hydrolase activity. In the present study, we examined the effect of these polymorphisms on phosphatase activity, enzyme stability and the ability of the enzyme to dimerize. The results show that mutants Lys55Arg, Arg103Cys, Cys154Tyr, Arg287Gln and the double mutant (Arg287Gln/Arg103Cys) have significantly lower phosphatase activity compared to the wild type hsEH. In addition, the stability of Arg287Gln and the double mutant at 37 degre C are significantly reduced compared to the wild type hsEH. HPLC gel-filtration studies of wild type full-length hsEH show that both dimer and monomer are active, however, the dimer form predominated. On the other hand, the double mutant showed an increased concentration of monomeric form, suggesting that these SNPs disrupt interactions presumably responsible for dimerization. We conclude that several polymorphisms occurring in the human EPHX2 gene affect enzyme specific activity, stability and quaternary structure.

969 POLYMORPHISMS IN ALCOHOL DEHYDROGENASE INFLUENCE TOPICAL CAPSAICINOID ACTIVITY IN HUMAN SKIN.

L. K. Pershing and Y. Chen. *Dermatology, University of Utah, Salt Lake City, UT.* Sponsor: G. Yost.

Topical capsaicin and its analog, nonivamide produce erythema and a stinging/ burning sensation in human skin that is influenced by alcohols. Erythema produced in propylene glycol is 3X greater than isopropyl alcohol and highly variable between subjects. Erythema is independent of skin capsaicinoid content. Polymorphisms in genes that encode alcohol dehydrogenase are known to alter the rate of alcohol metabolism. This study evaluated the genetic basis for the variable capsaicinoid-induced erythema as a function of alcohol dehydrogenase genes: ADHIB, ADHIC and ADHIV. Peripheral blood was collected from 8 Asians and 8 Caucasians previously evaluated for erythema to topical capsaicinoid in isopropyl alcohol (IPA), propylene glycol (PG), ethanol (EtOH) and mineral oil (MO) solutions (30 mg/ml). DNA extracted from peripheral blood lymphocytes was PCRamplified with primers designed to known fragments containing single nucleotide polymorphisms (SNPs) of interest in the three genes. PCR fragments were then denatured and resolved on polyacrylamide gels to detect distinct bands associated with known SNPs. Nucleotide sequencing confirmed band patterns. SNPs in ADHIV (G239C), ADHIC (G815A) and ADHIB (G143A) are associated with slow (0), slow (0), and fast (1) alcohol metabolizing isoforms, respectively. Six ADH haplotypes were associated with altered erythema to topical capsaicinoids in alcohols. Erythema varied with the number of alleles (2 per gene) associated with fast alcohol metabolizing isoforms in the order of importance ADHIV > ADHIC > ADHIB. For example, allele haplotype 110000 produced 2X, 2.2X, 2.6X, 3X and 5X greater erythema to capsaicinoids in PG than haplotypes 101010, 111110, 111111, 111100 and 001000, respectively. These data suggest that ADHIV dominates the resulting altered erythema with alcohols but is negatively modulated by ADHIC and positively modulated by ADHIB. Thus, the apparent alcohol-associated increase in capsaicinoid-induced erythema in human subjects is controlled by ADH genes regulating alcohol metabolism and is genetically determined.

970 ACUTE TOXICITY OF ACETALDEHYDE ON ALDEHYDE DEHYDROGENASE 2 GENE TARGETING MICE: SINGLE DOSE IP STUDY.

T. Isse<sup>1</sup>, T. Oyama<sup>1</sup>, N. Kunugita<sup>2</sup>, K. Matsuno<sup>3</sup>, K. Kitagawa<sup>4</sup>, A. Yoshida<sup>5</sup>, I. Uchiyama<sup>6</sup>, M. Ogawa<sup>1</sup>, T. Kinaga<sup>1</sup>, R. Suzuki<sup>1</sup>, T. Yamaguchi<sup>1</sup> and <u>T. Kawamoto<sup>1</sup></u>. <sup>1</sup>Environmental Health, University of Occupational and Environmental Health, Kitakyushu, Fukuoka, Japan, <sup>2</sup>Health Science, University of Occupational and Environmental Health, Kitakyushu, Japan, <sup>3</sup>Bio-information Research Center, University of Occupational and Environmental Health, Kitakyushu, Japan, <sup>4</sup> First Department of Biochemistry, Hamamatsu Medical University, Hamamatsu, Japan, <sup>5</sup>Beckman Research Institute of the City of Hope, Duarte, CA and <sup>6</sup>Environmental hygiene, School of technology, Kyoto University, Kyoto, Japan.

Half of Japanese have inactive aldehyde dehydrogenase (ALDH) 2. Toxicity of acetaldehyde to them and normal people thought to be different in same dose. For estimating the difference of acetaldehyde toxicity to these groups, we compare with 50% of lethal dose (LD50) of acetaldehyde of the Aldh2 inactive gene targeting (Aldh2 KO) mice and that of wild type (Aldh2 WT) mice by single dosage of acetaldehyde intra peritoneal injection. The LD50 of acetaldehyde of the Aldh2 WT mice was 602mg/kg (95% 577-624mg/kg) in male, 598mg/kg (95% 575-625mg/kg) in female, respectively. The acetaldehyde LD50 of the Aldh2 KO mice was 567mg/kg (95% 545-589mg/kg) in male, 587mg/kg (95% 564-616mg/kg) in female, respectively. The acetaldehyde LD50 of the Aldh2 KO mice was smaller than that of the Aldh2 WT. There were no differences in the symptoms of the both

mice, though Aldh2 KO mice showed rapidly appearance of the symptoms and latency appearance of the recovery than Aldh2 WT mice. The groups given more than 515mg/kg of acetaldehyde showed the loss activity, wobbling just after the administration. Pale skin, unconsciousness, abdominal raging posture and deeply breath were observed 5 min after the administration. The cases of death were observed from 15 to 30 min after the administration in the Aldh2 WT mice, and from 5 to 15 min in the Aldh2 KO. In the case of the death, dyspnoea, and low body temperature was observed. In the case of survive, couching, low breathing activity, reddishness of skin and standing of fur was observed from 45 min to 120 min after the administration in both mice.

971 ARRESTED LUNG DEVELOPMENT ASSOCIATED WITH CHANGES IN TEMPORAL EXPRESSIONS OF FIBROBLAST GROWTH FACTOR (FGF) RECEPTORS-3 AND -4 IN NEWBORN MICE EXPOSED TO SUBLETHAL HYPEROXIA

S. E. Welty, M. S. Park, B. L. Schanbacher, L. K. Rogers, A. C. Cook, T. N. Hansen, J. A. Bauer and C. V. Smith. Pediatrics, Columbus Children, Columbus, OH

With improved survival of very premature infants, chronic lung disease of prematurity, also known as bronchopulmonary dysplasia (BPD), is characterized increasingly as arrested lung development. Newborn mice have lungs that are comparable developmentally to lungs in prematurely born human infants and exhibit similarly arrested lung development and alveolarization with exposure to sublethal hyperoxia. In the present studies, we tested the hypothesis that inhibition of normal alveolarization by exposure of newborn mice to hyperoxia would be paralleled by alterations of expressions of FGFR3 and 4, FGF7, and HIF-1a. Newborn FVB mice were exposed to 85% O2 (O2) within 12 h of birth or left in room air. No pup mortality was observed, and body weight gains were not affected by hyperoxia. Pups were sacrificed at 1, 3, 7, or 14 d. Lungs were fixed at 25 cm H2O for morphometry or were freeze-clamped for RNA and protein analyses. Levels of FGFR-3 and -4, FGF7, and hypoxia-inducible factor (HIF)-1a mRNAs were assessed by real time PCR. At P14, lungs of O2 pups had fewer and larger alveoli and smaller alveolar surface-to-volume ratios than did AIR pups (14.3+0.4 vs 20.4+0.8 per HPF[640x]; 2038 vs 1402 mm2; and 0.111+0.002 vs 0.140+0.007 mm-1), respectively (different, P < 0.05). Lung FGFR3 and 4 mRNA levels were lower at P3 and higher at P7 in O2 pups than in AIR pups. In AIR mice, lung FGF7 mRNA levels were greater at P14 than at P1, but this increase was not observed in O2 mice. At P14, immunoreactivities of FGFR-3 and -4 were lower in lungs of hyperoxic mice than in controls. Lung HIF-1a mRNA levels decreased to 20% of the P1 level by P14 in both AIR and O2 mice. The arrested alveolar develoment observed in newborn mice exposed to 85% O2 resembles BPD of human preterm infants, and the alterations in the temporally and spatially orchestrated expressions of important growth regulatory genes, such as we observe, potentially contribute to this undesirable outcome.

#### 972 THIOREDOXIN AND THE TOXICITY OF ACROLEIN.

Y. Choi, X. Yang and J. P. Kehrer. Division of Pharmacology and Toxicology, College of Pharmacy, The University of Texas at Austin, Austin, TX.

Acrolein, an  $\alpha$ ,  $\beta$ -unsaturated aldehyde, is present ubiquitously in the environment and is also generated endogenously via lipid peroxidation. Acrolein exhibits strong electrophilic interactions, particularly with cysteine-containing molecules. While interactions with glutathione are well-documented, interactions with other cellular thiols are less clear. Thioredoxin (Trx), a highly conserved small (12 kDa) peptide with two cysteines at the redox-active catalytic site, is of particular interest because of the important roles it plays in regulating cell signaling and redox sensitive transcription factors. Trx exists in both cytosolic (Trx-1) and mitochondrial (Trx-2) forms. Although both forms provide protection against oxidative toxicities, interaction with, and protection against, electrophile toxicity has been little studied. Acrolein was used as a model electrophilic toxicant. Acrolein rapidly, and dose-dependently, decreased the activity of pure Trx. Using western blotting, acrolein did not affect the immunoreactivity of Trx. Human lung adenocarcinoma A549 cells treated with acrolein showed a loss of Trx activity, but not protein, except at very high doses where crosslinking and/or degradation may have occurred. Interestingly, the expression of Trx protein was induced in A549 cells at later times following acrolein treatment. A549 cells stably overexpressing Trx-1 and Trx-2 have been established. The Trx-2 overexpressing A549 cells showed more cell growth when treated with etoposide indicating that Trx-2 is an important survival/protective factor. The toxicity of acrolein to these cells remains unclear. (Supported by ES09791 and Center Grant ES07784.)

EFFECT OF OVEREXPRESSION OF HGSTA4-4 ON OXIDATIVE INJURY AND PROLIFERATION OF HEPG2 CELLS EXPOSED TO 4-HYDROXYNONENAL.

E. P. Gallagher and C. M. Huisden. Physiological Sciences, University of Florida, Gainesville, FL.

4-hydroxynonenal (4-HNE) is a major mutagenic aldehyde produced during oxidative injury. Although several aldehyde metabolizing pathways exist in human liver cells that protect against 4-HNE cell injury, the human glutathione S-transferase protein hGSTA4-4 exhibits a particularly high catalytic efficiency toward 4-HNE and other hydroxyalkenals. However, hGST4-4 expression is relatively low in human tissues, and there are other aldehyde metabolizing enzymes (including other GSTs) that also contribute to 4HNE detoxification. In the current study, we determined the effect of stable overexpression of hGSTA4-4 on the rates of HepG2 cell proliferation and sensitivity to 4-HNE injury. HepG2 cells transfected with an hGSTA4-4 vector construct exhibited elevated GST-4-HNE catalytic activities, high steady-state hGSTA4 mRNA expression, but lower glutathione (GSH) concentrations relative to wild type or insert-free vector cells. The hGSTA4-4-transfected cells exhibited a growth advantage relative to control cells when challenged with 4-HNE. Interestingly, exposure to  $5~\mu M$  or  $10~\mu M$  4-HNE caused an increase in GSH concentrations in both control and hGSTA4-4-transfected cells. Collectively, our data indicate that exposure to 4-HNE increases GSH biosynthesis in HepG2 cells, and that overexpression of hGSTA4-4 provides a growth advantage in the presence of 4-HNE. Supported by NIH ES09427.

## 974 REDUCED EXPRESSION OF 8-OXOGUANINE-DNA GLYSOSYLASE IN THE EKER RAT.

S. S. Lau, S. L. Habib, M. S. Chacko and T. J. Monks. Department of Pharmacology and Toxicology, College of Pharmacy, University of Arizona Health Sciences Center, Tucson, AZ.

The Eker rat (Tsc-2<sup>EK/+</sup>) bears a mutation in one allele of the Tsc-2 gene, which predisposes these animals to renal cancer. Treatment of either wild type (Tsc-2<sup>\*/+</sup>) Eker rats, or rats carrying the mutant Tsc-2 allele (Tsc-2<sup>EK/+</sup>) with 2, 3, 5-*tris*-(glutathion-S-yl)hydroquinone (TGHQ; 2.5 µmol/kg, i.p. for 4, 8 or 16 wks), a potent nephrotoxic metabolite of HQ, causes oxidative DNA damage, cell necrosis, and proliferation within the outer stripe of the outer medulla (OSOM) in both groups of animals, but renal cell carcinomas only arise in the OSOM of the mutant Tsc-2<sup>EK/+</sup> strain. Interestingly, considering  $2^{EK/*}$  strain. Interestingly, constitutive expression of 8-oxoguanine-DNA glycosylase (OGG1) in Tsc- $2^{+/*}$  rats is 2.5 fold higher than in Tsc- $2^{EK/*}$  rats. Moreover, the poor ability of Tsc- $2^{EK/*}$  rats to cope with the TGHQ-induced oxidative stress is exacerbated by their inability to rapidly upregulate this enzyme. The mechanism by which a germline insertion in one allele of the Tsc-2 gene modulates the expression, and regulation, of the OGGI gene is not known. We now report, using RT-PCR, that OGG-1 mRNA expression in Tsc-2<sup>+/+</sup> rats is 3.3 fold higher than in Tsc-2<sup>EK/+</sup> rats. Moreover, while OGG1 mRNA is significantly upregulated during 2 and 4 months of TGHQ treatment in Tsc-2<sup>+/+</sup> rats, OGG1 mRNA levels remain unchanged throughout the 4-months of treatment in Tsc-2<sup>-EK/+</sup> rats. To further investigation gate the link between Tsc-2 and OGG1, we restored tuberin expression in TGHQtransformed renal epithelial cells, by transient transfection with Tsc-2 cDNA. Re-expression of tuberin significantly increased OGG1 expression by 120-170%. In humans and rats, the Tsc-2 (16p13.3 and 10q respectively) and OGG1 (3p26.5 and 4 respectively) genes are located on different chromosomes. We conclude that the presence of a germline insertion in one allele of the Tsc-2 gene indirectly modulates the regulation of OGG1 gene expression. The mechanism by which tuberin influences OGG1 expression is under investigation. (GM39338, ÉS07784)

## 975 CARBONYL REDUCTASE CATALYZES REDUCTION OF 4-OXONONENAL.

D. R. Petersen<sup>1</sup>, J. A. Doorn<sup>1</sup>, E. Maser<sup>2</sup> and D. J. Claffey<sup>1</sup>. <sup>1</sup>Pharmaceutical Sciences, University of Colorado Health Sciences Center, Denver, CO and <sup>2</sup>Experimental Toxicology, University of Kiel, Kiel, Germany.

4-Oxononenal (4ONE) was demonstrated to be a product of lipid peroxidation, and previous studies found that it was reactive toward DNA and protein nucleophiles. Currently, metabolic pathways of 4ONE are unknown. The present study sought to determine whether carbonyl reductase (CR) catalyzes reduction of 4ONE. Recombinant human CR was incubated with NADPH and varying concentrations of 4ONE (pH 7.4, 37 C) and kinetic parameters calculated. Products of the enzyme mediated reaction were identified *via* TLC, GC/MS and LC/MS (ion trap). Aliquots of the CR/NADPH + 4ONE reaction were analyzed *via* HPLC to monitor time-dependent change of [4ONE] and [products]. 4ONE was found to be a substrate with KM and kcat of 345 uM and 220 min-1, respectively. TLC analysis with standards revealed the presence of three products resulting from the CR/NADPH + 4ONE reaction, and two were identified as 4-hydroxynonenal

(4HNE) and 1-hydroxynonen-4-one (1HNO). GC/MS analysis confirmed the identity of 4HNE and 1HNO. The unknown product did not correspond to standards representing reduction of both or either 4ONE carbonyls and was not reactive toward N-acetyl cysteine. GC/MS analysis identified the unknown as 4-oxononanal (40NA). Analysis of oxime derivatives of the reaction products via LC/MS (ion trap) confirmed the unknown as 4ONA. The time course for CR mediated, NADPH dependent 4ONE reduction and appearance of 4HNE and 1HNO was determined using HPLC, demonstrating that 4HNE and 1HNO are major (71%) and minor (9.0%) products on a molar basis, respectively. Based on these values, 4ONA was calculated to represent 20% of the total product. Results of the present study demonstrate that 4ONE is a substrate for CR/NADPH and the enzyme may represent a pathway for metabolism of the lipid aldehyde. Furthermore, these findings reveal that CR catalyzes selective reduction of the ketone, but also the aldehyde and C=C of 4ONE, resulting in 4HNE, 1HNO and 4ONA, respectively. DNA DAMAGE-INDUCED HISTONE H3
PHOSPHORYLATION DOES NOT INVOLVE SITES
NORMALLY ASSOCIATED WITH MITOTIC
CHROMOSOMAL CONDENSATION.

K. Cox<sup>1</sup>, A. H. Palmer<sup>1</sup>, S. S. Lau<sup>3</sup>, K. N. Dalby<sup>2</sup> and T. J. Monks<sup>3</sup>.

<sup>1</sup>Pharmacology and Toxicology, University of Texas at Austin, Austin, TX, <sup>2</sup>Medicinal Chemistry, University of Texas at Austin, Austin, TX and <sup>3</sup>Pharmacology and Toxicology, University of Arizona Health Sciences Center, Tucson, AZ.

Treatment of renal proximal tubular epithelial (LLC-PK1) cells with the reactive oxygen species (RÔS)-generating toxicant, 2, 3, 5-tris-(glutathion-S-yl)hydroquinone (TGHQ) causes DNA damage and premature chromatin condensation (PCC), which may contribute to cell death. Concurrent with PCC is an increase in the phosphorylation of histone H3. Phosphoamino acid analysis of histone H3 revealed that only serine was phosphorylated in response to TGHQ treatment. Phosphorylation of histone H3 at \$10 and \$28 is known to contribute to the condensation of chromosomes during mitosis, and these residues are phosphorylated by mitogen- and stress-activated kinase (MSK1). To ascertain whether MSK1 contributes to TGHQ-induced toxicity, LLC-PK1 cells were transfected with wild-type (WT) or dominant-negative (DN) MSK1. [32P]-orthophosphoric acid labeled cells expressing WT or DN MSK1 showed no change in TGHQ-induced histone H3 phosphorylation, compared with control TGHQ-treated cells. Accordingly, neutral red analysis revealed no change in cytotoxicity between WT MSK1, DN MSK1, and control cells. In support of these findings, Western analysis showed a decrease in the phosphorylation of histone H3 at both S10 and S28, following treatment with TGHQ. Together, the data suggest that the site of TGHQ-induced phosphorylation is at alternate serine residue(s) on histone H3. There are three isoform variants of histone H3, each with specific serine residue substitutions. Separation of histone H3 isoforms on acid urea triton gel established that only H3.3 is phosphorylated in response to TGHQ. Histone variant H3.3 contains a serine at position 31, in the highly modified tail region unique to H3.3. We conclude that increases in histone H3 phosphorylation in cells undergoing ROS-induced cell death is not due to phosphorylation of \$10 or \$28, but a novel site responsive to ROS-induced DNA damage. GENETIC MUTATION ANALYSIS OF THE GLUTATHIONE REDUCTASE HYPOMORPHIC MICE (GR1A1NEU) INDICATES A GENETIC KNOCKOUT ANIMAL.

C. V. Smith, T. Tamura, L. K. Rogers, B. J. Rogers, T. N. Hansen and S. E. Welty. Pediatrics, Columbus Children's Research Institute, Columbus, OH.

Glutathione reductase (GR) is a critical component of GSH-dependent antioxidant defense functions in all mammalian cells and tissues studied to date. Recently, a mutant strain (Neu) of mice with 5 to 10% of control GR activities was generated [Pretsch] by administration of isopropyl methanesulfonate and backcrossing through 15 generations into a C3H background. We obtained, rederived, and have studied progeny of these mice. We used genetic mutation analysis to determine the exact location(s) and extent(s) of the mutation(s). RNAs isolated from the Neu and C3H mice were analyzed by RT-PCR, using nested primers covering all 13 exons of the GR gene. RNA from the Neu mice produced a smaller PCR product than did RNA from the C3H mice. Use of primer sets that spanned smaller portions of the gene revealed that exons 2 through 5 were not present. Genomic DNA was isolated and analyzed, using long PCR and amplification of regions containing exons and introns, and Southern blot analyses. The results indicate that the breakpoints of the deletion are within intron 1 and intron 5, effectively deleting exons 2 through 5 and generating a frame-shift in exon 6, as well as inserting a premature stop codon. The coding region of the GR gene in the C3H mice was identical to the sequence in 129SV/J mice that we reported previously, but the GR gene in the Neu mice exhibited numerous polymorphisms with the other two strains. The polymorphisms in the GR gene of the Neu mice are identical with 14 out of 17 polymorphisms (2 missense, 12 silent) reported for GR in C57BL/6J mice, the remaining 3 silent polymorphisms are within the deleted region. The data presently available indicate that the Neu mice are functional knockouts for GR. The absence of major phenotypic effects from deletion of a gene so highly conserved through evolution is surprising, suggesting possible adequacy in unstressed cells of crosstalk with thioredoxin/thioredoxin reductase, which probably account for the low GR activities measured in the standard assays employed.

978 THE ROLE OF NRF2 AND ARE IN THE INITIATION AND PROGRESSION OF AMYOTROPHIC LATERAL SOLEPOSIS

J. C. Kern, A. D. Kraft and J. A. Johnson. Pharmaceutical Sciences, University of Wisconsin-Madison, Madison, WI.

Amyotrophic lateral sclerosis (ALS) is a disease of muscle atrophy, originating from unknown upstream motor neuron dysfunction. The antioxidant response element (ARE), a cis-acting element present in numerous detoxification enzymes, confers neuroprotective effects in response to oxidative stress and is completely dependent on the transcription factor NF-E2 related factor (Nrf2). By crossing transgenic mice containing ARE-driven human placental alkaline phosphatase (ARE-hPAP) with an ALS mouse model containing a mutation in superoxide dismutase (SOD G93A), we were able to identify temporal and spatial patterns of hPAP activity, indicative of oxidative stress. ARE-hPAP, SOD G93A mice demonstrated ~30-fold hPAP activation at 60 days of age (initiation of ALS symptoms) that increased to -70-fold activation at 120 days of age (muscle loss and paralysis) in the core tissues of ALS motor neuron degeneration-motor cortex, brainstem, and spinal cord. An adenoviral infection containing Nrf2 (Ad-Nrf2) has previously shown dramatic neuroprotection in cortical primary cultures. Since the muscle is of paramount importance in ALS and has the ability to transport survival factors retrograde to the spinal cord, we directly injected Ad-Nrf2 in the gastrocnemius muscle of AREhPAP -/ mice. In ARE-hPAP mice, there was a significant activation of hPAP in the motor cortex and brainstem (>=5-fold) and a >=40-fold activation in the spinal cord and muscle, although the Ad-Nrf2 remained sequestered in the muscle (as detected by RT-PCR). Overall, these data demonstrate a role for a Nrf2-mediated ARE response in ALS disease initiation and progression. It also presents a possible therapeutic intervention in amplifying detoxification mechanisms able to counter oxidative stress and muscle loss in SOD G93A mice.

979 CIGARETTE SMOKE INDUCIBLE HUMAN FRA-1
EXPRESSION IN AIRWAY EPITHELIAL CELLS IS
REGULATED BY EGFR-MEDIATED AND ERK/JNK/P38DEPENDENT MAP KINASE PATHWAYS.

S. P. Reddy and Q. Zhang. Environmental Health Sciences, Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD. Sponsor: K. Steven.

Cigarette smoke (CS) exposure is known to be a major cause of human cancers, especially lung cancer, and other respiratory diseases including emphysema. However, the underlying molecular mechanisms involved in these processes remain enigmatic. An aberrant expression of genes induced by CS can result in an altered phenotype, contributing to the respiratory pathogenesis. Given that the activator protein 1 (AP-1) family of transcription factors regulates genes involved in both physiological and pathophysiological processes, we have investigated the effects of CS on the expression of AP-1 (Jun/Fos) family members in 1HAEO airway epithelial cells. CS strongly up-regulated c-Jun, c-Fos, and Fra-1 expression, whereas it had no effect on Fra-2, Jun-B, and Jun-D. Since Fra-1 is overexpressed in various tumors and upregulates genes associated with tumor progression, we further examined the mechanisms regulating its expression by CS. Upregulation of Fra-1 (mRNA and protein) expression correlatedwell with its DNA binding activity. The fra-1 induction by CS was regulated primarily at the transcriptional level. Pretreatment of cells with the EGFR inhibitor, AG1498, strongly suppressed the induction. Similarly, inhibitors of the ERK, p38, and JNK MAP kinase pathways had a suppressive effect on CS-induced fra-1 expression. Consistent with this finding, CS caused a distinct activation of these kinases. The phosphorylation of ERK1 and ERK2, JNK1, and p38 was markedly elevated at 30 min after exposure. In contrast to its effect on JNK1, CS showed no significant effect on JNK2 phosphorylation. Together, these observations suggests that CS distinctly regulates Jun and Fos family members expression in airway epithelial cells. Among them, fra-1 induction is stimulated via EGFR-mediated and ERK/JNK/p38-dependent MAP kinase pathways, further underscoring a potential role for this signaling axis in perturbations of CS-induced gene expression by Fra-1 based AP-1 complexes in the lung.

4-HYDROXYNONENAL-MEDIATED INHIBITION OF ENZYME-CATALYZED OXIDATION OF THE REACTIVE ELECTROPHILE 3, 4 DIHYDROXYPHENYLACETALDEHYDE.

J. A. Doorn and D. R. Petersen. Pharmaceutical Sciences, University of Colorado Health Sciences Center, Denver, CO.

980

Dopamine (DA) undergoes enzyme-catalyzed deamination to yield 3, 4-dihydroxyphenylacetaldehyde (DOPAL), which is metabolized primarily via mitochondrial aldehyde dehydrogenase (ALDH2). Recent work implicates oxidative stress and lipid peroxidation products, e.g., 4-hydroxynonenal (4HNE), as factors in neurodegenerative disease. The goal of this study was to determine whether 4HNE inhibits enzymes that catalyze oxidation/reduction of DOPAL and if DOPAL is a reactive electrophile that can modify protein amines. DOPAL was obtained by incubating DA with rat liver monoamine oxidase. Human ALDH2 and rat brain ALR were incubated with DOPAL and increasing concentrations of 4HNE and activity measured. An amine containing peptide (i.e. RKRSRAE) was treated with DOPAL and DA (37 C, pH 7.4), and the products analyzed *via* mass spectrometry. It was found that at low concentrations of 4HNE (i.e. <10 uM), ALDH2 activity toward DOPAL was significantly inhibited. Concentrations of DOPAL at >50 uM led to a decrease in activity of ALDH2, indicating inhibition of the enzyme. Incubation of RKRSRAE with DOPAL but not DA resulted in adduction of the peptide with two molecules of the aldehyde. The mass of the modifications corresponded to Schiff base containing adducts. Inclusion of sodium cyanoborohydride in the incubation mixture resulted in a shift of 2 Da for the mass of the adducts, confirming the presence of an imine on the DOPAL modification. Treatment of the peptide with equal concentrations of 4HNE and DOPAL (i.e. 100 uM each) resulted only in DOPAL adducts, indicating that DOPAL is a more reactive toward amine nucleophiles than 4HNE. These data indicate that 4HNE can significantly impair enzyme mediated oxidation of DOPAL and ALDH2 is inhibited by DÔPAL. Furthermore, results of this study demonstrate that DOPAL is a reactive electrophile that can modify peptide amines, yielding stable Schiff base products. (Grants NIH/NIEHS F32ES11937 (JAD), NIH/NIAAA R01AA09300 and NIH/NIEHS R01ES09410 (DRP)).

981 RAPID ANALYSIS OF HEPATOCYTE TOXICITY USING BD OXYGEN BIOSENSORS.

L. E. Dike<sup>1</sup>, H. Xia<sup>1</sup> and M. Timmins<sup>2</sup>. <sup>1</sup>R&D, BD Biosciences, Woburn, MA and <sup>2</sup>R&D, BD Biosciences, Bedford, MA. Sponsor: D. Stresser.

Drug toxicity and in particular, the toxicity of xenobiotic metabolites, is a critical area of concern in drug development and is a major reason for compound failure in clinical trials. Toxicity studies in human hepatocytes are problematic because cultured hepatocytes rapidly lose their P450 activity in culture, whereas studies performed with hepatocytes in suspension, while maintaining P450 activity, juxtapose drug-induced toxicity with natural cell death. Such toxicity studies are typically 2 hours in duration and potentially miss slow acting toxins. We present here the use of BD Oxygen Biosensor System (BD OBS) for rat and human hepatocytes in suspension. These studies demonstrate that the BD Oxygen Biosensor System can be utilized for studies of longer duration for toxicity than the standard 2-4 hour assay. Hepatocytes, either fresh or cryopreserved, can be plated onto BD OBS and monitored over a 24 hour period. The hepatocytes appear to form spheroid-like structures, maintain their P450 activity and have minimal background cell death. IC50s have been derived for both direct acting and indirect acting toxins such as tamoxifen, ketoconazole and diclofenac. The BD Oxygen Biosensor System allows for rapid analysis in absence of additional sample manipulations, and thus provides an easy to use platform for obtaining accurate IC50s for hepatocyte toxicity.

982 IDENTIFICATION OF THE POTENTIAL OF I<sub>Kr</sub> (HERG)
BLOCKERS TO INDUCE QT PROLONGATION AND
TORSADE DE POINTES: EFFECTS OF TERFENADINE,
DL-SOTALOL AND VERAPAMIL IN ANESTHETIZED
GUINEA PIGS.

G. P. Thomas, J. G. Morahan and C. B. Spainhour. Pharmacology and Electrophysiology, Calvert Laboratories Inc., Olyphant, PA.

Most drugs linked to QT prolongation and Torsade de Pointes (TdP) arrhythmias do so by blocking the rapidly activating component of the delayed rectifier potassium current ( $I_{\rm KF}$ ) hERG). However, all  $I_{\rm Kr}$  blockers do not prolong QT interval or induce TdP. While dl-sotalol and terfenadine induce QT prolongation and TdP, veramall, another potent  $I_{\rm Kr}$  blocker protects from TdP. The in~vivo and in~vitro models currently used in pre-clinical studies do not accurately predict the potential risk of acquired long QT syndrome for drug candidates with  $I_{\rm Kr}$  blockade. The aim of the present study was to examine the validity of an anesthetized guinea pig model for identifying the potential of  $I_{\rm Kr}$  (hERG) blockers to induce QT prolongation. A

relatively selective blocker of  $I_{KT}$ , dl-sotalol, and terfenadine and verapamil, the two non-selective  $I_{KT}$  blockers with pro- and antiarrhythmic actions, were examined for their ability to prolong QTc interval in anesthetized guinea pigs. Guinea pigs were anesthetized by an intra-peritoneal injection of dialurethane. The trachea and the jugular vein were cannulated for positive pressure artificial respiration and administration of drugs, respectively. Dorsal, Axial and Inferior lead electrocardiograms were recorded on a Hewlett Packard Page Writer II (Model 4755A) prior to and 5, 10, and 20 minutes after each dose administration of each drug. QT interval measurements were made from the ECG strip and were corrected for heart rate using Bazett's formula. Intravenous administration of the pro-arrhythmic agents, dl-sotalol (5.0 mg/kg) and terfenadine (5.0 mg/kg), caused 32% and 22% prolongation of QTc interval respectively in anesthetized guinea pigs, while the antiarrhythmic agent, verapamil (1.0 mg/kg), had no significant effects on QTc. Our results validate the use of anesthetized guinea-pig model as a useful component in the preclinical assessment of QT prolongation and pro-arrhythmia risk.

983 EVALUATION OF RAT SERUM PROTEIN
ELECTROPHORESIS USING THE SEBIA HYDRASYS
SYSTEM

L. Le Sauteur, L. Huard, K. Larocque and Y. Deschamps. *Immunology, CTBR, Senneville, QC, Canada.* 

Serum protein electrophoresis patterns are useful biochemical markers that can be used to identify acute or chronic inflammatory reactions, protein deficiencies and renal diseases in safety assessment studies. The objective of this work was to confirm that Sprague-Dawley rat serum proteins could be well separated and quantified using the Sebia Hydrasys system. Precision (intra and inter-assay), accuracy, linearity of dilution, stability of the samples and preliminary reference intervals were determined. Accuracy was determined for each serum protein fraction using the control material (Normal Control Serum and Hypergamma Control Serum) and reagents of the manufacturer. Serum protein separation was done with the agarose gel support (Hydragel). Intra-assay precision was calculated by testing 10 consecutive measurements of the control material and of a fresh Sprague-Dawley rat serum sample while the inter-assay precision was obtained from 5 different analysis of the same samples; for all the samples, %CV (g/dL) was less than  $1.0\,\%$  for the major albumin fraction and less than 7.5% for all the other protein fractions. Each protein fraction (albumin, alpha1, alpha2, beta, gamma) was well separated from each other. Linearity of dilution was tested for each protein fraction; a correlation coefficient higher than 0.9890 and a slope within 5% of optimal linearity were obtained. Preliminary reference intervals were calculated from 20 rats; the results are consistent with expected physiological levels. Sample stability was verified with 5 rat serum samples; a mean sample difference of less than  $1.6\,\%$  was obtained following sample storage for 3 days at 2 to 8 deg. C, 31 days at -20 deg. C or 3 freeze-thaw cycles. In conclusion, the accuracy, precision and preliminary reference intervals obtained on the Sebia Hydrasys System for protein electrophoresis of Sprague-Dawley rat serum showed the method to be reliable in providing good separation of the serum protein fractions and excellent precision.

984 CIRCADIAN RHYTHM OF RATS: SHOULD CNS EFFECTS OF SMALL MOLECULES BE EVALUATED DURING THE DARK CYCLE.

K. Cardoza<sup>1</sup>, M. Gallacher<sup>1</sup>, C. Doherty<sup>2</sup>, <u>C. Alden<sup>2</sup></u>, D. Tumas<sup>2</sup> and V. J. Kadambi<sup>2</sup>. <sup>1</sup>Comparative Medicine, Millennium Pharmaceuticals, Inc., Cambridge, MA and <sup>2</sup>Drug Safety and Disposition, Millennium Pharmaceuticals, Inc., Cambridge, MA.

As mandated in the ICHS7A Guidance document, motor activity assessment is an integral component of the safety pharmacology core battery. Several studies have documented the circadian rhythm in rats which shows an increase in heart rate, blood pressure and activity during the dark cycle. Traditionally motor activity assessment is conducted during the light cycle when rats are not active. When animals are transferred to new cages for motor activity assessment there is an increase in exploratory behavior, which usually lasts for approximately 30 minutes. However, if the Tmax of the test compound is not reached during the period of exploratory behavior, depressive effects on motor activity may not be adequately captured. Radiotelemetry technology represents an approach to avoid test system artifact. Using the antipsychotic haloperidol, a prototype compound to assess motor affects, at a sub-threshold dose (0.03mg.kg SC) motor activity was assessed during the light cycle using male Sprague-Dawley rats (Charles River Laboratories, Portage, MI) instrumented with telemetry devices (Data Sciences International, St. Paul, MN). The light cycle was then reversed and the circadian rhythm was allowed to adjust over a one week period. Treatment with haloperidol was then repeated during the dark cycle. No change in activity could be detected during the light cycle (animal's

resting phase) as activity measured less than 1 count/minute. However, treatment with haloperidol during the dark cycle (animal's active phase) resulted in a 77% decrease in activity, from 4.8 counts/min to 1.1 counts/min. This decrease in activity was observed 2-4 hours post-dosing. Based on the results of this study we determined that consideration should be given to the animal's circadian rhythm and time of administration when evaluating CNS effects of novel small molecules.

985 EVALUATION OF STATISTICAL METHODS TO ANALYZE MOUSE LYMPHOMA ASSAY MUTATION

M. Moore<sup>1</sup>, J. Clements<sup>2</sup>, R. Delongchamp<sup>1</sup>, A. Thakur<sup>3</sup> and B. Myhr<sup>3</sup>. <sup>1</sup>NCTR, Jefferson, AR, <sup>2</sup>Covance, Harrogate, United Kingdom and <sup>3</sup>Covance, Vienna, VA.

The Mouse Lymphoma Assay (MLA) Workgroup of the International Workshop on Genotoxicity Tests (IWGT) is currently developing a new recommendation for the analysis of data. To evaluate the performance of statistical methods the group utilized 398 experimental data from 10 laboratories. Twenty-seven statistical methods were applied to the data sets. For the statistical analysis the dependent variable was defined by either the mutant frequency (MF), log(MF) or rank(MF); the independent variables were either dose, dose categories, dose + dose<sup>2</sup>, log(dose) or rank(dose); and the weight was either none or variance of the dependent variable. The presence of a dose response was evaluated by testing for a linear trend and/or a quadratic trend. In studies where there were more than single determinations of each data point, an analysis of variance was performed. When a P-value of less than 0.05 was used to determine whether an experiment was positive or negative, the statistical methods agreed for approximately 40% of the data sets. For the other 60% of data sets the methods gave different positive/negative calls. Graphical representations of the 398 experiments were used to classify the data into various curve shapes. A small subset (about 10%) of the data gave curve shapes that clearly defined positive responses (large dose-related increases in MF), while the rest of the data fell into categories that showed small dose-related increases, no dose-related increase or where it was difficult to visually discern a positive trend. It was this latter set of experiments where the statistical methods gave the most divergent determinations. In these situations the choice of statistical method would determine whether a response was positive or negative. Thus the Workgroup could not recommend a specific statistical method for MLA data analysis. However, because a uniform method is needed for MLA data analysis, the Workgroup is currently evaluating an approach that combines statistical analysis with the variability of the solvent/negative control MF.

986 APPLICATIONS OF AUTOMATED DIGITAL MICROSCOPY IMAGING IN INVESTIGATING MECHANISMS OF TOXICITY.

X. Ying, J. Dwyer, R. A. Schuhl, <u>T. M. Monticello</u>, <u>Z. Jayyosi</u> and <u>P. S. Rao</u>. Drug Safety Evaluation, Aventis, Bridgewater, NJ.

Microscopy imaging analysis has been used for the study of apoptosis, mitochondrial dysfunction, and oxidative stress. Our goal was to develop and validate multiendpoint assays using automated digital microscopy imaging to detect potential toxic liabilities, based on the mechanism of toxicity, in early drug development. Rat primary hepatocytes were treated with model toxicants affecting key biochemical pathways of apoptosis, mitochondrial health, and oxidative stress. Following 24 hours of treatment, the cells were loaded with fluorescent probes, propidium iodide, Hoechst 33342, YO-PRO-1, JC-1 and H2DCFDA, to measure cellular cytotoxicity, early and late-stage apoptosis, mitochondrial membrane potential, and oxidative stress, respectively. The cells with cellular/subcellular fluorescent probes were imaged utilizing automated digital fluorescence and/or brightfield microscopy, with laser microscopic auto-focusing, 12-bits cooled CCD digital camera and Imaging Research's AutoLead software, which ensured high data accuracy in the assessments. Various image analysis toolkits were utilized for image analyses and data processing. All assays were validated with model toxicants. For example, in the apoptosis assay, staurosporine and cyclosporine were used to induce apoptotic bodies which were assessed with Hoechst 33342 staining. Valinomycin was used as a positive control for loss of mitochondrial membrane potential that was detected as a change in aggregate formation using JC-1 dye. Hydrogen peroxide was used to induce reactive oxygen species formation in the oxidative stress assay with H2DCFDA. The validation studies indicate that automated microscopy imaging can be used in mechanistic assessment of toxicity in a chemical series to detect potential liabilities early in the drug development process. The applications also highlight the value of automated digital microscopy for toxicity assessment with high content and sufficient throughput.

### SAFETY EVALUATION OF SMALL MOLECULES USING RADIOTELEMETRY IN RATS.

M. Gallacher<sup>1</sup>, K. Cardoza<sup>1</sup>, C. Doherty<sup>2</sup>, <u>C. Alden</u><sup>2</sup>, D. Tumas<sup>2</sup> and V. J. Kadambi<sup>2</sup>. <sup>1</sup>Comparative Medicine, Millennium Pharmaceuticals, Inc., Cambridge, MA and <sup>2</sup>Drug Safety and Disposition, Millennium Pharmaceuticals, Inc., Cambridge, MA.

Non-clinical testing strategies predict with a high degree of confidence functional perturbations of small molecules prior to clinical testing. Radiotelemetry in conscious, freely moving animals offers a humane way of measuring adverse cardiovascular, respiratory and thermoregulation effects which may have relevance to human safety. We validated the use of a radiotelemetry system (Data Sciences International, St. Paul, MN) in male Sprague-Dawley rats (Charles River Laboratories, Portage, MI) at our facility using reference compounds oxotremorine, scopolamine, captopril and phenylephrine to measure effects on blood pressure, heart rate, core body temperature and baroreceptor reflex. Telemetered male Sprague-Dawley rats received subcutaneous administration of oxotremorine (0.2mg/kg). Methyl scopolamine (1.0mg/kg) was co-administered to block oxotemorine's peripheral effects. This central muscarinic stimulation resulted in elevated blood pressure (+30mmHg) and heart rate (+148BPM) with a decrease in body temperature (-2°C) that persisted 6 hours post administration. Captopril, an angiotensin converting enzyme inhibitor, was administered orally at dosages of 25mg/kg and 50mg/kg resulting in a 23 and 27mmHg decrease in mean arterial pressure respectively. Phenylephrine, an α-adrenergic receptor agonist, was administered intravenously through a jugular vein catheter in incremental doses of 1-15ug/kg to determine the effects on baroreceptor reflex sensitivity. Phenylephrine administration resulted in an acute and reversible increase in mean arterial pressure, with a concomitant reflex decrease in heart rate via stimulation of the baroreceptors. We concluded from our studies that radiotelemetry accurately captures physiologic data and is a valuable tool for assessing safety of novel small molecules.

## 988 MECHANISM FOR SHORTENING PT AND APTT IN DOGS AND RATS: EFFECT OF FIBRINOGEN ON PT AND APTT

M. Kurata, Y. Sasayama, N. Yamasaki, I. Kitazawa, Y. Hamada and I. Horii. Worldwide Safety Sciences, Pfizer Global Research & Development, Nagoya Laboratories, Pfizer Inc., Taketoyo, Aichi, Japan.

Although shortened prothrombin time (PT) and activated partial thromboplastin time (APTT) are frequently observed in pre-clinical toxicity studies, it has not been fully explored. In recent studies on human clinical pathology, shortened APTT was reported to associate with increased coagulation factors, and to be possibly useful to predict thrombosis. It is significant to investigate the mechanism for shortening PT and APTT in laboratory animals for the drug safety evaluation. The present study was therefore undertaken to investigate the mechanisms for shortening PT and APTT, using citrated plasma from dogs and rats in vitro, especially with a focus on increasing fibrinogen levels. For the method, PT and APTT were measured in plasma from dogs and rats, under various concentrations of fibrinogen. Clottable activity of fibrinogen was confirmed by measuring the thrombin time (TT). Furthermore, thromboelastogram (TEG) was used to evaluate the hypercoagulable status. As the results, (1) when purified canine fibrinogen was added to citrated canine plasma at the final concentrations of 2, 4 and 8 mg/mL (as added fibrinogen concentration), PT and APTT were significantly shortened. An increased clottable fibrinogen in the test tube was confirmed by a markedly shortened TT. Canine fibrinogen at a final concentration of 4 mg/mL induced an increased rate of clot formation and increased the maximum amplitude on the TEG, indicating a state of hypercoagulation. (2) In the case of citrated rat plasma, while purified rat fibrinogen had no effect on PT or APTT at the final concentrations of 2, 4 and 8 mg/mL, it did shorten TT. The TEG also showed hypercoagulation at a fibrinogen concentration of 1 mg/mL in rats. The present results indicate that an increased concentration of fibrinogen is associated with shortening PT and APTT in dogs, but not in rats.

## 989 A FLOW CYTOMETRIC ASSAY THAT PERMITS INTEGRATION OF CHROMOSOMAL DAMAGE ASSESSMENT WITH ROUTINE TOXICITY TESTING.

J. T. MacGregor<sup>1</sup>, M. E. Bishop<sup>2</sup>, <u>S. Dertinger</u><sup>3</sup>, J. McNamee<sup>7</sup>, <u>M. M. Moore</u><sup>2</sup>, A. Aidoo<sup>2</sup>, S. Harper<sup>4</sup>, R. Frobish<sup>5</sup> and M. Hayashi<sup>6</sup>. <sup>1</sup>USFDA NCTR, Rockville, MD, <sup>2</sup>USFDA NCTR, Jefferson, AR, <sup>3</sup>Litron Laboratories, Rochester, NY, <sup>4</sup>USFDA CFSAN, Laurel, MD, <sup>5</sup>USFDA CVM, Laurel, MD, <sup>6</sup>NIHS, Tokyo, Japan and <sup>7</sup>Health Canada, Ottawa.

The erythrocyte micronucleus assay, a "core" regulatory assay for assessment of genetic damage, is generally based on microscopic evaluation of micronucleated (MN) bone marrow (BM) reticulocytes ("retics") because the spleen removes MN

erythrocytes from the peripheral circulation in most species. We evaluated a flow cytometric method (Dertinger et al., Mutat. Res. 464: 195-200, 2000) that minimizes the effect of splenic selection in the rat, dog, and human, and requires only  $\mu l$ quantities of peripheral blood (PB). Young retics are labeled with FITC-anti-CD71 (transferrin receptor) and micronuclei with propidium iodide (with RNase treatment). We compared this method with microscopic scoring using standard or supravital acridine orange staining, using samples from normal and splenectomized Sprague-Dawley rats treated with a clastogen (cyclophosphamide, CP) or a spindle disrupter (vinblastine). We also report data that demonstrate the sensitivity of the flow cytometric assay in the beagle dog and human. In rats, the flow method did not eliminate the spleen effect on induced MN retic frequency, but spontaneous MN retics were found to be relatively insensitive to the spleen effect. Thus, effects on splenic efficiency would not lead to false positive responses. In eusplenic animals the dynamic range of induced effects was smaller in PB than in BM, but the flow method had superior counting statistics, lower variability, and higher sensitivity than manual scoring. MN retics derived from fragments or whole chromosomes (CP- vs. vinblastine-induced) behaved similarly. With appropriate validation, it appears flow cytometric assessment of micronucleus induction can be integrated into routine testing, eliminating the need for a separate bioassay.

## 990 EFFECTS OF SUBCHRONIC DERMAL APPLICATION OF BREAK-FREE CLP® IN CD-1 MICE.

D. P. Arfsten<sup>1</sup>, A. R. Thitoff<sup>1</sup>, E. W. Johnson<sup>1</sup>, A. Jung<sup>1</sup>, W. W. Brinkley<sup>2</sup>, D. Schaeffer<sup>3</sup> and K. R. Still<sup>1</sup>. <sup>1</sup>Naval Health Research Center Toxicology Detachment, Wright-Patterson AFB, OH, <sup>2</sup>Operational Toxicology, Air Force Research Laboratory, Wright-Patterson AFB, OH and <sup>3</sup>Department of Veterinary Biosciences, University of Illinois at Urbana Champaign, Urbana, IL.

Studies were conducted to determine the biological effects of subchronic dermal application of Break-Free CLP to the clipped backs of CD-1 mice. Break-Free CLP® is a military and commercial weapons cleaning compound. Groups of 20 CD-1 mice were treated topically with Break-Free (neat), deionized H<sub>2</sub>O, 2.5% croton oil (CO) in acetone (positive control), and 99% acetone (vehicle control). Materials were applied to a clipped 2 x 3 cm application site located directly behind the shoulder blades,  $50\,\mu\text{L/application}$ ,  $3\,\text{times/week}$  for  $90\,\text{days}$ . Application sites were left uncovered after treatment; the application site was clipped free of hair once a week every 2 weeks. Mice were sacrificed on Day 90 and histopathology and clinical chemistry profiles were compared between treatment groups. Moderate, persistent erythema occurred in greater than 50% of mice treated with CO; 25% of mice treated with Break-Free developed moderate and persistent erythema. Edema was evident for animals treated with CO but not for animals treated with Break-Free. Serum alkaline phosphatase (ALKP) activity was significantly decreased in animals treated with Break-Free and CO; mean serum glucose was significantly lower for animals treated with CO versus controls. Percent lymphocytes were significantly lower and percent segmented lymphocytes were significantly elevated for animals treated with Break-Free or CO. Histopathological analysis of application site skin sections showed that hyperplasia, hyperkeratosis, and moderate inflammatory cell infiltration was predominate for animals treated with Break-Free or CO; some ulceration was also evident and occurred more frequently for animals treated with CO. mRNA expression analysis of skin and liver sections from animals treated with Break-Free identified a 2-fold or greater increase in gene products involved in irritation response and cell cycle progression.

## 991 SUBCHRONIC TOXICITY 90-DAY ORAL GAVAGE STUDY OF 8-2 TELOMER B ALCOHOL IN RATS.

G. S. Ladics<sup>1</sup>, G. L. Kennedy<sup>1</sup>, J. O'Connor<sup>1</sup>, N. Everds<sup>1</sup>, S. R. Frame<sup>1</sup>, S. Gannon<sup>1</sup>, R. Jung<sup>2</sup>, H. Iwai<sup>3</sup> and S. Shin-ya<sup>4</sup>, <sup>1</sup>DuPont Haskell Laboratory, Newark, DE, <sup>2</sup>Clariant, GmbH, Sulzbach, Germany, <sup>3</sup>Daikin Industries, Ltd., Osaka, Japan and <sup>4</sup>Asahi Glass Co., Ltd., Tokyo, Japan.

8-2 Telomer B Alcohol is a fluorinated chemical intermediate used to manufacture specialty polymers and surfactants. The potential subchronic toxicity and the reversibility of the effects of this chemical were evaluated following approximately 90 days of oral gavage dosing to Crl:CD®(SD)IGS BR rats. A complete toxicological profile including neurobehavioral assessments and hepatic β-oxidation were conducted at selected intervals and a group of rats was included for a 90-day post-dosing recovery period. Dose levels tested were 0 (control), 1, 5, 25, and 125 mg/kg/day. No test-substance-related mortality occurred. Rats at 125 mg/kg/day developed striated teeth such that these animals were switched to ground chow on test day 77. No treatment-related alterations in body weight, food consumption, neurobehavioral parameters, or hematology/clinical chemistry were found. Hepatic β-oxidation was increased in males at 125 mg/kg/day and in females at 25 mg/kg/day. In both males and females, plasma fluoride levels were significantly increased at 125 mg/kg/day and urinary fluoride was elevated at ≥ 5 mg/kg/day. Degeneration/disorganization of enamel organ ameloblast cells was observed in males, but not females at 125 mg/kg/day. Liver weight increases accompanied by focal hepatic necrosis were seen at both 25 and 125 mg/kg/day in males and

chronic progressive nephrotoxicity occurred in females administered 125 mg/kg/day. With the exception of the hepatocellular necrosis observed in males administered 125 mg/kg/day and the incidence and severity of chronic progressive nephropathy in the 125 mg/kg/day female group, which increased after 3 months, all other changes showed evidence of reversibility. The no-observed-adverse-effect level for the 90-day study was 5 mg/kg/day. This study was sponsored by the Telomer Research Program.

## 992 SAFETY OF TINOSORB® M ACTIVE, A NEW SUNSCREEN INGREDIENT FOR BROAD SPECTRUM UV PROTECTION.

W. F. Salminen<sup>1</sup> and J. R. Plautz<sup>2</sup>. <sup>1</sup>Product Safety and Regulatory, Ciba Specialty Chemicals Corporation, High Point, NC and <sup>2</sup>PSR, Ciba Specialty Chemicals, Basel, Switzerland.

Tinosorb® M Active (MBBT; CASRN 103597-45-1: 2, 2'-methylenebis-(6-(2Hbenzotriazol-2-yl)-4-(1, 1, 3, 3-tetramethylbutyl) phenol)) is a new active sunscreen ingredient that provides broad spectrum UVA and UVB protection and is very photostabile. MBBT is currently approved for use as an active sunscreen ingredient in the European Union, Switzerland, Australia, and many other countries with the major exception being the US due to the high regulatory hurdles for registering new active sunscreen ingredients. We present here the results showing MBBT to be safe as an active sunscreen ingredient when tested in standard (OECD) protocols. MBBT is of low acute toxicity with rat dermal and oral LD50 values >2, 000 mg/kg. MBBT caused minimal irritation when applied to rabbit eyes and skin. MBBT did not cause skin sensitization, photoirritation, or photosensitization when applied to the skin of guinea pigs or human volunteers. MBBT was not genotoxic or mutagenic in standard in vitro and in vivo assays and in tests using UV exposure protocols. In an in vitro percutaneous absorption assay, MBBT exhibited low penetration (0.14%) across human skin. Rats given doses of radiolabelled MBBT showed very low systemic uptake after a single oral dose (<1% of dose) or after dermal dosing (<1% of dose). În 90-day oral gavage and dermal dosing studies in the rat the NOEL was 1, 000 mg/kg/day, which was the highest dose tested (HDT) in each study. In a developmental toxicity study, the maternal and fetal NOEL was 1, 000 mg/kg (HDT). MBBT did not show binding affinity or competitive inhibition of natural hormone binding to either estrogen or androgen receptors in vitro and effects did not occur in the uterotrophic assay with immature rats given MBBT orally. Additional safety tests are currently underway to assess the long-term photo(co)carcinogenicity and dermal carcinogenicity of MBBT. In conclusion, MBBT is a safe UV filter sunscreen ingredient that can be used to make highly photostabile, broad-spectrum sunscreens.

## 993 VAPOR INHALATION TOXICITY STUDY OF HEXAMETHYLCYCLOTRISILOXANE IN THE RAT.

P. A. Jean, J. M. Tobin and K. P. Plotzke. Dow Corning Corporation, Auburn, MI. Hexamethylcyclotrisiloxane (D3), a low molecular weight silicone used primarily as an intermediate in the synthesis of other silicone materials, was evaluated in an enhanced repeated-exposure toxicity study based on OECD Test Guideline #422 and USEPA Test Guideline 870.360. The study design included reproductive, developmental, and neurotoxicity screening assays. Male and female Sprague-Dawley rats were exposed by whole-body inhalation to 0, 100, 500, and 2500 ppm D3 vapor (6 h/day) for up to 39 days. Exposure to D3 vapor was well tolerated. Hepatomegaly and centrilobular hepatocellular hypertrophy was observed in both sexes exposed to 2500 ppm D3. Protein droplet nephropathy was diagnosed in males exposed to 500 and 2500 ppm D3. An încrease in kidney weight and other changes in clinical chemistry parameters were consistent with this finding. In males exposed to 2500 ppm D3 there was a decrease in absolute epididymal weight (10%) and in the absolute and relative seminal vesicle weight (≈30%). Slight seminal vesicle atrophy was identified in 40% of the males. The testes and epididymides were histologically normal. Female rats exposed to 2500 ppm D3 demonstrated decreased litter size (33%), litter weight (27%) and implantation site number (33%). Exposure to 2500 ppm D3 reduced locomotor activity in both sexes and reduced reactivity to handling in females. This study has demonstrated that exposure to high D3 vapor concentrations can elicit adaptive (liver), pathologic (protein droplet nephropathy) and functional/behavioral (reproductive capacity and locomotor) effects in Sprague-Dawley rats. (Study Sponsor: Silicones Environmental, Health and Safety Council of North America)

## 994 CHRONIC TOXICITY ASSESSMENT OF GENISTEIN IN SPRAGUE DAWLEY RATS.

B. Delclos<sup>1</sup>, C. Weis<sup>1</sup>, D. Doerge<sup>1</sup>, G. Olson<sup>2</sup>, R. Trotter<sup>2</sup>, N. Sadovova<sup>2</sup> and R. Newbold<sup>3</sup>. <sup>1</sup>NCTR, Jefferson, AR, <sup>2</sup>Pathology Associates, Jefferson, AR and <sup>3</sup>NIEHS, Research Triangle Park, NC.

Genistein is the major soy isoflavone and has been of interest as a possible beneficial agent in cancer prevention and the alleviation of adverse consequences of menopause. High human exposures can occur as a result of consumption of soy in-

fant formula and dietary supplements. In the present experiment, 5, 100, and 500 ppm genistein aglycone were administered in a soy- and alfalfa-free diet (Purina 5K96) to Sprague-Dawley rats during three exposure windows: Group 1, conception to 2 years; Group 2, conception to 140 days, followed by control diet to 2 years; Group 3, conception to 21 days, followed by control diet to 2 years. Exposure was monitored by serum genistein measurements in separate animals and found to be considerably lower during the nursing period than during the in utero or direct ingestion periods. Body weight gain in females was depressed in the 500 ppm group during periods of genistein consumption, but recovered when the compound was removed. Body weight depression was less in males than females, and there were no treatment-related gross or microscopic lesions in the aged males. The occurrence of aberrant estrous cycles with age started earlier than controls at 500 ppm in Groups 1 and 2 and at all doses in Group 3. Histopathological assessment of lesions, which is pending final review, indicated, as expected for Sprague-Dawley rats, a high spontaneous incidence of benign and malignant mammary tumors in control females and high incidences of pituitary adenomas in control animals of both sexes. There was no treatment effect on pituitary tumors in either sex. Apparent treatment-related effects were a reduction of female mammary gland fibroadenomas at 500 ppm in Group 1 and a marginal increase in mammary gland adenocarcinomas at 500 ppm in Groups 1 and 3. The relevance of these findings for humans consuming high levels of soy-derived products warrants further consid-

## 995 HEPAVIR B, A CYP3A4-ACTIVATED PRODRUG OF PMEA, SHOWED BETTER SAFETY THAN HEPSERA IN PRE-CLINICAL STUDIES.

D. Vitarella, S. Dadgostari and C. Lin. Drug Dev., ICN Pharmaceuticals, Inc., Costa Mesa, CA.

Hepsera (adefovir dipivoxil), a plasma esterase-activated prodrug of PMEA has been recently approved for the treatment of hepatitis B virus (HBV). However, its recommended dose is sub-optimum due to dose limiting nephrotoxicity. Hepavir B is also a prodrug of PMEA. It is metabolized primarily by CYP3A4 in the liver, but not in the kidney, resulting in 4-fold distribution of PMEA into the liver vs. kidney. Thus, hepavir B may be safer than hepsera. The safety of Hepavir B in general toxicity, genetic toxicity, and safety pharmacology studies was determined. A 28-Day study was conducted in rats at oral doses of 0-300 mg/kg and in monkeys at doses of 0-180 mg/kg. Genetox was evaluated in the Ames, mouse lymphoma, chromosome aberration assay in CHO and human lymphocytes, and in a mouse micronucleus test. Safety pharmacology evaluation included neuropharmacology in rats, cardiovascular in monkeys, renal in rats, respiratory in rats, and GI in mice. The 28-day study in rats demonstrated renal and hepatic effects in males only at hepavir B doses of ≥100 mg/kg. No toxicity was seen in females given up to 300 mg/kg. In contrast, a 28-day study in monkeys demonstrated acceptable safety at doses up to 60 mg/kg. Overall clinical pathology, cardiovascular, ophthalmic, and gross pathology were normal. Previously published data on hepsera indicate toxicity at doses of 12 mg/kg in rats and 8 mg/kg in monkeys. Hepavir B was marginally positive in the lymphoma assay and the CHO test. However it was negative in the Ames test, in the human lymphocyte assay and the micronucleus test in mice. Hepavir B was well tolerated by animals in safety pharmacology evaluations. In conclusion, Hepavir B was well tolerated in rats up to 30 mg/kg, and monkeys up to 60 mg/kg. While the chromosome aberration assay and mouse lymphoma assay were equivocal to positive for genotoxicity, the in vivo mouse micronucleus assay was negative. Hepavir B was well tolerated in safety pharmacology Studies. Compared to published data on Hepsera, hepavir B appears to be a safer candidate for HBV treatment.

# 996 INTRAPERITONEAL ADHESION FORMATION FOLLOWING IMPLANTATION OF HERNIA REPAIR GRAFT MATERIALS:COMPARISONS OF PERMACOL<sup>TM</sup> WITH SURGIPRO® AND SURGISIS GOLD<sup>TM</sup> IN THE RAT

S. L. Saynor<sup>1</sup>, G. Hale<sup>1</sup>, S. Bloor<sup>2</sup> and C. Curtis<sup>2</sup>. <sup>1</sup>Covance Laboratories Ltd., Harrogate, United Kingdom and <sup>2</sup>Tissue Science Laboratories Plc, Leeds, United Kingdom. Sponsor: D. Everett.

Hernia repair grafts commonly used in abdominal surgery can cause potentially dangerous adhesions. A novel biomaterial, a cross-linked stabilised porcine dermal implant (Permacol<sup>TM</sup> Tissue Science Laboratories Plc) is marketed in the US and Europe for hernia repair and is currently undergoing further investigation to demonstrate its effectiveness in comparison with existing products. Two separate studies in an experimental rat model assessed intraperitoneal adhesion formation following implantation of Permacol<sup>TM</sup> and compared the performance of two currently marketed repair materials, SurgiPro® and Surgisis Gold<sup>TM</sup>. Under anaesthesia, 1.5 cm x 1 cm samples of Permacol<sup>TM</sup>, Surgipro® and Surgisis Gold<sup>TM</sup> were sutured to the left and right inner abdominal wall of Sprague-Dawley rats following

a midline incision. After 1 and 3 months, the rats were sacrificed and the extent and severity of abdominal adhesions was assessed using a scoring system (0 to 3). In all cases the Permacol<sup>TM</sup> scores were significantly lower than the SurgiPro® and Surgisis Gold<sup>TM</sup> scores (P<0.05). Sections through the repair materials were examined histologically. Histology of the Permacol<sup>TM</sup> sites at 1 and 3 months showed cell infiltration across the implant following the natural pores in the material and 'keying' of the Permacol<sup>TM</sup> into the peritoneum. SurgiPro® sites on both occasions had a classical foreign body reaction with encapsulation and gross adhesions to bowel. Histology of the Surgisis Gold<sup>TM</sup> showed various degrees of fragmentation, the original collagen being separated by the inflammatory reaction and cystic spaces. These results demonstrated that adhesion formation was not as frequent or as severe when Permacol<sup>TM</sup> was sutured to the inner abdominal wall.

997

INTRODUCTION OF THE *IN VIVO* MINI-TOX STUDY AS AN EFFECTIVE TOOL TO IMPROVE CONFIDENCE IN SAFETY IN THE EARLY STAGE OF DRUG DEVELOPMENT.

Y. Sato, M. Nagata, T. Mako, H. Yamada and <u>I. Horii</u>. Worldwide Safety Sciences, PGRD Nagoya Laboratories, Pfizer Inc., Aichi, Japan.

Pharmaceutical companies are frequently required to perform a variety of toxicity assays in the early stages of drug development. This presentation will show a novel in vivo short-term toxicity assay called the in vivo mini-Toxicology study, which was developed at our Nagoya laboratories. In utilizing standard clinical administration routes, normal toxicity studies require relatively large amounts of bulk and large numbers of test animals. However, often only limited exposure to a test compound is required to detect an adverse effect(s) in an in vivo study, which is important when dealing with limited, precious bulk. Using jugular-vein cannulated (JVC) rats allows blood for toxicokinetics (TK) evaluation to be collected through the cannula for oral administration or s.c./i.p. injection studies and also allows i.v./infusion administration to be performed with relatively little stress to the test animal. In addition to routine toxicity study items, we can add special examinations to the in vivo mini-Toxicology studies in consideration of unique properties of a test compound. Among them we introduce two optional batteries of non-standard test items, which can capture other relevant data simultaneously. The first of these involves neurobehavioral examinations based on a functional observation battery (FOB) and/or locomotor-activity quantitation called Motor Activity. The second is a cardiovascular examination using non-heating tail cuff-type sphygmomanometry, which was recently developed in Japan (BP monitor for mice & rats Model MK-2000, Muromachi Kikai Co., LTD.). These special examination items can be invaluable in revealing any relationship between TK and functional or toxicity changes that may be present at the onset of compound toxicity, which allows greater ability to interpret in vivo results. The presentation will illustrate the items employed in the in vivo mini-Toxicology study, as well as data obtained from validation studies using chlorpromazine, scopolamine, R-+-Win55, 212-2 and norepinephrine in JVC rats.

998

IS 20% INHIBITION OF HERG CURRENT SUFFICIENT FOR PREDICTING FOR *IN VIVO* QT INTERVAL PROLONGATION.

C. Doherty, C. Claiborne, T. Glyptis, M. Holmqvist, M. Stewart, P. Eddy, V. Sasseville, <u>C. Alden</u> and V. Kadambi. *Millennium Pharmaceuticals, Inc., Cambridge, MA.* 

The recent withdrawal of several compounds from the market has led to a call for early testing of compounds for potential to prolong the QT interval in vivo. Inhibition of I<sub>Kr</sub>, the major current responsible for ventricular repolarization, leads to prolongation of the QT interval and is associated with Torsades de Pointes (TdP). Binding to the HERG (human ether à go-go related gene) channel by small molecules has been linked to in vivo QT prolongation and TdP in humans. A competitive binding assay, utilizing membranes from HEK 293 cells stably transfected with the HERG channel cDNA and 3H-dofetilide, provides a method of screening for interactions with the HERG channel. Inhibition curves, determined by test compound inhibition of 3H-dofetilide binding, were used to determine both IC<sub>50</sub> and IC<sub>20</sub> values. K<sub>0.5</sub> results from this binding assay showed a good correlation with published electrophysiology values (R2= 0.83, 36 marketed compounds). Traditionally, assessment of HERG inhibition and prediction for *in vivo* QT prolongation has relied on IC50 values. A recent manuscript by Redfern et al. (Cardiovas Res, 2003) used ratios of electrophysiology IC<sub>50</sub> and unbound therapeutic plasma concentration to categorize marketed compounds and correlate safety ratios with clinical incidences of QT interval prolongation and TdP. Calculation of safety ratios using binding  $K_{0.5}$  and  $K_{0.2}$  categorized marketed compounds in a similar manner. The HERG binding and electrophysiological methods identified false positive and negative compounds, such as verapamil and amiodarone respectively, with similar efficiencies. These results suggest that 20% inhibition of binding to the HERG channel is a sensitive predictor for compounds to prolong the QT interval in vivo.

999

THE COMMON MARMOSET (CALLITHRIX JACCHUS) AS A MODEL IN TOXICOLOGY: REFERENCE CONTROL DATA AND COMPARISON WITH MACAQUES.

S. Korte, University. Zuehlke, J. Kaspareit, S. Friedrichs-Gromoll, W. Mueller, F. Vogel and G. Weinbauer. *Covance Laboratories GmbH, Muenster, Germany.* Sponsor: P. Thomas.

Marmosets have become an important nonhuman primate model as an alternative primate species in the safety evaluation of new drugs (1). Based upon small body size, marmosets have gained particular value for toxicity studies with biotechnology products where compound supply is limited, and there is regulatory acceptance for this species (2). Here we present reference values and ranges for a large array of relevant diagnostic parameters for the normal male and female marmoset, and a comparison is made to macaque monkeys. These reference values are essential for the analysis and interpretation of findings during toxicity studies in the marmoset model. Overall, data were compiled from more than one thousand animals. Among the parameters collected were mortality and morbidity, body and organ weights, clinical chemistry and urine analysis, hematology, cardiology and blood pressure, ophthalmoscopy, respiration, neurology. reproductive physiology and the incidence of spontaneous histopathological lesions. When compared to macaques, marmosets are more sensitive to stress and mortality rate unrelated to test article administration was 2-3%. Digestive problems with secondary body weight loss were seen as the major cause of death, followed by acute infections following minor injuries. Respiratory rate was about two fold and heart rate about 2-3 fold higher than in macaques. Liver enzyme activity was 10-14 fold lower in the marmoset. Further differences were seen for hematology parameters, electrocardiography data, ocular and histopathological background lesions. In summary, an extensive reference data base for a large number of relevant diagnostic parameters is available that supports the use of marmosets in toxicology. 1. Zuehlke University, G Weinbauer 2003 Toxicol Pathol 31:123-127; 2. Smith D, P Trennery, D Farningham, J Klapwijk 2001 Lab. Anim 35:117-130.

DERMAL DOSING OF NEONATAL RATS: EFFECT OF MOTHER-INFANT SEPARATION AND OCCLUSIVE DOSING

J. F. Barnett<sup>1</sup>, D. B. Learn<sup>1</sup>, A. M. Hoberman<sup>1</sup>, T. G. Osimitz<sup>2</sup> and University. Vedula<sup>3</sup>. <sup>1</sup>Charles River Discovery and Development Services, Argus Division, Horsham, PA, <sup>2</sup>Science Strategies, LLC., Charlottesville, VA and <sup>3</sup>S.C. Johnson & Sons, Inc., Racine, WI.

Hazard identification studies for dermal application products intended for use in young children should be conducted using this exposure route and test systems of the same relative developmental status. Mother-Infant separation (MIS) prevents test substance (TS) ingestion by the mother and oral exposure via the mother's milk. An occlusive wrap fixes the TS in place and prevents oral ingestion from grooming. However, identification of any MIS and/or occlusion effects is critical. MIS and occlusive dermal dosing (six hours daily, PNDs 9 to 20) were used in four separate groups: pups remaining with the dam (Group I); pups separated, but untreated (Group II); separated, treated with water and occluded (Group III); separated, treated with TS and occluded (Group IV). Daily measurements included body weights and clinical observations. On PND 21, a Detailed Clinical Observation (DCO) evaluation was performed on each pup. No adverse clinical signs were observed. Body weight data indicated: 1) MIS alone had no effect on the pups (Group II v. I); 2) the occlusive procedure caused a statistically significant reduction in body weight gain (Group III v. II); 3) males receiving TS showed statistically significant reduction in body weight gain during PNDs 18 to 21, as compared with pups administered water (Group IV v. III). The use of MIS with occlusive dermal dosing allows precise TS exposure of young pups with only a slight reduction in body weight gain and without adverse clinical responses. This technique provides TS evaluation using age-appropriate test systems and minimizes inappropriate TS exposure.

## 1001 TAMPON RISK ASSESSMENT: A COMPREHENSIVE APPROACH.

A. E. Hochwalt. Procter & Gamble, Cincinnati, OH.

The safety of Tampax tampons is evaluated by a comprehensive, phased, risk assessment approach. Tampon risk assessment (TRA) builds on the principles of risk assessment by including vaginal and tampon-specific endpoints. The TRA assures that new tampons are safe as labeled and minimize the risk of Toxic Shock Syndrome (TSS). TRA begins with evaluation of new tampons to determine design, composition, and/or exposure modifications versus current tampons. TRA then guides the risk assessor to consider potential effects that may occur when using the modified tampon (effects on vaginal condition [vaginal abrasion, ulceration, or

laceration], vaginal microflora, risk of TSS, and local or systemic toxicity) and what data are necessary to support use of the tampon at each product development phase. Historical or newly generated in vitro or limited toxicity data support consumer studies. Robust clinical and toxicological data support commercialization. The assessment of Tampax Pearl tampons followed the TRA. Pearl uses the same materials with similar exposures as current Tampax tampons, but has a new shape and absorbent braid. Historical material safety and TSS epidemiology data supported consumer studies; commercialization required additional habits and practices, vaginal condition, and vaginal microflora data to address the design changes and confirmation that TSS risk should not be affected. Studies evaluated Pearl for potential to affect growth and cell density of sentinel vaginal microorganisms in vitro, growth of a TSST-1-producing strain of S. aureus and TSST-1 toxin production, vaginal condition, and vaginal microflora population and cell density (via inuse clinical studies and clinical assessment of normal vaginal microflora of the lower genital tract). The results of these studies indicated that Pearl did not promote or inhibit growth or cell density of vaginal microflora, promote TSST-1 toxin production, alter consumer habits, or adversely affect vaginal condition versus currently marketed tampons. Therefore consumers may use Tampax Pearl as safely as current Tampax tampons.

#### 1002

COMPARATIVE REPEATED-DOSE TOXICITY OF LIPOSOME-ENCAPSULATED VINCRISTINE SULFATE AND FREE VINCRISTINE SULFATE IN RATS.

P. M. Tam<sup>1</sup>, R. Oshanek<sup>1</sup>, N. Yasuda<sup>1</sup>, R. Namdari<sup>1</sup>, A. Janse<sup>1</sup>, O. Smals<sup>1</sup>, L. Armer<sup>2</sup>, J. Daniels<sup>3</sup> and C. Flowers<sup>1</sup>. <sup>1</sup>Preclincal Development, INEX Pharmaceuticals Corporation, Burnaby, BC, Canada, <sup>2</sup>CTBR Bio-Research Inc., Senneville, QC, Canada and <sup>3</sup>Cantox Health Sciences International, Mississauga, ON, Canada.

Liposomal vincristine (LV) is vincristine encapsulated into liposomes composed of sphingomyelin and cholesterol (55:45). It was designed to alter the PK and tissue distribution of vincristine (VCR) in order to achieve improved anti-tumor activity. LV is currently being evaluated for the treatment of multiply relapsed or refractory NHL disease. In the present study, the repeated-dose toxicity of LV was evaluated in Sprague-Dawley rats. Rats (15/sex/group) were administered weekly doses of LV (1, 2 and 3 mg/m<sup>2</sup>) or VCR (2 mg/m<sup>2</sup>) for a total of six treatment cycles. In addition, the liposomal carrier was evaluated by administration of drug-free liposomes corresponding to 3 mg/m<sup>2</sup> LV. LV induced dose-dependent toxicities that included body weight loss, peripheral neurotoxicity and toxicities to the bone marrow, developing dentition, and testes. No CNS toxicity was observed. Peripheral neurotoxicity was associated with secondary skeletal muscle injury. Dental toxicity was manifested as broken incisors that were associated with lesions to the abnormal dentition and lesions to ondontoblasts. Qualitatively VCR elicited the same toxicity profile as LV. However VSLI was less toxic to the bone marrow but was somewhat more toxic to the PNS. Toxicokinetic evaluation demonstrated that VSLI mediated significantly prolonged duration of exposure to vincristine than VCR. Drug-free liposomes were not toxic to rats at 60 mg/m<sup>2</sup>. In conclusion, the toxicity of VSLI and VCR was qualitatively similar and any differences in the degree of toxicity were attributed to the prolonged duration of exposure mediated by LV.

#### 1003

CONSTRUCTION OF A HUMAN ADVERSE EFFECTS DATABASE FOR MODELING QUANTITATIVE STRUCTURE-ACTIVITY RELATIONSHIPS (QSARS).

N. L. Kruhlak<sup>1</sup>, J. L. Weaver<sup>2</sup>, R. Benz<sup>1</sup>, <u>J. F. Contrera</u><sup>1</sup> and E. J. Matthews<sup>1</sup>.

<sup>1</sup>USFDA, Rockville, MD and <sup>2</sup>USFDA, Laurel, MD.

FDA/CDER's Spontaneous Reporting System (SRS) database contains reports of the post-market adverse effects of pharmaceuticals in humans not detected during pre-market trials. The database contains over 1.6 million ADR reports for 8620 drugs and biologics that are listed for 1191 Coding Symbols for Thesaurus of Adverse Reaction (COSTAR) terms of adverse effects. FDA/CDER's Informatics and Computational Safety Analysis Staff (ICSAS) has developed a database specifically for modeling quantitative structure-activity relationships (QSARs). The ICSAS Adverse Effects database links the trade names of pharmaceuticals to generic names and molecular structures for a subset of 1515 organic chemicals that are suitable for modeling with commercially available QSAR software packages. ADR reports from the SRS database are pooled for the first five years that a pharmaceutical was marketed. To estimate patient exposure during this period, the number of cases shipped for each pharmaceutical were used as a denominator, resulting in the creation of the Adverse Effect Index (AEI), where AEI = (# ADR reports/# cases shipped) × 1, 000, 000. We have identified the optimal conditions for defining a significant adverse effect by generating QSAR models for a subset of toxicologically related COSTAR endpoints using the MCASE/MC4PC software package in conjunction with a set of human expert data analysis rules. A pharmaceutical defined as active for a single COSTAR endpoint is characterized by ≥4 ADR reports, >20, 000 cases shipped and an AEI ≥4.0 during the first five years of marketing.

Furthermore, test chemicals evaluated as active must contain a statistically significant structural alert, called a decision alert, at two or more toxicologically related endpoints. We also report the use of a combination QSAR module which pools observations from two or more toxicologically related COSTAR term endpoints to provide signal enhancement for poorly represented adverse effects.

#### THE FERRET AS A MODEL OF EMETIC SENSITIVITY.

S. Mason, H. Penton and P. Mansell. *CTBR, Senneville, QC, Canada.* Sponsor: M. Vezina.

In order to provide an alternative to the established ipecac model in dogs for emesis research and testing of anti-emetic agents using smaller animals in a GLP compliant setting, an emetic sensitivity model was established in the ferret using several common emetic compounds with differing actions. Male ferrets (Mustela putorius furo), Marshall Farms, NY, approximately 1.2 kg were administered Cisplatin (10 mg/kg IV) or Ipecac Syrup USP (1 mL/kg PO) to assess an emetic response. Animals were food deprived overnight, and approximately 30 minutes prior to dosing, received ~50g commercially available cat food. Following dosing, animals were monitored and observed for episodes of emesis. The time prior to the first episode of retching or vomiting was recorded (latent period), together with the total number of retching and vomiting periods through the observation period. Episodes of retching and vomiting, characterized by rhythmic abdominal contractions with or without oral expulsion of solid or liquid material from the gastrointestinal tract were observed following both test article doses, the latent period for Cisplatin treated animals being significantly longer than that of Ipecac treated ferrets. The total number of retching and vomiting episodes for both sets of animals was similar, although resolution of effects was much earlier for Ipecac treated animals, consistent with its acute effects seen in the clinical setting. For assessment of anti-emetic activity, animals were treated and observed in the same manner as the emetic response assessment, however approximately one hour prior to vehicle/test article dosing received 0.5 mg/kg Ondansetron PO. Pretreatment with the 5-HT3 receptor antagonist Ondansetron completely inhibited the vomiting response to both Ipecac and Cisplatin, again consistent with the clinical use of this compound in treatment of emesis induced by chemotherapeutic agents. This model is therefore considered acceptable for use as an indicator of potential emetic or anti-emetic activity, in combination with an appropriate positive control.

#### 1005

EFFECTS OF 3, 3', 4, 4'-TETRACHLOROBIPHENYL (PCB 77) ON THE DISTRIBUTION AND METABOLISM OF SELENIUM IN RATS.

D. N. Stemm<sup>2</sup>, L. W. Robertson<sup>3</sup>, J. C. Tharappel<sup>1</sup> and H. P. Glauert<sup>1</sup>. <sup>1</sup>Grad. Center for Nutritional Sciences, University of Kentucky, Lexington, KY, <sup>2</sup>Graduate Center for Toxicology, University of Kentucky, Lexington, KY and <sup>3</sup>Department of Occupational and Environmental Health, University of Iowa, Iowa City, IA.

Selenium is an essential element that may influence the development of cardiovascular diseases and cancer. Environmental contaminants, like polychlorinated biphenyls (PCBs), produce oxidative stress, reduce selenium utilization, and affect antioxidant systems, including glutathione peroxidase, a selenoprotein. PCB 77, a dioxin-like, coplanar PCB, has been shown to reduce glutathione peroxidase activity in the liver. The aim of this study was to determine the effect of PCB 77 on the metabolism and distribution of selenium. Following PCB 77 i.p. bolus dose administration (300 µmole/kg), the daily excretion and 21-day post treatment tissue distribution of selenium in Sprague-Dawley rats were examined. We measured selenium levels in tissues (liver, kidney, heart, brain, spleen, thymus, adrenal, muscles, and intestine), urine, and feces using graphite furnace atomic absorption spectrometry after microwave digestion of samples. Selenium concentrations in the heart and adrenal tissues of the PCB 77 treated group were increased while in the other tissues, selenium concentrations were not significantly different from the control group. Interestingly, the selenium level in the liver at 21 days after PCB 77 treatment was not affected. Daily urinary selenium levels were significantly decreased from Day 1 to Day 9 following PCB 77 treatment, after which selenium excretion increased to levels similar to the control group except for Day 17, when selenium excretion was increased. These results indicate that PCB 77 affects urinary selenium excretion patterns and may be influencing distribution of selenium in tissues. (Supported by ES 97380 and ES 07266 from NIH).

DEVELOPMENT OF SOFTWARE THAT INTERFACES WITH THE FOOD ANIMAL RESIDUE AVOIDANCE DATABANK TO ESTIMATE EXTENDED WITHDRAWAL INTERVALS FOR VETERINARY DRUGS.

R. Gehring, J. Wang, X. Lou, <u>R. E. Baynes</u> and <u>J. E. Riviere</u>. Center for Chemical Toxicology Research and Pharmacokinetics, North Carolina State University, Raleigh, NC.

Estimation of extended withdrawal intervals following extralabel use of veterinary drugs requires knowledge of label withdrawal times, tolerances for marker residues and rate of depletion of marker residues from target tissues. This information is

contained in databases of the Food Animal Residue Avoidance Databank (FARAD). A software application was developed to interface with these databases and extract necessary information, which is then entered into an algorithm to calculate an extended withdrawal interval by extrapolation of the drug's depletion curve. Ideally, the elimination half-life of the drug is extracted from the FARAD database, but pharmacokinetic data is not available for all drugs or multiple pharmacokinetic studies have been performed, resulting in numerous database entries. The algorithm offers two options for the calculation of extended withdrawal intervals. The first option (Estimator A) uses actual tissue or plasma half-lives. The second option (Estimator B) estimates the tissue half-life from the label withdrawal time by assuming that 5 half-lives are required for the concentration of most drugs to deplete to tolerance levels. The software was used to calculate extended withdrawal intervals for selected antimicrobial drugs. Estimators A and B gave identical results for drugs with shorter label withdrawal times (<8 days) (n=8). For drugs with longer label withdrawal times, Estimator A gave more conservative estimates for all drugs except spectinomycin (>10 days) (n=5). The software is a useful tool for extracting information from various FARAD databases. Application of an algorithm ensures that reliable and repeatable extended withdrawal intervals are calculated considering all available pharmacokinetic data. Further research is required to develop and validate methods to meta-analyze pharmacokinetic data for drugs with multiple database entries. (Supported by USDA/CSREES 2002-45051-01362)

### 1007 EVALUATION OF THE SUBCHRONIC TOXICITY OF A TRANSGENIC MAIZE.

I. Lamb<sup>2</sup>, S. A. MacKenzie<sup>1</sup>, L. A. Malley<sup>1</sup>, N. E. Everds<sup>1</sup> and J. F. Hansen<sup>2</sup>.

<sup>1</sup>DuPont Haskell Laboratory, Newark, DE and <sup>2</sup>Pioneer Hi-Bred International, Inc., Johnston, IA.

Five groups of young adult male and female Crl:CD®(SD)IGS BR rats (12/sex/group) were administered diets containing 33% TC1507 (transgenic), 33% 33P66 (non-transgenic, near-isogenic control), 33% 33J56 (non-transgenic, commercial), 11% TC1507, or 11% 33P66 maize for approximately 90 days. All diets contained comparable levels of proximate analytes, fiber/energy, amino acids, minerals, vitamins, and heavy metals. The transgenic protein, Cry1F, was only detected in the 33% and 11% TC1507 diets, using Cry1F ELISA and/or European corn borer (ECB) bioassay. Analysis of these diets near the beginning and end of the study demonstrated that Cry1F was stable over the course of the study. No diet-related differences were observed among groups fed the different diets, with respect to clinical signs, ophthalmological observations, neurobehavioral assessments, clinical pathology (hematology, clinical chemistry, coagulation, or urinalysis parameters), organ weights, and gross or microscopic pathology. Statistically significant lower food consumption was observed in male rats fed 33% 33P66, compared to those fed 33% TC1507, but was not considered toxicologically significant as there were no meaningful differences between these groups in body weight gain or food efficiency. Under the conditions of this study, exposure of male and female rats to diets containing a transgenic strain of maize (TC1507) produced no adverse effects, compared to rats fed diets containing a non-transgenic, near isogenic strain of maize (33P66) or a non-transgenic, commercial strain of maize (33J56).

### 1008 HEALTH HAZARD ASSESSMENT FOR PEANUT ALLERGY.

S. A. Assimon and P. M. Bolger. CFSAN, USFDA, College Park, MD.

About 0.6 % of the general population in the US is allergic to peanut. For those affected, it is most often a persistent, life-long affliction. The hazards of exposure to peanut in this sensitive group can be serious and significant. The allergic response involves signs and symptoms associated with a number of physiological sites and systems. Severe reactions begin within minutes after peanut ingestion and can progress very rapidly. Allergy to peanut is the major cause of reported fatal and near-fatal anaphylaxis reactions to food. Avoidance of peanut is the principal tool for management of adverse effects. Thus, the determination of the tolerable intake level of peanut protein in sensitized individuals is relevant. A health hazard assessment of the allergenicity of peanut on this sensitive subpopulation was performed. The critical effects were derived from a published double-blind placebo-controlled food challenge study that administered peanut to sensitive adults and that included dose-response information on adverse effect levels. The no (NOAEL) and low (LOAEL) observable adverse effect level for both subjective (self-reported symptoms) and objective (observed symptoms) were identified. Utilizing an uncertainty factor of 10 for intra-individual differences and the NOAELs for subjective and objective adverse symptoms, estimations of the tolerable acute intake of peanut were determined. The tolerable intake for subjective symptoms and for objective symptoms are 5 and 100 µg peanut protein per person, respectively. The nature of individual sensitivities and responses suggests additional considerations in addressing uncertainty in this assessment may be warranted. Factors like the magnitude of intra-individual differences, severity of the effect, and limitations in the study subjects able to safely participate were also examined. The possibility exists that the tolerable acute intakes levels as derived above may very well provide a lower margin of safety than is normally considered appropriate on the basis of established severe effects in humans. Thus, in this case, additional adjustments in deriving the margin of exposure may be a reasonable consideration.

## **1009** METABOLISM AND PHARMACOKINETICS OF NEOTAME IN HUMAN VOLUNTEERS.

P. Aikens<sup>1</sup>, D. Kirkpatrick<sup>1</sup>, <u>D. Mayhew</u><sup>2</sup>, W. Stargel<sup>2</sup>, G. Wright<sup>2</sup> and J. Allen<sup>2</sup>.

<sup>1</sup>Huntingdon Life Sciences, Huntingdon, Cambs, United Kingdom and <sup>2</sup>The NutraSweet Company, Evanston, IL.

Neotame, N-[N-(3, 3-dimethylbutyl)-L-α-aspartyl]-L-phenylalanine l-methyl ester is a new high intensity sweetener. As part of the safety testing, studies were conducted to evaluate the absorption, pharmacokinetics, metabolism and excretion of neotame in healthy, adult male volunteers. For this purpose, neotame was labelled with C-14 at the 1-position in the dimethylbutyl side chain and with C-13 in the 2 terminal methyl groups of the same side chain. In one study volunteers ingested a single dose of the labelled test substance in water at a level approximately equivalent to 0.25 mg/kg, which corresponds to the amount of neotame needed to sweeten one litre of beverage. Neotame was rapidly, but incompletely absorbed and rapidly excreted. A mean of 98% of the administered radioactivity was recovered in urine and faeces, mostly within 72 hours of dosing. Mean plasma concentrations of neotame peaked at 0.4 hour post-dose and declined with a half-life of 0.6 hour. The major metabolite of neotame was de-esterified neotame formed by hydrolysis of the methyl ester group. Mean plasma concentrations of this metabolite peaked at 1 hour post-dose, were approximately 2.5 times higher than neotame concentrations and declined with a half-life of 1.5 hours. De-esterified neotame represented a mean of approximately 80% of the excreted dose. Two other metabolites were detected at greater than 1% of the dose. One, that was a mean of about 4.9% of the dose, was found in the faeces and was identified as N-(3, 3 dimethylbutyl)-L aspartic acid. The other metabolite was in urine and was identified by LC/MS/MS, NMR and original synthesis as a carnitine ester of 3, 3-dimethylbutanoic acid. All metabolites of neotame present at 1% or greater of the dose have been shown to occur in the species used in safety studies, confirming the safety of these metabolites. A comparison of the metabolism and pharmacokinetic data in humans with those in animals indicates that the animal species are relevant for predicting human safety.

#### 1010

EFFECTS OF DIETARY EXPOSURE TO POLYPHENOLIC COMPOUNDS IN DIFFERENT BERRIES ON COLON CANCER IN RATS.

J. H. Exon and T. Taruscio. Food Science and Toxicology, University of Idaho, Moscow, ID.

Small fruits such as berries are a good source of polyphenolic chemicals which are thought to have bioactive properties toward a number of diseases including cancer. The effects of these chemicals vary however between studies. The bioactive chemical profile of nine different types of the Vaccinium sp of berries have been recently characterized in our laboratory. The profiles show the different levels of four major groups of polyphenolics, flavanols, flavonols, phenolic acids and anthocyanidins, and the individual chemicals which make up these major groups. Three different profiles were chosen to study the effects on a colon cancer model in rats. The highbush blueberries contained high levels of phenolic acids, the huckleberries contained high levels of anthocyanidins (and the greatest antioxidant activity) and the cranberries contained intermediate levels of all major groups. Three groups of yearold male rats were exposed to dietary levels of individual berry groups at levels of 3%dw in the diet for nine weeks. One group served as the control. All rats were injected ip with azoxymethane to induce preneoplastic lesions, aberrant crypt foci (ACF), in the colon. Rats exposed to the huckleberry diet had significantly greater numbers of ACF compared to the control. Rats receiving the blueberry or cranberry diets tended to have increased numbers of total ACF but not significantly different from the control. These results indicate that diets high in anthocyanidins, phenolic acids and antioxidant activity did not protect against the development of ACF and in fact enhanced the effects of the colon carcinogen.

## 1011 VITAMIN E ANALOGUE LEVELS IN TISSUES OF OLD AND YOUNG RATS FED D- $\alpha$ -TOCOPHERYL SUCCINATE.

T. G. Taruscio<sup>1</sup>, <u>I. H. Exon</u><sup>1</sup>, G. D. Clifton<sup>2</sup> and <u>M. W. Fariss</u><sup>2</sup>. <sup>1</sup>Food Science and Toxicology, University of Idaho, Moscow, ID and <sup>2</sup>Pharmaceutical Science and Pharmacotherapy, Washington State University, Pullman, WA.

Recent studies have shown that different forms of vitamin E may have different bioactive properties. Female Sprague-Dawley rats, 20 (OLD) or 2 mo (YNG) of age, were fed commercial rodent chow or the same feed supplemented with either 1

(YNG) or 2 (OLD) g d-α tocopheryl succinate (αTS)/kg diet. The animals were sacrificed after 49 days and tissues were collected for analysis of  $\alpha$ -tocopherol ( $\alpha T$ ),  $\gamma$ -tocopherol ( $\gamma$ T) and  $\alpha$ -tocopheryl succinate ( $\alpha$ TS). Serum triglycerides and percent body fat were also measured. There was no significant difference in the intake of  $\alpha TS$  between YNG and OLD animals on a mg/kg body wt basis. All rats within each age group treated with  $\alpha TS$  had significantly greater levels of  $\alpha T$  in all tissues than the rats not treated with \alpha TS. OLD rats treated with \alpha TS retained significantly higher levels of  $\alpha T$  in all tissues compared to the YNG rats treated with  $\alpha TS$ . Detectable levels of  $\gamma T$  were only found in serum, heart, lung and colons of OLD rats not given  $\alpha TS$  and in the colons of OLD group of rats given  $\alpha TS$ . No detectable levels of  $\gamma T$  were found in any tissues of YNG rats. Levels of  $\alpha TS$  were found in all tissues except the brain of OLD and YNG rats which were treated with  $\alpha TS.$  The  $\alpha TS$  levels in all tissues except colon were 2-fold higher in the OLD animals compared to the YNG group. The OLD group of rats had significantly greater percent body fat and serum triglycerides than the YNG group. This is the first study to show that dietary exposure to  $\alpha TS$  will result in residues of the intact form in various tissues. It also shows that older rats accumulate more  $\alpha TS$ ,  $\alpha T$  and  $\gamma T$  than younger rats. This may be related to the greater fat content and serum triglyceride levels in old rats. The retention of  $\gamma T$  and  $\alpha TS$  in particular in tissues may be important in disease prevention that may be unique to these forms of vitamin E.

## 1012 METABOLISM AND PHARMACOKINETICS OF NEOTAME IN RATS AND DOGS.

<u>D. Mayhew</u><sup>2</sup>, P. Aikens<sup>1</sup>, D. Kirkpatrick<sup>1</sup>, W. Stargel<sup>2</sup>, G. Wright<sup>2</sup> and J. Allen<sup>2</sup>. <sup>1</sup>Huntingdon Life Sciences, Huntingdon, Cambs., United Kingdom and <sup>2</sup>The NutraSweet Company, Evanston, IL.

Neotame, N-[N-(3, 3-dimethylbutyl)-L-α-aspartyl]-L-phenylalanine l-methyl ester is a new high intensity sweetener. As part of the safety testing, studies were conducted to evaluate the absorption, distribution, pharmacokinetics, metabolism and excretion of neotame in laboratory rats and dogs. For this purpose, neotame was labelled with C-14 at the 1-position in the dimethylbutyl side chain and was administered to animals at doses of 15 or 120 mg/kg bodyweight. In rats and dogs, oral doses of neotame were rapidly, but incompletely absorbed and rapidly excreted with no evidence of potential for accumulation. In rats, absorbed C-14 was mainly associated with the gastrointestinal tract and organs of metabolism and excretion (liver, kidney and bladder). Almost no neotame was detected in (stabilised) plasma or excreta samples after oral dosing to rats. This was probably due to high activity of plasma esterases. The major metabolite of neotame was de-esterified neotame formed by hydrolysis of the methyl ester group. In rats, mean plasma concentrations of this metabolite peaked at 0.5 hour post-dose and declined with a half life of 1 hour. In dogs, which have a lower level of plasma esterase activity, neotame was detected in plasma and excreta after oral dosing. Mean plasma concentrations of neotame peaked at 0.5 hour post-dose and declined with a half-life of 0.4 hour. Deesterified neotame represented a mean of approximately 70-80% of excreted oral doses in both rats and dogs. Other metabolites detected included N-(3, 3 dimethylbutyl)-L aspartic acid (in rats and dogs about 2% of the dose) and a β-glucuronide conjugate of 3, 3-dimethylbutanoic acid (in rats and dogs about 5% of the dose). In addition the carnitine ester of 3, 3-dimethylbutanoic acid was present in the urine of female rats. The safety of these metabolites has therefore been assessed in toxicology studies conducted with neotame in these species. A comparison of the metabolism and pharmacokinetic data in animals with those in humans indicate that the animal species are relevant for predicting human safety.

# 1013 DOCOSAHEXAENOIC ACID DOSE-DEPENDENTLY SUPPRESSES DEOXYNIVALENOL INDUCED IGA NEPHROPATHY, INTERLEUKIN-6 AND CYCLOOXYGENASE-2 GENE EXPRESSION.

Q. Jia<sup>1, 2</sup> and J. J. Pestka<sup>1, 2</sup>. <sup>1</sup>Department of food science and human nutrition, Michigan State University, East Lansing, MI and <sup>2</sup>Institute for environmental toxicolocgy, Michigan State University, East Lansing, MI.

Dietary exposure to trichothecene deoxynivalenol (DON, vomitoxin) may induce experimental IgA nephropathy (IgAN) in mice by modulating mucosal immune function. Interleukin-6 (IL-6) and cyclooxygenase-2 (COX-2) may play important roles in the upregulation of IgA production *in vivo*. Both docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA) can retard progression of IgAN in this model, with DHA being more effective. The purpose of this research was to optimize the regime for DHA treatment and to test DHA effects on proinflammatory genes (IL-6 and COX-2) expression. Mice were fed for 18wks with AIN-93G diet containing DON and different concentration of DHA (0.2-6%). DHA dose-dependently inhibited serum IgA elevation, serum IgA immune complex and kidney mesangial IgA deposition. Although IL-6 mRNA and heterogeneous nuclear IL-6 RNA (hnIL-6) were not induced by DON in the chronic feeding study they were inhibited by DHA (1, 6%). COX-2 mRNA level was enhanced by DON and in-

hibited by DHA (6%). Both DON and DHA treatment did not affect CD40, CD40 ligand (T, B cell activation) or activation-induced cytidine deaminase (AID, IgA isotype class-switch related) gene mRNA level *in vivo*. Pre-feeding mice with 6% DHA for 4 wks significantly blocked induction of IL-6 and COX-2 mRNA by acute DON exposure, but failed to block mitogen activated protein kinase (MAPKs) activation triggered by DON. Together, the results suggested that DHA may retard DON-induced IgA superinduction and then IgA nephropathy progression by blocking IL-6 and COX-2 gene induction independent of MAPK activation. (Supported by NIH grants DK58833 and ES03358)

# 1014 EXPOSURE FOR ONE YEAR TO A METABOLIC NUTRITION SYSTEM CONTAINING EPHEDRA AND CAFFEINE DOES NOT ALTER SERUM CHEMISTRY PROFILE OR TARGET ORGAN HISTOPATHOLOGY OF

S. D. Ray<sup>1, 2</sup>, S. Stohs<sup>2</sup> and R. Hackman<sup>3</sup>. <sup>1</sup>Pharmacology & Toxicology, Long Island University, Brooklyn, NY, <sup>2</sup>Coll. of Pharmacy and Health Professions, Creighton University, Omaha, NE and <sup>3</sup>Department of Nutrition, University of California, Davis, CA.

B6C3F1 MICE.

Nutritional value and therapeutic benefits coupled with presumed safety have heightened interest in the use of custom designed dietary supplements. Their use has increased substantially since passage of the 1994 Dietary Supplement Health education Act. However, few well-controlled studies have been conducted to assess the safety and potential adverse effects of dietary supplements. MNSO (MNS Orange-AdvoCare) is a unique combination of vitamins, minerals, omega-3 fatty acids and herbal extracts designed to provide a strong foundation of nutritional support, enhance thermogenesis, and boost energy levels and immune status. This investigation was designed to explore the safety and toxic effects, if any, of 12 months continuous exposure to ephedra and caffeine containing MNSO on serum chemistry (enzyme, lipid, carbohydrate, electrolyte profiles) and histopathology of seven vital target organs in female B6C3F1 mice. MNSO is enriched with the extracts of citrus, ephedra, gingko, green tea and Ocimum. In this study, mice were fed control (-MNSO) or MNSO (1X-10X, 1X=daily human dose) diets. Blood was collected from control and variously treated animals every four months for serum chemistry analysis. Target organs (brain, liver, kidney, lung, spleen, duodenum and heart) were collected for histopathology. Food consumption and body weight changes were also monitored biweekly. Data shows that 12 month exposure of 10X-MNSO did not significantly influence organ histopathology or normal serum chemistry profile. MNSO-exposed animals were more active, consumed more food, and were relatively leaner compared to controls. This study indicates that a caffeine and ephedra containing metabolic nutrition system is nontoxic in mice at up to 10X the human consumption dose for ephedra. [Supported by AdvoCare International Carrolton, TX]

## SPHINGOSINE KINASE CONFERS RESISTANCE TO FUMONISIN B<sub>1</sub> APOPTOSIS IN HUMAN RENAL CELLS.

N. sharma and R. P. Sharma. Physiology and Pharmacology, University of Georgia, Athens, GA.

Fumonisin B<sub>1</sub>, a mycotoxin produced by Fusarium verticillioides, causes a variety of diseases in animals and humans, including cancer. Fumonisin B<sub>1</sub> interferes with sphingolipid metabolism due to its similarity to the long-chain backbone of sphingolipid bases. Sphingoid bases are toxic in cells and their accumulation is known to produce cellular apoptosis after fumonisin B<sub>1</sub> exposure. Fumonisin B<sub>1</sub> blocks de novo ceramide biosynthesis in all cells causing accumulation of free sphingoid bases; however, only some cell types are sensitive to its toxic effects. It was reported that African green monkey kidney cells (COS-7) and rat primary hepatocytes are resistant to the apoptotic and antiproliferative effects of fumonisin B<sub>1</sub>. Exposure to 50 μM fumonisin B<sub>1</sub> of human embryonic kidney (HEK-293) cells for 48 hours did not induce apoptosis while it did so in porcine renal cells. We hypothesized that HEK-293 cells may be resistant to apoptotic effects of fumonisin B<sub>1</sub> due to reduced levels of sphinganine and sphingosine because of their conversion to respective phosphates via sphingosine kinase. Coincubation with 5 µM DL-threo-dihydrosphingosine (DHS), an inhibitor of sphingosine kinase, considerably increased sensitivity of HEK-293 cells to 25 µM fumonisin B<sub>1</sub>. Annexin V, Hoechst 33258 and Tunnel staining confirmed both apoptosis and necrosis of cells. Sphingoid bases, sphinganine or sphingosine, added to cultures were only slightly cytotoxic; apoptosis was enhanced when coexposed with DHS or fumonisin B<sub>1</sub>. These findings indicate that sphingoid base metabolism is a critical event in the mechanism of rendering certain cells resistant to fumonisin B<sub>1</sub>-induced apoptosis. (Supported by ES 09403 from PHS).

#### 1016

DOWNREGULATION OF mdr1b mRNA EXPRESSION IN THE KIDNEY OF NEXT GENERATION EXPOSED TO TRIBUTYLTIN CHLORIDE.

K. Kobayashi<sup>1</sup>, T. Watanabe<sup>2</sup> and <u>Y. Sugita-Konishi</u><sup>1</sup>. <sup>1</sup>Division of Microbiology, National Institute of Health Sciences, Tokyo, Japan and <sup>2</sup>Division of Food, National Institute of Health Sciences, Tokyo, Japan.

We investigated the change of mdr1b mRNA expression in the kidney of offspring exposed to tributyltin chloride (TBTC) via dams by real-time reverse transcription-polymerase chain reaction. Pregnant ICR mice were given water containing TBTC (0, 15 and 50 mg/mL) ad libitum from first of pregnancy to weaning (exposure via placenta and lactation) or from parturition to weaning (exposure via lactation). TBTC exposure did not inhibit the growth of the offspring in any concentrations used in this study. In the kidney of the offspring exposed to TBTC via placenta and lactation, mdr1b mRNA expression was significantly lower than that of the control group, whereas TBTC exposure via lactation showed a tendency to decrease the expression as compared with the control group. These findings suggest that TBTC exposure through mother, in particular through placenta and lactation, may impair the ability of offspring to protect itself from environmental toxic compounds.

#### 1017

NAVIGATING THE REGULATORY WATERS AT FDA-TOXICOLOGY SAFETY REVIEWS OF FOOD AND COLOR ADDITIVES.

D. B. Carlson, T. L. Taras and T. Thurmond. FDA, College Park, MD.

Food and color additives that become components of our food supply, either directly or indirectly, are required to undergo pre-market safety review by the US Food and Drug Administration. Changes initiated by the Food and Drug Modernization Act resulted in the 2001 reorganization of the Center for Food Safety and Applied Nutrition's "Office of Premarket Approval" into the "Office of Food Additive Safety". While the safety standards and review criteria for potential food and color additives have not changed, under this Act there are now more options for industry and citizen submissions for new food and color additive uses. The toxicological testing standards for determining the safety of food and color additives are driven by the potential toxicity of the additive. The possibility for human toxicity can be estimated by coupling consumer exposure estimates with chemical structural alerts, determined by comparing the chemical moieties of the additive to known toxicant structures. Ultimately, the safety of potentially toxic substances can be supported by in vitro and/or in vivo toxicity tests. Well designed and executed toxicity studies are important, but a well prepared petition is equally critical to effectively navigate the regulatory process for new food or color additives. To facilitate an efficient and transparent review of petitions, the Office of Food Additive Safety encourages communication and consultation between stakeholders and the FDA throughout the submission and review process. The most efficient way to obtain approval of safe new uses of additives is to consult with FDA personnel, including toxicologists, prior to submitting a petition. Helpful guidelines for toxicology tests that ensure the safety of these additives can also be found in various published and online sources, such as the "Toxicological Principles for the Safety Assessment of Food Ingredients" (i.e. the "Redbook"). Proper toxicity testing and preparation of petitions are critical components for assuring both the safety of food and color additives and a smooth and efficient petition process.

### 1018 NATIONAL RESIDUE PROGRAM (NRP) AS A FOOD SAFETY TOOL.

R. Kishore, P. Zervos, <u>A. Brown</u>, C. Deyrup, R. Sutton and <u>J. Vodela</u>. Residue Branch, USDA/FSIS, Washington DC, DC.

The Food Safety and Inspection Service is a public health regulatory Agency of the USDA, which protects consumers health by regulating meat, poultry, and egg products. FSIS enforces the tolerances and action levels set by the Food and Drug Administration (FDA) and Environmental Protection Agency (EPA). The main component of FSIS residue prevention activities is the NRP, a multi-component analytical testing program for residues in domestic and imported meat, poultry and egg products. The NRP is designed to monitor, detect and identify drugs, pesticides and other chemical contaminants in meat, poultry and egg products in order to reduce and control chemical residues in animals. The Zoonotic Diseases and Residue Surveillance Division annually publishes the residue plan and the analytical results. The NRP also uses national data on chemical residues to support risk assessment, enforcement, and educational activities. In 2002, FSIS sampled and tested 12 compound classes of drugs and pesticides, comprising approximately 59 residues. Under the Domestic Monitoring Plan 26, 028 samples were analyzed. The preliminary results indicate 75 residue violations consisting of 23 antibiotics, 16 avermectins/milbemycins, 10 sulfonamides, two flunixins, 23 zeranol, and one chlorinated hydrocarbon/chlorinated organophosphate. No residue violations were found in the testing of arsenicals, chloramphenicol, and ractopamine. The most common cause of violations of approved drugs in livestock, poultry, and egg products is a failure to allow an adequate withdrawal time for the drugs to clear the animal system. The illegal residues are usually concentrated in the kidney, liver, or fat rather than muscle. The FSIS sampling focuses on kidney and liver tissues, since most FDA limits are established for these tissues.

#### 1019

TOXICOLOGICAL EVALUATION AND ANTIOXIDANT POTENTIAL OF A NOVEL BOTANICAL EXTRACT FOR USE IN AMELIORATING ALLERGIC RHINITIS.

M. Bagchi<sup>1</sup>, A. Amit<sup>3</sup>, V. S. Saxena<sup>3</sup>, N. Pratibha<sup>3</sup> and D. Bagchi<sup>2,1</sup>. <sup>1</sup>R & D, InterHealth Research Center, Benicia, CA, <sup>2</sup>Pharmacy Sciences, Creighton University Medical Center, Omaha, NE and <sup>3</sup>R & D, Natural Remedies Research Center, Bangalore, India.

A standardized botanical formulation (Aller-7/NR-A2), developed from 7 medicinal plants, was shown to ameliorate the symptoms of allergic rhinitis by mast cell stabilization, lipoxygenase and hyaluronidase inhibition, as well as potent anti-histaminic, anti-inflammatory, anti-spasmodic activities. The present study was designed to evaluate the acute oral, acute dermal, dermal irritation and eye irritation toxicities of Aller-7 in vivo. Furthermore, the concentration-dependent inhibitory effect of Aller-7 was assessed against superoxide anion, hydroxyl radicals and nitric oxide, the key inflammatory mediators in pulmonary damage and bronchoconstriction. The oral LD50 of Aller-7 was found to be greater than 5, 000 mg/kg b.w. in both male and female rats, and no mortality or signs of toxicity were observed at this dose. The acute dermal LD50 was found to be greater than 2, 000 mg/kg b.w. The skin irritancy index was 0.0 in rabbits and classified as minimal irritant to eye in rabbit. The superoxide scavenging IC50 values of Aller-7, gallic acid and catechins, as demonstrated by PMS-NADH non-enzymatic system, were found to be 24.65, 21.15 and 82.15 µg/ml, respectively. The nitric oxide scavenging IC50 values of Aller-7 and curcuminoids, as determined spectrophotometrically at 546 nm using Greiss reagent, were found to be 16.34 and 33.63 µg/ml, respectively. The hydroxyl radical scavenging IC50 values of Aller-7 and catechins, as determined spectrophotometrically at 532 nm using deoxyribose assay, were found to be 741.73 and 2193.39 µg/ml, respectively. In addition, Aller-7 was found to be significantly effective in protecting rat erythrocytes, as demonstrated by AAPH-induced lysis of rat RBC, against free radical injury in the concentration of 20-80 μg/ml as compared to BHA 15-50 μg/ml, respectively. These results demonstrate the safety and novel antioxidant potential of Aller-7 for use in treating allergic rhinitis

SAFETY STUDIES OF A NOVEL, NATURAL EXTRACT OF (-)-HYDROXYCITRIC ACID, A SUPPLEMENT FOR WEIGHT MANAGEMENT.

D. Bagchi<sup>1,2</sup>, M. Shara<sup>1</sup>, S. E. Ohia<sup>1</sup>, T. Yasmin<sup>1</sup>, M. Bagchi<sup>2</sup>, A. Chatterjee<sup>1</sup> and S. J. Stohs<sup>1</sup>. <sup>1</sup>Pharmacy Sciences, Creighton University Medical Center, Omaha, NE and <sup>2</sup>R&D, InterHealth Research Center, Benicia, CA.

Garcinia cambogia-derived (-)-hydroxycitric acid (HCA) is a competitive inhibitor of the enzyme ATP citrate lyase, a building block for fat synthesis. Results have shown that HCA-SX (a 60% calcium-potassium salt of HCA, Super CitriMax) promotes fat oxidation, enhances serotonin release and availability in the brain cortex, normalizes lipid profiles, and lowers serum leptin levels in obese subjects. Acute oral, acute dermal, primary dermal irritation and primary eye irritation toxicity demonstrated the safety of HCA-SX. HCA-SX did not induce mutagenic effect in the bacterial reverse mutation test in five Salmonella typhimurium strains (TA98, TA100, TA1535, TA1537 and TA102), either with or without metabolic activation. Similarly, HCA-SX did not induce mutagenic effects in the mammalian cell gene mutation test in L5178Y mouse lymphoma cells TK(+/-), either with or without metabolic activation. We evaluated the dose- and time-dependent effects of HCA-SX in Sprague-Dawley rats on body weight, selected organ weights, hepatic lipid peroxidation and DNA fragmentation, histopathology, hematology and clinical chemistry over a period of 90 days. The animals were treated with 0, 0.2, 2.0 and 5.0% HCA-SX of feed intake and were sacrificed on 30, 60 or 90 days of treatment. A significant reduction in body weight was observed in treated rats as compared to control animals. An advancing age-induced marginal increase in hepatic lipid peroxidation was observed in both male and female rats, while no such difference in hepatic DNA fragmentation was observed as compared to the control animals. Furthermore, selected organ weights individually and as a % of body weight and brain weight at 90 days of treatment exhibited no significant difference between the groups. The results show that 90 day treatment of HCA-SX results in a reduction in body weight, and does not cause any changes in major organs or in hematology, clinical chemistry, and histopathology.

THE USE OF STRUCTURE ACTIVITY RELATIONSHIP (SAR) ANALYSIS IN THE SAFETY ASSESSMENT OF FOOD CONTACT NOTIFICATIONS.

A. J. McDougal, <u>M. Twaroski</u>, R. Chanderbhan, N. Braier, K. Arvidson, J. Mayer, M. Cheeseman and A. Bailey. *Division of Food Contact Notifications*, *OFAS, USFDA, College Park, MD.* 

The food contact notification (FCN) process was established by Section 309 of the FDA Modernization Act of 1997. For the past 4 years, the FCN process has been the primary method in the US for the evaluation and authorization of new uses of food additives that are food contact substances (FCSs). The FCN process is divided into 2 phases: Phase 1 to verify that the FCN is complete regarding the regulatory, chemical, toxicological, and environmental information necessary to evaluate the FCS and its constituents, and Phase 2 to carefully analyze the manufacturing, exposure, and safety data, in order to reach a safety decision. SAR analysis is currently used in both phases as a tool to assist in the safety evaluation. Phase 1 SAR analysis focuses on identifying structural alerts and close analogs for which relevant mutagenicity and carcinogenicity data are available. The goal is to decide if additional testing should be recommended to address safety concerns. This decision incorporates data from commercial and in-house software and databases. For a constituent of a FCS determined in Phase 1 to be of potential concern, Phase 2 SAR analysis can, in some cases, assess the safety without the need for additional testing. If sufficient bioassay data are available for chemical analogs that adequately represent the structure of the constituent, a quantitative estimate may be determined of the upper-bound lifetime cancer risks for the analogs; these risks can then be used to extrapolate a range of associated risk for the untested constituent that may be useful in the safety assessment. Currently, analogs are identified using a structurally searchable version of the Carcinogenic Potency Database (CPDB), as well as inhouse and publicly available databases.

1022 TOXICOLOGICAL EVALUATION OF JOALA, A HOME-BREWED BEVERAGE, PREPARED FROM CORN CONTAMINATED WITH FUSARIUM VERTICILLIOIDES CULTURE MATERIAL.

K. A. Voss<sup>1</sup>, L. H. Couch<sup>2</sup>, P. C. Howard<sup>2</sup>, N. P. Keller<sup>3</sup>, M. Mabathoana<sup>4</sup> and C. W. Bacon<sup>1</sup>. <sup>1</sup>Toxicology & Mycotoxin Research Unit, USDA Agricultural Research Service, Athens, GA, <sup>2</sup>NCTR, USFDA, Jefferson, AR, <sup>3</sup>Plant Pathology, University of Wisconsin, Madison, WI and <sup>4</sup>Consultant, Maseru, Lesotho.

Fumonisins are water-soluble mycotoxins produced by Fusarium verticillioides and related fungi. They are liver and kidney toxins and the most common analogue, fumonisin B<sub>1</sub> (FB<sub>1</sub>), is carcinogenic to rodents. Fumonisins have been implicated as a risk factor for esophageal cancer and, more recently, neural tube defects in some human populations heavily dependent on fumonisin-contaminated corn as a dietary staple. Fumonisins are found in foods and have been detected in commercial beers. Joala is a type of home-brewed beverage consumed in rural southern Africa that is made from corn, malted sorghum, yeast, and water. The effect of the Joala making process on the fate and toxicity of fumonisins is unknown. Rats (n = 6/group) were dosed by gavage twice daily for two weeks with 10ml/kg of distilled water (negative controls), Joala made from sound corn (Joala-SC), Joala made from sound corn spiked with culture material of F. verticillioides (Joala-FC), or a water extract of the spiked corn (WE-FC). Decreased body weight gain and food consumption were found in the Joala-FC and WE-FC groups. Decreased kidney and liver weights and microscopic kidney and liver lesions typical of short-term fumonisin exposure were also found in animals given Joala-FC or WE-FC. The Joala and water extracts made from the spiked corn had similar FB<sub>1</sub> concentrations of about 0.1 mg/mL (determined by HPLC). Thus, fumonisins are readily extracted into Joala beer and the Joala making process did not affect their toxicity. The findings suggest that Joala and similar home-brewed beverages can be a significant source of fumonisin exposure in populations depending on foodstuffs made from contaminated homegrown corn.

## 1023 FUMONISINS IN MAIZE IN GUATEMALA AND A PRELIMINARY ESTIMATE OF DAILY INTAKES.

R. T. Riley<sup>1</sup>, E. Palencia<sup>2</sup>, O. R. Torres<sup>2</sup>, A. E. Glenn<sup>1</sup> and M. Fuentes<sup>3</sup>.

<sup>1</sup>Toxicology and Mycotoxins Research Unit, USDA-ARS, Athens, GA, <sup>2</sup>Institute of Nutrition of Central America and Panama, Guatemala City, Guatemala and <sup>3</sup>Institute of Agricultural Science and Technology, Guatemala City, Guatemala.

Maize samples were collected from highlands (> 1700 m) and lowlands (< 360 m) of Guatemala in 2000 to 2002. Samples were analyzed for fumonisin B1 (FB1) by high performance liquid chromatography (HPLC) in 2000 and 2001 and by LC ion trap mass spectrometry (LCMSMS) in 2002. The detection limit for HPLC and LCMSMS methods were 0.3 ppm and 0.05 ppm, respectively. The LCMSMS method also detected FB2 and FB3. Samples in 2002 that had detectable FB1 but

were < 0.3 ppm were assigned a value of 0 ppm. The mean FB1 level (2000 to 2002) in maize from the lowlands (1.2 ±0.3 ppm, n=205) was significantly higher than the maize from the highlands (0.26  $\pm$ 0.18 ppm, n = 142). The incidence of FB1 positive samples was significantly greater in the lowland maize (109/205) compared to that from the highlands (13/142). In the maize from the highlands, 9% of the samples contained  $\geq 0.3$  ppm FB1 with the highest being 7.3 ppm, whereas, in the lowland samples 53% were ≥0.3 ppm FB1 and 2.4 % were ≥10 ppm with one sample being 21 ppm. Analysis of the samples from 2002 by LCMSMS revealed that most FB1 positive samples contained FB2 and FB3 at a ratio of 1:0.4:0.3. In addition, approximately 92% (104/113) of the samples from the lowlands in 2002 contained detectable levels of FB1, whereas, all but 5 (5/92) of the samples from the highlands contained no detectable fumonisins. Based on a recall study in women conducted in the Central Highlands, a preliminary assessment of daily intake of total FBs was estimated. Consumption of nixtamalized maize products made from lowland maize could result in exposure exceeding the provisional maximal tolerable daily intake (2  $\mu g$  total fumonisins/kg bw) with over 50% of the maize samples. At the highest level, 2.4% of the samples would provide a daily intake that was on average 58 µg/kg bw (support: USDA FAS grant X01-4510-62-751071-4; ILSI NA Technical Committee on Food Toxicology and Safety Assessment).

## 1024 SAFETY EVALUATION OF A NATURAL TOMATO OLEORESIN EXTRACT DERIVED FROM TOMATOES.

R. A. Matulka, A. M. Hood and J. C. Griffiths. Burdock Group, Vero Beach, FL.

Experimental and epidemiological studies suggest that consumption of tomato products containing high levels of the carotenoid lycopene is associated with lowered cancer risk. The protective effects of lycopene may be related to its antioxidant potential, being the carotenoid with the highest singlet oxygen radical quenching ability. Lycopene has been demonstrated to inhibit oxidation in both DNA and lipid structures. A proprietary, natural tomato oleoresin extract (NTOE), is a purified tomato oleoresin containing 6% lycopene produced from tomatoes. The objective of this series of experiments was to analyze the safety assessment of NTOE. The acute, oral LD50 of NTOE in Sprague-Dawley rats was greater than 5000 mg/kg bodyweight. In a 13-week oral (*via* gavage) study at doses of 0, 45, 450 and 4500 mg NTOE/kg/day (addition of 0, 2.7, 27 and 270 mg/kg/day lycopene, respectively) in male and female CD rats, no changes in the bodyweight gains of the treated animals were noted. Plasma concentrations of lycopene at the end of the study were similar at 450 and 4500 mg NTOE/kg/day (57.33 and 57.43  $\mu$ g/l lycopene, respectively), but lower at the 45 mg/kg/day dose level (a range from 0 to 29.37 µg/l lycopene). Urinalysis investigations at Week 11 revealed no treatmentrelated abnormalities. Hematological and histopathological analysis at the end of the subchronic study found no significant treatment-related effects by NTOE. NOAEL was determined to be 4500 mg/kg/day NTOE. Mutagenic potential was determined via the Ames assay utilizing five strains of Salmonella typhimurium (TA98, TA100, TA1535, TA1537 and TA1538) and one strain of Escherichia coli (WP2uvrA-). There was no evidence of mutagenicity up to 5000  $\mu g/plate$ ; either with or without enzyme mix (S9) addition. Consumption analysis of lycopene-containing foods in the US population was performed, with the estimated mean daily intake of lycopene calculated at 8.2 mg/day. These results demonstrate the inability of NTOE to produce oral or mutagenic toxicity at doses greater than 300 times the normal human consumption of lycopene.

#### 1025 POLYUNSATURATED FATTY ACIDS INHIBIT TOXIN-INDUCED ACTIVATION OF MITOGEN ACTIVATED PROTEIN KINASES.

Y. Shi<sup>1</sup> and <u>J. J. Pestka<sup>1, 2</sup>. <sup>1</sup> Food Science and Human Nutrition, Michigan State University, East Lansing, MI and <sup>2</sup>Institute for Environmental Toxicology, Michigan State University, East Lansing, MI.</u>

Activation of the mitogen activated protein kinase (MAPK) cascade by environmental toxins, such as the mycotoxin deoxynivalenol (DON), lipopolysaccharide (LPS) and H2O2, can affect cellular differentiative, proliferative and apoptotic pathways. We investigated the effects of n-3 polyunsaturated farty acids (PUFA) on activation of MAPKs using the mouse macrophage RAW 264.7 cell line. Serum-deprived cells were incubated for 24 hours with 100 uM PUFA (arachidonic acid [AA, C20:4 n6], eicosapentaenoic acid [EPA, C20:5 n3] and docosahexaenoic acid [DHA, C22:6 n3]) complexed with bovine serum albumin and then phospholipids were extracted for fatty acid analysis. Gas chromatography revealed that each PUFA was incorporated into cell membrane effectively. Incubation with AA, USEPA or DHA increased their respective contents in cells from 1.96% to 6.89%, undetectable to 5.41%, and undetectable to 7.33% respectively. For analysis of MAPKs, DON (250 ng/ml), LPS (100 ng/ml) or H2O2 (0.5 mM) was added to the medium after fatty acid treatment and MAPK phosphorylation was analyzed by Western blot. JNK 1/2 phosphorylation was increased 5.7-, 2.7-, 4.0- fold; ERK 1/

2 phosphorylation was increased 1.7-, 3.0-, 1.3- fold; and p38 phosphorylation was increased 8.1-, 2.4-, 1.5- fold by DON, H2O2 and LPS, respectively. The three PUFAs inhibited DON and H2O2 activation of: (1)JNK 1 / 2 by 52-89%; (2) ERK 1 / 2 by 64-93%; and (3) p38 by 35-73%. PUFA inhibited LPS induced JNK 1 / 2 activation by 29-34%, but ERK1 / 2 and p38 were not affected. Taken together, the results suggested that the MAPK responses to toxins were differentially modified by PUFA and that no difference was observed between the effects of the n-3 and n-6 PUFA. (Supported by NIH grant DK58833)

## 1026 A 24-MONTH DIETARY CARCINOGENICITY STUDY OF DAG (DIACYLGLYCEROL) IN MICE.

J. B. Kirkpatrick<sup>1</sup>, <u>C. P. Chengelis</u><sup>1</sup>, R. H. Bruner<sup>1</sup>, O. Morita<sup>2</sup>, Y. Tamaki<sup>2</sup> and H. Suzuki<sup>2</sup>. <sup>1</sup>WIL Research Laboratories, Inc., Ashland, OH and <sup>2</sup>Kao Corporation, Haga Tochigi, Japan.

This study evaluated the possible carcinogenic effects of DAG, when given in the diet at levels up to 6.0% (60, 000 ppm) for 24 months to mice. DAG is a cooking oil which contains >80% diglycerides, <20% triglycerides and <5% monoglycerides. A special diet was prepared so that all of the dietary fat could be provided by DAG and/or the control oil, TG (triacylglycerol), at various concentrations. The TG contained >85% triglycerides, <10% diglycerides and <5% monoglycerides. The fatty acid composition for DAG and TG was closely matched. Dietary concentrations (% DAG/% TG) of 0%/6.0% (TG control), 1.5%/4.5%, 3.0%/3.0%, and 6.0%/0% were presented ad libitum, seven days per week, for 104 weeks. An additional control group (group 1) received the standard basal diet (Certified Rodent LabDiet 5002), which has a fat content of 4.5%. Each group consisted of 50 male and 50 female Crl:CD-1(ICR)BR mice. The clinical condition of the animals, body weights, body weight gains, gross and histopathologic findings were unaffected by DAG. The effects in the DAG-treated groups were no different than those observed in the TG control group. However, the 6.0% dietary fat level is 33% higher than the standard basal diet (4.5% fat). Both TG and DAG, when presented separately or together in the diet at a total fat level of 6.0%, caused some changes relative to the basal diet control (decreased survival, higher body weights, lower food consumption, and increased incidences of macroscopic and microscopic findings) related to the higher dietary fat content and/or the semi-purified diet. Thus, DAG at dietary concentrations up to 6.0% for 24 months produced no signs of systemic toxicity and had no effect on the incidence of neoplastic findings.

## 1027 COMBINATION TOXICITY OF ACRYLAMIDE AND HEAVY METALS – ADDITIVE EFFECTS OR MORE.

J. B. Schulze<sup>1</sup> and <u>C. Siegers<sup>2</sup></u>. <sup>1</sup>Office of the Dean, Frankfurt/Main, Germany and <sup>2</sup>Inst. Exp. CLin. Pharmacology Toxicol., Luebeck, Germany.

Acrylamide is a potent neurotoxicant; additionally it has been classified as a potential carcinogenic compound. Despite an extensive body of literature for acrylamide effects, scant data are available investigating acrylamide effects in combination with other toxicants. We investigated the combined cytotoxicity of acrylamide together with heavy metals, widely occuring in the environment, in the kidney cell line LLC-MK2, the hepatic cell line Hep G2 and an ocular cell line I-407. All three cells showed cytotoxicity at acrylamide concentrations above 100 ng/ml (no cytotoxicity observed at this concentration). For HgCl<sub>2</sub> alone IC<sub>50</sub> values ranged from 4.3 to 9  $\mu g/ml$ . When combining 60 ng/ml acrylamide with 1 to 30  $\mu g/ml$  HgCl<sub>2</sub>, ovalues for HgCl<sub>2</sub> were unaffected for I–407 cells and slightly lower by 20% for kidney and hepatic cells. However, when exposing these cells to 10 µg/ml HgCl, inducing a considerable cytotocix effect, IC<sub>50</sub> values for additionally applied acrylamide dropped to 3.4 to 8 ng/ml, i.e. by a factor of appr. 100. A similar drop in IC<sub>50</sub> values for acrylamide was seen when I–407 cells where simultaneously exposed to 6  $\mu$ g/ml CdCl<sub>2</sub> (IC<sub>50</sub> value for CdCl<sub>2</sub> alone 14  $\mu$ g/ml). In highly exposed groups, up to 500 ng/ml Hg has been detected in blood samples (Vahter et al. 1997 Int Arch Occup Environ Health 70 p.282), with blood values in the general US population of about 1 ng/ml blood. No serum concentrations for acrylamide have been published. Extrapolating from a daily uptake of 80 ng/kg bw per meal and a distributioon volume of 0.6 (for water soluble compounds), 0.13 ng/ml acrylamide may be reached as peak serum levels. We conclude that acrylamide has no major cytotoxic effect on healthy cell cultures but cytotoxic effects are drastically increased in cells already damaged. This implies that the combination toxicity of acrylamide may be high under conditions when the target cells are stressed by other factors.

## 1028 A 24-MONTH CARCINOGENICITY STUDY OF DAG (DIACYLGLYCEROL) IN RATS WITH DIETARY OPTIMIZATION.

C. P. Chengelis<sup>1</sup>, J. B. Kirkpatrick<sup>1</sup>, R. H. Bruner<sup>1</sup>, O. Morita<sup>2</sup>, Y. Tamaki<sup>2</sup> and H. Suzuki<sup>2</sup>. <sup>1</sup>WIL Research Laboratories, Inc., Ashland, OH and <sup>2</sup>Kao Corporation, Haga Tochigi, Japan.

This study evaluated the possible carcinogenic effects of DAG, when given in the diet at levels up to 5.5% (55, 000 ppm) for 24 months to rats. DAG is a cooking oil which contains >80% diglycerides, <20% triglycerides and <5% monoglycerides. A

special diet was prepared so that all of the dietary fat could be provided by DAG and/or the control oil, TG (triacylglycerol), at various concentrations. The TG contained >85% triglycerides, <10% diglycerides and <5% monoglycerides. The fatty acid composition for DAG and TG was closely matched. Dietary concentrations (% DAG/% TG) of 0%/5.5% (TG control), 1.0%/4.5%, 2.75%/2.75%, and 5.5%/0% were presented daily, seven days per week, for 104 weeks. An additional control group (group 1) received the standard basal diet (Certified Rodent LabDiet 5002), which has a fat content of 4.5%. Groups 1-5 (basal diet plus four DAG and/or TG-treated groups) each consisted of 50 male and 50 female Crl:CD(SD)IGS BR rats and were maintained on a daily dietary optimization schedule. Groups 6 -7 (5.5% DAG or TG) each consisted of 65 rats/sex and were fed ad libitum. The clinical condition of the animals, body weights, body weight gains, food consumption, body composition, gross and histopathologic findings were unaffected by DAG. While there were no differences between the effects of TG and DAG, both caused some changes relative to the basal diet control (decreased survival, higher body weights, and increased incidences of macroscopic and microscopic findings) related to the higher dietary fat content and/or the semi-purified diet. These changes were more marked in the ad libitum-fed groups than in the restricted diet groups. Thus, DAG at dietary concentrations up to 5.5% for 24 months produced no signs of systemic toxicity and had no effect on the incidence of neoplastic findings.

#### 1029

IN VITRO SCREENING FOR BIOLOGICAL ACTIVITY ASSOCIATED WITH FUMONISINS IN NIXTAMALIZED FOODS

L. D. Williams<sup>1,2</sup>, K. A. Voss<sup>2</sup>, W. P. Norred<sup>2</sup>, D. S. Saunders<sup>3</sup> and R. T. Riley<sup>2,1</sup> Invironmental Health Sciences, University of Georgia, Athens, GA, <sup>2</sup>Toxicology and Mycotoxin Research Unit, USDA, Athens, GA and <sup>3</sup>Department of Food Safety, Frito-Lay, Inc., Plano, TX.

Fumonisins (FB) are inhibitors of ceramide synthase, a key enzyme in the sphingolipid biosynthetic pathway. Nixtamalization, the alkali processing of corn, reduces the total FB in corn products. However, it is unclear whether hidden or more toxic FB metabolites are formed. To address this issue, the biological activity of FB contaminated corn before and after nixtamalization was determined in vitro. Sphinganine elevation was used as a biomarker for FB inhibition of ceramide synthase in LLC-PK1 and Vero cells. However, clean corn extracts, but not extracts of nixtamalized products, were toxic to cells. The objectives of this study were 1) determine a non-toxic exposure for FB-free corn extracts and 2) determine if a reduction in total detectable fumonisins by nixtamalization results in a similar reduction in biological activity. LLC-PK1 cells were treated for various times with various amounts of residues of corn extracts dissolved in growth medium. There was a dose and time dependent decrease in ATP-dependent dome formation and tight junction integrity based on visual observation. A 6h exposure to the equivalent of 0.086 g corn/ml of growth medium was used for subsequent experiments. In Vero cells exposure was for 48 h at 0.04 g corn equivalents/ml growth medium. Ceramide synthase inhibition by extracts of contaminated corn and nixtamalized products was determined. There was a significant decrease in sphinganine elevation in cells exposed to nixtamalized products compared to cells exposed to the FB contaminated corn used to make the products. These results indicate that nixtamalization of FBcontaminated corn does not produce increased fumonisin-like biological activity; results consistent with the conclusion that unknown or more toxic FB metabolites are not formed during the nixtamalization process.

#### 1030

COMBINATIVE TOXIC EFFECTS OF AFLATOXIN-B<sub>1</sub> AND MICROCYSTIN-LR IN HUMAN CELL LINES AND VERTEBRATES.

M. Billam, L. Tang, C. McKean, H. Luo, M. Tang and J. Wang. EnvTox/TIEHH, TTU, Lubbock, TX.

Aflatoxin-B<sub>1</sub> (AFB<sub>1</sub>) is a potent hepatocarcinogen and Microcystin-LR (MCLR) is a strong liver tumor promoter. Human exposure to these two toxins through diet and drinking water has been found in certain parts of the world, especially in high risk areas of liver cancer in China. Cocarcinogenic effect of these two toxins on rodents was also reported. In order to investigate mechanisms involved in their action, combinative toxic effect was studied in vertebrates and human liver and lung cells. Healthy mosquito fish (*Gambusia affinis*) were divided into 6 groups and each group treated with combinative doses of 1/8, 1/4, 3/8, 1/2, 1 and 0 of LC<sub>50</sub> of AFB<sub>1</sub> (LC<sub>50</sub> is 681.0 ppb) and MCLR (LC<sub>50</sub> is 135 ppb). The combinative LC<sub>50</sub> is 206.5 ppb with 95% CI at 151.7-304.8 ppb (K = 1.98). Young male F-344 rats were divided into 7 groups, each of 8 rats. Each group was treated respectively with 1.0, 3/4, 1/2, 3/8, 1/4, 1/8, and 0 of LD<sub>50</sub> of AFB<sub>1</sub> orally (LD<sub>50</sub> of 2.71mg/kg) and MCLR intra-peritoneally (LD<sub>50</sub> of 72 µg/kg) and observed for 14 days. The combinative LD<sub>50</sub> is 1.21 mg/kg with 95% confidence limit at 0.95-1.54 mg/kg (K = 1.154). Combinative cytotoxicity with these two toxins was tested in human

HepG2 and BEAS-2B cells using tetrazolium dye-based WST assay. IC $_{50}$  of MCLR in BEAS-2B cells is 76.7 μM (95% CI at 60.5 to 100.6 μM), and 1 μM for AFB $_1$  in HepG2 cells. MCLR has no apparent cytotoxic effect on HepG2 cell lines while AFB $_1$  has no cytotoxicity to BEAS-2B cells. Combinative cytotoxicity study was done in HepG2 cells using a fixed concentration of 50 μM MCLR with various concentrations of AFB $_1$  (1/8, 1/4, 3/8, 1/2 and 3/4 IC $_{50}$  values). The combinative IC $_{50}$  with the mixture is 50.81μM. Similar study carried out in BEAS-2B cells using fixed concentration of 100 μM AFB $_1$  and varied concentrations of MCLR (1/8, 1/4, 3/8, 1/2 and 3/4 IC $_{50}$  values) showed synergistic cytotoxicity with IC $_{50}$  of 100.30μM. The results show that AFB $_1$  and MCLR when ingested together may have additive or synergistic toxic effects in animals and humans. Supported by SBCCOM, USArmy Research Contract (DAAD13-02-C-0070).

## 1031 RECALL AND TRACE BACK: FEDERAL, STATE AND FOOD INDUSTRY COOPERATIVE EFFORTS TO ENSURE FOOD SAFETY.

A. Tawadrous<sup>1</sup>, A. M. Kadry<sup>2</sup>, E. Jensen<sup>2</sup>, W. Schlosser<sup>2</sup>, J. Kause<sup>2</sup> and C. Maczka<sup>2</sup>. <sup>1</sup>Recall Management Divsion, Food Safety and Inspection Service Department Of Agriculture, Washington, DC and <sup>2</sup>Risk Assessment Divison, Food Safety and Inspection Service Department Of Agriculture, Washington, DC.

The Food Safety and Inspection Service (FSIS) of the US Department of Agriculture (USDA) inspects and regulates meat poultry and egg products. FSIS is responsible for ensuring that these products are safe, wholesome, and accurately labeled. Recalls are voluntary product withdrawals carried out by food industry firms in cooperation with Federal and State agencies. Products may be recalled if they are found to be contaminated, adulterated, or mislabeled. FSIS recall database was analyzed. Between January 1990 and December 2002, FSIS conducted 684 recalls of a total of 262, 966, 547 lbs of meat, poultry and egg product. The maximum quantity recalled in any one episode was 35, 000, 000 lb. Sixty-eight percent of the recalls were Class I (cases presenting a reasonable probability of serious adverse health consequences), 23% were Class II (remote probability), and 9% were Class III (no adverse health consequences). Recalls were associated with a variety of contaminants. E. coli O157:Ĥ7 in raw ground beef prompted fifteen percent of all recalls, constituting a total of 58, 903, 051 lbs of meat and poultry withdrawn. Listeria monocytogenes in ready to eat products (RTE)was the reason for 31% of the recalls (137, 367, 610 lbs). Salmonella in RTE accounted for 25 recalls (3, 848, 073 lbs), while bacterial spoilage organisms resulted in 11 recalls (4, 928, 018 lbs). Ninety six recalls (18, 471, 925 lbs) were due to contamination with extraneous material (e.g. metals, bone, plastic or glass). There were also 14 recalls each due to chemical contamination (1, 972, 681 lbs) and mislabeling (2, 975, 653 lbs). The overall average number of recalls per year was 48 +/- 24. Analysis of the data showed nearly as many recalls between 1999 and 2002 as between 1990 and 1998 (306 vs. 316 combined, respectively). Various reasons for these recalls are discussed.

# 1032 EFFECTS OF SIX DIETARY PHYTOCHEMICALS ON AFLATOXIN B<sub>1</sub>-MEDIATED GENOTOXICITY AND GENE EXPRESSION IN HUMAN HEPATOCYTES AND HEPG2 CELLS

K. Gross-Steinmeyer<sup>1</sup>, K. M. Bradley<sup>1</sup>, P. L. Stapleton<sup>1</sup>, F. Liu<sup>1</sup>, J. H. Tracy<sup>1</sup>, <u>T. K. Bammler<sup>1</sup></u>, R. P. Beyer<sup>1</sup>, S. C. Strom<sup>2</sup> and <u>D. L. Eaton<sup>1</sup></u>. <sup>1</sup>Department Environment & Occup. Health Sciences, University Washington, Seattle, WA and <sup>2</sup>Department Pathology, University Pittsburgh, Pittsburgh, PA.

Six dietary phytochemicals, curcumin (CUR), 3, 3'-diindolylmethane (DIM), isoxanthohumol (IXN), 8-prenylnaringenin (8PN), phenethyl isothiocyanate (PEITC) and sulforaphane (SFN) protect animals against chemically induced tumors. The ability of these phytochemicals to reduce DNA-adduct formation of the hepatocarcinogen, aflatoxin B<sub>1</sub> (AFB), was examined in cultures of human primary hepatocytes (PH) and human hepatoma cells (HepG2). In PH, SFN (50 uM) significantly decreased, whereas DIM (10 uM) and 8PN (10 uM) increased AFB-DNA adduct levels. In HepG2 cells, PEITC (5 uM) and SFN (3 uM) also decreased, and DIM (3 uM) also increased AFB-DNA adduct levels. We determined the effects of phytochemicals on mRNA expression of enzymes involved in biotransformation of AFB (e.g. CYPs 1A1, 1A2, 3A4, 3A5, 3A7, GSTM1) by RT-PCR. CYP1A1/2 mRNA was up-regulated by all six chemicals at 10 and 50 uM. DIM induced CYP1A1 (up to 474-fold) and 1A2 (up to 113-fold) in a dose-related manner from 0.1-50 uM, and this was generally reflected in protein levels (Western blot) and enzyme activity (MROD). CYP3A4, 3A5 and/or 3A7 transcription was down-regulated by all phytochemicals whereas GSTM1 mRNA was not altered. CUR and DIM, but not SFN, inhibited human CYP1A2-mediated MROD activity in vitro. Inhibitory effects of PEITC and IXN on hCYP1A2 activity were reported previously by others. Microarray analysis in human hepatocytes revealed that mRNA levels of many genes were affected. For example, DIM significantly increased mRNA of more than 80 genes, including CYPs 1A1, 1A2, 2B6, UGT1A9, and

SULT1A3. Collectively, these data suggest that each compound exhibits its AFB-DNA damage modulating effects *via* different mechanisms. The increase in DNA damage by DIM raises potential safety risks involved in consuming dietary supplements of indole-3-carbinol, the precursor of DIM (Supported by NIH grants R01 ES05780 and P30 ES07033)

### 1033 EFFECTS OF INCREASING PERCENTAGE OF DIETARY MAIZE ON RATS.

S. A. MacKenzie<sup>1</sup>, N. E. Everds<sup>1</sup>, L. A. Malley<sup>1</sup>, G. S. Ladics<sup>1</sup>, J. F. Hansen<sup>1</sup>, I. Lamb<sup>2</sup> and G. Dana<sup>2</sup>. <sup>1</sup>DuPont Haskell Laboratory, Newark, DE and <sup>2</sup>Pioneer Hi-Bred International, Inc., Johnston, IA.

The objective of this study was to assess the maximum percent of dietary maize that could sustain adequate health and growth in rats. Six groups of male and female Crl:CD®(SD)IGS BR rats (10/sex/group) were fed diets containing 33, 55, 70, 80, 90, or 100% maize. An additional control group was fed PMI® Nutrition International, LLC Certified Rodent LabDiet® 5002 (contained 33% maize; referred to as 0%). Diets were supplemented to provide adequate nutrients, where possible. Rats were evaluated for body weights, food consumption, clinical signs, neurobehavioral, ophthalmological, clinical and anatomic pathology parameters, and allergenicity. The 100% group was sacrificed after 4 weeks due to mortality. In groups fed up to 90%, no effects were observed on survival, clinical or ophthalmological parameters, food consumption, hematology, urinalysis, neurobehavioral, anatomic pathology (females only), or allergenicity parameters. The NOEL in females was 90% maize, based on body weight loss and mortality in the group fed 100%. The NOAEL in males was 80% maize, based on lower body weight gain and food efficiency, clinical chemistry changes, and increased hepatic fatty change in groups fed 90% maize. The NOEL in males was considered to be 55% maize, as minimally increased prothrombin and activated partial thromboplastin times were observed in individual rats in groups fed 70% and above; however, the increased coagulation times were not associated with any correlative adverse effects in males fed up to 90% maize.

## 1034 IMPACT OF 30-DAY ORAL DOSING WITH N-ACETYL-L-CYSTEINE ON SPRAGUE-DAWLEY RAT PHYSIOLOGY.

E. W. Johnson<sup>1</sup>, A. R. Thitoff<sup>1</sup>, A. E. Jung<sup>1</sup>, J. S. Eggers<sup>2</sup>, S. L. Lohrke<sup>1</sup>, A. J. Bobb<sup>1</sup> and <u>D. P. Arfsten</u><sup>1</sup>. <sup>1</sup>Naval Health Research Center Toxicology Detachment, Wright-Patterson AFB, OH and <sup>2</sup>Air Force Research Laboratory, Brooks AFB, TX.

Clinical trials have shown that administration of N-acetyl-L-cysteine (NAC) has beneficial effects in persons afflicted with HIV, Sjogren's Syndrome, Alzheimer's disease, and acute lung injury. Studies in animals have demonstrated a protective effect of NAC when given prior to toxic chemical exposure. This effect may be attributed to free radical quenching by NAC or to NAC serving as a cysteine source for glutathione (GSH) synthesis. The long-term impact of NAC intake on liver, kidney, and skin GSH/GST levels, GI tract, liver, and kidney histopathology, and serum chemistries were evaluated in adult Sprague-Dawley (SD) rats. Groups of 20 SD rats (10 male, 10 female), 8 weeks of age, were dosed daily by oral gavage for up to 30 days with deionized H2O (negative controls) or NAC at a rate of 600 or 1, 200 mg/kg. Animals were euthanized on study days 5 or 30 at 6 hours after treatment. There were no significant differences in final body weights or weekly average weight gain between treatment groups at both the 5- and 30-day study endpoints. At study day 30, serum alanine aminotransferase (ALT) activities were significantly elevated (p≤0.05) for animals treated with NAC as compared with controls. Serum creatinine concentrations from animals treated with 600 mg/kg for 30 days were nearly 2 times higher (p≤0.05) than those for animals treated with dH<sub>2</sub>O or 1, 200 mg/kg NAC; 50% of these animals had concentrations above the normal cut-off of 0.65 mg/dl. No treatment-related histopathology was found in analysis of tissues from animals treated for 5 or 30 days. Repeat oral treatment with NAC did not increase skin, liver, or kidney GSH levels or GST activity. Further studies are planned to determine if NAC treatment possibly results in an increase in cysteine concentrations present in these tissues.

## 1035 COMBINATIVE TOXICITY OF MULTIPLE MYCOTOXIN MIXTURES IN ANIMALS AND HUMAN CELLS.

C. Mckean, L. Tang, M. Billam, H. Luo, M. Tang, C. Theodorakis, R. Kendall and J. Wang. EnvTox/TIEHH, TTU, Lubbock, TX.

Ubiquitous co-contamination of multiple mycotoxins in dietary components has been widely reported and is believed to play an important contributing role in high incidence of primary liver and esophageal cancers in certain areas of the world. Aflatoxin B $_{\rm 1}$  (AFB $_{\rm 1}$ ), T-2 Toxin (T2) and fumonisin B $_{\rm 1}$  (FB $_{\rm 1}$ ) are important foodborne mycotoxins that historically caused a variety of acute mycotoxicoses in ani-

mals and humans. In this study the combinative toxicity of AFB<sub>1</sub>, T-2, and FB<sub>1</sub> was tested in F-344 rats, Mosquitofish (Gambusia affinis), and the immortalized human cell lines HepG2 and Beas-2B. This was accomplished by obtaining the  ${\rm LD}_{50}$ ,  ${\rm LC}_{50}$ and IC50 for individual toxins in each model respectively, followed by testing the combinations beginning with two and based on those results finally three mycotoxins. Male F344 rats were divided into four treatment groups and dosed with 1/2, 1/3, 1/4, and 1/6  $\rm LD_{50}$  values for AFB $_{1}$  and T-2 respectively, while FB $_{1}$  remained constant at 10 mg/kg. Mortality in the highest dose group reached 83.33%, while no other deaths were recorded. Surviving animals had apparent toxic symptoms with the exception of the lowest dose. Healthy mixed sex mosquito fish (approx. 1:1 ratio) under optimized condition were divided into four treatments dosed with 1/3, 1/4, 1/6, and 1/12 LC<sub>50</sub> AFB<sub>1</sub>, T-2, and FB<sub>1</sub>. Observation extended for 7 days resulting in a mortality of 83.34%, 62.52%, 25.02%, and 12.49% respectively. The cytotoxicity of treated HepG2 and BEAS-2B were assessed. Treatment of cells with  $3/4,\,1/2,\,3/8,\,1/4,$  and 1/6 IC  $_{50}$  of AFB  $_1$  T-2, and FB  $_1$  yielded  $\it via$  bilities of 67.3%, 73.2%, 78.1%, 98.1%, and 93.2%. All models demonstrated a significant dose response in observed parameters to treatment. Overall, however, the combination of three toxins demonstrated decreased toxicity over our predicted values and results of two combination trials. These results will provide foundational knowledge for future studies on long-term combinative toxic and health effects of these mycotoxins. (Supported by the research contract DAAD13-02 C-0070 from the SBC-COM, ÛS Army).

APPLE JUICE EXTRACT AND CERTAIN POLYPHENOLS IN APPLE JUICE ACT AS INDUCERS OF CYP1A1 AND MPD2

C. Pohl<sup>1</sup>, V. Emmerlich<sup>1</sup>, H. Schmitz<sup>1</sup>, F. Will<sup>2</sup>, H. Dietrich<sup>2</sup> and <u>D. Schrenk</u><sup>1</sup>.

<sup>1</sup>Food Chemistry and Environmental Toxicology, University of Kaiserslautern, Kaiserslautern, Germany and <sup>2</sup>Forschungsanstalt Geisenheim, Geisenheim, Germany.

Flavonoids represent a group of phytochemicals exhibiting a wide range of biological activities such as antioxidant properties and their ability to modulate several enzymes. A number of reports have shown that flavonoids can induce the expression of several cytochromes P450 (CYPs) and ABC export pumps and inhibit or stimulate their activity. In this study we incubated the human colon carcinoma cell line Caco 2 with an apple juice extract (AJE) and also with single polyphenolic components of this extract (quercetin, rutin, phloridzin). In parallel experiments, the antioxidants ascorbate (0.25 mM) and a-tocopherol (0.05 mM) were added. AJE was cytotoxic at high concentrations (24 h; 1 mM as phloridzin), whereas the pure polyphenols and the glycoside rutin were cytotoxic at much lower concentrations: quercetin (1 h;  $> 50 \,\mu\text{M}$ ), phloridzin (1 h;  $> 5 \,\mu\text{M}$ ), rutin (1 h;  $> 5 \,\mu\text{M}$ ), measured as significant inhibition of MTT reduction. These effects were completely abolished by the antioxidants indicating the formation of reactive oxidation products of the polyphenols as cytotoxic mechanism. After 48 hours of incubation with AJE or pure polyphenols (with ascorbate/tocopherol) mRNA and protein levels of CYP 1A1, 1A2, 1B1, 3A4, P-glycoprotein (Pgp), and Multidrug resistance protein (MRP) 1 and 2 were determined. CYP1A1 mRNA was not detectable in untreated cells but was induced significantly with AJE (> 50 µM; as phloridzin). MRP2 mRNA was detectable in untreated cells and was induced about 3-fold with 100  $\mu M$  AJE (as phloridzin). All other genes tested were expressed in untreated cells but were not induced with AJE or the pure polyphenols. The polyphenols also induced CYP1A1 and MRP2. The effects at the mRNA level were paralleled by induction at the protein level. Calculations suggest that induction by AJE is almost exclusively due to phloridzin, one of the major polyphenolic constituents of apple juice.

#### 1037

ONCOGENICITY EVALUATIONS OF SOY ISOFLAVONES AND BOWMAN-BIRK INHIBITOR IN  $\mathsf{p53}^{(4/2)}$  MICE.

D. McCormick<sup>1</sup>, W. Johnson<sup>1</sup>, R. Selby<sup>1</sup>, L. Dooley<sup>1</sup>, R. Morrissey<sup>2</sup>, L. Arp<sup>2</sup> and J. Crowell<sup>3</sup>. <sup>1</sup>IIT Research Institute, Chicago, IL, <sup>2</sup>Pathology Associates, Chicago, IL and <sup>3</sup>National Cancer Institute, Bethesda, MD.

Epidemiologic data suggest that soy consumption may protect against cancer induction in several tissues. Although the soy components responsible for this activity remain unidentified, soy isoflavones (e.g., genistein) and soy-derived protease inhibitors (e.g., Bowman-Birk Inhibitor [BBI]) demonstrate chemopreventive activity in several experimental cancer models. As part of the preclinical development of soy isoflavones and BBI for cancer prevention, oncogenicity studies were conducted in p53<sup>(+/-)</sup> (heterozygous p53 knockout) mice. In each study, groups of 25 p53<sup>(+/-)</sup> mice per sex received daily gavage exposure to a soy component or vehicle for 6 months. PTI G-2535 (a soy isoflavone mixture containing 45% genistein, 23% daidzein, and 4% glycitein) was administered at 0, 250, 1000, or 2500 mg/kg/day in 0.5% aqueous carboxymethylcellulose. PTI G-2535 doses were selected using data from a subchronic dose tolerance study. BBI was administered at 0, 500, 1000, or 2000 mg/kg/day in distilled water. BBI dose was limited by viscosity. p-Cresidine (400 mg/kg/day) was used as a positive control article in both studies. Daily administration of PTI G-2535 to p53<sup>(+/-)</sup> mice induced a dose-related suppression of body

weight gain in males only. Both sexes demonstrated increased liver and spleen weights, decreased RBC counts, and increased RBC volume and mean corpuscular hemoglobin. Females demonstrated increased plasma cholesterol and triglycerides. Daily administration of BBI to p53<sup>(+/-)</sup> mice had no effect on body weight, food consumption, clinical pathology, or organ weights in either sex. Neither agent induced any clinical evidence of toxicity, and gross pathology was unremarkable in both studies. Histopathologic evaluation of tissues demonstrated no increases in the incidence of either benign or malignant tumors in any group exposed to PTI G-2535 or to BBI. Neither PTI G-2535 nor BBI demonstrated any evidence of oncogenicity in the p53<sup>(+/-)</sup> mouse model. (NCI-N01-CN-15142 and N01-CN-95140)

#### 1038

A SIMPLE CYTOTOXICITY AND GENOTOXICITY ASSAY FOR ENVIRONMENTAL MONTORING USING NOVEL PORTABLE INSTRUMENTATION.

A. W. Knight<sup>2, 3</sup>, P. O. Keenan<sup>1, 3</sup>, N. J. Goddard<sup>2</sup>, P. R. Fielden<sup>2</sup> and R. M. Walmsley<sup>1, 3</sup>, <sup>1</sup>BMS, UMIST, Manchester, United Kingdom, <sup>2</sup>DIAS, UMIST, Manchester, United Kingdom and <sup>3</sup>Gentronix Ltd., Manchester, United Kingdom. Sponsor: L. Walsh.

A simple assay capable of simultaneously measuring both general toxicity and more subtle genotoxicity, in aqueous environmental samples, will be described. The assay uses eukaryotic (yeast) cells, genetically modified to express a green fluorescent protein (GFP) whenever DNA damage, as a result of exposure to genotoxic contaminants, is repaired. A measure of cell proliferation is used to characterise general toxicity producing familiar EC50 and LOEC data. The assay protocol has been developed for proposed use in the field and hence employs dedicated, portable instrumentation, which will be described. A range of environmentally relevant substances has been evaluated using the assay, including solutions of metal ions, solvents and pesticides. Preliminary data comparing the response of the yeast assay to that of a standard Daphnia test in the analysis of the toxicity of 34 varied industrial waste effluents will be presented. The sensitivity to a wide range of substances suggests the assay should be useful for environmental toxicity monitoring.

### THE EFFECT OF URBAN PARTICULATE MATTER ON HUMAN LUNG CELLS.

A. Jalbert<sup>3</sup>, N. Gordon<sup>2</sup>, S. Langley-Turnbugh<sup>3</sup> and J. P. Wise<sup>1</sup>. <sup>1</sup>Wise Laboratory of Environmental and Genetic Toxicology, Center for Integrated and Applied Environmental Toxicology, University of Southern Maine, Portland, ME, <sup>2</sup>Department of Chemistry, University of Southern Maine, Portland, ME and <sup>3</sup>Department of Environmental Science and Policy, University of Southern Maine, Portland, ME.

Maine has the fastest growing asthma rate in the nation. The environmental factors behind the increasing rate and those that trigger asthma episodes are poorly understood. One factor is airborne particulate matter. We assessed the constituents of particulate matter that may be important in triggering asthma episodes. We evaluated the cytotoxic effect of, and the amount of metal uptake from, Urban Particulate Matter (UPM), in WTHBF-6 cells, a human lung cell line. UPM induced concentration-dependent cytotoxicity in cells grown in DMEM/F12 + CCS medium. The relative survival was 81, 65, 54, and 54% after exposure to 10, 50, 100 and 200 ug/cm<sup>2</sup> UPM respectively. We extracted UPM using 0.12 M NaCl solution (the largest component of the growth medium) at pH 7.0 for 24+ hours at 25oC or for 4 hours at 37°C. The metal levels were, in ug/mg (25°C values in parentheses): Mn 0.20 (0.18), Cd 0.036 (0.029), Cu 0.100 (0.088), Cr 0.004(0.003), Ni 0.022 (0.019), Zn 0.986 (0.466), and Pb 0.058 (0.034). Because the growth medium contains proteins that may extract and bind metals, we extracted using DMEM/F12 +CCS instead of the 0.12 M NaCl. The metal levels were, in ug/mg (25°C values in parentheses): Mn 0.053 (0.067), Cd 0.032 (0.032), Cu 0.451 (0.451), Cr 0.006(0.006), Ni 0.024 (0.027), Zn 1.63 (1.37), and Pb  $0.084\ (0.203)$ . Based on these results a solution of metals was prepared to reflect the predicted metal concentrations for the 200 ug/cm<sup>2</sup> UPM concentration. This solution induced 61% relative survival. Metal uptake and cytotoxicity studies of human lung cells treated with the same UPM concentrations showed increasing levels of Cu, Zn and Pb in the medium as the particle concentrations increased, but only increased levels of Zn and Pb inside the cells. This suggests that these biosoluble metals may be toxic to human lung cells and a triggering factor in asthma episodes. This work was supported by NIEHS grant 1R01 ES 10838-01(J.P.W.).

#### 1040

EFFECTS OF MOTORCYCLE EXHAUST INHALATION EXPOSURE ON CYTOCHROME P450 2B1, ANTIOXIDANT ENZYMES AND LIPID PEROXIDATION IN RAT LIVER AND LUNG.

T. Ueng, C. Hung and H. Wang. Institute of Toxicology, National Taiwan University, Taipei, Taiwan.

The effects of motorcycle exhaust (ME) on metabolic and antioxidant enzymes and lipid peroxidation were determined using male rats exposed to 1:10 diluted ME by inhalation 2 h daily for 4 wk. For microsomal cytochrome P450 (P450) enzymes,

ME resulted in 3- and 6-fold increases of 7-ethoxyresorufin O-deethylase activities and a 3-fold increase and an 80% decrease of pentoxyresorufin O-dealkylase activities in liver and lung, respectively. The results of immunoblot analysis of microsomal proteins revealed that ME increased liver and lung P450 1A1 with minimal effects on P450 2E1. ME increased P450 2B1/2 proteins in liver but decreased P450 2B1 in lung. Similar to ME, treatment with an ME constituent m-xylene intraperitoneally at 0.5 g/kg/d for 4 d increased liver but decreased lung pentoxyresorufin O-dealkylase activity and P450 2B1 protein. For phase II enzymes, ME resulted in 53% and 2-fold increases of cytosolic NAD(P)H:quinone oxidoreductase activities and no effect and a marginal increase of microsomal UDP-glucuronosyltransferase activities in liver and lung, respectively. For antioxidant enzymes, ME produced 23% and 35% decreases of superoxide dismutase, 9% and 27% decreases of catalase, and no changes of glutathione peroxidase activities in liver and lung cytosols, respectively. For lipid peroxidation, the results of thiobarbituric acid assay showed that ME resulted in 2- and 3-fold increases of formation of malondialdehyde by liver and lung microsomes incubated with FeCl<sub>3</sub>-ADP, respectively. The present study demonstrates that ME inhalation exposure differentially modulates P450 2B1 and antioxidant enzymes and increases susceptibility to lipid peroxidation in rat liver and lung.

## 1041 INTERACTION OF SIMULATED HUMAN BODY FLUIDS WITH MERCURY MINE WASTES.

J. E. Gray<sup>1</sup>, P. L. Higueras<sup>2</sup>, P. L. Hageman<sup>1</sup>, G. S. Plumlee<sup>1</sup> and <u>T. L. Ziegler</u><sup>1</sup>. 
<sup>1</sup>US Geological Survey, Denver, CO and <sup>2</sup>Universidad de Castilla-La Mancha, Almaden, Spain.

Abandoned Hg mines are found worldwide and human activities on these mines are generally unrestricted. Of particular concern, local road constructions sometimes utilize Hg mine wastes and farming activities are found in areas contaminated by such wastes. This study was designed to evaluate potential human exposure to Hg when such mine wastes are inhaled or ingested. Waste materials were studied from mines at Almaden, Spain, the worlds largest Hg district, which has produced about 250, 000 t of Hg, and from abandoned mines in the Terlingua district, Texas, which produced about 7, 000 t of Hg. The mine wastes contain abundant Hg sulfide, elemental Hg, and Hg salts, which constitute primary ore or compounds formed during Hg extraction. Mine waste samples were leached with simulated human body fluids to evaluate their capacity to release Hg. Leaching was carried out at 370 C for 24 hours (20:1, v/w) with a simulated gastric fluid, simulated lung fluid, protein-enriched fluid (RPMI-1640 with fetal bovine serium), and deionized water. The highest Hg concentrations were found in the simulated gastric fluid leachates, and then Hg decreased in the protein-enriched fluids, simulated lung fluids, and deionized water leachates, respectively. Gastric fluid leachates of mine wastes from the Almaden district were especially elevated in Hg, as high as 460 mg/L. Soot collected from the Terlingua mine retorts also produced gastric fluid leachates with elevated Hg concentrations (up to 9.5 mg/L). Protein-enriched leachates contained Hg as high as 81 mg/L; whereas simulated lung fluid leachates contained Hg as high as 48 mg/L. Data suggest that the Hg leaching capacity is most strongly controlled by the mineralogy of the mine wastes, and leachates with the highest Hg contents result from samples containing elemental Hg and Hg salts. Results indicate that ingestion or inhalation of even small amounts of Hg mine waste may lead to increased Hg contents in the human body, especially gastric fluids.

## 1042 THE TOXICOLOGICAL GEOCHEMISTRY OF DUSTS, SOILS, AND OTHER EARTH MATERIALS: INSIGHTS FROM *IN VITRO* LEACH TESTS.

G. S. Plumlee, P. J. Lamothe, G. P. Meeker, S. J. Sutley and <u>T. L. Ziegler</u>. US Geological Survey, Denver, CO.

Exposure to dusts, soils, and other earth materials results in chemical reactions between the materials and body fluids encountered along the exposure route such as lung or gastrointestinal fluids. In vitro physiologically-based leach tests provide useful insights into these chemical reactions and their potential toxicological implications. We have conducted such leach tests on asbestos, volcanic ash, dusts from drylake beds, mine wastes, wastes left from the roasting of mercury ores, mineral processing wastes, coal dusts and coal fly ash, various soils, and complex dusts generated by the World Trade Center collapse. Size-fractionated samples of well-characterized earth materials are reacted at 37°C for periods from 2 hours up to multiple days, with various proportions of simulated lung, gastric, intestinal, and/or plasma-based fluids (SLF, SGF, SIF, and PBF). Results show that different earth materials have different solubility and dissolution behavior in vivo. For example, biodurable asbestos and volcanic ash particles bleed off low levels of metals into the SLF, including metals such as Fe and Cr that may help generate reactive oxygen species and resulting DNA damage in vivo. In contrast, dry-lake dusts and concrete-rich dusts are highly alkaline and bioreactive, and cause substantial pH increases and other chemical changes in the SLF, SGF, and PBF. Many of the earth materials tested contain a variety of metals that can be quite soluble (bioaccessible). For example, acidic SGF readily solubilize metals (Hg, Pb, Zn, others) that form strong chloride complexes; although these metals partially reprecipitate in nearneutral SIF, complexes with organic ligands (amino, carboxylic acids) enhance their solubility. These metals are also quite soluble in near-neutral, protein-rich PBF because they form strong complexes with the proteins. In contrast, metalloids (As, Cr, Mo, W, V) that form oxyanion species are commonly more soluble in near-neutral pH SLF than in acidic SGF.

## THE CHEMICAL, PHYSICAL, AND TOXICOLOGICAL PROPERTIES OF AMPHIBOLE FROM LIBBY, MT.

T. L. Ziegler<sup>1</sup>, J. D. Hyde<sup>2</sup>, G. P. Meeker<sup>1</sup>, S. J. Sutley<sup>1</sup>, P. J. Lamothe<sup>1</sup>, I. K. Brownfield<sup>1</sup>, T. M. Hoefen<sup>1</sup>, G. S. Plumlee<sup>1</sup> and M. L. Witten<sup>2</sup>. <sup>1</sup>US Geological Survey, Denver, CO and <sup>2</sup>The University of Arizona, Tucson, AZ.

Fibrous amphibole minerals are suspected of being the causative factor in the high incidence of respiratory diseases in the residents of Libby, MT. Analysis of these materials has revealed a range of amphibole compositions, classified primarily as winchite with lesser amounts of richterite and tremolite. Because winchite and richterite are not among the 6 types of asbestos cited in the current OSHA regulations, their potential links to extensive health problems suggest that the mineralogical definitions currently used to regulate asbestos may be in need of refinement. The USGS has characterized a representative suite of 30 amphibole samples obtained from the site of the former vermiculite mining operations near Libby. Toxicological analysis of these samples, utilizing an alveolar epithelial type II cell model, indicates that the level of toxicological indicators is significantly greater than those measured on the toxicological standards of 5 types of asbestos minerals currently cited in OSHA regulations. Furthermore, the toxicological response varied among the 30 Libby samples. Extensive toxicity studies and geochemical solubility studies in biological fluids (simulated lung fluid, protein enriched, gastric fluid) are in progress. In addition to the range of amphibole mineral identity, a variety of morphologies was identified in the Libby amphiboles including asbestiform fibers, acicular crystals and prismatic crystals. The role of these varying morphologies in the toxicity of the Libby area amphiboles is uncertain but clearly in need of detailed study. Future data from this project will enhance the current state of knowledge about the mineralogical, geochemical, and toxicological perspective of asbestos amphibole and may provide a foundation for the reexamination of current definitions and analytical procedures.

## 1044 FLUORIDE MODIFIES ADHESION OF STREPTOCOCCUS PYOGENES.

J. Cao<sup>1</sup>, J. luengpailin<sup>2</sup> and D. Ron J.<sup>2</sup>. <sup>1</sup>Stomatology, The Great Wall Hospital, Beijing, China and <sup>2</sup>Microbiology, University of Louisville, Louisville, KY. Sponsor: G. Jiang.

Human streptococcal isolates are confronted with numerous environmental challenges, one of which is the necessity that they adhere to one or more of the varied mucosal surfaces between their points of entry into the host and the site where physiological conditions favor colonization. To maintain themselves in these environments, the streptococci must be able to interact with different receptors on the distinct surfaces. These interactions are important in promoting bacterial attachment to the mucosal surface. Fluoride in drinking water has been acclaimed as one of the greatest public health achievements of the 20th century. Although the exact mechanisms of action of fluoride have not been defined, it is thought that the anion acts on cariogenic streptococci as well as by promoting remineralization of hydroylapatite. Recent study shown that Streptococcus sobrinus grown in medium supplemented with fluoride anion resulted in loss of glucan-binding lectin from the cell. These results have prompted a study on the effects of fluoride on adhesion of group A streptococci. Our results shown that fluoride inhibit the growth of S. pyogenes. 10 - 200 mM of NaF prevent the attachment of several stereotypes of S. pyogenes to buccal cells and to surfaces coated with collagen, fibronectin and laminin. NaF inhibited the adhesion of 4 strains S. pyogenes to buccal cells in a dose-related manner. When cells were grown in <sup>3</sup>H-thymidine, in the presence and absence of fluoride, and test the adhesion to Ln, Fn and Cn, it was showed that NaF inhibited the adhesion of S. pyogenes M5 to Cn, Fn and Ln. NaCl has no effect on adhesion. Our results also indicated that fluoride increases the secretion of M3 and M5 proteins and affects the synthesis of several proteins. Importantly, when the bacteria are grown in 0.5-3.0 mM sodium fluoride, the bacteria lose abilities to adhere to buccal cells and to plastics coated with extracellular matrix proteins. These results provide a valuable clue to investigate the effects and mechanism of fluoride in treating streptococcal infection.

#### 1045

DEVELOPMENT OF SCREENING VALUES FOR SOIL AND SEDIMENT BASED ON PROTECTION OF FLORIDA WILDLIFE.

H. Ochoa-Acuna and <u>S. M. Roberts</u>. Ctr. Env. Human Toxicology., University of Florida, Gainesville, FL.

The current ecological risk assessment paradigm relies on first comparing site soil and sediment concentrations to screening values that are typically based on direct toxicity of the chemical(s) to invertebrates. When these criteria are exceeded, exposure and risks to wildlife (usually avian and mammalian species) are modeled. It has been our experience that there is little consistency in the modeling of wildlife risks, even when the same sources of information are ostensibly used. In an effort to develop reproducible, defensible modeling of wildlife risks from contaminated soils and sediments at sites in Florida, a database of information relevant to exposure and risks for Florida species was constructed. Toxicity data for approximately 400 organic and inorganic chemicals were collected, and uptake factors were developed for each through modeling based on approaches developed by the USEPA, the Dutch Ministry of the Environment, and published reports. Also, exposure factors were developed for 30 Florida wildlife species. Toxicity data were collected from bioassays in which survival, reproduction, or developmental effects were monitored endpoints. Toxicity values for each of the 30 modeled species were calculated taking into account allometric differences. Bioaccumulation factors for sediments were estimated through modeling based on approaches endorsed by the USEPA. For contaminants with measured bioaccumulation values available in the literature, the model predictions are within the variability observed for empirical data. For soils, accumulation factors for earthworms were developed using a physiologically-based model. Correction factors were used to account for the lesser uptake of some insects. For plant matter, uptake was estimated based on a partitioning model. The wide range of species included in the database allows selection of the most applicable screening values based on the habitats present at a site. This work was supported in part by a contract from the Florida Department of Environmental Protection.

## 1046 DETECTION OF ORGANOCHLORINE CONTAMINANTS IN THE SHED SKIN OF SNAKES.

S. D. Holladay and D. E. Jones. Veterinary Medicine, Virginia Tech, Blacksburg, VA.

Corn snakes (Elaphe guttata) were fed thawed mice once per week. On the first feeding of each month, the thawed mice were injected, into the peritoneal cavity, with vehicle or vehicle containing a mixture of the organochlorine (OC) compounds: chordane, lindane (gamma-hexachlorocyclohexane), and a polychlorinated biphenyl (PCB) mixture, arochlor 1254. Snakes were weighed prior to feeding of contaminated mice, after which chemicals were injected into mice to result in exposure to the snakes as follows: chlordane: 2 mg/kg; lindane: 8 mg/kg; PCB: 4 mg/kg. Remaining weekly feedings each month were with non-contaminated mice. Shed skins from snakes exposed to vehicle or the OC mixture were collected for a period of six months and pooled by animal. Skins were finely chopped into small pieces and then ground to a fine grain consistency using mortar and pestle. OC contaminants were extracted from ground skins using solvents, and analyzed by gas chromatography equipped with electron capture. OC contaminants were readily detected in the shed skins: chlordane: 0.155 to 0.213 ppm; lindane: 0.028 to 0.042 ppm; PCB: 3.49 to 7.01 ppm. These levels of OCs are similar to previous levels detected in livers of wild-caught turtles. All snakes exposed to vehicle only had nondetectable levels of OC. These data suggest that the shed skin of snakes may serve as an elimination route for chemical contaminants, and as such may have utility as a non-invasive, non-destructive indicator tissue for assessing local environmental contamination.

#### 1047 PATHOLOGY OF OCHRATOXISIS IN BROILERS.

A. -. Muthuswamy<sup>1</sup> and G. -. -<sup>2</sup>. <sup>1</sup> Toxicology, University of Kentucky, Lexington, KY and <sup>2</sup>Department of Pathology, Veterinary College and Research Institute, Namakkal, Tamil Nadu, India. Sponsor: M. Vore.

In India Ochratoxin A contamination in feed is widespread and causes massive reduction in production in the poultry industry. The present work was carried out, to characterize the pathology of Ochratoxin A in broilers. Broiler chicks (96 day-old) were randomly divided into four groups (24 each) and were given Ochratoxin A in feed at 0, 1.5, 2.5 and 4 ppm for 4 weeks. All birds were weighed on day-one and at weekly intervals. Six from each group were sacrificed from 1st to 4th week. A highly significant (P < 0.01) reduction in body weight was shown from 2nd week in birds treated with 4 ppm of Ochratoxin A. In toxin treated groups, there was significant reduction (P < 0.05) in values of packed cell volume (4 ppm), haemoglobin (all groups) and total erythrocyte count (all groups) from that of control birds. The values of serum total protein, albumin, cholesterol, uric acid, creatinine and serum alkaline phosphatase showed highly significant difference (all groups) from that of control birds. Clinical signs like listlessness, reduced feed intake, polydipsia, depression of growth and diarrhea were exhibited by Ochratoxin A treated birds. Grossly,

kidneys were enlarged, pale in colour; liver was enlarged with distended gall bladder; spleen was atrophic and bursa of Fabricious showed reduction in size from first week onwards. Microscopically, kidneys showed tubular dilatation, foci of mononuclear cell infiltration, vacuolar degeneration, apoptotic bodies and thickening of glomerular basement membrane. Liver showed focal mononuclear cell collection, Kupffer cells hypertropy, degeneration of hepatocytes, biliary epithelial hyperplasia and microgranuloma formation. Spleen, bursa of Fabricious and caecal tonsils showed lymphoid depletion. Pancreas showed acinar cell degeneration, hyperplastic and hypertrophic changes in islets. The histopathologic changes were found to be duration dependent, with the increased severity with increased time.

## 1048 MERCURY AFFECTS NEUROCHEMICAL RECEPTOR BINDING CHARACTERISTICS IN THE CEREBRAL CORTEX AND CEREBELLUM OF WILD RIVER OTTERS.

N. Basu<sup>1</sup>, K. Klenavic<sup>2</sup>, A. M. Scheuhammer<sup>3</sup> and H. M. Chan<sup>4, 5</sup>. <sup>1</sup>Natural Resource Science, McGill University, Montreal, QC, Canada, <sup>2</sup>Environmental and Resource Studies, Trent University, Peterborough, ON, Canada, <sup>3</sup>Canadian Wildlife Service, Ottawa, ON, Canada, <sup>4</sup>Center for Indigenous Peoples' Nutrition and Environment, McGill University, Montreal, QC, Canada and <sup>5</sup>Dietetics and Human Nutrition, McGill University, Montreal, QC, Canada.

Fish-eating wildlife, such as river otters (Lutra canadensis), can bioaccumulate high levels of mercury (Hg) through their natural diets. Hg can impair the neuro-behaviour of these wildlife, but few studies have explored the sub-clinical changes in neurochemistry that may precede permanent behavioural outcomes. The objective of this study is to determine the relationship between neurochemical receptor binding characteristics and mercury exposure in river otters. River otters were collected in Ontario and Nova Scotia (Canada) by local trappers, and concentrations of total Hg and methyl Hg (MeHg) were measured in the cerebral cortex and cerebellum. Receptor-binding assays for the cholinergic muscarinic acetylcholine (mACh) receptor were conducted to calculate the receptor density (Bmax) and ligand affinity (Kd). In the cerebral cortex, there was a significant correlation between Hg and mACh receptor density (total Hg: r = 0.72, p<0.001; MeHg: r = 0.82, p<0.001). In contrast to the cerebral cortex, a significant negative correlation was calculated between Hg and mACh receptor density in the cerebellum (total Hg: r= -0.55, p<0.05; MeHg: r = -0.61; p<0.05). Collectively, these results show that environmentally relevant concentrations of Hg may affect mACh receptor density in specific brain regions of river otters, and the physiological and ecological implications of these changes need to be addressed. In conclusion, neurochemical receptor binding characteristics (i.e. mACh and dopaminergic receptors) represent potentially novel biomarkers of Hg exposure and effect in wildlife.

## THYROID AXIS INHIBITION IN XENOPUS LAEVIS: GENE EXPRESSION CHANGES IN THE BRAIN.

S. J. Degitz<sup>1</sup>, J. J. Korte<sup>1</sup>, G. W. Holcombe<sup>1</sup>, P. A. Kosian<sup>1</sup>, J. E. Tietge<sup>1</sup>, C. M. Bailey<sup>2</sup>, N. Veldhoen<sup>2</sup>, F. Zhang<sup>2</sup> and C. C. Helbing<sup>2</sup>. <sup>1</sup>MED, USEPA, Duluth, MN and <sup>2</sup>Univesity of Victoria, Victoria, BC, Canada. Sponsor: J. Nichols.

Previously, we have proposed an amphibian-based thyroid axis screening assay in which NF stage 54 tadpoles are exposed for 14 day and disruption of the axis is determined by measuring developmental rate and thyroid morphology. Using this approach we have conducted experiments establishing comprehensive dose responses for three model thyroid axis antagonists methimazole, 6-propylthiouracil, and perchlorate. In the current experiments we have examined gene expression changes in the brain following exposure to these inhibitors using cDNA and oligonucleotide arrays specific to Xenopus laevis. Stage 54 tadpoles were exposed to methimazole (25 mg/L), 6-propylthiouracil (20 mg/L) and perchlorate (1000 ug/l) for 24, 48, or 96 hr, the brains were removed and processed to gene array analysis. We have previously shown that these chemical concentrations have comparable impacts on both developmental rate and thyroid gland morphology. A couple of the most interesting changes observed include those with myelin basic protein and myelin proteolipid protein. Both genes were up regulated by all three inhibitors in a time dependent fashion. These inhibitors are known to have their direct action on the thyroid gland and it is likely that these changes observed in the brain are a consequence of decreases in circulating T4, rather than a direct action of the chemicals. From these experiments we conclude that these genes show promise as biomarkers of thyroid axis inhibition in developing amphibians. This abstract does not necessarily reflect EPA policy.

### 1050 AQUATIC MICROBIAL POPULATION AND COMMUNITY RESPONSES TO SELECT SSRIS.

B. W. Brooks<sup>1</sup>, D. Fadelu<sup>1, 2</sup>, E. A. Glidewell<sup>1</sup> and R. Massengale<sup>2</sup>.

<sup>1</sup>Environmental Studies, Baylor University, Waco, TX and <sup>2</sup>Biology, Baylor University, Waco, TX. Sponsor: M. Kanz.

Select selective-serotonin reuptake inhibitor (SSRI) pharmaceuticals are reported to affect microorganisms, perhaps by inhibiting efflux pumps. Because microbial communities form the base of stream ecosystem food webs, such a potential effect

of SSRI on aquatic microorganisms is of particular interest. Recent research indicates that pharmaceutical and personal care products are found in effluent-dominated streams. Our objectives were to assess response of a model bacterium, Vibrio fischeri, and microbial communities following individual and combined exposures to the commonly prescribed therapeutics fluoxetine, fluvoxamine and citalopram. Community responses were assessed with carbon-utilization pattern analysis of aquatic microbial populations collected from an uncontaminated regional reference stream. Temporal community responses to SSRI exposure of 0, 10, 100, 1000, 10000 ng/L, which represent environmental realistic concentrations, were determined using Biolog ECOplates. For fluoxetine, carbon-utilization analyses indicated significant differences in carbon-utilization following exposure for 24-96 hours. Furthermore, analysis of average well-color development indicated that utilization of 5 carbon sources was significantly inhibited with increasing fluoxetine concentration. This inhibition was observed with fluoxetine concentrations as low as 1  $\,\mathrm{ng/L}$  suggesting that ambient aquatic microbial population carbon-utilization is suppressed by environmentally realistic fluoxetine exposures. Based on acute studies with three SSRI and a model marine microorganism, aquatic microbial responses to SSRI mixtures are suggested to be additive. However, future studies are required to assess microbial community responses to SSRI mixtures. Our preliminary data suggest that carbon-utilization patterns provide a valuable technique to study specific environmental or non-target effects of SSRIs on aquatic microorgan-

INHIBITION OF GERMINAL VESICLE BREAKDOWN (GVBD) IN XENOPUS OOCYTES *IN VITRO* BY A SERIES OF SUBSTITUTED GLYCOL ETHERS.

D. J. Fort<sup>1</sup>, J. H. Thomas<sup>1</sup>, J. H. Thomas<sup>1</sup>, P. D. Guiney<sup>2</sup> and J. A. Weeks<sup>2</sup>.

<sup>1</sup> Fort Environmental Laboratories, Stillwater, OK and <sup>2</sup> Product Safety, Toxicology & Environmental Assessment, SC Johnson & Son, Inc., Racine, WI.

A 24-h in vitro Xenopus oocyte maturation assay was used to screen chemicals for endocrine disruption activity. Under normal conditions, Xenopus oocytes undergo final maturation which is induced by progesterone via a membrane bound receptor (OMPR) or androgens via a classical intracellular receptor (AR). Final maturation is marked morphologically by germinal vesicle breakdown (GVBD). Because the Xenopus oocyte progesterone receptor is membrane bound, chemicals in the medium may directly interact with the OMPR. The progestin/antiprogestin activities of a series of substituted glycol ethers including: ethylene glycol monomethyl ether (EGME), -monoethyl ether (EGEE), -monopropyl ether (EGPE), monobutyl ether (EGBE), -monophenyl ether (EGPhE), diethylene glycol monomethyl ether (DGME), and triethylene glycol monomethyl ether (TGME) were screened using the in vitro Xenopus oocyte GVBD assay. Results suggested that each of these test materials were capable of inhibiting GVBD in vitro in a concentration dependent manner with the following relative potency: EGPhE > EGME >> EGPE >> EGBE >> DGME > TGME. Potency, expressed as an IC25, ranged from 1.0 ug/L for EGPhE to >10 mg/L for TGME. In each case, androstenedione was capable of reversing the inhibition. These results, combined with previous OMPR binding studies, suggest that effects of this glycol ether series may be mediated through the OMPR, and not the AR. Overall, results suggest that the Xenopus oocyte GVBD assay could be useful in high throughput progestin/androgen screening.

TOXICOKINETICS OF PCBs IN TADPOLES OF THE GREEN FROG (*RANA CLAMITANS*): DOES METAMORPHOSIS AFFECT ELIMINATION RATES.

J. L. Leney, D. G. Haffner and K. G. Drouillard. *Great Lakes Institute for Environmental Research (GLIER), University of Windsor, Windsor, ON, Canada.* Sponsor: R. Letcher.

In recent decades, worldwide declines in amphibian populations have been observed. One of the possible explanations for this phenomenon is the increase in levels of toxic chemicals in the environment. In order to determine the relative hazard of various chemicals to amphibians, a life cycle exposure model must be developed. Such a model could be used to identify critical exposure periods during the amphibian life cycle. The focus of the present study was to investigate the exposure dynamics of polychlorinated biphenyls (PCBs) in tadpoles of the green frog (*Rana clamitans*). This investigation involved determining the elimination rates of 79 PCB congeners from dosed tadpoles. Tadpoles were dosed by feeding fish food spiked with a 1:1:1 mixture of Aroclors 1248, 1254, and 1260. Over a period of 7 days, approximately 20 g of PCB-spiked fish flakes were placed into a tank containing *R. clamitans* tadpoles. The total PCB concentration in the food was found to be 229.1 mg/g (SEM=26.9 mg/g, n=3). Spiked tadpoles were then placed into clean water along with control tadpoles. Control and dosed tadpoles were kept separate by mesh dividers. Tadpoles were sampled on various dates over a 44-day pearate by mesh dividers. Tadpoles were sampled on various dates over a 44-day pearate by mesh dividers.

riod as they underwent metamorphosis. Sampled tadpoles were analyzed to determine tissue residue concentrations for 79 PCB congeners. The average initial total PCB concentration in the dosed tadpoles was 11.0 mg/g (SEM=1.3 mg/g, n=6). At many sampling dates, some tadpoles were undergoing metamorphosis, while others had not yet started to transform. PCB elimination rates were determined separately for metamorphosed and non-metamorphosed tadpoles and results compared. The loss of lipid that occurs as tadpoles become frogs is predicted to increase the fugacity of PCBs and cause increased mobilization of these chemicals during metamorphosis. Results confirmed that metamorphosed frogs could be distinguished from tadpoles based on PCB congener profiles.

## 1053 EFFECT OF TEMPERATURE ON TOXICITY OF HEAVY METALS IN AQUATIC INVERTEBRATES.

M. A. Khan. Biological Sciences, University of IL at Chicago, Chicago, IL.

The effect of acute thermal stress and thermal acclimation on toxicity of copper, zinc, cadmium, and lead was studied in selected freshwater micro- and macro-invertebrates. The rate of oxygen consumption increased in zebra mussels (Dreissena polymorpha) by 100% during a rise in temperature from 20° to 25°C and in crayfish (Procambrus clarki) by 60% during a rise from 15° to 23°C. In the water flea (Daphnia magna) the rate of heart beat increased by 25% during a rise from 15° to 23°C. The acute lethal limits were 30°C for all these species. Thermal stress increased the acute toxicity of metals to these species. In zebra mussels, a rise from 20° to 25°C reduced the 24-hour LC50 value of copper from 774 to 238 mg/L and of zinc from 45 to 23 mg/L. The toxicity to daphnids increased more than 2-fold for cadmium and lead, 5-fold for copper, and 10-fold for zinc by 8°C-rise in water temperature. The toxicity of these metals to crayfish increased only about 2-fold by an 8°C rise in temperature. Lead, which caused 100% mortality in 14 hr at 28°C, took more than a week to cause this at 15°C. The toxicity of these metals and their negative effect on metabolism increased by raising temperature, or prolonging the duration of exposure of animals. Acclimation at respective temperatures for 2 weeks or longer, lowered the intensity of the effect on metabolism observed during thermal stress, as seen above. However, thermal effect on metal toxicity was still observed. These data indicate that the mechanism/s of toxicity of these metals are sensitive to temperature and may not be directly related with their effects on metabolism. These bio-indicators demonstrate that the global warming of bodies of water can make sub-lethal concentrations of these metals become lethal to and, thus, threaten the survival of aquatic food-chains.

A DETERMINATION OF ARSENIC CONCENTRATIONS IN FISH FROM THE NORTH FORK OF AMERICAN FORK CANYON, UTAH.

W. Ball, T. Jewkes, J. Contreras and E. Revenaugh. Environmental Epidemiology Program, Utah Department of Health, Salt Lake City, UT.

The North Fork of the American Fork Canyon is located in the Wasatch Mountains approx. 40 miles SE of Salt Lake City, UT. In Aug 2002, three species of fish were collected for tissue sampling from the North Fork to assess the potential impacts from abandoned mining operations. Fifteen trout from the North Fork and five control fish from the Utah State Fish Hatchery in Springville, UT were collected and delivered to the Trace Element Research Laboratory at Texas A&M University for analysis. The fish were filleted (skin on) and analyzed for total arsenic and inorganic arsenic. Total arsenic was determined by inductively coupled plasma-mass spectroscopy. Inorganic arsenic was determined using hydride generation-atomic fluorescence spectroscopy. Arsenic concentrations were determined for two trout species native to the North Fork (brown and cutthroat trout) and for transplanted rainbow trout. Total arsenic concentrations in brown trout ranged from 0.098-0.612 mg arsenic per kg fish wet weight (mg/kg)with 0.9-6.9% inorganic arsenic. Cutthroat trout total arsenic was 0.062-0.137 mg/kg with 1.9-12.5% inorganic arsenic. Total arsenic in rainbow trout ranged from 0.065-0.244 mg/kg with <0.6-7.4% inorganic arsenic. Fish collected from the fish hatchery served as the control. The hatchery fish displayed higher concentrations of total arsenic, ranging from 0.413-0.748 mg/kg, but had a much lower percentage of inorganic arsenic, ranging from 0.3-0.7%. The hatchery trout presented the highest mean total arsenic concentration at 0.535 mg/kg. Brown trout had the highest mean inorganic arsenic concentration at 0.005 mg/kg. The mean percent inorganic arsenic content was comparable between the species; 3.15% for brown trout, 4.58% for rainbow, and 4.66% for cutthroat. The mean percent inorganic arsenic measured in hatchery trout was 0.52%. The percent of inorganic arsenic decreased with increasing concentrations of total arsenic. (This study is supported by Cooperative Agreement Number U61/ATU886120 from the Agency for Toxic Substances and Disease

NONSPECIFIC IMMUNE RESPONSES IN TWO POPULATIONS OF ATLANTIC TOMCOD (MICROGADUS TOMCOD) EXPERIMENTALLY EXPOSED TO PCB 126: CONTAMINATED HUDSON RIVER VS. REFERENCE MIRAMICHI RIVER.

E. A. Berg, J. T. Zelikoff, I. I. Wirgin, N. K. Roy, J. E. Duffy and E. A. Carlson. Environmental Medicine, New York University, Tuxedo, NY.

The Hudson River (HR) estuary (NY) is severely polluted with polychlorinated biphenyls (PCBs), a class of compounds that bioaccumulates in many wildlife species, and alters immune function in both fish and mammals. Resistance to PCBinduced toxicity has been observed in Atlantic tomcod (Microgadus tomcod) from the HR (compared to reference site fish, Miramichi River [MR] in Canada). This study seeks to determine the effects of a coplanar PCB congener on the nonspecific immune response of laboratory-reared Atlantic tomcod bred from feral parents caught either in the HR or the MR, and to explore the role of resistance in PCBmediated immunotoxicity. Fish were injected i.p. with either the vehicle control, 0.01, 0.1 or 1.0 ug PCB 126 / g BW, and examined after 7 and 14 d. Nonspecific immune function was evaluated by measuring intra- and extracellular superoxide (O2) production and phagocytic ability, by kidney phagocytes. Hepatic cytochrome P450 1A1 (CYP1A1) mRNA induction was quantified by slot blot hybridization. After 7 d, phagocytosis was significantly depressed in MR tomcod exposed to PCB at the highest dose (compared to controls). Extracellular O2 production was also decreased after 7 d, but only in HR fish exposed to 1.0 ug/g PCB; exposure to PCB had no effect on intracellular O<sub>2</sub> production in either population of fish. By 14 d, no effects were observed in either fish population for any endpoint. Moreover, no differences were observed between populations. The results demonstrate that the innate immune system of M. tomcod is only modestly sensitive to PCB 126-induced toxicity, and illustrates the importance of post-exposure duration for demonstrating immunotoxicity. Studies are currently ongoing to uncover the role of HAH-resistance in tomcod humoral and cell-mediated immune responsiveness. NIEHS Center Grant No. ES00260 and DOD Grant No. DAMD 17-99-2-9011.

SEX STEROID HORMONES IN A WATERSHED DOMINATED BY CONCENTRATED ANIMAL FEEDING OPERATIONS

E. Oberdoerster, P. Gravel, B. North, A. Dongell and J. H. Easton. Southern Methodist University, Dallas, TX.

The goal of this study was to determine the impact of Concentrated Animal Feeding Operations (CAFOs) on the Bosque River, TX. The levels of three sex steroid hormones, 17β-estradiol (E2), Progesterone (P), and Testosterone (T) were measured in the streams receiving effluent from the dairy CAFOs. In addition, largemouth bass were exposed to the levels of hormones found in the river to determine induction of vitellogenin (VTG) and changes in plasma hormone levels. Water samples were collected monthly from five sites on the Bosque River, four sites on tributaries, and one reference site. The Bosque sites are approximately 20 river miles apart, and one of the Bosque sites also receives municipal sanitary sewage discharge from the town of Stephenville, TX. Each month water samples were collected, sterile filtered, and extracted over a C18 disc, usually within 48 hours of collection. The hormones were eluted from the disc and analyzed using EIA. Hormone levels in the Bosque and it's tributaries showed a similar pattern each month, with hormone levels being highest near the northern end of the river (where the majority of the CAFOs are located), and then tapering off downstream. The reference site always had the lowest levels of hormones. The maximal hormone levels in the Bosque were 5 ng/L E2, 25 ng/L P, and 1 ng/L T. Juvenile bass were exposed in the laboratory to either 3 or 39 ng/L E2; 14 or 113 ng P; or a combination of 40 ng E2 and 13 ng P (measured doses). After two weeks, fish were sacrificed and plasma VTG, E2 and P were measured by ELISA and EIA, respectively. Under these conditions, there was no elevation of plasma VTG, E2 or P in the fish. Positive control fish that were injected with E2 had elevated VTG, E2 and P. In conclusion, sex steroid hormone levels were found at elevated levels in the Bosque River near the CAFOs. The hormone levels found in the Bosque were not high enough to induce VTG in a two-week fish exposure study. Others have shown that levels of E2 as low as 5 ng/L can induce VTG in other species of fish after a longer exposure period.

#### 1057

LOW SPECIFIC ANTIBODY RESPONSES AND ELEVATED BIOINDICATORS OF INNATE IMMUNITY IN CREOSOTE-ADAPTED MUMMICHOGS, FUNDULUS HETEROCLITUS.

L. A. Frederick and C. D. Rice. Biological Sciences, Clemson University, Clemson, SC.

Several populations of the mummichog, *Fundulus heteroclitus*, exhibit characteristics of resistance or adaptation to high levels of priority pollutants along their east coast North America range. One such population inhabits the upper Elizabeth

River estuary in Virginia at the Atlantic Wood site (AW). AW is a superfund site heavily contaminated with creosote containing a mixture of polycyclic aromatic hydrocarbons and some organometallics. Robust individuals comprise a thriving population at this site. Virtually all adults eventually develop various hepatic tumors. These fish are known to be resistant to BAP-induced CYP1A protein and EROD activity and over-express a form of GST, as well as p-glycoprotein multidrug resistance (MDR) protein. Although PAHs are known to be immunotoxic, the resident mummichog population seems to thrive. Mummichogs from the AW site and from a reference site, Kings Creek, Virginia were examined for circulating antibody titers against ubiquitous marine bacteria, including E. coli, M. marinum, V. anguillarum, V. parahemolyticus, and V. natriegens, as well as total immunoglobin and circulating lysozyme protein. The expression of lymphoid lysozyme protein and cycloxygenase 2 (COX 2) were also examined. Compared to high responses in reference fish, AW mummichogs had very low antibody titers against all bacteria examined, however expressed higher levels of circulating lysozyme. Lymphoid cells in the AW mummichogs also expressed more lysozyme and COX 2, which may indicate a state of activation and possible resistance. Taken together, our findings suggest that this chemical environment may be activating components of innate immunity, while suppressing humoral immune responses, thus compromising the AW mummichogs immune system. Present studies are underway to pathogen-challenge AW and KC mummichogs to further characterize possible differences in disease susceptibility and to determine possible mechanisms of action associated with overall differences in immune function between these two populations.

#### 1058

ESTROGENIC COMPOUNDS IN FISH BILE IDENTIFIED WITH BIOASSAY-DIRECTED FRACTIONATION.

C. J. Houtman, A. M. van Oostveen, M. H. Lamoree, <u>A. Brouwer</u> and J. Legler. *Institute for Environmental Studies, Vrije Universiteit, Amsterdam, Netherlands.* 

In fish, conjugates of many estrogenic chemicals, endogenous as well as xenobiotic, are excreted via bile into the intestine. Therefore, measurement of estrogenic activity in bile could yield useful information about the animal's internal exposure to (xeno-)estrogens. Although estrogenic activity in male fish bile has been reported before, the contribution of natural hormones and xenobiotic substances to this activity is unknown. To elucidate compounds responsible for estrogenic activity, we developed a bioassay-directed fractionation method for the identification of estrogenic chemicals in fish bile. In this approach, the in vitro reporter gene ER-CALUX assay (Estrogen Responsive Chemical Activated Luciferase Gene Expression) was used to assess estrogenic activity in deconjugated bile samples and to direct RP-HPLC fractionation and chemical analysis (by GC-MS/MS) of estrogenic compounds. The method was applied to bile from male breams (Abramis brama) collected at three locations in the Netherlands. At one of these locations, the small River Dommel, extremely high levels of plasma vitellogenin and high prevalence of intersex gonads in male bream have been observed, indicating the exposure of these fish to high levels of estrogens. In our study, we detected many xenobiotic chemicals in the bile fractions. Nevertheless, natural hormones (17\beta-estradiol, estrone and estriol) accounted for the majority of estrogenic activity in male bream bile. At the Dommel River, the synthetic contraceptive pill component ethynyl estradiol was detected in effective concentrations as well. Observed natural and synthetic hormones probably originate from an anthropogenic source, e.g. a sewage treatment plant, and may be responsible for the estrogenic effects observed in wild

#### 1059

EFFECTS OF ACUTE, SUB-LETHAL SODIUM ARSENATE EXPOSURE ON MIGRATORY BIRD MODELS:
MITOCHONDRIAL FUNCTION, OXIDATIVE STRESS AND TIME OF FLIGHT.

J. M. Brasel<sup>2, 1</sup>, R. Cooper<sup>2, 1</sup> and <u>C. A. Pritsos<sup>1, 2, 1</sup> Nutrition, University of Nevada, Reno, NV and <sup>2</sup> Environmental Sciences and Engineering, University of Nevada, Reno, NV.</u>

Arsenic is distributed in the environment at a wide range of concentrations. It is primarily transported in the environment by water and these concentrations vary due to both natural and anthropometric factors. Human factors contributing to higher than normal arsenic levels include: arsenical pesticide application; mining, and metal fabrication. Exposure of migratory birds to arsenic occurs as the result of agricultural runoff into surface waters and accumulation in mine waste ponds. The impact of this exposure has not been thoroughly investigated. We tested the impact of acute, sub-lethal exposure to arsenate on mitochondrial function, oxidative stress and time of flight using surrogate migratory bird species. Na-Arsenate toxicity at 0.0, 20.0, and 40.0 mg/kg via gavage were performed on mallard ducks as a surrogate species of migratory birds. Arsenic disrupts normal mitochondrial function, which can result in diminished intracellular ATP levels and also induce oxidative

stress. Brain, heart, and liver tissues were excised and analyzed two hours post exposure for mitochondrial respiratory control ratios (RCRs), antioxidant enzyme activities and lipid peroxidation. At 20mg/kg significant decrease (P<0.05) in RCRs were seen in both heart and brain tissues. A dose-dependent increase in superoxide dismutaste (SOD) activity was observed in all tissues, however, notable changes were not observed in catalase, glutathione peroxidase, or glutathione reductase. A dose-dependent increase in lipid peroxidation was also noted in heart and brain tissues with significance (P<0.05) in the brain at 40mg/kg. Significant increase (P<0.05) in sera creatine kinase (CK) indicating biological damage was demonstrated 24 hours following 20mg/kg exposures. Currently, studies with our Homing Pigeon Model are underway to determine if low-level acute exposures to arsenic have an affect on avian time of flight. This project was funded in part by USDA Hatch Grant NEV 00727 and the Nevada Ag. Experiment Station.

## 1060 ASSESSING ENDOCRINE-ACTIVE COMPOUNDS IN A JAPANESE QUAIL REPRODUCTION STUDY DESIGN.

L. Brewer<sup>1</sup>, J. Stafford<sup>1</sup>, E. Mihaich<sup>2</sup> and <u>R. A. Becker</u><sup>3</sup>. <sup>1</sup>Springborn Smithers Lab., Inc., Snow Camp, NC, <sup>2</sup>Rhodia, Raleigh, NC and <sup>3</sup>American Chemistry Council, Arlington, VA.

A reproduction study in an avian species is part of the EPA planned endocrine screening program. Japanese Quail, (Coturnix coturnix japonica, CCJ) offer advantages compared to other avian species. A single generation study in CCJ was designed to follow OECD guidance & included 4 additional endocrine endpoints to see if this enhanced design could improve assessment of endocrine-active compounds. Endpoints added were measurements of: 1) excreted steroid hormones; 2) egg yolk estrogen levels; 3) oviduct growth & development in 14-day hatchlings exposed to the test substance post-hatch; 4) circulating estrogen & testosterone levels. Methoxycholor (MXC), a prototypical estrogenic substance, was administered in dosed feed at 0, 5, 20, 80 & 320 ppm ad libitum for 6 weeks (commencing 2weeks after demonstrated egg production). MXC clearly suppressed estrogen levels in fecal/urate/urine samples collected at 3-day intervals from breeding pairs. Excreted testosterone levels seemed unaffected. Egg yolk estrogen was highly variable in all groups & was not significantly different among groups. MXC-treated chick oviduct weight increased, but not as much as in those of positive control birds exposed to estradiol, & the increase did not show a clear dose-response relationship. Body weight of MXC-exposed chicks increased at all exposure levels except 300 ppm (indicating systemic toxicity at this high dose). Mean blood estradiol & testosterone levels were not significantly different at 3 time points: acclimation, lights up & study termination. Monitoring excreted steroid hormone levels & 14-day oviduct & body weights in combination appear to be the most sensitive endpoints in this study. This study demonstrates the relative effectiveness of different endocrine-specific endpoints & the feasibility for using these with a CCJ reproduction study design within an endocrine assessment program. Additional evaluations with other estrogenic substances are recommended before final conclusions are made about the added value of these endpoints.

## 1061 THE AFRICAN FISH EAGLE: DEVELOPING A BIOSENTINEL MODEL TO STUDY ENVIRONMENTAL POLLUTION IN UGANDA.

W. K. Rumbeiha<sup>1</sup>, S. Hollamby<sup>1</sup>, J. Sikarskie<sup>4</sup>, C. Dranzoa<sup>2</sup>, J. Kaneene<sup>1</sup> and W. Bowerman<sup>3</sup>. <sup>1</sup>Pathobiology and Diagnostic Investigagtion, Michigan State University, East Lansing, MI, <sup>2</sup>Wildlife and Animal Resource Management, Makerere University, Kampala, Uganda, <sup>3</sup>Environmental Toxicology, Clemson University, Pendelton, SC and <sup>4</sup>Small Animal Clinical Sciences, Michigan State University, East Lansing, MI.

Uganda, like other developing countries, has in the past used persistent organic compounds in the agricultural, public health and industrial sectors. Besides, some of these compounds can drift across continents. There is no environmental biosentinel model to monitor enironmental pollution and to assess the impact of such pollutants on environmental health in this Great Lakes region of Africa. The objectives of this study were to develope the African Fish Eagle (Haliaeetus vocifer) as a biosentinel model in this region, and secondly to determine the concentrations of persistent organochlorinated pollutants (POPs) and their metabolites, and of total mercury in blood plasma and/or feathers collected from birds in the proximity of an industrial area (Entebbe) on the shores of Lake Victoria and a control site (Lake Mburo) in South Western Uganda. The hypothesis tested was that Fish eagle samples collected from Entebbe contain higher concentrations of POPs than those from L. Mburo. Samples were collected from 33 Fish eagles at the two study sites (15 at Entebbe and 18 at Lake Mburo) and analyzed for chlorinated pesticides, PCBs, or total mercury. Mercury concentration was significantly higher in samples collected from Entebbe than those from L. Mburo (p< 0.05). Five samples from Entebbe tested positive for 4, 4'-DDE at concentrations ranging from 0.001-0.005

ppm wet weight. No PCBs were detected in any samples at the limit of detection of 0.003 ppm. Considering the limited sample size, these results suggest that there is more POP pollution on the shores of Lake Victoria than Lake Mburo.

## 1062 DETECTION OF A CRITICAL PERIOD NECESSARY FOR ATRAZINE-INDUCED MAMMARY GLAND DELAYS IN

J. L. Rayner<sup>1</sup> and <u>S. E. Fenton</u><sup>2</sup>. <sup>1</sup>Department of Environmental Sciences & Engineering, University of North Carolina, Chapel Hill, NC and <sup>2</sup>Reproductive Toxicology Division, NHEERL, ORD, USEPA, Research Triangle Park, NC.

In utero exposure during gestational days (GD) 15-19 to 100 mg/kg atrazine (ATR) was shown to delay mammary gland (MG) development in the female offspring of Long Evans (LE) rats. To determine if there is a critical period of ATR exposure, dams were gestationally dosed at varying 3-day intervals and their offspring evaluated. Timed-pregnant LE rats (N= 8/group) were gavaged GD13-15, 15-17, 17-19, or 13-19 with 100 mg ATR/kg body weight (BW) or vehicle (controls, C) GD13-19. BW and MG development were compared on postnatal day (PND) 4, 22, 25, 33, and 46. No treatment effects on pup BW were detected at these times. MG whole-mounts were subjectively scored (2 scorers) for development (branching, lobules, end buds) and epithelial areas were measured (mm<sup>2</sup>). MG taken from GD15-17, 17-19, and 13-19 offspring (N>4dams/group, d/g) at PND4 displayed significant delays in epithelial development compared to C (p<0.002), and all exposed MG were smaller in area (p<0.001). At PND22 (N=3 d/g), MG taken from offspring in GD17-19 and 13-19 groups were developmentally delayed (p<0.009 vs. C), and areas were reduced in MG from those groups and GD15-17 (p<0.008). MG from animals in all groups were developmentally delayed at PND25 (N>5 d/g), 33 (N>6 d/g), and 46(N>4 d/g); p<0.05, p<0.0002, and p<0.0004 respectively, when compared to MG taken from C. Due to observed MG delays, we hypothesized that ATR-exposed animals may have difficulties in nursing their young. Females exposed *in utero* to either ATR (all groups as defined above) or C (N>3 in separate litters/group) were bred on PND68 and allowed to rear their offspring. Both female and male F2 fromGD17-19 and GD13-19 groups were significantly smaller in BW than those of C (p<0.0001, litter means, for both sexes) at PNDs 4 and 11, suggesting a need for further studies to clarify a possible adverse effect of ATR on MG development and function. (This abstract does not necessarily reflect EPA policy; Supported by NHEERL-DESE, USEPA CT826513.)

## 1063 DIFFERENTIATION OF MAMMARY TISSUE IS SEVERELY IMPAIRED IN PREGNANT MICE TREATED WITH TCDD.

B. A. Vorderstrasse<sup>1</sup>, S. E. Fenton<sup>2</sup>, A. A. Bohn<sup>3</sup>, J. A. Cundiff<sup>1</sup> and <u>B. Lawrence<sup>1,3</sup>. <sup>1</sup>Pharmaceutical Sciences, Center for Reproductive Biology, Washington State University, Pullman, WA, <sup>2</sup>RTD, NHEERL, USEPA, Research Triangle Park, NC and <sup>3</sup>Veterinary Clinical Sciences, Washington State University, Pullman, WA.</u>

The arylhydrocarbon receptor (AhR) is expressed in mammary epithelial cells, and inappropriate activation of the AhR during fetal development causes defects in mammary gland formation that persist into adulthood. However, it is not known whether the extensive differentiation of mammary tissue that occurs during pregnancy is also sensitive to disruption by AhR activation. To examine this, we exposed pregnant C57Bl/6 mice to a non-fetotoxic dose (5 µg/kg) of 2, 3, 7, 8-tetrachlorodibenzo-p-dioxin (TCDD) on days 0, 7 and 14 of pregnancy. Examination of mammary glands on days 9, 12, and 17 of pregnancy and on the day of parturition showed severe defects in development, including stunted growth, decreased branching, and poor formation of lobular alveolar structures. This impaired differentiation was biologically significant, as expression of milk protein in the gland was suppressed, and all pups born to TCDD-treated dams died within 24 hours of birth. Analysis of circulating progesterone, prolactin, and estradiol suggested that hormone production was impaired by TCDD exposure. However, hormone levels were affected only very late in pregnancy. Given that the observed defects in gland development preceded these hormonal effects, altered hormone levels are an unlikely mechanistic explanation for impaired mammary development. This novel finding that exposure to TCDD during pregnancy disrupts mammary gland development raises questions about the susceptibility of mammary tissue to direct injury by endocrine disrupting agents and the potential for AhR-mediated signaling to adversely affect lactation and breast tissue development in human populations.

## 1064 ONE-GENERATION REPRODUCTIVE TOXICITY STUDY OF FENITROTHION IN RATS.

N. Okahashi<sup>1</sup>, K. Miyata<sup>1</sup>, M. Sano<sup>2</sup>, S. Tamano<sup>2</sup>, H. Higuchi<sup>1</sup>, Y. Kamita<sup>1</sup> and T. Seki<sup>1</sup>. <sup>1</sup>Environmental Health Science Laboratory, Sumitomo Chemical Company, Ltd.,, Osaka, Japan and <sup>2</sup>Daiyu-Kai Institute of Medical Science, Ichinomiya, Japan. Sponsor: T. Yamada.

Fenitrothion is a broad-spectrum organophosphate insecticide. It has been reported recently that Fenitrothion showed anti-androgenic activity in some *in vitro* and *in vivo* screening assays, while other reports exhibited no such effects in Hershberger

or prepubertal assays. To provide a comprehensive and higher tire assessment of the effects of Fenitrothion on reproductive and endocrine system, especially on anti-androgenic activity, we conducted a one-generation reproductive toxicity study in rats. Fenitrothion was administered to Crj:CD(SD)IGS rats in the diet at concentrations of 10, 20, and 60 ppm. Parental animals (P) were exposed for 10 weeks prior to mating, and through gestation and lactation until euthanasia. Their offspring (F1) were exposed from weaning until maturation at the age of 10 weeks. In P generation, brain cholinesterase activity was remarkably inhibited with statistical significance at 60 ppm in males and at 20 and 60 ppm in females. The inhibition in maternal animals was severe (-19% and -73% at 20 and 60 ppm, respectively). There were no effects on clinical signs, body weights and food consumption with exception of slightly depressed male food consumption in the early treatment period. Reproductive performance, organ weights, histopathology, and sperm analytical parameters were not affected. In F1 generation, no effects were observed on general toxicity, anogenital distance, retained areolae/nipples, age at the onset of puberty (vaginal opening, or preputial separation), organ weights, organ histopathology, and sperm analysis. In conclusion, Fenitrothion had no effects on reproductive and endocrine systems of P and F1 generations and on development of F1 offspring even at the toxic doses that induced severe inhibition of brain cholinesterase activity in P animals. The parental systemic no-observed-adverse-effect level (NOAEL) was estimated to be 10 ppm (0.64 mg/kg/day). The reproductive and developmental NOAELs were estimated to be at least 60 ppm (3.81 mg/kg/day).

1065

EFFECTS OF 20 WEEK EXPOSURES IN FEMALE SPRAGUE-DAWLEY (S-D) RATS TO THE DRINKING WATER DISINFECTION BY-PRODUCT DIBROMOACETIC ACID.

A. S. Murr and J. M. Goldman. *RTD, NHEERL, ORD, USEPA, Research Triangle Park, NC.* Sponsor: <u>A. Cummings</u>.

The drinking water disinfection by-product dibromoacetic acid (DBA) has been shown to adversely affect reproductive function in both male and female rats, albeit at exposure levels well in excess of those normally present in finished water. The present study was designed to explore the reproductive effects in non-pregnant female rats of DBA administered in the drinking water over more extended exposures. Regularly cycling S-D females were provided with 0, 50, 150 or 300 ppm DBA (pH adjusted 5.5 - 6) beginning at 11 wks of age and continued for 20 wks. Estrous cycles were tracked during alternating 2 wk periods throughout the study. In rats continuing to exhibit 4-day cycles, small quantities of tail blood were taken on the day of estrus for estradiol (E2) measurements during the 3rd, 11th and 19th wks of exposure. All animals were killed during wk 20 (diestrous day, 7 3/4 mo.of age). Organ wts were taken, and serum stored for E2, estrone (E1) and corticosterone assays. Calculated intake for 50, 150 and 300 ppm DBA over the 20 wks averaged 5, 16 and 34 mg/kg body wt, respectively. No treatment-related effects on cyclicity were observed over the course of exposure, and by wk 20 50-60% of rats in each group were still cycling regularly. Serum E2 levels in 4d cycling rats on the 3rd & 11th wks, however, showed an increasing dose-related trend, which was consistent with previous reported changes (Goldman/Murr, Repro. Toxicol., in press). For E1 at sac, all DBA dose groups were significantly elevated over controls. In normally cycling rats at 20 wks, there were no significant changes in ovarian, uterine, pituitary or adrenal wts, although liver showed a dose-related increase. In females that exhibited a persistent vaginal cornification, ovarian wts decreased with dose. The data indicate that while DBA elevated circulating levels of estradiol and estrone, the alteration was without effect on estrous cyclicity in this moderately estrogen-sensitive strain of rat. (This is an abstract of a proposed presentation and does not necessarily reflect EPA policy.)

1066

A FIVE GENERATION REPRODUCTIVE TOXICITY ASSESSMENT OF *P*-NONYLPHENOL (NP) IN CD SPRAGUE-DAWLEY RATS.

<u>I. R. Latendresse</u><sup>2</sup>, C. C. Weis<sup>1</sup>, P. W. Mellick<sup>2</sup>, R. R. Newbold<sup>3</sup> and <u>B. Delclos</u><sup>1</sup>. <sup>1</sup>NCTR, Jefferson, AR, <sup>2</sup>Pathology Associates, Jefferson, AR and <sup>3</sup>NIEHS, Research Triangle Park, NC.

We are conducting a series of multigeneration studies under identical conditions with agents that have as one of their potential mechanisms of action interaction with estrogen receptors. NP, one of the test agents, is widely used as an intermediate in the manufacture of surfactants and polymer stabilizers. It has raised concern as a possible endocrine active toxicant because of its weak affinity for the estrogen receptor and reported reproductive effects in mammalian test systems and in aquatic organisms. In a dose range finding study, renal toxicity was found to be a limiting factor in dose selection. In the present multigeneration study, the parental generation was exposed to NP (25, 200, and 750 ppm) in a soy- and alfalfa-free diet (Purina 5K96) from 28 days prior to mating until necropsy at PND 140, the age at

which all generations were terminated. The  $F_1$  and  $F_2$  generations were exposed continuously from conception,  $F_3$  from conception until wean, and  $F_4$  was not exposed to NP. Under the conditions of the study, clear adverse effects on the multiple reproductive endpoints assessed or on general toxicity were not observed in male or female rats. Microscopic evaluation revealed treatment effects only in the male kidney at the 750 ppm dose. Mineralization in male kidneys was observed only in the 750 ppm group in the  $F_0$  through  $F_2$  generations, with the strongest response in the  $F_1$  and  $F_2$  generations where exposure occurred from conception through termination of the study. An apparent treatment-related increase in renal medullary cysts (minimal severity) occurred in the 750 ppm group in the  $F_1$  and  $F_2$  generations, but the toxicological significance of this effect is doubtful given the appearance of a variable incidence of lesions of similar severity in the control groups of some generations. This study confirmed and extended the data indicating the renal toxicity of NP and did not support the reproductive toxicity of NP under the conditions used in this study.

1067

THE ARYL HYDROCARBON RECEPTOR (AHR) MAY ALTER ESTROGEN PATHWAYS IN THE MOUSE OVARY.

K. R. Barnett<sup>1</sup>, W. Fritz<sup>2</sup>, T. Lin<sup>2</sup>, R. E. Peterson<sup>2</sup> and J. Flaws<sup>1</sup>. <sup>1</sup>Epidemiology and Preventive Medicine, University of Maryland, Baltimore, Baltimore, MD and <sup>2</sup>University of Wisconsin, Madison, WI.

The AhR is a ligand-activated transcription factor which functions in mediating the toxicity of various environmental toxicants. Although reproductive studies with AhR deficient (AhRKO) mice have shown defects in the female reproductive system, little is known about the role of the AhR in the mouse ovary. Previous studies in our laboratory have shown that AhRKO mice have a decreased number of antral follicles compared to wild-type (WT) mice. This decrease is not due to follicle death. Instead, it is a result of delayed follicular growth to the antral stage. Since estrogens are required for normal growth and maturation of ovarian follicles, one possible mechanism for this delayed follicular growth may be that the levels of estradiol (E2) or its receptors are altered in AhRKO mice compared to WT mice. Thus, these studies tested the hypothesis that AhRKO mice have lower levels of estradiol and its receptors (ERα & ERβ) than WT mice. To test this hypothesis, blood samples and ovaries were collected from AhRKO and WT mice at postnatal day (PD) 90. Blood samples were subjected to enzyme-linked immunoassay (ELISA) for the measurement of circulating estradiol levels. The ovaries were prepared for immunohistochemistry (IHC) and reverse transcriptase-polymerase chain reaction (rt-PCR) analysis to measure levels of ERa and ERB. The results indicate that AhRKO mice had significantly lower levels of estradiol compared to WT mice (WT=42±3pg/ml, n=3; ÅhRKO=23±4pg/ml, n=4, p≤0.014). In addition, AhRKO ovaries expressed lower levels of ER $\alpha$  mRNA and ER $\beta$  mRNA than WT ovaries. IHC experiments with ERα and ERβ antibodies, however, showed that AhRKO follicles ĥad lower levels of ERaand higher levels of ERB compared to WT follicles. These data suggest that the delayed follicular growth in AhRKO mice may be due to a disruption in estradiol and/or ER levels and that the AhR may be required for normal hormone responsiveness in the ovary. Supported by NIH 38955.

LACK OF INVOLVEMENT OF THE ARYL HYDROCARBON RECEPTOR IN 4-VINYLCYCLOHEXENE DIEPOXIDE-INDUCED OVARIAN FOLLICLE LOSS IN C57BL/6 MICE.

S. M. Bourguet<sup>1</sup>, H. L. Brooks<sup>1</sup>, M. R. McReynolds<sup>1</sup>, <u>I. G. Sipes<sup>2,3</sup></u> and <u>P. B. Hoyer<sup>1,3</sup>. <sup>1</sup>Physiology, University of Arizona, Tucson, AZ, <sup>2</sup>Pharmacology, University of Arizona, Tucson, AZ and <sup>3</sup>Southwest Environmental Health Sciences Center, Tucson. AZ.</u>

Repeated dosing of rats and mice with the occupational chemical, 4-vinylcyclohexene diepoxide(VCD) selectively destroys ovarian small pre-antral follicles via acceleration of the natural process of atresia(apoptosis). Previous data support that the aryl hydrocarbon receptor(AhR) is involved in VCD-induced small follicle loss in Fischer 344 rats. The AhR antagonist, alpha-naphthoflavone(ANF), protected against VCD-induced follicle loss, and AhR mRNA expression was stimulated by VCD in small follicles. The current study was designed to determine whether the AhR is also involved in VCD-induced follicle loss in mice. C57BL/6 female mice(age 28d) were injected daily (i.p., 15d) with sesame oil(vehicle control), VCD(80mg/kg), ANF(80mg/kg), or ANF+VCD. Following the final dose, ovaries were excised and processed for histological evaluation. Ovaries were sectioned and either stained with hematoxylin and eosin and evaluated for classification and counting of follicles, or prepared for immunostaining using confocal microscopy. Ovaries from another group of animals were dissociated, sorted into separate follicle fractions, and mRNA encoding the AhR was measured using real-time PCR. Compared with controls, primordial follicle numbers were decreased (p<0.05) by VCD dosing (Con, 67.8±11.3; VCD, 21.8±4.9). ANF failed to protect against VCD-induced follicle loss (ANF+VCD, 19.8±6.0). ANF alone had no effect

(72.0±6.0). Confocal microscopy in untreated mice localized AhR staining in nuclei of granulosa cells in all follicle types. There were no significant differences in levels of mRNA encoding the AhR in small follicles from ovaries of VCD-treated, versus control animals. These findings suggest that, unlike in rats, in C57BL/6 mice, VCD-induced follicle loss does not involve the AhR. The reason for these mechanistic species differences in VCD-induced follicle loss will be the subject of future investigations. (PBH, ES08979, ES09246; Center Grant ES06694)

DEVELOPMENTAL EXPOSURE TO A COMPLEX MIXTURE OF ENVIRONMENTAL TOXICANTS INTERACTS WITH POSTNATAL GENISTEIN TO INDUCE CHANGES IN REPRODUCTIVE DEVELOPMENT OF FEMALE SPRAGUE DAWLEY RATS.

W. G. Foster<sup>1</sup>, M. G. Wade<sup>2</sup>, C. L. Hughes<sup>3</sup> and E. V. YoungLai<sup>1</sup>. <sup>1</sup>OBS/GYN, McMaster University, Hamilton, ON, Canada, <sup>2</sup>Health Canada, Ottawa, ON, Canada and <sup>3</sup>Duke University, Durham, NC.

Estimates of safe exposure levels are based primarily on the results of animal studies employing single test chemicals, epidemiological studies, and estimates of potential human exposure. However, the consequences of chemical interactions to human reproductive and endocrine function remain unknown. The potential for interaction with hormonally active dietary constituents is also unknown. Therefore the objective of this study was to determine the effects of in utero exposure to a complex mixture of persistent environmental toxicants that have been quantified in human reproductive tissues. Pregnant Sprague-Dawley rats were exposed daily to a complex mixture at 1, 10, and 100 times the minimum risk level (MRL) or tolerable daily intake (TDI) as determined by the US-EPA on gestations days 9-16. The mixture used contained organochlorines (TCDD, PCBs, methoxychlor, DDT, DDE, dieldrin, endosulfan, hexachlorobenzene, hexachlorocyclohexane, mirex and heptachlor) and the metals lead and cadmium. Following delivery half the pups of each treatment group were injected subcutaneously with 10 ug genistein/g BW/day on postnatal days 2-8. Randomly selected pups from each litter were necropsied on days 21, 60, 120 and 200 days of age. Treatments had no effect on litter size, sex ratio, birth weight, reproductive organ weights or reproductive endocrine outcome measures. Treatment with the mixture had no effect on sexual maturation in either sex whereas the mixture/genistein combination induced a significant delay in vaginal opening but had no effect on preputial separation. These data suggest that developmental exposure to environmental toxicants representative of contemporary human tissue residues is unlikely to induce additive or synergistic effects on the reproductive tract. However, our data suggest that exposure complex mixtures of toxicants can interact with dietary components to induce adverse effects on reproductive development in the female.

#### 1070

THE INHIBITORY EFFECT OF CIGARETTE SMOKE AND ITS REACTIVE OXYGEN SPECIES ON HAMSTER OOCYTE CUMULUS COMPLEX PICKUP.

C. Gieseke<sup>1, 2</sup>, R. Pederson<sup>2</sup> and P. Talbot<sup>2, 1</sup>. <sup>1</sup>Environmental Toxicology Graduate Program, University of California, Riverside, Riverside, CA and <sup>2</sup>Cell Biology and Neuroscience, University of California, Riverside, Riverside, CA. Sponsor: <u>J. Arey</u>.

The hamster oviduct and oocyte cumulus complex (OCC) are targets of cigarette smoke. Pickup of the OCC by the ciliated oviduct is inhibited in hamsters during acute in vitro exposures of oviducts or OCCs to mainstream and sidestream whole, gas, and particulate smoke solutions. Smoke solutions inhibit OCC pickup by increasing adhesion between the OCC and oviduct and altering ciliary beating. Cigarette smoke generates many reactive oxygen species including superoxide anion and hydrogen peroxide, which are known to alter ciliary beat frequency (CBF) in numerous ciliated epithelia. The purpose of this study was to determine if superoxide anion or hydrogen peroxide is responsible for the observed adverse effects on OCC pickup rate (OPR), adhesion, and oviductal CBF. Chromogenic probes were used to detect the presence of superoxide anion and hydrogen peroxide in the smoke solutions. The antioxidants, superoxide dismutase (SOD) and catalase, were used to confirm specificity of the probes and to indirectly assess the role of superoxide anion and hydrogen peroxide on OCC pickup. When oviducts were exposed to each type of mainstream and sidestream smoke solution plus either 299 University/ml SOD or 2350 University/ml catalase, most adverse effects on OPR and adhesion were eliminated. However, catalase did not eliminate any of the adverse effects due to sidestream whole exposure, and SOD exaggerated the effect of sidestream whole on CBF. When OCCs were exposed to each type of smoke solution plus SOD or catalase, SOD, but not catalase, eliminated the adverse effect of MSW on OPR and adhesion. Both SOD and catalase partially eliminated the effect of SSW on OPR and adhesion. These results show that superoxide anion and hydrogen peroxide generated by cigarette smoke are at least partially, if not fully, responsible for inhibiting OCC pickup. Experiments are in progress that will clearly define the role that each of these reactive oxygen species plays in adversely affecting OPR, adhesion, and CBF.

1071

RESPONSE OF CULTURED MOUSE OVARIAN SURFACE EPITHELIUM (OSE) CELLS TO METHOXYCHLOR (MXC) AND BIS-HYDROXYMETHOXYCHLOR (HPTE).

D. A. Symonds, <u>K. P. Miller</u>, <u>C. Borgeest</u> and <u>J. A. Flaws</u>. *Program in Toxicology, University of Maryland, Baltimore, MD*.

The purpose of this study was to develop a method to isolate and culture mouse OSE cells and use this model to test the hypothesis that the pesticide MXC and its metabolite HPTE affect the growth of the OSE. Since little is known about the metabolic capacity of the OSE, this work also determined whether the OSE contained cytochrome P450 enzymes thought to be involved in MXC metabolism (3A4 and 2C19). To isolate OSE cells, mouse ovaries were incubated in supplemented Medium 199 containing collagenase (500 units; Crude Type XI) at 37° C for 1 hour and vortexed for 2-4 minutes. Aliquots containing 200-500 cells/100  $\mu L$ were inoculated into 96 well plates, and incubated in 5% CO2 at 37°C for 3 days to allow for cell attachment. After attachment, cells were incubated with vehicle (DMSO), MXC (1, 10, 100 $\mu g/ml),$  or HPTE (0.1 or  $1\mu g/ml)$  for 7 days. Cell proliferation was measured with the CyQUANT assay. As a control, the remaining ovary was histologically examined for residual OSE, and cultured OSE cells were evaluated for epithelial markers by immunohistochemistry (IHC) with a cytokeratin cocktail (AE1/AE3). The presence of 2C19 and 3A4 in OSE was assessed by IHC using ovaries from adult mice dosed for 20 days with either vehicle or 32 mg/kg/day MXC. The results indicate that OSE cells can be isolated and cultured for at least 7 days. The culture procedure yielded an average of 2-6 x 10<sup>3</sup> cells/mm<sup>3</sup>, achieving 60% denudement of the OSE, and cytokeratin positivity of harvested cells. The results also indicate that low doses of MXC and HPTE may stimulate proliferation of OSE in vitro (control = 466±39, MXC (1µg/ml) = 706±176, HPTE  $(1\mu g/ml) = 861\pm86$  total fluorescent units per 100 seeded cells; p< 0.05 for control versus MXC- or HPTE-treated cells). Further, the IHC analysis indicates that the mouse OSE contains 2C19 and 3A4. Collectively, these data indicate that OSE cells can be isolated and cultured for toxicity studies, MXC and HPTE may cause proliferation of the OSE, and the OSE may play a role in toxicant metabo-

1072

METHOXYCHLOR ALTERS THE EXPRESSION OF ANTIOXIDANT ENZYMES IN ANTRAL FOLLICLES OF THE MOUSE OVARY.

R. K. Gupta, K. P. Miller and J. A. Flaws. Program in Toxicology, University of Maryland, Baltimore, MD.

The mammalian ovary contains antral follicles, which are responsible for synthesis and secretion of hormones that regulate estrous cyclicity and fertility. Although the organochlorine pesticide methoxychlor (MXC) is known to cause atresia (follicle death via apoptosis) of antral follicles, little is known about the mechanisms by which MXC induces antral follicle atresia. Since oxidative stress is known to cause apoptosis in non-reproductive and reproductive tissues, the purpose of this current study was to test the hypothesis that MXC induces oxidative stress by altering the expression of antioxidant enzymes in antral follicles. Using in vitro follicle culture, antral follicles were isolated from 39-day-old CD1 mice and cultured in supplemented media in the presence of follicle-stimulating hormone and serum. Follicles were then treated with vehicle control (DMSO), positive control (3μM H<sub>2</sub>O<sub>2</sub>), or MXC (100µg/ml) for 1, 3, 6, 12, 24, and 48 hrs. Follicles were then snap-frozen and subjected to rt-PCR for measurement of the levels of superoxide dismutase (SOD), glutathione peroxidase (GPX) and catalase (CAT). The results indicate that SOD, GPX, and CAT are highly expressed in isolated mouse antral follicles. At 1-24 hrs MXC treatment did not alter the expression of SOD, GPX, or CAT in antral follicles as compared to vehicle control. Ât 48 hrs, however, MXC treatment increased the expression of CAT and reduced the expression of GPX in antral follicles as compared to vehicle control. Further, the effects of MXC on CAT and GPX expression were similar to that of H<sub>2</sub>O<sub>2</sub> (positive control), but the effects of MXC on SOD expression were distinct from those of H<sub>2</sub>O<sub>2</sub>. Collectively, these data indicate that antioxidant enzymes like SOD, GPX, and CAT are present in mouse annual follicles and that MXC alters expression of CAT and GPX in antral follicles. Therefore, it is possible that MXC may cause atresia by inducing oxidative stress through CAT and GPX signaling pathways. (Supported by NIH HD 38955)

1073

ROLE OF GAP JUNCTIONS IN THE MODIFICATION ON RAT UTERINE CONTRACTION BY 2, 2'-DICHLOROBIPHENYL.

D. Chung and R. Loch-Caruso. Environmental Health Sciences, University of Michigan, Ann Arbor, MI.

Previously, we reported that uterine strips from gestation day 10 pregnant rats suspended in isometric muscle baths and exposed to 2, 2'-dichlorobiphenyl (2, 2'-DCB) exhibited increased oscillatory frequency, decreased contraction ampli-

tude and desynchronization of contractions. The present study examined the hypothesis that inhibition of myometrial gap junctions leads to 2, 2′–DCB–induced modification of uterine contraction since gap junctions coordinate myometrial cell contractions, thereby increasing the force of contraction. When uterine strips from gestation day 10 pregnant rats were suspended in isometric muscle baths and exposed to a known gap junction inhibitor (50  $\mu$ M  $\beta$ –glycerrhetinic acid), the average peak amplitude per contraction and the synchronization of contractions decreased in a manner similar to that observed in 2, 2′–DCB–treated rat uterus, consistent with the hypothesis that modification of uterine contraction by 2, 2′–DCB might be through the inhibition of gap junctions. To determine whether myometrial gap junctions are inhibited by 2, 2′–DCB, we microinjected fluorescent Lucifer Yellow into myometrial cells isolated from gestation day 10 rats and assessed the percentage of dye transfer to the adjacent cells from an injected cell. The percentage of dye transfer decreased in a concentration-dependent manner to 70, 37, 18 and 18% after a 1–h treatment with 25, 50, 75 or 100  $\mu$ M 2, 2′–DCB. This study suggests that 2, 2′–DCB modifies uterine contraction by a mechanism that functionally inhibits gap junction communication between myometrial cells.

#### 1074 REPRODUCTIVE TOXICOLOGY STUDIES ON GT 56-252, A NOVEL ORALLY AVAILABLE IRON CHELATOR.

J. K. Marquis<sup>1</sup>, R. Dagher<sup>1</sup>, W. Gaoua<sup>2</sup>, O. Foulon<sup>2</sup> and <u>R. Forster</u><sup>2</sup>. <sup>1</sup>Genzyme Corporation, Boston, MA and <sup>2</sup>CIT, Evreux, France.

GT 56-252 is a novel orally available iron chelator, under development for the primary treatment of iron overload resulting from transfusion therapy in beta-thalassemia and sickle cell disease. A complete set of reproductive toxicology studies was performed with this candidate drug by oral administration in order to support the planned clinical development. A study for effects on male and female fertility and early fetal development was performed in the rat, and included additional groups of iron-loaded control and high-dose rats. This was done in order to distinguish between the pharmacological and toxic actions of the test material and to simulate the human therapeutic situation. Hematology and blood biochemistry investigations were included in this study to monitor any disturbances of iron metabolism. Standard studies for effects on embryo-fetal development were performed in the rat and rabbit. In the pre- and post natal development study performed in the rat, additional groups of iron-loaded control and high-dose animals and clinical pathology monitoring were again included in the study design; iron loading of the females was performed prior to mating. Drug levels were evaluated in samples of milk from the treated dams on Day 17 pp. Iron loading was achieved by repeated intraperitoneal injection with an iron dextran saline solution, followed by a 2 week period to permit physiological redistribution of iron within the body. In the fertility study transient general toxicity was observed at the high dose-level selected, accompanied by some expected alterations in iron and haematology parameters, but no effects on male or female fertility were observed. No harmful effects were detected on embryo-fetal development in the rat or rabbit. In the pre- and post natal study the only effect observed on the pups was lower body weight in the high dose group immediately following birth; these values returned to normal limits by the time of weaning. These studies show that treatment with GT56-252 does not exert any adverse effects on reproductive functions.

## 1075 MULTI-GENERATION REPRODUCTIVE TOXICITY STUDY OF IMPLANTED DEPLETED URANIUM IN RATS: RESULTS FROM THE 1ST GENERATION.

A. R. Thitoff, A. E. Jung, E. W. Johnson, S. L. Lohrke, S. A. Stutler, <u>K. R. Still</u> and <u>D. P. Arfsten</u>. Naval Health Research Center Toxicology Detachment, Wright-Patterson AFB, OH.

The risk for penetration injuries to battlefield personnel caused by depleted uranium (DU) projectiles has increased substantially since the 1970s. Removal of DU projectiles from the body may not always be possible because of their location in the body or their small size. Embedded DU solubilizes in the body over time and can translocate to various organs and tissues including the reproductive organs and developing fetus. DU is a toxic heavy metal and is possibly mutagenic, therefore, embedded DU fragments could have a negative impact on reproductive organ function and/or reproductive success. To test this hypothesis, 8 week male and female Sprague-Dawley rats (P1 generation) were implanted with 0, 4, 8, 12, or 20 DU 1 x 2 mm pellets approximating 0.03%, 0.06%, 0.10%, and 0.15% by weight of a 500 g rat, respectively. The animals were then cross-mated in various combinations at 30 days post-implantation. Parameters measured were reproductive success over a 7-day mating period, gestation weight gain, # of live-born pups, average pup weight at PND1, # of pups surviving to PND4, and pup weight gain through PND20. Collection of urine and feces from P1 animals at 25 days post-implantation showed that DU was being excreted in the urine of DU-implanted animals. No evidence of toxicity was apparent for P1 DU-implanted animals at 30 days post-implantation. Our preliminary findings suggest no large differences between study groups for live birth indices, PND4 and PND20 *via*bility indices, and average pup weight gain from PND4 to PND20. PND4 F1 pups born to DU-implanted animals did not contain any detectable levels of uranium (limit of detection: 0.5 microg/mg tissue). Investigations are on-going to determine the levels of DU detectable in PND4 pup tissues, specifically kidney, liver, GI tract, bone, brain, thymus, and ovaries/testes. P1 animals will also be mated at 120 days post-implantation and data for the listed parameters will be gathered.

### 1076 IMPACT OF MATERNAL TOXICITY ON PRE- AND POSTNATAL DEVELOPMENT OF RATS.

I. D. Waalkens-Berendsen, M. M. Tegelenbosch-Schouten, A. Dijkstra and A. P. Wolterbeek. *Target Organ Toxicology, TNO Nutrition and Food Research, Zeist, Netherlands.* Sponsor: V. Feron.

Developmental toxicity might be secondary to maternal toxicity, raising great difficulties for risk assessors involved in evaluation of drugs and chemicals to estimate or quantify the contribution of maternal toxicity to effects observed on pre- and/or postnatal development of the offspring. Maternal toxicity mainly manifest itself by decreased food consumption and body weight(gain), organ system toxicity and changes in hematology and clinical chemistry. In the absence of a toxicological active substance, maternal toxicity can be mimicked by changes in body weight(gain) induced by food restriction. In a prenatal developmental toxicity study, Wistar rats were fed ad libitum or a limited amount of food (approx.85 and 70% of ad libitum) from gestation day (GD) 0-21. On GD 21, fetuses were collected by Caesarian section and processed for skeletal (bone and cartilage) and visceral examination. Body weights of the dams of the food restricted groups were significantly decreased during the entire gestation period. Except for some skeletal retardations, no significant effects were observed on visceral and skeletal findings. The most prominent effects on fetal development were observed on fetal and placental weights. In a postnatal developmental study, rats were food restricted (approx. 85 and 70% of ad libitum)during the entire gestation and lactation periods. Body weights of the dams were significantly decreased during the entire study. On postnatal day 1 (PND1) no effects on pup weights were observed, but pup weight gain was significantly decreased during the lactation period. No or only minor effects were observed on physical and sensory examinations (surface and air righting, pinna unfolding, hair growth, tooth eruption, nipple retention, eye opening, auditory canal opening, auditory response, pupil reflex) and sexual development (anogenital distance, vaginal opening, preputial separation). These data suggest that maternal toxicity, as reflected by decreased body weight, influences pre- and postnatal developmental only to a limited extent.

## 1077 DEVELOPING CHEMILUMINESCENT ASSAYS FOR MEASURING ENDOCRINE DISRUPTION IN MAMMALS.

C. Morris<sup>1</sup>, E. Wood<sup>2</sup>, K. Roberts<sup>1,3</sup> and S. Woodhead<sup>1,1</sup> Molecular Light Technology Research, Cardiff, CF14 5DL, United Kingdom, <sup>2</sup>SafePharm Laboratories Ltd., PO Box 45, Derby, DE1 2BT, United Kingdom and <sup>3</sup>Cardiff University, School of Biosciences, PO Box 911,, Cardiff, CF10 3US, United Kingdom. Sponsor: A. Smith.

The aim of this study was to investigate if a novel chemiluminescent technique, the hybridisation protection assay (HPA), could be used to quantify gene expression changes in the uterus during treatment with estrogenic compounds. The HPA consists of three steps; the probe labelled with acridinium ester (AE) is hybridised to its target, then addition of an alkaline reagent causes preferential hydrolysis of unhybridised probe, followed by initiation of the chemiluminescent reaction. The AE molecule reacts rapidly with hydrogen peroxide under alkaline conditions to produce light at 430nm. The intensity of emitted light is directly proportional to the amount of target present and as little as 0.1 fmol of mRNA transcript can be accurately quantified by this method. Five groups of sexually immature female Sprague-Dawley rats (n=10) were treated with 1, 0.5, 0.1, and 0.01 mg/kg of Diethylstilbestrol (DES) by oral gavage on three consecutive days and a vehicle control group was included. The uterus weights of each group were recorded: mean uterus weights in the control group were  $80 \pm 23 \text{mg}$  compared to  $224 \pm 74 \text{mg}$  in the lowest dose group. The HPA was used to measure gene expression levels of rat complement C3 gene and beta actin. The levels of uterine C3 mRNA were below detectable limits in the control group and increased in all four groups treated with DES (to a maximum level of  $0.78\pm0.16$  fmol/mg in the lowest dose group). Beta actin mRNA was also quantified and the mean concentration was 2.4 fmol/mg RNA. However, actin expression was significantly lower in the control group (1.36  $\pm~0.18$  fmol/mg, p<0.0001) suggesting that its expression may also be related to uterine weight. In conclusion, the HPA can be used to measure the changes in uterine gene expression and these results confirm that expression of C3 mRNA parallels uterine weight changes in response to DES.

28-DAY ORAL AND REPRODUCTIVE/DEVELOPMENTAL SCREENING TOXICITY STUDIES OF 1, 2-ETHANEDIAMINE, N-{3-(TRIMETHOXYSILYL)PROPYL}- IN RATS.

W. H. SIDDIQUI<sup>1</sup>, L. S. Meeker<sup>1</sup>, T. R. Barfknecht<sup>2</sup>, S. D. Crofoot<sup>1</sup> and <u>K. P. Plotzke<sup>1</sup></u>. <sup>1</sup>Dow Corning Corporation, Midland, MI and <sup>2</sup>Celanese International Corporation, Dallas, TX.

The potential toxicity of 1, 2-ethanediamine, N-{3-(trimethoxysilyl) propyl}-, a High Production Volume (HPV) chemical, was evaluated in a combined repeated dose toxicity study with a reproductive/developmental toxicity screening test. The study design utilized the enhanced version of the protocol in accordance with the OECD and EPA test guidelines Nos. 422/426 and 870.3650, respectively. Developmental neurotoxicity endpoints including Functional Observational Battery (FOB) and Motor Activity were performed on male and female rats. The test substance was gavaged daily in corn oil to 10 male and 10 female rats at 0, 25, 125 or 500 mg/kg/day. Clinical signs exhibited by several high dose animals included perioral soiling, increased nasal sounds, labored respiration, or soft vocalization. A dose-related resistance to dosing, salivation, wetness around the mouth at 5-30 minutes following dosing were also observed. There were no effects on body weight or food consumption among the groups. No treatment-related changes were observed in any FOB or motor activity parameters. There were no alterations in hematology, serum chemistry, or macroscopic examination of organs/tissues for any of the animals. Also, no effects were noted in mean organ weights or organ to body weight ratios. Histopathological examination of all gross lesions, tissues and organs for control and high dose animals demonstrated no microscopic findings. No effects were observed in any of the reproductive parameters evaluated. Two high dose and one low dose reproductive group females that did not produce litters had positive evidence of copulation. Six of the eight surviving high dose reproductive group females produced litters that were similar in all respects to control litters. Based on the results of this study, the NOAEL for 1, 2-Ethanediamine, N-{3-(trimethoxysilyl)propyl}- in rats via the oral route was considered to be 500 mg/kg/day.(Supported by the Silicones Environmental, Health and Safety Council).

#### 1079

Q-SWITCH LASER AND TATTOO PIGMENTS, A CHEMICAL ANALYSIS OF LASER INDUCED DECOMPOSITION COMPOUNDS.

W. Baumler<sup>1</sup>, R. Vasold<sup>2</sup>, B. Koenig<sup>2</sup> and M. Landthaler<sup>1</sup>. <sup>1</sup>Department of Dermatology, Regensburg, Germany and <sup>2</sup>Institute of organic chemistry, Regensburg, Germany. Sponsor: P. Howard.

In the western world there are more than 50 millions of people with tattoos. Tattoo colorants are applied like medical drugs since the pigments are injected into the skin even colouring the lymph nodes. Most of the tattoos colorants have been never produced by the chemical industry to be used in humans but to stain consumer goods. A high number of people request for removing their tattoos due to an improved self-image or social stigmatization. Since several years laser light at very high intensities is applied to the skin in order to destroy these tattoo pigments. Based on a recent analysis of tattoo pigments two widely-used azo compounds (pigment red 22, pigment red 9) were irradiated in suspension using a laser pulse energy of 15 mJ at a pulse duration of 8 ns. After that the suspension was analyzed by using quantitative high performance liquid chromatography and mass spectrometry. A significant increase of decomposition products 2-methyl-5-nitroaniline and 4-nitrotoluene was found for pigment red 22. The irradiation of pigment 9 led to an increase of 2, 5-dichloraniline and 1, 4-dichlorobenzene These products are proven to be toxic or carcinogenic. Moreover, the results show that the tattoo colorants are already contaminated with these products prior to laser irradiation. In view of a high number of patients undergoing laser treatment of tattoos, it is high time and an important goal to perform a risk assessment in humans regarding laser induced decomposition products.

### 1080 OCHRATOXIN A: LACK OF FORMATION OF COVALENT DNA ADDUCTS.

W. Dekant<sup>1</sup>, H. Zepnik<sup>1</sup>, P. Wanek<sup>1</sup>, E. Eder<sup>1</sup>, K. Dingley<sup>3</sup>, H. Ihmels<sup>2</sup>, W. Voelkel<sup>1</sup> and A. Mally<sup>1</sup>. <sup>1</sup>Department of Toxicology, University of Wuerzburg, Wuerzburg, Germany, <sup>2</sup>Department of Organic Chemistry, University of Wuerzburg, Wuerzburg, Germany and <sup>3</sup>Lawrence Livermore National Laboratory, Livermore, CA

The mycotoxin Ochratoxin A (OTA) is a potent nephrotoxin and renal carcinogen in rodents. However, the mechanism of OTA induced tumor formation is unknown and conflicting results have been obtained regarding the potential of OTA to bind to DNA. OTA is poorly metabolized and no reactive intermediates capable of interacting with DNA have been detected *in vitro* or *in vivo*. Recently a hydroquinone/quinone redox couple and a carbon-bonded OTA-deoxyguanosine (OTA-

dG) adduct formed by electrochemical oxidation and photoreaction of OTA have been reported and suggested to be involved in OTA carcinogenicity. This study was designed to characterize the role of DNA-binding and to determine if formation of these derivatives occurs in vivo and in relevant activation systems in vitro. Horseradish peroxidase activation of OTA and its dechlorinated analogue ochratoxin B (OTB) yielded ochratoxin A - hydroquinone (OTHQ), but the postulated OTA-dG adduct was not detectable using LC-MS. In support of this, no OTA-related DNA adducts were observed by 32P-postlabelling. *In vivo*, only traces of OTHQ were found in urine of male F344 rats treated with high doses of OTA (2mg/kg bw) for two weeks, suggesting that this metabolite is not formed to a relevant extent. In agreement with the in vitro data, OTA-dG was not observed in liver and kidney DNA extracted from treated animals. In addition, DNA-binding of OTA and OTB was assessed in male rats given a single dose of 14C-OTA or 14C-OTB using accelerator mass spectrometry (AMS), a highly sensitive method for quantifying extremely low concentrations of radiocarbon. The 14C-content in liver and kidney DNA from treated animals was not significantly different from controls, indicating that OTA does not form covalent DNA adducts in high yields. In summary, the results presented here demonstrate that DNA binding of OTA is not detectable with sensitive analytical methods and is unlikely represent a mechanism for OTA induced tumor formation.

MITOCHONDRIAL AUTOPHAGY IS ASSOCIATED WITH A HIGH RATE OF MTDNA TURNOVER IN REMODELING RAT HEPATOCYTES.

Y. Kai, S. Rodriguez-Enriquez and J. J. Lemasters. Cell & Developmental Biology, UNC-CH, Chapel Hill, NC.

BACKGROUND. Stellate and other cells differentiate in culture in a manner similar to that occurring in pathophysiological states. Accordingly, hepatocyte de-differentiation or remodeling in vitro may be pathophysiologically relevant. Here, our AIM was to determine the relationship between mitochondrial autophagy and mitochondrial DNA (mtDNA) turnover during remodeling of cultured hepatocytes. METHODS. Isolated rat hepatocytes were cultured in Waymouth's medium with 10% fetal calf serum, 100 nM insulin and 100 nM dexamethasone for 1 to 3 days. Cytochrome c oxidase activity in cell extracts was determined polarigraphically. Total DNA was extracted, separated by agarose gel electrophoresis, and transferred onto membranes to be analyzed by Southern blot. Probes for mtDNA and 18 S rRNA gene were simultaneously used to estimate and normalize mtDNA content per cell. RESULTS. In agreement with our previous study showing a 51% decrease of mitochondrial number by the process of autophagy between 1 and three days of culture, respectively, cytochrome c oxidase activity also declined by 44%. By contrast, mtDNA per hepatocyte remained constant from the first to the third day of culture. Two days of treatment with ethidium bromide (0.5 ug/ml, an inhibitor of mtDNA replication) caused a 41 % decrease of mtDNA per hepatocyte from the first to the third culture day. CONCLUSIONS. During remodeling, cultured hepatocytes lose a large proportion of their mitochondria, but adaptive synthesis of mtDNA compensates for mtDNA loss during this autophagic remodeling. Thus, the content of the mitochondrial genome is preserved even as mitochondrial number and enzyme activity are lost during culturing. Thus, the content of the mitochondrial genome is preserved even as mitochondrial number and enzyme activity are lost during culturing, which indicates independent regulation of mitochondrial mass and mtDNA content.

DIETARY FAT RICH IN  $\omega$ -6 POLYUNSATURATED FATTY ACIDS MODULATES OXIDATIVE DNA DAMAGE AND REPAIR IN MOUSE LIVER.

C. Powell<sup>1, 2</sup>, P. Ross<sup>2</sup>, O. Kosyk<sup>2</sup>, B. Bradford<sup>2</sup> and <u>I. Rusyn<sup>1, 2</sup></u>. <sup>1</sup>Curriculum in Toxicology, University of North Carolina, Chapel Hill, NC and <sup>2</sup>Department of Environmental Sciences and Engineering, University of North Carolina, Chapel Hill, NC.

Dietary fats such as corn oil, which are rich in  $\omega$ -6 polyunsaturated fatty acids (PUFA), have been shown to increase the rate of growth of established tumors and promote metastasis in animal models. In contrast, fish oil, a rich source of  $\omega$ -3 eicosapentaenoic acid, has been shown to be protective. The  $\omega$ -6 PUFAs found in dietary oils are known to induce the production of free radicals that could serve as a possible source of DNA damage leading to carcinogenesis. Here, we hypothesize that dietary fats rich in  $\omega$ -6 PUFAs play an important role in carcinogenesis *via* modulation of oxidative DNA damage and its repair. C57BL/6J male mice were administered corn or fish oil acutely (by gavage) or in a diet (20.5% calories from fat) for up to 3 weeks. A highly sensitive slot blot assay was used to quantitate apurinic/apyrimidinic (AP) sites in DNA extracted from liver tissues. An increase in AP sites was observed only for corn oil treated mice. Total RNA was extracted from liver tissue and expression of base excision DNA repair (BER) genes was analyzed by a multi-probe RNase protection assay. Increases in expression of BER genes re-

sponsible for removal of oxidized DNA lesions were evident after a single dose of corn oil with 2 fold increases in 8-oxoguanine DNA glycosylase 1 (Ogg1) and AP endonuclease1 (APE) and a 3 fold increase in N-methylpurine DNA glycosylase (MPG). Fish oil had no effect. Similar up-regulation of BER genes was detected in dietary feeding studies with corn oil. In addition to DNA damage and repair, cell proliferation of liver parenchymal cells was enhanced by almost 2 fold based on BrdU uptake. Collectively, corn oil but not fish oil was shown to generate abasic sites, lead to selective induction of BER genes, and increased cell proliferation. These studies are important for better understanding of the molecular mechanisms that link high-fat diet and carcinogenesis.

1083 MECHANISMS FOR THE INDUCTION OF DNA DAMAGE (COMET) FOLLOWING 2-BUTOXYETHANOL

S. M. Corthals, <u>L. M. Kamendulis</u> and <u>J. E. Klaunig</u>. Department of Pharmacology and Toxicology, Indiana University School of Medicine, Indianapolis, IN

Previous studies showed that chronic exposure to 2-butoxyethanol induced an increase in liver hemangiosarcomas in B6C3F1 mice. We have proposed that liver hemangiosarcomas result from oxidative stress arising from Kupffer cell activation, secondary to hemolysis from selective metabolites of 2-butoxyethanol. The present study examined the effect of 2-butoxyethanol and activated mouse macrophages on mouse endothelial cell DNA damage as measured by the Comet assay. Treatment with 2-butoxyethanol (1, 5, and 10mM) failed to induce an increase in endothelial cell Comet over control after 24 hours of continuous treatment. In our proposed hypothesis, Kupffer cell activation is a key event in the induction of endothelial cell neoplasia. To further address this, the effects of hydrogen peroxide (an oxidant resulting from macrophage activation) and LPS activated macrophages on endothelial cell Comet were examined. Hydrogen peroxide (50, 75, and 100µM) resulted in increased Comet after 1, 2, and 4 hours (5-2, 3-6, and approximately 2-3 fold over control). Co-culture of endothelial cells with activated macrophages resulted in increased Comet in endothelial cells after 4 hours (2 fold over control). These results show that 2-butoxyethanol does not directly damage endothelial cell DNA. These studies also showed a correlation between the number of macrophages co-incubated with endothelial cells and the amount of endothelial cell Comet detected. Activated macrophages or hydrogen peroxide produced a dose dependent increase in endothelial cell DNA damage. This resulting damage may provide the mutational and/or cell proliferation events necessary for the neoplastic development (hemangiosarcoma) seen following chronic 2-butoxyethanol exposure.

## 1084 ATM-DEPENDENT, DNA DAMAGE-INDUCED G1 CHECKPOINT FUNCTION REGULATES GENE EXPRESSION IN HUMAN FIBROBLASTS.

T. Zhou<sup>1,3</sup>, D. A. Simpson<sup>1,3</sup>, Y. Zhou<sup>1,3</sup> and W. K. Kaufmann<sup>1,2,3</sup>. <sup>1</sup>Pathology & Lab. Medicine, University of North Carolina, Chapel Hill, NC, <sup>2</sup>Center for Environmental Health and Susceptibility, University of North Carolina, Chapel Hill, NC and <sup>3</sup>Lineberger Comprehensive Cancer Center, University of North Carolina, Chapel Hill, NC.

Cells from ataxia telangiectasia (AT) patients are radiation-hypersensitive and display defects in the G1 and G2 checkpoints in response to DNA damage due to inactivating mutations in ATM (ataxia telangiectasia mutated). We are testing the role of ATM in transcriptional responses to DNA damage that may relate to the checkpoint defects and hypersensitivity to ionizing radiation (IR). A telomerized human fibroblast (F1-TERT) and a telomerized AT fibroblast line (AT-TERT) were used in the study. Although no difference in DNA damage was measured after 0.5 to 4.5 Gy IR by using comet assay, clonogenic assay showed the AT cells to be radiation-hypersensitive. A 1.5 Gy dose of IR that inactivated colony formation by 45% in F1-TERT and 90% in AT -TERT was studied for its effects on G1 and G2 checkpoint functions using quantitative flow cytometric assays and for its effects on the patterns of gene expression using a 16K oligoDNA microarray. F1-TERT exhibited 95% G1 arrest and 97% G2 delay after 1.5 Gy IR, while AT-TERT displayed only 15% G1 arrest and 41% G2 delay. The patterns of changes in gene expression at 2, 6 and 24 hr after IR in F1-TERT cells indicated that the predominant response corresponded to the ATM- and p53-dependent G1 arrest. Several p53 target genes, including p21Waf1, TP53INP1 and BTG2, were significantly up-regulated, while several genes whose expression is regulated by E2F family transcription factors were significantly down-regulated including Cdc6 and all MCM family members. Several genes that participate in DNA metabolism and checkpoint functions including MSH, RFC4, topoII-alpha, Bub1, and BARD1 were also repressed by IR in normal fibroblasts but not AT fibroblasts. All the results indicate that ATM-dependent gene regulation in response to IR-induced DNA damage can be stuied globally. Supported by PHS grants ES11391 and ES10126

PHENOBARBITAL AND PREGENOLONE 16α-CARBONITRILE INDUCE HEPATIC EXPRESSION OF MDM2 INDEPENDENT OF P53.

D. M. Nelson, V. Bhaskaran, W. R. Foster, <u>B. Gemzik</u> and <u>L. D. Lehman-McKeeman</u>. *Discovery Toxicology, Bristol-Myers Squibb, Princeton, NJ*.

Mdm2 negatively regulates wild-type p53 activity by directly binding to p53 and mediating its ubiquitination and subsequent proteosomal degradation. Mdm2 is also directly oncogenic because it transforms cells when over expressed. In the present study, the hepatic gene expression patterns induced by phenobarbital (PB; 100 mg/kg) and pregenolone 16α-carbonitrile (PCN, 100 mg/kg) were evaluated in male and female Sprague-Dawley rats using Affymetrix Rat Genome U34A gene arrays. In addition to changes in the hepatic expression of well-characterized drug metabolizing enzymes associated with CAR and PXR activation, an increase in Mdm2 mRNA was observed with both compounds and detected consistently after single or repeat dosing (5 days). The results of the gene array analyses were confirmed by real time PCR, which indicated that PB increased Mdm2 mRNA by 1.4and 3.9-fold in male rat liver and 3.1- and 2-fold in female rat liver at 6 hr and 5 days, respectively. Similar results were noted in PCN-treated male rats, whereas the largest induction of Mdm2 mRNA was noted in PCN-treated female rats, reaching an 11-fold increase after 5 days of dosing. The results of real-time PCR analyses were further confirmed by Western blotting of liver homogenates, which again showed the highest increase in Mdm2 protein in PCN-treated female rats. Mdm2 expression is regulated at least in part in a p53-dependent manner. However, gene array analyses did not reveal changes in other p53-dependent genes. To determine whether the effects of PB and PCN on Mdm2 expression were related to p53 activation, homozygous p53 knockout mice were adminstered PB and PCN (100 mg/kg for 5 days) and hepatic expression of Mdm2 was measured by real time PCR. Mdm2 mRNA levels were similarly increased in wild type C57/Bl6 and the p53 knockout mice. These results indicate that PB and PCN increase hepatic mRNA and protein levels of Mdm2 through mechanisms independent of p53 and suggest that CAR and PXR activation directly regulate Mdm2 expression in rodent

## 1086 MOLECULAR EPIDEMIOLOGY OF ESOPHAGEAL CANCER USING THE IARC TP53 HUMAN TUMOR DATABASE.

R. K. Elespuru<sup>1</sup> and S. M. Jenning<sup>2</sup>. <sup>1</sup>Genetic Technology Lab., USFDA Federal Laboratories at White Oak, Silver Spring, MD and <sup>2</sup>School of Engineering, Columbia University, New York, NY. Sponsor: J. MacGregor.

Understanding specific causes of cancer is invaluable in the design of strategies for risk analysis of new products, and for developing preventive health measures for minimizing disease incidence. Mutations in the p53 gene are the most commonly occurring mutations in human cancer. A database of such mutations was initiated by Hollstein and Curtis and is maintained by Olivier and Hainaut at IARC. As the database grows and searching capabilities improve, new insights into cancer etiology may be found. We began our analysis with esophageal squamous cell carcinoma (ESCC), a cancer with known regional hot spots and life style associations, and a relatively large database at IARC. In our analysis, based on approximately 30 published studies reporting on more than 1000 mutations in IARC release R8 (June 2003), we stratified by pathology, gender, smoking status, and geographical location (comparing France, Japan, China, Iran and Brazil). We analyzed mutational sequence profile, mutant codon location, and DNA strand bias in mutations from males. An enhancement in AT to TA transversions was observed related to cigarette smoking, significant at a p value of .003. This result is in contrast to the mutation most associated with smoking related lung cancer, GC to TA. France, Japan and China exhibited the enhancement individually, while Brazil did not; studies on smoking were not reported in the data sets from Iran. The AT to TA sequence change exhibited substantial strand bias, consistent with an adenine lesion repaired on the transcribed strand. As observed by others, biomarker mutations occur in Iran (GC to AT) and China (G to T at codon 176, although this result has been criticized). GC to AT transitions occur with equal frequencies at CpG and non-CpG sites in most of the data sets, indicating that spontaneous deamination at CpG sites appears not to be a major pathway of mutation generation in this cancer.

### 1087 EFFECT OF TRICHLOROACETIC ACID IN MALE B6C3F1 MOUSE HEPATOCYTES.

D. J. Smith, L. M. Kamendulis and J. E. Klaunig. Department of Pharmacology and Toxicology, Indiana University School of Medicine, Indianapolis, IN.

Trichloracetic acid (TCA) is an organic acid formed in the chlorination of drinking water as well as through the metabolism of selected chloroethylene compounds. TCA is a known hepatocarcinogen in mice, but not in rats, and acts through an apparent non-DNA reactive mode of action. TCA has also been shown to induce peroxisome proliferation, DNA synthesis, and decrease apoptosis in mouse liver following a short term *in vivo* exposure. The present study examined the effect of TCA

on DNA synthesis, peroxisomal beta-oxidation (PBOX), and apoptosis in male B6C3F1 mouse primary hepatocytes. Hepatocytes were cultured for 24 hours with TCA (0—100.0 mM TCA), and toxicity measured. A dose dependent increase in cell death, as measured by trypan blue exclusion, was seen with TCA. Subsequent examination of DNA synthesis and PBOX used five sub lethal doses (0.5, 1.0, 2.5, 5.0, and 10.0 mM) of TCA. DNA synthesis was examined in hepatocytes dosed for 24 hours with TCA. TCA caused a decrease in DNA synthesis from control at 0.5 mM TCA (0.65 fold of control), and a dose related increase in DNA synthesis from 1 to 10 mM. Peroxisomal beta-oxidation was measured in hepatocytes dosed for 24 and 48 hours with TCA (0—10 mM). After 24 hours, TCA produced a dose related increase in PBOX activity. TCA treatment for 48 hours produced a similar dose related increases in PBOX. These studies are consistent to what has been previously reported *in vivo* and thus establish a model by which further investigations on the carcinogenic mode of action of TCA can be examined in rodent and human liver.

1088

QUANTITATION OF CARCINOGENESIS-INITIATING EFFECTS OF 2-ACETYLAMINO-FLUORENE AND THEIR NO-OBSERVED-EFFECT LEVELS IN RAT LIVER.

M. J. Iatropoulos, A. M. Jeffrey, J. D. Duan and G. M. Williams. Pathology, New York Medical College, Valhalla, NY.

In order to explore for potential thresholds in liver carcinogenicity, we conducted a series of studies utilizing a carcinogenesis initiation/promotion model in rat liver with the DNA-reactive carcinogen 2-acetylaminofluorene (AAF) (Toxicol. Sciences. 45, 152, 1998; Toxicol. Pathol. 28, 388, 2000). In two current studies, AAF was administered in exact intragastric doses during the initiation segment (IS) to male F344 rats for 12 or 16 weeks. The cumulative exposures at the end of initiation in these experiments were 0.094, 0.124, 0.94, 1.24, 9.4, 28.2, 94.1, 188.2 and 282.2 mg/kg. The findings at the end of the IS can be summarized as follows: (i) formation of AAF DNA adducts was nonlinear, with a no-observed-effect level (NOEL) at a cumulative exposure of 0.94 mg/kg over 12 weeks and with a plateau at higher exposures (282.2 mg/kg); (ii) cytotoxicity (necrosis) showed a NOEL at a cumulative exposure of 28.2 mg/kg over 12 weeks; (iii) for compensatory hepatocellular proliferation, the NOEL was at a cumulative exposure of 28.2 mg/kg over 12 weeks and it was supralinear at high exposures (282.2 mg/kg); (iv) formation of preneoplastic hepatocellular altered foci (HAF) had a NOEL at a cumulative exposure of 28.2 mg/kg over 12 weeks and was supralinear at high exposures (282.2 mg/kg); (v) the earliest parameter to be affected with very low exposure was the formation of DNA adducts, followed by increased cell proliferation. The finding of NOELs for critical events of initiation of hepatocarcinogenesis supports our finding that there is a NOEL for phenobarbital-promotable liver tumors initiated by AAF (Toxicol. Sciences. 45, 152, 1998). We conclude that there is a practical threshold for AAF-induced liver cancer in rats.

1089

DICHLOROACETIC AND TRICHLOROACETIC ACID INDUCED ALTERATION IN THE METHYLATION OF TUMOR SUPPRESSOR GENES AND IN THE ACETYLATION OF HISTONE H3 IN MOUSE LIVER AND TUMORS.

L. Li, L. Tao, P. M. Kramer and M. A. Pereira. Department of Pathology, Medical College of Ohio, Toledo, OH.

Dichloroacetic acid (DCA) and trichloroacetic acid (TCA) are mouse liver carcinogens that alter the methylation of DNA and genes. Mouse liver tumors promoted by DCA or TCA contained DNA hypomethylation. Furthermore, DCA and TCA induced DNA hypomethylation in mouse liver that was prevented by methionine. DNA hypomethylation releases histone deacetylase from DNA resulting in increased acetylation of histones. Hypermethylation of tumor suppressor genes, i.e. the estrogen receptor- alpha (ER- $\alpha$ ) and p16 genes has also been associated with hepatocarcinogenesis. Female B6C3F1 mice were administered 3.2gm/l DCA in their drinking water with/without 8.0gm/kg methionine in the diet for 4 and 8 weeks. The acetylation of histone 3 (H3) was increased by DCA. Methionine prevented the increased acetylation of H3. These findings support the hypothesis that DNA hypomethylation induced by DCA promotes liver carcinogenesis by increasing histone acetylation. Hypermethylation in the regulatory region of genes usually results in the silencing of the genes. DNA was isolated from mouse liver tumors induced by DCA and TCA, treated with bisulfite, PCR amplification for the ER- $\alpha$  or p16 genes and sequenced to determine the methylation status of 17 and 30 CpG sites in the regulatory region of the genes. The percentage of the CpG sites that were methylated in the ER- $\alpha$  gene was 3.9  $\pm$  1.9% in normal liver tissue, while in DCA and TCA-promoted tumors the percentages was increased to 42.3  $\pm$  10.9% and  $23.5 \pm 7.9\%$ . The extent to which the CpG sites in the p16 gene were methylated in normal liver ranged from 0-1 site, while DCA and TCA-promoted tumors contained 2-3 methylated CpG sites. Hence, DCA and TCA increased the methylation of the two tumor suppressor genes in liver tumors. This research was supported by a grant from the USEPA's Science to Achieve Results (STAR) program Grant number R82808301.

1090

PHENOBARBITAL (PB) INDUCES INITIAL HYPOMETHYLATION OF THE PROMOTER REGION OF HA-RAS, BUT NOT LINE-1 ELEMENTS, IN THE LIVER OF B6C3F1 MICE.

A. Carnell and J. I. Goodman. Pharmacology and Toxicology, Michigan State University, East Lansing, MI.

While mutagenesis is often considered to be important in carcinogenesis, it is clear that epigenetic mechanisms play a key role. In particular, DNA methylation as a regulator of gene expression is a central focus. We hypothesize that susceptibility to carcinogenesis is related inversely to the capacity to maintain normal DNA methylation patterns. Ha-ras an oncogene implicated in tumorigenesis, and the LINE-1 DNA element, a retrotransposable element capable of disrupting genomic stability when expressed, serve as two distinct gene regions whose expression may be influenced by changes in the methylation status of their 5' promoter regions. PB, a nongenotoxic rodent carcinogen, induces global hypomethylation in liver; however, few specific genes have been examined. Liver tumor-sensitive male B6C3F1 mice were administered PB, 0.05% (w/w), in drinking water for 2-wk. Hepatic DNA was isolated and the methylation of the promoter regions of Ha-ras and LINE-1 was assessed using the enzymatic regional methylation assay (ERMA). This involves bisulfite modification of DNA, PCR amplification with primers containing GATC sites (dam methylase recognition sequence) which serves as an internal control to normalize DNA quantity, incubation with dam methylase and [<sup>14</sup>C-methyl]Sadenosyl-L-methionine (SAM) followed by incubation with [3H-methyl] SAM and SssI methylase, which methylates C's 5' to G's, to quantify DNA methylation status. Hypomethylation is evidenced by a decreased  ${}^{3}H/{}^{14}C$  ratio as compared to control. The mean Ha-*ras* and LINE-1  ${}^{3}H/{}^{14}C$  ratios for controls were 30.2 $\pm$ 0.2 and 50.8±7.8 while the mean treated ratio was 24.1±0.4 and 53.3±4.4, respectively. The results were confirmed by bisulfite sequencing. PB caused a decrease in 5methylcytosine content of the promoter region of Ha-ras, but not LINE-1 elements. This leads to two conclusions: a) PB-induced hypomethylation is initially selective, and b) hypomethylation of Ha-ras, increasing potential for expression, may be an early event during PB-promotion of mouse liver tumorigenesis.

1091

SPECIES DIFFERENCES IN THE INHIBITION OF GAP JUNCTIONAL INTERCELLULAR COMMUNICATION (GJIC) BY DIETHANOLAMINE.

L. M. Kamendulis, D. J. Smith and J. E. Klaunig. Division of Toxicology, Indiana University School of Medicine, Indianapolis, IN.

Diethanolamine increased the incidence and multiplicity of liver tumors in the mouse following chronic dermal exposure. Tumor induction by diethanolamine appears to be through a non DNA reactive mode of action and has been suggested to involve inhibition of cellular choline uptake. Choline deficiency is known to produce tumors in rodents, therefore, one might postulate that diethanolamine, through depletion of choline, may result in the development of tumors in rodents. Previously, we have reported that diethanolamine as well as choline depletion produces a dose-related induction of DNA synthesis in primary cultured mouse and rat hepatocytes, while no increase was seen in primary human hepatocytes. Furthermore, the DNA synthesis induced by diethanolamine was blocked by choline supplementation. These results support the hypothesis that diethanolamine-induced neoplasia results from choline depletion. Another hallmark of non DNA reactive carcinogen exposure is the inhibition of gap junctional intercellular communication (GJĬC). The present studies examined the effect of diethanolamine and choline depletion on GJIC in primary cultured mouse, rat and human hepatocytes. Mouse and rat hepatocytes cultured with 0 - 500 µg/ml diethanolamine for 1, 4 and 24 hours showed a dose-related decrease in GJIC at all time points examined. Incubation of mouse and rat hepatocytes with medium containing reduced choline concentrations (1/100 of normal medium; 0.0898 vs. 8.98 mg/L) resulted in a similar decrease in GJIC at 1, 4 and 24 hours. Supplementation with medium containing 10-fold higher choline concentration restored GJIC in diethanolamine treated hepatocytes to control levels. No inhibition of GJIC was seen in human hepatocytes following diethanolamine treatment or choline depletion for 24 hours. These results showing a species selective inhibition of GJIC by diethanolamine that is reversed by choline supplementation provides further support that the mechanism for diethanolamine-induced neoplasia involves cellular choline depletion.

#### 1092

PURIFICATION OF THE BIOACTIVE INGREDIENT IN PSYLLIUM THAT UP-REGULATES GAP JUNCTIONAL COMMUNICATION IN RAS-TRANSFECTED RAT LIVER EPITHELIAL CELLS

Y. Nakamura<sup>1</sup>, N. Yoshikawa<sup>1</sup>, K. Sato<sup>1</sup>, K. Ohtsuki<sup>1</sup>, C. Chang<sup>2</sup>, B. L. Upham<sup>2</sup> and J. E. Trosko<sup>2</sup>. <sup>1</sup>Food Science, Kyoto Pref. University, Kyoto, Japan and <sup>2</sup>NFSTC, Michigan State University, Lansing, MI.

Psyllium is a common source of soluble fiber derived from the husk of the plant Plantago ovata, which is used for colon care with its moderate laxative effect. We previously determined that psyllium powder restores gap junctional intercellular communication (GJIC) in a tumorigenic WB-F344 rat liver epithelial cell line transfected with the *H-ras* oncogene (WB*ras*), but not on WB cell lines transfected with the src, neu and myc oncogenes. The mechanism is due to increased levels of connexin43 protein and reduced levels of the Ras protein resulting in reversing the tumorigenic phenotype, namely anchorage independent growth, of this cell line. In the current study, we used purification techniques to isolate the bioactive fraction of psyllium that employed non-toxic solvents, which are amendable to safe food preparation. The effective dose of the crude psyllium powder that up-regulated GJIC in WBras was 1.5 mg/ml. A simple ethanol extraction increased the activity of the extract to an effective dose of 50-200 ug/ml, suggesting that the active component is most likely not a fiber. This ethanol extract was further fractionated by adsorption chromatography using an HP-20 column. A step gradient ranging from 100% water to 100% ethanol was used to elute the bioactive component. The highest activity eluted at 90% ethanol, with an effective dose of 22 ug/ml. This is a purification-fold increase of 68 times that of the original crude powder. Additional purification was achieved using silica-gel adsorption column chromatography. The column (70-230mesh) was pre-eluted with hexane followed by elution with 70% ethylacetate. The active eluted fraction had an effective dose of 1.3 ug/ml, which is an 1154X purification-fold over the crude fraction. The final yield was 93ppm. In conclusion, adsorption chromatography can effectively increase the purity of the bioactive fraction of psyllium that decreases the tumorigenic phenotype of WBras cells by up-regulating GJIC.

### 1093 PPARβ AMELIORATES CHEMICALLY-INDUCED LIVER TOXICITY.

W. Shan<sup>1</sup>, M. T. Bility<sup>1</sup>, <u>C. J. Nicol</u><sup>2</sup>, M. J. Kennett<sup>1</sup>, J. M. Ward<sup>2</sup>, F. J. Gonzales<sup>2</sup> and <u>J. M. Peters</u><sup>1</sup>. Veterinary Science, Center for Molecular Toxicology and Carcinogenesis, Pennsylvania State University, University Park, PA and <sup>2</sup>Lab. of Metabolism, National Cancer Institute, Bethesda, MD.

Peroxisome proliferator-activated receptor β (PPARβ) has attracted central attention concerning its multiple effects in lipid metabolism, development and carcinogenesis, but its role in hepatic function remains elusive. Preliminary studies examining the role of PPARβ in colon cancer suggested that PPARβ protects the liver from environmental chemical agents and prevents toxicity and carcinogenesis. To begin to test this hypothesis, wild-type and PPAR\$\beta\$-null mice were exposed to azoxymethane (AOM) and carbon tetrachloride (CCl4) and markers of liver toxicity were examined. PPARβ-null mice showed extensive bile-duct hyperplasia and severe liver lesions in response to AOM treatment, and this was not observed in similarly treated wild-type mice. PPARB-null mice also exhibited abnormal lipid deposition around liver lobules as a result of CCl4, and this was not found in CCl4treated wild-type mice. Consistent with histological analyses, higher levels of serum GPT were found in both AOM and CCl4-treated PPARβ-null mice as compared to wild-type mice. While expression patterns of cytochrome P450s were similar between both genotypes treated with AOM or CCl4, CYP2B10 was differentially expressed between genotypes. Combined, these observations suggest that PPARB functions to attenuate liver toxicity induced by diverse environmental chemicals.

#### 1094

BIOCHEMICAL, HISTOLOGICAL AND MOLECULAR CHARACTERIZATION OF THE INFLUENCE OF INITIATION ON CLOFIBRIC ACID-INDUCED HEPATOCARCINOGENESIS IN THE RAT.

C. Michel<sup>1</sup>, C. Desdouets<sup>2</sup>, V. Guilpin<sup>1</sup>, M. Slaoui<sup>1</sup>, <u>R. A. Roberts<sup>1</sup></u> and E. Boitier<sup>1</sup>. <sup>1</sup>Drug Safety Evaluation, Aventis Pharmacology, Vitry sur Seine, France and <sup>2</sup>INSERM U370, Paris, France.

Clofibric acid (CA) is a non-genotoxic hepatocarcinogen in rodents that causes altered hepatocellular foci and /or hepatocellular neoplasms. The rate of appearance of foci and tumors can be accelerated by initiation using DNA-damaging agents such as diethylnitrosamine (DEN), although how initiation acts on tumor promotion and progression remains unknown. The aim of this study was to evaluate the impact of DEN on the promotion of CA-induced hepatocarcinogenesis. Male F344 rats were given a single injection of DEN (30 mg/kg). Thirteen days later, animals were fed diets containing 5000ppm CA for up to 12 months. Clinical pathol-

ogy, gross macroscopic evaluation and gene profiling (Affymetrix microarrays) in normal liver tissues and liver tumors were performed. Mildly elevated mean alkaline phosphatase, secondary to CA-induced liver toxicity, was observed in rats treated with DEN+CA or CA alone. Tumors were macroscopically visible in rats treated with DEN+CA at 9 months as compared to a latency of 12 months in rats administered CA only. Gene expression profiles of these tumors demonstrated similar patterns, such as the regulation of genes involved in apoptosis (apoptosis-inducing factor, Caspase 11). In order to evaluate the similarity of gene expression profiles in the normal liver tissue from the various groups, comparisons were performed using clustering methods. This showed that gene expression profiles from DEN and control groups clustered together; likewise those from normal tissue taken from DEN+CA and CA-treated animals were highly similar. Taken together, these results suggest that, even though DEN initiation accelerates tumor onset, it did not induce large changes in gene expression profiles of tumors and of normal tissues from treated animals. The next steps will be to focus on the evolution of DEN-initiated cells by comparing gene expression profiles of microdissected foci from DEN+CA rat livers with those obtained from CA rat livers.

## 1095 LACK OF BOTH HEPATIC PORPHYRIA AND TUMORS IN CYP1A2(-/-) MICE EXPOSED TO PCBs AND IRON.

A. G. Smith<sup>1</sup>, B. Clothier<sup>1</sup>, R. Davies<sup>1</sup>, R. E. Edwards<sup>1</sup>, T. P. Dalton<sup>2</sup>, D. W. Nebert<sup>2</sup> and P. Greaves<sup>1</sup>. <sup>1</sup>MRC Toxicology Unit, University of Leicester, Leicester, United Kingdom and <sup>2</sup>Environmental Health, University of Cincinnati, Cincinnati, OH

The mechanism of how environmental polyhalogenated aromatic chemicals cause liver tumors in rodents has never been elucidated, although of some pertinence to risk assessment. In rats, all chemicals of this type that have been investigated have shown marked sexual dimorphism towards females—both in propensity to induce liver tumors and development of porphyria. Evidence suggests a role for iron metabolism in these processes. In C57BL/10ScSn or C57BL/6 Cyp1a2(+/+) mice, porphyria and liver tumor incidence caused by hexachlorobenzene, polychlorinated and polybrominated biphenyls are markedly stimulated by iron overload. However, porphyria does not occur in C57BL/6 Cyp1a2(-/-) mice exposed to hexachlorobenzene or TCDD, even after additional treatment with iron. In this study, male Cyp1a2(+/+) and Cyp1a2(-/-) mice (5 per group) were administered the PCB mixture Aroclor 1254 in the diet (0.01%) for 7 weeks, with or without a prior sc dose of iron-dextran (800 mg Fe/kg). Hepatic porphyria was observed only in Cyp1a2(+/+) mice (mean value 12 nmol of uroporphyrin/g liver) and especially those also given iron (mean value 219 nmol/g). All other groups, including Cyp1a2(-/-) mice given iron and Aroclor, had mean values <1 nmol/g with no significant difference from untreated animals. When similar groups of male Cyp1a2(+/+) and Cyp1a2(-/-) mice (10 per group) were exposed to Aroclor for up to 57 weeks, survival time was decreased in the Aroclor/iron (+/+) mice but not in the null mice with correspondingly larger size livers (mean livers sizes of 21 and 16% of body weight respectively). All Aroclor or Aroclor/iron Cyp1a2(+/+) mice had large clear-cell or eosinophilic liver foci and/or adenomas; none was observed in the Cyp1a2(-/-) mice—although hepatocellular damage appeared as evident as the wild type. In conclusion, these findings support the hypothesis of a link between porphyria and liver tumor formation caused by polyhalogenated aromatic chemicals in rodents.

#### 1096

ISOLATION AND ENRICHMENT OF PRENEOPLASTIC HEPATOCYTES DURING MALIGNANT CELL TRANSFORMATION.

A. Ashley, M. Lohitnavy, Y. Lu, L. Chubb, <u>R. Billings</u>, J. Campain and <u>R. Yang</u>. Quantitative and Computational Toxicology Group, Center for Environmental Toxicology and Technology, Department of Environmental and Radiological Health Sciences, Colorado State University, Fort Collins, CO.

We modified Ito's medium-term liver foci bioassay by incorporating time-course sacrifices to study pharmacokinetics/pharmacodynamics related to the initiation-promotion process. In our earlier clonal growth modeling studies on a series of chlorobenzenes, the probable existence of two cell types in glutathione-S-trasferase  $\Pi$  (GSTP) foci became apparent. As suggested by other researchers, these two cell types are either susceptible or resistant to mitoinhibitory effects as a response to external chemical insults, and those resistant to mitoinhibitory effect would have a growth advantage serving as basis for malignant transformation. Thus, as preneoplastic GSTP foci form, isolation of GSTP positive (GSTP+) cells from liver across time allows capturing changing characteristics of an emerging malignant population. This study describes an attempt to isolate primary GSTP+ hepatocytes using Ito's bioassay protocol with diethylnitrosamine (DEN) as an initiating agent and a 2/3 partial hepatectomy with concomitant dosing of hexachlorobenzene (HCB;

28.4 mg/kg/day) with and without coexposure to PCB 126 (9.8 µg/kg/day) as promoting agents. Male F344 rats were sacrificed at 20, 24, 28, 47 and 56 days, and 3, 6, and 9 months following DEN injection. By day 56, a significant increase in liver weight was observed in rats coexposed to HCB and PCB 126. Either primary hepatocytes or liver sections were taken to analyze formation of GSTP+ foci. By treating cell suspension and/or culture with ethacrynic acid (EA) (Stenius et al., Carcinogenesis 15:1561-1566, 1994), GSTP+ hepatocytes were enriched by inducing toxicity to non-GSTP+ cells. In so doing, progressively more malignant cell populations can be subjected to cell cycle kinetic studies, genomic analyses, and clonal growth modeling to aid our insight into the carcinogenic process. ### 1097 MIPAFOX-INHIBITED ACHE YIELDS A DOUBLY AGED ACTIVE SITE.

T. J. Kropp and R. J. Richardson. Environmental Health Sciences, University of Michigan, Ann Arbor, MI.

Inhibition of AChE by organophosphorus (OP) compounds involves organophosphylation of the active site serine. Restoration of activity is prevented by aging of the inhibited enzyme. Aging usually involves loss of a ligand from the organophosphyl moiety to create a negative charge, e.g., AChE inhibited by diisopropylphosphorofluoridate (DFP) ages by net loss of an isopropyl group. In contrast, AChE phosphoramidated by tabun ages by scission of the P N bond to lose dimethylamine. The present study was undertaken to determine the mechanism of aging of MIP-inhibited AChE using DFP-inhibited AChE as a reference. The  $k_1$ ,  $k_3$ , and  $k_4$  for MIP-inhibited human recombinant AChE were  $1.47 \pm 0.047$  M<sup>-1</sup>min<sup>-1</sup>,  $78 \pm$  $1.442 \text{ min}^{-1}$ , and  $0.0192 \pm 0.00131 \text{ min}^{-1}$ , respectively, and for DFP-inhibited enzyme were  $404.5 \pm 21.5 \text{ M}^{-1}\text{min}^{-1}$ ,  $15 \pm 0.132 \text{ min}^{-1}$ , and  $0.0213 \pm 0.00156 \text{ min}^{-1}$ , respectively. Using peptide mass mapping with surface enhanced laser desorption/ionization mass spectrometry, m/z peaks corresponding to active site peptides and their intact or modified adducts were examined in control and treated samples at 0, 1, 2, 12, 24, and 36 h after inhibition. Time dependent mass shifts representing organophosphylation of the active site peptide and subsequent ligand loss from the organophosphyl group were found for MIP- and DFP inhibited AChE. Loss of a single ligand was not found for MIP-inhibited AChE. Instead, a peak corresponding to net loss of two isopropylamine ligands (doubly aged, yielding a simple inorganic phosphate on the active site peptide) was found at time points corresponding to the kinetically aged MIP-inhibited AChE. The presence of this doubly aged moiety was confirmed by immunoprecipitation with an anti phosphoserine antibody. Analysis of DFP inhibited AChE revealed a singly aged phosphylated active site as expected. The results suggest that MIP inhibited AChE might be stabilized in its mono-aged state, allowing for a second aging reaction. No singly aged intermediate was found, suggesting that the second aging reaction proceeds at a relatively rapid rate. (Supported in part by ARO grant DAAD19-02-1-

## 1098 EFFECTS OF CHRONIC DERMAL EXPOSURE TO METHYL PARATHION ON GLUTAMATE RECEPTOR SUBTYPES IN THE RAT BRAIN.

T. Ma, T. Sun, R. C. Baker, R. E. Kramer and I. K. Ho. Pharmacology & Toxicology, University of Mississippi Medical Center, Jackson, MS.

Toxicity to organophosphorus insecticides is mediated primarily through inhibition of acetylcholinesterase, which results in abnormally high cholinergic activity. However, organophosphorus compounds can influence other neurotransmitter systems, and actions at noncholinergic synapses may also contribute to organophasphate toxicity. For example, the excitatory amino acid plays a prominent role in the maintenance of organophosphate-induced seizures and in the subsequent neuropathology especially through an overactivation of glutamate receptor subtypes. In present study, we investigated the effects of chronic dermal exposure to sublethal doses of methyl parathion on glutamate receptor subtypes. Adult female rats (5 animals/treatment group) received 0, 0.1 or 1.0 mg/kg/day methyl parathion for 95 days. Receptor binding was analyzed be autoradiographic method. Methyl parathion treatments significantly increased [3H]MK-801 binding to the Nmethyl-D-aspartate (NMDA) receptor subtype in several brain regions including striatum as well as inter- and superior-colliculus. No significant change in [3H]AMPA binding to the AMPA receptor subtype was found in the two methyl parathion-treated groups. The results indicated that NMDA receptor is, but not AMPA, a target for the organophosphorus insecticide. Toxicological implication of methyl parathion-induced alteration of NMDA receptor needs to further study. (Supported by CDC grant RO6/CCR419466)

#### 1099

MOTOR FUNCTIONS BUT NOT ACQUISITION AND RETENTION OF ACTIVE AVOIDANCE RESPONSE ARE IMPAIRED IN METHYL PARATHION-TOLERANT RATS.

T. Sun<sup>1</sup>, I. A. Paul<sup>2</sup> and <u>I. Ho</u><sup>1</sup>. <sup>1</sup> Pharmacology and Toxicology, University of Mississippi Medical Center, Jackson, MS and <sup>2</sup> Psychiatry and Human Behavior, University of Mississippi Medical Center, Jackson, MS.

Previous work in this lab indicated that repeated exposure to methyl parathion (MP) caused prolonged inhibition of acetylcholinesterase (AChE) activity, and down-regulation of muscarinic receptors in the brain regions, which showed the neurochemical evidence of development of tolerance to MP. These changes were accompanied by a slower body weight gain and progressive deterioration of motor function in MP-treated Sprague-Dawley rats. MP produced substantial effects on several different aspects of motor function, including spontaneous locomotor function, rearing and sniffing and neuromuscular coordination. A lack of tolerance to the motor suppressant effects of MP was observed throughout the exposure with the proceeding in reduction of muscarinic receptors. But the neuronchemical changes did not cause impairment in the performance of acquisition and retention in active avoidance responding. Our studies indicate that prolonged inhibition of AChE activity and down-regulation of central nervous muscarinic receptors produced selected behavioral effects. The motor functions appear more sensitive to the chronic MP exposure comparing to cognitive behaviors. It is consistent with our previous finding that the most extensive down-regulation of muscarinic receptors was found in the striatum (-30%), the area believed to involve in the regulation of motor function.

## 1100 EFFECTS OF ESTROGEN ON THE NEUROTOXICITY OF DELTAMETHRIN IN THE RAT CORTICAL BRAIN SYNAPTOSOMES.

N. Shi, L. Chen, J. Dong, T. Li and D. Chen. Department of Health Toxicology, Tongji Medical College Huazhong University of Science and Technology, Wuhan, Hubei, China. Sponsor: Z. Lai.

Deltamethrin is a pyrethroid insecticide that shows neurotoxicity for the animals. It is still unclear how deltamethrin affect central neural system in the animals. In the present study, cortical brain synaptosomes from ovariectomized rats were incubated with deltamethrin in absent or present of estradiol and/or tamoxifen in order to investigate the effects of deltamethrin on cortical brain synaptosomes and to see if estradiol has neuroprotective effects against deltamethrin. Our results show that 2×10<sup>-5</sup> mol/L of deltamethrin induced significant increases in Asp and Glu release from the cerebral cortical synaptosomes at the depolarizing state evoked by 50 mmol/L KCl. However, these effects could be partial blocked by estradiol at the level of  $10^{-8}$  and  $10^{-11}$  mol/L, when the cerebral cortical synaptosomes were pre-incubated with estradiol for 1-hour before co-incubation with deltamethrin. Furthermore, the activities of ATPase of cortical synaptosomes were inhibited by 2×10<sup>-5</sup> mol/L of deltamethrin, and these effects could be blocked by 10<sup>-5</sup> mol/L of estradiol. No effects of tamoxifen either on the function of estradiol or on the effects of deltamethrin were found. Taken together, our findings confirm that the neurotoxicity of deltamethrin is related to the increases of Asp and Glu release and inhibition of ATPase, and estradiol can against the effects of deltamethrin on cerebral cortical synaptosomes. Tamoxifen did not alter the effects of estradiol against deltamethrin, suggesting that the effects of estradiol against deltamethrin might not be mediated through estrogen receptor. These results indicate a nongenomic mechanism of estradiol on its neuroprotective effects.

## 1101 MODULATION OF DOPAMINE METABOLISM BY SEVERAL METABOLITES OF THE HERBICIDE ATRAZINE IN RAT STRIATAL SLICES.

N. M. Filipov<sup>1</sup>, M. Tsunoda<sup>1, 2</sup> and S. C. Sistrunk<sup>1</sup>. <sup>1</sup>CEHS, Basic Sciences, Mississippi State University, Mississippi State, MS and <sup>2</sup>Public Health, Fukushima Medical University, Fukushima, Japan.

Environmental factors, such as pesticide exposure, have been postulated to contribute to the etiology of Parkinson's Disease. Recently, it was demonstrated that (1) the herbicide atrazine (ATR) modulates dopamine (DA) metabolism in PC-12 cells and (1) ATR exposure results in a dose-dependent decrease of tissue DA in rat striatal slices. Some of the major metabolites of ATR in the environment and in mammals are: hydroxyatrazine (HA), deethylchlorotriazine (DE), deisopropylchlorotriazine (DIP) and diaminochlorotriazine (DACT). The objective of the current study was to evaluate the ability of these ATR metabolites to modulate DA metabolism in rat striatal slices. Rat striata were incubated with up to 500 µM of each ATR metabolite in a metabolic shaker bath for 4 h. Tissue and media levels of DA and its metabolites 3, 4-dihydroxyphenylacetic acid (DOPAC) and homovanilic acid (HVA)) were determined by HPLC-ECD. Lactate dehydrogenase (LDH) release into the culture media was used as an index of non-specific cytotoxicity. Exposure

to all metabolites at the 100 and 250  $\mu$ M doses, increased media and tissue DOPAC levels and, to a lesser extent, media HVA levels. DE and DIP were the most effective ATR metabolites in increasing DOPAC levels. However, in contrast to the previously observed dose-dependent decrease in tissue DA levels by ATR, none of its metabolites tested in this study affected tissue DA levels significantly. The effects of the ATR metabolites on DA metabolism were observed in the absence of increased LDH release. Thus, it could be concluded that (i) all studied metabolites, contrary to ATR itself, are largely ineffective in decreasing tissue DA, (ii) these metabolites are nevertheless capable of modulating DA metabolism and (iii) of the four metabolites tested, DE and DIP were most effective whereas DACT, although showing similar trends, was least effective. Supported in part by: P20 RR017661 (NIH).

#### 1102

NEUROTROPHIN EXPRESSION IN THE SPINAL CORD OF CHICKENS DURING ACTIVE NERVE FIBER DEGENERATION FOLLOWING EXPOSURE TO ORGANOPHOSPHATE COMPOUNDS.

M. J. Pomeroy, D. Parran, M. Ehrich and B. Jortner. Virginia Tech, Blacksburg. VA

Exposure to certain organophosphates (OP) has been shown to induce a delayed neuropathy (OPIDN) characterized by Wallerian-like degeneration in certain animals, including humans. The hen serves as the major animal model for this neuropathy as it demonstrates clinical signs within days of OP dosing. We hypothesized that fiber degeneration induced by OP administration results in an upregulation of neurotrophin expression, particularly nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), and neurotrophin-3 (NT-3) in susceptible regions of the nervous system. Hens were exposed to TOTP (500 mg/kg), a neuropathy-inducing OP. By day 9, all hens demonstrated clinical signs of OPIDN ranging from clumsiness to postural alterations. On the day of sacrifice (day 14), all hens demonstrated ataxia and two birds had obvious difficulty standing. Hens were sacrificed by pentobarbital overdose. Microscopic study of the nerve of the biventer cervicis muscle confirmed the presence of a neuropathy. Cervical spinal cord tissue from each hen was used for enzyme-linked immunosorbant assays (ELISAs) in order to determine the presence of NGF, BDNF, and NT-3. Commercially available rat-derived NGF and mouse-derived NT-3 antibodies and mouse-derived BDNF antibody were suitable for these studies. Relative to controls, we detected a near doubling of NGF and BDNF levels, and an increase in NT-3 of almost 25% in the spinal cord of OP treated hens 14 days post-dosing. This study suggests levels of specific neurotrophic factors are increased in hens with OPIDN.

### 1103 CHLORPYRIFOS ALTERS FUNCTIONAL INTEGRITY AND STRUCTURE OF AN *IN VITRO* BBB MODEL.

D. Parran, G. Magnin, W. Li, B. S. Jortner and M. Ehrich. Virginia-Maryland Regional College of Veterinary Medicine, Virginia Tech, Blacksburg, VA.

The blood-brain barrier (BBB) is a structural and functional interface between the circulatory system and the brain. Organophosphorous (OP) compounds such as chlorpyrifos (CPF) may cross the BBB and disrupt BBB integrity and function. To determine possible mechanisms of action for CPF toxicity, we used an in vitro BBB model where bovine microvascular endothelial cells (BMEC) and neonatal rat astrocytes were co-cultured. We hypothesized that CPF is metabolized by the BBB to CPF-oxon leading to an inhibition of esterase activity and a disruption of the BBB. The co-culturing of BMECs and astrocytes resulted in tight junction formation as evident by electron microscopy, electrical resistance and western blot analysis of two tight junction-associated proteins (ZO-1 and e-Cadherin). We observed a time dependent increase in ZO-1 and e-Cadherin expression as well as electrical resistance during BBB formation, which was maximal after 9 to 13 days of co-culturing. The CPF concentration and production of its metabolites were monitored by HPLC following 24 hr exposure to CPF. We found that the BBB metabolized CPF, with the metabolite 2, 3, 6-trichloro-2-pyridinol being the major product. The detected quantity of CPF and its metabolites on the luminal and abluminal side of the BBB represented 1% or less of the initial quantity added to the incubation medium, suggesting that not all of the CPF (900 - 8, 600, 000 nM) crossed the BBB. At all tested concentrations (100 -10, 000 nM) CPF inhibited both carboxylesterase (CaE) and cholinesterase (ChE) activity by 43% to 100%, while CPF-oxon totally inhibited CaE and ChE activity. There was also a concentration-dependent decrease in electrical resistance. A decrease in electrical resistance was observed at CPF concentrations as low as 1 nM with complete inhibition at 1000 nM. These data suggest that low concentrations of CPF and its metabolites are trapped within the BBB. These metabolites, including CPF-oxon, are contributing to the inhibition of CaE and ChE activity and the alteration of BBB integrity and structure.

#### 1104

CONCURRENT CHRONIC STRESS AND CHLORPYRIFOS ATERED SWIMMING BEHAVIOR MORE THAN CHRONIC STRESS ALONE.

T. Pung, K. Knight, G. Magnin, K. Fuhrman, J. Hinckley and M. Ehrich. Virginia-Maryland Regional College of Veterinary Medicine, Virginia Tech, Blacksburg, VA.

Effects of concurrent chronic stress and chlorpyrifos (CPF) on swimming behavior, enzymes of acetylcholine synthesis and metabolism in brain, and blood chemistry were studied in Long Evans rats. Groups of rats (n=7) were handled 5 days/week, restrained 1 hour/day for 5 days/week, swum 30 minutes for 1 day/week, or restrained 4 days with swimming 1 day/week, for 28 days. On day 24, each group was gavaged either with corn oil or CPF 160 mg/kg SC 4 hours after restraint. Blood samples were collected on day 28 for acteylcholinesterase (AChE) activity and clinical pathology. Brains were dissected into hippocampus (HP) and cerebral cortex (CC) for levels of AChE, carboxylesterase (Cbxy), and choline acetyltransferase (ChAT). On day 28, CPF-treated rats that were swum and rats restrained and swum were less able to tolerate being in the water than rats treated with corn oil with average swim times of 27.1 and 28.9 minutes, respectively. Stressed rats given corn oil swum an average of 29.4 and 30 minutes, respectively. CPF inhibited AChE activity in blood, CC and HP, but stress did not affect AChE activity. CPF inhibited Cbxy activity in CC and HP. Restraint with swim stress also inhibited cortical Cbxy (40.05 2.21 compared to ranges of 53.49-56.54 nmole phenyl valerate hydrolyzed/min/mg protein in other groups). Neither chronic stress nor CPF affected ChAT activity in CC and HP. The levels of plasma total protein (6.71 0.08 g/dL), albumin (3.44 0.03 g/dL), and sodium (139.48 0.44 mEq/L) were higher in restrained and swum rats than in handled rats and restrained rats; however, potassium levels (7.01 0.26 mEq/L) were lower. CPF also decreased the levels of total protein and potassium but did not show an interaction with stress. Rats, therefore, responded differently to different types of stress.

#### 1105

DOSE RESPONSE OF NEUROPATHY TARGET ESTERASE INHIBITORS ON ATP PRODUCTION AT COMPLEX I AND II IN HUMAN NEUROBLASTOMA CELLS IN SITU.

K. M. Knight<sup>1</sup>, <u>C. Massicotte<sup>2</sup> and M. Ehrich</u><sup>1</sup>. <sup>1</sup>Virginia-Maryland Regional College of Veterinary Medicine, Virginia Tech, Blacksburg, VA and <sup>2</sup>Matthew J. Ryan Veterinary Hospital, University of Pennsylvania, Philadelphia, VA.

Organophosphate (OP) neurotoxicants that inhibit neuropathy target esterase (NTE) can cause delayed neuropathy (OPIDN) in susceptible animals. Altered energy production in target cells is a possible contributing mechanism and was investigated in human neuroblastoma SH-SY5Y cells. For these studies, mitochondrial ATP production was examined 30 min after exposure to 0.1 - 1 mM of the neuropathic OP, phenyl saligenin phosphate (PSP) and 0.1 - 5 mM phenyl methyl sulfonyl fluoride (PMSF), an inhibitor of NTE unable to induce OPIDN. After depletion of residual ATP, digitonin permeabilized cells were incubated at 37 C/5% CO2 in buffer supplemented with ADP and either glutamate and malate (Complex I substrates) or succinate (Complex II substrate). After 30 min, cells were lysed by addition of 8% trichloroacetate and neutralized with a MOPS/potassium hydroxide buffer. ATP was quantified using a luciferase enzyme assay (Sigma Chémical Co., St. Louis, MO). Results demonstrated an inhibition of ATP production at Complex I that was concentration dependent (0.1-1 mM for PSP; 1-5 mM for PMSF), with highest concentrations providing 88% and 74% less ATP than control cells, respectively. PSP also suppressed ATP production at Complex II in a concentration-dependent manner, with 46% inhibition at 1 mM. Inhibition of ATP production by the Complex I inhibitor rotenone was augmented in the presence of PSP but not PMSF. These results suggest that NTE inhibitors affect cellular energetics of SH-SY5Y cells in situ in a concentration-dependent manner, with PSP more potent than PMSF.

### 1106 ORAL BIOAVAILABILITY AND NERVOUS TISSUE DISTRIBUTION OF CYHALOTHRIN IN RATS.

M. R. Martinez-Larranaga, M. Martinez, M. A. Martinez, M. J. Diaz, M. T. Frejo and <u>A. Anadon</u>. Toxicology & Pharmacology, Faculty of Veterinary Medicine, Complutense University, Madrid, Spain.

The primary site of action of the pyrethroid insecticides is the nervous system. Type II pyrethroids, such as cyhalothrin, are characterized by blocking nerve conduction and by causing convulsions and paralysis. The nerve-blocking action of Type II pyrethroids has been associated with the release of neurotransmitters. Because the toxicokinetic data should be considered for the risk assessment of this drug, the objective of the present study was to determine the kinetic behaviour of cyhalothrin after oral administration. Male Wistar rats were treated orally with cyhalothrin (dissolved in corn oil) (single dose of 20 mg/kg) and killed at different time period after

treatment. Plasma and nervous tissue samples (hypothalamus, cerebellum, midbrain, spinal cord and ciatic nerve) were isolated, homogenized and extracted in acetonitrile to determine cyhalothrin levels by HPLC-UV. The cyhalothrin plasma and tissue profile could be adequately described by a two-compartment open model. The plasma disposition of cyhalothrin was characterized by a rapid absorption and distribution phases and a slow elimination phase ( $t^{1/2}a = 0.89$  hr,  $t^{1/2}\alpha = 1.87$  hr,  $t^{1/2}\beta = 9.90$  hr). The oral bioavailability was 71%. The tissue elimination half-lives and the ratios of tissue/plasma area under the concentration-time curves indicated a tendency of cyhalothrin to accumulate in nervous tissues. It is anticipated that knowledge of the kinetics of cyhalothrin would lead to a better understanding of its neurotoxicity.

### 1107 DECREASE OF 5-HT LEVELS AFTER FIPRONIL TREATMENT.

A. Anadon, R. Pita, Y. Garcia-Uzcategui, M. J. Diaz and M. R. Martinez-Larranaga. Department of Toxicology and Pharmacology, Faculty of Veterinary Medicine, Complutense University, Madrid, Spain.

Fipronil is the first phenylpyrazole insecticide introduced for pest control. It is highly effective broad-spectrum insecticide with many applications in agriculture, public health and animal health, and good efficacy against many resistant strains. While fipronil is known to be a highly effective blocker of insect GABA receptorand glutamate receptor-chloride channels, its neurotoxicity on mammals has been less characterized. Because of a variety of putative biochemical and physiological target sites may contribute to fipronil toxicity, the objective of the present study was to investigate neurochemical effects following the oral administration of fipronil (5 and 10 mg/kg for 6 days) in male Wistar rats (n =6/group). Animals were sacrificed 24 hours following drug administration and their brains were rapidly removed. The hypothalamus, hippocampus and striatum were dissected and analyzed for content of 5-hydroxytryptamine (5-HT) and its metabolite 5-hydroxy-3-indole acetic acid (5-HIAA) using a HPLC method with electrochemical detection. Fipronil produced a serotonin depleting effect in a dose-dependent maner. Fipronil (10 mg/kg for 6 days) decreased 5-HT levels in hypothalamus (29%, P<0.01), hippocampus (40%, P<0.01) and striatum (45%, P<0.001) and decreased 5-HIAA levels in hypothalamus (26%, P<0.05), hippocampus (34%, P<0.01) and striatum (45%, P<0.001) respect to corn oil controls. The data presented herein suggests that a lower activity of serotonergic system exists in the action of fipronil.

#### 1108

INHIBITION OF CHOLINESTERASE AND CARBOXYLESTERASE FOLLOWING *IN VIVO* EXPOSURE OF RATS TO MIXTURES OF PARATHION AND CHLORPYRIFOS.

E. Meek, R. Carr, H. Chambers, J. Kamykowski and J. Chambers. Mississippi State University, Mississippi State, MS.

The patterns of inhibition of brain and serum cholinesterase (ChE) and serum carboxylesterases (CbxE) were determined after oral administration of two (organophosphorus) insecticides singly or in simultaneous or sequential mixtures. The effective dose levels that would inhibit 10% of brain ChE at the time of peak inhibition were determined to be 1.0 mg/kg parathion (P) and 5.0 mg/kg chlorpyrifos (C) at 10 and 12 hr, respectively. Sequential exposures were performed with the first insecticide administered followed by the second insecticide at the peak inhibition time for the first. Tissue samples were collected at 2, 4, 8, 10, 12, and 24 hr. Brain and serum ChE levels were determined by continuous spectrophotometric assay, and serum CbxE inhibition was determined by discontinuous spectrophotometric methods. Inhibition of brain ChE for C was 4% at 4 hr, 7% at 8 hr, and 11% at 12 hr, and 5% at 24 hr; for P was 7% at 8 hr, 12% at 10 hr, and 0% by 24 hr. Simultaneous exposure prolonged inhibition from 2% at 8 hr to 21% at 12 hr. Sequential exposure (P followed by C) indicated greater-than-additive effects; inhibition ranged from 21% at 4 hours to 20% at 24 hr with peak inhibition at 8 hours (36%). C followed by P produced inhibition at earlier time points, compared to the single compounds; 15% at 2 hr, peak at 4 hr (25%), and 0% by 24 hr. Inhibition of serum ChE levels decreased at successive time points, and simultaneous and sequential exposures showed no increase in inhibition. Serum CbxE was greatly inhibited by P (from 81% at 2 hr to 28% at 24 hr) and C (from 93% at 2 hr to 50% an 24 hr). Inhibition of serum CbxE levels decreased at successive time points following simultaneous and sequential exposures. There is evidence of some interactions following sequential exposure to binary mixtures of these two insecticides administered at relatively low dosages with differences in patterns of response occurring with different order of administration of the two compounds. (Supported by American Chemistry Council CRAM 2a-99).

PHARMACOKINETIC DIFFERENCES MAY EXPLAIN THE AGE-RELATED SENSITIVITY OF DELTAMETHRIN, A PYRETHROID INSECTICIDE, IN RATS.

W. Haines<sup>1, 2</sup>, R. S. Marshall<sup>2</sup>, D. L. Hunter<sup>2</sup> and S. Padilla<sup>2, 1</sup>. <sup>1</sup>Toxicology, UNC- CH, Chapel Hill, NC and <sup>2</sup>NHEERL, USEPA, Research Triangle Park, NC.

This study was designed to examine the age-related sensitivity to the pyrethroid insecticide, deltamethrin [(S)-?-cyano-3-phenoxybenzyl (1R, 3R)-3-(2, 2-dibromomovinyl)2, 2-dimethylcyclopropanecarboxylate], in Long Evans, hooded, male rats. Deltamethrin has been shown to be more acutely toxic to weanling (21 days) rats (Sheets et al., Toxicol Appl. Pharmacology, 1994) than adults. Our hypothesis is that weanling rats are more sensitive than adults to deltamethrin due to pharmacokinetic differences. Therefore, we conducted time course studies in both weanling (PND 21) and adult (PND 90) male rats to determine the intensity of and time of peak toxic signs [i.e., salivation and choreoathetosis (jerky, involuntary movements)] as well as deltamethrin concentrations in the brain. Rats (n = 5 per age and treatment) were gavaged with either corn oil or 30 mg/kg deltamethrin for the adults and 4 mg/kg deltamethrin for weanlings. The toxic signs observed in the weanlings were as severe as the adults. Peak brain concentrations of deltamethrin were comparable in both the adult and weanling rats. These findings indicate that weanling animals given a dosage which is 13% of the adult deltamethrin dosage show toxic signs and brain concentrations of deltamethrin comparable to the adult. This abstract of a proposed presentation does not imply EPA policy.

TWO-GENERATION DIETARY REPRODUCTIVE TOXICITY STUDY WITH CHLORPYRIFOS-METHYL IN CD RATS: INHIBITION OF ACETYLCHOLINESTERASE.

B. Marable<sup>1</sup>, K. E. Stebbins<sup>1</sup>, A. B. Liberacki<sup>1</sup>, <u>S. Marty<sup>1</sup></u>, <u>R. Billington<sup>2</sup></u> and <u>E. W. Carney<sup>1</sup></u>. <sup>1</sup> The Dow Chemical Company, Midland, MI and <sup>2</sup>Dow Agrosciences, Oxon, United Kingdom.

As part of a two-generation study to assess the reproductive function and development of rats exposed to chlorpyrifos-methyl (CPM), acetylcholinesterase (AChE) activities were measured in the brains, red blood cells (RBC), and hearts of adults and pups (post-natal day (PND) 1, 4, and 22; n = 5/sex/group). Male and female CD rats were exposed to 0, 1.0, 3.0, or 10.0 mg/kg/day ČPM in their diets for 10 weeks prior to breeding, during gestation, and lactation for two generations. No treatment effects were seen on any of the reproductive or developmental parameters examined in either generation. Gross effects were limited to increased adrenal gland weights in P1 animals (high-dose males and females), and P2 animals (high-dose males and females; mid-dose females), which were correlated with vacuolization of the zona fasciculata of the adrenal glands. The no-observed-effect level (NOEL) for reproductive toxicity was 10 mg/kg/day and the no-observed-adverse effect level (NOAEL) for parental toxicity, based on adrenal histopathology in mid-dose females, was 1.0 mg/kg/day. In adults, dose-dependent inhibition of RBC AChE occurred at all doses levels, in both sexes, in both generations. In high-dose adults, brain and heart AChE activities were significantly lower (by 13.3 and 23.3%, respectively) than controls. Similar differences in adult heart AChE activities were not seen in the P2 generation. In high-dose pups (PND 1 and 4), RBC AChE activities were lower (by 21.3%) than controls, but these differences disappeared by PND 22 in both generations. No effects on pup brain or heart AChE activities were seen in any dose group at any time during the study. These data indicate that inhibition of RBC AChE occurs at much lower (10-fold) doses in adults exposed to CPM in their diets than pups exposed during gestation and lactation. Ôverall, pup brain and heart AChE activities were unaffected by exposure to CPM at any of the doses

### 1111 PROPERTIES AND FIPRONIL MODULATION OF INSECT GLUTAMATE-GATED CHLORIDE CHANNELS.

X. Zhao<sup>1</sup>, J. Z. Yeh<sup>1</sup>, V. L. Salgado<sup>2</sup> and <u>T. Narahashi<sup>1</sup></u>. <sup>1</sup>Molecular Pharmacology and Biological Chemistry, Northwestern University Medical School, Chicago, IL and <sup>2</sup>Global Biology Insecticides, Bayer CropScience, Monheim, Germany.

Glutamate-gated chloride channels (GluCls), found only in invertebrates but not in mammals, are an important target for some insecticides and may play a critical role in their selective toxicities between mammals and insects. The present study was to further characterize the properties of GluCls and to explore the mechanisms of action of fipronil, a phenylpyrazole insecticide, on the receptors in cockroach thoracic ganglion neurons using the whole-cell patch clamp technique. Two types of

GluCls, desensitizing and non-desensitizing GluCls, were elicited by glutamate, and they could coexist with and function independently of the GABA receptor chloride channels. The non-desensitizing GluCls exhibited a higher sensitivity than the desensitizing GluCls to picrotoxinin, a GABA receptor antagonist. Fipronil inhibited the desensitizing and non-desensitizing GluCls with IC $_{50}$ s of 801 nM and 10 nM, respectively. Kinetic analysis revealed that fipronil preferentially blocked open channels. The recovery of the desensitizing current from fipronil block required channel openings, whereas the recovery of non-desensitizing current from block was independent of channel openings but occurred in a time-dependent manner. The high potency of fipronil for inhibition of the non-desensitizing current was due to a slow unblocking rate constant. In addition, the non-desensitizing GluCls pre-occupied by picrotoxinin became less sensitive to fipronil block. It is concluded that GluCls are a critical target for fipronil forming the basis for the selective toxicity between mammals and insects. Supported by NIH grant NS14143.

## 1112 TIME AND CONCENTRATION DEPENDENT ACCUMULATION OF [<sup>3</sup>H]-DELTAMETHRIN IN XENOPUS OOCYTES.

J. A. Harrill<sup>1</sup>, C. A. Meacham<sup>2</sup>, T. J. Shafer<sup>2</sup> and K. M. Crofton<sup>2</sup>. <sup>1</sup>Curriculum in Toxicology, University of N. Carolina, Chapel Hill, NC and <sup>2</sup>Neurotoxicology Division, NHEERL, ORD, USEPA, Research Triangle Park, NC.

The primary target of pyrethroids is the voltage sensitive sodium channel, a channel protein that can be expressed in oocytes from Xenopus laevis. A common assumption when utilizing this experimental platform is that media concentration is a predictive marker of tissue concentration. This assumption may not hold true for lipophilic xenobiotics. [3H]-deltamethrin (DLT) was used to test the hypothesis that media concentration is a good surrogate for tissue concentration. Accumulation of [ $^3$ H]-DLT (97+%; 0.001-10  $\mu$ M) in oocytes exposed for 20 minutes was determined using liquid scintillation counting. The time course (1-180 min) of tissue accumulation of [3H]-DLT (1.0 µM (0.50ppm) in media) was also determined. Results demonstrate that DLT accumulates in oocytes as a function of time (~0.010 ppm at 1 min: ~1.04 ppm at 180 min). The relationship between media and oocyte concentration is non-linear. Below 0.5 µM DLT in the media, media and oocyte concentrations are approximately equivalent. Above 0.5 µM, media concentration under-predicts oocyte concentrations by up to 5-fold. No apparent asymptotes were found in the ranges tested for either variable. These data suggest that media concentration may not accurately predict tissue concentrations in in vitro studies of deltamethrin. (This abstract does not necessarily reflect USEPA

#### 1113

CHRONIC DIETARY EXPOSURE WITH INTERMITTENT SPIKE DOSES OF CHLORPYRIFOS FAILS TO ALTER SOMATOSENSORY EVOKED POTENTIALS, COMPOUND NERVE ACTION POTENTIALS, OR NERVE CONDUCTION VELOCITY IN RATS.

J. E. Graff, R. S. Marshall, D. L. Hunter and <u>D. W. Herr</u>. *Neurotoxicology, USEPA, Research Triangle Park, NC.* 

Human exposure to pesticides is often characterized by chronic low level exposure with intermittent spiked higher exposures. Cholinergic transmission is involved in sensory modulation in the cortex and cerebellum, and therefore may be altered following chlorpyrifos (CPF) exposure. This study examined the effects of chronic (1 year) dietary exposure (0, 1, or 5 mg/kg/day) to CPF in weight maintained (350g) male Long Evans rats (100-110 days old at study initiation) on somatosensory evoked potentials (SEPs). Peripheral compound nerve action potentials (CNAPs) and nerve conduction velocity (NCV) were also examined to differentiate possible changes in the central vs peripheral nervous system. The CPF doses were chosen to produce minimal and approximately 50% inhibition of brain cholinesterase activity, respectively. In addition to dietary exposure, half of the rats received an oral bolus of 45 mg/kg CPF (in corn oil) every other month (n = 16-17 rats/treatment). In order to examine only irreversible effects, the animals were tested 2.5 months after final exposure. Rats were implanted with screw electrodes over the cortex and cerebellum. One week later, unanesthetized animals were restrained and their tails inserted into a stimulation/recording device. Biphasic stimulation at 1, 2 and 3 mA was delivered via two pairs of stimulation electrodes (stainless-steel 25 ga needles) placed in the tail. Another pair of electrodes recorded the CNAP and NCV. The evoked potentials showed the expected intensity-dependent changes in all treatment groups, indicating that the animals' responses were under stimulus control. Chronic dietary CPF (alone or in combination with spike doses) did not produce any irreversible changes in cortical or cerebellar SEPs, CNAPs or NCVs in adult animals. This is an abstract of a proposed presentation and does not necessarily reflect EPA policy.

#### 1114

BLOOD LEAD IS A PREDICTOR OF HOMOCYSTEINE LEVELS IN A POPULATION-BASED STUDY OF OLDER ADULTS.

J. H. Schafer<sup>1</sup>, T. A. Glass<sup>2</sup> and <u>B. S. Schwartz<sup>1,2</sup>. <sup>1</sup>Environmental Health Sciences, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD and <sup>2</sup>Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD.</u>

Clinical and epidemiologic research suggests that homocysteine increases the risk of cardiovascular disease and cognitive dysfunction. Lead is also associated with these two outcomes. We evaluated relations between whole blood lead and serum homocysteine in an analysis of first visit data among subjects in the Baltimore Memory Study, a longitudinal study of 50-70 year old randomly- selected residents in Baltimore City. Households in the study area were randomly selected (Department of Planning database), and were telephoned for recruitment. Of the communitybased subjects on whom eligibility could be determined, 60.8% were scheduled for an enrollment visit; and 1, 140 were enrolled and tested. Subjects had a mean (SD) age of 59.3 (6.0) years, and were 65.8% female, 53.5% white, and 41.6% African American. Mean (SD) blood lead and homocysteine levels were 3.5 (2.2) µg/dL and 9.9 (3.9) µmol/L, respectively. Homocysteine levels varied by gender (mean [SD] 9.3 [3.6] in women and 11.2 [4.2] in men) but not by race/ethnicity. In unadjusted analysis, blood lead and homocysteine were moderately correlated (Pearson's r = 0.27, p < 0.01). After adjustment for age, gender, race/ethnicity, education, tobacco and alcohol consumption, and body mass index using multiple linear regression, results revealed that homocysteine levels increased 3.5 µmol/L per  $10\,\mu\text{g/dL}$  increase in blood lead (p < 0.01). The relations of lead with homocysteine levels did not differ in subgroups by age, gender, or race/ethnicity. To our knowledge, these are the first data to reveal an association between blood lead and homocysteine. The results suggest that homocysteine could be a mechanism that underlies the effects of lead on the cardiovascular and central nervous systems. We believe that inhibition by lead of cystathionine  $\beta$ -synthase, a heme-containing enzyme in the trans-sulfuration pathway of methionine metabolism that is regulated by redox changes, should be evaluated as a possible explanation.

## 1115 IMMUNOGLOBULINS TO AUTOANTIGENS OF NERVOUS AND REPRODUCTIVE SYSTEMS IN MALES OCCUPATIONALLY EXPOSED TO LEAD.

H. A. El-Fawal<sup>1</sup>, A. De Feo<sup>1</sup> and M. Shamy<sup>2</sup>. <sup>1</sup>Neurotoxicology Laboratory, Mercy College, Dobbs Ferry, NY and <sup>2</sup>Institute of Public Health, University of Alexandria, Alexandria, Egypt. Sponsor: M. Ehrich.

Lead is toxic to nervous and reproductive systems. Toxicity, in part, may be due to its disruption of vascular beds, including the blood-brain (BBB), blood-nerve (BNB) and blood-testicular barriers (BTB). In addition to neurodegeneration, the compromise of these barriers may allow interaction between system-specific autoantigens and the immune system as indicated by serum autoantibodies. In this study, demographically and socioeconomically matched male workers at a lead (Pb) battery factory (n=30; age=42+6) or a frozen food plant (reference group R; n=30; age=41+7) were given a neurological exam and blood was collected. Blood Pb (PbB, µg/dl) determination and enzyme-linked immunosorbent assay (ELISA) for autoantibodies to neurofilament (NF) proteins, myelin basic protein (MBP) and antisperm antibodies (ASA) were performed. PbB was 24 ±7, and 10 ±3 for the Pb group and R, respectively. Dorsal column or spinothalamic tract deficits were absent in R, however, 40% of those exposed to Pb had some signs of dorsal column (vibration and stereognosis) or spinothalamic (pain) deficits. Motor deficits, hand tremors or hyporeflexia, were rare and confined to the Pb group. Autoantibodies (IgG) to one, or more, of the NF triplet proteins, particularly NF-68, were detected in the Pb group, and only in 2 of the males in the R group. These IgG levels correlated significantly (r=0.5; p=0.001) with the clinical score and PbB. Only 6 of those exposed to Pb had IgG to MBP. Confirmation of these results was determined by Western immunoblot of random serum samples. ASA, IgA or IgG, were found in 40% of the Pb workers, but not in R. These correlated significantly with PbB (r=0.3; p=0.05). Autoantibodies to nervous system proteins have been reported to contribute to neuropathogenesis, while ASA contribute to immunological infertility. This study demonstrates that Ig to system-specific autoantigens may be generated as markers of insult resulting from exposure to agents that compromise barriers such as the BBB or BTB.

#### 1116

LOW LEVEL LEAD EXPOSURE ALTERS THE MESOCORTICOLIMBIC EXCITATORY/INHIBITORY AMINO ACID NEUROTRANSMITTER BALANCE.

Y. Gedeon and A. L. Jadhav. Texas Southern University, Houston, TX.

Environmentally relevant level of lead (Pb) exposure produces deleterious cognitive effects attributed to Pb-induced mesocorticolimbic neurotransmitter disruption. Previous report indicates that time plays a critical, region-specific role in Pb's effects

on the mesocorticolimbic dopaminergic system (Gedeon et al. 2001). Monoamine and amino acid neurotransmitter interaction plays a critical role in cognitive function. This study further examined whether these Pb-induced dopaminergic changes were accompanied with alterations in the temporal profile of aspartate (ASP), glutamate (GLÜ), serine (SER), glutamine (GLN), glycine (GLY), taurine (TAU), alanine (ALA) and γ-amino butyric acid (GABA) levels in the nucleus accumbens (NAC), hippocampus (HIP), and the frontal cortex (FC). 23-day old male Long-Evans rats were exposed to 0 and 50 ppm Pb for 180 days. At each 30-day interval of the 180-day exposure period, sets of animals from the control (n = 16-20) and Pb-exposed (n = 16-20) groups were sacrificed by cervical decapitation; blood Pb (BPb) and regional brain amino acids (i.e ASP, GLU, SER, GLN, GLY, TAU, ALA and GABA) were analyzed by atomic absorption spectroscopy and high performance liquid chromatography respectively. The exposure protocol produced BPb <  $2\,$ g/dl in the control group and BPb > 9 g/dl in the Pb-exposed group. Pb exposure changed the excitatory/inhibitory amino acid neurotransmitter balance in the mesocorticolimbic system producing transient hypoexcitatory/hyperinhibitory states in the NAC, the HIP and the FC. These findings suggest that low level Pb's effects on the mesocorticolimbic aminoacidergic system may play a role in Pb-induced cognitive impairments. Supported by ATSDR Cooperative Agreement # U50/ATU 398948.

#### 1117

INORGANIC LEAD (PB) EXPOSURE ACTIVATES STRIATAL CFOS EXPRESSION AT LOWER BLOOD LEVELS AND INHIBITS AMPHETAMINE-INDUCED STRIATAL CFOS EXPRESSION AT HIGHER BLOOD LEVELS IN THE RAT.

M. W. Lewis and D. K. Pitts. *Pharmaceutical Sciences, Wayne State University, Detroit, MI.* Sponsor: <u>G. Corcoran</u>.

This study examined the impact of inorganic lead (Pb) on dopamine (DA) neurotransmission in the basal ganglia. In the striatum, D-amphetamine (AMP)-induced activation of the immediate early gene (IEG), cFOS, is mediated by the DA D1 receptor. The effect of Pb on AMP-induced cFOS activation was examined, and the number of neurons showing cFOS immunoreactivity in the striatum was compared among 3 treatment groups. Weanling rats were exposed to 0, 50, or 250 ppm Pb acetate (con, Pb50 or Pb250) via drinking water for 3 weeks. On the day of the experiment, all the subjects were challenged with AMP (4mg/kg, i.p.) or vehicle (normal saline, i.p.), and 2 hours later were sacrificed for either immunohistological analysis or determination of blood and brain Pb concentrations. The untreated con group showed negligible cFOS expression in the absence of AMP challenge. AMP challenge in the untreated con group significantly increased cFOS expression by approximately 35 fold over con. However, in the Pb50 group, the vehicle challenged rats also showed a statistically significant increase in cFOS expression of approximately 7 fold over con. This strongly suggests that the Pb50 exposure induced cFOS expression. AMP induced a statistically significant increase in cFOS in the Pb50 group, which was not significantly different from the AMP-induced increase in the untreated con group. However, in the Pb250 group, neither vehicle nor AMP challenge significantly increased cFOS above the con. These results indicate that 50 ppm Pb exposure induced a low, but statistically significantly level of cFOS gene activation, and was without effect on the AMP-induced cFOS activation. However, 250 ppm Pb exposure inhibited the amphetamine-induced activation of cFOS in the striatum by about 90%. Therefore, Pb is capable of both activating cFOS expression at low levels of exposure (mean blood Pb level: 21.6+/-1.9 µg/dl), and inhibiting AMP-induced cFOS expression at higher levels of exposure (mean blood Pb level: 47.4+/-2.6µg/dl).

### 1118 INHIBITORY EFFECT OF LEAD ON PKC ISOFORMS AND NF-KAPPA B *IN VIVO* AND *IN VITRO*.

S. xu, <u>B. Rajanna</u> and C. Shan. *Biological Sciences, Alcorn State University, Alcorn state, MS.* 

In this study We examined the effect of lead on PKC isoforms associated with NF-kB, nNOS both *in vivo* and *in vitro*. *In vivo* 0.1% lead acetate in distilled water (DDW) was given to female rats from gestation through the 21st day old of the pups. Control rats were drinking DDW. Pups were sacrificed on postnatal days (PND) 1, 5, 7, 10, 15, 21, 30 and 45. Brain stem(BS), cerebellum (CB), hippocampus (HC) and front cortex(FC) of rat brain parts were collected. PKC isoforms-a, b, g, e and m, IKK-a, NF—kB and nNOS were examined by immunoprecipitation and western blotting. *In vitro* neurons were isolated from fetal rats at 14-16 days gestation, and planted in 6 wells plates for 10 days for use. Neurons were exposed to 10-10-10-7 M lead for 14 h. Cell extraction was immunoprecipitated and run western blotting. NO production was assayed by Griess reagent. Cell *via*bility was assayed by MTT. DNA damage was observed using acridine orange (AO) stain. Our results indicated *in vivo* that on PND 1, PKC-g both in cytosolic and membrane fraction was decreased in HC and FC by lead. IKK-a, NF—kB and

nNOS across all the regions, and particularly in HC and FC, were substantially suppressed; On PND 10, all of the above PKC isoforms were inhibited in BS, CB, HC and FC membrane fraction as well as IKK-a, NF—kB and nNOS; On PND 45 the above PKC isoforms as well as IKK-a, NF—kB and nNOS but not PKC-e in lead treated group were restored to normal. *In vitro* NO production was dose dependently decreased. Only 26.4% neurons survived after lead treatment as confirmed by MTT. Fluorescent intensity was enhanced in lead treated neurons. PKC isoforms-a, b, g, l except d, IKK-a, NF—kB and nNOS were dose-dependently inhibited. It was concluded that translocation of most PKC isoforms was suppressed in HC and FC by lead *in vivo*, particularly g and e, whose roles were pertinent to memory formation and long term potential. Concurrently, PKC isoforms expressions were dose-dependently decreased *in vitro*. The inhibition of nNOS was due to NF-kB-IKK a suppression.Lead directly caused DNA damage and mitochondria dysfunction *in vitro*.

### 1119 DIFFERENT MECHANISMS MEDIATE UPTAKE OF LEAD IN A RAT GLIAL CELL LINE.

I. P. Bressler<sup>2, 3</sup>, D. Bannon<sup>1, 2</sup>, L. Olivi<sup>3</sup>, J. Cheong<sup>4, 2, 3</sup> and K. Kim<sup>2, 5, 3</sup>.

<sup>1</sup>Center for Health Promotion and Preventive Medicine, US Army, APG, Aberdeen, MD, <sup>2</sup>Environmental Health Sciences, Johns Hopkins University, Baltimore, MD, <sup>3</sup>Neurotoxicology, Kennedy Krieger Institute, Baltimore, MD, <sup>4</sup>School of Pharmacy, Sahmyook University, Seoul, South Korea and <sup>5</sup>Department of Preventive Medicine, Soonchunhyan University, Seoul, South Korea.

The mechanism by which lead (Pb) enters glial cells was examined in order to characterize specific pathways for transport. Pb uptake was saturable at pH 5.5 and 7.4, although quantitative differences existed in the Michaelis-Menten constants. At pH 7.4, the Vmax and Km was 2700 fmoles/mg protein/min and 13.4  $\mu$ M Pb, respectively, whereas the Vmax and Km was 329 fmoles/mg and 8.2  $\mu$ M Pb in the buffer at pH 5.5, respectively. Extracellular iron inhibited uptake in a buffer at pH 5.5 but not at pH 7.4. Cells treated with the iron chelator deferoxamine displayed higher levels of the iron transporter divalent metal transporter 1 (DMT1) mRNA and protein, and consistent with increased DMT1 expression, displayed greater uptake of Pb in the buffer at pH 5.5 but not at pH 7.4. Alternatively at pH 7.4, the transport of Pb was blocked by the anion transporter inhibitor 4, 4-diisothiocyanatodihydrostilbene-2, 2-disulfonic acid (DIDS), which bound to cell surface proteins at concentrations that were similar to those that blocked Pb uptake. DIDS did not inhibit uptake in the buffer at pH 5.5. Greater uptake of Pb was observed in a buffer containing sodium bicarbonate, which was abrogated in the presence of DIDS. In summary, glial cells display two distinct pH sensitive transport mechanisms for Pb.

BRAIN-DERIVED NEUROTROPHIC FACTOR (BDNF)POLYMORPHISM ASSOCIATIONS WITH BEHAVIORAL MEASURES OF MEMORY IN MERCURY (Hg)-EXPOSED HUMANS.

D. Echeverria<sup>2, 1</sup>, J. S. Woods<sup>1, 2</sup>, N. J. Heyer<sup>2</sup>, A. C. Bittner<sup>2</sup> and F. M. Farin<sup>1</sup>. <sup>1</sup>Environmental Health, University of Washington, Seattle, WA and <sup>2</sup>Battelle Centers for Public Health Research and Evaluation, Seattle, WA.

Associations were hypothesized between BDNF polymorphisms and memory deficit, an adverse mercury-related health effect. A population of exposed subjects (n=480) provide buccal cells and were administered the Behavioral Evaluation for Epidemiologic Studies (BEES) Test Battery. We evaluated DNA samples for the presence of a previously identified SNP at nucleotide 196 (G/A), which produces a valine to methionine substitution at codon 66 (V66M). Genotyping results identified 68% WT, 28% Het, 4% Mut within this population. Discriminant and multiple regression analyses examed predictive associations between polymorphism status and seven summary behavioral factor scores; 1) Cognitive Reasoning (Trails A/B, Symbol Digit Rate, and Pattern Discrimination Rate), 2) Switching Attention (Letter, Picture, and Direction Comparison), 3) Finger Speed (Finger Tap: L, R, Alt.), 4) Hand Speed (Move from Simple and Choice RT), 5) Tracking (Tracking and Lift from SRT), 6) Memory (Digit and Spatial Span), and 7) Vigilance. Discriminant weightings of 0.118, -.003, and -2.329 for wild type, het, and mutant status are consistent with the magnitude of relative degradation reported with losses in episodic memory. The standardized correlation between performance on memory and BDNF ( $\beta$ =.91\*\*\*) was pronounced in the presence of the log of mercury  $(\beta=.10^{**})$ , vocabulary, that served as a surrogate for premorbid intelligence  $(\beta=.12^{**})$ , and age  $(\beta=.07^{**})$   $(p<.05=^{**})$ . Separate regression results tempered the association between memory and the BDNF polymorphism  $(\beta=.39^{***})$ . The second Switching factor was affected to a lesser extent (p<.04 directionally). Concurrent analyses also indicated associations between self-reported symptoms for poor attention and memory in the presence of the BDNF polymorphism. Our observations support the hypothesis that mercury-related memory deficits are exacerbated among subjects with the BDNF polymorphism. Supported by ES04696 and ES07033.

EVIDENCE FOR DIRECT MODULATION OF GLUTAMATE (AMPA) RECEPTOR CHANNEL PROPERTIES BY METHYLMERCURY.

T. Vaithianathan, V. Suppiramaniam and P. Dey. Pharmacal Sciences, Auburn University, Auburn, AL.

Persistent psychomotor disturbances and cognitive deficits are hallmarks of many heavy metal neurotoxicants, however the molecular mechanisms underlying these effects are poorly understood. Accumulating evidence from animal and cell culture model systems implicates derangements in AMPA subtype ionotropic glutamanergic receptor activity in learning and memory disorders. Studies investigating the ability of the organometal neurotoxicant methylmercury to directly alter ion channels have been complicated by the complex interactions of the compound with multiple cell surface receptors observed using traditional patch-clamp technique. We have utilized purified AMPA receptors reconstituted in tip-dip lipid bilayers to demonstrate the direct modulatory effects of methylmercury on AMPA receptor channels. In a related set of studies, hippocampal synaptoneurosomes were isolated and incorporated into bilayers in order to model the organometals action on synaptic AMPA receptors. Methylmercury concentrations ranging from 75  $\eta M$  to 75 µM were infused into receptor-reconstituted lipid bilayers. In purified AMPA receptors preparations, methylmercury decreased the AMPA receptor properties in a dose-dependent fashion. At the highest methylmercury concentration, a 50-60% reduction in the open probability of AMPA activated channels was observed. These studies indicate that methylmercury may directly modulate AMPA receptor channel kinetics, contributing to deficits in learning and memory observed following exposure to the neurotoxicant. Supported by a Auburn University Biogrant [V.S.] and Graduate School Funding [P.M.D].

## 1122 EFFECTS OF METHYLMERCURY ON GABA RECEPTOR-MEDIATED CURRENTS ( $I_{GABA}$ ) IN RAT CORTICAL CELLS IN CULTURE.

C. Herden<sup>2</sup>, <u>Y. Yuan<sup>1,2</sup></u> and <u>B. Atchison<sup>1,2</sup></u>. <sup>1</sup>Department Pharmacology/Toxicology, Mich State University, East Lansing, MI and <sup>2</sup>Neuroscience Program, Mich. State University, East Lansing, MI.

The cerebellum is particularly sensitive to acute and chronic exposure to methylmercury (MeHg). Inhibitory GABAergic synaptic transmission appears to be especially sensitive to the effects of MeHg, as it is blocked more quickly than is excitatory synaptic transmission in isolated brain slices. Pharmacological and electrophysiological properties of GABAA receptors vary depending on the phenotype or subunit composition of the GABA receptor. Previous studies in our lab using the cerebellar slice preparation have demonstrated that GABAergic synaptic transmission in cerebellar granule cells, which express a unique  $\alpha_6$  subunit-containing GABA<sub>A</sub> receptor, is more sensitive to the block by MeHg than is inhibitory synaptic transmission in neighboring Purkinje cells, which express the  $\alpha_1$  subunit-containing GABA<sub>A</sub> receptor. Thus, differential GABA<sub>A</sub> receptor expression may underlie the differential effects of MeHg observed in these cerebellar neurons. As an initial step in testing this hypothesis, we investigated the effects of MeHg on primary cultures of rat cortical cells, which contain the same α<sub>1</sub>-containing GABA<sub>A</sub> receptor phenotype as do Purkinje cells.  $I_{GABA}$  were obtained by means of the whole-cell voltage-clamp technique using a symmetrical chloride concentration. In cortical cells cultured for 10 - 15 days, MeHg (0.1 - 10  $\mu$ M) blocked  $I_{GABA}$  in a time- and concentration-dependent manner. Time to block of  $I_{GABA}$  by MeHg was not dependent upon GABA (10  $\mu$ M - 1 mM) concentration in these cells, suggesting that the block by MeHg is non-competitive. Moreover, stepping the voltage from -80 mV to +60 mV in the presence of MeHg produced a linear I-V relationship, suggesting that block of  $I_{GABA}$  by MeHg in cortical cells is voltage-independent. Thus in cells expressing the  $\alpha_1$  subunit of the GABA<sub>A</sub> receptor, MeHg causes a rapid and complete block of current. Supported by NIH grant ES11662.

#### 1123

ALTERATIONS BY METHYLMERCURY (MEHG) OF PRESYNATIC TERMINAL CA<sup>2+</sup> CONCENTRATION APPEAR TO BE RESPONSIBLE FOR MEHG-INDUCED INITIAL STIMULATION OF SPONTANEOUS INHIBITORY POSTSYNAPTIC CURRENTS.

Y. Yuan and W. D. Atchison. Pharmacology/Toxicology, Michigan State University, East Lansing, MI.

Bath application of methylmercury (MeHg) caused an initial stimulation prior to suppression of the frequency and amplitude of GABA<sub>A</sub> receptor-mediated spontaneous inhibitory postsynaptic currents (sIPSCs) in Purkinje cells of rat cerebellar slices, suggesting that both pre- and postsynaptic mechanisms are involved. The goal of the present study was to determine if the initial increases by MeHg in frequency and amplitude of sIPSCs in Purkinje cells are related the changes in intracellular Ca<sup>2+</sup> concentration ([Ca<sup>2+</sup>]<sub>i</sub>) in the presynaptic terminal and postsynaptic

sites. sIPSCs and temporal and spatial changes in [Ca²¹]; in presynaptic fibers (parallel- and climbing-fibers), dendrites and somata of Purkinje cells in cerebellar slices were examined by combination of fast confocal laser-scanning microscopy and whole-cell patch-clamp recording techniques in the absence and presence of MeHg. In slices preloaded with the Ca²¹-selective indicator Fluo-4, bath application of 10 - 100 μM MeHg induced prominent increases in fluorescence signals in the entire molecular layer (including parallel- and climbing-fibers, dendrites and the subplasmalemmal shell of Purkinje cells) and granule cells of cerebellar slices. However, no significant changes in fluorescent signals were observed in the soma region of Purkinje cells. Coincidental recordings of sIPSCs revealed a MeHg-induced increase in sIPSC frequency. The time to onset of change in fluo-4 fluorescent signals appeared to be correlated to the time to onset of increases in frequency of sIPSCs recorded from the soma of Purkinje cells. Thus, these results suggest that MeHg-induced increases in the presynaptic [Ca²¹], appear to be responsible for the initial increases in frequency of sIPSCs caused by MeHg in cerebellar Purkinje cells. Supported by NIH grants R01ES03299 and R01ES11662

#### 1124

CALBINDIN D-28K TRANSFECTED HUMAN EMBRYONIC KIDNEY (HEK 293) CELL LINE IS RESTANT TO METHYLMERCURY-INDUCED ALTERATIONS OF CALCIUM HOMEOSTASIS.

J. R. Edwards and W. D. Atchison. Michigan State University, East Lansing, MI.

Methylmercury (MeHg) acts in a time- and concentration-dependent manner to cause disruption of Ca<sup>2+</sup> homeostasis in a variety of neuronal cell types. Cerebellar granule cells are one of the more sensitive cell types to the cytotoxic effects of MeHg as well as disruption of Ca<sup>2+</sup> homeostasis. In comparison, Purkinje neurons are relatively less sensitive to disruption of Ca<sup>2+</sup> homeostasis and subsequent cytotoxicity caused by MeHg. One potential determinant of this selective sensitivity to MeHg cytotoxicity, and ability to disrupt Ca2+ homeostasis, is the expression of the Ca binding protein, calbindin D-28k (CB). Purkinje cells abundantly express CB while granule cells do not. CB is thought to prevent cell death and buffer against elevations of  $[Ca^{2+}]_i$ . In this study, CB-transfected, vector-transfected and non-transfected HEK cells were loaded with the calcium indicator, fura-2, then exposed to MeHg (1, 2.5 and 5 µM) and resulting changes in fura-2 fluorescence were recorded. Qualitatively, vector-transfected and non-transfected HEK cells displayed an abrupt spike in fura-2 fluorescence followed by a return to baseline in the 1 and 2.5 µM MeHg treatment groups. CB-transfected cells did not exhibit these abrupt changes in fura-2 fluorescence at 1 or 2.5 µM MeHg. However, at 5 µM MeHg cells in all treatment groups responded in a similar manner with a sustained increase in fura-2 fluorescence. Thus there appears to be a differential response of HEK 293 cells to low (1 and 2.5  $\mu$ M) and high (5  $\mu$ M) concentrations of MeHg. In addition, CB may be involved in attenuating MeHg-induced disruption of Ca<sup>2+</sup> homeostasis at 1 and 2.5  $\mu$ M, but not at 5  $\mu$ M MeHg in HEK 293 cells. Supported by NIH grant ES03299.

#### 1125

LACK OF EXPRESSION OF CALBINDIN-D 28K CORRELATES WITH INCREASED SENSITIVITY TO METHYLMERCURY CYTOTOXICITY IN GUINEA PIG MYENTERIC PLEXUS NEURONS.

A. Rodriguez, J. R. Edwards and B. Atchison. Department Pharmacology/Toxicology, Mich State University, East Lansing, MI.

In isolated cerebellar granule cells in culture methylmercury (MeHg) causes an elevation of [Ca<sup>2+</sup>], which is associated with a delayed-onset cell death. Granule cells do not express the Ca<sup>2+</sup>binding protein, calbindin-D 28k (CB); adjacent Purkinje neurons do express CB and are more resistant to MeHg-induced cytotoxicity and increased [Ca<sup>2+</sup>],. CB also protects neurons from other forms of Ca<sup>2+</sup>-mediated cell death. Thus CB may be an important cellular constituent in protecting neurons against MeHg-induced cytotoxicity. As granule and Purkinje cells have other differences including cell size, we investigated the cytoprotective role of CB against MeHg using an alternate model. Guinea pig myenteric plexus neurons are either CB-immunopositive or CB-immunonegative; myenteric plexus neurons immunonegative for CB are selectively immunopositive for nitric oxide synthase (NOS). We hypothesize that myenteric plexus neurons immunopositive for NOS (CB-negative) will be more sensitive to the cytotoxic effects of MeHg as compared to CB-positive myenteric plexus neurons. To examine this, myenteric plexus neurons were grown in culture, and exposed to 0.5, 1, 2 or 5 µM MeHg for 2 hr; viability was assayed 24 hr later. Cells were then immunostained for the presence of NOS or CB. Consistent with our previous studies, the proportion of viable CBpositive myenteric plexus neurons increased with increasing concentrations of MeHg. Little or no cell death occurred in control, or for NOS-positive cells at 0.5 or 1 µM MeHg. However, a significant proportion of NOS-positive cells died in the 2 µM MeHg treatment group, and no viable NOS-positive cells remained in

the 5  $\mu$ M MeHg treatment group. Compared to CB-positive myenteric plexus neurons, NOS-positive neurons (CB-negative)were more sensitive to the cytotoxic effects of MeHg. This study further supports the potential role of CB in attenuating MeHg cytotoxicity. Supported by NIH grant ES03299.

1126

TRANSFECTION OF PC12 CELLS WITH CALBINDIN-D 28K INCREASES RESISTANCE TO METHYLMERCURY-INDUCED DISRUPTION OF INTRACELLULAR CALCIUM HOMEOSTASIS.

J. R. Gomulka<sup>2, 1</sup>, <u>J. R. Edwards<sup>1</sup></u> and <u>B. Atchison<sup>1</sup></u>. <sup>1</sup>Department Pharmacology/Toxicology, Mich State University, East Lansing, MI and <sup>2</sup>College of Veterinary Medicine, Mich. State University, East Lansing, MI.

Methylmercury (MeHg) causes a preferential loss of cerebellar granule cells—cells which do not express the Ca<sup>2+</sup> binding protein, calbindin-D 28k (CB). This contrasts to adjacent Purkinje neurons which abundantly express CB and are much more resistant to MeHg cytotoxicity. An early, prominent effect of MeHg especially notable in granule cells is elevation of [Ca<sup>2+</sup>]; this leads to a delayed onset cell death. CB is thought to prevent cell death and buffer against elevations of [Ca2+]: CB-transfected pheochromocytoma (PC12) cells have greater resistance to cytotoxicity of glutamate exposure and serum withdrawal than do nontransfected cells. Also, CB-transfected cells exhibited less Ca<sup>2+</sup> entry through voltage-gated Ca<sup>2+</sup> channels than do wild-type cells. Thus, the purpose of this study was to determine if expression of CB imparts resistance to the dysregulation of Ca<sup>2+</sup> homeostasis caused by MeHg exposure. We also sought to determine if CB increases MeHg resistance *via* actions on Ca<sup>2+</sup> channels. MeHg was applied continuously by perfusion to PC12 and PC18 cells, a sub-clone of the PC12 cells lacking voltage-gated Ca channels. Cells were loaded with fura-2 and resulting changes in fura-2 fluorescence were recorded using microfluorometric imaging techniques. For both cell types, there was a typical time- and concentration-dependent biphasic increase in fura-2 fluorescence following MeHg exposure. CB-transfected PC12 cells had a delayed time-to-onset of MeHg-mediated increase in fura-2 fluorescence at 0.5, 1, 2 and 5 μM MeHg compared to non-transfected cells. In contrast, CB-transfected PC18 cells did not have a significantly delayed time-to-onset of fura-2 fluorescence compared to non-transfected PC18 cells at 1 µM MeHg. These data indicate a potential role of CB to protect against MeHg-mediated disruption of Ca<sup>2+</sup> homeostasis. Furthermore, CB may interact directly with Ca<sup>2+</sup> channels to delay the actions of MeHg. Supported by NIH grant ES03299 and 5T35RR017491.

1127

NEUROBEHAVIORAL AND MITOCHONDRIAL MEMBRANE POTENTIAL CHANGES IN CEREBELLAR GRANULE CELLS OF MICE EXPOSED TO METHYLMERCURY.

S. Bellum, K. A. Thuett and L. C. Abbott. CVM, VAPH, Texas A&M University, College Station, TX. Sponsor: E. Tiffany-Castiglioni.

Methylmercury (MeHg) is a potent environmental neurotoxicant, which is known to cause degeneration of neurons including cerebellar granule cells. Recent studies using cultured cerebellar granule cells exposed to MeHg indicate calcium ion homeostasis is altered leading to increased intracellular calcium concentrations and eventual cell death. However, key gaps still exist in our knowledge concerning the specific mechanisms that bring about granule cell death following acute in vivo MeHg exposure. Damage to mitochondria in general results in decreased ATP production and release of cytotoxic/cell death signals. We examined mitochondrial function by comparing mitochondrial membrane potential (MMP) of cerebellar granule cells taken from control, 1.0 mg/kg and 5.0 mg/kg MeHg-treated male and female C57BL/6J mice. In addition, motor coordination using rotarod and spontaneous locomotion and rearing activity in open field were completed. Cerebellar granule cells were acutely isolated using dissociation medium containing protease and plated onto poly-D-lysine coated coverslips. The cells were then loaded with TMRM, which is a lipophilic cation that accumulates in mitochondria in proportion to the membrane potential. Upon sufficient accumulation, the dye exhibits a red shift in absorption and fluorescence emission spectra. Fluorescent images of granule cells from all three treatment groups were acquired and analyzed. The MMP observed in the granule cells from 1.0 mg and 5.0 mg MeHg-treated mice were significantly lower than from controls. While the performance on the rotarod was not statistically significant among control, 1.0 mg/kg and 5.0 mg/kg MeHgtreated mice, the MeHg-treated mice showed a tendency to stay on the rotarod for a shorter time than the control mice. Performance on the open field is being analyzed. These observations suggest that in vivo MeHg exposure diminishes mitochondrial function in cerebellar granule cells, which ultimately could lead to death and/or dysfunction of these neurons.

1128

EFFECTS OF METHYLMERCURY ON EPH AND EPHRIN PROTEINS IN EMBRYONAL CARCINOMA CELL DERIVED NEURONS.

D. T. Wilson<sup>1</sup>, M. A. Polunas<sup>1</sup>, R. Zhou<sup>1, 2</sup>, H. E. Lowndes<sup>1, 3</sup> and K. R. Reuhl<sup>1, 3</sup> <sup>1</sup> JGPT, Rutgers University, Piscataway, NJ, <sup>2</sup> Chem. Biol., Rutgers University, Piscataway, NJ and <sup>3</sup> Pharmacology and Toxicol., Rutgers University, Piscataway, NJ.

Repulsive interactions between neuronal cells and their surroundings mediated by EPH tyrosine kinase receptors and their ephrin ligands guide and shape several morphogenetic events, including topographical mapping of CNS pathways. Methylmercury (MeHg) induces morphological changes during brain development suggestive of neuronal guidance errors. The effects of MeHg on EPH and ephrin mRNA expression in embryonal carcinoma (EC) cells and EC-derived neurons were previously investigated. The present report describes protein levels of these molecules in the EC cell culture system following MeHg exposure. Five days after induction by retinoic acid, EC-derived neurons were exposed to 0.0, 0.5, 1.5, or 3.0 uM MeHg for 24 hours and analyzed for Eph and ephrin levels using immunoblotting and immunofluorescence. Consistent with increased mRNA levels shown previously, the protein levels of EphA4 and ephrins-A3, A5, B1, and B2 were up-regulated by 0.5 and 1.5 uM MeHg. Despite elevated levels of Eph and ephrin mRNA at 3.0 uM, protein levels were comparable to control or slightly decreased. This apparently bi-phasic pattern was most evident for EphA4 and ephrins-A5, B1, and B2. These results indicate that MeHg affects the protein synthetic machinery directly, independent of changes in transcription. MeHg also affects Ephs and ephrins selectively as GAPDH and actin protein levels were unaffected by MeHg. The results support our hypothesis that Ephs and ephrins are involved in the disrupted morphogenesis seen in MeHg-exposed rodents. (Supported by NIH/EPA ES11256 and NIH ES05022).

1129

PROTECTIVE EFFECT OF GLUTATHIONE PEROXIDASE OVEREXPRESSION IN METHYLMERCURY NEUROTOXICITY.

M. Polunas<sup>1, 2</sup>, O. Prokopenko<sup>3</sup>, O. Mirochnitchenko<sup>3, 1</sup>, M. Philbert<sup>4</sup> and K. Reuhl<sup>1, 2</sup>, <sup>I</sup>GPT, Rutgers/UMDNJ, Piscataway, NJ, <sup>2</sup>Department Pharmacology/Toxicology, Rutgers University, Piscataway, NJ, <sup>3</sup>Department Biochem., UMDNJ, Piscataway, NJ and <sup>4</sup>Department Environment Health Sciences, University Mich., Ann Arbor, MI.

The precise mechanisms underlying methylmercury neurotoxicity remain obscure. Several lines of evidence implicate reactive oxygen species (ROS) as playing a key role in the mitochondrial dysfunction seen in MeHg poisoning. Previous in vivo and in vitro studies have shown that exogenous antioxidants protect against both ROS production and loss of mitochondrial membrane potential. The intracellular antioxidant enzyme glutathione peroxidase (GPx1) is localized both in the cytosol and mitochondrial matrix and efficiently utilizes lipid peroxides as well as H2O2 for substrates. Primary neocortical neuron cultures derived from transgenic mice (C57BL/6XCBA/J) overexpressing human GPx1 (GPx1 activity 0.29 and 0.12 University/mg protein for neurons derived from GPx1 and wild-type (wt) mice, respectively) were used to examine the potential of endogenous antioxidant systems to ameliorate MeHg-induced mitochondrial toxicity. MitoTracker Green (MTG), which passively diffuses across the plasma membrane and preferentially accumulates in active mitochondria due to their negative membrane potential, was used as an index of mitochondrial membrane integrity/loss of membrane potential. Day 10 wt or transgenic GPx1 neurons were pre-incubated with MTG for 30 min and exposed to 0, 1.5, or 2.5 µM MeHg for 60 min. Both concentrations of MeHg produced substantial dimming and diffusion of the bright, punctate MTG staining seen in live wt and GPx1 vehicle-treated controls, this loss reflecting relaxation of the mitochondrial membrane gradient. This correlated with a dose-dependent loss of β-III positive neurites and perikaryal microtubules. In contrast, GPx1 overproducing neurons were largely protected against MeHg-induced loss of MTG and exhibited fewer toxicity-induced cytoskeletal changes, suggesting MeHg-induced ROS production to be a mechanism contributing to the mitochondrial and morphological changes observed in MeHg neurotoxicity. INCREASE IN INTRACELLULAR REACTIVE OXYGEN SPECIES FORMATION INDUCED BY METHYLMERCURY IN CULTURED ASTROCYTES: A CONFOCAL MICROSCOPIC STUDY.

G. Shanker, L. A. Mutkus, Q. Wu and <u>M. Aschner</u>. *Physiology and Pharmacology, Wake Forest University School of Medicine, Winston-Salem, NC.* 

Oxidative stress has been implicated in a variety of neurodegenerative diseases, such as Alzheimer's and Parkinson's disease. There is a strong association between metal-induced oxidative stress and the accumulation of high levels of reactive species, in-

cluding reactive oxygen species (ROS), as well as unbound metal ions. ROS are highly oxidizing and damaging to cellular redox-sensitive proteins, enzymes, and DNA. The present study was carried out to test the hypothesis that ROS formation is an early event in methylmercury (MeHg)-induced neurotoxicity. MeHg-dependent increase in ROS formation was assessed with confocal microscopy in neonatal rat cortical astrocyte cultures with 2 redox sensitive fluorescent probes, 5, 6chloromethyl-2', 7'-dichloro-dihydrofluorescein diacetate (CM-H2DCFDA; reacts with intracellular ROS), and reduced chloromethyl-X-rosamine (CM-H2XRos; a mitochondria specific probe). Astrocytes were treated with 10 uM MeHg for 30 minutes, followed by addition of the probe/s and image collection at 25 minutes. The results showed significant MeHg-dependent increases in astrocytic fluorescence intensity (p<0.05) of both probes indicative of increased intracellular oxidized state. Additional time-series experiments in the presence of both dyes revealed that the initial fluorescence changes in response to MeHg treatment were associated with the mitotracker dye (CM-H2XRos), suggesting that mitochondria most likely represent early primary sites of ROS formation. The studies establish the early generation of ROS in MeHg treated cells and support a key role for astrocytes as a source for ROS and the ensuing demise of neurons. This work was supported by PHS grant NIEHS 07331.

## 1131 GENE EXPRESSION ANALYSIS OF THE MICE CEREBELLAR CELLS IN VITRO EXPOSED TO METHYL MERCURIC CHLORIDE.

E. S. Calderon-Aranda<sup>1, 3</sup>, A. E. Jedlicka<sup>2</sup>, A. S. Scott<sup>2</sup> and <u>E. K. Silbergeld<sup>1</sup></u>.

<sup>1</sup>EHS, Johns Hopkins University, Baltimore, MD, <sup>2</sup>MMI, Johns Hopkins University, Baltimore, MD and <sup>3</sup>Seccion de Toxicologia, Cinvestav, Mexico, DF, Mexico.

The immature CNS is an extremely sensitive target to methyl mercury (MeHg). In exposed children, effects ranged from subtle developmental delay to severe cerebral palsy. In animal models and cell cultures, low doses of MeHg induced alteration in neuronal migration and proliferation, particularly in cerebellar cortex, and microglia activation. However, the molecular mechanism through which MeHg might affect neuronal migration in the cerebellum remains to be defined. This study examined gene expression in cerebellar organotypic cultures exposed to MeHg to identify molecular targets associated with the mechanism of neuronal alteration induced by Hg. Organotypic cells were obtained from the cerebellum of five day old CD1 pups, and after five days in MEM media, unstimulated or LPSstimulated cells were exposed to 100nM MeHgCl, for 48h. Unexposed cultures were used as control, both unstimulated or stimulated with LPS. Total RNA was extracted from cultures and after cRNA synthesis, GeneChips (Affymetrix MOE430A) were hybridized and the arrays were analysed by Microarray Suite 5.1 and GeneSpring software. The preliminary results showed that, LPS modified the expression of many different genes. Increasing expression ranged from 1- to 500fold, compared with expression in control cells. MeHgCl exposure of LPS-stimulated cells resulted in alteration of genes induced with LPS, decreasing approximately 15% and inducing an additional increment around 25% in other. Hg exposure increased expression in around 20% of genes negatively regulated by LPS-stimulation whereas 15% of those genes had an additional decrement. In unstimulated cells MeHgCl induced alteration in the gene expression profile compared with the control, although the changes were more discrete than Hg in LPS-stimulated cells. The information obtained from this work will help to define the mechanisms involved in Hg toxicity in the cerebellum. This work was supported by Cure Autism Now and Heinz Family Foundations.

## 1132 MICE OLFACTORY BULB NEURONAL DEATH AFTER V2O5 INHALATION.

L. COLIN-BARENQUE<sup>2</sup>, <u>M. AVILA-COSTA</u><sup>2</sup>, V. DELGADO<sup>1</sup>, I. SANCHEZ<sup>1</sup>, I. LOPEZ<sup>1</sup>, F. PASOS<sup>1</sup> and <u>T. I. FORTOUL</u><sup>1</sup>. <sup>1</sup>BIOLOGIA CELULAR Y TISULAR, UNIVERSIDAD NACIONAL AUTONOMA DE MEXICO, MEXICO CITY, Mexico and <sup>2</sup>NEUROCIENCIAS, FES IZTACALA, MEXICO, Mexico.

Vanadium (V) inhalation exerts harmful effects, and its toxicity had been related with an increase of reactive oxygen species. Since there is no information about ultrastructural changes in granule cells of the olfactory bulb we decided to find out if the inhalation of this element induces changes in this structure. CD-1 male mice were exposed to vanadium pentoxide (V2O5) 0.02 M one hour twice a week for 12 weeks, and sacrificed each week. Olfactory bulbs were obtained and processed for transmission electron microscopy. Necrosis and apoptosis were observed, as well as, electrondense mitochondrion, dilated Golgi apparatus and cytoplasm vacuolation. Also increased lipofucsin granules at all exposure times were present. Oxidative stress could be the cause of the alterations observed but further analysis is needed to dilucidate the mechanisms by which V2O5 is inducing either apoptosis or necrosis. PAPIIT IN-210301

### 1133 DIFFERENTIAL RESPONSES TO CADMIUM IN AN *IN VIVO* AND *IN VITRO* MODEL OF NEUROTOXICITY.

C. Bolin, D. Cox and F. Cardozo-Pelaez. *Biomedical and Pharmaceutical Sciences, University of Montana, Missoula, MT.* Sponsor: <u>A. Holian</u>.

Cadmium is a ubiquitous environmental toxin found in industrial pollutants, drinking water, food contaminants, and is one of the major components in cigarette smoke. The accumulation of cadmium and its associated toxicity has been demonstrated in many organs such as kidney, liver, lung, testis, and brain. The specific mechanisms by which cadmium toxicity operates are unclear, however several reports have associated the effects of cadmium with an increase in reactive oxygen species (ROS); this is supported by evidence of elevated levels in markers of oxidative stress to cell biomolecules in vivo and in vitro. Cadmium cannot directly form ROS and it is therefore hypothesized that indirect action through the alteration in activity of important antioxidants and DNA repair mechanisms may be leading to the apparent accumulation of oxidative damage. The aim of this study was to determine the role of cadmium exposure in the activity of the base excision repair enzyme 8-oxoguanine-DNA glycosylase (OGG1) responsible for the removal of the oxidized DNA base product 8-hydroxy-2-deoxyguanosine (oxo8dG) in vivo and in vitro. We found that adult male SVJ/129 mice exposed to CdCl, in their drinking water for a period of twenty days do not exhibit a reduction in the activity of OGG1 in discrete brain regions, although there was an increase in the levels of reduced glutathione and alterations in the activity of the superoxide dismutase enzymes. In contrast, the PC12 catecholaminergic cell line exhibited a significant reduction in OGG1 activity after incubation with CdCl<sub>2</sub>. These conflicting findings suggest a differential response to cadmium in vivo and in vitro that needs to be addressed to elucidate its toxic effects.

### ARSENIC LEVELS AND GLUTATHIONE REDUCTASE ACTIVITY IN CD1 MICE BRAIN.

M. E. Gonsebatt<sup>1</sup>, J. H. Limon<sup>1</sup>, V. Rodriguez<sup>2</sup>, M. M. Giordano<sup>2</sup> and <u>L. M. Del Razo<sup>3</sup>. <sup>1</sup>Medical Genomics and Environmental Toxicology, Instituto de Investigaciones Biomedicas, Mexico, DF, Mexico, <sup>2</sup>Instituto de Neurobiologia, Queretaro, Queretaro, Mexico and <sup>3</sup>Toxicology Section, CINVESTAV, IPN, Mexico, DF, Mexico.</u>

Arsenic crosses the blood-brain barrier and accumulates in the brain where it has been shown to exert neurotoxic effects. In animals models as rats and mice effects on the basal ganglia and increased content of striatal dopamine have been reported respectively. Nevertheless, there is scarce information regarding the metabolism of arsenic in this tissue, especially with respect to the presence of methylated metabolites and the effects of the arsenicals on the activity of detoxifiying brain enzymes. To investigate the presence of methylated arsenic metabolites in brain tissue and to determine the activity and expression of glutahione reductase (GR), CD1 mice were treated orally with 0, 2.5, 5 and 10 mg/Kg of sodium arsenite daily during 10 days. Animals were killed by decapitation; the brain was removed and frozen in liquid nitrogen. The presence of inorganic arsenic (iAs), the monomethylated (MMA) and dimethylated As metabolites (DMA) was determined in liver and brain tissue by hydride generation-atomic absorption spectroscopy The presence of GR was ascertained by immunoblotting with a polyclonal antibody and the activity of the enzyme was determined by the NADPH+H assay. Treated animals showed significantly-increased amounts of the inorganic and methylated arsenic forms. Although the total amount of arsenic detected in brain mice treated with 5 or 10 mg/kg was similar (402.5  $\pm$  17.7 and 396.5  $\pm$  33.9 ng/g respectively) the proportion of DMA doubled the amount of MMA in the mice treated with 10 mg/kg. Interestingly, a significant inhibition of the expression and activity of GR was observed only at the highest concentration used.

THE TRIMETHYLTIN MODEL OF HIPPOCAMPAL INJURY: GENE ARRAY ANALYSIS REVEALS EARLY AND DIVERSE CHANGES IN GENE EXPRESSION ASSOCIATED WITH NEURONAL INJURY AND GLIAL ACTIVATION.

A. R. Little and J. P. O'Callaghan. TMBB, CDC-NIOSH, Morgantown, WV.

Damage to the CNS results in a complex series of molecular and cellular events involving the injured cells and their supportive environment. Understanding the earliest molecular changes associated with CNS injury offers the potential for developing neuroprotection strategies. The use of injury models with known cellular targets and a known time-course of damage facilitates this process. One such model is the hippocampal neurotoxicant, trimethyltin (TMT) which cause extensive loss of hippocampal neurons and an accompanying microglial and astroglial activation. Previously, we have shown that TMT causes a marked and early increase in the chemokine, Ccl2 (JE/MCP-1), coincident with microglial activation. Here were used the Affymetrix gene chip to obtain a more comprehensive portrait of gene expression changes during the earliest phases of TMT-induced damage. Changes seen on the chip were confirmed by Real Time PCR. After a single systemic dose of TMT (8.0 mg/kg) we confirmed an increase in expression of Ccl2 at two days post

dosing which was not accompanied by an increase in its two receptors, CCR2 and CCR5. Increases in mRNA expression for STAT5a, GSK3alpha and several proteasome-related enzymes were observed at 2 and 5 days post TMT. Immuno-blot analysis for phospho-GSK3 alpha and beta showed dramatic increases in p-GSK 3 (alpha & beta) by day 5. These data suggest an involvement of the protein degradation pathway during early stages of neuronal degeneration. Cellular localization of STAT5a induction remains to be clarified but induction of GSK3 implicates activation of the Wnt pathway, for which the upstream effectors have been associated with gliosis. These results link protein degradation and cellular differentiation events to the earliest stages of neuronal injury.

## 1136 HIPPOCAMPAL DENDRITIC SPINES LOSS AND MEMORY DETERIORATION IN MICE EXPOSED TO VANADIUM (V2O5) INHALATION.

G. Nino-Cabrera<sup>2</sup>, M. Avila-Costa<sup>1</sup>, L. Colin-Barenque<sup>1</sup>, P. Bizarro-Nevares<sup>2</sup>, S. Acevedo-Nava<sup>2</sup>, I. Sanchez-Cervantes<sup>2</sup>, I. Lopez<sup>2</sup>, A. Gonzalez-Villalva<sup>2</sup>, F. Pasos<sup>2</sup> and T. I. Fortoul<sup>2</sup>. <sup>1</sup>Neuroscience, UNAM campus Iztacala, Tlalnepantla, Edo. Mex., Mexico and <sup>2</sup>Facultad de Medicina, UNAM, MEXICO, D.F., Mexico.

Vanadium exposure exerts damage in different organs, but there is no information about damage in nervous system. It would be possible that if V produces alterations in nervous tissue, there will be alterations on its function. The mechanisms by which memories are acquired and stored in the mammalian brain are assumed to involve modifications in synaptic plasticity that implicates dendritic spines. We hypothesized that if vanadium produce alterations in neuronal structures of the hippocampus the memory could be alterated. CD-1 male mice were trained in spatial memory task and exposed by inhalation to 0.02 M of V2O5, one hour twice a week for 4 weeks, after each inhalations animals were evaluated for the memory task, then were sacrificed after the 2nd, 4th, 6th and 8th inhalation. The rapid Golgi stained sections of hippocampus were examined by counting the number of dendritic spines in 20?m of 5 secondary and 5 tertiary dendrites of 20 neurons. Our results showed that there was a significant decrease of dendritic spines after the different exposition times, these data correlate with memory alterations in a dose dependent way. Vanadium toxicity affects neuronal structure in the hippocampus and the formation of new memories. Supported by:PAPIIT IN210301.

#### 1137 ERYTHROPOIETIN PREVENTS TRIMETHYLTIN-INDUCED NEURONAL DEATH AND GLIAL ACTIVATION.

B. Viviani, S. Bartesaghi, E. Corsini, L. Lucchi, C. L. Galli and M. Marinovich. Department of Pharmacological Sciences, University of Milan, Milan, Italy.

Erythropoietin (EPO) is a glycoprotein originally identified as the principal regulator of erythroids progenitor cells. Nevertheless, EPO expression is upregulated in both glia and neurons following ischemic brain injury to promote neuronal survival. Trimethyltin (TMT), a neurotoxicant characterized by neuronal degeneration and reactive gliosis, was used in this study to identify the molecular mechanisms involved in EPO-induced neuroprotection. Increasing concentrations of EPO (1-100 University/ml) dose-dependently decreased TMT-induced death in primary hippocampal neurons. Treatment of hippocampal neurons with 10 University/ml EPO resulted in an increased expression and release of brain-derived neurotrofic factor (BDNF), an important neuronal survival factor, suggesting the involvement of this cytokine. Consistently, exposure of hippocampal neurons to BDNF prevented TMT-induced neuronal death, while BDNF neutralizing antibody inhibited EPOinduced neuroprotection. We have previoully demonstrated that TMT increases glial TNF-alfa production and release due to neuronal apoptosis, furtherly exacerbating neuronal damage. We thus evaluated whether EPO neuroprotection could be explained also by a reduction of TMT-induced TNF-alfa release by glial cells. The addition of EPO (10 University/ml) reduced the amount of TNF-alfa produced significantly. EPO did not affect glia-derived TNF produced by exposure to neuronal homogenate or to LPS, suggesting that TNF reduction is a consequence of the inhibited neuronal death rather than of an anti-inflammatory action directly exerted on glial cells. These findings suggest that EPO attenuates both glial activation and TMT-induced injury by increasing BDNF production, and provide new insights on the role of beneficial cytokines in the progression of a neurotoxic insult.

### 1138 DOPAMINERGIC CELL DEATH AND VANDIUM INHALATION.

Mussali-Galante<sup>2</sup>, V. Delgado<sup>2</sup> and T. I. Fortoul<sup>2</sup>. <sup>1</sup>Neuroscience, UNAM campus Iztacala, Tlalnepantla, Edo. Mex., Mexico and <sup>2</sup>Facultad de Medicina, UNAM, Mexico, DF, Mexico.

Vanadium (V), a transition metal has increased in the air as a component of suspended particles originated from fuel combustion. In this report a model of inhaled V in mice was implemented to identify the effect that V exerts in the substantia

nigra neurons, structure with high dopamine concentrations and scarce antioxidants burden. CD-1 male mice inhaled one hour twice a week 0.02 M V205; animals were sacrificed from 1 to 8 weeks of inhalation, perfused and processed for tyroxine hidroxylase (TH) inmunocytochemistry. The analysis consisted in counting the number of TH immunoreactive neurons in the substatia nigra compacta. Our results showed that there was a significant reduction of TH-positive neurons which decrease in a time dependent manner. Changes induced by V in the substantia nigra might have functional repercussions in motor and learning behaviors, and the fashion by which V is exerting its effect should be acknowledged. Supported in part by DGAPA-UNAM 210301 and PO.S Institute.

### 1139 INHALATION OF URANIUM OXIDE: PHYSIOLOGICAL EFFECTS ON RATS.

J. Lewis<sup>1</sup>, J. Karlsson<sup>1</sup>, G. Bench<sup>3</sup>, O. Myers<sup>1</sup>, W. Barrington<sup>1</sup>, E. Barr<sup>2</sup> and <u>F. Hahn<sup>2</sup>. <sup>1</sup> Community Environmental Health Program, University of New Mexico, Albuquerque, NM, <sup>2</sup> Lovelace Respiratory Research Institute, Albuquerque, NM and <sup>3</sup> Lawrence Livermore National Laboratory, Livermore, CA.</u>

Depleted uranium (DU) has been implicated as a potential factor contributing to Gulf War illness. Upon impact, DU-containing armor penetrators burn and release uranium dust particles of respirable size. Inhaled metals can be directly transported into the brain via the olfactory system, and inflammation in nasal epithelium may increase brain metal uptake further. We therefore investigated the deposition of uranium in brain and kidney as well as neuroinflammatory response in olfactory bulb. Rats were exposed to either: a) insoluble UO2, b) soluble UO3, c) 50% UO2 + 50% UO3, d) DU oxide (DUOx), e) TaO2 (negative control) or f) air (control) for 15 min in a nose-only inhalation chamber. The metal concentration in aerosols ranged from 300-600 mg/m3 and particle size was 1.5-2.4 µm. Nasal inflammation was induced in a subset of animals by endotoxin instillation in both nostrils 48 hours prior to air, DUOx or UO2 + ÚO3 exposure as above. Animals were sacrificed on day of exposure (0 day) or 30 days post-exposure for tissue analysis of uranium content. Astroglial response in olfactory bulbs at he same timepoints was evaluated using glial fibrillary acidic protein (GFAP) immunoreactivity. Of the 30 rats exposed to UO3, 12 females and 3 male rats died within 12 days after exposure and were found to have acute renal tubular necrosis and uremic pneumonia. There were no early deaths in other experimental groups. Uranium levels in kidneys as well as brain olfactory system were below the detectable level at 0 and 30 days in all experimental groups. Nevertheless, GFAP intensity in olfactory bulb glomeruli was significantly elevated in UO3 exposed animals at 0 and 30 days compared to air-exposed control rats. There was a trend for DUOx to increase GFAP response at 0 days. Thus, uranium oxide can, even at levels too low for detection in brain, lead to neuroinflammation. Effects of uranium on other tissue types and brain regions is currently under investigation.

## 1140 ACUTE EXPOSURE TO URANIUM (University) DECREASES POTASSIUM-STIMULATED HIPPOCAMPAL GLUTAMATE RELEASE.

S. M. Lasley and K. R. Vietti. Biomedical & Therapeutic Sciences, University of Illinois College of Medicine, Peoria, IL.

Gulf War veterans who retained fragments of depleted uranium (DU) shrapnel have exhibited lowered performance on neurocognitive tests, and rats chronically exposed to DU have displayed apparent decreases in neuronal excitability. The goal of this study was to determine if acute exposure to University in vitro disrupts synaptic processes underlying K+-stimulated glutamate release. A crude hippocampal P2 fraction was prepared from 1-2 month old Sprague-Dawley rats, and 0.8 mg synaptosomal protein loaded onto glass fiber filters. Synaptosomes were superfused with a phosphate-free 25 mM HEPES buffer saturated with O2/CO2 (95:5) and maintained at pH 7.4. Release was stimulated with brief perfusion of high K+-HEPES containing a glutamate reuptake blocker. Concentrations of University oxide (University(VI), 0.1 uM to 1.0 mM) were added to perfusion solutions, and 2-min fractions were collected beginning -45 min after exposure was initiated. Aliquots were derivatized and quantified by binary gradient liquid chromatography with fluorescence detection. In the absence of University, K+ stimulation resulted in a 2-4-fold elevation in glutamate concentration over baseline values. Perfusion of University(VI) diminished endogenous potassium-evoked glutamate release at 0.1 mM (-37%) and 1.0 mM (-70%) compared to control values, resulting in an approximate IC50 of 0.25 mM. The duration of University(VI) exposure is appropriate for investigating its effects on membrane calcium channels involved in exocytosis, but this form of the metal is less potent than other more well studied divalent cations such as Pb+2 or Cd+2. Other more biologically significant forms of University (e.g., uranyl ion, divalent UO2) may exhibit greater potency on transmitter release processes. The intracellular actions of University(VI) on exocytosis could also be important. These initial findings suggest a measurable effect of University(VI) on hippocampal glutamatergic transmission and indicate the need for further investigation. (Supported by USAMRMC grant DAMD17-02-1-0212)

MITOCHONDRIAL MEMBRANE POTENTIAL IN CEREBELLAR GRANULE CELLS OF CALCIUM CHANNEL MUTANT LEANER MICE UNDER VARIOUS CONDITIONS

K. A. Thuett, S. Bellum and L. C. Abbott. CVM, VAPH, Texas A&M University, College Station, TX. Sponsor: E. Tiffany-Castiglioni.

Homozygous leaner (tgla/tgla) mice carry an autosomal recessive mutation in the carboxy-terminus of the pore forming,  $\alpha 1A$  subunit of P/Q-type voltage-gated calcium ion channels. These channels are highly expressed in cerebellar granule cells. Leaner granule cells begin to die via apoptosis on postnatal days (P)10-12, with peak cell death at P20. Altered calcium signaling can damage mitochondria, resulting in the release of cell death signals. To determine whether mitochondrial damage is involved in leaner granule cell death, we examined mitochondrial membrane potentials (MMP) of leaner and age-matched wild type cerebellar granule cells at P20 and P30. Granule cells were acutely isolated, plated on coverslips and loaded with TMRM, a lipophilic cation that accumulates in mitochondria in proportion to the MMP. Fluorescent images of granule cells were acquired and analyzed. At P20, the MMP observed in leaner granule cells was significantly lower than in wild type cells. However, at P30 no difference was observed between leaner and wild type granule cells. We speculate that changes in calcium ion current and intracellular homeostasis alter leaner granule cell mitochondrial integrity, leading to activation of neuronal cell death signaling pathways. At P30, cell death has terminated and surviving cells exhibit no MMP differences. Methylmercury (MeHg) toxicity can alter  $[Ca^{2+}]$  in cerebellar granule cells *in vitro*, and death in cells exposed to MeHg occurs *via* apoptosis and necrosis. Since the  $[Ca^{2+}]$  and MMP of leaner mice are already altered at P20, we hypothesize that MeHg will have a profound affect on the MMP of leaner mice when compared to wild type, MeHg treated wild type, and non-treated leaner mice. MeHg treatment will occur via subcutaneous injection for a total dose of 5.0 mg/kg MeHg. Granule cells will be isolated and MMP measured at P20 and P30 as stated previously. The leaner granule cell death and any MeHg associated changes observed in mice treated with MeHg may be a result of mitochondrial damage due to alterations in calcium signaling.

### 1142 LEAD EXPOSURE IS A RISK FACTOR FOR OSTEOPOROSIS.

J. E. Puzas, K. O. Hochberg, R. J. O'Keefe, E. M. Schwarz, M. J. Zuscik, J. Campbell and R. N. Rosier. *Department of Orthopaedics, University of Rochester School of Medicine, Rochester, NY.* 

Relevance: We have taken a programmatic approach to investigate multiple skeletal systems for the effects of lead (Pb). Prior studies have suggested that Pb adversely affects bone metabolism, but there has been no comprehensive effort to document the extent and severity of this toxicant on the skeleton. We have examined the effects of Pb on bone cell function, growth plate activity, fracture healing and as a clinical factor affecting bone mineral density (BMD). Methods: Isolated osteoblast (OB) and osteoclast (OC) cell cultures were used to document the effect of Pb on TGFbeta, RANK ligand (RL) and osteoprotegerin (OPG) signaling pathways. Isolated growth plate chondrocytes were used to study the effect of Pb on endochondral ossification. Reporter analysis, RT-PCR and Western blots were employed for this work. Histological and biochemical assays were used to evaluate the effect of Pb in a fracture-healing model. Clinical evaluations with DEXA BMD were used to translate our findings into a human population. Results: 1) Pb adversely affects OB and OC function. The mechanism of the effect for OBs is mediated through an inhibition of TGFbeta signaling. The effect on OCs is through a down regulation of RL production and upregulation of OPG production. 2) Pb accelerates early chondrogenesis but blocks maturation of chondrocytes in the growth plate. That is, type II collagen synthesis is stimulated early, but type X collagen synthesis is dramatically delayed later. 3) A similar molecular picture exists for the fracture healing process, in vivo. 4) Early DEXA evaluations of Pb exposed humans indicate that they have higher BMDs than control subjects, however, we have discovered a potential artifact in the measurement of BMD by this low-energy x-ray technique that may account for this finding. Discussion: Pb adversely affects bone cells, chondrocytes and fracture callus. It also appears to influence BMD. All of these results, taken together, implicate Pb exposure as a serious risk factor for diseases such as osteoporosis.

## 1143 SODIUM ARSENITE (ASIII) MODULATORY EFFECT ON THE HEART AND BLOOD LEVELS OF GLUTATHIONE IN APOE(-/-)XLDLR(-/-) MICE.

F. E. Pereira, M. Hassani and H. D. Beall. Center for Environmental Health Sciences, The university of Montana, Missoula, Missoula, MT.

Arsenic is a potent toxicant, carcinogen and modulator of the antioxidant defense system and it may exert its toxicity by generating reactive oxygen species. Glutathione (GSH), a 3-amino acid thiol peptide, has been shown to have an im-

portant protective role against arsenic-induced oxidative damage. This study attempted to elucidate the impact of sub-acute (14-day) arsenic exposure on the blood and heart levels of GSH in apoE(-/-)xLDLR(-/-) mice. These double knockout mice are atherogenic and have been characterized as a model for investigating effects of arsenic on cardiovascular diseases such as atherosclerosis. Two groups, one saline and the other sodium arsenite (AsIII) treated apoE(-/-)xLDLR(-/-) mice were included in this study, 8 mice each. Each saline-treated mouse received an i.p. injection of 100  $\mu$ l saline and AsIII-treated mice received 1 mg arsenic per kg body weight via injection of adjusted volumes of a prepared arsenic stock solution. The mice were injected on a weekly basis for two weeks. The mice were bled, immediately sacrificed at the end of the second week and the hearts were collected. A GSH assay, measuring total non-protein thiols, was performed on the blood and heart samples of these mice. The assay for the blood samples showed a significant increase in GSH levels in arsenic-treated mice compared to the saline-treated group. Although there is a trend toward an increase in the heart GSH levels of the arsenictreated group compared to the control group, it is not statistically significant. The adaptive protective effect of GSH against this sub-acute exposure of arsenic is exhibited similarly in the blood and heart of these mice. It seems that due to possible arsenic-induced lipid peroxidation and oxidative stress, which can deplete GSH resources in these tissues shortly after exposure, the GSH compensating mechanisms are activated and increase GSH synthesis significantly in a time wise manner. This work was supported by NIH grant RR-017670.

## 1144 ARSENIC-INDUCED TRANSFORMATION CAUSES GENERALIZED RESISTANCE TO APOPTOSIS IN CULTURED HUMAN KERATINOCYTES.

J. Pi<sup>1</sup>, Y. He<sup>2</sup>, C. Bortner<sup>3</sup>, J. Huang<sup>2</sup>, J. Liu<sup>1</sup>, W. Qu<sup>1</sup>, J. M. Reece<sup>3</sup>, M. Styblo<sup>4</sup>, C. F. Chignell<sup>2</sup> and M. P. Waalkes<sup>1</sup>. <sup>I</sup>ICS, LCC, NCI at NIEHS, Research Triangle Park, NC, <sup>2</sup>LPC, NIEHS, Research Triangle Park, NC, <sup>3</sup>LST, NIEHS, Research Triangle Park, NC and <sup>4</sup>Department of Pediatr, UNC, Chapel Hill, NC.

Inorganic arsenic (As) is a well-documented human carcinogen that targets the skin, although the underlying carcinogenic mechanism is not well understood. Tumorigenesis is a multistep process in which acquired apoptotic resistance is a common event. In this study, when HaCaT cells, an immortalized, non-tumorigenic human keratinocyte cell line, were transformed by continuous exposure to low level (100 nM) inorganic arsenite [As(III)] for 28 weeks, a generalized resistance to apoptosis was observed. This included resistance to apoptosis induced by ultraviolet (UVA) radiation, a human skin carcinogen, or a high dose of As. Concurrent with this acquired resistance, the As-transformed cells exhibited morphological changes and increased secretion of matrix metalloproteinase 9, which plays a crucial role in tumor invasion and is often associated with malignant transformation. Since cellular apoptosis is dependent on the balance between proapoptotic and survival pathways, the roles of caspase and protein kinase B (PKB), a key antiapoptotic molecule, in As-induced apoptotic resistance were investigated. Western blot analysis indicated that the As-transformed cells exhibited much less caspase-3 and -7 activation than control cells after UVA or high dose As(III) exposure. In the control cells, UVA or high dose As(III) markedly decreased nuclear phosphorylated PKB (P-PKB) levels prior to the apoptosis, whereas the As-transformed cells exhibited an increased stability of nuclear P-PKB. Pretreatment of the As-transformed cells with LY294002 or wortmanin, which inhibit PKB phosphorylation, completely blocked the acquired apoptotic resistance. These data demonstrate that the acquired apoptotic resistance observed concurrently with As-induced cellular transformation is associated with increased stability of nuclear P-PKB. Asinduced acquired resistance to apoptosis may be an important event in skin cancer development by allowing damaged cells to escape normal cell population control.

# 1145 SUBCYTOTOXIC INORGANIC ARSENITE TARGETS MITOCHONDRIA IN HK-2 HUMAN PROXIMAL TUBULAR CELLS: IMPLICATIONS ON MECHANISM OF CELL DEATH.

M. Peraza, D. E. Carter and A. Gandolfi. Pharmacology and Toxicology, University of Arizona, Tucson, AZ.

The kidney is a known target organ for arsenic (As) and is critical for both As biotransformation and elimination. Previous studies have demonstrated that at high doses (ppm) inorganic As (arsenate) is toxic to mitochondria primarily by affecting cellular respiration. However the effect of inorganic As on mitochondria after low level exposures is not known, particularly in the kidney. Thus the mitochondrial toxicity of low level inorganic arsenite was investigated in a human proximal tubular cell line, HK-2. Subcytotoxic concentrations of arsenite (1-10  $\mu$ M) were found to affect MTT processing by mitochondria in the HK-2 cells. Mitochondrial injury was further assessed by examining the alteration of the mitochondrial membrane potential using MitoTracker Red, a mitochondrial membrane depolarization, which

could subsequently lead to permeability transition and apoptosis. Subcytotoxic arsenite also induced translocation of phosphatidylserine to the outer layer of the plasma membrane, indicative of apoptosis. To confirm whether subcytotoxic arsenite induces cellular and/or mitochondrial morphological alterations consistent with apoptotic cell death, HK-2 cells were evaluated with both light and transmission electron microscopy. Classic morphological changes indicative of apoptosis were not observed at either the light microscopic nor the electron microscopic level with subcytotoxic arsenite exposures; however, evidence of necrotic changes in cytoplasmic structure and morphology, particularly in the mitochondria, were apparent. Therefore, based on the externalization of phosphatidylserine, HK-2 cells appear to initiate apoptosis following subcytotoxic arsenite insult, but based on the morphological changes seen, fail to complete apoptosis and undergo necrosis instead. Subcytotoxic arsenite can be sufficiently toxic to mitochondria that they lose their ability to keep the cell on course for apoptotic cell death. (NIH ES 04940, ES 06694)

## 1146 ARSENIC TRIOXIDE INHIBITS NUCLEAR RECEPTOR SIGNALING BY PHOSPHORYLATION OF RXR.

K. K. Mann<sup>1</sup>, A. L. Colosimo<sup>1</sup>, H. Lee<sup>2</sup>, J. M. Kurie<sup>2</sup> and W. H. Miller<sup>1</sup>.

Molecular Oncology, Lady Davis Institute for Medical Research, McGill University, Montreal, QC, Canada and <sup>2</sup>Thoracic/Head and Neck Medical Oncology, University of Texas/MD Anderson Cancer Center, Houston, TX.

Arsenic is a wide spread environmental contaminant, but arsenic trioxide (ATO) is also used to treat patients with acute promyelocytic leukemia (APL). We have previously published that ATO inhibits APL cell differentiation induced by retinoic acid, the other common treatment for APL, complicating the development of combination therapy using these two effective agents. Upon further investigation, we have found that ATO inhibits the transcriptional activation in transient transfections not only of retinoic acid receptor, but also several other nuclear receptors, all of which heterodimerize with the retinoid X receptor (RXR). ATO does not inhibit transactivation of the estrogen receptor, which acts as a homodimer. Previously published data show that phosphorylation of RXR can inhibit nuclear receptor signaling. Indeed, we find that ATO phosphorylates RXR in the N-terminal ABC region exclusively on serine residues, as assessed by in vivo labeling and phosphoamino acid experiments. We have previously identified JNK as a kinase activated by ATO and therefore, sought to determine if RXR is a target of JNK-mediated phosphorylation. When JNK activation is impaired through pharmacologic inhibition or by genetic deletion of the upstream regulator, SEK1, the ability of ATO to inhibit transactivation of the RXR/vitamin D receptor heterodimer is abrogated. Inhibition of JNK activity also decreases the level of ATO-induced RXR phosphorylation. These data suggest ATO-induced JNK activation leads to RXR phosphorylation and the inhibition of transcription by RXR heterodimers. This suggests that consecutive use of retinoic acid and ATO in the treatment of patients with APL may be preferred. In addition, consideration of this interaction between ATO and nuclear receptor function may give some insight into molecular mechanisms of arsenic-induced carcinogenesis resulting from environmental exposure.

## 1147 EFFECT OF LOW DOSE AS(III) IN THE DRINKING WATER OF MICE ON TUMOR GROWTH AND ANGIOGENESIS.

M. A. Ihnat, L. Hess, S. Curilla and C. Clark. *OUHSC, Oklahoma City, OK.* Sponsor: R. Kaltreider.

Arsenite (As(III)), a major drinking water contaminant, is associated with many vascular abnormalities in contaminated populations. We have previously shown that As(III) at levels approaching the current US drinking water standard (10 PPB) stimulates angiogenesis and As(III) injected into tumor-bearing mice at levels below those used to treat cancer can actually stimulate tumor growth. We now show that B16-F10 melanoma tumor-bearing mice exposed to 10, 50, and 200 PPB As(III) in their drinking water for 10 weeks prior to tumor implantation show considerably higher tumor growth rates versus mice given nanopure water. Additionally, we show by immunohistochemistry that levels of HIF- $1\alpha$  and two of its regulated proteins, VEGF and PAI-1, are substantially increased in mice receiving 10 and 50 PPB As(III)), but not in mice receiving 200 PPB As (III). Interestingly, tumor blood vessel counts were substantially higher in animals given all doses of As(III). In isolated B16 cells, a 4 hr exposure to high dose (75 and 750 PPB) As(III) stimulated HIF-1α protein levels by immunoblot analysis. In contrast, a 72 hr exposure to low dose (0.75 and 7.5 PPB) As(III) caused comparable HIF-1α protein induction. Using the CAM angiogenesis assay, the VEGFR kinase inhibitor SU5416 (10μM) and an inhibitor of HIF-1α, YC-1 (10μM), abrogated the angiogenic effects of As(III). Finally, the antioxidants tocopherol (100 $\mu$ M), NAC (1mM), DMSO (0.5 percent) and TEMPOL (1mM) all reduced As(III)-mediated vessel formation in the CAM assay. These results indicate that the angiogenic

effects of low dose As(III) can enhance tumor growth and the angiogenic stimulation by low dose As(III) likely involves reactive oxygen species (ROS) and HIF signaling.

## 1148 PANCREATIC OXIDATIVE DAMAGE AND ENDOCRINE FUNCTION IN RATS SUBCHRONICALLY EXPOSED TO ARSENITE.

J. A. Izquierdo-Vega<sup>1</sup>, C. A. Soto<sup>2</sup>, L. C. Sanchez-Pena<sup>1</sup>, L. O. Valenzuela<sup>1</sup>, E. A. Garcia-Montalvo<sup>1</sup> and <u>L. M. Del Razo</u><sup>1</sup>. <sup>1</sup>Toxicology Section, Cinvestav-IPN, Mexico D.F, Mexico and <sup>2</sup>Biologic Systems Department, UAM-Xochimilco, Mexico D.F., Mexico.

Chronic exposure to inorganic arsenic (iAs) contributes to oxidative stress in several organs and systems through production of reactive oxygen species. Since the pancreas is a susceptible organ to the oxidative stress and target of the toxic action of iAs exposure, our study evaluated the presence of oxidative stress and endocrine function of pancreas in rats subchronically exposed to iAs. The oral glucose tolerance test (OGTT) was performed in male Wistar rats after 60 days of treatment with sodium arsenite at 1.7mgAs3+/kg/12h. The effect of subchronic iAs administration on blood glucose, serum insulin, lipid peroxidation (LPO), levels of glutathione (GSH) and As species in pancreas were evaluated after 90 days of iAs treatment in other group of male Wistar rats exposed with sodium arsenite at 1.7mgAs3+/kg/12h. The OGTT shown an impaired glucose tolerance. Hyperinsulinemia (2.7±0.9 vs 1.4±0.6 ng/ml of control group) and hyperglycemia  $(9.3\pm 0.7 \text{ vs } 7.1 \pm 0.8 \text{ mmol/l})$  was observed at the end of iAs treatment. On the other hand the pancreatic LPO and glutathione levels increased significantly in iAs exposed rats. Dimethylated arsenic (DMA) was the main specie present in the pancreas. The results of this study suggest that subchronic iAs exposure causes oxidative damage and pancreatic beta cell dysfunction related to insulin resistance and hyperglycemia. These results may be related with the presence of pre-diabetes status.

## 1149 HEAT SHOCK PROTEIN 70 AS AN INDICATOR OF EARLY LUNG INJURY CAUSED BY EXPOSURE TO

S. Han<sup>1, 2</sup>, <u>J. Nath</u><sup>2</sup> and <u>V. Vallyathan</u><sup>1, 1</sup> Pathology and Physiology Research Branch, Health Effects Laboratory Division, NIOSH, Morgantown, WV and <sup>2</sup> Genetics and Developmental Biology, West Virginia University, Morgantown, WV.

Heat shock proteins (HSPs) are a family of highly conserved proteins that are induced by stress, temperature, redox status, heavy metals, and inflammation. HSPs play a major role within a cell from folding of synthesized proteins or its degradation by proteosome. Intracellular transport and defects in folding can cause accumulation of these proteins resulting in several disease processes. HSP expression can be interpreted as an early and sensitive biomarker of cells in stress. Arsenic (As) is a naturally occurring metal that is distributed widely in the environment and is used in several industries. Exposure to As is associated with the development of pulmonary and skin cancers. The present study was undertaken to evaluate the expression levels of Hsp70 protein and mRNA induced by exposure to As which could be a sensitive and early biomarker. In addition, the cellular and molecular mechanisms of Hsp70 expression by As were investigated in the human bronchial cell line BEAS-2B. Cytotoxicity, lipid peroxidation and hydrogen peroxide generation were measured as indicators of cell injury and perturbed oxidative metabolism by As. Exposure of BEAS-2B cells to As(III) was associated with increased expression of Hsp70 protein and mRNA in a time and dose dependent manner. Hsp70 protein expression showed a significant five-fold increase by Western blot analysis and was increased 20-fold using an ELISA assay at a 50 uM As(III) concentration with a 6 hr exposure and an 8 hr recovery time. Hsp70 mRNA expression showed a 28% increase compared to controls. Cytotoxicity resulting from As(III) increased with a longer exposure time (48 hr). Lipid peroxidation increased six-fold at a concentration of 20 uM As(III) for 24 hr exposure, while H2O2 generation showed a twofold increase. These results suggest that the induction of Hsp70 was the most sensitive indicator of cell injury by As(III), and Hsp70 may be a valuable indicator of oxygen free radical-induced lung cell injury.

# 1150 ROLE OF CALCIUM AND MITOGEN-ACTIVATED PROTEIN KINASES ON CADMIUM-MEDIATED GROWTH ARREST AND CASPASE-3 ACTIVATION IN MURINE MACROPHAGES.

<u>I. Kim</u> and <u>R. P. Sharma</u>. physiology and pharmacology, University of Georgia, Athens, GA.

Cadmium (Cd) is a well-known carcinogen and immunotoxic metal commonly found in cigarette smoke. Proliferation and apoptosis is regulated to provide appropriate cell number and to avoid tumor growth. Present study was designed to deter-

mine the possible involvement of calcium (Ca2+) and mitogen-activated protein kinases (MAPKs) signaling pathways on Cd-induced growth arrest and apoptosis in J774A.1 macrophage cells. Concentration-dependent apoptosis was detected; response reached a peak at 16 hr and then declined. Inhibitors of caspase-3, -8, -9 and general caspases suppressed Cd-induced caspase-3 activation and apoptosis indicating the importance of caspase-3 on Cd toxicity. The Cd-induced growth arrest, caspase-3 activation, and cytotoxicity were attenuated when intracellular Ca2+ chelator 1, 2-bis(2-aminophenoxy)-ethane-N, N, N', N'-etracacetic acid tetrakis (acetoxy-methyl) ester and extracellular Ca2+ chelator ethylene glycol-bis(bera-aminoethyl ether)-N, N, N', N'-etracetic acid were used. Protein kinase C (PKC) activator phorbol myrisate acetate inhibited Cd-induced apoptosis and cytotoxicity but potentiated growth arrest, suggesting that an increased intracellular and extracellular Ca2+ levels and PKC activity status are important in regulation of proliferation and apoptosis. Pretreatment with cell-permeable Cd chelator N, N, N', N'-terakis-(2-pyridylmethyl)-ethylenediamine that has a low affinity for Ca2+ inhibited cytotoxicity but did not affect Cd-induced capase-3 activation, indicating that intracellular Cd is not responsible for the induction of apoptosis. Use of selective MAPK inhibitors suggested that all three MAPKs, c-Jun N-terminal kinase (JNK), extracellular signal-regulated kinase and p38 protected the Cd-induced cytotoxicity, but only JNK was involved in Cd-induced capase-3 activation. Our findings suggest that Ca2+ elevation triggers growth arrest and JNK and caspase-3 activation in Dei interrelated with Ca2+ foodulate Cd toxicity, (supported by UGA center for Academic Excellence in Toxicology and Fred Davison Endowment Fund)

## 1151 ARSENIC ALTERS THE SCAFFOLDING PROPERTIES OF THE MEKK4 KINASE.

University. M. Halfter, Z. E. Derbyshire and R. R. Vaillancourt. Pharmacology and Toxicology, University of Arizona, Tucson, AZ.

Toxicity of arsenite is well documented in whole organism studies where environmental exposure, i.e. mostly in drinking water and food, has caused elevated levels of cancers. Skin cancer, hyperpigmentation and hyperkeratosis or blackfoot disease are reported. We are interested in arsenite effects on cellular signal transduction mechanisms to document early effects of arsenite toxicity. We are studying the regulation of the mitogen-activated protein kinase/extracellular signal-regulated kinase kinase 4 (MEKK4) signaling pathway. Using immortalized human keratinocytes, HaCaT cells, as a model system we are investigating the regulation of the serine/threonine protein kinase MEKK4. Our previous evidence suggests that this pathway regulates cyclooxygenase II expression levels. The inflammatory mediator, interferon gamma, has been reported to activate cyclooxygenase II expression. Indeed, we demonstrate an interferon gamma dependent tyrosine phosphorylation of MEKK4. The tyrosine kinase Pyk2 co-immunoprecipitates with MEKK4, suggesting that this tyrosine kinase may mediate the phosphorylation of MEKK4. Employing calcium chelators we demonstrate the significance of calcium for the activation of the MEKK4 kinase. Annexin II is a calcium binding protein. We have identified annexin II being co-immunoprecipitated with MEKK4 suggesting its role as a mediator of the calcium dependency. Here we present our study of the effects of arsenite on the regulation of the MEKK4 pathway. Serial dilutions of sodium arsenite applied to HaCaT cells affect MEKK4 tyrosine phosphorylation. Moreover, we found the composition of components of the MEKK4 signaling complex are altered in response to arsenite exposure of keratinocytes. To corroborate data obtained with immortalized keratinocytes we, in addition, employ normal human epidermal keratinocytes (NHEK).

## TUMOR PROMOTER ARSENITE STIMULATES HISTONE H3 PHOSPHOACETYLATION AT C-fos AND C-jun IN HUMAN DIPLOID FIBROBLASTS.

Y. Liu<sup>1, 2</sup>, J. Li<sup>2</sup>, M. Gorospe<sup>2</sup> and J. Barnes<sup>2</sup>. <sup>1</sup>Children's Hospital, Children's Research Institute, Columbus, OH and <sup>2</sup>Laboratory of Cellular and Molecular Biology, NIA-IRP, NIH, Baltimore, MD. Sponsor: C. Smith.

BACKGROUND: Although epidemiological studies have clearly established that elevated arsenic levels in drinking water are associated with increased incidences of skin, lung, bladder, kidney, and liver cancers, the carcinogenic mechanism remains elusive. Recent studies have suggested that arsenic may act as a tumor promoter by perturbing key signaling pathways. We have shown that arsenite potently induces proliferation-associated genes, including c-jun and c-fos, through a pathway regulated by EGF receptor. Recent studies have demonstrated that chromatin remodeling mediated by histone H3 phosphoacetylation plays an important role in the induction of c-fos and c-jun. OBJECTIVE: To understand the molecular mechanisms underlying the tumor-promoting properties of arsenic and test the hypothesis that histone H3 phosphoacetylation are involved in the induction of c-fos and c-jun. DESIGN/METHODS: Early passage normal human lung fibroblast WI-38 cells were stimulated with arsenite. Expression of c-fos and c-fun was examined by Northern blot analyses. Histone H3 phosphorylation and acetylation at the global levels were assessed by immunofluorescence and Western blot analyses. Histone H3 phosphorylation and acetylation at the loci of c-fos and c-jun were measured by chromatin immunoprecipitation (ChIP) and real-time PCR assays. RESULTS: Both c-fos and c-jun by arsenite can be substantially inhibited by the MEK-selective inhibitor, but not by the p38 inhibitor. Arsenite dramatically induced the phosphorylation and acetylation of histone H3 preceding the mRNA induction of c-fos and *c-jun*. ChIP assays revealed that arsenite markedly induced histone H3 phosphorylation/acetylation at the *c-fos* and *c-jun* loci through an ERK-dependent pathway. CONCLUSION: Our results suggest that arsenic-triggered alterations in chromatin structure perturb gene transcription and may contribute to the carcinogenic process.

## 1153 SODIUM ARSENITE INHIBITS FOCAL ADHESION COMPLEX FORMATION AND DYNAMICS IN LIVE CELLS

S. L. Yancy<sup>2</sup>, E. A. Shelden<sup>1</sup> and M. J. Welsh<sup>1</sup>. <sup>1</sup>Cell and Developmental Biology, University of Michigan Medical School, Ann Arbor, MI and <sup>2</sup>Environmental Health Sciences (Toxicology), University of Michigan School of Public Health, Ann ARbor, MI

Arsenic is an environmental pollutant. It is converted in organisms to other forms, the most common of which is arsenite. Arsenite binds to protein thiols and its toxicity is thought to be non-specific. However, some thiols may be more critical for cell function than others. We previously showed that arsenite can inhibit FAK phosphorylation and cell motility. Here, we tested the hypothesis that arsenite decreases the dynamics and inhibits formation of focal adhesions (FAs) in live cells. H9C2 myoblast cells were transiently transfected with GFP-paxillin to allow observation of FAs. To ensure proper labeling of FAs by GFP-paxillin in living cells, cells were also prepared for immunofluorescence localization of the FA protein vinculin. Cells expressing GFP-paxillin were treated with 0, 1, 2.5 or 5 uM sodium arsenite for 24 hours. MTT cytotoxicity assay showed these doses did not cause reduced cell viability. Cells were observed for 6 hours by time-lapse video fluorescence microscopy. Sodium arsenite-treated cells exhibited dose-dependent reductions in FA migration rates and reduced numbers of FAs per cell. FA complex formation rate was decreased, as measured by recruitment of FAK, vinculin and paxillin to FAs of cells treated with RGD-beads. Sodium arsenite-treated cells exhibited a significant reduction in ability to attach to a substrate over a 1 hour period. Sodium arsenite caused a reduction in cell contraction, indicating that arsenite might affect actomyosin-mediated contraction in H9C2 cells, a process necessary for FA formation. These data indicate that sodium arsenite alters FAs by interfering with FA formation, FA dynamics and cell contraction thereby interfering with cell behaviors dependent on FAs including cell attachment and migration and presumably other aspects of FA function and integrin signaling. # 1154 CADMIUM-INDUCED APOPTOSIS, ACTIVATION OF MAPK SIGNALING PATHWAYS AND ACCUMULATION OF UBIQUITINATED-PROTEIN-CONJUGATES IN PRIMARY RAT NEONATAL SERTOLI-GONOCYTE COCULTURES.

X. Yu, J. S. Sidhu, S. Hong and E. M. Faustman. Env. & Occ. Health Sciences., IRARC, University of Washinton, Seattle, WA.

In this study, we employed our recently established and well characterized in vitro Sertoli-gonocyte co-culture system to examine whether Cadmium (Cd) affects development of the neonatal testis at low doses and to investigate the underlying mechanisms associated with such perturbations. We hypothesized that exposure to Cd during neonatal periods in vivo reduces the number of the Sertoli and gonocyte cell numbers by inhibiting proliferation and inducing apoptosis; and furthermore, that the activation of MAPK signaling pathways and the alterations in the ubiquitin-proteasome pathway (UPS) are involved in such perturbations. We investigated the time- and dose-dependent induction of stress signaling pathways, and the disruption of UPS function to explore the association with the corresponding induction of apoptosis. We also compared these effects to two known proteasomal inhibitors (MG132 and Lactacystin). Our results demonstrated that Cd exposure resulted in dose- and time-dependent alterations of morphology consistent with the induction of apoptosis as demonstrated by the increase of caspase-3 like activity and cleaved caspase-3 protein expression. We further observed that Cd treatment, in a dose- and time-dependent manner, resulted in activation of p38 MAPK, SAPK/JNK, c-jun and ATF-2, and accumulation of high molecular weight ubiquitin conjugated proteins (HMW-Ub). Furthermore, we identified two specific targets of UPS induced by Cd, namely p53 and Nrf 2. Nrf 2 is an important transcription factor in regulating the expression of detoxifying and anti-oxidant enzyme genes. In summary, the current study suggests that Cd-induced UPS dysfunction may be a critical mechanism underlying the toxicity associated with in vivo developmental testicular toxicity. Future studies will address these specific targets which render the developing neonate testis sensitive to environmental toxicants. Support: NIEHS ES09601-02, ES10613-01 and ES07033 and EPA R 826886-01-0.

DEFINING P53-DEPENDENT AND INDEPENDENT MECHANISMS OF CADMIUM-INDUCED CYTOTOXICITY, STRESS SIGNALING, APOPTOSIS AND UBIQUITIN PROTEASOME PATHWAY PROCESSING.

J. S. Sidhu, S. Hong, X. Yu, E. Kim, A. Erickson, J. F. Robinson, S. Kim, M. Vredevoogd and E. M. Faustman. Env. & Occ. Health Sciences., IRARC, University of Washington, Seattle, WA.

The activity of the tumor suppressor oncoprotein p53, a critical cell cycle checkpoint modulating genotoxic stress, is regulated via the concerted function of the Ubiquitin Proteasome pathway (UPP) with stress-induced disruption leading to increased accumulation of p53 and resulting growth arrest. Recent studies have suggested that aberrant cellular responses observed with certain environmental contaminants, such as cadmium (Cd), is associated with the accumulation of high molecular weight poly-ubiquitinated protein conjugates (HMW-Ub). In the present study we investigated the role of p53 status in determining the sensitivity to Cd exposure and whether induction of stress signaling responses and perturbation of the UPP were central in mediating the metal-induced cytotoxicity and apoptosis. Utilizing synchronous cultures of p53 transgenic mouse embryonic fibroblasts we treated +/+ and -/- cells with increasing concentrations of Cd (0.5-20  $\mu M)$  for 24h. We compared the metal response to two classic proteasomal inhibitors, MG 132 and lactacystin as well as a non-metal stress-inducing agent, anisomycin. Cd-induced cytotoxicity, assessed by disruption of cellular morphology and attenuated neutral red dye uptake, was partially dependent on p53 status with the wild type exhibiting a 2-fold greater sensitivity. Parallel analyses of cell extracts confirmed a Cd dose-dependent modulation of stress signaling responses (as evidenced by p38 MAPK and SAPK/JNK phosphorylation) and these responses corresponded to an accumulation of HMW-Üb as well as induction of apoptosis (as evidenced by western and activity determination of cleaved caspase-3 expression). We conclude that although Cd-mediated cytotoxicity is partially p53 dependent, the effects of this metal on induction of stress signaling responses, accumulation of HMW-Ub and resulting apoptosis appear to be independent of p53 status. Support: EPA and NIEHS R 826886-01, ES09601-02, ES07033 and ES10613-01.

THE MECHANISM OF NF-kB SUPPRESSION IN CADMIUM-INDUCED APOPTOSIS IN RAT KIDNEY EPITHELIAL CELLS.

J. Xie and <u>Z. A. Shaikh</u>. Department of Biomedical Sciences, University of Rhode Island, Kingston, RI.

Cadmium (Cd) exposure induces apoptosis in different cell types including kidney cells. The oxidative stress elicited by Cd appears to exert a central role in promoting apoptosis. Redox sensitive transcription factors, such as NF-κB, are reported to participate in this process. However, the mechanism of NF-κB involvement in Cd-induced apoptosis has not yet been elucidated. In the present study, semiconfluent culture of a rat kidney epithelial cell line, NRK-52E, were exposed to 10-20 µM CdCl, for 5 hr and maintained for up to an additional 12 hr period. While apoptotic DNA fragmentation was detected 11 hr after starting the Cd exposure, both NF-KB activity and protein level were decreased at 5 hr of Cd exposure. The effect of Cd on NF-kB, assessed by EMSA and Western blotting, was dependent upon the dose and duration of Cd treatment. In comparison with Cd, other metals such as copper, zinc, lead and mercury increased rather than decrease NF-KB DNA binding activity. Preincubation of nuclear extract with 1-100 µM CdCl, showed that Cd had no direct effect on NF-kB DNA binding activity. Pretreatment of cells with antioxidants, U8386E and BHT, prevented loss of NF-KB DNA binding activity. Furthermore, Cd exposure inhibited TNF-α-induced IκB kinase α, the enzyme that phosphorylates  $\tilde{I}\kappa B$  and releases NF-  $\!\kappa B$  from NF-  $\!\kappa B$  -  $\!I\kappa B$  complex. In addition, RT-PCR analysis showed that Cd caused a decline in NF-κB mRNA level. Suppression of NF-KB by Cd also down regulated NF-KB target genes, cIAP-1 and cIAP-2, and activated caspase -3, 7 and 9. These results suggest that in kidney cells suppression of oxidative stress-sensitive transcription factor, NF-κB, is an early event in Cd-induced apoptosis and that the mechanism appears to involve both inhibition of NF-κB release and its synthesis. OXIDATIVE STRESS AND CYTOKINES CO-STIMULATES METALLOTHIONEIN EXPRESSION IN CADMIUM TREATED HEPG2 CELLS.

C. Escobar, V. Souza, L. Bucio, E. Hernandez, L. Gomez-Quiroz and <u>C. Gutierrez-Ruiz</u>. Ciencias de la Salud, Universidad Autonoma Metropolitana, Mexico, DF, Mexico.

The liver is the target organ of acute cadmium poisoning and the principal site of synthesis of metallothionein (MT), a metal-binding protein that is purposed to cause resistance to Cd-induced hepatotoxicity. MT works as a defense mechanism

against oxidative stress and some reports indicate that reactive oxygen species and some cytokines could induce it. The aim of this study is to determine the effect of IL-1β, IL-6 and TNF-α and oxidative stress on the expression of MT-II mRNA in HepG2 cells. Cell viability was determined by MTT assay in a wide range of cadmium concentrations. HepG2 cells were exposed to 5 µM CdCl2 for 6 h, because cell viability is higher than 90% in presence of this concentration. MT-II induction was determined by Northern blot. ÎL-1β, IL-6 and TNF-α (2.5ng/ml in each case) were added to HepG2 cells and MT-II induction was determined. A one hour pretreatment with anti-IL-1β (5 ng/ml) and anti-TNF-α (10 ng/ml) in Cd-treated HepG2 was also evaluated. In order to explore the oxidative stress in MT-II induction, HepG2 cells were treated with 0.25 mM H2O2 or with 2mM BSO that depletes cell glutathione content. Antioxidants pretreatment effect (10 mM NAC, 10 mM TMTU, and 2U/ml catalase) was also determined in Cd exposed cells. Cd increased 5-fold MT-II mRNA control values. All cytokines tested, increased also MT-II expression comparing with control cells values (266% TNF-α, 228% IL-6 and 239% IL-1β). Pretreatment with anti-IL-1β and anti-TNF- $\alpha$  of HepG2 Cdtreated cells diminished 23% MT-II expression. H2O2 and BSO induces two times MT-II mRNA. NAC and TMTU decreased 40% Cd-induced mRNA-MT-II, while a 44% decrease was obtained with catalase treatment. Oxidative stress and cytokines participate in Cd induced MT-II in HepG2 cells. The mechanism of MT-II induction as response of Cd damage must be a multi-factorial process in which cytokines and oxidative stress participates in order to protect cells of being damaged as consequence of metal exposure. CONACYT No. 400200-5-30671-M.

OXIDATIVE STRESS INDUCED BY LEAD, CADMIUM AND ARSENIC MIXTURES: 30-, 90-, AND 180-DAY DRINKING WATER STUDIES IN RATS.

M. H. Whittaker, M. Lipsky, G. Wang, X. Chen and B. A. Fowler. Toxicology Program, The University of Maryland, Baltimore, Baltimore, MD.

Lead, cadmium, and arsenic warrant continued scrutiny because all three are found at 95% of Superfund sites. Moreover, they are associated with adverse health effects such as cancer and nephrotoxicity. Oxidative stress is thought to play a major role in the development of adverse health effects from exposure to these trace elements, and may occur through the generation of free radicals due to the accumulation of aminolevulinic acid (ALA) and free iron. In order to investigate mechanisms of trace element-induced oxidative stress, 8 groups of male Sprague-Dawley rats were exposed to deionized water, single trace elements (Pb (25 ppm as lead acetate), Cd (10 ppm as cadmium chloride), As (5 ppm as sodium arsenite)), or element mixtures for 30-, 90-, or 180-days. These doses were selected from a series of dose-response studies at LOEL dose levels. After 30 days, urinary ALA (mg/day) was increased in all groups compared to control (+18%-+287%). After 90 days, urinary ALA was increased in 6 groups (+15%-+52%). After 180 days, urinary ALA was increased in 4 groups (+25%-+77%). Urinary iron (µg/day) was decreased in all groups after 30 days (-8%-50%); after 90 days urinary iron was increased only in the Pb and As groups (+12%-+17%). After 180 days, urinary iron was decreased in all test groups (-3%-30%). When expressed in units of µg Fe/ml urine, urinary iron was increased in 4 of the 7 groups after 30 days (Pb, PbxCd, CdxAs, PbxCdxAs)(+14%-+77%); after 90 days, iron was increased in 6 of the 7 groups (all except PbxAs)(+10%-+30%); and after 180 days, iron was increased in 3 of the 7 groups (PbxAs, CdxAs, PbxCdxAs)(+8%-+30%). These data indicate that ALA and iron accumulate after acute exposure to trace elements or their mixtures. The accumulation of these two oxidative stress precursors appears to level off over 180 days, suggesting that some type of adaptation to oxidative stress occurs following repeat exposures to trace elements or their mixtures [Supported by USEPA Star Grant R827161-01-0].

### 1159 INTERACTIONS OF LEAD, CADMIUM AND ARSENIC IN RAT KIDNEYS.

G. Wang, X. Chen, M. M. Lipsky, W. H. Margaret and B. A. Fowler. Toxicology Program, University of Maryland, Baltimore, MD.

Lead, Cadmium and Arsenite are renal toxicants on an individual basis. This study explored the interactive effects of Pb, Cd, and As at empirically determined LOEL dose levels (Pb, 25 ppm, Cd, 10 ppm, As (As3+), 5 ppm) in drinking water for 30, 90 or 180 days using a factorial design. Histopathological evaluation of Sprague-Dawley rat kidneys showed no specific pathological changes for most treatments but increased kidney histopathology was observed in the combination groups at 180 days. Erythrocyte zinc protoporphyrin (ZPP) concentration increased in all exposure groups except the As group at 30 days and increased in the As and Pb\*Cd\*As groups at 180 days. No change in ZPP was seen in any treatment group at 90 days. Blood delta-aminolevulinic acid (ALAD) activity was inhibited in all treatment groups at 30 and 90 days. At 180 days, blood ALAD activity was inhibited only in the Pb group and was increased in all combination treatment groups. Kidney ALAD activity was inhibited in all groups at all time points except the

Pb\*As group at 30 days and the As and Cd\*As groups at 90 days. Kidney 8-hydroxy-2'-deoxyguanosine (8-OHdG), an oxidative DNA adduct, increased in only the Cd\*As treatment group at 180 days. This adduct was decreased in all combined treatment groups at 90 days. Heme oxygenase (Hsp 32) expression displayed an increase in only the Pb\*Cd\*As group at 180 days. Metallothionein (MT) was induced in P1 and P2 segments of the proximal tubules in the Cd and Pb\*As treatment groups at all three time points. MT staining intensity from high to low was: Pb\*Cd\*As=Cd\*As=Pb\*Cd=Cd>Pb\*As>As=Pb=control. These data suggest that at 90 days there was a compensatory response to the toxic effects of these elements. Concomitant Cd\*As exposure at 180 days produced significant oxidative DNA damage, not observed with Cd or As alone. The general compensatory response observed at 90 days and increased oxidative damage in combination treatment groups at 180 days cannot be explained solely by MT expression levels but must involve other regulators of oxidative damage. (Supported in part by EPA STAR grant #827161)

#### 1160

ACUTE RENAL FAILURE INDUCED BY CHROMATE TREATMENT AND CLAUDIN-2 EXPRESSION IN MURINE KIDNEY.

L. Arreola-Mendoza<sup>1</sup>, J. L. Reyes<sup>2</sup>, D. Martin<sup>2</sup>, M. C. Namorado<sup>2</sup>, J. C. Luna<sup>2</sup> and <u>L. M. Del Razo</u><sup>1</sup>. <sup>1</sup> Toxicology Section, Cinvestav-IPN, Mexico D.F, Mexico and <sup>2</sup> Physiology, Biophysics & Neurosciences, Cinvestav-IPN, Mexico D.F., Mexico.

Renal epithelia and endothelia have tight junctions (TJs) that regulate the passage of ions, water and molecules through the paracellular pathway. Integrity of TJs is responsible for the passive permeability of polarized epithelia. Chromate (Cr6+) administration induces nephrotoxicity in humans and experimental models. It also increases formation of reactive oxygen species and oxidative damage. Oxidative stress compromises TJs, but the mechanisms are unknown. Our objective was to study the oxidative damage and effects on renal function and structure of TJs induced by chromate administration. Wistar female rats received potassium dichromate (15 mg/kg, SC, single dose). Renal function, lipid peroxidation, and claudin-2 (a protein of TJs) immunohistochemical pattern were monitored on days 0, 1, 2, 3, 7, 10 y 14. Confocal microscopy immunofluorescence of claudin-2 showed a clear presence at the cell borders of proximal tubules. This pattern was severely disorganized after chromate administration with spontaneous recovery after day 7. In agreement with morphological alterations, renal function was maximally altered on day 3 and thereafter recovery ensued. Glomerular filtration decreased and glucose and sodium fractional excretions increased. Oxidative damage showed a similar time-course. Our results suggest that chromate administration induces acute renal failure, oxidative damage and disorganization of the claudin-2 renal pattern. The excelent technical support of Gerardo Sierra is acknowledgement.

#### 1161

SELECTIVE SIGNALING PATHWAYS FOR CHROMIUM(VI) INDUCED PATTERNS OF TRANSCRIPTION FACTOR BINDING IN EXPOSED AIRWAY EPITHELIAL CELLS.

K. A. O'Hara<sup>1, 2</sup>, L. R. Klei<sup>1, 2</sup>, R. J. Vaghjiani<sup>2</sup> and A. Barchowsky<sup>1, 2</sup>.

Department of Environmental and Occupational Health, University of Pittsburgh, Pittsburgh, PA and Department of Pharmacology and Toxicology, Dartmouth Medical School, Hanover, NH.

Inhaled hexavalent chromium (Cr(VI)) promotes pulmonary disease and lung cancer through poorly defined mechanisms. To explore these potential mechanisms, Beas-2B airway epithelial cells were used to investigate the hypothesis that nontoxic Cr(VI) exposures selectively activate cell signaling pathways which lead to changes in the profile of transcription factor binding to specific cis-elements in DNA. These studies demonstrated that non-toxic doses (1-5 µM) of Cr(VI) increased the abundance of tyrosine kinases. Two of these kinases, bone marrow X kinase (Bmx) and focal adhesion kinase (Fak), were detected by western blot analysis, and protein tyrosine kinase 2 (Pyk2) was detected by a Kinetworks<sup>TM</sup> protein kinase screen. As the levels of Pyk2 increased, so did its association with Fyn, a Src family kinase member. Futher, the kinase activities of both Fyn and Lck increased in response to Cr(VI). The DNA binding of various transcription factors (TF) are responsive to upstream signaling cascades that are altered in response to Cr(VI). Two protein/DNA array systems were used to demonstrate that protein binding to 9 out of a total of 150 targeted cis-elements changed over a 24 h exposure period. Significant increases were seen in both Stat 5 and AP-1 binding, which may be related to activation of tyrosine kinase activity by Cr(VI). The most significant decrease was seen in the level of nuclear protein that binds to the antioxidant/electrophile response element (ARE). These findings suggest that airway cell phenotype may be changed as low concentrations of Cr(VI) selectively activate signaling pathways that lead to prolonged changes in transcription factor binding. Supported by NİEHS grant ES10638.

MODULATORY EFFECT OF THE GREEN TEA FLAVONOID EPIGALLOCATECHIN 3-GALLATE ON ARSENITE- AND HYDROGEN PEROXIDE-STIMULATED MITOGEN-ACTIVATED PROTEIN KINASE PHOSPHORYLATION AND HEME OXYGENASE-I EXPRESSION IN HUMAN DERMAL FIBROBLASTS.

K. J. Trouba, J. D. Britton, A. C. Smith, Y. D. Rebolloso and <u>D. R. Germolec</u>. *NIEHS, Research Triangle Park, NC.* 

Reactive oxygen species (ROS) are proposed to contribute to arsenic carcinogenesis and in skin ROS activate mitogen-activated protein kinases (MAPKs) that regulate cell growth. Green tea polyphenols are effective cancer chemopreventive agents and exert their scavenging effects against ROS and also modulate MAPK activity. Because carcinogenesis, ROS, and MAPKs can be modulated by polyphenols, we examined the activation (phosphorylation) of p42/44 and p38 MAPKs in human dermal fibroblasts (HDF) by sodium arsenite (AsIII) alone and in the presence of the small molecular weight green tea polyphenol epigallocatechin 3-gallate (EGCG). Induction of the cellular antioxidant enzyme and stress sensor heme oxygenase-1 (HO-1) also was examined under these conditions. Western blot analyses indicate that noncytotoxic AsIII (< 5 µM) and hydrogen peroxide ([H202] positive ROS control) stimulate p42/44 and p38 phosphorylation and elevate HO-1 protein expression in HDF. Short-term (3 hr) EGCG treatment (< 40 µM) inhibited p42/44 phosphorylation independent of AsIII or H202 exposure. In addition, it reduced p42/44 and p38 phosphorylation at 15 and 30 minutes post-H202 treatment. No effect on HO-1 induction stimulated by AsIII or H202 was observed after short-term EGCG treatment. Long-term (24 hr) EGCG treatment (< 40 µM) had no inhibitory effect on p42/44 or p38 phosphorylation, or the induction of HO-1 stimulated by either AsIII or H202. These data indicate that EGCG has little to no effect on AsIII-stimulated MAPK activation and HO-1 induction in our experimental system. It is anticipated that data from this study will contribute to a better understanding of arsenic skin carcinogenesis and the mechanisms of polyphenols as cancer chemotherapeutics.

#### 1163

DIFFERENTIAL REGULATION OF AKT SIGNALING PATHWAY IN P53 WILD AND MUTATED CELLS AND RESISTANCE TO COPPER TOXICITY.

E. Ostrakhovitch and G. Cherian. Pathology, UWO, London, ON, Canada.

Previous studies have suggested that cells may differ in their response to metal stress depending on their p53 status. Human breast cancer epithelial cells, MDA-MB-231 cells (ER-/p53-) with mutated p53 are resistant to copper and cadmium, while, MCF-7 cells (ER+/p53+) with wild type p53 are sensitive with high degree of apoptosis. This study was undertaken to investigate the role of PI3K/Akt signaling pathway in metal resistance in these cells with different p53 status. Exposure to copper (25uM) and zinc (25uM) increased Akt phosphorylation with its nuclear localization only in MDA-MB-231 cells. The effect of zinc was transient and copper effect was persistent. Cyclin D1 expression and cell cycle progression followed the metalinduced Akt phosphorylation. Treatment with LY294002, an inhibitor of PI3K, abrogated these effects, suggesting the requirement of PI3-kinase for up-regulation of Akt and cyclin D1. In contrast in MCF-7 cells, metals increased the phosphorylation of p53 at serine 15 with transactivation of p53. In addition, metals up-regulated p21 expression and resulted in cell cycle arrest at G1 phase with apoptosis in MCF-7 cells. Addition of LY294002 had little effect on metal-induced p53 and p21 protein expression. These results demonstrate that copper induced apoptosis in MCF-7 cells is p53 dependent while the metal resistance in MDA-MB-231 cells may be due to activation of Akt phosphorylation and cell cycle progression in the absence of a functional p53 in these cells. (Supported by grants from CIHR, Canada).

#### 1164

EFFECTS OF TRIBUTYLTIN ON APOPTOSIS IN LEYDIG CELLS: CYTOCHROME C RELEASING AND CASPASE-3 ACTIVATION BY DISTURBANCE OF CA2+.

J. Choi<sup>1, 2</sup>, K. Lee<sup>1, 2</sup> and <u>H. Jeong<sup>1, 2</sup></u>. <sup>1</sup>Pharmacy, Chosun University, Kwangju, Kwangju, South Korea and <sup>2</sup>Research Center for Proteineous Materials, Chosun University, Kwangju, Kwangju, South Korea.

Tributyltin (TBT) used world-wide in antifouling paints for ships is a widespread environmental pollutant. In this study, we investigated that the mechanisms underlying apoptosis induced by TBT in rat leydig cell line, R2C. Effects of TBT on intracellular Ca2+ level and reactive oxygen species were investigated in R2C cells by fluorescence detector. TBT significantly induced intracellular Ca2+ level in a time-dependent manner. The rise in intracellular Ca2+ level was followed by a time-dependent generation of reactive oxygen species at the cytosol level. Simultaneously, TBT induced the release of cytochrome c from the mitochondrial membrane into

the cytosol. Furthermore, ROS production and the release of cytochrome c were reduced by BAPTA, an intracellular Ca2+ chelator, indicating the important role of Ca2+ in R2C during these early intracellular events. In addition, Z-DEVD FMK, a caspase-3 inhibitor, decreased apoptosis by TBT. Taken together, the present results indicated that the apoptotic pathway by TBT might start with an increase in intracellular Ca2+ level, continues with release of reactive oxygen species and cytochrome c from mitochondria, activation of caspases, and finally results in DNA fragmentation.

#### 1165

AMPLIFICATION OF THE CELLULAR RESPONSE TO PARTICULATES THROUGH TUMOR NECROSIS FACTOR AUTOCRINE SIGNALING.

B. chin, G. Holtom, C. chen and <u>B. D. thrall</u>. Molecular Biosciences Division, Pacific Northwest National Laboraoty/Battelle, Richland, WA.

The synthesis and secretion of tumor necrosis factor  $\alpha$  (TNF) by macrophages plays an important role in mediating protective responses to a known environmental hazard, particulate matter (PM). However, when exacerbated, release of TNF from macrophages may also contribute to tissue damage. We investigated the relationship between particle uptake and TNF secretion in the cellular response to PM. Using model fluorescent particles of a defined diameter (500nm), we found a dose dependent relationship between total intracellular particle ingestion and extracellular TNF release in RAW 264.7 cells. Analysis of intracellular TNF protein levels by quantitative fluorescent immunocytochemistry revealed newly synthesized TNF intensely localized in the Golgi compartment. Interestingly, despite the fact that PM ingestion was complete within 24 hours, TNF synthesis and shedding remained elevated for at least 48 hours. However, co-treatment with either a neutralizing antibody that sequesters shed TNF, or with a metalloprotease inhibitor that blocks shedding of TNF, attenuated intracellular TNF protein levels. RT-PCR and western blot analysis showed that TNF stimulates its own synthesis through an ERK-dependent mechanism. Thus, the results demonstrate an intracellular amplification mechanism in response to PM insult, mediated through autoregulation of TNF synthesis and autocrine signaling. We hypothesize that this mechanism of signal amplification plays an important role in mediating toxicity at the tissue level in response to localized PM insult

SILENCING OF THROMBOSPONDIN-1 EXPRESSION BY ESTROGEN IS REQUIRED FOR ESTROGEN-INDUCED ENDOTHELIAL CELL PROLIFERATION AND MIGRATION AND IS MEDIATED THROUGH NONGENOMIC ER-MAPK-JNK SIGNALING PATHWAY.

K. Sengupta, B. Snigdha, N. Saxena and <u>S. K. Banerjee</u>. Hematology and Oncology, University of Kansas Medical Center & VA Medical Center, Kansas City, KS

The natural hormone  $17\beta$ -estradiol ( $17\beta$ -E2) induces tumor angiogenesis in various target organs by activating positive regulators of angiogenesis. In this study, first time we show that in human umbilical vein endothelial cells (HUVECs)  $17\beta$ -E2 transiently down-regulates the expression of a potent negative regulator of angiogenesis, thrombospondin-1 (TSP-1). Furthermore, this inhibitory effect of estrogen is mediated through an estrogen receptor (ER) and can be blocked by U0126, a mitogen activated protein kinase kinase (MAPKK) inhibitor as well as by an inhibitor of JNK/SAPK, a down stream signaling protein of MAPK in these cells. These findings together suggest that the down-regulation of TSP-1 expression by  $17\beta$ -E2 is mediated through non-genomic ER-MAPK-JNK/SAPK signaling pathways. However the effect is lost with prolonged exposure to  $17\beta$ -E2, as the level of TSP-1 protein becomes stabilized. We also show that, addition of recombinant TSP-1 protein significantly reduced the migration and proliferation of HUVECs stimulated by  $17\beta$ -E2, and indicated a negative regulatory role of TSP-1 in estrogen-induced endothelial cell proliferation and migration and provides a framework for understanding the role of TSP-1 in estrogen-induced angiogenesis.

### 1167 SP600125, AN ANTHRAPYRALOZOLONE INHIBITOR OF JNK, INHIBITS B LYMPHOMA GROWTH.

M. Gururajan<sup>1,3</sup>, R. Chui<sup>3</sup>, A. K. Karuppannan<sup>2,3</sup> and S. Bondada<sup>1,2,3</sup>.

<sup>1</sup> Graduate Center for Toxicology, University of Kentucky, lexington, KY,

<sup>2</sup> Microbiology & Immunology, University of Kentucky, Lexington, KY and <sup>3</sup> Center on Aging, University of Kentucky, Lexington, KY. Sponsor: M. Vore.

The c-Jun NH2-terminal kinase (JNK), one of the three major groups of MAP Kinases, can cause cell death of many cell types by activating the mitochondrial apoptotic pathway. JNK is a stress-activated protein kinase that can be induced by inflammatory cytokines, bacterial endotoxin, osmotic shock and UV radiation. To

understand the role of JNK in B lymphoma cells, we used a panel of B cell lines viz., BKS-2, CH31 and CH12-LX of murine; Ramos and BJAB of human origin. Treatment with the recently identified pharmacological JNK inhibitor SP600125 with concentrations ranging from 0 to 20  $\mu$ M induced a dose dependent reduction in the proliferation and growth arrest at G1 phase of cell cycle in B lymphoma cells as opposed to vehicle treated cells. Moreover, the CH31 B lymphoma cells underwent apoptosis as determined by Annexin V binding. Inhibition of ERK MAP Kinase using PD98059 or UO126 had no effect on cell proliferation in BKS-2 and BJAB cells. In addition, proliferation of normal murine splenic B cells induced by a variety of mitogens was also inhibited by SP600125. We have reported earlier that inhibition of Egr-1, a pro-survival transcription factor, leads to growth arrest in BKS-2 B lymphoma. Hence we hypothesized that JNK mediated survival signals may be Egr-1 dependent. Egr-1 protein levels were reduced in BKS-2 cells treated with SP600125. Additionally, ICAM-1, a target gene of Egr-1 is downregulated in SP600125 treated BKS-2 cells suggesting that JNK mediated signals involve Egr-1. These findings reveal a pro-survival role for JNK in both murine and human models of B lymphoma. Interestingly, SP600125 had no effect on a hybridoma cell line AK11, suggesting its therapeutic potential in treating B cell lymphomas. Current studies are focused on identifying pro-apoptotic and pro-survival targets of JNK in SP600125 treated B lymphoma cells (supported by NIH grants to SB).

STRUCTURAL STABILIZATION OF CELLS DETECTED BY FTIR IS POSSIBLY DUE TO TYROSINE PHOSPHORYLATION BY RHO KINASE IN SPLENOCYTES: EFFECT OF WATER EXTRACT OF THUNBERGIA LAURIFOLIA LINN.

P. Sinhaseni<sup>1</sup>, V. Taechakitiroj<sup>1</sup>, T. Suramana<sup>2</sup>, T. Posayanonda<sup>3</sup>, N. Nuntharatanapong<sup>1</sup>, R. Sindhuphak<sup>1</sup>, S. Chivapat<sup>4</sup>, P. Chavalittumrong<sup>4</sup> and N. Dusitsin<sup>1</sup>. <sup>1</sup>Institute of Health Research, Chulalongkorn University, Bangkok, Thailand, <sup>2</sup>Pharmacology and Toxicology Unit, Faculty of Sciences, Rangsit University, Pathumthani, Thailand, <sup>3</sup>Food Control Division, Food and Drug Administration, Nonthaburi, Thailand, <sup>4</sup>Department of Medical Science, Medicinal Plant Research Institute, Nonthaburi, Thailand and <sup>5</sup>Department of Pharmacology, Faculty of Pharmaceutical, Chulalongkorn University, Bangkok, Thailand.

Rho is a small molecular weight GTP-binding protein shuttling between the GDPbound inactive form and GTP-bound active form. Rho-kinase is required for sustained ERK signaling and the consequent mid G1 phase induction of cyclin D1 in fibroblasts, as well as for stress fiber formation. We earlier reported that Balb/c3T3 cocultured with 25  $\mu$ M arsenite and 25-100  $\mu$ M apigenin (a potent flavone from Thunbergia laurifolia Linn.) could block the disruption of vinculin and actin expression induced by arsenite. Water extract of leaves of T. laurifolia was orally given to rats at 20, 200, 1000 and 2000 mg/kg/day for 180 days. Rat spleens showed FTIR shifts at amide I and phosphodiester bond when exposed to the extract at 1000 mg/kg/day. In addition, the water extract at 2000 mg/kg/day could also lead to the increase in spleen weight (p<0.05). Similar FTIR shifts were observed in the nerve dysfunction by tyrosine specific phosphorylation and tighter packing of phosphorylated proteins induced by botulinum neurotoxins. Since apigenin could inhibit in vitro effects of arsenite - which acts through EGFR signaling, Rho-kinase, and non-receptor tyrosine kinase - on actin disruption of fibroblast stress fiber observed on confocal microscope, effects of apigenin on spleens detected by FTIR could possibly be explained by the downstream effect of serum response factor (SRF)-dependent Rho A and Rho kinase leading to cellular activation and regulation of smooth muscle gene-expression. This study suggests that FTIR could be proposed as a tool used to screen/study the Rho GTPase regulation of transcription factor SRF and toxicant activated stress-signaling pathways.

#### 1169

DOES THALIDOMIDE ALTER HAVE THE ABLITIY TO ALTER PROTEIN KINASE C SIGNALING TRANSDUCTION PATHWAY.

T. N. Ezell. Biology, Morgan State University, Baltimore, MD.

In immune cells, calcium, Protein Kinase A, and Protein Kinase C (PKC) pathways are highly implicated in the expression of cytokine genes. Previous studies have shown that the over production of TNF-alpha, produced by immune cells is involved in inflammatory conditions as such septic shock, leprosy, tuberculosis, and rheumatoid arthritis. Studies have shown that thalidomide, an anti TNF- alpha agent, is know to decrease cell proliferation and decrease cell-cell adhesion potential treatment for inflammatory disorders. Yet little is known about its cellular and molecular mechanism of action. The present study explores whether thalidomide alters the PKC pathway in human monocytic cells, U937 cells and adenocarcinoma cells, HeLa cells . U937 cells at a concentration of 2 x 106 cells/ml were supplemented with RPMI 1640 medium without serum and harvested in 6 well culture plates. Next, the cells were transfected with EGFP-PKC vector using the transfection reagent DMIR-C. HeLa cells at a concentration of 1 x 105 cells/ml were supple-

mented with meduim without serum and harvested in 12-well culture plates. The HeLa cells were transfected with EGFP-PKC vector using the transfection reagent Lipofectin and Plus Reagent. After 72 hours, the transfected cells were isolated by adding 50 ng/ml of neomycin to each culture well and a stable transfected cell line was established. The stable cell lines were then treated with 0, 10, 25, and 50 ug/ml thalidomide and incubated for 24, 48, and 72 hours. The cells were then observed, photographed using fluorescence microscopy and analyzed by flow cytometry to measure alterations in PKC expression. Thalidomide treated cells exhibited a dose dependent decrease in EGFP-PKC expression. This data suggest PKC maybe involved in thalidomide-induced antinflammatory activities. (Supported by RCMI grant # G12RR017581).

#### 1170

PCB ACTIVATION OF EXTRACELLULAR SIGNAL-REGULATED KINASES (ERKS) IS MEDIATED THROUGH EPIDERMAL GROWTH FACTOR RECEPTOR AND INTRACELLULAR CALCIUM.

B. V. Madhukar, G. Chen and B. F. Wood. Pediatrics/Human Development, Michigan State University, East Lansing, MI.

Signal transduction pathways play a central role in cell proliferation, differentiation and many physiological processes. Aberrant activation of signaling cascades may lead to failure of growth control mechanisms and neoplastic growth. In ongoing studies with polychlorinated biphenyls (PCBs) we observed that orthochlorine substituted congeners activated the extracellular signal-regulated kinases (ERKs) a subgroup of mitogen activated protein kinase (MAPK) family of signal transduction kinases in liver epithelial cells. In this study, we examined the potential mechanisms of ERK activation 2, 2', 4, 4'-tetrachlorobiphenyl (TCB) a diothochlorinated PCB. Using pharmacological inhibitors and immunoblot analysis we examined the upstream targets of PCB interaction leading to activation of ERKs. TCB caused a 6to 8-fold increase in liver cells after one-hour treatment at 20 μ?M. Pre-treatment of the liver cells with an inhibitor of ERK kinase University-0126, or a tyrosine kinase inhibitor genistein, or compound-56 an inhibitor of epidermal growth factor receptor activity, or an antagonist of calcium release from endoplasmic reticulum TMB-8 prior to TCB exposure abrogated ERK activation by more than 90%. ERK activation by the TCB was not inhibited by bisindolylmaleimide (inhibitor of protein kinase C) or by the src-kinase inhibitor PP1. These results suggest that ERK activation by TCB is mediated by activation of EGF receptor tyrosine kinase. We believe that the EGF receptor activation is achieved via activation of a calcium regulated tyrosine kinase (supported by NIEHS/Superfund grant no. ES-04911 and a Philip Morris Research grant).

#### 1171

CALCIUM REGULATION OF BRAIN MITOCHONDRIAL CALCIUM / CAMP RESPONSE ELEMENT BINDING PROTEIN (CREB).

R. A. Schuh, T. Kristian, C. Chinopoulos and G. Fiskum. Anesthesiology, University of Maryland Baltimore, Baltimore, MD.

Calcium-mediated signaling regulates nuclear gene transcription by CREB via calcium-dependent kinases and phosphatases. This study tested the hypothesis that CREB is also present in mitochondria, interacts with the mitochondrial genome, and is subject to calcium-dependent modulation of its phosphorylation state. Antibodies to CREB and phosphorylated CREB (pCREB) were used to demonstrate the presence of both in highly purified mitochondrial fractions isolated from rat brain. Gel mobility shift assays using oligonucleotides containing a partial CREB response element (CRE) located in the displacement loop regulatory region of the mitochondrial DNA (mtDNA) heavy strand indicated that mitochondrial extracts contain proteins capable of binding to this site. When energized mitochondria were exposed to physiological levels of Ca2+, pCREB levels were reduced while total CREB remained constant. Additionally, the calmodulin antagonist calmidazolium decreased pCREB levels. Conversely, EGTA, okadaic acid, cyclosporin A and FK506 treatment increased pCREB levels suggesting phosphatase activity plays a role in mitochondrial pCREB/CREB levels. Exposure of mitochondria to the pore-forming molecule alamethicin resulted in osmotic swelling, disruption of the outer membrane, and a reduction in CREB but not pCREB mitochondrial immunoreactivity. These results suggest that pCREB is located exclusively in the mitochondrial matrix or inner membrane while CREB resides in the intermembrane space. Thus, a calcium-dependent phosphatase such as calcineurin may regulate the intramitochondrial distribution and possibly the transcriptional activating activity of mitochondrial pCREB/CREB. This form of regulation may affect mitochondrial gene expression following acute brain injury as early, post-ischemic pCREB dephosphorylation and delayed pCREB hyperphosphorylation were observed in brain mitochondria isolated following global cerebral ischemia and reperfusion. (Supported by NIH NS34152, DAMD 17-99-1-9483 and AHA 0256359U)

#### 1172

COX-2 INDUCTION BY BOVINE TYPE I COLLAGEN IN MACROPHAGES VIA C/EBP AND CREB ACTIVATION.

M. Cho, Y. Cho, G. Lee and <u>S. Kim</u>. College of Pharmacy, Seoul National University, Seoul, South Korea.

Bovine type I collagen (Col-I) is utilized for medical purposes such as cosmetic surgery and wrinkle removal. Cyclooxygenase-2 (COX-2) plays roles in pathophysiological processes including inflammation and tumorigenesis. This study examines the effects of Col-I on the COX-2 expression in macrophages and the signaling pathways responsible for the enzyme induction. Col-I increased the levels of COX-2 protein and mRNA in Raw264.7 cells in a time- and concentration-dependent manner. Treatment of cells with Col-I increased protein binding to the CCAAT/enhancer binding protein (C/EBP) binding oligonucleotide. Antibody supershift experiments revealed that C/EBP DNA binding activity induced by Col-Î depended largely on C/EBPβ and C/EBPδ. Col-I caused C/EBPβ translocated to the nucleus and overexpression of the dominant-negative mutant form of C/EBP abolished COX-2 induction by Col-I. Col-I increased binding of other transcription factors CREB and NF-κB to DNA. Inhibition of focal adhesion kinase (FAK) or downstream PI3-kinase and p70S6 kinase by specific chemical inhibitors prevented COX-2 induction by Col-I and also C/EBP and CREB from binding to their consensus DNA oligonucleotides. Experiments using chemical inhibitors or dominant negative mutant vectors showed that the MAP kinase pathways including p38 kinase and ERK1/2, but not JNK1, simultaneously regulated COX-2 induction by Col-I. This was in agreement with inhibition of Col-I-inducible C/EBP and CREB DNA binding in the cells concomitantly treated with SB203580 and PD98059. These results provide evidence that Col-I induces COX-2 in macrophages and that the multiple cell signaling pathways involving FAK, PI3-kinase and MAP kinases regulate COX-2 induction by Col-I via C/EBPβ and CREB activation.

### 1173 GSTA2 GENE REPRESSION BY GR-ASSOCIATED SMRT BINDING TO ACTIVATING C/EΒΡβ AND NRF2.

S. Ki, I. Cho, D. Choi, M. Cho and <u>S. Kim</u>. College of Pharmacy, Seoul National University, Seoul, South Korea.

The expression of glutathione S-transferase (GST) gene, whose induction accounts for cancer chemoprevention, is regulated by activation of CCAAT/enhancer binding protein-β (C/EBPβ) and NF-E2-related factor-2 (Nrf2). The present study investigated the repressing effect of ligand-bound glucocorticoid receptor (GR) on C/EBPB- and Nrf2-mediated induction of the GSTA2 gene and explored the mechanistic basis for the gene repression. Dexamethasone (10-100 nM) that activates GR persistently inhibited constitutive GSTA2 expression in H4IIE cells. Induction of GSTA2 by oltipraz or tert-butylhydroquinone (t-BHQ) was also markedly repressed by dexamethasone. Inhibition of the constitutive and inducible GSTA2 expression by dexamethasone was abolished by treatment of cells with a GR antagonist RU486. Dexamethasone-GR activation did not suppress nuclear translocation of C/EBP\$ or Nrf2 nor their DNA binding activities induced by oltipraz or t-BHQ, but suppressed inducible luciferase reporter-gene activity in the cells transfected with the -1.65 kb flanking region of the GSTA2 gene. Deletion of the distal glucocorticoid response element (GRE) abolished dexamethasone inhibition of the GSTA2 gene induction. Immunoprecipitation-immunoblot and GST pulldown assays revealed that silencing mediator for retinoid and thyroid-hormone receptors (SMRT), a corepressor recruited to steroid-GR complex, bound to activating C/EBPB and Nrf2. Decreases in the constitutive and inducible GSTA2 promoter-luciferase activities by transfection of cells with the plasmid encoding SMRT directly evidenced the functional role of SMRT in GSTA2 repression. These results demonstrate that dexamethasone antagonizes C/EBPβ- and Nrf2-mediated GSTA2 gene induction via ligand-GR binding to the GRE and that steroid-mediated GSTA2 repression involves inactivation of C/EBPB and Nrf2 by SMRT recruited to steroid-GR complex.

### 1174 REGULATION OF NRF-2 BY GLUTATHIONE AND THIOREDOXIN.

J. M. Hansen<sup>1</sup>, W. H. Watson<sup>2</sup> and D. P. Jones<sup>1</sup>. <sup>1</sup>Biochemistry, Emory University, Atlanta, GA and <sup>2</sup>Environmental Health Sciences, Johns Hopkins University, Baltimore, MD.

Nrf-2 is a redox-sensitive transcription factor implicated in the regulation of genes controlled by the antioxidant response element (ARE). While oxidative signals appear necessary for initial Nrf-2 activation in the cytoplasm, extensive oxidation would result in the loss of DNA binding in the nucleus. Reducing environments, which are largely maintained by glutathione (GSH) and other small biothiols, effectively block Nrf-2 activation. HeLa cells transfected with an ARE4-Luciferase reporter were treated with BSO to deplete GSH and showed a 93% increase in Nrf-2 activity, while N-acetylcysteine (NAC) and glutathione monoethylester (GSHM)

treatments decreased Nrf-2 activity significantly. The addition of tert-butyl hydroquinone (TBHQ), a Nrf-2 activator, increased Nrf-2 activity by 20%. BSO pretreatment prior to TBHQ treatment resulted in a 173% increase in Nrf-2 activity, but NAC and GSHM pretreatments were not significantly different from non-TBHQ treated cells. Immunocytochemistry verified BSO stimulation and NAC and GSHM inhibition of Nrf-2 activation and translocation to the nucleus. Thioredoxin-1 (TRX1) expression vectors, both the wild type and the active site mutant (C35S), also affected Nrf-2 activity. TRX1 increased Nrf-2 activity by 70% in unstimulated cells, while C35S TRX1 decreased activity by 44%. The addition of TBHQ to TRX1 transfected cells resulted in a 95% increase as compared to control, but there was no change in cells transfected with C35S TRX1. Because TRX1 overexpression does not inhibit Nrf-2 activity it indicates that TRX1 regulation most likely occurs at a step other than activation in the cytoplasm. Transfection with a TRX1 construct containing a nuclear localization sequence potentiated Nrf-2 activity both with and without TBHQ by 220 and 140%, respectively, implicating TRX1 to play a specific role in the nucleus. These findings suggest Nrf-2 activation in the cytoplasm is primarily regulated by GSH while Nrf-2/DNA binding is primarily regulated by TRX1.

## 1175 HMGA1A BEHAVES AS A STRESS-REGULATED TRANSCRIPTION FACTOR IN VASCULAR SMOOTH MUSCLE CELLS.

L. R. Chapman<sup>1, 2</sup>, C. D. Johnson<sup>1, 2</sup>, M. H. Falahatpisheh<sup>1, 2</sup> and <u>K. S. Ramos<sup>1, 2</sup></u> Biochemistry and Molecular Biology, University of Louisville, Louisville, KY and <sup>2</sup>Center for Genetics and Molecular Medicine, University of Louisville, Louisville, KY.

High mobility group A1a (HmgA1a) is a non-histone chromosomal protein that preferentially binds in a non-sequence specific fashion to the minor groove of A-T rich DNA via highly conserved motifs called "A-T hooks". HmgA1a functions as an architectural transcription factor that regulates gene expression by controlling the assembly of stereo-specific multi-protein complexes in the regulatory region of target genes. The interaction of HmgA1a with DNA removes the intrinsic bend of the double helix to allow binding of transcription factors in the opposing major groove. Overexpression of Hmg genes correlates with neoplastic transformation and increased metastatic potential in cancer cells and chromosomal rearrangements in benign tumors of human mesenchymal cells. Here we report that oxidative injury by benzo(a)pyrene (BaP) modulates expression of the *HmgA1a* gene in vascular smooth muscle cells (vSMCs). In these experiments, murine vSMCs were established in serial culture using standard procedures and challenged with 3  $\mu M$  BaP for 1, 2, 8, 16 and 24 hr. At the end of the desired treatments, cultures were processed for measurements of HmgA1a, HmgA2, HmgB1, HmgB2, HmgB3 and HmgN1 gene expression by Real Time PCR. BaP increased HmgA1a expression in a time-dependent manner with a greater than seven-fold increase in mRNA levels observed by 8 hr and a return to control levels by 16 hr. These findings are consistent with recent DNA microarray experiments in the laboratory showing that the adaptive response of vSMCs to BaP injury is associated with redox-independent increases in the expression of the HmgA1a gene. Only transient increases in the expression of the HmgB2 and HmgB3 genes were observed by 2 hr in BaP-treated cells. These findings implicate HmgA1a as a stress-regulated architectural transcription factor in the response of vSMCs to atherogenic stimuli. (Supported by NIH grants ES04849, ES09106 to KSR, ES012117 to CDJ and ES012542 to MHF).

## 1176 GROWTH FACTOR-INDUCED REACTIVE OXYGEN SPECIES OXIDIZE GLUTATHIONE AND THIOREDOXIN-1 IN A DIFFERENTIAL MANNER.

P. J. Halvey<sup>1, 3</sup>, <u>W. H. Watson</u><sup>2</sup>, Y. Go<sup>1</sup>, <u>J. M. Hansen</u><sup>1</sup> and <u>D. P. Jones</u><sup>1</sup>.

<sup>1</sup>Biochemistry, Emory University, Atlanta, GA, <sup>2</sup> Environmental Health Sciences, Johns Hopkins University, Baltimore, MD and <sup>3</sup>Biochemistry, NUI Galway, Galway, Connacht, Ireland.

During oxidative stress conditions, the redox state of specific thiol redox couples is altered in proportion to the applied stress. Glutathione (GSH) and thioredoxin-1 (TRX1) are two such couples. GSH is the most abundant non-protein thiol, while TRX1 is a 12kDa oxidoreductase involved in regulation of redox-dependent proteins. Epidermal growth factor (EGF) signaling leads to the production of reactive oxygen species (ROS). Here we examine the effects of EGF-signaling on GSH and TRX1 in human keratinocytes (HaCaT). Using a dichlorofluorescein assay, we observed a 22% increase in ROS in EGF (200 ng/ml) treated cells after five minutes. GSH and the disulfide form (GSSG) were quantified by HPLC. EGF did not cause any significant oxidation of the GSH/GSSG redox couple compared to untreated controls. A Redox Western blot methodology for quantification of TRX1 redox state revealed a more robust oxidation of cytoplasmic TRX1 compared with nuclear TRX1 after EGF treatment. The redox potential of cytoplasmic TRX1 increased by 15mV, whereas a much smaller increase was noted in the nucleus (<2mV) at two minutes EGF treatment. Nuclear TRX1 also recovers faster than cytoplasmic

TRX1. Nuclear TRX1 redox state returned to control levels after 10 minutes, but cytoplasmic TRX1 redox state remained more oxidized than untreated controls even after 30 minutes. Taken together these results suggest that TRX1 is a specific target for oxidation during EGF-signaling, while the GSH pool is not. The differential response of nuclear and cytoplasmic TRX1 to EGF-induced ROS has implications for growth factor signaling. Low nuclear TRX1 oxidation may confer a protective effect on the nucleus during proliferation, thus insuring that all TRX1-dependent processes function normally.

### 1177 A ROLE FOR P38 MAPK IN ROS-INDUCED ONCOTIC CELL DEATH IN RENAL CELLS.

J. Dong, S. Ramachandiran, S. S. Lau and T. J. Monks. Department of Pharmacology & Toxicology, University of Arizona Health Sciences Center, Tucson, A7

Reactive oxygen species (ROS) are associated with a variety of human diseases, and toxicities mediated by redox-active chemicals and/or their metabolites. 2, 3, 5-tris-(glutathion-S-yl)hydroquinone (TGHQ), a reactive metabolite of the nephrotoxicant hydroquinone, induces the ROS-dependent activation of p38 mitogen activated protein kinases (MAPK) in renal proximal tubule epithelial cells (LLC-PK<sub>1</sub>). TGHQ-induced histone H3 phosphorylation precedes oncotic cell death following MAPK activation. Cell death and histone H3 phosphorylation are both attenuated by inhibition of p38 MAPK (SB202190). To further investigate the role of p38 MAPK in TGHQ-induced ROS-dependent cell death, we transfected LLC-PK, cells with dominant negative p38 MAPK expressing plasmid (pcDNA3-DNp38), and functional p38 MAPK expressing plasmid (pcDNA3-p38). Although pcDNA3-DNp38 transfected cells express identical levels of constitutive p38 MAPK as pcDNA3-p38 transfected cells, TGHQ fails to induce p38 MAPK phosphorylation only in the pcDNA3-DNp38 transfected cells. TGHQ also fails to induce phosphorylation of MAPK activated protein kinase-2 (MK-2), a kinase activated by p38 MAPK, only in pcDNA3-DNp38 transfected cells, indicating loss of function of p38 MAPK. In pcDNA3 and pcDNA3-p38 transfected LLC-PK, cells, Hsp27, a downstream effector of MK-2, is intensively phosphorylated after TGHQ treatment, whereas in pcDNA3-DNp38 transfected cells, TGHQ fails to induce Hsp27 phosphorylation. Immunocytochemical staining of p-Hsp27 revealed association of p-Hsp27 with cell death in TGHQ-treated LLC-PK, cells. Thus, p38 MAPK activation by TGHQ leads to activation of two downstream signaling cascades: histone H3 and Hsp27 phosphorylation, which have in common the potential ability to remodel chromatin. Because inappropriate chromatin condensation has been linked to TGHQ-induced cell death, p38 MAPK activation and downstream signaling factors may play important roles in ROS-mediated oncotic cell death in LLC-PK<sub>1</sub> cells. (DK59491)

## 1178 EFFECTS OF BENZOQUINONE (BQ) ON CELL PROLIFERATION VIA ERK/MAPK SIGNALING PATHWAY ACTIVATION AND ROS PRODUCTION.

R. Ruiz-Ramos<sup>1</sup>, <u>M. E. Cebrian</u><sup>1</sup> and E. Garrido<sup>2</sup>, <sup>1</sup>Toxicology Section, CINVESTAV IPN, Mexico City, D.F., Mexico and <sup>2</sup>Genetics and Molecular Biology, CINVESTAV-IPN, Mexico City, D.F., Mexico.

Benzene (BZ) is a hydrocarbon present in the atmospheric air, and is a common component of gasoline, tobacco smoke and other daily used petroleum derivative products as cosmetics, medicines, etc. In the last few years, BZ has been associated to blood and bone marrow pathologies, expressed as lymphocytopenia, pancytopenia, aplastic anemia and acute myelogenous leukemia. BZ metabolism produces BQ as well as free radicals and other reactive oxygen species (ROS), which are believed to be involved in the activation of signaling pathways that regulate transcription factors and the expression of genes that regulate proliferation, differentiation and apoptotic processes. BQ acute exposure induced cell growth, as measured by BrdU incorporation, in human promyelocytic HL-60 cells. This effect was related with increases in reactive oxygen species (ROS) levels, as measured by 2, 7-dichloro fluorescein diacetate oxidation. In addition, we detected ERK activation by using specific antibodies against phosphorylated ERKs proteins, suggesting the potential involvement of this pathway in BZ/BQ-induced proliferation.

## 1179 INDUCTION OF ANTIOXIDANT AND DETOXIFICATION RESPONSE WITH H<sub>2</sub>O<sub>2</sub> IN CARDIAC CELLS

S. E. Purdom<sup>1</sup>, J. A. Johnson<sup>2</sup> and Q. M. Chen<sup>1,3</sup> <sup>1</sup> Graduate Program in Genetics, University of Arizona, Tucson, AZ, <sup>2</sup> School of Pharmacy, University of Wisconsin, Madison, WI and <sup>3</sup> Department of Pharmacology, University of Arizona, Tucson, AZ.

Oxidants have been shown to contribute to the toxicity of various environmental toxicants and to a number of diseases including heart disease. The two major cell types in the heart are cardiomyocytes and fibroblasts. While cardiomyocytes de-

velop hypertrophy, fibroblasts contribute to fibrosis during heart injury. We tested the response of these two cell types to oxidants by analyzing their gene expression profiles and identifying the transcription factors responsible for the changes in gene expression. Microarray analyses using Affymetrix chips containing 20K genes found that a sublethal dose of H2O2 (100 µM) caused about 1% of genes to increase expression to 2-fold or higher in cardiomyocytes and cardiac fibroblasts. Among those induced are antioxidant and detoxification genes containing the antioxidant response element (ARE) in their promoters, such as NAD(P)H:quinone oxidoreductase-1 (NQO1) and heme oxygenase-1 in cardiomyocytes and NQO1 and glutathione S-transferase in fibroblasts. ARE promoter-luciferase reporter assays demonstrated that the ARE is activated in an H<sub>2</sub>O<sub>2</sub> dose-dependant manner in cardiomyocytes. The peak activation of ARE, an average of about 5 fold, occurred at 4 hrs post 10-min treatment with 100  $\mu M$   $H_2O_2$ . This level of activation was comparable to the positive control tert-butylhydroquinone. No induction was detected with a luciferase reporter plasmid containing an empty or a mutant ARE promoter after H<sub>2</sub>O<sub>2</sub> treatment. NF-E2-related factor 2 (Nrf2) is a basic leucine zipper transcription factor that can bind to the ARE. Expression of dominant-negative Nrf2 abolished ARE activation by H2O2. A dominant negative form of c-Jun, which is thought be a dimerization partner of Nrf2 in certain experimental systems, did not affect ARE activation by H2O2. These data suggest that oxidants can induce survival or adaptive responses by activating the expression of antioxidant and detoxification genes in cardiomyocytes and cardiac fibroblasts.

1180

DIFFERENTIAL REGULATION OF THE NRF2- AND AP-1-RESPONSE ELEMENTS BY 4-HYDROXY-2-NONENAL, t-BUTYLHYDROQUINONE AND PHORBOL 12-MYRISTATE 13-ACETATE IN CULTURED HEPATIC STELLATE CELLS.

J. F. Reichard and D. R. Petersen. Toxicology, University of Colorado Health Sciences Center. Denver. CO.

Stellate cell activation is a central event in liver fibrosis characterized by increased extracellular matrix production and cell proliferation. Oxidative stress has been implicated as an activator of the bZIP transcription factors Nrf2 and AP-1 through shared kinase signaling pathways that purportedly mediate stellate cell activation. The present study examined Nrf2- and AP-1-mediated gene expression following oxidative stress in cultured hepatic stellate cells. Reporter constructs generated by mutation of the AP-1- and Nrf2-binding elements of the human nqo1 promoter demonstrated that the Nrf2 element was fully responsible for mediating inducible gene expression in response to the prooxidants 4-hydroxy-2-nonenal and tertbutylhydroquinone. Contrastingly, the AP-1 element was incapable of mediating inducible expression in response to either oxidative stress or PMA, despite the presence of Fos- and Jun-related nuclear proteins. When present together, the Nrf2 and AP-1 elements acted synergistically to mediate high-level basal promoter activity. Identification of AP-1 family proteins revealed heterodimeric binding complexes consisting predominantly of Fra-1, Fra-2, JunB and JunD proteins, with little c-Fos, FosB or c-Jun. With exception of a 2-fold increase in nuclear c-Fos following PMA treatment, neither electrophiles nor PMA treatment appreciably altered the presence of AP-1 proteins. Taken together, these data demonstrate that, although overlapping kinase-signaling pathways activates AP-1 and Nrf2 transcription factors, oxidative stress discretely activated Nrf2, while AP-1 was insufficient to convey independent reporter induction. This observation is significant in context of the physiologic importance attributed to the AP-1 in mediating essential profibrogenic gene expression during liver fibrogenesis.

### 1181 INDUCTION OF CYCLOOXYGENASE-2 BY H<sub>2</sub>O<sub>2</sub> AND CORTICOSTERONE IN CARDIOMYOCYTES.

H. Sun and Q. M. Chen. Pharmacology, University of Arizona, Tucson, AZ.

Heart disease is the number one cause of natural death worldwide. A large body of evidence has indicated a role of oxidants in myocardial infarction and other types of heart disease. Although cyclooxygenase-2 (COX-2) can contribute to an inflammatory response, induction of COX-2 has been shown to be cytoprotective in cardiomyocytes in vitro and in vivo. Oxidants and the stress hormone corticosterone are thought to be detrimental to the heart. However, our gene array work has found COX-2 and a number of cytoprotective genes induced by these two stimuli in cardiomyocytes. An increase of ĈOX-2 mRNA and protein was detected with either oxidants or corticosterone treatment by RT-PCR and Western blot. The optimal dose for COX-2 induction was 50-100 µM for H<sub>2</sub>O<sub>2</sub> and 0.25-1 µM for corticosterone. The peak increase of COX-2 protein occurred at 2-4 hour after 1 hour treatment with 100 μM H<sub>2</sub>O<sub>2</sub> or at 32 hour in cells treated with 1 μM corticosterone. While the induction of COX-2 is transient and returned to basal level within 10 hours for H<sub>2</sub>O<sub>2</sub>, elevation of COX-2 is sustained for 3 days with corticosterone treatment. The p38 MAPK inhibitor SB202190 but not inhibitors of JNKs, ERKs or PI3K prevented H<sub>2</sub>O<sub>2</sub> from inducing COX-2 elevation. In contrast, the glucocorticoid receptor antagonist mifepristone inhibited COX-2 induction by corticosterone. Using the TranSignal array technique to screen for activated transcription factors, we found that oxidants and corticosterone activated several transcription factors in common. The roles of these transcription factors in elevation of COX-2 expression are under investigation.

1182

INDUCTION OF METALLOTHIONEIN I BY PHENOLIC ANTIOXIDANTS REQUIRES METAL-ACTIVATED TRANSCRIPTION FACTOR 1 (MTF-1) AND ZINC.

Y. Bi<sup>1</sup>, R. D. Palmiter<sup>2</sup>, K. M. Wood<sup>1</sup> and Q. Ma<sup>1</sup>. <sup>1</sup>HELD/CDC, TMBB/NIOSH, Morgantown, WV and <sup>2</sup>Biochemistry, Howard Hughes Medical Institute, University of Washington School of Medicine, Seattle, WA.

Phenolic antioxidants, such as tert-butyl-hydroquinone (tBHQ), induce metallothionein (Mt1) gene expression. Induction of Mt1 mRNA correlates with oxidationreduction functions of the antioxidants. Here we analyzed the biochemical pathway of the induction. Induction depends upon the presence of MTF-1, a transcription factor that is required for metal-induced transcription of Mt1, but does not require Nrf2, a tBHQ-activated CNC bZip protein that is responsible for regulating genes encoding phase II drug-metabolizing enzymes. Moreover, tBHQ induces the expression of MRE-bGeo, a reporter gene driven by five metal regulator elements (MREs) that constitute an optimal MTF-1 binding site. Reconstitution of Mtf1null cells with MTF-1 restores induction by both zinc and tBHQ; however, reconstitution with only the DNA-binding domain of MTF-1 fused to VP16 activation domain allows in induction by zinc but not by tBHQ. Unlike activation of phase II genes by tBHQ, induction of Mt1 expression does not occur in the presence of EDTA, when cells are cultured in zinc-depleted medium, or in cells with reduced intracellular 'free' zinc due to overexpression of ZnT1, a zinc-efflux transporter, indicating that induction requires zinc. These findings establish that phenolic antioxidants activate Mt1 transcription by a zinc-dependent mechanism that involves MTF-1 binding to MREs.

1183

PI3-KINASE REGULATES CA<sup>2+</sup>-DEPENDENT NRF2 TRANSLOCATION FROM THE CYTOPLASM TO THE PLASMA MEMBRANE PRIOR TO ITS NUCLEAR TRANSLOCATION.

K. Kang  $^{1,\,2}$  and <u>S. Kim</u>  $^2$ .  $^1$  College of Pharmacy, Chosun University, Gwang-Ju, South Korea and  $^2$  College of Pharmacy, Seoul National University, Seoul, South Korea.

Expression of phase II detoxifying genes is regulated by NF-E2-related factor 2 (Nrf2)-mediated antioxidant response element (ARE) activation. Phosphatidylinositol 3-kinase (PI3-kinase) regulates nuclear translocation of Nrf2 through the rearrangement of actin microfilaments in response to prooxidants. We further studied the role of PI3-kinase signaling pathway in the rise of cellular Ca<sup>2+</sup> and the translocation of Nrf2 to the plasma membrane. Immunocytochemistry and subcellular fractionation analyses revealed that pretreatment of cells with tert-butylhydroquinone (t-BHQ) inhibited the translocation of Nrf2 to the plasma membrane, whereas treatment of cells immediately after addition of PI3-kinase inhibitors (control experiment) caused Nrf2 to migrate to the plasma membrane before nuclear translocation. t-BHQ treatment stimulated a rise in [Ca<sup>2+</sup>]i, which was prevented by PI3-kinase inhibition. Chelation of cellular calcium suppressed Nrf2 migration to the plasma membrane. Conversely, A23187 a calcium ionophore, allowed cytoplasmic Nrf2 to move to the plasma membrane in the cells exposed to both t-BHQ and Pl3-kinase inhibitor. Immunoblot analysis confirmed that either Pl3-kinase inhibition or Ca<sup>2+</sup> chelation prevented GSTA2 induction by t-BHQ. These results demonstrated that the PI3-kinase pathway regulates Ca<sup>2+</sup>-dependent translocation of Nrf2 from the cytoplasm to the plasma membrane prior to its nuclear translocation.

1184

NICOTINE USES T CELL ANTIGEN RECEPTOR-INDEPENDENT AND -DEPENDENT SIGNALING PATHWAYS TO AFFECT INFLAMMATORY AND ADAPTIVE IMMUNE RESPONSES.

N. C. MISHRA, <u>S. Razani-Boroujerdi</u>, S. Singh, R. Langley, <u>R. Kalra</u>, J. C. Pena-Philippides and <u>M. L. Sopori</u>. *Immunology Program, Lovelace Respiratory Research Institute, Albuquerque, NM*.

Development of adaptive T cell immunity requires activation of the T cell antigen receptor (TCR), leading to increased intracellular Ca2+ levels ([Ca2+]i), T cell proliferation, and differentiation, while activation (nuclear translocation) of the transcription factor NF-KB is the hallmark of an inflammatory response. Activation of TCR through ligation by anti-TCR antibodies, increases Ca2+ and nuclear localization of NF-KB. Chronic exposure to cigarette smoke/nicotine suppress both

adaptive and inflammatory responses. Immunosuppression by nicotine is causally associated with constitutive activation of protein tyrosine kinases (PTKs) and the impaired Ca2+ response. We now show that chronic NT treatment of rats via subcutaneously implanted Alzet pumps constitutively activates the Src-like PTKs, Fyn and Lck, and nuclear localization of the transcription factor NF-κB in T cells. Mammalian T cells have α7-nicotinic acetylcholine-like receptors, and exposure of rat T cells or the human T cell line (Jurkat cells) to nicotine or anti-TCR antibodies activates Fyn kinase activity, increases the intracellular Ca2+ concentration ([Ca2+]i), and promotes nuclear localization of NF-κB. However, neither anti-TCR antibodies nor nicotine treatment stimulate Fyn kinase or the Ca2+ response in CD3- $\zeta$  or Lck deficient Jurkat cells, indicating that effects of nicotine on the Ca2+ response in T cells requires a functionally intact TCR. Interestingly, in the mutant Jurkat cells, nicotine promoted the activation of ERK and nuclear localization of NF-KB. These results strongly suggest that while activation of TCR induces both Ca2+ and NF-κB responses, nicotine may affects the two responses through different signaling pathways. Moreover, acute effects of nicotine on T cell function may be distinct from its chronic effects.

### THE EFFECTS OF THALIDOMIDE ON C-MYB SIGNALING.

N. A. Thadani<sup>1</sup> and <u>L. M. Winn<sup>1, 2, 1</sup> Pharmacology and Toxicology</u>, Queen's University, Kingston, ON, Canada and <sup>2</sup>School of Environmental Studies, Queen's University, Kingston, ON, Canada.

Despite its devastating birth defects thalidomide is being used therapeutically to treat a number of diseases, including leukemia. While thalidomide's mechanism of action remains unknown, it is postulated that exposure to thalidomide leads to increased ROS, which can inhibit NF-kappa B, which upregulates the anti-apoptotic kinase Pim-1. Pim-1 signaling involves the transcription factor c-Myb, which is involved in the regulation of differentiation and apoptosis. We hypothesize that thalidomide acts by interfering with the c-Myb signaling pathway and ultimately leads to increased apoptosis. To investigate this hypothesis, human K-562 cells were transfected with a Myb-responsive luciferase reporter plasmid derived from the chicken mim-1 promoter, along with control DNA and a plasmid expressing c-Myb. Subsequently, cells were exposed to thalidomide (0-80 µg/ml) for 1 hour. Luciferase activities were then measured to evaluate c-Myb activity using a dual-luciferase protocol. Results showed that cells exposed to thalidomide (20-80 µg/ml) had significantly decreased c-Myb activity compared to cells exposed to the vehicle control. A one hour pre-incubation of these cells with either the anti-oxidative enzyme catalase (1600 units/ml), or the NF-kappa B inhibitor SN-50 (20 μM) prevented the decrease in c-Myb activity, suggesting a role for ROS and NF-kappa B in the c-Myb signaling pathway. In addition, western blot analysis on thalidomide exposed (20-80 µg/ml) untransfected cells showed a decrease in Pim-1 expression, but not in NF-kappaB expression. Futhermore, in cells transfected with a plasmid containing the c-myb gene we found that thalidomide (20-80  $\mu g/ml$ ) caused a decrease in phosphorylated c-Myb expression. These results suggest that the decrease in Pim-1 and phosphorylated c-Myb expression may be responsible for the observed decreases in c-Myb activity. This study supports the hypothesis that ROS, NF-kappa B and Pim-1 are factors in the thalidomide-induced changes on c-Myb, which may mediate thalidomide's toxicity and therapeutic action. ESTABLISHMENT OF THE PUBLIC SAMPLE BANK TO MONITOR A LONG-TERM TREND OF HUMAN EXPOSURE TO PERSISTENT ORGANIC POLLUTANTS (POPS).

K. Inoue, A. Koizumi, T. Yoshinaga, K. Harada and N. Saito. *Health Environmental Sciences, Kyoto University Graduate School of Medicine, Kyoto, Japan.* Sponsor: R. Reitz.

The Pops is a class of chemicals that are persistent in the environments. A large majority of current Pops is banned or under tight regulations but new classes of Pops, such as perfluorooctane sulfonate (PFOS) and perfluorooctanoic acid (PFOA), are emerging. To evaluate risks of these chemicals and efficacy of regulations and management, long-term trends of human exposures to Pops should be evaluated. The aim of the present study is to establish a public sample bank for monitoring human exposures. Materials and methods:Samples-The samples were composed of three groups.Group I: Samples were composed of human serums and meals. Those samples were collected twice at 55 sites in Japan in the early 1980s and middle of 1990s. Serums were collected from those who donated meals. Group II: Samples are composed of breast milk and serums. These were collected local health centers. Three centers (Sendai, Akita and Yokote) donated the samples. Samples were collected from the late 1970s to 1990s. Group III: Samples are composed of current samples, consisting of breast milk, meals, and serums. Sampling sites will cover all over Japan. Results and Discussion: Group I samples were composed of 1, 700 samples. These samples were suitable for long term biological monitoring for Pops. Group II samples were composed of 90 breast milk samples and 3, 000 serum samples. The group III is now under construction and its sampling sites will cover all

over Japan. This will provide the basis of modern samples. These samples were stocked at -20C.Volumes of serum and meal samples were 1-2ml and 1kg. Therefore, we should develope analytical methods using trace amounts of samples for monitoring. (This project is supported grant-in aids by Research on Environmental Health, H15-KAGAKU-004).

### 1187 CHRONIC TOXICITY INCLUDING CARCINOGENICITY OF HPCDD OBEYS THE C X T = K PARADIGM.

K. K. Rozman<sup>1,3</sup>, M. Lebofsky<sup>1</sup> and D. M. Pinson<sup>2</sup>. <sup>1</sup>Pharmacology, Kansas University Medical Center, Kansas City, KS, <sup>2</sup>Pathology, Kansas University Medical Center, Kansas City, KS and <sup>3</sup>Toxicology, GSF, Neuherberg, Germany.

Prior to this study, the carcinogenicity of TCDD, but not of 1, 2, 3, 4, 6, 7, 8-heptachloro-dibenzo-p-dioxin (HpCDD), had been reported in great detail. It was expected that under conditions of continuous exposure the spectrum of chronic effects of HpCDD would be identical to those of TCDD even in single dose experiments because of the long half-life(314 days)of HpCDD. The hypothesis tested was that chronic toxicities of HpCDD also occur according to the  $c \times t = k$ paradigm. A total of 338 female SD rats (180 days old, bw 270-310 g) were housed individually and provided feed and water ad libitum. HpCDD was administered as a single dose via oral gavage at 4 mL/kg in four dose rates at 12 hour intervals due to low solubility of the HpCDD in corn oil. The last dose rate was considered day 0 of each experiment. The doses and number of animals per group (in parenthesis) were: 0(36), 1.0(30), 2.5(30), 2.8(60), 3.1(30), 3.4(32), 3.8(30), 4.1(30), 5(30), and 10(30) mg/kg. Rats were allowed to live out their allotted life span. Each rat was necropsied and bone, kidneys, lungs, liver, GI-tract and heart were procured and stored in 10% neutral buffered formalin for histological analysis. Doses of 2.5 mg/kg and higher decreased life expectancy in a highly predictable fashion. Average life expectancy of control animals was 540 days (+ 180 days = day 0 of study). For survivors of the acute toxicity, the chronic c x t product was remarkably constant  $(1180 \pm 52.6 \text{ mg/kg·day})$  with a mere 4.5% variability. In contrast, the lowest dose (1.0 mg/kg) prolonged the life of rats by about 2 months. Squamous cell carcinoma of the lungs was the most sensitive and most frequent (up to 73.3%) endpoint of toxicity. There was neither lung nor liver cancer at the lowest dose and overall cancer rate was reduced.

COMPARISON OF OVERALL METABOLISM OF 1, 2, 3, 7, 8-PENTACHLORODIBENZO-P-DIOXIN (PECDD) IN CYP1A2 (-/-) KNOCKOUT (KO) AND C57BL/6N PARENTAL STRAINS OF MICE.

J. J. Diliberto<sup>1</sup> and H. Hakk<sup>2</sup>. <sup>1</sup>PKB, ETD, NHEERL ORD, USEPA, Research Triangle Park, NC and <sup>2</sup>ARS, BRL, USDA, Fargo, ND. Sponsor: <u>L. Birnbaum</u>.

The toxic dioxin congener, PeCDD, induces hepatic cytochrome CYP1A2 to which it subsequently binds. Metabolism of PeCDD is very limited. Whether it is a poor substrate for metabolizing enzymes or unavailable for metabolism due to its strong affinity to CYP1A2 is not known. Thus, we tested the hypothesis that sequestration of PeCDD by CYP1A2 makes PeCDD unavailable for metabolism that would readily occur in its absence. Male C57BL/6N mice which possess or lack the CYP1A2 gene were given orally 116 ug [14C]PeCDD/kg. After 4 da, mice housed in metabolism cages with separate collection of urine and feces every 24h were killed & tissues collected. Tissue deposition & overall metabolism in urine/feces were quantitated. Similar to previously reported studies, liver:fat ratios were different, 5.8 (C57BL/6N) vs 0.4 (KO). Slightly higher 14C-derived PeCDD levels were excreted in C57BL/6Ns feces at each time pt compared to KOs; similar levels were excreted in urine of both strains. Overall level of metabolism of PeCDD was determined as sum of 14C in 0-96h urine, non-extractable feces, & metabolites in extractable feces. Parental strain had greater overall metabolism than KO mice: 15.0% vs 7.8% dose, respectively. Lower overall metabolism in KO than parental strain is probably due to low hepatic retention & rapid redistribution of PeCDD into lipophilic tissues for storage, which made PeCDD unavailable to hepatic metabolizing enzymes. The present results provide a basis for understanding the pharmacokinetic behavior of toxic dioxins at low environmental exposures, levels that are insufficient to induce hepatic CYP1A2. In conclusion, the data contradicts the hypothesis but confirms that PeCDD has an inherently slow metabolism in mammals, perhaps via the inducible CYP1A1, 1A2, and 1B1 isozymes and/or non-P450 dependant mechanisms.(This abstract does not reflect USEPA.)

#### 1189

DEVELOPMENT OF A PBPK MODEL FOR HEXACHLOROBENZENE IN THE CONTEXT OF ITO'S MEDIUM-TERM LIVER FOCI BIOASSAY.

Y. LU, M. Reddy, M. Lohitnavy, O. Lohitnavy, A. Ashley and R. S. Yang. Quantitative and Computational Toxicology Group, Center for Environmental Toxicology and Technology, Colorado State University, Fort Collins, CO.

Hexachlorobenzene (HCB) is an important environmental contaminant. Due to its high lipophilicity and persistence in the environment, human exposure to HCB has continued despite the curtailment of its usage. HCB is carcinogenic to laboratory

animals with the liver as one of the primary target organs. We have incorporated the study of the relationship between pharmacokinetics and pharmacodynamics into the Íto's medium-term liver foci bioassay. Thus, we describe here the development of a PBPK model for HCB in the context of Ito's bioassay protocol. The model was built based on two data sets: one from a single intravenous dosing study (Scheufler et al. 1984) and the other from a single oral gavage study (Yamaguchi et al. 1986). It was then modified to simulate the exposure conditions in the Ito's bioassay and verified with data from our laborotary. The PBPK model includes five compartments: blood, liver, fat and rapidly and slowly perfused tissues. As HCB can bind to red blood cells, the blood compartment was divided into red blood cells and plasma. The fat compartment was divided into two subcompartments, one with a higher perfusion rate and lower partitioning and the other with a lower perfusion rate and higher partitioning. Uptake of HCB was diffusion-limited in the fat compartments and flow-limited in the others. HCB was eliminated by metabolism in the liver and by passive transfer from plasma to the intestinal lumen. Reabsorption of HCB from the intestine was incorporated in the model. The resultant model adequately described the available data sets. This model may be linked with a clonal growth model to quantitatively describe the relationship between an external exposure to HCB and the consequent preneoplastic liver foci development. (Supported by NIOSH/CDC grant 1 RO1 OH07556 and NIEHS Training Grant 1 T32 ES 07321)

1190

TOXICITY AND RELATIVE POTENCY OF 1, 2, 3, 4, 6, 7-HEXACHLORONAPHTHALENE (PCN66) AND 1, 2, 3, 5, 6, 7-HEXACHLORONAPHTHALENE (PCN67)IN FEMALE SPRAGUE-DAWLEY RATS.

L. M. Fomby<sup>1</sup>, M. Hejtmancik<sup>1</sup>, D. Vasconcelos<sup>1</sup>, A. Fuciarelli<sup>2</sup>, M. Vallant<sup>3</sup>, R. Chhabra<sup>3</sup>, H. Toyoshiba<sup>3</sup>, N. Walker<sup>3</sup> and M. Hooth<sup>3</sup>. <sup>1</sup>Battelle Columbus, Columbus, OH, <sup>2</sup>Battelle Northwest, Richland, WA and <sup>3</sup>NIEHS, Research Triangle Park. NC.

Polychlorinated naphthalenes (PCNs) have been shown to produce toxicity similar to 2, 3, 7, 8-tetrachlorodibenzo-p-dioxin (TCDD). PCN 66 and PCN 67 have been found in human liver, adipose, and breast milk samples. The purpose of this study was to determine the toxicity of PCN 66 and PCN 67 and to evaluate the potency relative to TCDD in female Sprague-Dawley rats. Formulations of PCN 66 or PCN 67 in corn oil:acetone (99:1) were administered by gavage at dosages of 0, 500, 1500, 5000, 50, 000, and 500, 000 ng/kg for up to 5 days a week for 12 days. TCDD in corn oil:acetone (99:1) was similarly administered by gavage at dosages of 1, 3, 10, 100, and 300 ng/kg. Rats receiving 500, 000 ng/kg of PCN 66 or PCN 67 failed to gain weight. Histopathologic changes were observed in the livers of rats receiving  $\geq$  100 ng/kg TCDD, 500 ng/kg PCN 66, and 50, 000 ng/kg PCN 67. Thymus atrophy was observed in rats receiving  $\geq$  10 ng/kg TCDD, 5000 ng/kg PNC 66 and 500, 000 ng/kg PCN 67. Significantly increased hepatic CYP1A1 activity was observed in rats receiving≥ 1 ng/kg TCDD, 500 ng/kg PCN 66, and 1500 ng/kg PCN 67. Significantly increased hepatic CYP1A2 activity was observed in rats receiving  $\geq$  10 ng/kg TCDD, 5000 ng/kg PCN 66, and 50, 000 ng/kg PCN 67. Likelihood ratio analysis indicated that the sigmoidal dose response curves (Hill model) for induction of CYP1A1 activity were not significantly different between each of the three compounds. Relative potency factors (RPFs) were calculated as the ratio of the ED50s of PCN to TCDD when all data were fit using common dose response parameters. Relative potency factors for PCN 66 and PCN 67 for increases in CYP1A1 activity were 0.00151 and 0.00036, respectively. These are comparable to RPFs calculated using previously published in vitro data. Based on these RPFs, PCN 66 and PCN 67 would not be predicted to contribute significantly to the human body burden of dioxin-like activity.

1191

ROLE OF THE AROMATIC HYDROCARBON RECEPTOR (AHR) IN CAUSING NEONATAL LETHALITY IN MICE EXPOSED TO COPLANAR HEXABROMOBIPHENYL (CHBB).

C. P. Curran, K. Miller, T. Dalton, M. Miller, H. G. Shertzer and D. W. Nebert. Environmental Health, University of Cincinnati, Cincinnati, OH.

Polybrominated biphenyls (PBBs) are part of a larger class of brominated fire retardants and exhibit toxic effects similar to those by polychlorinated biphenyls. PBBs were the primary component of a commercial product, Firemaster-BP6, which was accidentally mixed with cattle feed in Southern Michigan in 1973. Widespread contamination led to toxicity and many deaths among cattle, pigs and chickens, and neurological symptoms (somnolence, amnesia, confusion) among humans consuming farm products. To determine the cause of PBB neurotoxicity, we have studied two stereoisomers - coplanar 3, 3', 4, 4', 5, 5' hexabromobiphenyl (cHBB) and noncoplanar 2, 2', 4, 4', 6, 6' hexabromobiphenyl (ncHBB) - in C57BL/6J (B6, having the high-affinity AHR) and B6.D2-Ahrd (having the DBA/2J pooraffinity AHR in a B6 genetic background) mice. Pregnant dams were given either

cHBB or ncHBB (100 mg/kg, i.p.) on GD5; although all pups appeared normal at birth, all cHBB-treated B6 died within 72 h. Using Hepa-1 cells containing stably transfected AHRDtk-LUC, which is activated when exposed to AHR ligands, we confirmed that cHBB and not ncHBB binds to the AHR. Further, cHBB-treated B6 fetal liver and brain at GD18 showed (via RT-PCR) induced CYP1A1 mRNA (cHBB-treated B6.D2-Ahrd and ncHBB-treated B6 and B6.D2-Ahrd did not), evidence that cHBB given on GD5 crosses the placenta and has a persistent effect 13 days later. Significant lethality occurred in cHBB-treated B6 newborns at doses as low as 2.5 mg/kg, whereas all cHBB-treated B6.D2-Ahrd and Ahr(-/-) and ncHBBtreated B6 and B6.D2-Ahrd survived until the end of the experiment (90 days) at the 100 mg/kg cHBB dose. No histopathology or increases in oxidative stress parameters were evident in the liver or brain of the GD18 fetuses or newborns that die 2-3 days later. We conclude that neonatal lethality of the cHBB-treated B6 mice is mediated by the AHR receptor, but the precise cause of death remains under investigation. -Supported, in part, by NIH grants P30 ES06096, R01 ES06321 and R01 ES08147.

NEONATAL EXPOSURE TO PCB 180 AFFECTS THE PREPUBERTAL REPRODUCTIVE ORGAN DEVELOPMENT IN FEMALE RATS BY ANTIESTROGENIC ACIVITY.

G. Rhee<sup>1</sup>, S. Kim<sup>1</sup>, R. Lee<sup>1</sup>, S. Kwack<sup>1</sup>, K. Lim<sup>1</sup>, H. Yhun<sup>1</sup>, G. Lee<sup>2</sup>, E. Jeung<sup>2</sup> and K. Park<sup>1</sup>. <sup>1</sup>Specialized Toxicology, National Institute of Toxicological Research, KFDA, Seoul, South Korea and <sup>2</sup>Veterinary Medicine, Chungbuk National University, Chung-Ju, South Korea. Sponsor: J. Hong.

Many environmental chemicals have hormonal activity, and thus can adversely affect the reproductive and developmental systems of wildlife and mammals including human. Polychlorinated biphenyls (PCBs) including 2, 2', 3, 4, 4', 5, 5'-Heptachlorobiphenyl (PCB 180) are environmental persistent chemicals and are now widespread in the world due to their high lipophilicity and chemical resistance, providing potential for encironmental exposure. This study investigated the developmental effect of neonatal exposure to PCB 180 in the prepubertal reproductive organ development and its action mechanism in Sprague-Dawley female rat. Neonatal exposure to PCB 180 at 1 to 5 days after birth caused reductions in uterine and ovarian wet weights at prepuberty (PND 18) and this effect was statistically significant at certain doses. În addition, meonatal treatment with PCB 180 led to decreases in serum E2 concentration and uterine and ovarian ERa mRNA expressions on PDN 18. These results suggest the antiestrogenic effect of this chemical on female reproductive system. Therefore, we examined the potential antiestrogenic activity of PCB 180 by immature rat uterotrophic and estrogen-reponsive calbindin-D9k gene expression assays. In the uterotrophic assay using 18-day old female rat, subcutaneous treatment with PCB 180 (0.1 mg/kg/day) for 3 days led to significantt decreases in absolute and relative uterine wet weights and inhibited the E2-induced weight increases. Northern blot analysis showed the reduction of calbindin-D9k mRNA expression in response to PCB 180 as well as E2. Our results indicated that PCB 180 affects the prepubertal development of reproductive system in female rat, and this effect may be due to its antiestrogenic activity.

### 1193 AROCLOR 1254 CHEMICAL MODEL FOR REYE'S SYNDROME.

K. Ebner<sup>1, 2, 3</sup>. <sup>1</sup>09ZC, Abbott Labs, Abbott Park, IL, <sup>2</sup>Department of Pharmacol, Ohio St University, Columbus, OH and <sup>3</sup>Department Pharmacol/Toxicol, Mich St. University, East Lansing, MI.

PCBs were tested in male Wistar/Sprague-Dawley rats for changes in hepatic mitochondria (Hm)  $\mathrm{NH_4}^+$  metabolism associated with RS. PCB (PCB vs C, p<0.05, 30-300 mg/kg-d in corn oil & 1-4 d) elicited fatty-enlarged liver, hypoglycemia with suppressed gluconeogenesis and high blood urea with increased ureagenesis after ip NH<sub>4</sub>Acetate, urea excretion, and negative nitrogen balance with wasting. HM after PCBs in vivo exhibited 1) general ion leakiness to K+, H+, Cl- & Acetate in energy-dependent swelling or passive contraction, respiratory control & ATP synthesis with younger rats being more susceptible than older, larger rats; 2) HM (PCB vs fasting) carbamoylphosphate synthesis was stimulated with extra-M ATP but not ADP; 3) HCO<sub>3</sub> (>5mM) inhibited sonicated HM (cp) synthesis; 4) sensitized octanoate (9 uM) inhibition (doses:0.03-300 mg/kg-d, 4d) of HM CP synthesis; and 5) altered HM NH<sub>4</sub>+α-KG dismutase regulated CP synthesis after dietary nitrogen (8, 24 and 70%) adaptations. HM uncoupler SARs for hydroxylated PCBs (i.e., inner membrane leakiness) increased directly with chlorination, diazomethane treated PCBOHs were ineffective, and uncoupling was not dependent on planar configuration and pKa. Non-lytic ARO concentrations facilitated HM energy-dependent swelling, RC and transmembrane potential but potentiated PCBOH HM uncoupling. These finds support a pharmacodynamic interaction of environmental PCBs with their obligatory PCBOH metabolites to uncouple HM NH<sub>4</sub> regulation and gluconeogenesis leading to endocrine disruption and wasting toxicity. The energy-linked transhydrogenase and reverse electron transport are the most likely uncoupling sites since they are more sensitive to uncoupling than F<sub>1</sub>-ATPase and are physiologically poised to drive reductive amination through GDH and nitrogen assimilation and de novo amino acid, protein, and pyrimidines syntheses. Hyperammonemia is characteristic and a prognostic indicator of RS. The NH<sub>4</sub>Acetate probe with biomarker responses could benefit as a RS diagnostic test to determine HM uncoupling of ammonia metabolism.

### 1194 EFFECTS OF PCB 126 ON LIVER ENZYMES AND THE THYROID AXIS.

T. L. Almekinder<sup>2</sup>, J. L. Campbell<sup>2</sup>, S. Muralidhara<sup>2</sup>, <u>I. V. Bruckner</u><sup>2</sup>, D. C. Ferguson<sup>3</sup>, <u>M. Mumtaz</u><sup>4</sup>, <u>H. El-Masri</u><sup>4</sup> and <u>J. Fisher<sup>2</sup></u>. <sup>1</sup>Environmental Health Science, University of Georgia, Athens, GA, <sup>2</sup>Interdisciplinary Toxicology Program, University of Georgia, Athens, GA, <sup>3</sup>Physiology and Pharmacology, University of Georgia, Athens, GA and <sup>4</sup>Division of Toxicology, ATSDR, Atlanta, GA.

PCB 126 is known to interfere with thyroid hormone (TH) homeostasis by inducing microsomal enzymes and increasing TH excretion. The aim of the present study is to evaluate the temporal effects of PCB 126 (3, 3', 4, 4', 5-pentachlorobiphenyl) on the thyroid system, as mediated by induction of liver cytochrome P450 (total P450 and CYP1A1) and UDP-glucuronosyltransferase. A pharmacodynamic model for PCB 126-induced effects on the thyroid system is also under development. Adult male Sprague-Dawley rats were administered a single oral bolus dose of 0. 7.5, 75, or 275  $\mu g$  PCB 126/kg bw dissolved in corn oil. The rats were killed periodically over 59 days for evaluation. PCB 126 caused a dose-related decrease in body weight gain. Thyroid weights, normalized to body weight, increased in a dose-and time-related fashion compared to controls. Total P450 levels were elevated for 59, 22, and 5 days for the 275, 75, and 7.5  $\mu g/kg$  dosage groups, respectively. Ethoxyresorufin-O-deethylase activity, a marker for CYP1A1, was increased for 35, 5, and 1 days in the 275, 75, and 7.5  $\mu g/kg$  groups, respectively. Analysis of serum thyroid hormones is ongoing. These data demonstrate that PCB 126 interferes with thyroid homeostasis. Funded by ATSDR (Grant No: U61/ATU472105-01).

BIOMEDICAL APPLICATION OF ACCELERATOR MASS SPECTROMETRY (AMS): PLACENTAL AND LACTATIONAL TRANSFER OF PCB 126 IN SPRAGUE-DAW! FV RATS

B. Buchholz<sup>2</sup>, <u>S. Lee<sup>1</sup></u>, M. B. Reddy<sup>1</sup>, <u>K. H. Liao<sup>1</sup></u>, M. Lohitnavy<sup>1</sup>, <u>I. Vogel<sup>2</sup></u> and <u>R. Yang<sup>1</sup></u>. <sup>1</sup>Environmental and Radiological Health Sciences, Colorado State University, Fort Collins, CO and <sup>2</sup>Center for Accelerator Mass Spectrometry, Lawrence Livermore National Laboratory, Livermore, CA.

In earlier pharmacokinetic studies in our laboratory, we had great difficulty quantifying PCB 126 by gas chromatography in both adult rats and fetuses/pups because: (1) PCB 126 uniquely accumulated in the adult liver; (2) The dose was limited because of high toxicity; and (3) Tissue samples available from fetuses/pups were too small. To overcome analytical limitations on perinatal pharmacokinetics of environmental contaminants with trace amounts in minute fetus or pup tissue samples, accelerator mass spectrometry (AMS) was used to measure 14C-PCB 126 in the tissues of pregnant/lactating rats and their fetuses/pups during perinatal developmental stages. AMS is a highly sensitive method which can quantify attomole levels of isotopically labeled compounds in milligram-sized tissue samples to a precision of <5%. In this study, 14C-PCB 126 (20 nCi, 10 ug/kg) was given to pregnant rats on gestational day (GD) 9 via oral gavage and the maternal and fetal/pup's tissues were collected on GD 14 and postnatal day (PND)2. Preliminary results showed that PCB 126 was successfully quantified in all tissues we collected and the data will be highly useful in building PBPK models for perinatal pharmacokinetics. We believe that this biomedical application of AMS will greatly aid our understanding of perinatal transfer of PCB 126 and other persistent environmental pollutants. (Supported by NIEHS R03 ES 10116, NIH RR 13461 and ATSDR Cooperative Agreement U61/ATU 881475. ### 1196 DIETARY AROCLOR 1254-INDUCED CHANGES IN GLOBAL GENE EXPRESSION IN FISHER RATS.

T. M. Basford and <u>I. C. Means</u>. Environmental Institute & Department of Chemistry, Western Michigan University, Kalamazoo, MI.

Dietary intake is a primary route for biomagnification of environmentally persistent polyclorinated biphenyls (PCBs) within humans and animals, as these hydrophobic compounds partition to and accumulate in lipid tissues. Exposure to PCBs in vivois associated with varied toxic responses such as alterations in blood and lipid biochemistry, immune suppression, neoplastic lesions, and impaired nerological function (Safe, 1993; Waring, et.al., 2001). To date, no microarray studies of the impact of PCB ingestion on global gene expression, at either acute or chronic levels, have been reported. Changes in expression of 8800 hepatic genes in Fisher 344 male rats were assessed by Affymetrix microarray analysis to identify important physiological pathways affected by dietary PCBs. Six week old animals were fed control food or food containing 10 ppm or 50 ppm Aroclor 1254 for 7 days (acute) and 84 days (chronic). Two arrays were prepared from liver mRNA for each dose and timepoint; a threefold or greater change in signal between control and treated genes was considered significant. Blood serum levels of lipids (cholesterol, triglycerides), bilirubin, and enzyme markers of liver health (ALT, AST, ALP, GGT) were also measured and correlated to changes in gene expression. Safe S., Toxicology, structure-function relationship, and human and environmental health impacts of polychlorinated biphenyls: progress and problems. Environ Health Perspect. 1993 Apr;100:259-68. Waring JF, et.al.Clustering of hepatotoxins based on mechanism of toxicity using gene expression profiles. Toxicol Appl Pharmacology 2001 Aug 15;175(1):28-42.

#### MULTI-FACTOR ANALYSIS OF TEQ-EQUIVALENT AROCLOR AND TCDD TREATED RATS REVEALS DIFFERENTIAL GENE EXPRESSION PROFILES.

K. Illouz<sup>1</sup>, A. Possolo<sup>1</sup>, M. Zhao<sup>1</sup>, S. B. Hamilton<sup>2</sup>, <u>G. M. Hoffman</u><sup>3</sup>, Y. Huang<sup>4</sup>, S. Goodwin<sup>4</sup>, <u>T. R. Sutter<sup>4</sup> and J. B. Silkworth<sup>1</sup>. <sup>1</sup> Global Research Center, GE, Schenectady, NY, <sup>2</sup> Corporate Environmental Programs, GE, Fairfield, CT, <sup>3</sup> Huntingdon Life Sciences, East Millstone, NJ and <sup>4</sup> Feinstone Center for Genomic Research, University Memphis, Memphis, TN.</u>

Toxicogenomics has the great potential to enhance our understanding of PCB and TCDD tumorigenesis in rats. However, current methods of data analysis and interpretation present a challenge and require validation. This study was designed to compare current findings with previously conducted chronic studies that showed that female SD rats are more susceptible than males to Aroclor 1254 induced hepatotumorigenesis. TCDD and Aroclor doses were TEQ-matched to each other and to the previous study. Rats (n=4) were administered corn oil or 0.3 or 3.0 µg/kg TCDD or 0.6, 6.0, or 60 mg/kg Aroclor 1254 mg/kg po for 3 consecutive days. Day 4 hepatic cDNA was hybridized to Affymetrix RG U34 arrays. A novel multifactor, additive model was fitted to each gene probe set, with background adjusted, normalized, and log transformed perfect match intensities as the response variable. The model included treatment effects (corn oil, TCDD, Aroclor), gender effects, gender-treatment interactions, and probe affinity effects. Preliminary results for the control and highest doses indicated that, using cut-off criteria of ≥ 2-fold induction and p≤ 0.001, TEQ equivalent doses of TCDD or the Aroclor 1254 mixture induced 53 and 92 early response genes, respectively, with similar expression of most P450 1A genes between treatments. Eight genes were unique to TCDD, while 48 genes, including many Phenobarbital-related genes, were unique to the Aroclor mixture. At ≥1.5-fold and p≤ 0.001, CYP1B1 and CYP3A genes were induced only in females. There were 59 male specific genes responsive to Aroclor 1254 and 8 to TCDD. These preliminary results suggest that equivalent TEQ doses induce combinations of genes that are both strongly similar and strongly dissimilar between both genders and treatments.

DIFFERENTIAL ACTIVATION OF GENES BY TCDD AND RELATED COMPOUNDS: ANALYSIS BY MICROARRAYS.

S. Khan<sup>1</sup>, P. Beremand<sup>2</sup>, T. Thomas<sup>2</sup> and <u>S. Safe<sup>1</sup></u>. <sup>1</sup>Veterinary Physiology & Pharmacology, Texas A&M University, College Station, TX and <sup>2</sup>Biology, Texas A&M University, College Station, TX.

The toxic equivalency factor (TEF) approach has been used for risk assessment of 2, 3, 7, 8-tetrachlorodibenzo-p-dioxin (TCDD) and related polychlorinated dibenzop-dioxins (PCDDs), dibenzofurans (PCDFs) and biphenyls (PCBs). The toxic or dioxin equivalents mixture is the sum of the concentrations of the individual components times the functional potency (TEF) relative to TCDD. This methodology is based on the common aryl hydrocarbon receptor (AhR) mediated mechanism of action for the major toxic PCDDs, PCDFs and PCBs. The validity of this approach has been tested in Ah-responsive MCF-7 and other cancer lines treated with equipotent (for CYP1A1 induction) doses of 2, 3, 7, 8-TCDD, 1, 2, 3, 7, 8pentaCDD, 2, 3, 4, 7, 8-pentaCDF, 3, 3, '4, 4', 5-pentachlorobiphenyl (PCB126) and the AhR active flavonoid, chrysin. All five compounds induced CYP1A1 and CYP1B1 gene expression and four other genes; however chrysin induced or decreased 800 and 826 genes, respectively, and the pattern significantly differed from the halogenated aromatics. 2, 3, 7, 8-TCDD, 1, 2, 3, 7, 8-pentaCDD, 2, 3, 4, 7, 8pentaCDF and PCB126 increased/decreased 82/11, 114/10, 105/32 and 100/29 genes, respectively (> 2-fold increase or 0.5-fold decrease). Compared to TCDD as a reference compound the percentage of common genes induced by 1, 2, 3, 7, 8pentaCDD, 2, 3, 4, 7, 8-pentaCDF and PCB126 were 32, 28 and 27%, respectively, and the percentage of common genes decreased were 60, 11 and 10%, respectively. Moreover although all four congeners induced 22 common genes, approximately 40-60% of the genes induced by each compound were not induced by any of the other congeners. These results suggest that even for structurally-related AhR-active halogenated aromatics, their pattern of induced/decreased gene expression is highly compound specific. (Supported by NIEHS ES04917 and the American Chemistry Council)

### 1199 SEX-DEPENDENT LIVER GENE EXPRESSION PROFILES OF TCDD-TREATED SPRAGUE-DAWLEY RATS.

Y. Huang<sup>1</sup>, S. Goodwin<sup>1</sup>, K. Illouz<sup>2</sup>, J<u>. B. Silkworth<sup>2</sup></u>, <u>G. M. Hoffman<sup>3</sup> and <u>T. R. Sutter<sup>1</sup></u>. <sup>1</sup>Feinstone Center for Genomic Research, University of Memphis, Memphis, TN, <sup>2</sup>Global Research Center, General Electric, Schenectady, NY and <sup>3</sup>Huntingdon Life Sciences, East Millstone, NJ.</u>

In rats, the sensitivity to the hepatotumorigenic effect of TCDD (2, 3, 7, 8-tetrachlorodibenzo-p-dioxin) is sex-dependent. Female rats are more sensitive than male rats. In order to determine whether sex-specific gene expression profiles are present in rats treated with TCDD, we used oligonucleotide micoarray analysis (Affymetrix RG U34A arrays) to examine global gene expression in rodent liver tissue samples. Four groups of rats (n=4 per group) were studied. Males and females were orally administered either corn oil or 3ug/kg/day TCDD for 3 days. We used the Affy and Multtest packages of Bioconductor (www.bioconductor.org) to compare RMA (robust multiple average), dChip and MAS5 procedures for calculating expression values. When using the Westfall-Young procedure for controlling Family-wise error rate for the multiple hypothesis tests (F-test), 67.7 percent genes in the gene list of RMA were also present in that of dChip. However, only 46.6 percent genes in the gene list of RMA were present in that of MAS5. When using RMA with Westfall-Young correction, we generated a gene list of 282 genes having an adjusted p-value smaller than 0.05. The gene expression levels across the 16 samples were used to generate a 282x4 data matrix based on the 4 groups for SOM (self organizing map) analysis (www.genome.wi.mit.edu). The 282 genes segregated into 12 partitions. The resulting SOM automatically revealed genes that displayed either and both sexand treatment-dependent expression levels. The identification of these specific gene clusters supports the hypothesis that sex-dependent gene expression may, in part, account for the reported sex differences in hepatic sensitivity to TCDD in rats.

## 1200 TCDD-INDUCED OXIDATIVE STRESS IN DIFFERENT BRAIN REGIONS OF RATS : MODULATION BY VITAMIN E SUCCINATE AND ELLAGIC ACID.

E. A. Hassoun, J. Vodhanel, A. Abushaban and M. Al-Ghafri. *Pharmacology, University of Toledo, Toledo, OH.* 

The effects of vitamin E succinate and ellagic acid on TCDD-induced oxidative stress in different brain regions of rats, have been studied. Groups of female Sprague-Dawley rats were administered either vitamin E succinate (80 mg/kg) or ellagic acid (1 mg/kg), p.o, every other day during a treatment period of 90 day. Half of the animals in each group were also treated p.o, with daily doses of 46 ng TCDD/kg. Control groups received the vehicles used to dissolve TCDD, ellagic acid and vitamin E succinate. At the end of the treatment period, the rats were sacrificed and their brains were removed and dissected into various brain regions, including, hippocampus (H), cerebral cortex (Cc), brain stem (BS) and cerebellum ( C). Production of superoxide anion (SA) and lipid peroxidation (LP), as well as the activities of the antioxidant enzymes superoxide dismutase (SOD), catalase (CAT) and glutathione peroxidase (GSH-Px) were determined in those regions. Administration of vitamin E succinate and ellagic acid resulted in significant decreases in TCDD-induced LP and SA production in Cc and H, significant increases in SOD and CAT activities in those two regions and significant increases in GSH-Px activity in H, Cc, Bs and C. Statistical analyses of the effects of vitamin E succinate and ellagic acid on TCDD-induced oxidative stress in brain regions of rats have revealed better protective effects provided by vitamin E succinate than ellagic acid. The results suggest that vitamin E succinate and ellagic acid can protect against TCDD-induced oxidative stress in different brain regions of rats by increasing the activities of different antioxidant enzymes in those regions. (Supported by NIH/NIEHS grant ES11048).

#### 1201 TCDD ALTERS THE p53 RESPONSE TO DNA DAMAGE.

M. Viluksela<sup>1</sup>, University. Stenius<sup>2</sup>, R. Pohjanvirta<sup>3, 4, 1</sup> and J. Hogberg<sup>2</sup>.

<sup>1</sup>Department of Environmental Health, National Public Health Institute, Kuopio, Finland, <sup>2</sup>Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden, <sup>3</sup>National Food and Veterinary Research Institute, Kuopio, Finland and <sup>4</sup>Department of Food and Environmental Hygiene, Faculty of Veterinary Medicine, University of Helsinki, Helsinki, Finland.

Tumor suppressor p53 plays a key role in the prevention of cancer and developmental defects. Carcinogenicity and developmental defects are characteristic effects of dioxins, but the role of p53 in dioxin-induced toxicity has not been clarified. We

studied the effects of TCDD pretreatment on the expression of p53 in response to diethylnitrosamine (DEN) induced DNA damage. We used TCDD sensitive Long-Evans (*TurkulAB*; L-E) rats and TCDD resistant Han/Wistar (*Kuopio*; H/W) rats as well as cultured human HepG2 hepatocytes. TCDD attenuated the DEN-induced increase in p53 protein levels in both rat strains. In addition, TCDD treatment increased the amount of phosphorylated MDM2 protein that is involved in the degradation of p53. Similar results regarding p53 and MDM2 were also obtained in TCDD-treated HepG2 cells. In addition, a deceased p21 response after TCDD treatment was seen. It seems likely that alterations in MDM2 levels and phosphorylation patterns in this protein resulted in reduced p53 response. The data indicate that TCDD affects p53/MDM2 regulation and suggest that interactions between TCDD and genotoxic carcinogens may result in a deteriorated repair or control of DNA damage.

### 1202 MITOCHONDRIAL PROTEIN EXPRESSION IN MOUSE LIVER FOLLOWING TCDD EXPOSURE.

X. Shi, D. Shen, S. N. Schneider, M. Genter, D. W. Nebert, T. P. Dalton and H. G. Shertzer. Department of Environmental Health and Center for Environmental Genetics, University of Cincinnati Medical Center, Cincinnati, OH.

2, 3, 7, 8-Tetrachlorodibenzo-p-dioxin (TCDD; dioxin) is a persistent environmental contaminant that can cause diverse pathological outcomes. The mechanism of TCDD toxicity results, in part, from its stimulation of a mitochondrial respiration-dependent oxidative stress response. In order to examine the mechanism of TCDD-stimulated mitochondrial reactive oxygen production, we compared changes in protein composition in liver mitochondria from C57BL/6J mice treated with TCDD (15 μg/kg body weight) with vehicle-treated controls. After one week, liver mitochondria were isolated; proteins were separated by pH-molecular weight (MW) 2-dimensional electrophoresis. Gels were stained with CYPRO Ruby, scanned, and analyzed with INVESTIGATE HT Analyzer software (Genomic Solutions). More than 550 individual spots were identified in mitochondria from control or TCDD-treated mice. Of these, 160 appeared only in control mitochondria, while 116 appeared only in TCDD-treated mitochondria. While most proteins distributed in the pH=4-6 range, TCDD treatment shifted the distribution toward pI values greater than 7. Among the 287 common spots, the 2-fold, 3-fold, 6-fold and 10-fold up- or down-regulated expression following TCDD treatment included 20 proteins up-regulated/27 proteins down-regulated, 11/35, 2/7, and 4/4, respectively. Spots matched for pI and MW were examined using the ExPASy Molecular Biology Proteomics Server. Candidate proteins associated with large increases in protein expression levels were associated with complex 3 electron transport, associated with the urea cycle, and associated with high rates of protein turnover. Thus, TCDD produces major changes in the protein composition of mouse liver mitochondria, which may be related to TCDD-mediated physiological and biochemical alterations in mitochondria. (Supported by grants R01 ES10133, R01 ES06321, R01 ES08147 and P30 ES06096)

## 1203 HYDRONEPHROSIS AND RENAL CYP1A1 INDUCTION IN THE RAT KIDNEY BY LACTATIONAL EXPOSURE TO DIOXIN.

N. Nishimura<sup>1, 2</sup>, J. Yonemoto<sup>1, 2</sup>, Y. Takeuchi<sup>1</sup>, C. Yokoi<sup>1, 2</sup>, H. Nishimura<sup>3</sup> and C. Tohyama<sup>1, 2</sup>. <sup>1</sup>NIES, Tsukuba, Japan, <sup>2</sup>CREST, Kawaguchi, Japan and <sup>3</sup>Aichi Mizuho University, Toyota, Japan.

Cleft palate and hydronephrosis are the major phenotype of teratogenicity in mice induced by a relatively high dose of 2, 3, 7, 8-tetrachlorodibenzo-p-dioxin (40  $\mu g/kg$  TCDD) during pregnancy. We investigated the critical period of TCDD exposure for the occurrence of hydronephrosis in TCDD-exposed rat pups by crossfostering studies, and also a possible involvement of the arylhydrocarbon receptor (AhR) in the developmental of hydronephrosis by using AhR-null mice. In the cross-fostered pups at the weaning (PND21), hydronephrosis was detected in the C/T (lactational exposure only), and T/T (both prenatal and lactational exposure) groups with a high incidence, while no incidence of hydronephrosis was observed in pups from the C/C (control) and T/C (prenatal exposure only) groups. Serum and liver in the C/T and T/T groups showed higher concentrations of TCDD, as compared to the T/C group. No differences in TCDD concentrations were observed among the cortex, outer medulla and inner medulla. Milk in the stomach from the T/T and C/T groups on PND1 contained a large amount of TCDD compared to the C/C and  $\check{T}/C$  groups. The RT-PCR analysis of the renal cytochrome P450 (CYP)1A1 mRNA showed that it was greatly induced in the C/T and T/T groups in contrast to nearly no expression in the C/C and T/C groups. Immunohistochemical staining for CYP1A1 was found in a very limited area of the kidney, the ascending Henle's loop, from the C/T and T/T groups. Pups from TCDD-exposed AhR-null mice did not manifest hydronephrosis but those from AhR-heterozygotes (AhR+/-) mice showed an incidence of 37.5 %. Taken together, we conclude that lactational exposure to TCDD is primarily responsible for the renal developmental malformation in neonates and that this teratogenicity is mediated by the AhR. Despite the even distribution of TCDD in kidney, region-specific

expression of AhR and CYP1A1 in the developing kidney may suggest that AhR-dependent genes or CYP1A1-related cellular events that might lead to the occurrence of hydronephrosis.

1204

EFFECTS OF *IN UTERO* AND LACTATIONAL 2, 3, 7, 8-TETRACHLORODIBENZO-*P*-DIOXIN (TCDD) EXPOSURE ON THE PROSTATE AND ITS RESPONSE TO CASTRATION IN SENESCENT C57BL/6 MICE.

W. A. Fritz, T. Lin and R. E. Peterson. School of Pharmacy, University of Wisconsin, Madison, WI.

In utero and lactational (IUL) TCDD exposure inhibits ventral, dorsolateral, and anterior prostate development in C57BL/6 mice. To determine if these effects persist into senescence, mice born to dams given TCDD (5 µg/kg, po) or vehicle on gestation day 13 were examined at 100 and 510 days of age. Androgen responsiveness was also assessed by castrating half the mice ten days prior to necropsy and sham operating on the other half. In TCDD-exposed mice the ventral prostate was absent at 100 days of age, but a few individuals had rudimentary ducts in senescence. Castration of vehicle-exposed mice caused far greater reductions in organ weight, epithelial cell height, and androgen-dependent gene expression (MP25 and probasin) in young mice than in senescent ones. Responses to castration were similar in vehicle- and TCDD-exposed mice at 100 days of age. At 510 days, however, TCDD-exposed mice were substantially more responsive to castration than vehicleexposed mice. These results suggest that IUL TCDD exposure protects mice against the decline in androgen responsiveness that normally occurs with aging. The only result that did not follow this pattern was proliferating cell nuclear antigen (PCNA) labeling, where the age-dependent change in the response to castration was not affected by TCDD. The percentage of dorsolateral prostate ducts with cribriform structure was 2-3% in vehicle-exposed senescent mice regardless of castration, but was 16% in sham-operated TCDD-exposed senescent mice and 7% following castration. Collectively, these results demonstrate that effects of IUL TCDD exposure on the prostate persist through senescence, and suggest that IUL TCDD exposure retards the aging process in the prostate. However, because cribriform structures are often considered to be a pre-cancerous lesion, these results also suggest that TCDD exposure early in development may increase susceptibility to prostate cancer. (Supported by NIH Grant ES 01332.)

1205

DECREASED CARDIOMYOCYTE PROLIFERATION AND DOWN-REGULATION OF CELL-CYCLE-SPECIFIC GENES FOLLOWING *IN UTERO* 2, 3, 7, 8-TETRACHLORODIBENZO-P-DIOXIN EXPOSURE.

E. A. Thackaberry and M. K. Walker. College of Pharmacy, University of New Mexico, Albuquerque, NM.

2, 3, 7, 8-Tetrachlorodibenzo-p-dioxin (TCDD) has been demonstrated to alter proliferation in a number of cell lines. While some cell types, such as keratinocytes, respond with increased proliferation, other cell types, such as thymocytes and cardiomyocytes, have been shown to experience a reduction in proliferation. Previous work in our laboratory has demonstrated that fetal mice treated in utero (day 14.5) with 6 ug/kg TCDD have reduced heart weights by d17.5 of gestation. Furthermore, cardiac proliferation is reduced, as measured by proliferating cell nuclear antigen (PCNA) staining. These results suggest that TCDD may alter cell cycle control in the developing heart. While the majority of the cardiac volume is made up by cardiomyocytes, cardiac fibroblasts can account for up to 50% of the total cell number in the heart, and represent a second possible target of TCDD-induced growth arrest. In the current studies, we have sought to investigate this effect, and determine the cell types and mechanisms involved. Real-time PCR quantification analysis using whole heart samples revealed that the G1/S cyclins A2 and E2 were reduced, suggesting a delay in this cell cycle checkpoint. In order to determine if the cardiomyocytes are the primary cell-type with reduced proliferation following TCDD treatment, two cardiomyocyte cell lines, the murine HL-1 and the rat H9C2 are being used in an attempt to reproduce this effect. Growth curves for both cell lines have been conducted, and preliminary dose-response studies suggest a decrease in cardiomyocyte proliferation. These *in vitro* models will be used to dissect the mechanism by which TCDD causes cardiomyocyte growth arrest. (Supported by ES09804 to MKW, ES012855-01 to EAT, and NMNIEHS Center ES12072)

1206

LOSS OF ARNT2 IS INSUFFICIENT TO PROTECT AGAINST TCDD DEVELOPMENTAL TOXICITY IN ZEBRAFISH.

A. L. Prasch, W. Heideman and R. E. Peterson. Molecular and Environmental Toxicology Center and School of Pharmacy, University of Wisconsin, Madison, WI.

ZfAHR2 has been identified as the receptor that is essential for mediating the developmental toxicity caused by 2, 3, 7, 8-tetrachlorodibenzo-p-dioxin (TCDD) in the zebrafish embryo. *In vitro* molecular evidence demonstrates that one form of zfARNT2, zfARNT2b, forms a functional heterodimer with zfAHR2 that specifi-

cally recognizes DREs in gel shift experiments and induces DRE-driven transcription in COS-7 cells treated with TCDD. However, whether zfARNT2b is the physiological dimerization partner for zfAHR2 in developing zebrafish has yet to be determined. An insertional mutagensis screen performed in the lab of Nancy Hopkins from the Massachusetts Institute of Technology has generated a line of mutant zebrafish which lack expression of the *zfarnt2* gene. We have used the *zfarnt2* mutant zebrafish to test the hypothesis that zfARNT2 is required for mediating the developmental toxicity of TCDD. Adult fish heterozygous for the insertion were pair mated and the eggs treated with TCDD within 4 hpf. Surprisingly, immunostaining results performed at 96 hpf demonstrate that the zfarnt2 embryos show a similar pattern of TCDD-induced zfCYP1A expression as WT embryos. TCDD dose response studies were also performed and the embryos assessed at 96 hpf for three endpoints of TCDD toxicity: pericardial edema, reduced trunk blood flow, and shortened lower jaw. For all three endpoints *zfarnt2*-f- mutant embryos showed a similar response to TCDD as WT embryos. RT-PCR results confirm that the zfarnt2'- mutants do, in fact, lack expression of all splice forms of zfARNT2 mRNA. These results demonstrate that zfARNT2 is not essential for mediating several responses to TCDD in developing zebrafish and suggest that alternate dimerization partner(s) exist for zfAHR2 in vivo. (Supported by UW Sea Grant).

### 1207 TCDD INHIBITS REGRESSION OF THE COMMON CARDINAL VEIN IN DEVELOPING ZEBRAFISH.

S. M. Bello, W. Heideman and R. E. Peterson. Pharmacy, University of Wisconsin - Madison, Madison, WI.

A role for the aryl hydrocarbon receptor (AHR) in vascular development has been implicated by studies in Ahr null mice. Select fetal vascular structures that normally regress during development fail to regress in Ahr null mice. We hypothesized that 2, 3, 7, 8-tetrachlorodibenzo-p-dioxin (TCDD) would affect regression of vessels programmed to regress in developing zebrafish. Several vessels have been identified in zebrafish that undergo regression during normal development including the common cardinal vein (CCV) and subintestinal vein / hepatic portal vein (SIV/HPV). Fli1-eGFP transgenic zebrafish embryos were exposed to TCDD for 1h between 1 and 6 hpf and the effects on programmed regression monitored. The CCV, the inflow tract of the zebrafish heart, begins to regress around 74 hpf as the position of the heart within the pericardium migrates dorsally. This regression is inhibited in larvae exposed to 1 or 10 ng TCDD/ml. Knocking down expression of AHR2 with a zebrafish ahr2 specific morpholino (zfahr2-MO) protected against the TCDD induced inhibition of regression. However, use of the zfahr2-MO alone did not significantly affect regression of the CCV. The SIV develops over the yolk with connections to the posterior cardinal vein and the CCV beginning around 60 hpf. Between 84 and 96 hpf the anterior portion of the SIV becomes the HPV as the hepatic sinusoid develops. During the development of the SIV/HPV, sprouts grow both dorsally and ventrally off the horizontal portion of the SIV/HPV. These ventral sprouts normally regress during development disappearing by 96 hpf. TCDD exposure (1 ng/ml) results in retention of these ventral sprouts past 96 hpf. Use of zfahr2-MO protects against the TCDD induced retention of these ventral sprouts. However as with inhibition of regression of the CCV, the zfahr2-MO alone does not inhibit regression of the ventral sprouts. These results demonstrate that TCDD can inhibit regression of vessels programmed to regress in an AHR2 dependent manner. (UW SeaGrant, NRSA) Provided by B. M. Weinstein and N. D. Lawson, NIH.

## 1208 WATER PERMEABILITY AND TCDD-INDUCED EDEMA IN EARLY LIFE STAGES OF ZEBRAFISH.

A. J. HILL, S. M. BELLO, <u>A. L. PRASCH</u>, <u>R. E. PETERSON</u> and W. HEIDEMAN. *School of Pharmacy, University of Wisconsin, Madison, WI.* 

A common response to 2, 3, 7, 8-tetrachlorodibenzo-p-dioxin (TCDD) exposure in teleost embryos is blue sac disease, characterized by pericardial and yolk sac edema. The cellular and extracellular fluids of freshwater fish are hyperosmotic compared to the surrounding water. In order to maintain osmotic balance, freshwater fish must have a barrier to minimize water entry and be able to excrete excess water. It was hypothesized that edema observed between 72 and 168 hours postfertilization (hpf) in zebrafish exposed for 1 h to TCDD (0.1, 0.5, 1, 5 or 10ng/ml) was due to degradation of water barrier function. To test this hypothesis, the osmotic gradient was decreased by increasing the osmolarity of the surrounding water with 250 mM mannitol. This significantly reduced pericardial and yolk sac edema. Late addition of mannitol only partially reversed edema already formed. An alternate hypothesis is that TCDD impairs water excretion. In situ hybridization studies showed that expression of the key pronephric developmental genes sim 1, pax 2a, and wt 1 were unaffected by TCDD exposure. Histological analysis revealed a significant alteration in glomerular shape (flattened) from 52 hpf. However, in larvae treated with 175 mM mannitol, this change in TCDD-exposed larvae was not evi-

dent and hence was thought to be dependent on edema. Likewise, blocking edema formation using *zfahr2*-morpholino also prevented flattening of the glomerulus. At 56 hpf, glomerular filtration of injected fluorescently labelled dextran from the bloodstream was similar in both control and TCDD-exposed larvae. Expression of Na<sup>+</sup>/K<sup>+</sup> ATPase in the pronephric ducts and membrane polarity of the ductal epithelium, indicated through alkaline phosphatase expression, was unaffected in TCDD-exposed larvae. These results tend to rule out a role for dioxin-induced malfunction of the pronephros in causing edema. In conclusion, TCDD exposure may inhibit the function of a permeability barrier in the skin to water that is critical for maintaining osmotic balance in early development. (UW SeaGrant, NRSA).

1209

MORPHOLINO KNOCKDOWN OF CYP1A DOES NOT PROTECT AGAINST 2, 3, 7, 8-TETRACHLORODIBENZO-*P*-DIOXIN INDUCED EMBRYOTOXICITY IN ZEBRAFISH.

S. Carney, W. Heideman and R. E. Peterson. University of Wisconsin, Madison, WI.

In zebrafish embryos exposure to 2, 3, 7, 8-tetrachlorodibenzo-p-dioxin (TCDD) during a developmental window before 96 hpf reduces blood flow throughout the embryo and causes pericardial edema. These endpoints of toxicity occur upon activation of the AHR2 signaling pathway and can be blocked in embryos injected with an AHR2 morpholino prior to treatment with TCDD. The TCDD-induced upregulation of cytochrome P4501A (CYP1A) is also blocked in AHR2 morphants. Therefore it is possible the toxicity that results from TCDD activation of AHR2 is mediated by CYP1A. To test this hypothesis, a morpholino that blocks translation of CYP1A was injected into one-cell stage embryos and compared to embryos injected with the AHR2 morpholino or a control morpholino. Embryos from each group were exposed to TCDD or vehicle within 4 hpf, and CYP1A protein levels were measured in each group from 48 to 96 hpf. Blood flow in the trunk segmental vessels and development of pericardial edema were then measured at 72 and 96 hpf to assess effectiveness of the two morpholinos in blocking TCDD toxicity. From 48 to 96 hpf the CYP1A morpholino blocked the TCDD-dependent induction of CYP1A even more effectively than the AHR2 morpholino. Blood flow in AHR2 morphants treated with TCDD was no different from vehicle controls at 72 and 96 hpf. Despite the lower levels of CYP1A protein in embryos injected with the CYP1A morpholino these morphants had decreased blood flow in the trunk segmental vessels at 72 and 96 hpf when treated with TCDD. Likewise CYP1A morphants treated with TCDD developed pericardial edema starting at 72 hpf while AHR2 morphants treated with TCDD did not develop pericardial edema even at 96 hpf. Both morpholinos blocked TCDD induction of CYP1A through 96 hpf. However, the AHR2 morpholino blocked TCDD-induced decreases in blood flow and development of pericardial edema while the CYP1A morpholino did not. Therefore CYP1A is not a mediator of these endpoints of TCDD developmental toxicity in zebrafish. (UW Sea Grant)

### 1210 CHRONIC EXPOSURE TO LOW DOSES OF TCDD ALTERS REPRODUCTIVE SUCCESS IN ZEBRAFISH.

T. King Heiden, B. Wimpee, R. Hutz and M. J. Carvan. UW-Milwaukee Great Lakes WATER Inst and NIEHS Marine and Freshwater Biomedical Sciences Center, Milwaukee, WI.

Dioxins are prevalent within the environment and are formed as by-products from several anthropogenic processes. 2, 3, 7, 8-TCDD (TCDD) in particular is especially toxic, and has been shown to act as a teratogen, embryotoxin, carcinogen, immune system suppressor, and endocrine disruptor. Fish embryos are among the most sensitive vertebrates to the toxic effects of TCDD. Wild fish populations exposed to high environmental levels of TCDD have reduced reproductive success. The long-range goal of this project is to facilitate a better understanding of the mechanisms by which TCDD modulates reproductive function in fishes, using zebrafish (Danio rerio) as a model organism. The first objective was to determine the effects of chronic exposure to low concentrations of TCDD on the reproductive success of zebrafish. Adult female zebrafish were fed different concentrations of TCDD for a period of three weeks, and subsequently spawned with untreated males to determine the effects of TCDD exposure on egg production and offspring survival. While females did not exhibit an overt toxic response, there was a significant decrease in the ovosomatic index and a slight decrease in overall egg production. Additionally, there was a dose-dependent increase in early life-stage toxic response, including yolk sac edema, cranial edema, morphological anomalies, and mortality. Ongoing investigations into the molecular mechanisms by which TCDD alters reproductive success of zebrafish will contribute to our understanding of the dangers that endocrine disrupting chemicals such as TCDD have on vertebrates systems, and provide insight into ways that we can protect wildlife and human populations from such toxicants.

1211

EFFECTS OF 2, 3, 7, 8-TETRACHLORODIBENZO-P-DIOXIN (TCDD) ON MATRIX METALLOPROTEINASE (MMP) EXPRESSION IN A FISH MODEL OF WOUND REPAIR.

K. Hogan<sup>1</sup>, B. Wall<sup>2</sup>, K. Cooper<sup>1,2</sup> and L. White<sup>1,2</sup>. <sup>1</sup>Joint Graduate Program in Toxicology, Rutgers/UMDNJ, Piscataway, NJ and <sup>2</sup>Department of Biochemistry, Rutgers, New Brunswick, NJ.

MMPs, a family of zinc-dependent enzymes, degrade the extracellular matrix (ECM) at critical stages of wound repair. The present studies investigate the effect of the ubiquitous environmental toxicant TCDD on expression of MMP-2 and -9 in the wounded caudal fin of the Japanese medaka fish. Exposure to TCDD has been shown to: 1) increase expression of MMPs in cultured human keratinocytes; and 2) inhibit angiogenesis, an MMP-dependent process, during fin regeneration in zebrafish. Because medaka are both TCDD-responsive and capable of caudal fin regeneration, we believe these fish are an ideal model to test the hypothesis that exposure to TCDD alters expression of MMPs during wound repair. In the present studies fish were administered two doses of TCDD (25 or 50 pg/g food x 4 days) and recovered (-2d) prior to surgical ablation of a portion of the caudal fin (~2mm). Total RNA was isolated from tissue collected from the margins of wounded tail fins 3, 6, 12, and 24h post-wounding. Quantitative real time RT-PCR revealed temporal and dose-dependent changes in expression of MMPs in wound margins of TCDD and vehicle-treated fish. At 3h post-wounding, dose-dependent expression of MMP-2 (-7-12 fold) was observed in fish pretreated with TCDD. No changes were observed at 6h post-wounding. At 12h post-wounding, increased expression of MMP-2 (-6 fold) and MMP-9 (-3 fold) were observed in the wound margins of fish treated only with vehicle control. Fish exposed to the lower dose of TCDD (25 pg/g) showed expression of MMP-2 at 12h and MMP-9 at 3 and 24h post-wounding. In these studies, real time RT-PCR reactions were performed in triplicate on RNA extracted from ~15 caudal fin tails/treatment group/time point. Data were normalized to actin and are represented as fold change over vehicle control. These studies are the first to show an effect of TCDD on MMP expression following wounding in an alternative animal model.

1212 TCDD DECREASES RESPONSIVENESS OF THE CHICK EMBRYO HEART TO ISOPROTERENOL BUT NOT TO AGENTS EFFECTING DOWNSTREAM EVENTS OF THE BETA-ADRENERGIC RECEPTOR.

R. J. Sommer<sup>1</sup> and M. K. Walker<sup>2</sup>. <sup>1</sup>Biology Department, Bates College, Lewiston, ME and <sup>2</sup>College of Pharmacy, University of New Mexico, Albuquerque, NM.

2, 3, 7, 8-Tetrachlorodibenzo-p-dioxin (TCDD) causes cardiovascular toxicity in laboratory animals, including decreased contractility and heart rate, decreased myocyte proliferation, increased cardiac apoptosis and inhibition of coronary vasculogenesis. Beta-adrenergic receptor (β-AR) signaling plays an important role in each of these processes, thus, our laboratory investigated the effects of TCDD on  $\beta$ -AR signaling. Fertile chicken eggs were injected with vehicle (corn oil) or 0.3 pmol TCDD/g egg prior to incubation (D0). On D10 embryos were anesthetized and silver wire electrodes, connected to a bioamplifier, were inserted through the shell. Embryos were placed in a 37°C incubator and ECGs were recorded digitally for 10 min followed immediately by injection of vehicle or isoproterenol (β-AR agonist), forskolin (activates adenylate cyclase), theophylline (inhibits cAMP degradation), or BayK8644 (opens L-type calcium channels). Baseline heart rates (HR) of control  $(219.9 \pm 4.0 \text{ bpm}, \text{ n=39})$  and TCDD-exposed  $(221.8 \pm 4.4 \text{ bpm}, \text{ n=36})$  embryos were similar. Isoproterenol (30-120 μg/egg) significantly increased HR of controls  $(16.1 \pm 6.8-29.5 \pm 11.2 \text{ bpm above baseline}, n=5-6 \text{ per dose})$  compared to saline controls (-0.5 ± 2.3 bpm change from baseline, n=5). TCDD-exposed embryos did not increase HR in response to isoproterenol. However, TCDD-exposed embryos increased HR similar to control values following pharmacological agents that stimulate signaling downstream of β-AR. Theophylline (2.5 mg/egg) and BayK8644 (10  $\mu$ g/egg) increased HR of control and TCDD-exposed embryos 17.2  $\pm$  6.3 and  $14.0 \pm 2.0$ , and  $34.8 \pm 5.6$  and  $30.0 \pm 7.4$  bpm above baseline, respectively. TCDD-exposed embryos were more sensitive than controls to forskolin (25  $\mu g/egg$ ), increasing HR 21.8  $\pm$  3.5 vs control at 6.3  $\pm$  2.7 bpm above baseline. These data suggest that TCDD decreases the response of the chick embryo heart to β-AR agonists upstream of adenylate cyclase. Supported by NIH R15 ES011806.

## 1213 2, 3, 7, 8-TETRACHLORODIBENZO-P-DIOXIN (TCDD) EXPOSURE AFTER ANGIOBLAST DIFFERENTIATION INHIBITS CORONARY VASCULOGENESIS.

I. D. Ivnitski-Steele, M. M. Friggens, M. K. Chavez and M. K. Walker. College of Pharmacy, University of New Mexico, Albuquerque, NM.

TCDD exposure on day 0 (d0) of embryo development reduces coronary vascular outgrowth in chick embryos *in vivo* and in heart explants *in vitro*. In this study, we investigated whether TCDD reduces coronary vasculogenesis by affecting (a) the

proepicardial organ, which is the source of angioblast precursors, and/or (b) VEGF-A-dependent angioblast assembly into coronary endothelial tubes. Fertile chicken eggs were treated with control (corn oil) or TCDD (0.3 pmol TCDD/g) on d5 after coronary angioblasts have differentiated. On d6, cardiac ventricle explants were cultured on a collagen gel and coronary endothelial tube outgrowth assessed. On culture day 4, recombinant VEGF-A (rcVEGF-A) or soluble flt-1 receptor plus rcVEGF-A were added to explant media. In a second experiment, condition media from control explants was added to TCDD explants, while conditioned media from TCDD explants was added to control cultures. Lastly, VEGF-A protein in condition media was measured by ELISA. TCDD exposure on d5 reduced coronary artery number in vivo by 53±8% and reduced the length and number of outgrowing coronary endothelial tubes from explant cultures by 30±3% and 58±2%, respectively, compared to controls. The soluble flt-1 receptor blocked outgrowth in control cultures and blocked rcVEGF-A-mediated rescue of outgrowth from TCDD explants. Additionally, media from control explants rescued coronary outgrowth from TCDD explants, while media from TCDD explants had no effect on controls. Finally, VEGF-A protein secreted into media from TCDD explants was 43±3% lower than from control explants. These data suggest that 24 hr TCDD exposure is sufficient to inhibit coronary vasculogenesis and that the proepicardial organ is not involved in this inhibition. Further, TCDD does not stimulate the secretion of an inhibitory factor, but significantly reduces cardiac VEGF-A secretion. Finally, media from control cultures containing physiological levels of VEGF-A can rescue TCDDs inhibitory effect. Supported by ES09804 and NM Center ES12072.

## 1214 ARSENIC DISRUPTION OF CELL CYCLE: MECHANISMS AND EFFECTS ON APOPTOSIS, DIFFERENTIATION AND CARCINOGENESIS.

<u>I. States</u><sup>1</sup> and <u>M. J. McCabe</u><sup>2</sup>. <sup>1</sup>Pharmacology & Toxicology, University of Louisville, Louisville, KY and <sup>2</sup>Environmental Medicine, University of Rochester, Rochester, NY.

Epidemiological studies indicate that arsenic is a human carcinogen, but the mechanism of arsenic carcinogenesis is unknown and a subject of great debate. Paradoxically, arsenic is an effective anti-leukemia agent. There is great interest in understanding and exploiting the potential chemotherapeutic effects of arsenic compounds to treat other malignancies. Recent discoveries detailing arsenic's effects on cell cycle regulation may provide insight into the mechanisms underlying its carcinogenic and chemotherapeutic activities. Collectively, recent studies suggest that arsenic may influence cell cycle regulators at either the transcriptional or post-translational levels, and effects on specific protein-protein interactions also have been postulated. Arsenic recently has been shown to interfere with protein ubiquitination — an important finding given the role of ubiquitination of cell cycle regulatory proteins (e.g., cyclins) in normal cell cycle control. Disruption of normal cell cycle checkpoints is thought to be a key feature of the carcinogenic process. Similarly, disrupting cell cycle control is a contemporary strategy for chemotherapy. Determining which cell cycle regulators are targeted by arsenic and how such targeting is linked to cellular processes (i.e., differentiation, apoptosis) will provide an understanding of the carcinogenic mechanism and molecular targets that may be useful for chemotherapeutic benefit. This symposium will present an overview of the role of protein ubiquitination in cell cycle regulation, as well as the latest research investigating arsenic effects on protein ubiquitination and on regulation of genes and signaling pathways controlling cell cycle, differentiation and apoptosis. The presentations will discuss mechanisms that may explain the paradoxical effects of arsenic as both a cancer causing and a chemotherapeutic agent.

## 1215 UBIQUITINATION IN THE CONTROL OF CELL CYCLE, GROWTH AND ONCOGENESIS.

A. Banerjee. Inst. of Env. Health Sciences, Wayne State University, Detroit, MI. Sponsor: J. States.

Regulatory signals as well as environmental pollutants/carcinogens trigger cells to enter a new cell division cycle. Knowledge of mechanistic controls of cell cycle is critical for understanding the underlying defects in developmental abnormalities as well as in diseases such as cancer. Cell cycle regulatory mechanisms involving proteins include synthesis, degradation, phosphorylation, binding of inhibitors, and checkpoints. As a regulatory mechanism, ubiquitin-dependent proteolysis is required for cell division, as well as for differentiation, oncogenesis, DNA repair, transcription, and removal of abnormal proteins. Ubiquitination targets proteins for degradation by the 26S proteasome. Our efforts are directed to address the following questions: i) is there a particular kind of domain for recognition by each ubiquitination sub-pathway catalyzed by a specific ubiquitin conjugating enzyme (E2s); ii) whether proteins that have undergone conformational changes in the presence of substrates or ligand/protein partner binding can be recognized by the same ubiquitination sub-pathway as in the absence of substrates or ligand/protein partner binding. Efforts are directed to unravel the mechanism of action of E2s and

the kinetics of association and activation of E2 associated multi-protein ubiquitin ligation complex (E3s). For the former, protein structures of about 200 E2s (homology models and crystal structures) were aligned and centered on a 96ų virtual grid. The hydrophobic potentials of the E2s were computed and analyzed. Investigation is underway to analyze the electrostatic potential similarity between the specific amino acid surface patches that have been identified and their functional significance is being examined. These are also being exploited for their potential to bind small molecule inhibitors and thereby for the development of specific E2 enzyme inhibitors, by *in silico* small molecule screening. Leads from the development of *in vitro* inhibitors would provide a method for the development of *in vivo* inhibitors as experimental tools, and potentially as therapeutic agents. (Supported by NIH grant GM59467.)

## 1216 EFFECTS OF *IN VITRO* EXPOSURE TO ARSENIC ON THE UBIQUITIN PATHWAY IN HUMAN RENAL AND BLADDER CELLS.

A. J. Gandolfi, D. S. Kirkpatrick, T. G. Bredfeldt and X. H. Zheng. Pharmacology and Toxicology, University of Arizona, Tucson, AZ.

The ubiquitination of proteins within a cell plays a key role in maintaining the appropriate regulatory balance of processes such as cell cycle, apoptosis, and stress response. During cellular stress, such as following arsenic exposure, the ubiquitin pathway rapidly degrades damaged and misfolded proteins to maintain the fidelity of the cellular machinery. In studies performed in rabbit renal cortical slices, HEK293 cells, and UROtsa cells, low-level arsenic (0.5 uM - 10 uM) causes an accumulation of ubiquitin modified proteins within cells. Microarray analysis of arsenic exposed cells has shown a number of alterations in ubiquitin family genes that help to explain the changes seen. Studies from the rabbit slices and HEK293 cells show that 20S proteasome activity, but not ubiquitin-conjugating activity, was affected by arsenic. Depletion of glutathione with buthionine-L-sulfoximine during coexposure with As (III) greatly increases the levels of ubiquitin-conjugated proteins compared to arsenic treatment alone. This suggests overlapping possibilities that glutathione is directly preventing arsenic mediated protein damage, or that oxidants are involved in the damage of proteins by arsenic. Understanding the effects of low-level arsenic on protein homeostasis will be instrumental to further characterization of the mechanisms behind arsenic carcinogenicity. Because the kidney and bladder are exposed to significant levels of arsenic during urine processing, and because exposed human populations are at increased risk of developing bladder cancer, these organ systems appear to be well suited for the study of the proteotoxic effects of arsenic.

# 1217 ARSENIC-INDUCED DISRUPTION OF MITOTIC PROGRESSION: IMPLICATIONS FOR CARCINOGENESIS AND POTENTIAL FOR CHEMOTHERAPY.

<u>J. States</u><sup>1</sup>, S. C. McNeely<sup>1</sup> and <u>M. J. McCabe</u><sup>2</sup>. <sup>1</sup>Pharmacology & Toxicology, University of Louisville, Louisville, KY and <sup>2</sup>Environmental Medicine, University of Rochester, Rochester, NY.

SV40 transformed human cells and p53 deficient tumor cells are sensitive to arsenite induced mitotic arrest followed by apoptosis. In contrast, arsenite induces only a mitotic delay in diploid human cells. Abrogated p53 function is a common feature of arsenite sensitive cells. Therefore, we investigated the potential for p53 to modulate the response to arsenite using TR9-7 human fibroblasts in which p53 is under exogenous control (tet-off). Effects of high (p53hi), low (p53lo) and no (p53-) p53 expression on arsenite induced cytotoxicity and mitotic arrest were examined. TR9-7 p53hi cells grew very little and were relatively resistant to arsenite induced toxicity. In asynchronous TR9-7 p53- cells, 5 µM arsenite caused a 3-fold increase in mitotic index and induced apoptosis as indicated by morphological criteria. TR9-7 p53lo cells were resistant to arsenite induced increase in mitotic index. Rather, arsenite treated p53lo cells passed through mitosis and accumulated in G1 as indicated by bromodeoxyuridine incorporation and DNA content analyses by flow cytometry. In TR9-7 cells released from G2 synchronization, arsenite treatment caused a p53 independent delay of entry into mitosis. However, exit from mitosis was p53 dependent in arsenite treated cells. Microarray analyses of gene expression in synchronized cells exiting G2 and entering mitosis indicate that arsenite treatment alters the expression of 11-fold more genes in the presence than in the absence of p53. Genes with altered expression include stress responsive genes as well as genes involved in ubiquitin pathways. These results suggest that p53 expression prevents arsenite induced mitotic arrest but does not affect delayed exit from G2 and entry into M phase. Thus, arsenic induced carcinogenesis is likely independent of p53 inactivation. Conversely, arsenic chemotherapeutic effectiveness may be dependent on loss of p53 mediated cell cycle regulation. (Supported by ES06460, ES011314 and Kentucky Research Challenge Trust Fund).

**1218** CELL CYCLE DYSREGULATION BY ARSENITE: IMPLICATIONS FOR ITS CHEMOTHERAPEUTIC ACTIONS.

M. J. McCabe and G. McCollum. Environmental Medicine, University of Rochester,

Arsenic has been implicated in certain human cancers. It also is being used currently as an anti-leukemia agent. Arsenite is effective in treating acute promyelocytic leukemias expressing the PML-RAR $\alpha$  oncoprotein. However, arsenite induces apoptosis in a variety of cancer cells regardless of PML-RAR $\!\alpha$  expression. We have been studying arsenite effects on U937 cells, a human promonocytic leukemia that lacks PML-RARα. Low micromolar levels of arsenite induce U937 cells to differentiate as assessed by increased CD11b expression and increased directional motility in a chemotaxis assay. Thus, the anti-leukemic effects of clinically achievable levels of arsenite may be due to the induction of cell differentiation rather than cell death. Both arsenite-induced apoptosis and differentiation are preceded by cell cycle changes. Using bromodeoxyuridine (BrdU) and flow cytometry, we have found that arsenite impairs cell cycle transit. Cell synchronization and BrdU pulsechase experiments have established that arsenite delays progression through all cell cycle phases with the most pronounced effect being delayed transit through G2/M followed by mitotic arrest-associated, caspase-3 dependent apoptosis in a fraction of the cells. Over the long term (i.e., ~96), arsenite induces the accumulation of cells in G1. Given the importance of the cyclin-dependent kinase inhibitor p21 in regulating G1 to S phase transition and U937 cell differentiation, we have hypothesized that arsenite-induced differentiation is preceded by increased p21 activity and arrest in G1. As regulation of p21 is largely transcriptional, the effects of arsenite on p21 mRNA levels as well as other cell cycle regulators is being measured by ribonuclease protection assay. Arsenite-induced changes in p21 mRNA and protein abundance are being correlated with the onset of cell cycle arrest and differentiation, and a causal role for p21 in these processes also is being examined. These studies are providing an explanation of how disruption of distinct cell cycle stages is linked to the anti-leukemogenic effects of arsenite. (Supported by ES01247).

1219 MOLECULAR EVENTS DURING TRANSPLACENTAL INORGANIC ARSENIC CARCINOGENESIS IN MICE: ABERRANT ACTIVATION OF GENES LINKED TO CELL CYCLE DYSREGULATION.

M. P. Waalkes<sup>1</sup>, J. Liu<sup>1</sup>, H. Chen<sup>1</sup>, W. E. Achanzar<sup>1</sup> and B. A. Diwan<sup>2</sup>. <sup>1</sup>LCC, NCI at NIEHS, Research Triangle Park, NC and <sup>2</sup>SAIC, NCI-Frederick, Frederick,

Defining carcinogenic mechanisms is critical to assessing the human health hazard of arsenic exposure. As gestation is a time of high sensitivity to chemical carcinogenesis, we have performed several in utero exposure studies with inorganic arsenic. Pregnant mice received drinking water containing sodium arsenite at various levels, and the offspring were observed for up to 2 years. As adults, male offspring consistently developed hepatocellular carcinoma (HCC) and adrenal tumors, while female offspring showed ovarian and lung tumors, as well as uterine and oviduct preneoplasia. The livers of adult male mice bearing arsenic-induced HCC after in utero exposure showed marked over-expression of estrogen receptor-alpha (ER) at both the protein and RNA levels. ER is an estrogen activated transcription factor mediating cell proliferation. ER was intensely localized within the liver cell nucleus, indicating the active form. Activation of hepatic cyclin D1, which can be turned on by ER, was also seen in arsenic exposed mice. Cyclin D1 is critical in cell cycle regulation and, if over-expressed, is considered a hepatic oncogene. In utero arsenite induced hypomethylation of the ER promoter region DNA, probably accounting for its over-expression. The cyclin D1 promoter was constitutively unmethylated, and unaltered by arsenic exposure, indicating over-expression was a secondary event. As further evidence that ER over-expression had functional impact, a female pattern of metabolic enzymes occurred in adult male liver after in utero arsenic exposure, including over-expression of female-dominant CYP2A4 and CYP2B9, and reduced expression of male-dominant CYP7B1. In summary, altered gene expression occurred in the livers of adult mice bearing HCC induced by in utero arsenite exposure that likely resulted in cell cycle dysregulation and enhanced proliferation. Thus, aberrant estrogen signaling, possibly from methylation errors, may play a role in liver cancers induced by in utero arsenic exposure.

1220 OCCUPATIONAL SKIN EXPOSURE: CURRENT TRENDS AND FUTURE DIRECTIONS FROM THE FIELD TO GENOMICS.

<u>A. A. Shvedova</u> and <u>M. Luster</u><sup>2</sup>. <sup>1</sup>HELD/PPRB, NIOSH, Morgantown, WV and <sup>2</sup>HELD/TMBB, NIOSH, Morgantown, WV.

The purpose of this symposium is to address important and emerging areas of occupational skin toxicology with respect to current trends and future directions from the field to genomics. For many years, skin has been considered primarily as a route

of exposures for toxic chemicals and not as a target organ. As a result, research in skin toxicology per se is extremely underemphasized and under-represented in the discipline of toxicology. Advances in cellular and molecular skin biology have provided insightful opportunities to explore dermal toxicology at different levels. There is no doubt occupational and environmental exposures play a substantial role in skin maladies. A comprehensive discussion of recent developments and trends in occupational skin toxicology will provide novel approaches to elucidate exposure outcomes. This group of selected topics will bring together leading experts representing diverse perspectives in this important field. Ample time will be allotted for full discussion of major skin programs and current findings in Europe and the US. This symposium will address innovative issues in the area of skin toxicology ranging from disease incidences and causes to dermal toxicogenomics.

1221 A RASH OVERVIEW OF OCCUPATIONAL SKIN DISEASES

B. D. Lushniak. DSHEFS, NIOSH, Cincinnati, OH. Sponsor: A. Shvedova.

The importance of skin exposures in occupational settings has become more apparent. Skin can serve as both a target organ of occupational exposures as well as a route of absorption. This presentation will review the field activities of the National Institute for Occupational Safety and Health (NIOSH) involving direct effects on the skin and dermal exposure responses. It will review the wide spectrum of occupational skin diseases (ÔSDs), describe the epidemiology and public health importance of OSDs, emphasize the causes of contact dermatitis, and review results from NIOSH surveillance and health hazard evaluation investigations.

1222 MOLECULAR MECHANISMS OF ANTIOXIDANT DEFENSE IN THE SKIN.

A. A. Shvedova. HELD/PPRB, NIOSH, Morgantown, WV.

Antioxidant deficiency is a component of nutrition shortage. A growing body of evidence suggests that exposure to a number of occupational and environmental toxicants caused oxidative stress leading to short or long-term antioxidant deficiency and cellular dysfunction. Antioxidants, including vitamin E, vitamin C, glutathione and beta-carotene are among the body's natural defense mechanisms against oxidative stress. The skin is recognized as a barrier to absorption, a primary target and route of entry to the systemic circulation. The skin cells may create an oxidative or reductive environment, depending on predominance of redox processes catalyzed by both enzymic and non-enzymic systems. The talk will focus on recent advances in genetic and molecular mechanisms of chemical induced oxidative skin injury, oxidation of skin cellular constituents by reactive oxygen species leading to necrotic/apoptotic death pathways, phospholipid oxidation and signaling, bio-markers of oxidative stress determined in human cells and skin tissues obtained from alimentary vitamin E deficient and knockout tocopherol (alpha) transporter protein Ttpa mice. Value of antioxidants in occupational exposures causing skin damage will be addressed.

**1223** BASIC AND CLINICAL ASPECTS OF SKIN DISEASES.

K. D. Cooper. Case Western University, Cleveland, OH. Sponsor: A. Shvedova.

Skin toxicants share an ability to cause activation of cell signaling, often resulting in inflammatory and immunologic mechanisms. Skin has a limited number of reaction patterns, usually represented by various specific diseases. Allergic, irritant and atopic contact dermatitis, psoriasiform dermatitis/psoriasis, sunburn/photoxicity, and physical trauma to the epidermis represent some of the reactions that can occur in response to occupational toxicant exposures. Discussed here will be the pathogenesis of allergic contact dermatitis, atopic dermatitis, psoriasis and photoinjury. Keratinocyte inflammatory mediators, cytokines and chemokines can often initiate or propagate cellular immunologic mechanisms. These include Langerhans cell migration, T cell recruitment and activation, macrophage activation, and associated epidermal changes, ranging from spongiosus to hyperplasia or dermal-epidermal junction targeted toxicity to basal keratinocytes. Psoriasis as a model of Type I T cell mediated immune reactions (IFNg, IL-12, TNF) will be compared to the Type II immune responses (IgE, IL-4, 5, 13) associated with Atopic Dermatitis. The immunomodulatory effects of skin perturbation will be exemplified by the intersecting innate and adaptive immune response mechanisms initiated by solar radiation photons in the UVA and UVB region.

#### 1224 DISSECTING MECHANISMS OF SKIN TOXICITY IN THE AGE OF PROTEOMICS AND GENOMICS.

J. D. Laskin. UMDNJ, Piscataway, NJ.

This talk will describe the results of using newer techniques coupling multidimensional protein separation and liquid chromatorgraphy/mass spectrometery to characterize the proteosome, and microarray analysis to describe the transcriptosome, in defining mechanisms of skin toxicity. The ultimate goal of these studies will be to identify genes that regulate the changes that occur in tissues during skin toxicity that are likely to offer novel targets for risk assessment and therapeutic intervention. Newer techniques coupling two dimensional gel electrophoresis, liquid chromatography/mass spectrometry and micro-array analysis have provided many important new leads to understand mechanisms of skin toxicity. Characterizing genes that regulate the changes that occur in tissues during skin toxicity are likely to offer novel targets for occupational risk assessment and therapeutic intervention.

1225 EXTRA CUTANEOUS ORGAN ENDPOINTS AND DEFINING KNOWLEDGE HIATUS (CLINICAL, CONCEPTUAL AND LABORATORY) WHOSE SOLUTIONS SHOULD LEAD TO INCREASED WORKER

H. I. Maibach. Department of Dermatology, UCSF, San Francisco, CA.

Occupational dermal toxicology surged forward in the half century since publication of the Schwartz Tullipan text. With increasing clinical experience and advancing bioanalytic and other laboratory technology in Europe, Asia, and the United States, we have become increasingly aware of the strength and weakness of current workplace health knowledge. This presentation will focus on current knowledge in the field of skin diseases, e.g., irritant dermatitis syndrome, photoirritation, allergic contact dermatitis, and contact urticaria syndrome. The talk will address the ability of the skin to inhibit percutaneous penetration, and the converse, failure to protect strength and weakness of the models systems for quantifying flux as related to the workplace (vitro vs. vivo, Q S A R, and recent shortcuts, Rougier System); models systems for quantifying decontamination in theory, practice, and need; extracutaneous end points (human organ effects) from clinical medicine and how they could be avoided; and an abridged bibliographic system permitting toxicologists to efficiently follow developments in this rapidly evolving science.

1226 XENOBIOTIC-ACTIVATED RECEPTORS: BIOLOGICAL FUNCTIONS AND DISEASE PREVENTION.

R. D. Palmiter. University of Washington, Seattle, WA.

Xenobiotic-activated receptors comprise several classes of structurally distinct receptor/transcription factors, which sense changes in the chemical environment of cells, mediate transcriptional responses to the chemical stimuli, and thereby control the homeostasis of cells. Overactivation or dysfunction of the receptors is often associated with altered responses to chemicals, including toxicity and disease states. The rapid advances in understanding of signal transduction and molecular mechanism of action of these receptors provide new insights into the biological functions of the receptors and their relation to disease pathogenesis. Moreover, increasing evidence reveals that many xenobiotic-activated receptors represent important targets for developing effective therapeutic and preventive strategies in disease control and prevention. The objective of this symposium is to bring together leading experts to present new advances in the concept and understanding of the biological functions of a number of receptors in relation to disease development and prevention. Topics include ligand-receptor interactions and implications for therapy/chemoprotection; receptor-mediated antioxidant/oxidative responses and relation to autoimmune regulation/embryonic development; and control of metal homeostasis.

A NEW CLASS OF PEROXISOME PROLIFERATOR-ACTIVATED RECEPTOR γ AGONISTS: 1, 1-BIS(3'-INDOLYL)-1-(P-SUBSTITUTEDPHENYL)METHANES.

S. Safe. Veterinary Physiology & Pharmacology, Texas A&M University, College

Diindolylmethane (DIM) and several ring-substituted analogs exhibit aryl hydrocarbon receptor (AhR) agonist activities and inhibit growth of breast and other cancer cell lines. Substitution of the methylene bridging carbon with various substituted phenyl groups resulted in loss of AhR-dependent activity. However, several of the resulting C-substituted DIMs containing p-substituted phenyl groups (pPhX) inhibited growth of cancer cell lines in vitro and carcinogen-induced rat mammary

tumor growth in vivo. A series of 1, 1-bis(3'-indolyl)-1-(p-substitutedphenyl) methanes (DIM-pPhX) were synthesized and screened as potential ligands for receptors that bind lipophilic compounds. DIM-pPhX compounds induced a structure-dependent activation of PPARγ in MCF-7 breast and several other cancer cell lines. Analogs with p-trifluoromethy, p-cyano, p-phenyl, p-t-butyl and p-dimethylamino substituents were active (5 - 20 µM), whereas p-methyl, p-methoxyl, p-hydroxy or p-halo-substituted compounds were inactive at similar concentrations. DIM-C-pPhCF $_3$  and other active analogs and 15-deoxy- $\Delta$ 12, 14-prostaglandin J2 (PGJ2) exhibited similar activities; however, in mammalian two-hybrid assay using PPARγ and coactivator constructs, DIM-C-pPhCF<sub>3</sub> but not PGJ2 induced interactions with PPAR $\gamma$  coactivator-1 (PGC-1). Like PGJ2, the PPAR $\gamma$  active compounds inhibited MCF-7 cell growth and  $G_0/G_1$  to S phase progression, downregulated cyclin D1 and estrogen receptor α proteins, and induced apoptosis. However, the comparative mechanisms of cancer cell growth inhibition and induction of apoptosis by C-substituted DIMs, PGJ2 and other synthetic PPARy agonists were variable and dependent on cell context.

1228 THE AH RECEPTOR: DIVERSITY IN LIGAND BINDING AND BIOLOGICAL/TOXICOLOGICAL RESPONSES.

M. Denison<sup>1</sup>, A. Padini<sup>3</sup>, L. Bonati<sup>3</sup> and <u>S. Safe<sup>2</sup></u>. <sup>1</sup>Environmental Toxicology, University of California, Davis, CA, <sup>2</sup>Vet. Physiol. & Pharmacology, Texas A&M University, College Station, TX and 3di Scienze dell, University of Milano-Bicocca, Milano, Italy.

The aryl hydrocarbon receptor (AhR) is a ligand-dependent transcription factor that mediates many of the biological and toxic effects of chemicals, including that of 2, 3, 7, 8-tetrachlorodibenzo-p-dioxin (TCDD). The highest affinity AhR ligands include a variety of hydrophobic toxic and carcinogenic halogenated and polycyclic aromatic hydrocarbons, however, recent evidence demonstrates that the AhR can be bound and activated by a structurally diverse range of synthetic and naturally-occurring chemicals. While activation of the AhR and AhR-dependent gene expression by TCDD and other AhR ligands are known to produce a variety of toxic effects, anticarcinogenic/antiproliferative effects of AhR ligands have also been observed in rodent uterine and mammary tumors and in breast, endometrial, prostate and pancreatic cancer cell lines. Given the potential of AhR ligands as chemotherapeutic agents, we have carried out chemical screening in order to identify novel nontoxic selective AhR modulators (SAhRMs). High throughput screening assays using cell lines containing stably transfected AhR-responsive reporter genes has identified a variety of relatively potent new AhR agonists including a variety of flavones, benzoflavones, indirubins, tryptanthrins and related chemicals. The structural diversity of AhR ligands also suggests that the AhR contains a promiscuous ligand binding domain (LBD). Using a 3D homology model of the AhR LBD based on the crystal structures of homologous PAS family members that we developed we are attempting to identify and characterize the residues involved in AhR ligand binding. Structure-activity relationships of these toxic and nontoxic SAhRMs for AhR ligand binding and analysis of the binding of these diverse ligands within the modeled AhR LBD will provide insights into the mechanism of ligand-dependent activation of the AhR by toxic and nontoxic SAhRMs and can lead to the identification of new chemotherapeutic agents.

NRF2, AN ANTIOXIDANT ACTIVATED CNC BZIP TRANSCRIPTION FACTOR: MECHANISM OF ACTION AND ROLE IN AUTOIMMUNE FUNCTION.

Q. Ma. Toxicology and Molecular Biology Branch, CDC/NIOSH, Morgantown, WV.

NF-E2 related factor 2 (Nrf2) is a member of the cap n collar, basic leucine zipper family of transcription factors. Nrf2 mediates gene regulation by a range of chemicals with diverse structures. Activation of Nrf2 by phenolic and other antioxidants involves redox signaling. Induction of phase 2 drug-metabolizing enzyme NQO1, which catalyzes two electron reductions of quinone and quinoid chemicals, is used as a model for analyzing mechanism of gene transcription by Nrf2. Biochemical and genetic evidence demonstrate Nrf2 is required for three types of transcription of the gene: the basal expression, induction by antioxidants, and induction by AhR ligands, suggesting it serves as a master regulator of multiple signal transduction pathways in the transcription of target genes. Loss of Nrf2 function by targeted gene knock out increases the sensitivity of mice and cells to toxicity of oxidative chemicals. Moreover, Nrf2 null mice develop an early-onset, Lupus-like, autoimmune syndrome, characterized by appearance of anti-double strand DNA antibodies in young adulthood (as early as 2 month of age), multi-organ inflammatory lesions, enhanced proliferation of lymphoid cells, deposition of immunoglobulin complexes in glomerular membranes, and death due to rapid progressing, diffuse membranoglomerular nephritis. Taken together, these findings suggest Nrf2 plays critical roles in maintaining cellular homeostasis to oxidative toxicants and in physiological surveillance of autoimmune functions.

### 1230 THE NRF1 TRANSCRIPTION FACTOR IN OXIDATIVE STRESS RESPONSE AND DEVELOPMENT.

J. Chan. Pathology, University of California at Irvine, Irvine, CA. Sponsor: Q. Ma.

Nrf1 is a transcription factor of the CNC bZIP family, which includes Nrf1, 2, 3, p45NFE2, Bach1 and Bach2. Knockout studies show that Nrf1 mutants die at lategestation secondary to anemia and presumed fetal liver abnormality. The importance of Nrf1 in antioxidant gene expression was examined. Nrf1 mutant fibroblasts exhibited a low level of glutathione content and enhanced sensitivity to the toxic effects of oxidants. Moreover, these analyses revealed a direct role of Nrf1 in the regulation of genes important in glutathione synthesis. Nrf1 is broadly expressed during development, but defects in tissues other than liver were not apparent in mutants. To gain further insights into the function of Nrf1, we generated chimeric mice using ES cells deficient in Nrf1 to determine the cell type(s) in which Nrf1 is important during development. Characterization of the chimeric mice indicated that Nrf1 mutant ES cells contribute to most tissues in adult animals including those in which Nrf1 is normally expressed at high levels. Deficiency in Nrf1 is associated with impaired contribution of ES cells to adult but not fetal hepatocytes. While Nrf1 function is not required for normal fetal liver ontogeny, liver cells in chimeric embryos undergo apoptosis late in gestation, suggesting a cell type and developmental stage- specific requirement for Nrf1 in protecting hepatocytes from apoptosis during development. Our findings suggest that Nrf1 plays an important role in maintaining redox balance in the fetal liver cells through regulating antioxidant gene expression. As oxidative stress is thought to play an important role in promoting cell death in response to various stimuli, these findings draw attention to the potential importance of Nrf1-antioxidant pathway in various pathological conditions.

### 1231 DEFENSE AGAINST ZINC AND CADMIUM TOXICITY.

R. D. Palmiter<sup>1, 2</sup>. <sup>1</sup>Biochemistry, University Washington, Seattle, WA and <sup>2</sup>Howard Hughes Medical Institute, University of Washington, Seattle, WA. Sponsor: Q. Ma.

Zinc is an essential cofactor of some metalloenzymes and a structural component of thousands of zinc-finger proteins. Zinc enters cells via zinc-influx transporters and calcium channels but at high concentrations it becomes toxic to cells. Cells can cope with excess zinc by transporting it out of the cell via zinc-efflux transporters, sequestering it in intracellular compartments or by inducing proteins such as metallothioneins that bind it tightly. Exposure of cultured cells or mice to high levels of zinc results in the induction of metallothioneins and the zinc efflux transporter, ZnT1. Induction of these proteins depends on the metal-responsive transcription factor, MTF-1. Loss of either Znt1 or Mt gene function in cultured cells results in sensitivity to zinc toxicity, whereas resistance is conferred by amplification of either of these genes. Mice lacking either Mtf1 or Znt1 gene function die as embryos, but mice lacking Mt 1 and Mt2 genes are viable. A large family of membrane proteins related to ZnT1 facilitates the sequestration of zinc in various cellular compartments, including Golgi complex, secretory granules, endosomes and synaptic vesicles. Zinc in these compartments probably serves specific biological functions but it may also protect against zinc toxicity. Cadmium probably enters cells via the same routes as zinc but no transporters are known that transport cadmium out of the cytoplasm. Cadmium is toxic because it displaces zinc in critical metalloproteins. The major mechanism of defense against cadmium toxicity is induction of metallothioneins.

### 1232 OVERVIEW OF THE ILSI "AGRICULTURAL CHEMICAL SAFETY ASSESSMENT" PROJECT.

N. G. Carmichael. Toxicology, Bayer CropScience, Sophia-Antipolis, France.

This workshop will present and debate a series of proposals which result from a fundamental re-examination of the process of evaluating the safety of agricultural chemicals. This project has had the support and active participation of internationally recognised expert scientists from industry, international government agencies and academia. The intention was to propose a scheme which would provide a robust evaluation of these chemicals while reducing wasteful use of animals and other resources. Since October 2002 three multisector task forces have been working on proposals for a tiered approach to the evaluation of toxicology dossiers, guided by existing precedents for the evaluation of other types of chemicals and taking into accounts the specificity of agricultural chemicals. Thus, the approach is oriented towards the risk assessments which are dictated by the use of these products and the emphasis on hazard is decreased. The three groups were charged to look at potentially vulnerable life stages, the design of the systemic toxicity evaluation package and the role of ADME in study design and choice. The integration of ADME into the toxicology package is seen as key to a more modern and appropriate approach to study design and interpretation. Availability of good data from such studies is intended to permit a well informed choice of studies and a justification for avoiding unnecessary use of animals and other resources. As for any tiered evaluation, the triggers for higher tiers are critical and require thought and debate. The scheme allows the efforts to be concentrated on the studies which will be needed to perform critical risk assessments and suggests study designs that are most appropriate.

### 1233 DEVELOPMENT OF ADME DATA IN AGRICULTURAL CHEMICAL SAFETY ASSESSMENTS.

T. Pastoor<sup>1</sup> and H. Barton<sup>2</sup>. <sup>1</sup>Syngenta Crop Protection, Greensboro, NC and <sup>2</sup>EPA Office of Research and Development-NHEERL, Research Triangle Park, NC.

A multi-stakeholder series of discussions developed a set of general considerations, recommendations, and specific strategies to help guide generation of useful pharmacokinetic (PK) data in agricultural chemical testing. The value of this information is predicated on determining the relationship between the concentration of free compound in plasma and the biological/toxicological response. Careful, tierwise collection of PK data would better define dose across route, frequency, and duration of exposure as well as across species and life stages. The recommendations include: Develop basic kinetic data early, before or in conjunction with initial toxicity testing. Generate more focused kinetic data based on results of endpoint-specific toxicity studies. Once toxicity data become available, then the kinetics data should be revisited to aid in interpretation and development of an understanding of mode of action (MOA) and dose-response relationships. More focused kinetic data will define a systemic dose (versus administered dose) and provide a logical means to establish route-specific reference doses. Collect appropriate kinetics data from repeated toxicity studies. The purpose of such studies is to clearly understand the disposition of a compound in the body, improve understanding of its disposition after multiple dosing and, ultimately, to be able to define systemic dose for a variety of dosing scenarios. Obtain human kinetics data to validate and compare with animal data. Kinetic studies, coupled with PK modeling, converts administered dose into an "internal" dose that can be compared from animals to humans. Integrate Dose and Response. Tying tissue dose metrics and mode of action (MOA) together has the potential to lead to more rational and accurate health risk assessments.

### 1234 INCORPORATING LIFE STAGE TESTING INTO AGRICULTURAL CHEMICAL SAFETY ASSESSMENT.

J. C. Lamb. BBL Sciences, Reston, VA.

The ILSI HESI committee has undertaken a complete re-examination of how to test for special sensitivity of life stages, while reducing the number of studies and test animals required. Current testing strategies result in thousands of laboratory animals including mice, rats, rabbits and dogs for the approval by regulatory agencies of a crop protection chemical that will be used on food crops. The committee has developed a strategy that will substantially decrease animal use, without compromising confidence that sufficient testing has been performed. The committee has developed a hierarchy of study types, endpoints, and triggers for a tiered approach that would ensure coverage of life stages. While low exposure and low toxicity would necessitate only a basic testing package, either higher exposures or evidence of higher toxicity would lead to additional testing. This is similar to the strategy already being applied by the US Food and Drug Administration. Through assessment of available study design alternatives, recommendations were made concerning the form and scope of successive tiers, including the use of exposure estimates at certain decision points in safety assessment. Options for incorporating pharmacokinetic and metabolism data are considered throughout the tiered approach. The proposed strategy will save animals, resources, while providing adequate information on life stage susceptibility.

### 1235 INCORPORATING SYSTEMIC TOXICITY TESTING IN AGROCHEMICAL SAFETY ASSESSMENT.

A. Moretto. Environmental Medicine and Public Health, Universita di Padova, Padova, Italy.

A decision tree for systemic toxicity endpoints to be used for the safety assessment of agrochemicals has been developed by the ILSI HESI Committee. The proposal was based upon examination of existing toxicological databases, and criteria and end-points used to define NOAELs and consequently to establish the reference values. The proposal takes into account recent advances in biological and toxicological sciences. The latter include the increased specificity and sensitivity of analytical methods, a better understanding of the mechanisms/mode of toxic action of chemicals, the characterisation of the time-courses and/or steps during the development of toxic lesions. In addition, consideration of the use patterns of the agrochemical was also taken into account. On this basis a tiered approach has been proposed. The

first tier comprises a set of core studies based on use patterns (i.e.: foreseeable duration and characteristics of human exposure). All basic study designs should include full clinical and pathological evaluation of animals, as well as a recovery group. The approach will be that of identifying key markers for specific effects and triggers for next tiers. In fact, other additional studies would be triggered based on evidence of toxicological concern from the shorter-term studies, and from data of the absorption, distribution, metabolism and excretion studies (ADME). More detailed ADME data than those currently requested would help in designing repeated dose studies (especially in dose selection, duration of exposure, route of exposure, lifestage, and species) and may be used to justify the waiving of some other studies. The proposed approach will lead to generation of data more suited to risk assessment, better identification of key effects, less use and improved welfare of animals and more efficient use of resources by regulatory authorities and industry.

### **1236** AN EPA PERSPECTIVE: A NEW TESTING PARADIGM FOR PESTICIDES.

V. Dellarco. Office of Pesticide Programs, USEPA, Washington DC, DC.

The current testing requirements for pesticides were put in place over 20 years ago. Since the promulgation of FQPA, the data needs for pesticides are changing with increased emphasis on, for example, life stage sensitivities, mechanisms of toxicity, and the effects of chemical mixtures. Thus, there is a need to improve and revise the toxicity testing of pesticides to ensure that data supporting pesticide registrations will represent the best science. Through the efforts of the ILSI HESI Technical Committee on Agricultural Chemical Safety Assessment, a tiered testing approach is proposed that provides an efficient and thorough assessments of potential human health risks. The ILSI HESI project represents an international perspective, which is important to EPA, given the Agency's commitment to international harmonization of testing guidelines. The proposed testing approach utilizes available information about each chemical and its toxicity to design a rational, science-based assessment strategy. The program design includes the need to reduce animal usage, the need to include new methods, the need to modify existing studies to provide coverage of life stages, a more complete and systematic evaluation of toxicokinetics, and a more focused evaluation of the potential toxicities of pesticides. Although there will be future advancements in toxicology testing (e.g., genomics and proteomics), the ILSI HESI project provides important near-term recommendations for improving the testing of pesticides.

## 1237 HISTOMORPHOLOGY AND BEYOND: CORRELATING NON-CLINICAL IMMUNE MODULATION WITH CLINICAL DATA.

<u>I. Schuh</u><sup>1</sup> and <u>L. Reid</u><sup>2</sup>. <sup>1</sup>Applied Veterinary Pathobiology, PLLC, Bainbridge Island, WA and <sup>2</sup>Division of Reproductive and Urologic Drug Products, USFDA, Rockville, MD.

Histopathology is an important component for assessing immunomodulation as part of immunotoxicology profiling in non-clinical studies. Histomorphological evaluation of lymphoid organs and tissues in animals captures the accumulation of both background and treatment-specific immunomodulation and careful evaluation can provide evidence of altered immune function. However, immunomodulatory changes in tissues need to be interpreted in the context of variation due to genetic modifiers, stress and degree of environmental antigenic exposure. In the last few years, experiences with expanded immunotoxicology testing have resulted in availability of data sets that allow correlation of histomorphology to functional data and clinical studies. Additionally, compartments of the mucosal immune system are also beginning to be more thoroughly analyzed. Many challenges remain in our efforts to fully understand non-clinical immunohistology relative to functional data. The increasing need for immunotoxicology assessment as part of regulatory submissions reinforces our need to continually improve our abilities to correctly interpret and apply immunotoxicology information. Periodic reassessment of completed and ongoing immunohistology and immune function studies is important to monitoring the robustness of testing guidelines, directing testing modifications and to establish predictive value of animal studies for clinical studies. The purpose of this workshop is to present and examine several available data sets that have evaluated histomorphology and immunomodulation in animals and resulting correlations to clinical data. Representative data sets from immunomodulation subsequent to chemical and pharmaceutical exposure conducted by laboratories in The Netherlands and by the NTP, USFDA and ILSI will be highlighted. Discussions on these current and ongoing experiences with correlative data sets will be relevant to individuals involved in gathering and evaluating data in all aspects of the rapidly progressing field of immunotoxicology.

### 1238 IMMUNOTOXICOLOGY AND THE MUCOSAL IMMUNE SYSTEM.

C. F. Kuper. TNO Nutrition and Food Research, Zeist, Netherlands. Sponsor: J. Schuh.

Aside from histomorphological examination of Peyer's patches (PP), mesenteric lymph nodes (MLN) and secretion of immunoglobulins, immunotoxicology studies pay little attention to the mucosal immune system. On the one hand this is hard to understand because a). mucosae are most often the first site of contact for xenobiotics, b). mucosa-associated lymphoid structures (MALT) such as bronchial (BALT) and nasal (NALT) structures and intestinal cryptopatches are strategically situated to have extensive contact with inhaled or ingested substances, and c). Tlymphocytes disseminated diffusely in the epithelium (IEL) and lamina propria (LPL) of the mucosae form the body's largest T-lymphocyte pool. It is questionable whether PP and MLN can be used as sole representatives of the mucosal immune system because the various organized mucosa-associated lymphoid structures differ from each other and the single T-lymphocyte pool is quite unique in phenotype and function. Moreover, the lymphocyte maturation process in the intestinal epithelium may be particularly sensitive to immunotoxins, as it is in the thymus. On the other hand, the mucosal lymphoid structures and the IEL and LPL are difficult to sample and examine, which may have attributed to the scarcity of reported toxic effects on the mucosal immune system. Nevertheless the rise in incidence of allergic reactions, especially those expressed in the respiratory tract, the increasing use of nasally applied medicines and enhanced studies with the respiratory allergens trimellitic anhydride (TMA) and toluene diisocyanate (TDI), the immunosuppressive drug azathioprine, the industrial substance hexachlorobenzene (HCB) and the food contaminant vomitoxin (deoxynivalenon or DON) demonstrate the need to address the mucosal immune system in immunotoxicology studies more extensively than is currently done.

### 1239

## PROTOCOLS AND VALIDATION STUDIES OF HISTOPATHOLOGY AND IMMUNE FUNCTION IN NON-CLINICAL STUDIES.

<u>I. G. Vos.</u> Laboratory of Pathology and Immunology, National Institute for Public Health and the Environment, Bilthoven, Netherlands.

The toxicologic pathology discipline plays an important role in the process of identifying and defining the health effects following exposure to xenobiotics. This is also true for the identification of immunomodulatory agents as part of the toxicologic profiling. In assessing immunomodulation, a two-tier testing system is usually employed in which the first tier is a general screen for (immuno)toxicity including enhanced histopathology of lymphoid organs and the second tier consists of specific immune function studies including host resistance tests or mechanistic studies. Studies with TCDD, TBTO, HCB, azathioprine and cyclosorin A will be discussed that provided data correlating histopathology with induced immune function changes. This will be followed by a discussion of i) the outcomes of enhanced histomorphology in the interlaboratory validation studies of azathioprine, cyclosporin A and HCB in the rat; and ii) the recent study of a working group of veterinary/toxicologic pathologists evaluating the sensitivity and predictability of extended histopathology in the mouse as an indicator of immunotoxicity, as compared with the NTP's functional testing battery. In the latter study, standardized slide sets from thymus, spleen and mesenteric lymph nodes were generated for 11 chemicals that had previously been evaluated for their immunotoxicity using functional tests. While overall there was good agreement between histopathology and functional tests, the antibody forming cell (AFC) assay detected immune suppression in two instances where no changes in pathology were indicated. In contrast, the AFC assay failed to detect oxymetholone as immunotoxicant, although extended histopathology indicated immunologic changes. Data collected over the past two decades on these studies in rodents have been the basis for a number of regulatory activities. These will be discussed and suggestions will be given to further improve the identification and (semi)quantitation of histopathologic changes in lymphoid organs and tissues.

#### 1240

REGULATORY IMPLICATIONS OF NON-CLINICAL IMMUNOTOXICOLOGICAL FINDINGS DURING THE DRUG DEVELOPMENT PROCESS IN THE UNITED STATES.

D. Mellon. Division of Anesthetics, Critical Care and Addiction Drug Products, Center for Drug Evaluation and Research, US Food and Drug Administration, Rockville, MD. Sponsor: L. Reid.

Assessment of the potential for compounds to alter the immune system is critical to the logical and cost-effective development of new therapeutics. Although, extensive research in the field of immunotoxicology has provided essential clues to the mech-

anisms of adverse drug reactions, a unified consensus on an appropriate manner to assess changes in the immune system as part of drug development process is just beginning to be developed. To date, global harmonization has not yet been attained. The US Food and Drug Administration has published a Guidance for Industry titled "Immunotoxicology Evaluation of Investigational New Drugs" which can be found on the FDA website (http://www.fda.gov/cder/guidance/4945fnl.PDF). This presentation will discuss the rationale behind the FDA's approach toward immunotoxicology assessment, as described in the guidance. FDA ascertains that evidence of immunotoxicity can usually be observed in standard non-clinical toxicology studies. However, in some cases, additional studies are recommended. To illustrate this approach, several examples of how detailed immunohistological assessment of lymphoid tissues can be used to assess immunotoxicity will be presented. The circumstances when additional non-clinical studies should be conducted will be described.

1241

CONCORDANCE OF ANIMAL TOXICITY AND SAFETY PHARMACOLOGY DATA WITH HUMAN TOXICITIES FOR THERAPEUTIC AGENTS: FOCUS ON THE IMMUNE SYSTEM.

M. P. Holsapple<sup>1</sup>, K. Thomas<sup>1</sup>, J. Sanders<sup>2</sup> and E. Kadyszewski<sup>3</sup>. <sup>1</sup>Health and Environmental Sciences Institute, International Life Sciences Institute, Washington, DC, <sup>2</sup>Aventis Pharmaceuticals, Bridgewater, NJ and <sup>3</sup>Pfizer Central Research,

There is a widespread perception that laboratory animals are appropriate models for predicting the adverse effects of chemicals in humans. For many classes of chemicals, testing this assumption is not practical. By contrast, for pharmaceuticals, an extensive body of relevant data exists to explore the validity of this assumption. Consequently, the ILSI HESI Non-Clinical / Clinical Safety Correlations Technical Committee is building a database to develop an improved understanding of the extent to which various types of human toxicities (HTs) could be predicted from standard toxicology studies. The database is being developed to evaluate the concordance of animal data with HTs exhibited during clinical trials for a number of pharmaceuticals. The database will also help to determine whether the range of preclinical tests that are currently performed produce data that are relevant in the design and/or interpretation of human studies. To establish a comprehensive measure of the utility of non-clinical animal studies for human risk assessment, the project features a prospective collection of compounds entering the in vivo toxicology stage of drug development, which ensures studies have been conducted according to modern guidelines. In addition, the details of those toxicities manifested in animals that are considered to be counterparts of the human clinical toxicity profile will be fully documented. The database also captures toxicokinetic and metabolic interspecies comparison data. Ultimately, the database provides a unique forum for examining the value of animal studies as surrogates for predicting the toxicity of drugs in humans and addressing how non-clinical tests can be optimized to improve drug safety. The presentation will focus on the existing dataset for immune system toxicity, and will provide a comparison of the concordance of immune system toxicity with toxicities in other organ systems.

1242 ZEBRAFISH-A MODEL ORGANISM FOR ASSESSING DEVELOPMENTAL TOXICITY IN DRUG DISCOVERY/ENVIRONMENTAL RISK ASSESSMENT.

R. R. Dugyala<sup>1</sup> and J. M. Rogers<sup>2</sup>. <sup>1</sup>Reproductive Toxicology, Schering-Plough Research Institute, Lafayette, NJ and <sup>2</sup>Reproductive Toxicology Division, National Health and Environmental Effects Research Laboratory, Research Triangle Park, NC.

Several organisms such as the worm (C. elegans), fly (D. melanogaster), frog (X. laevis) and zebrafish (D. rerio) have been discussed as alternative models for assessing developmental toxicity of environmental agents in higher mammals. Zebra fish seems to be an appropriate model for several reasons. It is a vertebrate, its genetics and development is well understood and transgenics/knockdowns can be easily made. The zebrafish life cycle is short therefore; its specific developmental phenotypes can be screened effectively. Zebrafish are easily bred throughout the year in the laboratory and individual females can give rise to hundreds of progeny on a year-round basis. Several zebrafish mutants are representative of known forms of human genetic disorders. In addition, its genomic sequence will be available from the Sanger Sequencing Center and this has already allowed easy isolation and identification of gene regions. Commercial sources of DNA libraries for microarray analysis are now available. Moreover, they can be easily exposed to environmental agents; can be used to screen environmental agents that have developmental risk in a semi or high-throughput manner. Mechanistic data involving specific genes/pathways can also be effectively generated to help better estimate the human developmental risk. Therefore, zebrafish can be an effective alternative model in the drug discovery process or environmental risk assessment.

1243

TRANSGENESIS, MICROARRAY ANALYSIS AND ANTI-SENSE KNOCKDOWNS OF ZEBRAFISH GENES-TOOLS FOR USING ZEBRAFISH AS A TOXICOLOGICAL

E. Linney<sup>1</sup>, L. Upchurch<sup>1</sup>, S. Donerly<sup>1</sup>, Q. Xhao<sup>1</sup>, C. Lassiter<sup>1</sup> and <u>E. Levin</u><sup>2</sup>. <sup>1</sup>Department of Molecular Genetics and Microbiology, Duke University Medical Center, Durham, NC and <sup>2</sup>Department of Psychiatry, Duke University Medical

There are distinct advantages to using zebrafish as an experimental, embryonic, vertebrate model: 1)it develops outside the mother as a microscopically viewable organism; 2)the DNA sequencing of the genome by the Sanger Centre is providing sequence and gene information which allows the generation of large microarrays for the analysis of gene expression during normal development and after toxicant challenge; 3)a growing number of transgenic lines of fish which express fluorescent marker proteins in response to small molecules or in specific structures(such as the developing nervous system) allows the continuous visual monitoring of changes produced by toxicant challenge; and 4)the availability of anti-sense morpholino technology allows one to combine the above advantages with selective down-regulation of specific genes. These advantages plus the sharing or regulatory pathways observed in mammalian models allows one to scan the breadth of development at various levels under normal conditions and after exposure to environmental toxicants. Transgenic models will be presented to illustrate their potential use in toxicant studies. Specifically, an example of the combined use of these technologies in exploring the effects of chlorpyrifos exposure, the effects of exposure upon acetylcholine esterase, and resulting behavioral changes in the treated, adult fish will be presented. (Supported by NIEHS Superfund and Toxicogenomics Consortium

1244

ZEBRAFISH AND DIOXIN DEVELOPMENTAL TOXICITY: POISED TO IDENTIFY CRITICAL GENES FOR SPECIFIC ENDPOINTS.

R. E. Peterson<sup>1</sup>, A. L. Prasch<sup>1</sup>, E. A. Andreasen<sup>2</sup>, R. L. Tanguay<sup>2</sup> and W. Heideman<sup>1</sup>. <sup>1</sup>School of Pharmacy, Molecular and Environmental Toxicology, University of Wisconsin, Madison, WI and <sup>2</sup>Environmental and Molecular Toxicology, Oregon State University, Corvallis, OR.

Zebrafish have emerged as the premier teleost species for use in molecular, genetic, and developmental studies and may reveal novel mechanisms of 2, 3, 7, 8-tetrachlorodibenzo-p-dioxin (dioxin) developmental toxicity applicable to human health risk assessment. Endpoints of dioxin toxicity in the zebrafish embryo include impaired cardiac development, reduced peripheral blood flow, anemia, edema, and impaired jaw development. Some of these endpoints have also been observed in avian and mammalian embryos. Since most, if not all, endpoints of dioxin toxicity are generally considered to be mediated by the aryl hydrocarbon receptor (AHR), components of the AHR signal transduction pathway have been identified and characterized in zebrafish. In contrast to mammals, zebrafish have two AHRs (AHR1 and AHR2) that are products of two distinct genes. Transcripts of both AHRs are expressed in the zebrafish embryo and larva but AHR2 mRNA is far more abundant. AHR nuclear translocator (ARNT), and the AHR interacting protein (AIP), AHR repressor (AHRR), and CYP1A have also been cloned in zebrafish. To determine the role that each zebrafish AHR may play in dioxin toxicity, their functional properties were determined revealing that AHR2 supports high affinity binding of dioxin whereas AHR1 does not, AHR2 supports sequence-specific binding to mammalian AHRE sequences but AHR1 binding is weak, and AHR2 supports dioxin induction of reporter gene expression while AHR1 does not. These findings suggest that AHR2, not AHR1, is involved in dioxin developmental toxicity. This interpretation is supported by morpholino experiments where AHR2 repression protects dioxin-exposed zebrafish embryos from toxicity. (Supported by UW Sea Grant and NIEHS)

1245 NICOTINE-INDUCED DEVELOPMENTAL TOXICITY IN ZEBRAFISH.

R. L. Tanguay<sup>1</sup>, K. R. Svoboda<sup>2</sup> and S. Vijayaraghavan<sup>3</sup>. <sup>1</sup>Environmental and Molecular Toxicology, Oregon State University, Corvallis, OR, <sup>2</sup>Department of Biological Sciences, Louisiana State University, Baton Rouge, LA and Department of Physiology and Biophysics, University of Colorado Health Sciences Center, Denver,

Exposure of the developing fetus to nicotine from the maternal serum has been linked to a number of physical abnormalities including; an increase in induced abortions, low infant birth weights, increased need for neonatal intensive care units, perinatal disorders and deaths. Furthermore, there is increased concern that fetal exposure to nicotine is also associated with significant cognitive, intellectual and behavioral impairments. At this time there is a gap in our understanding of precisely how nicotine leads to these serious consequences. It is accepted that the actions of nicotine are mediated via the activation of neuronal nicotinic acetylcholine receptors (nAChRs). The presence of both ACh and nAChRs during embryogenesis also suggest that nAChRs play a significant role during development. We are using zebrafish as a model system to gain insight into how nicotine exposure alters neuronal development and behavior. Transient exposure of embryonic zebrafish to nicotine delays development of secondary spinal motoneurons. Furthermore, there is a long-lasting alteration in axonal pathfinding in secondary motoneurons that is not ameliorated by drug withdrawal. Mammalian nicotinic receptor antagonists reversed these effects of nicotine. At the behavioral level, continuous exposure of embryos to nicotine beginning at 12hpf abolished spontaneous bending of the axial musculature, which occurs between 17hpf and 24hpf. On the other hand, transient exposure of embryos to nicotine between 22hpf and 30hpf induces a swimminglike behavior. Overall, our results show that transient embryonic exposure to nicotine leads to long lasting effects on the developing vertebrate nervous system. These results also demonstrate that the zebrafish is a useful model system to examine the effects of nicotine specifically, and drugs of abuse in general, on the development of the central nervous system in vertebrates.

### 1246 ZEBRAFISH AS A MODEL FOR SMALL MOLECULE SCREENING/DISCOVERY.

R. T. Peterson, D. Milan, C. MacRae, T. Peterson and M. Fishman. *Cardiovascular Research Center, Massachusetts General Hospital, Charlestown, MA.* Sponsor: R. Dugyala.

The transparency of the zebrafish embryo makes it possible to rapidly identify chemical perturbations of organ structure and function. As a result, high-throughput chemical screens can be performed to characterize systematically the biological effects of thousands of small molecules. We have used this chemical screening approach in several ways. First, we have identified small molecules that cause cardiovascular malformations. After screening through more than 10, 000 small molecules, we have identified dozens of compounds that affect cardiac size, shape, or function. By database comparisons and structure activity relationship studies, we have identified relationships between chemical substructures and the malformations they cause. We are identifying the mechanisms of action of several of these compounds. Second, we have developed automated assays for identifying small molecules that affect cardiac physiology. These assays can be used to predict the cardiotoxic effects, including QT prolongation, of hundreds of drugs and drug combinations. Finally, we have used high-throughput chemical screening to identify small molecules that reverse the effects of a genetic mutation. Compounds identified in this screen suppress a genetic vascular defect by upregulating expression of vascular endothelial growth factor. Therefore, zebrafish small molecule screens provide a systematic means of linking chemical structures with their biological activities, with applications ranging from developmental toxicology to drug discovery.

EVALUATING THE TOXICITY OF ENVIRONMENTAL SAMPLES USING ZEBRAFISH DEVELOPMENTAL ENDPOINTS AND ALTERATION OF GENE EXPRESSION.

M. J. Carvan, B. A. Wimpee, T. King-Heiden, E. J. Loucks and K. A. VanDerel. Great Lakes WATER Institute and Marine & Freshwater Biomedical Sciences Center, University of Wisconsin-Milwaukee, Milwaukee, WI.

The dynamic progression of development often makes the embryonic and larval stages of vertebrates exquisitely sensitive to environmental stressors, including toxic chemicals. Toxic environmental chemicals often perturb interdependent pathways that regulate developmental processes in a manner that is both characteristic and predictable. Many of the most common developmental abnormalities in zebrafish are easily identified by careful observation of live embryo/larvae. These abnormalities include: delayed development, edema, pooling of blood, and a number of gross abnormalities generally of skeletal origin that involve the craniofacial and neurocranial skeleton, spine, and fins. Morphometric analysis of stained cartilaginous structures in the larval skeleton reveals very subtle teratogenic effects resulting from exposure to very low concentrations of toxic chemicals. Staining of apoptotic cells in live embryos localizes tissue-specific toxic affects that otherwise don't become apparent until much later in life. Utilization of transgenic fish expressing tissue-specific green fluorescent protein (GFP) greatly simplifies analysis of cardiovascular deficits in living larvae. We are also developing transgenic lines of zebrafish in which DNA motifs that respond to selected classes of environmental pollutants induce a GFP reporter gene. A battery of fish with different pollution-inducible enhancers will provide a very sensitive bioassay for the identification of specific chemical classes in a complex environmental mixture. Subsequent gene expression analysis using microarrays or real-time RT-PCR provides sufficient data for the identification of specific chemical(s) to which the GFP-expressing embryo/larvae have been exposed. In summary, integration of all these endpoints will identify bioavailable toxic chemical species within a complex environmental mixture, and provide strong biologically-based support for environmental risk assessment.

### 1248 INDIVIDUAL VARIATIONS IN CIGARETTE MAINSTREAM SMOKE BIOMARKERS OF EXPOSURE.

C. J. Smith, M. J. Morton, B. G. Brown, D. W. Bombick, D. L. Heavner, M. W. Ogden, J. H. Robinson and D. J. Doolittle. Research and Development, RJ Reynolds, Winston-Salem, NC.

Biomarkers of tobacco smoke exposure were measured in urine, buccal cells and buccal cell mouthwash supernatants from 56 smokers of full-flavor low "tar" (FFLT) cigarettes to evaluate the degree of individual variation. Biomarkers were measured while each individual smoked their usual brand of FFLT cigarette (UB) and after all smoked the same leading commercial FFLT cigarette brand (LC). Twenty-four hour urine collections and spot buccal mouthwash samples were taken while smoking each cigarette. Biomarkers were determined for nicotine; benzene; acrolein; the tobacco-specific nitrosamine 4-(N-methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK); the PAH surrogate marker 1-hydroxypyrene (a metabolite of pyrene); oxidative stress (8-hydroxydeoxyguanosine [8-OHdG] and 15-F2t -isoprostane-M); carbonyl protein adducts; and the 1, 3-butadiene metabolites monohydroxybutenyl mercapturic acid (MHBMA) and dihydroxybutenyl mercapturic acid (DHBMA). The standard deviations of the logarithms of the biomarker measurements did not differ while smoking the UB or LC cigarettes, indicating there was not a statistically significant difference in biomarker variability when smokers used their usual brands of FFLT or all smoked the same FFLT cigarette. Intra-subject variability in biomarker concentrations was minimal between the two cigarettes while inter-subject variability was quite large, typically spanning one or more orders of magnitude. These data demonstrate the wide range of individual exposures to cigarette mainstream smoke components experienced when different individuals smoke the same cigarette.

### 1249

LARGE WITHIN CHILD VARIABILITY FOR OP PESTICIDE URINARY BIOMARKERS LIMITS OUR ABILITY TO IDENTIFY HIGH EXPOSURE FARM WORKER CHILDREN.

W. C. Griffith<sup>2, 1</sup>, C. L. Curl<sup>1</sup>, E. M. Faustman<sup>2, 1</sup>, C. A. Li<sup>1</sup> and R. A. Fenske<sup>1</sup>. <sup>1</sup>DEOHS, University of Washington, Seattle, WA and <sup>2</sup>Institute for Risk Analysis and Risk Communication, University of Washington, Seattle, WA.

The diakyl metabolites of organophosphate (OP) pesticides have been measured in the urine of children by a number of studies. Interpretation of measurements of these urinary metabolites about population and individual exposures is complicated since a number of OP pesticides produce the same metabolites. Estimates of seasonal variability and intra and inter individual variability have been made from a longitudinal study (Koch, et al, Environmental Health Perspectives, 2002). Children, 2 to 5 years of age, of agricultural orchard workers were recruited in the Yakima Valley through a Women, Infants, and Children clinic, and 44 were followed over a 21month period with twice monthly urine measurements. Statistical analysis of levels of the diakyl OP metabolites in urine is complicated because a large fraction of the urinary metabolite levels were below the limit of detection. Statistical methods for censored data were developed for a maximum likelihood mixed effects model. The seasonal trends in the data showed a decrease in the second year in OP metabolite levels because of decreased pesticide use due to unusually cold weather, with higher dimethyl metabolites during the spray seasons. The variance in urine concentrations within children is over an order of magnitude larger than the variation between children. The large within child variance has implications for using diakyl metabolites to distinguish which children in a population may be more highly exposed. When metabolite concentrations are measured on only one or a few days the large within child variability makes it difficult to judge which children are more highly exposed. Conclusions can be drawn about the distribution of exposures for a population but not about whether the exposure of a particular child is high or low in relation to the rest of the population. Support for this work was from the Center for Child Health Risk Research NIEHS (PO1 ES09601) / EPA (R826886).

### 1250

A REVERSED PHASE HPLC METHOD FOR THE DETERMINATION OF EPOXIDES OF 1, 3-BUTADIENE AND OTHER PETROCHEMICAL ALKENES.

B. Kandlakunta, J. L. Allison and R. M. Uppu. Environmental Toxicology, Southern University and A&M College, Baton Rouge, LA. Sponsor: J. Ward.

1, 3-Butadiene (BD) is an environmental pollutant widely distributed in petrochemical industrial areas in the US. A recent evaluation by IARC indicates that BD is a probable human carcinogen falling under group 2A. 1, 3-Butadiene is metabo-

lized by enzymes of the cytochrome P450 system, forming electrophilic metabolites, 1, 2-epoxy-3-butene (EB) and 1, 2;3, 4-diepoxybutane (DEB), which, in turn, mediate the toxicity of BD. During the course of a study undertaken to examine the role of oxidative stress and cell signaling in the establishment of cellular injury by BD, a need arose for the development of a rapid and convenient method for the estimation of EB and other epoxides. Here we describe a new reversed phase HPLC method to quantify low levels of epoxides of BD and other alkenes in cell culture. The method involves derivatization of epoxides using a 100-1, 000-fold molar excess of N, N-diethyldithiocarbamate (DTC) at 70  $^{\circ}$ C for a period of 10 min as a first step. The excess, unreacted DTC is then decomposed (to carbon disulfide and diethyl amine) by acidification with phosphoric acid (pH<sub>final</sub> ca. 1-2). Finally, a suitable aliquot of the derivatized sample is analyzed by HPLC using a ODS column (4 mm x 150 mm; Supelco) with 40% acetonitrile in water as mobile phase and the system is programmed for a flow of 1 mL/min. The HPLC analysis is performed using a Waters 660 liquid chromatograph equipped with a Waters 996 diode array detector. Upon monitoring at 278 nm, we find linearity in the concentration range of 0.1 to 100  $\mu$ M. The present method is highly reproducible with recoveries  $\geq$ 96% of spiked samples, and as low as 5 pmol of the analyte could be successfully detected. (Funding support from NIEHS grant ÉS10018 is acknowledged. Corresponding author: Rao M. Uppu. E-mail: rao\_uppu@cxs.subr.edu. Fax: 225/771-5350.)

## 1251 DEVELOPMENT OF AN LCMS METHOD FOR THE QUANTITATIVE MEASUREMENT OF AFLATOXIN $\mathbf{B}_1$ SERUM ALBUMIN ADDUCTS.

P. F. Scholl<sup>1</sup>, L. McCoy<sup>2</sup>, R. Schleicher<sup>2</sup> and J. D. Groopman<sup>1</sup>. <sup>1</sup>Environmental Health Sciences, Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD and <sup>2</sup>National Center for Environmental Health, Inorganic Toxicology and Nutrition Branch, Centers for Disease Control and Prevention, Atlanta. GA.

The lysine adduct formed by the reaction of aflatoxin B<sub>1</sub> (AFB<sub>1</sub>) epoxide or dialdehyde with serum albumin is an established biomarker of AFB, exposure. HPLC with fluorescent detection, RIA and ELISA methods were previously used to detect this adduct in rats and human molecular epidemiologic studies. Here we report a new synthetic technique for preparing lysine-AFB, standards and an LCMS method for the quantitative measurement of lysine-AFB<sub>11</sub> in serum samples. Nα-t-Boc-L-lysine-AFB<sub>1</sub> was synthesized by the reaction of AFB<sub>1</sub> dialdehyde with Nα-t-Boc-L-lysine. Deprotection was performed using 40% TFA. D4, 4, 5, 5-L-lysine-AFB $_1$  was prepared via the reaction of AFB $_1$  dialdehyde with Cu²+(L-lysine) $_2$ . Blood samples (100 µL) were drawn from rats dosed with AFB<sub>1</sub>. Serum samples were spiked with deuterated lysine-AFB $_1$  as an internal standard and enzymatically digested. Digests were desalted using C18 solid phase extraction cartridges. Samples were eluted with MeOH and directly injected onto a cyano HPLC column (2 x 150 mm) for positive ESI-MS and fluorescent detection. Complete deprotection of Na-t-Boc-L-lysine-AFB, was obtained in 2 hours without loss of the product lysine-AFB<sub>1</sub>. Solid phase extraction recovery of lysine-AFB<sub>1</sub> was 85%. LCMS analysis was performed in 15 min and enabled the detection of lysine-AFB, in the serum of rats dosed with AFB<sub>1</sub>. Optimization of LCMS assay conditions is expected to enable the high throughput and quantitative measurement of approximately 1 pg lysine-AFB<sub>1</sub> in 100 μL blood samples.

## 1252 CYCLIN AND HOX GENE EXPRESSION ASSOCIATED WITH DRUG-INDUCED BILIARY HYPERPLASIA AND CELL PROLIFERATION IN CYNOMOLGUS MONKEYS.

C. M. Bral, F. M. Goodsaid, R. J. Smith, F. Poulet and I. Y. Rosenblum. Genetic and Molecular Toxicology, Schering-Plough Research Institute, Lafayette, NJ.

There are no predictive biomarkers for bile duct hyperplasia (BDH) for pre-clinical or clinical applications. BDH is a consequence of cell proliferation within the hepatobiliary tree. The expression of cyclin genes can be used as a marker for cell proliferation. Expression of Hox genes is associated with tissue differentiation and with the activation of growth-regulating cyclins. We have measured by quantitative RT-PCR (qRT-PCR) cyclin and hox gene expression changes associated with BDH and cell proliferation in Cynomolgus monkeys treated with an experimental S-P compound. BrdU incorporation at days 7, 14 and 28 was measured for monkeys receiving a daily dose of this compound and for days 21 and 42 for monkeys in recovery groups. Peak BrdU incorporation and BDH concurrent with BrdU incorporation were detectable in the day 14 group. qRT-PCR measurements of these samples were made for 21 cyclin and 41 hox genes. All of the 21 cyclin amplicons and 24 of the hox gene amplicons were induced in a preliminary screen against a pool of samples from active lesions (concurrent BrdU incorporation and BDH). Gene expression measurements for samples from all the monkeys in this study were made for genes shown to be induced in this screen. Cyclins E2 and E2v2 genes showed dose-response but no correlation with BrdU incorporation. Cyclins A, B and D1 genes showed both dose-response as well as a peak signal preceding that for BrdU incorporation. Cyclins A and D1 showed peak induction on day 7, and cyclin B showed induction for samples from both days 7 and 14. Hox gene induction was detected for genes in the Hox A and B series, as well as for Pitx 2. An induction profile similar to that for cyclins A and D1 was measured for Hox A7 and Pitx 2, with induction for these genes becoming undetectable in samples from tissues with undetectable BrdU incorporation. These results suggest that it may be possible to identify genomic markers not directly associated with cell division that are indicators of BDH.

### DMBT1 IS A BIOMARKER OF BILE DUCT HYPERPLASIA IN F344 RATS.

D. E. Watson<sup>1</sup>, I. Kadura<sup>1</sup>, B. Li<sup>1</sup>, G. Searfoss<sup>1</sup>, K. Rodocker<sup>2</sup>, J. Sullivan<sup>2</sup> and B. Berridge<sup>2</sup>. <sup>1</sup>Global Exploratory Toxicology Team, Eli Lilly and Company, Greenfield, IN and <sup>2</sup>Experimental Pathology, Eli Lilly and Company, Greenfield, IN. Sponsor: C. Thomas.

Bile duct hyperplasia (BDH) is a hepatotoxicity caused by many compounds. The molecular mechanisms by which this toxicity arises are not well understood. Moreover, there is a lack of in vivo biomarkers for this condition in non-clinical and clinical settings. In an attempt to identify biomarkers of BDH, we investigated gene expression changes in rats exposed to methapyrilene, a compound that causes BDH. From the outset we were challenged by the fact that biliary epithelial cells are few in number relative to the total cell population of the liver. We therefore attempted to enrich the liver samples for bile ducts by conducting a collagenase perfusion of the liver prior to harvest. Portal vein perfusion with collagenase reduced by ~80% the wet weight of the liver through elimination of hepatocytes. Portal trees isolated by this process were examined by light microscopy and processed for RNA and protein analysis. Affymetrix® analysis led to identification of a number of genes that had promise as in vivo biomarkers of BDH, including Ebnerin, a secreted protein originally identified in the epithelial cells of the von Ebner gland in the tongue of the rat. Literature review and TaqMan® analyses led to the identification that the gene detected by the Ebnerin probe sets on the Affymetrix® RGU34A array was actually a gene called Deleted in Malignant Brain Tumors 1 (DMBT1). TaqMan® and western blot analyses confirmed the induction of DMBT1 mRNA and protein, respectively, in the liver of rats exposed to methapyrilene. Additional experiments with more than 20 compounds indicate that DMBT1 may be both a sensitive and specific biomarker for BDH in the rat. The known function of DMBT1 includes differentiation and proliferation of proto-epithelial cells in vitro and in a variety of tissues (liver, intestinal tract, kidney) and species (rat, rabbit, human) in vivo, lending further support to the use of DMBT1 as a biomarker of BDH.

## 1254 BIOMARKERS OF HEPATOTOXINS IDENTIFIED USING MURINE EMBRYONIC STEM CELL DIFFERENTIATION SYSTEMS.

Y. S. Kim<sup>1</sup>, Y. Luo<sup>1</sup>, O. A. Callan<sup>1</sup>, <u>A. Vickers<sup>2</sup> and H. R. Snodgrass<sup>1</sup></u>. <sup>1</sup>VistaGen Therapeutics, Burlingame, CA and <sup>2</sup>Novartis Pharmaceuticals, East Hanover, NJ.

The in vitro differentiation of embryonic stem (ES) cells represents a complex biological system which may be useful for studying the effects of compounds on a wide range of tissues and biological processes. Our goal in these studies is to identify biomarker profiles that are characteristic of heptatoxins using an early stage of differentiation of ES cells as the biological system. Training sets were selected from 20 compounds that are known to induce varying levels of liver injury (troglitazone, rosiglitazone, pioglitazone, Wy-14643, bezafibrate, fenofibrate, KRP297, AZ242, dimethylformamide, methotrexate, carbon tetrachloride, ibupofen, naproxen, etoposide, indomethacin, methapyrilene hydrochloride, arsenic, allyl alcohol, aroclor 1254, and 3-methylchloranthrene), 3 renal toxins (tobramycin, kanamycin, gentamycin), 4 neural toxins (quinolic acid, glutamic acid, kainic acid, domoic acid), and 8 mixed toxins (diquat, amiodarone hydrochloride, dimethylnitrosamine, crotaline, carbamazepine, cyclosporine, cisplatin, and dimethyl sulfoxide) and evaluated to identify predictive gene-expression biomarker profiles characteristic of tissue-specific toxicity. Initially compound doses were selected to yield a 30-70% decrease in cell number at the end of a 6-day murine embryoid body (EB) assay. The effect of each compound was evaluated by monitoring gene expression microarrays. The data were analyzed by a variety of statistical tools including analysis of variance, hierarchical clustering, principal component analysis, and class prediction algorithms. Preliminary analyses indicate that biomarkers could be identified which are 80% predictive for the three classes of tissue toxins. Furthermore, the hepatotoxic compounds form distinct clusters, many of which are related to mechanism and/or relevant biochemical pathways. These data suggest that the ES cell differentiation system may be a valuable early predictive screen for toxins, and for early information about effects of compounds on known biological and/or biochemical pathways.

DIFFERENTIATION BETWEEN RENAL INJURY AND COMPENSATORY RESPONSES BY THE USE OF SPECIFIC BIOMARKERS.

A. Coyle<sup>1</sup>, P. R. Maxwell<sup>2</sup> and D. Gordon<sup>3</sup>. <sup>1</sup>Biotrin, Dublin, Ireland, <sup>2</sup>Biochemistry, Stobhill Hospital, Glasgow, United Kingdom and <sup>3</sup>Medicine, Stobhill Hospital, Glasgow, United Kingdom. Sponsor: R. Chandra Gupta.

Based on the early release of the enzyme N-Acetyl-β-D-glucosaminidase (NAG), it was previously believed that proximal tubular injury, was an early event in diabetic renal injury. However, NAG can be up-regulated in response to proteinuria and is a marker of increased lysosomal turnover, as well as overt injury. In this study, NAG was compared with the cytosolic injury biomarkers alpha glutathione S-transferase ( $\alpha$ GST, ) and pi glutathione S-transferase ( $\pi$ GST).  $\alpha$ GST is a cytosolic protein specific for the proximal convoluted tubule and  $\pi$ GST is found in the distal tubules. Their presence in urine indicates that cytolysis is occurring to cells in distinct parts of the nephron. 128 diabetic subjects were studied, 57 without albuminuria (group 1), 50 with microalbuminuria (group 2) and 21 with proteinuria (group 3) plus 20 age-matched controls. Urinary NAG was measured using a colorimetric method (Roche) and  $\alpha$  and  $\pi$ GST were assayed using the Biotrin Urinary Alpha and Pi GST EIA kits respectively (Biotrin International, Dublin Ireland). Urinary NAG levels expressed as University/mmol creatinine and  $\alpha$  and  $\pi$ GST levels, expressed as  $\mu g$  / mmol creatinine were (median: range): group 1, NAG 0.54 (0.21-2.96),  $\alpha GST$  0.21 (0.03-4.60),  $\pi GST$  2.27(0.13-19.2); group 2, NAG 0.69(0.23-2.16), αGST 0.2(0.032.5), πGST 2.55(0.14-33.3) and group 3, NAG 1.12(0.42-2.60),  $\alpha GST$  0.18(0.03-1.55),  $\pi GST$  5.34(1.37-11.98). Urinary NAG,  $\alpha$  and  $\pi GST$  in the control group were 0.33 (0.11-0.53), 0.31(0.04-1.15) and 0.84(0.18-1.32) respectively. NAG and  $\pi$ GST levels in the diabetic subgroups were significantly different to controls (p<0.05), whereas no significant differences in  $\alpha GST$  were seen (p>0.05). These results suggest that proximal tubular dysfunction or compensation (increased NAG release), rather than damage (no \alpha GST release), occurs in diabetic renal injury and that distal tubular damage ( $\pi GST$  release) is a very early event in the development of renal injury. By the use of biomarkers released according to different mechanisms and from different sites, new mechanisms of renal injury were

## 1256 EVALUATION OF A HIGH-THROUGHPUT ARRAYPLATE TEST PLATFORM FOR GENOMIC BIOMARKERS OF TOXICITY.

I. Botros<sup>1</sup>, F. M. Goodsaid<sup>2</sup>, B. Seligmann<sup>1</sup>, J. W. Davis<sup>2</sup>, M. Crawford<sup>1</sup>, R. J. Smith<sup>2</sup>, R. Martel<sup>1</sup> and <u>I. Y. Rosenblum<sup>2</sup></u>. <sup>1</sup>High-Throughput Genomics, Tucson, AZ and <sup>2</sup>Genetic and Molecular Toxicology, Schering-Plough Research Institute, Lafayette, NJ.

An important milestone in the development of genomic biomarkers of toxicity is their application in a high-throughput screening format. The gold standard for testing limited numbers of genomic biomarkers of toxicity per compound is quantitative RT-PCR (qRT-PCR). This platform can detect single copies of mRNA per test well and has a dynamic range over at least 108 copies of mRNA per test well. However, the real-time measurements are constrained by limited throughput in the range of 1500-3000 test wells per day. Hybridization endpoint platforms have the potential for throughput in the range of 3000-30000 test wells per day. These platforms are limited due to a lower sensitivity and dynamic range compared to qRT-PCR. We compared the sensitivity and dynamic range of the high-throughput ArrayPlate genomic test platform from High-Throughput Genomics (HTG) with those of qRT-PCR for HAVcr-1 and clusterin, two genomic biomarkers of nephrotoxicity we have studied in Cynomolgus monkeys. The ArrayPlate format measures hybridization for 16 genes per well. We found the sensitivity of the HTG platform using standard ArrayPlate reagent sets to be in the qRT-PCR CT range of 20-25, corresponding to approximately 105 copies of mRNA per test well. Its dynamic range is over a minimum of 103 copies of mRNA per test well. Clusterin was readily measured, while the sensitivity for detection of HAVcr-1 was limited by sample size. These results suggest that the sensitivity of the ArrayPlate test platform is within an order of magnitude of that needed for an accurate measurement of gene expression of HAVcr-1 using small samples in a high-throughput screening format. However, this platform provides values of at least an order of magnitude higher than similar array platforms we have tested. We will show the results using high sensitivity ArrayPlate reagent sets to bridge the sensitivity gap remaining for this platform.

## 1257 EVIDENCE OF AN IMMUNE-MEDIATED MECHANISM FOR NEVIRAPINE-INDUCED SKIN RASH IN THE BROWN NORWAY RAT.

J. M. Shenton and J. P. Uetrecht. Pharmaceutical Sciences, University of Toronto, Toronto, ON, Canada.

Rationale: The characteristics of a potential animal model of nevirapine-induced idiosyncratic skin rash in the female Brown Norway rat revealed a possible immune-mediated mechanism for the reaction. Specifically, an inflammatory infiltrate

composed of T cells and macrophages was present in the skin of treated animals, rats rechallenged with nevirapine developed the skin rash faster than on first exposure, and splenocytes from rechallenged rats could transfer rash susceptibility to naive recipients. Consequently, the role of the immune system in this reaction was further investigated. Methods and Results: Cotreatment of rats with nevirapine (150 mg/kg/day) and either the immunosuppressant tacrolimus (1 mg/kg/day) or cyclosporin (20 mg/kg/day) prevented the development of skin rash during nevirapine treatment. CD8 T cells were depleted in thymectomized rats by administering the monoclonal antibody OX-8 prior to treatment with nevirapine; however, the rats still developed a skin rash. Correspondingly, splenic T cells or CD4 T cells isolated from rats after nevirapine rechallenge transferred susceptibility to rash to naive recipients; however, CD8 T cells did not. Finally, splenocytes and lymph node cells (mesenteric and popliteal) were prepared from untreated rats, rats on initial nevirapine exposure, and rats on rechallenge and stained for flow cytometric analysis to characterize changes in cell populations related to nevirapine treatment. Paradoxically, the CD4 to ČD8 T cell ratio was significantly decreased in lymph nodes from treated rats compared to control rats (due to an increase in CD8 T cells); whereas, in spleen the results were inconsistent. Conclusions: Nevirapine-induced skin rash has an immune-mediated mechanism; and thus the mechanism is likely to be similar to the mechanism of nevirapine-induced rash in humans. (Funded by the Canadian Institutes of Health Research).

## 1258 CONTRIBUTION OF MAJOR HISTOCOMPATIBILITY COMPLEX DIFFERENCE ON OCCURRENCE OF SYSTEMIC ANAPHYLAXIS IN MICE.

Y. Heo<sup>1</sup>, H. Kim<sup>2</sup> and S. Hur<sup>3</sup>. <sup>1</sup>Occupational Health, Catholic University of Daegu, Kyongsan si, Kyongbuk, South Korea, <sup>2</sup>Preventive Medicine, The Catholic University of Korea, College of Medicine, Seoul, South Korea and <sup>3</sup>Biological Products, Korea Food & Drug Administration, Seoul, South Korea.

This study was undertaken to investigate contribution of major histocompatibility complex difference on systemic anaphylaxis occurrence following vaccination. Anaphylaxis has been induced in BALB/c (H-2d), DBA2 (H-2q), C3H (H-2k), and C57BL/6 (H-2b) mice through intraperitoneal sensitization with chicken egg ovalbumin (OVA) followed by intravenous challenge with OVA. The magnitude of anaphylaxis occurrences was determined by measuring levels of plasma histamine, IgE, OVA-specific IgG, total IgG1, IgG2a, cytokine production from splenocytes stimulated in vitro, and expression of CD23 low affinity IgE receptors, CD16 FcγIII/II IgG receptors. The highest histamine level was obtained in the DBA/2 mice and the lowest in the C57BL/6 mice. Comparing levels of IgE between the OVA sensitized mice and the mice administered to saline or adjuvant (cholera toxin plus alum), significant elevation was observed in the DBA/2 and BALB/c mice, but not in the C3H and C57BL/6 mice. Furthermore, level of plasma OVA-specific IgG1, another anaphylaxis marker previously reported by the authors, was higher in the DBA/2 and BALB/c than C3H mice, and lowest in the C57BL/6 mice. Order of IL-4 versus IFN γ ratio, which indicates skewing of helper T cell reactivities, was BALB/c > DBA/2 > C57BL/6 > C3H. Significant increase in expression of CD23 was resulted in B cells from the DBA/2 mice developing anaphylaxis compared with the control mice, but not in other strains. This study endows the scientific evidence on a hypothesis that differences in the immuno-genetic background could significantly contribute the occurrence of systemic anaphylaxis observed in children following various vaccinations.

### 1259 INVESTIGATING IMMUNOGENICITY OF 2-PHENYLPROPENAL, A REACTIVE METABOLITE OF FELBAMATE.

M. Popovic<sup>1</sup>, S. Nierkens<sup>2</sup>, W. Santos<sup>3</sup>, R. Pieters<sup>2</sup> and J. Uetrecht<sup>1</sup>.

<sup>1</sup>Pharmaceutical Sciences, University of Toronto, Toronto, ON, Canada, <sup>2</sup>IRAS-IT, Utrecht, Netherlands and <sup>3</sup>Harvard University, Cambridge, MA.

Felbamate is an anti-epileptic drug with unique efficacy against difficult cases of epilepsy. Within the first year of its widespread use, felbamate therapy was associated with an occurrence of aplastic anaemia and hepatotoxicity. The mechanism of felbamate-induced idiosyncratic reactions has not been elucidated; however, most such reactions appear immune-mediated. Furthermore, it has been proposed that the formation of the reactive metabolite 2-phenylpropenal is responsible for felbamate-induced adverse reactions. To investigate the immune stimulating potential of felbamate and its metabolites *in vivo*, we performed reporter antigen popliteal lymph node assay (RA-PLNA) using TNP-Ficoll antigen and Balb/C mice. Immunological effects of felbamate, 2-phenylpropenal and its precursor monocarbamate felbamate were investigated. Mice foot pads were s.c. injected with one of the compounds, and a week later the PLN was removed and presence of immune response analyzed. We found that neither felbamate nor monocarbamate felbamate induced an immune response in PLNs in mice *in vivo*. However, 2-phenylpropenal appeared immunogenic, causing inflammation of foot pads, followed by their hard-

ening, increase in thickness and crustiness. The PLN cell count showed a nine-fold increase in the 2-phenylpropenal-treated mice compared to the controls. Immunohistochemical analysis of the PLNs revealed germinal center formation, indicating B cell proliferation. Cytokine analysis suggested an increase in the production of IL-4 and to a lesser extent IFN-g. Flow cytometry on PLN confirmed previous findings; total B cell numbers increased, the majority of B cells being activated, co-expressing CD54 and CD19 cell surface markers. In addition, it appears as if B cells had a role as antigen presenting cells, because they co-expressed both CD86 and CD19. Our study supports the hypothesis that 2-phenylpropenal is responsible for the idiosyncratic reactions associated with felbamate.

1260

CHARACTERIZATION OF HARDWOOD AND SOFTWOOD DUST INDUCED EXPRESSION OF CYTOKINES AND CHEMOKINES IN MOUSE MACROPHAGE RAW 264.7 CELLS.

J. Maatta<sup>1</sup>, M. Majuri<sup>1</sup>, A. Lauerma<sup>2</sup>, K. Husgafvel-Pursiainen<sup>1</sup>, H. Alenius<sup>1</sup> and <u>K. Savolainen<sup>1</sup></u>. <sup>1</sup>Department of Industrial Hygiene and Toxicology, Finnish Institute of Occupational Health, Helsinki, Finland and <sup>2</sup>Department of Occupational Medicine, Finnish Institute of Occupational Health, Helsinki, Finland.

In addition to nasal and sino-nasal adenocarcinomas, wood dust exposure can induce several nonmalignant, mainly respiratory diseases such as allergic rhinitis, chronic bronchitis, and asthma. To find out whether wood dust is able to influence to development of inflammatory process through macrophages, we have elucidated the effects of wood dust exposure on the cytokine and chemokine expression of mouse macrophage cell line cells (RAW 264.7). The cells were exposed to graded doses of selected hardwood (birch, beech, oak, and teak) and softwood dusts (pine, spruce, and heat-treated pine). TiO<sub>2</sub> and LPS were used as controls. The mRNA expression of major proinflammatory cytokines (IL-1β, TNF-α, and IL-6), an antiinflammatory cytokine (IL-10), and several chemokines (CCL2, CCL3, CCL4, CCL5, and CCL24) were assessed by real time PCR at several time points after wood dust exposure. TNF-α, IL-6, and CCL2 expression was studied also at the protein level using the ELISA method. Wood dust had in general more effects on cyto- and chemokine expression than inorganic dust TiO2. All wood dusts induced TNF-α, IL-6, CCL3, and CCL4 expression and inhibited IL-1β and CCL24 expression. However, many differences were detected in the strength of induction or inhibition between different wood dusts. In the case of CCL2, birch, beech, pine, spruce, and heat-treated pine induced CCL2 production, but oak and teak dusts had no effect. Oak dust, that has been previously shown to be carcinogenic, appears to be a weaker inducer of inflammatory response than the other wood dusts. Our results show that exposure to different wood dusts elicits dose-dependent changes in the levels of inflammatory mediators in mouse macrophage cells. These findings suggest that exposure to wood dust may significantly influence development of inflammatory process in the airways by modulating the expression of proinflammatory cytokines and chemokines.

1261

CAN THE POPLITEAL LYMPH NODE (PLN) ASSAY BE USED TO PREDICT SPECIFIC IgE ADJUVANT ACTIVITY OF AMBIENT AIR PARTICLES? RESULTS FROM THE EUROPEAN RAIAP PROJECT.

M. Lovik, T. Lovdal, E. Groeng and E. Dybing. Environmental Medicine, NIPH, Oslo, Norway.

For the project Respiratory allergy and inflammation due to ambient particles: a European-wide assessment (RAIAP), ambient particulate matter was collected with high-volume samplers during three seasons (spring, summer, and winter) in Oslo (Norway), Rome (Italy), Lodz (Poland) and Amsterdam (The Netherlands), and at the Dutch seaside background site de Zilk (winter only). Coarse (PM<sub>2,5-10</sub>) and fine (PM<sub>0.1-2.5</sub>) particles were collected, and altogether 26 different particulate matter (PM) preparations were obtained. The PM preparations were examined for allergy adjuvant activity in two different assays in BALB/c mice. In the PLN assay the cellular response in the draining popliteal lymph node was measured after injection into the footpad of PM alone or PM plus allergen (ovalbumin, OVA). In the specific antibody assay, serum anti-OVA IgE, IgG1 and IgG2a were measured after similar immunization with PM + OVA. In the PLN assay, the cellular response to particles without allergen reflects the inflammatory capacity of the PM, while after co-injection of PM and allergen the response may be dominated by the immune response to the allergen. Coarse particles were generally found to have stronger inflammatory capacity than fine particles. Few statistically significant differences between PM preparations of the same type (coarse or fine) from different cities were observed. Similarly, few differences between PM preparations of the same type were observed in the PLN assay after injection of PM + OVA. Fine particles generally had stronger adjuvant activity than coarse particles in the antibody assays. A high inflammatory capacity in the PLN assay did not predict high adjuvant activity after co-injection of PM and allergen, neither in the PLN nor in the antibody assays. The antibody assays appeared to discriminate better between different PM preparations than the PLN assay with regard to adjuvant activity. Further, the antibody response represents a more well-defined and relevant parameter in relation to allergy than the PLN response.

SENSITIVITY AND SPECIFICITY OF A SEROLOGICAL TEST THAT DETECTS HUMAN IGE ANTIBODY TO THE BACILLUS ENZYME Y217L BPN'.

K. Sarlo<sup>1</sup>, B. Schnell<sup>1</sup>, R. J. Harbeck<sup>2</sup>, D. Leto<sup>2</sup>, E. Finn<sup>1</sup> and B. Kirchner<sup>1</sup>. Miami Valley Laboratories, Procter & Gamble Company, Cincinnati, OH and <sup>2</sup>National Jewish Medical and Research Center, Denver, CO.

A fluorescence immunoassay (FEIA UniCAP®) was developed to detect Bacillus protease Y217L BPN' specific IgE antibody in serum from humans exposed via the work environment or via clinical tests. Receiver-operating characteristic analysis (ROC) was done to determine the sensitivity and specificity; concordance correlation coefficients (CCC) were calculated to measure reproducibility of the assay. Serum from workers that were exposed to the enzyme and defined as skin prick test (SPT) positive or negative for enzyme-specific IgE antibody were used to define true IgE positive and true IgE negative samples. In addition, serum from clinic test subjects SPT (-) to the enzyme were used to supplement the true IgE negative population. A total of 561 samples were tested. The World Health Organization (WHO) IgE/anti-IgE standard was used to define the threshold for positive response in the assay. Sensitivity was defined by the percentage of SPT (+) subjects with positive IgE in serum; specificity was defined by the percentage of SPT (-) subjects with negative IgE in serum. ROC curves were generated by plotting sensitivity (y-axis) vs. 1-specificity (x-axis). Area under the curve (AUC) was used to assess accuracy where 1.0 represents perfect accuracy. The AUC for the enzyme UniCAP assay was 0.944 showing that this assay has a high ability to distinguish between SPT (+) and (-) individuals. Using the WHO threshold for positive response in the UniCAP, the sensitivity from the ROC curve was 81.8% and the specificity was 95.2%. The false positive rate for the assay was 0.59%. The CCC that measured the agreement between replicate data generated on the same serum samples and a 45degree line on a coordinate system was 0.999. Perfect agreement = 1.0. In summary, the UniCAP enzyme assay was highly specific, sensitive and reproducible for human enzyme-specific IgÉ serum antibody.

### 1263 DIFFERENTIAL GENE EXPRESSION IN OCCUPATIONAL ASTHMA.

J. F. Regal<sup>1</sup>, A. L. Greene<sup>1</sup>, R. R. Regal<sup>2</sup>, M. S. Rutherford<sup>3</sup>, G. H. Flickinger<sup>3</sup>, J. A. Hendrickson<sup>3</sup> and M. E. Mohrman<sup>1</sup>. <sup>1</sup>Pharmacology, University of Minnesota, Duluth, MN, <sup>2</sup>Mathematics and Statistics, University of Minnesota, Duluth, MN and <sup>3</sup>Veterinary Pathobiology, University of Minnesota, St. Paul, MN.

Trimellitic anhydride (TMA) is a small molecular weight chemical, and ovalbumin (OA) is a reference protein allergen in immunology. Both are known causes of occupational asthma, and effector mechanisms for both allergens are presumed to be the same. To determine if unique genes were expressed for each allergen, gene expression in lungs of mice sensitized and challenged with either TMA or OA was examined. Balb/c mice were sensitized intradermally on days 1 and 3 with TMA (3%) or OA (0.3%) in corn oil vehicle, and intratracheally day 12 with 30 µg of either TMA conjugated to mouse serum albumin (TMA-MSA) or OA. To elicit the allergic response, mice were challenged intratracheally on day 19 with 400 µg TMA-MSA, OA or control MSA. 72 hours later, lung lobes were removed for RNA isolation and analysis of eosinophil peroxidase as a measure of eosinophilia. Challenge with either OA or TMA resulted in similar significant lung eosinophilia. To assess gene expression, separate Affymetrix U74Av2 microarrays were used for each of 6-8 animals in 4 treatment groups. Data were normalized using Robust Multichip Analysis in GeneTraffic software. ANOVA p values were calculated with SAS. The q values (false discovery rates) were calculated using R and considered significant if less than 0.12. OA and TMA sensitization and challenge resulted in differential expression of 79 genes and 44 genes, respectively. Fold changes in gene expression in the OA sensitized and challenged group were consistent with recent reports of others. Comparing the difference in gene expression in OA vs OA control to the difference in TMA vs TMA control revealed significant differences in 15 genes. These data demonstrate clear differences in gene expression depending on the allergen and suggest that unique effector mechanisms may exist for different causative agents of occupational asthma. (Support: Graduate School & Academic Health Center, University of Minnesota; US Army Med. Res Acquisition Activity DAMD 17-02-1-0191).

M. K. Selgrade, E. H. Boykin, N. H. Coates, D. L. Doerfler and S. H. Gavett. ORD/NHEERL, University. S. EPA, Research Triangle Pk, NC.

Exposure to certain low molecular weight chemicals is associated with asthma. A simple test is needed to identify chemicals that pose this hazard. Increases in total serum IgE or Th2 cytokines in draining lymph nodes following dermal exposure have been pursued as means to screen potential asthmagens. It would be useful to relate these responses to a respiratory effect. We hypothesized that dermal exposure to certain isocyanates would result in enhanced pulmonary hyperresponsiveness to methacholine challenge. We assessed 4 treatment groups including 2 chemicals associated with asthma, 2% diphenylmethane-4, 4'-diisocyanate (MDI) and 2% dicyclohexylmethane-4, 4'-diisocyanate (HMDI); a contact sensitizer not associated with asthma, 1% dinitrochlorobenzene (DNCB); and a vehicle control (4 acetone:1 olive oil). BALB/c mice received 5 dermal exposures over a period of 2 wks. Mice were then challenged with increasing doses of methacholine and responsiveness was assessed using whole body plethysmography (Buxco). Half of each group was killed and serum, bronchoalveolar lavage fluid (BALF), and lymph nodes were collected for total IgE, cell counts, and cytokine profiling. The remaining mice were exposed for an additional 2 wks and reassessed. There were no changes in total or differential cell counts for any of the exposure groups at any time compared to vehicle. Significant increases in serum IgE were apparent for the 3 exposure groups at 2 and 4 wks, with differences greater at 4 wks. Mice exposed to HMDI showed significant hyperresponsiveness at 2 wks; these differences were greater at 4 wks. Neither MDI nor DNCB produced significant hyperresponsiveness at either time. This data suggests a disconnect between the total serum IgE response and hyperresponsiveness. Also, using the current protocol hyperresponsiveness occurred after dermal exposure for only one of the two asthmagens. (This abstract does not reflect EPA policy).

SUITABILITY OF AFFYMETRIX HUMAN GENECHIPS FOR ANALYSIS OF RNA SAMPLES FROM NON-HUMAN PRIMATES

M. Derbel, S. Szak, M. Rosenberg, <u>M. Cooper</u>, D. Enke, M. Subramanyam and <u>J. Green</u>. *Preclinical and Clinical Development Sciences Division, Biogen, Cambridge, MA*.

New drugs are screened for adverse reactions using a laborious, costly process and still some promising therapeutics are withdrawn from the marketplace because of unforeseen human toxicity. Gene expression profiling, through the use of microarray technology, is rapidly becoming a standard analysis in toxicology studies, and has the potential to play a pivotal role in all stages of drug safety evaluation. Non-Human primates are widely used in the development of biotechnology-derived products. Indeed, their close phylogenic distance to humans often makes them the only pharmacological responsive species. Our genomic sequence analysis revealed that the chimpanzee and human genomes are sufficiently similar to warrant cross-species use of human Affymetrix GeneChips. The genes of cynomolgus and rhesus monkeys, on the other hand, are too dissimilar to human genes to be reliably assayed on a human-specific chip. Data also suggest that rhesus and cynomolgus monkeys' genes are at least as similar to each other as those of human and chimpanzee. Results from this study will be useful in assessing biomarkers development strategies for biotechnology-derived products.

DEVELOPMENT OF A PUBLIC TOXICOGENOMICS SOFTWARE FOR MICROARRAY DATA MANAGEMENT AND ANALYSIS.

W. Tong, S. Harris, X. Cao, H. Fang, L. Shi, H. Sun, <u>J. Fuscoe</u>, H. Hong, Q. Xie, R. Perkins and <u>D. Casciano</u>. *NCTR, Jefferson, AR*.

Robust bioinformatics capability is widely acknowledged as central to realizing the promises of toxicogenomics. Successful application of the toxicogenomics approach, such as DNA microarray, is inextricably relied on appropriate data management, the ability to extract knowledge from massive data and the availability of functional information for data interpretation. At the FDA's National Center for Toxicological Research (NCTR), we are developing public microarray data management and analysis software, named ArrayTrack. ArrayTrack is MIAME (Minimum Information About A Microarray Experiment) supportive to store both microarray data and experiment parameters associated with a toxicogenomics study. A quality control mechanism is implemented to assure the quality of entered expression data. ArrayTrack also provides a rich collection of functional information about genes, proteins and pathways enriched from various public biological databases for facilitating data interpretation. In addition, several data analysis and visualization tools are also developed in ArrayTrack and more tools will be available in the next released version. Importantly, gene expression data, functional information

and analysis methods are fully integrated so that the data analysis and interpretation process is simplified and enhanced. ArrayTrack is publicly available online to noncommercial use and the prospective user can also request a local installation version by contacting the authors.

#### 1267

DRUG SIGNATURES PREDICT CHRONIC RENAL TUBULE INJURY FOLLOWING SUB-ACUTE DRUG ADMINISTRATION.

M. R. Fielden, S. Baumhueter, G. Day, S. Dunlea, B. Eynon, S. Fujimoto, B. Ganter, R. Idury, K. Jarnagin, K. Kolaja, M. Lee, R. Nair, G. Natsoulis, S. Nicholson, C. Pearson, A. Roter, S. Thode, A. Tolley, S. Tugendreich, S. Tugendreich and S. Tugendreich. *Iconix Pharmaceuticals, Mountain View, CA*.

To improve compound selection during drug development we have developed a large library of gene biomarkers, Drug Signatures<sup>TM</sup>, for important toxicities and mechanisms of action. These signatures are derived from a comprehensive database of ~13, 000 microarray expression profiles derived from treating rats with 580 drugs, in addition to traditional clinical pathology and pharmacology measurements. Using long-term low-dose drug-induced tubular nephrosis in the rat kidney as a model system, we demonstrate the utility of a large reference database to identify Drug Signatures™ predictive of chronic pathology after sub-acute administration. Male adult SD rats were dosed daily for 5, 14 or 28 days with one of 11 renal tubular toxicants including platinum drugs, aminoglycoside antibiotics and heavy metals. Clinical and histological pathology data confirmed that treatment with 10 of 11 compounds did not produce renal tubule injury on day 5, while histopathological evidence of progressive and degenerative tubular injury was subsequently observed for 9 of these 10 compounds on days 14 and 28. Using a linear discriminant-based SVM algorithm and a reference database of over 400 kidney expression profiles, representing >100 compounds, a Drug Signature™ predictive of tubular nephrosis was developed. Cross-validation of the signature demonstrates an accuracy of >98% for identifying tubular nephrosis based on 5-day gene expression data. Genes in the signature included GH receptor and the immediate early gene Fn14, suggestive of an early regenerative response prior to the appearance of injury. These results demonstrate the utility of a comprehensive database to identify gene biomarkers predictive of chronic pathology after sub-acute administration, thus saving time and expense during drug development decision making.

DECISION FOREST FOR PREDICTING PROSTATE CANCER BASED ON SELDI-TOF MS DATA - SHOW ME THE CONFIDENCE.

W. Tong<sup>1</sup>, Q. Xie<sup>2</sup>, H. Hong<sup>2</sup>, H. Fang<sup>2</sup>, L. Shi<sup>1</sup>, R. Perkins<sup>2</sup> and R. Kodell<sup>1</sup>.

<sup>1</sup>Nat. Ctr for Toxicology Research, Jefferson, AR and <sup>2</sup>Bioinformatics and Computational Science Group, Northup Grumman Information Technology, Jefferson, AR. Sponsor: D. Casciano.

Class prediction using proteomics data from SELDI-TOF MS are playing an increasing role in diagnosis, prognosis and risk assessment. Usually, SELDI-TOF data has very many predictor variables (i.e. m/z peaks) over relatively few samples and, sometimes, is noisy. The nature of the data manifests that the challenge in class prediction is no longer in constructing a fitted model that is internally consistent; rather, it is how to quantify the predictivity of the fitted model for classifying unknown samples. Commonly, the predictivity of a fitted model is assessed by predicting a test set that contains samples not used in the model development. This external validation procedure offers a sense of real-world application, but the conclusion might not reflect the predictivity of the model due to the limitation of the sample representation of the test set. We developed a class prediction model for early detection of prostate cancer based on SELDI-TOF data using a novel ensemble method, Decision Forest. Decision Forest combines the results of multiple heterogeneous but comparable decision trees to produce a single prediction. Using an extensive leave-10-out (L10O) cross-validation procedure, we were able to assess two essential characteristics associated with the model's predictivity for predicting the samples not included in the model development, i.e. the level of prediction confidence and the degree of chance correlation. The results demonstrated that the proposed extensive L10O cross-validation provides an unbiased and rigorous way to validate the predictivity of a Decision Forest model for class prediction.

### 1269

INTEGRATION OF GENOMICS AND METABONOMICS DATA WITH ESTABLISHED TOXICOLOGICAL ENDPOINTS. A SYSTEMS BIOLOGY APPROACH.

K. Kramer<sup>1</sup>, S. Patwardhan<sup>3</sup>, K. A. Patel<sup>3</sup>, S. T. estrem<sup>2</sup>, J. M. Colet<sup>1</sup>, <u>R. A. Jolly<sup>2</sup></u>, G. S. Ganji<sup>3</sup>, N. J. Lewin-Koh<sup>3</sup>, H. Gao<sup>2</sup>, I. L. Smyej<sup>1</sup>, S. Huang<sup>2</sup>, H. R. Qian<sup>2</sup>, P. Chen<sup>2</sup> and V. K. Kanjilal<sup>3</sup>. <sup>1</sup>Lilly Development Centre, Mont Saint Guibert, Belgium, <sup>2</sup>Eli Lilly, Indeanapolis, IN and <sup>3</sup>Eli Lilly, Singapore, Singapore.

Introduction: The purpose was to develop and evaluate methods to integrate genomics and metabonomics data with histopathological and clinical pathology data obtained in 5 *in vivo* single dose studies in the rat. An integrated approach

analysing parameters monitored in tissues and those accessible in biofluids is essential for the identification of markers that potentially can be transferred to clinical studies. It also facilitates a better understanding of mechanisms of toxicity. Study design: Rats were treated with a minimally toxic or toxic single dose of either Adriamycin, Bromobenzene, Clofibrate, Diethylhexyl Phthalate, Valproate or respective vehicle. 1H NMR data were collected in urine samples up to 168h after dosing. Gene expression profiles were determined in livers 4, 24, 48 and 168h, histopathological assessment was carried out 48 and 168h after dosing. Clinical chemistry parameters were measured at various time points up to 168h after dosing in urine and serum samples. Data Analysis: Methods employed, in addition to well described statistical approaches, included knowledge based integration based on pathway mapping and clustered correlation. Conclusions: Integrated transcriptome and metabolome pathway mapping is an effective approach for mechanistic investigations. For example: In the case of the PPAR agonists good correlation was found between ketone bodies monitored in urine samples and genes involved in ketogenesis. Phenotypical anchoring of the data based on histopathological assessment is important. Integrated analysis provides better separation between treatment groups compared to individual genomic or metabonomic analysis. For example: Whereas in the clofibrate study neither genomics nor metabonomics data alone were able to sufficiently separate low dose versus control, an integrated data analysis separated well both low and high dose groups from control samples.

1270

TARGETED PROTEOMICS PROFILING: USE OF LECTIN AFFINITY CHROMATOGRAPHY TO ISOLATE CANCER-RELATED FUCOSYLATED PROTEINS FROM SERUM.

C. R. Wilson<sup>1</sup>, C. L. Feasley<sup>2</sup>, F. E. Regnier<sup>2</sup> and S. B. Hooser<sup>1</sup>. <sup>1</sup>Animal Disease Diagnostic Laboratory, Purdue University, West Lafayette, IN and <sup>2</sup>Chemistry, Purdue University, West Lafayette, IN.

Differential expression of  $\alpha(1, 6)$ -fucosylated proteins has been shown to occur in various types of neoplasia including lymphoma, hepatocarcinoma, and colorectal cancer. Using targeted proteomics profiling, a method has been developed and optimized for the isolation of  $\alpha(1, 6)$ -fucosylated peptides from tryptically digested canine serum. Isolation of these peptides was accomplished using HPLC and an affinity chromatography column with L. tetragonolobous lectin (LTL), which binds  $\alpha(1, 6)$ -fucosylated proteins and peptides with high specificity. The LTL column was synthesized by conjugating the lectin to diol-silica by reductive amidation following periodate oxidation. It was connected inline with HPLC/UV. Selecting fucosylated peptides from normal canine serum was accomplished using optimized sample preparation procedures and LTL affinity column selections. Briefly: 1) conditions for tryptic digestion of proteins from normal canine serum were optimized, 2) tryptically digested peptides from normal canine serum were injected onto an LTL affinity column to select for  $\alpha(1, 6)$ -fucosylated peptides, 3) the selected  $\alpha(1, 6)$ -fucosylated peptides, 3) 6)-fucosylated peptides were separated using reverse phase chromatography resulting in the isolation of peptide-containing fractions for identification by mass spectrometry. Procedures are being optimized for deglycosylation of the peptides followed by mass spectral analysis. MALDI-TOF and ESI-MS are being performed to characterize and identify the fucosylated serum proteins. Overall, this procedure is unique in that it selects for cancer-related proteins which, when coupled to Global Internal Standard Technology (GIST) labeling, will facilitate the identification and quantification of the differential expression of these proteins in normal serum versus serum from dogs with cancer. When applied to humans, this will allow diagnosis of some types of cancer and permit evaluation of treatment efficacy and prognosis following chemotherapy.

1271

GENE EXPRESSION CHANGES IN PRIMATES ARE DIFFERENT FROM THOSE IN RODENTS FOLLOWING EXPOSURE TO THE HEPATOTOXIN ACETAMINOPHEN.

M. S. Lawrence, D. Redmond, R. Roth, J. Elsworth, S. Tam, R. Jensen and S. Gullans. *RxGen, Hamden, CT.* Sponsor: <u>Y. Dragon</u>.

Early and sensitive detection of potential hepatotoxins is essential to assuring efficiency of drug development and minimizing post marketing health risks and liability. Toxicogenomics offers such predictive potential, but in determining possible human risk important attention must be paid to the animal models employed. Nonhuman primates offer the greatest promise of yielding truly predictive toxicogenomic modeling. To establish the feasibility of primate toxicogenomics we have used microarrays to evaluate the *in vivo* gene transcriptional changes in the liver of the African green monkey following the administration of acetaminophen, a classic and prevalent hepatotoxin. Acetaminophen was delivered to 8 monkeys *via* nasogastric tube in a single dose of either 200 or 400 mg/kg 48 hours prior to sacrifice. Blood and liver tissue were collected and compared to 4 control animals. Histopathology revealed microvascular change in acetaminophen exposed liver tissue relative to controls, and serum chemistries were consistent with early liver in-

jury. Preliminary microarray analyses using Amersham CodeLink human arrays demonstrated hepatic transcriptional changes in response to acetaminophen that are different from those previously reported in rodents. Given these preliminary findings with an important hepatotoxin primate toxicogenomics may offer a more relevant, sensitive and ultimately cost effective means of improving predictive toxicology.

1272

GENOMIC CHARACTERIZATION OF IDIOPATHIC AND DRUG-INDUCED DILATED AND HYPERTROPHIC CARDIOMYOPATHY IN THE RAT HEART.

D. Donna<sup>1</sup>, M. R. Fielden<sup>2</sup>, K. Kolaja<sup>2</sup>, J. Moehlencamp<sup>3</sup>, M. Peden<sup>3</sup> and <u>B. Car</u><sup>1</sup>. <sup>1</sup>Bristol-Myers Squibb, Princeton, NJ, <sup>2</sup>Iconix Pharmaceuticals, Mountain View, CA and <sup>3</sup>Bristol-Myers Squibb, Evansville, IN.

Over-expression of the Gaq-coupled serotonin 2B receptor (5-HT2BR) leads to non-patĥological cardiac hypertrophy, whereas over-expression of Gαq leads to dilated cardiomyopathy (CM). Paradoxically, congenital deletion of 5-HT2BR also results in dilated CM. Thus, drug-induced activation or inhibition of 5-HT2BR signaling could cause CM. To understand and predict CM induced via diverse yet overlapping signaling pathways, we evaluated expression profiles derived from drug-induced models of CM in the rat in the context of a large chemogenomic reference database (DrugMatrix<sup>TM</sup>). Adult male SD rats were dosed for 5 days with BW-723C86, a 5-HT2BR agonist, a 5-HT2BR antagonist, or tri-iodothyrinine (T3) as a model for cardiac hypertrophy. Aged rat heart was also profiled as a model of idiopathic CM. Utilizing Iconix proprietary analysis tools and Drug Signatures<sup>TM</sup>, we were able to delineate the agonist vs antagonist effects of the 5-HT2BR ligands on cardiac gene expression. Further, expression profiles were consistent with BW-723C86 and the 5-HT2B antagonist to induce hypertrophic and dilated CM, respectively, consistent with genetic models of activation and deletion of 5-HT2BR signaling. These findings were also identified prior to the appearance of histopathological injury in the heart. T3 was identified as being cardiotoxic since it induced expression changes consistent with hyperthyroidism and remodeling of the extracellular matrix. Evaluation of other compounds in DrugMatrix<sup>TM</sup> with sub-micromolar affinity for 5-HT2BR reveals expression changes similar to anthracycline drugs, including suppression of cell-cycle genes (CDČ2A, Cyclin A2) and induction of clock genes (Dbp, Tef). Collectively, these results show the value of expression profiling for identifying mechanisms of CM, and reveal novel insights into the mechanism of action of 5-HT2B ligands, as well as anthracycline drugs.

1273

FTICR-MS ACCURATE MASS AND TIME TAG ANALYSIS OF HUMAN PROTEOME ORGANIZATION REFERENCE SERA AND PLASMA.

J. N. Adkins, K. J. Auberry, N. Tolic, M. E. Monroe, R. Karin, R. D. Smith and J. G. Pounds. *Biological Sciences Division, Pacific Northwest National Laboratory, Richland, WA*.

Characterization of the human blood plasma proteome is important to discovery of useful biomarkers for disease diagnosis, susceptibility, and prognosis. The Human Proteome Organization (HUPO) has begun to evaluate the proteomes of human blood sera/plasmas in a systematic multi-pronged approach. Our contribution to this study uses a combination of powerful mass spectrometry technologies with improvements in sample preparation to perform a global proteomic analysis of the proteins found in sub-mL quantities of the HUPO reference sera/plasmas. We used an extensively characterized MS/MS database of serum-derived peptides as the basis for an AMT approach using Fourier-transform ion cyclotron mass spectrometry (FTICR-MS). Due to peptide sequence variability, immunoglobulins were depleted from serum/plasma using protein A/G. The IgG-depleted serum/plasma was then digested with modified-trypsin and analyzed by capillary-LC FTICR MS. Approximately 550 proteins are detected in serum and plasma with high confidence based on reproducibility of measurement; 150 proteins are detected with less confidence. Approximately 590 proteins were identified in both serum and plasma and about 120 were detected in only serum or the plasma samples to give a total of 850 proteins identified. Among the proteins identified are lower abundance serum/plasma proteins known to be in the ng/mL range. We also used the program, SEQUEST, to compare peptides identified from the NCBI vs. the IPI human protein databases. Analysis of LC-MS/MS data against the IPI database produced about 10% fewer protein identifications than the NCBI database. These analyses demonstrate the sensitivity of the AMT strategy and the high resolution of MS instruments such as the FTICR-MS to identify low abundance proteins. The data also underscore the importance of the database used for protein identifications. The AMT approach will improve sample throughput to improve characterization and understanding of how biological systems interact with their environment

TRANSCRIPTIONAL PERTURBATION OF LYSYL OXIDASE BY CIGARETTE SMOKE CONDENSATE IN CULTURED LUNG FIBROBLASTS.

W. Li<sup>1</sup>, K. Chen<sup>1</sup>, Y. Zhao<sup>2</sup>, L. Chen<sup>1</sup>, P. Toselli<sup>1</sup>, <u>I. Chou<sup>2</sup></u> and P. Stone<sup>1</sup>.

<sup>1</sup>Biochemistry, Boston University School of Medicine, Boston, MA and <sup>2</sup>Microbiology, Boston University School of Medicine, Boston, MA.

Lysyl oxidase (LO) catalyzes crosslinking of collage and elastin playing a central role in maintenance of the structural integrity of the lung extracellular matrix (ECM). To understand mechanisms of cigarette smoke (CS)-induced emphysema, we investigated the effects of cigarette smoke condensate (CSC) on LO mRNA expression in cultured rat fetal lung fibroblasts (RFL6). Exposure of RFL6 cells to CSC at 0- $120\,\mu\text{g/ml}$  for 24 h induced a dose-dependent downregulation of LO mRNA as exemplified by the reduction of LO mRNA levels in the presence of 80-120  $\mu g$ CSC/ml to below 10% of the control. The trypan blue exclusion assay indicated no significant effects of CSC on cell viability under the same conditions. Furthermore, identical CSC treatments did not change mRNA levels of internal controls, e.g., actin and GAPDH. Using actinomycin D, an inhibitor of mRNA synthesis, in a chase assay we showed that LO mRNA exhibited relative stability in control cells with t1/2 = 24 h. However, CSC exposure reduced the stability of LO transcripts as evidenced by a 50% decrease in the level of LO mRNA in cells treated with actinomycin D (5  $\mu$ g/ml) in the presence of CSC (120  $\mu$ g/ml for 24 h) in comparison to cells in the absence of CSC. Moreover, nuclear-run on assays indicated a 2.5-fold decrease in the amount of LO transcripts found in nuclei isolated from cells treated with CSC (120 µg/ml for >6 h) relative to that of nuclei from control cells. Thus, the reduction of LO mRNA stability combined with the suppression of transcriptional initiation both contributed to downregulation of LO mRNA in CSC-treated cells. Note that inhibition of LO mRNA expression by CSC was closely accompanied by markedly decreased levels of transcripts of collagen type I and tropoelastin, two substrates of LO. Thus, transcriptional perturbation of LO and its substrate may be a critical mechanism for ECM damage in CS-induced emphysema (supported in part by Philip Morris Foundation and NIH grant R01-ES 11340).

INHIBITION OF LYSYL OXIDASE AT PROTEIN AND CATALYTIC LEVELS AND CELLULAR THIOL HOMEOSTASIS IN RAT LUNG FIBROBLASTS TREATED WITH CIGARETTE SMOKE CONDENSATE.

L. Chen<sup>1</sup>, Y. Zhao<sup>2</sup>, K. Chen<sup>1</sup>, P. Toselli<sup>1</sup>, <u>I. Chou</u><sup>2</sup>, P. Stone<sup>1</sup> and W. Li<sup>1</sup>.

<sup>1</sup>Biochemistry, Boston University School of Medicine, Boston, MA and <sup>2</sup>Microbiology, Boston University School of Medicine, Boston, MA.

Lysyl oxidase (LO) plays a critical role in the formation and repair of the extracellular matrix (ECM) by oxidizing the epsilon-amino group of peptidyl lysine residues in elastin and collagen. To better understand the role of LO in cigarette smoke-induced emphysema, we examined changes in LO at the level of protein expression and LO catalytic activity, the levels of its substrates, elastin and collagen type I, as well as cellular thiols, e.g., glutathione (GSH), gamma glutamylcysteine synthetase (GCS) and metallothionein (MT) in cigarette smoke condensate (CSC)-treated rat fetal lung fibroblasts (RFL6). Exposure of RFL6 cells to CSC at 0-120 µg/ml for 24 h decreased the levels of catalytic activity and protein species of LO, i.e., 46 kDa preproenzyme, 50 kDa proenzyme and 32 kDa mature enzyme and its substrates, i.e., elastin and collagen type I, in a dose-dependent manner. Meanwhile, cellular thiols including GSH, GCS and MT were markedly upregulated in these CSCtreated cells. Since LO is a Cu-dependent enzyme and MT and GSH have high affinities for Cu ions, elevated levels of MT and GSH may interfere with Cu bioavailability for LO. To test this possibility, we further examined effects of glutathione monoethyl ester (GME), a GSH delivery system, on LO protein expression and catalytic activity. Interestingly, exposure of cells to GME at 1.0 mM, 2.0 mM and 4.0 mM, which effectively increased intracellular GSH levels, induced a dose-dependent decrease in LO protein species and catalytic activity. These results suggest that upregulation of cellular thiols by CSC has the potential to limit cellular availability of Cu for LO and may be important for downregulation of LO and destabilization of the ECM in CS-induced emphysema (supported in part by Philip Morris Foundation and NIH grant R01-ES 11340).

#### 1276

NANOPARTICLES ARISING FROM COMBUSTION OF 1, 3-BUTADIENE TRANSPORT PAHS AND OXIDANTS TO RESPIRATORY EPITHELIAL CELLS.

A. penn, W. Henk, G. Murphy, W. Catallo and S. Barker. comp biomed sci, lsu vet med, baton rouge, LA.

1, 3-Butadiene (BD), is a high volume (3x109 lbs/yr, US) petro-chemical. BD that escapes industrial processing is burned. This generates butadiene soot (BDS), a homogeneous, PAH-rich particulate mixture. 90 percent of laboratory-generated BDS is <2.5um in size. BDS particulates are aggregates of 50-100 nm (diam)

nanoparticles. When added to serum-free cultures of BEAS-2B cells, BDS elicits a time- and dose-dependent autofluorescence (AF) that progresses from diffuse (30-120 min) to punctiform by 4 hours. When freshly prepared BDS is extracted with organic solvents of widely differing polarity and the filtrates (0.45um) are added to the cultures, all elicit AF, while solvent-washed BDS, Buckminsterfullerene and graphite do not. Thus, fine carbon particles and graphitic lattices, which lack PAHs and a nanoparticle substructure, are inadequate to elicit AF. Benzoyl peroxide, H2O2, styrene, naphthalene, acetaldehyde and BD alone do not elicit ÅF. Thus, neither strong oxidants alone nor low molecular weight compounds adsorbed onto BDS are responsible for AF in this system. BDS-associated AF rarely co-localizes with a lysosomal marker (LysoTracker Red), an autophagic vacuole marker (monodansylcadaverine) or an endosomal compartment marker (dextran-rhodamine). Thus, the punctiform AF apparently develops neither from an endocytic process nor through lysosomal association. When BDS in medium is placed in transwells (0.4um) within a 24-well plate, cells in the plate display punctiform AF at 48 hr. Mass spectrometry of dichloromethane (DCM) extracts of these cells yields PAHrich spectra that are indistinguishable from spectra of fresh BDS extracted with DCM. BEAS-2B cells exhibit a significant decrease in proliferative capacity while exposed to BDS. This is reversed by thorough washing, which attenuates the AF. These results suggest that PAHs adsorbed onto BDS nanoparticles are strongly associated with BEAS-2B AF and also suggest a general mechanism whereby combustion-generated particles of respirable size can deliver toxicants to target cells.

CHANGES IN INFLAMMATORY MEDIATORS AND LUNG PERMEABILITY MARKERS IN RATS AFTER ACUTE EXPOSURE TO CIGARETTE MAINSTREAM SMOKE.

P. Vanscheeuwijck<sup>2</sup>, E. Van Miert<sup>2</sup> and P. Kuhl<sup>1</sup>. <sup>1</sup>PHILIP MORRIS Research Laboratories GmbH, Cologne, Germany and <sup>2</sup>PHILIP MORRIS Research Laboratories bvba, Leuven, Belgium. Sponsor: H. Haussmann.

Exposure to cigarette mainstream smoke (MS) is known to induce inflammatory changes in the respiratory tract. While acute exposures (1 day) are often used to evaluate the toxicity of airborne pollutants such as dusts, fumes, and residual oil fly ash, the effects of MS are usually evaluated after longer exposure periods. Here we report on respiratory tract and systemic changes in Sprague-Dawley rats after a single 2-hour exposure to MS at concentrations of 250, 500, 750, 1000, and 1250 µg total particulate matter (TPM)/l. This MS-concentration range goes well beyond exposure levels representative for human smokers. In rats, the toxicity of such high concentrations was evidenced by a body temperature decrease of 8 °C observed immediately after exposure to 1250  $\mu g$  TPM/l. Bronchoalveolar lavage fluid (BALF) and serum were collected at 2, 4, 15, and 24 h post-exposure and the concentrations of pro-inflammatory cytokines (IL-1, TNFα, GM-CSF, IL-6), chemokines (CINC-1, CINC-3, MIP-1α, MCP-1), and lung permeability markers (CCSP in serum and albumin in BALF) were determined. Cytokines in BALF were increased after exposure to the highest MS concentrations at 15h and 24h (up to 6-fold for IL-1β). Chemokines in BALF were increased after exposure to low concentrations of MS at 4h (2-fold for CINC-1) and, to a greater extent, after exposure to high concentrations of MS at 15h and 24h (up to 7-fold for MCP-1). Cytokines in serum were increased at 2h and 4h at 1250  $\mu g$  TPM/l only. Chemokines in serum were increased at 2h and 4h in an MS concentration-dependent way. CCSP and albumin levels revealed an MS concentration-dependent increase in lung permeability, which was most prominent at 2h and 4h. Results indicate that acute inhalation exposure to MS increases the concentration of inflammatory mediators in BALF and serum as well as lung permeability markers, suggesting that this may be a valuable short-term assay to assess the activity of cigarette mainstream smoke.

### 1278

IN VIVO DETECTION OF LUNG TUMORS IN MICE BY HIGH-RESOLUTION X-RAY MICROTOMOGRAPHY.

K. Meurrens<sup>1</sup>, H. Weiler<sup>2</sup>, N. M. De Clerck<sup>3</sup> and A. A. Postnov<sup>3</sup>. <sup>1</sup>PHILIP MORRIS Research Laboratories bvba, Leuven, <sup>2</sup>PHILIP MORRIS Research Laboratories GmbH, Cologne, Germany and <sup>3</sup>University of Antwerp, Antwerp, Belgium. Sponsor: H. Haussmann.

The major application of micro-CT in biomedical research has been the imaging of calcified tissues. *In vivo* high-resolution X-ray microtomography (micro-CT) is a promising technique for the non-invasive imaging of soft tissues of small laboratory animals. For example, detection and evaluation of structural lung disorders has up to now required many animals to be killed at many timepoints, and for emerging lesions, such as small tumors, time-consuming step-serial histological sectioning is unavoidable. As a possible alternative, the application of X-ray micro-CT to detect lung tumors was investigated in live mice at an early and more advanced stage of tumor development. A/J mice were treated with urethane 1000 mg/kg bodyweight ip and examined at 3.5 and 9 months post treatment. Healthy age-matched groups of mice were used as control. The chest area of anesthetized mice was scanned for

lung tumors by X-ray micro-CT (Skyscan 1076, Aartselaar, Belgium) without gating for cardiac or respiratory motion. Positioning the mice on their backs in the X-ray micro-CT and banding the chest area reduced motion artifacts. Scans lasted 17 minutes per mouse: spatial resolution was 35  $\mu m$  and radiation load was 0.4 Gy. All mice survived the procedure with no apparent ill effects. Reconstructed virtual CT cross sections of the lungs (Feldkampf cone beam algorithm) confirmed the macroscopic evaluation. Tumors in the hilar region or at the periphery of the lungs were more difficult to localize on the CT cross sections. In step-serial sections (every 100  $\mu m$ ) from one pair of lungs, the tumors detected by CT were seen plus a few additional, very small tumors ( $\leq 150~\mu m$   $\frac{1}{7}$ ). The *in vivo* X-ray micro-CT method opens broad perspectives for non-invasive imaging. Continued improvements in resolution and detection in soft tissue imaging may make this a powerful research tool for monitoring tumor development and progression.

### 1279 NRF2 DEFICIENT MICE DEVELOPS PULMONARY EMPHYSEMA IN RESPONSE TO CIGARETTE SMOKE.

S. Biswal<sup>1</sup>, T. Rangasamy<sup>1</sup>, R. K. Thimmulappa<sup>1</sup>, K. H. Mai<sup>1</sup>, S. Srisuma<sup>1</sup>, T. W. Kensler<sup>1</sup> and R. M. Tuder<sup>2</sup>. <sup>1</sup> Environmental health Sciences, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD and <sup>2</sup> Deapartment of Pathology, Johns Hopkins Medical Institution, Baltimore, MD.

Nrf2 is a CNC b-zip transcription factor involved in the transcriptional induction of an array of antioxidant enzymes and cytoprotective genes in response to oxidative stress. The role of Nrf2 in conferring protection against cigarette smoke (CS) induced pulmonary emphysema was investigated. Nrf2 +/+ and -/- mice were exposed to CS (7 h/day, 7 days/week) for various time periods (1.5, 3 and 6 months) using a smoke machine and emphysema in the lung was assessed by morphometric measurements. There was a 3 fold and 4 fold increase in mean linear intercept and lung alveolar diameter respectively, in the 6 months CS exposed Nrf2 -/- mice relative to +/+. Hydroxy proline, a marker of collagen destruction is increased in the lungs of CS exposed Nrf2 -/- mice. Fluorescent TUNEL and imunohistochemical staining revealed the greater number of apoptotic, caspase-3 and 8-Oxo-dG positive cells in the lungs of CS exposed Nrf2 -/- mice suggesting the occurrence of increased oxidative stress and apoptosis. Differential cell counts of the branchoalveolar lavage fluid showed increased infiltration of inflammatory cells into the lungs of CS exposed Nrf2 -/-. Oligonucleotide microarray analysis (Affymetrix) with the RNA from the lungs of CS exposed mice revealed the expression of more than 60 different antioxidant enzymes and cytoprotective genes containing antioxidant response elements in the lungs of CS exposed Nrf2+/+ mice which are uninduced in ĈS exposed Nrf2 -/- mice. Based on these observations we suggest that Nrf2 plays a critical role in the protection of lungs against CS induced emphysema in Nrf2 +/+ mice, by the positive regulation of various antioxidant enzymes and cytoprotective proteins. (This work was supported by grants: P50 CA058184-09 and NIEHS center grant P30 ES 03819)

## 1280 ACUTE RESPONSES IN MICE EXPOSED TO POLYMER AND TOBACCO COMBUSTION PRODUCTS USING A DIN FURNACE.

R. Lemus<sup>1</sup>, K. M. Lee<sup>2</sup> and M. S. Werley<sup>1</sup>. <sup>1</sup>Philip Morris USA, Richmond, VA and <sup>2</sup>Battelle Toxicology NW, Richland, WA.

The acute toxicity of combustion products (CP) from polymers possibly found in manufacturing parts was evaluated using a previously validated system consisting of a Deutsches Institut für Normung (DIN) 53-436 furnace connected to an animal exposure unit. Polymers [wool, Nylon 6, 6/6, and 12, acrylonitrile-butadiene (AB), or AB-styrene] were individually mixed with tobacco blend (TB) at 0, 3, 10, & 30% (w/w). Male Swiss Webster (SW) mice were exposed to  $150\,\mu g$  of total particulate matter (TPM)/L for 30-min by nose-only inhalation to CP generated at ~750°C. CO/CO2, NO/NOx, TPM, hydrogen cyanide (HCN), formaldehyde, acetaldehyde, acrolein, and nicotine were measured in the test atmosphere. Respiratory function (Buxco Biosystems) during exposure, postexposure blood cyanide (CN) and carboxyhemoglobin (COHb) levels, respiratory tract histopathology (1 & 7 days postexposure), alveolar macrophages (AM), LDH and protein changes in BAL fluid (Day 1) were evaluated. Experimental replacement of tobacco mass with polymer generally increased TPM, HCN, some aldehydes and CO, while nicotine was decreased. Body weights were overall comparable among polymer, TB and sham groups. Postexposure COHb levels were not different among all exposed groups. Blood CN levels were below ELOQ (0.2 µg/g) for all groups. More respiratory irritation was observed in the groups with 30% Nylon 6/6 or AB based on delayed postexposure recovery of depressed respiratory function. Day-1 postexposure lesions in nasoturbinates, lateral wall, and maxilloturbinates in exposed groups were minimal to moderate and limited to the anterior nose area. Necrosis was observed with some of the 30% groups compared to TB or lower polymer ratio groups, but all lesions were resolved by day 7. The only change in BAL parameters was a slight decrease in the ratio of resting/activated AM in the exposed groups compared to control. These results show that nose lesions were the most distinct acute toxicity related to CP from these polymer-TB mixtures and from the polymers tested Nylon 6/6 and AB were potentially more toxic in SW mice.

## 1281 INVESTIGATION OF A METHOD OF PREPARING A SINGLE CELL SUSPENSION IN THE LOCAL LYMPH NODE ASSAY USING CHEMICAL DISSOLUTION.

D. Dreher and D. Everett. Covance Laboratories Ltd., Harrogate, United Kingdom.

In the murine local lymph node assay (LLNA), sensitising chemicals induce a primary proliferation of lymphocytes in the lymph nodes draining the site of chemical application. To assess this proliferation radioactive labelling is used, and to measure the degree of radioactive labelling a single cell suspension of lymph node cells is prepared. The method detailed in OECD Test Guideline 429 describes the use of mechanical disaggregation which is time consuming, and is also open to potentially large degrees of error if cells are lost during the disaggregation process. A comparison was performed of mechanical disaggregation and a chemical dissolution method using SolueneR-350 in a series of assay's using known sensitisers. The results obtained from chemically dissolved samples were generally lower than values obtained from lymph nodes processed by mechanical disaggregation. It was shown that dissolving lymph nodes in SolueneR-350 was not a suitable method for evaluating the proliferation of lymphocytes in the LLNA in our laboratory.

## 1282 RETROSPECTIVE ASSESSMENT OF THE RABBIT ENUCLEATED EYE TEST (REET) AS A SCREEN TO REFINE WORKER SAFETY STUDIES.

E.J. Guerriero<sup>1</sup>, C. W. Seaman<sup>2</sup>, M. J. Olson<sup>3</sup>, R. Guest<sup>4</sup> and A. Whittingham<sup>4</sup>.

<sup>1</sup>GlaxoSmithKline, King of Prussia, PA, <sup>2</sup>GlaxoSmithKline, Ware, Herts, United Kingdom, <sup>3</sup>GlaxoSmithKline, Research Triangle Park, NC and <sup>4</sup>SafePharm Laboratories, Shardlow, Derbyshire, United Kingdom.

The REET is an ex vivo alternative that has been studied as a screen to identify severe eye irritants in the workplace. GSK has incorporated the REET into a tiered protocol designed to reduce the use of the traditional Draize eye protocol. Corneal opacity and thickness, fluorescein dye uptake and the condition of the corneal surface are observed after in vitro exposure to test materials. Previously 30 pharmaceutical process materials which had been evaluated with the Draize method were assessed by the REET. An evaluation of the REET data suggested that a score for any one of the following parameters appeared highly predictive of the Draize response: corneal opacity/area >/= 3; corneal swelling >/= 25; fluorescein dye uptake/area >/= 4 or select gross morphological changes. The REET-positive criteria was met by 17/30 materials and included 13 labeled severe (R41) with 1 moderate and 3 mild by in vivo evaluation. Thirteen chemicals did not meet the REET criteria: 9 were minimal/mild eye irritants and 4 were moderate. An additional 14 materials have now been assessed using the REET with data for the in vivo comparison obtained from the published literature. The REET-positive criteria were met by 8/14 materials and included 2 labeled severe (R41) with 5 moderate and 1 mild. Six chemicals did not meet the REET criteria: 5 were non/minimal/mild eye irritants and 1 was a moderate. Pooling data resulted in REET positive criteria being met by 25/44 materials and included 15 labeled severe (R41) with 6 moderate and 4 mild. Nineteen chemicals did not meet the REET criteria: 14 were non/minimal/mild eye irritants and 5 were moderate. There were no false negatives in either dataset. Based on accumulated experience, those materials with REET scores meeting or exceeding the threshold values are labeled internally as severe eye irritants (R41). When used as a pre-screen in conjunction with the Draize assay, the REET contributes to significant reduction in the number of animals used to test for eye irritant potential.

## 1283 PRECISION-CUT RAT LIVER SLICE TECHNOLOGY: EFFECTS OF CARBON DIOXIDE VS. "RAT MIX" ANESTHESIA.

W. Y. Ho, M. H. French, J. Singh, A. V. Valles and J. B. Ulreich. Surgery, University of Arizona, Tucson, AZ.

Carbon dioxide or "rat mix" (2:5:8, acepromazine:ketamine:xylazine) are commonly used general anesthetics in survival and non-survival rat surgeries. High concentrations of carbon dioxide cause excitation, followed by depression, of the central nervous system resulting in loss of consciousness. The components of "rat mix" have the effects of a dissociative anesthetic by producing sedation and muscle relaxation. Ketamine/acepromazine produces medium to deep anesthesia sufficient for major surgery and peripheral vasodilation by acepromazine reduces blood pressure, inducing moderate respiratory depression. The addition of xylazine prolongs recovery but produces hyperglycemia. Our goal was to determine whether the choice of

anesthetic affected endpoints in assays commonly used in precision-cut liver slicing. Fischer F344 rats were anesthetized either in a carbon dioxide inhalation chamber until unconscious, or by intramuscular injection of 1.0ml/kg "rat mix". Total hepatectomies were performed and livers placed in V-7 cold preservation solution. Livers were cored (8mm) and precision-cut at 250 $\mu$ . Slices were loaded on titanium carriers. Incubation was in a Vitron rolling incubation system under 95% oxygen / 5% carbon dioxide for 24, 48, or 72h in complete Waymouth's medium. At various timepoints, liver slices were harvested and weighed. The following indices of slice viability were employed: 1) potassium content was measured by flame photometry, 2) lactate dehydrogenase (LDH) release was measured spectrophotometrically using a Sigma kit and 3) ATP reactions with luciferin-luciferase were measured using a luminometer. The only significant difference between the two anesthetics for these parameters was at 0h, where the carbon dioxide group significantly lowered ATP levels. However, there were no significant differences at 24, 48, and 72h. These results might be different for liver slices incubated with drugs and/or diluents. Supported by the Siegel Foundation and the UA Undergraduate Biology Research

### 1284 IGE MEASUREMENTS : COMPARISON OF RBL AND PASSIVE CUTANEOUS ANAPHYLAXIS (PCA) ASSAYS.

R. Skinner, N. Deakin, D. Shaw, <u>R. J. Dearman</u> and <u>I. Kimber</u>. Syngenta CTL, Macclesfield, United Kingdom.

Specific IgE antibody production is a critical event in immediate type hypersensitivity reactions, including asthma and food allergy. Due to the presence of much higher concentrations of other immunoglobulin isotypes, the accurate assessment of specific serum IgE antibody poses substantial technical challenges. We have examined the utility of the rat basophilic leukemia (RBL) cell line for the measurement of murine IgE responses in vitro. This cell expresses high affinity receptors specific for IgE. Receptor-bound IgE is cross-linked with protein allergen, releasing granules that have been prelabelled with 3H-serotonin. RBL cells were sensitized with mouse monoclonal anti-dinitrophenyl (DNP) IgE antibody (1-125ng/ml) and challenged with DNP-albumin conjugates (10-40ng/ml) with various hapten substitution ratios (SR). Polyclonal anti-OVA IgE antiserum of low and high titer (raised in BALB/c strain mice) were also assessed for activity in the RBL assay. Results were compared with titers measured in homologous PCA assay. Marked degranulation of RBL cells (40% to 60% specific release) was induced by conjugates with SRs of between 16 and 32 molecules of DNP per molecule of protein, whereas conjugates with lower SRs (of 10 or 3) failed to elîcit significant serotonin release. In all cases where significant serotonin release was recorded, clear bell-shaped dose response curves were observed. All conjugates were able to induce mast cell degranulation in vivo in an homologous PCA assay. Anti-OVA antisera with titers of 1/32 to 1/64 (as measured by PCA) failed to stimulate RBL cell degranulation, whereas high titer antibody (1/2048 to 1/4096 by PCA) induced a positive RBL cell response. Successful stimulation of RBL cell degranulation requires not only appropriate epitope densities but also high affinity antibody. These data indicate that this assay is inappropriate for the routine analysis of specific polyclonal IgE antibody responses.

THE IMPORTANCE OF MULTIPLE ENDPOINT ANALYSIS (MEA) USING RECONSTITUTED HUMAN TISSUE MODELS FOR IRRITATION AND COMPATIBILITY TESTING.

B. De Wever, M. Cappadoro and M. Rosdy. SkinEthic Laboratories, Nice, France. Sponsor: A. Goldberg.

The use of in vitro reconstituted human tissue models has become an established standard screening method in pharmaceutical and consumer-product/cosmetic product development. Because of the morphological and biochemical similarity with the in vivo tissues, these models are an unique tool to investigate different endpoints / aspects of irritation mechanism . Products are applied directly on the tissue, at the same doses and exposure time used in vivo and after topical exposure, the irritation potential of actives and finished products can be assessed in a very reproducible way by Multiple Endpoint Analysis (MEA) including tissue viability, histological evaluation and the release of inflammatory mediators. MTT test is used for cell viability assessment compared to negative and positive controls, but too often however, MTT is being used as a single endpoint to evaluate the biocompatibility of test products. Since MTT is mainly converted by the basal and suprabasal cells in 3D constructs, necrosis of the upper superficial layers of the tissue model is not detected, and requires histological tissue analysis. Furthermore a very common need in the safety assessment of the products is to discriminate between slightly irritant and very slightly irritant products: they can be detected because they induce the release of pro-inflammatory mediators (IL-1alpha, IL-8) without affecting tissue integrity measured by MTT and histology. Therefore, critical evaluation of each endpoint in the MEA strategy is equally important for accurate *in vitro* predictions whether in the field of cutaneous risk assessment phototoxicity, ocular toxicity or oral irritation, amongst others. In this work, different examples of MEA approach will be described and discussed.

1286

AN IN VITRO MODEL OF DRUG-INDUCED ARRHYTHMOGENESIS USING MYOCARDIAL REFRACTORINESS: COMPARISON TO hERG ELECTROPHYSIOLOGY AND RUBIDIUM EFFLUX.

R. G. Caccese, H. G. Barthlow, G. D. Yasay, J. S. Smith, C. W. Scott and R. A. Bialecki. *Neuroscience, AstraZeneca Pharmaceuticals, Wilmington, DE.* Sponsor: <u>M. Dvroff</u>.

Drug-induced QT interval prolongation on the electrocardiogram is associated with a potentially fatal arrhythmia, torsades de pointes. One mechanism for this effect is increased ventricular repolarization time via blockade of hERG (human ether-a-go-go-related gene) cardiac ion channels. However, several ion currents contribute to the cardiac action potential and together determine functional outcome. Therefore, it is important to evaluate the sum of all currents contributing to repolarization. Our aim was to validate the intact ferret papillary muscle as a functional predictor of drug-induced changes in refractoriness. Myocardial effective refractory period (ERP) was measured with 19 drugs clinically linked to QT prolongation. The drug concentration causing a 10% increase in ERP ( $\text{EC}_{10}$ ) was correlated with IC50 values for hERG block in cells transfected with the channel and tested with either whole cell patch clamp electrophysiology or rubidium efflux measured by atomic absorption spectroscopy. Baseline ERP at 37 °C without drug was 145±3 msec. Significant increases in ERP were found for 16 of 19 drugs. The class III antiarrhythmic E4031 was most potent in all assays with an EC<sub>10</sub> of 0.024 uM. Class I antiarrhythmics, antipsychotics, antimalarials and other agents demonstrated EC<sub>10</sub> values from 1-105 uM. Calcium channel antagonists terodoline and bepridil had EC<sub>10</sub> values of 12-14 uM. Surprisingly, astemizole and terfenadine had little effect on ERP with EC<sub>10</sub> values of 100 uM and were similar to probucol and erythromycin. The ERP and Rb efflux assays correlated strongly (r=0.89) whereas the correlation between ERP and patch clamp data was less (r=0.66). We conclude that hERG, Na+ and Ca2+ channel blockers can significantly change ERP of ferret papillary muscle. Because papillary muscle represents the integration of relevant ion channel contribution to repolarization, this assay may serve as a viable adjunct to hERG ion channel tests to determine the potential for drug-induced cardiac anom-

#### 1287

SPECIES AND TISSUE DIFFERENCES IN ENDOPLASMIC RETICULUM CA<sup>2+</sup>-INDEPENDENT PHOSPHOLIPASE A, EXPRESSION.

G. R. Kinsey<sup>1</sup>, B. S. Cummings<sup>3, 1</sup>, J. Mchowat<sup>2</sup> and R. G. Schnellmann<sup>1</sup>. 

<sup>1</sup>Pharmacology Sciences., Med. University of South Carolina, Charleston, SC, 

<sup>2</sup>Pharmacology and Biomed. Sciences., University of Georgia, Athens, GA and 

<sup>3</sup>Pathology, St. Louis University, St. Louis, MO.

We recently demonstrated the presence of a novel Ca<sup>2+</sup>-independent phospholipase A, in the endoplasmic reticulum (ER-iPLA<sub>2</sub>) of rabbit renal proximal tubular cells. Further, inhibition of ER-iPLA2 activity potentiated oxidant-induced lipid peroxidation and oncotic cell death, suggesting that ER-iPLA2 acts to protect these cells during oxidative stress. Since oxidants play a role in the injury of numerous tissues, the goals of this study were to determine if ER-iPLA2 is present, 1) in other rabbit tissues, 2) in corresponding rat tissues and 3) in several cancer cell lines. Using plasmenylcholine and diacylcholine as substrates in the presence of EGTA, ER-iPLA, activity was observed in rabbit and rat kidney, brain and heart microsomes, and in microsomes from all five cancer lines tested (Caki-1, A172, A549, PC-3 and L1210). ER-iPLA, activities in rabbit and rat kidney and heart were sensitive to the iPLA, inhibitor bromoenol lactone (BEL) but not the iPLA, inhibitor methyl arachidonyl fluorophosphonate (MAFP). In contrast, rat brain ER-iPLA, activity was inhibited by both BEL and MAFP, while rabbit brain was BEL insensitive and MAFP sensitive. Reverse transcriptase polymerase chain reaction and/or immunoblot analysis revealed iPLA<sub>2</sub>γ expression in rabbit kidney and heart, rat kidney, heart and brain and in all five cancer cell lines tested. Since BEL-sensitive  $iPLA_2\gamma$  and MAFP-sensitive  $cPLA_2\gamma$  are the only  $PLA_2$  family members known to reside in the ER, these data suggest that ER-iPLA2 activity in rabbit and rat kidney and heart is mediated by iPLA,  $\gamma$ , while ER-iPLA, activity in rabbit brain is mediated primarily by cPLA<sub>2</sub>γ. Rat brain microsomes appear to contain both iPLA<sub>2</sub>γ and cPLA<sub>2</sub>γ. These results demonstrate broad expression of ER-iPLA<sub>2</sub> activity across species and tissues, and in cancer cell lines, and differential tissue expression of iPLA<sub>2</sub> $\gamma$  and cPLA<sub>2</sub> $\gamma$ .

A. D. Weissman. NovaScreen Biosciences Corp, Hanover, MD. Sponsor: J. Sina.

There is a current need to develop credible *in vitro* endpoints that parallel the toxic effects of chemical compounds in humans. This information, incorporated into a relational database, would be useful for the virtual screening of compounds at an early stage in their development. Improving the predictive capabilities of current *in vitro* testing requires a battery of endpoints that include mechanism-based assays as well as general cxytotoxicity in cells appropriate to the target organ of interest. Towards this end we have tested a library of 204 compounds thought to be relevant to neurotoxicity in both a proliferative and differentiated human neuronal cell line. We examined seven measures of cellular toxicity with these compounds at six concentrations in duplicate across seven days of treatment. This has resulted in an initial *in vitro* toxicity database annotated with chemical data and LD50 values from *in vivo* studies. The database has shown internal consistency between *in vitro* toxicity measures, as well significant correlations with animal and human toxicity data.

LYSIS OF ADHERENT HUMAN EPIDERMAL KERATINOCYTES IN SITU BY A MISONIX TISSUE CULTURE PLATE SONICATOR.

C. L. Gross, O. E. Clark, E. W. Nealley, M. T. Nipwoda and W. J. Smith. *USAMRICD, APG-EA, MD.* Sponsor: A. Sciuto.

Human epidermal keratinocytes (HEK) are used extensively in our laboratories as an in vitro model of human epidermis to study the vesicant action of sulfur mustard (HD). These adherent cells are released from their tissue culture vessels by proteolytic treatment that detaches the HEK from their plastic supports. However, this common procedure may compromise cells that are struggling to survive and influence the interpretation of damage from these moribund cells. Biomarkers of damage are isolated by lysing cells using specialized buffers or by subjecting the cellular pellet to sonication or other means of disruption. It is especially critical to be able to lyse cells in the desired buffer in situ to minimize losses of biological material used in analysis. Using a Misonix tissue culture plate sonicator, both 24- and 96-well plates of HEK were subjected to 30-sec bursts in a 4oC tray horn ultrasonic bath at the maximum setting of 10. There was 1 min of cooling between bursts for total sonication times of 2 to 5 minutes. The plates were inspected by microscopy, and wells were photographed to give a rough measurement of HEK lysis. Sonicated plates were also checked for the number of *via*ble cells remaining on the plate or in the supernatant by an MTS-PMS chromogenic viability assay. The supernatant fluid was removed from the well and wells were again checked for the percentage of remaining adherent cells by microscopy. Glutathione levels in the supernatant fluid by both sonicated HEK and acid-extracted HEK were measured and appeared identical. From these results, it appears that the sonication technique may be a useful alternative for the proteolytic method commonly used for the isolation of specific biochemical markers.

DIFFERENTIATION OF THE ABSORPTION KINETICS OF JET FUEL HYDROCARBONS WITH AN ETHANOL/WATER SYSTEM AND A MEMBRANE-COATED FIBER TECHNIQUE.

X. Xia and J. E. Riviere. Center for Chemical Toxicology Research and Pharmacokinetics, North Carolina State University, Raleigh, NC.

After dermal exposure to jet fuel, hydrocarbon components will penetrate the stratum corneum, transport and deposition through the epidermis and dermis into the vascular system. The distribution and transport mechanisms of different hydrocarbons through the lipophilic and aqueous routes are unknown. We have used an ethanol/water system to simulate the lipophilic and aqueous routes and studied their absorption kinetics with a membrane-coated fiber technique. The major aromatic and aliphatic components in jet fuel were selected as study compounds. The equilibrium absorption amounts of the aromatics in log scale decreased linearly with increasing ethanol/water ratio, while their absorption rates among different aromatics were not significantly different. Aliphatics showed quite complicated absorption kinetics as all of the jet fuel aliphatics are hydrophobic compounds with very small water solubility. The absorption rate of the aliphatics in water could be linearly predicted with their carbon number. When the carbon number was larger than 14 (tetradecane), the water solubility was so low that the absorption rate approached zero. Increasing the ethanol/water ratio will increase the hydrocarbon solubility. At a given ethanol/water ratio, the absorption rates were higher for smaller aliphatics, while the equilibrium absorption amounts were higher for larger aliphatics. When the ethanol/water ratio reached 50%, all of the aliphatics reached their highest absorption rates and could reach absorption equilibrium within 200 min. Further increasing the ethanol/water ratio, the equilibrium absorption amounts were decreased, while the absorption rates did not change significantly. These experimental results could aid in the understanding of the absorption and transport mechanisms of hydrocarbons in a human body after jet fuel exposure.

### 1291

THE PERFORMANCE OF *IN VITRO* TEST BATTERIES AS PRE-SCREENS TO *IN VIVO* SKIN AND EYE IRRITATION TESTS

D. I. Lees and R. W. Lewis. *CTL, Syngenta, Cheshire, United Kingdom.* Sponsor: <u>I. Kimber</u>.

Our approach to rabbit skin and eye irritation tests has been refined to include elective in vitro pre-screens. For the detection of severe eye irritants, a simple cytotoxicity test is used followed, where necessary by the isolated rabbit eye test. The outcome of this test strategy is used to guide subsequent in vivo testing, and represents a refinement and potential reduction in the use of animals. Materials predicted to be severe irritants are initially tested at low volume in a single animal. Only if less that severe in vivo results are obtained is the full group size of animals completed. Test battery performance over a number of years shows an 86% ability of this approach to correctly predict materials that are less than severe ocular irritants in vivo. The ability of this battery of tests to correctly predict severe eye irritants is lower at 67%. For the assessment of skin corrosion, the Transcutaneous Electrical Resistance (TER) test followed by a dye binding step is used as the pre-screen. Materials identified as potentially corrosive in vitro may not need to be tested in the live animal. The ability to correctly predict materials as non-corrosive in vivo by this approach is high at 94%. The ability to correctly predict materials as corrosive is lower at 40%. However, this outcome may be influenced by the low prevalence of corrosive materials assessed. Data from over 300 tests covering a wide range of chemical classes are presented in this analysis.

#### 1292

UPTAKE KINETICS OF JET FUEL AROMATIC HYDROCARBONS FROM AQUEOUS SOLUTIONS STUDIED BY A MEMBRANE-COATED FIBER TECHNIQUE.

<u>I. E. Riviere</u> and X. Xia. Center for Chemical Toxicology Research and Pharmacokinetics, North Carolina State University, Raleigh, NC.

The absorption of aromatic hydrocarbons from aqueous media is a critical step involved in their transport and deposition in a human body after jet fuel exposure. We have developed a membrane-coated fiber (MCF) technique to study this process, in which a polymer membrane is coated on an inert fiber as a permeation membrane. A polydimethylsiloxane (PDMS) membrane intending to simulate human stratum corneum and a polyacylate (PA) membrane intending to simulate cell membrane were used in this study. The uptake kinetics of the major aromatic components in jet fuel were studied in a flow system, which provided a constant concentration for the prolonged permeation experiments. The absorption profiles of the aromatic compounds were regressed with a mathematical model of the MCF technique. The equilibrium absorption amount and a kinetic parameter that determined the absorption kinetics were obtained from the regression for each compound. The uptake and elimination rate constants of 6 benzene derivatives and 3 naphthalene derivatives were determined with PDMS and PA MCFs. An equilibration method and a regression method were developed to determine membrane/water partition coefficients. The PDMS/water partition coefficients of the benzene and naphthalene derivatives were linearly correlated with their octanol/water partition coefficients (LogKpdms/w=0.871LogKo/w-0.241, R2=0.995). The PA/water partition coefficients of the benzene derivatives and the naphthalene derivatives were correlated differently with their octanol/water partition coefficients. The correlation equations for benzene and naphthalene deriva- $\hat{R2}=0.997$ LogKpa/w=0.865LogKo/w+0.0045, LogKpa/w=0.763LogKo/w+0.911, R2=1.00, respectively. This shows that the MCF technique can detect the subtle differences in intermolecular interactions of the two group derivatives between the two-membrane/water systems.

### 1293

DEVELOPMENTAL TOXICITY OF TRIETHYLENE GLYCOL, TRIETHYLENE GLYCOL MONOMETHYL ETHER AND TRIETHYLENE GLYCOL DIMETHYL ETHER IN INTACT DROSOPHILA MELANOGASTER.

D. Lynch. Biomonitoring and Health Assessment Branch, NIOSH, Cincinnati, OH.

To further characterize the *Drosophila*-based prescreen to detect developmental toxicants, triethylene glycol (TEG), triethylene glycol monomethyl ether (TEGMME) and triethylene glycol dimethyl ether (TEGDME) were evaluated using our published protocol (*Teratogenesis, Carcinogenesis, and Mutagenesis* 11:147-173, 1991). One or two experiments, each employing 10 equimolar concentrations (.0013-1.64mM/vial) of test chemical and including a concurrent control, were conducted per chemical. *Drosophila* were exposed throughout development (egg through third instar larva) in culture vials to medium containing the test chemical. Each vial contained 1g of powdered medium and 5ml of distilled deionized water or a solution of test chemical in water. A mated, untreated, Oregon-R wild-type female (Mid-American Drosophila Stock Center, BGSU, Ohio) was added to each culture vial

and allowed to oviposit for 20 hours, then removed. Emerging offspring were collected over 10 days and examined microscopically (25x) for bent humeral bristles - a morphological defect shown to occur with an increased incidence in fruit flies exposed to developmental toxicants. The incidence of bent bristles was statistically increased compared to concurrent controls (chi-square) at the two highest TEG concentrations - 1.32mM, 38/181, p<0.001 and 1.64mM, 29/99, p<0.001. For TEGMME, the incidence of bent bristles was statistically increased at the four highest concentrations - 0.66mM, 8/155, p<0.01; 0.99mM, 12/134, p<0.001; 1.32mM, 11/75, p<0.001; and 1.64mM, 3/5, p<0.001. For TEGDME, the incidence of bent bristles was statistically increased at three concentrations - 0.34mM, 10/159, p<0.01; 0.66mM, 28/171, p<0.001; and 0.99mM, 6/25, p<0.001) - no flies emerged at 1.32 and 1.64mM. Based on these results, TEGDME > TEGMME > TEG in terms of developmental toxicity. Results with TEG, TEGMME and TEGDME parallel the developmental toxicity seen in mammals and support further utilization of this *Drosophila*-based assay as a prescreen for developmental toxicants.

## 1294 THE IMPACT OF ETHANOL ON THE *IN VITRO* SKIN PENETRATION RATES OF CAFFEINE IN ENGINEERED SKIN CONSTRUCTS.

G. Pugh<sup>1</sup>, G. O. Moyer<sup>2</sup>, H. A. Raabe<sup>2</sup>, J. W. Harbell<sup>2</sup> and <u>D. M. Bagley<sup>1</sup></u>. <sup>1</sup>Colgate-Palmolive Co., Piscataway, NJ and <sup>2</sup>Institute for In Vitro Sciences, Inc., Gaithersburg, MD.

The reference material, caffeine (prepared in ethanol), was evaluated in 3 in vitro models to compare the rates of skin penetration in each of the models. The models were human donor skin, an engineered skin construct (MatTek Corporation, Model EPI-606X) and slaughterhouse-derived pig skin. The tissues were mounted in flow-through diffusion cells (PermeGear, Inc., 0.64 cm<sup>2</sup> surface area), qualified for barrier function by  $^3H_20$  passage, followed by the application of a 9  $\mu L$  dose of  $^{14}C$ -caffeine in ethanol ( $^4\mu g/cm^2$ ). The study duration was 24 hours. Total recovery of caffeine was acceptable (typically 95 to 100%) in each model. In human and pig skin, the rates of skin penetration were uniform and continuous throughout the 24-hour period. The mean amounts of caffeine that had been absorbed after 24 hours were 11% and 15% of applied dose, respectively (n=2 trials each). However, in the engineered skin model, the rate of penetration was remarkably high in the first 3 hours, followed by an abrupt decrease in the penetration rate thereafter. The amount absorbed after 3 hours was approximately 60% of applied dose. After 24 hours, the amount had increased to only 62% of applied dose. Subsequent experiments were conducted to evaluate the impact of the vehicle on caffeine's penetration rate in engineered skin. In the first experiment, caffeine prepared in water was tested in parallel with caffeine prepared in ethanol. A notable penetration rate lag phase was observed in the water-based preparation as compared to the ethanolbased preparation, but totals absorbed were 87% vs 66% of the applied dose, respectively. In the second experiment, engineered skin was pre-treated with ethanol followed by topical application of caffeine. Caffeine penetration rates and total caffeine absorption were similar in ethanol pre-treated and non-treated engineered skin. These results suggest that ethanol may have enhanced skin penetration upon initial exposure, but the solvent effect may have been rapidly modulated.

### 1295 PRECISION-CUT TISSUE CHIPS AS A TOXICOLOGICAL TOOL.

J. M. Catania, A. Fernandez and A. Gandolfi. Pharmacology and Toxicology, University of Arizona, Tucson, AZ.

The premise of these studies is to use precision-cut tissue chips from multiple organs from mice to simultaneously examine the *in vitro* toxicity of chemical agents. The use of the smaller tissue chips allows more samples since the small organs from the mouse only provide a limited amount of slices while 4-10 fold more tissue chips can be prepared from an organ. Tissue chips are produced by using a biopsy punch to make multiple 4 mm tissue chips from one 8 mm, 250 micron-thick tissue slice. Additionally, larger-sized diameter coring tools were explored to expedite and maximize chip production and quantity. Alterations to the Vitron Tissue Slicer have allowed more consistent slices, while some modifications allow the potential to generate multiple tissue slices at once. Tissue chips are incubated in 24 well plates, placed into a rotating 37 C shaking incubator and oxygenated with 95:5 O2:CO2. Due to the smaller amount of biomass in the tissue chip, fluorescent biomarkers have been used to assess viability. TMRE, Mitotracker Far Red, 6-carboxy fluorescein, and NBD-TMA have been used for their permeability and detection characteristics, and for the assessment of cellular processes. Neutral red and MTT assays have been employed to expedite processing of tissue chips, and have been compared to our previous, more time-consuming viability indicators (e.g. intracellular K+ content/DNA). Iodoacetemide (IAM) treatment (0-1000 uM), a fast-acting alkylator, has shown increases in TMRE fluorescence (500 uM IAM, 45 min), indicating increased mitochondrial activity, with a subsequent decrease in *via*bility in liver and kidney tissue chips as determined by both neutral red uptake and MTT assays. IAM treatment of 10 uM in liver and kidney tissue chips showed more than 50% decrease in *via*bility with a 12 h incubation. Kidney chips exhibit decreases in *via*bility in 2 h incubations with 1000 uM IAM treatment. This system will allow for a rapid examination of toxic effects in multiple target tissues to expedite toxicity profiling of potential new agents. (NIH R33 CA97449)

## 1296 EVALUATION OF THE BCOP ASSAY AS A PREDICTOR OF OCULAR IRRITATION OF PETROCHEMICAL PRODUCTS.

P. T. Bailey<sup>1</sup>, J. J. Freeman<sup>1</sup>, R. D. Phillips<sup>1</sup> and J. C. Merrill<sup>2</sup>. <sup>1</sup>Toxicology and Environmental Sciences Division, ExxonMobil Biomedical Sciences, Inc., Annandale, NJ and <sup>2</sup>Institute for In Vitro Sciences, Inc., Gaithersburg, MD.

Many initiatives have been undertaken in recent decades to reduce, refine, and replace the use of animals in evaluating toxicity, however, relatively few alternative studies have been conducted with petrochemical products. Therefore, a program was implemented to facilitate the development and validation of alternative in vitro test methodologies that could predict ocular irritation and acute systemic toxicity of petrochemicals. The Bovine Corneal Opacity and Permeability (BCOP) assay, a test that measures opacity and epithelial integrity to corneas, was used to evaluate 16 petrochemical products (e.g., lubricant additives, cutting fluids, solvents). Based on in vivo ocular irritation data and risk phrases, test articles were subdivided into the following three main categories: Category A (risk of serious damage to eyes), Category B (irritating to eyes), and Category C (non-irritating). Test article treated corneas were incubated at 32±1°C for two exposure times of 3- and 10-minutes. BCOP assay correctly classified the products in >95% of cases with the 10-minute exposure data, suggesting that it is valid for certain petrochemicals as a screening tool before in vivo testing (refinement) and as an alternative stand alone assay (replacement) for assessing hazard. The same 16 test articles were examined in the 3T3 Neutral Red Uptake (NRU) Bioassay as a predictor of dose selection and for assessing potential acute systemic toxicity. Poor predictability (<60%)was observed in the NRU assay, which was likely associated with their low solubility in water and the inability of cells being exposed to concentrations below desired concentrations. Although poor predictability was observed, results did indicate the possible use of the NRU assay as a refinement-screening tool for specific chemicals. Based on this body of data, these results could facilitate the validation and acceptance of alternative testing methodologies that will ultimately benefit animal welfare.

# 1297 IMPROVED 'ACCOUNTABILITY' OF *IN VITRO*METHODS USED FOR ASSESSING DERMAL ABSORPTION OF ENVIRONMENTAL CONTAMINANTS.

R. P. Moody, M. Akram and I. Chu. Health Canada, Federal Government, Ottawa, ON, Canada.

As part of our research to examine in vitro methods for quantifying dermal absorption, we have refined the method used to evaluate this process. Since both the amount and persistence of chemical remaining in the skin and of that more completely absorbed into the receivor blood simulant solution is important to measure for hazard risk assessment, the method used must provide complete 'accountability' of the chemical dose used. Human skin permeation data for the lipophilic compound, nonyl phenol, obtained using our in-house developed Automated In vitro Dermal Absorption (AIDA) method will be presented to show the importance of having a complete mass balance for such 'accountability' purposes. This will include simple considerations such as loss of the applied test 14C-radiolabeled chemical to the test apparatus including the plastic pump tubing used to circulate the donor chemical treatment solution. We have previously reported very significant loss of this lipophilic compound (Log octanol/water partition coefficient = 6) to peristaltic pump tubing (Akram et al., 2003). We expand this here to show 14C-nonyl phenol data for several soap water and solvent apparatus washes obtained from human skin absorption tests. The results showed loss of as much as 60 percent of the applied radiolabel test chemical and that most of this loss was due to adsorption into the test apparatus, particularly the peristaltic pump tubing used. In order to provide a possible solution to this problem, tests with 1 percent soap added to the donor solution were conducted. Although tests with 1 percent soap added prevented adsorption to pump tubing and full mass balance was obtained, further tests are needed to determine the suitability of this 'quick-fix' since the presence of soap in the donor solution, even at low concentration, could affect skin permeability and/or chemical depot storage/bioavailability and so adversely influence the data used for regulatory toxicology risk assessment.

N. Choksi<sup>1</sup>, J. Haseman<sup>2</sup>, <u>R. Tice</u><sup>1</sup> and <u>W. Stokes</u><sup>3</sup>. <sup>1</sup>ILS, Inc., Research Triangle Park, NC, <sup>2</sup>NIEHS, Research Triangle Park, NC and <sup>3</sup>NICEATM, NIEHS, Research Triangle Park, NC.

Alternative in vitro test methods proposed to substitute or replace an in vivo test method should provide equivalent or improved protection of human or animal health in order to gain regulatory and general acceptance. The ICCVAM and NICEATM are collaborating with the ECVAM to conduct a validation study of three in vitro dermal irritation assays. To assess the acceptability of these in vitro assays, an effort was undertaken to estimate the false negative rate of the in vivo test as defined by its ability to consistently identify irritants, mild irritants, and non-irritants according to the Globally Harmonized Classification Scheme. Data for 187 substances was obtained from the ECETOC database for skin irritation and corrosion. The distribution of rabbits with mean erythema or oedema scores of <1.5, between 1.5 and 2.3, or >2.3 was determined for each of the substances classified as negative, mild irritant or irritant. Since the true classification of each substance is unknown, a simplifying assumption was made that the results are correct for substances tested once only. For multiple-tested substances, the classification obtained from a majority of the studies was used. The analysis indicated: (1) the likelihood of a mild irritant being under-classified as a non-irritant was <5 percent when based on all substances and <10percent when based on multiple-tested substances, (2) the under-classification rate of irritants as non-irritants was <1 percent, and (3) the under-classification rate of irritants as mild irritants ranged from 9-30percent, depending on whether all substances or only multiple-tested substances were considered. Additional in vivo irritation data for studies using currently accepted procedures was requested from US federal agencies and industry. Appropriate data received will be added to the database and the false negative analysis refined. This evaluation emphasizes the need for high quality in vivo dermal irritation data that can be used to assess the performance of proposed new alternative test methods. ILS staff supported by NIÊHS contract N01-ÊS-35504.

### 1299 ESTIMATE OF FALSE NEGATIVE RATES FOR THE *IN VIVO* RABBIT DERMAL CORROSION ASSAY.

R. Tice<sup>1,2</sup>, N. Choksi<sup>1,2</sup>, J. Haseman<sup>3</sup>, R. Hill<sup>4</sup>, M. Lewis<sup>4</sup>, D. Lowther<sup>4</sup> and W. Stokes<sup>2</sup>. <sup>1</sup>ILS, Inc., Research Triangle Park, NC, <sup>2</sup>NICEATM, NIEHS, Research Triangle Park, NC, <sup>3</sup>NIEHS, Research Triangle Park, NC, <sup>4</sup>EPA, Washington, DC and <sup>5</sup>FDA, College Park, MD.

Alternative in vitro test methods proposed to substitute or replace an in vivo assay should provide equivalent or improved protection of human or animal health to gain regulatory and general acceptance. ICCVAM evaluated four in vitro dermal corrosivity assays as potential replacements for the in vivo dermal corrosivity assay. ICCVAM recommended that these assays be used in accordance with the globally harmonized tiered testing scheme in a weight-of-evidence approach. In this approach positive substances could be classified and labeled as corrosives and negative substances are further evaluated in accordance with an internationally accepted testing scheme. This recommendation was based largely on the 12-17 percent false negative rates of the in vitro assays in identifying corrosive substances. ICCVAM concluded that these false negative rates likely exceeded that of the currently used in vivo assay and would not provide adequate public health protection. To estimate the likelihood of a false negative result in the in vivo assay, the available data was reviewed. Relevant in vivo dermal corrosivity data were obtained from federal agencies and the published literature. The database consisted of 50 corrosive substances. Since the true likelihood of a corrosive response for each of the substances in the database was unknown, the sample rate was considered the best estimate of the true positive response rate. Initial analysis of the database indicated that the current in vivo dermal corrosivity test has an estimated false negative rate of 5.5 percent. The analysis also suggests that under-classification of a substance would most likely occur only for weak corrosives. NICEATM continues to seek additional high-quality in vivo corrosivity data to refine the estimated in vivo assay false negative rate. This evaluation emphasizes the need for high quality in vivo dermal corrosivity data that can be used to evaluate the performance of proposed alternative assays. ILS staff supported by NIEHS contract N01-ES-35504.

### 1300 CHARACTERIZATION OF BPA GLUCURONIDATION BY RAT AND HUMAN HEPATOCYTES.

R. K. Kuester, D. Castro, A. M. Solyom and S. Glenn. Pharmacology, The University of Arizona, Tucson, AZ.

Bisphenol A is monomer of polycarbonate plastics with weak estrogenic activity. Since the predominate metabolite of BPA, BPA-monoglucuronide, is devoid of estrogenicity, it is important to examine its rate of glucuronidation across species. This study compared the *in vitro* kinetic constants for the glucuronidation of BPA

by male Sprague-Dawley rat and human hepatocytes obtained from various sources. When hepatocytes from both species were incubated for 20 min as suspensions in the presence of 14C-BPA (1.3-52 μM) BPA-monoglucuronide was the predominate metabolite. Metabolic constants (Vmax and Km) from freshly isolated rat hepatocytes were compared to fresh or cryopreserved rat hepatocytes obtained from commercial sources to evaluate if cryopreservation and/or delivery time affects the ability of hepatocytes to glucuronidate BPA. When rat hepatocytes were isolated and shipped on ice (18-24 h) prior to incubation with BPA, metabolic clearance (Vmax/Km) decreased from 0.015 to 0.01 ml/min compared to freshly isolated hepatocytes. Shipped cryopreserved rat hepatocytes incubated in suspensions produced BPA-glucuronide at rates comparable to those obtained with suspensions of freshly isolated rat hepatocytes (clearance rates of 0.016 and 0.015 ml/min per 375, 000 cells, respectively). Preliminary results demonstrate that suspensions of cryopreserved human hepatocytes conjugate BPA at rates similar to those obtained from recently isolated rat hepatocytes. Thus, cryopreserved human hepatocytes may be a useful model to assess variability among humans in rates of BPA glucuronidation. This research was supported in part by the Southwest Environmental Health Science Center (ES 06694) and the American Plastics Council.

## 1301 FURTHER DEVELOPMENT OF A FLOW CYTOMETRY-BASED LOCAL LYMPH NODE ASSAY WITH EAR SWELLING AND IMMUNOPHENOTYPIC ENDPOINTS.

S. Young, D. R. Cerven, T. L. Ripper and G. L. DeGeorge. MB Research Laboratories, Spinnerstown, PA.

The local lymph node assay (LLNA) is an alternative to the guinea pig sensitization test used to identify and characterize dermal sensitizers. We have applied flow cytometric techniques to the ICCVAM-validated LLNA protocol to enhance the basic LLNA and to increase sensitivity/specificity. Lymph node cell (LNC) proliferation is measured by BrdU incorporation, instead of 3H-thymidine uptake. In addition, dermal irritation (% ear swelling) and immunophenotypic markers such as B220 (CD45R), CD69, CD44, CD62L, CD3, CD4, CD8, I-Ak and CD25, were evaluated for predictivity of sensitization potential and discrimination of false-positive irritants. The most useful endpoints in the Enhanced LLNA (E-LLNA) were the number of proliferating LNC (BrdU +cells), B:T cell ratio, %B220+, %CD69+ and %IAk+ cells. Several key human sensitizers including oxazolone, DNCB, HCA, mercaptobenzothiazole (MBT) and chlorpromazine+UVA were correctly classified. SLS, which is a false positive in the standard radiometric LLNA, was correctly classified as a non-sensitizing irritant by the E-LLNA. SLS failed to induce changes that are characteristic of true sensitizers which include increases in %B220+, %CD69+, %IAk+ and the B:T cell ratio. The flow cytometry-based LLNA yields Stimulation Indices (SI) similar to those in the ICCVAM validation report for DNCB, HCA and many other chemicals. In the E-LLNA, the EC3 (concentration which induces a SI > 3) for HCA ranges from 4.2% to 9.8%, and for DNCB it ranges from 0.01% to 0.05%, consistent with ICCVAM LLNA test results using 3H-thymidine. In summary, we have developed an enhanced, flow cytometry-based LLNA which 1) can sensitively and specifically identify and characterize dermal contact sensitizers; 2) does not require radioactivity; and 3) allows better discrimination of false-positive irritants from true sensitizers when compared to the basic radiometric LLNA.

### 1302 DEVELOPMENT OF AN *IN VITRO* MODEL FOR ASSESSING PULMONARY INFLAMMATION.

J. M. Kennedy and <u>J. M. Carter</u>. Central Product Safety, Procter & Gamble, Cincinnati, OH.

Because of the complexity of the biology of the lung, in vitro tools to investigate the mechanisms of inhaled toxicants have not been fully explored as they have been in other fields. There exists an increasing need to develop new tools that are mechanistically based, less expensive and less time consuming than traditional assays that allow for the reduction of animal use whenever possible. Here we describe work done in our lab to develop tools to assess the inflammatory potential of inhaled particles. Briefly, in vivo particle-induced rat inflammatory studies involving the use of genomic/proteomics in our lab have identified key pro- and anti- inflammatory markers we are exploiting for use in developing a rat inflammatory in vitro assay system. The use of an immortalized rat alveolar macrophage cell-line has considerably advanced our in vitro mechanistic research and is aiding in the development of an in vitro screening assay. However, the macrophage alone cannot tell the entire story of the inflammatory process. We are also developing techniques to isolate and culture rat blood neutrophils that mimic in vitro the egression and maturation process of the neutrophils. We have used genomic data from in vivo studies to develop a cytokine cocktail similar to those used for dendritic cell maturation assays. This has facilitated in vitro mechanistic studies pertaining to particle-induced inflammation. This work correlates well with studies performed in vivo relating particle-induced inflammation to the pro-and anti-inflammatory markers used in this assay. We have seen good correlation between the measurement of release of reactive

oxygen and nitrogen species after exposure of neutrophils to particles *in vitro* and to *ex vivo* measurements of particle-induced reactive oxygen and nitrogen release of *in vivo* inflammatory cells. The development of these assay systems will lead to improvement in *in vitro* screening assays which ultimately reduce animal usage and provide less expensive assays for screening potential toxicants.

1303

PERFORMANCE OF THE PH 6.7 SYRIAN HAMSTER EMBRYO (SHE) CELL TRANSFORMATION ASSAY IN PREDICTING THE CARCINOGENIC POTENTIAL OF CHEMICALS.

H. Zhang and B. C. Myhr. Genetic and Molecular Toxicology, Covance Laboratories Inc., Vienna, MD.

The Syrian hamster embryo (SHE) cell transformation system is a well-developed in vitro short-term testing system for evaluating the carcinogenic potential of chemicals. Using morphological transformation as the end point, the SHE cell transformation assay has been used to study mechanisms of chemical carcinogenesis in vitro, as well as to predict rodent carcinogens. Early applications of the SHE cell transformation assay suffered from some operational difficulties, most of which have been overcome by culturing the SHE cells in a slightly acidic (pH 6.7) environment. From studies beginning in the 1980s, approximately 107 chemicals have been tested using the reduced pH method. Among these, rodent carcinogenicity data has been reported for 100 chemicals (68 carcinogens and 32 noncarcinogens). SHE cell transformation assays in vitro yielded an overall concordance rate of 81% (81/100) with the results of the rodent bioassay, a sensitivity of 85% (58/68), and a specificity of 72% (23/32). In addition, the SHE cell transformation assay correctly evaluated all but one (phenacetin) of the 30 known or suspected human carcinogens classified by the NTP/IARC, which indicated a high sensitivity of 97%. Assay evaluations are compiled for each tested chemical. Collectively, these data suggest that the SHE cell transformation assay out-performed other commonly used shortterm tests for assessing the carcinogenic potential of chemicals. The SHE cell assay clearly provides a valuable short-term test for screening new chemicals for carcinogenic potential.

### 1304 DEVELOPMENT OF A CELLOMICS-BASED *IN VITRO* SCREEN FOR PHOSPHOLIPIDOSIS.

J. K. Morelli, M. Buehrle, <u>F. Pognan</u> and <u>P. Ciaccio</u>. Safety Assessment, AstraZeneca Pharmaceuticals, Wilmington, DE.

Several cationic, amphiphilic drugs induce local or systemic phospholipidosis (PLD), generally after chronic exposure in preclinical species and humans. PLD is characterized by the accumulation of drug, phospholipid and concentric lamellar bodies in lysosomes. We developed a fluorescence-based in vitro screen that is predictive of PLD using the Cellomics Arrayscan high content screening platform, which captures images from 96-well cell culture plates using multichannel fluorescence microscopy. I-13.35 adherent mouse spleen macrophage cells were plated and cultured with fluorescent phospholipid NBD-PE, and drug. Concentrations were in a range from 1 to 100 uM. After 24 h incubations, the cells were fixed and nuclei were identified by Hoechst staining and dead cells by ethidium homodimer-2 (EthD-2) incorporation. NBD-PE is taken up into the lysosomes passively and the effect of drug on its normal breakdown was monitored using the Arrayscan by quantification of fluorescence intensity in the FITC channel. Several parameters were tested for their effect on both relative and absolute NBD-PE fluorescence, including cell number (10, 000/well), matrix (collagen), cell exposure (24 h), NBD-PE concentration, and image analysis algorithm. For validation efforts, amiodarone, erythromycin, amitriptyline, chloroquine, chlorpromazine, memantine, chlormipramine & imipramine were used as positive controls. Chloramphenicol, tetracycline, & Zyvox were used as negative controls. Positive samples responded in a dynamic range of up to 5-7 fold-increases over vehicle controls; meaningful doseresponses over at least 2 concentrations; day-to-day, reproducible differences in NBD-PE accumulation between top concentrations and vehicle controls; and statistical significance. In addition, artifact of NBD-PE accumulation coming from excess cytotoxicity (30-100 uM) could be eliminated by ethidium staining and employing cell gating (dead cell rejection). Thus, in following these criteria, the assay was found to be both sensitive and selective in that 6/7 positive controls and 3/3 negative controls were correctly called.

## 1305 COMPARATIVE MICROARRAY ANALYSIS OF BASAL GENE EXPRESSION IN MOUSE HEPA-1C1C7 WILD-TYPE AND MUTANT CELL LINES.

C. J. Fong, L. D. Burgoon, M. D. Ramer and T. R. Zacharewski. Department of Biochemistry & Molecular Biology, Department of Pharmacology & Toxicology, Institute of Environmental Toxicology, National Food Safety and Toxicology Center, Michigan State University, East Lansing, MI.

cDNA microarrays containing 4858 unique genes were used to examine differences in basal gene expression between mouse Hepa-1c1c7 wild-type and mutant (C1 - aryl hydrocarbon hydroxylase activity deficient, C4 - Ah receptor nuclear transloca-

tor deficient and C12 - 10% Ah receptor levels) cell lines. Using a modeled t-test approach, 728 unique genes were identified in the mutant cell lines that exhibited a significant (p < 0.01) difference in basal expression when compared to wild-type. Surprisingly C1 cells exhibited the greatest number (260 unique genes) of expression differences while 186 and 92 differences where identified in C4 and C12 cell lines, respectively, when compared to wild-type cells. Up-regulated functions unique to the C1 line include glutathione S-transferases and tRNA synthetases while genes associated with oxidative stress (Prdx) and lipid metabolism (Apobec1, Fasn) were down-regulated. C4 up-regulated genes are primarily associated with the mitochondrial function (Atp5g1, Atp5o) while down-regulated pathways include glucose metabolism (Gapd, Gpi1). Significant up-regulation of cell cycle (cyclins) and structural (Vcl) genes in the C12 line may be compensatory and related to their slow growth and unique cellular morphology compared to the wild-type cells. Quantitative RT-PCR has verified microarray data for 6 uniquely (C1 - Xcl1, Prdx3; C4 - Cldn3, Fosb; C12 - Cyp1a1, Tmem9) and 3 (Esr1, Rdbp, Rpl6) commonly expressed genes. These studies further characterize Hepa-1c1c7 wild-type and mutant cell line characteristics and provide further insights into the endogenous role of the AhR as well as potential mechanisms of toxicity of TCDD and related compounds. Supported by ES 11271.

PHASE TWO: EVALUATING THE EYE IRRITANCY OF SOLVENTS IN A SIMPLE FRAGRANCE MIXTURE WITH THE BOVINE CORNEAL OPACITY AND PERMEABLITY (BCOP) ASSAY.

N. Cuellar<sup>1</sup>, P. H. Lloyd<sup>2</sup>, J. E. Swanson<sup>1</sup>, J. C. <u>Merrill</u><sup>3</sup>, G. Mun<sup>3</sup>, J. W. Harbell<sup>3</sup> and K. L. Bonnette<sup>4</sup>, <sup>1</sup>S.C. Johnson & Son, Inc., Racine, WI, <sup>2</sup>SCJ EURAFNE Ltd., Egham, Surrey, United Kingdom, <sup>3</sup>Institute for In Vitro Sciences, Inc., Gaithersburg, MD and <sup>4</sup>Charles River Laboratories Inc., Spencerville, OH.

Fragrances are complex mixtures used in many consumer products. Organic solvents, such as ethanol, are major components of fragrance formulations functioning mainly as solubilizers and fragrance delivery mechanisms. In Phase One (Cuellar et al, 2002), the BCOP assay and primary eye irritation study (EPA-OPPTS 870.2400) were conducted using simple fragrance mixtures containing six commonly used solvents. The corneal depth of injury was assessed histologically both in vitro and in vivo. In the BCOP assay, corneas were exposed for 1 and 3 minutes, rinsed and incubated for 20 hours before the opacity and permeability endpoints were assessed. *In vivo*, animals were scored at 1, 4, and 24 hours. Individual solvents impacted the level of irritation of these formulations. Phase Two evaluated the time course of lesion development after exposure in the BCOP assay and determined those early lesion that would be predictive of damage observed after 20+ hours in vitro and in vivo. Bovine corneas were exposed for 3 minutes, rinsed, and incubated for 2 or 4 hours before the endpoints were assessed and tissue taken for histology. In vivo, certain solvents increased the rate of lesion development but not the overall intensity or duration compared to the fragrance alone. Other solvents decreased the overall intensity and duration. The BCOP assay showed a generally similar pattern of lesion development. Those combinations that showed opacity at 4 hours in vivo, showed epithelial and stromal lesion in the BCOP by 4 hours post-exposure. Fragrance alone was slower to develop opacity in vivo and required the 20-hour post-exposure to produce appreciable lesions in vitro. These data suggest that the standard post exposure can be predictive of irritation potential of fragrance/solvent

1307

COMPARISON OF *IN VITRO* EYE IRRITATION POTENTIAL BY BCOP ASSAY TO ERYTHEMA SCORES IN HUMAN EYE STING TEST OF SURFACTANT-BASED FORMULATIONS.

K. C. Cater<sup>1</sup>, E. Patrick<sup>2</sup>, J. W. Harbell<sup>3</sup>, J. C. Merrill<sup>3</sup> and S. L. Schilcher<sup>1</sup>. <sup>1</sup>The Dial Corporation, Scottsdale, AZ, <sup>2</sup>Consultant, Westfield, NJ and <sup>3</sup>Institute for In Vitro Sciences, Gaithersburg, MD.

The BCOP assay can be used to predict relative eye irritation potential of surfactant-based personal care formulations relative to a corporate benchmark (*Toxicologist*, March 2001). The Human Eye Sting test is typically used to evaluate product claims of no tears/no stinging for children's bath products. A preliminary investigation was conducted to test a hypothesis that the BCOP assay could be used as a prediction model for relative ranking of human eye irritation responses under conditions of a standard Human Eye Sting test to surfactant-based formulations. BCOP assays and Human Eye Sting tests were conducted on four commercial body washes (BW) and one prototype body wash developed specifically for children or as mild bath products. In the Human Eye Sting assay 10 ul of a 10% dosing solution is instilled into one eye of each panelist (n=20), and the contra-lateral eye is dosed with sterile water as a control. Bulbar conjunctival erythema responses of each eye are graded at 30 seconds by an ophthalmologist. The BCOP assay permeability values (OD<sub>490</sub>) for the five BWs ranged from 0.438 to 1.252 (i.e., least to most irritat-

ing). By comparison, the number of panelists exhibiting erythema responses (mild to moderately pink) ranged from 3 out of 20 panelists for the least irritating BW to 10 out of 20 panelists for the most irritating BW tested. The relative ranking of eye irritation potential of the five BWs in the BCOP assay compares favorably with the relative ranking of the BWs in the Human Eye Sting test. Based on these findings, the BCOP assay as described for surfactant-based formulations shows promise as a prediction model for relative ranking of conjunctival erythema responses in the human eye. Consequently, screening of prototype formulations in the BCOP assay allows for formula optimization of mild bath products prior to investment in a Human Eye Sting test.

THE USE OF A HUMAN RECONSTITUTED EPIDERMAL MODEL FOR THE OCCUPATIONAL HAZARD ASSESSMENT OF PHARMACEUTICAL PROCESS MATERIALS.

C. W. Seaman<sup>1</sup>, B. De Wever<sup>2</sup>, M. Cappadoro<sup>2</sup>, A. Whittingham<sup>3</sup>, R. Guest<sup>3</sup> and C. Prusiewicz<sup>1</sup>. <sup>1</sup>clo GlaxoSmithKline, Ware, Herts, United Kingdom, <sup>2</sup>SkinEthic Laboratories, Nice, France and <sup>3</sup>SafePharm Laboratories, Derby, United Kingdom.

Irritant dermatitis is a continuing problem arising from occupational exposure to chemicals. Traditionally, evaluation of the irritant potential of novel chemicals has relied on the use of in vivo studies . The requirement for ethical testing strategies and availability of new technologies has recently driven the assessment of alternative methods. This presentation describes the preliminary evaluation of a reconstituted epidermal culture system (SkinEthic) for determining the dermal irritant potential of pharmaceutical process materials. Briefly, epidermal cultures were treated with test materials for periods of 4 and 24 hours after which they were assessed for viability (MTT ), histopathology, and cytokine release (IL-1 alpha and IL-8). Positive controls (0.1% Triton and 20% SDS) induced severe tissue destruction as expected. Untreated controls showed normal morphology and viability throughout the experiment. Test materials V-006, V-007 and V-021 showed minimal to no effects, dead tissue and moderate tissue damage, respectively. Increases in cytokine generation were also seen with V-007 and V-021. These results were consistent with known in vivo dermal irritant potential of these materials. The assay was readily transferred between laboratories and results between facilities generally consistent. In conclusion, results of this preliminary study indicate this system merits further evaluation as a model of the dermal irritant potential of pharmaceutical process materials. The results of this study also demonstrate the utility of multi-end point analysis in improving the predictivity of this model.

1309

THE USE OF A HUMAN RECONSTITUTED CORNEAL EPITHELIUM MODEL FOR THE OCCUPATIONAL HAZARD ASSESSMENT OF PHARMACEUTICAL PROCESS MATERIALS.

R. Guest<sup>3</sup>, <u>C. W. Seaman</u><sup>1</sup>, B. De Wever<sup>2</sup>, M. Cappadoro<sup>2</sup>, A. Whittingham<sup>3</sup> and C. Prusiewicz<sup>1</sup>. <sup>1</sup>clo GlaxoSmithKline, Ware, Herts, United Kingdom, <sup>2</sup>SkinEthic Laboratories, Nice, France and <sup>3</sup>SafePharm Laboratories, Derby, United Kingdom.

Ocular irritation is a potentially serious problem arising from contact with workplace chemicals. Prospective identification of the irritant potential of novel chemicals has traditionally relied on the use of in vivo studies. However, a growing requirement for ethical testing strategies and availability of new technologies has led to an increased focus on the need for alternative methods. This presentation describes a preliminary assessment of a reconstituted corneal epithelial culture system produced by SkinEthic for determining the ocular irritant potential of pharmaceutical process materials. Briefly, reconstituted corneal epithelial cultures were treated with test materials for periods of 5, 10 and 60 minutes after which they were assessed for viability (MTT evolution), histopathology and cytokine release (IL-1 alpha IL-6 and IL-8). Positive controls (0.5 % and 1% SDS) showed severe tissue destruction as expected. Negative controls showed normal morphology and viability throughout the experiment. Test materials V-006, V-007 and V-021 showed minimal to no damage, dead tissue and moderate tissue damage respectively. Although increases in Interleukin-1 alpha were observed, modified treatment regimes will be necessary to obtain useful results with IL-6 and IL-8. Test results reported by two laboratories were generally consistent with each other and with the known in vivo ocular irritant potential of the test materials. In conclusion, the results of this preliminary study show that the reconstituted corneal epithelial model merits further evaluation as an alternative to animal assays, for identifying the ocular irritation potential of pharmaceutical process materials. The results of this study also demonstrate the utility of multi-end point analysis in improving the predictivity of these models.

### 1310 IN-VITRO FIBER DISSOLUTION RATE AS A PREDICTOR OF FIBER CLEARANCE FROM THE LUNG.

R. M. Potter and <u>J. G. Hadley</u>. Product Stewardship, Owens Corning Science and Technology Center, Granville, OH.

Dissolution rates of silicate glass fibers from a wide compositional range have been measured in the laboratory in a modified pH 7.4 Gamble's solution. The dissolution was followed by three methods: mass loss, solution analysis for dissolved components, and fiber diameter decrease. The repeatability of each test method was within 10% of the measured value with good agreement among the three methods. This study includes 28 fiber compositions for which in-vivo long-fiber clearance rates had been determined after intratracheal instillation or short-term inhalation. In-vivo dissolution rates had been calculated for these fibers assuming uniform dissolution as the clearance mechanism. There is good agreement between the dissolution rates measured *in vitro* and those calculated from the in-vivo data except for a class of fibers characterized by low silica and high alumina contents. Fibers in this class are distinct in that they dissolve more rapidly under acid conditions than under the near-neutral conditions of the extracellular lung fluid. Their clearance mechanism is thought to involve breakage due to acidic conditions within phagocytic cells.

### 1311 COCAETHYLENE-INDUCED CHANGES IN ENDOTHELIAL PERMEABILITY AND CATION FLUX.

D. H. Tacker and A. O. Okorodudu. Department of Pathology, The University of Texas Medical Branch at Galveston, Galveston, TX.

Cocaethylene (CE) is a metabolite of cocaine and ethanol that has been implicated in ischemic tissue pathology associated with abuse, thus suggesting a role of the microvascular endothelium in pathogenesis. We previously used a CE exposure model in human microvascular endothelial cells (HMEC-1) to demonstrate that exposure to 1mM CE shifts the metabolic activity of HMEC-1 to an anaerobic state without causing lethality. Our current hypothesis is that CE induces vasculotoxicity by affecting endothelial permeability via alteration of intracellular calcium flux. For permeability studies, HMEC-1 grown on glass slips were treated with 1mM CE for 0, 1, 4, 12, and 24 hours, respectively, and fixed. Slips were then soaked in a silver nitrate solution, exposed to light, and visualized for intercellular gaps. Monitoring of intracellular calcium levels was performed using the indicator Fura-2 AM. HMEC-1 monolayers loaded with indicator were exposed to 1mM CE during kinetic measurement of ion levels or after a 1-hour pre-treatment with CE. After obtaining maximum intracellular calcium with digitonin stimulation, and minimum intracellular calcium with EGTA chelation, calculation of the intracellular calcium concentration was performed and compared between groups. Ion experiments were repeated using Mag-Fura-2 AM for determination of intracellular magnesium. We observed intercellular gap formations in CE-treated HMEC-1 that were not observed in the control monolayers. This occurred as soon as 1 hour of CE exposure. Intracellular calcium levels showed no immediate change in the treated group relative to controls, but pre-treatment with CE significantly (p<0.05, n=4) increased the maximum levels of intracellular calcium after stimulation. Baseline and minimal calcium were not affected by CE treatment. Maximal intracellular magnesium levels were also increased after pre-treatment (p<0.05, n=3). We conclude that the alteration in permeability was due to the alterations in calcium flux, since calcium is closely linked to cytoskeletal stability.

## 1312 A NON-ANIMAL PHOTOTOXICITY TEST USING EPIDERMAL TISSUE MODELS AND CYTOKINE ENDPOINTS.

D. R. Cerven, A. C. Gilotti, M. K. Reeder, C. A. Kirk, T. L. Ripper and <u>G. L. DeGeorge</u>. *MB Research Laboratories, Spinnerstown, PA*.

The phototoxic potential of chemicals, cosmetics, consumer products and pharmaceuticals are of increasing concern to regulatory agencies and industry. Currently in the US, there are no regulatory agency-accepted *in vitro* assays or alternatives to costly, low-throughput animal phototoxicity tests. To address this need, we have developed and pre-validated a high-throughput *in vitro* screening test for phototoxicity, designated the Enhanced Phototoxicity Assay in Reconstituted Skin (EPARS). EPARS overcomes many of the limitations of the 3T3 NRU Viability test, which has been validated in Europe by ECVAM. Specifically: 1) EPARS is based upon a differentiated tissue model that closely parallels human skin morphology, instead of a fibroblast monolayer; 2) the tissues are composed of primary human keratinocytes, a more relevant model than a mouse tumor cell line; 3) test substances can be applied directly, avoiding the often problematic solubilization of formulations into culture media. In EPARS, the test substance is applied topically to the reconstituted human skin models, +/- UV irradiation. Phototoxic effects are determined by measuring MTT uptake of irradiated vs. non-irradiated tissues. In

addition, to increase the sensitivity and specificity of the test, we measured the release of cytokines into the culture media *via* ELISA. Overall, EPARS proved to be an accurate and sensitive test for detecting phototoxic (photo-irritating) substances. PGE2 release was shown to be an early predictor of the toxic effects demonstrated in the *via*bility assay. Release of IL-1 alpha, IL-1ra, IL-8 and TNF-alpha supported the results of the cell *via*bility endpoint. Microarray analysis of gene expression showed that chlorpromazine treatment with UVA irradiation caused changes in gene expression that were not observed in untreated control tissues, tissues treated with UVA only, or chlorpromazine without UVA.

### 1313 ALTERNATIVE PHOTOSENSITIZATION ASSAY IN THE MOUSE (PHOTO-LLNA).

G. L. DeGeorge, T. L. Ripper, S. Young and D. R. Cerven. MB Research Laboratories, Spinnerstown, PA.

Although the Local Lymph Node Assay protocol has been validated as a sensitization test alternative for several years, several factors have limited its widespread application and development. These include the propensity for irritants to cause falsepositive results in the assay, and the need to use radioactive chemicals. We have developed an alternative photosensitization test deemed the "PHOTO-LLNA" test to overcome some of these limitations. This test uses a non-radiometric method to assess lymph node cell (LNC) proliferation, and irradiation via a solar simulator to photo-activate test chemicals. The PHOTO-LLNA measures bromodeoxyuridine uptake into the DNA of proliferating cells using a BrdU-specific antibody and flow cytometry. Other immunophenotypic parameters including the B:T cell ratio, and the % B220+, CD69+, and I-A+ cells allow the discrimination of false-positive irritants from true photosensitizers. The PHOTO-LLNA correctly classified several photosensitizers including chlorpromazine (EC3UV = 0.095%), promethazine, bithionol, sodium omadine and tetrachlorosalicylanilide (TSCA), as well as the sensitizers DNCB and oxazalone, and the irritants benzalkonium chloride and SLS. Ear swelling measurements and theimmunophenotypic markers CD69, I-AK, B220 (CD45R) and the B:T cell ratio were the most useful immunophenotypic endpoints for discriminating true sensitizers and photosensitizers from false positive irritants such as SLS. In summary, we have developed a modified non-radiometric PHOTO-LLNA test to identify and characterize photosensitizers, which is sensitive enough to detect weak phototoxins. In addition, the enhanced PHOTO-LLNA can employ multiple immunophenotypic markers to discriminate between true photosensitizers and false-positive irritants which interfere with the interpretation of the results in standard sensitization tests.

# 1314 MULTI-CENTER PREVALIDATION USING *IN VITRO*RECONSTITUTED HUMAN CORNEAL EPITHELIAL MODEL TO ASSESS THE EYE IRRITATING POTENTIAL OF CHEMICALS.

B. De Wever<sup>1</sup>, M. Cappadoro<sup>1</sup>, F. Straube<sup>2</sup>, N. Alepee<sup>4</sup>, F. Van Goethem<sup>3</sup>, P. Vanparys<sup>3</sup> and E. Adriaens<sup>5</sup>. <sup>1</sup>SkinEthic Laboratories, Nice, France, <sup>2</sup>Novartis Pharmacology, Basel, Switzerland, <sup>3</sup>Johnson & Johnson Pharmaceutical R&D, Beerse, Belgium, <sup>4</sup>Pfizer Global R&D, Amboise, France and <sup>5</sup>University of Ghent, Ghent, Belgium. Sponsor: A. Goldberg.

The development of in vitro alternatives to in vivo Draize eye testing is stimulated by scientific and ethical considerations. This multi-center study aimed at evaluating the predictive power of a new commercially available human cornea model (SkinEthic, Nice, France) to assess acute ocular irritation. When cultivated in vitro on filter inserts at the air-liquid interface using in chemically defined medium, the Human Corneal Epithelial cells of the cell line HCE form a corneal epithelial tissue, resembling histologically the outer epithelial cell layers of the human cornea. For this interlaboratory evaluation, a prevalidation approach (protocol optimization, transfer and performance) was used in order to provide sufficient evidence of the relevance (predictivity) and reliability (reproducibility) of the human corneal(HCE) model. At each of the 4 participating laboratories, 25 reference chemicals, ranking from non to very severe eye irritating, were applied topically to the HCE cultures and different treatment times were applied. The rate of cytotoxicity (tissue viability and histological analysis) was compared to published in vivo acute eye irritation as well as existing data obtained in the Bovine Corneal Opacity Permeability (BCOP) test. A very good inter-laboratory reproducibility was obtained (correlation coefficient r > 0.82). Additionally, the *in vitro* data correlated well with BCOP scores, however correlation analysis with available Draize eye data resulted in lower values due to the often conflicting existing Draize eye test information. The final outcome of this study will establish whether this in vitro model is adequate to enter formal validation. In addition to reducing the number of animals required for safety testing, this in vitro eye irritation model is rapid and requires less compound than other in vitro assays.

### 1315 COMPUTATIONAL MODEL FOR RADIATION-INDUCED CELL DEATH AT LOW DOSES IN THE DEVELOPING NEOCORTEX.

N. M. DeFrank, W. C. Griffith, <u>J. M. Gohlke</u> and <u>E. M. Faustman</u>.

Environmental and Occupational Health Sciences, University of Washington, Seattle, WA

Substantial evidence has demonstrated that low dose radiation exposures (10 to 50cGy) during particular gestational periods can result in permanent neuronal perturbations and eventual abnormalities in behavior and mental activity. It has been hypothesized that the mechanism underlying these effects includes radiation-induced cell death among neuronal precursors in the proliferative ventricular zone, thus disrupting the normal processes and timing of neurogenesis and leading to insufficient neuron production. Existing data sets were used in the construction of a computational model to describe the extent and pattern of cell death in the neocortex and the subsequent effects on neuron number at the end of neurogenesis. Results indicate that the induced death of a small fraction of neuronal precursors, expressed as a function of time and dose, leads to a significant decrease in the final neuron count compared to control embryos. The most drastic effects correspond to times of rapid proliferation and differentiation. For example, a single maternal dose of 24cGy on the 13th day of gestation induces cell death in a quarter of neuronal precursors of the fetal mouse. The model provides a means for comparing differences in absorbed dose, time of exposure, and duration of exposure. The model predicts about a 1% decrease of neuronal precursor cells per cGy during the most sensitive time window of neurogenesis and about a 0.5% decrease per cGy during other times of neurogenesis. The model is of risk assessment utility as it includes evaluation of alterations in specific developmental dynamic processes and permits comparisons of inter-species susceptibility, including mice, rats, and humans, across time and dose. Supported by the Center for Child Health Risk Research (R 826886-01-0 and P01 ES09601) and the Department of Energy (DE-FG02-03ER63674).

#### 1316

CONTRIBUTION OF EXPERIMENTAL AND INTER AND INTRASPECIES VARIABILITY IN A COMPUTATIONAL MODEL FOR ETHANOL-INDUCED PERTURBATIONS OF NEOCORTICAL DEVELOPMENT.

J. M. Gohlke, W. C. Griffith and E. M. Faustman. Environmental and Occupational Health Sciences, University of Washington, Seattle, WA.

We are quantitatively evaluating normal and chemically perturbed neocortical neurogenesis, migration and synaptogenesis with a biologically based model that allows for evaluation of sources of experimental and biological uncertainty. Data used to establish key parameters include the growth fraction, the founder cell population, the cell death rate during neurogenesis and synaptogenesis and the clearance time of cell death labeled neurons. This new model construct compares intra and interspecies variability in model parameters and model output based on independent, stereologically determined neocortical parameters in the rat, mouse, and monkey. Consideration of programmed cell death (PCD) during neocortical neurogenesis can reduce neuron output by as much as 24% in the rat. Higher PCD rates would deplete the progenitor population, not allowing for the vast proliferation that is the hallmark of neurogenesis. Furthermore, our simulations suggest the growth fraction may be less than 100% for most of the neurogenesis period and the clearance time of dying neurons labeled by TUNEL or pyknosis is relatively short, between 1 and 4 hrs. Based on the variability in estimates of adult neocortical neuron number (coefficient of variation (CV) between 7- 25%), true biological variation in rates of proliferation, transformation and death must be low (CV ≤ 2.5%), however variation estimates in experimental studies for parameter estimation are much larger (CV 10-30%). These results suggest experimental error can account for the majority of the observed variability in parameter estimation data, thus highlighting the importance of reduced experimental variability to discover subtle toxicant-induced effects. Our model framework allows for in silico evaluation of the variability in normal and perturbed states of neocortical development, providing a scientificallyframed, quantitative construct to inform inter and intra species variability considerations for risk assessments.

#### 1317

PREDICTIVE MODELING OF *IN VITRO* BRAIN CHOLINESTERASE INHIBITION FOLLOWING SIMULTANEOUS OR SEQUENTIAL EXPOSURES TO BINARY MIXTURES OF ORGANOPHOSPHATES.

J. E. Chambers<sup>1</sup>, R. L. Carr<sup>1</sup>, H. W. Chambers<sup>2</sup>, J. A. Kamykowski<sup>1</sup>, E. C. Meek<sup>1</sup>, S. F. Oppenheimer<sup>3</sup> and J. R. Richardson<sup>1</sup>. <sup>1</sup>Coll Veterinary Med., Mississippi State University, Mississippi State, MS, <sup>2</sup>Department Entomology, Mississippi State University, Mississippi State, MS and <sup>3</sup>Department Mathematics, Mississippi State University, Mississippi State, MS.

The active metabolites (oxons) of many common organophosphorus insecticides persistently inhibit nervous system cholinesterase as the primary mechanism of toxicity. Individuals are likely to encounter more than one organophosphate. These ex-

periments exposed rat brain homogenates to binary mixtures of organophosphates, either simultaneously for a 15 minute incubation period or sequentially (second oxon added 15 minutes after the first, with a subsequent 15 minute incubation period). Levels of inhibition of individual oxons did not exceed 30%. The cholinesterase activity was then determined spectrophotometrically using acetylthiocholine as a substrate, and the cholinesterase inhibition was calculated. Mass action models were developed for the resultant inhibition in the binary mixture, with model calibration occurring from the inhibition of the individual compounds with a 15 minute exposure. Subsequently, the mass action models were adapted to partial order models (using guidance of existing reaction models present in the agronomy literature). The partial order models were more effective in prediction with the simultaneous exposures to the binary mixtures than were the mass action models. The partial order models were also more effective in prediction of the sequential exposures to binary mixtures within the calibration range (i.e., 15 minute exposures and lower levels of inhibition), but the mass action models are more robust for the longer time of incubation and the higher levels of inhibition. However, both types of models predict greater inhibition than the experimental data, indicating that there are factors influencing the levels of cholinesterase inhibition with binary mixtures that we have not yet identified for the mathematical models. (Supported by American Chemistry Council 0161).

## 1318 STOCHASTIC MATHEMATICAL MODELING OF TUMOR GROWTH AND DIFFERENTIATION IN HUMAN CARCINOGENESIS.

S. Y. Whitaker<sup>1</sup>, A. Kopp-Schneider<sup>2</sup> and <u>C. J. Portier</u><sup>1</sup>. <sup>1</sup>LCBRA, NIEHS, Research Triangle Park, NC and <sup>2</sup>Biostatistics, DKFZ, Heidelberg, Germany.

Researchers generally agree that cancer is a multistage process where abnormal cells mutate to become cancerous cells. However, current research explores quantitative methods to describe the path and mechanisms that lead to the malignant state. As cancer is the unregulated growth of cells, there is a need for models that incorporate more biological realism while maintaining mathematical tractability. A stochastic multistage model with the expected number, variance and co-variance formulae expressed as ordinary differential equations is presented as a novel approach for characterizing possible carcinogenic mechanisms. The controlled growth and differentiation (CGD) model (Whitaker et al., 2003) was originally proposed to describe mechanisms in developmental toxicology. However, the model construct also allows for the implementation of a host of possibilities when modeling cancer. This model has a highly controlled birth and death process for cells at any stage of maturity. The formulation of the CGD model easily allows for the inclusion of an unspecified number of states in any biological process. The number of replications allowed in the progression of a cell colony is controllable and is able to more closely reflect the presence of a true stem cell population. The CGD model is able to provide a mathematical approximation to the number (and hence the size) of cells at each stage of the process. Expanding the model to calculate the size distribution of a cell colony can be incorporated and then compared to the observed size distribution. Here, we propose to fit the CGD model to the liver foci data set described in Kopp-Schneider et al. and compare the results of the CGD model, the existing onestage clonal expansion model3, and the color-shift model (Kopp-Schneider et al., 1998).

## PHARMACOKINETIC (PK)/PHARMACODYNAMIC (PD) RELATIONSHIP OF PCB126 UNDER THE CONDITIONS OF MODIFIED ITO MEDIUM-TERM LIVER BIOASSAY.

M. Lohitnavy, L. Chubb, O. S. Lohitnavy, C. C. Yang, J. Homburg, J. A. Campain and R. S. Yang. Quantitative and Computational Toxicology Group, Center for Environmental Toxicology and Technology, Environmental and Radiological Health Sciences, Colorado State University, Fort Collins, CO.

PCB126 is the most toxic congener of PCBs with carcinogenic potential. By using the modified Ito medium-term bioassay protocol, male F344 rats were given a single ip dose of 200 mg/kg of diethylnitrosamine (DEN) as an initiator. Daily oral PCB126 administration (3.3 and 9.8  $\mu g/kg/day)$  was started at week 2 after DEN injection. One week after PCB126 dosing, a 2/3rd partial hepatectomy was conducted. Rats were sacrificed at 20, 24, 28, 47 and 56 days post-DEN injection. Tissue concentrations in the liver, fat, whole blood, kidney and muscle were measured by using GC/ECD following liquid extraction and clean up. Morphometric analysis of glutathione-S-transferase (GST)- P foci formation in the liver slices was performed as a PD endpoint to determine numbers and sizes of preneoplastic foci. Concentration-time courses of PCB126 in the liver, fat, kidney, muscle and whole blood were obtained. Despite high lipophilicity of PCB126, liver concentrations were the highest with the ratio between liver and fat concentrations of about 110-400 to 1. Assuming this is protein binding in the liver, our results revealed that PCB126 binds to liver about 11 to 40 times more strongly than TCDD. Proteomic analyses will shed further light on this interesting binding phenomenon. Dose- and

time-dependence of GST-P foci formation were studied. Correlation analyses between area under the curve of PCB126 in the liver (AUC $_{\rm Liver}$ ) as an internal dose and PD endpoints (foci numbers, area, and relative foci area) demonstrate linear relationship at low AUCs and nonlinear response at higher AUCs . The linkage of PBPK and clonal growth models will enable us to predict target tissue dosimetry as well as preneoplastic foci formation in F344 rats upon exposure to PCB126 in an Ito medium-term bioassay. (Supported by NIOSH/CDC grant 1 RO1 OH07556)

## 1320 REACTION NETWORK MODELING OF BENZO(A)PYRENE METABOLIC PATHWAYS: FURTHER DEVELOPMENT

K. H. Liao<sup>1,2</sup>, A. N. Mayeno<sup>1,3</sup>, K. F. Reardon<sup>1,2</sup> and <u>R. S. Yang<sup>1,3</sup></u>.

<sup>1</sup>Quantitative and Computational Toxicology Group, Center for Environmental Toxicology and Technology, Colorado State University, Fort Collins, CO, <sup>2</sup>Department of Chemical Engineering, Colorado State University, Fort Collins, CO and <sup>3</sup>Department of Environmental and Radiological Health Sciences, Colorado State University, Fort Collins, CO.

We have been developing a modeling tool for predicting the complex biotransformation pathways of xenobiotics by using a chemical engineering approach, Reaction Network Modeling (RNM). RNM generates the reaction pathways automatically based on the chemical structures of the parent compounds and reaction rules. Graph theory is used to encode chemical structures and reaction rules at the molecular level. Benzo[a]pyrene (BaP) was used as the substrate for the first application of RNM to toxicology since it is a human carcinogen as well as a ubiquitous environmental pollutant. Despite thousands of papers in the literature on BaP, quantitative data on human enzyme kinetics useful for RNM are lacking. Thus, to obtain reaction rate constants for RNM, the time course profiles of BaP metabolic pathways were studied using recombinant human cytochrome P450 1A1 and epoxide hydrolase. In addition, considerable effort was devoted to developing HPLC methods for the analysis of 12 major BaP metabolites including dihydrodiols, phenols, tetrols, and quinones with detection limits in the nM range. The high detection sensitivities of BaP-quinones were achieved by an on-line post-column zinc reduction column, which converts the non-fluorescent quinones to their corresponding fluorescent hydroquinones. RNM provided good predictions of the time course profiles of these major BaP metabolites when compared with experimental data. The next phase is to link RNM with PBPK models. Ultimately, we will be able to simulate the entire reaction network of BaP from whole body pharmacokinetics down to the level of molecular interactions among enzymes, BaP, and its metabolites. Since RNM is encoded at the molecular structure level, it is a promising approach to handle the extremely complex biochemical reactions and reaction networks. (Supported by NIEHS Grant R01 ES09655).

## 1321 QUANTIFYING GENE EXPRESSION NETWORKS USING BAYESIAN METHODS: KNOWN NETWORK STRUCTURE.

H. Toyoshiba, T. Yamanaka, F. M. Parham, J. M. Martinez, H. Sone, N. J. Walker and C. J. Portier. LCBRA, National Institute of Environmental Health Sciences, Research Triangle Park, NC.

Gene expression arrays (gene chips) have enabled researchers to roughly quantify the level of mRNA expression for a large number of genes in a single sample. Several methods have been developed for the analysis of gene array data including clustering, outlier detection, correlation studies, etc. Most of these analyses are aimed at a qualitative identification of what is different between two samples and/or is there a relationship between two genes. Several researchers have also suggested the use of gene interaction mapping as a tool for the analysis of gene array data. Dynamic models, usually based on ordinary differential equations, have also been proposed and in some cases used for the analysis of microarray data; in most cases, these analyses have shown limited use of formal statistical methods. In this study, we propose a quantitative, statistically sound methodology for the analysis of gene regulatory networks using gene expression data sets. The model was developed based on Bayesian networks to formalize the direct quantification of gene-expression networks. Using this method, it is not only possible to determine the qualitative relationships between genes but the quantitative relationship and the probabilities associated with these quantitative connections. Using gene expression data from HPL1A lung airway epithelial cells after exposure to TCDD at levels of 0.1, 1.0 and 10.0 nM for 24 hours, a hypothetical gene expression network was assumed and the developed method applied to the data and the hypothetical network. Different from seeing gene by gene correlations, the method allows us to see the relationship between genes in terms of network. A new statistical approach to analyze microarray data is shown in this study.

PATHWAYS TO UNDERSTANDING THE METABOLISM OF CHLORINATED ENVIRONMENTAL CONTAMINANTS THROUGH BIOCHEMICAL REACTION NETWORK MODELING.

A. N. Mayeno, <u>B. Reisfeld</u> and <u>R. Yang</u>. *Quantitative and Computational Toxicology Group, Center for Environmental Toxicology and Technology, Department of Environmental and Radiological Health Sciences, Colorado State University, Fort Collins, CO.* 

Chlorinated hydrocarbon solvents, such as trichloroethylene (TCE), perchloroethylene (Perc), methyl chloroform (MC), and chloroform (CF), are common groundwater contaminants, all of which can exert harmful health effects. Toxicity of these chemicals is, in large part, attributed to the formation of reactive species after bioactivation by cytochrome P450 enzymes. A single chlorinated solvent may produce several reactive species through complex metabolic pathways. For a mixture of compounds, the situation is much more complicated. Experimental studies of pure chemicals and the multitude of chemical mixture combinations to understand the formation of these toxic intermediates and the interconnections between these pathways of metabolism can be resource prohibitive; hence, novel, alternative approaches are needed. Here, we report the use of an in silico and systems biology approach, "Biochemical Reaction Network Modeling" (BRNM), to describe, inter-connect, and understand the metabolism of TCE, Perc, MC, and CF. BRNM is a computer-assisted modeling tool that, when validated, not only predicts possible metabolites but depicts and connects the metabolic pathways through common metabolites, thereby creating a comprehensive and interwoven network of reaction pathways. Using this tool, we were able to predict metabolites of the four pollutants, describe their metabolic pathways, depict metabolites in common and intermediates expected to be unstable or reactive. Each step in the pathway results from "reaction rules" based on empirical metabolism studies and mechanistic organic chemistry. Our work represents the first steps in using BRNM to study, describe, and understand the interwoven and complex metabolic pathways of environmental toxins. (Supported in part by NIEHS Career Development Award 01 K25 ES11146 and Training Grant 1 T32 ES 07321)

1323

APPLICATION OF A STATISTICAL DYNAMIC MODEL INVESTIGATING THE SHORT-TERM CELLULAR KINETICS INDUCED BY RIDDELLIINE, A HEPATIC ENDOTHELIAL CARCINOGEN.

M. V. Smith<sup>1</sup>, A. Nyska<sup>2</sup> and <u>C. Portier<sup>2</sup></u>. <sup>1</sup>Constella Health Sciences, Constella Group, Durham, NC, NC and <sup>2</sup>NIEHS, Research Triangle Park, NC.

In recent studies, riddelliine, a pyrrolizidine alkaloid, was found to increase rates of replication and apoptosis and induce hemangiosarcoma in the liver of rats and mice . In our current investigation, applying a kinetic model, we used the data from a short-term study (Nyska et al., 2002) in which 42 male F334/N rats were dosed by gavage with riddelliine (0, 1.0, and 2.5 mg/kg/day) for 6 weeks; 7 animals/group were sacrificed after 8 consecutive daily doses, and the remaining rats were terminated after 30 daily doses, excluding weekends. Cellular kinetics were investigated using immunohistochemical stainings for bromodeoxyuridine (BrdU) and TUNEL. We now report a predictive mathematical model for describing BrdU labeling and apoptotic processes for hepatocytes and hepatic endothelial cells in rats, using the data from this previous experiment. The model predictions were used with multivariable nonlinear regression techniques to estimate replicative and apoptotic rate constants for both cell types and all treatment groups. Information on the total numbers of each cell type in each animal was utilized as a covariate to increase the accuracy of the predictions. Hypothesis tests were used with the predicted rates to separate the competing effects of riddelliine on proliferation and apoptosis of hepatocytes and endothelial cells. That estimated replicative rates were found to be significantly higher for endothelial cells than hepatocytes supports the supposition of induction of hemangiosarcoma by riddelliine in the liver. Additional hypothesis testing suggested a differential effect of BrdU on the kinetic rates of hepatocytes and endothelial cells in the control groups. Although the replicative rates were found to be approximately the same, the apoptotic rates were found to be significantly higher for endothelial cells in the control groups.

1324

A FEEDBACK MODEL FOR TESTICULAR-PITUITARY AXIS HORMONE KINETICS AND THEIR EFFECTS ON THE REGULATION OF THE PROSTATE IN ADULT MALE RATS.

H. A. Barton<sup>2</sup>, M. G. Zager<sup>1</sup> and L. K. Potter<sup>1</sup>. <sup>1</sup> Toxicology, University of North Carolina, Chapel Hill, NC and <sup>2</sup>NHEERL, USEPA, Research Triangle Park, NC.

The testicular-pituitary axis regulates male reproductive system functions. A model describing the kinetics and dynamics of testosterone (T), dihydrotestosterone (DHT) and luteinizing hormone (LH) was developed based on a model by Barton

and Anderson (1997). The model describes the metabolism of T to DHT by  $5\alpha$ -reductase with feedback loops for the positive regulation of T synthesis by LH and negative regulation of LH by T and DHT, and simulates the maintenance of the adult prostate as a function of hormone concentrations. The regulatory processes involved in prostate maintenance include cell proliferation, apoptosis, fluid production and 5α-reductase activity, which is controlled by the occupancy of a single gene by the DHT-androgen receptor (AR) dimerized complex. The other processes are regulated by the occupancy of multiple genes, but each process is represented as a single DNA binding site in the model. The model simulates prostate dynamics for intact, castrated, T injected and T or DHT subcutaneously implanted rats. The activities of environmental antiandrogens, such as the fungicide vinclozolin and the therapeautic drug finasteride, are modeled as competitive ligands for the AR. After calibration, the model is able to simulate the castration-induced regression of the prostate with accuracy compared to experimental data, which show that the prostate regresses to approximately 17 percent of its intact weight at 14 days postcastration and 5 percent at 30 days post-castration. The model demonstrates accuracy compared to the data in predicting serum T and AR levels following castration. This model sets a basis for quantifying the kinetics and effects of exogenous endocrine active compounds on the prostate. Furthermore, it provides a framework to extend modeling efforts to the pubertal developmental period, including growth and changes in hormone synthesis and metabolism. PRELIMINARY ANALYSIS OF ALGORITHMS PREDICTING BLOOD:AIR AND TISSUE:BLOOD PARTITION COEFFICIENTS FROM SOLVENT PARTITION COEFFICIENTS.

T. R. Sterner<sup>1</sup>, P. J. Robinson<sup>2</sup>, <u>D. R. Mattie<sup>3</sup></u> and G. A. Burton<sup>4</sup>, <sup>1</sup>OpTech, Dayton, OH, <sup>2</sup>ManTech Environmental Technology, Dayton, OH, <sup>3</sup>Air Force Research Laboratory, Wright-Patterson AFB, OH and <sup>4</sup>Wright State University, Dayton, OH.

Algorithms predicting tissue and blood partition coefficients (PCs) from solvent properties (octanol:water, saline or water:air, oil:air coefficients) were compared to assess their usefulness for a petroleum mixtures physiologically based pharmacokinetic/pharmacodynamic model. Measured blood:air and tissue:blood PCs were sought from literature resources for 14 JP-8 components. PCs, mainly from vial equilibration experiments, were separated by species (rat and human) and averaged by tissue and chemical. Average experimental PCs were then compared with predicted PCs calculated using algorithms from nine published sources. The algorithms chosen use solvent PCs due to the relative accessibility of these parameters. Tissue:blood PCs were calculated from ratios of predicted tissue:air and experimental blood:air values ( $PC_{EB}$ ). Calculated PCs were evaluated using percent error compared to the experimental value. Of the 231 calculated values, 30% performed within ± 20% of the experimental PC values. Algorithms were divided into three main types. Empirical equations (derived from linear regression of experimental PC data), physiologically based equations (based on water and lipid components of a tissue type), and hybrid equations (physiological parameters and empirical factors combined) each performed equally well. PCEB values were compared with tissue:blood PCs calculated from ratios of predicted tissue:air and predicted blood:air values ( $PC_{PB}$ ). Overall, 68% of  $PC_{EB}$  values had smaller absolute percent errors than  $PC_{PB}$  values. Physiological equations should not be used to calculate  $PC_{PB}$  values as 100% of these  $PC_{PB}$  values had higher absolute percent errors than corresponding  $PC_{EB}$  values. If calculated PC values must be used in models, a comparison of experimental and predicted PCs for chemically similar compounds is advisable, so one understands the expected error level in calculated values.

### 1326 STEADY STATE TOXICOKINETICS OF METHYLMERCURY IN HUMANS.

G. Balagopal and <u>H. Chan</u>. Nutrition and Dietetics, McGill University, Ste-Annede-Bellevue, QC, Canada.

Chronic low dose exposure to methylmercury (MeHg) above the reference dose recommended by USEPA (0.1  $\mu g/kg/day)$  is common in populations that consume fish and marine mammals. High recalcitrance property with low body clearance increases the bioavailability of MeHg in different body compartments. In spite of such dogma, steady state toxicokinetic end points have never been characterized for MeHg exposure. The objective of this study is to estimate internal doses at the target organs at steady state of exposure. Multicompartmental toxicokinetic model of Eular and Gear algorithms with mass balanced differential equation were used to simulate MeHg exposure and the model applicability were shown with a scenario, assuming daily intake of 200g of fish resulting in MeHg exposure of 0.1  $\mu g/kg$  over a year. Steady state burden of both organic and inorganic mercurials was calculated for different tissue groups like brain, liver, kidney, hair and nail. Results showed

that Hg concentrations reached steady state in all the tissue compartments after 150 days of exposure and the minimum clearance time in all the tissue compartments was 120 days. Blood MeHg concentration was 23.7  $\mu$ g/L and the concentration of MeHg in brain, liver and kidney were 0.169  $\mu$ g/kg, 3.53  $\mu$ g/kg and 2.70  $\mu$ g/kg respectively. The inorganic mercury concentration in the routes of elimination like hair and nail were 1 ng/g and 3.5 ng/g respectively. This approach can be used by policy makers in generating reference values based on MeHg body burden.

1327 DEVELOPMENTAL EXPOSURE TO LEAD PROMOTES NEURODEGENERATION IN THE SENESCENT RAT

B. Brock, N. H. Zawia and M. Basha. Biomedical Sciences, University of Rhode Island, Kingston, RI.

The Fetal Basis of Adult Disease (FeBAD) hypothesis states that many adult diseases have a fetal origin. Virtually little data is available that has examined the impact of environmental exposures during early development on delayed dysfunctions or diseases in the adult brain. To bridge this gap we have examined if any associations exist between developmental exposure to lead (Pb) and neurodegenerative diseases in the aging brain. We exposed rats to 0.2% Pb-acetate in the drinking water in the following manner: 1) control unexposed group; 2) early exposure to Pb (from birth to weaning); 3) late exposure to Pb (17-20 months of age); 4) early and late exposure. The brains of all the groups were prepared for immunohistochemistry and analyzed by the Campbell-Switzer silver neurodegeneration stain. The brains of aging animals chronically exposed to Pb exhibited pathological features of neurodegeneration (astrocytic activation), which were more prominent and widespread in aging rats exposed to Pb as neonates, indicating that early exposure to Pb has made the animals more susceptible to chemical stressors later in life.

1328 DEVELOPMENTAL OVEREXPRESSION OF ALPHA(2)ADRENERGIC RECEPTORS: ROLE IN CELL
PROLIFERATION AND CROSS-REGULATION BY BETAADRENERGIC RECEPTOR NEUROTOXICANTS.

M. L. Kreider, F. J. Seidler and T. A. Slotkin. Pharmacology & Cancer Biology, Duke University Med. Ctr, Durham, NC.

Catecholamines serve as neurotrophins that coordinate cell replication and differentiation in the developing brain. The alpha(2)-adrenergic receptor (A2AR) is overexpressed during periods of high mitotic activity in the fetus and is thought to be involved in promoting cell proliferation. Terbutaline, which is commonly administered to arrest preterm labor, increases the expression of A2ARs in the neonatal rat brain while suppressing DNA synthesis and evoking neural dysmorphology. We examined whether there is a mechanistic link between the effects on A2ARs and neural cell replication by examining regional alterations in [3H]thymidine incorporation into DNA in animals treated with an A2AR agonist (clonidine, 2 mg/kg) or antagonist (yohimbine, 2.5 mg/kg), during three developmental time periods: gestational day (GD) 20, postnatal day (PN) 1 and PN8. Clonidine elicited dramatic decreases in DNA synthesis in the forebrain, brainstem, and cerebellum during both gestational and postnatal time periods. However, blockade of the A2AR with yohimbine also resulted in decreases in DNA synthesis, albeit on a more moderate scale than seen with the agonist; the effects of the antagonist may be related to A2AR autoreceptor control of norepinephrine release and subsequent actions of the neurotransmitter/neurotrophin on cell proliferation. The dual actions of A2AR agonists and antagonists indicate that low, tonic A2AR input is necessary to maintain cell replication in the developing brain but that inappropriate overstimulation in-hibits mitotic activity. Involvement of A2ARs in the control of brain cell development implies that perturbations in A2AR expression elicited by terbutaline may contribute to neurobehavioral anomalies. Supported by NIH HD09713.

1329 EFFECT OF ETHANOL ON CARBACHOL-STIMULATED PHOSPHOLIPASE D SIGNALING IN ASTROGLIAL CELLS

M. Guizzetti<sup>1</sup>, B. D. Thompson<sup>1</sup>, Y. Kim<sup>1</sup>, K. VanDeMark<sup>1</sup> and <u>L. G. Costa<sup>1, 2</sup></u>.

<sup>1</sup>Environmental and Occupational Health Sciences, University of washington, Seattle, WA and <sup>2</sup>Department of Pharmacology and Human Physiology, University of Bari, Bari, Italy.

Inhibition of astrocyte proliferation has been hypothesized to be an important event involved in the developmental neurotoxicity of ethanol. We have previously shown that the acetylcholine analogue carbachol induces astroglial cell proliferation and that ethanol strongly inhibits this effect, primarily by targeting activation of PKC z and its down-stream effectors p70S6K and NF-kB. We hypothesized that a primary upstream target for ethanol may be the PKC zeta activator phosphatidic acid (PA), which is formed by hydrolysis of phosphatidylcholine by phospholipase

D (PLD). In this study, we investigated whether inhibition by ethanol of the main signal transduction pathway involved in carbachol-induced cell proliferation may be due, at least in part, to inhibition of PA formation. Suramin, an inhibitor of PLD activity, inhibited DNA synthesis induced by carbachol; similarly, 1-butanol, which is a substrate for PLD and inhibits PA formation, inhibited carbachol-induced cell proliferation and the underlying intracellular signaling, while its analog tert-butanol, which is not a substrate for PLD, was ineffective. Furthermore, exogenous PA was able to increase DNA synthesis, and to activate PKC zeta and p70S6K. Ethanol had only a small inhibitory effect on PA-induced astrocyte proliferation. Furthermore, in carbachol-stimulated cells, ethanol increased the formation of phosphatidylethanol and inhibited the formation of PA. Altogether, these results indicate that PLD activation plays an important role in carbachol-induced astroglial cell proliferation, probably by generating the second messenger PA. Moreover, the effect of ethanol on carbachol-induced proliferation appears to be mediated, at least in part, by its ability to interact with PLD leading to the formation of phosphatidylethanol and to inhibition in the formation of PA, thus affecting a major singaling pathway leading to astroglial cell proliferation. THE EFFECTS OF EARLY POSTNATAL CHLORPYRIFOS EXPOSURE ON PERFORMANCE IN THE 12-ARM RADIAL MAZE. FRANK JOHNSON AND RUSSELL L. CARR. CENTER FOR ENVIRONMENTAL HEALTH SCIENCES, COLLEGE OF VETERINARY MEDICINE, MISSISSIPPI STATE UNIVERSITY, MISSISSIPPI STATE, MS 39762, USA.

F. O. Johnson and R. L. Carr. College Of Veterinary Medicine, Center For Environmental Health Sciences, Mississippi State University, Starkville, MS.

Developmental exposure to chlorpyrifos (CPF) has been associated with cognitive deficits in children. The current study investigated the effects of early postnatal exposure to CPF on spatial learning and memory using a 12-arm radial maze paradigm. Using an incremental dosing regimen, Sprague-Dawley rats were orally gavaged daily with either corn oil or chlorpyrifos at a low dose of 1 mg/kg from postnatal day 1 (PND1) to 21; a medium dose of 1 mg/kg from PND1-5, 2mg/kg from PND6-13, and 4mg/kg from PND14-21; or a high dose of 1.5mg/kg from PND1-5, 3mg/kg from PND6-13, and 6mg/kg from PND14-21. Rats were then tested beginning on PND36 for 4 weeks (4 sessions per week for 16 total sessions) on a working/reference memory task. Developmental CPF exposure elicited persistent cholinesterase inhibition with 65-70% inhibition on PND20 and 28-32% on PND40. Interestingly, control females committed greater numbers of working and reference memory errors than did control males in the 12-arm radial maze. In females, the number of working errors were increased with the medium dosage of CPF but the number of reference memory errors was not affected. In males, neither working or reference memory were affected. These data suggest that neonatal exposure to CPF alters spatial memory formation in a gender specific manner.

1331 DEVELOPMENTAL EXPOSURE TO CHLORPYRIFOS ELICITS SEX-SELECTIVE ALTERATIONS OF SEROTONERGIC SYNAPTIC FUNCTION IN ADULTHOOD

J. E. Aldridge, F. J. Seidler and T. A. Slotkin. Pharmacology & Cancer Biology, Duke University Med. Ctr, Durham, NC.

During brain development, serotonin (5HT) provides essential neurotrophic signals and we found that gestational or neonatal exposure of rats to the commonly used insecticide chlorpyrifos (CPF) elicits immediate changes in 5HT systems. In the current study, we evaluated the effects in adulthood after CPF exposures from the neural tube stage (gestational days GD9-12) and the late gestational period (GD17-20), through postnatal (PN) neuronal differentiation and synaptogenesis (PN1-4, PN11-14), utilizing treatments below the threshold for systemic toxicity. With exposure on GD9-12, CPF elicited global elevations in 5HT1A and 5HT2 receptors and in the 5HT presynaptic transporter. The GD17-20 treatment elicited larger effects that displayed selectivity for regions with 5HT nerve terminals and that were preferential for males. Although similar receptor upregulation was seen after PN1-4 exposure, the effects were larger in regions with 5HT cell bodies; in addition, the presynaptic transporter was downregulated in the nerve terminal zones of females. The PN11-14 exposure had much smaller effects on receptors but still elicited transporter suppression with the same regional and sex selectivity. Although CPF exposure on GD17-20, PN1-4 or PN11-14 altered the ability of 5HT to modulate adenylyl cyclase, these did not correspond to the effects on 5HT receptors, suggesting an additional set of effects on proteins that transduce the 5HT signal. Our results indicate that CPF elicits long-lasting changes in 5HT receptors, the presynaptic 5HT transporter, and 5HT-mediated signal transduction after exposure in discrete developmental windows that range from the neural tube stage through synaptogenesis. These effects are likely to contribute to neurobehavioral teratology of CPF. Supported by NIH ES10387 and ES10356.

NICOTINE IS A DEVELOPMENTAL NEUROTOXICANT AND NEUROPROTECTANT: STAGE-SELECTIVE INHIBITION OF DNA SYNTHESIS COINCIDENT WITH SHIELDING FROM EFFECTS OF CHLORPYRIFOS.

D. Qiao, F. J. Seidler, J. D. Violin and T. A. Slotkin. Pharmacology & Cancer Biology, Duke University Med. Ctr, Durham, NC.

Although nicotine is now well-recognized as a developmental neurotoxicant, it also may have neuroprotectant properties. In the current study, we used PC12 cells to characterize the specific developmental phases in which these effects are expressed. In undifferentiated cells, nicotine had a modest effect on DNA synthesis (10% reduction), that was nevertheless selective, as no significant reductions were seen for RNA or protein synthesis. The effects were blocked by mecamylamine, indicating mediation by nicotinic acetylcholine receptors. Initiation of differentiation with nerve growth factor, which greatly increases the receptor concentration, produced a commensurate increase in the sensitivity of DNA synthesis to nicotine, while RNA and protein synthesis again remained unaffected. The organophosphate insecticide, chlorpyrifos, also interferes with DNA synthesis in undifferentiated PC12 cells, but by mechanisms independent of nicotinic receptors. Accordingly, the effects of a combination of nicotine and chlorpyrifos should be additive. However, simultaneous exposure of undifferentiated cells to both agents produced less-than-additive effects at low concentrations of chlorpyrifos, and at high chlorpyrifos concentrations, nicotine produced outright protection: the combination of nicotine and chlorpyrifos had lesser effects than chlorpyrifos alone. The same neuroprotection was seen when cells were exposed to nicotine for 24 hours, washed free of the drug for 24 hours, and then exposed to chlorpyrifos. We also obtained similar results with human SH-SY5Y neuroblastoma cells. The results indicate that nicotine interferes with neural cell replication, with peak effects in early stages of differentiation. At the same time, nicotine promotes trophic actions that protect against neurotoxicants that work through other mechanisms. Support: USPHS DA14247, ES10387, ES10356, and Philip Morris USA.

1333 PRENATAL NICOTINE EXPOSURE ALTERS THE RESPONSE TO NICOTINE ADMINISTRATION IN ADOLESCENCE.

Y. Abreu-Villaca, F. J. Seidler and T. A. Slotkin. Pharmacology & Cancer Biology, Duke University Med. Ctr, Durham, NC.

Maternal smoking during pregnancy leads to increased incidence of smoking in the offspring, with typical onset in adolescence. We used a rat model to investigate whether prenatal nicotine exposure alters the subsequent neurochemical response to nicotine. Pregnant rats were given nicotine (6 mg/kg/day) or saline by minipump infusion throughout pregnancy and the offspring were treated again with nicotine or saline during adolescence (postnatal days PN30-47). We assessed nicotinic cholinergic receptor (nAChR) binding, choline acetyltransferase (ChAT) activity and [3H]hemicholinium-3 (HC-3) binding to the high affinity choline transporter in the midbrain, cerebral cortex and hippocampus. Measurements were made during the period of nicotine administration (PN45) and at various intervals for up to one month after the termination of treatment (PN50, 60, 75). Prenatal nicotine alone did not alter nAChRs in adolescence but adolescent nicotine administration evoked substantial increases during and after treatment. Prenatal nicotine exposure reduced the nAChR response to adolescent nicotine treatment. For ChAT, a constitutive marker for cholinergic nerve terminals, prenatal nicotine exposure elicited increased overall activity, but again the effects of combined prenatal and adolescent exposure were less than additive. HC-3 binding, which is responsive to cholinergic neuronal impulse activity, showed long-lasting decreases with either prenatal or adolescent nicotine exposure. Combined treatment produced either additive (midbrain) or less-than-additive (cerebral cortex, hippocampus) effects but notably, there was synergism toward the effect of adolescent nicotine withdrawal (PN50, cerebral cortex). Our results suggest that prenatal nicotine exposure alters the subsequent effect of nicotine administered in adolescence, both with regard to nAChR upregulation and indices of cholinergic synaptic integrity and neural activity, especially during withdrawal. TERBUTALINE IS A DEVELOPMENTAL NEUROTOXICANT: EFFECTS ON NEUROPROTEINS AND MORPHOLOGY IN CEREBELLUM, HIPPOCAMPUS, AND SOMATOSENSORY CORTEX.

M. C. Rhodes<sup>1</sup>, F. J. Seidler<sup>1</sup>, A. Abdel-Rahman<sup>1</sup>, A. Nyska<sup>2</sup>, H. L. Rincavage<sup>1</sup> and T. A. Slotkin<sup>1</sup>. <sup>1</sup>Pharmacology & Cancer Biology, Duke University Med. Ctr, Durham, NC and <sup>2</sup>NIEHS, Research Triangle Park, NC.

Beta2-Adrenoceptor agonists, especially terbutaline, are widely used to arrest preterm labor but they also cross the placenta to stimulate fetal beta-adrenoceptors that control neural cell differentiation. We evaluated the effects of terbutaline administration in neonatal rats, a stage of neurodevelopment corresponding to human fetal development. Terbutaline administered on postnatal days PN2-5 elicited neurochemical changes indicative of neuronal injury and reactive gliosis: immediate increases in glial fibrillary acidic protein and subsequent induction of the 68 kDa neurofilament protein. Quantitative morphological evaluations carried out on PN30 indicated structural abnormalities in the cerebellum, hippocampus, and somatosensory cortex. In the cerebellum, PN2-5 terbutaline treatment reduced the number of Purkinje cells and elicited thinning of the granular and molecular layers. The hippocampal CA3 region also displayed thinning, along with marked gliosis, effects that were restricted to females. In the somatosensory cortex, terbutaline evoked a reduction in the proportion of pyramidal cells and an increase in smaller, nonpyramidal cells; again, females were affected more than males. Although abnormalities were obtained with later terbutaline treatment (PN11-14), in general the effects were smaller than those seen with PN2-5 exposure. Our results indicate that terbutaline is a neurotoxicant that elicits biochemical alterations and structural damage in the immature brain during a critical period. These effects point to a causal relationship between fetal terbutaline exposure and the higher incidence of cognitive and neuropsychiatric disorders reported for the offspring of women receiving terbutaline therapy for preterm labor. Support: USPHS HD09713, ES07031, USEPA STAR Fellowship.

1335

ELEVATED EXPRESSION OF GLIAL FIBRILLARY ACIDIC PROTEIN IN THE CEREBELLUM OF THE OFFSPRING AT LATE PUBERTY FOLLOWING MATERNAL EXPOSURE TO NICOTINE DURING GESTATION.

W. A. Khan, A. Abdel-Rahman, A. M. Dechkovskaia, J. M. Sutton, X. Guan and M. B. Abou-Donia. Pharmacology and Cancer Biology, Duke University Medical Center, Durham, NC.

In the present study, histopathological and cholinergic changes were evaluated in the offspring following maternal exposure to nicotine and chlorpyrifos, alone and in combination. Female Sprague-Dawley rats (300-350 gm) with known pregnancy date were treated daily with nicotine (1mg/kg, s.c.) or chlorpyrifos (0.1 mg/kg, dermal) or a combination of nicotine and chlorpyrifos from gestational days (GD) 4-20. Control animals were treated with saline and ethanol. On PND 60, the offspring were evaluated for cholinergic changes and pathological effects. Plasma butyrylcholinesterase (BChE) activity from the female offspring from chlorpyrifos treated mothers showed a significant increase (~183% of control). Male offspring from mothers treated with either chlorpyrifos or nicotine alone showed a significant increase in the AChE activity in the brainstem while female offspring from mothers treated with either nicotine or a combination of nicotine and chlorpyrifos showed a significant increase (~134 and 126 % of control, respectively) in acetylcholinesterase (AChE) activity in the brainstem. No significant changes were observed in the ligand binding densities for a4b2 and a7 nicotinic acetylcholine receptors in the cortex. Histopathological evaluation using cresyl violet staining showed a significant decrease in surviving Purkinje neurons in the cerebellum of the offspring from nicotine treated mothers. An increase in glial fibrillary acidic protein (GFAP) immunostaining was observed in the cerebellum of the offspring from the mothers treated with nicotine. These data suggest that maternal exposure to nicotine causes differential regulation of brainstem AChE activity, a decrease in the surviving neurons and an increased expression of GFAP in cerebellum of the offspring on PND 60. These changes may have long-term adverse health effects later in life. Supported by the USEPA (EPA grant # R829399-01-0).

1336

MATERNAL EXPOSURE TO NICOTINE VIA INFUSION DURING GESTATION PRODUCES NEUROBEHAVIORAL DEFICITS AND ELEVATED EXPRESSION OF GLIAL FIBRILLARY ACIDIC PROTEIN IN THE CEREBELLUM IN THE OFFSPRING AT PUBERTY.

M. B. Abou-Donia, A. Abdel-Rahman, A. M. Dechkovskaia, J. M. Sutton and W. A. Khan. Pharmacology and Cancer Biology, Duke University Medical Center, Durham, NC.

Developmental exposure to nicotine due to maternal smoking during pregnancy causes neurological deficits in the offspring. The present studies were carried out in the offspring following maternal exposure to nicotine via osmotic pump. Female Sprague-Dawley rats (300-350 gm) with known pregnancy date were treated daily with nicotine (3.3mg/kg, in normal saline *via* s.c. implantation of the pump) from gestational days (GD) 4-20. Control animals were treated with saline *via* s.c. implantation of the pump. On postnatal day (PND) 30 and 60, the offspring were evaluated for changes in the ligand binding for various types of nicotinic acetylcholine receptors, oxidative stress load and pathological effects. On PND 60, the neurobehavioral evaluations for sensorimotor functions, beam-walk score, beam walk time, incline plane and grip time response were carried out. Beam-walk time and forepaw grip time showed significant impairments in both male and female offspring. Ligand binding densities for [3H]epibetadine, [3H]cytisine and [3H]abungarotoxin did not show any significant changes in the cortex at PND 30 and 60. A significant decrease in the levels of reduced glutathione (GSH) was observed in the female offspring on PND 30 and 60. Histopathological evaluation using cresyl violet staining showed a significant decrease in surviving Purkinje neurons in the cerebellum, and an increase in glial fibrillary acidic protein (GFAP) immunostaining at PND 30 in both male and female offspring. These data suggest that maternal exposure to nicotine produces significant neurobehavioral deficits, a decrease in the surviving neurons and an increased expression of GFAP in cerebellum of the offspring on PND 30. These changes may have long-term adverse health effects later in life. Supported by a grant from the External Research Program of Philip Morris Inc.,

#### 1337 GENE EXPRESSION CHANGES ASSOCIATED WITH A DEVELOPMENTAL PESTICIDE EXPOSURE MODEL OF PARKINSON'S DISEASE

M. Thiruchelvam<sup>1</sup>, A. I. Brooks<sup>2</sup>, E. K. Richfield<sup>1</sup> and D. A. Cory-Slechta<sup>1</sup>.

<sup>1</sup>Environmental and Community Medicine, University of Medicine and Dentistry of New Jersey, Piscataway, NJ and <sup>2</sup>Environmental Medicine, University of Rochester,

It still remains to be determined whether developmental insults or cumulative insults across life could underlie the etiology of Parkinson's disease (PD). We have shown that developmental exposure to paraquat (PQ) and maneb (MB) produce permanent and progressive changes in the nigrostriatal dopaminergic (DA) system, with enhanced vulnerability to subsequent adult pesticide re-exposure. Mice were treated daily with saline, 0.3 mg/kg PQ, 1 mg/kg MB or PQ MB from postnatal (PN) days 5-19. A subset were re-challenged as adults (PN AD) with saline, 10 mg/kg PQ, 30 mg/kg MB, or PQ MB and another group treated only as adults (AD). PN AD treatment produced greater neurotoxicity than either PN or AD only regardless of endpoint. Relative to globally normalized signal values, significant changes in expression of >2000 genes were found in striatum of PN and PN AD groups, and >300 in the AD group; 73 genes changed in common across the 3 groups, 1589 in the PN and PN AD groups, and 28 in the AD and PN AD groups. Functional clustering of the outcomes indicated significant changes in dopaminergic (D2, D3 and D4), GABAergic (GABA A and B), and glutamatergic (NMDA, AMPA and kainite) receptor function and expression of glutathione metabolism-related molecules. A significant dose relationship was obtained, with the greatest changes observed with the PN AD treatment paradigm. Similar changes were observed when functional clustering of genes related to ubiquitin and protein degradation as well as apoptotic cell death were analyzed. These findings demonstrate that developmental pesticide exposure can produce permanent and progressive nigrostriatal DA lesions and enhance adult vulnerability, consistent with a developmental etiology for the PD phenotype. Changes in profiles of gene expression can be used to elucidate the mechanism of action of these compounds but possibly also biomarkers associated with the PD phenotype.

#### 1338 ONTOGENY OF PROTEINS FOR USE AS BIOMARKERS OF DEVELOPMENTAL NEUROTOXICITY.

B. L. Robinette and W. R. Mundy. Neurotoxicology Division, NHEERL, ORD, USEPA, Research Triangle Park, NC.

The developing nervous system can be uniquely susceptible to adverse effects following exposure to environmental chemicals, and several advisory panels (e.g. ILSI, NRC, NAS) have highlighted the need for rapid and sensitive developmental neurotoxicity testing methods. Measurement of changes in biochemical markers that are linked to the cellular processes underlying nervous system development is one approach to developing such methods. The current research examined the ontogeny of proteins in the CNS that are associated with neuronal differentiation and growth. Frontal cortex and hippocampal tissue were obtained from male Long Evans rats on postnatal days 1, 7, 14, 21, 28, and 83-125 (adults) and the expression of structural and signaling proteins was determined by SDS-PAGE and western blotting optimized with respect to antibody dilution and protein load to obtain semi-quantitative results. The expression of GAP-43 and tau, proteins associated with axonal and dendritic elongation, was high during the early postnatal period and decreased by one half in adulthood. In contrast, expression of the synaptic proteins synapsin and synuclein increased 15-fold from very low levels on postnatal day 1 to maximal levels at adulthood. SMAD, CREB, ERK, and CaMKII are all signaling proteins that are part of pathways activated during neuronal growth and synaptic plasticity. Expression of all four proteins increased during development (SMAD 2-fold; CREB 10-fold; ERK 3-fold, CaMKII 100-fold). However, the levels of the phosphorylated (active) form of these proteins were highest during the early postnatal period then decreased during adulthood. The unique ontogeny of these proteins suggests that they can be used to monitor several aspects of nervous system development. Further research will determine whether changes in the ontogenic profile of these proteins can be used to detect developmental neurotoxicity produced by environmental chemicals. (This is an abstract of a proposed presentation and does not necessarily reflect EPA policy).

### 1339

NEUROPATHOLOGICAL EXAMINATION OF FETAL. RAT BRAIN EXPOSED TO THE GENOTOXIC COMPOUND, 5-BROMO-2-DEOXYURIDINE (BRDU).

T. Ogawa<sup>1</sup>, K. Muneoka<sup>2</sup>, M. Kuwagata<sup>1</sup> and S. Shioda<sup>1</sup>. <sup>1</sup>Anatomy, Showa University School of Medicine, Tokyo, Japan and <sup>2</sup>Hatano Research Institute, FDSC, Kanagawa, Japan.

Prenatal exposure to chemicals such as alcohol, nicotine and PCBs is well known to induce developmental abnormalities in the central nervous system (CNS) of children. In the developmental neurotoxicity, the majority of studies focus on the postnatal subjects rather than the fetus. Even in the study of endocrine disrupters, and area of current scientific interest, there has been little focus on the assessment of alteration in the fetal brain shortly after experimental in utero toxicant exposure. Among the reasons for this are 1) the difficulty in obtaining histological preparations of satisfactory quality and level of section, 2) the absence of clear endpoints for use in histological evaluation of such material. Despite such difficulties, the evaluation of the fetal brain is an important step in assessing toxic alterations of neurodevelopment. In this study, we show a method of preparing rat fetal brain, using gelatin-embedding, complete vibratome serial sectioning and Nissl or hematoxylin staining. We also demonstrate its suitability for immunohistochemistry using the neuronal marker, MAP2. It has been reported that prenatal treatment with a genotoxic compound, BrdU (50 mg/kg, i.p., gestation days 9-15) induces hyperactivity, impaired learning and memory, and impaired male reproductive behavior in rat offspring. In this study, we examined the fetal rat brain shortly after BrdU exposure (gestation day 16). BrdU induced TUNEL-positive cell death in the neuroepithelial layer and the intermediate zone of the cortex, striatum and hippocampus. Fuzziness or destruction of the cortical plate was also detected. Although almost all offspring born after prenatal exposure to BrdU showed behavioral abnormalities, our pathological studies demonstrated variation in the degree of cell death among the fetuses, even in the same litter. Therefore, even very mild induction of cell death may contribute to the behavioral abnormalities.

#### 1340

EPA SCREEN FOR DEVELOPMENTAL NEUROTOXICITY: RESULTS WITH SIX ORGANOPHOSPHORUS (OP) INSECTICIDES.

L. P. Sheets. Toxicology, Bayer CropScience, Stilwell, KS.

Developmental neurotoxicity (DNT) studies (OPPTS 870.6300) were conducted with methamidophos, azinphos-methyl, disulfoton, trichlorfon, coumaphos and fenamiphos in response to a data call-in notice issued by the USEPA. Each OP was administered via the diet at three dietary levels, plus control, to mated female Wistar rats (20-23/dietary level) from gestation day (GD) 0 (sperm-positive) through postnatal day (PND) 21. The offspring were evaluated for clinical signs, weight gain, sexual maturation, motor activity (figure-8 maze), auditory startle habituation, associative learning and memory (M-maze and passive avoidance), neuropathology and brain measurements. Whole-brain, erythrocyte and plasma cholinesterase (ChE) activities were measured in the dams on LD 21 and in the pups on PND 4 and PND 21. Overt maternal toxicity at the high dose in some studies (e.g., decreased body weight, clinical signs) was associated with pronounced toxicity in the pups, including mortality, a marked decrease in weight gain and decreased motor activity during exposure, a reduced startle response on PND 22 and some delays in vaginal patency and/or preputial separation, while minimal effects were seen in pups at doses that caused more modest maternal toxicity. Pup exposure during lactation was shown by inhibition of ChE activity. The only effect that persisted to term on PND 70-75 was reduced body weight at high doses. Measures of cognition and habituation (motor activity and auditory startle) were not affected and neuropathology was not evident with any OP at any dose. The lowest NOEL in each study was ChE inhibition in the dam, which is consistent with the results from the two-generation reproduction studies. These results support the continued use of ChE inhibition as a conservative measure to protect for adverse effects in the adult and young.

AUDITORY STARTLE REFLEX HABITUATION IN DEVELOPMENTAL NEUROTOXICITY TESTING: A CROSS-LABORATORY COMPARISON OF CONTROL

W. Sette<sup>2</sup>, K. Crofton<sup>3</sup>, S. Makris<sup>1</sup>, J. Doherty<sup>1</sup> and K. Raffaele<sup>1</sup>. <sup>1</sup>OPP, USEPA, Washington, DC, <sup>2</sup>OSA, USEPA, Washington, DC and <sup>3</sup>NHEERL, ORD, USEPA, Research Triangle Park, NC.

The USEPA Developmental Neurotoxicity (DNT) Study Test Guideline (OPPTS 870.6300) calls for a battery of functional and neuropathological assessments in offspring during and following maternal exposure. Auditory startle reflex habituation is assessed around the time of weaning and around 60 days of age. The Guideline specifies only that mean response amplitude be measured using 5 blocks of 10 trials per session on each day of testing; the type of device, stimulus intensity, or inter-stimulus interval are not specified. To compare types of devices, testing conditions, age, and laboratory, we evaluated startle reflex data generated in control animals from 26 studies in terms of: 1) variability of mean amplitudes across ages, both within a laboratory and across laboratories; and 2) startle amplitude habituation across ages, within a laboratory and across laboratories. Data from 12 laboratories (1-4 studies/laboratory) were evaluated. Many laboratories submitted reports with incomplete procedural information (e.g., no description of device type). There was large variability in auditory startle habituation data for some studies; in almost all laboratories, variability was greater in adults than in weanlings. Startle amplitude varied among laboratories and with postnatal age. Within laboratories, some demonstrated stable startle amplitude at a given age across studies, while others had variable control data between studies. Degree of habituation also varied across laboratories, with some laboratories finding little habituation in weanlings, while other laboratories demonstrated similar habituation for adults and weanlings. More complete reporting of procedural information would allow for improved understanding of the sources of variability in auditory startle habituation data. Review of control data by testing laboratories as additional studies are generated would also aid in understanding and reducing data variability. This abstract does not reflect official policy of the USEPA.

#### 1342

LEARNING AND MEMORY TESTS IN
DEVELOPMENTAL NEUROTOXICITY TESTING: A
CROSS-LABORATORY COMPARISON OF CONTROL
DATA

K. Raffaele<sup>1</sup>, M. Gilbert<sup>2</sup>, K. Crofton<sup>2</sup>, S. Makris<sup>1</sup> and W. Sette<sup>3</sup>. <sup>1</sup>OPP, USEPA, Washington, DC, <sup>2</sup>NHEERL, ORD, USEPA, Research Triangle Park, NC and <sup>3</sup>OSA, USEPA, Washington, DC.

The USEPA Developmental Neurotoxicity (DNT) Study Test Guideline (OPPTS 870.6300) calls for functional tests to assess the impact of chemicals on cognitive function in offspring following maternal exposure. A test of associative learning and memory is to be conducted around the time of weaning and around 60 days of age, and flexibility is allowed in the choice of test. The present study was undertaken to: 1) survey the types of learning and memory tests typically used by companies submitting DNT data to EPA, 2) evaluate the consistency of protocols for such tests across laboratories, 3) identify the variables routinely reported for any given test protocol, and 4) estimate the variability in control values on a number of test endpoints. Datasets from 15 laboratories were examined, comprising learning and memory tests for 35 test substances and 7 positive control treatments. The survey revealed a total of 8 learning and memory tests were employed. The two most common tests in both age groups were position discrimination in a 3 compartment water maze and passive avoidance conditioning. Preliminary findings reveal a range in the stimulus parameters and protocols for any given test. Similarly the dependent measures recorded and the format of the data report varied broadly, complicating efforts to evaluate control variability and limiting direct comparisons of proficiency among laboratories. A number of cases utilized the same animals for young and adult testing. Data presentation and statistical evaluation were often inadequate; incomplete reporting of individual animal and trial data limited our ability to re-analyze submitted data. More complete reporting of procedural information and inclusion of complete individual animal and trial data may help identify sources of variability and facilitate cross-laboratory comparisons. This abstract does not reflect official policy of the USEPA.

### 1343 DEVELOPMENTAL NEUROTOXICITY OF PYRETHROID INSECTICIDES: CRITICAL REVIEW.

T. J. Shafer<sup>1</sup>, D. A. Meyer<sup>2</sup> and K. M. Crofton<sup>1</sup>. <sup>1</sup>Neurotoxicology Division, NHEERL, ORD, USEPA, Research Triangle Park, NC and <sup>2</sup>Curriculum in Toxicology, University of N. Carolina, Chapel Hill, NC.

Pyrethroids are widely utilized insecticides whose primary action is the disruption of voltage-sensitive sodium channels (VSSC). Although these compounds have been in use for over 30 years and their acute neurotoxicity has been well characterized, there is considerably less information available regarding the potential developmental neurotoxicity of this class of compounds. The current effort reviewed results of 22 studies on the developmental neurotoxicity of pyrethroids. Nineteen of the studies were from peer-reviewed journals. These studies included developmental neurotoxicity studies of 7 different type I and II pyrethroid compounds, with deltamethrin and allethrin being the most studied compounds. Although numerous endpoints were examined, changes in motor activity as well as muscarinic acetylcholine receptor levels were among the most common endpoints examined and were reported to be altered by developmental exposure to pyrethroids in several studies. Review of all of these studies indicate that many of the developmental neurotoxicity studies contained inadequacies in study design and/or statistical analysis. In addition, several studies utilized formulated products and inadequate controls,

which limited interpretation of results from these studies. In conclusion, no definitive statements regarding the potential developmental neurotoxicity of pyrethroid insecticides can be made on the basis of currently available scientific data. (This is an abstract of a proposed presentation and does not reflect EPA policy)

### 1344

NEUROPATHOLOGICAL STUDY OF LONG-TERM CONCURRENT EXPOSURE TO TWO ORGANOPHOSPHATES (OPS) IN RATS.

B. S. Jortner, S. Hancock, J. Hinckley, L. Tobias, L. Flory and M. Ehrich. Laboratory for Neurotoxicity Studies, Virginia Tech, Blacksburg, VA.

Exposure to multiple chemicals is a likely event in industrial societies, yet few related neuropathological studies exist. We report results of a 90 day study which sequentially evaluated such effects in rats administered two neurotoxic OPs. Adult male Long-Evans rats were exposed to a 60 mg/kg sc dosage of chlorpyrifos on days 7 and 42. In addition, seven 75, 150, or 300 mg/kg gavage dosages of tri-orthotolyl phosphate (TOTP) were given during both the day 14-28 and 49-63 intervals. Appropriate controls were used. Rats were sacrificed on days 28, 63 and 90 days, for determination of neurotoxic esterase (NTE) levels, or perfusion-fixed for neuropathological study. Activity of NTE was diminished in a dose-related fashion by TOTP on days 28 and 63. At the latter interval, the 300 mg/kg group had regional brain activity below 50% of controls, with recovery seen at day 90. In rats administered this dose of TOTP, the distal (medullary) gracile fasciculus had occasional swollen myelinated axons on day 28. By day 63 in rats given the 300 mg/kg dose, this had evolved into prominent Wallerian-like myelinated fiber degeneration, and some lesions were also noted in more proximal levels of this tract, and in peripheral nerves. Lesser involvement was seen at the 150 mg/kg dose. On day 90, after a 4week period without additional OP exposure, the fiber degeneration was enhanced in rats given the 300 mg/kg dose (the lower two TOTP doses were not examined at this interval). One reflection of this was the greater extent of the lesions in more proximal levels of the gracile fasciculus and peripheral nerve. These changes are related to TOTP dose. Chlorpyrifos did not elicit this lesion, nor significantly modify the TOTP effect. The nature and location of the fiber degeneration, and its association with brain NTE inhibition indicates this is OP ester-induced delayed neuropathy. This study demonstrates the post-dosing progression of this neuropathic state after cessation of multiple toxicant administration in rats. Supported by US-AMRMC, DAMD 17-99-1-9489.

#### 1345

THE EFFECT OF REPEATED ORAL INGESTION OF CHLORPYRIFOS ON CHOLINESTERASE AND CARBOXYLESTERASE ACTIVITY IN ADULT RATS.

A. M. Betancourt and R. Carr. Mississippi State University, MS State, MS.

The organophosphurus (OP) insecticide chlorpyrifos (CPS) is used worldwide in agricultural and commercial settings for insect control. In many developmental studies, appropriate maternal weight gain is used as a marker for no negative effects during OP exposure to pregnant dams. This project was designed to investigate the effects of CPS exposure on cholinesterase (ChE) and carboxylesterase (CbxE) activity in non-preganant female rats to determine the extent to which female rats will be affected by repeated exposure during the gestational and the lactational periods. Every day for 36 days, adult female rats were fed vanilla wafers onto which 5 mg/kg chlorpyrifos, dissolved in safflower oil, had been applied. Treatment had no effect on body weight. Rats were sacrified on days 6, 12, 18, 24, and 36. ChE activity in the cerebral cortex (CC), corpus striatum (CS), cerebellum (CE), hippocampus (HC), and medulla oblongata (MO) and CbxE in the liver and serum were determined. By 6 days of treatment, ChE in the brain regions was inhibited greater than 45% in all regions except the CS which was 26%. As treatment progressed, the amount of inhibition gradually increased to maximum on day 24 with little change through day 36. Inhibition did not exceed 80%. Inhibition of liver CbxE was 79% by day 24 with a slight decrease through day 36. The data agree with previous studies demonstrating brain area specific inhibition of ChE. These data suggest that substantial enzyme inhibition can occur in the absence of negative effects on weight gain. (Supported by NIH 1 P20 RR17661-01).

#### 1346

EFFECTS OF REPEATED EARLY POSTNATAL EXPOSURE TO EITHER CHLORPYRIFOS OR METHYL PARATHION ON SPATIAL LEARNING AND MEMORY AND MOTOR ACTIVITY.

R. L. Carr, A. M. Betancourt, J. E. Chambers, F. O. Johnson and J. A. Kamykowski. Center for Environmental Health Sciences, College of Veterinary Medicine, Mississippi State University, Mississippi State, MS.

There is currently significant concern about the exposure of children to the organophosphorus insecticides (OP). Since the brain is not fully developed during early childhood, introduction of known neurotoxic agents could disrupt this developed.

opment leading to long-term alterations in function and behavior. This project investigated the effects of early postnatal exposure to two agricultural OP insecticides, chlorpyrifos (CPS) and methyl parathion (MPS), on spatial learning and memory in a Morris water maze and on motor activity and habituation using the figure 8 maze. Using an incremental dosing regimen, postnatal rats were gavaged daily with either corn oil or CPS at a low dose of 1 mg/kg from postnatal day 1 (PND1) to 21; a medium dose of 1mg/kg from PND1-5, 2mg/kg from PND6-13, and 4mg/kg from PND14-21; a high dose of 1.5mg/kg from PND1-5, 3mg/kg from PND6-13, and 6mg/kg from PND14-21, or MPS at a low dose of 0.2mg/kg from PND1-21; a medium dose of 0.2mg/kg from PND1-5, 0.4mg/kg from PND6-13, and 0.6 mg/kg from PND14-21; a high dose of 0.3mg/kg from PND1-5, 0.6mg/kg from PND6-13, and 0.9mg/kg from PND14-21. Rats were tested in a figure 8 maze on PND35, in the Morris water maze on PND36-39 followed by a probe trial on PND42, and then retested in a similar manner on PND70, PND71-74, and PND77, respectively. Neither insecticide appears to have an effect on spatial learning or memory. Neither insecticide had effects on overall activity or habituation in males. In females, the low dosage of CPS caused an increase in activity and decreased habituation on PND35 while on PND70, the medium and high dosages of CPS caused a significant increase in activity and decreased habituation. MPS had no effects. These data suggest that developmental exposure to CPS but not MPS can exert gender-related effects on activity and habituation which vary with exposure level and time. (Supported by NIH R01 ES 10386).

## DNA MICROARRAY ANALYSIS OF RAT BRAIN TO ASSESS CHANGES IN GENE EXPRESSION AND NEUROTOXICITY OF FOUR CONAZOLES.

L. D. White<sup>1</sup>, D. B. Tully<sup>2</sup>, W. Bao<sup>2</sup>, J. E. Schmid<sup>2</sup>, H. Ren<sup>2</sup>, A. K. Goetz<sup>4</sup>, G. Sun<sup>3</sup>, S. Nesnow<sup>3</sup>, D. J. Dix<sup>2</sup> and S. Barone<sup>1</sup>. Neurotoxicology, USEPA, Research Triangle Park, NC, <sup>2</sup>Reproductive Toxicology, USEPA, Research Triangle Park, NC, <sup>3</sup>Environmental Carcinogenesis, USEPA, Research Triangle Park, NC and <sup>4</sup>Department Envir. & Molecular Toxicology, NCSU, Raleigh, NC.

Conazoles are azole fungicides widely used both pharmaceutically and agriculturally. This study focused on four conazoles that exhibit a range of cancer and noncancer effects, to ascertain if any neurotoxic effects are present and to identify possible modes of action. Conazoles target cytochrome P450s (CYPs), and the inhibition and induction of various CYP activities may be part of the toxic modes of action in brain. We used gene expression profiling to characterize a broader range of conazole effects and to identify potential modes of action. Adult male Sprague-Dawley rats were dosed by gavage for 14 days with fluconazole, propiconazole, myclobutanil or triadimefon (three doses per chemical). All four conazoles induced cytochrome 2B and/or 3A CYPs in liver microsomes and caused increases in liver weights relative to body weights. Spotted oligonucleotide microarrays utilizing cy3/cy5 labeling interrogated the expression of over 4000 genes in hippocampus from control and treated rats. Log-transformed data were normalized using an intensity dependent local (Lowess) regression model. Genes expressed consistently in at least one treatment group were analyzed individually using a one-way anova. The analysis was repeated with various modifications to the data or analysis: with and without local background subtraction, with and without a range normalization, and with and without a random predictor for date of array experiment added to the anova. Gene expressions consistently different for at least one treatment versus control were selected for further analysis. Comparison of hippocampal expression profiles between control and fluconazole-, myclobutanil-, propiconazole-, and triadimefon-treatment identified 107, 71, 138, and 130 differentially expressed genes, respectively, including genes involved in programmed cell death and neurotrophic factor production. This abstract does not necessarily reflect EPA policy.

## 1348 BEHAVIORAL AND NEUROCHEMICAL ALTERATIONS ASSOCIATED WITH ACUTE AND CHRONIC ATRAZINE EXPOSURE.

V. M. Rodriguez, M. Thiruchelvam and D. A. Cory-Slechta. Environmental and Community Medicine, EOHSI, University of Medicine and Dentistry of New Jersey and Rutgers State University, Piscataway, NJ.

Atrazine (ATR) is a broad-spectrum herbicide commonly used to control weeds and grass in a wide variety of crops. Given its abundant use, ATR has been found as a contaminant in ground and surface water resulting in human exposure. Aside from its effects on the hormonal systems, it may also impact the nervous system. Behavioral and neurochemical alterations associated with chronic ATR exposure were examined in Long Evans rats exposed to 5 or 10 mg/kg ATR daily for 3 or 6 months via food. The 6 months exposure to 5 mg/kg ATR increased cortical dopamine (DA) levels but did not alter locomotor activity. Exposure to 10 mg/kg ATR increased locomotor activity, which was more pronounced when challenged with 1 mg/kg amphetamine. This exposure paradigm also decreased both striatal

DA and hypothalamic serotonin (5-HT) levels when measured 2 weeks post-termination of exposure. A 3 months exposure to 10 mg/kg ATR also increased locomotor activity level. ATR exposure blunted the increases in locomotor activity produced by MPTP exposure. Acute exposure to either 100 or 200 mg/kg ATR i.p. decreased basal as well as high potassium-evoked striatal DA release measured using microdialysis. Collectively, these studies indicate that ATR can adversely affect monoaminergic systems of the brain, systems important in mediating movement as well as cognition and executive function. Thus, ATR may be an environmental risk factor for disorders related to these systems, underscoring the need for further investigation of its mechanism of action. Supported by ES01247 & ES10791.

## 1349 INFLUENCE OF 14-DAY EXPOSURE TO ATRAZINE ON STRIATAL NEUROCHEMISTRY IN JUVENILE MALE C57BL/6 MICE.

A. Coban, A. B. Norwood, S. C. Sistrunk and N. M. Filipov. CEHS, Basic Sciences, Mississippi State University, Mississippi State, MS.

Previous in vitro studies have suggested, and we recently demonstrated ex vivo, that the herbicide atrazine (ATR), decreased striatal dopamine (DA) levels. The present study had the objective of assessing the ability of ATR to modulate DA în vivo. Juvenile animals appear to be more sensitive to certain neurotoxicants (i.e., lead). Thus, in this study, 1-month-old male C57BL/6 mice were exposed to ATR by daily gavage for 14 d at doses of 5, 25, 125, 250 mg/kg x BW<sup>-1</sup>. Groups of mice were sacrificed and brains collected at 1, 7 and 49 d post termination of ATR exposure. Sub-groups of mice were administered MPTP (4 X 10 mg/kg, 2 h apart, *i.p.*). DA and its metabolites, 3, 4-dihydroxyphenylacetic acid (DOPAC) and homovanilic acid (HVA), were analyzed in the striatum by HPLC. Expression of several key proteins involved in DA homeostasis (i.e., tyrosine hydroxylase [TH], dopamine transporter, and vesicular monoamine transporter-2), as well as striatal TH immunoreactivity (IR) and the number of TH-positive neurons in the substantia nigra were analyzed by immunoblots and immunocytochemistry/unbiased stereology, respectively. ATR, at doses of 125 and 250 mg/kg, decreased striatal DA, DOPAC and HVA levels at 1, but not at 7 d, after the last ATR dose and this decrease was accompanied by a moderately-decreased TH-IR in the striatum. As expected, MPTP decreased striatal levels of DA and its metabolites. The degree of DOPAC and HVA decrease, but not of DA, was potentiated in animals that were exposed to ATR (125 and 250 mg/kg) prior to the MPTP challenge. Thus, it appears that (i) ATR is capable of decreasing striatal DA levels in juvenile mice, (ii) this effect is apparently short-lived, and (iii) previous ATR exposure enhances the dopaminergic toxicity of MPTP mainly by augmenting its effects on the DA metabolites DOPAC and HVA. Supported by: P20 RR017661 (NIH).

## 1350 SPECIES, STRAIN, AND SEX INFLUENCE ON THE DOPAMINERGIC TOXICITY OF THE HERBICIDE ATRAZINE *EX VIVO*.

J. A. Whitehead, S. C. Sistrunk and N. M. Filipov. CEHS, Basic Sciences, Mississippi State University, Mississippi State, MS.

In light of the suggested link between Parkinson's Disease (PD) and pesticide exposure, using striatal slices derived from male Sprague-Dawley (SD) rats, we demonstrated that exposure to the herbicide atrazine (ATR) selectively decreases tissue levels of the neurotransmitter dopamine (DA) in the absence of general cytotoxicity. However, when it comes to other indexes of toxicity, it appears that there are strains of rats that are more sensitive to ATR than others. For example, in some reproductive toxicity studies, the SD strain was affected by ATR the most. Therefore, an argument could be made that in our previous studies we have used as a source of tissue a strain of rats that is uniquely sensitive to ATR, and thus, not representative for a generalized effect of ATR. To address these issue, series of experiments were performed in which striata derived from male and female SD and Fisher 344 rats, as well as from C57BL/6 and BALB/c mice, were exposed ex vivo to ATR at concentrations of up to 500 µM for 4 h and levels of DA and its metabolites 3, 4-dihydroxyphenylacetic acid (DOPAC) and homovanilic acid (HVA) in tissue and media were determined. At the highest dose, ATR exposure decreased tissue DA and increased media DA concentrations regardless of sex, strain or species. At lower doses of ATR, there were important sex- and strain-dependent differences in that BALB/c mice and female SD rat striata were the most and least sensitive to ATR, respectively. Taken together, results from this study suggest that ATR, at higher concentrations, acts as a dopaminergic toxicant regardless of sex, strain, and species. At lower ATR concentrations, the source of striatal tissue does matter. However, striata from male SD rats are not the most sensitive to ATR in this experimental paradigm and this fact, when it comes to basal ganglia toxicity, argues against a unique sensitivity of SD rats to ATR. Supported in part by: P20 RR017661 (NIH).

PARAOXONASE ABUNDANCE AND Q192R GENOTYPE ARE IMPORTANT DETERMINANTS OF ORGANOPHOSPHATE TOXICITY DURING DEVELOPMENT.

T. B. Cole<sup>1, 2</sup>, C. Pettan-Brewer<sup>2</sup>, R. Richter<sup>2</sup>, D. M. Shih<sup>3</sup>, A. Tward<sup>3</sup>, A. J. Lusis<sup>3</sup>, <u>L. G. Costa<sup>2</sup></u> and C. E. Furlong<sup>1</sup>. <sup>1</sup> Genome Sciences and Medicine, Division of Medical Genetics, University of Washington, Seattle, WA, <sup>2</sup> Environmental Health, University of Washington, Seattle, WA and <sup>3</sup> Microbiology and Molecular Genetics, UCLA, Los Angeles, CA.

Paraoxonase (PON1) is an HDL-associated enzyme that metabolizes organophosphorous (OP) compounds, drugs, and oxidized lipids. PON1 activity is determined in part by a coding region polymorphism (Q192R) that affects its catalytic efficiency and in part by differences in PON1 levels, which vary widely (>13-fold). Infants are particularly susceptible to OP toxicity due to low abundance of PON1 and variable onset of expression. To assess the importance of PON1 for protecting against the developmental toxicity of chlorpyrifos oxon (CPO), PON1 knockout (PON1-/-) and wild-type (WT) mice were exposed chronically (PN4 to PN21) to low levels of CPO. Endpoints included cholinesterase activity, histopathology, gene expression, and behavior. Even at PN4, when PON1 levels were low in WT mice, PON1-/- mice were more sensitive to inhibition of brain cholinesterase by CPO. At PN22, and persisting as long as 4 months, chronic developmental exposure to 0.18 mg/kg/d or 0.25 mg/kg/d CPO resulted in perinuclear vacuolization of cells in a discrete area of the neocortex and irregular distribution of neurons in the cortical plate, with an increase in the number of affected cells at 0.25 mg/kg/d. To assess the importance of the Q192R polymorphism for OP detoxication, transgenic mice were used that expressed human transgenes encoding hPON1Q192 or hPON1R192 at equal levels in place of mouse PON1. Mice expressing hPON1R192 were significantly more resistant than hPON1Q192 mice to CPO toxicity. The developmental onset of expression was similar for the hPON1Q192 and hPON1R192 transgenes, allowing these mice to be used to assess the importance of the Q192R polymorphism during development. Our studies indicate that children less than 2 yr old, especially those homozygous for PON1Q192, are particularly susceptible to OP toxicity. Supported by T32 AG00057, ES09601/EPA-R826886, ES09883, ES04696, ES07033.

## 1352 EVALUATION OF EPIDEMIOLOGICAL AND ANIMAL DATA ASSOCIATING PESTICIDES WITH PARKINSON'S DISEASE

A. A. Li<sup>1</sup>, P. Mink<sup>2</sup>, L. McIntosh<sup>1</sup>, J. Teta<sup>2</sup> and B. Finley<sup>1</sup>. <sup>1</sup>Toxicology/Human Health Risk Assessment, Exponent, San Francisco, CA and <sup>2</sup>Health/Epidemiology, Exponent, Washington D.C., DC.

The potential role of pesticide exposure in the development of Parkinson's Disease (PD) has been examined in numerous epidemiologic studies and animal models. Although some epidemiologic studies have reported elevated PD risk among those with rural residences and/or a history of farming occupations, no single class of pesticides or any specific pesticide has been linked consistently with PD. The reason for the lack of consistency across studies is due, in part, to methodological differences such as PD case definition, completeness of case ascertainment, selection of appropriate controls in case-control studies and variable quality and specificity of exposure assessments. In addition, animal data, linking pesticide exposure to neurotoxic effects related to those observed in PD patients, has been reported for specific pesticides and for chemicals similar in structure to some pesticides. We have performed a comprehensive evaluation of the epidemiological and animal data. Epidemiological studies of PD that have included information on pesticide exposure (i.e., either pesticide class, specific pesticide, or dose-response for general category "pesticide") were stratified into three different tiers based on strengths and limitations of study design features including case definition, case and control selection, and exposure assessment. The animal studies were evaluated with respect to specificity of PD-like effects and the exposure levels required to produce the observed effects. This qualitative analysis provides an initial systematic weight-of-evidence approach to evaluating the evidence linking pesticide exposure with Parkinson's disease.

NEUROTOXICOLOGICAL AND STATISTICAL ANALYSES OF A MIXTURE OF FIVE ORGANOPHOSPHORUS PESTICIDES USING A RAY DESIGN.

<u>V. C. Moser</u><sup>1</sup>, A. Hamm<sup>2</sup>, M. Casey<sup>2</sup>, W. H. Carter<sup>2</sup>, <u>J. E. Simmons</u><sup>1</sup> and C. Gennings<sup>2</sup> <sup>1</sup>NHEERL, USEPA, Research Triangle Park, NC and <sup>2</sup>Biostatistics, VCU, Richmond, VA.

Pesticide application patterns generally result in exposure to mixtures instead of single chemicals. Of particular importance in the estimation of pesticide mixture risks is the detection and characterization of their interactions. This research tested for interaction(s) in a mixture of five organophosphorus (OP) pesticides (chlorpyrifos, diazinon, dimethoate, acephate, and malathion). The ratio of pesticides in the mixture reflected the relative dietary exposure estimates projected by the USEPA Dietary Exposure Evaluation Model (DEEM). The approach first required characterization of dose-response curves for each OP alone to build an additivity model. Neurochemical (blood and brain cholinesterase [ChE] activity) and behavioral (motor activity [MA], gait score, tail-pinch response score) endpoints were assessed in adult male Long-Evans rats following acute oral exposure. The additivity model was used to predict the effects of the pesticide mixture along a ray of increasing total doses (full ray, 10-450 mg/kg), using the same fixed ratio of components. The mixture data were similarly modeled and statistically compared to the additivity model along the ray. To evaluate the influence of malathion, a second pesticide mixture was tested using the same proportions of OPs but without malathion (reduced ray, 2-79 mg/kg). Analysis of the full ray revealed significant synergism for all endpoints except the tail-pinch response, which was additive. For gait score, the reduced ray was additive, indicating that the non-additivity detected before was due to malathion in the mixture. For blood ChE and MA, the curves for the full and reduced rays were different from each other, but for brain ChE they were not. Therefore, there is evidence that malathion interacts with the other OPs, at least in terms of the effects on blood ChE, MA, and gait; however, the deviation from additivity cannot fully be attributed to the malathion in the mixture. This is an abstract of a proposed presentation and does not necessarily reflect EPA policy

#### 1354

CHOLINESTERASE INHIBITION AND HYPOTHERMIA FOLLOWING EXPOSURE TO BINARY MIXTURES OF ANTICHOLINESTERASE AGENTS: LACK OF EVIDENCE FOR CAUSE-AND-EFFECT.

C. J. Gordon<sup>1</sup>, <u>D. Herr</u><sup>1</sup>, C. Gennings<sup>2</sup> and <u>C. M. Mack</u><sup>1</sup>. <sup>1</sup>Neurotoxicology, USEPA, Res. Tri. Park, NC and <sup>2</sup>Virginia Commonwealth University, Richmond, NC

Inhibition of plasma cholinesterase (ChE) activity and hypothermia were used as benchmarks of exposure to anticholinesterase insecticides to test the assumption of additivity of binary mixtures of chlorpyrifos (CHP) and carbaryl (CAR) in the Long-Evans rat. Male rats were dosed orally with mixtures of CHP and CAR in 2:1 and 1:1 ratios while core temperature (Tc) was monitored continuously by radiotelemetry. Plasma ChE activity was measured at 4 hr after dosing in duplicate sets of rats dosed with CHP:CAR mixtures. Doses were selected that coincided with a predicted threshold or maximal decrease in Tc. An additivity model was developed and predicted a threshold total mixture dose for hypothermia of 12 mg/kg for the 2:1 ratio and 14 mg/kg for the 1:1 ratio. The hypothermic response of the 2:1 ratio was antagonistic with significant hypothermia not observed until the dose equaled 35 mg/kg. The hypothermic response of the 1:1 ratio was additive at all doses tested. CHP and CAR reference doses of 30 and 70 mg/kg led to 84 and 37% reductions in plasma ChE activity, respectively. Plasma ChE activity was inhibited by 60 and 50% for total doses of 14 and 35 mg/kg for the 2:1 CHP:CAR ratio; for the 1:1 ratio, ChE was inhibited by 54 and 64% for total doses of 12 and 42 mg/kg. The inhibition in ChE activity was not correlated with the magnitude of the thermoregulatory response. The inhibition in plasma ChE activity was not proportional to mixture dose. Overall, binary mixtures of CHP and CAR were either additive or antagonistic, depending on their ratio in a mixture, in terms of their effects on temperature regulation. These effects on Tc are not reflected in the inhibition in plasma ChE activity. Hence, the physiological response (i.e., decrease in Tc) is not necessarily correlated with the inhibition in plasma ChE activity for binary mixtures of CHP and CAR. This is an abstract of a proposed presentation and does not necessarily reflect EPA policy.

### 1355 ESTERASE PROFILES FOR A DIALKYLPHOSPHATE SERIES: QSAR APPROACH.

G. Makhaeva<sup>1</sup>, V. Malygin<sup>1</sup>, A. Aksinenko<sup>1</sup>, V. Sokolov<sup>1</sup> and <u>R. J. Richardson</u><sup>2</sup>.

<sup>1</sup>Institute of Physiologically Active Compounds, RAS, Chernogolovka, Russian Federation and <sup>2</sup>Toxicology Program, University of Michigan, Ann Arbor, MI.

Esterase profiles were generated for a series of O, O-dialkyl-O-(1-carboethoxy-2, 2, 2-trifluoroethyl) phosphates (CFP, R= Me, Et, Pr, i-Pr, n-Bu, i-Bu, n-Pent) by determining the bimolecular rate constants of inhibition (ki) against acetyl-cholinesterase (AChE), neuropathy target esterase (NTE), butyrylcholinesterase (BChE) and carboxylesterase (CE). Log ki was 1.20 to 4.93 for NTE and 2.62 to 4.32 for AChE. CFP with short R (Me, Et) were more potent inhibitors of AChE than NTE. Anti-NTE activity and NTE selectivity [ki(NTE)/ki(AChE)] increased with rising hydrophobicity. High values for R = Bu (2.19) and Pent (4.07) suggest that these compounds would be neuropathic at sublethal doses. Log ki was 3.55 to 5.37 for BChE and 2.41 to 5.93 for CE. Potency against both esterases increased with rising hydrophobicity. QSAR analysis found a linear dependence of NTE selectivity on R hydrophobicity. To consider the role of nonspecific esterases in CFP

toxicity, relationships between CFP structure and ki(CE)/ki(AChE), ki(BChE)/ki(AChE), ki(CE)/ki(NTE) and ki(BChE)/ki(NTE) were analyzed by polynomial regression. A family of parabolic equations was obtained, which along with the equation for ki(NTE)/ki(AChE), describe the change in esterase profile of CFP with hydrophobicity. The data suggest that interactions with nonspecific esterases would have different potential effects on acute and delayed neurotoxicity. For compounds with short R-groups, binding to CE and BChE could reduce their interaction with NTE. For more hydrophobic compounds, binding to nonspecific esterases has a low effect on NTE inhibition and decreases AChE inhibition. The results agree with data on the low neuropathic potential of OP compounds with short-R (Me, Et) and high neuropathic potential of long-R compounds. Taking the first derivative of the QSAR equations permits determining structures for which binding to BChE and CE is the most effective for toxic effects. (Supported by CRDF projects #RB-2035 and #RB2-2488).

## 1356 CHARACTERIZATION OF LARGEMOUTH BASS ACETYLCHOLINESTERASE AND ITS INHIBITION BY ANTIESTERASE PESTICIDES.

D. S. Barber and T. Knowles. Center for Environmental and Human Toxicology, University of Florida, Gainesville, FL.

The largemouth bass (Micropterus salmoides, LMB) is a ubiquitous freshwater fish that is ecologically and economically important in Florida and much of the United States. Much of its habitat is adjacent to agricultural and residential lands and receives significant inputs organophosphate (OP) and carbamate insecticides through runoff and direct application. It is well documented that OP and carbamate insecticides produce overt toxicity and behavioral impairment in fish by inhibition of acetylcholinesterase (AChE), though susceptibility of fish species to toxicity from these compounds varies widely. These studies demonstrated that LMB brain cholinesterase activity was exclusively AChE, based on lack of inhibition by iso-OMPA. The activity of brain AChE was unchanged between temperatures of 20 and 35°C, but declined by 20% at 15°C. AChE activity was optimal between pH 7.0-7.5 and decreased dramatically below pH 6.0 and above 8.0. Using acetylthiocholine as a susbstrate, brain AChE exhibited Michaelis-Menten behavior with an apparent Km of 250µM and Vmax of 263.4 nmol/min/mg. Plasma cholinesterase activity was 60.5 nmol/min/ml. In contrast with many fish, 65% of this activity was apparently butyrylcholinesterase. Brain AChE was 40-100-fold more sensitive to *in vitro* inhibition by chlorpyrifos-oxon, malaoxon, and carbofuran than diazinon-oxon or propoxur, with IC50s of 11nM, 27nM, and 11nM versus 1.1µM and 1µM, respectively. As in other species, phosphorothioate insecticides were very weak AChE inhibitors compared to their oxygen analogs. While kinetic factors will affect *in vivo* sensitivity, our results suggest that largemouth bass are very susceptible to toxicity from exposure to malathion, chlorpyrifos, and carbofuran.

## 1357 DELTAMETHRIN INCREASES DOPAMINE TRANSPORTER EXPRESSION AND ENHANCES COCAINE-INDUCED LOCOMOTION

T. S. Guillot, J. R. Richardson and G. W. Miller. Center for Neurodegenerative Disease, Rollins School of Public Health, Emory University, Atlanta, GA.

Deltamethrin (DM), a type II pyrethroid insecticide, was introduced in the early 1980s and has become one of the most widely used insecticides in both agricultural and household settings. Recently, pyrethroid exposure has been shown to preferentially affect nigrostriatal dopaminergic neurons. In particular, a functional upregulation of the dopamine transporter (DAT) has been demonstrated in the striatum of C57BL/6 mice exposed to DM. DAT, in addition to its normal role in dopamine clearance, is a target for psychostimulants such as cocaine. In fact, mice in which DAT was genetically overexpressed by 20-30% exhibited increased locomotor activity in response to cocaine challenge. Therefore, we hypothesized that an upregulation of DAT by DM would enhance cocaine induced hyperlocomotion. Male C57BL/6 retired breeder mice were treated with 6 mg/kg DM i.p. on days 1, 8, and 15. On day 16, half of the treated mice were challenged with cocaine (15 mg/kg) and open field activity was then measured. Animals were sacrificed one day later and the striatum was removed for neurochemical determinations. DM increased habituated locomotor activity (LA) by 400% and enhanced cocaine-induced LA by an additional 58%. DAT expression was increased by about 36% in DM treated animals as measured by both western blotting and [3H] WIN 35, 428 binding. Additionally, DM increased tyrosine hydroxylase (TH) by 52%, serine 40 phosphorylated TH by 13% and vesicular monoamine transporter 2 (VMAT2) by 12%, as measured by western blotting. These data suggest that upregulation of DAT by DM enhances the motor excitatory effects of cocaine and may lead to behavioral sensitization. This could have important implications for interactions between the environment and development of drug abuse. (supported by DOD 00267036).

## DIETARY SUGAR-INDUCED MODULATION OF PARATHION TOXICITY IN JUVENILE AND ADULT

J. Liu, S. Karanth and C. Pope. Physiol Sciences, Oklahoma State University, Stillwater, OK.

Sugar feeding (15% glucose in the drinking water) markedly enhanced parathion (PS) toxicity in adult rats, delayed recovery of acetylcholinesterase (AChE) activity, and decreased chow intake. We hypothesized that dietary sugars exacerbate PS toxicity by limiting intake of precursors for AChE synthesis, thereby impairing enzyme and functional recovery. Consumption of high fructose corn syrup (HFCS) has increased dramatically. We evaluated the effects of 15% HFCS in drinking water on PS toxicity in adult and juvenile rats. Rats were given access to feed and either water or 15% HFCS, for 10 days and challenged with PS (6 or 18 mg/kg, sc, in juveniles or adults, respectively) on the 4th day. SLUD signs and involuntary movements, body weight and chow/fluid intake were recorded daily. AChE activity and immunoreactivity (AChE-IR) in frontal cortex and diaphragm were measured at 2, 4 and 7 days after dosing. In another study, adult rats were fed ad lib or pair-fed to evaluate the effects of reduced chow intake alone on PS toxicity. When allowed to choose, there was a marked preference for HFCS over water. HFCS intake was associated with a significant reduction in chow intake in both young (25-35%) and adult (35-40%) rats. Cholinergic toxicity was markedly increased by HFCS in both age groups. HFCS did not, however, affect AChE inhibition in either tissue or either age group. AChE-IR in cortex was generally not affected. Diaphragm AChE-IR was significantly reduced, however, in adults by both PS (14-17%) and HFCS (19-27%), with a greater reduction (32-39%) in sugar-fed/PS-treated rats. In juveniles, diaphragm AChE-IR was reduced only in sugar-fed/PS-treated rats. Food restriction alone had no apparent effect on PS toxicity. The results suggest that consumption of HFCS can markedly increase the acute toxicity of PS in both adult and juvenile rats. Parathion and dietary HFCS reduced AChE-IR in a tissue-dependent manner, possibly by limiting de novo synthesis of new AChE molecules. The interaction between nutrient deficiency and excess sugar intake appears important in the modulation of PS toxicity.

## 1359 EFFECTS OF *IN VIVO* EXPOSURE TO ENDOSULFAN AND PERMETHRIN ON THE STRIATAL DOPAMINERGIC PATHWAYS.

C. Aguilar<sup>1</sup> and <u>H. P. Misra<sup>1, 2</sup>. <sup>1</sup> College of Osteopathic Medicine, Blacksburg, VA and <sup>2</sup> Biomedical Sciences and Pathobiology, Virginia Tech, Blacksburg, VA.</u>

Pesticides have been suggested to play an important role in the development of many neurodegerative diseases. Several studies indicate that exposure to certain pesticides may cause degeneration of the nigrostriatal pathway leading to the development of Parkinson's disease. We hypothesized that exposure to mixtures of certain pesticides may exaggerate this effect. We studied the effects of permethrin (a pyretroid type I) and Endosulfan (an organochlorine) on the levels of dopamine and its metabolites in the brain of mice. These pesticides have different structures but both are known to modify the kinetics of voltage-sensitive ion channels and calcium ion flux/homeostasis that could affect the release of several neurotransmitters. C57Bl/6 mice of 7-9 months old were injected, i.p., with each of the pesticides and their mixture every-other day during a two week period. Mice were sacrificed 24 hrs after the last injection. The corpora striatum was extracted and analyzed by HPLC for dopamine and its metabolites. All the treatment groups exhibited lower dopamine levels and higher DOPAC and HVA as compared to controls (corn oil). Because reactive oxygen species have been implicated in the development of Parkinson's disease, and are known to cause degradation of certain neurotransmitters, we monitored the levels of lipid peroxides in brain cortex as an indicator of free radical tissue damage. The peroxide levels were measured by thiobarbituric acid reactive products. Increased levels of lipid peroxides were observed in brain tissues of animals exposed to these pesticides. These results indicate animal exposure to endosulfan and permethrin causes decreased levels of dopamine and increased levels of its metabolites, DOPAC and HVA, in the corpora striatum. Furthermore, a free radical mechanism involving lipid peroxidation may also be involved in pesticideinduced pathogenesis of Parkinson's disease.

## THE EFFECTS OF ZINEB AND ENDOSULFAN ON MPTP-INDUCED STRIATUM DOPAMINE DEPLETION IN MICE.

Z. Jia¹ and <u>H. P. Misra</u>². ¹Virginia-Maryland Regional College of Veterinary Medicine, Virginia Tech, Blacksburg, VA and ²Edward Via Virginia College of Osteopathic Medicine, Blacksburg, VA.

The thiocarbamate fungicides are ubiquitous environmental contaminants. These pesticides are known to enhance the depletion of striatal dopamine levels and are implicated behind the pathogenesis of Parkinsons Disease. Zineb (zinc-ethylenebis-dithiocarbamate) is used extensively to control unwanted plants. The organochlorine insecticide, endosulfan is a potent inhibitor of acetylcholinesterase (ACHE)

and is known to adversely affect neurotransmitters. Both are used as pesticides on a variety of crops worldwide and pose potential health risks to humans and animals. We hypothesized that these two pesticides either individually or in combination would increase MPTP (1-methyl-4-phenyl-1, 2, 3, 6-tetrahydropyridine)-induced neurotoxicity. Male C57Bl/6 mice (six weeks old) were exposed to zineb (50 and 100 mg/kg), endosulfan (1.55 and 3.1 mg/kg) and their mixtures every other day over a 2-weeks period. The levels of dopamine and its metabolites in striatum and the activity of ÂCHE in cerebral cortex were monitored by high-performance liquid chromatography (HPLC) and spectrophotometric analysis, respectively. Results of these studies showed that zineb alone, but not endosulfan, could significantly (P<0.05) enhance MPTP-induced striatal dopamine depletion. Preliminary data also showed that mixtures of pesticides produced more exacerbation of MPTP-induced striatal dopamine depletion than when exposed to individual pesticides. However, the activity of ACHE was not significantly affected by these treatments. These data suggest that mixtures of these pesticides enhance the depletion of the nigrostriatal dopamine system.

### 1361 PREGNANCY ALTERS THE MECHANISM OF ALCOHOL-INDUCED BONE LOSS.

M. J. Ronis<sup>1, 5</sup>, M. Hidestrand<sup>1</sup>, K. Shankar<sup>1</sup>, C. K. Lumpkin<sup>2</sup>, T. M. Badger<sup>3, 5</sup>, J. Aronson<sup>4</sup>, R. Skinner<sup>4</sup>, W. Hogue<sup>4</sup>, C. Jo<sup>2</sup>, P. Simpson<sup>2</sup>, M. Zipperman<sup>3</sup>, R. Haley<sup>5</sup> and L. Humphrey<sup>5</sup>. <sup>1</sup>Pharmacology and Toxicology, University of Arkansas for Medical Sciences, Little Rock, AR, <sup>2</sup>Pediatrics, University of Arkansas for Medical Sciences, Little Rock, AR, <sup>3</sup>Physiology, University of Arkansas for Medical Sciences, Little Rock, AR, <sup>4</sup>Orthopedics, University of Arkansas for Medical Sciences, Little Rock, AR and <sup>5</sup>Arkansas Children's Nutrition Center, Arkansas Children's Hospital, Little Rock, AR.

We examined skeletal toxicity of ethanol in cycling and pregnant female rats. Rats were infused liquid diets i.g. beginning at gestational d. 6 for 14 d. Diets containing ethanol, 10~g/kg/d or 13~g/kg/d were infused overnight from 1800~till~0800~h. All diets were made isocaloric by substituting ethanol for carbohydrate. Urine ethanol concentrations averaged  $93 \pm 2$  mg/dl and  $197 \pm 10$  mg/dl in the pregnant groups and  $137 \pm 13$  and  $271 \pm 17$  mg/dl in the non-pregnant groups (p  $\leq 0.05$ ). Pregnancy increased tibial trabecular bone mineral density (BMD) in control rats as determined by pQCT scan (p  $\leq$  0.05) accompanied by an increase in the plasma concentrations of the bone formation marker osteocalcin and of 1, 25 (OH)2 vitamin D3 (p ≤ 0.05). Ethanol produced a dose-dependent loss in tibial trabecular and sub-cortical BMD (p  $\leq$  0.05) in both pregnant and non-pregnant rats accompanied by reduced serum osteocalcin and 1, 25 (OH)2 vitamin D3 (p < 0.05). However, loss of BMD was greater in the non-pregnant females (p  $\leq$  0.05). Static histomorphometric analysis of tibial bone in ethanol-treated pregnant rats demonstrated decreases in osteoblast surface (ObS/BS) and osteoid surface (OS/BS) (p ≤ 0.05). In contrast, ObS/BS was unaffected in the non-pregnant rats and at the high ethanol dose these animals had lower bone volume, decreased trabecular number and increased trabecular separation (p  $\leq$  0.05) accompanied by increased mean osteoclast surface (Oc.S/BS) and eroded surface (ES/BS). These data suggest that ethanol inhibits bone formation in pregnant rats while in non-pregnant rats the data are consistent with ethanol-induced bone resorption. Supported in part by AA12928 (M.R.).

#### 1362 DIRECT BONE FORMATION IN NUDE (NU/NU) MICE.

L. Liu<sup>3</sup>, J. Aronson<sup>1, 2, 3</sup>, E. C. Wahl<sup>3</sup>, R. A. Skinner<sup>2</sup>, B. G. Fowlkes<sup>3</sup>, <u>T. M. Badger</u><sup>1</sup> and C. K. Lumpkin<sup>1, 3</sup>. <sup>1</sup>Department of Pediatrics, University of Arkansas for Medical Sciences, Little Rock, AR, <sup>2</sup>Department of Orthopaedics, University of Arkansas for Medical Sciences, Little Rock, AR and <sup>3</sup>Laboratory for Limb Regeneration Research, Arkansas Children's Hospital Research Institute, Little Rock, AR.

The combination of a novel limb lengthening protocol (distraction osteogenesis, DO) and T cell deficient (nu/nu) mice has allowed the comparative study of direct bone formation in the absence of functional T cells. To determine how athymic mice deficient in T cells would compare to their euthymic littermate controls in regard to bone formation during DO, twelve male mice (30g) of each genotype (nu/nu; nu/+) underwent placement of an external fixator and osteotomy on the left tibia. Distraction began three days after surgery (3 day latency) at a rate of 0.075 mm twice a day (0.15 mm/day) and continued for 14 days. At sacrifice the left tibias were harvested. Comparison of the distracted tibial radiographs demonstrated excellent regenerate bone formation in both strains (80.4%  $\pm$  7.8 nu/nu vs  $87.2\% \pm 4.0 \text{ nu/+}$ ). In addition, comparison of the distracted tibial histology demonstrated robust endosteal new bone formation in both groups (67.4%  $\pm$  5.6 nu/nu,  $71.2\% \pm 6.7$  nu/+). This suggests that T cell activity is either not necessary for bone formation during DO in adult animals, or that other factors/cells are compensating for the loss. This model should allow for study of the role of T cells in skeletal pathologies impacting direct bone formation. Supported in part by NIH grant AÂ12223.

## ADMINISTRATION OF RMTNF- $\alpha$ INHIBITS ENDOSTEAL BONE FORMATION IN A MOUSE DISTRACTION OSTEOGENESIS MODEL.

J. Aronson<sup>1, 2</sup>, L. Liu<sup>2</sup>, E. C. Wahl<sup>2</sup>, P. S. Daniel<sup>2, 1</sup>, R. A. Skinner<sup>1</sup>, <u>T. M. Badger</u><sup>1, 2</sup> and C. K. Lumpkin<sup>1, 2</sup>. <sup>1</sup>University of Arkansas for Medical Sciences, Little Rock, AR and <sup>2</sup>Arkansas Children's Hospital Research Institute, Little Rock, AR.

Tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) is a pro-inflammatory cytokine that modulates osteoblastogenesis. TNF-α has been shown to inhibit osteoblast differentiation and to induce osteoblast apoptosis. In addition, the demonstrated inhibitory effects of chronic ethanol exposure on direct bone formation may be mediated by TNF-α signaling. We hypothesized that administration of recombinant mouse TNF-α (rmTNF-α) would inhibit direct bone formation in a mouse model of limb lengthening (distraction osteogenesis, DO). Nineteen CB57BL/6 12-week-old male mice (average weight 25.5g) were divided into two groups: vehicle group and rmTNF treated group. Following acclimation and under nembutal anesthesia, each mouse underwent placement of an external fixator and osteotomy to the left tibia. Fourteen day, 100 µl Alzet pumps (Model 1002) were placed subcutaneously on the back for systemic delivery of rmTNF-α (10 µg/kg/day) or vehicle. Distraction began three days after surgery (3 day latency) at a rate of 0.075 mm twice a day (0.15 mm/day) and continued for 14 days. All mice were sacrificed on postoperative day 17. The distracted and contralateral tibiae and trunk blood were harvested. The blood was assayed for serum TNF-α measurement by bead array. Systemic rmTNF- $\alpha$  administration increased circulating levels of serum TNF- $\alpha$  over controls (13.05±5.99 pg/ml vs undetected in controls, p<0.01). Weight changes were equivalent in both groups. Radiographically, the percent of mineralized new bone per gap was 59.5% in the vehicle group vs 38.8% in the rmTNF-α group, p<0.001. Histologically, the percent of endosteal (intercortical/marrow) bone formation per gap was 69.6% in the vehicle group vs 29.3% in the rmTNF- $\alpha$  group, p<0.001. Systemic delivery of rmTNF-α leads to prolonged, elevated circulating levels of serum TNF-α and is associated with inhibition of direct endosteal bone formation during DO. Supported by NIH grant AA12223.

### 1364

EFFECT OF OVARIECTOMY ALONE AND IN COMBINATION WITH CALCIUM/VITAMIN D-DEFICIENT DIET ON THE BONE MINERAL DENSITY IN CYNOMOLGUS MONKEYS.

M. Niehoff¹, S. Mohr² and G. Weinbauer¹. ¹ Covance Laboratories GmbH, Muenster, Germany and ² F. Hoffmann-La Roche Ltd., Basel, Switzerland. Sponsor:  $\underline{P}$ . Thomas.

Numerous studies have shown that estradiol, vitamin D and calcium play an important role in bone metabolism in primates. We used peripheral quantitative computed tomography (pQCT) yielding true volumetric density (mg/cm3) and separation of trabecular and cortical bone to investigate the effect of ovariectomy and/or calcium/vitamin D-deficiency in 22 female monkeys (>8 years of age). Assignments were: Group 1: control (standard diet); Group 2: ovariectomy and calcium/vitamin D-deficient diet; Group 3: ovariectomy and standard diet; Group 4: calcium/vitamin D-deficient diet. Bone mineral density (BMD) was measured in distal radius, proximal tibia and femur, lumbar vertebra and femoral neck before and 13, 26, 39, 52, 66 and 79 weeks after treatments. Overall, a decrease of BMD occurred in Groups 2 and 3, being more pronounced in Group 2. Total BMD decrease occurred in Week 13 in tibia, femur and lumbar vertebra in Groups 2 and 3 (approx. 5%) and in femoral neck of Group 2 (approx. 5%). Total BMD of the radius decreased in Week 26 by approx. 5% in Group 2 and by 5-10% in Group 3 whereas trabecular BMD decreased from Week 39 onwards for both groups by approx. 10%. The trabecular BMD decreased in the tibia by Week 13 and in the femur by Week 26 (approx. 6%). Cortical BMD of Groups 2 and 3 decreased in tibia and femur by approx. 3% in Week 52 and in lumbar vertebra by approx. 3% in Week 79 but BMD of radius and femoral neck remained unaltered. BMD in Groups 1 and 4 was unaltered. Unexpectedly, BMD in Group 4 increased slightly. These data indicate that a calcium/vitamin D-deficient diet may not accelerate ovariectomy-induced BMD loss but aggravates BMD loss in the long term. For the purpose of a primate osteoporosis study, a special diet does not provide an experimental advantage over ovariectomy alone.

#### 1365

INHIBITION OF DIRECT BONE FORMATION
ASSOCIATED WITH CHRONIC ETHANOL EXPOSURE
IN A MOUSE MODEL OF DISTRACTION
OSTEOGENESIS.

E. C. Wahl<sup>2</sup>, L. Liu<sup>2</sup>, D. S. Perrien<sup>2, 1</sup>, J. Aronson<sup>1, 2</sup>, W. R. Hogue<sup>1</sup>, R. A. Skinner<sup>1</sup>, M. Hidestrand<sup>2</sup>, M. J. Ronis<sup>1, 2</sup>, T. M. Badger<sup>1, 2</sup> and C. K. Lumpkin<sup>1, 2</sup>. <sup>1</sup>University of Arkansas for Medical Sciences, Little Rock, AR and <sup>2</sup>Arkansas Children's Hospital Research Institute, Little Rock, AR.

Excessive alcohol consumption has been reported to interfere with human bone homeostasis and repair in multiple ways. Previous studies have demonstrated that chronic ethanol (EtOH) exposure in the rat inhibits direct bone formation during

distraction osteogenesis (DO, limb lengthening). The opportunity to extend the rat EtOH studies into mice is now possible due to the development of mouse models of DO. Recent studies support the lack of confounding nutritional effects in the liquid EtOH diet mouse model. This study employed the liquid EtOH diet combined with the murine DO model to test the hypothesis that chronic EtOH exposure would result in deficits in direct bone formation during DO in contrast to the pair-fed controls. Twenty-eight C57BL/6 male 12-month-old mice were acclimated to the Lieber-DeCarli liquid control diet #710027 (Dyets Inc.) over a week's period. The mice were separated into two diet groups (n=14): control and EtOH (diet #710260). The control mice were pair-fed to the EtOH mice. The EtOH group started on 1% EtOH and were slowly increased to 6.45% EtOH over a period of 16 days. After being on diet for 82 days, all mice underwent placement of an external fixator and osteotomy on the left tibia. Following a six-day latency, distraction began at a rate of 0.075mm b.i.d. for 14 days. At sacrifice the left tibiae and contralaterals were harvested. The weight changes were equivalent for both groups. The hypothesis of ethanol toxicity (p= EtOH < control) was supported by radiographic (p=.011) and histologic (p=.002) analyses of the % new bone formation in the DO gaps, by pQCT analysis of the total vBMD of the contralateral proximal tibiae (p<.001) and femoral necks (p=.012), by 3 point bending on the contralateral tibiae (p<.001 energy to break), by pin site bone formation measures (p<.001), and by EtOH associated increased marrow fat percentages (p<.002). Supported by NIH grant AA12223.

1366

EFFECT OF PERCHLORATE ON DISPLACEMENT OF THYROXINE FROM SERUM BINDING PROTEINS AND BINDING OF PERCHLORATE TO SERUM PROTEINS.

J. L. Campbell<sup>1</sup>, L. Narayanan<sup>3</sup>, D. C. Ferguson<sup>2</sup>, M. Mumtaz<sup>4</sup>, H. El-Masri<sup>4</sup> and J. Fisher<sup>1</sup>. <sup>1</sup>Interdisciplinary Toxicology Program, University of Georgia, Athens, GA, <sup>2</sup>Physiology and Pharmacology, University of Georgia, Athens, GA, <sup>3</sup>Geocenters, Inc., Wright-Patterson AFB, Dayton, OH and <sup>3</sup>Division of Toxicology, ATSDR, Atlanta, GA.

Perchlorate, a highly water soluble and widely dispersed water contaminant, exerts its primary mode of action by inhibiting the active uptake of iodide into the thyroid gland. In animals perchlorate has been shown to cause thyroid cancer, hypothyroidism, and possible neurodevelopmental defects. We examined another feasible mode of action for perchlorate based on reports that perchlorate could displace thyroid hormones from proteins. Under normal conditions most of the circulating thyroid hormones are protein bound in serum, thus conserving the thyroid hormones for use by the body. Serum binding of perchlorate was determined by dialyzing perchlorate, dissolved in physiological saline at concentrations of 0, 10, 50, 100, 200, 300, 400, 500, 1, 000 µg/l, against undiluted rat serum until the system was at equilibrium. Both the dialysate and deproteinated serum were analyzed for perchlorate by HPLC. Displacement of thyroxine from serum proteins was investigated by spiking rat or human serum with <sup>125</sup>I-thyroxine followed by perchlorate at concentrations of 0, 1, 10, 50, 100, 200, 300 mg/l and then determining the amount of free thyroxine by dialyzing the serum against phosphate buffer and then determining the amount of <sup>125</sup>I-thyroxine in the dialysate and serum with a gamma counter. In the rat, approximately 100% of the mass of perchlorate added was bound to serum constituents for concentrations up to  $100\,\mu\text{g}/l$ , followed by a rapid decline in the bound fraction from  $100\,\mu\text{g}/l$  to  $500\,\mu\text{g}/l$  where only 0.355% was bound. Over the range of concentrations tested, perchlorate did not significantly alter the percent of thyroxine bound to serum proteins for either rat (p=0.1302) or human (p=0.9610). Displacement of thyroxine from serum proteins is not an imporatant mechanism of action for perchlorate induced thyroid disturbances. Funded by ATSDR (Grant No: U61/ATU472105-01).

1367

ENHANCED RAT HERSHBERGER ASSAY APPEARS RELIABLE FOR DETECTION OF NOT ONLY (ANTI-) ANDROGENIC CHEMICALS BUT ALSO THYROID HORMONE MODULATORS.

T. Yamada, T. Kunimatsu, K. Miyata, S. Yabushita, T. Sukata, S. Kawamura, T. Seki, Y. Okuno and N. Mikami. *Environmental Health Science Laboratory, Sumitomo Chemical Company, Ltd.*,, Osaka, Osaka, Japan.

Development of an internationally recognized standard for the Hershberger assay as a screening tool to detect potential (anti-)androgenic chemicals is in progress. In the present preliminary study, we evaluated the reliability and specificity of the enhanced Hershberger assay to detect thyroid hormone modulating activity, while concentrating attention on possible confounding influence on evaluation of (anti-)androgenic activity. Castrated or testosterone propionate (TP, 0.2 or 0.25 mg/kg/day)-injected castrated male Crj:CD(SD)IGS rats (7 weeks old) were dosed for 10 days by oral gavage with vehicle (corn oil) or the following chemicals (mg/kg/day): propylthiouracil (PTU, 2.5), a potent inhibitor of thyroid hormone synthesis, phenobarbital and 2, 2-bis(4-chlorophenyl)-1, 1-dichloroethylene (PB,

125; and p, p'DDE, 100), two hepatic enzyme inducers that enhance the clearance of thyroid hormones. PTU markedly increased thyroid weights, and decreased serum T3 and T4, and increased serum TSH, also causing marked microscopic alteration of the thyroid gland. PB and p, p'DDE treatment was also associated with similar findings but less pronounced. The alterations appeared to be equally induced irrespective of the presence/absence of TP. Furthermore, data for p, p'DDE demonstrated anti-androgenic effects as documented in our earlier publication, whereas PTU and PB had no effects on the weights of androgen-related accessory glands/tissues (the ventral prostate, dorso-lateral prostate, seminal vesicles with coagulating glands, glans penis, Cowper's glands, and levator ani plus bulbocavernosus muscles). Although further investigations, including dose-response studies, should be performed, the present study provides evidence that the enhanced Hershberger assay, with evaluation of thyroid histopathology and weights, and hormone levels, is reliable for screening for not only (anti-)androgenic chemicals but also thyroid hormone modulators.

1368

HIGH-THROUGHPUT REPORTER GENE TRANSCRIPTION ASSAY FOR THE DETERMINATION OF THYROID HORMONE DISRUPTING EFFECTS OF FOOD ADDITIVES OR CONTAMINANTS.

J. Cho, S. Jeong and J. Park. Toxicology Division, National Vet. Res. Quarant. Service, Anyang City, South Korea.

Thyroid hormonal system is very important for the regulation of metabolism, growth and reproductive organs development. Thyroid hormones (T3 and T4) bind to thyroid receptor or retinoic acid receptor (RXR) and then the complexes are located to thyroid hormone responsive elements (TREs) that induce thyroid hormonal activity. In this study, recombinant human uterus carcinoma cells (HELA) express TREs and luciferase reporter genes were used to determination of thyroid hormone disrupting effects of chemicals. The limit of response of this recombinant cell to T3 and T4 were 6.5 fg and 8.9 fg, respectively. 14 compounds of food additives or contaminants were investigated on the thyroid hormone disrupting effects using the recombinant HELA cells. Ethoxyquin, sorbic acid, genisteine and tetrabromodiphenyl ether (TBDE) induced transcription activity with dose-responsive pattern. În addition, butylated hydroxytoluene (BHT), butylated hydroxylanisole (BHA), ethoxyquin, zearalane, genisteine, and TBDE showed agonistic reaction with T3 while cadmium showed antagonistic reaction in the study of agonistic and antagonistic transcription assay. These results demonstrate that reporter gene transcription assay using recombinant HELA cells can be recognized as high-throughput bioassay system for the detection of thyroid hormone disruptors.

1369

CHANGES IN SERUM TSH LEVEL AND T4/T3 RATIO IN DEVELOPMENTAL TOXICITY STUDIES OF PERCHLORATE IN RATS FED HIGH-IODINE DIETS REFLECT ADAPTIVE INCREASES IN IODIDE UPTAKE NOT RELEVANT TO HUMANS.

G. Goodman. Intertox, Inc., Seattle, WA.

The T4/T3 ratio is the most stable measure of thyroid hormones (TH) in the fetal and postnatal rat; T4 and T3 are changing rapidly but their ratio is highly regulated. A research study in pregnant rats fed an iodine-restricted diet with perchlorate added at > 3.6 mg/kg-day found a lower T4/T3 ratio and an order-of-magnitude higher TSH level in both maternal and fetal serum compared to controls (Schroeder-van der Elst et al., Endocrinology 142: 3736-3741, 2001). These results conform to the pattern observed in both rats and humans when iodide uptake is completely blocked or dietary iodine is severely deficient. A quite different pattern emerged in rats fed a high-iodine diet (ordinary lab chow) in subchronic and developmental toxicity studies of perchlorate performed for regulatory purposes (USEPA 2002): an *unchanged or higher* T4/T3 ratio (calculated in the present analysis) and an *unchanged or only slightly higher* TSH. The effects were extremely inconsistent between studies and across groups, suggesting an external variable such as iodine. Importantly, the effects were found at doses for which (in other studies in rats given a high-iodine diet) upregulation of the sodium-iodide symporter leads rapidly to full compensation for inhibition of thyroidal iodide uptake (Yu et al. 2000). Nevertheless, the observed changes in hormone levels were interpreted by USEPA as evidence of an adverse effect at the lowest dose tested (0.01 mg/kg-day). To the contrary, the changes were similar in pattern and magnitude to those found in iodine-sufficient rats and humans given supplemental dietary iodine in excess; they are best explained as being secondary to the compensatory increase in thyroidal iodide uptake in rats that occurs when the uptake is pharmacologically inhibited. Humans exposed to perchlorate at doses as high as 0.5 mg/kg-day do not upregulate iodide uptake. The adaptive hormone changes observed at lower doses in the regulatory studies in rats are irrelevant to humans and should not be interpreted as adverse for risk assessment purposes.

P. C. Das<sup>1</sup>, J. M. Hedge<sup>2</sup>, <u>D. C. Wolf<sup>2</sup></u> and <u>K. M. Crofton<sup>2</sup></u>. <sup>1</sup>Curriculum In Toxicology, UNC, Chapel Hill, NC and <sup>2</sup>NHEERL, ORD, USEPA, Research Triangle Park, NC.

The environmental contaminant perchlorate disrupts thyroid homeostasis *via* inhibition of iodine uptake into the thyroid. This work tested whether iodine deficiency exacerbates the effects of perchlorate. Female 27 day-old LE rats were fed a custom iodine deficient diet with 0, 50, or 75% iodine deficiency for 28 days. After 14 days on the diet 0, 31, or 250 mg/L perchlorate were provided in drinking water for 14 days. Serum total T4, T3, and TSH were assayed by RIA, and standard histopathology was performed on thyroid. Neither the 50% deficient diet nor 31 mg/L perchlorate produced effects when given alone, but together reduced T4 -35%, and elevated TSH -5- fold. A 75% deficient diet plus 250 mg/L perchlorate also caused additive effects on T4 and T3. TSH was induced -14-fold. Follicular cell hypertrophy was present in all treated rats, but was more severe with both treatments than either alone. Colloid depletion was present only after perchlorate treatment but not iodine deficiency. The marginal iodine deficient rat could represent a model for a sensitive sub-population for studying disruptions in thyroid homeostasis. *This is an abstract of a proposed presentation and does not necessarily reflect University.S.EPA policy.*

AN ADDITIVE EFFECT OF A MIXTURE OF AMMONIUM PERCHLORATE AND SODIUM CHLORATE ON THE PITUTARY-THYROID AXIS IN MALE F344 RATS.

M. A. Khan<sup>1, 2</sup>, S. E. Fenton<sup>3</sup>, A. E. Swank<sup>1</sup>, G. W. Knapp<sup>1</sup>, S. D. Hester<sup>1</sup> and D. C. Wolf<sup>1</sup>. <sup>1</sup>Environmental Carcinogenesis Division, USEPA, Research Triangle Park, NC, 2NRC, Research Triangle Park, NC and <sup>3</sup>Reproductive Toxicology Division, USEPA, Research Triangle Park, NC.

Humans are exposed to mixtures of chemicals through drinking water. Ammonium perchlorate (AP) and Sodium chlorate (SC) are present in public drinking water supplies in many parts of the US. AP is used as an oxidizer in solid rocket propellants, munitions, fireworks, and air bag inflators. SC is a drinking water disinfection by-product of chlorine dioxide and is also used as an oxidizing agent in industrial processes. Exposure to either of these chemicals causes perturbations in pituitary-thyroid homeostasis. AP and SC competitively inhibit iodide uptake preventing the synthesis of thyroglobulin, thus reducing circulating T4. Persistent long-term exposure to either of these chemicals can result in persistent stimulation of the pituitary-thyroid axis resulting in thyroid tumor development in rats. The present study was designed to describe the potential of an additive effect in rats following short-term exposure to both chemicals. Adult male F344 rats were exposed to AP (0.1, 1.0, 10 mg/L) or SC (10, 100, 1000 mg/L) or their mixtures through the drinking water for 7 days. Serum and tissues were collected for biochemical, histological, and molecular endpoints. Serum T4 was decreased (p < 0.05) in rats exposed to the mixtures, but not to the individual chemicals. Serum T3 levels were unaffected by each treatment and TSH was only elevated in the high dose chlorate group. Histological examination of the thyroid gland showed, colloid depletion and significant (p < 0.05) hypertrophy of follicular epithelial cells in all the single chemical and mixture treated animals while hyperplasia was observed only in AP 10 + SC 10, AP 0.1 + SC 1000, and AP 10 + SC 1000 mg/L mixture groups. The data suggest that the combined exposure to chlorate and perchlorate results in an additive effect on the rat thyroid. This abstract does not reflect the policies and opinions of the USEPA.

### 1372 CUMULATIVE EFFECTS OF ENDOCRINE DISRUPTERS (EDCS): SYNERGY OR ADDITIVITY.

L. E. Gray<sup>1</sup>, J. Ostby<sup>1</sup>, J. Furr<sup>1</sup>, C. Lambright<sup>1</sup>, A. Hotchkiss<sup>2</sup> and <u>V. S.</u>
<u>Wilson</u><sup>1</sup>. <sup>7</sup>ORD, NHEERL, RTD, EB, USEPA, Research Triangle Park, NC and
<sup>2</sup>Psychology, Ohio State University, Columbus, OH.

Several EDCs have been shown to disrupt sex differentiation by interfering with androgen signaling. Vinclozolin (V) and procymidone (P) are androgen receptor (AR) antagonists while some phthalate esters (PE) inhibit fetal testis hormone production. Linuron (L) and prochloraz act as AR antagonists and by inhibiting steroid hormone production. Of the above EDCs, only PEs reduce insl3 gene expression required for gubernacular development. Although risk assessments are typically conducted on a chemical-by-chemical basis, the 1996 FQPA mandated that the USEPA consider cumulative risk from chemicals that act *via* a common mechanism. Our studies begin to provide a framework for assessing the cumulative effects of "antiandrogenic" EDCs. SD rats were dosed orally on days 14-18 of gestation with EDCs singly or in pairs at dosage levels equivalent to about 50% the ED50 for hypospadias including 1) two AR antagonists (V plus P, each at 50

mg/kg/d), 2) two PEs with a common metabolite (DBP and BBP, each at 500 mg/kg/d), 3) two PEs with different metabolites (DEHP and DBP (500)), 4) a PE plus an AR antagonist (DBP (500) plus P(50)), and 5) L (75 mg/kg/d) plus BBP (500). We expected that V, P, L, DBP, DEHP and BBP individually would not induce hypospadias using this dosing regimen, but mixing any two together would induce hypospadias in about 50% of the males and induce cumulative effects on other androgen-dependent organs. In the current study, all combinations produced cumulative effects on every androgen-dependent tissue. However, only the PE combinations caused agenesis of the insl3-dependent gubernacular ligaments. We found that EDCs that alter differentiation of the same reproductive tissues during sexual differentiation produce cumulative, apparently dose-additive effects when combined. However, the relative potency factors vary from tissue to tissue based upon the mechanism and mode of toxicity of each chemical. This is an abstract of a proposed presentation and does not necessarily reflect EPA policy.

MALFORMATIONS IN GUBERNACULAR LIGAMENT DEVELOPMENT INDUCED BY DEHP, DBP, AND BBP ARE ASSOCIATED WITH DECREASES IN INSL3 GENE EXPRESSION IN THE FETAL RAT TESTIS.

<u>V. S. Wilson</u>, C. Lambright, J. Furr, C. Wood, G. Held and <u>L. E. Gray</u>. *Reproductive Toxicology Division, USEPA, ORD, NHEERL, Research Triangle Park, NC* 

Targeted inactivation of the insulin-like hormone 3 (insl3) gene in male mice results in altered gubernacular development, disrupted testis decent, and cryptorchidism. Cryptorchidism is a fairly common human malformation, being displayed in about 3 males per 100 at birth, but only a small percentage has been linked directly to genetic defects. Recently, concern has arisen over the apparent increase in male reproductive health problems and the potential role of endocrine disrupting chemicals in the etiology of these conditions. The phthalate esters (PE) are high production volume, ubiquitous environmental chemicals, some of which alter sexual differentiation, inducing gubernacular agenesis and other male rat reproductive tract malformations. We hypothesized that phthalate-induced gubernacular lesions likely result from an inhibition of Leydig cell insl3 gene expression. Three phthalates, di-n-ethylhexyl phthalate (DEHP), dibutyl phthalate (DBP) and benzyl butyl phthalate (BBP) were administered orally to the dam (750 mg/kg/day) on gestation day (GD) 14 through 18 and the fetal testes examined on GD18 for effects on steroid hormone production and insl3 gene expression. Compared to chemicals like vinclozolin, linuron, and prochloraz that act as AR antagonists and/or inhibit fetal Leydig cell testosterone production, only the three phthalates significantly reduced both ex vivo testosterone production and insl3 gene expression when quantified by real-time rtPCR. Dose response studies with DEHP (0, 100, 300, 600 or 900 mg/kg/day) also showed a dose dependent decrease in both testicular testosterone production and insl3 message levels in the GD18 rat fetus. These results provide the first demonstration of dose dependent PE-induced alteration of insl3 mRNA in the fetal male rat testis. Disclaimer: Abstract of a proposed presentation and does not necessarily reflect EPA policy.

DI-BUTYL PHTHALATE ACTIVATES THE NUCLEAR RECEPTORS CAR AND PXR AND ENHANCES THE EXPRESSION OF CYP 2B1 AND 3A1 IN MATERNAL AND FETAL LIVER IN THE RAT.

L. You<sup>1</sup>, M. Wyde<sup>1</sup>, S. Kirwan<sup>1</sup>, A. Laughter<sup>1</sup>, E. Bartolucci-Page<sup>1</sup>, <u>K. Gaido<sup>1</sup></u> and <u>B. Yan<sup>2</sup></u>. <sup>1</sup>CIIT Centers for Health Research, Research Triangle Park, NC and <sup>2</sup>Department of Biological Sciences, University of Rhode Island, Kingston, RI.

The plasticizer di-butyl phthalate (DBP) is a reproductive toxicant in rodents at high doses. Exposure to DBP in utero causes alterations in sexual and reproductive development in male rats as a result of inhibition of testicular steroidogenesis during sexual differentiation. DBP is also known to alter expression of hepatic enzymes. This study was to delineate the effects of DBP exposure during gestation on the expression of enzymes in the maternal and fatal liver that are involved in the metabolism of steroid hormones. Pregnant Sprague-Dawley rats were dosed with DBP through gavage in the dose range of 10 to 500 mg/kg/day from gestation day 12 to 19. Maternal and fetal liver samples were collected approximately 2 hrs after the last dosing. Protein and mRNA levels of CYP 2B (testosterone 16β-hydroxylase), CYP 3A (testosterone 6β-hydroxylase), and CYP 4A were increased in both the maternal and fetal liver tissue in the 500 mg dose group, but not in the groups of 50 mg or lower. The high-dose DBP treatment also caused increase in the mRNA of hepatic estrogen sulfotransferase and UDP-glucuronosyltransferase 2B1 in the dams, but not in the fetuses. In vitro transcriptional activation assay showed that DBP, but not its metabolite mono-butyl phthalate, was able to activate the nuclear receptor pregnane X receptor (PXR). DBP by itself did not increase the activity of the constitutive androstane receptor (CAR), but it did activate androstanolrepressed CAR. These data indicate that maternal and fetal liver enzymes are susceptible to DBP induction during pregnancy. Such effects on enzyme expression are likely mediated through DBP interactions with the nuclear receptors that transcriptionally regulate these liver enzymes. While these enzymes are known to participate in controlling steroid bioavailability, the potential role of their altered expression in DBP-caused reproductive toxicity remains to be understood.

EFFECTS OF GESTATIONAL PROCHLORAZ ADMINISTRATION ON MALE REPRODUCTIVE DEVELOPMENT IN RATS. *IN VIVO* ASSESSMENTS OF A FUNGICIDE WITH MULTIPLE *IN VITRO* EFFECTS.

N. Noriega, J. Ostby, <u>C. Lambright</u>, <u>V. S. Wilson</u> and <u>E. Gray</u>. *USEPA*, *Research Triangle Park*, *NC*.

Prochloraz (PZ) is an imidazole fungicide that shows multiple endocrine activities, including androgen receptor (AR) antagonism and inhibition of testosterone and estradiol synthesis via reductions in P450 activity. In the current study, we confirmed in-vitro reports that PZ is an AR antagonist, and described PZ effects on male sex differentiation. PZ concentrations above 1µM caused a dose-dependent inhibition of DHT (0.1nM)-induced AR-mediated activity in cells (MDA-kb2) containing endogenous AR and stably expressing the MMTV-luc reporter. PZ inhibited androgen (1nM R1881) binding to the rat AR (IC<sub>50</sub> approx 60μM). *In vivo*, pregnant Sprague-Dawley rats were gavaged daily from GD 14-18 at PZ doses of 31.25, 62.5, 125 and 250 mg/kg bodyweight/day. Pup delivery was delayed in a dose-dependent manner and resulted in stillbirths at the two highest doses. In male pups, AGD was reduced at birth but was highly correlated with reduced bodyweight. Female-like areolas were observed in PZ-treated 13 day old males at frequencies ranging from 31% in the low-dose group, to 71% at the high dose. Males in the two highest dose groups showed reduced androgen-dependent tissue weights (testis, epididymis, seminal vesicle, ventral prostate and levator ani + bulbocavernosus) and 40% of high-dose males had vaginal pouches. All high-dose males and some in the 125 mg/kg treatment group showed permanent phallus abnormalities including hypospadias. In animals without malformations, PZ did not affect age at preputial separation. PZ appears to affect sexual differentiation via two independent mechanisms; steroidogenesis inhibition (similarly to other antifungal imidazoles) and AR antagonism. This is an abstract of a proposed presentation and does not necessarily reflect EPA policy.

STEROID AND THYROID HORMONAL RECEPTOR GENE TRANSCRIPTION ASSAY AND ONE-GENERATION REPRODUCTION STUDY OF CHLORPYRIPHOS-METHYL.

S. Jeong, B. Kim, S. Kim, J. Cho and J. Park. Toxicology Division, National Vet. Res. Quarant. Service, Anyang City, South Korea.

Chlorphyriphos-methyl (CPM) has been widely used as an organophosphate insecticide especially useful in controlling foliage crop pests and household insects. It is classified as suspected carcinogen and endocrine disrupter. We investigated endocrine disrupting effects of CPM in steroid and thyroid hormone receptor gene transcription assay system and in rat one-generation reproduction study. CPM induced weak transcription activity by binding with estrogen, androgen or progesterone receptor as induction ratio (IR) compared to β-estradiol, testosterone, and progesterone was 1.48% at 10-8 M, 1.50% at 10-8 M and 1.39% at 10-6 M, respectively. While it did not induce any apparent transcription activity or agonistic reaction with T3 in thyroid receptor transcription assay. In one-generation reproduction study, CPM (1, 10, 100 mg/kg BW) induced increase of relative organ weight of liver, kidney, adrenal gland and brain in F0 generation. Also, estradiol and testosterone content in serum of female rats were increased while estradiol in serum of male rats was decreased. Lowering of mating rate, sperm head width and T4 in serum were observed in F0 rats. In F1 rats, increase of organ weights of liver, kidney, spleen, adrenal gland and brain and decrease of that of prostate gland were observed. Sex ratio of male rats was higher but number of implantation, living births, anogenital distances, sperm number and estradio1 and testosterone content in serum were lower than control. Conclusively, CPM is a disruptor of steroid hormonal system in vitro and in vivo study and NOAEL and ADI of CPM according to the results from one-generation reproduction study were estimated as 1 mg/kg B.W. and 0.01 mg/kg B.W./day, respectively.

1377

EFFECTS OF PRENATAL EXPOSURE TO PCB METABOLITES 4-OH-CB 107 AND 4-OH-CB 187 ON ENDOCRNE STATUS AND REPRODUCTIVE CYCLE OF THE FEMALE RAT.

C. Buitenhuis<sup>1</sup>, P. Cenijn<sup>1</sup>, A. Bergman<sup>2</sup>, A. Gutleb<sup>1</sup>, J. Legler<sup>1</sup> and <u>A. Brouwer<sup>1</sup></u>. <sup>1</sup>Institute for Environmental Studies (IVM), Vrije Universiteit, Amsterdam, Netherlands and <sup>2</sup>Department of Environmental Chemistry, Stockholm University, Stockholm, Sweden.

Recently, hydroxylated metabolites of organohalogenated compounds have been identified in human and cord blood. The major aim of this study was to determine the long-term consequences of low-level prenatal exposure to hydroxylated poly-

chlorinated biphenyls (PCBs) on brain development, reproduction and endocrine status of the rat. Pregnant rats were orally dosed with hydroxylated PCBs during gestation day 10-16. The major human plasma PCB metabolites 4-OH-CB 107 (0.1, 0.5 and 5 mg/kg/day) and 4-OH-CB 187 (0.5 and 5 mg/kg/day) were chosen as test compounds. Starting on postnatal day (PND) 1, offspring were scored for developmental landmarks including onset of hair grow, pinna detachment, bilateral eye opening, vaginal opening and preputial separation. Endocrine endpoints were measured, such as thyroid hormone- and estrogen levels. Female rats were monitored daily for estrous cycle length during 3 different periods in the experiment. The first period was directly after vaginal opening (PND 30-68), the second between PND 150-170 and the last between PND 210-230. No effects of the PCB metabolites were observed on developmental landmarks. A marked reduction in plasma total thyroxin was found at PND 4 in male and female offspring following prenatal exposure to 0.5 mg/kg/day of 4-OH-CB 107 and 0.5 mg/kg/day 4-OH-CB 187. Analysis of the estrous cycle showed a prolongation the estrous cycle length in the high dose groups of 4-OH-CB 107 only in the last period of estrous cycle monitoring. This suggests an aging effect of prenatal exposure to hydroxylated PCB metabolites. Coinciding with this increase in estrous cycle length, a 250% increase in plasma estradiol concentrations in the same female rats was found, implying involvement of sex steroid hormones in prolongation of the estrous cycle. This work has been supported by the EU, contract no. QLK4 2000-00261.

THE CHARACTERIZATION AND HORMONAL REGULATION OF KIDNEY ANDROGEN-REGULATED PROTEIN (KAP)-LUCIFERASE TRANSGENIC MICE.

S. Malstrom<sup>1</sup>, A. F. Purchio<sup>2</sup> and D. B. West<sup>1</sup>. <sup>1</sup>LPTA, Xenogen Corporation, Alameda, CA and <sup>2</sup>Xenogen Corporation, Alameda, CA.

Transgenic mice expressing luciferase (luc) under the control of the kidney androgen regulated protein (Kap) promoter were characterized. Kap-luc expression was observed at high levels in kidneys, epididymies, testes and seminal vesicles in male mice; and in kidneys, ovaries and uterus in female mice. Kap-luc expression was modulated by androgen and anti-androgen treatment in male and female mice. Male mice were treated daily with the anti-androgenic compound, cyproterone acetate, flutamide or vehicle for 16 days. Endpoints evaluated included in vivo biophotonic imaging, body weight, organ weights (liver, kidney, testes, epididymies, preputial gland and seminal vesicles) and protein luciferase assays. Biophotonic images were acquired from each animal throughout the experiment using a sensitive imaging system. These imaging results were correlated with traditional endpoints of body and organ weights. Following treatment with anti-androgens, luciferase signal significantly decreased in the intact male mouse in vivo and by measuring luciferase activity in homogenized organ extracts. The decrease in epididymal and seminal vesicle weight confirmed the action of the anti-androgens. In vivo imaging documented significant changes in luciferase expression within the first few days of the experiment, indicative of the anti-androgenic activity of the drugs. Testosterone treatment significantly increased the Kap-luc bioluminescent signal in female mice. Biophotonic imaging may provide a useful approach for tracking noninvasively the effects of endocrine disruptors in specific tissues.

AIRWAY HYPERRESPONSIVENESS AND PULMONARY INFLAMMATION IN PULMONARY HYPERTENSIVE RATS EXPOSED TO CONCENTRATED AMBIENT PARTICLES.

T. Cheng<sup>1</sup>, Y. Lei<sup>1</sup>, M. Chen<sup>1</sup>, C. Chan<sup>1</sup> and P. Wang<sup>2</sup>. <sup>1</sup>Institute of Occupational Medicine and Industrial Hygiene, National Taiwan University College of Public Health, Taipei, Taiwan and <sup>2</sup>Institute of Environmental Engineering, National Central University, Chung Li, Taiwan. Sponsor: T. Ueng.

Epidemiology studies have shown associations between particulate air pollution and exacerbation of respiratory disease, but the exact biological mechanism remains unclear. In this study, we exposed pulmonary hypertensive rats to concentrated ambient particles (CAPs) using particle concentrator to examine airway hyperresponsiveness and inflammation. This study was conducted at an EPA supersite located at a traffic busy urban area nearing Taipei. Exposure group (n=5) was exposed to CAPs for 6 hrs each day for 3 consecutive days (mean mass concentration = 371.7 µg/m3), and control group (n=6) was exposed to HEPA filtered air. Airway responsiveness was measured as enhanced Penh using whole-body barometric plethysmography (BUXCO, NY) before and after PM exposure. We also controlled temperature, humidity and the restrictive stress resulted from nose-only exposure chambers when pulmonary function test was performed. Bronchoalveolar lavage fluid (BALF), lung tissue and peripheral plasma were collected 48hr after the experiment. Our results showed airway responsiveness difference of Penh with methacholine challenge measured before and after experiment were higher for CAPs than that for filtered air group. Additionally, BALF neutrophils and total protein were increased in CAPs group. Elevated plasma 8-OHdG and depletion of total GSH in

the lung tissue were also observed in CAPs group, although it did not reach a statistic significance. Our findings indicate that potential confounders need to be controlled when we use whole-body barometric plethysmography. We conclude that CAPs could induce airway hyperresponsiveness and increase lung inflammation and injury in pulmonary hypertensive rats after exposed to concentrated ambient PM.

RESPONSES TO SUBCHRONIC INHALATION OF DIESEL EXHAUST (DE) AND HARDWOOD SMOKE (HWS) MEASURED IN RAT BRONCHOALVEOLAR LAVAGE FLUID.

<u>I. Seagrave</u><sup>1</sup>, S. K. Seilkop<sup>2</sup> and <u>I. L. Mauderly</u><sup>1</sup>. <sup>1</sup>Lovelace Respiratory Research Institute, Albuquerque, NM and <sup>2</sup>SKS Consulting, Siler City, NC.

Air pollution exposure is associated with adverse health effects, but the components and mechanisms that cause these effects are unclear. As part of a larger program to develop a database to correlate health effects with chemical constituents of various types of air pollution, we exposed male (M) and female (F) F344 rats to DE or HWS. Exposure conditions were 0 (filtered air), 30, 100, 300, or 1000 µg/m<sup>3</sup> of TPM, 6 h/d, 7 d/w. After 6 mo, the rats were killed and lungs were removed. The right lung was lavaged with PBS. Cell-free lavage fluid was assayed for lactate dehydrogenase (LDH), alkaline phosphatase (APase), ßglucuronidase (ßgluc), MIP-2, IL-1 $\beta$ , TNF $\alpha$ , and total glutathione (GSH). Statistical analyses included pair-wise comparisons with control and exposure-related trends. Most effects were mild, but the largest effects often occurred at sub-maximal exposures. LDH increased in HWS-exposed M and DE-exposed M and F. βGluc decreased in HWS-exposed M and F and DE-exposed M. MIP-2 in HWS-exposed M and F and DE-exposed F showed exposure-related decreases. In contrast, APase showed a statistically insignificant increase in DE-exposed F, but decreased in HWS-exposed M and F. TNFα levels decreased in DE-exposed M and F, but HWS-exposed M showed some evidence of an increase. In F, HWS significantly decreased GSH but DE weakly increased it, while in M, DE caused little change, but 100 μg/m<sup>3</sup> HWS increased GSH with a trend to decrease from the peak response at higher doses. These results show that these two combustion emissions may differentially affect various types of responses in the lung, and that effects may be non-monotonic functions of exposure levels. This work is supported by the National Environmental Respiratory Center, which is funded by numerous industry, state, and federal sponsors, including the USEPA, US Department of Energy (Office of Freedom CAR and Vehicle Technologies), and US Department of Transportation. ## TOXICOLOGICAL ASSESSMENT OF DIESEL-WATER EMULSION [PURINOX™ (SUMMER FUEL BLEND)] EXHAUST EMISSIONS.

R. Kraska<sup>1</sup>, E. Barr<sup>2</sup>, I. Daly<sup>3</sup>, R. Gudi<sup>4</sup>, J. D. McDonald<sup>2</sup>, M. Mercieca<sup>5</sup>, <u>D. Naas<sup>8</sup></u>, J. O'Callagan<sup>6</sup>, N. Ronsko<sup>1</sup>, S. Seilkop<sup>7</sup>, V. Wagner<sup>4</sup> and <u>M. D. Reed<sup>2</sup></u>. 

<sup>1</sup>Lubrizol Corporation, Wickliffe, OH, <sup>2</sup>Lovelace Respiratory Research Institute, Albuquerque, NM, <sup>3</sup>Regulatory and Technical Associates, Lebanon, NJ, <sup>4</sup>BioReliance, Rockville, MD, <sup>5</sup>Pathology Associates, Frederick, MD, <sup>6</sup>CDC/ NIOSH, Morgantown, WV, <sup>7</sup>SKS Consulting, Silver City, NC and <sup>8</sup>AccuTox Consulting, Midland, MI.

A type of fuel shown to decrease combustion emissions vs. traditional diesel is the diesel-water emulsion. Utilizing a collaborative approach, a toxicological assessment of the exhaust of PuriNOx<sup>™</sup> fuel emulsion was recently conducted. Whole exhaust from one of two, 2001 model Cummins 5.9L ISB engines was diluted to exposure levels of 100, 200, and 400  $\mu g$  particulate matter (PM)  $/m^3.$  The engines were operated on a repeating EPA heavy-duty certification cycle. F344 rats were housed in Hazleton H2000 exposure chambers and exposed to exhaust 6 h/day, 5 days/wk for the first 11 weeks and 7 days a week thereafter. Exposure days ranged from 58-70 days. Exposure- start was staggered to account for multiple health endpoints. Toxicological assays were conducted during and following exposures and subsequent to a recovery period. General toxicity (body weight, organ weight, clinical pathology, and histopathology), neurotoxicity (glial fibrillary acidic protein assay, GFAP), genotoxicity (Ames, micronucleus, sister chromatid exchange), and reproduction and development were assessed. Effects observed were mild. Exhaust was not associated with neurotoxicity, reproductive/developmental toxicity, or in vivo genotoxicity. Small decreases in serum cholesterol and small increases in platelet values were treatment related. PM accumulation within alveolar macrophages was noted in all exposure groups. Other sporadic statistically significant responses were observed but not clearly treatment related. Exhaust subfractions induced mutagenic responses in S. typh. Based on the cholesterol and platelet results, the 100  $\mu g/m^3$ exposure level was the NOAEL. In general, these observations were consistent with rodent and bacteria exposure to petroleum diesel exhaust.

1382

USING TOXICOLOGY TO PREDICT THE HEALTH EFFECTS OF DIESEL PARTICLE MATTER (DPM) IN THE University.S.

L. C. Green, M. Ames and E. Crouch. Cambridge Environmental, Cambridge, MA

Background and methods: Diesel particle matter (DPM) is a complex, well-studied mixture. We used exposure-response information from rodent bioassays of DPM to estimate the health benefits of a proposal to reduce non-road DPM emissions. In rats, the most sensitive response to chronic DPM exposures is lung inflammation: the log-probit exposure-response has an EC50 of 3.1 mg DPM/m3 "human equivalent concentration" and a standard de viation of a factor of 3.2. We applied this relationship to US populations with extreme occupational or average ambient exposures, and compared our results to the non-toxicologic analysis performed by USEPA. Results: About 8, 000 underground, non-coal miners in the US are exposed to 8-hr DPM levels of up to 2 mg/m3. Applying the inflammation exposureresponse curve to these miners yields an expected occurrence of 13 lung effects. Enforcement of EPA's proposed non-road diesel engine rule would reduce airborne DPM concentrations in mines by some 56% and the expected prevalence of lung effects to 1 in 8, 000. In contrast, ambient, non-occupational concentrations of DPM in the US average < 0.001 mg/m3. Such small ambient exposures yield an estimated 0.0004 (i.e., 0) lung effects in the US population as a whole, so that the non-road diesel rule is expected to have no effect on morbidity or mortality in the general population. Disregarding the toxicology on DPM, USEPA applied "health damage functions" from selected observational epidemiologic studies of total PM2.5 to assess the health benefits of the proposed rule. EPA thus estimated that reducing ambient DPM levels by 0.00046 mg/m3 would avert 9, 600 premature deaths each year in the US, and would substantially reduce morbidity. Conclusions: The toxicology on DPM predicts some morbidity and no mortality due to current DPM exposures to underground miners, and no morbidity or mortality for the general US population. In contrast, extrapolating selected observational epidemiologic data on PM2.5 predicts substantial morbidity and mortality from current ambient DPM exposures. Both approaches cannot be correct.

## 1383 INHALATION OF DIESEL EXHAUST AFFECTS CALCITONIN GENE-RELATED PEPTIDE (CGRP) DENSITY IN F344 RATS.

S. S. Wong<sup>1</sup>, I. M. Keith<sup>2</sup>, N. N. Sun<sup>1</sup>, C. Kweon<sup>3</sup>, <u>I. J. Schauer</u><sup>4</sup>, D. E. Foster<sup>3</sup>, <u>R. Lantz</u><sup>1</sup> and <u>M. L. Witten</u><sup>1</sup>. <sup>1</sup>Center for Toxicology, The University of Arizone, Tucson, AZ, <sup>2</sup>School of Veterinary Medicine, The University of Wisconsin, Nadison, WI, <sup>3</sup>Engine Research Center, The University of Wisconsin, Madison, WI and <sup>4</sup>Wisconsin College of Engineering & State Laboratory of Hygiene, The University of Wisconsin, Madison, WI.

CGRP is a neuropeptide of sensory C-fibers with proposed pro-inflammatory properties. To characterize the mechanism underlying diesel exhaust (DE)-induced neurogenic inflammation, female Fischer 344 rats (~175g, 4-weeks old) were randomly assigned to 6 groups in a 2 X 3 factorial design [Capsaicin vs. non-capsaicin (vehicle) pretreatment to stimulate C-fiber and room air vs. low and high levels of DE]. The rats were then exposed nose-only to DE at 0 (filtered room air), 35.3, and 669.3  $\mu g/m3$  particulates directly from a Cummins N14 research engine run at 75% throttle for 4 hours/day, 5 days/week for 3 weeks. Immunohistochemical data indicated that airway and alveolar parenchyma of rats exposed to the high level of DE appeared to have more CGRP fibers than their controls. More alveolar CGRPcontaining neuroendocrine cells were also observed, which were accompanied by plasma extravasation increase and inflammatory response. Histological evidence showed that activation of mast cells and alveolar macrophages was associated with CGRP. However, capsaicin pretreatment did not significantly attenuate DE-induced changes in the CGRP profile in the lungs. This finding suggests that DE-induced inflammatory responses may be mainly attributed to CGRP-containing neuroendocrine cells. Moreover, the efforts were made to determine the physical aspects and the chemical composition of DE particles that induce the deleterious effects. The results showed that the neurogenic response highlighted above may possibly be related to the particle number, volume, and mass concentration as well as its carbon and sulfate contents, rather than particle sizes or the trace metals (Na, Mg, Ca, Fe, Cr, Mn, and Ph) measured in this study. (Supported by Health Effects Institute).

### 1384 SURFACE AREA AS DETERMINANT OF ULTRAFINE PARTICLE-INDUCED OXIDATIVE STRESS.

Y. Lei and T. Cheng. Institute of Occupational Medicine and Industrial Hygiene, National Taiwan University, Taipei, Taiwan. Sponsor: T. Ueng.

Epidemiological studies have shown that exposure to particulate matters (PM) is associated with increasing cardiopulmonary morbidity and mortality. Recent studies further suggest that ultrafine fraction of PM may play an important role in car-

diopulmonary toxicity. It has been proposed that surface area of ultrafine PM is more closely associated with PM-related toxicity. In this study, we investigated the effect of ultrafine polystyrene particles on inflammation and oxidative stress markers in pulmonary hypertensive rats to determine whether surface area of ultrafine polystyrene particles play an important role in ROS generation in diseased animals. Each exposed group (n=5) were treated with ultrafine polystyrene in the combination of three sizes (64, 202 and 535 nm) and two concentrations (100 and 50  $\mu g/ml)$ using intratracheal instillation. Control group (n=4) received PBS. Bronchoalveolar lavage fluid (BALF), lung tissue and peripheral plasma were collected 24hr after experiment. The results showed that instillation with 100 and 50µg/ml of ultrafine polystyrene particle can induce increased total cells, neutrophil proportion, total protein and LDH compared to fine polystyrene particle at same mass concentration in pulmonary hypertensive rats. We also observed that ultrafine polystyrene induced significant higher proinflammatory cytokine IL-6 and TNF- $\alpha$  as compared to fine particles. Furthermore, the result revealed that the depletion of total GSH in the lung tissue and formation of plasma 8-OHdG were associated with total surface area of particles instilled. In conclusion, we found inert ultrafine polystyrene may cause lung inflammatory effects on pulmonary hypertensive rats, and the formation of ROS was associated with instilled total surface area of ultrafine PM. The exact mechanism warrants further study.

TOXICOLOGICAL ASSESSMENT OF DIESEL-METHANOL-WATER EMULSION [PURINOX™ (ALL WEATHER) GENERATION 2 FUEL] EXHAUST FMISSIONS

M. D. Reed<sup>1</sup>, I. Daly<sup>3</sup>, R. Gudi<sup>4</sup>, J. D. McDonald<sup>1</sup>, M. Mercieca<sup>5</sup>, J. O'Callagan<sup>6</sup>, N. Ronsko<sup>2</sup>, S. Seilkop<sup>7</sup>, V. Wagner<sup>4</sup> and R. Kraska<sup>2</sup>. <sup>1</sup> Toxicology, Lovelace Respiratory Research Institute, Albuquerque, NM, <sup>2</sup>Lubrizol Corporation, Wickliffe, OH, <sup>3</sup>Regulatory and Technical Associates, Allendale, NJ, <sup>4</sup>BioReliance, Rockville, MD, <sup>5</sup>Pathology Associates, Frederick, MD, <sup>6</sup>CDC/NIOSH, Morgantown, WV and <sup>7</sup>SKS Consulting, Silver City, NC.

A type of fuel shown to decrease combustion emissions vs. traditional diesel is the diesel emulsion. Utilizing a colaborative approach, a toxicological assessment of the exhaust of PuriNOx<sup>™</sup> fuel emulsion was recently conducted. Whole exhaust from one of two, 2002 model Cummins 5.9L ISB engines was diluted to exposure levels of 125, 250, and 500 µg particulate matter (PM)/m<sup>3</sup>. The engines were operated on a repeating EPA heavy-duty certification cycle. F344 rats were housed in Hazleton H2000 exposure chambers and exposed to exhaust 6 h/day, 5 days/wk for the first 11 weeks and 7 days a week thereafter. Exposure days ranged from 58-70 days. Exposure- start was staggered to account for multiple health endpoints. Toxicological assays were conducted during and following exposures and subsequent to a recovery period. General toxicity (body weight, organ weight, clinical pathology, and histopathology), neurotoxicity (glial fibrillary acidic protein assay, GFAP), genotoxicity (Ames, micronucleus, sister chromatid exchange), and reproduction and development were assessed. Effects observed were mild. Exhaust was not associated with neurotoxicity, reproductive/developmental toxicity, or in vivo genotoxicity. Small decreases in serum cholesterol were noted in males and females of the high level exposure. PM accumulation within alveolar macrophages was noted in all exposure groups. Other sporadic statistically significant responses were observed but not clearly treatment related. Exhaust subfractions induced mutagenic responses in S. typh. Based on the cholesterol results, it can be concluded that the 250 μg/m<sup>3</sup> exposure level was the NOAEL. In general, these observations were consistent with rodent and bacteria exposure to petroleum diesel exhaust.

### 1386 INDUCTION OF IL-6 IN LUNG CELLS BY PM2.5 PARTICLES FROM DESERT SOILS AND COAL FLY ASH.

J. M. Veranth, M. M. Veranth and G. S. Yost. Pharmacology and Toxicology, University of Utah, Salt Lake City, UT.

Fine particle air pollution is a complex mixture containing materials from geological, combustion, and atmospheric sources. The mechanisms linking various particle types to specific health effects remain elusive, but many studies have associated ambient particles with pro-inflammatory cytokine signaling pathways. In this study, PM2.5 particles were aerodynamically separated from three western United States desert soils and from a sample of fly ash collected at a power plant burning bituminous coal. Cultured human lung epithelial cells (type BEAS-2B) were treated with doses from 10 - 160 microgram/cm2 of the particles. Viable cell count and the interleukin-6 (IL-6) concentration in the media were determined 24 h after treatment. The IL-6 response correlated with negative charge on the particles (zeta potential) but did not correlate with particle surface area or with transition metal content. Capsazepine, an antagonist of the TRPV-1 receptor, decreased the IL-6 response. One desert dust induced an exceptionally high IL-6 response compared to treatment with the other soils, kaolin clay, or soluble metal salts. The LAL chromagenic assay showed that this dust contained the highest level of endotoxin (20-50

EU/mg particles which equals <10 EU/mL as applied to the cells). The measured endotoxin concentration in the dust was considerably lower that the amount of soluble lipopolysaccaride required to elicit a comparable IL-6 response (> 2000 EU/mL). This suggests that either the particles interfere with the LAL endotoxin assay or that other soil dust properties are responsible for the cytokine response. This work was sponsored by NIH research career award 1 K25 ES011281-01A1 by Southwest Center for Environmental Research and Policy project EH-03-03.

### 1387 EFFECTS OF PARTICULATE MATTER ON GLUTAMATE CYSTEINE LIGASE IN RAW CELLS.

S. M. Leaman<sup>1</sup>, P. Vliet<sup>1</sup>, <u>D. L. Luchtel</u><sup>1</sup>, M. E. Rosenfeld<sup>2</sup> and <u>T. J. Kavanagh</u><sup>1</sup>. 

<sup>1</sup>Department of Occupational and Environmental Health Sciences, University of Washington, Seattle, WA and <sup>2</sup>Department of Pathobiology and Nutritional Sciences Program, University of Washington, Seattle, WA.

Epidemiological studies have consistently shown associations between ambient particulate matter (PM) and respiratory and cardiovascular mortality and morbidity. The mechanisms responsible for this association remain unclear. One hypothesis with supportive toxicologic evidence is that PM acts to cause oxidative stress in the lung leading to upregulation and systemic release of pro-inflammatory mediators from immune defense cells such as macrophages. These pro-inflammatory mediators such as cytokines and reactive oxygen species can negatively impact cardiovascular function. Many studies have revealed the importance of antioxidants in protection of the lung from oxidative stress. The thiol antioxidant glutathione (GSH) is a major antioxidant in the lung and inhibition of its synthesis has been shown to exacerbate lung injury by a large number of toxicants. Glutamate cysteine ligase (GCL), a heterodimer composed of a catalytic (GCLc) and a modifying (GCLm) subunits, catalyzes the rate-limiting step in glutathione (GSH) biosynthesis. Exposing the murine macrophage cell line, RAW 264.7 to 100  $\mu$ g/ml PM1648 for 3-24 hours caused an upregulation of the GCLm protein while exposing cells to 300 µg/ml PM1648 upregulated GCLc protein over the same time course. These data suggest that GCL plays a role in protecting cells in the lung, such as alveolar macrophages from injury caused by PM exposure.

## 1388 EFFECTS OF COMBUSTION-DERIVED PARTICULATE MATTERS CONTAINING ARSENIC IN NF-κB LUCIFERASE TRANSGENIC MICE.

J. Park<sup>1</sup>, B. Park<sup>2</sup>, G. Yang<sup>2</sup>, M. Young<sup>3</sup>, N. Colburn<sup>3</sup> and <u>M. Cho<sup>1</sup></u>.

<sup>1</sup>Laboratory of Toxicology, College of Veterinary Medicine, Seoul National University, Seoul, South Korea, <sup>2</sup>Laboratory of Combustion and Air Pollution Control, College of Environmental Engineering, Chunbuk National University, Chunju, South Korea and <sup>3</sup>Basic Research Laboratory, National Cancer Institute, Frederick, MD.

Inhalation of combustion-derived particulate matters (PMs) can have a variety of negative impacts on human health. Some heavy metals are also known to play a substantial role in adverse health effects. The potential toxic effects of inhaled combustion-derived PMs containing arsenic, one of the most frequently present heavy metals in the air, were examined usinf NF-KB luciferase reporter mice. The male mice (5-6 weeks old) were exposed to different concentrations of PMs (124±24.5, 220±34.5, 426.4±40.3  $\mu$ /m3) for 6h per day, 5 days per week for 4 weeks in 1 m3 whole-body chambers. Significant increase of the luciferase activity in heart, liver, and lung was observed. Among them, the pulmonary luciferase activity was changed dramatically. EMSA indicated that the exposed PMs inhibited NF-kKB DNA binding activity in the lung. Western blot analysis in the lung indicated that p65 and p50 protein levels were increased while IKB was decreased in a concentration-dependent manner. The PMs also induced increase of Akt, Bcl-2, c-Myc and Erk proteins. Our results suggest that combustion-derived PMs containing arsenic can be a significant cause of adverse human health. Supported by BK21 grant

## 1389 CYTOTOXICITY AND CELL SIGNALING IN MH-S CELLS: RELATIVE POTENCY OF DIESEL AND COAL COMBUSTION PARTICLES.

P. Singh<sup>1</sup>, Y. Kostetski<sup>2</sup>, M. Daniels<sup>1</sup>, T. Stevens<sup>3</sup> and <u>I. Gilmour</u><sup>1</sup>.

Pulmonary exposures to combustion source particulate matter (PM) are known to induce inflammatory lung diseases, however it is not well understood how these particles exert their effects and how different sources and types of PM rank in potency. We have previously demonstrated in mice that diesel exhaust particles (DEP) high in organic carbons produced macrophage influx, while DEP, high in elemental carbon, induced neutrophilic inflammation in the lung. In the present study we tested the *in vitro* effects of these DEP (SRM-DEP, A1-DEP) along with a third

DEP sample (A2-DEP) and two coal particulate samples (M-Coal, K-Coal) on ATP levels and necrosis as well as JNK and p38 MAP kinase activation in a mouse alveolar macrophage cell line. The particulate samples were analyzed by electron paramagnetic resonance (EPR) to determine whether surface free radical concentrations were associated with cytotoxicity or bioactive potency. All particle treatments produced a dose-dependent decrease in ATP levels at 1, 4, and 24 h post exposure, however the relative potencies of the different samples were distinct: SRM-DEP = A2-DEP > A1-DEP > M-Coal = K-Coal. All particle-exposed cells showed significant increases in necrosis above control levels at 24 h. A2-DEP stimulated the earliest increase in phosphorylated p38 MAP kinase, while A1-DEP induced a later but far more dramatic rise. A1-DEP was also the most potent stimulator of phosphorylated JNK in these cells. EPR analysis showed that SRM-DEP had the highest concentration of surface free radicals followed by A2-DEP, which had about half and A1-DEP, which had about 1/10 the activity. These results indicate that surface free radical concentration is related to a reduction in ATP levels. However, the relative potency of activation was not associated with levels of surface free radicals, suggesting that mechanisms of PM-induced cellular activation and injury are distinct. (This abstract does not reflect EPA policy.)

INFLAMMATORY AND GENOTOXIC RESPONSES AND PULMONARY FUNCTION CHANGES DURING 60 DAYS OF WELDING FUME EXPOSURE PERIOD.

J. Sung<sup>1</sup>, <u>I. Yu</u><sup>1</sup>, S. Maeng<sup>1</sup>, S. KIm<sup>1</sup>, B. Choi<sup>1</sup>, K. Song<sup>2</sup>, J. Han<sup>1</sup>, Y. Chung<sup>1</sup> and J. Hyun<sup>1</sup>. <sup>1</sup>Center for Occupational Toxicology, Occupatinal Safety & Health Research Institute, KOSHA, Daejeon, South Korea and <sup>2</sup>College of Veterinary Medicine, Seoul National University, Seoul, South Korea.

Respiratory effects in full time welders include bronchitis, airway irritation, lung function changes, and lung fibrosis. In previous studies, we developed a three-phase lung fibrosis model to study the pathological process of lung fibrosis. In this study, we have attempted to investigate the inflammatory responses and pulmonary changes during this 60 day welding fume inhalation exposure period to elucidate the process of fibrosis. The rats were exposed to manual metal arc-stainless steel welding fumes (MMA-SS) with concentrations of  $64.8 \pm 0.9$  (low dose) and 107.8 ± 2.6 mg/m<sup>3</sup> (high dose) total suspended particulates for 2 hrs per day in an inhalation chamber for 60 days. Animals were sacrificed after the initial 2 hr exposure and after 15, 30 and 60 days. Pulmonary function was measured every week. The rats exposed to the welding fumes showed a statistically significant (P<0.05-0.01) body weight decrease as compared to the control during the 60 days exposure period. Elevated levels of cellular differential count, albumin, LDH, B-NAG, TNF-α and IL-1β were measured in the acellular bronchoalveolar lavage fluid of the rats exposed to the MMA-SS fume for 60 days. In addition, the DNA damage from 60 days welding fume exposure was also confirmed by Comet assay and immunohistochemistry for 8-OH dG. Among the parameters for pulmonary function test, only tidal volume showed a statistically significant and dose dependent decrease during 60 days of MMA-SS welding fume exposure. The elevation of inflammatory and genotoxic indicators along with lung function change confirms the lung injury and inflammation caused by the MMA-SS welding fume exposure.

1391

INDUCTION OF TGFβ PRODUCTION IN HAMSTER LUNGS FOLLOWING PERTURBATION WITH PULMONARY FIBROTIC AGENTS AMIODARONE AND PARAQUAT.

H. M. Conway, University. Doshi and J. M. Cerreta. *Pharmaceutical Sciences, St. John's University, New York, NY.* 

Pulmonary fibrosis, regardless of its etiology, is characterized by increased accumulation of cells and excessive synthesis and deposition of extracellular matrix components. Several different agents can set in motion a series of pathogenic events that result in significant changes in lung connective tissue content and distribution. However, the precise events from initial insult of the lung to fibrosis remains uncertain. The aim of the current study was to investigate perturbation of the lung in Syrian Golden hamsters by known pulmonary toxicants amiodarone and methyl viologen (paraguat). Such agents were introduced into the respiratory system of experimental animals by intratracheal insufflation. At various time points (6 to 12 weeks following treatment) the animals were euthanized, lungs removed, fixed in formalin and processed for histologic examination. Lungs from animals euthanized at earlier time points (24 to 72 hours) were frozen in liquid nitrogen or lavaged with sterile saline. Tissue sections from different time periods were examined by light microscopy to study the process of developing fibrosis. Frozen sections were stained using immunohistochemical methods to determine the location of and cell types producing transforming growth factor beta (TGF $\beta$ ) in toxicant treated lungs. It was found that TGF $\beta$  levels peaked at 24 hrs. after amiodarone treatment with declining levels at 48 and 72 hrs. With paraquat treatment peak levels of TGF $\beta$  appeared at 48 hrs with subsequent decline at 72 hrs. TGF $\beta$  was seen in the lung epithelial cells and pulmonary macrophages. Bronchioalveolar lavage also demonstrated a rise and decline in TGF $\beta$  levels parallel to those seen by immunohistochemical staining. These data suggest that hamster lung cells are responding to different pulmonary toxicants that produce fibrosis through similar pathways.

SEASONAL METAL CONTENT MEASURED IN BALTIMORE  $PM_{2.5}$  SEAS SAMPLES CORRELATES WITH CYTOKINE AND CHEMOKINE RELEASE IN AN *IN VITRO* ASSAY SYSTEM.

R. J. Mitkus<sup>1</sup>, J. L. Powell<sup>1</sup>, J. P. Pancras<sup>2</sup>, J. M. Ondov<sup>2</sup> and <u>K. S. Squibb<sup>1</sup></u>.

<sup>1</sup> Epidemiology and Preventive Medicine, University of Maryland School of Medicine, Baltimore, MD and <sup>2</sup> Chemistry and Biochemistry, University of Maryland, College Park, MD.

The association between human cardiopulmonary disease and exposure to fine particulate matter (PM, 5) has been well established. Metals are hypothesized to be responsible for this relationship. To test this hypothesis, we exposed human alveolar type II cells (A549) and monocytic-like cells (RAW 264.7) to fine particulate matter (PM2.5) collected at the Baltimore Supersite during summer and winter intensive sampling periods in 2002. Production of the chemokine, MCP-1, was measured from alveolar epithelial cells, while the release of the pro-inflammatory cytokine, TNF-α, was quantitated from monocytes in two similar in vitro assay systems. Mean levels of TNF-α for July 17-19 were 1800.8 (+/- 1092.1) pg/ml, while mean levels for November 19-25 were 1994.7 +/- 1455.0 pg/ml. MCP-1 release for July had a mean value of 101.1 +/- 223.4 pg/ml, whereas it was -836.2 +/- 246.5 pg/ml for November. A comparison of the concentrations of eleven metals measured by GFAAS revealed that Al, Fe, and Zn were the most abundant in both the July (Fe>Al>Zn) and the November (Fe>Zn>Al) samples. Statistical analyses demonstrated significant Pearson correlations (P<0.05) between ambient Fe and Cu concentrations and subsequent TNF-α and MCP-1 release for both sampling periods. Ambient Al concentrations from both July and November correlated with TNF- $\alpha$  release. In contrast, Zn correlated well with TNF- $\alpha$  (r = 0.507) released in response to the November samples and MCP-1 (r = -0.576) released in response to the July samples. Our results demonstrate that summer and winter samples differed in the associations between metal content and induced cytokine or chemokine release and that MCP-1 inhibition correlates well with Zn concentration in these samples. They also support other reports that certain metals found in PM25 affect the expression and release of specific intercellular signaling molecules in in vitro systems. EPA grant R828063

1393

METHOD OF DUST EXTRACT PREPARATION AFFECTS CYTOKINE PRODUCTION BY RESPIRATORY EPITHELIAL CELLS AFTER DUST EXPOSURE.

R. D. Massengale and J. J. Balsam. *Biology, Baylor University, Waco, TX.* Sponsor: M. Kanz.

A number of studies have been conducted in recent years to determine the effect of agricultural dust on the respiratory immune response. Many of these studies involved in vitro exposure of cell cultures to various concentrations of dust and subsequent measurement of cytokine production. However, the method of preparing the dust for cell exposure varied widely between studies. This variation in protocol limits data comparison between studies. Therefore, the overall objective of the current study was to develop a systematic method of agricultural dust exposure assays by comparing three different methods of dust extract preparation for their effect on cytokine production by respiratory epithelial cells. Samples of various agricultural dusts were collected and dust extracts of each type were prepared (unfiltered dust extract, filtered dust extract, heat-killed dust extract). A549 respiratory epithelial cells were then exposed to each of the dust extract preparations and assessed by ELISA for induction of interleukin-8. The heat-killed dust extracts induced the highest levels of interleukin 8 from A549 cells (range 50-250 ng IL-8 per million A549 cells). The levels of IL-8 induced by filtered dust exposures were significantly less (0-20 ng IL-8 per million A549 cells) than both unfiltered and heat-killed dust exposures at some dust concentrations. Furthermore, the results of the study showed that dust concentrations of 1000-10, 000 g/ml from some dust types were toxic to the A549 cells regardless of dust preparation method. Based on these results, the heat-killed method of dust extract preparation appears most appropriate for agricultural dust exposure assays. This study suggests that 1) direct dust-to-cell interaction is critical for maximum cytokine induction in dust-exposure assays, 2) heat-killed dust extract preparations induce the highest cytokine levels, and 3) developing a standard method of dust extract preparation is critical to effective comparison between experiments and between studies.

ROLE OF TNFα AND CAVEOLIN-1 IN OZONE-INDUCED INFLAMMATORY MEDIATOR RELEASE AND TOXICITY

L. Fakhrzadeh, J. D. Laskin and D. L. Laskin. Environmental and Occupational Health Sciences Institute, Rutgers University/UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ.

Exposure to toxic levels of ozone (O3) cause alveolar epithelial damage. We have previously demonstrated that alveolar macrophages (AM) and inflammatory mediators including nitric oxide generated via nitric oxide synthase, PGE2 and TNF-α contribute to the pathogenesis of tissue injury. The generation of these mediators is regulated, in part, by the transcription factor, NF-κB. Our findings that NF-κB p50 knockout mice are unable to generate inflammatory mediators and are protected from O3 induced lung injury, demonstrate a critical role for this protein in the pathogenic process. In the present studies we analyzed mechanisms regulating NF-KB activation in the lung after O<sub>3</sub> inhalation. Treatment of wild type (WT) mice with ozone (0.8 ppm, 3 h) resulted in a rapid increase in NF-κB binding activity in AM which peaked after 6-12 h. This response was attenuated in mice with a targeted disruption of TNF-α. TNF-α signaling involves p42/44 (ERK 1/2) MAP kinase, and phosphatidylinositol 3'-kinase/protein kinase B (PI3K/PKB) which are important in NF-KB activation and the generation of inflammatory mediators. O<sub>3</sub> inhalation resulted in increased ERK1/2 expression and activation in WT mice which was evident immediately after exposure. Activated ERK 1/2 is known to downregulate caveolin-1 (Cav-1), a negative regulator of PI3K. O<sub>3</sub> inhalation markedly reduced constitutive Cav-1 expression in AM. This was directly correlated with  $\rm O_3$ -induced activation of PI3K and PKB. In contrast, in TNF- $\rm \alpha$ -/mice, O<sub>3</sub> had no effect on Cav-1 or PI3K expression. These data, together with our findings that TNF-α suppresses Cav-1 expression in vitro, demonstrate that TNF- $\alpha$  and downstream signaling molecules are important in activation of NF-  $\!\kappa B$  and the regulation of inflammatory genes involved in  $\mathrm{O}_3$  toxicity. Supported by NIH grants ES04738, GM34310 and ES05022.

DIFFERENTIAL EXPRESSION OF TREFOIL FACTORS 1 AND 3 FOLLOWING AIRWAY EPITHELIAL CELL INJURY.

G. L. Baker, L. S. Van Winkle, M. V. Fanucchi, D. C. Kim and C. G. Plopper. Veterinary Medicine: Anatomy Physiology and Cell Biology, UC Davis, Davis, CA.

Trefoil factors are rapidly induced following mucosal injury in the gastrointestinal tract and function to protect the intestinal mucosa, enhance epithelial cell migration and are essential for epithelial repair in the GI tract. Recently TFF1 and TFF3 have been identified in the human respiratory tract, suggesting that trefoil factors may play a similar role in airway mucosal protection and injury repair processes. The present study was designed to determine whether trefoil peptides are modulated following injury in a well-defined model of airway epithelial cell injury using the Clara cell specific bioactivated pulmonary toxicant naphthalene (NA). Male Swiss Webster mice received an intraperitoneal injection of 200-mg/kg NA dissolved in corn oil carrier. Airways RNA was isolated 0, 1, 3, 6, 12 and 24 hours following naphthalene treatment. Real-time RT-PCR was performed on the isolated RNA to measure airway TFF1 and TFF3 expression. Six hours following naphthalene treatment TFF1 expression was increased 4 fold in the airways and at 24 hours it was increased 7 fold. TFF3 expression was increased 2 fold 1-3 hours following naphthalene treatment and was non-detectable from 6-24 hours following NA treatment. These results demonstrate that TFF1 and TFF3 are differentially modulated following acute airway injury. The increase in TFF3 that occurs immediately following NA administration may represent in an immediate mucosal protective mechanism, while the later TFF1 increase and the loss of TFF3 expression, which first occurs at a time when glutathione depletion occurs, may represent involvement in both airway mucosal protection and repair of injury. Supported in part by NIEHS ES06700, ES04311, ES05707 and the California Tobacco Related Disease Research Program of the University of California Grants TRDRP 121T-0191 and 11RT-0258.

### 1396

PRE-TREATMENT WITH DIESEL EXHAUST EXTRACT ALTERS INFLUENZA VIRUS REPLICATION IN LUNG EPITHELIAL CELLS.

I. Jaspers<sup>1, 2</sup>, J. Ciencewicki<sup>3</sup>, M. Beck<sup>2</sup>, W. Zhang<sup>1</sup> and M. Brighton<sup>1</sup>. <sup>1</sup>Center for Env. Med., Asthma, & Lung Biology, University of North Carolina, Chapel Hill, NC, <sup>2</sup>Pediatrics, University of North Carolina, Chapel Hill, NC and <sup>3</sup>Curriculum of Toxicology, University of North Carolina, Chapel Hill, NC.

Diesel Exhaust (DE) has been demonstrated to generate inflammatory responses in the lung and modify immune responses to inhaled allergens. However, little is known about the effects of DE on common respiratory viral infections. Previous studies have demonstrated that exposure to DE enhances influenza virus replication

in mice. We examined whether exposure to DE extracts (DEE) modifies influenza infections of human lung epithelial cells. Differentiated human bronchial epithelial (HBE) cells or A549 cells were exposed to DEE prior to infection with influenza A Bangkok/1/79. At 24 hours - 5 days post-infection total RNA was analyzed for the expression viral genes, as well host cell inflammatory and antiviral genes. Analysis of hemagglutinin (HA) mRNA, a marker for viral propagation, indicates that pretreatment with DEE enhances viral replication in both differentiated HBE and A549 cells as early as 24 hours post-infection in a DEE dose-dependent manner. This was not caused by a reduced antiviral defense response of the host cells, since influenza-induced mRNA levels for interferon  $\beta$  and MxA, a major interferon  $\beta$ -inducible antiviral defense gene were also enhanced by pre-treatment with DEE. In addition influenza-induced nuclear translocation of phospho-STAT1 and ISGF3y, transcription factors mediating interferon β-induced gene expression, were also upregulated by prior exposure to DEE, indicating that interferon β-induced signal transduction pathways are also enhanced by pre-treatment with DEE. Taken together these data indicate that exposure to DE can enhance influenza virus replication in human lung epithelial cells possibly without altering the ability of the host cell to defend itself against the invading pathogen.

SOLUBLE METALS ASSOCIATED WITH ROFA SUPPRESS LUNG IMMUNE DEFENSE AND ALTER CYTOKINE PROFILES AFTER INFECTION IN RATS.

J. R. Roberts<sup>1, 2</sup>, M. D. Taylor<sup>1</sup>, V. Castranova<sup>1, 2</sup> and J. M. Antonini<sup>1, 2</sup>.

<sup>1</sup>NIOSH, Morgantown, WV and <sup>2</sup>WVU, Morgantown, WV.

Residual oil fly ash (ROFA), a by-product of fossil fuel combustion and a component of air pollution, has been associated with increased morbidity in susceptible populations. We have shown that soluble metals in ROFA cause lung inflammation and increase susceptibility to infection in rats. The objective was to examine the mechanisms by which soluble metals in ROFA may enhance susceptibility to infection. ROFA was suspended in saline, separated into soluble and insoluble fractions, and the soluble portion (ROFA-SOL) was retained. At day 0, rats were intratracheally instilled (IT) with ROFA (2.0mg/rat) or equivalent quantities of ROFA-SOL, or saline. At day 3, rats were separated into two groups and received an IT dose of either 5x10<sup>4</sup> or 5x10<sup>5</sup> Listeria monocytogenes. Rats were euthanized on days 3 prior to infection, and on days 6, 8, and 10, bronchoalveolar lavage (BAL) was performed on the right lungs, and bacterial clearance was assessed using the left lung. BAL fluid was centrifuged and the supernatant was retained for measurement of cytokine levels. Exposure to ROFA-SOL significantly decreased pulmonary clearance of bacteria at both doses and decreased animal survival after treatment with the high bacterial dose. Prior to bacteria inoculation on day 3, IL-2 was decreased and IL-6 was increased in rats treated with ROFA-SOL compared to saline. After exposure to both doses of bacteria, IL-2 was decreased whereas IL-6 and IL-10 were elevated in ROFA-SOL-treated rats compared to saline. An elevation in IL-6, a pro-inflammatory cytokine associated with the acute phase response, may partially account for the ROFA-SOL-induced inflammation. An increase in IL-10, a cytokine involved in macrophage inhibition, and a reduction in IL-2, a cytokine promoting T-cell growth and proliferation, may result in a suppression of the innate and adaptive immune response to infection, respectively. ROFA and its associated soluble metals alter cytokine production which may affect the ability of the animals to respond to the infection.

SHORT-TERM EXPOSURE TO INHALED DIESEL EXHAUST PARTICLES ENHANCES ASTHMA-LIKE SYMPTOMS AND INCREASES CYP1A1 mRNA LEVELS.

M. J. Whitekus<sup>1</sup>, N. Brechun<sup>2</sup>, S. K. Nelson<sup>2</sup>, O. Hankinson<sup>1</sup> and D. Diaz-Sanchez<sup>3</sup>. <sup>1</sup>Department of Pathology and Laboratory Medicine and Jonsson Comprehensive Cancer Center, UCLA, Los Angeles, CA, <sup>2</sup>Webb-Waring Antioxidant Research Institute, Denver, CO and <sup>3</sup>Division of Clinical Immunology and Allergy at UCLA School of Medicine, UCLA, Los Angeles, CA.

Epidemiological studies suggest a correlation between exposure to ambient particulate matter and adverse health effects in humans, however, there is still a fundamental lack of understanding of the mechanisms involved. We have established a C57BL/6 mouse model to study the adjuvant effects of short-term inhaled diesel exhaust particle (DEP) exposure on asthma. In this model, animals treated with DEP + ovalbumin (OVA) display cellular infiltration in the lung (eosinophila) and demonstrate increased levels of IgG1 in sera compared to ovalbumin treated mice. Our current hypothesis is that DEP mediates some of its adjuvant effects through oxidative stress. However, when we measure the carbonyl content of total mouse lung in our model we found that there was no difference between DEP+OVA and OVA treated mice, suggesting that oxidative stress is not responsible for DEPs modulatory effects on cellular infiltration. Preliminary data using qPCR also suggests that CYP1A1 mRNA levels in total mouse lung increased by 18 fold in DEP+OVA treated mice. Thus, in our mouse model the adjuvant effect of DEP on cellular infiltration might function through another pathway besides oxidative stress, possibly through stimulation of the Ahr. Supported by US Public Health Service Grant AI50495.

DISPARATE ALLERGIC AIRWAY RESPONSES TO DIESEL EXHAUST INHALATION DURING ALLERGEN SENSITIZATION VERSUS ALLERGEN CHALLENGE.

<u>I. Wagner</u><sup>1</sup>, <u>E. Barrett</u><sup>2</sup>, J. McDonald<sup>2</sup> and <u>J. Harkema</u><sup>1</sup>. <sup>1</sup>Pathobiology and Diagnostic Investigation, Michigan State University, East Lansing, MI and <sup>2</sup>Lovelace Respiratory Research Institute, Albuquerque, NM.

Diesel engine exhaust (DEE) has been studied as a potential contributor to allergic responses in laboratory animals and humans. We compared the response of rodents exposed to DEE in two allergic models; one focused on allergen sensitization and one on allergen challenge. Brown Norway rats were sensitized to ovalbumin (OVA) by 3 daily intranasal (IN) instillations of 0 or 0.5% OVA, and then 2 weeks later were challenged with IN OVA for 3 days. Rats were exposed to DEE diluted to 30 or 300 micro-g/m3 particulate matter or clean air during either sensitization or challenge to OVA. Rats were sacrificed 24h after the last OVA challenge, bronchoalveolar lavage fluid (BALF) was collected and analyzed for cellularity and secreted mucins, and lungs were processed for morphology and histochemical analysis of intraepithelial mucosubstances (IM). OVA sensitization and challenge caused increased total inflammatory cells, neutrophils, eosinophils, and mucin glycoprotein 5AC in BALF, and IM in proximal (2-fold increase) and distal (10-fold) pulmonary axial airways. The lowest DEE exposure during OVA sensitization enhanced OVA-induced BALF cellularity by 1.6-fold, mostly due to neutrophils. By contrast, exposure to this same exposure level during OVA challenge resulted in attenuation of OVA-induced BALF total cells, neutrophils and eosinophils by 50%. Exposure to the high DEE exposure level had no effect on OVA-induced changes in BALF cellularity or mucin secretion. OVA-induced increases in IM were unaltered by DEE exposure during allergen sensitization, but both DEE exposure levels during allergen challenge inhibited OVA-induced increases in IM in distal airways by 50%. These data demonstrate that inhalation exposure to DEE can both inhibit and enhance allergic airway inflammation and mucus production. Modulation of these responses is dependent on the time of DEE exposure during the development of allergic disease. (Supported by the Health Effects Institute 03-8)

CHANGES IN THE COMPOSITION OF DIESEL EXHAUST RESULTS IN CHANGES IN THE MAGNITUDE OF SEVERAL ACUTE INHALATION RESPONSES.

J. McDonald, K. S. Harrod, <u>I. Seagrave</u>, S. Seilkop and <u>J. Mauderly</u>. *Toxicology, Lovelace Respiratory Research Institute, Albuquerque, NM*.

Diesel engine exhaust changes in composition with modification of engine operation/configuration, including the addition of emission reduction technologies such as low sulfur fuel and catalyzed ceramic traps. While previous studies have shown that diesel exhaust can cause inflammation in rodents and humans and decreased resistance to respiratory infection in mice (Harrod et al., Am. J. Resp. Cell Mol. Biol., V. 28, pp. 451-463), there is little information on the impact of changes in exhaust composition on these effects. To address this, identical inflammation, oxidative stress, and respiratory infection assessments were conducted after exposure of mice to diesel exhaust generated from a single cylinder diesel engine generator under three steady-state operating conditions: 1) High-load operation, number 2 cert. fuel, diluted to 200 micro-g/m3 particle mass (PM), 2) Low-load operation, number 2 cert. fuel, diluted to 200 micro-g/m3 PM, and 3) High-load operation with ultra-low sulfur fuel and catalyzed ceramic trap, with same dilution rate as condition 1. Changing the operation (load) of the engine resulted in a 4-fold change in particle organic content and a difference in particle size. The high load engine condition resulted in increased lung response (inflammatory/oxidative stress signals, altered viral clearance) for all endpoints, while low engine load resulted in mild increases in an oxidative stress indicator. No lung responses were observed with the emission reduction technologies in place. The ultimate goal of this work is to develop a framework that can be used to identify the physical/chemical components, or interactions among components, that are the most important in driving the acute toxicity of engine emissions. Work supported by the FreedomCar and Vehicle Technology Program of the US Department of Energy.

IN VITRO AND IN VIVO EFFECTS OF WORLD TRADE CENTER DUSTS: STUDIES IN HUMAN AND MOUSE CELL LINES AND IN INFLUENZA-COMPROMISED YOUNG AND OLD RATS.

A. Elder<sup>1</sup>, J. Finkelstein<sup>2</sup>, R. Gelein<sup>1</sup>, N. Corson<sup>1</sup>, P. Mercer<sup>1</sup>, C. Reed<sup>2</sup>, D. Oakes<sup>3</sup>, S. Eberly<sup>3</sup>, D. Topham<sup>4</sup> and <u>G. Oberdorster</u><sup>1</sup>. <sup>1</sup>Environ Med., University of Rochester, Rochester, NY, <sup>2</sup>Peds, University of Rochester, Rochester, NY, <sup>3</sup>Biostat, University of Rochester, Rochester, Rochester, NY and <sup>4</sup>Immunol, University of Rochester, Rochester, NY.

It is estimated that the initial airborne dust concentration after the collapse of the World Trade Center (WTC) towers was in the tens of g/m<sup>3</sup>. Emergency respondents were exposed to these high concentrations in the first several hours after the

disaster and their lingering cough may be due to the inhaled bolus of dust. Aerosol samples were taken at indoor and outdoor sites and then fractionated by size. In vitro studies in human and mouse IL-8 reporter cell lines were done first with all 20 samples to identify the most active ones. This was followed by single in vivo dust instillations of 500  $\mu g$  (to mimic responders' exposure) in young and old rats that were compromised with influenza virus either one or 29 days after dust exposure. The three most active dusts from in vitro studies were compared to fine-mode TiO<sub>2</sub>, a frequently-used "inert" control particle. Parameters of lung inflammation and oxidative stress were measured 3 and 31 days after dust exposure. Influenza virus caused significant lung inflammation by itself, as expected. The very mild WTC dust-induced inflammatory cell influx was characterized by maximal lavage neutrophil responses of 2.8% and 4.4% in young and old rats, respectively. The WTC dusts had significant main effects on total cell number, percentage of macrophages, and viability of lavage cells and the percentage of blood neutrophils (all small decreases). In general, there were no significant interactions between the dusts and virus; the exception to this was for total cell number, which increased slightly when the two factors were combined. There were no large increases in response from 3 to 31 days post-exposure. Lastly, there were no consistent differences between the WTC dusts and TiO2. These results suggest that an instilled high-dose bolus of WTC dust produces minimal inflammation that is much like the response to a nuisance dust and that subsequent viral infection does not unmask any toxicity associated with dust exposure.

## 1402 OXIDATIVE STRESS OF POLAR AND NONPOLAR AIR PARTICULATE MATTER COMPONENTS.

A. Kubatova<sup>1</sup>, L. C. Dronen<sup>1</sup>, S. B. Hawthorne<sup>1</sup> and <u>M. J. Picklo<sup>2</sup></u>. <sup>1</sup>EERC, University of North Dakota, Grand Forks, ND and <sup>2</sup>School of Medicine and Health Sciences, University of North Dakota, Grand Forks, ND.

Extensive epidemiological and inhalation studies link atmospheric particulate matter (PM) to cardiopulmonary diseases. PM exacerbates oxidative stress and inflammation in the respiratory system. Most of the toxicological research is focused on inorganic species (metals, sulfates) and nonpolar organics (PAHs), however, few studies have addressed polar organic PM. This is due to the analytical difficulty in purifying and identifying specific fractions, and the necessity to employ more than one solvent to extract a wide polarity range of organics. In this work, two samples representing different polarity matrices were studied: nonpolar diesel exhaust and polar wood smoke PM. We employed hot pressurized water (25°-300°C) at pressures sufficient to maintain the liquid state to fractionate these samples into polar and nonpolar components. At low temperatures water extracts polar organics while at high temperatures water extracts nonpolar organics. The importance of different polarity fractions was evaluated in relation to oxidative stress, based on the glutathione (GSH) depletion, and cytotoxicity to murine alveolar macrophages RAW 264.7. In addition, a bacterial genotoxicity assay SOS Chromotest was performed on each PM fraction. Both polar and nonpolar species contributed significantly to the toxicity of both PM samples. For wood smoke particulate, mid-polarity and nonpolar fractions exhibited more pronounced GSH depletion. In the mid-polarity fractions, methoxyphenols (syringol dimers), oxyPAHs, and PAHs were selectively extracted. For diesel exhaust particulate, the highest GSH depletion was observed in the nonpolar fraction, but also (unexpectedly) in the polar fraction, possibly corresponding to dicarboxylic acids. The genotoxic response was observed in mid-polarity fractions corresponding to the presence of nitropyrene. In summary, the results indicate toxicological importance of polar air PM fractions. Moreover, this work demonstrates the potential of hot pressurized water to selectively extract polar and nonpolar species for toxicological testing.

## 1403 THE ALLERGY ADJUVANT EFFECT OF PARTICLES: CHARACTERISATION OF THE PRIMARY CELLULAR RESPONSE IN THE LOCAL LYMPH NODE.

University. C. Nygaard, A. Aase and M. Lovik. *Environmental Immunology, Norwegian Institute of Public Health, Oslo, Norway.* Sponsor: E. Dybing.

Traffic pollution may contribute to the increased incidence of asthma and allergy in the western countries. Diesel exhaust particles (DEP) is the main particle type in traffic pollution, consisting of a complex mixture of small particles with several hundred different compounds adsorbed. Polystyrene particles as a surrogate for the DEP core have been shown to have an adjuvant effect on the allergic response in mice. In the present study, the primary immune response in the draining lymph node was examined after footpad injection of polystyren particles (PSP) and allergen (ovalbumin, OVA). PSP and OVA were injected into the hind footpad of Balb/cA mice. The popliteal lymph node (PLN) was excised on different days after injection, and cell numbers, cell types, several cell surface molecules and cytokine production were assessed. Particle-containing cells were observed in the lymph node already on day 1 after injection of PSP or OVA+PSP, and the number increased continuously until day 21. In the OVA+PSP group, the total and B-cell

numbers increased 3-4 times compared to the control groups, peaking on day 5 after injection. The increase in B cell numbers was twice the increase in T cell numbers. On day 5, most surface markers measured (MHCclassII, CD86, CD23, CD69) increased significantly in the OVA+PSP group compared to the control groups. PLN-cells from OVA+PSP injected animals gave an increased production of IL-4, but not IFN-7, when stimulated *in vitro* by ConA. We conclude that the adjuvant effect of PSP on the IgE antibody response to OVA was associated with a cellular response in the draining lymph node, peaking on day 5 after injection. The cellular response in the OVA+PSP group on day 5 included increased cell numbers, altered surface marker expression and a selective increase in Th2 cytokine production. PSP alone, however, did not influence any of the immunologic markers studied in the PLN.

### 1404 IMMUNOLOGIC SENSITIZATION OF GUINEA PIGS VIA INHALATION.

W. Lee, C. Banks and A. Viau. CTBR, Senneville, QC, Canada.

In October 2002 the FDA finalized guidelines for the Immunotoxicology Evaluation of Investigational New Drugs the requirements are not all inclusive as the European guidelines (promulgated by EMEA in July 2000), but rather specified assays according to the dose route or indication. For drugs to be administered by the inhalation route, respiratory sensitization must be evaluated. CTBR has been conducting immunologic sensitization studies according to GLP in guinea pigs *via* the inhalation route for over 10 years. The design utilized consists of sensitizing Hartley albino guinea pigs to the test material via the inhalation route. Additional control groups such as a positive control sensitized with a proven sensitizing agent (ovalbumin) and saline control groups are included. There are 2 phases to the study, the sensitization phase consisting of nose-only inhalation exposure to either saline, ovalbumin or the test material for a period of 30 minutes over 5 days, followed by a latent untreated period of 17 days. The second phase consists of the challenge inhalation exposure when animals are exposed for 15 minutes to the test material, saline or ovalbumin. Two days prior to the challenge exposure, animals that have been exposed during the sensitization phase to ovalbumin will undergo a skin reaction test to confirm that they have been sensitized. Half the population of each group will be protected from acute anaphylaxis by intraperitoneal injection of pyrilamine maleate 30 minutes prior to challenge exposure. Several endpoints may be evaluated following or during the challenge exposure and include respiratory minute volume (derived from the tidal volume and respiratory rate of the animal is monitored prior to the challenge and during the challenge exposure), antibody titers, histopathological examination and bronchiolo-alveolar lavage (BAL), performed 24 hours post challenge. From the lavage fluid obtained, total cell number, cell differentials for total protein, albumin and globulins are determined. Over the years, this GLP model has been shown to be successful as an indication of respiratory sensitization.

### 1405

DIFFERENTIAL GENE EXPRESSION PROFILES IN RAT TRACHEAL EPITHELIAL (RTE) CELLS IN RESPONSE TO COMBUSTION-SOURCE PARTICULATE MATTER (PM) AND VANADIUM (V) A PRIMARY METAL CONSTITUENT.

S. Nadadur, J. A. Dye and D. L. Costa. Pulmonary Toxicology Branch, USEPA, Research Triangle Park, NC.

Epidemiological studies have associated increased mortality and morbidity in people with cardiopulmonary diseases with increased levels of ambient particulate matter (PM). The molecular basis for the cardiopulmonary health effects of PM and its constituents are still largely unknown. As one of our efforts to identify key target cell populations within the cardiopulmonary system, in the present study, we examined the acute cell responses in a primary airway epithelial cultures using microarray analysis. The RTE cells were exposed to an aqueous extract of model combustion PM, residual oil fly ash (ROFA, 50 µg/ml) and one of its major metal constituents, vanadium (V, at 1 and 7.7 µM), or saline for 25 min. Atlas Rat 4K plastic microarray (Clontech, Palo Alto, CA) was hybridized with <sup>33</sup>P-labeled cDNA probe generated from poly A+ RNA isolated from the saline, ROFA or V exposed RTE cells. The spot intensities on the microarray were analyzed using AtlasImage 2.7 software (Clontech, Palo Alto, CA). Gene expression data was analyzed using GeneSpring software (Silicon Genetics, Redwood City, CA). A minimum three-fold exposure specific differential expression was observed in 870 genes. Of these, 479 genes were found up regulated. ROFA induced up regulation was seen in 139 genes, while 82 genes were suppressed. Induction of 293 genes by  $1\mu M$ of V and suppression of an equivalent number of genes by 7.7 μM of V suggested concentration dependent transcriptional activation. Differential induction of chemokines, colony stimulating factor-2 by ROFA and V, and induction of colony stimulating factor-3 and CXC chemokine LIX by V only suggest possible roles for these genes in the initiation and progression of epithelial cell injury. (This abstract does not reflect USEPA policy).

#### 1406

ANALYSIS OF GENE EXPRESSION IN RAT ALVEOLAR EPITHELIAL CELLS IN RESPONSE TO ORGANIC EXTRACT OF DIESEL EXHAUST PARTICLES.

E. KOIKE<sup>1</sup>, <u>S. Hirano</u><sup>2</sup> and T. Kobayashi<sup>2, 1</sup>, <sup>1</sup>PM2.5 and DEP Research Project, National Institute for Environmental Studies, Tsukuba, Ibaraki, Japan and <sup>2</sup>Environmental Health Sciences Division, National Institute for Environmental Studies, Tsukuba, Ibaraki, Japan.

Previous reports have been shown that diesel exhaust particles (DEP) induce pulmonary diseases including asthma and chronic bronchitis. The comprehensive evaluation has been required to know the toxic effects of air pollutants including DEP on the lung diseases. We focused the lung cells such as alveolar macrophages and alveolar epithelial cells, and searched the toxicological index. In this study, we investigated the gene expression in rat alveolar epithelial cells in response to organic extract of DEP using cDNA microarray. The DEP extract was prepared using dichloromethane. Rat alveolar type II cells (SV40T2) were subcultured extended to confluent and exposed to 30 µg/ml DEP extract for 6 h. Total RNA was extracted from the cells using TRIZOL. The gene expression was analyzed by using Motorola CodeLink Bioarray (KURABO, Japan) that includes 10000 rat cDNAs. Major indicator observed significant changes in the cDNA microarray analysis were further confirmed these protein activities. The expressions of many transcriptions on the cDNA microarray were changed by exposure to DEP extract. These were categorized according to the function. Significant increases were observed in the genes associated with drug metabolisms (aldose reductase-like protein), antioxidative enzymes (heme oxygenase1, glutathione S-transferase, heat shock protein 90), regulation of extracellular matrix (plasminogen activator inhibitor 2, tissue inhibitor of metalloproteinase 3) and so on. Furthermore, the expression of heme oxygenase 1 protein was also induced by exposure to DEP extract and the induction was decreased by treatment of N-acetyl cysteine as an anti oxidative agent. These results shows that the early response against oxidative stress caused by DEP may induce the pulmonary defense. Present study suggests that cDNA microarray analysis provides useful information to investigate the biological response to toxicants and to search the toxicological index.

### 1407

HEAVY METALS AND ELEMENTAL AND ORGANIC CARBON IN ATMOSPHERIC FINE PARTICLES (PM2.5) FROM PUERTO RICO.

B. D. Jimenez<sup>1,2</sup>, D. Acevedo<sup>2</sup> and C. Rodriguez-Sierra<sup>3,2</sup>. <sup>1</sup>Biochemistry, University of Puerto Rico, San Juan, PR, Puerto Rico, <sup>2</sup>Center for Environmental and Toxicological Research, University of Puerto Rico, San Juan, PR, Puerto Rico and <sup>3</sup>Public Health, University of Puerto Rico, San Juan.

Fine atmospheric particulate PM2.5 were sampled in an urban industrialized area (Guaynabo) and in a reference unpolluted site (Fajardo) from Puerto Rico. Samples (72 hrs) were obtained during November/2000 to September/2001 using a RAAS2.5-400 Andersen Instrument. Composite samples were prepared representing a month of digested material using the appropriate field blanks. As, Cd, Cu, Fe, Ni, Pb and Zn were analyzed by Atomic Absorption and elemental and organic carbon (EC/OC) were also determined. Factor and cluster analyses were performed in order to grouped variables indicating common origin sources. All metal species analyzed, except Fe, were significantly higher in Guaynabo when compared to Fajardo. Average levels of PM2.5 in Guaynabo were 11.6 ug/m3 versus 8.5 ug/m3 in Fajardo. The average levels of EC and OC in Guaynabo were 1.5 ug/m3 and 2.2 ug/m3, respectively. Fajardo, EC levels were <0.14 ug/m3 and OC levels were <1 ug/m3. However, Ni and V concentrations from Guaynabo, were the highest from all sites studied and were the highest concentrations found when compared to other studies from different regions of the World (Ni= 17 ng/m3 and V=40 ng/m3). The levels of Ni and V found in the Guaynabo are of a serious health concern. These metals have been identified as causative agents of cancer and acute lung injury. Multivariate analyses showed a strong relationship between Ni and V, PM2.5 and Fe, As, Cu and Pb in samples from the urban site (Guaynabo). Similarly, PM2.5 and Fe, were highly correlated in Fajardo but other relationships were found between Cd and V, as well as a negative relationship between Ni, Pb and Cu. Studies performed in PR have shown that the population living in Guaynabo had more types and cases of cancer than any other regions in the island and suffered respiratory health problems such as asthma, particularly children and elder people.

### 1408

QSAR STUDY FOR THE ACTIVATION OF THE ARYL HYDROCARBON RECEPTOR BY POLYCHLORINATED NAPHTHALENES.

<u>I. Olivero-Verbel</u> and <u>K. Kannan</u><sup>2</sup>. <sup>1</sup>University of Cartagena. Environmental and Computational Chemistry Group, Cartagena, Colombia and <sup>2</sup>Wadsworth Center and Department of Environmental Toxicology and Health, State University of New York, Albany, NY.

Polychlorinated naphthalenes (PCNs) are persistent environmental toxicans derived from the chlorination of naphthalene and also formed during the combustion of municipal waste. Due to their planarity and molecular similarity to dioxins, these

molecules can induce several toxic effects by activating the aryl hydrocarbon receptor (AhR). Using the potencies relative to 2, 3, 7, 8-tetrachlorodibenzo-p-dioxin (TCDD) for 20 individual PCN congeners according to the H4IIE-luc *in vitro* bioassay, and quantum chemically-derived molecular descriptors generated by the functional B3LYP model from the density function theory (DFT), a discriminant analysis was performed for a series of active and non-active PCN congeners to generate a suitable QSAR model for understanding the molecular characteristics responsible for the activation of AhR. The model suggests that PCNs with less than four chlorine atoms are not activators of the AhR. In addition, congeners IUPAC number 47, 50, 51, 52, 60, 63, 64 and 69, were predicted as compounds that can activate the AhR. The sum of atomic charges of the fused carbons within the PCN ring (SQC9-10) and the number of chlorine atoms, were identified by the QSAR model as the best predictors of AhR-dependent biochemical changes induced by these compounds.

1409 APPLICATION OF CALUX BIOASSAY FOR DETERMINING DIOXIN EXPOSURE LEVEL IN HUMAN BLOOD AND ENVIRONMENTS.

K. Joung and Y. Y. Sheen. *Pharmacy, Ewha Womans University, Seoul, seoul, South Korea.* Sponsor: Y. Cha.

For the determination of dioxin and dioxin like compounds, high resolution gas chromatography/mass spectrometer (HR-GC/MS) has been used as a standard method. Chemical analysis using HR-GC/MS has limitations to its application for large scale screenings. However, in vitro bioassay may overcome limitations of chemical analytic methods. Numberous bioassay systems have been developed that are mainly based on the AhR-dependent mechanism. Chemically Activated LUciferase gene eXpression assay (ĈALUX assay) is based on the CYP1A1 gene transcription. which is widely used as a functional parameter for AhR activations. In this study, we tried to establish CALUX bioassay and compare the results with that of chemical analysis. We have carried out CALUX assay for over 200 human blood samples and environmental samples such as Korean water, sediment, and soil. When the results measured by both HR-GC/MS and CALUX assay were compared, the correlation coefficient was as high as 0.96 in case of blood samples and also good in environmental samples except few samples. Dioxin exposure of Korean women without endometriosis turned out to be 14.6 pg/L TEQ and endometriosis patients turned out to be 31.9 pg/L TEQ. Most Korean river water showed minimal levels of dioxin like activity. Korean river sediment showed that 154 pg/g TEQ for Kumho river, 325 pg/g TEQ for Kum river, 216 pg/g TEQ for Mankyung river, 251 pg/g TEQ for Miho stream. These results suggest that the CALUX assay is applicable as an economical and quick method. However, the TEQ values of CALUX assay tended to be higher than that of HR-GC/MS.

### 1410 RECOVERY DETERMINATIONS FOR DIOXIN ANALYSIS WITH THE CALUX® BIOASSAY.

G. C. Clark<sup>1</sup>, A. C. Chu<sup>1</sup>, J. D. Gordon<sup>1</sup>, D. J. Brown<sup>1</sup>, M. Nakamura<sup>2</sup>, M. D. Chu<sup>3</sup>, H. Murata<sup>2</sup> and M. S. Denison<sup>4</sup>. <sup>1</sup>Xenobiotic Detection Systems, Inc., Durham, NC, <sup>2</sup>Hiyoshi Corporation, Omihachiman, Shiga, Japan, <sup>3</sup>Alta Analytical Perspectives, Wilmington, NC and <sup>4</sup>Department of Environmental Toxicology, University of California, Davis, Davis, CA.

Recovery determinations are important for quantitative methods such as high resolution gas chromatography/high resolution mass spectrometry (HRGC/HRMS) and bio-analytical methods such as CALUX® for dioxins. Recovery determinations in HRGC/HRMS are performed by spiking isotopically labeled congeners into the sample prior to extraction, with recovery based on the amount of labeled compound recovered. Bioassays do not differentiate between isotopically labeled and unlabeled analytes. Recovery determinations in bioassays can be accomplished with a surrogate sample spiked with a radiolabeled congener of dioxin. We demonstrate here that 1, 2, 3, 4-TCDD, a biologically inactive congener of the dioxin family of chemicals, can be used as an internal spike to determine recoveries of dioxin-like chemicals. Samples were spiked with <sup>14</sup>C labeled 2, 3, 7, 8-TCDD or 1, 2, 3, 4-TCDD and submitted to extraction and clean up using Xenobiotic Detection Systems, Inc. patent pending XCARB sample clean up method (acid silica column in series with an XCARB column). The XCARB column is differentially eluted to yield a PCB and PCDD/F fraction. The 1, 2, 3, 4-TCDD spiked samples were resuspended in toluene containing four PCB injection standards, and recoveries determined by gas chromatograph with electron capture detection or scintillation counter. Average recoveries determined by 1, 2, 3, 4-TCDD with paired samples spiked with <sup>14</sup>C- 2, 3, 7, 8-TCDD indicated that the recoveries determined by the two methods were very similar, 88.5% (± 1.2%) and 87.2% (± 2.4%), respectively. Recovery determinations were also verified by HRGC/HRMS. This procedure allows for quantitative determination of dioxin-like chemicals in various sample matrices. Supported by SBIR Grant from NIEHS ES 08372-03.

1411 ACTIVATION OF ARYL HYDROCARBON RECEPTOR BY TCDD INDUCES GENE SILENCING BY PROMOTER METHYLATION: A NOVEL MECHANISM FOR TCDD MEDIATED TUMOR PROMOTION.

S. S. Ray and H. I. Swanson. Molecular and Biomedical Pharmacology, University of Kentucky, Lexington, KY.

The aryl hydrocarbon receptor (AHR) is a ligand activated transcription factor that belongs to the bHLH-PAS superfamily and has been shown to mediate most of the effects of TCDD or dioxin. Our previous study has shown that in the primary human keratinocytes, TCDD inhibits the expression of the tumor suppressor proteins p53 and p16<sup>INK4a</sup>, while decreasing senescence and increasing proliferation. This study focuses on determining whether p16<sup>INK4a</sup> and p53 are direct targets of the TCDD/AHR signaling pathway. Using both the pharmacological antagonist MNF (3'-methoxy-4-nitroflavone) and siRNA designed specifically for AHR we have found that the inhibition of p53 and p16<sup>INK4a</sup> occurs in an AHR-dependent manner. Analysis of newly synthesized unspliced RNA reveals that the TCDD mediated inhibition is transcriptional. Downregulation of p53 and p16<sup>INK4a</sup> has been reported as a crucial first step in the onset of many cancer types and often occurs via promoter methylation. Using 5-aza-2'-deoxycytidine (5-aza-dC), a DNA hypomethylating agent that can transiently reverse the transcriptional silencing, we have observed a complete reversal in TCDD's ability to inhibit the expression of p53, whereas only partial reversal occurs with respect to p16<sup>INK4a</sup>. The evidence for promoter methylation was further confirmed using methylation specific PCR. In addition, we report that in the primary keratinocytes, the antagonist MNF inhibits nuclear uptake and 26S mediated degradation of AHR similar to that shown in other cell types. Further, the presence of a 26S proteosome inhibitor reverses the inhibitory effects of TCDD on p53 and p16<sup>INK4a</sup> expression. These novel findings imply that p53 and p16<sup>INK4a</sup> are targets of the TCDD/AHR signaling pathway and that this regulation involves increased methylation in the promoter regions of these genes. It also suggests that the AHR may be an important player in determining epithelial cell fate (i.e., senescence versus immortality) via its ability to regulate p16  $^{\rm INK4a}$  and p53.

1412 SUPPRESSOR OF CYTOKINE SIGNALING-2: A NOVEL TCDD INDUCIBLE GENE IN CH12.LX MURINE B-CELLS.

E. Tam, D. R. Boverhof, R. B. Crawford, <u>N. E. Kaminski</u> and <u>T. R. Zacharewski</u>. Department of Biochemistry and Molecular Biology, Department of Pharmacology and Toxicology, and Institute for Environmental Toxicology, National Food Safety and Toxicology Center, Michigan State University, East Lansing, MI.

The B-cell, a major component of humoral immunity, is a sensitive target for the immunotoxic effects of 2, 3, 7, 8-tetrachlorodibenzo-p-dioxin (TCDD) possibly by rendering cells less responsive to antigenic or mitogenic stimulation. Potential mechanisms of TCDD action on B-cells were examined in murine B-cell lymphoma cells (CH12.LX) treated with 3 nM TCDD or DMSO vehicle for 0, 2, 4, 6, 8, 12 and 24 hrs using sequence verified cDNA microarrays representing 3068 genes/ESTs. One transcript that was significantly induced by TCDD was Socs2, a suppressor of cytokine signaling. Changes in Socs2 mRNA levels paralleled that of Cyp1a1 with maximal induction of 3-fold observed at 4 hrs as determined by quantitative real-time PCR. TCDD-mediated induction of Socs2 mRNA was dose-dependent and exhibited the characteristic structure activity relationships observed for the aryl hydrocarbon receptor (AhR) ligands PCB-126, ICZ and BNF. Experiments with cycloheximide and AhR deficient B-cells indicated that Socs2 mRNA induction is a primary effect that is AhR dependent. Western analysis confirmed that Socs2 and Cyp1a1 protein levels were also induced in CH12.LX cells. Promoter analysis revealed the presence of 4 dioxin response elements within 1000 bp upstream of the Socs2 transcriptional start site and Socs2 promoter regulated reporter gene activity is inducible by TCDD. These results indicate that Socs2 is a primary TCDD inducible gene that may represent a novel mechanism by which TCDD elicits its immunosuppressive effects. Supported by NIEHS grants ES11271 and ES02520.

1413 EFFECTS OF 2, 3, 7, 8-TETRACHLORODIBENZO-P-DIOXIN EXPOSURE ON HYPOXIA DRIVEN GENES IN HUMAN MICROVASCULAR ENDOTHELIAL CELLS.

K. N. De Abrew<sup>1</sup>, K. K. Graven<sup>1, 2</sup> and B. Allen-Hoffman<sup>1, 3</sup>. <sup>1</sup>Molecular and Environmental Toxicology Center, University of Wisconsin, Madison, WI, <sup>2</sup>Medicine, University of Wisconsin, Madison, WI and <sup>3</sup>Pathology and Labarotary Medicine, University of Wisconsin, Madison, WI.

Although the cellular responses to 2, 3, 7, 8-tetrachlorodebenzo-p-dioxin (TCDD) and the environmental stress of hypoxia are well studied, investigations of potential cross-talk are limited. Endothelial responses to these combined stresses are un-

known. Aryl hydrocarbon receptor nuclear translocator (ARNT) is a common dimerization partner for both aryl hydrocarbon receptor (AhR) and hypoxia inducible factor-1α (HIF-1α). Possible cross-talk between these two pathways was studied using gene array technology. Human lung microvascular endothelial cells were exposed to either 10nM TCDD, hypoxia (0%O2) or both TCDD and hypoxia for 24 hrs and resulting RNA was analyzed using Affymetrix gene arrays. Statistical analysis of triplicate studies was performed using Affymetrix microarray suite and Affymetrix data mining tool. Twenty one genes were upregulated during exposure to TCDD and 3 of these genes contain known active XREs. Five hundred and eighteen genes were upregulated during exposure to hypoxia alone which included 18 known HRE-driven genes. A total of 365 genes were upregulated during exposure to both TCDD and hypoxia. Fourteen of the 18 HRE driven genes upregulated during exposure to hypoxia alone were also upregulated when exposed to both TCDD and hypoxia. Four HRE-driven genes were upregulated when exposed to hypoxia only but were not upregulated when exposed to both hypoxia and TCDD together. These 4 genes are insulin growth factor binding protein-3, erythroblastosis virus oncogene homolog-1, vascular endothelial growth factor receptor-1 and endothelial cell specific molecule. This data suggests that cross-talk exists between the hypoxia and TCDD mediated pathways but only for a specific subset of genes. This cross-talk may be cell type specific, may involve multiple transcription factors and may or may not occur at the level of transcription via the transcription factor ARNT.

GENE EXPRESSION RESPONSES TO 2, 3, 7, 8-TETRACHLORODIBENZO-P-DIOXIN (TCDD) IN MULTIPOTENTIAL C3H10T1/2 FIBROBLASTS EXHIBIT CLUSTER ACCORDING TO THE FUNCTIONAL STATE OF THE CELLS

P. Hanlon<sup>2</sup> and C. Jefcoate<sup>1, 2</sup>. <sup>1</sup>Pharmacology, University of Wisconsin, Madison, WI and <sup>2</sup>Molecular & Environmental Toxicology Center, University of Wisconsin, Madison, WI.

Although the environmental contaminant 2, 3, 7, 8-tetrachlorodibenzo-p-dioxin (TCDD) produces most of its toxicity through activation of the aryl hydrocarbon receptor (AhR), other signaling pathways are now recognized. Genomic profiling of multipotential C3H10T1/2 fibroblasts shows that TCDD produces very different effects on quiescent cells versus cells exposed to a mitogenic epidermal growth factor (EGF) or an adipogenic differentiation stimulus of insulin, dexamethasone, isobutylmethylxanthine, and the thiazolidinedione BRL46593, hereafter referred to as IDMB. In quiescent confluent cells, a 72 hour TCDD exposure changed the expression of over 1000 genes without visibly affecting the cells. These changes included several large functional gene clusters: increased cell cycle regulation and cell signaling mRNA and decreased glycolytic, mitochondrial, and ribosomal mRNA. TCDD completely reversed many gene responses induced by EGF (10 percent) and the IDMB (30 percent), while these stimuli after 24 hours suppressed the quiescent responses. By contrast, 33 genes responded to TCDD regardless of these other stimuli, including 4 genes with recognized AhR response elements (CYP1B1, CYP1A1, NQO1 and ALDH3A1) but also genes that could mediate broad secondary effects (glypican 1 and cysteine dioxygenase). 76 of 311 IDMB responses which were reversed by TCDD were similarly reversed by EGF (R<sup>2</sup>=0.87) suggesting shared regulatory factors. 42 IDMB-responsive genes, including the adipogenesis regulator PPARy, were cooperatively reversed by a combined EGF/TCDD addition in parallel with the need for cooperation in the suppression of differentiation. Most of these genes showed small but equal reversals by TCDD and EGF alone (R<sup>2</sup>=0.73) which suggests mechanistic overlap in nuclear regulation. TCDD treatment did not alter EGF stimulated MEK/ERK/Rsk signaling.

## 1415 INHIBITION OF INTERFERON-γ INDUCED APOPTOSIS BY TCDD IN HUMAN PERIPHERAL LUNG EPITHELIAL CELLS.

M. Richards<sup>1, 2</sup>, J. M. Martinez<sup>2</sup>, D. M. Mays<sup>2</sup> and <u>N. J. Walker<sup>2</sup></u>. <sup>1</sup>Toxicology, University of North Carolina, Chapel Hill, NC and <sup>2</sup>Laboratory of Computational Biology and Risk Analysis, NIEHS, NIH, Research Triangle Park, NC.

The major route of human exposure to 2, 3, 7, 8 tetrachlorodibenzo-p-dioxin (TCDD) and other dioxin-like compounds is through the ingestion of food containing animal fat. Minute mounts of TCDD can be found in meat, fish and dairy products since it bioaccumulates in the food chain. High levels of TCDD exposure in humans have been associated with lung cancer and chronic obstructive pulmonary disease. We have previously performed toxicogenomic microarray analyses that showed repression, following TCDD exposure, of at least four Interferon (IFN) inducible genes of interest, IFIT1, IFIT2, ISG15, and MX1. We hypothesize

that TCDD interacts with the IFN signaling pathway and results in repression of IFN induced phenotypes in human peripheral lung epithelial (HPL1A) cells. The purpose of this study was to look at the anti-apoptotic effects of TCDD on human lung cells treated with IFN-gamma. Initially, the effect of TCDD on cell proliferation was investigated. HPL1A cell proliferation, as measured by the MTS cell viability assay, returned to near basal levels with simultaneous exposure to TCDD [10 nM] and IFN gamma, at the following concentrations of IFN gamma: 1000, 5000, and 10, 000 Units/ml. Flow cytometry was used to quantify the level of apoptosis observed in the HPL1A cells after treatment with TCDD [10 nM], IFN gamma, and a combination thereof. Increased apoptosis levels were observed in HPL1A cells treated with IFN gamma, as compared to cells exposed only to vehicle. With concurrent TCDD exposure, the level of apoptosis we observed was attenuated. These data show that the IFN-gamma induced phenotypes in HPL1A cells, apoptosis and reduced cell proliferation, are inhibited following TCDD exposure. While the correlation between the repression of IFN regulated genes and the attenuation of phenotypic responses to IFN in HPL1A cells is not yet known, this study underscores the interference of TCDD on biological signaling pathways regulated by interferon.

## 1416 TCDD ATTENUATES VITAMIN A INDUCED GROWTH AND DIFFERENTIATION IN HUMAN LUNG EPITHELIAL CELLS.

D. M. Mays<sup>1</sup>, J. M. Martinez<sup>1</sup>, M. P. Richards<sup>2, 1</sup> and N. J. Walker<sup>1</sup>. <sup>1</sup>Laboratory of Computational Biology and Risk Analysis, NIEHS, Research Triangle Park, NC and <sup>2</sup>Toxicology, University of North Carolina, Chapel Hill, NC.

Human exposure to 2, 3, 7, 8-tetrachlorodibenzo-p-dioxin (TCDD) is linked to chronic obstructive pulmonary disease and lung cancer. Studies indicate that depletion of Vitamin A is also linked to cancer. Our laboratory used in vitro cell culture of non-malignant human alveolar type II epithelial cell line (HPL1A) to determine if TCDD alters or disrupts cell growth and differentiation caused by Vitamin A. To understand the method of action, cells were treated with TCDD 10 nM, Vitamin A (all trans retinoic acid) [10, 20, and 40 nM], or a combination of 10 nM TCDD and Vitamin A. The MTS assay was used to determine the amount of viable cells after 48 hours of treatment. These experiments show that Vitamin A [10, 20, and 40 nM] significantly inhibits cell proliferation in HPL1A cells when compared to basal levels. Vitamin A decreases the percentage of viable cells in a dose-dependent manner to 45% at 10nM, 34% at 20nM, and 26% at 40 nM. However, TCDD added in combination with Vitamin A attenuates Vitamin A inhibition of cell proliferation. The viable cells increase to 50% at 10 nM, 59% at 20 nM, and 69% at 40 nM Vitamin A. Western blot analysis indicates that acute exposure to TCDD induces, while Vitamin A decreases, the differentiation marker human keratin 1/cytokeratin (HK1). Overall results suggest that TCDD attenuates the effect of Vitamin A on cell proliferation and also causes an altered state of differentiation as compared to Vitamin A. How TCDD disturbs Vitamin A homeostasis is unclear, but studies such as this and their relationship to gene expression will help to clarify the biochemical mechanism of action.

### 1417 HISTONE MODIFICATION IN ARYL HYDROCARBON RECEPTOR MEDIATED GENE TRANSCRIPTION.

A. Fretland<sup>1,2</sup> and <u>O. Hankinson</u><sup>1,2</sup>. <sup>1</sup>Department of Pathology and Laboratory Medicine, University of California, Los Angeles, Los Angeles, CA and <sup>2</sup>Jonsson Comprehensive Cancer Center, Los Angeles, CA.

The ligand activated aryl hydrocarbon receptor (AHR) mediates a variety of transcriptional responses to environmental insults. Ligands include a diverse array of common environmental compounds, including 2, 3, 7, 8-tetrachlorodibenzo-pdioxin (TCDD). Upon ligand binding, AHR requires dimerization with the aryl hydrocarbon nuclear translocator (ARNT) protein to exert its toxic effects. The AHR/ARNT heterodimer is able to activate gene transcription of target genes, including cytochrome P4501A1 (CYP1A1). Activation of transcription by the AHR/ARNT complex requires the recruitment of numerous coactivators to the enhancer region of target genes. Certain coactivators probably cause local modifications of histone structure resulting in a more permissive state for gene transcription. Our laboratory has previously shown the recruitment of coactivators with histone modifying activity to the 5'-region of mCYP1A1 in response to TCDD treatment. To more fully understand the transcriptional regulation of CYPIA1 by TCDD, we have characterized the histone modifications induced by TCDD using the chromatin immunoprecipitation (ChIP) assay. The mouse hepatoma cell line, Hepa-1, was treated with 10 nM TCDD and cells were harvested at selected time points. ChIP assays using antibodies to specific modified histones and PCR primers specific for the 5'-region of mCYP1Â1 were used to identify histone modifications induced by TCDD. Our results show TCDD-dependent acetylation of lysine 14 and

lysine 23 of histone H3 and methylation of arginine 17 of histone H3 in the 5'-region of *CYP1A1*. We also observed a TCDD-dependent acetylation of lysines in histone H4 in the 5'-region of *CYP1A1*. These results suggest that histone modification in the 5'-region of *mCYP1A1* is an important step in the regulation of transcription in response to TCDD. Further studies will investigate which specific coactivators are responsible for each histone modification. Adrian Fretland is a postdoctoral trainee supported by USHHS Institutional NRSA #T32 CA09056.

## 1418 EVIDENCE OF AN INDUCTION THRESHOLD IN LIVER CELL LINES TREATED WITH 3, 3', 4, 4', 5-PENTACHLOROBIPHENYL.

C. Broccardo<sup>1</sup>, <u>R. E. Billings</u><sup>1</sup>, L. S. Chubb<sup>1</sup>, <u>M. E. Andersen</u><sup>2</sup> and <u>W. H. Hanneman</u><sup>1</sup>. <sup>1</sup>Department of Environmental & Radiological Health Sciences, Colorado State University, Fort Collins, CO and <sup>2</sup>CIIT, Research Triangle Park, NC.

Some chemicals are known to induce a threshold response versus a linear response at low doses. Further, the shape of the dose-response curve may vary depending on whether one examines response at a population or a single cell level. Often a population of cells will exhibit a graded response whereas on a single cell basis the response appears threshold or switch-like. By studying the single cell level of gene induction one may be able to determine the mechanistic basis for a switch-like response to a chemical. The goal of this research was to determine the mechanistic basis for the switch-like behavior of Cytochrome P450 1A1 (CYP1A1) to 3, 3', 4, 4', 5-pentachlorobiphenyl (PCB 126). CYP1A1 is the prototypical biomarker of activation of the aryl hydrocarbon receptor pathway. Two hepatoma cell lines, H4IIE and Hepa 1c1c7 cells were used in these studies. Both cell lines were analyzed via dose-response and time-course studies using quantitative real-time PCR. A sigmoidal dose-response curve for CYP1A1 induction was found in the two cell lines, describing the shape of the curve at the population level. Induction shifted to maximal between 2.5 x  $10^{-11}$  to 2.5 x  $10^{-9}$  M PCB 126 in both cell lines. Increased expression of CYP1A1 with time was observed, with the H4IIE cells showing maximal induction of 2000-fold by 16 h, and Hepa 1c1c7 cells showing 100-fold induction at 48 h. In order to study CYP1A1 induction on a single cell level, flow cytometry was employed. Both cell lines displayed a well-defined shift of induction from the "off" to the "on" state with increasing doses of PCB 126, with induced cells displaying similar levels of CYP1A1. The shape of the dose-response curve at the single cell level was sigmoidal. Moreover, immunocytochemistry studies also support this conclusion. Thus, in conclusion, these data support the hypothesis that PCB 126 induces CYP1A1 in an all-or-none fashion, indicating a threshold at the single cell level.

## 1419 INHIBITION OF AROMATASE ACTIVITY BY METHYL SULFONYL PCB METABOLITES IN H295R CELLS AND IN PRIMARY CULTURE OF HUMAN MAMMARY FIBROBLASTS.

M. Heneweer<sup>1</sup>, M. van den Berg<sup>1</sup>, P. C. de Jong<sup>2</sup>, A. Bergman<sup>3</sup> and J. T. Sanderson<sup>1</sup>. <sup>1</sup>Institute for Risk Assessment Sciences (IRAS), Utrecht University, Utrecht, Netherlands, <sup>2</sup>Department of Internal Medicine, St. Antonius Hospital, Nieuwegein, Netherlands and <sup>3</sup>Department of Environmental Chemistry, Stockholm University, Stockholm, Sweden.

Aromatase activity in human mammary tissue is mainly located in fibroblasts and a positive feedback loop is thought to be responsible for accelerating estrogen-responsive breast tumor growth through stimulation of estrogen synthesis. Tumor cells secrete factors such as PGE2 and IL-6 that are able to upregulate aromatase gene expression in fibroblasts surrounding tumors. Various in vitro studies have shown that pharmacological agents and xenobiotics are able to interfere with the aromatase enzyme. In this study we compared the aromatase expressing human cell line H295R with primary human mammary fibroblasts as in vitro screening tools for aromatase inhibition by methyl sulfonyl PCB metabolites. Both cell types were exposed for 24h to 100 nM dexamethasone (DEX) to induce aromatase activity. Levels of aromatase induction in fibroblasts differed greatly among patients, varying from 20- to 650-fold; aromatase activity was induced about 4-fold in H295R cells. In both cell types the  $\mathrm{EC}_{50}$ -value of DEX was around 20 nM. Since DEX upregulated aromatase activity in a highly effective manner in both cell types, we hypothesized that methyl sulfonyl PCB metabolites, which have anti-glucocorticoid properties, would decrease DEX induced aromatase activity. A 24h-exposure to 100 nM DEX, together with 0.1-10 µM 3-MeSO<sub>2</sub>-CB-91, 3-MeSO<sub>2</sub>-CB-101, 3-MeSO<sub>2</sub>-CB-132, 4-MeSO<sub>2</sub>-CB-132, 4-MeSO<sub>2</sub>-CB-149, and 3-MeSO<sub>2</sub>-CB-174 resulted in dose-dependent reduction of aromatase activity in both cell types with IC<sub>50</sub>-values around 1 μM. The anti-glucocorticoid RU486 inhibited aromatase activity (IC50-value of 5 nM), indicating that inhibition was glucocorticoid receptor mediated. Relative potencies of methyl sulfonyl PCB metabolites were between 2 and 3 orders of magnitude less compared to RÚ486. Catalytic inhibition and cytotoxicity were not observed at tested concentrations.

## 1420 2, 2', 4, 4'-TETRACHLOROBIPHENYL STIMULATES RELEASE OF ARACHIDONIC ACID FROM NEUTROPHILLIC HL-60 CELLS.

S. Bezdecny<sup>1, 2, 3</sup>, R. A. Roth<sup>1, 2, 3</sup> and P. E. Ganey<sup>1, 2, 3</sup>. <sup>1</sup>Department of Pharmacology and Toxicology, Michigan State University, East Lansing, MI, <sup>2</sup>Institute for Environmental Toxicology, Michigan State University, East Lansing, MI and <sup>3</sup>National Food Safety and Toxicology Center, Michigan State University, East Lansing, MI.

Polychlorinated biphenyls (PCBs) affect a number of cellular systems including neutrophils. Effects in rat neutrophils are mediated by ortho- substituted, noncoplanar PCBs like 2, 2', 4, 4'-tetrachlorobiphenyl (2244-TCB). The objective of these experiments was to explore further the mechanisms by which 2244-TCB affects neutrophil function using a human-derived cell line. The promyelocytic leukemia (HL-60) cell line was differentiated with dimethylsulfoxide to a neutrophil-like phenotype. The effect of 2244-TCB and a coplanar congener of the same molecular weight, 3344-TCB, on release of arachidonic acid were examined. In addition, alterations in expression of mRNA for cyclooxygenase-2 (COX-2) were evaluated using real-time PCR. Treatment of differentiated HL-60 cells with 30 µM 2244-TCB caused a time-dependent increase in COX-2 mRNA expression that was maximal after 30 minutes of exposure and returned to baseline after 90 minutes of exposure. Treatment with 30  $\mu M$  3344-TCB did not increase COX-2 mRNA levels. 2244-TCB increased release of [3H]-arachidonic acid ([3H]-AA) from labeled neutrophillic HL-60 cells in a concentration-dependent manner. The inhibitor of calcium-independent phospholipase A2 (iPLA2), bromoenol lactone, significantly decreased the release of [3H]-AA from cells treated with 30 µM 2244-TCB. PCB-stimulated release of [3H]-AA was unaffected by pretreatment with either an inhibitor of secreted PLA2 or an inhibitor of the MAP kinase p38. Treatment with 30 µM 3344-TCB did not increase release of [3H]-AA. These results demonstrate that the noncoplanar PCB congener 2244-TCB upregulates COX-2 and increases iPLA2 activity in neutrophillic HL-60 cells, whereas the coplanar PCB congener 3344-TCB lacks these effects. (Supported by ESO4911.)

## 1421 A NON-COPLANAR POLYCHLORINATED BIPHENYL INDUCES OXIDATIVE STRESS AND CELL DEATH IN A MID-BRAIN DOPAMINERGIC CELL LINE.

R. F. Seegal<sup>1</sup>, A. G. Kanthasamy<sup>2</sup> and S. Kaul<sup>2</sup>. <sup>1</sup>Wadsworth Center, New York State Department of Health, Albany, NY and <sup>2</sup>Department Biomedical Sciences, Iowa State University, Ames, IA.

Polychlorinated biphenyls (PCBs) are associated with developmental deficits in children and behavioral and neurochemical changes in laboratory animals. Following in vivo and in vitro exposure PCBs reduce dopamine (DA) concentrations and elevate intra-neuronal or media concentrations of DA. These changes may be mediated by inhibition of monoamine transporters, including the DA transporter and the vesicular monoamine transporter. To better understand the consequences of PCB exposure on neuronal function, we exposed the rat mesencephalic dopaminergic neuronal cell line (N27) to a non-coplanar PCB congener (2, 3, 6, 2', 5'-PtCB, 10, 30 and 100  $\mu M$ ) and measured changes in oxidative stress (using dihydroethidine and flow cytometry) and cell death (using the Sytox Green Cytotoxicity assay). PtCB resulted in significant time and dose dependent increases in ROS formation with elevations seen at 30 and 100 µM and as early as five min after exposure. Pretreatment with a cell permeable superoxide dismutase mimetic MnTBÂP (5 µM for 15 min) significantly attenuated PtCB-induced ROS production, indicating that PtCB predominantly generates superoxide species. Cell death was measured in serum free media following 1, 2 or 4 hr exposure to PtCB with significant elevations seen at 30 and 100  $\mu$  M after 2 and 4 hr. These results demonstrate the second of the service of the second o strate that ROS formation occurs prior to cell death and may thus contribute to loss of cell viability. Most importantly, PtCB induced ROS formation in N27 cells was greater than that reported following exposure to the same concentrations of MPP+, the active metabolite of MPTP. Taken together, these results provide continuing support for the hypothesis that PCBs may contribute to mid-brain DA neuronal cell loss and thus ultimately play a role in the etiology of parkinsonism. Supported by NIH grant ES11263 and EPA grant 829390 to RFS and NIH grants ES10586 and NS45133 to AGK.

# 1422 PHARMACOKINETICS AND IMPROVED ORAL BIOAVAILABILITY OF TWO NANOSTRUCTURED DRUG CRYSTALS: COMPARISON OF PARTICLE ENGINEERING TECHNOLOGIES.

S. A. Saghir, G. B. Kupperblatt, D. A. Markham, T. L. Rogers, C. J. Tucker, J. E. Hitt and E. J. Elder. *The Dow Chemical Company, Midland, MI.* 

As many as 60% of drug candidates exhibit poor water solubility in physiochemical testing and poor absorption from the GI tract. Poor oral absorption limits the usefulness of a drug. In order to overcome this limitation, one of the emerging tech-

niques is particle engineering of the drug crystals to increase the surface area-to-volume ratio and adding excipients to prevent reaggregation. Nanosizing drug crystals traditionally involves milling, however other emerging techniques are more effective. The Dow Chemical Company has developed a number of technologies to produce novel nanostructured drug particles that enhance oral bioavailability of poorly water soluble drugs. Early determination of ways to enhance oral bioavailability of a drug candidate is important in order to generate accurate kinetic and toxicological data. Two poorly absorbed drugs (danazol and ketoconazole) were processed by various technologies and excipients and evaluated in beagle dogs. Male dogs were dosed orally with danazol (200 mg/dog) or ketoconazole (100 mg/dog) in capsule or tablet form and blood collected from the jugular vein at 0, 0.5, 1, 2, 4, 8, 12, and 24 h post-dosing. Concentration of parent drugs were determined in plasma by LCMS. WinNonlin was used for kinetic analysis. The technologies evaluated for danazol showed 15-64 times higher AUC than the micronized drug (as received). Two technologies, emulsion and controlled precipitation, were effective in enhancing the oral bioavailability of danazol by 64 and 51 times, respectively. The Tmax of the nanostructured and micronized drug remained same, however plasma t1/2 of the nanostructured danazol formulations was 2-3 times longer than micronized drug, similarly Cmax of the nanostructured drug was 18-45 fold higher. The nanostructured ketoconazole showed 2-8 times higher AUC and Cmax, no change in Tmax and plasma t1/2 was observed. The oral bioavailability of ketonazole prepared by emulsion and controlled precipitation technologies was significantly higher than controls.

1423

γ-SECRETASE (γ-SEC) INHIBITORS THAT MODULATE NOTCH PROCESSING CAUSE INTESTINAL GOBLET CELL METAPLASIA (GM) AND SPLENIC MARGINAL ZONE LYMPHOID DEPLETION. PART I, PATHOLOGY.

P. Ciaccio<sup>1</sup>, J. McKay<sup>2</sup>, C. Louden<sup>1</sup>, C. Dagenais<sup>1</sup>, R. Gadient<sup>1</sup>, Q. Jiang<sup>1</sup>, L. Foster-Brown<sup>1</sup>, F. Pognan<sup>1</sup>, T. Piser<sup>1</sup>, J. Stahl<sup>1</sup> and B. Greenberg<sup>1</sup>. AstraZeneca Pharmacology R&D, Wilmington, DE and AstraZeneca Pharmacology R&D, Alderley Park, United Kingdom.

Amyloid deposits constitute a primary neuropathological hallmark within vulnerable regions of the Alzheimer patient brain. These deposits consist of A $\beta$  amyloid peptide, derived from amyloid precursor protein (APP) by a series of proteolytic events, the last of which is mediated by an enzyme complex called  $\gamma$ -sec. In addition to APP,  $\gamma$ -sec cleaves a variety of type-1 transmembrane proteins, including the Notch receptor.  $\gamma$ -Sec inhibitors reduce the cleavage of such substrates. This relaxed substrate specificity could potentially lead to untoward mechanism-based side-effects for e.g., signals transduced from the intracellular domain of Notch play an essential role in cell fate decisions. Thus, it was anticipated that  $\gamma$ -sec inhibitor treatment will alter differentiation of cell populations in tissues whose architecture is governed by Notch signaling. To explore this hypothesis, we selected compounds from 3 chemical series that lower AB amyloid in vivo and which variously inhibit Notch in vitro (Notch IC50): an arylsulfonamide (AS) (250 nM), a dibenzazepine (DBZ)(2 nM), and a benzodiazepine (BZ)(1 nM). Rats were dosed ip for up to 5 days at 0, 10, 30 and 100 µmol/kg bid. The AS produced no detectable in vivo toxicity despite relatively high exposure. The 2 potent inhibitors caused dose-dependent intestinal GM with villous stunting and splenic marginal zone lymphoid depletion (SMLD). There was a temporal progression of intestinal histopathology with mid-dose BZ. Small intestinal crypt and large intestinal glandular epithelial apoptosis was observed on days 1-4, followed by GM on days 2-5 and crypt epithelial and glandular epithelial regenerative hyperplasia on days 4-5. SMLD occurred from day 2. While these lesions are consistent with Notch pathway alteration, the absence of toxicity in animals dosed with AS suggests that it is possible to inactivate the processing of  $\gamma$ -sec substrates selectively in vivo.

## 1424 OTOTOXICITY STUDY WITH CIPRODEX STERILE OTIC SUSPENSION® IN THE GUINEA PIG.

<u>L. E. Lemke</u><sup>1</sup>, <u>D. H. McGee</u><sup>1</sup>, D. M. Prieskorn<sup>2</sup>, R. A. Altschuler<sup>2</sup>, <u>R. B. Hackett</u><sup>1</sup> and J. M. Miller<sup>2</sup>. <sup>1</sup> Toxicology, Alcon Research, Ltd.., Fort Worth, TX and <sup>2</sup> Kresge Hearing Research Institute, University of Michigan, Ann Arbor, MI.

This study investigated the ototoxic potential of a combination of Ciprofloxacin 0.3% and Dexamethasone 0.1% (CiproDex®) when administered directly to the round window niche of the guinea pig middle ear. Animals from four test groups (n=10) and two control groups (n=5) were all confirmed to have hearing within normal limits before selection. Positive and negative control groups were treated with 10% neomycin or normal saline, respectively. Test groups were treated with CiproDex Vehicle, CiproDex, Ciprofloxacin 1.0% plus Dexamethasone 0.3%, or Ciprofloxacin 0.3%. Each subject was implanted with an injection port mounted on the skull and attached to a cannula which passed through the temporal bone into the bulla and terminated at the round window niche. Test or control article (10

 $\mu L)$  was injected through the cannula BID for 4 weeks. Administration of test and control articles to the round window niche provided a rigorous test of the compatibility of these test and control articles for otic administration by ensuring access to this portal into the inner ear. Auditory brainstem responses were collected at 2, 8 and 16 kHz after 2 and 4 weeks of dosing. At the termination of the study middle ear tissues were examined grossly and histopathology was performed on inner ear tissues. No statistically significant hearing losses were observed in any of the test groups at either timepoint. Histopathologic examination of the Organ of Corti for the CiproDex Otic, other test groups and saline control each revealed hair cell counts within normal limits. A significant elevation in hearing threshold was observed in animals receiving Neomycin. Profound hair cell loss, corresponding to loss of auditory function was observed in the neomycin positive control group only. The results of this study support the conclusion that CiproDex Sterile Otic suspension is safe for administration to the open middle ear cavity.

## 1425 THG213.29: SAFETY OF A NOVEL PEPTIDE FOR TREATMENT OF ACUTE RENAL FAILURE.

G. Washer<sup>1</sup>, E. Ferdinandi<sup>1</sup>, K. High<sup>1</sup>, K. Peri<sup>1</sup>, J. Praslicka<sup>2</sup>, J. Laliberte<sup>2</sup>, C. Pare<sup>3</sup>, C. Thompson<sup>3</sup> and S. Cote<sup>4</sup>. <sup>1</sup>Theratechnologies Inc., Montreal, QC, Canada, <sup>2</sup>ITR, Montreal, QC, Canada, <sup>3</sup>CTBR, Montreal, QC, Canada and <sup>4</sup>Anapharm, Quebec City, QC, Canada.

THG213.29 and its shortmers: THG213.291 (N-1) and THG213.292 (N-2), are potent EP4-receptor antagonists. EP4 mRNA is detected in renal glomeruli & collecting ducts. Potency of THG213.29 was established by in vitro screens and in vivo efficacy has been demonstrated in rat models of ischemic renal failure and acute tubular necrosis. Acute IV toxicity & toxicokinetics were studied in rats & dogs. Escalating doses, up to 200 mg/kg in rats and 50 mg/kg in dogs, indicated no effect levels of 30 (rat) and 10 mg/kg (dog). In rats, body weight, clinical pathology and renal pathology effects were found at 100 mg/kg and mortality occurred at ≈150 mg/kg. In dogs, transient dose-related reductions in blood pressure and alterations in urine volume & electrolytes occured at 20 & 50 mg/kg. Toxicokinetics, determined by LC-MS/MS plasma analysis, indicated dose-related increased exposure (based on Cmax & AÛC) to THG213.29 and shortmers, in both species. Low THG213.29 levels (with high levels of shortmers) 10 min post dose, indicated rapid cleavage of parent. Renal & cardiovascular IV safety pharmacology studies were conducted in rats & dogs, respectively. Doses of 5 & 10 mg/kg to dogs had no effect on hemodynamics or electrocardiograms (ECG). At 20 & 50 mg/kg there were transient, dose-related reductions in blood pressure and increases in heart rate, but no ECG changes. In rats, effects at 1 & 10 mg/kg were limited to slight increases in creatinine clearance. At 100 mg/kg there were also transient alterations in Ca, urea, glucose & protein excretion. Mouse lymphoma & Ames tests were negative for genotoxicity. These studies established a safety profile for THG213.29 and its metabolites. Effects were either transient & related to the pharmacological action, or were at a high multiple of the clinical dose, providing an acceptable safety margin for initiation of human trials.

## 1426 SAFETY EVALUATION OF TELBERMIN IN RABBITS USING A FULL THICKNESS EXCISIONAL DERMAL WOUND MODEL.

T. R. Gelzleichter<sup>1</sup>, A. L. Fuller<sup>3</sup>, N. Pelletier<sup>2</sup>, S. M. Eppler<sup>2</sup>, D. Fei<sup>2</sup> and S. Brignoli<sup>2</sup>. <sup>1</sup> Safety Assessment, Genentech, South San Francisco, CA, <sup>2</sup>Develepment Sciences, Genentech, South San Francisco, CA and <sup>3</sup> Covance, Madison, WI.

Telbermin (recombinant human vascular endothelial growth factor-165) is currently in clinical trials as an investigational drug for the treatment of diabetic foot ulcers. The following study was designed to evaluate the safety of telbermin using a full thickness excisional dermal wound model in rabbits. Dermal wounds (2.5 x 2.5 cm<sup>2</sup>)were surgically created on the dorsal skin of New Zealand white rabbits. Rabbit wounds were treated by topical administration of telbermin in 3 percent methyl cellulose at a concentration of 0, 0.08, 0.8, or 1.7 mg/mL in a 0.6 mL delivery volume. Treatments were repeated every 2 or 3 days for a total of 12 administrations over 4 weeks. Following each administration, wounds were covered with semi-occlusive dressing and protected with a wound jacket. All doses were well tolerated and no adverse effects were observed that were directly attributable to telbermin. Dose site infections did occur more often in telbermin-treated rabbits, but the incidence was low and therefore difficult to attribute directly to telbermin administration. All infections were readily treatable with antibiotics. Systemic absorption of telbermin was relatively slow with peak serum concentrations detected three hours after telbermin administration. Only a small fraction of the total dose (0.1 percent) was adsorbed systemically. The maximum mean telbermin plasma concentration did not exceed 400 pg/mL for any of the dose groups at any of the measured time

points, however, peak values were roughly six-fold higher than the mean endogenous plasma level of 66±16 pg/mL. Assuming a similar rate of systemic absorption occurs in humans, telbermin treatment is not anticipated to significantly affect plasma VEGF concentrations in clinical use. By week 4, 83 percent of rabbits developed antidrug antibodies; therefore, longer-term safety studies in this model may not be feasible. Overall, telbermin was safe and well tolerated at all doses tested throughout the study.

## 1427 TOXICOLOGICAL PROFILE OF AVI-4020, AN ANTISENSE MORPHOLINO OLIGOMER FOR TREATMENT OF WEST NILE VIRAL INFECTIONS.

V. Arora, M. L. Cate, M. T. Reddy, D. H. Mason and P. L. Iversen. AVI BioPharma, Inc., Corvallis, OR.

Antisense oligomers can selectively inhibit target gene expression and have great therapeutic potential. AVI-4020 is an antisense phosphorodiamidate Morpholino oligomer (PMO) targeted to the translation initiation region of the open reading frame of West Nile virus. The toxicological profile of AVI-4020 has been examined in rodents and non-human primates. • A 28-day once-daily IP administration study in Sprague-Dawley rats identified no significant toxicological concerns. A slight elevation of liver:body weight ratio was observed in male rats (two-tailed p value = 0.0179). • A 7-day twice-daily bolus IV administration study in cynomolgus monkeys identified no significant toxicological concerns. Liver:body weight ratio changes were not observed in either sex. 

Biodistribution studies following bolus IV administration in rats indicated that organs with the largest distribution were kidney, followed by liver. Smaller quantities were recovered from lungs, spleen and heart. AVI-4020 residence time in these organs was rather prolonged and not determined by plasma pharmacokinetics. 

An examination of blood coagulation indices revealed no changes in prothrombin time or activated partial thromboplastin time following twice-daily administration for five days in Sprague-Dawley rats. Degradative metabolism was not observed. Only full-length oligomers were recovered from various tissues and excreta in rat studies. • Urine and feces were the major routes of elimination in rat studies. 

Full-length oligomer was recovered in cerebrospinal fluid following bolus IV administration in rats at time points well beyond its presence in plasma. This observation is remarkable for a macromolecule (FW=7624) yet desirable for treatment of West Nile disease, which often has central nervous involvement. The toxicity profile of the anionic PMO AVI-4020 is remarkably different when compared to multiple reports for the negatively-charged phosphorothioate class of antisense agents. This drug is currently being evaluated in a Phase I clinical trial.

### 1428 GENOTOXICITY STUDIES WITH PURE *TRANS*-CAPSAICIN.

S. Chanda<sup>1</sup>, G. Erexson<sup>2</sup>, C. Riach<sup>3</sup>, D. Innes<sup>3</sup>, F. Stevenson<sup>3</sup>, H. Murli<sup>2</sup> and K. Bley<sup>1</sup>. <sup>1</sup>Toxicology, NeurogesX, Inc., San Carlos, CA, <sup>2</sup>Covance Laboratories, Vienna, VA and <sup>3</sup>Inveresk Research, Tranent, Scotland, United Kingdom.

Both positive and negative effects have been found in classical genetic toxicology assays with capsaicin. However, the capsaicin tested in most studies has been derived from pepper plant extracts, which is likely to display varying degrees of purity and possibly diverse impurity profiles. Therefore, the objective of the series of studies reported here was to test the genotoxic potential of pure, synthetic trans-capsaicin (the only naturally- occurring stereoisomer of capsaicin), using four genotoxicity assays widely used to evaluate drug substances. These included the Ames, mouse lymphoma cell mutation, mouse in vivo bone marrow micronucleus and chromosomal aberration in human peripheral blood lymphocytes assays. In the Ames assay, pure capsaicin was not mutagenic to Salmonella typhimurium or Escherichia coli when dissolved in dimethylsulfoxide and tested at concentrations extending into the cytotoxic range. Capsaicin was weakly mutagenic in mouse lymphoma L5178Y cells, in the presence of S9 mix, when dissolved in dimethylsulfoxide and tested at concentrations extending into the cytotoxic range. Limited evidence for very weak activity was also obtained in the absence of S9 mix. Capsaicin did not induce micronuclei in bone marrow cells when tested to the maximum tolerated dose of 800 mg/kg/day in male and 200 mg/kg/day in female CD-1 mice using a 0 hr plus 24 hr oral dosing and 48 hr sampling regimen. Finally, capsaicin did not induce structural or numerical chromosomal aberration when evaluated for its ability to induce clastogenicity in blood lymphocytes. Taken together, these data suggest that the genotoxic potential of pure trans-capsaicin is very low, especially as the clinical significance of weak mutagenicity in the mouse lymphoma assay for catechol-moiety containing compounds is unclear. Moreover, the different genotoxicity profiles of pure *trans*- capsaicin and purified chili pepper extracts suggest that the purity and source of capsaicin should always be an important consideration for toxicological evaluations.

## 1429 GLYCOGEN SYNTHASE KINASE (GSK3) INHIBITORS STIMULATE CELLULAR PROLIFERATION VIA WNT SIGNALING PATHWAY *IN VITRO* AND *IN VIVO*.

C. E. Ruegg<sup>1</sup>, B. R. Berridge<sup>2</sup>, D. E. Watson<sup>1</sup>, D. K. Monteith<sup>1</sup>, B. Li<sup>1</sup>, J. L. Blackbourne<sup>1</sup>, S. W. Queener<sup>3</sup>, C. M. Love<sup>3</sup>, J. W. Ryder<sup>3</sup>, R. A. Owens<sup>3</sup>, T. E. Eessalu<sup>3</sup>, E. A. Misener<sup>5</sup>, T. A. Engler<sup>4</sup> and J. T. Brozinick<sup>5</sup>. \*Lead Optimization Toxicology, Lilly Research Labs, Greenfield, IN, \*Lead Optimization Investigative Pathology, Lilly Research Labs, Greenfield, IN, \*Lead Optimization Biology, Lilly Research Labs, Indianapolis, IN, \*Discovery Chemistry, Lilly Research Labs, Indianapolis, IN and \*Discovery Biology, Lilly Research Labs, Indianapolis, IN.

GSK3 is responsible for phosphorylating several protein substrates including glycogen synthase leading to its inactivation. Inhibitors of GSK3 could have therapeutic benefits in controlling blood glucose levels by allowing glycogen synthase to shunt glucose into glycogen. However, GSK3 is also integral to the Wnt signaling pathway where inhibition leads to stabilization and translocation of B-catenin into the nucleus resulting in transcription of several factors leading to cell proliferation. In these studies we show that selective small molecule inhibitors of GSK3 result in cellular proliferation both *in vitro* and *in vivo*. This proliferative effect correlates well with the inhibitory potency and exposure of the GSK3 inhibitors and has been associated with increases in B-catenin, cyclin D1, and mitotic figures within liver, kidney, adrenal, and bone tissues. These studies suggest that GSK3 inhibitors targeted to regulate glucose control may need to either avoid interaction with GSK3 in the Wnt signaling pathway, or have an adequate margin of safety relative to these proliferative effects.

## 1430 DRUG-INDUCED CARDIOMYOPATHY IN RATS: MORPHOGENISIS AND IDENTIFICATION OF POTENTIAL BIOMARKERS.

J. D. Moehlenkamp, W. A. Kelly, R. L. Kowalski, W. M. Peden, W. J. Saunders and G. D. Pilcher. Drug Safety Evaluation, Bristol-Myers Squibb Company, Mt. Vernon, IN.

Serum levels of cardiac troponins and lactate dehydrogenase isoenzymes have been shown to be increased after insult with cardiotoxicants (i.e., doxorubicin) and are used clinically as markers of cardiac damage. During 1-month toxicity studies with BMS-505130, cardiomyopathy was observed in male and female rats at 200 mg/kg/day. The cardiomyopathy, similar to the spontaneous change that commonly affects aged rats, was characterized by the presence of a combination of degenerate and/or necrotic muscle fibers, subacute inflammation, proliferation of muscle fiber nuclei, and/or muscle fiber regeneration. Studies were conducted to identify potential biomarkers and further characterize the dose- and time-dependence of cardiomyopathy in rats after BMS-505130 treatment. In the initial study, male and female rats were treated at 75 and 125 mg/kg/day for 1-month. Minimal to mild cardiomyopathy, similar to that observed on the previous study, was observed in females after the 1-month dosing period. Additional findings at 75 and 125 mg/kg/day included minimal to mild increases in lactate dehydrogenase (LDH) isoenzymes LDH-1 and LDH-2. The largest increases in LDH-1 and LDH-2 were in the high dose females where the cardiomyopathy was noted also. In a second timecourse study, females rats were administered BMS-505130 at 200 mg/kg/day and evaluated for changes in serum biomarkers and evidence of myocardial pathology on day 1 at 6 and 24 hours postdose, and on study days 4, 8, 15, and 29. Minimal to moderate cardiomyopathy was observed on day 8 with increasing severity over time. In correlation with the hisopathologic changes, time-dependent increases in troponin T and LDH-1 and LDH-2 were evident at day 8 and remained elevated for the duration of the study. The results of these studies demonstrate that the cardiomyopathy induced by BMS-505130 is both dose- and timedependent and suggest that cardiac troponin T and LDH-1 and LDH-2 are potentially useful serum biomarkers of drug-induced myocardial damage.

## 1431 γ-SECRETASE INHIBITORS THAT MODULATE NOTCH PROCESSING CAUSE INTESTINAL GOBLET CELL METAPLASIA. PART II: GENE EXPRESSION.

J. Milano<sup>1</sup>, S. Matis<sup>2</sup>, <u>F. Pognan</u><sup>1</sup> and <u>P. Ciaccio</u><sup>1</sup>. <sup>1</sup> Safety Assessment, AstraZeneca Pharmaceuticals, Wilmington, DE and <sup>2</sup>EST Infx, AstraZeneca Pharmaceuticals, Wilmington, DE.

 $\gamma$ -Secretase ( $\gamma$ -sec) is an intramembranous multi-subunit aspartyl protease that catalyzes the final cleavage step of amyloid precursor protein (APP). The resulting extracellular domain,  $\beta$ -amyloid accumulates in the brain and is associated with cognitive impairment in Alzheimer's disease (AD). Inhibiting  $\gamma$ -sec may prevent the deposition of  $\beta$ -amyloid and is sought as a preventative therapy for AD. However, many  $\gamma$ -sec substrates have been identified, including the Notch receptor. Inhibitors of  $\gamma$ -sec effectively reduce the cleavage of such substrates. This relaxed substrate specificity may lead to deleterious mechanism-based effects. Signals trans-

duced from the intracellular domain of Notch play an essential role in cell fate decisions. Knock out (KO) studies of the transcriptional regulators Hes1 and Math1, which are downstream of the Notch signal, illustrate this pathway's role in the regulation of intestinal stem cell differentiation. A recent report showed that adipsin (ADN) may be under Hes1 control and is a potential biomarker for intestinal goblet cell metaplasia. (Ryan et al. JBC in Press). We dosed Han Wistar rats with 3 γsec inhibitors ip at 0, 10, 30 and 100 µmol/kg/bid for 5 days with a benzodiazepine (BD), and a dibenzazepine (DBZ) both known to interrupt the Notch signal, and an arylsulfonamide (AS) that shows weaker Notch signal interruption. Using gene expression profiling we detected several deregulated factors that are consistent with Hes-1 KO data. We confirmed the up-regulation of ADN mRNA in intestinal tissue by DBZ and BZ treatment but not AS treatment. However, the induction of Math1 was markedly higher than ADN at earlier time points and at lower dose with DBZ and BZ. This up-regulation preceded the appearance of goblet cell metaplasia in the crypts. Also, these elements showed a temporally distinct response to  $\gamma$ sec inhibition. These data suggest an alternative control mechanism for ADN that is not limited to Notch signal interruption but may also be a product of cell differentiation in the metaplastic lesion.

## 1432 SOCIALIZATION AND ENVIRONMENTAL ENRICHMENT IN LONG-TERM TOXICITY STUDIES IN MICE

L. Bonnet<sup>1</sup>, J. Golfier<sup>1</sup>, B. Heritier<sup>1</sup> and <u>J. Descotes<sup>2</sup></u>. <sup>1</sup>MDS Pharmacology Service, L'Arbresle, France and <sup>2</sup>Poison Center, Lyon, France.

The forthcoming European regulations (GT 123) require that more appropriate housing conditions are used during toxicity studies. This study was performed to compare various housing conditions in groups of 12 male and 12 female B6C3F1 mice for 13 weeks. The reference group was housed singly in stainless-steel cages. The four other groups were housed in threes in enriched cages of a size compliant with the new European guidelines. Of these, two were kept in stainless-steel cages containing either a small plastic box or a mat of hemp fibres for nesting, and two in plastic cages with sawdust and either a small plastic box or a mat of hemp fibres. Food consumption was measured weekly. Hematology and clinical chemistry endpoints were assessed at the end of the study. Clinical observations were performed daily and included a careful examination of the animal behavior. Necropsy was performed at the end of the study. Marked wounds were observed in males housed in plastic cages, which led to the isolation of some animals and were associated with increased neutrophil counts. Body weight gain was higher and food consumption lower in males housed in groups, whereas both body weight gain and food consumption were lower in females housed in groups. The mean relative weight of adrenals in females housed in groups in metallic cages with a mat was statistically lower than in animals of the reference group. The mean relative thymus weight of females housed in groups in plastic cages was statistically higher than in animals of the reference group. In addition, serum corticosterone levels at the end of the study were statistically lower in animals housed in plastic cages. No other changes were noted. Overall, it appears that the most appropriate housing conditions for toxicity studies in mice are group-housed animals in metallic cages with a vegetable fibre mat as enrichment.

## 1433 BILIARY EXCRETION OF <sup>14</sup>C-DIAZEPAM IN MALE RATS AFTER PRETREATMENT WITH TACROLIMUS.

L. Faure<sup>1</sup>, P. Vignand<sup>1</sup>, A. Raynard<sup>1</sup>, F. Pasello-Legrand<sup>1</sup> and <u>J. Descotes</u><sup>2</sup>. <sup>1</sup>MDS Pharmacology Services, L'Arbresle, France and <sup>2</sup>Poison Center, Lyon, France.

The immunosuppressant tacrolimus is known to impair biliary excretion. As diazepam is extensively eliminated by this route in rats, the present study was conducted to determine whether acute or repeated administrations of tacrolimus influence the biliary excretion of <sup>14</sup>C diazepam in male Sprague-Dawley rats. Anesthetized rats were catheterized for subsequent bile collection as freely moving animals. One extremity of the catheter was inserted into the bile duct toward the liver and the other extremity into the duodenum. The catheter was tunneled from the neck of the animal with an exteriorized loop assuring a free flow of the bile flow during the post-operative recovery of the animals. On day 2 post-surgery, approximately 80% of the catheterized animals had liver enzymes within the normal range. Only these animals were included in the study. A group of 12 rats received an intravenous injection of 10 mg/kg <sup>14</sup>C-diazepam (corresponding to 1.11 MBq/kg) and the total and sequential amounts of diazepam excreted in the bile were measured over 72 hours. Diazepam biliary excretion accounted for 80% of elimination in these animals. On days 7 and 8, these rats were given an oral dose of 3 mg/kg tacrolimus followed by the same intravenous dose of <sup>14</sup>C-diazepam. Another group of 10 rats were treated with an oral daily dose of 3 mg/kg tacrolimus for 3 weeks and catheterized one week before receiving a single intravenous administration of <sup>14</sup>C-diazepam. No changes in diazepam biliary excretion were observed following

either an acute or repeated-dose administration of tacrolimus. Nevertheless, this study demonstrates the feasibility of drug biliary excretion investigations under GLP conditions as a complement to regulatory acute or repeat dose toxicity studies.

## 1434 THE ACUTE SAFETY PHARMACOLOGY PROFILE OF CM-2, 239: A NEW THERAPEUTIC AGENT FOR THE TREATMENT OF MILD COGNITIVE IMPAIRMENT AND ATTENTION DEFICITS.

D. R. Helton<sup>1</sup>, D. B. Fick<sup>1</sup>, S. Nadjsombati<sup>2</sup>, E. Pfadenhauer<sup>1</sup>, M. Piacente<sup>2</sup>, J. P. Sharp<sup>1</sup> and P. Mazur<sup>2</sup>. <sup>1</sup>Cenomed, Inc., Lake Forest, CA and <sup>2</sup>Biological Test Center, Irvine, CA.

CM-2, 239 (4-[3-(4-Oxo-4, 5, 6, 7-tetrahydroindol-1-yl)propionylamino]benzoic acid (ethyl ester) is a novel heterocyclic compound that is currently in pre-clinical development for the treatment of mild cognitive impairment and attention deficits in aging, and for the treatment of attention deficit hyperactivity disorder (ADHD) in children. CM-2, 239 has been shown to be efficacious in animal models of memory and attention, as well as in ADHD models. The purpose of the current series of studies was to characterize the acute secondary pharmacological activity (safety pharmacology) of CM-2, 239 in tests evaluating central nervous system (CNS), cardiovascular and respiratory function. The clinically effective ADHD drug, methylphenidate (Ritalin) was evaluated as a reference agent. Both compounds were administered orally in Sprague-Dawley rat or Beagle dogs. Methylphenidate (1, 3 and 10 mg/kg) produced significant stimulatory effects in CNS motor and reactivity measures in both rats and beagle dogs. Acute transient alterations were also seen in both cardiovascular (dogs) and respiratory endpoints (dogs and rats). In contrast, CM-2, 239 produced no significant alterations in CNS, cardiovascular, or respiratory function in these species at doses up to 100 mg/kg or 100 times the anticipated clinical dose. Evaluation of the safety of CM-2, 239 is currently ongoing in age appropriate models. These data support the safety of CM-2, 239 clinical use as a novel therapeutic agent for MCI, ADD and ADHD without the side effects and stimulatory properties of the currently prescribed medications.

## 1435 BIOAVAILABILITY OF INSULIN FOLLOWING PULMONARY ADMINISTRATION TO THE BEAGLE DOG VIA A SURGICALLY PREPARED TRACHEOSTOME.

G. Cow and P. McDonald. *Inhalation Toxicology, Inveresk Research, Edinburgh, United Kingdom.* Sponsor: R. Greenough.

Administration of drugs to experimental animals in inhalation studies results in a large proportion of the drug depositing in the oral cavity or upper respiratory tract. Where the absorption of drugs from the respiratory tract needs to be evaluated, a method of direct delivery to the lower respiratory tract is necessary to provide an estimation of pulmonary bioavailability. One method would be to dose Beagle dogs under general anaesthesia and administer via tracheal intubation. A more practical method (without anaesthesia) is surgical preparation of a permanent tracheostome to give access to the lower respiratory tract and allow direct pulmonary administration. This technique allows repeated use of the same animals for cross-over studies and testing of multiple drug formulations. The objective of this study was to investigate the bioavailability of 3 dry powder insulin formulations (A, B and C) following pulmonary administration to 4 male Beagle dogs via a surgically prepared tracheostome. Each formulation was administered via an endotracheal tube inserted into the tracheostome and the dry powder delivered as a bolus aerosol using a PennCenturyTM device. To demonstrate bioavailability of the pulmonary delivered insulin, endogenous insulin was suppressed over the experimental period by continuous intravenous administration of somatostatin (0.5 µg/kg/min after an initial loading bolus dose of 37.5 µg/kg). For each test formulation, systemic insulin and glucose levels were determined from serial blood samples taken over an approximate 15 hour period. Results indicated that pulmonary administration, via a tracheostome, of the 3 dry powder insulin formulations was well tolerated and produced no adverse effects. Assessment of plasma insulin showed that for all 3 formulations insulin profiles increased in a time dependent manner, peaking at 15-60 minutes post administration, correlating with a related reduction in blood glucose. The tracheostomed Beagle dog is therefore considered a suitable model for investigation of drugs intended for pulmonary delivery.

### 1436 NINETY DAY TOXICOLOGICAL EVALUATION OF THE ORAL TOXICITY OF GBR 12909 IN DOGS.

R. Krishnaraj<sup>1</sup>, R. L. Morrissey<sup>2</sup> and <u>B. S. Levine</u><sup>1</sup>. <sup>1</sup> Toxicology Research Laboratory, University of Illinois at Chicago, Chicago, IL and <sup>2</sup> Pathology Associates, Chicago, IL.

The toxicity of GBR 12909 (Vanorexine), a dopamine reuptake inhibitor, was evaluated in dogs during 13 weeks of daily oral (capsule) administration at doses of 0, 1, 5 and 20 mg/kg/day (control, low, mid and high dose groups, respectively; 4

dogs/group/sex) with a 4 week recovery period for high dose and control animals (2 additional dogs/group/sex). Animals were examined for mortality, clinical signs, changes in body weight, food consumption, clinical pathology, gross pathology, histopathology, organ weights, and ophthalmologic and electrocardiogram parameters. One high dose male showed neurological signs (reversed by haloperidol injection) and was moribund sacrificed on day 36. A second male was sacrificed on day 60 due to a non-treatment-related event. Increased (locomotor) activity was observed in high and mid dose group animals. At the high dose, other behavioral changes (head bobbing and weaving) were seen in 4/6 and 5/6 males, respectively, and in 2/6 and 6/6 females, respectively. In the mid dose group, head weaving was seen in 1/4 males and 1/4 females, and head bobbing seen in 1/4 males. Treatmentrelated diarrhea and emesis were seen in high and mid dose groups. These changes (behavioral, locomotor activity) were considered CNS pharmacologic effects of GBR 12909. Toxicological effects were also seen. Mild adverse effects on body weight gains and food consumption were noted in the high dose group, mostly the females. The weight gain reduction reversed during recovery period. Thrombocytosis was noted in the high dose group females. Mild serum electrolyte imbalance (hyperphosphatemia, hyperkalemia) in high dose males was not due to nephrotoxicity. No treatment-related histopathologic changes were seen. The No-Observed-Pharmacologic Effect-Level of GBR12909 was 1 mg/kg/day. Physical signs due to excessive CNS stimulation and reduced body weight gains noted at 20 mg/kg/day were considered signs of toxicity (Scientific consultation with Dr. James Terrill, NIDA is acknowledged; Supported by NIDA Contract No. NOIDA-9-8099).

## 1437 CONTINUOUS SUBCUTANEOUS INFUSION IN RODENTS.

M. Stilianesis, S. Groom and C. Copeman. CTBR, Senneville, QC, Canada. Sponsor: M. Vezina.

The subcutaneous route is often used for drug administration in humans. Continuous subcutaneous infusion offers an alternative to subcutaneous injection particularly to assess the potential biological effects of compounds having a short half-life. The use of implantable mini-pumps has become increasingly popular, and while these have been used in several applications at CTBR, their use does present several potential limitations in terms of infusion volumes and rates of infusion. Therefore, we have developed our own method of subcutaneous infusion for both large animals and rodents that allows higher infusion rates and volumes to be administered and a means to account for daily dosimetry. This poster presents data generated using this method in rodent studies ranging from 1 week to 13 weeks duration. Using saline as a vehicle, infusion rates as high as 1.0 mL/kg/h have been employed in studies of up to 28 days duration and rates of up to 0.4 mL/kg/h have been employed for up to 13 weeks. These rates correspond to daily dose volumes of 24 mL/kg and 10 mL/kg respectively. Our method of infusion has repeatedly been demonstrated to be both well-tolerated and without biologically significant effects upon hematology, clinical chemistry or tissue pathology. While some localized background tissue responses are inevitable with the presence of a small diameter silicone catheter in the subcutaneous space, these reactions are typically confined to a minimal cellulitis and/or fibrosis. Furthermore, this low level of tissue reactions appears to be less than that associated with the presence of an implantable pump. Therefore, we consider our method of infusion to provide a suitable means to evaluate the safety and kinetics of pharmaceutical products intended for subcutaneous administration.

### 1438 SAFETY EVALUATION OF XMP.629, A NOVEL PEPTIDE FOR ACNE TREATMENT.

R. Hawks<sup>1</sup>, J. Secrest<sup>2</sup>, <u>S. Frantz</u><sup>2</sup>, E. Serbinova<sup>3</sup>, T. Merriman<sup>4</sup>, D. Learn<sup>5</sup> and K. Meyer<sup>1</sup>. <sup>1</sup>XOMA US, Berkeley, CA, <sup>2</sup>MPI Research, Mattawan, MI, <sup>3</sup>Dow Pharmaceuticals, Petaluma, CA, <sup>4</sup>Charles River Springborn, Spencerville, OH and <sup>5</sup>Charles River Argus, Horsham, PA.

XOMA (US) LLC is currently developing a topical formulation of XMP.629 for the treatment of moderate to severe acne vulgaris. XMP.629 is a novel D-linked 9-amino acid peptide based on a variant of a natural antimicrobial protein. Safety evaluation studies have characterized the toxicological profile of formulated XMP.629, including genotoxicity studies, acute toxicity studies, photosafety studies, and 30-day repeat dose toxicity studies. Ames, mouse micronucleus, and chromosome aberration assays showed that XMP.629 was not genotoxic. An acute oral toxicity study in rats showed no toxic effects at doses tested up to 10 mg/mL XMP.629. Studies in rabbits determined that XMP.629 is neither a primary dermal nor ocular irritant. A photosafety study in guinea pigs showed that XMP.629 did not cause primary irritation, phototoxicity, contact hypersensitivity or photoallergy. In a 30-day study in the rat, XMP.629 was administered subcutaneously to maxi-

mize systemic exposure. The results showed no signs of systemic toxicity up to the highest dose tested. Findings considered secondary to inflammation arising at the injection site were noted in hematology, clinical chemistry and organ weight changes. The no-observed-effect level (NOEL) for systemic toxicity was determined to be 3.0 mg/kg administered subcutaneously, a dose level about 45-times higher than the anticipated clinical dose. A 30-day topical application study in the minipig showed no XMP.629-related toxicity in any of the parameters evaluated, and the NOEL for systemic and local toxicity was determined to be 700  $\mu g/kg/day$ , a dose about 10-times higher than the anticipated clinical dose. The results from this evaluation support the use of this novel compound in clinical studies.

## 1439 MONITORING THE PRIMARY AND SECONDARY ANTIBODY RESPONSE TO KLH IN A DEVELOPMENTAL IMMUNOTOXICITY (DIT) STUDY.

G. Desilets, N. Rouleau, P. Louise and L. LeSauteur. CTBR, Senneville, QC, Canada. Sponsor: L. LeSauteur.

A T-cell dependent antibody response assay was used to monitor the primary and secondary antibody response in a DIT study. KLH was used as an antigen and a quantitative enzyme linked immunosorbent assay (ELISA) was used to monitor the anti-KLH IgM and anti-KLH IgG response. KLH (300 µg in 0.1 mL, or 150 µg in 0.05 mL) was administered intravenously via the tail vein. Blood samples were collected from Sprague-Dawley rats aged from 30 to 125 days. As expected, for Groups 1 and 2, no anti-KLH IgM or anti-KLH IgG antibodies were detected since animals were not immunized with KLH. Group 3 animals produced a substantial primary and secondary response, measured on Day 71 since KLH was administered on Days 57 and 64. Group 4 animals produced a substantial primary and secondary response on Day 125 since KLH was administered on Days 112 and 129. The primary response measured on Day 118 for Group 4 animals was lower than on Day 125. Group 5 animals produced a measurable but very low primary immune response since KLH was administered on Day 23. Group 6 animals were immunized with KLH twice (Days 16 and 23) and produced a greater primary antibody response on Day 30 than Group 5 animals. Group 6 animals were re-immunized with KLH a third time on Day 119 and a substantial primary and secondary immune response was observed on Day 125. In conclusion, the primary and secondary immune response can be measured in weanling Sprague-Dawley rats (30 days post-natal). However, the response is suboptimal. An intravenous KLH dose of 150 µg in 0.05 mL has shown to be adequate to induce a detectable immune response.

## 1440 PHARMACOKINETIC AND TOXICITY STUDIES OF GENTAMICIN IN AFRICAN GREEN MONKEYS.

D. J. Auyeung<sup>1</sup>, S. Cyrek<sup>1</sup>, J. Schindler-Horvat<sup>2</sup>, L. Iyer<sup>2</sup>, R. Swezey<sup>2</sup>, Y. Li<sup>2</sup>, J. Arezzo<sup>3</sup>, K. Draper<sup>1</sup> and J. Mirsalis<sup>2</sup>. <sup>1</sup>CRL DDS Sierra Division, Sparks, NV, <sup>2</sup>SRI International, Menlo Park, CA and <sup>3</sup>Albert Einstein College of Medicine, Bronx, NY.

As part of the national biodefense program, the antibiotic gentamicin sulfate (GS) is being considered for treatment of aerosolized Yersinia pestis, the causative agent of pneumonic, bubonic and septicemic plague. We conducted pharmacokinetics and toxicity studies in African green (AG) monkeys, the efficacy model used for this disease. GS was administered to AG monkeys as a single intramuscular (IM) injection or 20-min intravenous (IV) infusion at doses of 3.0, 4.5, or 6.0 mg/kg or as twice daily IM or IV doses of 1.5, 2.25, or 3.0 mg/kg/dose for 14 days. There were no GS-related clinical signs or changes in food consumption, body weight, serum chemistry, hematology, coagulation or urinalysis parameters. There was no measurable auditory damage following multiple doses as determined by brainstem auditory evoked potential (BAEP). GS-related microscopic alterations were limited to persistent injection site edema and necrosis and reversible, minimal hyaline droplet formation in renal tubular epithelium following multiple IM doses. No adverse effects were seen following IV administration. Following a single dose, mean  $T_{max}$  values ranged from 0.33 to 0.4 hr for all dose levels  $\emph{via}$  IV or IM administration.  $C_{max}$ values ranged from 12.9 to 49.6  $\mu g/ml$  IM and 17.0 to 31.8  $\mu g/ml$  IV at low to high doses. Dose-dependent increases in  $C_{max}$  and AUC values were linear after IM and IV doses, and apparent  $V_z$  values indicated distribution of GS to extravascular tissues. Bioavailability values indicate possible saturation of tissue binding sites at IM doses ≥ 4.5 mg/kg. No major differences in GS PK were observed between males and females. Toxicokinetic evaluations also showed a linear increase in  $C_{\mathrm{max}}$ and AUC with dose on both Days 1 and 14 of dose administration; there were no differences in the PK parameters on these two days. In summary, GS is well tolerated in AG monkeys when administered IV or IM for up to 14 days. Work supported by NIAID Contract N01-AI-05417.

#### 1441

SUBCHRONIC TOXICITY OF ZICONOTIDE ADMINISTERED BY CONTINUOUS INTRATHECAL INFUSION IN RAT AND DOG.

G. M. Shopp<sup>1</sup>, M. J. Skov<sup>1</sup> and <u>T. L. Yaksh<sup>2</sup></u>. <sup>1</sup>Safety Evaluation, Elan Pharmaceuticals, Inc., South San Francisco, CA and <sup>2</sup>Anesthesiology, University of California, San Diego, La Jolla, CA.

Ziconotide (PRIALT<sup>TM</sup>) is the synthetic equivalent of a 25-amino acid, polybasic peptide found in the venom of the marine snail, Conus magus. Ziconotide is a potent and selective N-type calcium channel blocker being developed as an intrathecal (IT) analgesic agent for severe, chronic pain. The potential toxicity of ziconotide was evaluated by continuous IT infusion for 28 days at doses in rats up to 1500 ng/kg/hr and in dogs up to 1200 ng/kg/hr; at least 30-fold the highest expected dose in patients. Mean plasma drug levels measured in high-dose rats and dogs were approximately 3 and 10-fold greater than human, respectively, although overall systemic exposure to ziconotide was low (< 4 ng/mL). Expected treatment-related pharmacological effects on the CNS, consisting mainly of tremors, shaking-behavior and/or ataxia, were of sufficient severity in dogs to require moribund euthanasia in 4/16 animals at ≥ 600 ng/kg/hour. There were no treatment-related changes in body weight, food intake or clinical pathology parameters nor was any target organ toxicity identified in either species at termination. Neurohistopathologic examinations revealed spinal cord compression with associated chronic inflammation in control and ziconotide-treated rats and dogs, which was attributed to pressure exerted by the IT catheter. This finding was not exacerbated with ziconotide exposure and no other histopathologic changes were observed. In conclusion, behavioral and neurological effects observed in rats and dogs receiving 28-day continuous IT infusions of ziconotide appeared related to the pharmacological activity of ziconotide with no associated neurotoxicity or histopathology. Further, no granuloma formation at the catheter tip was observed in ziconotide-treated dogs when infusion site tissue sections were examined, as has been reported with IT morphine administration (Yaksh et al, Anesthesiology 2003; 99:174-87).

## 1442 FORMULATION OF POORLY WATER SOLUBLE DRUGS FOR PRE-CLINICAL TESTING.

B. Rabinow, J. Wong, M. Doty, M. Chaubal, J. Kipp, P. Papadopoulos and J. Kerzee. Baxter Healthcare, Round Lake, IL.

Purpose: A broadly applicable formulation approach for poorly water-soluble drugs is desirable, in order to overcome problems in pre-clinical testing. High drug loading, elimination of interfering solvents, and ability to use the same formulation for both PO and IV administration would optimize progress for lead drug candidates. A nanocrystalline formulation platform has been developed which accomplishes these objectives. Additional advantages include ability to control dissolution rates. Fast dissolution in plasma, results in conventional PK profiles and tissue distribution. Slow dissolution results in targeting of the monocyte phagocytic system, reducing systemic toxicity and enhancing efficacy in some cases, permitting salvage of lead drug candidates. Dissolution rates can be modified depending upon alteration of process parameters. This in turn affects plasma PK profiles and tissue distribution, thus altering efficacy. Experimental: A process was developed that would be broadly applicable to formulate poorly water-soluble drugs. Particle size distribution, stability, X-ray analysis, dissolution rates, pharmacokinetic profiles, tissue distributions and efficacy studies of various drug formulations involving flurbiprofen, budesonide, carbamazepine, tetracaine, and itraconazole were examined. Results: A combined process featuring microprecipitation of water insoluble drugs, followed by homogenization for annealing particle characteristics was refined and developed. Using this approach, the use of co-solvents was eliminated. Stable formulations, maintaining particle size distribution and crystallinity were obtained for the drugs studied at levels up to 10-15% w/v. Conclusions: A formulation platform generally applicable to the rapid formulation of poorly water-soluble drugs has been developed that overcomes many of the impediments to subsequent pre-clinical testing. The same formulation could be used both for IV and PO routes of administration. Novel features include the ability to tune the particle characteristics to modify pharmacokinetics for the purpose of salvaging lead candidates.

### PHIP PRODUCES DNA ADDUCTS FOLLOWING IN SITU PHASE I AND II METABOLISM IN MCF10A CELLS.

R. D. Thomas<sup>1</sup>, M. R. Green<sup>1</sup>, T. A. Kocarek<sup>2</sup> and M. Runge-Morris<sup>2</sup>. <sup>1</sup>Basic Pharmaceutical Sciences, Florida A&M UNiversity, Tallahassee, FL and <sup>2</sup>Institute of Environmental Health Sciences, Wayne State University, Detroit, MI.

Heterocyclic amines (HCAs) are formed when meat products such as beef, chicken, pork and fish are cooked at high temperatures. These amines cause colon, breast, and prostate cancer in rats; liver, lung, and forestomach cancer in mice and have been associated with increased risk of prostate and breast cancer development in humans. 2-amino-1-methyl-6-phenylimidazo[4, 5-b] pyridine (PhIP) is the most

abundant and potent carcinogenic HCA found in food. PhIP produces DNAadducts which lead to mutations and cancer. PhIP is hydroxylated by cytochrome P450 then conjugated by sulfur estrogen transferase to the ultimate carcinogen. Conventionally the first step (N-hydroxylation) occurs in liver and the second step (conjugation) occurs in the breast. We propose that PhIP is completely metabolized to the ultimate toxin in the breast tissue. To test this hypothesis MCF10A cells were treated with PhIP (100 mM) and N-OH-PhIP (100 mM) with and/or without a napthoflavone. DNA from treated cells was isolated and DNA adduct analysis was performed by 32P post-labeling analysis. Results from this study revealed that 100 mM PhIP produces DNA-adducts after 24 hours and N-OH-PhIP produces DNA-adducts as early as 3 hours. Treatment with a napthoflavone inhibited PhIP induced DNA-adducts by 49% but did not inhibit N-OH-PhIP induced DNAadducts. This data demonstrates that the complete bioactivation of PhIP occurs in the breast epithelial cells. It also suggests that Cytochrome P450 1A1 is expressed in the breast epithelial cells at high enough concentrations to metabolize PhIP to N-OH-PhIP. Further studies are on going to determine the role of the sequential metobolism of PhIP in the induction of breast cancer.

COMPARATIVE METABOLISM AND DISPOSITION OF  $1^{-14}$ C- AND 2,  $3^{-14}$ C-ACRYLAMIDE IN CYTOCHROME P450 2E1-NULL (KO) AND WILD-TYPE (WT) MICE.

L. El-Hadri and B. I. Ghanayem. NIEHS/NIH, Research Triangle Park, NC.

Acrylamide (AM) is a heavily produced industrial chemical, which is used to synthesize polyacrylamide for use in paper and textile industries, cosmetics, and in chromatography gels. Presence of AM in baked and fried carbohydrate-rich foods such as french fries, potato chips, bread, and cereals increased fears that human exposure to this chemical is more wide-spread than originally thought. AM is a known animal carcinogen, reproductive toxicant, and a potent neurotoxin. AM is metabolized via 2 competing pathways: conjugation with reduced glutathione and epoxidation to form glycidamide. Glycidamide formation is suspected to be responsible for the induction of toxicity and carcinogenicity by AM. Recent urinary metabolites identification studies demonstrated that CYP2E1 is the principal enzyme responsible for glycidamide formation. Current studies were undertaken to compare the metabolism and disposition of  $1^{-14}$ C-AM and 2,  $3^{-14}$ C-AM using KO and WT mice. AM was administered (IP) to mice at 50mg/5 ml saline/kg. Mice were immediately placed in metabolism cages that allowed for the quantification of expired <sup>14</sup>CO2, organic volatiles, urine, and feces. Animals were euthanized at 24 hr after dosing, and blood and tissues were collected. Preliminary data showed that urine is the primary route of AM elimination and accounted for 24-29 % of 1-14C-AM dose vs. 46-49 % of 2, 3-14C-AM dose regardless of the genotype of the animals. Elimination of AM-derived CO2 accounted for 2-5 % of the administered dose in 24 hr after the administration of either chemical to KO or WT mice. Elimination of AM-derived radioactivity in the feces and in the expired air, as organic volatiles, accounted for less than 1 and 2% of the administered dose in 24 hr, respectively. Further, the concentration of AM-derived radioactivity was significantly higher in the RBCs vs. plasma in all dose groups. Studies are currently in progress to compare the tissue distribution and to identify and quantitate the urinary metabolites of 1-14C-AM and 2, 3-14C-AM in KO and WT mice.

## 1445 METHACRYLONITRILE: EFFECT OF CAFFEINE AND ALCOHOL ON TOXICITY IN MALE SPRAGUE-DAWLEY

M. Farooqui and R. Ruiz. Biology, University of Texas Pan American, Edinburg, TX.

Effect of caffeine and alcohol pre-treatment was studied on the toxicity of methacrylonitrile (MeAN) in male Sprague-Dawley rats. One group of experimental rats received an oral dose of 6 % MeAN solution in corn oil (equivalent to 0.5 LD50). Other three groups of rats were pre-treated with alcohol (2 ml of 50 % solution in water), caffeine (1 ml of 2 % solution in water) or both alcohol and caffeine twelve hours before receiving MeAN dose. The rats were closely observed for mortality, cholinomimetic effects (salivation, lacrimation, vasodilation and diarrhea), central nervous system (CNS) effects (ataxia, trembling, convulsions and irregular breathing) and urinary dysfunction (urine retention in the bladder) for six hours. The cholinomimetic and CNS effects were graded on a scale of 0-4. Three, six and twenty four hours after the treatments the rats were sacrificed under ether anesthesia for collection of blood, liver, kidney and brain. None of the rats died in control group and the group pre-treated with caffeine alone. Three out of ten rats died with MeAN alone and 5 out of ten each died in rats pre-treated with alcohol alone and alcohol + caffeine. Alcohol and alcohol + caffeine pre-treatment caused significant increase (2-4 fold) in cholinomimetic, CNS and urinary dysfunction effects of MeAN. However, caffeine alone pre-treatment protected rats from any of these effects. These results suggest that alcohol pre-treatment enhanced metabolism of MeAN to cyanide resulting in a significant increase in CNS effects even in the presence of caffeine. This effect may be through enhancement of microsomal activity for the metabolism of MeAN to cyanide. Čaffeine appears to provide protection

probably through inhibition of microsomal metabolism of MeAN to cyanide. (Supported by NIH South Texas Doctoral Bridge Program Grant # 2 R25GM50080).

### 1446

HYDROLYSIS OF ISOEUGENYL-ACETATE AND EUGENYL-ACETATE BY RAT AND HUMAN HEPATIC MICROSOMES

D. J. Castro, C. J. Sweet, <u>R. K. Kuester</u> and <u>G. Sipes</u>. *Pharmacology and Center for Toxicology, University of Arizona, Tucson, AZ.* 

Isoeugenyl-acetate (IA) and eugenyl-acetate (EA) are fragrance materials and flavoring agents that are also esters of the fragrance/flavor materials, isoeugenol and eugenol. If the hydrolysis of these esters is rapid and complete, the existing toxicity profiles for isoeugenol and eugenol should be appropriate for the safety assessment of IA and EA. This study quantified the rate of hydrolysis of these esters in rat (male SD) and human hepatic microsomes. Incubation of IA or EA (500  $\mu$ M) with microsomal protein (0.0125 mg/ml) revealed that hydrolysis was complete within 15 min of incubation. Kinetic analysis of the hydrolytic reaction in hepatic microsomes (4.8 to 970 µM, 3.0 min incubation) yielded the following kinetic constants for IA: Vmax of 3822-(rat), 3795-(human male) and 3072-(human female) nmol/min/mg of protein; Km ( $\mu$ M) of 91-(rat), 72-(human male) and 51-(human female). For EA the kinetic values were: Vmax of 3829-(rat), 3656-(human male) and 2748-(human female) nmol/min/mg of protein; Km (µM) values were 97-(rat), 72-(human male) and 52-(human female). Preliminary results demonstrate that rat plasma and preparations of rat skin also readily hydrolyze these esters into their respective alcohols. This extensive hydrolysis of IA and EA by liver, plasma, and skin enzymes will minimize systemic exposure of these agents when used under appropriate conditions as fragrance/flavoring materials. This research was supported by the Research Institute for Fragrance Materials and the Southwest Environmental Health Sciences Center (ESO6694).

## 1447 EFFECTS OF ROXARSONE AND ITS METABOLITES ON CACO-2 CELL PROLIFERATION.

G. S. Bayse<sup>1</sup>, <u>W. G. Kirlin</u><sup>2</sup> and P. D. Kirkland<sup>1</sup>. <sup>1</sup>Chemistry, Spelman College, Atlanta, GA and <sup>2</sup>Pharmacology & Toxicology, Morehouse School of Medicine, Atlanta, GA.

Roxarsone (4-hydroxy-3-nitrobenzenearsonate) is a poultry feed additive used routinely since the 1960's with FDA approval, for prevention of microbial infections and for growth promotion. In excess of 90% of the additive is excreted unchanged and the massive amounts (>2 million lbs/year) added to waterways, especially from giant farm operations, have brought expressions of concern both from USGS and from USEPA. Literature reports indicate that reduced roxarsone (3-amino-4-hydroxybenzenearsonate;AHBA) is formed by microbial and geologic action, and is found in groundwater and in sediments; a proposed azobenzene derivative has been described, as well. The human intestinal cell line, Caco-2, was synchronized in culture prior to exposure to roxarsone, AHBA, and acetarsone (3-N-acetylamino-4hydroxybenzene-arsonate), as well as to inorganic arsenite (AsIII) and arsenate (ÅsV). The cells' proliferative response to the arsenic compounds was determined by tritiated thymidine incorporation into DNA. At micromolar levels, except in the case of AsIII, proliferation of cells was increased significantly when compared to growth of controls. AsIII is a potent inhibitor of proliferation at the same level. These results indicate potential mutagenesis effects of the organoarsenicals and AsV, and toxicity of AsIII. Related in vitro studies in our laboratory have shown the N-acetylation of AHBA to acetarsone, catalyzed by human N-acetyl- transferase. The acetarsone product was detected in two independent HPLC systems by comparison with a commercial standard. In addition, preliminary experiments indicate that human CYP3A4 catalyzes oxidation of AHBA, as determined by NADPH disappearance and by product appearance in the 430nm spectral region. Thus, bioactivation of AHBA and related metabolites may be involved in the Caco-2 cell proliferation observed. (Support:RIMI RR11598;MBRS/RISE 1R25GM-6056601;RCMI RR03032;MBRS/GM-029248).

#### 1448

EPOXIDATION OF COUMARIN IS THE MAJOR DETERMINANT OF COUMARIN-INDUCED CLARA CELL TOXICITY IN THE MOUSE.

J. D. Vassallo and <u>G. P. Daston</u>. Central Product Safety, Procter & Gamble, Cincinnati, OH.

Coumarin causes Clara cell toxicity in the mouse. We hypothesized that this effect is caused by metabolism of coumarin to coumarin 3, 4-epoxide (CE), which spontaneously rearranges to o-hydroxyphenylacetaldehyde (o-HPA), a cytotoxic metabolite. The purpose of the present work was to characterize the metabolism of

coumarin in mouse (susceptible), rat (not susceptible) and human lung. In B6C3F1 mouse lung microsomes, coumarin was metabolized in the absence of glutathione to o-HPA with a Km of 155 µM and a Vmax of 7.3 nmol/min/mg of protein. In the F344 rat, where no toxicity is observed, the Km and Vmax were 2574  $\mu\text{M}$  and 1.75 nmol/min/mg protein, respectively. Since the intrinsic clearance was 69-times higher in the mouse, the epoxidation was shown to correlate with speciessensitivity to toxicity. Metabolism of coumarin to o-HPA did not occur in sixteen different human lung microsomes indicating human lung is likely resistant to the toxic effect of coumarin. In order to determine whether detoxification reactions contribute to species differences in toxicity, the fate of CE and o-HPA were also determined. Detoxification of CE via conjugation with glutathione was examined in lung microsomes containing cytosol and the Km of this reaction was  $827~\mu\text{M}$  and 751 µM in mice and rats, respectively. Detoxification of o-HPA via oxidation to ohydroxyphenylacetic acid (o-ĤPAA) was also examined in lung cytosol and the Km of this reaction was 1.5 µM and 1.4 µM in mice and rats, respectively. Since the detoxification pathways of CE and o-HPA were similar between mice and rats these reactions do not predict species sensitivity to coumarin. Instead, lung toxicity correlates with the rate of epoxidation, and this is different from the liver in that detoxification pathways do not appear to play an important role in determining toxicity. Furthermore, human lung microsomes did not metabolize coumarin to the epoxide suggesting that humans are unlikely to show lung toxicity following human expo-

IN VITRO METABOLISM OF ERGOTAMINE BY MOUSE LIVER MICROSOMES FROM ENDOPHYTE SUSCEPTIBLE AND RESISTANT BREEDING LINES.

J. M. Duringer<sup>1</sup>, R. M. Lewis<sup>2</sup>, L. A. Kuehn<sup>2</sup>, T. J. Fleischmann<sup>1</sup> and M. Craig<sup>1</sup>.

<sup>1</sup>Biomedical Sciences, Oregon State University, Corvallis, OR and <sup>2</sup>Animal and Poultry Sciences, Virginia Polytechnic Institute and State University, Blacksburg, VA.

Fescue toxicosis causes significant economic losses to livestock production. Clinical signs include summer syndrome, fescue foot and fat necrosis. All disorders are associated with decreased average daily weight gains and reproductive efficiency. Research on livestock tall fescue toxicoses strongly implicates the ergopeptine alkaloids as the toxic moiety. Mice from lines previously selected for resistance or susceptibility to growth depression from endophyte-infected (E+) fescue seed diets were used in these experiments. Mice were fed a diet containing endophyte-free (E-) seed for two weeks followed by two weeks of E+ or E- seed. Metabolism of ergotamine, a representative ergot alkaloid, was analyzed by HPLC using liver microsome preparations from the experimental groups. During the first two weeks, gender differences were observed for the transformation of metabolites 1 (M1 and M1,), 3, 4 and 5 and ergotamine (ET and ET,). After challenge with the E+ diet, differences were seen for line and gender for metabolite 3 and for gender for metabolites 4, 5, and ergotamine (ET and ET). The finding of gender differences in metabolism of ergotamine has not been reported in this mouse line or in other species used to study ergot alkaloid metabolism. This adds a potential source of variation in the development of fescue toxicosis and would be of value to investigate further in terms of livestock management practices. Metabolites were then isolated by sequential chromatographic procedures and identified by mass spectroscopy (MS). Results of MS analysis showed a metabolite consistent with epimerization of ergotamine and four components consistent with hydroxylation of ergotamine. The site of hydroxylation was consistent with oxidation of the peptine portion of the molecule with no evidence of oxidative transformation of the lysergic acid half of the molecule.

### 1450 METABOLISM OF VINCLOZOLIN AND ITS METABOLITES IN RAT.

A. Sierra-Santoyo<sup>1</sup>, R. A. Harrison<sup>2</sup>, H. A. Barton<sup>2</sup> and M. F. Hughes<sup>2</sup>.

<sup>1</sup>TOXICOLOGY, CINVESTAV-IPN, Mexico City, D.F., Mexico and <sup>2</sup>ETD, NHEERL, ORD, , USEPA, Research Triangle Park, NC.

Vinclozolin (V) is a fungicide used in agricultural settings. V administered to rats is hydrolyzed to 2-[[(3, 5-dichlorophenyl)-carbamoyl]oxy]-2-methyl-3-butenoic acid (M1), 3'5'-dichloro-2-hydroxy-2-methylbut-3-enanilide (M2), and 3, 5-dichloroaniline (M3). V, M1 and M2 have antiandrogenic properties by interacting with the androgen receptor. However, data on disposition of V, M1 and M2 is limited. Our objective was to study the metabolism of V, M1 and M2 in vitro and in vivo. Non-treated adult male Long-Evans rat liver microsomes (2 mg) were incubated (30 min, 37°C) in 0.1 M phosphate buffer (PB) pH 7.4, 5 mM MgCl<sub>2</sub>, 2 mM NADPH with V (50  $\mu$ M), M2 or M1 (200  $\mu$ M). Rats were administered a single po dose of V (100 mg/Kg) in corn oil. Animals were sacrificed (24 h) and serum and liver were removed and analyzed for V and metabolites. Metabolites from enzyme reactions and serum and liver were extracted in acetonitrile after dilution of samples in PB pH 3.3 (1:4) and analyzed by HPLC/DAD/MS. M1 and M2 formation was evident from V chemical hydrolysis. Another product was observed

from V and M2 *in vitro* metabolism. This metabolite, in both cases had the same  $t_{\rm ret}$  and using UV/Vis spectrum and negative ESI mass spectra ([M] at m/z 294 and [M-H] at m/z 293) was identified as 3', 5'-dichloro-2, 3, 4-trihydroxy-2-methylbutylanilide (M4). M3 was detected only from M2 but its formation was not NADPH-dependent. No metabolites from M1 were detected. Analysis of serum and liver extracts of treated rats showed the presence of M4, M1 and V. M4 levels were at least 5- and 9-fold higher in serum and liver, respectively, than M1 or V. These results indicate that metabolism of V is both enzymatic and non-enzymatic. M4 is an abundant metabolite of V, and may be used as an exposure biomarker for pharmacokinetic modeling of V. These results may clarify the relationship between toxicity and tissue dose of V and its metabolites. (Funded in part by NRC CR 828790. This abstract does not represent USEPA policy).

## 1451 *IN VITRO* METABOLISM OF CARBOFURAN BY HUMAN, MOUSE, AND RAT LIVER MICROSOMES, AND HUMAN CYTOCHROME P450 ISOFORMS.

K. A. Usmani, E. Hodgson and R. L. Rose. Environmental & Molecular Toxicology, North Carolina State University, Raleigh, NC.

Carbofuran is a widely used carbamate pesticide in agricultural practice throughout the world. Its effect as a pesticide is due to its ability to inhibit acetylcholinesterase activity. The present study was designed to investigate the in vitro metabolism of carbofuran by pooled human liver microsomes (HLM), rat liver microsomes (RLM), mouse liver microsomes (MLM), and human cytochrome P450 (CYP) isoforms. Carbofuran is metabolized by CYPs leading to the production of a major ring oxidation metabolite, 3-hydroxycarbofuran, and two minor metabolites. Pooled HLM have a significantly higher Km value (1950  $\mu\text{M})$  than RLM Km (210 μM) and MLM Km (550 μM) for metabolism of carbofuran to its major metabolite, 3-hydroxycarbofuran. Intrinsic clearance rate calculations indicate that HLM metabolize carbofuran to 3-hydroxycarbofuran almost 14-fold lower than RLM and MLM. Among 16 human cDNA-expressed CYP enzymes examined, CYP3A4 and 2C19 were the major isoforms responsible for carbofuran metabolism to 3-hydroxycarbofuran. Use of phenotyped HLM demonstrated that individuals with high levels of CYP3A4 and 2C19 have the greatest potential to metabolize carbofuran to its major metabolite. The variation in carbofuran metabolism among 17 single-donor HLM samples is over 5-fold and the best correlation between CYP isoform activity and carbofuran metabolism was observed with CYP3A4. (Supported by NIOSH grant OH07551-ECU)

## 1452 COMPARISON OF DETOXIFICATION AND BIOACTIVATION PATHWAYS FOR BROMODICHLOROMETHANE IN THE RAT.

M. K. Ross<sup>1</sup>, C. R. Eklund<sup>2</sup> and R. A. Pegram<sup>2</sup>. <sup>1</sup>Curriculum in Toxicology, UNC-CH, Chapel Hill, NC and <sup>2</sup>ETD, USEPA, Research Triangle Park, NC.

Bromodichloromethane (BDCM) is metabolized via high-(CYP2E1) and low-(GSTT1) affinity pathways. The CYP2E1 pathway is thought to be a detoxification pathway at low concentrations. The GST pathway produces a labile genotoxic intermediate that is unlikely to escape from within cells where it is formed. Evidence for GSTT1-specific metabolism is supported by experiments which demonstrate that BDCM competitively inhibits GSTT1 activity toward the model substrate 1, 2-epoxy-3-(4-nitrophenoxy)propane (ENPP) (Ki = 4.2 mM). The flux of BDCM through the CYP2£1- and GSTT1-pathways has been investigated in vitro in nontarget (liver) and cancer target tissues (kidney and large intestine) of the F344 rat. Compared to the liver, the intrinsic clearance (Vmax/Km) of BDCM *via* CYP-metabolism in target tissues was significantly reduced (8- and 16-fold for kidney and large intestine, respectively) while GST-metabolism in the same tissues was only slightly lower (-2-3-fold), suggesting less efficient detoxification particularly at high tissue concentrations of BDCM that saturate CYP2E1. The kinetic parameters of GSTT1 metabolism in liver and kidney have been incorporated into a previously published rat PBPK model for BDCM. Model simulations following constant inhaled exposures to BDCM indicate that CYP is the dominant pathway in liver and kidney following low inhaled concentrations; however, at high inhaled concentrations, the flux through CYP2E1 in kidney becomes saturated and the GSTT1 pathway becomes more pronounced than ĆYP in terms of total flux (at 3200 ppm, 235 mg BDCM metabolized by CYP2E1/liter per 6 h compared with 265 mg BDCM metabolized by GSTT1/liter per 6 h). Model simulations of oral doses in the dose range used in the cancer bioassay study do not result in saturation of hepatic or kidney CYP2E1 and thus flux through the GST pathway is limited. The model simulations suggest that greater genotoxic outcomes from BDCM exposure may occur from the inhalation route rather than the oral route. (Does not reflect USEPA policy. Supported by F32 ES11111-01).

## 1453 EFFECT OF DIMETHYL SULFOXIDE ON METABOLISM AND TOXICITY OF MODEL HEPATOTOXICANTS IN

M. Yoon<sup>1, 2</sup> and <u>Y. Kim<sup>2</sup></u>. <sup>1</sup> Research Associateship Program, National Research Council, Chapel Hill, NC and <sup>2</sup> College of Pharmacy, Seoul National University, Seoul, South Korea.

Effect of dimethyl sulfoxide (DMSO) pretreatment on the metabolism and hepatotoxicity of several model hepatotoxicants including acetaminophen, chloroform and carbon tetrachloride was examined in adult mice. Administration of DMSO (2.5 ml/kg, ip) decreased acetaminophen and chloroform-induced hepatotoxicity, but not the hepatotoxicity of carbon tetrachloride as measured by elevation of serum alanine aminotransferase and sorbitol dehydrogenase activities. Hepatic microsomal metabolizing enzyme activities were depressed by DMSO, but hepatic CYP2E1 activity measured with p-nitrophenol as a substrate was increased to 144% of control. In vitro study using hepatic microsomes showed that the metabolic degradation of acetaminophen, dichloromethane or chloroform was all inhibited by addition of DMSO, however, metabolism of carbon tetrachloride was not affected. Lineweaver-Burk plot analysis of acetaminophen metabolism in vitro indicated that the inhibition pattern produced by addition of DMSO was competitive in nature. To explain the observation that DMSO decreased the hepatotoxicity of acetaminophen and chloroform despite significant induction of CYP2E1 activity, a reconstituted enzyme study was conducted employing a hepatic microsomal fraction reconstituted with a hepatic cytosolic fraction each prepared from DMSOtreated or control animals. The metabolic degradation of acetaminophen, dichloromethane and chloroform was greater in a system containing cytosolic fraction from control mice (DMSO-free) plus microsomes from DMSO-treated mice than a system with control microsomes. However, addition of DMSO-present cytosol to microsomes from DMSO-treated animals failed to increase the metabolic degradation of these chemicals. This result suggests that the direct inhibitory activity of DMSO on metabolism of model hepatotoxicants be responsible for the reduction of hepatotoxicity. Competition of DMSO and model hepatotoxicants for CYP2E1 appears to play an important role here.

## 1454 METABOLISM OF ORALLY ADMINISTERED N, N-DIMETHYL-P-TOLUIDINE (DMPT) IN F344 RATS AND B6C3F1 MICE.

K. Ghanbari, K. J. Dix, D. Kracko and J. McDonald. *Toxicology, Lovelace Respiratory Research Institute, Albuquerque, NM.* 

DMPT is a high-production-volume chemical used in the manufacture of bone cements and dental materials, is found in industrial glues and artifical fingernail preparations, and is used as an intermediate in dye and pesticide synthesis. Human exposure to DMPT has resulted in methemoglobinemia and allergic responses; suspected from the formation of a toxic metabolite, p methylphenylhydroxylamine, an analog of the aniline metabolite phenylhydroxlyamine (thought to be responsible for methemoglobinemia from aniline exposure). We have previously reported results of disposition studies of DMPT in Fisher 344 (F344) rats and B6C3F1 mice after oral administration of [14C]DMPT. The majority of [14C]DMPT-derived radioactivity was excreted in urine by 24 hours. Here we report on the metabolism of orally administered DMPT. The profile of radiolabeled metabolites was determined by liquid chromatography (HPLC) using a C18 stationary phase and a mobile phase that transitioned from mostly water (polar) to mostly organic (neutral). The same four radiolabeled chromatographic peaks were observed in both rats and mice. Due to the limited volume of mouse urine, further work to elucidate the DMPT metabolite structures was performed with rat urine only. All four peaks have been isolated and preliminary structural elucidation by gas chromatography/mass spectrometry (GC/MS) and comparison to authentic standards confirmed excretion of the parent compound. We have tentatively identified a second peak by GC/MS as N-methyl-p-toluidine. A third peak had different HPLC and GC retention times than DMPT but an identical electron impact mass spectrum. Attempts at preliminary identification of the most polar metabolite have been unsuccessful. Further purification coupled with infrared and nuclear magenetic resonance spectroscopy will be employed along with incubation of isolated metabolites with glucuronidase and sulfatase enzymes (to assess conjugation) to complete structural elucidation/confirmation. Supported by NIEHS.

## 1455 SUBSTRATE SPECIFICITY OF THE INDIVIDUAL RAT UGT1A FAMILY OF ENZYMES.

L. J. Webb, F. K. Kessler and J. K. Ritter. Pharmacology and Toxicology, Virginia Commonwealth University, Medical College of Virginia Campus, Richmond, VA.

UDP-glucuronosyl transferases (UGT) are phase II enzymes that contribute to the elimination of xenobiotic substances and drugs. UGTs are expressed in a variety of tissues and play a major role in their metabolic activities. Due to the overlapping

substrate specificity of these enzymes, it is difficult to determine exactly which isoforms contribute to the glucuronidation of specific substrates. To this end, in vitro systems, adenovirus infected COS-7 cells or transfected HEK cells, individually expressing rat UGT1A1, UGT1A2, UGT1A3, UGT1A5, UGT1A6, UGT1A7 and UGT1A8 were developed. Using thin layer chromatography, the glucuronidating activity of each enzyme was examined for the following substrates: bisphenol A, naphthol, p-nitrophenol, hydroxybiphenyl, 4-methyl-umbelliferone, 7-hydroxycoumarin, phenol red (phenols), chrysin, quercetin, (-)epicatechin, dinitrocatechol (flavonoids/catechols), 16α-hydroxy-pregnenolone, 4-hydroxyestradiol, testosterone, estradiol, estriol, estrone, ethylnylestradiol (steroids), propofol, t-butylated hydroquinone, butylated hydroxytoluene (butylated), serotonin, buprenorphine, acetaminophen, and mycophenolic acid (drugs). In addition, a <sup>14</sup>C-UDPGA assay was utilized to determine the activity of these UGT forms towards bilirubin. It was found that most substrates were glucuronidated by multiple UGT isoforms. However, certain substrates were primarily glucuronidated by specific isoforms: bisphenol A, quercetin, (-)epicatechin, estriol, and propofol by UGT1A7; serotonin by UGT1A6; and bilirubin by UGT1A1. Several substrates, phenol red, testosterone and butylated hydroxytoluene, were not glucuronidated by any of the UGT1A isoforms studied. In conclusion, while many UGT1A isoforms have overlapping substrate specificities, unique substrate-isoform relationships can be determined. Further identification of these relationships could enable their use in in vitro and in vivo UGT1A inhibition and metabolic probe studies. (Supported by 1R01ES07763 from the NIEHS.)

INVESTIGATION OF UDP-GLUCURONOSYLTRANSFERASES INVOLVED IN GLUCURONIDATION OF MYCOPHENOLIC ACID IN RATS

K. Miles<sup>1</sup>, S. Stern<sup>2</sup>, F. Kessler<sup>1</sup>, <u>P. Smith</u><sup>2</sup> and <u>J. Ritter</u><sup>1</sup>. <sup>1</sup>Pharmacology and Toxicol., VCU, Richmond, VA and <sup>2</sup>Drug Deliv. and Dispos., UNC, Chapel Hill, NC

UDP-Glucuronosyltransferases (UGTs) glucuronidate a wide array of substrates. Mycophenolic acid (MPA), the active metabolite formed from Mycophenolate Mofetil, is primarily metabolized by glucuronidation and undergoes enterohepatic recycling. This may lead to increased intestinal exposure levels and associated gastrointestinal (GI)-toxicity. The mechanism responsible for this GI-toxicity is unknown. Intestinal UGT expression is hypothesized to modulate this phenomenon. The objectives of this study were to evaluate the UGT isoforms that are active in MPA metabolism in rats, and assess the potential roles of these forms in hepatic, renal, and intestinal MPA glucuronidation. Liver microsomes from homozygous Gunn j/j rats exhibited marked decreases in MPA glucuronidating activity. Recombinant rat UGT1A isoforms were expressed in HepG2 cells and membrane fractions were prepared and used for MPA activity assays. Rat UGT1A1, 1A6, and 1A7 but not 1A2, 1A3, 1A5, and 1A8 possessed MPA activity with Gunn rat liver microsomes exhibiting lower activity. The apparent Km (mM) values of: 0.446, 0.655, 0.511 and Vmax (mmol MPAG/min/mg) values of: 4.48 x 10<sup>-7</sup>, 1.84 x 10<sup>-7</sup> , and 1.1 x 10<sup>-6</sup> were determined for 1A1, 1A6, and 1A7, respectively. Intrinsic clearance (CL<sub>int</sub>) values (mL/min/mg) of 1.0, 0.28, and 2.15 were determined for 1A1, 1A6, and 1A7, respectively. CL<sub>int</sub> for 1A7 was 2.2-fold higher than 1A1 and 7.7-fold higher than 1A6. Rat microsomes from liver, kidney, and intestine were analyzed for 1A1, 1A6, 1A7, and total UGT1A relative levels and MPA glucuronidating activity. All three isoforms were detected in each tissue. 1A1 levels were highest in liver whereas 1A7 was highest in intestine. In addition, MPA glucuronidating activity was highest in intestine when compared to the other tissues examined. These findings, suggest that multiple isoforms may be involved in modulating MPA-related GI-toxicity in rat. However, 1A7 may be particularly important in intestinal MPA glucuronidation. Supported by NIGMS grant 1R01GM61188.

### 1457 THYROID HORMONE METABOLISM IN SPRAGUE DAWLEY AND UGT2B2-DEFICIENT FISCHER 344 RATS.

T. A. Couch<sup>2, 1</sup> and C. D. Klaassen<sup>2</sup>. <sup>1</sup> Pharmacology, Emory University, Atlanta, GA and <sup>2</sup> Pharmacology, Toxicology and Therapeutics, University of Kansas Medical Center, Kansas City, KS.

Microsomal enzyme inducers (MEI) that increase UDP-glucuronosyltransferases (UGTs) can significantly affect the hypothalamic-pituitary-thyroid axis and thyroid hormone (TH) homeostasis. Increased TH glucuronidation by UGTs can lead to reductions in serum TH, and an increase in thyroid stimulating hormone (TSH). Of the many UGT isoforms, UGT2B2 is thought to glucuronidate triiodothyronine (T3). The purpose of this research was to determine whether increased T3 glucuronidation mediates increased TSH observed after MEI treatment. Male Sprague-Dawley (SD) and UGT2B2-deficient Fischer 344 (F344) rats were fed control diet or diet containing pregnenolone-16a-carbonitrile (PCN; 800 ppm), 3-

methylcholanthrene (3-MC; 200 ppm), or Aroclor 1254 (PCB; 100 ppm) for 7 days. Free and total thyroxine (T4), T3, TSH, androsterone/T4/T3 glucuronidation, and thyroid follicular cell proliferation were determined. PCN, 3-MC, and PCB treatments decreased serum T4, whereas serum T3 was generally maintained in both SD and F344 rats. T4 *in vitro* glucuronidation increased after MEI treatment: PCN (417 and 436 %), 3-MC (207 and 174 %), and PCB (327 and 324 %) in livers from SD and F344 rats, respectively, as compared to controls. Only PCN treatment significantly increased T3 *in vitro* glucuronidation (281 and 497 %) in livers from SD and F344 rats, respectively, despite little or no UGT2B2 activity present in F344 rats (as shown by androsterone glucuronidation). In both rat strains, PCN treatment increased serum TSH (160 and 379 %), and thyroid follicular cell proliferation (as shown by labeling index). These data demonstrate a strong correlation between increases in T3 glucuronidation, TSH, and follicular cell proliferation after PCN treatment. These data also suggest that, T3 is glucuronidated by other PCN-inducible UGTs in addition to UGT2B2. (Supported by NIEHS grants ES-08156 and ES-07079).

### 1458 IN VITRO CONJUGATION OF ETHANOLAMINE WITH FATTY ACIDS

S. H. Khan, B. S. Khaphalia and G. Ansari. Pathology, UTMB, Galveston, TX.

Previous studies from our laboratory have shown the enzymatic formation of fatty conjugates of alcohols and amines. Present study describes the formation of fatty acid conjugates of a bifunctional compound, ethanolamine. The choice of ethanolamine is based on its endogenous presence and known formation of annandamide (a bioactive arachidonic acid amide of ethanolamine). Ethanolamine has the possibilities of conjugating with fatty acids through ester and/or amide bonds. [1-14C]-Oleic acid was incubated with ethanolamine at 370C in presence of any C]-Oleic acid was incubated with ethanolamine at 370C in presence of rat liver post nuclear fraction. The resultant product(s) was separated by thin layer chromatography and the radioactivity corresponding to the relative flow of amide/ester was evaluated. The rate of formation of oleic acid conjugate(s) of ethanolamine was time- and dose-dependent. The optimum formation of ethanolamine conjugate was 16.4±1.7mol/hr/mg protein at 25mM ethanolamine and 1mM oleic acid. Formations of conjugates with other fatty acids (palmitic, stearic, linoleic, linolenic and arachidonic) were also found to be 6.25±0.09, 6.6±1.7, 5.9±0.93, 5.8±0.85 and 6.4±0.32 nmol/hr/mg protein, respectively, using different [1-14C] fatty acids. These results indicate formation of fatty acid conjugates of ethanolamine. However, the structure of the compound formed needs to be established. Efforts to purify the product in sufficient quantities for spectral analysis and characterization of the enzyme responsible for the synthesis are under way.

1459

CHARACTERIZATION OF THE PHASE 2 METABOLITES OF RUTAECARPINE AS GLUCURONIDE/SULFATE CONJUGATES BY LIQUID CHROMATOGRAPHY-ELECTROSPRAY IONIZATION TANDEM MASS SPECTROMETRY.

S. Lee<sup>1</sup>, D. Lee<sup>1</sup>, J. Lee<sup>2</sup>, D. Kim<sup>2</sup>, E. Lee<sup>1</sup>, Y. Jahng<sup>1</sup> and <u>T. Jeong</u><sup>1</sup>. <sup>1</sup>Pharmacy, Yeungnam University, Kyungsan, Kyungbuk, South Korea and <sup>2</sup>Bioanalysis and Biotransformation Research Center, KIST, Seoul, South Korea.

From previous studies on the phase 1 metabolism of rutaecarpine, the metabolites formed were identified as products of hydroxylation on the aromatic rings. In the present studies, phase 2 metabolites of rutaecarpine in vivo and in vitro were studied in order to determine the possible metabolic fate of rutaecarpine by using highperformance liquid chromatography/electrospray ionization-tandem mass spectrometry. An in vitro incubation of rutaecarpine in isolated rat hepatocytes produced six main metabolites, corresponding to glucuronide/sulfate conjugation. When hepatocytes were incubated with 50  $\mu M$  rutaecarpine for up to two hours, two metabolites (U1 and U2) formed were believed to be glucuronidated on the aromatic ring of the indole moiety. Other four metabolites (S1, S2, S3 and S4) were sulfate-conjugated on the aromatic ring of the indole moiety. Characteristic product ions for the identification of glucuronide/sulfate conjugates were observed at m/z 304, indicating the hydroxylated form of the aromatic ring of indole moiety. The main rutaecarpine metabolites in vivo were represented by two groups of compounds. One group was equal to the in vitro metabolism, i.e, glucuronidated conjugates (U1 and U2). The serum concentration of glucuronide conjugates reached a maximum two hour after the administration. The other group was identified as three sulfated conjugates (S'1, S'2 and S'3), but these were not equal to the in vitro metabolism, because they had different retention times from liquid chromatography. The serum concentration of this group reached a maximum one hour after administration. Therefore, it was concluded that the metabolism of rutaecarpine in vivo and in isolated hepatocytes would be somewhat different. SUBCELLULAR LOCALIZATION OF SOLUBLE EPOXIDE HYDROLASE IN HUMAN TISSUES USING CONFOCAL MICROSCOPY.

A. Enayetallah<sup>1</sup>, <u>D. F. Grant</u><sup>1</sup> and M. Barber<sup>2</sup>. <sup>1</sup>Pharmaceutical sciences, University of Connecticut, Storrs, CT and <sup>2</sup>BIOTECHNOLOGY / BIOSERVICES CENTER, UNIVERSITY OF CONNECTICUT, AT STORRS, CT.

Soluble epoxide hydrolase (sEH) is considered a phase I xenobiotic metabolizing enzyme, however, its physiological roles have not been clearly identified. Endogenous substrates include linoleic acid and arachidonic acid epoxides, some of which have been suggested to be involved in regulating blood pressure and inflammation. Following the documentation that sEH was not microsomal epoxide hydrolase (mEH), it was suggested to be mitochondrial. However, the enzyme was later shown to have a peroxisomal targeting sequence (PTS), and subsequent studies suggested that sEH was exclusively peroxisomal, or both cytosolic and peroxisomal. Previously, we studied the distribution of soluble epoxide hydrolase in normal and malignant human tissues using immunohistochemistry techniques. Interestingly, we found sEH in cells devoid of peroxisomes. In this study, we applied immunofluorescence and confocal microscopy techniques using markers for different subcellular compartments to evaluate sEH co-localization in an array of human tissues. Results showed that sEH is both cytosolic and peroxisomal in some tissues, and exclusively cytosolic in other tissues. We also show that it is not exclusively peroxisomal in any of the tissues included in this study. These data suggest that sEH contains a context dependent PTS, or there exists an sEH enzyme variant responsible for the dual localization.

THE *IN VITRO* INHIBITION OF DIETHYLSTILBESTROL-DNA ADDUCTS BY DIALLYL SULFIDE: A POSSIBLE MECHANISM OF BREAST CANCER PREVENTION.

M. R. Green, C. L. Wilson, M. McCaskill and R. D. Thomas. Basic Pharmaceutical Sciences, Florida A&M UNiversity, Tallahassee, FL.

Estrogen related cancer is the second leading cause of death in women. The biotransformation of estrogen is a critical factor in the initiation of estrogen-induced cancer. It has been demonstrated that diethylstilbestrol (DES), a stilbene estrogen, is biotransformed to reactive chemicals that produce DNA Adducts. Diallyl sulfide (DAS), a potent chemopreventive compound found in garlic, has been shown to inhibit the biotransformtion of several procarcinogens such as benzo(a)pyrene and dimethylbenzsanthracine (DMBA). We propose that DAS will prevent DES induced breast cancer by inhibiting its biotransformation. This biotransformation leads to the formation of DNA adducts which results in cancer initiation. To test this hypothesis, we investigated the ability of DES to produce DNA adducts in the presence of microsomes, mitochondria, and nuclei in vitro metabolic systems. We also investigated the ability of DAS to inhibit DNA adduct formation. Microsomes, mitochondria, and nuclei were isolated from breast tissue of female ACI rats. These organelles were used to catalyze in vitro reactions containing DES and/or DAS, cumen hydroperoxide and 200mg DNA buffered with phosphate buffer at pH 7.4. The DNA was extracted and analyzed by P32 post labeling. We found that DES produced DNA adducts in all three systems. The relative adduct level was 2.2 x 10-4 in microsomal reactions, 6.2 x 10-6 in mitochondrial reactions, and 2.9 x 10-7 in nuclear reactions. DAS was able to inhibit DES induced DNA adducts in all three systems. The percent inhibition ranged from 86% in the microsomes to 93% in the nuclei. These findings suggest that DAS could inhibit DES induced breast cancer by inhibiting its metabolism. This inhibition may help explain the mechanism of the chemopreventive actions of DAS. Supported by DOD Grant # BC011376

## 1462 COMPARATIVE BIOSYNTHESIS OF FATTY ACID ETHYL ESTERS IN AR42J CELLS AND HEPG2 CELLS.

B. S. Kaphalia<sup>1</sup>, H. Wu<sup>1</sup>, D. L. Clemens<sup>2</sup>, T. R. Jerrells<sup>2</sup>, M. Khan<sup>1</sup> and G. Ansari<sup>1</sup>. <sup>1</sup>Pathology, University of Texas Medical Branch, Galveston, TX and <sup>2</sup>Pathology and Microbiology, University of Nebraska Medical Center, Omaha, NE.

Nonoxidative versus oxidative metabolism of ethanol is altered during chronic alcohol abuse due to inhibition of hepatic alcohol dehydrogenase (ADH, catalyzes the oxidation of alcohols). Previous studies have shown inhibition of ADH in chronic alcoholics and in rats subchronically exposed to ethanol, and significantly increased biosynthesis of fatty acid ethyl esters (FAEEs; nonoxidative metabolites of ethanol) in rats. Hepatic and pancreatic toxicity of some of these esters have also been reported *in vivo* as well as *in vitro*. Therefore, present study was undertaken to evaluate comparative biosynthesis of FAEEs 6 hr after 100-800 mg% ethanol exposure in rat pancreatic tumor (AR42J) cells and human hepatocellular carcinoma (HepG2) cells with or without ADH transfection. The FAEE levels in the AR42J cells (56 nmol/25 x 106 cells) were found to be significantly higher than those in

 $HepG2\ cells\ (45\ nmol/25\ x\ 106\ cells).$  A three-fold increase of FAEE levels detected in  $HepG2\ cells\ (ADH-deficient)$  as compared to  $HepG2\ cells$  transfected with ADH suggests role of nonoxidative metabolism in disposition of ethanol during chronic alcoholism.  $HepG2\ cells$  transfected with cytochrome 450 2E1 had comparable levels of FAEEs to those found in the  $HepG2\ cells$ , indicating its limited role in oxidation of ethanol. The results of the present study suggest increased formation of FAEEs during chronic alcoholism and pancreas is a preferred organ system involved in such a metabolism. Although formation of FAEEs was found to be dose-dependent irrespective of cell types, further studies on quantitation of individual FAEEs in these cell lines and resultant toxicity will address the biological significance of FAEEs.

THE UP-REGULATION OF STRESS RESPONSIVE GENES IN THE RAT KIDNEY GLOMERULUS FOLLOWING SINGLE INTRAVENOUS DOSE OF PUROMYCIN AMINONUCLEOSIDE (PAN).

T. Shimizu, N. Masutomi, T. Sakairi, Y. Inoue, N. Shimada, T. Hamano, <u>J. Sugimoto</u> and M. Mutai. *Mitsubishi Pharmacology Corporation, Kisarazu, Chiba, Japan.* 

Puromycin aminonucleoside (PAN) is known to induce oxidative damage to glomerulus. In this study, we examined gene expression changes in glomerulus following the administration of PAN using DNA microarray to speculate the molecular mechanisms of its toxicity. Male SD(IGS) rats were intravenously injected with PAN at a dose of 100 mg/kg body weight or with saline. Animals were sacrificed 10 days after PAN injection. Histologically, a mild degree of hypertrophy was observed in glomerular epithelial cells. After glomeruli were collected from frozen section of kidney by laser microdissection, the extracted RNA was analyzed by Rat Toxicology U34 array (Affymetrix). Gene expression analysis revealed that genes belonging to the stress responsive MAPK cascade such as GADD45 and SAPK, oxidative stress responsive genes such as catalase and glutathione peroxidase and wide variety of cytochrome P450 (CYP) genes were up-regulated. When the RNA from renal cortex that dominantly contained the RNA from tubular cells was examined, the up-regulation of cell cycle and regeneration related genes was observed, while that of stress responsive genes was in the less extent. These results indicate that PAN induces oxidative stress and up-regulates various CYP genes in the glomerulus, when the tubular regeneration is in progress. Comparing the transcriptional profiles of glomelurus and renal cortex, laser microdissection was shown to be a powerful tool to investigate gene expression changes of the focused region of the heterologous tis-

#### 1464

ONTOGENY OF P-GLYCOPROTEIN (PGP) IN THE BRAIN AND GONADS OF NEONATAL MALE AND FEMALE SPRAGUE-DAWLEY RATS.

S. J. Yavanhxay<sup>1</sup>, J. T. Stevens<sup>1</sup>, J. Eldridge<sup>1</sup>, M. S. Chistian<sup>2</sup> and A. M. Hoberman<sup>2</sup>. <sup>1</sup>Physiology and Pharmacology, Wake Forest University School of Medicine, Winston-Salem, NC and <sup>2</sup>Charles River Laboratories, Horsham, PA.

P-glycoprotein, a member of the ABC transporter superfamily, is a vital constituent of the blood-organ-barrier. It is expressed in capillary endothelial cells and acts as a transmembrane pump to facilitate removal of drugs and toxicants. We have assessed the development of PGP expression in female rat brain and ovaries, and brain, testes, and prostate of males, on PND 1, 5, 10, 15, 20 and 60. Using RT-PCR, PGP mRNA levels in female brain increased from 20% adult level at PND1 to 85% at PND20, and in males from 30% to 70%. A similar pattern was noted in the ovaries (10% on PND1 to 90% on PND20) and testes (15 to 75%) and prostate (25 to 80%). Using Western immunoblotting, measures of PGP protein in brain increased between PND 1-20 in a very similar pattern to PGP message: from 15 to 70% adult level in male and from 10 to 100% in females. Although expression of protein in testis and prostate failed to rise above 60% adult level by PND20, ovarian expression achieved 100% adult level at PND20. It can be concluded that the ontogeny of mRNA and protein expression of PGP, in the blood-brain barrier of the neonatal Sprague-Dawley rat, increases from a very low level at PND1 to nearly adult levels at PND20. PCR further suggests that the development of the blood-gonad-barriers and blood-prostate-barrier follows a similar pattern to development of the blood-brain-barrier, but the findings were not confirmed by immunoblotting techniques. It would appear from the data that the ontogeny of PGP in the Sprague-Dawley rat differs from that of human infants and children, which is completely developed from birth. It calls into serious question the validity of using neonatal rodent models to assess the potential toxic effects of natural hormones, pesticides, and environmental endocrine disrupting chemicals that interact with the P-glycoprotein pump, because rodent barriers remain far from completely developed at birth.

S. C. Buist and C. D. Klaassen. University of Kansas Medical Center, Kansas City, KS

Organic anion transporter 2 (Oat2) is highly expressed in kidney with female predominance in adult rats. In conjunction, gender divergent gene expression has been linked to endocrine factors, including gonadal steroids, growth hormone (GH) and thyroid hormones (TH). Thus, the goal of this study was to identify the mechanism of the Oat2 gender difference using gonadectomy, hypophysectomy (HX) and thyroidectomy (TX) as models of endocrine disruption. Additionally, Oat2 heteronuclear RNA (hnRNA) was measured to determine whether the gender difference is due to a transcriptional event. Oat2 mRNA and hnRNA levels were determined by branched DNA signal amplification and protein expression was qualitatively determined by immunohistochemistry. Oat2 mRNA was 4-fold higher in intact female kidney as compared with male kidney. Gonadectomy did not alter Oat2 mRNA levels in male or female kidney. Thus, gonadal steroids do not appear to regulate the female-predominant expression of Oat2 mRNA. After HX, female levels of Oat2 mRNA, hnRNA and protein decreased markedly to intact male levels, but male levels were not significantly changed. GH was administered to HX rats by injection (GH-IJ) or continuous infusion (GH-IF) to simulate the male or female GH secretion pattern, respectively. Oat2 mRNA, hnRNA, and protein increased after GH-IF (female pattern), but not after GH-IJ (male pattern). Therefore, the female GH secretion pattern may be partially responsible for the female-predominance of Oat2. TX produced a smaller decrease in Oat2 mRNA in kidney of female rats than after HX. However, TX did not change Oat2 mRNA levels in male rat kidney. Therefore, TH does not appear to directly effect Oat2 expression. In conclusion, this study indicates that the female GH secretion pattern is at least partially responsible for higher Oat2 levels in female kidney as compared with male kidney. Furthermore, elevated Oat2 hnRNA levels indicate that the gender difference occurs at the level of transcription. The effects of TH are minor, and may indicate an indirect role of thyroid hormones in basal expression of Oat2. (Supported by NIH grants ES-09716 and ES-07079)

### 1466

ALTERATIONS IN GENE EXPRESSION OF HEPATIC DRUG TRANSPORTERS BY THE LOSS OF THE TRANSCRIPTIONAL FACTOR HNF1α.

T. Callaghan<sup>1</sup>, A. L. Slitt<sup>1</sup>, J. M. Maher<sup>1</sup>, C. Cheung<sup>2</sup>, F. J. Gonzalez<sup>2</sup> and <u>C. D. Klaassen</u> . <sup>1</sup> University of Kansas Medical Center, Kansas City, KS and <sup>2</sup>National Cancer Institute, NIH, Bethesda, MD.

Several transporters in liver are responsible for organic anion (OA) uptake and excretion. The organic anion transporting polypeptide (Oatp) family, along with the Na+-taurocholate cotransporting polypeptide (Ntcp), mediate bile salt and OA uptake into liver. In contrast, the multidrug resistance protein (Mrp) family and the bile salt export pump (Bsep) mediate bile salt and OA export from liver. The transcription factor HNF1 $\alpha$  regulates the basal expression of many genes in liver. HNF1α increases the expression of several cytochrome P450s and decreases others. Therefore, it was hypothesized that HNF1 \alpha is important for the regulation of transporters in liver. To examine whether HNF1 $\alpha$  regulates the basal expression of transporters, mRNA expression of eight Oatp and nine Mrp transporters, as well as Ntcp and Bsep, was quantified in liver of wild-type (WT) and HNF1α-knockout (KO) mice. The expression of four of the eight Oatp mRNAs in the livers of the KO mice was lower (Oatp1, 3, 4, and 9), with two almost completely absent (Oatp1 and 9), three increased (Oatp2, 5, and 14) and no changes in Oatp12 from WT mice. Only two of the export transporters (Bsep and Mrp6) were lower in the KO than in WT mice, whereas three were higher (Mrp4, 5 and 9) and five were similar in KO and WT mice. These data indicate that  $\hat{H}NF1\alpha$  is important in the regulation of many, but not all, hepatic transporters. As with cytochrome P450s, HNF1α does not have a consistent effect on transporter expression, as loss of  $HNF1\alpha$  may increase, decrease, or have no effect on expression of transporters in liver. In general, the expression of the hepatic uptake transporters is affected more by lack of HNF1 $\alpha$  than the expression of hepatic export transporters. (Supported by NIH grants ES-09716, ES-09649, and ES-07079, ASPET SURF Program)

#### 1467

DISTRIBUTION OF THE MULTIDRUG RESISTANCE-ASSOCIATED PROTEINS (MRPS) IN TESTES, OVARY, AND PLACENTA OF MICE.

J. M. Maher, <u>A. L. Slitt</u>, <u>T. M. Leazer</u> and <u>C. D. Klaassen</u>. *Pharmacology, KU Medical Center, Kansas City, KS*.

Recent analysis of the genome has revealed that there are a minimum of nine Mrp transporters in mice. Many recently discovered mouse Mrps are orphan transporters, with no known substrates, and little is known about their tissue distribution. Mrp2 (abcc2), Mrp3 (abcc3), and Mrp4 (abcc4) are thought to transport bile

acids and xenobiotics out of liver, whereas Mrp4 and Mrp5 (abcc5) have been shown to transport cyclic nucleotides into urine. To investigate the expression profile of Mrp1-9 in reproductive tissues, the mRNA expression in testes, placenta, and ovary was determined, and compared to expression in other major organs. Expression of Mrp1 (abcc1) was 7, 6, and 4-fold higher in testes, ovary, and placenta, respectively, than in stomach, the non-reproductive organ exhibiting the highest relative expression. Transporters known to be highly expressed in liver, namely Mrp2, Mrp3, and Mrp6 (abcc6), showed little expression in testes, ovary or placenta. The expression of Mrp4 and Mrp5 in reproductive organs is similar to that in most other tissues. Mrp7 (abcc10) was most highly expressed in testes, and its expression in ovary and placenta was similar to the non-reproductive organs (intestine and kidney) that exhibited the highest expression. The most pronounced result was with Mrp8 (abcc11), which appears to be expressed solely in testes. Similarly, Mrp9 (abcc12) was minimally expressed in most tissues, but was expressed about 20-fold higher in testes and ovary than any other organ. Mrps move chemicals out of cells, and have been demonstrated to transport estrogens and dehydroepiandrosterone. Thus, the Mrps highly expressed in ovary and testes may play a role in endocrine function. Alterations in Mrp expression could lead to changes in hormone levels, and thus may serve as targets for endocrine disrupting xenobiotics. In addition, Mrps may protect the ovary and testes from some xenobiotics. (Supported by NIH grants ÉS-09716 and ES-07079)

#### 1468

REGULATION OF MOUSE ORGANIC ANION TRANSPORTING POLYPEPTIDES (OATPS) IN MOUSE LIVER BY CLASSES OF PROTOTYPICAL MICROSOMAL ENZYME INDUCERS THAT ACTIVATE VARIOUS TRANSCRIPTIONAL PATHWAYS.

X. Cheng and C. Klaassen. University of Kansas Medical Center, Kansas City, KS.

Phase I and phase II drug-metabolizing enzymes, as well as transporters are involved in the disposition of endogenous and exogenous compounds in the body. Phase I and II biotransformation enzymes can be up-regulated by classes of microsomal enzyme inducers (MEIs). For example: AhR ligands (TCDD, polychlorinated biphenyl 126, indole-3-carbinol and b-naphthoflavone) induce Cyp1A1/2; CAR ligands (phenobarbital, TCPOBOP, diallyl sulfide and trans-stilbene oxide) induce Cyp2B1/2; PXR ligands (PCN, spironolactone and dexamethasone) induce Cyp3A; PPARa ligands (clofibrate, ciprofibrate, diethylhexylphthalate and perfluorodecanoic acid) induce Cyp4A14; Nrf2 activators (oltipraz, ethoxyquin and butylated hydroxyanisole) induce quinone reductase; and isoniazid, aspirin and streptozotocin are Cyp2E1 inducers. Some chemicals need to be transported into the liver by Oatps for biotransformation. Therefore, it was hypothesized that the expression of drug-metabolizing enzymes and Oatps might be coordinately regulated in liver. However, there is little information concerning the effects of MEIs on the expression of Oatps in mouse liver. In the present study, the effects of the aforementioned MEI classes on the hepatic mRNA expression of 10 known mouse Oatps (Oatp1-5, 9, 11, 12, 14 and prostaglandin transporter (Pgt)) were determined by the branched DNA assay. Three of the four AhR ligands increased mRNA expression of Oatp9 and 11 in liver. CAR ligands down-regulated Oatp1 mRNA, but up-regulated Oatp2 mRNA. PXR and PPARa ligands decreased Oatp1, 4, 9 and Pgt mRNA levels in liver. Nrf2 activators down-regulated Oatp1 mRNA, but up-regulated Oatp2 and 9 mRNA. Cyp2E1 inducers increased Oatp2, 5 and 9 mRNA levels in liver. In conclusion, microsomal enzyme inducers up-regulate the expression of some Oatps in liver, but down-regulate others. These data also indicate that there is not always a coordinated induction of drug-metabolizing enzymes and Oatps in mice. (Supported by NIH grant ES-09649)

#### 1469

REGULATION OF HEPATIC TRANSPORTERS DURING CHOLESTASIS IS INDEPENDENT OF TNFα, IL-1, AND IL-6 ACTIVITY

A. J. Lickteig<sup>1</sup>, A. L. Slitt<sup>2</sup>, N. Li<sup>2</sup>, C. D. Klaassen<sup>2</sup> and N. J. Cherrington<sup>1</sup>.

<sup>1</sup>University of Arizona, Tucson, AZ and <sup>2</sup>University of Kansas Medical Center, Kansas City, KS.

Hepatic transporters play a critical role in the uptake and efflux of bile acids as an essential aspect of liver function. When the normal vectoral transport of bile acids by the basolateral uptake and canalicular excretion transporters is disrupted, cholestasis ensues, and the decreased flow of bile causes accumulation of toxic bile constituents and considerable hepatocellular damage. The purpose of this study was to assess how two models of cholestasis, lipopolysaccharide (LPS) administration and bile duct ligation (BDL) alter expression of transporters in mouse liver. Additionally, the potential involvement of cytokines was examined in knockout mouse strains lacking TNF- $\alpha$ -receptor, interleukin (IL)-1-receptor, and IL-6. Transporter mRNA levels in liver were determined using branched DNA signal amplification 16h following LPS administration or 3 days after bile duct ligation. LPS treatment tended to decrease mRNA levels of Bsep, Oat2, Ntcp, Oatp1, Mrp2 and

Mrp6 in comparison to saline treatment, whereas it increased Mrp1, Mrp3 and Mrp5 levels. Similar changes after LPS were observed in both wild type and knockout strains. Bile duct ligation did not cause a similar decrease in transporter expression as LPS administration, and only Oat2 expression was decreased. Like LPS treatment, bile duct ligation increased Mrp1, Mrp3, Mrp5, and Oatp2 expression in wild type and knockout strains. These data clearly reflect dissimilarity in hepatic transporter regulation in the bile duct ligation and LPS models of cholestasis. It is concluded that the differences in regulation of hepatic transporters during BDL and LPS-induced cholestasis are not due to the individual cytokine activity of TNF $\alpha$ , IL-1 and IL-6, respectively, but to the differences in the mechanism of cholestasis.

## 1470 XENOBIOTIC TRANSPORTER EXPRESSION IN THE BLOOD-TESTIS BARRIER.

N. J. Cherrington<sup>1</sup>, R. J. Markelewicz<sup>2</sup> and K. Boekelheide<sup>2</sup>. <sup>1</sup>University of Arizona, Tucson, AZ and <sup>2</sup>Brown University, Providence, RI.

A major function of xenobiotic and endobiotic transporters is to move a wide range of organic substances across cell membranes. Sertoli cells play an important role in protecting developing germ cells by forming a physiological barrier, limiting exposure to potentially toxic substrates, or conversely, facilitating uptake of xenobiotics to the testis. The aim of this study was to quantitatively determine the constitutive expression of various transporters in isolated Sertoli cells from adult Sprague-Dawley rats. The mRNA levels of Mdr1a, 1b and 2; Mrp1, 2, 3, 4, 5, and 6; Oatp1, 2, 3, 4, 5, 9, and 12 and Pgt; Oat1, 2, 3, and K; Oct1, 2, 3, N1 and N2; Ntcp, Bsep, Ibat; Menke's and Wilson's transporters, Dmt1, Znt1; Pept1 and 2; Ent1 and 2; as well as Cnt1 and 2 were measured in isolated Sertoli cells by the branched DNA signal amplification method. The mRNA levels of these genes were also determined in liver, kidney, ileum and whole testis in order to provide a reference for determining relative expression levels. Ent1 and 2 were expressed in isolated Sertoli cells at higher levels than in liver, kidney or ileum, whereas Mrp1, 3 and 5, Oatp3, Oct3 and N2, Menke's and Wilson's transporters, Dmt1 and Znt1 were all significantly expressed in isolated Sertoli cells, but Sertoli cell expression was not the tissue of highest expression. The remaining transporters were expressed at low levels in isolated Sertoli cells. Additionally, xenobiotic transporter expression levels in whole testis were similar to levels observed in isolated Sertoli cell isolations. The constitutive expression levels of different transporters in isolated Sertoli cells may provide an insight into the range of xenobiotics that can potentially be transported by Sertoli cells and thereby provide a mechanistic understanding of blood-testis barrier function. (Supported by NIH grant P30 ES-06694 and R01 ES-05033)

## 1471 DEVELOPMENT OF GENE CHIPS FOR EARLY DETECTION OF WELDER'S PNEUMOCONIOSIS.

<u>I. Yu</u><sup>1</sup>, K. Park<sup>2</sup>, K. Rim<sup>1</sup>, J. Sung<sup>1</sup>, B. Choi<sup>1</sup>, Y. Chung<sup>1</sup> and J. Han<sup>1</sup>. <sup>1</sup>Center for Occupational Toxicology, Occupatinal Safety & Health Research Institute, KOSHA, Daejeon, South Korea and <sup>2</sup>Pharmacogenechips, Chuncheon, South Korea.

Welders with radiographic pneumoconiosis abnormalities have exhibited a gradual clearing of the X-ray identified effects following removal from exposure. In some cases, the pulmonary fibrosis associated with welding fumes appears in a more severe form in welders. Accordingly, for the early detection of the welding fume exposure-induced pulmonary fibrosis, we have attempted to develop gene chips. Rats were exposed to welding fume with concentrations of  $107.82 \pm 2.58$  mg/m<sup>3</sup> of total suspended particulates for 2 hrs per day in an inhalation chamber for 30 days. After 30 days exposure, rats were sacrificed and mononuclear cells were prepared from peripheral blood. Total RNA and mRNA were prepared from the mononuclear cells. cDNA was synthesized from total RNA by SMART TM PCR cDNA method, then the subtractive hybridization was performed to select welding fume exposure regulated genes. The cDNAs identified by subtraction were sequenced after transformed into plasmid miniprep. The sequences were analyzed by the NCBI BLAST program and compared with the commercially available microarray data. Two hundred six genes were elevated from 2 to 13 fold and 742 genes were decreased from 0.1 to 0.5. These data demonstrated the differential gene regulation occurs following inhalation exposure of welding fumes. Some differentially regulated genes will be selected to develop gene chips to screen welder's pneumoconio-

#### 1472 RENAL TOXICOLOGICAL GENE RESPONSE TO ANTI-HEPATITIS B PRODRUGS HEPAVIR B AND HEPSERA IN RATS

C. Fang, R. Yan, C. Lim, <u>D. Vitarella</u>, P. Srivastava and <u>C. Lin</u>. R & D Department, ICN Pharmaceuticals Inc., Costa Mesa, CA.

Background: PMEA is an acyclic nucleoside phosphonate analog with potent antihepatitis B virus activity. However, it had low oral bioavailability and kidney toxicity. Hepsera (adefovir dipivoxil) is an approved, orally bioavailable prodrug of PMEA, whereas Hepavir B is a liver-targeting prodrug of PMEA. Aims: To profile renal toxicological gene expression and elucidate the molecular mechanism of PMEA-induced nephrotoxicity. Methods: 5 male rats per group received orally Hepsera (40 mg/kg/day) or Hepavir B (300 mg/kg/day) for 8 days and 28 days. RNA samples were isolated from the kidney tissue and Affymetrix Rat Toxicology Arrays were employed. Results: Significant increase of the mRNA level of Mdr1b (>20 fold), cyclin B and G, Mdm2 and c-jun (3-6 fold) could be detected as early as on the 8th day of treatment with either of these two prodrugs, before the appearance of any significant pathology in the kidney. Changes in expression of Mdr1b, cyclin B and G were further confirmed by RT-competitive PCR. Twenty-eight-day dosing with either of these two prodrugs changed the expression of additional 40 genes more than 3 fold, including the up-regulation of cell cycle regulators (i.e. p21 and cyclin D), signaling genes (c-myc and MEKK1), heat shock protein 27, apoptosis genes (Caspase-3 and -1), tissue regenerators (glycoprotein CD44 and Pro ?1 collagen type III) as well as down-regulation of CYP2C, 2D, 2E, 3A and 4A and antioxidant enzymes (GSTA3, GSHPx and catalase). Consistent with the gene expression, pathological examination showed renal proximal tubular inflammation and necrosis as well as scattered apoptosis detected only on day 28, not day 8. Conclusions: (1) microarrays can be a useful tool for early predictive toxicology. (2) Hepavir B at 300 mg/kg/day had a similar renal toxicological gene response as Hepsera at 40 mg/kg/day, suggesting better safety for Hepavir B than Hepsera at same dose. (3) PMEA-mediated nephrotoxicity appears to be involved in the development of apoptosis in proximal tubule cells.

## 1473 RAT LIVER TRANSCRIPTOMICS AFTER (COMBINATORIAL) 28-DAY EXPOSURE TO BENZENE AND TRICHLOROETHYLENE.

W. H. Heijne, M. J. Bart, D. Jonker, R. H. Stierum, B. van Ommen and J. Groten. Biomolecular Sciences, TNO Nutrition and Food Research, ZEIST, Utrecht, Netherlands

The mechanisms of hepatotoxicity of Benzene (B) and Trichloroethylene (TCE), and combinatorial effects were studied at the transcriptome level in rat liver. Although liver is not the primary target organ for toxicity, after a 28 day exposure to B or T, (modest) toxic effects were observed in liver, though not at all three dose levels. Besides elaborate routine toxicological examinations, transcriptomics was performed to find more sensitive markers of effects, elucidate mechanisms of action and evaluate the use of gene transcription patterns in combinatorial toxicology. Additionally, metabolomics analyses revealed compound and dose specific metabolite profiles in urine. Since routine toxicological examinations did not markedly reveal hepatotoxicity, these could not be used to describe the combinatorial effects. On the contrary, transcriptome data revealed toxicant specific effects that enabled to build a mechanism-based hypothesis on combined action of B and TCE in rat liver. This hypothesis was tested in the second phase of the study, where actual combined exposures were analyzed. Two dose levels of the compounds were used in single and the 4 possible combined exposures, and individual rat livers were measured using oligonucleotide DNA arrays. Several drug-metabolizing enzymes, but also genes involved in other biological processes were identified to be induced or repressed by Benzene, TCE or by both. Bioinformatics methods like pattern recognition techniques were applied to compare the response between the different exposure groups and between individual rats. Concluding, transcriptomics provided a better way to deduce putative health risks of combined exposure to B and TCE, based on mechanistic insights rather than empirical evidence.

### 1474 BIOMARKER SETS THAT CHARACTERIZE BILE DUCT HYPERPLASIA.

K. Jarnagin, C. Pearson, A. Roter, A. Tolley, B. Eynon, B. Ganter, G. Natsoulis, G. Day, <u>K. Kolaja</u>, <u>M. Fielden</u>, M. Lee, R. Nair, S. Dunlea, J. Yang, L. Gong, S. Nicholson, S. Tugendreich, S. Fujimoto and S. Baumhueter. *Iconix Pharmaceuticals, Inc., Mountain View, CA*.

To improve compound selection during drug discovery we have developed a large library of biomarkers for important toxicities and mechanisms of action. These signatures come from a comprehensive database that marries ~13, 000 microarray gene expression results derived from treating rats with 580 drugs at two doses and four time points in triplicate with traditional measurements of toxicity, pathology and pharmacology. Bile duct hyperplasia (BDH) occurs when cholangiocytes that line the bile ducts proliferate in response to toxicants. A signature that indicates BDH induction was derived using gene expression results from experiments in which histologically confirmed BDH occurred. Compounds that caused BDH include 1-naphthyl isothiocyanate (ANIT), lomustine, carmustine, methylene dianiline, lipopolysaccharide, vinblastine, carvedilol and fenofibrate. Hyperplasia generally occurred concomitantly with other liver pathologies, such as necrosis, apoptosis, leukocytosis and hypertrophy. RNAs that changed during BDH include those involved in cell adhesion, morphology, motility, extracellular matrix, fibrosis

and immunity. These changes reflect the remodeling of the liver during BDH. Most RNAs that increase are expressed in relatively rare cells that are increasing in number, such as cholangiocytes, and those that are activated, such as liver macrophages. Most RNAs that decrease are expressed in cells that are dying or functionally impaired, such as hepatocytes. Many of the treatments that cause BDH induce RNAs that increase during fibrosis, although only ANIT caused histologically confirmed fibrosis. Thus, the BDH signature not only discriminates those compounds that cause BDH but may also predict if these compounds induce fibrosis later. These mechanistic and predictive findings may hasten and improve decison making during drug discovery, thus improving efficency.

### 1475 TRANSCRIPTIONAL PROFILE OF CIGARETTE SMOKE INDUCED EMPHYSEMA LUNGS

K. H. Mai<sup>1</sup>, T. Rangasamy<sup>1</sup>, R. M. Tuder<sup>2</sup> and <u>S. Biswal</u><sup>1</sup>. <sup>1</sup>Environmental Health Sciences, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD and <sup>2</sup>Deapartment of Pathology, Johns Hopkins School of medicine, Baltimore, MD

Pulmonary emphysema is a major component of the morbidity and mortality of chronic obstructive pulmonary disease, that affects more than 14 million persons in the United States. Cigarette smoking is the main risk factor for the development of emphysema. This study investigates the gene expression pattern in the emphysematous lung tissues of A/J mice. The A/J mice (8 weeks old) were exposed to cigarette smoke (CS) - 7 h/day and 7 days/week for 6 months using a smoke machine. Lung alveolar measurements revealed 25 % and 30 % increase respectively, in the mean linear intercept and lung alveolar diameter of CS exposed A/J mice when compared to air exposed control mice. Fluorescent TUNEL and immunohistochmical analysis revealed the increased number of capase-3 positive, apoptotic cells and 8-OxodG positive cells in the lungs of CS exposed A/J mice. Differential cell count analysis showed 3 fold increase in the total inflammatory cells (80% macrophages) in the branchoalveolar lavage fluid of the CS exposed A/J mice. In order to identify the genes which are expressed in emphysematous lung tissues, oligonucleotide microarray analysis was carried out using Affimetrix chips (Mouse 430A chips) which contains 11, 400 genes. The data was analysed using MAS 5.0 and Data Mining Tool 3.0 program (Affymetryx, CA). Some of the selected genes from the microarray data were validated by Real Time PCR. Microarray analysis revealed the expression of numerous genes (expression of various proteases, genes involved in lipid metabolism, apoptosis associated genes, and inhibition of different genes encoding for various types of collagen, serine protease inhibitor, TGF beta 2, sodium channel protein, cell adhesion molecules and genes involved in signal transduction) which may play a critical role in development of emphysema. (This work was supported by grants: P50 CA058184-09 and NIEHS center grant P30 ES 03819).

### 1476 EFFECTS OF MULTIPLE CARDIAC APEX NECROSIS AGENTS ON GENOME WIDE EXPRESSION.

A. L. Castle, B. W. Higgs, <u>C. G. Chang</u> and <u>D. L. Mendrick</u>. *Toxicogenomics, Gene Logic Inc., Gaithersburg, MD*.

The differential gene expression and potential mechanisms of toxicity of several adrenergic agonists known or suspected to cause cardiac apex necrosis were compared to determine what mechanisms were in common or distinct among the compounds. One hundred and thirty four rats were treated once per day with either a high or low dose of mixed alpha/beta agonists epinephrine (EPI) and norepinephrine (NEP); beta agonist isoproterenol (ISO); atypical beta agonist clenbuterol (CLB) or time matched vehicle controls. High doses of 1.0, 0.5, 0.5, 4.0 mg/kg/day of EPI, NEP, ISO, or CLB respectively were previously determined to cause mild to moderate toxicity. Low doses were 1/10th the concentration of high doses. Animals were sacrificed at 3, 6, 24 hrs for EPI, ISO, and NEP. CLB animals were sacrificed at 6, 24, 120, 336 hrs post first administration. Affymetrix RGU34 GeneChip® and histopathology analyses were conducted on all samples. Mixed alpha/beta, beta, and atypical beta agonists had differential effects, albeit modest, on gene expression at both high and low doses. The diphtheria toxin receptor was significantly affected in EPI, NEP, and ISO with a corresponding trend in CLB. Gadd45a was upregulated to a greater extent in both EPI and NEP than ISO and CLB suggesting alpha mediated responses contributed to cellular damage. Transient up-regulation of Myc occurred with all treatments but the magnitude differed greatly at 24hrs suggesting a different duration or magnitude of effect. In addition, several genes linked to KEGG or BioCarta metabolic, inflammation, signal transduction and hypertrophy related pathways were affected. In general gene expression changes suggest common mechanisms among all compounds, with some differences that may allow both mechanism of toxicity and mechanism of action at the genome wide scale to be elucidated.

## 1477 MONITORING INDICATIONS OF LEAD EFFICACY AND TOXICITY WITH A MULTIPLEX GENE EXPRESSION ASSAY DURING EARLY DRUG

DEVELOPMENT

G. Vansant, P. Pezzoli, J. Monforte and <u>F. Ferre</u>. *eXpress Profiling, Althea Technologies, Inc., San Diego, CA*.

a) Many promising lead compounds are uncovered during the early high throughput screening process only to fail in preclinical safety studies. Out of 5000 compounds that are evaluated for safety in animals, approximately 5 are deemed safe enough to enter clinical trials. Animal studies cost 2-4 million dollars and can take 2 years to complete. Development of assays that can measure efficacy and safety indications simultaneously before long term and costly animal studies could substantially reduce drug development costs, and increase the productivity of toxicology labs. b) We have developed an RT-PCR based multiplex assay that simultaneously monitors the impact of compounds on three gene sets: lipid lowering genes controlled by the PPAR alpha receptor, genes that monitor a biological system's oxidative stress status, and selected metabolizing cytochromes. Rats were treated with various doses of clofibrate for 1 week. The expression of the genes shown in Table I was analyzed and compared to the expression in control rats. c) The impact of clofibrate on lipid lowering genes, stress related genes and the selected cytochrome genes was successfully monitored in a single reaction d) The results clearly illustrate that a compound's impact on a targeted pathway, as well as on toxicologically relevant pathways, can be monitored by multiplex gene expression analysis carried out in a single reaction. ## 1478 MITOCHONDRIAL TOXICITY OF 3'-AZIDO-3'DEOXYTHYMIDINE (AZT) IN THE ABSENCE OF MITOCHONDRIAL DNA (MTDNA) DEPLETION.

K. C. Lund and K. B. Wallace. Biochemistry and Molecular Biology, University of Minnesota School of Medicine, Duluth, MN.

A growing concern in the treatment of HIV/AIDS is the increased incidence of hyperlacticacidemia and cardiac myopathy. Nucleoside analog reverse transcriptase inhibitors (NRTIs) have been implicated in these and a variety of other mitochondrial related pathologies believed to be precipitated by the inhibition of the native DNA polymerase  $\gamma$ . The objective of this study was to determine if the inhibition of polymerase  $\gamma$  in cardiac tissue is causally related to mitochondrial toxicity. Rats were treated with AZT in their drinking water (1 mg/mL) for 32 days. Serum lactate was monitored weekly, and mitochondrial function was determined at 32 days by measuring NADH-dehydrogenase, cytochrome oxidase, and  $F_1$ ,  $F_0$ -ATPase enzyme activities. The possible inhibition of polymerase  $\gamma$  was assessed by the mtDNA copy number using quantitative PCR, and the expression of four mitochondrially encoded genes (ND1, COX1, ATPase6, and ND4) was measured using quantitative RT-PCR. The results indicate that mtDNA replication was not affected by longterm treatment with AZT; no difference in mtDNA copy number was observed between control and treated animals. There were no broad differences in mitochondrially encoded mRNAs or enzyme activities; with the exception of an elevated ND4 mRNA copy number and an increased activity of NADH-dehydrogenase in the AZT treatment group. AZT treatment caused an increase in serum lactate (22.9% compared to 12.5% for control) and a decrease in final body weight. A linear correlation was observed between cardiac NADH-dehydrogenase activity and serum lactate suggesting a compensatory response to AZT treatment. These data demonstrate that in vivo treatment with AZT induced cardiac mitochondrial dysfunction in the absence of mtDNA depletion, suggesting that AZT has a direct effect on mitochondrial targets independent of inhibition of mitochondrial DNA? polymerase γ. (Supported by HL-72715).

## 1479 PHTHALATES INFLUENCE THE EXPRESSION OF FATTY ACID HOMEOSTASIS REGULATING PROTEINS IN HRP-1 CELLS.

Y. Xu, P. Shah, T. J. Cook and G. T. Knipp. Department of Pharmaceutics, Rutgers, The State University of New Jersey, Piscataway, NJ. Sponsor: K. Reuhl.

Di(2-ethylhexyl)phthalate (DEHP) is a widely used plasticizer and ubiquitous environmental contaminant. The potential health hazards from exposure to DEHP and its metabolites, mono(2-ethylhexyl)phthalate (MEHP) and 2-ethylhexanoic acid (EHA), may be related to their role in the transactivation of peroxisome proliferator-activated receptors (PPAR)  $\alpha$  and  $\gamma$ , established regulators of cellular fatty acid (FA) homeostasis. The maternal-to-fetal transfer of FAs is highly directional from

the mother to the fetus and plays a critical role in fetal development. Changes in placental FA homeostasis may result in abnormal fetal development. This study demonstrates the effects of DEHP, MEHP and EHA on the mRNA and protein expression of PPAR $\alpha$ ,  $\beta$ , and  $\gamma$ , and fatty acid transfer conferring proteins in a rat placental cell model (HRP-1). HRP-1 cells were grown as monolayers and treated with DEHP, MEHP and EHA in a dose and time dependent manner for RNA and protein isolation. RT-PCR were performed under optimized conditions and normalized to β-actin expression using gene specific primers for PPAR isoforms and fatty acid transporters including fatty acid transport protein 1 (FATP1), plasma membrane fatty acid binding protein (FABPpm) and heart cytoplasmic fatty acid binding protein (hFABP). Western and slot blotting was utilized to support the RT-PCR results. All mRNA and protein expressions of each target of interest were observed in the HRP-1 cell at baseline. In the DEHP, MEHP and EHA treated cells, the expression of PPAR $\alpha$  and  $\gamma$ , FATP1, and hFABP were up regulated in a dose and time dependent manner. PPAR β, FABPpm demonstrated variable expression in these samples, consistent with literature reports. These results demonstrate that DEHP, MEHP and EHA can influence the expression of proteins involved in FA homeostasis in a rat placental cell line. This implies that these compounds may contribute to aberrant placental FA homeostasis through peroxisome proliferation and potentially result in abnormal fetal development. Financial support from NAAR.

## 1480 6-HYDROXYDOPAMINE-INDUCES OXIDATIVE STRESS AND TOXICITY IN HUMAN NEUROBLASTOMA CELLS.

C. hu, M. A. Tirmenstein, P. K. Narayanan, H. C. Thomas and L. W. Schwartz. GlaxoSmithKline, King of Prussia, PA.

6-Hydroxydopamine (6OHDA) has been implicated in the pathogenesis of Parkinson's disease (PD) and is frequently used in animal models of PD. Previous studies have demonstrated that 6OHDA is selectively toxic to catecholaminergic cells and is toxic to the human dopaminergic neuroblastoma cell line, SH-SY5Y, in vitro. Studies suggest that formation of free radicals by 6OHDA is an important causative factor in cellular toxicity in SH-SY5Y, but there is no direct evidence for 6OHDA-induced oxidative stress in SH-SY5Y cells. In our study, we examined cellular viability, reduced to oxidized glutathione ratios, ATP levels, and mitochondrial membrane potential ( $\Delta\Psi m$ ) in ŠH-SY5Y cells treated with 6OHDA at concentrations of  $50 - 500 \,\mu\text{M}$  and  $5 - 50 \,\mu\text{M}$  for 4 and 24 h, respectively. 6OHDA produced slight but significant increases in cell death after 4 h. After 24 h, a concentration-dependent increase in cell death was observed, but only the highest dose (50 μM) induced significant increases. After a 4 h incubation, 6OHDA decreased reduced glutathione (GSH) and increased oxidized glutathione (GSSG) levels in a concentration dependent manner resulting in substantial reductions of GSH/GSSG ratios. 6OHDA induced a dramatic (12-fold) concentration-dependent elevation of GSH at 24 h . Significant ATP depletion occurred in cells treated with 6OHDA at  $\geq$  100  $\mu$ M for  $\tilde{4}$  h and at  $\geq$  25  $\hat{\mu}$ M for 24 h. The  $\Delta\Psi$ m of SH-SY5Y cells was also decreased by 6OHDA (≥ 50 µM) at 4 h. These findings demonstrate that 6OHDA induces mitochondrial dysfunction, oxidative stress and toxicity, in SH-SY5Y cells.

## 1481 A MODEL OF TOXICANT-INDUCED OXYGEN FREE RADICAL PRODUCTION FROM ISOLATED BOVINE RESPIRATORY CHAIN COMPLEX I.

J. E. Johnson<sup>1, 2</sup>, K. Choksi<sup>2</sup> and W. R. Widger<sup>2</sup>. <sup>1</sup>Optometry, University of Houston, Houston, TX and <sup>2</sup>Department Biology and Biochemistry, University of Houston, Houston, TX. Sponsor: D. Fox.

The free radical theory of toxicant-induced injury and aging states that cell metabolism and function progressively decline in response to oxidative stress produced by reactive oxygen species (ROS). ROS production also is implicated in neurodegenerative disorders such as Parkinson's, Alzheimer's, and mitochondrial diseases. Multiple sites within the mitochondrial respiratory chain are hypothesized to produce ROS. The extent to which respiratory chain complex I contributes to ROS production is a topic of debate and clinical importance. Our aim was to determine whether ROS production co-isolated with respiratory complex I. Piericidin A, a potent inhibitor of complex I, and ubiquinone-1 (Q1) were used to stimulate ROS production from complex I. The ROS production was measured by two independent techniques: superoxide dismutase- (SOD) and catalase-sensitive oxygen consumption and SOD-sensitive cytochrome c reduction. Oxygen turnover and SODsensitive cytochrome c turnover were 150 - 550 per min. and 0 - 1000 per min., respectively. Q1-dependent ROS production was linear and non-saturating with increasing Q1 concentrations, suggesting that thie ROS production was largely nonspecific. Diphenyleneiodonium inhibited complex I ROS production, indicating that the site of ROS production was prior to the piericidin A block, possibly at one or more iron-sulfur centers and/or the flavin mononucleotide (FMN). Most importantly, the ROS production co-isolated with complex I FMN indicating that complex I is a potential site of mitochondrial ROS production. These results have mechanistic and therapeutic relevance for the diagnosis and treatment of free radical-induced injury in many tissues, especially those with high aerobic demand such as heart, kidney, and brain. Supported by the Welch Foundation Grant E-1381.

## 1482 LACK OF INHIBITION BY MELATONIN OF THE TOXIC AND PROLIFERATIVE EFFECTS OF DIETARY DIMETHYLARSINIC ACID ON RAT UROTHELIUM.

M. Wei, S. M. Cohen, M. Cano and L. L. Arnold. Path/Micro, University of Nebraska Med. Ctr, Omaha, NE.

Arsenic is a known human carcinogen of the skin, lung, bladder, and possibly other internal organs. Dimethylarsinic acid (DMA), a major organic metabolite of arsenic in most mammals including humans, has been shown to be a bladder carcinogen in rats when administered in the diet or in the drinking water. Oxidative stress has been suggested as a mechanism for DMA-induced carcinogenesis. Our recent results suggest that the induction of cytotoxicity with necrosis and consequent regenerative proliferation of the urothelium may be involved in the process of DMA-induced urinary bladder carcinogenesis. Dimethylarsinous acid (DMA<sup>III</sup>) generated from reduction of DMA, probably contributes to the process. To determine whether an antioxidant, melatonin, could inhibit the cytotoxic and proliferative effects of DMA, female F344 rats were concurrently treated with 1000 ppm melatonin and 100 ppm DMA in the diet. Histopathology, bromodeoxyuridine (BrdU) immunohistochemistry and scanning electron microscopy (SEM) were used to evaluate proliferative and cytotoxic changes in the urothelium. Melatonin did not show significant inhibitory effects on urothelial proliferation when compared with DMA alone. The BrdU labeling index was significantly increased in the DMA-treated rats with or without melatonin and by light microscopy there was no difference between the DMA and the DMA plus melatonin groups. However, there was the suggestion of a slight protective effect against DMA-induced cytotoxicity based on SEM observations. These results show that melatonin had little inhibitory effect on DMA-induced urinary bladder toxicity or proliferation in the rat. In addition, melatonin (0.2 mM) did not inhibit DMA (0.6 mM) or DMA<sup>III</sup> (0.4 µM)induced cytotoxicity in vitro

# 1483 CARBON NANOTUBE EXPOSURE CAUSED FORMATION OF FREE RADICALS, INDUCTION OF OXIDATIVE STRESS AND CYTOTOXICITY IN HUMAN KERATINOCYTES AND BRONCHIAL EPITHELIAL

E. Kisin<sup>1</sup>, A. R. Murray<sup>2</sup>, D. Schwegler-Berry<sup>1</sup>, V. Z. Gandelsman<sup>3</sup>, M. R. Ganther<sup>2</sup>, <u>V. Castranova<sup>1,2,4</sup> and A. A. Shvedova<sup>1,2,1</sup> PPRB, NIOSH, CDC, Morgantown, WV, <sup>2</sup>Physiology and Pharmacology, WVU, Morgantown, WV, <sup>3</sup>Advanced Technology Group, NASA-JSC/SAIC, Houston, TX and <sup>4</sup>GSPH, University of Pittsburgh, Pittsburgh, PA.</u>

Carbon nanotubes are new members of carbon allotropes similar to fullerenes and graphite. Because of their unique electrical, mechanical and thermal properties, carbon nanotubes are being evaluated for novel applications in the electronics, aerospace and computer industries. Exposure to graphite and carbon materials has been associated with increased incidence of skin and lung diseases, e.g., carbon fiber dermatitis, hyperkeratosis, naevi, asthma, COPD, pneumoconiosis and cancer. However, the potential toxicity of single wall carbon nanotubes (SWCNT) has yet to be completely evaluated. The present study investigated adverse effects of SWCNT using a cell culture of immortalized human epidermal keratinocytes (HaCaT) or bronchial epithelial cells (BEAS-2B). Exposure to SWCNT resulted in ultra-structural and morphological changes in cultured human cells. Treatment of keratinocytes and bronchial epithelial cells with SWCNT for 18 hr caused oxidative stress and cellular toxicity indicated by the formation of hydroxyl radicals, accumulation of peroxidative products, antioxidant depletion, loss of cell viability and apoptosis. These data suggest that dermal and respiratory exposure to unrefined SWCNT may lead to dermal and pulmonary toxicity due to accelerated oxidative stress.

## 1484 GREEN CHEMISTRY CATALYST CAUSES DEPLETION OF GSH, OXIDATIVE STRESS AND CYTOTOXICITY IN KERATINOCYTES IN THE PRESENCE OF H,O,.

J. Kisin<sup>1</sup>, Y. Y. Tyurina<sup>2</sup>, E. Kisin<sup>3</sup>, C. P. Horwitz<sup>1</sup>, T. J. Collins<sup>1</sup>, <u>V. E. Kagan</u><sup>2</sup>, <u>V. Castranova<sup>3,4</sup> and A. A. Shvedova<sup>3,4</sup>. <sup>1</sup>Carnegie Melon University, Pittsburgh, PA, <sup>2</sup>GSPH, University of Pittsburgh, Pittsburgh, PA, <sup>3</sup>PPRB, NIOSH, Morgantown, WV and <sup>4</sup>WVU, Morgantown, WV.</u>

The Pollution Prevention Act of 1990 (US CODE, 42) is a national policy to prevent or reduce pollution to protect human health and the environment. A practical, inexpensive, green chemical process for degrading environmental pollutants is

greatly needed, especially for persistent chlorinated pollutants. Chlorophenols (CP) have been widely used as components of pesticides, disinfectants, wood preservatives, personal care formulations, and many other products, and they are substantial by-products of wood pulp bleaching with chlorine. A newly developed chemical protocol for degradation of pentachorophenol (PCP) and 2, 4, 6-trichlorophenol (TCP) using iron complexes of tetraamidomacrocyclic ligand-Fe-TAML activators was successfully applied for rapid total destruction of CP. Introduction of novel Fe-TAML chemical catalysts into industry requires evaluation of their safety and understanding of the impact on the environment, biological species, and human health. The present study investigated cytotoxic effects of Fe-TAML using human keratinocytes (HaCaT). Free radical production was assessed by ESR-detectable ascorbate radicals. GSH content in cells was evaluated by measurements of its content in cells lysates using a specific maleimide reagent, ThioGlo- $1^{\text{TM}}$ . Additionally, fluorescent imaging of GSĤ-ThioGlo-1 adducts in cells was performed using a Nikon TE-200 system. Cell viability was estimated by Alamar Blue-based assay. After 8-18 hr of Fe-TAML exposure in the presence of H<sub>2</sub>O<sub>2</sub>, oxidant generation and cellular toxicity (as indicated by the formation of free radicals, accumulation of peroxidative products, antioxidant depletion, and loss of cell viability) was detected. Exposure to Fe-TAML alone did not induce either oxidative stress or cytotoxicity in HaCaT cultured cells. These data indicated that exposure to Fe-TAML can cause accelerated oxidative stress and toxicity to skin only in the presence of H,O,.

1485

INDUCTION OF ENDOGENOUS GLUTATHIONE BY  $\alpha$ -LIPOIC ACID IN HUMAN NEUROBLASTOMA SH-SY5Y CELLS: PROTECTION AGAINST 4-HYDROXYNONENAL- AND PEROXYNITRITE-MEDIATED NEUROTOXICITY.

S. S. HALLUR, Z. CAO and <u>Y. LI. PHARMACEUTICAL SCIENCES</u>, ST.JOHN'S UNIVERSITY, JAMAICA, NY.

Oxidative stress is believed to play a key role in the pathogenesis of neurodegenerative diseases, such as Parkinson's disease (PD). Early depletion in the levels of thiol antioxidant glutathione (GSH) which may lead to generation of reactive oxygen species is an important biochemical feature of PD. Recent evidence suggests that 4hydroxynonenal (HNE) and peroxynitrite, two cytotoxic compounds, significantly contribute to the pathogenesis of PD. This study was undertaken to determine whether α-lipoic acid (LA) treatment could increase endogenous antioxidant GSH and whether such increased cellular defense could afford protection against HNEand peroxynitrite-induced toxicity in the human neuroblastoma SH-SY5Y cells. Incubation of SH-SY5Y cells with micromolar concentrations of LA (50-200µM) for 24, 48 and 72 h resulted in a significant 2-3-fold induction of cellular GSH in a concentration-dependent fashion. Induction of GSH by LA did not show a timedependent manner; a maximal induction of GSH was observed 24 h after incubation with LA. To investigate the protective effects of the LA-induced cellular defense on toxic neuronal injury, SH-SY5Y cells were pre-treated with LA for 24 h and then exposed to HNE or peroxynitrite. We observed that LA pre-treatment of SH-SY5Y cells led to a significant protection against HNE- or peroxynitrite-induced neurotoxicity as determined by the MTT reduction assay. To further determine the role of cellular GSH in protecting against the above neurotoxicant-mediated cytotoxicity, buthionine sulfoximine (BSO) was used to inhibit cellular GSH biosynthesis. It was observed that depletion of cellular GSH by BSO led to a marked potentiation of peroxynitrite- or HNE-mediated cytotoxicity in SH-SY5Y cells. Taken together, our results demonstrate for the first time that LA potently induces cellular GSH biosynthesis, and that the LA-elevated cellular antioxidant defense appears to afford a marked protection against HNE- or peroxynitrite-induced toxicity in neuronal cells.

### 1486

MECHANISM OF GLUTATHIONE S-TRANSFERASE A4-4 IN PROTECTION AGAINST OXIDATIVE STRESS INDUCED APOPTOSIS IN ENDOTHELIUM.

Y. Yang<sup>1</sup>, Y. Yang<sup>2</sup>, M. B. Trent<sup>1</sup>, S. D. Lick<sup>3</sup>, <u>P. Zimniak<sup>4</sup></u>, <u>Y. C. Awasthi<sup>2</sup></u> and <u>P. Boor<sup>1</sup></u>. <sup>1</sup> Pathology, University of Tex. Med. Branch, Galveston, TX, <sup>2</sup> 2Human Biological Chemistry and Genetics, University of Texas Medical Branch, Galveston, TX, <sup>3</sup> 3Department of Surgery, University of Texas Medical Branch, Galveston, TX and <sup>4</sup> 4Department of Pharmacology and Toxicology, University of Arkansas for Medical Sciences, and Central Arkansas Veterans Healthcare System, Little Rock, AR.

Our previous studies demonstrated that glutathione-S-transferase (GSTs) play a protective role against oxidant damage in vascular smooth muscle cells and endothelium. In order to study the mechanism of GSTs protection of endothelium, we examined the intracellular signalling pathway and the protective role of a specific GST isozyme, mGSTA4-4. Stable transfection of mouse islet endothelial cells (MS1) with mGSTA4-4 was established; transfected cells demonstrated enzyme activity three times (toward 1-chloro-2, 4-dinitrobenzene, CDNB) and four times(to-

ward 4-HNE) higher than wild-type MS1 cells or cells transfected with vector alone. Transfected cells expressed significantly increased resistance to cell apoptosis confirmed by TUNEL and caspase activation due to the cytotoxicity of allylamine, acrolein, 4-HNE, and H2O2. Immunoblotting studies of signal transduction pathway indicated that mGSTA4 transfection protected MS1 endothelial cells from oxidative stress induced apoptosis by inhibiting phosphorylation of c-Jun N-terminal kinases (p-JNK) and consequent activation of p53 and Bax. Application of JNK inhibitor blocked p53 and Bax activation in endothelium. Subcellular localization studies by immunolocalization and electronic microscope indicated that mGSTA4-4 localized in cell vesicles close to plasma membrane that may contain the major substrate(s) for this enzyme. Our results indicate that the mechanism of mGST A4-4 in protection of endothelial cells is through inhibiting the JNK activation pathway, most likely at cytoplasmic sites; thus GSTs may play a key role in protecting blood vessels against oxidative stress and are likely to be a critical defense against atherogens.

### 1487 MGSTA4-4 NULL (-/-) MICE ALTERS THE COURSE OF CCL4 INDUCED HEPATOTOXICITY.

S. Dwivedi<sup>1</sup>, R. Sharma<sup>2</sup>, A. Sharma<sup>2</sup>, <u>Y. C. Awasthi</u><sup>2</sup> and <u>P. Boor</u><sup>1</sup>. <sup>1</sup> Pathology, University of Tex. Med. Branch, Galveston, TX and <sup>2</sup> Human Biology and Genetics, University of Texas Medical Branch, Galveston, TX.

Glutathione S-Transferases(GSTs) play a key role in cellular detoxification of environmental toxicants through their conjugation to glutathione(GSH). Recent studies have shown that the  $\alpha$ -class GSTs also provide protection against oxidative stress and lipid peroxidation(LPO). GSTA4-4 is a member of a sub group of the α-class GSTs. It has been shown to metabolize 4-hydroxynonenal (4-HNE) with high catalytic efficiency through its conjugation to glutathione (GSH) and has been suggested to be a major component of defense mechanisms against toxic electrophiles such as 4-HNE generated during LPO. Since the hepatotoxicity of carbon tetrachloride (CCl4) has been suggested to be due to the generation of free radicals leading to membrane LPO, present studies were designed to compare hepatotoxicity of CCl4 in null (-/-) and wild type (+/+) mice. The results of these study showed that administration of a single dose of CCl4 (0.1ml/kg i.p) resulted in time dependent hepatotoxicity in both -/- and +/+ mice; the extent of cellular damage by serum enzymes suggested that progression was more rapid in -/- mice, although totals were similar by 24h. Histopathologic exam showed similar degrees of centrilobular necrosis but much greater surrounding degenerative change, including cellular swelling, disarray, and vacuolization, was observed in the liver of -/- mice. As expected -/- mice did not show any expression of mGSTA4-4 only slight compensatory increase in the activities of total GST activity was noted at 24h; major alterations in other antioxidant enzymes was not observed. 4-HNE levels in the liver of -/- mice were about four fold higher as compared to +/+ mice, suggesting a positive correlation between 4-HNE levels and the altered course of CCl4 hepatotoxicity. These studies suggest that GSTA4-4 may be an important component of defense mechanism against oxidative stress and LPO.

### 1488 MITOCHONDRIAL METABOLISM: THE ROOT OF HYPEROIXC CELL DAMAGE.

<u>I. Li</u><sup>1</sup>, X. Gao<sup>2</sup>, M. Qian<sup>2</sup> and J. W. Eaton<sup>2</sup>. <sup>1</sup>Department of Pharmacology and Toxicology, University of Louisville, Louisville, KY and <sup>2</sup>Department of Medicine, University of Louisville, Louisville, KY.

Exposure of mammals to hyperoxia causes pulmonary and ocular pathology. Hyperoxic damage and cell death may derive from enhanced intracellular formation of reactive oxygen species (ROS), probably of mitochondrial origin. There is, however, controversy on this point. When wild-type and respiration-deficient (rho0) HeLa cells were cultured in 80% O2, wild-type cells stopped growing after 5 days and died thereafter whereas rhoo cells survived and grew to confluence. This tolerance of rho0 cells to high oxygen was not associated with greater resistance to oxidants such as hydrogen peroxide and t-butyl hydroperoxide. Under both 20% and 80% O2, rho0 cells exhibited substantially decreased ROS production and, under 80% O2, rho0 cells showed no suppression of aconitase activity or mitochondrial protein carbonyl formation. Replacement of normal mitochondria in rho0 cells restored ROS production and susceptibility to hyperoxia. Two other strategies which diminish mitochondrial ROS generation also increased tolerance to hyperoxia. HeLa cells constantly exposed to the protonophoric uncoupler, carbonyl cyanide m-chlorophenylhydrazone (which enhances respiration but decreases ROS production), showed preferential survival under 80% O2 as did HeLa cells in the presence of chloramphenicol (which suppresses both respiration and mitochondrial ROS production). We conclude that interactions between respiring mitochondria and O2 are primarily responsible for hyperoxic cell damage.

### OXYGEN TOXICITY AND MITOCHONDRIAL FUNCTION

E. C. Campian<sup>1</sup>, J. Li<sup>1</sup>, X. Gao<sup>2</sup>, M. Qian<sup>2</sup>, H. Joenje<sup>3</sup> and J. W. Eaton<sup>2</sup>.

<sup>1</sup>Department of Pharmacology and Toxicology, University of Louisville, Louisville, KY, <sup>2</sup>Department of Medicine, University of Louisville, Louisville, KY and <sup>3</sup>Department of Clinical Genetics and Human Genetics, VU University Medical Center, Amsterdam, Newberlands

Oxygen is critical to aerobic metabolism, but excessive oxygen (hyperoxia) will injure most mammals. An oxygen tolerant strain of HeLa cells which proliferates even under 80% O2, termed "HeLa-80", was studied for clues to the nature of hyperoxic damage. These oxygen tolerant cells have wild-type (HeLa-20) levels of antioxidant defenses and are equally susceptible to peroxide killing. However, under both 20% and 80% O2, intracellular ROS production is >2-fold higher in wild-type vs. tolerant HeLa cells as assessed by (1) dihydrodicholorfluorescein oxidation, (2) dihydroethidium oxidation, (3) hyperoxia-mediated suppression of aconitase activity and (4) mitochondrial protein carbonyl content. The ROS generation is evidently mitochondrial because, in both HeLa-20 and HeLa-80 cells, the mitochondrial uncoupler carbonyl cyanide m-chloro phenylhydrazone almost totally inhibits ROS production as does the combination of rotenone and thenoyltrifluoroacetone (complex I and II inhibitors). Interestingly, the tolerant HeLa-80 cells have ~ 2-fold higher cytochrome c oxidase (COX) activity and preferential blockade of this terminal complex of mitochondrial electron transport chain, by treatment with nmethyl protoporphyrin which selectively diminishes synthesis of heme-aa3 in COX, abrogates the oxygen tolerance and increases ROS production in HeLa-80 cells under hyperoxia. In the oxygen tolerant HeLa cells, the elevated COX activity may be due to a >2-fold increase in COX Vb (a regulatory subunit of COX) whereas expression levels of other COX subunits (COX I, II and IV) are very close to wild-type. Overall, our results suggest that the oxygen tolerance may derive from tighter coupling of the electron transport chain in HeLa-80 cells which, in turn, depletes electron-rich intermediates within the chain and, thereby, diminishes the leak of ROS.

### 1490 PROTEIN MODIFICATION BY 4-HYDROXYNONENAL MODULATES 26S PROTEASOMAL DEGRADATION.

D. L. Carbone and D. R. Petersen. Pharmaceutical Sciences, University of Colorado Health Sciences Center, Denver, CO.

Damaged or otherwise unwanted proteins are selected for degradation via the iterative attachment of ubiquitin to specific lysine residues. The  $\alpha$ ,  $\beta$  unsaturated aldehyde 4-hydroxynonenal (4-HNE) is a major product of lipid peroxidation, shown to readily form Michael addition products with multiple nucleophilic amino acids. Given the ability of 4-HNE to covalently modify lysine residues, we have hypothesized that protein modification by 4-HNE may lead to impaired ubiquitination, ultimately inhibiting degradation by the 26S proteasome. This hypothesis was tested using alcohol dehydrogenase (ADH), mitochondrial aldehyde dehydrogenase (ALDH2), and microsomal cytochrome P450 2E1 (CYP2E1) as model substrates. Model proteins were modified by 4-HNE, and adducts confirmed through immunoblot or MALDI-TOF-MS techniques. The effects of this modification on each protein were evaluated using either rabbit reticulocyte (RRL) or rat hepatocyte cytosol, supplemented with ATP, to provide the necessary components for polyubiquitination and 26S proteasomal degradation. Treatment of the proteins with excess concentrations of 4-HNE resulted in the predicted effect, in which degradation of the proteins was inhibited. Interestingly, exposure of ADH and ALDH $\bar{2}$  to lower concentrations of the aldehyde have resulted in a 40% and 25% increase, respectively, in the rate of protein degradation. Involvement of the 26S proteasome was implicated through the use of the proteasome inhibitor MG-132 and non-hydrolyzable ATP analogues. Finally, purification of ubiquitinated proteins followed by immunoblotting demonstrated an enhanced rate of polyubiquitination following exposure to lower concentrations of the aldehyde. These data demonstrate a concentration-dependent ability of the lipid aldehyde 4-HNE to modulate ubiquitin-mediated proteasomal degradation. This work was supported by NIH/AA09300 (DRP) and NIH/AA1F31AA014308-01 (DLC).

### 1491

THE PROTECTIVE EFFECTS OF CHEMICALLY-INDUCED ENDOGENOUS GLUTATHIONE ON DOPAMINE AND 6-HYDROXYDOPAMINE-MEDIATED TOXICITY IN RAT PHECHROMOCYTOMA PC12 CELLS.

X. PENG and Y. LI. Pharmaceutical Sciences, St. John's University, Jamaica, NY.

Dopamine (DA) and 6-hydroxydopamine (6-OHDA) are well-recognized neurotoxins, which are also used to induce experimental Parkinson's disease (PD). Glutathione (GSH) depletion has been suggested to contribute to the pathogenesis of PD, since GSH levels are reduced in PD substantia nigra pars compacta. This study was undertaken to investigate the induction of endogenous GSH by the

unique chemoprotective agent, 3H-1.2-dithiole-3-thione (D3T) and its protective effects against DA and 6-OHDA-mediated toxicity in rat pheochromocytoma PC12 cells. Incubation of PC12 cells with micromolar concentrations of D3T resulted in concentration-dependent elevation of GSH. To examine the protective effects of D3T-induced cellular GSH on DA and 6-OHDA-mediated toxicity, PC12 cells were pretreated with D3T for 24 h and then exposed to either DA or 6-OHDA for another 24 h. We found that D3T-pretreatment of PC12 cells led to a significant protection against DA and 6-OHDA-mediated toxicity, as assessed by 3-[4, 5-dimethythiazol-2yl]-2, 5-diphenyltetrazoliium bromide reduction and trypan blue exclusion assays. To further demonstrate the critical involvement of GSH in protecting against DA and 6-OHDA-mediated toxicity, buthionine sulfoximine (BSO) was used to inhibit cellular GSH biosynthesis. Depletion of cellular GSH by BSO caused a marked potentiation of DA and 6-OHDA-mediated toxicity. Cotreatment of cells with BSO was found to largely abolish the D3T-mediated GSH elevation and greatly reverse the protective effects of D3T on DA and 6-OHDAmediated-toxicity. These data demonstrate for the first time that induction of endogenous GSH by D3T affords significant protection against DA and 6-OHDAmediated toxicity in rat pheochromocytoma PC12 cells.

#### 1492

DIFFERENTIAL EFFECTS OF CHRONIC ESTRADIOL TREATMENT ON INDUCTION OF PHASE II ANTIOXIDANT ENZYMES IN BRAIN AND LIVER OF ACI RATS.

T. M. Stakhiv, R. I. Sanchez and F. C. Kauffman. Joint Graduate Program in Toxicology, Rutgers University/UMDNJ, Piscataway, NJ.

Estrogen has been implicated in protecting against oxidative stress in certain neurological diseases (eg. Parkinson's Disease, Alzheimer's Disease); however, there is little information regarding the actions of estrogen on the levels or activities of antioxidant enzymes. Chronic exposure of ACI rats, which are highly sensitive to low doses of estradiol (E2), to E2 confers protection against oxidative stress in brain slices. The present study examines the action of chronic E2 treatment of ACI rats on expression and activities of antioxidant enzymes including (NAD(P)H-quinone oxidoreductase (NQO1), glutathione S-transferase (GST), and phenol sulfotransferase 1A1 (SULT1A1)) in brain and liver. Male and female ACI rats were treated for 6 weeks with 3mg of E2 implanted subcutaneously in a cholesterol pellet. Activities of these enzymes measured spectrophotometrically and radiochemically in the striatum, an area particularly sensitive to oxidative stress induced by catecholamine metabolism, were markedly increased (NQO1 +28% male, +7% female; GST +17% male, +7% female; SULT1A1 +110% male, +49% female) in rats treated with E2. A tight correlation existed between blood E2 levels and activities of all three enzymes in male striata (p<0.05). This relationship was not evident in female striata (p>0.17). Liver enzymes followed a different profile when compared to striatum where enzyme activities of NQO1 decreased in males (-70%) and increased in females (+260%). Amounts of enzyme protein in liver detected by immunoblotting correlated with measured activities of NQO1 and SULT1A1 activities in both genders treated with  $E_2$ . These results strongly suggest that enhanced expression of antioxidant enzymes including NQO1, GST, and SULT1A1 is a mechanism related to protection by E2 against oxidative stress. Regulation of the expression of these enzymes in ACI rats treated chronically with E<sub>2</sub> varies in different tissues in a gender-specific manner. (Supported in part by NIEHS Training Grant No.ES-07148)

### 1493 ANILINE-INDUCED ACTIVATION OF REDOX-SENSITIVE TRANSCRIPTION FACTOR NF-KB IN THE RAT SPLEEN.

S. Kannan, J. Wang, H. Li and M. Khan. Pathology, University of Texas medical branch. Galveston. TX.

Exposure to aniline results in selective toxicity to the spleen, and fibrosis appears to be an important initiating preneoplastic lesion. However, the molecular mechanism(s) by which aniline leads to fibrogenic response in spleen is not well understood. Our previous studies have shown that aniline exposure causes iron overload in the spleen, resulting in oxidative stress and upregulation of several fibrogenic cytokines. These observations lead us to hypothesize that aniline-induced oxidative stress in the spleen induces transcriptional upregulation of fibrogenic cytokines via activation of redox-sensitive transcription factor, nuclear factor-kappa B (NF-kB). In order, to determine the activation of NF-kB in aniline-induced fibrogenic response of the spleen, male SD rats were given 0.5 mmol/kg/day aniline hydrochloride (AH) through drinking water for 30 days, and splenocytes were isolated from control and aniline-treated rats. For the detection of activated NF-kB, we chose to determine NF-kB p65, which represents the activated form of the heterodimer

complex (p65/p50) that translocates to nucleus, using an ELISA specific for NF-kB p65. Nuclear extracts obtained from cultured splenocytes of aniline-treated rats showed a two fold increase in NF-kB p65 level compared to the controls. The binding activity of NF-kB, as determined by electrophoretic mobility shift assay (EMSA) using NF-kB consensus motifs, clearly showed an increase in NF-kB binding in the nuclear extracts of the splenocytes from aniline-treated rats in comparison to controls. The specificity of NF-kB p65 binding for relevant DNA motifs was verified by competition EMSA assays, using an excess of unlabelled consensus and mutant oligonucleotides. Furthermore, super shift EMSA and Western blot analysis confirmed the specificity of NF-kB p65 binding activity. These observations thus provide an evidence for aniline-induced activation and increased binding activity of NF-kB, which could mediate upregulation of fibrogenic cytokines in the spleen.

### 1494

PHARMACOLOGIC SUPPRESSION OF OXIDATIVE DAMAGE AND DENDRITIC DEGENERATION FOLLOWING KAINIC ACID-INDUCED EXCITOTOXICITY IN MOUSE CEREBRUM.

D. Milatovic<sup>1</sup>, S. Milatovic<sup>1</sup>, R. C. Gupta<sup>2</sup> and T. J. Montine<sup>1</sup>. <sup>1</sup>Pathology, University of Washington, Seattle, WA and <sup>2</sup>Toxicology, Murray State University, Hopkinsville, KY.

Intense seizure activity associated with status epilepticus and excitatory amino acid application initiates neuronal injury in CA1 of the ventral hippocampus. Oxidative stress is an important participant in excitotoxicity. As a measure of oxidative stress, lipid peroxidation and nitric oxide synthase (NOS) activity, changes in F2-isoprostanes (F2-IsoPs), F4-neuroprostanes (F4-NeuroPs) and citrulline levels were studied in the brain of C57Bl/6 mice exposed to intracerebroventricular administration of kainic acid (KA, 1 nmol/5 µl). Ĥippocampal pyramidal neuron dendrites and spines were evaluated using rapid Golgi stains and Neurolucida system. KA produced severe seizures in mice immediately after administration and a significant increase in F2-IsoPs (158%), F4-NeuroPs (237%) and citrulline (249%) levels were seen 30 min following treatment compared to controls (100%). At the same time, pyramidal neurons in the hippocampus had 62 % and 37 % reduction in dendritic length and spine density, respectively. No significant change in neuronal dendrites and spine and F<sub>2</sub>-IsoP, F<sub>4</sub>-NeuroPs and citrulline levels were found in mice pre-treated with α-tocopherol (100 mg/kg, i.p.) for 3 days or those exposed to indomethacin or ibuprofen (inhibitors of cyclooxygenase, COX, 14 µg/ml of drinking water) for 2 weeks prior to KA. These findings indicate novel interactions among free radical-induced generation of F2-IsoPs and F4-NeuroPs, the COX pathway, nitric oxide and dendritic degeneration and point to possible interventions to limit cerebral oxidative damage (Supported by AFAR, PD 02043 to D.M.).

### 1495 OVEREXPRESSION OF CYTOKINES IN SPLENIC FIBROGENIC RESPONSE TO ANILINE.

J. Wang, H. Li, S. Kannan, <u>B. S. Kaphalia</u> and <u>M. Khan</u>. *Pathology, University of Texas Medical Branch, Galveston, TX.* 

Molecular mechanisms for aniline-induced fibrogenic response in spleen are not well understood. Previously we have shown that excessive iron deposition, increased lipid peroxidation (LPO) and formation of LPO-derived aldehydes are important events in the splenic toxicity of aniline. Increased steady-state production of LPOderived aldehydes may upregulate the expression of fibrogenic cytokines leading to splenic fibrosis. The present study was aimed to determine transcriptional and posttranscriptional regulation of cytokines in aniline-induced fibrogenic response. To achieve this, male SD rats were orally administered with 1 mmol/kg/day aniline hydrochloride (AH) for 7 days. RNA from the spleens of control and aniline-treated rats was extracted, and mRNA for IL-1 alpha, IL-6 and TNF-alpha was quantitated by real-time PCR. Aniline treatment resulted in 4.8, 2.7 and 2.4 fold increase in mRNA level of IL-1 alpha, IL-6 and TNF-alpha, respectively, compared to the controls, indicating transcriptional upregulation of these cytokines. Cytokine protein levels, measured in the splenocyte culture supernatants by specific ELISAs, also showed significantly greater release of these cytokines in the aniline-treated rats. Furthermore, to determine the expression of these cytokines after a subchronic exposure (when splenic fibrosis is evident), rats were treated with 0.5 mmol/kg/day AH for 30 days. Spleens from aniline-treated rats showed 6.9, 2.9 and 2.6 fold increase in mRNA levels of IL-1 alpha, IL-6 and TNF-alpha, respectively, in comparison to the controls. The increases in mRNA levels were also associated with enhanced secretion of these cytokines in the splenocyte culture supernatants. Overexpression of these cytokines preceding fibrosis as well as during fibrosis suggests that these cytokines have an important regulatory role in aniline-induced splenic fibrosis.

#### 1496

THE GENES INVOLVED IN THE ONSET OF PARAQUAT INJURY AND THE INDIVIDUAL DIFFERENCE OF THE TOXIC EFFECT.

M. Tomita<sup>1</sup>, T. Okuyama<sup>1</sup> and T. Nohno<sup>2</sup>. <sup>1</sup>Medical Toxicology, Kawasaki Medical School, Kurashiki, Japan and <sup>2</sup>Molecular Biology, Kawasaki Medical School, Kurashiki, Japan. Sponsor: <u>L. Birnbaum</u>.

Paraquat (PQ), a quaternary nitrogen herbicide, is highly toxic to humans and animals and death due to accidental PQ exposure have been reported over the past few decades. In addition, it is known that PQ-treated animals have been divided into "minimally" and "severely" affected group. Excessive production of oxygen free radicals has been proposed to play an important role in the pulmonary pathology. The aim of the present work is to find out the genes that are involved in the onset of PQ injury in lungs and in the individual difference of the toxic effect of PQ. We extracted RNAs from rat lungs 3 hr after injection of PQ (20 mg / kg; i.p.), and hybridized to cDNA array membranes that contain 1, 176 rat genes (Clontech Toxicology 1.2 array). PQ exposure showed 29 genes differentially expressed (>1.5fold) when compared with those in control. Some positive genes isolated in this screen were further validated and quantitated with real-time RT-PCR performed in an ABI Prism 7700 Sequence Detection System (Applied Biosystems). The expression of PDGF, thioredoxin, glutathione S-transferase, superoxide dismutase was significantly up-regulated, suggesting that the oxygen free radicals were major contributors to the onset of PQ poisoning. The up-regulation of cytochrome P450s 2C6 and 2C7 particularly drew our attention. As expected, the expressions of these two enzymes in normal lungs of control rats were not/little observed. On the contrary, the expressions in the lungs of 3h-PQ exposed rats were remarkably increased and also showed individual differences (from normal level to above 100-fold). This phenomenon was peculiar to lungs, and not to liver and kidneys. The genes were amplified about 2-fold in PQ-exposed liver, but not in kidneys. The up-regulation of the genes observed in lungs at 3h-PQ exposure declined remarkably at 24h after injection. These results suggest that cytochrome P450s 2C6 and 2C7 are involved in the onset of PQ-induced serious pulmonary injury and the individual difference of the toxic effect.

### 1497

HO-1 PROMOTER/ENHANCER LUCIFERASE ASSAY: A PROMISING *IN VITRO* TOOL FOR MEASURING CELLULAR OXIDATIVE STRESS.

C. Knoerr, S. Gebel and T. Mueller. *PHILIP MORRIS Research Laboratories GmbH, Cologne, Germany.* Sponsor: H. Haussmann.

Cigarette smoke (CS) harbors a strong oxidative stress potential, which broadly impacts exposed cells. A special feature of the cellular response to CS is a strong transcriptional up-regulation of antioxidant genes, among which heme oxygenase-1 (ho-1) was found to be the most strongly induced gene in in vitro and in vivo microarray studies conducted in our laboratories. In order to test CS-fractions or individual smoke constituents for their potential to induce oxidative stress, we generated a stable transfected NIH3T3 cell-line expressing the luciferase gene under the control of the ho-1 promoter/enhancer region. The efficiency of the system was checked by exposing cells to aqueous extracts of CS (smoke-bubbled (sb) PBS) and then comparing the expression of ectopic luciferase on mRNA and protein levels to the expression of endogenous ho-1. Results showed the regulation of the two genes to be the same with regard to both kinetics and dose response. Experiments with the particle phase of CS (total particulate matter (TPM)) revealed that sbPBS and TPM induced luciferase activity to a similar extent in this system. Testing of oxidants known to be present in sbPBS and TPM showed that acrolein and hydroquinone induced luciferase activity, but to a lesser extent than sbPBS or TPM, demonstrating that both sbPBS and TPM contain additional constituents that induce ho-1. These results suggest that this system may be a promising tool for helping to identify and quantify those constituents in CS that are responsible for oxida-

INDUCIBLE GLUTAMATE-CYSTEINE LIGASE TRANSGENIC MICE EXHIBIT PROTECTION AGAINST ACETAMINOPHEN INDUCED LIVER INJURY.

D. Botta, <u>S. Shi, C. C. White</u>, S. Chatterton-Kirchmeier, P. A. Vliet and <u>T. J. Kavanagh</u>. *Environmental and Occupational Health Sciences, University of Washington, Seattle, WA*.

The antioxidant tripeptide glutathione (GSH) is important in xenobiotic detoxification, free radical scavenging, and maintaining cellular redox status. Glutamatecysteine ligase (GCL) is the rate limiting enzyme in GSH synthesis and is composed of catalytic (GCLC) and modifier (GCLM) subunits. We have generated transgenic mice designed to conditionally overexpress both GCLC and GCLM

using the GeneSwitchTM system. This system employs a liver specific promoter (transthyretin) to drive expression of a chimeric progesterone receptor composed of a mutated ligand binding domain, the Gal4 protein DNA binding domain and the herpes simplex VP16 transactivator domain (GLVP). The GLVP transactivator protein dimerizes in the presence of mifepristone (RU486) and then binds to and transactivates target transgenes containing Gal4 DNA binding domain recognition sequences upstream of the transgene. Acetaminophen (APAP) is a known hepatotoxicant, and APAP overdose results in over 10, 000 cases being treated annually by US regional poison control centers. APAP is metabolized to the reactive intermediate NAPQI. GSH is known to scavenge NAPQI making APAP a good candidate drug to test the hypothesis that transgenic mice overexpressing GCL are protected against APAP-induced liver injury. The GCL trigenic mice were administered both RU486 and acetaminophen and showed reduced liver injury, as measured by serum ALT levels (p<0.05) and histopathology (p<0.05), when compared to either control mice (those carrying the GCL transgenes but not the transactivator GLVP), or trigenic mice administered only acetaminophen. This transgenic mouse system will be useful in investigating other hepatotoxicants known to deplete GSH or cause oxidative stress in the liver. Supported by NIH Grants ES10849-02, ES04696, and

## QUANTITATION OF 4-HYDROXY-TRANS-2-NONENAL AND ITS METABOLITES BY LIQUID CHROMATOGRAPHY-MASS SPECTROMETRY.

M. J. Meyer<sup>1</sup>, M. Miyagi<sup>2</sup> and <u>M. J. Picklo<sup>1</sup>. <sup>1</sup>Pharmacology and Physiology, University of North Dakota, Grand Forks, ND and <sup>2</sup>Biochemistry and Molecular Biology, University of North Dakota, Grand Forks, ND.</u>

A liquid chromatography tandem mass spectrometry (LC-MS-MS) method has been developed to quantify 4-hydroxy-trans-2-nonenal (HNE) and its metabolites. This method utilizes a high pressure liquid chromatography system (Agilent) coupled to an API 3000 triple quadrupole mass spectrometer (PerkinElmer-Sciex). Samples were prepared and run isocratically using 50:50 acetonitrile:water with 0.1% of acetic acid at 200 uL/min on a C8 reverse-phase column. Sample analysis times were under 4 minutes. Turbo ionspray was used at 400 C with a nebulizer gas flow rate of 6 L/min. Unique ion pairs were determined for each metabolite and the analogous deuterated internal standards. Due to the structure of the acid metabolite of HNE, 4-hydroxy-trans-2-nonenoate (HNEAcid), analysis under negative ion mode was more favorable than positive ion mode. The d11-HNEAcid was analyzed in the same manner as HNEAcid. All other metabolites, such as glutathione-HNE, were more amenable to analysis under positive ion mode. The mass spectrometer was capable of operating in negative and positive ion modes in the same sample analysis. Limits of detection were 250 fmol for the oxime-derivatized metabolite of HNE (HNEoxime) and for HNEAcid. Utilizing this HPLC-MS method, we were able to detect the formation of HNEAcid and the glutathione-HNE adduct in respiring rat brain mitochondria treated with HNE.

### 1500 MEMANTINE PROTECTS SKELETAL MUSCLES AGAINST OXIDATIVE STRESS.

R. C. Gupta<sup>1</sup>, D. Milatovic<sup>2</sup>, T. J. Montine<sup>2</sup> and W. D. Dettbarn<sup>3</sup>. <sup>1</sup>Toxicology, Murry State University, Hopkinsville, KY, <sup>2</sup>Pathology, University Washington, Seattle, WA and <sup>3</sup>Pharmacology, Vanderbilt University, Nashville, TN.

This study was undertaken to determine whether memantine pretreatment protects carbofuran-induced oxidative stress in slow (soleus) and fast (EDL) muscles of rats. Both muscles were analyzed for markers of lipid peroxidation/ROS (F2-isoprostanes), RNS (citrulline, determinant of NO), high-energy phosphates (ATP and PCr), and AChE (target enzyme) to establish their time courses under the influence of acute carbofuran toxicity. Among the muscles of control rats, EDL contained greater levels of all the markers than the soleus, with the exception of citrulline, which was higher in the soleus. Rats acutely intoxicated with carbofuran (1.5mg/kg, sc) showed the onset of toxic signs within 5-10 min, and maximal severity (muscle fasiculations and convulsions) at 1 hr. At this time, carbofuran caused significant inhibition of AChE (39%), increases of F<sub>2</sub>-isoprostanes (147-178%) and citrulline (267-304%), and decreases of ATP and TAN (54-57% and 57-58%, respectively) and PCr and TCC (54-56% and 57-59%, respectively). Rats pretreated with memantine HCl (MEM, 18mg/kg, sc) and atropine sulfate (ATS, 16mg/kg, sc), 45 min and 15 min prior to carbofuran administration, showed no signs of toxicity. In addition, MEM and ATS significantly protected muscles of both types against AChE inhibition, increases in F2-isoprostanes and citrulline, and declines in energy phosphates. These findings indicated that MEM in combination with ATS protected the muscles from carbofuran-induced toxicity and oxidative stress by multiple mechanisms.

## 1501 ANTIOXIDANT EFFECTS ON ETHANOL-INDUCED OXIDATIVE STRESS AND HEPATOXICITY IN RATS FED VIA TOTAL ENTERAL NUTRITION.

T. M. Badger<sup>1,3</sup>, S. Korourian<sup>2</sup>, M. Ferguson<sup>3</sup>, B. Sampey<sup>4</sup>, E. Albano<sup>5</sup>, D. Petersen<sup>4</sup> and M. J. Ronis<sup>6,3</sup>. <sup>1</sup>Physiology, University of Arkansas for Medical Sciences, Little Rock, AR, <sup>2</sup>Pathology, University of Arkansas for Medical Sciences, Little Rock, AR, <sup>3</sup>Arkansas Children's Nutrition Center, Arkansas Children's Hospital, Little Rock, AR, <sup>4</sup>Pharmacy, University of Colorado Health Sciences Center, Denver, CO, <sup>5</sup>Medical Sciences, University "A Avogadro" of East Piedmont, Novara, Italy and <sup>6</sup>Pharmacology & Toxicology, University of Arkansas for Medical Sciences, Little Rock, AR

We examined the effects of antioxidants N-acetyl cysteine (NAC) and butylated hydroxytoluene (BHT)in rats fed ethanol i.g. Groups of 8-13 rats were infused diets where ethanol (12-13 g/kg/d) replaced carbohydrates isocalorically for 45 d. Additional groups were treated with BHT at 150 mg/kg/d or NAC at 1.2 g/kg/d. Serum ALT and liver pathology were measured. Liver slices were stained with antisera against malondialdehyde (MDA) and hydroxynonenal (HNE) adducts and serum was assayed for antibodies directed towards hydroxyethyl radical-, MDAand HNE-adducts. Liver microsomes were assayed for CYP2E1-associated CCl4dependent lipid peroxidation and CYP2E1 apoprotein by Western blot. Ethanol treatment resulted in hepatotoxicity characterized by steatosis, macrophage infiltration, focal necrosis and elevated ALT (p  $\leq$  0.05). Ethanol also induced hepatic CYP2E1 and oxidative stress as measured by presence of MDA and HNE adducts  $(p \le 0.05)$  and induced antibody titers towards MDA-adducts  $(p \le 0.05)$ . NAC treatment effectively abolished hepatic adducts and reduced ALT (p  $\leq 0.05)$  in the absence of effects on CYP2E1 but resulted in no significant decrease in liver pathology score. In contrast BHT had no effect on liver adducts but did reduce CYP2E1  $(p \le 0.05)$  and abolished elevations in antibody titers against adducts without effects on ALT or liver pathology. The relative lack of protection afforded by either NAC or BHT suggests that CYP-2E1 mediated oxidative stress might not be the only mechanism underlying alcohol-induced hepatotoxicity. Supported in part by AA08645; AA12931 (TMB) and AA09300 (DRP).

### 1502 IMPAIRED TISSUE REPAIR IN THIOACETAMIDE TREATED DIABETIC RATS: NF-KB AS A RINGMASTER.

S. S. Devi and H. M. Mehendale. Toxicology, The University of Louisiana at Monroe, Monroe, LA.

A nonlethal dose of thioacetamide (TA) causes 90 % mortality in diabetic (DB) rats due to impaired tissue repair. The objective of this study was to test our hypothesis that down regulation of NF-kB/DNA-binding in DB liver leads to down regulation of cell proliferative genes transcribed by NF-kB and is responsible for inhibited tissue repair in DB group. Gel shift assay revealed lower NF-kB/DNA binding in the DB liver, due to lower nuclear translocation of NF-kB consequent to lower degradation of I-kBα, the endogenous cytoplasmic inhibitor of NF-kB. Lower degradation of I-kBa is due to down regulated IKK enzyme. Investigation of EGFR/MAPKs pathway revealed down regulation of EGFR, and MAPKs (ERK1 and ERK2) in the DB rats, which may further explain lower degradative dissociation of I-kBa. In contrast, in the NDB group receiving the same dose of TA, up regulation of EGFR/MAPK pathway stimulates prompt and efficient degradation of I-kB $\alpha$ , facilitating nuclear translocation and higher NF-kB/DNA binding. NFkB/DNA binding transcribes antiapoptotic as well as cell proliferation genes. Lower NF-kB/DNA-binding in the DB liver, indicates lower transcription of antiapoptotic genes, explaining higher apoptosis in DB liver (histology: Ĥ & E staining and Tunnel assay) as compared to NDB liver. NF-kB also transcribes cyclin D1, which in association with cdk4 and cdk6 clears hepatocytes through the G1 to S-phase checkpoint to progress through the cell cycle. Immunoblotting showed that cyclin D1, cdk4 and cdk6 were down regulated in DB rats. Real time RT-PCR analysis confirmed that not only cyclin D1 expression but also the expression of ICAM1 and VCAM1, cell proliferative genes transcribed by NF-kB was also decreased in TA-treated DB rats, whereas in the NDB group, higher NF-kB/DNA binding leads to higher cell proliferative gene expression (cyclin D1, ICAM1 and VCAM1). These findings suggest that lower NF-kB/DNA binding in DB group underlies the down regulation of cell proliferative genes, explaining impaired tissue repair in DB rats. (Supported by Kitty DeGree Endowed Chair and LBRSF).

### 1503 ROLE OF CALPAIN IN ENDOTOXIN-MEDIATED HEPATIC INJURY.

University. M. Apte, R. McRee, J. Nguyen and S. K. Ramaiah. Department of Pathobiology, Texas A&M University, College Station, TX.

Calpain, a Ca<sup>2+</sup> dependent cytosolic cystein protease is known to be involved in a variety of pathological conditions including anoxia-induced liver injury. It has recently been reported that inhibition of calpain protects from progressive injury induced by hepatotoxicants such as acetaminophen and CCl<sub>4</sub>. However, the role of

calpain in endotoxin-mediated hepatic injury is unknown. Bacterial endotoxin (LPS) is a potent hepatotoxicant which stimulates hepatic neutrophilic infiltration resulting in hepatocyte death by apoptosis and necrosis. The hypothesized role of calpain in endotoxin-mediated hepatic injury was tested using a specific calpain inhibitor in this study. Male Sprague-Dawley rats were treated with 20 mg/kg LPS ( E. coli 0111:B4) followed by a single dose of a specific inhibitor of calpain, CBZ-VAL-PHE methyl ester (CBZ, 60 mg/kg) 1 hr after LPS administration. All rats were sacrificed 24 hrs following LPS and assessed for liver injury by plasma transaminase activities and histopathology. LPS treatment resulted in a significant increase in plasma ALT and AST activities which was corroborated by extensive hepatocellular necrosis as evaluated in H&E sections. Extensive hepatocyte apoptosis as evaluated by TUNEL assay and neutrophil infiltration was also noted in the LPS-treated rats. Calpain inhibition with CBZ significantly decreased LPS-mediated liver injury as evidenced by decreased plasma transaminase activity, necrosis and neutrophilic infiltration. Degradation of  $\alpha$ -fodrin, the cellular substrate of calpain evaluated by Western blot analysis indicated lower calpain activity in LPS+ CBZ treated rats compared to LPS alone group. Although the number of apoptotic cells decreased in CBZ treated rats, it was not completely abolished. These data suggest the likely role of calpain in endotoxin-mediated hepatic necrosis. Although calpain inhibition, partly mitigated LPS-induced apoptosis, a calpain independent pathway of apoptosis seems to be operational as evidenced by persistent apoptosis in the LPS+ CBZ treated rats.

### 1504

OSTEOPONTIN-MEDIATED INDUCTION OF MATRIX METALLOPROTEINASE-9 ACTIVITY VIA NF-KB IN ALCOHOLIC STEATOSIS.

S. K. Ramaiah, R. McRee, J. Nguyen, S. J. Smith, M. Garza, E. Wellberg and University. M. Apte. Department of Pathobiology, Texas A&M University, College Station TX

Alcoholic liver disease (ALD) is a major complication of heavy alcohol (EtOH) consumption characterized by four sequential pathologic stages namely steatosis (fat accumulation), steatohepatitis, fibrosis and cirrhosis. Although the steatosis stage is considered benign and reversible, it is known that the biochemical abnormalities in fatty liver leads to hepatic inflammation and steatohepatitis. The overall objective of this study is to investigate the role of osteopontin (OPN), an important matricellular protein in the progression of liver pathology from alcoholic steatosis to steatohepatitis. The hypothesized role of OPN in NF- $\kappa$ B-mediated induction of matrix metalloproteinases (MMP) during steatosis stage of ALD was tested in this study. Male Sprague-Dawley rats fed Lieber-DeCarli diet containing either EtOH or maltose-dextrin for 5 weeks, resulted in panlobular steatosis with mild increase in liver injury as measured by plasma transaminase activities and histopathology. A significant induction of OPN was observed in the EtOH treated rats by week 1, which further increased and reached a peak at week 2 following EtOH treatment. OPN induction correlated with higher NF-KB DNA binding. Hepatic MMP-9 activity as measured by collagen zymography indicated a temporal increase with a peak activity at week 5 following EtOH ingestion. Higher MMP-9 activity significantly correlated with hepatic fibronectin degradation, as measured by Western blot analysis. These data strongly suggest the role of OPN in MMP induction, possibly mediated via NF-κB. Significant induction of MMP-9 together with hepatic fibronectin degradation in steatotic liver, may likely predispose fatty liver to steatohepatitis by facilitating neutrophil migration into hepatic parenchyma (SUP-PÔRTED IN PART BY ES09106).

OVERACTIVATION OF POLY(ADP-RIBOSE)
POLYMERASE-1 ACCOMPANIES CARBON
TETRACHLORIDE-INDUCED CENTRILOBULAR
NECROSIS

M. Banasik<sup>1, 2</sup>, T. Stedeford<sup>1, 2</sup>, C. Muro-Cacho<sup>3</sup> and <u>R. D. Harbison<sup>1</sup></u>.

<sup>1</sup>Department of Environmental and Occupational Health, University of South Florida, Tampa, FL, <sup>2</sup>Laboratory of Toxicology and Risk Assessment, Polish Academy of Sciences, Gliwice, Poland and <sup>3</sup>Department of Interdisciplinary Oncology, H. Lee Moffitt Cancer Center and Research Institute, Tampa, FL.

Overactivation of poly(ADP-ribose) polymerase-1 (PARP-1) in response to oxidative stress has been shown to contribute to necrotic cell death by consuming NAD+ and ATP. In the present study, PARP-1 overactivation was determined by identifying the distribution and accumulation of poly(ADP-ribose) in mouse liver tissue following intraperitoneal administration of a hepatotoxic dose of carbon tetrachloride (572 mg/kg). Treated animals exhibited lipid peroxide levels 16.5-fold higher than controls. Serum activities of glutamic pyruvic transaminase and glutamic oxalacetic transaminase were increased by 6.1-fold and 22.8-fold, respectively. Lactate dehydrogenase activity was significantly increased by 1.2-fold. Histopathological analyses revealed severe necrosis and increased poly(ADP-ribosylation) of cells in

the centrilobular region of treated animals versus saline controls. These results demonstrate the role of PARP-1 overactivation in chemical-induced pathologies and suggest the potential role of PARP-1 inhibitors at preventing toxicity.

#### 1506

STRESS-RESPONSIVE MAP KINASES REGULATE RUBRATOXIN B-INDUCED CYTOKINE SECRETION IN HEPG2 CELLS.

H. Nagashima, K. Nakamura and T. Goto. National Food Research Institute, Tsukuba, Ibaraki, Japan. Sponsor: M. Fukayama.

Rubratoxin B is a potent hepatotoxic mycotoxin produced by various Penicillium fungi. Last year, we reported that rubratoxin B induced the levels of IL-8, M-CSF and GM-CSF in the culture supernatants of the human hepatoma cell lines HepG2 and HuH-7. To our knowledge, ours was the first report that an exogenous stimulus induced the secretion of M-CSF and GM-CSF in hepatocyte-derived cells, suggesting that rubratoxin B is an excellent model compound for studying the mechanisms of M-CSF and GM-CSF secretion. This year, we investigated the effects of the stress-responsive MAP kinases on rubratoxin B-induced cytokine secretion. We first measured the amounts of the stress-responsive MAP kinases JNK and p38. While treatment of cells with rubratoxin B did not change the total amounts of both kinases, the amounts of the activated (phosphorylated) forms of both kinases significantly increased. These results indicate the possibility that JNK and p38 play pivotal roles in exerting the toxicity of rubratoxin B. According to results from ELISA, treatment with the JNK inhibitor SP600125 decreased the rubratoxin Binduced release of IL-8, M-CSF and GM-CSF. In addition, the p38 inhibitor SB203580 decreased rubratoxin B-induced IL-8 and M-CSF secretion. On the other hand, SB203580 augmented rubratoxin B-induced GM-CSF secretion. To identify the step(s) crucial for regulations by JNK and p38, we used RT-PCR to measure the amounts of cytokine mRNAs. The RT-PCR results for cells treated with both rubratoxin B and the inhibitors of the stress-responsive MAP kinases showed similar tendencies to ELISA. However, the inhibitor-associated effects were much lower than ELISA, suggesting that the amounts of the secreted proteins were chiefly determined by post-transcriptional step(s). Our results suggest that A) the stress-responsive MAP kinases JNK and p38 regulate the rubratoxin B-induced secretion of IL-8, M-CSF and GM-CSF, B) these regulations mainly occur at the post-transcriptional level, and C) the mechanism of regulation of GM-CSF secretion differ from those of the other two cytokines.

## 1507 INHIBITION OF PHAGOCYTOSIS IN PRIMARY RAT KUPFFER CELLS BY METHYL PALMITATE.

P. Cai, B. S. Kaphalia and G. Ansari. Pathology, UTMB, Galveston, TX.

Kupffer cells play an important role in the early events of liver injury by releasing biologically active mediators. Methyl palmitate (MP) is known to modulate Kupffer cell functions (phagocytosis and release of chemokines). In order to evaluate the efficacy of MP towards Kupffer cell function, primary Kupffer cells were isolated from the rat liver and the cells cultured in RPMI 1640 medium. After 48h incubation, cells were treated with MP and phagocytic activity was measured by their capacity to phagocytize latex beads after 2 and 24h post incubation. A dose-dependent decrease (71%, 64% and 50% for 2h post incubation; 48%, 33%, and 12% for 24h and with LPS treatment for 6h) was observed at 0.25mM, 0.5mM and 1mM, respectively. The phagocytosis at 0.5mM MP was also found to be timedependent with a maximum decrease of 49% at 6h (control 77%). TNF-a release from these treated cells was decreased to 1567pg/ml at 1mM, as compare to control (2532pg/ml) with lipopolysaccharide (LPS) stimulation. IL-10 release was also decreased (76 pg/ml vs. 555pg/ml). Similarly MP, reduced nitric oxide production in the supernatant was found to be 0.35, 0.33, and 0.30uM at 0.25mM, 0.5mM and 1.0mM respectively, 24h post incubation, as compared to control (0.53uM). These results indicate that MP inhibits phagocytosis and mediates the release of several chemokines from the Kupffer cells. The mechanism of such inhibition and down regulation of chemokines by MP needs to be thoroughly investigated.

### 1508

DIETARY ZINC SUPPLEMENTATION ATTENUATES CHRONIC ALCOHOL-INDUCED LIVER INJURY IN MICE THROUGH INHIBITION OF OXIDATIVE STRESS.

Z. Zhou<sup>1</sup>, L. Wang<sup>1</sup>, J. T. Saari<sup>2</sup>, C. J. McClain<sup>1</sup> and <u>Y. Kang<sup>1</sup></u>. <sup>1</sup>University of Louisville, Louisville, KY and <sup>2</sup>Human Nutrition Research Center, USDA, Grant Forks, ND.

Zinc depletion in the liver has long been noted in alcoholic liver disease. However, there is limited information about the role of zinc in the pathophysiology of alcohol-induced liver injury. The present study was undertaken to determine whether dietary zinc supplementation confers resistance to chronic alcoholic liver injury.

Because metallothionein (MT) may participate in the regulation of cellular zinc homeostasis, MT-knockout (MT-KO) mice along with their wild-type (WT) 129/Sv controls were used and fed Lieber-DeCarli liquid diets following a 2x2 factorial design; ethanol x zinc. Zinc was supplemented at a level of 100 mg zinc ion/l. An improved feeding protocol was established as follows: 1) The alcohol content (%, w/v) in the diet started from 3.2, with an increase of 0.2 every week, reached 5.0 at the end, and 2) an one-day-stop on the last day of each week was introduced in the alcohol feeding schedule. Both WT and MT-KO mice fed ad libitum for 10 weeks showed significant liver injury, as indicated by increased plasma alanine aminotransferase activity, pathological changes, and hepatocyte apoptosis. Zinc supplementation attenuated alcohol-induced liver injury in both WT and MT-KO mice. Zinc supplementation also abrogated ethanol-induced oxidative injury including lipid peroxidation and protein oxidation. Dihydroethidine fluorescent microscopy demonstrated that zinc suppressed ethanol-induce superoxide accumulation in the liver. Zinc also inhibited ethanol-induced increases in hepatic CYP2E1 and xanthine oxidase, and the decrease in hepatic glutathione peroxidase. Furthermore, ethanol-induced depletion of hepatic zinc concentration was repleted by zinc supplementation. These results thus demonstrate that zinc is a potent hepatoprotective agent against alcoholic liver injury, whose action is related to depressed oxidative stress. (Supported in part by NIH grants AA13601, AA01762, and HL59225)

1509

CHENODEOXYCHOLIC ACID-MEDIATES INDUCTION OF THE MITOCHONDRIAL PERMEABILITY TRANSITION THROUGH ALTERED MEMBRANE FLUIDITY.

A. P. Rolo, P. J. Oliveira, A. J. Moreno and <u>C. M. Palmeira</u>. *Center for Neurosciences and Cell Biology of Coimbra, Department of Zoology, University of Coimbra, Coimbra, Portugal.* 

Chenodeoxycholic acid (CDCA), a primary bile acid mostly implicated in cholestatic liver injury, is toxic to hepatocytes by mechanisms involving mitochondrial dysfunction. In this study we have investigated the involvement of membrane fluidity and cytochrome c release in CDCA-induced mitochondrial permeability transition (MPT), and the preventive role of carvedilol. Within this context, mitochondrial swelling, membrane potential, and mitochondrial calcium fluxes were monitored. The involvement of alterations on membrane fluidity, as probed by membrane labelling with fluorescent dyes, and cytochrome c release in CDCA-induced MPT was also studied. Treatment of calcium-loaded hepatic mitochondria with CDCA was found to cause osmotic swelling and release of cytochrome c, associated with an increase in membrane fluidity, in both surface and membrane core regions. Carvedilol and cyclosporine A (CyA) reduced both cytochrome c release and alterations in membrane fluidity induced by CDCA. The hydroxylated metabolite of carvedilol, BM-910228, had no effect. Thus, modulation of membrane fluidity, play an important role in MPT pore opening promoted by CDCA. As a result, we have delineated a pathway for the preventive role of carvedilol in mitochondrial dysfunction induced by CDCA. (Supported by PRAXIS XXI/21454/99 and Portuguese Research Council (POCTI/CBO/42486/2001) FCT)

## 1510 IN VITRO DEVELOPMENT OF BIOMARKERS FOR ACETAMINOPHEN TOXICITY IN PRIMARY MOUSE HEPATOCYTES.

<u>I. N. Mayes</u><sup>1, 2</sup>, R. Edmondson<sup>3</sup>, R. Jones<sup>3</sup> and <u>Y. P. Dragan</u><sup>2, 1</sup>. <sup>1</sup>Pharmacology and Toxicology, University of Arkansas for Medical Sciences, Little Rock, AR, <sup>2</sup>Hepatic Toxicology, NCTR, Jefferson, AR and <sup>3</sup>Chemistry, NCTR, Jefferson, AR.

Hepatotoxicity is an important concern in drug development, as well as a primary reason for drug recall. Therefore, biomarkers that detect the potential for agents to induce adverse liver effects are of great need. Acetaminophen (APAP) is a known toxin to mouse and human liver and is responsible for a large percentage of acute liver failure cases in this country. The availability of early, specific and selective biomarkers that are accessible in biofluids could permit the detection of liver damage prior to the presence of morphological evidence of damage. Clinically, serum enzyme levels are used as an indicator of liver function; we hypothesize that proteins réleased into cell culture media following toxin exposure are equivalent indicators of liver damage and a proteomic analysis of these proteins can be used to identify these potential biomarkers. Our studies used primary hepatocytes isolated from 5 male C57BL/6 mice to perform a dose response and time course analysis of APAP and its stereoisomer, 3'-hydroxyacetanilide (AMAP). Hepatocytes were isolated and cultured on collagen coated plates. ALT activities increased as a function of dose (0, 0.3, 1, 3, and 10mM) and time (6, 12, 18, and 24 hr) with both APAP and AMAP administration. Morphological evidence of hepatic damage preceded the increase in alanine aminotransferase (ALT) serum enzyme levels. The cell culture media from APAP treated hepatocytes was concentrated with deoxycholic acid / trichloroacetic acid (DOC/TCA), normalized for protein content and solublized for two-dimensional gel electrophoresis (2DGE). Proteins that were altered as a function of dose or time in a manner suggestive of correlation with toxicity were excised, digested with trypsin, and subjected to LC/MS/MS analysis. Several differentially expressed proteins were identified using this approach, but their relationship to the induction or progression of toxicity is unclear.

1511 PREDICTION FOR HEPATOTOXINS IN A PRIMARY HEPATOCYTE TEST SYSTEM WITH TRANSCRIPTIONAL PROFILING OF TOXICITY RELATED GENES.

P. Eddy, J. Lin, E. Fedyk, S. Badola, V. Sasseville and C. L. Alden. Drug Safety and Disposition, Millennium Pharmacology, Cambridge, MA.

The prediction of development limiting toxicity in lead optimization using 5 day repeat dose toxicity studies in rat and higher species has significantly reduced development attrition. Repeat dose in vivo toxicity testing engenders significant cost for synthesis of test agent. The opportunity for the toxicology discipline to create a discontinuity in the efficiency of the drug discovery process exists through leveraging molecular technology in cell based systems. Cell based toxicity testing using biochemical or functional endpoints are not useful in predicitng for systemic toxicity. Cell based systems using microarrays have been demonstrated to predict successfully for pharmacology specific patterns of gene expression. Only a few companies have focused on toxicity related patterns of gene expression in cell based assays. Although debate continues on the value of microarray data versus select subsets of genes for predicting systemic toxicity potential, a small number of genes specific to toxicologic responses in cell based systems represents a more practical approach for screening at early stages in lead optimization. Using transcriptional profiling of a few stress and cell cycle related genes in a cryopreserved human hepatocyte test system to predict for human hepatotoxicity enables reliable differentiation of over one half of the hepatotoxins via robust upregulation of several of the toxicity genes. While none of the agents predicted to be toxic were nontoxic, an additional subset of hepatotoxins without modest upregulation of toxicity genes can not be differentiated from certain nontoxins, specifically nontoxins causing upregulation of p450 microsommal enzymes such as phenobarbital. Over 40 drugs of known toxicity potential including drugs causing idiosyncratic injury have been evaluated in this testing paradigm. Predicting for a significant proportion of hepatotoxins utilizing miniarrays in a human cell test system will create substantial cost benefit applied antecedent to repeat dose in vivo preclinical efficacy testing.

VISUALIZATION AND QUANTITATION OF PEROXISOMES USING QUANTUM DOTS™:
DETECTION IN THE LIVER FOLLOWING TREATMENT OF RATS AND MONKEYS WITH FIBRATES.

<u>G. Falls</u><sup>1</sup>, H. M. Colton<sup>1</sup>, H. Ni<sup>1</sup>, <u>P. Kwanyuen</u><sup>1</sup>, D. R. Creech<sup>1</sup>, N. F. Cariello<sup>1</sup> and G. Hamilton<sup>2</sup>. <sup>1</sup>Safety Assessment, GlaxoSmithKline, Research Triangle Park, NC and <sup>2</sup>Hepatotech Inc., Pittsboro, NC.

Peroxisome proliferation has been well documented in rodents following treatment with hypolipidemic drugs such as fibrates, and extensive research has focused on the induction of peroxisome proliferation by compounds in drug development. Levels of peroxisome proliferation have been estimated by measuring gene expression and enzyme activity as well as with immunolabeling and direct counting using electron microscopy. Although each method has its benefit, high levels of cost, labor, and sample manipulation require a more efficient and reproducible method for peroxisome visualization. To address this issue, we developed a method for immunofluorescent staining of peroxisomes using a polyclonal antibody to the 70kDal peroxisomal membrane protein (PMP70) and fluorescent cadmium selenide-based nanocrystals called Quantum Dots<sup>TM</sup>. The unique composition and structure of these nanocrystals lead to highly desirable optical properties including quantum yields of over 50%, narrow emission peaks, remarkable photostability, and large Stokes shifts provided by the exceptionally broad excitation range. Using streptavidin-coated Quantum Dots™ and a PMP70 antibody, we were able to stain and visualize peroxisomes in standard formalin-fixed paraffin-embedded rat and monkey liver after in vivo treatment with fenofibrate and ciprofibrate, respectively. A dose-dependent increase in peroxisome number and area compared to controls was observed in cynomolgus monkeys given 3, 30, 150, and 400 mg/kg/day of ciprofibrate. This finding correlated with an increase in peroxisome count determined by electron microscopy. In liver sections from male Wistar rats treated for 10 days with fenofibrate (0, 10, 20, or 200 mg/kg/day), there was a dose-dependent increase in PMP70 staining, indicative of peroxisome proliferation. We have also utilized this method to detect peroxisomes in sections from human liver and rat soleus muscle, and in rat primary hepatocytes.

### 1513

GENOMIC ANALYSIS OF SUSCEPTIBILITY FACTORS ASSOCIATED WITH HALOTHANE-INDUCED LIVER INJURY IN GUINEA PIGS.

M. Holt<sup>1</sup>, <u>M. Bourdi</u><sup>1</sup>, A. Elkahloun<sup>2</sup>, D. Erias<sup>1</sup> and <u>L. Pohl</u><sup>1</sup>. <sup>1</sup>Melecular and Cellular Toxicology Section/LMI, NHLBI/NIH/DHHS, Bethesda, MD and <sup>2</sup>Cancer Genetics Branch, NHGRI/NIH/DHHS, Bethesda, MD.

Halothane causes a mild form of liver injury in guinea pigs that appears to model the hepatotoxicity seen in approximately 20% of patients treated with this drug. Although the increased susceptibility of some outbred guinea pigs to halothane-induced liver injury (HILI) has been associated with elevated levels of trifluoroacetylated (TFA) protein adducts in the liver, the role of other susceptibility factors in this toxicity remains to be more thoroughly explored. In the current study, we have addressed this issue by comparing the hepatic gene expression of susceptible guinea pigs (SGP) to those of resistant guinea pigs (RGP) following halothane treatment using a cDNA microarray that can detect the expression of over 30, 000 genes and ESTs. It was found that several genes that encode for antioxidant and stress proteins were underexpressed in the liver of SGP relative to those of RGP including catalase, peroxiredoxins, glutathione S-transferase family members, ferritin heavy chain, selenoprotein P, and heat shock proteins as were genes involved in lipid synthesis and regulation including 3-hydroxy-3-methylglutaryl-CoA synthase 2, apolipoprotein A-IV, fatty acid synthase, low density lipoprotein receptor-related protein 1, and sterol carrier protein 2. These finding suggest that the increased susceptibility of a subset of guinea pigs to HILI is not only due to the increased formation of TFAprotein adducts but also to deficiencies in the expression of multiple hepatoprotective factors and proteins involved in lipid homeostasis. Similar factors may have a role in predisposing patients to HILI and to liver injury caused by other drugs.

### 1514

EFFECTS OF FLAVONOID TREATMENT ON THE PERMEABILITY OF CYCLOSPORIN A ACROSS CACO-2 CELL MONOLAYERS.

J. E. Mata<sup>1</sup>, R. Rodriguez-Proteau<sup>1, 2</sup>, C. L. Miranda<sup>2</sup>, D. R. Buhler<sup>2</sup> and J. Brown<sup>1</sup>. <sup>1</sup>Pharmaceutical Sciences, Oregon State University, Corvallis, OR and <sup>2</sup>Environmental and Molecular Toxicology, Oregon State University, Corvallis, OR.

Flavonoids present in plant materials have demonstrated activity in cancer chemoprevention, cancer treatment paradigms, modulation of signal transduction pathways and drug transport processes. The ability of specific flavonoids such as xanthohumol, quercetin, epigallocatechin gallate (EGCG), epicatechin gallate (ECG), genestein, naringenin, genestin, and naringin to modulate the permeability of cyclosporin A (CSA), a P-glycoprotein substrate, across Caco-2 cell monolayers was evaluated. Flavonoid concentrations of 100 µM were used in the transport experiments with the exception of xanthohumol, EGCG and ECG which were at a concentration of 30 µM. Experiments were performed in sink conditions from basolateral (BL) to apical (AP) direction and in non-sink conditions from AP → BL with <sup>3</sup>H-CSA concentrations of 0.5, 1.0, 2.0, 5.0, 10.0 and 20.0 μM. The aglycone form of the flavonoids tested reduced the permeability (Pe) of CSA to a greater extent than the glycosylated form with xanthohumol producing the greatest overall effect. Thirty  $\mu$ M xanthohumol reduced the P<sub>o</sub> of CSA from 7.2 x  $10^{-6} \pm 4.8 \times 10^{-7}$ cm/sec to 6.6 x  $10^{-7} \pm 3.99$  x  $10^{-7}$  cm/sec from the BL  $\rightarrow$  AP direction. <sup>3</sup>H-Xanthohumol demonstrated a saturable efflux from the BL  $\rightarrow$  AP compartments with significant inhibition at 5  $\mu$ M, p < 0.05. These studies suggest that flavonoids are capable of reducing the efflux of CSA across Caco-2 cell monolayers with differences in potency. Xanthohumol is an effective inhibitor of CSA permeability and is capable of limiting its own efflux. Supported by NIH grant AT00853.

### 1515

ABSENCE OF LIVER CANALICULAR MRP2 TRANSPORTER SHIFTS METHYLENE DIANILINE INJURY FROM BILIARY EPITHELIAL CELLS TO HEPATOCYTES.

M. F. Kanz<sup>1</sup>, F. Nayeem<sup>1</sup>, V. Santa Cruz<sup>1</sup>, T. R. Dugas<sup>2</sup> and M. Treinen-Moslen<sup>1</sup>. <sup>1</sup>Pathology, University of Texas Medical Branch, Galveston, TX and <sup>2</sup>Pharmacology, LSU Health Sciences Center, Shreveport, LA.

Background. Methylene dianiline (4, 4'-diaminodiphenylmethane, DAPM), a compound used in the production of polyurethanes and epoxy resins, initially injures biliary epithelial cells (BEC) *in vivo. In vitro* studies indicate that BEC are injured by proximate toxicant(s) in bile. Two biliary DAPM metabolites have been preliminarily identified as glutathione and cysteinyl-glycine conjugates of DAPM. Mutant transport-deficient (TR') rats lack expression of the canalicular multispecific organic anion transporter (cMOAT or MRP2) and have deficient biliary excretion of organic anions, GSH and GSH conjugates. We hypothesized that absence of the MRP2 transporter would modulate DAPM-induced injury of BEC. Methods. Time course (25 mg/kg) and dose response (25 to 100 mg/kg) studies were conducted in male or female TR' rats (16-20 wks old). DAPM was given po in

35% ethanol and tissues and blood were analyzed for injury. Results. *Time Course:* Liver weights were increased in female rats at 24, 48, 72, 168 hr but only at 24 and 48 hr in male rats. Spleen weights increased in females at 48 and 72 hr but only at 72 hr in males. Serum bilirubin was elevated in male rats at 24, 48, 72 hr while serum indices were highly variable in both treated and control TR female rats. Scattered, small foci of necrosis and inflammation were observed in centrolobular to midzonal regions in both genders at 24 hr with peak injury at 48 hr. Recover occurred faster in male than female rats. *Dose-Response:* Significant centrolobular necrosis with bridging between lobules was apparent at 48 hr after 50 mg/kg. At 100 mg/kg, 50% of the females died before 48 hr. In the remaining animals, massive liver congestion was observed with 70-90% of the hepatic parenchyma destroyed. Only minimal injury to BEC was seen at the highest dose. Conclusion. The MRP2 transporter is involved in excretion of DAPM metabolites into bile that injure BEC. (Supported by NIH grants ES06348; DK56494; T32-ES07254)

### 1516 MULTIPLE DRUG RESISTANCE GENE REGULATION IN MICE

J. M. Brady, X. G. Cheng, J. M. Maher and <u>C. D. Klaassen</u>. *University of Kansas Medical Center, Kansas City, KS*.

Multiple drug resistance (Mdr) genes encode P-glycoprotein, which is responsible for resistance to some cancer chemotherapeutic drugs and efflux of xenobiotics out of cells. Thus, Mdr can protect organs from xenobiotic toxicity. There are two Mdr1 gene products in mice capable of xenobiotic transport, Mdr1a (Abcb1a) and Mdr1b (Abcb1b). A third related gene product, Mdr2 (Abcb4), is associated with phospolipid transport into bile. The aims of the present study were to determine 1) the tissue distribution of mouse Mdr mRNAs, 2) the ontogeny of Mdr mRNAs, and 3) whether microsomal enzyme inducers that increase phase I and II drug-metabolizing enzymes coordinately regulate Mdr genes. Mdr1a mRNA expression was high in small intestine; moderate in large intestine and brain; and low in liver and kidney. The highest expression of Mdr1b mRNA was in kidney, where the concentration was about 3-fold higher than most other tissues. In brain, Mdr1b mRNA levels were higher in males than females. The highest Mdr2 mRNA level was observed in liver, with female-predominance. Ontogeny studies showed that in liver, Mdr1a mRNA increased from day 10 through day 35. Mdr1b mRNA expression showed a slight increase after birth through day 15. Male-predominant expression of Mdr1b mRNA was observed from days 5-35, but there was no gender difference in adults. Mdr2 mRNA levels were highest at birth with a decrease throughout days 5-30. The induction of Mdr mRNA transcripts in liver by treatment with 22 chemicals representing AhR ligands, CAR ligands, PXR ligands, PPARa ligands, Nrf2 activators, and Cyp4502E1 inducers was also assessed. Mdr mRNA transcripts in liver were not significantly altered by treatment of mice with any of these classes of inducers. In conclusion, the primary expression of mouse Mdr1a gene is in the gastrointestinal tract where it functions to decrease absorption of some xenobiotics. Mouse Mdr gene expression is not readily increased by microsomal enzyme inducers through coordinate mechanisms with phase I and II drug-metabolizing enzymes. (Supported by NIH Grants ES-09716 and ES-07079)

### 1517

TISSUE DISTRIBUTION AND HORMONAL REGULATION OF THE BREAST CANCER RESISTANCE PROTEIN (BCRP/ABCG2) IN RATS AND MICE.

Y. Tanaka, A. L. Slitt, J. M. Maher, T. M. Leazer and C. D. Klaassen. University of Kansas Medical Center, Kansas City, KS.

Breast cancer resistance protein (Bcrp/Abcg2), also known as the mitoxantrone resistance protein or the placental ABC transporter, is a member of the ABC transporter family. The purpose of this study was to quantify Bcrp mRNA in rat and mouse tissues, and to determine whether there are gender differences in Bcrp mRNA expression by the branched DNA assay. Rat Bcrp mRNA levels were high in intestine and kidney; intermediate in testes; and low in other tissues, including liver. Bcrp expression in mouse was highest in kidney, followed by liver, ileum and testes. BCRP mRNA expression is known to be very high in human placenta, but its expression in rat and mouse placenta was much lower than that in other tissues. Male-predominant expression of Bcrp was observed in rat kidney, and mouse liver. Female-predominant expression of Bcrp was observed in rat brain. Furthermore, gonadectomy and hypophysectomy (HX) experiments were conducted to determine whether sex steroids and/or growth hormone (GH) are responsible for Bcrp gender-divergent expression patterns in rat kidney and mouse liver. Ovariectomy increased Bcrp expression in female rat kidney, but Bcrp expression in male rat kidney was unaffected by castration. HX had no significant effect on Bcrp mRNA levels in male or female rat kidney. In mice, gonadectomy reduced Bcrp expression markedly in male liver, but only slightly in female liver. Administration of 5α-dihydroxytestosterone or  $17\beta$ -estradiol, to castrated males and ovariectomized females respectively, resulted in an increase in Bcrp mRNA by testosterone but not estra-

diol. In summary, species differences exist in the tissue distribution of Bcrp, especially with regard to intestinal expression. Gender differences were observed within both species. Male-predominant expression of Bcrp in rat kidney appears to be due to the suppressive effect of estradiol. Male-predominant expression of Bcrp in mouse liver appears to be due to the inductive effect of testosterone. (Supported by NIH grants ES-09714 and ES-07079)

1518

LIPOPOLYSACCHARIDE-MEDIATED DOWN-REGULATION OF ORGANIC ANION TRANSPORTING POLYPEPTIDE 4 (OATP4; SLC21A10) IS INDEPENDENT OF TUMOR NECROSIS FACTOR-α, INTERLEUKIN-1β, INTERLEUKIN-6, OR INDUCIBLE NITRIC OXIDE SYNTHASE.

N. Li and C. D. Klaassen. University of Kansas Medical Center, Kansas City, KS.

Organic anion transporting polypeptide 4 (Oatp4) is expressed almost exclusively in liver, where it mediates uptake of a variety of anionic compounds, including bile acids, across hepatic sinusoidal membranes in a Na+-independent manner. Lipopolysaccharide (LPS) has been shown to decrease Oatp4 mRNA concentrations in a dose- and time-dependent manner in Toll-like receptor 4 (TLR4) normal (C3H/Ou]) mice, but not in TLR4-mutant (C3H/He]) mice. Moreover, after LPS administration, serum concentrations of tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), interleukin-1β (IL-1β), and interleukin-6 (IL-6) are markedly lower in TLR-4 mutant mice than in TLR-4 normal mice. Thus, TLR4 is considered an upstream mediator of LPS-induced decrease in mouse Oatp4 mRNA and increase in some serum cytokines. LPS is thought to alter liver gene expression, including that of hepatic transport proteins, through TLR4-mediated TNF-α, IL-1β, IL-6, or nitric oxide (NO) release. TNF receptor p55 (TNFRp55) and type I IL-1 receptor (IL-1RI) mediate the biological functions of TNF-α and IL-1β, respectively. Therefore, to determine whether endogenous cytokines or NO are mediators of LPS-induced down-regulation of mouse Oatp4 mRNA, Oatp4 mRNA levels were determined in mice deficient in the TNFRp55, IL-1RI, IL-6, or inducible nitric oxide synthase (iNOS) after LPS administration. Mice homozygous for a targeted deletion in genes for TNFRp55, IL-1RI, IL-6, or iNOS exhibited similar decreases in Oatp4 mRNA levels as wild-type mice after LPS administration. Moreover, in mouse hepatoma cells, treatment with TNF-α, IL-1β, or IL-6 individually or in combination did not suppress activity of a mouse Oatp4 promoter construct (-4.8kb/+30). Therefore, LPS-induced down-regulation of Oatp4 appears to be independent of TNF-α, IL-1β, IL-6 or iNOS. (Supported by NIH grant ES-09649)

#### 1519 ROLE OF NAD(P)H:QUINONE OXIDOREDUCTASE 1 IN CLOFIBRATE MEDIATED HEPATOPROTECTION FROM ACETAMINOPHEN TOXICITY.

J. Moffit<sup>1</sup>, M. Kardas<sup>1</sup>, L. M. Aleksunes<sup>1</sup>, A. M. Slitt<sup>2</sup>, C. D. Klaassen<sup>2</sup> and J. E. Manautou<sup>1</sup>. <sup>1</sup>Department of Pharmaceutical Sciences, University of Connecticut, Storrs, CT and Department of Pharmacology, Toxicology, and Therapeutics, University of Kansas Medical Center, Kansas City, KS.

Acetaminophen (APAP) is an analgesic and antipyretic agent that produces liver toxicity at high doses. The toxicity of APAP is highly dependent on hepatic bioactivation and detoxification pathways. Pretreatment with the hypolipidemic drug clofibrate (CFB) reduces APAP hepatotoxicity significantly in male CD-1 mice. However, the mechanism of this resistance is not entirely known. Previous studies showed that CFB reduces APAP binding to hepatic proteins and depletion of cellular glutathione independently of changes in bioactivation and conjugative pathways for APAP. These results suggest that CFB pretreatment enhances the detoxification of the APAP reactive intermediate, N-acetyl-p-benzoquinone imine (NAPQI). Since NAD(P)H quinone oxidoreductase 1 (NQO1) is involved in the reduction of cellular quinones, we investigated the effect of CFB on the expression and activity of this detoxifying enzyme. Administration of CFB (500 mg/kg, i.p.) to male CD-1 mice for 5 or 10 days resulted in a modest induction of NQO1 activity, which was only significant for the 5 day dosing regimen. Branched DNA signal amplification and western blot analysis showed that CFB treatment does not significantly increase NQO1 gene transcription or protein levels. Additionally, inclusion of human recombinant NQO1 does not alter the amount of NAPQI generated by an in vitro microsomal activating system. In conclusion, CFB treatment does not appear to alter NQO1 expression or function in a manner consistent with its hepatoprotective capacity. The lack of NQO1 induction coupled with the inability of recombinant NQO1 to alter NAPQI availability, suggests that the detoxification of APAP active metabolites by quinone reduction is not a mechanism involved in hepatoprotection afforded by CFB. Supported by NIH ES10093 and the University of Connecticut Research Foundation.

### 1520 DIFFERENTIAL GENE EXPRESSION OF MEMBRANE

TRANSPORT AND DETOXIFICATION PROTEINS DURING HEPATIC INJURY.

L. Aleksunes<sup>1</sup>, A. Slitt<sup>2</sup>, M. Thibodeau<sup>1</sup>, C. Klaassen<sup>2</sup> and J. Manautou<sup>1</sup>. <sup>1</sup>Pharmaceutical Sciences, University of Connecticut, Storrs, CT and <sup>2</sup>Pharmacology, Toxicology, and Therapeutics, University of Kansas Medical Center, Kansas City, KS.

Drug metabolizing enzymes and membrane transporters are responsible for the detoxification and elimination of xenobiotics from the liver. Following acute chemical injury, hepatocytes are generally more resistant to toxicant re-exposure. Alterations in the production of transport and cellular defense proteins may contribute to this resistance. Characterization of transcriptional changes is one approach for studying regulation of detoxification and elimination pathways. The goal of this study was to identify alterations in mRNA levels of transport and detoxification proteins as a result of pro-oxidant liver injury. These included the multidrug resistance-associated proteins (Mrp 1-4), organic anion transport proteins (Oatp 1, 2 and 4) and sodium taurocholate co-transporting protein (Ntcp), in addition to heme oxygenase (HO), quinone reductase (QR) and epoxide hydrolase (EH). For this purpose, groups of male C57BL/6J mice received acetaminophen (APAP, 200, 300 or 400 mg/kg, i.p.) or carbon tetrachloride (CCl<sub>4</sub>, 10 or 25 ul/kg, i.p.). Liver samples were collected at 6, 24 and 48 hrs for total RNA isolation and histopathological analysis of injury. Gene expression was determined using branched DNA signal amplification. Although EH expression was unaltered, APAP and CCl<sub>4</sub> increased HO and QR levels by 21- and 2.5-fold, respectively. A uniform reduction in transcription of Oatp1, 2, 4 and Ntcp was observed with CCl4 treatment. By contrast, expression of Mrps 1-4 was increased differentially by APAP and CCl<sub>4</sub>. Notably, a marked elevation of Mrp4 was observed 24 hrs after APAP (5fold) and CCl<sub>4</sub> (37-fold). Collectively, these expression patterns suggest a coordinated regulation of both transport and detoxification genes during liver injury. This reduction in expression of uptake transporters and enhanced transcription of detoxification enzymes and export transporters may contribute to the resistance of hepatocytes to subsequent toxicant exposure.

#### 1521 TRANSPORT CHARACTERISTICS OF 3, 3'-DIINDOLYLMETHANE USING HUMAN DERIVED INTESTINAL CELLS, CACO-2 AND P27.7 CELLS.

A. J. Rodriguez<sup>1</sup>, R. Rodriguez-Proteau<sup>1,2</sup>, S. C. Tilton<sup>2</sup>, J. Chen<sup>1</sup>, K. P. Hall<sup>1</sup>, J. E. Mata<sup>1</sup> and D. E. Williams<sup>2,3,4</sup>, Pharmaceutical Sciences, Oregon State University, Corvallis, OR, Department of Environmental and Molecular Toxicology, Oregon State University, Corvallis, OR, Linus Pauling Institute, Oregon State University, Corvallis, OR and Marine and Freshwater Biomedical Science Center, Oregon State University, Corvallis, OR.

Indole-3-carbinol (I3C) is a major component of cruciferous vegetables that has been shown to be chemoprotective in animal studies and is under evaluation for chemoprevention of breast cancer in women. I3C undergoes acid condensation in the stomach to numerous products such as 3, 3'-diindolylymethane (DIM). DIM has been shown to be antiestrogenic in MCF-7 cells and presumably interacts with the aryl hydrocarbon receptor (AHR) to inhibit tumor development. This study evaluated the transport characteristics of DIM using the in vitro intestinal drug transport/metabolism models, Caco-2 cells and P27.7 cells. The transport of <sup>3</sup>H-DIM (0.1, 0.5, 0.75, 1, and 10  $\mu M)$  over 3 hrs was investigated using sink conditions from the apical (A) to basolateral (B) direction and vise versa,  $B \to A$ , in Caco-2 and P27.7 cells. The permeability (Pe) of DIM was slightly greater from the  $A \to B$  direction than the  $B \to A$  with the Caco-2 cells at all concentrations evaluated. There were no differences seen with the P27.7 cells (expressing CYP3A4), in either direction without and with 100 µM verapamil, a P-glycoprotein (P-gp) inhibitor.  ${}^{3}H$ -DIM demonstrated a saturable efflux from the  $B \to A$  compartments without and with verapamil with significance seen between the 0.75  $\mu\dot{M}$  and 1.0  $\mu M$ , Pe from 1.54 x 10  $^5$   $\pm$  2.91 x 10  $^6$  cm/sec to 8.13 x 10  $^6$   $\pm$  1.51 x 10-6  $^{cm/sec}$  and 1.69 x 10  $^5$   $\pm$  1.30 x 10  $^6$  cm/sec to 9.48 x 10  $^6$   $\pm$  9.74 x 10  $^7$  cm/sec, respectively, p < 0.05. These studies suggest that DIM is not a substrate for P-gp; however, DIM can limit its own efflux. Also, in the clone of Caco-2 cells, P27.7 cells, Pe of DIM was increased in both directions without and with verapamil when compared to the parent cell line; thus, the transport characteristics of DIM was altered compared to the Caco-2 cells. Supported by NIH grants ES007316 and CA90890.

#### 1522 EFFECT OF TROGLITAZONE (TGZ) ON BASOLATERAL AND CANALICULAR TRANSPORT OF MODEL ORGANIC ANIONS.

D. C. Kemp<sup>1</sup> and K. L. Brouwer<sup>2, 1</sup>. <sup>1</sup>Curriculum in Toxicology, University of North Carolina, Chapel Hill, NC and <sup>2</sup>Drug Disposition and Delivery, School of Pharmacy, University of North Carolina, Chapel Hill, NC.

Studies in this laboratory have shown that TGZ decreased taurocholate (TC) accumulation in sandwich-cultured rat hepatocytes (SCRH). The primary objective of this study was to determine whether TGZ modulates basolateral transport protein

function; a secondary objective was to determine whether TGZ alters Mrp2-mediated transport. Initial substrate uptake (15-60 sec) in freshly isolated male Wistar rat hepatocytes was evaluated. In addition, substrate uptake and biliary excretion were examined in SCRH. Suspended hepatocytes were isolated from male Wistar rats in Dulbecco's Modified Éagle's Medium (DMEM), and uptake determined using standard methodology. Isolated hepatocytes from male Wistar rats were cultured for 4 days between two layers of gelled collagen. Culture media consisted of DMEM, supplemented with 5% fetal bovine serum and insulin (4 mg/L) for the first 24 hrs; subsequently DMEM was supplemented with 1% ITS (insulin, transferring, selenium, linoleic acid) and 0.1 µM dexamethasone, replaced every 24 hrs. The TC (1 µM) uptake rate in suspended hepatocytes was decreased ~3-fold by TGZ (10  $\mu \dot{M})$  over a 60 sec time range. To determine whether this effect was due to impaired Oatp-mediated TC uptake, the effect of TGZ on estradiol- $17\beta$ -D-glucuronide (E217G) uptake was examined. TGZ inhibited E217G (1 µM) uptake in isolated hepatocytes -2-fold (0.06±0.02 to 0.03±0.004 nmol/mg protein/60 sec, mean±S.E.M). In SCRH, TGZ (10 μM) also decreased E217G 10-min accumulation ~2-fold (150±19 vs. 68±11 pmol/mg protein, mean±S.E.M) in standard HBSS (Hanks balanced salt solution) (cell + bile canaliculi). TGZ decreased accumulation of carboxydichlorofluorescein, an Mrp2 substrate, in standard HBSS, but differences were not statistically significant (733±91 vs. 566±98, mean±S.E.M). These data suggest that 10  $\mu\text{M}$  TGŽ primarily alters basolateral uptake with modest alterations in Mrp2-mediated transport of organic anions in hepatocytes. Supported by 5-T32-ESO7126 and NIH GM41935.

## 1523 AUTOPROTECTION: SUBCHRONIC LOW DOSE ADMINISTRATION OF CHLOROFORM RENDERS RESISTANCE TO A LETHAL DOSE OF CHLOROFORM.

H. M. Mehendale<sup>1</sup>, S. S. Anand<sup>1</sup>, P. S. Palkar<sup>1</sup> and M. M. Mumtaz<sup>2</sup>.

<sup>1</sup>Department of Toxicology, University of Louisiana, Monroe, monroe, LA and <sup>2</sup>ATSDR, Atlanta, GA.

The aim of the study was to develop a subchronic autoprotection model for CHCl 3 and to investigate the role of toxicokinetics and tissue repair. Swiss-Webster mice were treated with 150 and 300 mg CHCl<sub>3</sub>/kg *via* aqueous gavage for 30 d before challenging with a LD90 dose (750 mg CHCl<sub>3</sub>/kg) resulted in 100% survival of mice. Another set of mice receiving only the LD90 dose died within 3 d. Liver and kidney injury were measured by ALT and BUN, respectively, and by histopathology. Tissue repair was assessed by (<sup>3</sup>H-T) thymidine incorporation into hepato- and nephro-nuclear DNA and by PCNA. These were measured from 24 to 96 h after the lethal dose. Blood, liver and kidney levels of CHCl<sub>3</sub> were quantified over 15 to 360 min. Only the high dose caused 20% mortality during the 30 d dosing regimen. Blood CHCl $_{\rm 3}$  levels in 150 and 300 mg/kg groups were 40 and 60% lower, respectively, than the mice receiving only 750 mg CHCl<sub>3</sub>/kg. Without the priming treatment, 750 mg CHCl<sub>3</sub>/kg caused significant hepatic and renal injury at 24 h, peaking at 48 h. While liver injury resolved, kidney injury was still evident at 72 h. Mortality occurred between 48 to 96 h. In the absence of priming, lethal dose inhibited tissue repair in liver and kidney. Tissue repair was significantly higher in autoprotected mice at 48 and 72 h. Liver and kidney injury were remarkably lower in the primed mice. The biochemical findings were supported by histopathology and PCNA. Significantly larger numbers of cells entered S-phase in liver and kidney of pretreated mice. Presence of the resistant new cells from ongoing tissue repair and lower blood CHCl<sub>3</sub> levels could be the reason for the lower infliction of injury. Next wave of tissue repair occurring at 48 and 72 h offered second line of defense and stops the progression of injury. These findings suggest that ongoing tissue repair initiated by the priming doses in addition to altered toxicokinetics of CHCl<sub>3</sub> is critical and vital to the subchronic CHCl<sub>3</sub> autoprotection (supported by ATSDR U61/ATD 681482).

### 1524 ANALYSIS OF GENOMIC AND PROTEOMIC DATA FROM TRANSGENIC RAT LIVER NEOPLASMS.

Y. Dragan<sup>1</sup>, F. Hong<sup>2</sup>, W. Tong<sup>2</sup>, J. Ward<sup>3</sup>, S. Yim<sup>4</sup>, R. Perez<sup>5</sup>, L. Zhang<sup>5</sup> and M. Freitas<sup>5</sup>. <sup>1</sup>Hepatic Toxicology, NCTR, Jefferson, AR, <sup>2</sup>Bioinformatics, NCTR, Jefferson, AR, <sup>3</sup>Pathology, NCI, Frederick, MD, <sup>4</sup>Metabolism, NCI, Bethesda, MD and <sup>5</sup>Chemistry, Ohio State University, Columbus, OH.

The development of liver neoplasms in the rat is of concern for analysis of two year bioassays since there is a low spontaneous occurrence. Albumin SV40-T antigen transgenic rats (TG+) spontaneously develop neoplasms within 6-9 months of age and can be used as a genetic model to understand the genetic changes that accompany rat liver neoplasm induction and progression. Neoplasms (N=4) from TG+ were examined by microarray analysis using the NCI Incyte Mouse Chip. RNA was isolated from laser capture microdissected tissue and amplified prior to gene expression analysis. Initial clustering and gene expression analysis was performed with Spotfire and ArrayTrack. Numerous genes had expression differences including those important in cell cycle control, cell proliferation, transgene specific effects,

and tumor maintenance and progression. Previous studies indicated that specific cytogenetic changes are associated with the induction and progression of rat liver neoplasms and the microarray data was organized by chromosomal location. Real time PCR, dot blot, or Northern analysis was used to confirm altered expression of selected genes. In addition, 2D gel analysis was performed for whole cell lysates. The whole cell lysates were run on tube gels or IEF strips (ampholytes pH 3-10) in the first dimension and on 12% SDS gels in the second dimension. Gels were stained with Coomassie blue or Sypro Ruby and proteins differing between a concurrently run control and neoplasm were handpicked, digested with trypsin, and analyzed by Maldi in ten neoplasms from these rats. Protein identification was confirmed by ESI-MS/MS fragmentation patterns. For example, calregulin was consistently decreased at the message and protein level.

### 1525

QUANTITATIVE RNA INVADER ANALYSIS AS A FAST METHOD TO SCREEN FOR INDUCTION POTENTIAL OF DRUGS USING PRIMARY CULTURES OF HUMAN AND RAT HEPATOCYTES.

V. Kostrubsky, S. Kulkarni, J. Hanson and <u>S. Duddy</u>. Safety Sciences, Pfizer, Ann Arbor, MI.

Using primary cultures of human and rat hepatocytes we investigated whether Invader mRNA (Third Wave Technology, Inc.) analysis can be used as a fast method to study induction potential of drugs and whether changes in mRNA expression would associate with changes in appropriate enzyme activity and protein expression. Cultured hepatocytes were treated with beta-naphthoflavone, dexamethasone (Dex), rifampicin, phenobarbital (PB) and chenodeoxycholic (CDCA) acid for 48 h, and mRNA expression of CYP1A2, CYP3A4, CYP3A, CYP2B1/2, and biliary transporters, BSEP and MRP2, were analyzed. Corresponding enzymatic activities and protein expression were also measured. Different quantities of total RNA isolated from induced and control cells, as well as positive control mRNA, produced linear responses as detected by Invader. The specificity of detection was validated via exposing cells to positive or negative control inducers as well as in cells transfected with genes of interest. Increases of 8-, 12-, 6-, 30-, 30- and 3fold in CYP3A4, rat CYP3A (Dex), rat CYP3A (PB), CYP2B1/2, CYP1A2 and human BSEP mRNA, respectively were detected. Increases in mRNAs correlated with increases in enzymatic activities and protein expression, though the increases in enzyme activities were generally smaller magnitude relative to corresponding mRNAs suggesting that the sensitivity of mRNA detection is greater than changes in activities. These data suggest that the mRNA Invader assay provides fast (3 h, 96well plate), quantitative and sensitive method for evaluation of different mRNA expression profiles.

### 1526 DOES FUNDING SOURCE INFLUENCE RESEARCH INTEGRITY.

S. G. Gilbert<sup>1</sup>, B. J. Kelman<sup>2</sup>, L. A. Bero<sup>3</sup>, R. L. Brent<sup>4</sup> and J. I. Goodman<sup>5</sup>.

<sup>1</sup>INND, Seattle, WA, <sup>2</sup>Global Tox, Seattle, WA, <sup>3</sup>Clinical Pharmacy, University of California, San Francisco, CA, <sup>4</sup>Pediatrics, Radiology and Pathology, duPont Hospital for Children and Thomas Jefferson University, Wilmington, DE and <sup>5</sup>Pharmacology and Toxicology, Michigan State University, East Lansing, MI.

The integrity of research and its subsequent interpretation, presentation, and publication influences the development of new drugs, control of environmental contaminants, regulatory policy, and litigation. Often these decisions have significant public health and economic consequences. The purpose of this session is to examine the subtler aspects of the question Does funding source influence research integrity? All sponsors (including NIH) have expectations of those conducting research on their behalf. GLP guidelines were adopted to try to ensure the quality of data submitted to regulatory agencies, e.g. USFDA and EPA. In contract research or litigation the client may be an industry sponsor with a direct financial stake in the outcome. The client may wish to influence study design or interpretation of results. In academia expectations or pressures can take different forms. Researchers may desire certain results to ensure continued funding or the generation of significant publications for tenure. The controversy engendered by a funding source is exemplified by tobacco industry support of research. Some researchers and even institutions have decided not to accept funds from specific groups such as the tobacco industry. Others have argued that research can and should be judged on it merits and not on the funding source. Increasingly, authors and researchers are asked to disclose the source of funding or support related to their work, along with other potential conflicts of interest. Our panelists represent a range of views and professional experiences. The primary goal of this Roundtable is to generate discussion and explore the real, imagined and/or perceived expectations and conflicts related to the source of research funding. This Roundtable was supported in part by a grant from the US Department of Health and Human Services, Office of Research Integrity.

1527

COMPARISON OF THRESHOLD DOSE-RESPONSE METHODS FOR ENTIRE DATA SETS: COPPER AS A CASE STUDY.

S. Baker. International Copper Association, New York, NY.

Copper is an essential element with a high redox potential, and therefore can be highly toxic. The complete range of physiologic response (toxicity of deficiency, essentiality, and toxicity of excess) was considered in a dose-response assessment of copper. The data set on the biological effects of copper is difficult to interpret because the cascade of effects occurs over a very narrow dose range, making it hard to define the critical effect and dose. Dose-response data from the entire database on health effects of copper (observations on acute human poisoning, chronic toxicity, nutritional essentiality/homeostasis, animal nutrition and toxicity, and molecular/genetic mechanisms of copper control and action) were subjected to biological and mathematical modeling to better understand the human response. This was particularly important to better define the regions of marginal deficiency and excess, where adverse effects are subtle and where individuals with mild inborn errors of metabolism are positioned on the University- shaped dose-response curve. The purposes of this approach to dose-response analysis are to better define quantitative ranges for marginal deficiency and excess, bound the limits of essentiality and uncertainty, account for broad interindividual variability, and use the power of the entire database to define the human response to copper exposure. The comparative analysis of NOAEL/LOAEL, Benchmark Dose, and Categorical Regression approaches to understanding how copper behaves in the body and the thresholds for effects will applicable to other essential trace elements, in developing more precise RDAs and regulatory/guidance limits for metals in food, diet, and water.

**1528** THE ESSENTIALITY AND TOXICITY OF COPPER: IMPLICATIONS FOR DOSE-RESPONSE ASSESSMENT.

C. Keen. Department of Nutrition, University of California, Davis, CA. Sponsor: L. Plunkett.

Copper plays a role in several critical processes in the body, including energy production, immune function, oxidative defense, iron mobilization and trafficking, red and white blood cell maturation, neuropeptide synthesis, vessel and bone integrity, and myocardial contractility. In the United States a significant proportion of the population consume diets that contain less than the RDA for copper. In addition to low dietary intakes (primary deficiency), copper deficiency can arise secondary to genetic abnormalities, nutritional interactions, drug interactions, and disease-induced alterations in copper metabolism. Copper deficiency during pregnancy can result in early embryonic death, and gross structural abnormalities of the skeletal, pulmonary, cardiovascular, and central nervous systems. The teratogenicity of copper deficiency can be attributed in part to excessive oxidative damage, altered angiogenesis, altered composition of extracellular matrix, and low activities of several copper enzymes. Perinatal copper deficiency can result in persistent immunological and behavioral abnormalities even after the correction of the deficiency. Copper deficiency in adulthood increases the risk for bone and cardiovascular disease. At any stage of life, copper deficiency can impair iron metabolism, thus signs of iron deficiency can also occur in copper deficient individuals. Potential mechanisms that underlie the above copper deficiency induced pathologies will be discussed. An excess of copper can also pose significant health risks, as excessive tissue copper can trigger the production of reactive oxygen and reactive nitrogen species. In contrast to copper deficiency, dietary copper toxicity is rare. However, certain genetic disorders can result in copper toxicosis. The relative risks for copper deficiency and copper toxicity will be discussed, with an emphasis on how these relative risks impact the dose-response assessment, its interpretation, risk assessment, and public health policy.

1529

QUALITATIVE INTERPRETATION OF COMPLEX AND DISPARATE DATA SETS FOR DOSE-RESPONSE ASSESSMENT OF ESSENTIAL TRACE ELEMENTS: COPPER AS A CASE STUDY.

L. M. Plunkett. Integrative Biostrategies, LLC, Houston, TX.

In order to perform a dose-response assessment for essential trace elements such as copper it is necessary to identify bounds on both essentiality and excess and then to delineate the interface of the two conditions, resulting in what has been labeled a University-shaped dose-response curve. No single study is able to define the complete dose-response curve for an essential element. Thus, the first step was to systematically organize and categorize the available data to determine what would be useful for defining the likely human responses to copper deficiency as well as excess. This presentation will describe how the large amount of disparate data on copper deficiency and excess was systematically screened and then categorized in order to provide a framework for the dose-response assessment. The copper data set for tox-

icity, data concerning both deficiency and excess, was considered as a whole. The goal of the screening exercise was to identify the bounds around the homeostatic range wherein toxicity is not evident, as well as identify levels associated with adaptive changes in physiological systems, and finally levels associated with frank toxicity in a variety of organ systems. Data was categorized based on affected systems (e.g., enzyme systems, hematopoietic parameters, gut, liver, cardiovascular system, kidney) and then according to outcome (e.g., adaptive changes, biochemical derangement, architectural disruption, histopathological changes). Data were weighted in the assessment according to standard approaches to screening such as number of doses tested or administered in a study, number of test subjects or animals in a study, existence of multiple outcomes, whether data were from humans versus animals versus cells, and adequacy of data reporting by the authors. The studies identified through this screening process were then used as the basis for a quantitative dose-response assessment of copper deficiency and excess. This integrative approach to examining the entire databases for copper will be applicable to other essential trace elements.

1

1530 A CRITICAL COMPARISON OF DOSE-RESPONSE ASSESSMENT APPROACHES FOR COPPER, AN ESSENTIAL TRACE ELEMENT.

T. B. Starr. TBS Associates, Raleigh, NC.

The University-shaped dose-response curve for copper toxicity arises from the multiple, distinct toxicologic processes that are triggered by varying degrees of copper deficiency and excess, with adaptive responses such as dose-dependent absorption contributing to a flattening of the dose-response relationship in the intermediate homeostatic range. Three different empirical techniques are used to characterize the shape of the dose-response curves for copper toxicity in laboratory animals and humans: 1) a graphical approach based upon NOAELs and LOAELs as obtained from toxicity individual studies; 2) equivalent Benchmark Dose analyses of all data from the same studies; and 3) an integrated approach that utilizes categorical regression to simultaneously analyze the data from multiple studies. Four strategic questions are addressed: 1) are the existing data sufficient to characterize the limits of the homeostatic range, 2) what is the best analytical approach to defining this range, 3) what critical data gaps should be filled by future studies, and 4) how should those future studies be designed to be optimally useful in better-defining the shape of the dose-response curve for copper toxicity.

1531 DOSE-RESPONSE MODELS FOR COPPER: IMPLICATIONS FOR RISK ASSESSMENT.

D. Krewski. McLaughlin Centre for Population Health Risk Assessment, University of Ottawa, Ottawa, ON, Canada. Sponsor: L. Plunkett.

The establishment of exposure guidelines for substances that present risks to human health requires careful consideration of dose-response relationships indicating how risk varies with dose. Whereas most chemicals demonstrate monotonically increasing dose-response curves, essential elements such as copper exhibit University-shaped dose-response relationships as a consequence of the adverse effects of both deficiency and excess. The establishment of a homoeostatic region of acceptable copper intake therefore requires the application of dose-response models that take into account both of these effects. Additional factors of importance in modelling copper dose-response include inter-individual variability due to genetic and other factors, and the biologically competitive interplay between copper, zinc, and iron. With the extensive database on copper toxicity, including a large amount of information on copper toxicity in humans, analyses of combined data from multiple sources may be used to better define the region of copper essentiality. These and other factors involved in characterizing copper dose-response are examined, and their implications for copper risk assessment evaluated.

1532

SUMMARY: SELECTING AND ASSESSING BIOLOGICAL DATA IN TOXICITY, DOSE-RESPONSE, AND RISK ASSESSMENTS FOR ESSENTIAL TRACE ELEMENTS: USE IN SETTING SAFE LIMITS.

M. L. Dourson. Toxicology Excellence for Risk Assessment, Cincinnati, OH.

This presentation will tie the conclusions of the previous four presentations together, exploring (1) the impact of inclusion or exclusion of biological data on the downstream assessments of the safety of essential trace elements, (2) the advantages and disadvantages of each of the three dose-response methods examined, and (3) options for considering different dose-response methods in a single assessment of toxicity and risk for copper. The presentation will also describe the path forward to creating stronger data sets for characterizing the dose-response assessment for essential trace elements, with greater certainty and accountability for marginal effects, human variability, and sensitive populations

1533 ENVIRONMENTAL POLLUTION AND THE IMMUNE SYSTEM: MECHANISMS OF IMMUNOTOXICITY ACROSS PHYLA.

B. Luebke<sup>1</sup> and D. Germolec<sup>2</sup>. <sup>1</sup>Immunotoxicology Branch, USEPA, ORD, NHEERL, ETD, Research Triangle Park, NC and <sup>2</sup>Environmental Immunology, NIEHS, Research Triangle Park, NC.

Our current understanding of immunotoxicology comes largely from studies done in rodents or using in vitro systems, as surrogates for potential human effects. However, innate and adaptive immune responses are remarkably similar across a broad range of species: innate immunity, which appeared billions of years ago, is evident at lower levels of biological complexity and adaptive immune responses made an evolutionary appearance 400 million years ago in cartilaginous fish. Recent evidence indicates that plant responses to environmental factors depend on a family of pattern-recognition receptors that are homologous to Toll-like receptors that in animals are critical to both innate and adaptive responses. This phylogenetic conservation of effector mechanisms suggests that a given xenobiotic may cause immunotoxicity in a range of species extending beyond vertebrates. Immunotoxicology studies in plants and wildlife support this concept, with reported adverse effects following exposure to oxidant gases, various hydrocarbons, metals or endocrine disruptors. It is important for mammalian immunotoxicologists to develop an understanding of immune system organization and homeostasis across a broad phylogenetic scale, as well as an appreciation for the effects that similar xenobiotics have on immune system health across species. Field studies of populations in polluted environments, which are unable to escape exposure, provide insight into the risk xenobiotics pose to biologically diverse members of the ecosystem, from plants to mammals. This symposium will address shared and unique features of immune system organization and responses by selected species at diverse levels of biological complexity and immune system sophistication, and the mechanisms whereby selected xenobiotics alter immune function.

1534 DISEASE RESISTANCE AND INNATE IMMUNITY IN PLANTS

K. R. Davis and R. V. Mulpuri. *Paradigm Genetics, Inc., Research Triangle Park, NC.* Sponsor: R. Luebke.

Disease resistance in plants is mediated by a complex surveillance system that detects potential pathogens and activates a resistance reaction- the hypersensitive response (HR). HR can be induced by at least two distinct signaling pathways and includes activation of programmed cell death (PCD) and the accumulation of antimicrobial compounds. There are similarities between the activation of HR in plants and innate immunity in animals. A key similarity is the role of plant Resistance (R) genes important for pathogen-specific recognition that belong to the Toll/interleukin receptor (TIR) class of genes. Plant R genes containing TIR domains also contain a unique nucleotide binding site (NBS) and a leucine-rich repeat (LRR) domain of variable length. Current data suggest plant TIR-NBS-LRR R proteins perform signaling functions similar to the structurally related Toll-like receptor (TLR) proteins in animals. Besides the similarities of pathogen recognition in plants and animals, there are also some similarities in downstream signaling events. These include the importance of an oxidative burst, nitric oxide production, and the involvement of lipases and lipids as signals for the activation of resistance mechanisms. Another aspect of plant responses to pathogens that may have relevance to animals is that abiotic stresses can induce resistance mechanisms using the same signaling mechanisms employed during pathogen resistance. Responses to ozone represent one such example. Ozone induces PCD via an oxidative burst and the activation of the same signaling pathways utilized during HR. It appears that plant cell damage caused by ozone may be due to the inappropriate activation of a defense response that evolved to limit pathogen growth. Recent studies of animal responses to ozone exposure suggest that cell damage may be caused by a similar in-appropriate activation of PCD. Taken together, it is clear that there are some significant similarities in how plants and animals respond to biotic and abiotic signals, and that there is significant potential for researchers investigating resistance mechanisms in plants and animals to learn from one another.

1535

CHEMICAL TOXICITY AND HOST DEFENSE IN INVERTEBRATES: AN EARTHWORM MODEL FOR IMMUNOTOXICOLOGY.

A. Goven and L. Fitzpatrick. *Department of Biological Sciences, University of North Texas, Denton, TX.* Sponsor: <u>B. Luebke</u>.

Prediction of chemical-induced immunotoxic risk across key wildlife taxa and to ecosystems requires use of sentinel and surrogate species. Sufficient basic and comparative information exits on the immune systems of several invertebrate taxa to support using their immune function to assess the sublethal immunotoxicity of en-

vironmentally relevant chemicals. Measurements of innate immune responses that are homologous across taxa such as immunohistology, phagocytosis and associated biochemical responses involved in ingestion and destruction of foreign material, and host resistance to challenge infection show the most promise for predicting risks to other wildlife, including mammals. Earthworms, Lumbricus terrestris and Eisenia fetida, have emerged as standard invertebrate organisms for modeling the chemical-induced immunotoxic potential of xenobiotics in terrestrial ecosystems. Assessment of innate immune function using protocols modified for earthworms demonstrate immunomodulatory effects of metals (Cu, Cd, Cr) and organic chemicals (polychlorinated biphenyls, chlordane, pentachlorophenol, DDT) on earthworm lysozyme activity; cytology as total and differential coelomocyte counts and viability; and phagocytosis as activation, ingestion, oxidative burst, and bacterial killing. General acceptance of invertebrate or earthworm immune components as biomarkers of eco-immunotoxicity in risk assessment will ultimately depend upon results of future research focusing on normalization of exposure metrics across taxon-specific toxicokinetics, consideration of and control for natural variability in immune marker performance, and affirmative link of immune markers to endpoints having ecological significance.

1536 ENVIRONMENTAL CHEMICALS AND AMPHIBIAN IMMUNITY: WHAT ARE THE RISKS TO AMPHIBIAN HEALTH.

L. A. Rollins-Smith. Microbiology and Immunology, Vanderbilt University Medical Center, Nashville, TN. Sponsor: L. Rollins-Smith.

The amphibian immune system is very similar to that of mammalian species. The adaptive immune system is characterized by organs and cells that serve similar functions as those of mammals. Amphibians have T and B lymphocytes that express rearranging T cell receptors (TCR) and immunoglobulin (Ig) receptors. They have a major histocompatibility complex (MHC) encoding classical class I and class II molecules. Amphibians express several Ig isotypes, and they can produce leukocytederived cytokines. Their innate immune system includes phagocytic cells, a complement system, and natural killer (NK) cells. In addition, amphibians possess granular glands in the dermis of the skin that release a variety of bioactive peptides including antimicrobial peptides. The immune system may be harmed during embryonic, larval, or adult stages by contamination from xenobiotic chemicals in the water. It may be especially at risk during embryonic life and during metamorphic transition. Chemicals in the water may affect adult amphibians by altering the function of antigen presenting cells in the skin or by inhibiting synthesis of antimicrobial peptides produced in granular glands of the skin. Environmental chemicals that contribute to ozone depletion may result in increased UV-B exposure. The loss of effective skin defenses may predispose amphibians to infection by skin pathogens such as the chytrid fungus, Batrachochytrium dendrobatidis, associated with global population declines. Recent studies illustrate the possible negative effects of xenobiotic chemicals or increased UV-B on the development of embryonic components of the immune system, development of larval allograft rejection responses, and the production and secretion of antimicrobial peptides by young postmetamorphic

1537

FISH AS EXPERIMENTAL MODELS IN IMMUNOTOXICOLOGY: EVOLUTIONARY CONSERVED MECHANISMS OF ACTION.

C. D. Rice. Biological Sciences, Clemson University, Clemson, SC.

Teleost fish represent the lowest group of vertebrates with immune systems that are "mammalian-like". Both RAG-1 and RAG-2 genes, as well as T-cells and B-cells are present. In terms of innate immunity, the toll-like receptors (TLR) and NF-kappa beta signaling have been demonstrated in fish, and the expression of these activation- and pro-inflammatory-associated genes and proteins follow patterns that are mammalian-like. Using Tier-I and Tier-II immunotoxicity testing protocols modified for fish, environmental immunotoxicologists show that fish respond to a particular contaminant in a manner similar to rodents. A few species of fish have emerged as standard models. Notably, the rainbow trout, channel catfish, and medaka are now fairly standard fresh water fish models in immunotoxicology. The mummichog, a common marsh killifish, as emerged as a standard representative of estuarine ecosystems. As a case in point, certain populations of the mummichog along their east coast North America range exhibit characteristics of resistance or adaptation to high levels of priority pollutants. One such population inhabits the upper Elizabeth River sub-estuary in Virginia at the Atlantic Wood site (AW). Atlantic Wood is a heavily contaminated Superfund site containing a mixture of PAHs from creosote. Although PAHs are known to be immunotoxic, the resident mummichog population seems to thrive. Mummichogs from the AW site and from

a reference location at Kings Creek (KC) Virginia were examined for circulating antibody titers against several ubiquitous marine bacteria. The expression of inducible innate immune proteins were also examined. Compared to high responses in reference fish, AW mummichogs had very low plasma immunoglobulins and very low antibodies against all bacteria examined, but they expressed higher circulating lysozyme. Lymphoid cells in the AW mummichogs also expressed more lysozyme and COX 2, which may indicate a state of activation and possible resistance. Taken together, these and other findings suggest that exposed animals may compensate for this loss with higher innate immune responses.

#### 1538 ANALYSIS OF NEUROTOXICITY IN VESICULAR MONOAMINE TRANSPORTER KNOCKOUT MICE.

G. W. Miller. Emory University, Atlanta, GA.

Numerous diseases and toxic agents target the brain monoamine systems. Disruption of the normal handling of these neurotransmitters can have devastating consequences on the function of these neuronal systems. The uptake, storage, and release of dopamine, serotonin, and norepinephrine are mediated by the vesicular monoamine transporter (VMAT2). Given the critical nature of VMAT2 in monoamine function, we have created a mouse model of enhanced neurotoxicity by decreasing the expression of VMAT2. Homozygote knockout mice die within a few days after birth, while heterozygote VMAT2 knockout mice (VMAT2 +/-) survive into adulthood and appear healthy. We have subjected the VMAT2+/- mice to various neurotoxicants and assessed vulnerability to toxicity. The classical parkinsonian-inducing toxin, MPTP, was more toxic to the mice with reduced VMAT2 and this was attributed to the decreased ability to sequester to toxic metabolite of MPTP. Methamphetamine was also found to be more toxic in VMAT2+/- mice, which was attributed to an inability to handle elevated intracellular dopamine. There has been some question as to whether the administration of L-DOPA (a dopamine precursor) to patients with Parkinsons disease may exacerbate dopamine neuron cell death. Since the VMAT2+/- mice have an impaired ability to handle dopamine, we hypothesized that they would be vulnerable to L-DOPA-induced toxicity. We subjected the VMAT2+/- mice to L-DOPA three times a day for 28 days and found no enhanced toxicity. Indeed, the VMAT2+/- and wild type did not exhibit any toxicity to a dose of L-DOPA 10x higher than that used in humans. In addition to the generation of animal model of neurotoxicity, our lab has been working on more sensitive assays for detecting damage to the nigrostriatal dopamine system, including the development of novel behavioral tests to assess dopaminergic toxicity in mice and the use of laser capture microdissection and quantitative PCR to analyze gene expression in dopamine neurons. This work has been supported by NIEHS and NINDS.

#### USE OF MOLECULAR APPROACHES TO EXAMINE 1539 MECHANISMS OF NEUROTOXICITY.

W. D. Atchison. Mich State University, East Lansing, MI.

Genomic and molecular biological techniques provide powerful tools to study perturbations in cellular processes which occur normally, or in pathophysiological conditions. At the whole animal level these modifications include knock-in, upregulation or knock-out of protein function. Use of small interfering RNAs permits protein function to be impaired temporarily, while heterologous expression of recombinant protein permits study of chemical modification on specific protein functions in isolation. Moreover, with "chimeric" proteins, or "site-directed mutants" the role of specific regions of the protein in neurotoxicity can be probed. Thus these techniques permit the study of mechanisms of chemical action or disease progression in the nervous system at the intact animal to isolated proteins. This symposium will present results of recent studies using three levels of genomic modification to study mechanisms of neurotoxicity. The use of chimeric proteins and site-directed mutagenesis to understand how distinct sites of interaction of pyrethroid insecticides with voltage-sensitive Na+ channels relate to insecticide resistance will be discussed. Heterologous expression of chimeric Ca<sup>2+</sup> channels as a tool to understand differences in sites of action of Pb<sup>2+</sup> and Hg<sup>2+</sup> will be discussed. The use of small interfering mRNAs to downregulate calnexin, or mutations in Ca<sup>2+</sup> release channels of the SER to prevent necrotic neuronal cell death in *C. ele*gans will be described. The ability of Bcl-xL overexpression in mice to block apoptosis of rod photoreceptors in response to lead exposure will be described, as will the role that genetic deletion in mice of the vesicular monoamine transporter (VMAT2) has to increase vulnerability to dopaminergic damage. This symposium provides the opportunity for investigators with interests in mechanistic neurotoxicity to consider new and powerful approaches to enhance understanding of initiation of disease processes or chemical-induced damage to the nervous system.

1540

THE USE OF BCL-XL OVEREXPRESSING TRANSGENIC MICE HELPS DECIPHER THE MITOCHONDRIALLY-MEDIATED MECHANISM OF LEAD-INDUCED ROD PHOTORECEPTOR APOPTOSIS.

D. A. Fox. College of Optometry, University of Houston, Houston, TX.

Transgenic animal models are an integral component in determining the molecular mechanisms that underlie normal physiological processes and toxicant-induced pathophysiology. Photoreceptor apoptosis and resultant visual deficits occur in humans and animals with inherited and chemical-, disease- and injury-induced retinal degeneration. A clinically-relevant mouse model of progressive rod photoreceptorselective apoptosis was produced by low-level developmental lead exposure. To enhance our mechanistic knowledge, our lead model was studied in combination with transgenic mice overexpressing Bcl-xL only in the photoreceptors. A multiparametric analysis of rod apoptosis and mitochondrial structure-function was performed. Mitochondrial cristae topography and connectivity, matrix volume and contact sites were examined using three-dimensional electron tomography. The lead-induced rod-selective apoptosis was accompanied by rod calcium and lead overload, rhodopsin loss, translocation of Bax from the rod cytosol to the mitochondria, decreased rod mitochondrial respiration and membrane potential, rod mitochondrial cytochrome c release, caspase-3 activation and an increase in the number of rod mitochondrial contact sites. These effects occurred without mitochondrial matrix swelling or outer membrane rupture, caspase-8 activation or Bid cleavage. Bcl-xL overexpression completely blocked all apoptotic events, except the calcium and lead overload, and maintained normal rod mitochondrial function throughout adulthood. These findings extend our in vitro retinal studies with lead and calcium and suggest that developmental lead exposure produced rod-selective apoptosis without mitochondrial swelling by translocating cytosolic Bax to the mitochondria. The translocation of Bax likely sensitized the calcium and lead overloaded rod mitochondria to release their intermembrane cytochrome c. The results have relevance for therapies in a wide variety of progressive retinal and neuronal degenerations where calcium overload, lead exposure and/or mitochondrial dysfunction occur.

1541

MOLECULAR APPROACHES TO DEFINE NECROTIC-LIKE NEURONAL DEATH AND STRATEGIES OF PHYSIOLOGICAL DEATH SUPPRESSION IN C. ELEGANS.

M. Driscoll. Molecular Biology and Biochemistry, Rutgers University, Piscataway, NJ.

Neuronal death is the catastrophic outcome of stroke, ischemia, physical injury and devastating neurodegenerative diseases. Although apoptosis has been implicated in these conditions, considerable evidence now supports that alternative death mechanisms are activated in parallel to apoptosis. One critical component in neuronal injury and disease is necrotic cell death. In C. elegans we have characterized a necroticlike death prototype, distinct from apoptosis, associated with neuronal swelling and death. The necrotic paradigm we study involves death initiation by hyper-activated ion channels and requires elevation of intracellular Ca<sup>+2</sup>. This Ca<sup>+2</sup> rise activates calpain and cathepsin proteases. Several features of the basic pathway are shared with mammalian necrosis, supporting that, like apoptosis, necrotic death mechanisms are conserved from nematodes to humans. Using approaches uniquely applied in C. elegans, such as genome-wide RNA interference and genetic screens, we are elaborating molecular mechanisms of a necrotic-like death and defining physiological death suppression strategies.

1542 MOLECULAR BASIS OF DIFFERENTIAL SENSITIVITIES OF INSECT SODIUM CHANNELS TO PYRETHROID INSECTICIDES.

K. Dong<sup>1, 2</sup>. <sup>1</sup>Entomology, Michigan State University, East Lansing, MI and <sup>2</sup>Neuroscience Program, Michigan State University, East Lansing, MI. Sponsor: <u>B.</u> Atchison.

The voltage-gated sodium channel is the primary target-site of pyrethroid insecticides. Pyrethroids induce prolonged sodium current by inhibiting the inactivation and deactivation of sodium channels. To understand the interaction between insect sodium channels and pyrethroids at the molecular level, we cloned and sequenced cDNAs of the cockroach sodium channel gene para  $^{\text{CSMA}}$  from a pyrethroid-susception. tible and several pyrethroid-resistant German cockroach strains. Three point mutations, E434K, C764R and L993F, were found to be associated with pyrethroid resistance. E434K and C764R are located in the intracellular linker connecting domains I and II, and L993F is located in the segment 6 of domain II. The wildtype and pyrethroid-resistant sodium channels carrying single, double or triple mutations were expressed in Xenopus oocytes and the channel properties and channel sensitivity to pyrethroids were examined using two-electrode voltage-clamp. The L993F mutation reduces the channel sensitivity to deltamethin, a type II pyrethroid, by 5-fold, whereas E434K or C764R alone had no affect. However, £434K or C764R combined with L993F further reduces the channel sensitivity to deltamethrin by 100-fold. Furthermore, the channel carrying the triple mutations was almost completely resistant to deltamethrin. Theses results demonstrate that amino acid residues, E434, C764 and L993, are critical for the action of pyrethroids.

### 1543 EFFECTS OF NEUROTOXIC METALS ON HUMAN RECOMBINANT CALCIUM CHANNELS- ROLE OF THE $\alpha_1$ SUBUNIT.

W. D. Atchison. Department Pharmacology/Toxicology, Mich State University, East Lansing, MI.

Voltage-gated Ca2+ channels are targets of a number of naturally occurring toxins, as well as certain environmental toxicants including Pb and Hg. These metals reduce Ca<sup>2+</sup> influx through the channel when applied acutely, and also apparently use the Ca<sup>2+</sup> channel as a path to enter the cell. Ca<sup>2+</sup> channels are multimeric proteins which typically consist of 3 subunits- $\alpha_1$ ,  $\beta$  and  $\alpha 2\delta$ . The  $\alpha 1$  subunit is the largest, and forms the ion conducting pore. It also is the primary determinant of the phenotypic identity of the channel; different types of Ca<sup>2+</sup> channels have distinct α<sub>1</sub> subunits. To date 6 subtypes of Ca<sup>2+</sup>channels and 10  $\alpha_1$  subunits have been identified. In many cells and most neurons, multiple subtypes of Ca2+ channels coexist; this permits precise regulation of Ca<sup>2+</sup> entry to match the specific cellular function. However, it makes analysis of the effects of neurotoxic agents on function of specific types of Ca<sup>2+</sup> channel extremely difficult. By use of recombinant channels of known identity, and expressed heterologously in a system which normally does not contain these channels, the effects of metals on distinct types of Ca<sup>2+</sup> channels can be examined in isolation. Additionally, by constructing chimeric channels, in which known combinations of channel subunits are co-expressed, specific effects of a toxicant on a particular portion of the protein can be examined. We used transient heterologous expression of recombinant  $\alpha_{1B}$ ,  $\alpha_{1C}$ , and  $\alpha_{1E}$  subunits - comprising respectively, N-, L- and R-type Ca<sup>2+</sup> channels of human origin in the HEK 293 expression system to compare the actions of Pb, Hg and methylmercury using whole cell current recording methods. A constant  $\beta$  and  $\alpha 2\delta$  subunits were used; only the  $\alpha 1$  subunit was varied. In comparing these various metals, differences in potency of blocking action, reversibility, and kinetics of block were observed among the different subtypes of  $\text{Ca}^{2+}$  channels to a given metal and of a given channel subtype to different metals. Thus differences in the  $\alpha_1$  subunit of  $Ca^{2+}$  channels confer distinct responses to neurotoxic metals. Supported by NIEHS grants ES03299 and ES05822.

### 1544 BIOMARKERS: DEVELOPMENT, EVALUATION AND

R. Roberts<sup>1</sup> and T. Monticello<sup>2</sup>. <sup>1</sup> Drug Safety Evaluation, Aventis, Vitry sur Seine, France and <sup>2</sup> Drug Safety Evaluation, Aventis, Bridgewater, NJ.

Interest in biomarkers continues to grow at a rapid pace. In part, this interest is attributed to the potential utilization of biomarkers in the many aspects of toxicology. Biomarkers of toxicity are characteristics that can be measured and evaluated as indicators of adverse or pathological responses to a drug or xenobiotic. This workshop will feature four stimulating, state-of-the-art presentations on the different aspects of biomarker development, evaluation and use in the field of toxicology. Topics to be covered will include the utility of biomarkers for nonclinical toxicity during drug development, including current applications, validation procedures and regulatory interest, and an evaluation of the newer genomic and proteomic technologies that can contribute to the discovery of potential novel biomarkers of toxicity. In addition, biomarkers for rodent nongenotoxic carcinogenesis will be described and evaluated in the context of screening assays. Finally, the development and utilization of biomarkers for environmental exposure to toxicants and human risk assessment will be addressed in the session. This workshop will suit those who wish to update and extend their knowledge in this rapidly moving field. It is of general interest to all toxicologists, particularly those concerned with drug development, carcinogenesis and risk assessment.

### **1545** BIOMARKERS OF NONCLINICAL TOXICITY.

T. M. Monticello. Drug Safety Evaluation, Aventis, Bridgewater, NJ.

Over the last 5 years there have been tremendous advances in the identification and potential utilization of novel biomarkers of cell and tissue integrity that would allow the monitoring of pathological processes. The advent of newer "omic" technologies, such as proteomics and metabonomics, has also resulted in the discovery of potential novel biomarkers of toxicity. This presentation will introduce the session on biomarkers by first discussing definitions of interest in the field and acceptable criteria of an adequate biomarker. Requirements for establishing a biomarker including the characterization and validation process will be discussed. Current and specific examples of biochemical and bioimaging biomarkers of target organ and cell toxicity will also be presented. Finally, regulatory acceptance and interest in biomarkers that improve predictivity of nonclinical studies and provide an enhanced interface between nonclinical and clinical studies will be discussed.

#### 1546 BIOMARKERS FOR NONGENOTOXIC CARCINOGENS.

J. K. chipman. Biosciences, University of Birmingham, Birmingham, United Kingdom. Sponsor: R. Roberts.

Nongenotoxic carcinogens are thought to act via disturbance of the balance between cell death and cell proliferation, leading to clonal expansion of pre-neoplastic cells. The precise mechanisms that can lead to this disruption are varied and this complicates the ability to use short term tests to predict nongenotoxic carcinogenic potential. Biomarkers indicative of a chemical's ability to influence cell survival and proliferative advantage are important in recognising this activity in rodent studies. This may be helpful in the interpretation of rodent carcinogenicity that may occur in the absence of genotoxicity, and to be able to extrapolate to human risk assessment. The dose response relationships and species differences in response are critical parameters in this process. Biomarkers can be relatively non-specific relating to apoptosis and proliferation in target organs but may be optimised and more refined by interrogation of the modulation of specific molecules involved in key signalling processes. Both the modulation of connexin-mediated gap junction intercellular communication and the status of DNA methylation have shown particular promise as relevant biomarkers in conjunction with functional studies as above. For example, the rodent non-genotoxic hepatocarcinogens Wy-14, 643, 2, 3, 7, 8-tetrachlorodibenzo-p-dioxin, methapyrilene and hexachlorobenzene and the rat kidney carcinogens chloroform and p-dichlorobenzene all disrupt gap junction plaques containing connexin 32 in the target organs in the absence of toxicity and they all cause proliferation at the carcinogenic dose. Furthermore, compounds that deplete glutathione such as chloroform and carbon tetrachloride have the ability to induce a secondary genotoxicity through oxidative stress but only at high concentrations. Transcriptomic analyses are leading to the identification of further novel potential biomarkers associated with species- and tissue- specific nongenotoxic carcinogenesis such as the induction of hepatic fibrinogen / angiopoietin-related protein by monoethylhexylphthalate.

#### BIOMARKERS OF ENVIRONMENTAL EXPOSURE TO GENOTOXICANTS.

D. E. Shuker. Chemistry, The Open University, Milton Keynes, United Kingdom. Sponsor: R. Roberts.

The latest technologies for detection and measurement of biomarkers of exposure to environmental genotoxicants can be seductive. Ever lower exposures can be detected using increasingly sophisticated analytical tools. 32P postlabelling has revealed many types of DNA damage. Mass spectrometry has been used to characterise a range of modified amino acids in proteins. Accelerator mass spectrometry can quantitate DNA damage with exquisite sensitivity. Does this information improve our ability to make better risk assessments or increase our knowledge about the mechanisms of cancer? The few exposures for which we have extensive data, in both animals and humans, such as aflatoxin B1, suggest that it does. However, there remain some significant challenges: What is the significance of background levels of DNA and protein adducts? Are measurements of average levels of DNA adducts informative or do we need to look for gene-specific DNA damage? These issues will be addressed using exposures to environmental genotoxicants that are of current concern, such as 1, 3-butadiene, acrylamide and benzene.

### 1548 BIOMARKERS FROM NEW TECHNOLOGIES.

R. Roberts<sup>1</sup>, J. Leonard<sup>1</sup>, M. Duchesne<sup>2</sup>, P. Fabiene<sup>2</sup>, M. Courcol<sup>1</sup>, C. Saulnier<sup>1</sup> and J. Gautier<sup>1</sup>. <sup>1</sup>Drug Safety Evaluation, Aventis, Vitry sur Seine, France and <sup>2</sup>Functional Genomics, Aventis, Vitry sur Seine, France.

During the development of a new product, toxicity may not be seen until after repeat dose toxicity studies in rodents. However, much is being done to integrate toxicology as early as practically possible in order to provide early warning and even to guide chemistry away from potential toxicity. Biomarkers offer great potential to give early indication of potential problems. This is exemplified by the class of drugs known as kinase inhibitors. This class is relevant to several therapeutic areas but some compounds have, in some cases, been associated with liver and kidney toxicity. The discovery and evaluation of potential biomarkers of this drug-induced toxicity would be invaluable in guiding drug development to avoid this potential issue. In order to detect potential biomarkers, we used a toxicoproteomics (TPX) approach to ask which proteins were altered in rat liver after 14 days of dosing at the toxic but not at the pharmacologically active dose. At the pharmacologically active dose, 52 proteins were up-regulated and none were down-regulated but at the toxic dose of 200mg/kg/day, 88 and 26 were up- and down-regulated, respectively. The bioanalysis of proteomics data showed that many biochemical pathways of lipid, fatty acid and carbohydrate metabolism were affected as well as proteins belonging to the oxidative stress pathways. Interestingly, toxicity was associated with the modulation of pI variants within several protein families. This suggests that these modifications could be used as a toxicity-specific signature of compounds within a chemical class; this approach can be evaluated by correlating toxicity with protein expression using specific antibodies and an isoelectric Western blot technique.

### 1549 HORMONE REPLACEMENT THERAPY: A CHALLENGE OF RISKS AND BENEFITS.

V. C. Moser<sup>1</sup> and A. R. Scialli<sup>2</sup>. <sup>1</sup>Neurotoxicology Division, USEPA, Research Triangle Park, NC and <sup>2</sup>Department of Obstetrics and Gynecology, Georgetown University Medical Center, Washington, DC.

A large epidemiological study of the risks and benefits of estrogen plus progestin hormone therapy was stopped early due to the unanticipated but significantly higher incidence of invasive breast cancer, coronary heart disease, and stroke in postmenopausal women receiving this therapy (JAMA 2002, 288:321-333). The medical community was faced with difficult questions, since estrogen has been so commonly prescribed for relieving menopausal symptoms and preventing bone loss. Questions remain, including whether the results are valid for other pharmaceutical formulations and whether clinicians could have predicted the toxicity of estrogen and progestin based on experimental studies and previous clinical trials. This workshop will present the basic and epidemiological studies of hormone therapy for women and men, as well as the challenge of managing the apparent and real risks and benefits of hormone therapy.

### 1550 HORMONE THERAPY IN MENOPAUSE: THE CLINICAL CONTEXT.

A. R. Scialli. Ob-Gyn, Georgetown University Hospital, Washington, DC.

Estrogen has been prescribed for menopausal women for more than fifty years. Some estrogen prescriptions have been for resolution of vasomotor symptoms; however, there has been substantial prescription of estrogen for prevention or treatment of diseases associated with aging such as heart attack, stroke, dementia, and osteoporosis. The concept that estrogen represented a fountain of youth was adopted by many consumers in response to popular books, advertising, and physician recommendation. The association of estrogen use and increased endometrial cancer risk in the mid 1970s caused a transient decrease in popularity of these preparations, but the addition of a progestin to the prescription was believed to reduce the excess risk to zero. Concerns about breast cancer arose from theoretical considerations, in vitro and experimental animal studies, and observational studies in women, but were dismissed as unproven. Randomized clinical trials of estrogen with or without progestin began to appear in the 1990s, demonstrating a lack of effectiveness of menopausal hormone therapy in the prevention or treatment of cardiovascular disease. The largest of these studies, the Women's Health Initiative (WHI) issued its first publication in July 2001. This and subsequent publications from the WHI demonstrate clearly that the estrogen-progestin product most commonly prescribed in the United States does not improve quality of life measures or decrease the incidence of cardiovascular disease or dementia; in fact there is an increase in these diseases associated with hormone therapy. The incidence of breast cancer is increased by this hormone combination and the associated breast cancers are more aggressive. Hip fracture and colon cancer are reduced by the hormone combination, but overall measures of total harm do not favor estrogen-progestin therapy. The WHI publications have not to date addressed estrogen-only regimens, nor did the WHI include formulations other than equine estrogen and medroxyprogesterone acetate; however, data from small studies do not suggest that use of estradiol alone, even without a progestin, provides cardiovascular benefits.

#### **1551** ALTERNATIVES TO HORMONE THERAPY.

A. Fugh-Berman. Health Care Sciences, George Washington University School of Medicine, Washington DC, DC. Sponsor: V. Moser.

The use of herbs and dietary supplements has become very popular, especially among women. There are a variety of CAM treatments promoted for hot flashes, depression, prevention of osteoporosis, etc. Large, appropriately designed trials are

lacking for many CAM therapies. For hot flashes, clinical trials have not supported a beneficial effect for red clover (Trifolium arvense), evening primrose oil, vitamin E, dong quai (Angelica sinensis) or ginseng. Trials of soy or other dietary phytoestrogens for menopausal symptoms are mixed, and trials on black cohosh are mixed. The herbs and dietary supplements that are most commonly used for hot flashes have not been linked to serious adverse effects. Possible long-term adverse effects will be discussed. So-called natural or bioidentical hormones, including estriol, Tri-Est (estrone, estradiol, and estriol, usually 1:1:8), and natural progesterone cream, are also popular. Although some alternative medicine practitioners have promoted estriol as safe for breast and uterus, recent studies have confirmed that estriol does stimulate endometrial proliferation, and that systemic use increases the risk of endometrial cancer. Additionally, there is no credible evidence for claims that estriol reduces the risk of breast cancer. Clinical trials have shown that topical progesterone cream does not improve bone density and does not provide adequate serum levels to protect the uterus from estrogen-induced stimulation.

### 1552 RESULTS AND PREDICTABILITY OF ANIMAL STUDIES FOR HUMAN RISK.

A. jordan. fda, rockville, MD. Sponsor: G. moser.

To determine if studies in animals were predictive of the outcomes of the Womens Health Inititive study, published literature and information submitted to the FDA were examined. The increased incidence of breast cancer in women was preceded by studies showing an icreased incidence of mammary gland cancer in rats. This carcinogenic response to sex steroids is highly variable between rodent species and strains. Because of the variable response and the availability of what was then considered a better model, the dog, the results from 2 year rodent carcinogenicity studies were largely discounted as being predictive of human risk. The beagle was considered the most predictive model for carcinogenicity due to its apparent ability to differentiate between progestins in their carcinogenic response. Results from studies in beagles led to the removal from the US market of medroxyprogesterone acetate. After a study by the World Health Organization showed no increase in breast cancer in women injected with depot MPA, the FDA eliminated the beagle testing requirement. Ten year studies in monkeys were essentially negative for tumors with some increases in breast cellular proliferation. Studies of coagulation were initiated in animals after the first reports of stroke and thromboembolism in women taking oral contraceptives. The early data were inconsistant but tended to show little if any clear effect of estrogens and progestins on various parameters of blood clotting. More recent studies with the progestin nomegestrol showed no effects on coagulation factors IX and X and antithrombin III in ovariectomized rats or on coronary vascular reactivity in intact and ovariectomized monkeys. It is clear the estrogens and progestins are carcinogenic in some animals at some dose. There is little evidence that safe doses in humans can be extrapolated from results in animals using current testing methods. The data for hormone induced blood coagulation are inconsistent. Newer research paradigms such as genomics and a better understanding of the underlying mechanisms of disease may help increase the relevance of preclinical testing of hormonal steroids.

## 1553 TESTOSTERONE AND AGING: CLINICAL RESEARCH DIRECTIONS; INSTITUTE OF MEDICINE REPORT ON TESTOSTERONE THERAPY IN OLDER MEN.

E. Vaughan<sup>17</sup>, D. Blazer³, E. Barrett-Connor², B. A. Brody⁴, R. M. Califf³, J. P. Costantino⁵, D. D. Federman⁶, L. P. Fried⁻, D. G. Grady⁶, W. R. Hazzardゥ, S. B. Heymsfield¹⁰, S. W. Moset.

In 2002, the National Institute on Aging and the National Cancer Institute asked the Institute of Medicine to conduct a 12-month study to review and assess the current state of knowledge related to the potential beneficial and adverse health effects of testosterone therapy in older men, and to make recommendations regarding clinical trials of testosterone therapy, including the parameters that should be considered in study design and conduct. More specifically, the committee was asked to review and consider the epidemiologic data on normal levels of testosterone during

the lifespan and the associations with morbidity and mortality; the risks and benefits of testosterone therapy; the potential public health impact of testosterone therapy in the United States; and the ethical issues related to the conduct of clinical trials of testosterone therapy. This presentation will provide an overview of the committee's findings and recommendations regarding future clinical trials of testotserone therapy in older men.

### 1554 STRATEGIES TO IDENTIFY BIOACTIVE SUBSTANCES IN COMPLEX AIR POLLUTANT MIXTURES.

M. C. Madden<sup>1</sup> and J. R. Harkema<sup>2</sup>. <sup>1</sup>NHEERL\Human Studies Division, USEPA, Chapel Hill, NC and <sup>2</sup>Department National Food Safety and Toxicology, Michigan St. University, East Lansing, MI.

Both indoor and outdoor air contains a very complex mixture of gas and particulate matter (PM) pollutants. The assessment of the role of each pollutant in the complex atmosphere in the induction of an associated health effect or a response can be difficult due to many factors, including the vast number of pollutants that may potentially induce or modify the health effect. The aim of this session is to present different strategies that have been used by researchers in attempts to identify airborne toxic components in complex mixtures. The range of strategies to be presented spans a wide spectrum of possible approaches (from study of whole populations to predictive toxicology modeling). Findings will be presented on: appropriately designed field epidemiological studies and controlled exposure studies with humans subjects aimed at determining the components of airborne ambient PM that induce increased morbidity and mortality (e.g., premature deaths, hospitalizations, asthma symptomatology); determination of airway irritants in indoor air using rodent exposures; comparative potencies of components of diesel exhaust using controlled in vitro cell exposures; and prediction of toxicity using quantitative structure-activities relationships. In each case, individual components of a polluted atmosphere were isolated or considered, and then assessed for potential bioactivity using a variety of methods. In some cases where individual components appeared to be relatively biologically inactive, different individual components were added together to assess potency. This session is timely in that the topics provide insights that may be utilized by researchers to aid in risk assessment and management of complex atmospheres such as combustion emissions, outdoor PM, and indoor air quality, all currently subject to regulation at local to federal levels. [This abstract may not represent official EPA policy.]

### 1555 THE EPIDEMIOLOGICAL APPROACH TO INVESTIGATING AIR POLLUTION MIXTURES.

J. M. Samet. Department of Epidemiology, Johns Hopkins University, Baltimore, MD. Sponsor: M. Madden.

Air pollution comprises a mixture of diverse gaseous and particulate components that vary spatially and temporally. Epidemiologic research, while often focused on estimating the effect of particular pollutants, can also address the effects of mixtures. A means of estimating population exposure to the mixture is needed; for this purpose, multiple components may be measured to profile the mixture or, one or several components may be used as summary indicators. To carry out epidemiologic research on mixtures, populations are needed that experience measurable variation in exposures to the air pollution mixture, across spatial or temporal gradients. Multi-site studies may be most informative. This presentation will consider epidemiological approaches to investigating the health risks of air pollution mixtures in urban environments. Emphasis is given to approaches that may prove informative and to the data resources on exposures and health outcomes that will be needed. Air pollution mixtures have long been a vexing problem for epidemiologists and toxicologists, but new approaches and data resources could lead to further insights.

## 1556 LUNG RESPONSES IN HEALTHY HUMAN SUBJECTS INHALING COARSE FRACTION PARTICULATE MATTER (PMCF).

N. E. Alexis<sup>1</sup>, W. Bennett<sup>3</sup>, T. Huang<sup>2</sup> and S. Becker<sup>2</sup>. <sup>1</sup>Pediatrics, UNC-Chapel Hill, Chapel Hill, NC, <sup>2</sup>Human Studies Division, USEPA, Chapel Hill, NC and <sup>3</sup>Pulmonary Medicine, UNC Chapel, Chapel Hill, NC. Sponsor: M. Madden.

Based on results from our laboratory, *in vitro* exposures of human lung macrophages to coarse fraction particulate matter (PMcf) appears to induce phagocyte responses to a greater degree than smaller sized PM, and bacterial endotoxin was implicated as the most responsible agent generating this effect. To further assess the role of PMcf and endotoxin in inducing lung toxicity *in vivo*, ambient Chapel Hill (NC) PMcf was collected, sterilized (UV irradiation) and split into two for in-

halation directly (naive PMcf) or following heat inactivation of endotoxins by baking at 120oC for 20 hours. Subjects underwent 3 inhalation challenges (filtered air (FA) first, then randomly PMcf-treated or PMcf-untreated)each challenge separated by at least 2 weeks. PMcf was delivered and deposited (0.5 mg)to each subject's airways via a closed inhalation system (mouthpiece/pneumotachograph attached to an aspirator). Controlled shallow breathing (500 ml tidal volume at 30 breaths/min) was used to achieve preferential deposition of PMcf to the central airways. Following the FA exposure, subjects also inhaled saline droplets with radiolabeled Tc99m-sulfur colloid (SC) particles (5um MMAD)and then received a 2h gamma camera scan to measure lung dosimetry and mucociliary clearance. Induced sputum was collected at the end of the gamma camera scan to examine particle uptake by airway macrophages. Two hours following each PMcf exposure, induced sputum was collected. Its contents were analyzed for various markers of inflammation, and its cells used for in vitro functional assays (phagocytosis, cell-surface phenotype expression, oxidative burst). Other endpoints that were measured 2 hours after PMcf exposure were symptoms and lung function. To date, 10 subjects (N=15) have completed all arms of the study. Data analysis is in progress.

## **1557** AIRWAY AND PULMONARY EFFECTS OF TERPENE/OZONE REACTION PRODUCTS IN MICE.

A. C. Rohr. Electric Power Research Institute, Palo Alto, CA. Sponsor: M. Madden.

Reactions between ozone and unsaturated hydrocarbons (e.g., terpenes) produce gas- and condensed-phase products that may be more irritating than their precursors. Indeed, while neither terpenes nor ozone alone induce airway irritation in mice, when combined the mixture has a marked effect, indicating the formation of irritating substances. Terpenes are emitted from vegetation, and are common volatile organic compounds (VOCs) in consumer/cleaning products. Ozone is present both indoors and outdoors. Some gas-phase products formed through terpene ozonlysis, including methacrolein and formaldehyde, are highly irritating. Ultrafine particles are also formed from these reactions. In mice, the oxidation products of d-limonene, α-pinene, and isoprene have been shown to cause airway irritation in mice during 30-minute acute exposures, as evidenced by a reduction in respiratory rate (f). Two subsequent studies have shown additional effects. Over a 60-minute exposure, with pre-reaction concentrations of 3.4 ppm (ozone), 47 ppm (pinene), 51 ppm (limonene), and 465 ppm (isoprene), airway irritation was a prominent effect. Airflow limitation also developed, persisting for at least 45 minutes. During repeated exposures (3 hours/day for 4 days) to isoprene oxidation products (OPs), marked enhancement of the irritation and airflow limitation effects was observed, suggesting a cumulative effect. Respiratory frequency decreased from  $46.0 \pm 2.3\%$  of baseline (Day 1) to  $34.2 \pm 2.1\%$  (Day 4)(p=0.00002). Peak expiratory flow normalized for tidal volume (PEF/VT; a measure of airflow limitation) decreased from 75.6  $\pm$  3.9% of baseline (Day 1) to 53.1  $\pm$  3.7% (Day 4)(p<0.00001). A significant reduction in airway responsiveness was observed, suggesting possible mucous accumulation. These findings have important implications for indoor environments, where terpenes are common and building occupants may be chronically exposed to terpene OPs. The findings are also relevant to outdoor environments, where the reaction products of ozone with biogenic terpene emissions may partition onto existing PM in the atmosphere to contribute to secondary organic aerosol.

### 1558

## AIR-LIQUID INTERFACE CULTURE: TOWARDS MORE PHYSIOLOGICAL *IN VITRO* TOXICOLOGY OF AEROSOLS.

<u>J. Seagrave</u>, J. D. McDonald and <u>J. L. Mauderly</u>. Lovelace Respiratory Research Institute, Albuquerque, NM.

Exposure to combustion emissions has been convincingly shown to be associated with adverse health effects. However, the chemical/physical properties of the emissions and toxicological mechanisms responsible for health effects are still unclear. Understanding these processes is important in terms of modifying technology, regulating the emissions, or interventions to protect public health. This has created a need for rapid, inexpensive methods to screen for biological responses to these pollutants. Such methods must accurately model biologically relevant exposure pathways, doses, and responses, as well as the emissions' physical properties and chemical composition. We evaluated air-liquid interface exposure of cultured lung epithelial cells to diesel exhaust as a model of air pollution constituent-induced biological effects. We used two types of diesel engines, with or without modification of the emissions by removal of particles or stripping of semi-volatile organics. One engine was evaluated at two loads and several dilutions of the exhaust. In some cases, the cells were "primed" by pre-treatment with TNFa. We examined the effects of these alterations in exposure conditions on various toxicological endpoints including membrane damage, metabolic inhibition, oxidant stress, and pro-inflammatory potential. Effects were observed at exposure levels close to the physiologically relevant. However, there were differences in the types and magnitudes of the responses as a function of the exposure parameters. Most conditions tested caused little overt cytotoxicity, but metabolic inhibition and oxidant stress were reasonably sensitive to exposure conditions. Oxidant stress appeared to be a transient effect of exposure, but metabolic inhibition was more sustained. This method has potential applications for assessing the effects of alterations in engine technology as well as for mechanistic studies of the biological responses. Supported by FreedomCAR and Vehicle Technology Program of the US Department of Energy, Office of Energy Efficiency and Renewable Energy.

1559 THE RELATIVE TOXICITY OF SUBSTITUTED PHENOLS REPORTED IN CIGARETTE MAINSTREAM

<u>C. J. Smith</u><sup>1</sup>, T. A. Perfetti<sup>4</sup>, M. J. Morton<sup>4</sup>, A. Rodgman<sup>4</sup>, R. Garg<sup>2</sup>, C. D. Selassie<sup>3</sup> and C. Hansch<sup>3</sup>. <sup>1</sup>Wake Forest University, Winston-Salem, NC, <sup>2</sup>Clarkson University, Potsdam, NY, <sup>3</sup>Pomona College, Claremont, CA and <sup>4</sup>RJRT, Winston-

Cigarette mainstream smoke (MS) is a very complex aerosol with more than 4800 identified chemical constituents. MS and its fractions display a number of biological and toxicological activities. Only a minority of MS biological activities are attributable to a single compound, e.g., relative hypoxia with carbon monoxide. Quantitative structure-activity relationship (QSAR) studies can be conducted on structurally similar families of MS constituents. A QSAR study on 253 different substituted phenols reported in MS is shown here as an example of the application of QSAR to a complex mixture. From a laterally validated equation based on published data on the toxic effects of phenols on cultured cells, the relative toxicity, on a molar basis, of the 253 MS phenols has been determined. Based on this scheme, the most toxic phenols in MS include in descending order of toxicity: 2-(dimethylamino)-phenol, 2-ethyl-6-methyl-1, 4-benzenediol, 2-methoxy-1, 4-benzenediol and 4-ethyl-2-methoxy-6-methylphenol. The least toxic phenols include in ascending order of toxicity: 4-hydroxybenzoic acid and 3-hydroxybenzenepropanoic acid. In the human exposure situation, the toxicity of MS phenols is a complex interaction with contributions made by the following factors: toxicity per mole; MS concentration; synergistic, additive or antagonistic interactions with other MS components; host susceptibility; metabolism; and individual smoking behavior and inhalation patterns. QSAR studies of this type can play an important role in identifying MS components for reduction or removal by rank ordering their potential toxicity. A QSAR rank ordering process can help guide future toxicology testing.

### 1560

NEUROMODULATION OF TELEOST CATECHOLAMINES BY PROPRANOLOL AND FLUOXETINE.

W. Smith<sup>1</sup>, L. Blank<sup>1</sup>, C. M. Foran<sup>2</sup>, D. B. Huggett<sup>3</sup> and B. W. Brooks<sup>4</sup>. <sup>1</sup>Chemistry and Biochemistry, University of Oklahoma, Norman, OK, <sup>2</sup>Biology, West Virginia University, Morgantown, WV, <sup>3</sup>Pharmacology, University of Mississippi, University, MS and <sup>4</sup>Environmental Studies, Baylor University, Waco, TX. Sponsor: M. Kanz.

Information on mechanistic toxicity of pharmaceuticals to aquatic vertebrates is insufficient, particularly for neurologically active therapeutics. Recent research has identified fluoxetine and propranolol in municipal effluents and effluent-dominated streams, characterized fluoxetine and propranolol ecotoxicity to model organisms, and assessed fish neuro-endocrine responses after fluoxetine and propranolol exposures. To assess potential neuromodulatory effects of waterborne propranolol exposure on fish, Japanese medaka (Oryzias latipes) were exposed to 0, 0.5, 1, 50 and 100 ug/L for 28 days. A second study with a similar experimental design was performed with medaka exposed to 0, 0.1, 0.5, 1 and 5 ug/L fluoxetine for 28 days. Analysis of whole medaka brains for norepinephrine, epinephrine, dopamine, 3, 4-dihydroxyphenylacetic acid, 5-hydroxytryptamine, and 5-hydroxyindole-3-acetic acid content was performed by liquid chromatography with electrochemical detection. All propranolol treatment levels significantly increased norepinephrine levels in female fish and decreased male dopamine and norepinephrine levels. Similar to previous fluoxetine studies with rat models, an upregulation of dopamine in male fish was observed by 0.1, 1, and 5 ug/L fluoxetine treatment levels. We also detected a decrease of norepinephrine in male medaka at all fluoxetine treatment levels and an increase of 5-hydroxyindole-3-acetic acid at 5 ug/L. These studies provide baseline information for fish neurotransmitter responses to widely prescribed medications. In addition, these data indicate that neuromodulation following aqueous exposure to fluoxetine and propranolol may occur in fishes at concentrations similar to those reported in environmental matrixes.

### 1561

BEHAVIORAL AND NEUROLOGICAL BIOMARKERS OF STRESS EXPOSURE IN A FISH MODEL.

J. Salierno<sup>1</sup>, A. Murphy<sup>2</sup>, J. Shields<sup>3</sup> and A. Kane<sup>1</sup>. <sup>1</sup>Vet. Med., University MD, College Park, MD, <sup>2</sup>Biology, Georgia State University, Atlanta, GA and <sup>3</sup>VIMS, College of William & Mary, Gloucester Pt, VA. Sponsor: K. Squibb.

Chemical or physical stress exposure can alter behavior and have deleterious consequences for the survival of an organism in the wild. This work developed and tested the utility of behavioral and neurological assays as biomarkers of stress exposure in a killifish model, Fundulus heteroclitus. Alterations in startle behavior and brain activity were evaluated from fish exposed to brevetoxin, domoic acid, and swarming Pfiesteria shumwayae dinoflagellates (harmful algal bloom stressors); MS-222 (an anesthetic); and physical transport stress. Startle responses were quantified using a computer-controlled, video-based behavioral exposure system. Fos expression, visualized using immunocytochemistry, was investigated because it is a biomarker of neural activation in mammals. Fos is the protein product of c-Fos, an immediateearly gene, expressed in stimulated neurons. Startle response behaviors were significantly reduced when fish were exposed to brevetoxin and MS-222. This response was associated with longer reaction times and decreased reaction velocities. Exposure to domoic acid, dinoflagellates, and transport stress increased Fos labeling in the optic lobes of exposed fish brains. A dose response was observed in brains of fish exposed to dinoflagellates, where increases in dinoflagellate density were associated with increased Fos labeling. A six- and two-fold maximal increase in Fos expression was observed in brains of fish exposed to P. shumwayae and transport stress, respectively. Transport stress, dinoflagellates, and to a lesser extent domoic acid, increased neuronal Fos expression. Unlike mammals, Fos expression in fish brains appears to be more sensitive to physical than chemical stress. General alterations in brain activity, as well as knowledge of specific, stress-activated regions within the brain, may provide valuable insights into the neural control of fish behavior and sublethal effects of environmental stressors.

### 1562

IMMUNOTOXIC EFFECTS OF IN VIVO CHLORPYRIFOS EXPOSURE ON MURRAY COD (MACCULLOCHELLA PEELI).

P. F. Wright<sup>1</sup>, A. J. Harford<sup>1</sup> and K. O'Halloran<sup>2</sup>. <sup>1</sup>Key Centre for Toxicology, RMIT-University, Melbourne, VIC, Australia and <sup>2</sup>CENTOX, Landcare Research, Lincoln, Canterbury, New Zealand. Sponsor: M. Karol.

Murray cod is the largest freshwater fish in Australia and an important economic species. Our group has adapted several functional assays to test the immunotoxicity of chemicals that either pollute the Australian Murray-Darling basin, or are relevant to the aquaculture of this species. Organophosphate (OP) chemicals are neurotoxic and may have immunotoxic activity through disruption of the hypothalamo-pituitary-interrenal axis. This study investigated the immunotoxic effects of the OP pesticide chlorpyrifos, 14 days after in vivo exposure (single i.p. dose of 0, 0.4, 2, 10 and 50 mg/kg). Immune parameters analysed were: immune organ somatic indices and cell yields, serum lysozyme concentration, phagocytosis (via flow cytometry) and lymphoproliferation. Results: there was a dose-related decrease in fish body weight, splenic somatic index, and cell yields from head kidney and spleen. Serum lysozyme concentration was increased by 20% at 50 mg/kg. Lymphoproliferation was initially increased by 15% at 0.4 mg/kg, before being reduced by 17% at 50 mg/kg. Flow cytometry revealed an increase in granulocyte counts, while lymphocytes were marginally decreased. Phagocytic activity (i.e. number of granulocytes with engulfed fluorescent beads) increased by 40% at 2 mg/kg. This study has demonstrated that chlorpyrifos causes a dose-dependant atrophy of the spleen and reduction in spleen and head kidney immune cell numbers. It can also modulate the immune system, causing stimulation of some parameters at lower doses (i.e. phagocytosis and lymphoproliferation) and then suppression of many immune parameters at very high doses (50 mg/kg), where neurotoxicity is also apparent.

#### 1563

USING STRUCTURAL EFFECTS ON THE ORGANIZATION OF THE CYTOSKELETON OF RAINBOW TROUT HEPATOCYTES TO SORT PATHWAYS OF REACTIVE TOXICITY.

K. Flynn, P. K. Schmieder and R. D. Johnson. USEPA, Duluth, MN. Sponsor: I.

Reactive toxicants have been shown to be more acutely toxic to aquatic organisms than chemicals neither capable of direct interaction with cellular nucleophiles nor potentially metabolized to free radicals. For the development of accurate QSAR models, in vitro toxicity assays are being used to distinguish the more toxic arylating chemicals from those that primarily redox cycle. The cytoskeleton has multiple components providing an array of potential targets for direct arylation or oxidative stress induced by redox cycling. Four quinones served as "model" chemicals used to determine if alterations in the organization of the cytoskeleton of rainbow trout

(RBT) hepatocytes could adequately distinguish toxic pathways. Primary cultures of RBT hepatocytes were exposed to 2-methyl-1, 4-naphthoquinone (MNQ), 1, 4naphthoquinone (NQ), 1, 4-benzoquinone (BQ), or 2, 3-dimethoxynaphthoquinone (DMONQ). At several time points, exposed cells were collected, and labeled via immunocytochemistry for confocal imaging of three principle cytoskeletal components: microtubules (MT), intermediate filaments (IF) and microfilaments (MF). The organization of each component was quantified and a toxic "fingerprint" was determined for each quinone. BQ, which primarily arylates, altered MT and MF immediately, and IF after a longer exposure. NQ, considered to primarily arylate but also redox cycle, also affected MT and MF before IF. MNQ altered IF and MT most with little effect on the MF, presumably through mixed reactivity with redox cycling dominating over arylation. DMONQ redox cycles only, and like MNQ, altered IF structure first, followed by effects on MT. These results indicate that trout MT are the most sensitive to arylation, while MF are the least sensitive; with IF most susceptible to redox cycling, but only after much longer exposures. Therefore, a cytoskeletal endpoint assay shows promise in its ability to distinguish pathways of soft electrophile chemical reactivity.

**1564** ME

MECHANISMS OF PAH- AND PCB-MEDIATED IMPACTS ON EMBRYONIC DEVELOPMENT IN THE KILLIFISH, FUNDULUS HETEROCLITUS.

D. Wassenberg and R. T. Di Giulio. Integrated Toxicology Program, Duke University, Durham, NC.

Mechanisms by which polycyclic aromatic hydrocarbons (PAHs) and polychlorinated biphenyls (PCBs) perturb development in vertebrates, including fish, are not completely understood. Previous studies have shown that some PAHs and PCBs are agonists for the aryl hydrocarbon receptor (AHR) and induce AHR regulated genes such as cytochrome P4501A (CYP1A), while some PAHs and PCBs inhibit CYP1A enzyme activity. Interactions between CYP1A inducing and inhibiting compounds in environmental mixtures may be important to consider when addressing mechanisms by which real world mixtures impact fish development. In this study, we explored the relationships among CYP1A induction, CYP1A inhibition, and developmental deformities in Fundulus heteroclitus embryos. We exposed embryos to aqueous doses of an environmental PAH mixture from a creosote-contaminated sediment, a model PAH-type CYP1A inducer, β-naphthoflavone (BNF), or a model PCB-type CYP1A inducer, PCB126 alone and in combination with the AHR antagonist and CYP1A inhibitor, α-naphthoflavone (ANF). The PAH mixture, BNF and PCB126 all induced CYP1A activity, and co-treatment with ANF dampened this induction. Embryonic deformities were observed in embryos treated with the all three CYP1A inducers. Embryos co-exposed to PCB126 with 100 ug/L ANF were less severely deformed than those exposed to PCB126 alone, suggesting an ANF-mediated rescue of PCB126-induced deformities. However, embryos coexposed to the PAH mixture and ANF were deformed at concentrations of the mixture two orders of magnitude lower than those exposed to the mixture alone. Similar increases in deformities were observed in BNF and ANF co-treated embryos. The interaction between the PAH-type inducers and ANF on deformities cannot be explained by an additive model of toxicity. Ongoing research is exploring mechanisms behind the differences observed between the effects of co-treatment with ANF on PCB versus PAH-type CYP1A inducers and the impacts environmentally occurring CYP1A inhibitors may have on predicting the embryotoxicity of PAH and PCB mixtures.

1565

DEVELOPMENT OF A QUANTITATIVE VITELLOGENIN ELISA FOR DETECTION OF ENDOCRINE DISRUPTOR EFFECTS IN ZEBRAFISH (*DANIO RERIO*).

F. F. Mikkelsen<sup>1</sup>, J. K. Eidem<sup>1</sup>, B. M. Nilsen<sup>1</sup> and A. Goksoyr<sup>1,2</sup>. <sup>1</sup>Biosense Laboratories AS, Bergen, Norway and <sup>2</sup>Department of Molecular Biology, University of Bergen, Bergen, Norway. Sponsor: <u>E. Dybing</u>.

The yolk protein precursor vitellogenin (Vtg) is normally produced in response to estradiol in mature female fish, but is also produced in juvenile and male fish after exposure to environmental estrogens. During the last decade, Vtg in plasma or whole body homogenate of fish has become an accepted measure of xenoestrogenic potency of chemicals, effluents and discharges. Within international bodies such as the Organization for Economic Cooperation and Development (OECD), work is ongoing to develop screening and testing programmes for endocrine disrupting effects of new chemicals, and in the focus of this development are the small fish test species zebrafish (*Danio rerio*), fathead minnow (*Pimephales promelas*) and Japanese medaka (*Oryzias latipes*). We have developed quantitative ELISAs for detection of vitellogenin in all these species, and here we present results from the development and validation of a zebrafish Vtg ELISA. The zebrafish ELISA was developed using a combination of a monoclonal antibody as a capture antibody and a polyclonal antibody as a detecting antibody in an indirect sandwich assay. Stabilized Vtg purified from zebrafish was used as calibration standard. The zebrafish Vtg ELISA has a

working range of 0.5- 63 ng/mL and a minimal detection limit of 0.4 ng/mL. Various sample matrices (plasma, whole body homogenate) were tested and the practical detection limit in whole body homogenate samples was 250 ng/mL. The intra-and inter-assay coefficients of variations were below 20 percent. The assay was evaluated using a set of samples spanning the wide dynamic range of Vtg-levels found in fish exposed to environmental estrogens, and the results showed that the assay distinguished between samples with Vtg concentrations ranging from about 2  $\mu g/mL$  up to several mg/mL. Work is currently ongoing to increase the sensitivity of the assay. An international inter-lab validation of the assay has been performed.

1566

ACUTE TOXICITY AND BIOACCUMULATION OF TRIBUTYLTIN IN TISSUES OF UROLOPHUS JAMAICENSIS (YELLOW STINGRAY). J DWIVEDI AND L D TROMBETTA. ST. JOHNS UNIVERSITY, NEW YORK, NY.

J. Dwivedi<sup>1</sup> and <u>L. D. Trombetta<sup>2</sup></u>. <sup>1</sup>Biological Sciences, St. John's University, New York, NY and <sup>2</sup>Pharmaceutical Sciences, St. John's University, New York, NY.

Tributyltin (TBT) is a widely used biocide with many industrial applications including the manufacture of marine antifouling paint. TBT has been shown to cause imposex in several marine gastropods, immune suppression in marine mammals, and is a known endocrine disruptor. This study is concerned with the effects and bioaccumulation of TBT in tissues of the elasmobranch Urolophus jamaicensis (yellow stingray) following acute exposure to 4 ppb, 2 ppb and .2 ppb. Individuals of a captured population of University.jamaicensis were housed in isolated tanks, and after a minimum of 30 days of acclimation, were exposed to one of the three experimental doses. A fourth group was isolated as a control population. Three hours after exposure, individuals were sacrificed and blood, brain and gill tissue were collected from both control and exposed animals. Electron microscopy was performed on gill tissue to determine any morphological changes in gill epithelium. Graphite furnace AA spectrophotometry was performed on tissue samples to determine the concentration of Sn. Results indicate that University.jamaicensis is hypersensitive to TBT exposure. Elasmobranch gill showed a distorted, swollen epithelium with exfoliation following acute exposure to 4 ppb TBT for 3 hours. GFAAS results indicate that exposed gill tissue and blood contained significantly elevated concentrations of Sn compared to controls. Marine teleosts have been reported to have less than 40% necrosis in gill tissue following 30 day exposure to 4 ppb TBT. The threat of moderate exposure to TBT may be greater to apex predators such as elasmobranchs, due to the effects of bioconcentration of Sn in the food web. Stingrays such as University. jamaicensis may be at still greater risk since they inhabit the sediment where ambient TBT concentrations are reportedly higher.

1567

CORRELATION BETWEEN OBSERVED ACUTE AQUATIC TOXICITY OF A SERIES OF OLEFINIC MATERIALS USING SOLID PHASE MICROEXTRACTION - BIOAVAILABLE PETROLEUM HYDROCARBON.

D. J. Caldwell, E. J. Febbo, D. J. Letinski, C. L. Dzamba, R. F. Blattenberger,
 D. A. Winkelmann and T. F. Parkerton. Toxicology and Environmental Sciences
 Division, ExxonMobil Biomedical Sciences, Inc., Annandale, NJ.

Bioavailable petroleum hydrocarbon (BPH) refers to the measurement of dissolved, bioavailable hydrocarbons from aqueous samples using solid phase microextraction (SPME) as a lipid surrogate. In the present study, the existing data set on hydrocarbons has been expanded to include olefinic substances. In this study, extracted hydrocarbons/olefins from increasing loading rates of complex chemical substances in water accommodated fractions are analyzed by gas chromatography with flame ionization detection and quantified against a series of hydrocarbon standards. Measured BPH levels can be correlated with exposure concentrations assessed for toxicity potential in guideline studies. As such, BPH is considered a biomimetic extraction technique in which analytical methodologies are employed to estimate the exposure and effects of hydrocarbon mixtures on aquatic organisms. The correlation between BPH and aquatic toxicity is predicated on the fish acute toxicity syndrome of non-polar narcosis, where the sum of individual hydrocarbons exerts a cumulative narcotic effect on an aquatic organism, eventually reaching a critical body concentration and imparting a toxic effect. BPH has previously been demonstrated to be an accurate predictor of the acute aquatic toxicity of hydrocarbon solvents and petroleum mixtures. BPH results compared favorably with observed toxicity and further validates SPME - BPH as a cost effective tool for evaluating toxicity and developing testing strategies for use in the classification of substances for aquatic toxicity. Additionally, it provides a viable alternative to animal testing.

## NOTOCHORD DISTORTION BY THIURAM AND OTHER DITHIOCARBAMATE IN ZEBRAFISH EMBRYO.

H. Teraoka<sup>1</sup>, S. Urakawa<sup>1</sup>, S. Nanba<sup>1</sup>, W. Dong<sup>1</sup>, T. Imagawa<sup>2</sup>, H. Handley<sup>3</sup>, J. J. Stegeman<sup>3</sup> and T. Hiraga<sup>1</sup>. <sup>1</sup>School of Veterinary Medicine, Rakuno Gakuen University, Ebetsu, Hokkaido, Japan, <sup>2</sup>Faculty of Agriculture, University of Tottori, Tottori, Tottori, Japan and <sup>3</sup>Woods Hole Oceanographic Institution, Woods Hole, MA.

Dithiocarbamates include major agricultural chemicals, used as fungicide or rejectant for several decades. It has been reported that dithiocarbamates including thiuram caused wavy distortion of notochord in rainbow trout embryos. In the present study, we studied the mechanism of toxicity by thiuram and other dithiocarbamates with zebrafish embryos. When newly hatched embryos were exposed to thiuram (5-20nM) in 3.5cm petri dish from 30% epiboly until 24 hours post fertilization (hpf), wavy notochord, disorganized somite and shortened yolk sac extension with almost the same concentration dependency. Mortality at 24hpf was not increased for up to 1, 000nM thiuram. Body length but not notochord is shortened upon thiuram exposure. Distortion of the notochord began from 18 somite stage, when rhythmic spontaneous trunk contraction occurred. Abolishment of spontaneous contraction by anesthesia with tricaine blocked notochord malformation. While mRNA expression of no tail (zebrafish brachyury) and chondromodulin was not affected, specific expression of collagen type 2a in notochord was not markedly decreased by thiuram treatment. Other dithiocarbamates such as ziram or zisulfiram caused similar malformation to thiuram. These results suggest that thiuram disrupts rigidity of the trunk in zebrafish embryos, followed by notochord distortion upon voluntary trunk contraction. As the concentration of thiuram we used was under the environmental quality standard for environmental water in Japan, urgent laboratory and field investigation is required.

## 1569 REPROGRAMMING OF THE GENETIC NETWORK FOR CELLULAR DEFENSE AGAINST OXIDATIVE STRESS.

C. N. Giroux, J. Fan and A. Weiss. Center for Molecular Medicine and Genetics, Wayne State University, Detroit, MI.

The cellular responses to oxidative stress are highly conserved and comprise a dose dependent, graded phenotypic series: adaptation, cell cycle checkpoint delay, apoptosis, and necrosis. We hypothesize that these distinct phenotypes are determined by the gene expression program (i.e. the cellular state) of an underlying and similarly conserved genetic response network. The discrete response states of this network have been visualized by microarray gene expression profiling of hydrogen peroxide stressed yeast cells. Similarity clustering of genes based on their co-responsive behavior over multiple states of stress identifies specific pathways and processes whose gene expression levels are coordinated during the phenotypically complex cellular responses to oxidant challenge. To further characterize these cellular stress responses, we have developed a high-throughput, cell growth based assay system that provides quantitative phenotypic data for modeling of gene-environment interactions in yeast. Using this assay system, we demonstrate that the discrete oxidative stress response states are stable and that they are separated by unstable transitions in which cell populations exhibit increased variability in their quantitative behavior. In the adaptation response to oxidative stress, exposure to a low concentration of hydrogen peroxide results in increased cellular resistance to subsequent challenge by a high concentration or oxidant. This protective response is acquired in less than 1 hour and gradually decays over 24 hours. Establishment of the adapted state requires protein synthesis and the action of the stress-activated YAP1 transcription factor. These observations support our working hypothesis that adaptation is accomplished by a reprogramming of the genetic response network to create a novel, meta-stable protective state. We conclude that the graded series of phenotypic responses to oxidative stress reflects the action of an underlying genetic network whose expression state can be modulated by the interaction of genetic and environmental factors.

### 1570

DISSECTING ANTIOXIDANT RESPONSE ELEMENT (ARE)-DRIVEN GENE EXPRESSION INDUCED BY TERT-BUTYLHYDROQUINONE: A COMPARATIVE STUDIES USING LONG AND SHORT OLIGONUCLEOTIDE MICROARRAYS.

J. A. Johnson, J. Li and M. L. Spletter. School of Pharmacy, University of Wisconsin at Madison, Madison, WI.

At present, there are three popular microarray systems: in situ synthesized short oligonucleotide (oligo) arrays, long oligo arrays, and long cDNA array. Data are lacking on the comparison of the three platforms in the same biological system. In this study, we investigate the gene expression profiles identified by short or long oligo arrays. We have already established a model for upregulation of a cluster of antioxidant responsive element (ARE)-driven genes in human neuroblastoma cell line (isogenic) and neural progenitors (nonisogenic) by treatment with tert-butylhydro-

quinone (tBHQ) for 24h. Total RNA was generated and accessed using an Agilent Bioanalyzer, and the high-quality RNA was used for cRNA synthesis. Widely used Affymetrix U95AV2 arrays (25 mer) and Agilent Human 1A arrays (60 mer) were chosen to do the comparative study. Based on our stringent screening process (fold change over 2.0, coefficient of variation (CV) below 1.0) on three pair-match comparisons, both platforms showed similar gene expression patterns for upregulation of ARE-driven phase II detoxification enzymes and antioxidant genes in neuroblastoma cells and neural progenitors. RT-PCR confirmed these changes. The Agilent system showed greater dynamic changes in gene expression and lower CV values for those changed genes compared to the Affymetrix system. In terms of the sample preparation and hybridization, however, success with the Agilent system relies more heavily on the experimenter's expertise due to the lack of automation. There was a definite set of overlapping genes in all functional categories. The data generated from both systems, however, also revealed unique gene expression profiles after tBHQ treatment based on the platform used for the analysis. In conclusion, both short- and long- oligo microarray technologies offer reproducible and relatively reliable data, and could become the major competing microarray platforms.

### 1571

AGE-RELATED IMPAIRMENT OF THE TRANSCRIPTIONAL RESPONSES TO OXIDATIVE STRESS IN THE MOUSE HEART AND SKELETAL MUSCLE.

T. Prolla. University of wisconsin, Madison, WI. Sponsor: J. Kramarik.

To investigate the transcriptional response to oxidative stress in the heart and how it changes with age, we examined the cardiac gene expression profiles of young (5mo-old), middle-aged (15-mo-old), and old (25-mo-old) C57BL/6 mice treated with a single intraperitoneal injection of paraquat (50 mg/kg). Mice were killed at 0, 1, 3, 5, and 7 h after paraquat treatment, and the gene expression profile was obtained with high-density oligonucleotide microarrays. Of 9, 977 genes represented on the microarray, 249 transcripts in the young mice, 298 transcripts in the middleaged mice, and 256 transcripts in the old mice displayed a significant change in mRNA levels (ANOVA, P < 0.01). Among these, a total of 55 transcripts were determined to be paraquat responsive for all age groups. Genes commonly induced in all age groups include those associated with stress, inflammatory, immune, and growth factor responses. Interestingly, only young mice displayed a significant increase in expression of all three isoforms of GADD45, a DNA damage-responsive gene. Additionally, the number of immediate early response genes (IEGs) found to be induced by paraquat was considerably higher in the younger animals. These results demonstrate that, at the transcriptional level, there is an age-related impairment of specific inducible pathways in the response to oxidative stress in the mouse heart. Similar experiments aimed at understanding the transcriptional response to oxidative stress in skeletal muscle are in progress.

# 1572 ENHANCED EXPRESSION OF MAMMALIAN PROTEASOME THROUGH THE KEAP1-NRF2 SIGNALING PATHWAY.

M. Kwak<sup>1</sup>, N. Wakabayashi<sup>1, 2</sup>, J. L. Greenlaw<sup>1</sup>, M. Yamamoto<sup>2</sup> and <u>T. W. Kensler<sup>1</sup></u>. <sup>1</sup> Environmental Health Sciences, Johns Hopkins University, Baltimore, MD and <sup>2</sup>University of Tsukuba, Tsukuba, Japan.

26S proteasomes can recognize and remove oxidatively damaged proteins, thereby promoting cell survival. Decreased function of the proteasome system in aged subjects is strongly associated with the development of tissue degeneration. Transcription factor Nrf2 is a critical factor in governing the regulation of xenobiotics detoxifying genes. Keap1 inhibits the action of Nrf2 by confining it in the cytoplasm of cells. In the present study, we suggest that the proteasome system is a novel gene category regulated by the Keap1-Nrf2 signaling pathway in mouse. Dithiolethione increased levels of transcripts for 24 genes out of 34 subunits of the 26S proteasome in gene chip analysis using mouse liver. Seventy nine percent of the proteasome subunits increased by dithiolethione were only elevated in wild-type mice but not in nrf2-disrupted mice. Protein levels of proteasome subunits PSMA1, PSMB5 and PSMC1 were elevated up to 3-fold and proteolytic activities toward fluorogenic peptides were enhanced in wild-type mice following dithiolethione treatment. No induction was seen in mice where Nrf2 was disrupted. The promoter of *PSMB5* encoding catalytic subunit of the 20S proteasome was activated by dithiolethione-treatment and overexpression of Nrf2. Basal activity of the PSMB5 promoter was 10 times higher in keap 1-deficient cells and stimulation of PSMB5 promoter by dithiolethiones was blunted in nrf2-deficient cells. Further studies using promoter truncation and mutation showed that tandem AREs located in the proximal promoter of PSMB5 were necessary for the activation of this promoter în response to inducers and Nrf2. Results from chromatin-immunoprecipitation assays also indicated that these AREs can bind Nrf2 in intact cells. Taken together, we propose that the proteasome system can be enhanced through the Keap 1-Nrf2 pathway, implicating possible contribute to the protection/retardation against human degenerative diseases associated with aging.

W. HuangFu and J. Ninomiya-Tsuji. Environmental and Molecular Toxicology, North Carolina State University, Raleigh, NC.

Environmental stress stimuli such as osmotic shock and UV irradiation trigger activation of cell signaling to adapt the cells to or resist the stress. Mitogen-activated protein kinases (MAPs) JNK and p38 are major mediators of stress signaling, which are activated through the MAP kinase cascade, a protein kinase cascade composed of MAP3K, MAP2K, and MAPK. A number of MAP3Ks that can activate JNK/p38 have been identified. However, which MAP3K is involved in each stress and how MAP3K is regulated are largely unidentified yet. Here we found that TAK1 MAP3K was activated by osmotic stress. Furthermore, we isolated a kinase TAO1 (thousand and one amino acid protein kinase 1) as a TAK1 binding protein from the yeast two-hybrid screen with TAK1 bait. TAO1 has been reported to have a MAP3K-like activity. TAO1 was also activated by osmotic stress, suggesting that the TAK1-TAO1 complex participated in osmotic stress signaling. It was demonstrated that TAK1 could activate JNK/p38 as well as NF-kB pathway. However, osmotic stress solely activates JNK/p38 but not NF-kB pathway. We found that TAO1 did not activate NF-kB, but rather inhibited TAK1-induced NF-kB activation. These results suggest that TAK1, when activated by osmotic stresses, forms a complex with TAO1 resulting in activation of JNK/p38 but not NF-κB pathway.

#### 1574

USE OF AFFINITY CHROMATOGRAPHY TO IDENTIFY NOVEL PROTEINS THAT MEDIATE STRESS-INDUCED GENE ACTIVATION.

N. Macdonald, D. A. Clynes, J. G. Moggs, <u>I. Kimber</u> and G. Orphanides. Syngenta Central Toxicology Laboratory, Alderley Park, United Kingdom.

Exposure of cells to mitogenic or stress stimuli, including a broad range of toxicants, results in the induction of immediate-early (IE) protein kinase cascades and gene activation. The resulting changes in gene expression induce alterations in cell growth, division, differentiation, and metabolism. The mechanisms by which IE cascade activation promotes transcription are yet to be clearly defined, but involve the rapid modification of the histone components of chromatin. In particular, the N-terminal tail of histone H3 is phosphorylated at serine 10 (S10p) and acetylated at lysines 9 and 14 (K9ac and K14ac). However, the way in which these post-translational modifications promote the remodelling of chromatin required for gene activation is unclear. Using affinity chromatography, we have identified human proteins that recognise histone H3 tails containing stress- and mitogen-associated modifications. Synthetic peptides corresponding to unmodified (H3um), diacetylated (H3K9acK14ac), and phospho-diacetylated (H3K9acK14acS10p) histone H3 tails were immobilised onto agarose beads and incubated with HeLa cell nuclear extract. Six proteins bound in a modification-specific manner and were identified by peptide mass spectrometry. RbAp46/48, nucleophosmin, and NAP1, bound preferentially to H3K9acK14ac or H3um. Three proteins with molecular masses of 27.7, 28.3 and 29.1 kDa bound only to the H3K9acK14acS10p peptide, suggesting that they may play a role in mediating the stress and mitogen-induced transcriptional response. Peptide binding competition assays using surface plasmon resonance confirmed that these proteins bind to H3K9acK14acS10p with high affinity and revealed that the S10p modification was the major determinant of binding. Identification of these proteins will shed light on mechanisms by which toxicants induce changes in chromatin structure that facilitate gene activation and the pleotropic stress response.

### 1575

INHIBITION OF NUCLEAR FACTOR KAPPA B BY PHENOLIC ANTIOXIDANTS: INTERPLAY BETWEEN ANTIOXIDANT SIGNALING AND INFLAMMATORY CYTOKINE EXPRESSION.

Q. Ma and K. Kinneer. HELD/TMBB, CDC/NIOSH, Morgantown, WV.

Phenolic antioxidants inhibit the induction of inflammatory cytokines by inflammatory stimuli. Here, we analyzed the mechanism by which the antioxidants inhibit LPS-induced expression of TNF $\alpha$  in macrophages. Hydroquinone (HQ) and t-butyl hydroquinone (tBHQ), prototypes of phenolic antioxidants, block LPS-induced transcription of TNF $\alpha$  and a NF- $\kappa$ B-mediated reporter gene expression, suggesting NF- $\kappa$ B as a target in the inhibition. Analyses of the NF- $\kappa$ B activation pathway revealed that the antioxidants do not inhibit LPS-induced activation of the I $\kappa$ B kinase activity, degradation of I $\kappa$ B $\alpha$ , or translocation of activated NF- $\kappa$ B into the nucleus, but block the formation of NF- $\kappa$ B/DNA binding complexes. *In vitro* experiments showed that the antioxidants do not directly interfere with DNA binding of NF- $\kappa$ B. Structure-activity analyses suggest that inhibition of NF- $\kappa$ B function involves the redox cycling property of the antioxidants. These findings implicate a redox-sensitive factor important for the binding of NF- $\kappa$ B function and inflammatory cytokine expression by phenolic antioxidants.

#### 1576

RESTRAINT STRESS ACTIVATES STAT3 VIA ADRENOCEPTOR STIMULATION AND IL-6 PRODUCTION IN MOUSE LIVER.

E. A. Johnson<sup>1</sup>, <u>J. P. O'Callaghan</u><sup>2</sup> and <u>D. B. Miller</u><sup>1</sup>. <sup>1</sup>Chronic Stress and Neurotoxicology Laboratory, Toxicology and Molecular Biology Branch, Centers for Disease Control-NIOSH, Morgantown, WV and <sup>2</sup>Molecular Neurotoxicology Laboratory, Toxicology and Molecular Biology Branch, Centers for Disease Control-NIOSH, Morgantown, WV.

In vivo stress causes an activation of the JAK-STAT signaling pathway as evidenced by the large magnitude increases in phosphorylated STAT3 in the livers of mice subjected to restraint. Restraint can elevate IL-6 levels in the liver and this cytokine is known to instigate signaling through the JAK-STAT pathway but the role of the stress mediators, epinephrine, norepinephrine and corticosterone in this cascade is not well understood. Using a combination of focused microwave irradiation to preserve protein phosphorylation state, and phospho-specific immunoblotting, we found that the greater than 10 fold increase in liver PSTAT3tyr705 caused by 2 hrs of restraint is blocked by both alpha and beta adrenergic antagonists. Adrenergic agonists (phenylephrine 10 mg/kg or isoproterenol 10 mg/kg s.c.) which mimic the stress response in vivo also activate liver STAT3. Liver responses to both restraint stress and the adrenergic agonists were reduced in IL-6 deficient animals, suggesting that IL-6 is required for signal transduction initiated by activation of adrenoceptors. Pretreatment of IL-6 deficient mice with exogenous IL-6 (1 mg/kg i.p. 60 min before restraint) restored liver STAT3 activation in response to restraint stress. Hepatocyte growth factor and epidermal growth factor were ruled out as potential mediators of restraint stress-induced activation of STAT3 using real time PCR as only message for IL-6 was elevated. Altogether, these data suggest that restraint stress and adrenergic agonist-induced activation of liver STAT3 are dependent on IL-6 synthesis mediated by activation of adrenoceptors in liver. Stress is known to modulate the liver toxicity of numerous compounds. Stress-induced changes in JAK-STAT signaling and subsequent protein transcription will help to clarify the molecular basis of stress-induced modulation of liver toxicity. This work was supported by intramural funds of CDC-NIOSH

### 1577

EVALUATION OF THE DERMAL BIOAVAILABILITY OF AQUEOUS XYLENE IN F344 RATS AND HUMAN VOLUNTEERS.

K. D. Thrall and A. D. Woodstock. Battelle, Pacific Northwest Laboratories, Richland, WA.

Xylene is a clear, colorless liquid used as a solvent in the printing, rubber, and leather industries and is commonly found in paint thinners, paints, varnishes, and adhesives. Although humans are most likely to be exposed to xylene *via* inhalation, xylene is also found in well and surface water. Therefore, an assessment of the dermal contribution to total xylene uptake is useful for understanding human exposures. To evaluate the significance of these exposures, the dermal absorption of oxylene was evaluated in F344 male rats and human volunteers using a combination of real-time exhaled breath analysis and physiologically based pharmacokinetic (PBPK) modeling. Animals were exposed to o-xylene at a 0.2 mg/ml aqueous concentration using a 2.5-cm diameter occluded glass patch attached to a clippershaved area on the back of the rat. Immediately following the initiation of exposure, individual animals were placed in a glass off-gassing chamber and exhaled breath was monitored. Human volunteers participating in the study placed both legs into a stainless steel hydrotherapy tub containing an initial concentration of approximately 0.5 mg/L o-xylene. Exhaled breath was continually analyzed from each volunteer before, during, and after exposure to track absorption and subsequent elimination of the compound in real time. In both animal and human studies, a PBPK model was used to estimate the dermal permeability coefficient (Kp) to describe each set of exhaled breath data. Rat skin was found to be approximately 12 times more permeable to aqueous o-xylene than human skin. The estimated human and rat aqueous o-xylene Kp values were 0.005 +/- 0.001 cm/hr and 0.058 +/- 0.009 cm/hr, respectively. (Supported by NIEHS grant 1-P42-ES10338-01).

### 1578 A NEW QSAR MODEL FOR HUMAN SKIN ABSORPTION.

W. Luo<sup>1</sup>, H. Nguyen<sup>1</sup>, Q. Telesford<sup>2</sup> and W. Fung<sup>1</sup>. <sup>1</sup>Toxicology, L'Oreal USA, Clark, NJ and <sup>2</sup>Bioengineering, Rutgers University, New Brunswick, NJ.

The objective of this study was to create a model for the quantitative prediction of percutaneous absorption based on physicochemical properties of chemicals. Such a model is valuable as a tool for screening and prioritization purposes for safety evaluation and risk assessment. It is very beneficial to the industry to be able to predict the skin permeability of compounds before they are made or on occasions when no experimental values exist. A five-parameter QSAR model to predict the permeability coefficient Kp, was completed using a training set of 270 chemicals and their

physico-chemical descriptors. All Kp values were experimentally determined and obtained from literature sources, while the values for the selected molecular descriptors were experimentally measurable and can be calculated readily. The analyzed descriptors included calculated octanol-water partition coefficient (Kow), octanol-water partition coefficient of all species (unionized and ionized) at pH 5 and 7.4 (D), molecular weight (MW), molecular volume, polar surface area, water solubility (Sw), topological polar surface area, melting point (m.p.) and hydrogen donors/acceptors. Using the CAChe program's (Fujitsu America Inc., Portland, OR) stepwise regression analysis, five out of the ten molecular descriptors in the data set were determined to have significant statistical correlation: log P, log DpH 7.4, molecular weight (MW), solubility (SW), and Melting Point (m.p.). LogKp = -0.005530X(MW) + 0.6205X(log Kow) + 3.030e-07X(Sw) + 0.08239X(log DpH7.4) - 0.001483\*(m.p.) - 2.759 In conclusion, an algorithm to estimate human skin absorption is derived based on physical properties of over three hundred compounds. Compared to other skin absorption QSAR models in the literature, our model has incorporated more physical properties like Sw, log DpH7.4 and m.p. in addition to the commonly used MW and log Kow with good correlation coefficient. An independent test data set will be generated to test the reliability of this model.

# 1579 DERMAL TOXICITY OF SUPER VASMOL 33 WITH AYURPRASH, SUPER VASMOL 33, COMBINED EXTRACT AND TWO SOLUTION DYE SAMPLES.

S. L. Bodhankar, S. Sankaran, K. R. Khandelwal, S. N. Shah and N. A. Mhetre. *Pharmacology, Bharati Vidyapeeth Deemed University, Pune, Maharashtra, India.* Sponsor: H. Mehendale.

Hair dye containing hydrogen peroxide and para-phenylenediamine is popularly used for cosmetic purpose. Ayurprash, a combination of Embilica officinalis, Trigonella foenum graecum, Eclipta alba, Hibiscus rosasinensis in definite proportion imparts glow and smoothens hair. Toxicity reports of Ayurprash in combination with hair dye/hydrogen peroxide are not available. The objective was to compare and investigate acute dermal toxicity of the following formulations in rabbits 1) Super Vasmol 33 with Ayurprash (SVA), 2) Super Vasmol 33 without Ayurprash (SVWA), 3) Combined extract (CE) of the plant material used as Ayurprash. Two marketed hair dye samples containing hydrogen peroxide viz., 4) Sample A(SA) and 5)Sample B(SB) were also used for the study. New Zealand white rabbits of either sex weighing 1.54 to 2.0 kg with its back shaved in 4 round patches of equal diameter, 2 on each side were used. After application of 1ml/kg of formulations to the shaved patches on the dorsal side of rabbits hair growth and color, skin color, its texture and toxicity (inflammation) were noted weekly for 10 weeks. SA group showed slight rough texture of skin till 10th week. SVA, CE groups showed slow hair growth on days 7 and 14 and rapid hair growth subsequently. SVWA, Control, SA, SB groups showed no hair growth upto day 21. SA showed roughness of skin and SB showed deposition of black dye leading to darkening of skin. SVA, SVWA, SA and SB showed brownish black color and CE and control groups showed white hair colour. Hydrogen peroxide formulations showed more dermal toxicity than SVA. These studies indicate that SVA is safer than hair dyes containing hydrogen peroxide. Ayurprash was beneficial for rapid hair growth and is non toxic to skin.

### 1580 THE PIG AS AN EXPERIMENTAL MODEL IN WOUND HEALING RESEARCH.

P. Glerup, M. Skydsgaard, J. T. Jensen and S. Klastrup. General toxicology and pharmacology, Scantox A/S, Lille Skendsved, Denmark. Sponsor: R. Harling.

The use of pigs in studies of wound repair is known to provide results of high reproducibility and reliability for the efficacy and safety evaluation of new pharmaceuticals or medical device products. The skin of pigs has been shown to be anatomically, biochemically and immonulogically similar to human skin. The poster gives an overview of some methods and practical procedures, in the context of the investigations currently performed at Scantox. They are based on extensive experience with pigs and minipigs as animal models. Studies are performed using Gottingen minipigs or Landrace pigs. The wounds, excisional split-thickness or full-thickness wounds, are surgically prepared under general anaesthesia. A number of variations in the nature of wound models are possible, for example wound shape and size, eschar induction (for evaluation of debriding agents) or determination of infectious burden. Dressings can be changed on a daily basis until complete healing. During the recovery phase wounds are evaluated macroscopically in detail, including planimetric measurement of wound areas. In addition, bacteria in the wound site can be determined, or blood samples may be taken in order to assess systemic exposure to test article(s). After harvesting, histopathological analysis of the wound tissues is performed, including special stainings to estimate angiogenesis and collagen formation. The generation of collagen may also be evaluated indirectly by HPLC assay of hydroxyproline concentration. A full necropsy evaluating possible adverse systemic effects of test compound may be performed. Data from wound observations and planimetric measurements will be presented in the poster as well as histopathological results.

# 1581 SIMULATED SOLAR UV LIGHT (SSL) INDUCES INFLAMMATION AND OXIDATIVE STRESS IN THE SKIN OF SKH-1 HAIRLESS MICE.

A. R. Murray<sup>1</sup>, E. Kisin<sup>2</sup>, V. Castranova<sup>1, 2</sup>, B. J. Miller<sup>3</sup>, P. C. Howard<sup>3</sup> and A. A. Shvedova<sup>1, 2</sup>, Physiology and Pharmacology, West Virginia University, Morgantown, WV, <sup>2</sup>PPRB, NIOSH, Morgantown, WV and <sup>3</sup>NCTR, USFDA, Jefferson, AR.

The skin is continuously exposed to a variety of hazardous environmental insults, such as ultraviolet light, ozone, and ionizing radiation. These exposures result in the production of free radicals and reactive oxygen species, which may play a role in the development of inflammatory skin disorders, skin cancer, cutaneous autoimmune disorders, phototoxicity, and premature ageing. A variety of antioxidant defense mechanisms are present to prevent oxidative stress; however, UV irradiation has been shown to overwhelm these mechanisms. We hypothesized that UV-light exposure results in the formation of free radicals, which causes antioxidant depletion, lipid peroxidation and DNA damage. To experimentally evaluate the effects of simulated solar light (SSL) on SKH-1 hairless mice, animals were exposed to SSL (13.7 mJ (CIE)/cm<sup>2</sup>) for 1 hour, 5 days a week for 3 weeks. Twenty-four hours following the last exposure, mice were sacrificed. The skin was evaluated for changes in several parameters of oxidative stress. A significant amount of GSH oxidation as well as decreases in the levels of protein thiols, total antioxidant reserves, and vitamin E were seen as a result of exposure to SSL. A significant increase in lipid peroxidation and myeloperoxidase activity (MPO), indicating infiltration of neutrophils into the skin, was observed following SSL irradiation. The production of pyrimidine dimers seen after exposure is indicative of DNA damage occurring as a result of the direct action of SSL on DNA. Histological evaluation of the skin following exposure to SSL irradiation showed increased skin thickness and inflammatory cell infiltration. These data indicate that SSL exposure induces the production of pyrimidine dimers and free radicals in the skin, which result in the development of oxidative stress and inflammatory cell infiltration.

## MOLECULAR CHANGES IN RAT SKIN RELATED TO IRRITATION BY JP-8 JET FUEL.

J. N. McDougal, C. M. Garrett and C. M. Amato. Pharmacology/Toxicology, Wright State University, Dayton, OH.

Dermal irritation due to occupational exposure of Air Force personnel to jet fuels can be an important occupational health issue. Irritant contact dermatitis from a wide variety of chemicals is the most common occupational skin disease. It costs the US government millions of dollars each year. Having a mechanistic understanding of the early process of skin irritation provides the potential for prophylactic and therapeutic intervention. We have previously studied the changes in gene and protein expression in rat skin for up to four hours after one-hour cutaneous exposures to JP-8. These studies in male, Fisher 344 rats address molecular changes in the skin induced by longer in vivo exposures; 4, 8 and 24 hours. Five hundred microliters of JP-8 was placed in a modified Hill Top Chamber and held in place on the clipped back with a modified Lomir rodent jacket. Sham-treated controls with an empty chamber to control for the effect of hydration were used for comparisons at each time point. At the end of the exposures, skin was excised, flash frozen and pulverized for the isolation of total RNA and proteins. Affymetrix gene array (RG-U34A) was used to determine changes in gene expression. Real time PCR was used to quantify changes in mRNA levels and sandwich enzyme linked immunosorbent assay (ELISA) was used to quantify changes in specific protein levels. Gene array studies showed that the JP-8 treatment caused up regulation of genes involved in the process of inflammation and protein synthesis. Genes down regulated were related to metabolism and support functions of the skin. Real time PCR confirmed up and down regulation in some but not all genes investigated. ELISA measurements of some of the inflammatory and regulatory proteins related to the gene changes showed that protein levels in whole skin are affected by the JP-8 treatment especially at later time points. The results of this study increase our understanding of the JP-8-induced inflammatory process and may allow us to build quantitative mathematical models of the irritant process. (supported by the Air Force Office of Scientific research)

## 1583 ASSESSMENT OF SKIN BARRIER CREAMS TO LOWER PENETRATION OF JP-8 JET FUEL.

J. J. Schlager<sup>1</sup>, D. L. Pollard<sup>2</sup> and A. J. Guilfoil<sup>1</sup>. <sup>1</sup>AFRL/HEST, Wright-Patterson AFB, OH and <sup>2</sup>Mantech Environmental Technology, Inc., Wright-Patterson AFB, OH.

Skin irritation as well as skin and systemic toxicity from accidental JP-8 jet fuel exposure is a concern for the USAF and their fuel handling personnel. Personal protection equipment and clothing (PPEC) is a necessity under normal operations; but

requirements to meet workload goals can lengthen individual exposure causing PPEC failure under non-life threatening JP-8 discharge or accident. To insure work conditions are amended to produce the lowest JP-8 exposure, we proposed to add a skin-enhancement barrier cream to the PPEC armament. Initial work was to select an over-the-counter product that claims to have skin enhancement and/or barrier properties, which could be quickly fielded. For studies to assess penetration lowering performance of 13 products to JP-8, we applied either 0.1 mm (neat) or 0.22 mm (cotton gauze supported) barrier formulation on a 10 cm<sup>2</sup> silastic membrane, allowed a 1 hr drying time, and placed the coated membrane into a static penetration cell containing 2 ml of JP-8 in the upper chamber over the barrier. JP-8 component membrane penetration was isolated with 20 ml VOLPO-saline in the lower receiving chamber over a 4 hr period. Samples (20 µl) were withdrawn from the lower chamber sidearm and capped into 20 ml headspace sample vials for gas chromatography analysis. Samples were heated (140°C) to stable vapor phase using a headspace sampler and components separated on a non-polar SPB-1 column with FID detection. Total area of eluted hydrocarbon vapor from the sample was compared between the coated and non-coated membrane penetration. Generally, products tested had either 1) no to little barrier properties, 2) initial barrier properties but latent breakthrough rates often similar to the non-coated surface or 3) a constant lower penetration rate through the 4 hr test. The most successful barrier to JP-8 was SERPACWA cream having breakthrough rates of 3.4 to 8% of control depending on coating thickness. The results show that not all creams promoting non-polar barrier qualities would create a sufficient barrier for JP-8 penetration.

1584 A NEW TECHNIQUE TO ASSESS DERMAL ABSORPTION OF CHEMICAL VAPORS *IN VITRO* BY

THERMAL GRAVIMETRIC ANALYSIS.

T. S. Isaksson and G. Johanson. Work Environment Toxicology, Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden.

There is a lack of quantitative dermal absorption data for industrial chemicals. When available, absorption rates can vary up to 5 orders of magnitude for the same chemical. This indicates a need for a standardized approach. The aim of this study was to explore the possibility to use a gravimetric in vitro method, to measure dermal absorption of solvent vapors. Method: Epidermal membranes from stillborn porcine were placed in a Thermal Gravimetric Analysis (TGA) balance (TA Instruments, USA) under constant air flow (90 ml min<sup>-1</sup>), temperature (35°C) and humidity (RH 45%). After equilibration, a constant level of chemical vapor (corresponding to 45% saturation) was added to the air flow. Results: The weight changes during exposure of vapors (water, methanol, toluene, ethanol, dimethylformamide, trimethyl benzene, isopropyl alcohol, gamma-butyrolactone and n-hexane) were readily recorded. Upon addition of vapor, as expected, the skin weight initially increased rapidly and approached steady-state. A reverse pattern was seen following removal of chemical vapor. The gravimetric method seems to be a promising approach for dermal absorption studies. The method can easily be automated and only small amount of skin is required. However, the method cannot be used with chemicals with low vapor pressure. Future directions: Studies of additional chemicals, development of a model that translates the weight curves to absorption rates, and validation against a standardized method for dermal absorption, using diffusion cells. This study was supported by the Swedish Council for Working Life and Social Research (FAS).

INFLUENCE OF CUTTING FLUID CONTAMINANTS ON THE DERMAL DISPOSITION OF THE BIOCIDE, TRIAZINE.

R. E. Baynes, J. D. Brooks, B. Beth, R. Wilkes and J. E. Riviere. Center for Chemical Toxicology Research and Pharmacokinetics, North Carolina State University, Raleigh, NC.

Cutting fluids can become contaminated with metals (e.g., nickel, Ni) and nitrosamines (e.g., N-nitrosodiethanolamine, NDELA), and there is concern that these classes of contaminants will modulate dermal disposition and ultimately the toxicity of cutting fluid additives such as biocides (e.g., triazine, TRI). Biocides are added to these formulations to prevent bacterial degradation of commercial cutting fluids. The purpose of this study was to assess the dermal absorption and deposition of C14-TRI when topically applied to porcine skin in an *in vitro* flow-through diffusion cell system as mineral oil (MO) or polyethylene glycol (PEG) mixtures. C14-TRI mixtures were formulated with NDELA and/or Ni or with 3 other cutting fluid additives (5% linear alkylbenzene sulfonate, 5% triethanolamine, and 5% sulfurized ricinoleic acid) and one or both of these contaminants. C14-TRI absorption ranged from 2.72 - 3.29% dose in MO and 2.29 - 2.88% dose in PEG with significantly greater TRI absorption in MO than PEG when all additives and contaminants were present. TRI permeability was consistently and significantly greater

in MO than in PEG when NDELA was present. Ni appears to have little or no effect on TRI absorption, although the trends suggest a possible negative effect on triazine permeability and deposition in skin. These observations suggest that metal-machining workers should not only be concerned about dermal toxicity of these contaminants, but they may also enhance dermal disposition of cutting fluid additives. (Supported by NIOSH Grant R01-OH-03669)

A COMPARATIVE INVESTIGATION OF THE EFFECTS OF WATER, ETHANOL AND WATER/ETHANOL MIXTURES ON CHEMICAL PARTITIONING INTO PORCINE STRATUM CORNEUM AND PERMEABILITY IN PORCINE SKIN.

D. van der Merwe and <u>J. E. Riviere</u>. Center for Chemical Toxicology Research and Pharmacokinetics, North Carolina State University, Raleigh, NC.

The effects of vehicles on transdermal skin absorption is a critical factor in determining risk from skin exposure to toxins and for assessing the transdermal route for drug delivery. Water and ethanol are commonly used solvents in the chemical and pharmaceutical industries. 0%, 50% and 100% aqueous ethanol solutions were used as solvents for radio labeled phenol, 4-nitrophenol, pentachlorophenol, nonylphenol, methyl parathion, ethyl parathion, chlorpyrifos, fenthion, triazine, atrazine, simazine and propazine. The porcine stratum corneum/solvent partitioning coefficients of these compounds were estimated. Permeability in porcine skin of these compounds in the same solutions was estimated using flow-through diffusion cells. Partitioning into the stratum corneum was highest when water was used as a solvent across all compounds. Partitioning from 50% ethanol was higher than from 100% ethanol, except for ethyl parathion, atrazine and propazine. Stratum corneum partitioning was significantly correlated with octanol/water partitioning. Divergence between octanol/water partitioning and stratum corneum/solvent partitioning became wider in 50% and 100% ethanol as the octanol/water partitioning coefficient increased. This divergence was more marked in 100% ethanol than in 50% ethanol. Correlation also existed between molecular weight and stratum corneum partitioning, but with a lower significance. Stratum corneum partitioning was not correlated with porcine skin permeability. It was concluded that chemical partitioning into the stratum corneum from water and aqueous ethanol solutions is dependent on differences in thermodynamic activity between the solvent and stratum corneum. Among the compounds tested, stratum corneum partitioning can be predicted using the compound's physico-chemical properties, but stratum corneum partitioning does not predict skin permeability.

1587

INVESTIGATION OF THE SENSITIZATION POTENTIAL OF VARIOUS ESSENTIAL OILS IN THE LOCAL LYMPH NODE ASSAY (LLNA).

J. Lalko and <u>A. Api</u>. Research Institute for Fragrance Materials, Inc., Woodcliff Lake, NI.

Essential oils are commonly used fragrance ingredients. The oils themselves are complex mixtures, which may contain varying amounts of naturally occurring contact sensitizers. As part of a dermal sensitization risk assessment, the local lymph node assay (LLNA) was used to evaluate the sensitization potential of 7 essential oils and 3 of their major components. The essential oils tested were clove leaf oil, citronella oil, geranium oil, basil oil, lemon grass oil, litsea cubeba and palmarosa oil. The components of each essential oil were characterized by GC/MS. The individual components tested were eugenol, citral and geraniol. The LLNAs were conducted according to OECD guideline 429. Each fragrance material was tested at five dose levels ranging from 2.5 to 50% w/v in 1:3 ethanol:diethyl phthalate. The Stimulation Index (SI) values were calculated for each dose level, an SI of 3 or more was considered to give a positive response. Linear interpolation of the dose response data from each LLNA was then used to derive an estimated concentration (EC3) required to elicit an SI value of 3. The EC3 value was then taken as a measure of relative potency. Eugenol, geraniol and citral were observed to have SI values greater than 3 and, as such, were considered to be potential sensitizers under the conditions of the test. The EC3 values were calculated to be 5.4%, 6.3% and 11.4%, respectively. Based on EC3 values, the potency of each of these three materials can be classified as weakly sensitizing. Positive responses were observed with lemon grass, litsea cubeba, palmarosa and basil oil. The respective EC3 values and subsequent potency classification for each material are 6.5% (weak), 8.4% (weak), 9.6% (weak), 7.1% (weak) and <2.5% (<=moderate). Citronella and geranium oil were not observed to elicit a positive response. However, a mild dose response and SI values nearing three at the highest dose indicate that a positive response and subsequent EC3 value could be expected at doses > 50% classifying each material as extremely weak to non-sensitizing.

TOPICAL HYDROCARBON ABSORPTION IN PORCINE SKIN PREVIOUSLY EXPOSED TO JP-8 JET FUEL.

F. Muhammad, N. A. Monteiro-Riviere and J. E. Riviere. Center for Chemical Toxicology Research and Pharmacokinetics, North Carolina State University, Raleigh, NC.

The percutaneous absorption of topically applied jet fuel hydrocarbons (HC) through skin previously exposed to JP-8 has not been investigated, although this exposure scenario is the occupational norm. Pigs were exposed to JP-8 soaked cotton fabrics for 1 and 4 days with repeated daily exposures. Pre-treated and untreated skin was then dermatomed and placed in in-vitro diffusion cells. Five cells with exposed skin and four cells with unexposed skin were dosed with a mixture of 14 different HC consisting of nonane, decane, undecane, dodecane, tridecane, tetradecane, pentadecane, hexadecane, ethyl benzene, o-xylene, trimethyl benzene (TMB), cyclohexyl benzene (CHB), naphthalene, and dimethyl naphthalene (DMN) in water + ethanol (50:50) as diluent. Another five cells containing JP-8 exposed skin were dosed with diluent only in order to determine the residue potential of jet fuel HC in skin. The data indicated that there was 2-3-fold and 3-4-fold increase in absorption of nonane, undecane, dodecane and tridecane through 1 and 4 days JP-8 pre-exposed skin respectively. Similarly, ethyl benzene, o-xylene and TMB were absorbed 2-3 times more than in controls in 1 day while > 4 times in 4 days JP-8 preexposed skin experiments. The absorption of naphthalene and DMN was 1.5 times higher than controls in both 1 and 4 days pre-exposures. The CHB, naphthalene and DMN were found to have significant persistent skin residues capable of considerable further absorption in 4 days pre-exposures as compared to 1-day exposures. The absorption parameters of flux, diffusivity and permeability were calculated for the studied HC. The possible mechanism of increased HC absorption in fuel pre-exposed skin may be via lipid extraction from stratum corneum as indicated by electron microscopy. This study suggests that single dose application data for jet fuel HC cannot be used to predict the toxic potential for repeated exposures and that for certain compounds, persistent absorption may occur days post-exposure. Supported by USAFOSR F49620-01-1-0080.

## 1589 A MURINE MODEL FOR CUTANEOUS PHOTOAGING: OBSERVATIONAL, HISTOPATHOLOGIC AND MOLECULAR ENDPOINTS.

D. B. Learn<sup>1</sup>, C. P. Sambuco<sup>1</sup>, P. D. Forbes<sup>1</sup>, M. J. Mayo<sup>2</sup>, C. S. Johnson<sup>2</sup> and A. M. Hoberman<sup>1</sup>. <sup>1</sup>Charles River Discovery and Development Services, Argus Division, Horsham, PA and <sup>2</sup>Pathology Associates, West Chester, OH.

Photoaging connotes changes in aging skin chronically exposed to sunlight. Clinically, the changes involve skin texture and appearance (wrinkling, sagging, discoloration), microarchitecture (e.g., epidermal thickness, elastin and collagen fiber content and arrangement, cell type and number, ) and functional capacity (e.g., repair). Identifying compounds that affect (e.g., increase, halt or reduce) these deleterious responses to solar exposure begins with employing a reliable experimental model to define those responses. The (HRS/Skh-1) hairless albino mouse undergoes photoaging changes when chronically exposed to UVR. Groups of female hairless mice were exposed to 0, 3, 3.75, 4.5, 5.25 or 6 minimal erythema doses (MED) of solar-simulated, environmentally relevant UVR per week, for 4 or 8 weeks. Clinical observations were performed weekly and skinfold thickness (SFT) measured at weeks 0, 2, 4, 6 and 8 weeks. Skin samples harvested at 4 or 8 weeks were frozen or formalin-fixed, sectioned, stained and evaluated histopathologically using visual and image analysis techniques. Mean SFT increased in a UVR dose-dependent manner up to 5.25 MED/week. Incidence and severity of erythema, edema, flaking, thickening (assessed visually) and wrinkling increased in a UVR dose-dependent manner up to 4.5 MED/week. Mast cell density (MSD) and average epidermal thickness (AET) was greatest at 4 weeks at UVR exposures of 5.25 MED and 6.0 MED, respectively. Elastin content (EC) was increased at 4 weeks but the increase was not UVR dose-dependent. MSD, AET and EC was reduced at 8 weeks for all groups, as compared with 4 weeks. The hairless mouse along with the use of environmentally relevant UVR is a predictable and repeatable photoaging model for the evaluation of both safety (i.e., enhancement) and efficacy (i.e., prevention and/or amelioration) by novel compounds using these observational and histopathological endpoints.

## 1590 DIFFERENTIAL REGULATION OF COX-2 EXPRESSION BY ULTRAVIOLET LIGHT IN KERATINOCYTES AND MACROPHAGES.

A. T. Black<sup>1</sup>, A. M. Vetrano<sup>1</sup>, R. Sur<sup>1</sup>, <u>D. E. Heck<sup>1</sup></u> and <u>J. D. Laskin<sup>2</sup></u>. <sup>1</sup>Rutgers University, Piscataway, NJ and <sup>2</sup>Environmental and Community Medicine, UMDNJ-Robert W Johnson Medical School, Piscataway, NJ.

Chronic exposure to sunlight is a significant causative factor in the development of skin cancer. Modifications of DNA and other critical cellular macromolecules by the higher energy shorter solar wavelengths comprising the UVB spectra (290 to

320 nm) are the most damaging to the skin. Recent studies have demonstrated a link between expression of cyclooxygenase-2 (COX-2), formation of prostaglandins and the development of skin cancer. UVB is also known to induce COX-2 in human skin cells. In the present studies, we compared the effects of UVB on COX-2 expression in JB-6 and PAM 212 cells, two murine keratinocyte cell lines, and RAW264.7, a murine macrophage cell line. In macrophages, bacterially derived lipopolysaccharide (LPS, 1 µg/ml) was found to rapidly induce COX-2 protein expression as determined by western blotting. The keratinocyte cell lines constitutively expressed COX-2. LPS caused a 3-4 fold increase in expression of this protein. Whereas in PAM 212 cells, UVB light (10-25 mJ/cm<sup>2</sup>) caused a 3-4 fold increase in COX-2 expression, it had no effect on expression of the protein in JB6 keratinocytes or RAW264.7 macrophages. In PAM 212 cells, the combination of UVB light and LPS did not further increase COX-2 expression while in JB6 cells, UVB light had no effect on LPS-induced COX-2 expression. In contrast, in macrophages, UVB light was found to suppress LPS-induced expression of COX-2. In macrophages, UVB light-induced the JNK and p38 MAP kinases. Inhibition of these kinases with JNK inhibitor II (1, 9-pyrazoloanthrone) or the p38 kinase inhibitor SB-203580 was found to reverse the inhibitory effects of UVB light on LPS-induced expression of COX-2. Taken together these data indicate that the effects of UVB light on COX-2 expression is dependent on cell type. In macrophages, MAP kinases appear to mediate the inhibitory effects of UVB light on LPS-induced COX-2 expression. Supported by NIH grants CA100994, ES005022 and ES006897.

## 1591 EPIDERMAL CYTOKINE SECRETION INDUCED BY CHEMICAL CONTACT AND RESPIRATORY ALLERGENS.

M. Cumberbatch, R. J. Dearman and I. Kimber. Syngenta CTL, Macclesfield, United Kingdom.

Repeated topical exposure of BALB/c strain mice to chemical contact and respiratory allergens results in preferential T helper (Th)1- and Th2-cell activation, respectively. In addition, it has been shown that respiratory allergens, such as trimellitic anhydride (TMA), stimulate epidermal Langerhans cell (LC) migration with delayed kinetics compared with contact allergens, such as 2, 4-dinitrochlorobenzene (DNCB). Experiments using anti-interleukin (IL)-10 antibodies in vivo suggest that cutaneous IL-10 may contribute to the differential regulation of LC migration by these chemicals. To investigate further the mechanistic basis for the development of polarised immune responses, we have examined the production of epidermal cytokines provoked following a single topical application to BALB/c strain mice of DNCB (1%), TMA (25%) or vehicle (acetone:olive oil, 4:1; AOO). Skin explants were excised from mice exposed on the dorsum of both ears for various periods (30min-6hr) to chemical and were cultured on medium prior to analysis of supernatants for the presence of tumour necrosis factor  $\alpha$  (TNF- $\alpha$ ), IL-1 $\dot{\beta}$ , IL-1α, IL-6, IL-10, IL-12p40, IL-12p70 and IL-17 using the Bio-PlexTM cytokine array system. Enhanced production of IL-1β, a cytokine involved in the initiation of LC migration, was detected only following exposure to DNCB, with 15fold increases induced by 6hr of exposure. In addition, only exposure to DNCB was associated with early (2hr) secretion of IL-17. In contrast, up-regulation of IL-10, a cytokine that inhibits LC mobilization, was evident only for TMA during the first 3hr of exposure, with 2 to 3-fold increases in IL-10 release being induced. Small increases in IL-1α levels were apparent for both chemicals. No alterations in either IL-6, IL-12p40 or IL-12p70 secretion were recorded and TNF-α remained undetectable throughout. These data suggest that discrete epidermal cytokine secretion profiles induced following exposure to chemical contact and respiratory allergens might contribute to the polarisation of immune responses, possibly through effects on LC function.

## 1592 IN VIVO AND IN VITRO DERMATOTOXICITY OF CUTTING FLUID MIXTURES.

N. A. Monteiro-Riviere, A. Inman, B. Barlow and R. E. Baynes. Center for Chemical Toxicology Research and Pharmacokinetics, North Carolina State University, Raleigh, NC.

Cutting fluids are widely used in the metal-machining industry to lubricate and reduce heat generation when metals are cut by a metal-cutting tool. Unfortunately, these cutting fluids have caused occupational contact irritant dermatitis (OCID), and many of the additives used in these cutting fluid mixtures are thought to be responsible for OCID in workers. The purpose of this study was to assess single or various combinations of these additives in initiating the OCID response following an acute 8 hr exposure in porcine skin in vivo and in vitro using the isolated perfused porcine skin flap (IPPSF). Pigs (n=4) were exposed to 5% mineral oil (MO) or 5% polyethylene glycol (PEG) aqueous mixtures containing various combinations of 2% triazine (TRI), 5% triethanolamine (TEA), 5% linear alkylbenzene sulfonate (LAS), or 5% sulfurized ricinoleic acid (SRA). Erythema and edema were evaluated and skin biopsies for histology were obtained at 4 and 8 hrs. IPPSF's

(n=4) were exposed to control MO or PEG mixtures and complete MO or PEG mixtures, and perfusate samples were collected hourly to determine IL-8 release. The only significant mixture effects were SRA+MO+LAS+TRI+TEA causing an increase in IL-8 release. Exposure to TRI alone appeared to increase erythema, edema, and dermal inflammation compared to the other additives, while SRA alone was least likely to initiate a dermal inflammatory response. In 2-component mixture exposures, the presence of TRI appeared to increase the dermal inflammatory response at 4 and 8 hrs especially with the PEG mixtures. In the 3- and 4-component mixtures, MO mixtures are more likely to incite an inflammatory response than PEG mixtures. In summary, these preliminary studies suggest that the biocide, TRI, is the more potent of the 4 performance additives in causing dermal irritation, and this may vary depending on whether the worker is exposed to a synthetic- or MO-based fluid. (Supported by NIOSH Grant R01-OH-03669)

1593

INVESTIGATION OF THE SENSITIZATION POTENTIAL OF FRAGRANCE INGREDIENT 3 AND 4-(4-HYDROXY-4-METHYLPENTYL)-3-CYCLOHEXENE-1-CARBOXALDEHYDE (HMPCC).

A. Api, J. Cocchiara and C. Letizia. Research Institute for Fragrance Materials, Inc., Woodcliff Lake, NJ.

3 and 4-(4-Hydroxy-4-methylpentyl)-3-cyclohexene-1-carboxaldehyde (HMPCC, CAS Nos. 31906-04-4 and 51414-25-6) is a fragrance ingredient with a sweet, light and floral odor used in all types of cosmetic and household products. Three guinea pig studies (a modified Draize and two Magnusson and Kligman maximization tests) and a murine local lymph node assay indicate that the material has a weak potential to induce skin sensitization. The results from human predictive tests (numerous repeated insult patch tests and one human maximization test) conducted at various concentrations, also predict that the material is a weak skin sensitizer. The diagnostic patch test data indicate that the material is a moderate to strong skin sensitizer. The skin sensitization potential of this material is summarized and a dermal sensitization risk assessment is presented.

1594

ASSESSMENT OF SKIN ABSORPTION AND METABOLISM OF ARACHIDONIC ACID & GLYCERYL ARACHIDONATE USING *IN VITRO* DIFFUSION CELL TECHNIQUES.

A. R. Eppler<sup>1, 2</sup>, M. E. Kraeling<sup>1</sup>, R. R. Wickett<sup>2</sup> and R. L. Bronaugh<sup>1</sup>. <sup>1</sup>Office of Cosmetics and Colors/ Cosmetic Toxicology Branch, US Food & Drug Administration, Laurel, MD and <sup>2</sup>College of Pharmacy, University of Cincinnati, Cincinnati, OH.

Arachidonic acid (AA), has been used in cosmetics as a surfactant-cleansing and emulsifying agent. Glyceryl arachidonate (GA), a skin conditioning agent and emollient, may be partially metabolized by ester hydrolysis in skin to AA. Based on the Cosmetic Ingredient Review (CIR) Panel's concern that there was a lack of dermal absorption data for AA, in vitro percutaneous absorption and metabolism studies were initiated. To simulate normal consumer use, AA and GA were applied in an oil in water emulsion (2mg/cm<sup>2</sup>) to skin samples 200um thick in flow-through diffusion cells perfused with a physiological buffer. To assay for permeation, viable fuzzy rat and human skin were dosed with [\frac{14C}{2}AA containing -0.5uCi (0.01mg) AA /cell while [3H]GA was applied to viable and cadaver human skin at ~0.5uCi (0.003mg) GA/cell. For metabolism analysis, the skin equivalent Epiderm was dosed with [3H]GA under similar conditions. Receptor fluid fractions were collected at 6h intervals over a 24h dosing period. Skin penetration was determined by liquid scintillation counting and expressed as a percent of the applied dose. High performance liquid chromatography was used to assess metabolism to AA. Absorption of AA through rat skin was  $19.8 \pm 5.3 \%$  (mean  $\pm$  SEM) compared to only 1.4 ± 0.3 % through human skin. Total AA penetration (receptor fluid plus skin levels) in rat and human skin was  $52.3 \pm 7.3$  and  $20.1 \pm 5.4$  %, respectively. Total GA penetration of *via* ble skin was found to be  $11.3 \pm 2.1\%$  with only  $3.2 \pm$ 0.5% absorbed through the skin. In cadaver skin, 4.8  $\pm$  0.8% GA was absorbed through skin with a total penetration of  $6.7 \pm 1.2\%$ . Assay of the Epiderm receptor fluid found ~50% absorption of radioactivity and 3.0  $\pm$  2.1% GA conversion to AA. In conclusion, percutaneous absorption of AA was less through human than rat skin, while GA absorbed through Epiderm was metabolized to AA.

1595

MIXTURE EFFECTS OF JET FUEL ALIPHATIC AND AROMATIC HYDROCARBONS ON HUMAN EPIDERMAL KERATINOCYTES.

C. Chou<sup>1</sup>, J. Yang<sup>2</sup>, C. Lee<sup>1</sup> and N. A. Monteiro-Riviere<sup>3</sup>. <sup>1</sup>Veterinary Medicine, National Chung-Hsing University, Taichung, Taiwan, <sup>2</sup>Chung-Shan Medical University, Taichung, Taiwan and <sup>3</sup>Center for Cutaneous Toxicology and Research Pharmacokinetics, NC State University, Raleigh, NC.

Jet fuels are complex mixtures of aliphatic (ALI) and aromatic (ARO) hydrocarbons that vary significantly in individual cytotoxicity and proinflammatory activities in human epidermal keratinocytes (HEK). In order to elucidate the dermatotoxicity

of a complex mixture like jet fuels, structural differences, exposure time and dosage were investigated on HEK toxicity assessed by mortality and IL-8 release. ALI and ARO hydrocarbons were grouped into 4 categories: highly cytotoxic (octane, nonane, decane for aliphatics and cyclohexalbenzene, trimethylbenzene, xylene for aromatics), low cytotoxic (tetradecane, pentadecane, hexadecane for aliphatics and benzene for aromatics), high IL-8 release (decane, undecane, dodecane for aliphatics and dimethylnapthalene, cyclohexylbenzene, ethylbenzene for aromatics) and low IL-8 release (tetradecane, pentadecane, hexadecane for aliphatics and benzene, toluene, xylene for aromatics). The 4 categories of ALI hydrocarbons were mixed with each other, or cross-mixed with each of the 4 categories of ARO hydrocarbons. The resulting cytotoxicity and IL-8 production from HEK were evaluated at 24 hrs. The results showed an antagonistic cytotoxic effect between ALI and ARO hydrocarbons in which ALI attenuated the degree of HEK mortality caused by the ARO hydrocarbons. On the other hand, the ARO hydrocarbons reduced the significant increase of IL-8 induced by ALI hydrocarbons. Synergistic effects between low IL-8 inductive and low cytotoxic hydrocarbons were found and the highest cytotoxic and IL-8 inductive responses did not completely correspond to the mixture of highly cytotoxic and highly IL-8 inductive hydrocarbons. This study supports the concept that the ARO dictate the degree of HEK mortality, while the ALI are the major contributor to inciting the proinflammatory response. Mixture effects must be considered when evaluating cytotoxicity to HEK. Support: NSC Taiwan 92-2313-B-005-117

## 1596 DIPHOTERINE:SKIN SENSITIZATION STUDY IN THE GUINEA PIG.

L. MATHIEU<sup>1</sup>, F. BURGHER<sup>1</sup> and <u>A. H. HALL</u><sup>2</sup>, <sup>1</sup>Researches and Communication, PREVOR, TALENCE, France and <sup>2</sup>TCMTS, Inc., Elk Mountain, WV

Diphoterine is an eye/skin decontamination solution for chemical splashes, produced by the PREVOR laboratory, France. Its chemical and physical properties allow a quasi polyvalent rinsing of chemical splashes with a quick return to a physiological state. Diphoterine has been used since several years by workers in industries on European Market. No sensitization cases have been reported. Here we present the results obtained on a possible delayed sensitizing capacity of Diphoterine. It was evaluated in the Guinea pig, in accordance with the general requirements of OECD Guideline and Directive 67/548/EEC. The experimental technique is based on those of Magnusson-Kligman and Guillot and coll. The sensitivity and the reliability of the experimental method are verified at least six months, by use of a positive control group in which animals are treated with DNCB used as a 1% alcoholic solution. The application of the test substance Diphoterine did not induce coloration of the application site. Grading of any skin lesions was therefore possible. Primary induction was performed at day 1 by intradermal injection, the sensitization phase by topical application at day 9 and the challenge at day 22 by topical application with 100% v/v concentration of the substance. Determination of the degree of allergenicity at times 24 and 48 hours was based upon the percentage of animals in the group showing a reaction, rather than on the severity on the latter. Under the experimental conditions adopted, results obtained were as follows:no irritation reaction was noted at times 24 and 48 hours in animals of the negative control group and in animals treated during the challenge phase with Diphoterine at the Maximum Non-Irritant Concentration. The test substance showed no allergenicity at 24 and 48 hours. The test substance showed no allergenicity of Class at 24 hours and 48 hours. According to the terminology employed, it is considered that Diphoterine is free of sensitizing capacity in the Guinea pig. Keywords:Diphoterine, Skin, Allergy

ROLE OF SP-1 IN SDS-INDUCED ADIPOSE DIFFERENTIATION RELATED PROTEIN SYNTHESIS IN HUMAN KERATINOCYTES.

C. L. Galli, O. Zancanella, L. Lucchi, B. Viviani, M. Marinovich and E. Corsini. Department Pharmacological Sciences, University of Milan, Milan, Italy.

Skin irritation is a complex phenomenon, and keratinocytes, owing of their anatomical location and production of inflammatory mediators, play an important role in it. We have recently characterized the expression and protective role of adipose differentiation related protein (ADRP) in skin irritation (J. Invest. Dermatol. 121: 337, 2003). In particular, ADRP expression is induced to recover functional cell membrane following the cell damage induced by skin irritants. The purpose of this study was to characterize in a human keratinocyte cells line (NCTC 2544) the biochemical events that lead to ADRP expression following SDS treatment, and, in particular, to investigate the role of transcription factor SP-1. Analysis of ADRP promoter region revealed indeed a potential binding site for the transcription factor SP-1 together with AP-2, NF-1, c-myc and Pax-1. We found that SDS induces a dose and time related SP-1 activation as evaluated by measuring the DNA binding activity, which is correlated with SDS-induced ADRP mRNA expression. Furthermore, SDS-induced SP-1 activation, ADRP mRNA expression and lipid droplets accumulation could be modulated by mithramycin A, an antibiotic that selectively binds to the GC box preventing SP-1 binding and gene expression,

demonstrating that SDS-induced ADRP expression is mediated in part through the transcription factor SP-1. SDS-induced SP-1 activation as well as ADRP expression could be modulated by the calcium chelator BAPTA, indicating a role of calcium in ADRP-induction. The following scenario can be proposed: every time an irritant perturbs membrane barrier and renders the membrane leaky, extracellular calcium can enter the cells triggering SP-1 activation and ADRP expression to help restore normal homeostasis and to repair membrane. Acknowledgement. This work was partially funded by FIRST, UNIPRO and by the Center for Risk Assessment of the University of Milan.

INFLUENCE OF SKIN THICKNESS ON PERCUTANEOUS PENETRATION OF CAFFEINE, BUTOXYETHANOL AND TESTOSTERONE *IN VITRO*.

S. C. Wilkinson<sup>1</sup>, L. Greaves<sup>2</sup> and <u>F. M. Williams</u><sup>1</sup>. <sup>1</sup>Clinical and Lab. Sciences, University of Newcastle, Newcastle upon Tyne, Tyne and Wear, United Kingdom and <sup>2</sup>Neurology, University of Newcastle, Newcastle upon Tyne, Tyne and Wear, United Kingdom.

In vitro percutaneous penetration studies have historically used full or split thickness skin. As part of a multicentre study of in vitro dermal absorption measurement using diffusion cells (part of the EDETOX project), the influence of skin thickness on the percutaneous penetration of test chemicals with different physicochemical properties (caffeine, testosterone and butoxyethanol) was investigated. Test compounds and their 14C-labelled analogues were applied to full thickness (less than 1 mm thick) or dermatomed (330 µm) human skin from the same donors (2 per study, 3 cells each) mounted in flow through diffusion cells (skin temperature approximately 32°C, 0.64 cm<sup>2</sup>. The receptor fluid was saline (pH 7.4, 1.5 ml/h) with 5% (w/v) BSA added for studies with testosterone. Caffeine and testosterone were applied in ethanol:water (1:1 v/v) at 4 mg/ml (100 µg/cm<sup>2</sup>) and receptor fluid samples collected. After 24 h, the skin surface was swabbed with vehicle, the diffusion cell washed with ethanol, and the skin digested in 1.5 M KOH in ethanol:water (4:1 v/v). Butoxyethanol was applied in water (50% v/v) at 200 μl/cm<sup>2</sup> and the skin surface swabbed as above after 4 h. Receptor fluid samples were collected for 8 h and the diffusion cell washed and skin digested as above. All studies were carried out with occlusion. The maximum flux of testosterone increased from  $0.18 \pm 0.04$  $\mu g/cm^2/h$  with full thickness skin to 1.82  $\pm$  0.37  $\mu g/cm^2/h$  with dermatomed skin, whilst the maximum flux of butoxyethanol increased from  $674.6 \pm 92.8 \,\mu\text{g/cm}^2/\text{h}$ to  $1694.8 \pm 178.9 \,\mu\text{g/cm}^2/\text{h}$ . Significant effects on distribution were limited to the receptor fluid. Caffeine penetration was not significantly affected. Use of split skin clearly contributed to an increase in flux but did not greatly increase the coefficient of variation when compared with full thickness skin. This increase in flux was not limited to the lipophilic test compound.

AN *IN VITRO* MODEL FOR CUTANEOUS PHOTOAGING USING A LUCIFERASE REPORTER GENE TO MEASURE HUMAN ELASTIN PROMOTER ACTIVITY

D. B. Brown, M. D. Schwartz, S. M. Ksenzenko, E. F. Bernstein, <u>P. D. Forbes</u>, C. P. Sambuco and <u>A. M. Hoberman</u>. *Charles River Discovery and Development Services, Argus Division, Horsham, PA*.

Using transgenic mice, we have previously reported on the correlation between elevated levels of human elastin promoter (HEP) activity after exposure to UVR, and increased expression of steady-state mRNA and elastotic deposition, considered hallmarks of *solar-aged* skin. In order to develop a rapid and sensitive *in vitro* screening model for evaluating the *anti-aging* potential of compounds, immortalized human skin fibroblasts containing the HEP/luciferase reporter gene construct and selected ultraviolet radiation sources were used. Exposure to unfiltered FS lamps produced a 5.5-fold increase over baseline promoter levels with 2 mJ/cm² (using an erthyma weighted detector, corresponding to about 10% of a human erythema dose (p<0.0001). Using a Xenon Arc solar simulator with cut-off filters of different thickness revealed increases in relative promoter activity from 2.5- to 1.5-fold over baseline activity (p<0.001). Initial results indicate that this sensitive and quantitative, solar simulator-based model is readily applicable to evaluating potential photo-screening and photo-protection compounds for reducing the development of photodamaged and *photoaged* skin.

RETINOIC ACID INDUCED EXPRESSION OF THE HELIX-LOOP-HELIX INHIBITORY PROTEIN ID-1 IN NORMAL HUMAN KERATINOCYTES.

C. Villano<sup>2</sup>, <u>L. A. White<sup>1</sup></u> and E. Myers<sup>1</sup>. <sup>1</sup>Biochemistry and Microbiology, Rutgers University, New Brunswick, NJ and <sup>2</sup>Joint Graduate Program in Toxicology, Rutgers University, New Brunswick, NJ.

Retinoids, vitamin A analogues, are powerful regulators of cell growth and differentiation and is necessary for the maintenance of epithelial differentiation. We have found that exposure of normal human keratinocytes to all-trans retinoic acid, the

main signaling retinoid in the body, results in a significant increase in Id-1 mRNA and protein. The Id proteins, which lack a DNA binding domain, function by forming inactive heterodimers with other helix-loop-helix (HLH) proteins and reducing their transcriptional activity. Importantly, ectopic overexpression of Id-1 results in immortalization or delayed senescence of normal keratinocytes, demonstrating that Id-1is an important regulator of keratinocyte differentiation. Our hypothesis is that retinoic acid induced expression of Id-1 is a critical step in retinoic acid mediated transcription in normal human keratinocytes. Our data show that retinoic acid stimulation of Id-1 is specific; no change was observed in Id-2 and Id-3 expression following retinoic acid exposure. Retinoic acid stimulation of Id-1 does not involve mRNA stability, suggesting that it is regulated at the level of transcription. To investigate this possibility, we have isolated 2.2 kb of the Id-1 promoter and linked it to a reporter gene (luciferase; pGL3) for transfection into normal human keratinocytes. The goals of these experiments are to determine the mechanism of retinoic acid induced Id-1 expression, as well as elucidate the role of Id-1 in mediating retinoic acid effects in skin. These data will provide a better understanding of the mechanism of action of retinoic acid in skin, as well as to define the role of Id-1 in this pathway.

IN VITRO PERCUTANEOUS ABSORPTION OF SALICYLIC ACID IN HAIRLESS MOUSE AND HUMAN SKIN.

M. E. Kraeling and R. L. Bronaugh. Office of Cosmetics and Colors, USFDA, Laurel, MD.

Salicylic acid (SA) is one of the most commonly used beta hydroxy acids used in skin care products. This study was conducted in support of a SA photocarcinogenicity study conducted at the National Center for Toxicological Research (NCTR). The purpose of this study was to determine the rate of skin absorption of SA from cosmetic creams and to determine the amount of SA residing in hairless mouse (HM) skin at the time of UV irradiation. SA penetration was determined from 2% and 4% [14C]SA creams applied to excised viable HM skin (full thickness) and human skin (200 um thick) mounted in flow-through diffusion cells perfused with a physiological buffer (HEPES-buffered Hanks balanced salt solution, pH 7.4). In HM skin, the formulations remained on the skin for 4 and 24 h. Four hours after application of SA cream, half of the skin was exposed to UVB radiation (16 mJ/cm2) while the unexposed half was used as the control. At the end of the studies, the amount of SA penetrated into skin layers and receptor fluid was determined and expressed as the applied dose penetrated for each formulation. At both concentration levels, SA was rapidly and extensively absorbed into HM skin in 24 h. Total penetration of SA was 90-94%, with 87-91% absorbed into receptor fluid and 2-3% remaining in skin. UVB treated and control skin showed similar absorption profiles with no difference in SA penetration. In the 4 h studies, absorption of SA into receptor fluid at both SA concentration levels was rapid at 37-39%. At the time of UV exposure, 3-5% of the SA applied resided in HM skin. Human skin absorption studies were conducted with only a 24 h application of 2% and 4% [14C]SA creams. SA absorption was less extensive with 34-44% of the applied SA absorbed into receptor fluid in 24 h and 6.5-10.5% of the SA remaining in skin. Variability in SA skin penetration through human skin was observed. SA penetration increased as the permeability of the human skin to [3H]water increased. In conclusion, SA rapidly penetrated HM skin and was found in skin at the time of irradiation.

### 1602

RESPONSE OF SKH-1 MOUSE SKIN FOLLOWING THE ACUTE INJURY OF TATTOOING.

N. V. Gopee<sup>1, 2</sup>, Y. Cui<sup>1, 2</sup>, G. Olson<sup>3</sup>, A. Warbritton<sup>3</sup>, B. J. Miller<sup>1, 2</sup>, L. H. Couch<sup>1, 2</sup>, W. G. Wamer<sup>4</sup> and P. C. Howard<sup>1, 2</sup>. <sup>1</sup>Division Biochemical Toxicology, NCTR, USFDA, Jefferson, AR, <sup>2</sup>NTP Center for Phototoxicology, NCTR, USFDA, Jefferson, AR, <sup>3</sup>Charles River Companies, Jefferson, AR and <sup>4</sup>CFSAN, USFDA, College Park, MD.

Tattooing is a rapidly increasing art form in the US. The toxicity of the pigments used in tattoo inks have not been reported. As an initial step to assess their phototoxicologic properties we have studied the cutaneous impact of tattooing using SKH-1 hairless mice and commercial tattoo inks or inks made with CdS or Fe<sub>3</sub>O<sub>4</sub>. The dorsal tattoos were ~2x25 mm, and the mice were sacrificed at 0.5, 1, 3, 4, 7 or 13 days (d) following tattooing. Histological evaluation of the skin revealed dermal hemorrhaging at 0.5 and 1 d, and necrosis at 3 d decreasing to 17% by 13 d. Dermal inflammation was present from 3-13 d. Epidermal necrosis and inflammation were immediately apparent and decreased in occurrence and frequency to 0% by 13 d. External inguinal and axillary lymph nodes contained tattoo pigments, the inguinal being the most reactive evidenced by hyperplasia at all timepoints. Orinithine decarboxylase (ODC), cyclooxygenase-1 (COX1) and COX2 protein levels increased significantly at 0.5-4 d and decreased to control levels by 13 d. The increase was greatest in the tattooed skin compared to the intra-tattooed skin.

ODC and COX2 protein were elevated in the inguinal lymph nodes. Interleukin-1 $\beta$  (IL-1B) and IL-10 proteins were dramatically increased at all timepoints in the inguinal lymph nodes but suppressed in the tattoo and intra-tattoo skin, with maximal suppression between 0.5-4 d. Concentrations of cutaneous nuclear factor-kappa B (NF-kB) protein, the transcription factor for several inflammatory mediators, were elevated between 0.5-4 d. Inducible nitric oxide synthetase mRNA was increased in tattooed (1 d) and intra-tattoed (0.5 d) skin and lymph nodes (1 d). These data demonstrate that tattooing skin induces an inflammatory response similar to acute injury, inflammatory cells respond to the presence of the pigment removing the pigment to the regional lymph node, and the skin in general recovers from the insult within 13 d.

## 1603 MECHANISM OF PARAQUAT-INDUCED TOXICITY IN MOUSE KERATINOCYTES.

A. Vetrano<sup>1</sup>, <u>D. E. Heck</u><sup>1</sup>, A. T. Black<sup>1</sup>, M. Thiruchelvam<sup>2</sup>, E. Richfield<sup>3</sup>, <u>D. A. Cory-Slechta<sup>2</sup></u> and J. D. Laskin<sup>2</sup>. <sup>1</sup>Pharmacology and Toxicology, Rutgers University, Piscataway, NJ, <sup>2</sup>Environmental and Community Medicine, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ and <sup>3</sup>Pathology and Lab. Medicine, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ.

An important herbicide known to cause significant dermatotoxicity in exposed field workers including both allergic and contact dermatitis is paraquat (1, 1'-dimethyl-4, 4'-bipyridinium). In cells, paraquat undergoes redox cycling and, during intracellular metabolism, it can generate active radical species which cause modifications in cellular macromolecules and promote lipid peroxidation. In the present studies we examined the cytotoxicity of paraquat in PÂM 212 cells, a skin-derived mouse keratinocyte cell line. We found that paraquat caused a time- and concentration-dependent inhibition of keratinocyte cell growth. Cells exposed to paraquat for prolonged periods (96 hr) were significantly more sensitive to growth inhibition that cells exposed to the herbicide for 3 or 6 hr (IC50 = 50  $\mu$ M and 100-300  $\mu$ M, respectively). In keratinocytes, redox sensitive agents and oxidants readily deplete intracellular glutathione. At concentrations up to 1 mM and for periods up to 6 hr, paraquat had no effect on this thiol tripeptide in PAM 212 cells. Previous studies have demonstrated that redox active agents and oxidants readily glutathionylate cellular proteins and are potent activators of NF-KB. We found that paraquat did not induce protein glutathionylation in PAM 212 cells. Moreover, it inhibited NFκB activation in the cells, as measured by electrophoretic mobility shift assays. Taken together, these data demonstrate that paraquat is highly cytotoxic to keratinocytes. However, its mechanism of action in these cells may not be due to altered intracellular redox balance. Supported by NIH grants ES05022, ES10791, ES03647 and CA100994.

## 1604 MECHANISMS OF UVB LIGHT-INDUCED OXIDANT FORMATION IN THE SKIN.

D. E. Heck. Pharmacology and Toxicology, Rutgers University, Piscataway, NJ.

It is recognized that modifications of critical cellular macromolecules by the higherenergy shorter solar wavelengths comprising the UVB spectra (290-320 nm) are the most damaging to the skin. This process is mediated, in part, by the intracellular generation of reactive oxygen species. In previous studies we identified catalase as an important protein responsible for UVB-induced reactive oxidant-generating activity in keratinocytes. To investigate the mechanism by which this protein converts damaging solar radiation into less energetic oxidant species, we analyzed the effects of inhibitors of the peroxide degrading catalatic activity of catalase on UVB-mediated oxidant generation. The inhibitor 3-amino-1, 2, 4-triazole, which blocks the formation of the enzyme-hydrogen peroxide transition state C1, and sodium azide, an inhibitor of the dissociation of C1, stimulated hydrogen peroxide production. Interestingly, cyanide, which interacts directly with the heme iron to inhibit electron transfer, was ineffective in inhibiting the UVB-stimulated peroxidatic reaction. This profile of inhibition is strikingly similar to that of the peroxidase activity of some bacterial bifunctional catalase-peroxidases, and prompted us to analyze the heme binding pockets of human red blood cell catalase, a representative monofunctional catalase, the heme binding pocket derived from the crystal structure of pea cytosolic ascorbate peroxidase, a mono-functional Class I intracellular peroxidase, and the heme environs of Burkholderia pseudomallei catalase-peroxidase Katg, a bifunctional catalase-peroxidase. Structural analysis identified several critical residues in the active site likely to be important in the activities. Taken together, these data imply that there are distinct reaction pathways for the catalatic and UVB catalyzed reactions. We hypothesize that UVB alters the overall electronic environs at the catalase heme to render the distal histidine less imidazole-like in character, and similar to the highly polar distal histidine in the active site of bifunctional catalases undergoing peroxidase activity. Support: NIH CA093798 and ES03647.

SUNSCREENS WITH PHYSICAL UV BLOCKERS CAN INCREASE TRANSDERMAL ABSORPTION OF THE HERBICIDE 2, 4 D.

R. M. Brand, J. M. Pike and A. R. Charron. *Internal Medicine, Evanston Northwestern Healthcare and Feinberg School of Medicine, Evanston, IL.* Sponsor: <u>P.</u> Iversen.

Farmers are encouraged to wear sunscreen to reduce the risk of skin cancer. We have demonstrated that the dermal penetration of agrochemicals can be enhanced by chemical UV absorbers and the insect repellent DEET. We have extended these studies to determine whether commercially available sunscreens containing either/or titanium dioxide or zinc oxide enhance the transdermal absorption of the herbicide 2, 4 D. Hairless mouse skin was placed in an in vitro Bronough Style flow through diffusion chamber. The epidermal side of the skin was pre-treated for 30 minutes with one of nine commercially available sunscreens purchased through the internet. One hundred microliters of 2, 4 D in the amine form spiked with <sup>14</sup>C labeled 2, 4 D was placed on top of the epidermis for 24 hours. The radiolabeled pesticide diffused through the skin, into the receiver compartment where it was collected in 90 minute fractions and placed in a liquid scintillation counter. Data were compared by ANOVA followed by a Dunnett's Multiple Comparison Test and are reported as mean  $\pm$  sem. The total percentage of 2, 4 D penetrating through the skin in 24 hours ranged from  $36.8 \pm 2.4$  for the no sunscreen control to  $57.6 \pm 6.3$ for the TiSilc product. Five of the nine sunscreen tested led to a significant enhancement of total 2, 4 D penetration as compared to the control (p<0.01). This demonstrates that physical UV absorbers can also enhance transdermal absorption similar to the chemical absorbers. Inert ingredients appear to be the major factor in determining the enhancement produced by the active chemicals. Careful selection of sunscreen during pesticide application could reduce potential exposure.

DERMAL ABSORPTION AND CHEMISTRY OF ARSENIC IN RESIDUES FROM WOOD PRESERVED WITH CHROMATED COPPER ARSENATE (CCA).

Y. W. Lowney<sup>1</sup>, R. Wester<sup>2</sup>, P. Nico<sup>3</sup> and M. Ruby<sup>1</sup>. <sup>1</sup>Health Risk Group, Exponent, Boulder, CO, <sup>2</sup>Department of Dermatology, University of California, San Francisco, CA and <sup>3</sup>Chemistry Department, California State University, Stanislaus, Turlock, CA. Sponsor: J. Tsuji.

In assessing possible risks associated with dermal exposure to arsenic, regulatory agencies have relied on information from the early 1990s that assessed dermal absorption of arsenic from radiolabeled soluble arsenic, either in solution or freshly mixed with soil. Because the naturally high background intake of arsenic in the diet precludes detection of low-level absorption of arsenic, studies on environmental matrices (i.e., natural soils or CCA-treated wood, which cannot be radiolabeled) have not been undertaken previously. However, recent efforts using specific low-arsenic diets for lab animals has lowered the limit of detection for absorbed arsenic. Based on this new animal research model, this study was undertaken to evaluate whether the arsenic in residues from CCA-treated wood demonstrates a different dermal absorption profile than soluble arsenic. The dermal absorption research was conducted in Rhesus monkeys, and was designed to replicate, to the extent possible, the earlier research using radiolabeled arsenic. In tandem with the dermal absorption research, state-of-the-art spectroscopic techniques were used to understand the nature of arsenic in the CCA residues. Specifically, x-ray absorption spectroscopy was used to evaluate the chemical structure of arsenic in the residue on the surface of new and weathered wood. These two lines of research provide evidence both from a biological system standpoint and from chemical analyses to demonstrate that the arsenic in CCA residues is present in a stable, complexed form that is not well absorbed compared to soluble arsenic.

### 1607 IN VITRO ASSESSMENT OF STYRENE ABSORPTION THROUGH HUMAN SKIN.

S. Madden, C. Roper and <u>R. Greenough</u>. In Vitro Sciences, Inveresk Research, Edinburgh, United Kingdom.

Skin absorption studies provide data that can be an alternative to the use of worst case default values in risk assessments of dermal exposure. Historically, these studies have been performed in animal models *in vivo*, however, in recent years there has been growing acceptance by regulatory authorities for alternative *in vitro* models. In this present study we have assessed the absorption of styrene in human skin *in vitro*. The study examined skin absorption of pure styrene and also styrene as formulated into an unsaturated polyester resin. The resin was typical of the worst case that might be found in the glass reinforced composite industry (high styrene content and long cure time). Human skin was obtained with full informed consent from elective plastic surgery patients. Split thickness membranes were prepared from the sample at a thickness of *ca* 350 µm using a Zimmer electric dermatome. Sections of skin membranes were then mounted in flow through diffusion cells and a tritiated

water barrier integrity assessment performed. [¹⁴C]styrene or [¹⁴C]styrene in resin was applied to the stratum corneum of intact sections. The cells were covered with non-occlusive carbon filters to allow collection of volatile materials. Receptor fluid (tissue culture medium) was collected until 24 h post dose application. At 24 h, the majority of the [¹⁴C]styrene (*ca* 70-80%) from both formulations had been collected in the charcoal filters. Recovery of radioactivity in the receptor fluid (absorbed dose) was 1.25% for the [¹⁴C]styrene and 1.15% for the [¹⁴C]styrene in resin. Dermal delivery was 1.68 and 1.23% in each formulation, respectively. Total recovery was *ca* 88% for [¹⁴C]styrene and 95% for [¹⁴C]styrene in resin. In conclusion, following topical application of [¹⁴C]styrene or [¹⁴C]styrene in resin to human skin the extent of absorption, and, therefore, predicted human systemic exposure, was similar. The degree of absorption was much lower than would be considered from default risk assessment assumptions.

STUDIES ON PERCUTANEOUS ABSORPTION, BIOPHYSICAL AND BIOCHEMICAL CHANGES IN THE SKIN BY NONANE AND DODECANE IN HAIRLESS RATS

<u>I. B. RAMAPURAM</u><sup>1</sup>, A. Chatterjee<sup>1</sup>, B. Locke<sup>2</sup>, S. Gibbs<sup>2</sup> and <u>M. Singh</u><sup>1</sup>.

<sup>1</sup>COLLEGE OF PHARMACY, FLORIDA A&M UNIVERSITY, TALLAHASSEE, FL and <sup>2</sup>Department of Chemical Engineering, FAMU-FSU College of Engineering, Tallahassee, FL.

Occupational skin diseases are one of the most significant health concerns in the US and cost the government millions of dollars each year. Skin exposures can occur from occupational chemicals such as organic solvents and fuels leading to irritant contact dermatitis. Understanding the mechanisms of chemical irritation will assist in assessing the risks to exposures. Nonane and dodecane were investigated for (a) their in vitro skin permeation and retention using Franz diffusion cells, (b) skin barrier changes due to acute chemical exposures by measuring transepidermal water loss (TEWL) and magnetic resonance imaging (MRI) of skin and (c) expression of molecular markers (IL-1 $\alpha$ , TNF $\alpha$ , and MCP-1 by enzyme immunometric assay and NF-κB and IkB by western blot analysis) in the skin due to acute chemical exposures. The flux and deposition in the skin layers (stratum corneum, epidermis and dermis) of nonane was significantly lower than dodecane (P < 0.001) and nonane showed higher TEWL than dodecane (P < 0.05). The MRI of nonane treated skin showed significantly higher signal intensities in the epidermis, dermis, hair follicles and lipid regions of skin than control (P < 0.05). Further, nonane produced higher cytokine and chemokine expressions in the skin (P < 0.01) mediated through NF-κB activation and its corresponding IkB deactivation. Dodecane, even though demonstrated higher retention in the skin layers, did not show significant increase in the TEWL as compared with control (P>0.05). Further, cytokine and chemokine expression in the skin was not significantly increased by dodecane as compared with control (P > 0.05) and this data was in agreement with the results of NF-kB and IkB levels in the skin, which did not alter due to dodecane treatment. The results indicate that MRI and TEWL showed strong correlations with cytokine and chemokine expressions in the skin and can serve as powerful tools for dermal risk assessment of irritant chemicals.

## 1609 PHOTODECOMPOSITION OF PIGMENT YELLOW 74, A PRIMARY COLOR CHEMICAL IN TATTOO INKS.

L. H. Couch<sup>1,3</sup>, Y. Cui<sup>1,3</sup>, A. Spann<sup>1</sup>, N. V. Gopee<sup>1,3</sup>, F. E. Evans<sup>2</sup>, M. I. Churchwell<sup>1</sup>, L. Williams<sup>1</sup>, D. R. Doerge<sup>1</sup> and P. C. Howard<sup>1,3</sup>. <sup>1</sup>Division of Biochemical Toxicology, NCTR, USFDA, Jefferson, AR, <sup>2</sup>Division of Chemistry, NCTR, USFDA, Jefferson, AR and <sup>3</sup>NTP Center for Phototoxicology, NCTR, USFDA, Jefferson, AR.

Tattooing has become a popular recreational practice in the past decade. Very little is known concerning the pigments used in the inks or the toxicity, phototoxicity, or photochemistry of the pigments. Yellow tattoo inks were obtained from commercial sources and the organic chemical responsible for the color was extracted and quantitatively determined by HPLC with UV-VIS and mass spectral (MS) detection. The monoazo pigment yellow 74 (PY74; CI 11741) was the major chemical pigment used in seven yellow tattoo inks. PY74 was dissolved in tetrahydrofuran, deoxygenated using argon gas, and exposed in 2 mm cuvettes to simulated solar light equivalent to terrestrial irradiance using a 6.5 kWatt xenon arc solar simulator. Spectrophotometric and HPLC analysis indicated PY74 photodecomposed in the simulated solar light. Multiple products were isolated using a combination of silica chromatography and HPLC. Two of the major products were identified by NMR and MS as N-(2-methoxyphenyl)-3-oxobutanamide and its 2-hydrazine derivative. These products are indicative of photochemical reduction at the hydrazone of PY74. The rate of formation of these products is solvent dependent and decreased in the presence of oxygen. These results suggest that the photochemical decomposition of PY74 results in the release of aromatic amine products.

#### 1610

PHOTOCHEMICAL DECOMPOSITION OF THE DICHLOROBENZIDINE-BASED TATTOO PIGMENT ORANGE 13 IN SIMULATED SOLAR LIGHT.

P. C. Howard<sup>1,3</sup>, N. V. Gopee<sup>1,3</sup>, Y. Cui<sup>1,3</sup>, F. E. Evans<sup>2</sup>, L. H. Couch<sup>1,3</sup>, M. I. Churchwell<sup>1</sup> and D. R. Doerge<sup>1, 1</sup>Division of Biochemical Toxicology, NCTR, USFDA, Jefferson, AR, <sup>2</sup>Division of Chemistry, NCTR, USFDA, Jefferson, AR and <sup>3</sup>NTP Center for Phototoxicology, NCTR, USFDA, Jefferson, AR.

The art of tattooing has experienced a renaissance over the past several decades, with an increase in popularity especially amoung youth, and migrating from the use of inorganic metals (e.g. HgS) as the color agent to organic pigments. Many of the yellow, orange or red pigments used in tattoo inks are derivatives of 3, 3'dichlorobenzidine. We used Pigment Orange 13 (PO13; CI 21110), a bisazo pigment of 3, 3'-dichlorobenzidine and 3-methyl-1-phenyl-2-pyrolozin-5-one (MPPone), as a model bisazo pigment for examining photochemical stability of this class of compounds. PO13 was dissolved in tetrahydrofuran, deoxygenated using argon, and exposed in 2 mm cuvettes to simulated solar light using a 6.5 kW xenon arc solar simulator, with irradiance equivalent to terrestrial summer sunlight. The PO13 solution decolorized indicating photochemical decomposition. The products were analyzed by HPLC and isolated using a combination of column and thin layer silica chromatography and HPLC, and analyzed using NMR and mass spectroscopic (MS) methods. The initial photochemical reduction of PO13 involves cleavage at one of the hydrazone groups to yield the mono-MPPone derivative of 3, 3'dichlorobenzidine and the mono-MPPone derivative 3'-dichloro-4-aminobiphenyl. 3, 3'-Dichlorobenzidine and 3, 3'-dichloro-4aminobiphenyl were also identified, presumably through sequential photochemical reduction. The identification of other photochemical products is in progress to elucidate further the pathways for photodecomposition of this pigment. These data demonstrate that photochemical decomposition of a representative 3, 3'dichlorobenzidine-based tattoo pigment using simulated solar light in an aprotic solvent results in the release of potentially carcinogenic 3, 3'-dichlorobenzidine and 3, 3'-dichloro-4-aminobiphenyl.

## 1611 CUTANEOUS UVR AND CIS-UROCANIC ACID EXPOSURE ENHANCES BURULI ULCER DISEASE IN THE CRL:IAF(HA)-HRBR HAIRLESS GUINEA PIG.

R. Cope<sup>1</sup>, N. Stang<sup>1</sup>, B. Valentine<sup>1</sup>, P. L. Small<sup>2</sup> and L. Bermudez<sup>1</sup>. <sup>1</sup>College of Veterinary Medicine, Oregon State University, Corvallis, OR and <sup>2</sup>Department of Microbiology, University of Tennessee, Knoxville, TN.

Buruli ulcer disease (BUD) is a significant, high morbidity, emerging human cutaneous disease caused by Mycobacterium ulcerans (MU) infection. In endemic areas, it is now the second most common mycobacterial infection of humans. MU ulcers are primarily located on the appendages and a single lesion can cover up to 15% of body surface area. Antibiotic therapy is ineffective in human cases and current treatment regimes are based on local excision/skin grafting or amputation. In rodent models, ultraviolet radiation (UVR) exposure increases the severity of tuberculosis and leprosy; however the effects of UVR on BUD have not been previously examined. Thus, the aim of this study was to test the hypotheses that exposure to ultraviolet radiation (UVR) or cis-urocanic acid (cUCA), an initiator of photoimmunosuppression, would result in an increased severity of MU infection in a hairless guinea pig model of BUD. Pre-infection exposure to UVR or cUCA results in substantial and significant (p < 0.001) increases in size of MU lesions. UVR exposure was associated with significant (p < 0.001) delays in the healing of MU infected skin sites. Both UVR and cUCA exposure were associated with significant (p < 0.001) suppression of delayed-type hypersensitivity responses to MU cell wall antigens in infected animals. These results suggest that UVR exposure is a significant factor in the development of BUD and that UVR/cUCA susceptible immune pathways are important in the pathogenesis of BUD.

## 1612 HELICOBACTER PYLORI AND ETHANOL INDUCED TOXICITY AND APOPTOSIS IN GASTRIC EPITHELIAL CELLS.

A. N. Nunley<sup>1</sup>, R. L. Copeland<sup>1</sup> and D. T. Smoot<sup>2</sup>. <sup>1</sup>Pharmacology, Howard University College of Medicine, Washington, DC and <sup>2</sup>Medicine, Howard University Hospital, Washington, DC.

Infection with Helicobacter pylori (HP) induces chronic gastritis in virtually all infected persons, which is associated with increased risk of developing gastric cancer. In the gastric mucosa, ethanol increases histamine, gastrin and acid secretion, and stimulates ulcer formation. This study examined the effects of HP, ethanol, and acetaldehyde on gastric epithelial cells. AGS cells were infected with either a cag+ HP strain or cag- HP strain for 24 hrs (37oC). AGS were then exposed to EtOH (100, 500, 1000, 1500mM) or Acet (10, 50, 100, 200uM) for 1, 3 and 6 hours. EtOH caused a concentration dependent increase in toxicity (500-1500mM) which was

enhanced by its combination with HP. EtOH (1500mM) alone and HP/EtOH (500-1500mM) decreased AGS cell viability (trypan blue and proliferation assays). Acetaldehyde did not significantly increase AGS toxicity. However, the combination of acetaldehyde and HP was toxic and lead to decreased *via*bility. To elucidate underlying mechanisms behind the observed damage, apoptosis and p53 and bcl-x expression studies were performed. Both HP and EtOH alone induced apoptosis. AGS cells exposed to the cag+ HP strain or HP/EtOH did not induce apoptosis. AGS cells exposed to cag- HP strain induced apoptosis at a higher rate compared to control AGS cells. p53 and bcl-x expression (western blot analysis) found increased expression of p53 following EtOH exposure, cag- HP strain infection, and HP/EtOH. Bcl-x expression was increased following exposure to cag+ HP strain and HP/EtOH. Acetaldehyde treatment induced the expression of both p53 and bcl-x in all treatment groups. This study demonstrated the toxic effects of EtOH and its combination with HP on AGS cells. The effect of acetaldehyde on AGS cells may be due to its rapid metabolism or evaporative properties. Furthermore, the EtOH and cag- HP strain damage may be irreparable as seen by the induction of apoptosis and p53 expression in those cells. This damage may somehow bypass the signals to terminate and elude apoptosis.

## 1613 INVOLVEMENT OF APOPTOSIS IN THE HMG-COA REDUCTASE INHIBITOR-INDUCED MYONECROSIS IN HUMAN SKELETAL MUSCLE CELLS.

A. Wolf<sup>1</sup>, L. Ndountse-Tchapda<sup>1</sup>, S. Ursula<sup>1</sup> and W. E. Trommer<sup>2</sup>. <sup>1</sup>Biomarker Development, Novartis Pharmacology AG, Basel, Switzerland and <sup>2</sup>Department of Chemistry, University of Kaiserslautern, Kaiserslautern, Germany.

3-Hydroxymethylglutaryl-CoA reductase inhibitors (HMGCRI) are potent cholesterol lowering agents, causing rhabdomyolysis as a clinically relevant side effect in man. Previous studies in human skeletal muscle cells (hSkMC) suggested that caspase-3 activation might be an important early event in the development of HMGCRI-induced rhabdomyolysis and that the intracellular ATP pool might serve as a checkpoint, which could drive cells into necrosis. A direct link between necrosis and apoptosis however has not been shown so far. In the present study, we investigated caspase-3 activation (apoptosis) and LDH-leakage (necrotic membrane damage) in hSkMCs after incubation with the HMGCRIs simva-, lova-, atorva-, prava-, and fluva-statin and co-incubation with the caspase-3 inhibitor Ac-DEVD-CHO or the major down stream HMGCR metabolites mevalonate, geranylgeranyl- pyrophosphate, farnesyl-pyrophosphate, geranylgeraniol, farnesol and mevalonic acid. The results showed that the caspase-3 inhibitor completely inhibited caspase-3 activity and reduced, but did not completely suppress, the HMGCRI-induced LDH-leakage. All metabolites reduced the HMGCRI-induced capase-3 activation, with farnesol showing the strongest effect. Similar potencies were found concerning the reduction of the HMGCRI-increased LDH-leakages. Among the metabolites farnesol was most effective. The present results confirm that apoptosis is an important event, which at least partially contributed to the generation of the HMGCRI-induced myonecrosis in human skeletal muscle cells.

# 1614 PULMONARY TOXICANTS AMIODARONE AND PARAQUAT CAUSE INJURY BY APOPTOSIS IN RAT PLEURAL MESOTHELIAL CELLS.

S. Seth and J. Cerreta. *Pharmaceutical Sciences, St. John's University, New York, NY.* Sponsor: L. Trombetta.

The antiarrhythmic drug amiodarone and the herbicide paraquat are known to cause pulmonary fibrosis, but their mechanisms remain unclear. We hypothesized that such dissimilar agents may cause injury in part through induction of apoptosis in rat pleural mesothelial cell line. Cell viability was determined using the MTT assay. Apoptosis was measured by DNA Fragmentation assay, Caspase-3 enzyme activity and In Situ terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling assay (TUNEL). MTT cytotoxicity assay determined that cells treated with amiodarone at concentrations of 0.93nM to 15.6µM and with paraquat at concentrations of 9.3nM to 2.4µM for 24 hrs. had no significant loss of viability. Cultures incubated with 50µM amiodarone and 100µM paraquat for 24 hrs. had a significant decline in cell viability as compared to controls (approx.50%). and these concentrations were selected as the test concentrations for the study. For DNA fragmentation assay, paraquat treatment resulted in the formation of fragments that could be visualized by gel electrophoresis as a characteristic ladder pattern. In the caspase assay, after 24hr. amiodarone and paraquat exposure the concentration of DEVD-pNA cleavage product of the treated was found to have increased significantly above that of the control. The numbers of TUNEL positive cells were greater in treated groups as compared to controls. Amiodarone and paraquat appear to activate specific intracellular death-related pathways indicated by the caspase-3 enzyme activation. Such data support the hypothesis that dissimilar toxicants may cause lung injury by acting in part through an apoptotic pathway.

SUPPRESSION OF TGF- $\beta_1$  INDUCED APOPTOSIS *IN VITRO* BY THE ALDOSE REDUCTASE INHIBITOR, ZOPOLRESTAT.

L. Fasulo and <u>D. Amacher</u>. Safety Sciences - Groton, Pfizer Global Research and Development, Groton, CT.

The aldose reductase inhibitor (ARI) zopolrestat was developed for the treatment of late-stage diabetic complications such as neuropathy, nephropathy, cataractogenesis, and macrovascular disease. Recently, some ARIs were shown to prevent apoptosis in lens epithelial cells (Murata et al., Chemico-Biol. Interact. 130:617, 2001) and retinal pericytes (Naruse et al., Exp. Eye Res. 71: 309, 2000). Because apoptosis is readily studied in primary hepatocyte cultures, it was of interest to determine if zopolrestat had properties similar to these other ARIs. The present study was conducted in primary rat hepatocyte cultures to investigate the ability of zopolrestat to suppress apoptosis induced by transforming growth factor- $\beta_1$  (TGF- $\beta_1$ ). We have employed a working model for the experimental study of the induction or suppression of apoptosis in vitro using primary rat hepatocytes. Cells were cultured in collagen-coated flasks using serum-free hormone defined medium for 48 hours. The cultures were then treated with zopolrestat in the presence or absence of 1ng/ml TGF- $\beta_1$ . Twenty-four hours later cell *via* bility was determined by trypan blue exclusion and apoptosis assessed using Hoechst 33258 staining method for nuclear morphology. In the presence of  $TGF-\beta_1$ , apoptosis increased 4-fold while the coaddition of 150µM zopolrestat significantly inhibited (p≤0.001) TGF-β₁ induced apoptosis. Further, zopolrestat alone suppressed intrinsic apoptosis as evident by its decrease in apoptosis compared with control cultures. In comparative studies, we have shown that  $TGF-\beta_1$  caused up to a 7-fold increase in apoptosis in primary rat hepatocytes and that the hypolipidemic drug nafenopin (100µM) suppressed TGF- $\beta_1$  induced apoptosis. These *in vitro* data confirm that inhibition of apoptosis may be a common property of ARIs that is not confined to ocular tissues.

THE ROLE OF DIMINISHED JNK SIGNAL TRANSDUCTION IN THE ACQUISITION OF APOPTOTIC RESISTANCE IN CADMIUMTRANSFORMED HUMAN PROSTATE EPITHELIAL CELLS.

W. Qu<sup>1</sup>, D. Broderick<sup>1</sup>, <u>W. E. Achanzar</u><sup>1</sup>, M. M. Webber<sup>2</sup> and <u>M. P. Waalkes</u><sup>1</sup>. <sup>1</sup>Inorganic Carcinogenesis Section, NCI at NIEHS, Research Triangle Park, NC and <sup>2</sup>Departments of Zoology and Medicine, Michigan State University, East Lansing, MI.

Cadmium (Cd) is a known human carcinogen that induces malignant transformation of human prostate epithelial cells upon chronic exposure. Our prior work shows these transformed prostatic cells (termed CTPE cells) acquire tolerance to the Cd cytotoxicity and become resistant to apoptosis. The present work sought to link Cd-induced apoptotic resistance to altered JNK signaling. After continuous exposure to 10 mM Cd for 8 weeks, CTPE cells became malignantly transformed, as confirmed by production of tumors upon inoculation into nude mice. Assessment of the cytotoxicity of Cd (as CdCl2) showed that the 24 hr LC50 in CTPE cells was 2.2-fold more than control cells, indicative of Cd tolerance. There was also a significant cross-tolerance to zinc in CTPE cells. Flow cytometry using annexin/FITC was used to evaluate apoptosis. Cd-induced apoptosis in transformed CTPE cells was markedly suppressed when compared to control cells. Apoptosis induced by the chemotherapeutics etoposide and cisplatin was also suppressed in CTPE cells. Immunocytochemical and densitometric protein analysis showed a dose-dependent decrease in phosphorylated JNK1/2 protein in CTPE cells. In addition, JNK kinase activity was suppressed in CTPE cells. RT-PCR analysis of RNA showed expression of the JNK1 and JNK2 genes in CTPE cells was reduced by 70% and 22%, respectively. A decrease in the expression of the apoptosis-related genes c-Jun and p-53 was also observed in CTPE cells, suggesting the involvement of these as factors in acquired resistance to apoptosis. These results indicate that Cd-transformed cells acquire a generalized resistance to apoptosis, and that the down-regulation of the JNK pathway plays an important role in tolerance. Generalized resistance to apoptosis may allow damaged cells to survive and promote tumor formation as a result of Cd exposure.

CYTOPROTECTIVE EFFECTS OF GLYCYRRHIZAE RADIX EXTRACT AND ITS ACTIVE COMPONENT LIQUIRITIGENIN AGAINST CADMIUM-INDUCED TOXICITY.

K. Sangchan<sup>1, 2</sup>, B. Sung Hui<sup>1</sup>, Y. Chae Ha<sup>1</sup>, K. Chul Young<sup>2</sup>, K. Jin Woong<sup>2</sup> and <u>K. Sang Geon<sup>2</sup></u>. <sup>1</sup>College of Oriental Medicine, Daegu Hanny University, Daegu, South Korea and <sup>2</sup>College of Pharmacy, Seoul National University, Seoul, South Korea.

Cadmium (Cd)-induced cell death mechanism, in which alterations in cellular sulfhydryls participate, involves Bad translocation, decrease in mitochondrial BclxL and cytochrome c, and PARP cleavage. Glycyrrhizae radix has been popularly used

as a frequently employed botanical in herbal medicine, and occupies an important place in food products. In the present study, we determined the effects of Glycyrrhizae radix extract (GRE) and its representative components on apoptotic and non-apoptotic cell death induced by Cd and explored the mechanistic basis of GRE protection against Cd-induced cell injury. Incubation of H4IIE cells with GRE (0.3-1 mg/ml) inhibited cell death induced by Cd. Also, GRE effectively blocked Cd-induced cell death potentiated by buthionine sulfoximine (BSO) without restoration of cellular GSH. GRE prevented both apoptotic and non-apoptotic cell injury induced by Cd or BSO+Cd. Inhibition of Cd-induced cell injury by pretreatment of cells with GRE suggested that the cytoprotective effect result from altered expression of the protein(s) responsible for cell viability. GRE inhibited mitochondrial Bad translocation by Cd or BSO+Cd and caused restoration of mitochondrial BclxL and cytochrome c levels. Cd-induced poly(ADP-ribose)polymerase (PARP) cleavage in control cells or cells with sulfhydryl deficiency was prevented by GRE treatment. Among the major components present in GRÉ, liquiritigenin, but not glycyrrhizin, isoliquiritigenin or liquiritin, was active for cytoprotection against Cd. These results showed that GRE blocked Cd-induced cell death by inhibiting the apoptotic processes involving translocation of Bad into mitochondria, decreases in mitochondrial BcLxL and cytochrome c, and PARP cleav-

# 1618 INTERACTION OF ARSENITE WITH B-CELL RECEPTOR- AND CD40- MEDIATED SIGNALING AND EFFECT ON APOPTOSIS IN B-LYMPHOMA CELLS.

D. Muscarella. Cornell University, Ithaca, NY.

Cell lines derived from human Burkitts lymphoma (BL) are an important in vitro model for receptor-mediated negative/positive selection of germinal center B-lymphocytes since they undergo apoptosis upon cross-linking of the surface IgM/B-cell receptor (sIgM) and are rescued from sIgM-induced apoptosis by ligation of CD40. These cell lines are also highly sensitive to the induction of apoptosis by many chemicals, including sodium arsenite, a significant environmental contaminant with immunotoxic activity. The purpose of this study was to identify the interactions of arsenite exposure with sIgM- and CD40- mediated signaling and subsequent effects on apoptosis induction. I found that cross-linking of sIgM initially provided protection against the early induction of apoptosis by arsenite. Specifically, sIgM-activation protected against arsenite-induced mitochondrial depolarization and the cleavage of caspase 9 and poly (ADP) ribose polymerase. The sIgM-mediated protection against apoptosis required the activation of two signaling pathways, the extracellular-signal regulated kinase (ERK) and the phosphoinositide-3 kinase (PI3-K) pathways. Inhibition of either pathway partially blocked the ability of sIgM-activation to protect against apoptosis induction. However, sIgM-mediated protection was transient, and decayed over a period of several hours, consistent with a model in which initial engagement of sIgM induces an immediate and potent anti-apoptotic response, but in the absence of appropriate costimulation (i.e. by CD40 engagement) the protective signals decay and the cells undergo apoptosis. Importantly, I also found that arsenite blocked the ability of CD40 to rescue BL cells from sIgM-mediated apoptosis by interfering with an important pro-survival pathway activated by CD40 ligation, the nuclear factor kappa-B pathway. Moreover, I have identified several key regulatory points within this pathway that are differentially sensitive to higher (≥ 200 μM) compared to lower (≤ 20 μM) concentrations of arsenite. (Supported by NIEHS grant ES-10815)

### 1619 MECHANISMS OF OCHRATOXIN A-INDUCED APOPTOSIS IN HUMAN LYMPHOCYTES.

H. Assaf<sup>1, 2</sup>, H. Azouri<sup>2</sup> and <u>M. Pallardy</u> <sup>1</sup>. <sup>1</sup>INSERM U461, Chatenay-Malabry, France and <sup>2</sup>Toxicology laboratory, Faculty of Pharmacy, Beirut, Lebanon.

Mycotoxins are a group of fungal secondary metabolites that elicit a wide spectrum of toxicological effects. Of particular interest is ochratoxin A (OTA), a potent mycotoxin contaminating feed and food, which has been implicated in nephropathy in animals and humans in the Balkan states. In addition to being a nephrotoxin, animal studies indicate that OTA is a liver toxin, an immune suppressant, a potent teratogen and a carcinogen. The hazard that OTA poses to human health arises from both its widespread occurrence and its long plasma half-life of 35.5 days. All these toxicities coupled with its ability to be carried through the food chain, merit some concern. The aim of this study was to evaluate the apoptotic effects of OTA on human lymphocytes. We used two models: human peripheral blood lymphocytes (PBL) and the lymphoid T cell line, Kit 225. PBL, activated or not by phytohemagglutinin, as well as Kit 225 cells, underwent apoptosis in a time- (7, 24 and 48 h) and OTA dose- (10-6, 5x10-6 and 10-5 M) dependent manner. Moreover, OTA triggered mitochondrial membrane permeabilization, as shown by 3, 3' dihexyloxacarbocyanine iodide (DiOC6)/propidium iodide staining. Apoptosis was inhibited by z-VAD.fmk, a pan-caspase inhibitor, suggesting that caspases are responsible for the induction of apoptosis. Caspase-8 was not activated which suggest that the death receptor (Fas, TNF-R) pathway was not implicated. Conversely, caspase-9 and caspase-3 were activated. Interestingly, the Bcl-xL protein expression was decreased by OTA treatment as shown by western blot. On the contrary, the Bcl-2 protein was not affected. On the other hand, overexpression of Bcl-xL in Kit 225 cells protected them against mitochondrial perturbation and blocked OTA-induced apoptosis. These data suggested that mitochondria are a central component in OTA-induced apoptosis, and the loss of Bcl-xL due either to the degradation of the protein or to transcriptional downregulation of the bcl-xL mRNA was responsible for the OTA-induced cell death.

### THE ROLE OF APOPTOSIS IN THE OTA/OTB INDUCED NEPHROPATHY.

K. Kobras, E. O'Brien, A. H. Heussner and D. R. Dietrich. Environmental Toxicology, University of Konstanz, Konstanz, Germany.

The mycotoxins ochratoxin A (OTA) and ochratoxin B (OTB) are regularly found in human and animal food. Long-term exposure to OTA causes nephropathy and renal tumors in animals and is also associated with Balkan Endemic Nephropathy (BEN) and urothelial tumors in humans. Previous *in vitro* studies indicated a role for apoptosis in these processes. In the present study, the LLC-PK1 and NRK-52E cell lines were exposed to 0-50  $\mu$ M OTA and OTB for up to 48 hours in the presence of serum. Standard assays revealed significant cytotoxicity after exposure to 50  $\mu$ M OTA or OTB. Hoechst staining yielded no evidence of apoptosis with the same exposure regimen. In contrast, DNA-laddering was apparent after exposure of the LLC-PK1 cells to 25-50  $\mu$ M OTA for 16 to 24 h. Interestingly, laddering could only be observed in cells which detached during OTA incubation. No DNA-fragmentation could be seen in adherent cells. OTB exposure did not result in apoptotic alterations in LLC-PK1 cells and neither method yielded evidence of apoptosis in NRK-52E cells following exposure to OTA or OTB. These results suggest OTA and OTB to have different mechanisms of action and furthermore, that the pro-apoptotic action of OTA is cell-type- or species-specific.

DIELDRIN EXPOSURE IMPAIRS THE UBIQUITIN-PROTEOSOME FUNCTION AND PROMOTES  $\alpha$ -SYNUCLEIN AGGREGATION IN MESENCEPHALIC DOPAMINERGIC NEURONAL CELLS: RELEVANCE OF ENVIRONMENTAL FACTORS IN THE ETIOPATHOGENESIS OF PARKINSON'S DISEASE.

F. Sun, V. Anantharam and <u>A. Kanthasamy</u>. Biomedical Science, Iowa State University, Ames, IA.

Exposure to pesticides has been linked to the etiopathogenesis of Parkinson's disease. Recently, we showed that dieldrin induces apoptosis in dopaminergic cells via caspase-3-dependent proteolytic activation of proapoptotic protein kinase PKCδ. Abnormal accumulation and aggregation of α-synuclein and impairment of the ubiquitin-proteosome system have been suggested to contribute to the dysfunction, degeneration and ultimate death of dopaminergic neurons in PD. To further understand the cellular mechanisms underlying dieldrin-induced dopaminergic neurodegeneration, we examined the effects of dieldrin on ubiquitin-proteosomal function in rat mesencephalic dopaminergic cells overexpressing human α-synuclein (α-SYN cells). Low dose (30 μM) dieldrin induced time-dependent cytotoxicity over a 24 hr period in α-SYN cells compared to vector expressing cells. α-SYN cells were slightly resistant to dieldrin toxicity up to 12 hr post exposure but were more sensitive at 24 hr. Dieldrin treatment for 24 hr also resulted in a significant increase in caspase-3 enzyme activity in α-SYN cells. Dieldrin treatment significantly increased the proteosomal activity at 3 hr in vector cells but not in α-SYN cells. At a later time point (24 hr), a significant reduction in proteosomal activity was observed in both vector and α-SYN cells, however, the impairment of proteosomal function was more pronounced in α-SYN cells than in vector cells. Immunocytochemical analysis of dieldrin-treated α-SYN cells showed aggregation of  $\alpha$ -synuclein in a time-dependent manner, with small aggregates appearing as early as 6 hr and progressively increasing over a 24 hr. The proteosomal inhibitor lactacystin also induced a profound aggregation in α-SYN cells. Overall, these results suggest that α-SYN cells are more sensitive to dieldrin-induced apoptosis and that impairment of the ubiquitin-proteosome function may contribute to dieldrin-induced  $\alpha$ -synuclein aggregation [NIH grant NS 045133].

# 1622 EFFECTS OF ENDOSULFAN AND PERMETHRIN EXPOSURE ON APOPTOTIC AND NECROTIC CELL DEATH OF MURINE SPLENOCYTES, *IN VITRO*.

V. Vemireddi<sup>1</sup> and H. P. Misra<sup>1, 2</sup>. <sup>1</sup>Biomedical Sciences and Pathobiology, Virginia Maryland Regional College of Veterinary Medicine, Virginia Tech, blacksburg, VA and <sup>2</sup>Biomedical Science, Edward Via Virginia College of Osteopathic Medicine, Blacksburg, VA.

The pesticides endosulfan and permethrin negatively affect the immune system in non-target organisms. We hypothesized that these pesticides cause immune suppression, at least in part, by enhanced apoptotic cell death. Splenocytes from adult

C57Bl/6 male mice were exposed to endosulfan, or permethrin or mixtures of these chemicals, in vitro. Cytotoxicity was evaluated using flow cytometer in combination with 7-amino-actinomycin D (7-AAD) staining. Endosulfan decreased the vi-ability (47-22%) in a dose-dependent manner (25-150  $\mu$ M) when exposed for 12 hours. A dose-dependent increase in early apoptotic (28-32%) and late apoptotic/necrotic (25-46%) cell populations was also obsreved with endosulfan exposures. Endosulfan at 100 µM also caused a time-dependent (4-12 hours) decrease in live cells (71-30%), and an increase in early apoptotic (15-33%) and late apoptotic/necrotic (14-36%) populations. Permethrin exposure resulted in neither a time-dependent/dose-dependent loss of splenocyte viability nor an induction of apoptosis in splenocytes. With mixtures of permethrin and endosulfan, depressed viability and enhanced early apoptosis and late apoptosis/necrosis were also observed. Exposure to mixtures of 50  $\mu$ M endosulfan with 50 or 100  $\mu$ M permethrin increased the late apoptosis/necrosis compared to the results of exposure to either chemical alone. Visual evaluation of cell death using DNA ladder assay confirmed the contribution of both apoptotic and necrotic processes. These findings suggest that the immunotoxicity of endosulfan both individually and in mixtures with permethrin is associated with the occurrence of early and late apoptotic/necrotic processes.

1623

GENE EXPRESSION ANALYSIS DURING DIELDRIN EXPOSURE IN RAT MESENCEPHALIC DOPAMINERGIC NEURONAL CELLS: POTENTIAL MECHANISMS INVOLVED IN ENVIRONMENTAL CHEMICALINDUCED DOPAMINERGIC DEGENERATION.

Y. yang, K. D. Petry, <u>A. Vellareddy</u>, A. Kanthasamy and <u>A. Kanthasamy</u>. *Biomedical Sciences, Iowa State University, Ames, IA*.

Environmental chemicals have been linked to the etiology of Parkinson's disease. Previously we demonstrated that dieldrin, a lipophilic organochlorine pesticide, can induce apoptosis in dopaminergic neuronal cells through proteolytic activation of protein kinase C delta (PKCδ). To fully understand the potential mechanisms of dieldrin-induced apoptotic death in dopaminergic neuronal cells, genomic gene expression analysis was performed using Affymetrix oligonucleotide microarray chips. Rat mesencephalic dopaminergic neuronal cells were exposed to either vehicle or 100 µM dieldrin for 6 hr and total RNA was isolated and labeled for hybridization with oligonucleotide gene chips. The hybridization signals were analyzed and compared in the vehicle and dieldrin-treated groups. A total of 40 genes were up-regulated and 33 genes were down-regulated. The following genes were increased by at least 4 fold: heme oxygenase (16 fold), an enzyme involved in oxidative stress; GRP78 (10 fold), an endoplasmic reticulum (ER) chaperone usually binding to unfolded protein to reduce ER stress; GADD153 (10 fold), a transcription factor C/EBP homologous protein-10; p38 MAP kinase (4 fold), a MAP kinase associated with cell death; MAP kinase phosphatase (10 fold), regulator of MAP kinase activation and Fra-1 (64 fold), a stress-induced immediate early gene. The genes that were down-regulated include: Mx3 (16 fold), DNA polymerase  $\alpha$ (16 fold), Agrin (8 fold), etc. We also verified the transcription and translation of some of the above genes by using RT-PCR and Western blotting, respectively. Together, dieldrin treatment increases some key molecules that are associated with ER stress and apoptotic cell death. Greater understanding of the interaction of these signaling proteins in the orchestration of apoptotic cell death may provide new insights into mechanisms of environmental factor-induced dopaminergic degeneration (NS 45133 and ES 10586)

## 1624 DETERMINATION OF APOPTOSIS IN PLATEABLE CRYOPRESERVED HUMAN HEPATOCYTES.

T. A. Moeller, P. M. Silber and N. S. Jensen. In Vitro Technologies, Baltimore, MD.

Cryopreservation of human hepatocytes has provided the opportunity for study of toxicity and drug metabolism of compounds without the need to wait for fresh tissue. Some cryopreserved hepatocytes have the ability to form an adherent monolayer when thawed and plated on collagen-coated tissue culture plates. Previous work with these plateable cryopreserved human hepatocytes (PCHH) has demonstrated their usefulness for long-term (4 day) toxicity studies for necrosis. In this work we present data on the use of PCHH for evaluating chemically-induced apoptosis. PCHH were plated on collagen coated 48-well flat bottom plates and incubated for 24 hours at 37°C, 5% CO $_2$  in a humidified incubator. After monolayers were established, they were treated with camptothecin (100 nM, 1  $\mu$ M, 10  $\mu$ M and 100  $\mu$ M) in serum–free medium for 4, 24 and 48 hours. Three different endpoints were determined; MTT assay for necrosis, and caspase 3/7 and DNA fragmentation for apoptosis. After 4 hours, no necrosis or apoptosis was identified by any of the assays. However, a significant increase in apoptotic markers was identified at 24 hours in both caspase 3/7 and DNA fragmentation assays. After 24 hours, at camptothecin levels of 10 and 100  $\mu$ M, caspase 3/7 levels increased 4 fold, and DNA

fragmentation levels increased 3–4 fold. At 48 hours, caspase 3/7 levels increased 7–8 fold, while DNA fragmentation results increased 2.5 fold. Small increases in caspase 3/7 and DNA fragmentation were seen at 1  $\mu$ M camptothecin, with little or no increase at 100 nM. Viability, as measured by MTT, demonstrated little or no decrease after 48 hours at camptothecin levels of 100 nM and 1  $\mu$ M, but decreased with 10 and 100  $\mu$ M concentrations after 24 hours (50%  $\emph{viable}$ ) and 48 hours (<25 %  $\emph{viable}$ ). Camptothecin induced apoptosis in a time-dependent and concentration-dependent manner as indicated by both caspase 3/7 and DNA fragmentation assays. These results indicate that PCHH is a useful system for evaluating the ability of unknown compounds to initiate apoptosis in human hepatocytes.

1625 CELL-CELL CONTACT IS REQUIRED FOR PAH-INDUCED, STROMAL CELL-DEPENDENT, BONE MARROW B CELL APOPTOSIS.

D. H. Sherr, H. Ryu, J. K. Emberley, J. J. Schlezinger and L. L. Allan. Environmental Health, Boston University School of Public Health, Boston, MA.

Polycyclic aromatic hydrocarbons (PAHs) and related environmental aryl hydrocarbon receptor (AhR) agonists are immunotoxic in a variety of in vitro and animal model systems. In a model system of B lymphopoiesis, PAH exposure rapidly induces CD43- pre-B and CD43+ pro/pre-B cell apoptosis. Apoptosis induction by DMBA is dependent upon AhR+ bone marrow stromal cells and likely involves DMBA metabolism. However, it was not known if PAH-treated stromal cells elaborate metabolites or soluble factors that may directly induce B cell death. In the present study it was demonstrated that supernatants from 7, 12dimethylbenz(a)anthracene (DMBA)-treated stromal cells contained an activity capable of inducing apoptosis in pro/pre-B cells co-cultured with cloned stromal cells. This activity: 1) was produced at concentrations > 10-7 M DMBA, 2) was not produced when stromal cells were co-treated with DMBA and a-naphthoflavone, an AhR and cytochrome P450 inhibitor, 3) was retained by filtration through 50 kDa exclusion filters, 4) was ablated by trypsin or heat treatment, 5) did not directly interact with pro/pre-B cells to induce their death, 6) was partially dependent on the presence of a functional AhR in stromal cells supporting pro/pre-B cell growth, and 7) was able to induce AhR-regulated, CYP1A1 mRNA. The results: 1) argue against the likelihood of a stromal cell-derived metabolite or death factor which acts directly on developing B lymphocytes, 2) suggest the production of a relatively stable DMBA metabolite-protein complex capable of initiating a change in AhR+ stromal cell function at some distance, and 3) support the hypothesis that a DMBA-dependent death signal is delivered by stromal cells to neighboring B cells by cell-cell contact.

DMBA-INDUCED PRO/PRE-B CELL APOPTOSIS: CASPASE 8-MEDIATED, TNF RECEPTOR-INDEPENDENT SIGNALING PATHWAYS.

J. K. emberley<sup>1</sup>, H. Ryu<sup>2</sup>, L. L. Allan<sup>1</sup>, J. J. Schlezinger<sup>2</sup> and D. H. Sherr<sup>2, 1</sup>.

<sup>1</sup>Microbiology, Boston University Sch. of Medicine, Boston, MA and <sup>2</sup>Environmental Health, Boston University Sch. of Medicine, Boston, MA.

PAH are common environmental pollutants which suppress the immune system in part by inducing bone marrow B cell apoptosis. Previously, we demonstrated that prototypic PAHs, including DMBA, induce pro/pre-B cell apoptosis when these cells are co-cultured with cloned bone marrow stromal cells (BMS2). The purpose of this study was to determine if DMBA-induced B cell apoptosis involves the initiator caspase 8 and/or TNF receptors which can activate caspase 8. Kinetics studies indicated that caspase 8 was induced within 4 hours of DMBA treatment while caspase 3 was not activated until 8-12 hours after DMBA treatment. Inhibitors of caspase 8 and effector caspase 3 almost completely protected pro/pre-B cells from DMBA-induced death. Since DMBA-induced pro/pre-B cell death required B cellstromal cell contact, and since caspase 8 activation has been linked to TNFR signaling, the possibility that stromal cells deliver death signals through TNF-TNFR interactions was investigated. Vehicle- or DMBA-treated BMS2 cells did not make detectable levels of TNF- $\alpha$ , - $\beta$ , or LT- $\beta$  mRNA and/or protein. Furthermore, DMBA-treated stromal cells from TNF-α knock out mice were as effective at killing pro/pre-B cells as wildtype stromal cells. To assess whether caspase 8 activation was mediated by ligand-independent TNFR activation, populations of primary pro/pre-B cells from TNFR1<sup>-/-</sup>/2<sup>-/-</sup> double mutant mice were expanded in rIL-7 and then co-cultured with BMS2 cells. Addition of DMBA induced the same percentage of TNFR1<sup>-1</sup>/2<sup>-1</sup>- B cells to undergo apoptosis as with wildtype B cells. Collectively, these results indicate that: 1) the PAH-induced apoptosis pathway in pro/pre-B cells involves caspases 8 and 3 and 2) ligand-dependent or ligand-independent TNFR activation appears not to be responsible for caspase 8 activation. The possible role of other death receptors is under investigation.

#### 1627

THE ROLE OF P53 IN DEATH RECEPTOR EXPRESSION AND ACTIVITY IN MOUSE TESTIS AFTER MONO-2-(ETHYLHEXYL) PHTHALATE (MEHP) EXPOSURE.

Y. Chandrasekaran and J. H. Richburg. College of Pharmacy, The University of Texas at Austin, Austin, TX.

Testicular germ cell apoptosis is preceded in different injury models by the up regulation of various death receptor (DR)/ligand-signaling pathways, most notably Fas/FasL and DR5/TRAIL. The expression of both Fas and DR5 can be transcriptionally up regulated by the tumor suppressor protein p53. This protein may also be capable of influencing the expression of the DRs on the cell membrane in a transcription-independent manner. The aim of our current work is to clarify the role of p53 in death receptor expression and its influence on germ cell apoptosis induced after exposure to the Sertoli cell toxicant MEHP (1 g/kg). We examined death receptor expression in p53 knock-out (p53-/-) mice and their wild type littermates (p53 / ; C57BL/6J-129S/v mice) after toxicant exposure. After MEHP exposure p53-/- mice did not show increases in Fas or DR5 protein by western blot analysis of membrane fractions of testis homogenates. On the other hand, early DR5 increases (1.5-6h) and later increases in Fas membrane levels (12h) can be observed in p53 / mice. Similarly, the processing of pro-caspase 8, an indicator of DR activity, was unchanged in testes of p53-/- mice. Interestingly after toxicant exposure, the lack of processing of pro-caspase 8 in the p53-/- mice coincided with an increased expression of the caspase 8 inhibitor, c-FLIP, as early as an hour after exposure. A robust expression of c-FLIP protein (by western blots) and mRNA expression (via RT-PCR) in p53-/- mice indicates an alternate mechanism by which germ cell apoptosis is modulated after MEHP exposure. Future studies are directed at further examining the influence of p53 on receptor activity that occur independent of its transcriptional activity. (Supported, in part by grants from NIH/NIEHS ES09145 & ES07784).

#### 1628

THE PROTEASOME INHIBITOR, BORTEZOMIB, STIMULATES APOPTOSIS BY INDUCING ENDOPLASMIC RETICULAR STRESS AND PROTEOTOXICITY.

S. Nawrocki, J. S. Carew and D. J. McConkey. Cancer Biology, UT M.D. Anderson Cancer Center, Houston, TX.

The role of the proteasome in regulating cell growth, survival, and metastasis of cancer cells make it an attractive therapeutic target. Bortezomib (PS-341) is the first proteasome inhibitor for use in cancer therapy, whose antineoplastic effects have been attributed to inhibition of nuclear factor kB (NF- $\kappa$ B) activity. However, this only accounts for a small fraction of the anticancer activity of the drug. Inhibition of proteasomal activity also prevents the clearance of misfolded proteins by the endoplasmic reticulum associated degradation (ERAD) pathway, resulting in endoplasmic reticular (ER) stress. ER stress activates signaling pathways that are collectively termed the unfolded protein response (UPR), which are required if the cell is to survive the stress. The UPR upregulates ER chaperone proteins (BiP) to increase protein-folding activity, attenuates translation by activation of PKR-like endoplasmic reticulum kinase (PERK) to reduce ER load, and increases protein degradation via ERAD. We hypothesize that proteasome inhibition causes ER stress-mediated apoptosis, which contributes to its anti-tumor activity. The pancreatic cancer cell line, L3.6pl, was selected to test this hypothesis. Consistent with known ER stress agents, bortezomib treatment resulted in an increase in BiP expression, indicating that proteasome inhibition results in ER stress. However, bortezomib treatment prevented phosphorylation of the PERK substrate, eukaryotic initiation factor 2a (eif2a), which is necessary for translational attenuation. Bortezomib treatment inhibits protein degradation and translational control resulting in an accumulation of proteins, which induces proteotoxicity. This toxicity induces apoptosis by activation of the cJUN NH2-terminal kinase (JNK) pathway and cleavage of caspase-3. Inhibition of translation by cyclohexamide treatment completely abrogates bortezomib-induced apoptosis. Therefore, the induction of proteotoxicity by bortezomib contributes significantly to the cytotoxic activity of the drug.

### 1629

THE ASSOCIATION OF APOPTOSIS WITH THE INDUCTION OF NEUTROPHIL GELATINASE ASSOCIATED LIPOCALIN (NGAL).

<u>I. P. Kehrer</u>, <u>Z. Tong</u> and X. Wu. Division of Pharmacology and Toxicology, College of Pharmacy, The University of Texas at Austin, Austin, TX.

We previously identified a potential link between the induction of the murine lipocalin 24p3 by the 5-lipoxygenase activating protein inhibitor MK886 and apoptosis [Biochem. J. 372: 203-210 (2003)]. The human homolog of 24p3 is NGAL, and the current study was designed to determine if a similar association exists in human cells. Human adenocarcinoma A549 cells treated with MK886 exhibited a dose- and time-dependent increase of NGAL expression that correlated

with the extent of apoptosis. A similar induction of NGAL was observed in human breast cancer MCF7 cells. Treatment of MCF7 cells with 4 µg/ml of vitamin E succinate, another apoptosis inducing xenobiotic, also increased NGAL expression. The induction of NGAL in A549 cells was not *via* the alteration of the DNA binding activity of NF-kB. Treatment of A549 cells with purified NGAL had no effect on apoptosis. These data indicate that the induction of NGAL correlates with apoptosis, but that extracellular NGAL is not toxic. It remains possible that NGAL acts intracellularly or that NGAL/24p3 does not directly activate apoptosis pathways. It is also possible that 24p3/NGAL functions as a survival factor and the induction is a compensatory response to inhibition by these xenobiotics. (Supported by CA83701 and Center Grant ES07784.)

AKT PLAYS A ROLE IN THE APOPTOSIS INDUCED BY THE 5-LIPOXYGENASE ACTIVATING PROTEIN (FLAP) INHIBITOR, MK886.

Z. Tong, X. Wu and J. P. Kehrer. Division of Pharmacology and Toxicology, College of Pharmacy, The University of Texas at Austin, Austin, TX.

MK886, a FLAP-inhibitor, induces apoptosis independently of both FLAP and lipoxygenase activities [Biochem. J. 340: 371-375 (1999)]. The apoptosis-inducing mechanism of MK886 remains unclear. The serine/threonine kinase Akt plays a crucial role in cell proliferation and survival, particularly by preventing cells from undergoing apoptosis. In the present study, we examined the possible role of the Akt pathway in MK886-induced apoptosis. Exposure of cells to an apoptosis-inducing dose of MK886 inhibited IL3-induced and serum-induced Akt phosphorylation at Ser473 in murine pro-B FL5.12 and human Jurkat T cells, respectively. Treatment of FL5.12 cells with 0.5 µM of wortmannin, a PI3K inhibitor that will block upstream activation signals to Akt, significantly enhanced MK886-induced apoptosis. Furthermore, FL5.12 cells stably expressing constitutively active Akt were resistant to MK886-induced apoptosis and caspase-3 activation. In contrast, these cells were not resistant to etoposide-induced apoptosis. These results suggest that MK886 may inhibit the Akt pathway, at least partially explaining its ability to induce apoptosis. Similar mechanisms appear to apply with cyclooxygenase-2 inhibitor and related compounds that induce apoptosis independently of COX-2 activity. (Supported by CA83701 and Center Grant ES07784. Thanks are extended to Dr. David Plas, University Pennsylvania, for providing the Akt-FL5.12 cells.)

α-SYNUCLEIN PREVENTS MITOCHONDRIAL AND NUCLEAR LOCALIZATION OF PRO-APOPTOTIC KINASE PKCδ DURING 1-METHYL-4-PHENYLPYRIDINIUM (MPP')-INDUCED CELLULAR APOPTOSIS IN DOPAMINERGIC NEURONAL CELLS. NOVEL ROLE OF α-SYNUCLEIN IN DOPAMINERGIC DEGENERATION.

S. Kaul, V. Anantharam and A. Kanthasamy. Iowa State University, Ames, IA.

We previously demonstrated that MPP+ induced cellular apoptosis in rat mesencephalic dopaminergic neuronal cells (N27) via the proteolytic cleavage of PKC8(Kaul et al., 2003) and that the apoptotic cell death was completely attenuated by the expression of human wild-type  $\alpha$ -synuclein ( $\alpha$ -SYN) in these cells (Kaul et al., 2002). In the present study, we investigated the cellular mechanisms involved in the protective effect of α-SYN against MPP<sup>+</sup>-induced neuronal apoptosis. Expression of α-SYN in N27 cells significantly attenuated MPP+(300 μM)-induced proteolytic activation of pro-apoptotic kinase PKCS. Sub-cellular fractionation studies showed that PKC was proteolytically cleaved in VEC cells and the cleaved fragments translocated to the mitochondrial and nuclear compartments in a time-dependant manner. Interestingly this MPP\*-induced sub-cellular translocation of PKC  $\!\delta\!$  was completely absent in  $\alpha\textsc{-SYN}$  cells at all exposure periods. Co-immunoprecipitation analysis in the α-SYN cells revealed a physical association between α-SŶN and PKCδ in untreated cells which was further increased following MPP+ exposure. Additionally, MPP+ treatment induced parallel increases in the association of α-SYN and the pro-apoptotic protein BAD, but none with the antiapoptotic protein Bcl-2. These results suggest that α-SYN preferentially associates with the proapoptotic proteins PKC $\delta$ and BAD. MPP\* treatment also led to a increased translocation of cytosolic  $\alpha$ -SYN to the nucleus over a 24 hr period, declining thereafter. Together, our results suggest that human wild-type  $\hat{\alpha}\text{-SYN}$  rescues dopaminergic neuronal cells from MPP\*-induced apoptotic cell death by acting as a molecular chaperone to regulate the proapoptotic functions of PKCδand BAD. Furthermore, translocation of α-SYN to the nucleus during MPP<sup>+</sup> treatment suggests that α-SYN may also function as a nuclear modulator protein during environmental neurotoxin exposures.[Supported by NIH grants ES10586 and NS38644].

J. M. Brown and A. Holian. CEHS, University of Montana, Missoula, MT.

Epidemiological studies have shown associations between silica exposure and several autoimmune diseases, including scleroderma and systemic lupus erythematosus. We have previously reported that lupus-prone New Zealand mixed mice develop an exacerbated autoimmune disease following exposure to crystalline silica. Fourteen weeks following exposure to silica, NZM mice develop high levels of autoantibodies to nuclear antigen. These mice also develop high levels of proteinuria due to increased immune complex and complement deposition within the glomerulus of the kidney. Silica exposure increases the level of pulmonary fibrosis and alters the numbers of T helper cells, B1a B cells and regulatory T cells. We have also reported that autoantibodies from silica-exposed mice specifically recognize apoptotic alveolar macrophages. Protein Kinase Cδ has been reported to induce apoptosis in many cell types and by several different stimuli. Recently, many reports have implicated apoptosis as playing a significant role in the development of several autoimmune diseases, therefore an increase in apoptotic proteins following silica exposure may provide a possible mechanism for the exacerbation of autoimmunity in NZM mice. In the present study, we are examining the activation of PKCδ in alveolar macrophages following silica exposure. PKCδ RNA and protein is increased 2-fold within the AMs of silica treated NZM mice. Lung sections obtained 14 weeks following silica exposure in NZM mice show increased staining of PKCδ and the staining appears to occur within the AM population as demonstrated by colocalized staining of PKCδ and F4/80. In vitro, using bone marrow derived macrophages, silica exposure increases the level of PKCδ within 2 hours following exposure. This increase in PKCδ at 2 hours also correlates with an increase in caspase-9 within 2 hours following silica exposure. Therefore, silica exposure appears to induce apoptosis by the activation of PKC8 which leads to activation of caspase-9 and the subsequent apoptosis may expose excess antigen to the immune system allowing the exacerbation of systemic autoimmune disease.

### 1633 MECHANISMS OF NORDIHYDROGUAIARETIC ACID (NDGA)-MEDIATED APOPTOSIS IN FL5.12 CELLS.

V. S. Deshpande and J. P. Kehrer. Division of Pharmacology and Toxicology, College of Pharmacy, The University of Texas at Austin, Austin, TX.

NDGA is a general lipoxygenase (LOX) inhibitor that induces apoptosis in a variety of cells, including human Jurkat T lymphocytes and FL5.12 cells (murine pro-B lymphocytes), independent to its role as a LOX inhibitor. Effects on various kinases may be involved in this pro-apoptotic effect. Western immunoblotting experiments showed that treatment of FL5.12 cells with 10 µM NDGA leads to phosphorylation of extracellular signal-regulated kinases (ERK1/2), peaking at 1 h post-treatment. Although ERK1/2 is mainly known as a pro-survival protein there is evidence that activation of ERK is involved in apoptosis [Cancer Res. 61: 6569-6576 (2001)]. Consistent with this report, pre-treatment of FL5.12 cells with an ERK1/2 inhibitor, PD98059 (50  $\mu$ M), followed by 10  $\mu$ M NDGA, attenuated the apoptosis induced by NDGA. Another kinase signaling system involved in cell survival is the PI-3K/Akt pathway. Akt phosphorylation and activation is protective to cells as this kinase then phosphorylates and inactivates various pro-apoptotic substrates including ASK1 and members of the Bcl-2 family. Inhibition of the PI-3K/Akt pathway usually drives cells to apoptosis. NDGA treatments that induced apoptosis inhibited phosphorylation of Akt. In addition, pre-treatment of FL5.12 cells with the PI-3K inhibitor wortmannin (100 nM) enhanced NDGA-mediated apoptosis. These data support the hypothesis that NDGA-mediated apoptosis involves both activation of ERK1/2 as well as inhibition of the Akt survival pathway. These data further suggest a possible crosstalk between the MAP kinase and the PÍ-3K pathways. (Supported by CA83701 and Center Grant ES07784).

# 1634 ENVIRONMENTAL STRESS-MEDIATED SENSITIZATION OF B-LYMPHOID CELLS TO PESTICIDE-INDUCED APOPTOSIS AND INDUCTION

S. E. Bloom and D. E. Muscarella. Microbiology and Immunology, Cornell University, Ithaca, NY.

OF MAP KINASE PATHWAYS.

Lymphocytes, at different stages of differentiation, can differ in resistance to drugs and environmental chemicals depending on expression level of Bcl-2 and other apoptotic proteins. Furthermore, cell resistance may be altered as a result of exposure to multiple environmental stresses. We have shown previously that a stress resistant B-lymphoid cell line, overexpressing Bcl-2, can be sensitized to arsenic-in-

duced apoptosis following exposure to sub-lethal heat stress. However, it is unknown whether resistant B-cell lines can be sensitized to other classes of environmental chemicals. Therefore, we investigated whether the EW36 resistant B-cell line can be sensitized by heat stress to pesticide-induced apoptosis. The involvement of the c-jun N-terminal kinase (JNK) pathway in regulating enhanced apoptosis induction by the combination treatments was also investigated. EW36 cells were exposed to sub-lethal heat stress for 1 hr and then treated with 0, 5, 10, 25, 50 micromolar antimycin A (piscicide) or pyridaben (miticide) and incubated at 37 C. Cells were harvested at 2 hr post-treatment for studies of JNK activation and at 24 and 48 hours for c-jun expression and apoptosis induction. Exposure of EW36 cells to heat or antimycin individually failed to activate JNK or induce apoptosis. However, the heat plus antimycin combination treatment activated JNK, induced c-jun expression, and induced substantial apoptosis. An AP-1 inhibitor blocked apoptosis induction by the combination of heat plus antimyicn, and c-jun expression was not induced. The heat plus pyridaben combination treatment also induced substantial apoptosis compared to controls, but this effect was independent of activation of the JNK/c-jun pathway. These findings show that heat stress can sensitize resistant EW36 B-cells to pesticide-induced apoptosis, but the particular pesticide exposure determines whether the JNK/c-jun pathway will be activated. This signaling pathway, along with Bcl-2, may play an important role in regulating apoptotic cell death induced by pesticides.

### THIOREDOXIN AND TGHQ-INDUCED APOPTOSIS IN HL-60 CELLS.

M. Yang, S. S. Lau and T. J. Monks. Pharmacology and Toxicology, University of Arizona Health Sciences Center, Tucson, AZ.

2, 3, 5-tris-(Glutathion-S-yl)hydroquinone (TGHQ) is present in the bone marrow of rats and mice co-treated with hydroquinone and phenol, hematotoxic metabolites of benzene. TGHQ is also hematotoxic in rats, and induces DNA damage, growth arrest, and apoptosis in human promyelocytic leukemia (HL-60) cells. During TGHQ-induced apoptosis of HL-60 cells reactive oxygen species (ROS) generation occurs, with concomitant deceases in cellular glutathione (GSH). However, although co-treatment of HL-60 cells with catalase protects against TGHQ-induced apoptosis, it does not prevent depletions in cellular GSH. We have now investigated whether other cellular thiol pools, specifically thioredoxin (TRX), modulate TGHQ-induced apoptosis. Western blot analysis and flow cytometry revealed that TGHQ (200 µM) treatment of HL-60 cells decreased TRX levels. Consistent with this finding, c-Jun N-terminal kinase (JNK) and p38 MAPK were activated in response to TGHQ. Interestingly, although catalase treatment did not block TGHQ-induced depletions of cellular GSH, it did prevent decreases in TRX levels. Although cytochrome c is released from mitochondria, concomitant with the dephosphorylation of pS70 Bcl-2 and the translocation of Bax to mitochondria 2h after TGHQ treatment,  $\Delta\Psi_m$  remained intact for at least 4h after treatment. The data indicate that TGHQ facilitates ROS production, which causes subsequent decreases in cellular TRX, which may be subsequently coupled to the apoptosis signal-regulating kinase 1 (ASK1) - JNK/p38 apoptosis signaling pathway, culminating in the release of cytochrome c without interruptions in  $\Delta\Psi_{\rm m}$ (ES09224).

### THE FATE OF INSTILLED APOPTOTIC MACROPHAGES IN THE LUNGS.

R. R. Mercer, J. Scabilloni, <u>J. Antonini</u>, <u>V. Castranova</u> and L. Wang. *HELD*, *NIOSH*, *Morgantown*, *WV*.

Our previous studies of particle exposures have implicated abnormal accumulations of apoptotic macrophages and apoptotic bodies in lung injury from high burdens of low toxicity particles and low burdens of highly toxic particles. To determine how the lungs process abnormal accumulations of apoptotic cells, we have used intratracheal instillation of apoptotic or normal macrophages from autologous donor rats. We characterized the fate of instilled apoptotic and normal macrophages by prelabeling the cells with UV fluorescent beads (0.5 micron, bright blue, polystyrene). One million labeled cells were instilled and the animals sacrificed at 4 hrs, 1 day, 1 week or 4 weeks after instillation. The right lung of each animal was lavaged with PBS and the left lung was inflation fixed with cryopreservative. Cytospins of lung lavage and cryosections of lung were stained for apoptotic cells with yellow-green fluorescence labeled nucleotides by terminal deoxytransferase (TdT). At 4 hours, 50% of the microsphere labeled, apoptotic cells which had been instilled were phagocytized. By 1 day, greater than 90% of the instilled apoptotic macrophages were phagocytized. There were no TdT positive nuclei in microsphere labeled cells at one week. No microsphere labeled, normal macrophages were found to be phagocytized at any time point. TdT positive cells in the lungs receiving normal

macrophages was too low to quantify. The results demonstrate that instilled apoptotic macrophages are rapidly ingested and processed by resident alveolar macrophages while otherwise normal macrophages are not.

# 1637 APOPTOTIC CELL INSTILLATION RESULTS IN ELEVATED TGF- $\beta$ and apoptosis-induced-apoptosis in rat lung.

L. Wang<sup>1</sup>, J. Scabilloni<sup>1</sup>, <u>J. Antonini</u><sup>1</sup>, Y. Rojanasakul<sup>2</sup>, <u>V. Castranova</u><sup>1</sup> and R. R. Mercer<sup>1</sup>. <sup>1</sup>PPRB, NIOSH, Morgantown, WV and <sup>2</sup>School of Pharmacy, West Virginia University, Morgantown, WV.

Results from animal inhalation with either high burden or highly toxic particles showed increased apoptosis in the lungs. Previous studies by our group indicated that pulmonary administration of apoptotic lung cells induced inflammatory cell influx and lung fibrosis, indicating a direct linkage between apoptosis and fibrotic lung disorders (Ref.1). In this study, we further characterized the kinetics of pulmonary response to apoptotic cell instillation in rats and investigated the possible role of TGF-β in this process. Rats instilled with apoptotic cells showed a decrease in lung cell apoptosis at 1 week post-treatment, consistent with our previous finding showing the clearance of labeled apoptotic cells in rat lungs after 1 week (Ref.2). However, the level of lung cell apoptosis was higher at 4 and 12 weeks post-treatment compared to the control groups instilled with normal non-apoptotic cells. These results suggest that the apoptotic cells observed at latter time points were not those originally instilled but were subsequently induced after the treatment. Analysis of BAL fluids from treated rats showed an increase in TGF-B expression at 1 and 4 week post-treatment compared to the control groups.  $TGF-\beta$  is a known inducer of apoptosis and a key mediator of lung fibrosis, our results therefore suggest that increased TGF-\$\beta\$ by apoptotic cell instillation may be responsible for the increased lung cell death and subsequent development of pulmonary fibrosis. ## 1638 PERTURBATION OF TESTICULAR CELL PROLIFERATION USING SODIUM ARSENITE.

N. L. Harmon and J. W. DuMond. Biology, Texas Southern University, Houston, TX.

In this study we report the effects of sodium arsenite exposure on the cell proliferation of the normalized mouse Leydig cell line, TM3. The Leydig cells were grown in culture medium containing 5% horse serum, 2.5% fetal bovine serum. Cell cultures were switched to serum-free medium prior to treatment with test compound. The treatments consisted of 1pg, 10pg, 10pg, 1ng, 10ng, and 100ng per ml sodium arsenite, along with a control. Results indicated a significant (p≤0.05) increase in cell proliferation in all treatments with growth ranging from 119.79 to 191.80%, with the exception of 100ng/ml when compared to the control. Peak proliferation for sodium arsenite was noted at 10pg/ml (191.80%). The other growth was recorded as follows: 166.88% at 1pg/ml, 163.03% at 100pg/ml, 155.32% at 1ng/ml, 126.80% at 10ng/ml, and 119.79% at 100ng/ml. These results are of concern given that sodium arsenite has previously been reported to decrease DNA repair. Hence, when coupled with our findings here, a mechanism for the induction of genomic instability can be postulated. This then may explain the carcinogenic activity of sodium arsenite.

### 1639

ARSENIC ACTIVATES NADPH OXIDASE THROUGH CDC42 AND THEIR INVOLVEMENT IN ACTIN FILAMENT REMODELING AND CELL MOTILITY IN ENDOTHELIAL CELLS.

Y. Qian<sup>1</sup>, D. C. Flynn<sup>2</sup>, <u>V. Castranova</u> and X. Shi<sup>1</sup>. <sup>1</sup>The pathology and Physiology Research Branch, National Institute for Occupaptional Safety and Health, Morgantown, WV and <sup>2</sup>Microbology, Immunology and cell biology, West virginia University, Morgantown, WV.

Although arsenic is a human cancinogen, the molecular mechanisms of its action remain to be understood. By stimulating mouse endothelial cell lines (SVEC4-10) with 10  $\mu M$  arsenic, we found that arsenic induced activation of NADPH oxidase as determined by the nitroblue tetrazolium test. Using confocal microscopy, the generation of O $_2$  and  $H_2O_2$  was observed to be increased in SVEC4-10 cells after exposure to arsenic. We also found that arsenic activated Small Rho GTPase CDC42. Disruption of CDC42 with a dominant negative CDC42 abolished ar-

senic-induced activation of NADPH oxidase and subsequent generation of  $O^{\cdot}_{\ 2}$  and  $H_2O_2$ , suggesting that CDC42 may mediate the effects of arsenic on NADPH oxidase. Furthermore, it was found that arsenic stimulation induced actin filament remodeling and increased cell motility in SVEC4-10 cells. These changes were abrogated by either disruption of CDC42 or inhibition of NADPH oxidase, indicating that the cell signaling changes induced by arsenic are relevant to these cellular functions. Taken together, the data imply that arsenic may promote motility-dependent metastasis of cancer cells through CDC42, NADPH oxidase and reactive oxygen species.

#### 1640

TRANSGENERATIONAL EFFECTS OF CHROMIUM(III) ON OFFSPRING WEIGHT, SERUM TIIODOTHYRONINE, AND HEPATIC GENE EXPRESSION.

R. Y. Cheng and <u>L. M. Anderson</u>. Laboratory of Comparative Carcinogenesis, National Cancer Institute, Frederick, MD.

Exposing male mice to chromium(III) chloride before mating results in increased tumors in offspring. An epigenetic mechanism has been postulated, involving alterations in hormones and in gene expression in the offspring. In pursuit of this hypothesis, male Swiss mice were injected i.p. with 1 mmol/kg chromium(III) chloride, 2 wks before mating. Offspring (10 wks old) were weighed and assessed for serum triiodothyronine (T3)and hepatic gene expression by cDNA microarray analysis. Both male and female offspring of Cr(III)-treated fathers were significantly heavier than those of control fathers: 31.4 + 1 - 0.4 g (S.E.) (N = 62) vs 30.6 + 1 - 0.2 (N = 90) (P = 0.035) for males and 24.6 + 1 - 0.3 (N = 54) vs 23.0 + 1 - 0.3 (N = 54) (P = 0.0003) for females. Serum T3 levels were also greater in the offspring of Cr(III)-treated fathers: 107.7 +/- 2.0 ng/dl vs 95.6 +/- 3.4 for males (P<0.0001) and 96.4 +/- 2.2 vs 89.3 +/- 2.8 for females (P = 0.054). Microarray analysis was carried out on eight pairs of livers from female offspring of Cr(III)-treated and control fathers, chosen to represent serum T3 ratios over the range 1.04 to 2.68. Linear regression analysis selected for hepatic genes showing microarray ratios correlating with serum T3 ratios with a significance of P <= 0.001. Fifty-eight genes met this criterion, including 25 named genes. Several are known to be regulated by T3, e.g. beta 2 adrenergic receptor and the calcium-regulator phospholamban. Others may pertain to growth: protein tyrosine phosphatase 4a2, pancreatic colipase, and complement component 3a receptor 1. Expressions of several genes associated with tumor suppression were negatively associated with serum T3 ratios: the transcription factors Ikaros, zinc finger protein 161, and Kruppel-like factor 5, as well as single-strand DNA binding protein and natural killer tumor recognition sequence. These results are consistent with hormone-mediated effects of paternal Cr(III)treatment on offspring physiology, and with an epigenetic mechanism of transgenerational carcinogenesis.

# 1641 INDUCTION OF THE HYPOXIA MARKERS, CARBONIC ANHYDRASE IX AND Cap43, BY NICKEL OR CELL DENSITY IS RELATED TO ASCORBATE DEPLETION.

A. A. Karaczyn<sup>1</sup>, K. S. Kasprzak<sup>1</sup>, S. Ivanov<sup>2</sup> and K. Salnikow<sup>1</sup>. <sup>1</sup>Laboratory of Comparative Carcinogenesis, National Cancer Institute at Frederick, Frederick, MD and <sup>2</sup>SAIC, NCI-Frederick, Frederick, MD.

Nickel compounds are known carcinogens and represent potential hazard for environmentally and occupationally exposed people. Mechanisms of nickel-induced carcinogenesis are currently unknown. Recently, we have shown that carcinogenic nickel compounds induced HIF-1 transcription factor and all known hypoxia-inducible genes. HIF-1 activation likely plays important an role in malignant transformation caused by nickel since stimulation of soft agar growth by nickel can be observed in HIF-1 alpha normal but not in knock-out cells. In this study we further investigated mechanisms of nickel-induced activation of hypoxia-inducible genes. We have found that both carbonic anhydrase IX (CAIX) and Cap43, known as intrinsic marker of hypoxia and a tumor marker, are also induced by exposure to soluble nickel compounds in human lung epithelial (HAE) cells. In cells exposed to 0.5 mM nickel(ÎI) sulfate, the induction of both proteins was observed as early as after 2 hrs. The involvement of HIF-1 transcription factor in the induction of these proteins was also confirmed in cells exposed to cobalt(II), desferoxamine and dimethyloxoglycine (DMOG). Additionally, both CAIX and Cap43 were induced in HIF-1 alpha normal but not in knock-out cells. The induction of CAIX and Cap43 by nickel(II), cobalt(II) and desferoxamine, but not by DMOG, can be abolished by 0.1 mM of ascorbic acid added to culture media. These data suggest that nickel exposure may result in depletion of cellular ascorbate, leading to a shift in the iron oxidation status. CAIX and Cap43 could be also induced by high cell culture density. Here we show that the density-dependent induction of Cap43 and CAIX may be associated with the depletion of ascorbate in dense cultures.

### 1642

THE BENZENE METABOLITES HYDROQUINONE AND BENZOQUINONE INCREASE C-MYB ACTIVITY IN HD3 CELLS: AN INSIGHT INTO BENZENE MEDIATED LEUKEMOGENESIS.

<u>J. Wan</u><sup>1</sup> and <u>L. M. Winn</u><sup>1, 2</sup>. <sup>1</sup>Pharmacology and Toxicology, Queen's University, Kingston, ON, Canada and <sup>2</sup>School of Environmental Studies, Queen's University, Kingston, ON, Canada.

Benzene, a ubiquitous environmental toxicant, has been proposed to lead to carcinogenesis. While the mechanism behind benzene mediated leukemogenesis remains unknown, it is generally accepted that benzene exerts its toxicity after being metabolized in the body by cytochrome P450s. During blood cell development, the transcription factor c-Myb plays an important role such that mice lacking expression of this protein die in utero and are anaemic. Furthermore, overexpression of c-Myb prevents differentiation of induced erythrocytes. Therefore we hypothesize that c-Myb may be involved in benzene-mediated leukemogenesis. To investigate this hypothesis, cells were transiently transfected with a luciferase reporter gene containing the chicken mim-1 promoter and then exposed to 0-100 µM of hydroquinone and benzoquinone for up to 24 hours. Our results show that the benzene metabolites benzoquinone and hydroquinone can significantly increase c-Myb activity at 24 hours but not at 6 hours in a dose dependant fashion. Previous studies indicate that exposure to catechol, but not benzene or phenol, can increase c-Myb activity. In light of these past results, this study supports the hypothesis that benzene must be metabolized before mediating its toxicity and provides insight into benzene's actions on the c-Myb signalling pathway as a potential mechanism of leukemogenesis. (Support:CIHR and PREECAN)

### 1643

ACTIVATION OF DOWNSTREAM RAS EFFECTORS IN LUNG LESIONS FOLLOWING DOXYCYCLINE (DOX) REGULATED EXPRESSION OF MUTANT HUMAN KI-ras IN A BITRANSGENIC MOUSE MODEL.

H. S. Floyd<sup>1</sup>, C. L. Farnsworth<sup>2</sup>, N. D. Kock<sup>1</sup>, J. L. Little<sup>1</sup>, S. T. Dance<sup>1</sup> and M. S. Miller<sup>1</sup>. <sup>1</sup> Cancer Biology, Wake Forest University, Winston-Salem, NC and <sup>2</sup>Cell Signaling Technology, Beverly, MA.

Previous studies from our laboratory reported the development of a bitransgenic mouse model that expresses the mutant human Ki-ras/CYS<sup>12</sup> allele in alveolar type II and/or Clara cells in a DOX-regulated, lung-specific manner. When DOX was administered in the drinking water for up to 12 months, macroscopically visible lung lesions were first detected by 3 months, showing an increase in number and size during the course of DOX treatment. Microscopically, hyperplasia could be seen as early as 12 days and had progressed to adenomatous lesions by 6 months. Interestingly, none of the tumors progressed beyond the adenoma stage even after 12 months of DOX treatment. Withdrawl of DOX for 1 month resulted in a lack of proliferative lesions, suggesting tumor regression in the absence of Ki-ras expression. A 2-fold activation of both the RAS and RAL pathways in DOX-treated mice was detected by measuring the binding of tissue lysates to the Ras Binding Domain of Raf or Ral Binding Protein, respectively. Immunohistochemical analyses of the lung tissues demonstrated elevated phosphorlylation of downstream RAS effectors. Increased phosphorlyation of Erk,  $\hat{p}90$  ribosomal S6 kinase, ribosomal S6 protein, and the transcription factor CREB was detected with antibodies specific for phosphorylated residues of these proteins. The highest levels of activated signaling proteins were seen in bronchiolar epithelium, cells surrounding blood vessels, and the hyperplasic or adenomatous tissue. These results suggest that mutant RAS-mediated activation of the RAF-MEK-ERK and possibly the RAL pathways plays a critical role in the early stages of lung tumorigenesis. Continued studies with this *in vivo* model will allow the delineation of the role of these and other RAS effector pathways in the lung neoplastic process. (Supported by NCI grant CA91909 and CA91909-S1)

### 1644

OVEREXPRESSION OF PKC EPSILON IN THE MOUSE EPIDERMIS LEADS TO POLYMORPHONUCLEAR NEUTROPHIL INFILTRATION AND EPIDERMAL DESTRUCTION AFTER A SINGLE TOPICAL DMBA-TPA TREATMENT.

Y. li, D. Wheeler, H. Anathaswamy, A. Verma and T. D. Oberley. Molecular and Environmental Toxicology, University of Wisconsin, Madison, WI.

We have previously reported that FVB/N transgenic mice which overexpress protein kinase C epsilon (PKC£) in basal epidermal cells and cells of the hair follicle developed papilloma-independent metastatic squamous cell carcinoma (mSCC) elicited by an initiation (7, 12-dimethylbenz[a]anthracene, DMBA) - promotion (12-O-tetradecanoylphorbol-13-acetate, TPA) protocol. The present studies were performed to determine early morphological events in PKC£ transgenic mouse skin treated with DMBA/TPA. FVB/N wild type mice and PKC£ transgenic mice were

initiated with a single dose of 100 nmol DMBA, followed by a single topical application of 5 nmol TPA one week later. Dorsal skin samples were fixed for histological examination at 0, 12, 24, 48, 72, and 96 hrs after TPA treatment. At 12 and 24 hrs, polymorphonuclear neutrophils (PMNs) infiltrated into the epidermis in both wild type and PKCε transgenic mice, and the epidermal area involved by PMN infiltration was not significantly different. However, complete epidermal necrosis by 48 h was observed in PKCE transgenic mice, not in their wild type littermates. Epidermal cell regeneration was observed at 72 h post TPA treatment in PKCE transgenic mice. The regenerated skin was disordered and showed extensive hyperplasia and hyperkeratosis. In addition, lack of staining with the differentiation marker keratin 10 showed the regenerated epidermis to be poorly differentiated. These histological changes were not observed in PKC $\delta$  overexpressing transgenic or in wild type mice. These data suggested that a single TPA treatment of the dorsal skin of PKCE transgenic mice resulted in epidermal destruction by PMNs, followed by hyperproliferation of cells of the basal layer and hair follicle and resulting in a hyperplastic, poorly differentiated epidermis. Our results may provide insights into the mechanism of the development of papilloma independent mSCC in PKCE

### 1645

ACTIVATION OF AP-1 AND PRO/ANTIOXIDANT STATUS IN SKIN OF AP-1 TRANSGENIC MICE DURING CANCER PROMOTION WITH CUMENE HYDROPEROXIDE.

M. Xu<sup>1</sup>, E. Kisin<sup>2</sup>, A. R. Murray<sup>1</sup>, C. Kommineni<sup>2</sup>, V. Vallyathan<sup>2</sup>, V. Castranova<sup>1, 2</sup> and A. A. Shvedova<sup>1, 2</sup>. <sup>1</sup> Physiology and Pharmacology, WVU, Morgantown, WV and <sup>2</sup>PPRB, NIOSH, Morgantown, WV.

Organic peroxides, widely used in the chemical and pharmaceutical industries, can act as skin tumor promoters and cause epidermal hyperplasia. They are also known to trigger free radical generation. The present study evaluated the effect of cumene hydroperoxide (Cum-OOH) on the induction of activator protein-1 (AP-1), which is linked to the expression of genes regulating cell proliferation, growth, and transformation. Previously, we reported that topical exposure to Cum-OOH caused formation of free radicals and oxidative stress in skin of vitamin E deficient mice. In addition, in vitro studies found that exposure to Cum-OOH reduced levels of GSH in JB6 P+ cells and caused the induction of AP-1. The present study used AP-1-luciferase reporter transgenic mice to identify whether exposure to Cum-OOH in vivo caused activation of AP-1, oxidative stress, depletion of antioxidants and tumor formation during two-stage carcinogenesis. Mice primed with dimethylbenz[ $\alpha$ ]anthracene (DMBA) were treated topically with Cum-OOH (82.6  $\mu$ mol) or 12-O-tetradecanoylphorbol-13-acetate (TPA, 17 nmol) twice weekly for 20 weeks. Activation of AP-1 in skin was detected as early as 2 weeks following Cum-OOH and TPA exposures. Maximum AP-1 expression was detected 4 weeks post initiation with Cum-OOH or TPA. No AP-1 activation was found 19 weeks post initiation. Papilloma formation was observed in both the DMBA/TPA and DMBA/Cum-OOH exposed animals, while skin carcinomas were found only in the DMBA/Cum-OOH treated mice. A greater accumulation of peroxidative products (TBARS), inflammation, and decreased levels of GSH, vitamin E and total antioxidant reserves were also observed in the skin of DMBA/Cum-OOH exposed mice. These results suggest that Cum-OOH induced carcinogenesis is accompanied by increased AP-1 activation and changes in antioxidant status.

### 1646

REDUCTION OF COX-2 EXPRESSION IN THYROID FOLLICULAR EPITHELIAL CELLS DURING DHPNINDUCED CARCINOGENESIS IN RATS.

T. Imai, M. Hasumura, J. Onose, M. Ueda, T. Takizawa, Y. Cho and M. Hirose. *National Institute of Health Sciences, Tokyo, Japan.* Sponsor: M. Ema.

In thyroid follicular epithelial cells, constitutive expression of cyclooxygenase-2 (COX-2) has been demonstrated. To assess the role of COX-2 during rat thyroid carcinogenesis, we evaluated its expression in the proliferative lesions induced by goitrogens with or without N-bis(2-hydroxypropyl)nitrosamine (DHPN)-initiation. DHPN was subcutaneously injected once to 40 male F344 rats at age of 6-week. One week after the initiation, goitrogens such as propylthiouracil (PTU) and sulfadimethoxine (SDM) were administered in drinking water for 4 or 10 weeks, and then thyroid samples were collected for histopathology and immunohistochemistry for COX-2. Goitrogen alone groups were also placed. At week 4, multiple focal follicular cell hyperplasias and adenomas were frequently observed in DHPN + PTU and DHPN + SDM groups. In DHPN + SDM and SDM alone groups, severe inflammation with fibrosis in the thyroid capsule with migrated follicular epithelial cells into the capsule were also observed. At week 10, increased incidences and multiplicities of focal hyperplasias and adenomas in DHPN + PTU and DHPN + SDM groups were observed. In addition, invasive adenocarcinomas to capsule were also detected in 3 of 10 rats of the DHPN + SDM group. These carcinomas were suggested to originate in the focal hyperplasias and adenomas adja-

cent to the capsule. In the proliferative lesions observed in DHPN + PTU and DHPN + SDM groups as well as the migrated follicular epithelial cells in DHPN + SDM and SDM alone groups, COX-2 reactivity was frequently reduced or negative. These results suggested that capsular inflammation and reduction of COX-2 expression in the preneoplastic and neoplastic lesions play roles in the development of invasive adenocarcinomas and promotion/progression of rat thyroid carcinogenesis, respectively.

### 1647

INHIBITION OF ESTROGEN RECEPTOR NEGATIVE MDA-MB-453 AND BT-474 BREAST CANCER CELL GROWTH BY ARYL HYDROCARBON RECEPTOR AGONISTS.

L. Kotha and <u>S. Safe</u>. Veterinary Physiology & Pharmacology, Texas A&M University, College Station, TX.

MDA-MB-453 and BT-474 are estrogen receptor (ER) negative breast cancer cell lines that over express epidermal growth factor receptor 2 (EGFR2, erbB2) and exhibit high constitutively active kinase activities. Treatment of both cell lines with 2, 3, 7, 8-tetrachlorodibenzo-p-dioxin (TCDD) induced CYP1A1 expression and proteosome-dependent degradation of the aryl hydrocarbon receptor (AhR). Low but significant induction of CYP1A1 was also observed for the selective AhR modulators (SAhRMs) 6-methyl-1, 3, 8-trichlorodibenzofuran (MCDF) and 3'3-diindolylmethane (DIM). However these compounds did not downregulate AhR levels. TCDD (10 nM), MCDF (2 and 5  $\mu$ M), and DIM (10 and 20  $\mu$ M) all significantly inhibited MDA-MB-453 and BT-474 cell proliferation but did not significantly affect the percent distribution of the cells in  $G_0/G_1$ , S or  $G_2/M$  phases of the cell cycle. TCDD and the SAhRMs had minimal effects on the expression of erbB2 and phospho-erbB2, mitogen activated protein kinase 1/2 (MAPK1/2) or phospho-MAPK1/2, whereas the MAPK inhibitor UO126 inhibited cell proliferation and phosphorylation of MAPK. These data coupled with results obtained for other activated kinase pathways demonstrate that TCDD and SAhRMs uniquely inhibit growth of ER-negative MDA-MB 453 and BT-474 breast cancer cells through kinase-independent pathways. (Supported by NIEHS ES09106 and

## 1648 ESTROGEN THROUGH CALCIUM MEDIATED SIGNALING INDUCES CELL GROWTH IN BREAST CANCER CELLS.

M. K. Singh and D. Roy. Environmental Health Sciences, University of Alabama at Birmingham, Birmingham, AL.

Natural estrogen, 17 Bestradiol (E2) and its catechol metabolite 4-hydroxyestradiol (4-OH-E2), are implicated to be involved in the development of breast cancer. The mechanism by which E2 and 4-OH-E2 participate in breast carcinogenesis is not clear. In this study we have examined the effects of E2 and 4-OH-E2 on the proliferation of MCF-7 cells and intracellular ROS production. Cells were treated with varying concentration of E2 and 4-OH-E2 in DMEM-F12. Cell growth was assessed by cell count and sulforhodamineB assay, and cell proliferation by measuring BrdU incorporation. Intracellular ROS production was measured by a micro-fluorometric assay using 2, 7-dichlorofluorescin diacetate after treatment with different concentration of E2 and 4-OH-E2 with and without co treatment with calcium chelator BAPTA/AM . E2 (100pg/ml) and 4-OH-E2 (10ng/ml) treatments increased cell number by 200% and 250%, respectively. Co treatments of E2 and 4-OH-E2 with BAPTA revealed that BAPTA inhibited the stimulatory growth produced by E2 and 4-OH-E2 treatments. Both E2 and 4-OH-E2 increased intracellular ROS production in a dose dependant manner. BAPTA inhibited E2 and 4-OH-E2-induced increases in intracellular ROIs production. These data suggest that estrogen through regulating calcium signaling pathway stimulates the growth of MCF-7 breast cancer cells.

## 1649 ESTROGEN-INDUCED UPREGULATION OF CRE CONTAINING GENES IN BREAST CANCER CELLS.

Q. H. Felty and D. Roy. Environmental Health Sciences, University of Alabama at Birmingham, Birmingham, AL.

The second messengers calcium (Ca2+) and cyclic AMP (cAMP) activate nuclear target genes containing the CRE binding motif through signaling within the cytoplasm. The CRE motif is present in the promoters of genes that encode growth factors and proteins involved in cell cycle progression. Both cAMP/Ca2+ activate the transcription factor CREB which in turn binds the CRE response element leading to transcription of various target genes. Estrogen-dependent tumors account for the majority of breast cancer cases in women. A hierarchy of organ tissue response to the endogenous estrogen 17-?-estradiol (E2) has shown that calcium metabolism is

the most sensitive followed by epithelial cell growth. E2 has been demonstrated to rapidly activate adenylate cyclase responsible for cAMP synthesis as well as increase intracellular [Ca 2+]. Although E2 modulation of intracellular cAMP/Ca2+ levels are known, the role that cAMP/Ca2+ play in controlling the cell growth of estrogen dependent breast cells is not clear. In this study we present data that demonstrates E2 controls the transcription of cAMP/Ca2+ responsive genes, which may play a role in the paracrine or autocrine stimulation of breast cancer cell growth. Super GEArray analysis of cAMP/Ca 2+ genes at 6h revealed a 3.5- and 2.9 fold-induction of TGF ?3 and the substance P receptor in MCF-7 breast cancer cells when treated with 100pg/mL E2 for 6h. Interestingly, the substance P receptor is distributed in the breast, uterus, and brain tissue. Whether increases in mRNA levels of substance P receptor and TGF ?3 correlate to changes in estradiol stimulated breast tumor cell growth remains to be elucidated. The biological significance of our findings from this study may provide a basis for the development of a breast cancer therapy, which targets cAMP/Ca 2+ signaling pathways.

## 1650 LONG TERM EXPOSURE OF HUMAN MAMMARY EPITHELIAL CELLS TO HEXACHLOROBENZENE (HCB) INDUCES A PROCARCINOGENIC PHENOTYPE.

R. M. Audet, S. Girard, G. Lassonde and M. Charbonneau. INRS-Institut Armand-Frappier, Universite du Quebec, Montreal, QC, Canada.

Organochlorines are environmental lipophilic contaminants found in breast tissue with a debated role in breast cancer development (BCD). HCB, a widespread organochlorine in the environment, is virtually present in 100% of North American women. Epidemiological studies indicated that some breast cancer patients have higher HCB levels. We observed that long term exposure of human mammary epithelial cells to HCB increases the phosphorylation of c-erbB2 (neu). Cells with such epigenetic alterations can be considered procarcinogenic taking into account the bad prognostic role of c-erbB2 in BCD. In order to further evaluate the potential of HCB in causing epigenetic changes akin to a procarcinogenic phenotype, cultures of a non-tumorigenic human mammary epithelial cell line, MCF10-A, were chronically exposed to 20 μM HCB (0.1% in DMSO) or to DMSO alone. Following approximately 25 passages of continuous exposure to HCB, an increase in proliferation was observed. These cells showed an increase in the phosphorylation of the integrin-linked kinase (ILK), with a decrease in Akt/PKB levels. E-Cadherin, an important cell adhesion molecule, was also decreased. Control cells sub-cultured on Matrigel® showed a distinctive branching pattern after 24h. However, HCB-exposed cells exhibited a rounded shape with minimal cellular contacts. This is suggestive of a decrease in intercellular communication and cell adhesion; the latter is supported by the decrease in E-Cadherin expression in these cells. Moreover, after 10 d in culture HCB-exposed cells migrated differently into the Matrigel® layer as compared to controls. Overall, data suggest that HCB induces a procarcinogenic phenotype characterized by reduced intercellular communication and that this may result from overactivation of ILK, known to be a down-stream target of c-erbB2, leading to down-regulation of Akt, which controls E-cadherin expression. This work brings biological plausibility to the involvement of environmental contaminants in BCD. (Supported by PREECAN)

## 1651 MAPPING AND GENOMIC ANALYSIS OF RESISTANCE TO AZOXYMETHANE-INDUCED COLORECTAL CANCER.

D. J. Barrick<sup>1</sup>, J. Uronis<sup>2</sup> and D. Threadgill<sup>2, 1</sup>. <sup>1</sup>Curriculum in Toxicology, UNC-Chapel Hill, Chapel Hill, NC and <sup>2</sup>Genetics, UNC-Chapel Hill, Chapel Hill, NC.

Colorectal cancer (CRC) is the 3rd most diagnosed malignancy in the United States with approximately 1 in 17 people expected to develop the disease. Although some incidences of CRC occur in dominantly inherited patterns, the majority of CRCs are classified as "sporadic" (i.e. non-familial). However, many incidences of sporadic CRC occur in individuals with heightened genetic susceptibility. The chemical carcinogen azoxymethane (AOM), an alkylating agent that is a specific colorectal carcinogen in rodents, induces tumors that are pathologically similar to human colorectal tumors. Moreover, there are strain specific differences in susceptibility. Earlier work in this laboratory screened 32 inbred strains of mice for susceptibility to AOM-induced CRC. These studies revealed that A/J mice are extremely sensitive to AOM as nearly 100 percent of animals developing colorectal tumors, while SPRET/Ei mice are resistant. A better understanding of the AOM model using these two strains may provide clues to genetic predisposition to CRC. To further investigate genetic differences in susceptibility to sporadic CRC, we have taken two approaches. First, comparative genome hybridization (CGH) studies have identified chromosomal aberrations in colorectal tumors from AOM-exposed A/J mice. Potential amplifications were detected in the distal ends of chromosomes 9, 10, 14, 16, and 17, while deletions were observed on chromosomes 1 and 19. Second, we are in the process of mapping genetic loci responsible for resistance of the SPRET/Ei strain to AOM-induced colon cancer. While nearly 100 percent of AS-PRET F1 mice are tumor-free, over 40 percent of progeny from a backcross of F1

mice to A/J parents ((ASPRET)A N2) develop AOM-induced colorectal tumors, implying that SPRET/Ei resistance genes are dominant. Using di-nucleotide microsatellite markers, we are scanning the genome of the (ASPRET)A N2 mice and have thus far identified three putative loci which demonstrate significant correlation to colon tumor resistance. Together, these studies will reveal potential CRC modifier genes. DJB T32 ES07126

### 1652

MAPPING RAT MAMMARY CANCER SUSCEPTIBILITY LOCI THAT CONTROL N-METHYL-N-NITROSOUREA-INDUCED MAMMARY CARCINOGENESIS IN FISCHER 344 RAT.

<u>H. Zarbl</u><sup>1, 2</sup>, L. Jing<sup>1</sup>, A. M. Mikheev<sup>1</sup>, H. Xie<sup>1</sup>, Y. Gao<sup>1</sup>, X. Ren<sup>1</sup>, J. Lew<sup>1</sup> and X. Zhang<sup>1, 1</sup>Human Biology and Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA and <sup>2</sup>Center for Ecogenetics and Environmental Health, NIEHS/ University of Washington, Seattle, WA.

Rat strain differ dramatically in their susceptibility to mammary carcinogens such as 7, 12-dimethylbenz[a]anthracene (DMBA), N'-nitroso-N'-methylurea (NMU), and ionizing radiation. The Copenhagen (Cop) and Wistar-Kyoto strains are remarkably resistant while pubescent females of most other rat strains are susceptible to mammary carcinogenesis, although they vary with respect to tumor incidence and latency. Genetic crosses among susceptible and resistant strains have been used to genetically map and identify genes that control sensitivity and susceptibility to mammary carcinogenesis. However, genome wide linkage studies have failed to detect a major suppressor locus. Instead the data suggested that susceptibility is a multigenic trait controlled by multiple Quantitative Trait Loci (QTL), termed Mammary Cancer Susceptibility (Mcs) loci. None of the gene(s) comprising these loci locus has been identified to date. In the present study, we focussed on genetic mapping of the Mcs loci that conferred susceptibility to NMU-induced mammary carcinogenesis. We generated ~600 N2 backcross progeny using the highly resistant Cop strain and the susceptible F344 strains. Linkage analysis and interval mapping in this model demonstrated that susceptibility in the F344 strain segregated as a recessive Mendelian trait. The Mcs locus mapped to a ~10 centimorgan (cM) interval (LOD score ~ 9) close the centromere on the long arm of chromosome 12. A second locus mapped to the long arm of rat chromosome 1 (LOD-4). We are using comparative genomics, gene expression profiling and function genomics approaches to identify candidate genes within these loci. Identification of the putative Mcs genes in the rat model will undoubtedly lead to enhanced understanding of human breast cancer risks, and possibly lead to new strategies for risk assessment and early detection.

### 1653

GENISTEIN AND ESTROGEN REGULATION OF ANDROGEN RECEPTOR AND EXTRACELLULAR REGULATING KINASES IN RAT PROSTATE. C E HARPER, C A LAMARTINIERE. DEPARTMENT OF PHARACOLOGY AND TOXICOLOGY, UNIVERSITY OF ALABAMA AT BIRMINGHAM, BIRMINGHAM, AL.

C. E. Harper. Pharmacology and Toxicology, University of Alabama at Birmingham, Birmingham, AL.

Prostate cancer is the second leading cause of death in men. Asian men consuming a diet high in soy have a lower incidence of hormone-dependent cancers. The primary isoflavone and phytoestrogen of soy, genistein, has been shown to suppress prostate cancer in rodent models. We have hypothesized that genistein elicits its effects via crosstalk between sex steroid and growth factor signaling. Thirty-five day old male Sprague-Dawley CD rats were given one subcutaneous injection of 500 mg genistein/kg BW, 500 ug estradiol benzoate (EB)/kg BW, or dimethylsulfoxide (DMSO). The rats were killed 16 hours after treatment. Dorsolateral and ventral prostates were dissected from each rat and Western blot analyses were performed to evaluate sex steroid and growth factor signaling. The dorsolateral prostate has been reported to be the embryologic homologue to the human prostate while the human does not have a ventral prostate. In the dorsolateral prostate, EB, but not genistein, significantly decreased phosphorylated extracellular regulating kinases 1 and 2 (P-ERKs 1 and 2). Neither genistein nor EB caused significant changes to androgen receptor (AR), epidermal growth factor receptor (EGFR) and total ERKs 1 and 2 in the dorsolateral prostate. In the ventral prostate, genistein and EB treatments resulted in decreases in AR and P-ERKs 1 and 2 and no significant effect on total ERKs 1 and 2 and EGFR. The action of genistein appears to be prostate tissue selective and there is a difference in the action of genistein and estrogen in the dorsolateral prostate. The embryologic origin of prostate tissue appears to dictate the action of genistein and estrogen. Understanding the selective action of genistein and estrogen should reveal how genistein suppresses prostate cancer and estrogen causes toxicity in the prostate.

#### 1654

INHALATION DELIVERY OF AEROSOL CONTAINING PEI-GLUCOSE-PTEN COMPLEX INDUCED CHANGE OF PROTEIN TRANSLATION IN KRAS KNOCKOUT LUNG CANCER MODEL MICE.

H. Kim<sup>1</sup>, I. Park<sup>2</sup>, C. Cho<sup>2</sup>, G. Beck<sup>3</sup>, N. Colburn<sup>3</sup> and <u>M. Cho<sup>1</sup></u>. <sup>1</sup>Laboratory of Toxicology, College of Veterinary Medicine, Seoul National University, Seoul, South Korea, <sup>2</sup>Laboratory of Biomedical Polymer and Tissue Engineering, College of Agricultural Biotechnology, Seoul National University, Seoul, South Korea and <sup>3</sup>Basic Research Laboratory, National Cancer Institute, Frederick, MD.

Difficulties of long-term survival of lung cancer patients treated with conventional therapies require the need for novel approaches and gene therapy holds promise in this area. Several genes are known to have anti-tumor activities and have been used as genes of delivery, however, a number of problems such as low efficiency and specificity hinder the application of gene therapy. Such traditional problems have re-emerged the aerosol gene delivery as a *via*ble and a noninvasive approach to lung cancer therapy. In this study, glucose conjugated polyethyleneimine (PEI-Glu) was used as a carrier particle. Aerosols containing PEI-Glu and recombinant plasmid pcDNA3.0-PTEN complex were transferred into Kras knockout lung cancer model mice through nose-only inhalation. Western blo revealed that aerosol gene delivery was successful. PTEN and Erk proteins were highly expressed in the mouse lung. PTEN delivery also induced increasde of Bax, c-Myc, p21, p65. Also, PI3K expression was increased significantly. However, increase of mutant p53 and decrease of Akt1, PDK1, eIF4E, eIF4E-BP1, p70S6K, phosphorylated mTOR, and phosphorylated p70S6K were observed. Our data strongly suggest that our carrier system is compatible with in vivo gene delivery and could be applicable to gene therapy. Supported by BK21 grant.

#### 1655

PREVENTION BY METHIONINE OF DICHLOROACETIC ACID-INDUCED LIVER CANCER AND DNA HYPOMETHYLATION IN MICE.

M. A. Pereira, W. Wang, P. M. Kamer and L. H. Tao. Pathology, Medical College of Ohio, Toledo, OH.

Dichloroacetic acid (DCA) is a mouse liver carcinogen. One of the epigenetic mechanisms for carcinogens is the ability to induce DNA hypomethylation. Methionine has been shown to prevent DNA hypomethylation induced by carcinogens. To test the involvement of DNA hypomethylation in the carcinogenic activity of DCA, we determined the ability of methionine to prevent DCA-induced DNA hypomethylation and liver tumors. Female B6C3F1 mice were administered DCA in their drinking water and 0, 4.0 and 8.0gm/kg methionine added to their AIN-76A diet. After 8 weeks of exposure, DCA increased the liver/body weight ratio and caused DNA hypomethylation, glycogen accumulation and peroxisome proliferation. Methionine prevented completely the DNA hypomethylation, reduced by only 25% the glycogen accumulation and did not alter the increased liver/body weight ratio and the proliferation of peroxisomes induced by DCA. DCA induced foci of altered hepatocytes and liver adenomas. The multiplicity of foci of altered hepatocytes/mouse was increased from  $2.41\pm0.38$  to  $3.40\pm0.46$  by 4.0gm/kg methionine and decreased to  $0.94 \pm 0.24$  by 8.0gm/kg methionine suggesting that methionine slowed the progression of foci to tumors. The low and high concentrations of methionine reduced the multiplicity of liver tumors/mouse from  $1.28 \pm 0.31$  to  $0.167 \pm 0.093$  and  $0.028 \pm 0.028$ , i.e. by 87 and 98%, respectively. Thus, the prevention of liver tumors by methionine correlated best with its prevention of DNA hypomethylation indicating that DNA hypomethylation was critical for the carcinogenic activity of DCA. This research was supported by a grant from the USEPA's Science to Achieve Results (STAR) program Grant number R82808301.

### 1656

LACK OF MODIFICATION OF MEIQX RAT LIVER CARCINOGENESIS BY CAFFEINE INDUCTION OF CYP1A2.

H. Kandori<sup>1, 2</sup>, M. Kuribayashi<sup>1, 3</sup>, M. Asamoto<sup>1</sup>, S. Suzuki<sup>1</sup> and <u>T. Shirai<sup>1</sup></u>.

<sup>1</sup>Department of Experimental Pathology and Tumor Biology, Nagoya City University Graduate School of Medical Sciences, Nagoya, Japan, <sup>2</sup> Takeda Chemical Industries Ltd., Drug Safety Research Laboratories Hikari Branch, Hikari, Japan and <sup>3</sup>Ono Pharmaceutical Co. Ltd., Safety Research, Fukui, Japan.

2-Amino-3, 8-dimethylimidazo[4, 5-f]quinoxaline (MelQx), a heterocyclic amine in cooked meat and fish, is speculated to be associated with human carcinogenesis. MelQx is known to be metabolically activated by several enzymes, especially CYP1A2. In order to evaluate modifying effects of CYP1A2 inducers on MelQx hepatocarcinogenesis, caffeine or diethylnitrosamine (DEN) was given together with MelQx to rats. Modification was assessed using a medium-term liver bioassay system. After initiation of hepatocarcinogenesis in F344 rats with a single dose of DEN, MelQx was given together with or without 0.1% caffeine or 0.01% DEN in

the diet or drinking water, respectively for 6 weeks. First, we analyzed the numbers and areas of glutathione S-transferase (GST-P) positive liver foci, putative preneoplastic lesions, after immunohistochemical staining. Then, mRNA expression levels of several metabolic enzymes were compared between GST-P positive foci and the surrounding liver tissue. As a result, DEN given together with MeIQx showed a synergistic promoting effect on development of GST-P positive foci. However, no modification was found with caffeine, although it up-regulated CYP1A2 mRNA expression. DEN is reported to also be a CYP1A2 inducer but we could not confirm this. In the GST-P positive foci, phase II detoxifying enzymes were up-regulated. In the background tissue of rat livers after exposure to DEN as a CYP inducer, specific expression of extracellular matrix-related genes including sparc and laminin receptor 1 was detected. These results suggest that modifying effects of caffeine on MeIQx through CYP1A2 are limited because caffeine also up-regulates various phase II detoxifying enzymes. Moreover, our findings indicate that changes in extracellular matrix-related genes in the surrounding tissue are important for progression of GST-P positive foci.

1657

CURCUMIN PROTECTS AGAINST 2-AMINO-1-METHYL-6-PHENYLIMIDAZO[4, 5-B]PYRIDINE (PHIP) CARCINOGENECITY THROUGH MODULATION OF ITS METABOLISM.

R. Thimmulappa<sup>1</sup>, M. Knize<sup>2</sup>, K. Mai<sup>1</sup>, J. S. Felton<sup>2</sup> and S. Biswal<sup>1</sup>. <sup>1</sup>Johns Hopkins University, Baltimore, MD and <sup>2</sup>Biology and Biotechnology Research Program, Lawrence Livermore National Laboratory, Livermore, CA.

Colorectal cancer is the second leading cause of death among Americans. Epidemiological evidences suggest the association of colon cancer with increased exposure of heterocyclic amines (HA) due to consumption of well-done cooked red meat and other dietary carcinogens. PhIP, the most abundant HA, has been reported to be a carcinogen in rodents and an etiological factor for colon and breast cancer. PhIP is activated by cytochrome P4501A2 (CYP1A2), and detoxified by phase 2 enzymes such as UDP-glucuronosyltransferase (UGT), glutathione-Stransferase (GST). Curcumin, a yellow pigment from Curcuma longa, is an important component of the spice turmeric. which shows anti-inflammatory, antioxidant properties and is being developed as a cancer chemopreventive agent. This study was designed to test the efficacy of curcumin to alter the PhIP metabolism. There was significant increase in hepatic GST and UGT levels as well as inhibition of CYP1A2 in rats fed with 1% curcumin for 14 days. Administration of PhIP by gavage (1mg/kg body weight, single dose) to rat fed on 1% curcumin resulted in significant increase in the PhIP-glucuronide metabolites such as N2-OH-PhIP-N2-glucuronide, N2-OH-PhIP-N3-glucuronide, and PhIP-N2-glucuronide compared to PhIP-treated group fed on control diet as measured by LC/MS/MS. Recent studies have demonstrated that Nrf2, a bzip transcription factor plays a pivotal role in induction of phase 2 enzymes. Administration of PhIP to the Nrf2-wild type and Nrf2-deficient mice fed on curcumin for 14 days resulted in higher levels of PhIPglucuronide metabolites in urine of Nrf2-wildtype mice type than Nrf2-deficient mice indicating that mechanism of curcumin function might be through activation of Nrf2 In conclusion, data indicate that curcumin can protect against PhIP carcinogenecity by enhancing its detoxification (Supported by Howard/Hopkins Partnership grant).

# 1658 CURCUMIN ENHANCES EGCG-MEDIATED CYTOTOXICITY *IN VITRO* AND MODULATES LIVER ENZYMES *IN VIVO*.

S. Valentine, M. J. Le Nedelec and <u>R. J. Rosengren</u>. *Pharmacology & Toxicology, Univeristy of Otago, Dunedin, New Zealand.* 

Both curcumin and epigallocatechin gallate (EGCG), are potent inhibitors of ER $\alpha$ negative breast cancer cell proliferation. The aim of this work was to determine if curcumin and EGCG would be synergistically cytotoxic in the ER\alpha negative breast cancer cell line, MDA-MB-231. Cells were plated at 20, 000 cell/well in a 24 well plate in DMEM media. 24 hours later cells were treated with either 2-8 µmol curcumin, 20-40 µmol EGCG or a combination of the two. Control cells were treated with 0.005% DMSO. After 3, 5 or 7 days cell number was determined by the sulforhodamine B assay. All values are expressed as mean ± SE of at least 3 independent determinations performed in duplicate. At 3 days, either 4 or 5 µmol curcumin plus 25 µmol EGCG resulted in synergistic cytotoxicity, causing 20% greater cell death than the highest individual treatment (46±3% vs 24±4%). 5 days of treatment was even more effective with 3 µmol curcumin and 20 µmol of EGCG causing 11±4% and 34±2% cell death, respectively. While in combination the treatment was cytotoxic to 65±2% of cells, therefore showing even greater synergism. These results demonstrate that the administration of EGCG and curcumin in vitro, at concentrations similar to human plasma levels obtained during clinical trials, produce synergistic cytotoxicity in MDA-MB-231 cells. Additionally we have previously shown that EGCG modulates the activity of drug metabolizing enzymes in vivo. To determine if curcumin would act in a similar manner, female Swiss Webster mice were dosed with DMSO control, 200 mg/kg or 400 mg/kg curcumin p.o. for 1 and 2 weeks. Liver microsomes and cytosol were prepared 24 hours after the last dose. Results showed that curcumin did not alter hepatic GSH stores, but 400 mg/kg (2 week) increased GST activity. Furthermore 200 mg/kg (2 week) decreased CYP1A activity. Results indicate that the combination of curcumin and EGCG in vivo are likely to have greater effects on enzyme systems important in chemoprevention.

1659

COMPARATIVE EFFECTS OF NNK AND RESVERATROL ON INOS EXPRESSION AND INITIATION OF TUMORIGENESIS IN THE LIVER OF FEMALE A/J MICE.

R. H. Nsaif, O. M. Philip and <u>C. S. Mehta</u>. College of Pharmacy and Health Sciences, Texas Southern Univesity, Houston, TX.

4-(Methylnitrosoamino)-1-(3-pyridyl)-1-butanone (NNK) is an established potent lung tumorigen in rodents and humans, but there is a paucity of date regarding its action on the liver. Resveratrol (trans-3, 4', 5-trihydroxystillbene), a polyphenolic phytoalexin found in red grapes and fruits, is a known anti-inflammatory and antitumorigenic agent. The potential effects of resveratrol and NNK on iNOS expression and initiation of tumorigenesis were compared in the liver of A/J mice. The first group, served as control, was allowed free access to food and water ad libitum. The second group of 15 female A/J mice (5-6 weeks old) was administered resveratrol (50 ppm) in the diet for 28 weeks. The third group received NNK (9.1mg/mouse) in the drinking water for 7 weeks; this dose of NNK was sufficient to initiate tumorigenesis in the liver. The experiment was terminated 28 weeks later. Levels of iNOS and nitric oxide were determined by western blot and Griess reaction. Liver tissues were stained with H&E stain for tumor assessment. It was observed that administration of NNK significantly (p < 0.010) induced iNOS expression in the liver, whereas resveratrol had no effect on the levels of iNOS when compared to the control group. Measurement of nitric oxide production in urine by the Griess reaction showed that resveratrol significantly (p < 0.004) increased the production of nitric oxide, while NNK significantly (p < 0.004) reduced that production when compared to the control group. NNK caused an abnormal increase in cell size and induced cellular aggregation in the liver, but resveratrol had no effect on cell size when compared to that of the control group. In conclusion, effects of resveratrol on NNK-induced iNOS expression and initiation of tumorigenesis needs additional study in the liver.

### 1660

EPIGENETIC MECHANISMS OF ORGANIC TUMOR PROMOTERS AND THE ANTICARCINOGENIC ROLE OF RESVERATROL.

B. L. Upham, J. P. Scott, J. M. Carbone, L. Lee, A. M. Rummel and <u>J. E. Trosko</u>. Pediatrics & Human Development, National Food Safety and Toxicology Center, Michigan State University, East Lansing, MI.

Dicumyl and benzoyl peroxides act as tumor promoters in SENCAR mice, while di-t-butyl-peroxide does not. Tumor promotion requires the removal of growth suppression by decreasing gap junction intercellular communication (GJIC) and the induction of mitogenic intracellular pathways. N-acetylcysteine was needed to prevent cytotoxicity of benzoyl- but not dicumyl peroxide. Dicumyl and benzoyl peroxides both reversibly inhibited GJIC and transiently activated mitogen-activated protein kinase (MAPK), specifically extracellular receptor kinase, in WB-F344 rat liver epithelial cells, while the non-tumor promoting di-tert-butyl peroxide did not inhibit GJIC or activate MAPK. The consumption of red wine has been linked to the lower incidence of cancer and heart disease among the French population and the active component is thought to be the antioxidant resveratrol. Pretreatment with resveratrol prevented the GJIC-inhibitory effects by dicumyl but not benzoyl peroxide. These results clearly indicate that specific signaling and not general oxidative events are involved in the promoting effects of organic peroxides and anticarcinogenic effects of the antioxidant, resveratrol. Supported by the #P42 ES04911-07.

### 1661 MOLECULAR CLONING OF CYTOCHROME P450 2 AND 3A FROM LARGEMOUTH BASS.

A. McNally, T. Knowles and <u>D. S. Barber</u>. Center for Environmental and Human Toxicology, University of Florida, Gainesville, FL.

The largemouth bass (Micropterus salmoides, LMB) is a ubiquitous freshwater fish that is ecologically and economically important in freshwater ecosystems in Florida and much of the continental United States. Toxicity from exposure to environmental chemicals has been proposed as the cause of declining bass populations in several

Florida ecosystems. Despite the importance of biotransformation reactions in toxicity, very little is known about the ability of LMB to metabolize xenobiotics. The cytochrome P450 superfamily of enzymes are the primary mediators of phase I xenobiotic metabolism and lack of information on LMB P450 has hampered metabolism studies. We designed degenerate primers for CYP3A and CYP2 based on amino acid alignment of these proteins from numerous phyla including fish, mammals, and invertebrates. PCR amplification of cDNA prepared from male largemouth bass liver using these primers resulted in four products identified as P450. Two 886 bp fragments were obtained with the 3A primers that shared 73% and 81% identity with CYP 3A isoforms from Fundulus heteroclitus but were only 60% identical to each other. Using the CYP2 primers, a 666 bp fragment with 78% identity to CYP 2N1 and a 666 bp fragment with approximately 80% identity to CYP 2P isoforms from F. heteroclitus were obtained. This work provides the foundation to study the regulation of LMB phase I metabolic genes by environmental chemicals.

### 1662 ROLE OF USF AND NF-1 PROTEINS IN THE BASAL EXPRESSION OF HUMAN CYP1A2.

M. J. Narvaez<sup>2</sup>, G. V. Pickwell<sup>1</sup> and L. C. Quattrochi<sup>1</sup>. <sup>1</sup>Medicine, University of Colorado Health Sciences. Ctr., Denver, CO and <sup>2</sup>Pharmaceutical Sciences, University of Colorado Health Sciences. Ctr., Denver, CO.

Cytochrome P450 1A2 (CYP1A2) is a major cytochrome P450 present in the adult human liver. This enzyme is involved in the metabolism of many therapeutic compounds and shows high catalytic activity towards procarcinogens, such as arylamines, dietary heterocyclic amines, and aflatoxin B1. To better understand the molecular mechanisms of CYP1A2 regulation, we have characterized a region of the promoter (+3 to -176) which contains consensus E-box and NF-1 sites. Both sites were shown to specifically bind nuclear proteins from the human hepatoma cell line HepG2. Supershift analysis with specific antibodies to USF-1 and USF-2 indicated that the USF1/2 dimer interacts with the E-box motif. Analysis with specific antibodies to NF-1 proteins showed that some NF-1 protein members interact with the NF-1 motif. Site-directed mutagenesis of the USF and NF-1 binding sites was used to examine the role of these sites in basal CYP1A2 expression. Mutation of the Ebox site resulted in approximately 50% reduction in basal reporter gene activity, while mutation of the NF-1 site resulted in approximately 80% reduction in activity. These results further demonstrate the complex regulatory mechanisms governing the constitutive expression of human CYP1A2. This research was supported by grant NIHGM 54477.

## 1663 NONYLPHENOL ATTENUATES P450 INDUCTION BY TCPOBOP IN FVB/NJ MICE.

J. P. Hernandez and <u>W. Baldwin</u>. *Biological Sciences, University of Texas at El Paso, El Paso, TX*.

4-Nonylphenol (NP) binds and activates both the estrogen receptor (ER) and the pregnane-X-receptor (PXR), and 7-day exposure to NP has been shown to induce CYP2B and 3A family members. However, recent work demonstrated that gestational treatments and chronic treatments (32 weeks) of mice with 4-nonylphenol (NP) reduced some CYP3A family members and attenuated induction of CYP2B family members, potentially by down-regulating RXRa, PXR's dimerization partner. Therefore, we are interested in determining if NP could reduce the ability of FVB/NJ mice to respond to CAR or PXR ligands. Mice were treated for six weeks with honey as vehicle control or 50mg/kg/day NP in honey. At the end of six weeks control and NP-treated mice were split further into groups, and vehicle control mice were injected for three days with corn oil vehicle, dexamethasone (PXR inducer), or 1, 4-bis [2-(3, 5-dichloropyridyloxy)] benzene (TCPOBOP)(CAR inducer). NP treated mice were also split into more groups and injected with corn oil, dexamethasone, or TCPOBOP. Mice were euthanized and microsomes were prepared for immunoblot analysis of CYP3A1 and CYP2B6, which are transcriptionally activated by CAR and PXR. Immunoblots demonstrate TCPOBOP significantly induced CYP2B6, and that this induction was reduced by more than 50% lower in mice pre-treated with NP prior to TCPOBOP injections. NP had no significant effect on CYP3A induction by TCPOBOP. Furthermore, testosterone hydroxylation assays indicate that chronic treatment with NP can reduce TCPOBOP induction of P450s, suggesting that long-term exposure to NP may decrease an organism's ability to respond to toxicants. Mice treated with dexamethasone in conjunction with NP are currently being examined. The mechanism by which NP reduces an organism's ability to respond to toxicants is being investigated, and may include a reduction in RXRa, or an increase in co-repressors such as short heterodimeric protein, which represses steroid hormone receptor activity and is inducible by estrogens.

### 1664 DEVELOPMENT OF CHEMILUMINESCENT ASSAYS FOR MEASURING CYTOCHROME P450 ISOFORMS.

K. Roberts<sup>1, 2</sup>, R. Morgan<sup>1</sup>, C. Morris<sup>1</sup> and S. Woodhead<sup>1</sup>. <sup>1</sup>Molecular Light Technology Research, Cardiff, CF14 5DL, United Kingdom and <sup>2</sup>Cardiff University, School of Biosciences, PO Box 911, Cardiff, CF10 3US, United Kingdom. Sponsor: A. Smith.

Hybridisation protection assays (HPA) assays have been optimised to measure rat cytochrome p450 (CYP) 1A1 and 1A2 mRNA transcripts. These assays utilise short DNA oligonucleotides labelled with a chemiluminescent acridinium molecule as a probe to quantify the levels of mRNA transcripts. A hydrolysis step, that destroys any unhybridised probe or mismatched probe-target duplexes, is included making this technique ideally suited to measure specific mRNA transcripts where there are closely related gene products. The AE molecule reacts rapidly with hydrogen peroxide under alkaline conditions to produce light and the intensity of emitted light is a function of the amount of target present. As little as 0.1 fmol of transcript can be accurately quantified by this method. The assays were used to measure both the CYP1A1 and 1A2 levels, independently, in the rat hepatoma cell line H4IIE. When H4IIE cells were exposed to increasing concentrations of benzo(a)pyrene (0, 5, 10, 20 & 30mM) for 24 hours, CYP1A1 levels increased 50 fold in treated cells compared to untreated. An increase in expression of both 1A1 and 1A2 was seen in cells exposed to 30mM benzo(a)pyrene for 0, 6, 12 & 24 hours though a decrease was seen at 48 hours. Assays for b-actin and cyclophilin B, whose transcription levels can be monitored as internal control genes, were also designed. In conclusion, the HPA technique has been used successfully to measure changes in gene expression of specific CYP isoforms. The measurement of the specific mRNA from individual members of the CYP family will provide the ability to predict the potential of new compounds to activate certain cellular pathways and therefore provide mechanistic and toxicological information.

DEVELOPMENTAL CYTOCHROME P450 EXPRESSION IN THE MOUSE LUNG: SUSCEPTIBILITY DIFFERENCES TO METABOLICALLY-ACTIVATED PULMONARY CYTOTOXICANTS.

A. Taff<sup>1, 2</sup>, M. Bartosiewicz<sup>1</sup>, D. Rocke<sup>3</sup>, K. Ruggiero<sup>4</sup>, K. Butler<sup>5</sup>, <u>A. Buckpitt<sup>1</sup></u> and <u>C. Plopper<sup>2</sup></u>. <sup>1</sup>Molecular Biology, School of Veterinary Medicine, University of California, Davis, CA, <sup>2</sup>Anatomy, Physiology, Cell Biology, School of Veterinary Medicine, University of California, Davis, CA, <sup>3</sup>Applied Science, University of California, Davis, CA, <sup>4</sup>CSIRO Mathematical and Informational Sciences, Canberra, ACT, Australia and <sup>5</sup>Primary Industries Research, Victoria, VIC, Australia.

Earlier studies demonstrate substantial differences in susceptibility of adult and early postnatal animals to metabolically activated pulmonary toxicants. With the rise in incidence of chronic lung diseases in children and adults there is increasing public health concern about the effects of these substances on the lung. One chemical of particular concern is naphthalene, a polyaromatic hydrocarbon of consequence in the environment. To determine which other factors account for the higher susceptibility of neonates to toxicants like naphthalene, we have compared gene expression profiles using RNA isolated from mouse lungs. Tissue was harvested from neonatal (day 0), juvenile (day 7), weanling ng (day 21), and adult (day 56) mice. Total RNA was extracted from fresh tissue with Trizol, and quantified. CDNA was prepared from purified mRNA samples, fluorescent dye probes created, hybridized onto microarray slides, and read. Glass slides were spotted with 10, 000 mouse-specific 50mers purchased from MWG. Preliminary data reveal that CYP450 gene expression is generally upregulated with increasing age, with one notable exception: CYP2F2 which decreases approximately 25 % from neonatal to adult age (p < .01). In the mouse, naphthalene is predominantly metabolized by CYP2F2. This suggests that differential naphthalene toxicity seen at distinct developmental stages may be due to decreased levels of CYP2F2. Changes in injury/repair processes and their associated genes may also be important in delineating specific naphthalene toxicity at unique ages (analyses in progress). ### 1666

SYNERGISTIC INDUCTION OF CYP3A4 EXPRESSION BY RIFAMPICIN AND TCDD IN PXR-ENHANCED HEPG2 CELLS.

X. Gu<sup>1</sup>, T. Sheng<sup>1</sup>, S. Ke<sup>1</sup>, <u>P. E. Thomas<sup>2</sup></u>, W. Xie<sup>3</sup> and <u>Y. Tian<sup>1</sup></u>. <sup>1</sup>Vet. Physiology and Pharmacology, Texas A&M University, College Station, TX, <sup>2</sup>EOHSI, Rutgers University, Piscataway, NJ and <sup>3</sup>Center for Pharmacogenetics, School of Pharmacy, University of Pittsburgh, Pittsburgh, PA.

Cytochrome P450 3A4 is responsible for biotransformation of 50-60% of clinical drugs in the human liver. Rifampicin, a common clinical drug, is a putative ligand of pregnane X receptor (PXR) which activates the transcription of CYP3A4 upon binding of PXR to the regulatory regions of CYP3A4. TCDD (2, 3, 7, 8-tetra-

chlorodibenzo-p-dioxin), an ubiquitous environmental contaminant of public concern, exerts its toxic effects primarily by binding to the aryl hydrocarbon receptor (AhR) which acts as a transcription factor for cytochrome P450 1A1. In order to analyze the CYP3A4 inducers in cell culture, we developed cell lines by stable cotransfection of human PXR and luciferase reporter gene into HepG2 cells. The luciferase reporter gene was constructed using a combination of enhancer (-7836 to -7208) /promoter (-362 to +53) modules from CYP3A4 gene. The reporter gene is highly responsive to classic CYP3A4 inducer, rifampicin, in these PXR-enhanced cells. Interestingly, we found that rifampicin and TCDD show synergistic induction of the luciferase reporter gene. To investigate if rifampicin and TCDD exert synergistic effect on transcription of CYP 3A4 gene in natural state, we use real-time PCR to quantitate the relative levels of CYP3A4 mRNA in PXR-enhanced HepG2 cell line in response to rifampicine and/or TCDD treatment. The results indicate a synergistic induction of CYP3A4 expression by rifampicin and TCDD, suggesting AhR may be involved in the transcriptional regulation of CYP3A4. Supported in part by NIEHS grants ES09859 and ES09106.

### 1667 ALTERED HEPATIC CYTOCHROME P450 ENZYME EXPRESSION IN A CHOLESTATIC MOUSE MODEL.

S. M. Bandiera<sup>1</sup>, E. G. Hrycay<sup>1</sup>, D. Forrest<sup>2</sup>, R. Wang<sup>2</sup> and V. Ling<sup>2</sup>. <sup>1</sup>Faculty of Pharmaceutical Sciences, University of British Columbia, Vancouver, BC, Canada and <sup>2</sup>British Columbia Cancer Research Center, British Columbia Cancer Agency, Vancouver, BC, Canada.

The biosynthesis, metabolism, and transport of bile acids in liver are tightly regulated. Cytochrome P450 (CYP) enzymes play a major role in the biosynthetic pathway and may catalyze bile acid metabolism. The sister of p-glycoprotein (spgp), also known as the bile salt export pump, mediates biliary bile acid secretion. Spgpknockout mice lacking the spgp gene are mildly cholestatic, display enhanced bile acid hydroxylation, and develop severe cholestasis when fed a cholic acid (CA)-supplemented diet. The purpose of the present study was to investigate hepatic expression of individual CYP enzymes in spgp-/- mice to ascertain whether bile acids regulate CYP gene expression and to explore the role of CYP enzymes in bile acid metabolism. Female wild-type (WT) and spgp-/- mice were maintained on a normal diet or WT mice were fed a diet containing 0.5 % CA for a period of 4 days, after which they were killed and hepatic microsomes prepared. Immunoblot analysis was carried out using antibodies directed against various CYP enzymes. Total CYP content was lower by 38% and 20% in spgp-/- and CA-fed WT mice, respectively, relative to WT control mice. When expressed on a per mg protein basis, hepatic levels of Cyp1a2 were decreased in spgp-/- and CA-fed WT mice by 56% and 42%, respectively, compared to control mice. Levels of Cyp 2b9 and Cyp 2b10 were also diminished in spgp-/- mice by 29% and 36%, respectively. Moreover, hepatic expression of one Cyp3a enzyme was reduced by almost 70%, whereas expression of a second Cyp3a enzyme was increased in spgp-/- mice. NADPH-CYP-reductase levels remained unchanged. In conclusion, results of immunoblot analysis indicate that hepatic CYP expression profiles are altered markedly in the spgp-/cholestatic mouse model. Experiments are ongoing to determine which CYP enzymes catalyze synthesis of the tri- and tetrahydroxylated bile acid metabolites that accumulate during hepatic cholestasis.

### 1668

EXPRESSION OF CYPIA1 AND 1B1 MNRA IN BLOOD LYMPHOCYTES FROM TWO POPULATIONS IN SLOVAKIA COMPARED TO TOTAL PCBs LEVELS AND TEQS IN BLOOD.

M. van den Berg¹, R. Fernandez Canton¹, A. Kocan², H. T.Besselink³, <u>T. Sanderson¹</u> and <u>B. Brouwer</u>⁴. <sup>1</sup>Institute for Risk Assessment Sciences, Utrecht, Netherlands, <sup>2</sup>National Reference Center for Dioxins and Related Compounds, Bratislava, Slovakia, <sup>3</sup>Biodetection Systems B.V., Amsterdam, Netherlands and <sup>4</sup>Institute for Environmental Studies, Amsterdam, Netherlands.

Cytochrome P450 1A1 (CYP1A1) and 1B1 (CYP1B1) are enzymes that are inducible by low levels of halogenated polycyclic aromatics such as chlorinated dioxins (PCDDs), dibenzofurans (PCDFs) and biphenyls (PCBs) through activation of the aryl hydrocarbon receptor (AhR). The possible relationship between CYP1A1 or 1B1 mRNA levels in lymphocytes and dioxin and/or PCBs blood levels was examined using real time quantitative PCR analysis. CYP1A1 and 1B1 mRNA levels were determined in two different human populations in Slovakia; one highly PCB contaminated area and one representing background exposure. PCB blood levels were measured using gas chromatography-mass spectrometry and total dioxin equivalents (TEQs) using the DRE-Calux® assay. The average of total PCBs was greater in the contaminated population (1-35 mg/kg lipid) than background (1-5 mg/kg lipid). Fifteen individuals from the contaminated area had PCB levels 7 times higher than those to be considered background in both populations. The average of TEQs in blood was not different between the two populations. A distinct relationship was observed between intraindividual CYP1A1 and CYP1B1 expressions (r

sions  $(r_{=0.647, p(0.005, n = 268), reflecting the similar pathway of gene regulation mediated through the AhR. No relationship could be found between the gene expressions and total PCB levels; the same was true when adjusted for smoking and$ 

gender. However, stratified analyses showed that TEQs values were associated with CYP1A1 expression in the group of men living in the contaminated area (p(0.001; n=91). In conclusion, this study shows that CYP1A1 expressions in blood lymphocytes might be a useful biomarker for exposure to dioxin like compounds at levels that are close to background exposure.

### 1669

HISTONE DEACETYLATION EFFECTS OF THE CYP1A1 PROMOTER ACTIVITY, PROLIFERATION AND APOPTOSIS OF CELLS IN HEPATIC, PROSTATE AND BREAST CANCER CELLS.

K. Min, K. Joung, M. Cho, J. An, D. Kim and Y. Y. Sheen. *Pharmacy, Ewha Womans University, Seoul, South Korea.* Sponsor: Y. Cha.

We have studied the mechanism of action of TCDD on CYP1A1 promoter activity in both Hepa-1 and MCF-7 cells using transient transfection system with p1A1-Luc reporter gene. When HDAC inhibitors, such as trichostatin A, HC toxin and a novel HDAC inhibitor, IN2001 were cotreated with TCDD to the cells transfected with p1A1-Luc reporter gene, the basal promoter activity of CYP1A1 was increased by HDAC inhibitors. Also, in MCF-7 human breast cancer cells, HDAC inhibitors, such as IN2001 and trichostatin A increased the basal activity of CYP1A1 promoter but TCDD stimulated CYP1A1 promoter activity was not changed by HDAC inhibitors. And, in stably-transfected Hepa-1 cells with p1A1-Luc, HDAC inhibitors increased the basal promoter activity only. Also, we have investigated the effects of HDAC inhibitors on the human breast and prostate cancer cells in terms of cell proliferation and apoptosis based on SRB assay. IN2001 as well as trichostatin inhibited the MĈF-7, MDA-MB-231, MDA-MB-468, T47D, ZR75-1, PC3 cell growth dose-dependently. The growth inhibition of these cells with HDAC inhibitors was associated with profound morphological change, which suggests the HDAC inhibitors induced apoptosis of cells. The result of cell cycle analysis after 24h exposure of IN2001 showed G2/M cell cycle arrest in MCF-7 cells and apoptosis in T47D and MDA-MB-231 cells. [This work was supported by the grant from the ministry of environmental science]

#### 1670

EFFECTS OF QUERCETIN AND AMENTOFLAVONE ON CYP1 EXPRESSION IN RL95-2 ENDOMETRIAL CARCINOMA CELLS.

Z. R. Master and <u>K. L. Willett</u>. *Pharmacology, University of Mississippi, Oxford, MS.* 

Endometrial cancer is the most common gynecological malignancy in women. To model this disease and identify potential chemopreventatives, RL95-2 endometrial cancer cells derived from a moderately differentiated adenosquamous endometrial carcinoma were used. RL95-2 cells are estrogen- and Ah-receptor positive, and CYP1 genes are induced by BaP and TCDD exposure. Previous work in our laboratory screened a series of flavonoids for their ability to inhibit recombinant human microsomal CYP1-mediated ethoxyresorufin-O-deethylase (EROD) activity. Ouercetin (OT) and amentoflavone (AF) were identified for further study. RL95-2 cells were induced with TCDD (10 nM/24 hrs). To investigate the CYP1 inhibition pattern in intact induced cells, 30 min prior to EROD assays, quercetin and amentoflavone (0.5 to 5  $\mu$ M) were added. Quercetin (IC50 = 1.9  $\mu$ M) inhibited EROD activity in a dose-dependent manner. In intact cells, EROD measurements are not CYP1 isoform specific. Thus, western blots on cell microsomes prepared after 24 hr dosing with DMSO, TCDD (10nM), QT (5 µM), AF (5 µM), TCDD + QT and TCDD + AF were done. While immunoreactive CYP1B1 was non-detectable, CYP1A1 protein was increased 7-fold by TCDD alone and 14-fold by TCDD + AF, relative to DMSO control. Quercetin alone did not increase CYP1A1 protein above control levels, but CYP1A1 was increased 2.4-fold by AF alone. CYP1A1 levels in the TCDD + QT cotreated cells were decreased 41% compared to the TCDD alone. Because CYP1 family P450s have been implicated in both detoxifying chemotherapeutic drugs and activating xenobiotics to genotoxic intermediates, finding compounds that inhibit CYP1-mediated metabolism is an important goal in cancer and chemoprevention research. To determine the relative inhibition of CYP1A1 and CYP1B1 at the message level, we are also doing quantitative real time RT-PCR. CYP1A1 enzyme activity and protein levels were inhibited by quercetin in these endometrial cells which suggests that quercetin may be efficient in preventing the metabolic activation of carcinogens. (Supported by American Assoc. of Colleges of Pharmacy)

#### 1671

NO RELATIONSHIP BETWEEN NF- $\kappa$ B ACTIVATION BY PPAR $\alpha$  AGONISTS AND TCDD-MEDIATED INDUCTION OF *CYP1A1*.

D. E. Machemer<sup>1</sup>, A. Galijatovic<sup>1</sup>, D. J. Beaton<sup>1</sup>, Z. Li<sup>1</sup>, M. Karin<sup>1</sup> and <u>R. H. Tukey<sup>1,2</sup>. <sup>1</sup>Department of Pharmacology, University of California San Diego, La Jolla, CA and <sup>2</sup>Department of Chemistry & Biochemistry, University of California San Diego, La Jolla, CA.</u>

Cytochrome P450 1A1 (Cyp1a1) catalyzes the hydroxylation of a variety of xenobiotic compounds and is strongly induced by halogenated and polycyclic aromatic hydrocarbons through activation of the aryl hydrocarbon receptor (AhR).

Induction of Cyp1a1 and NF-κB activation appear to be linked in terms of function and regulation. Peroxisome proliferators stimulate NF-KB and production of inflammatory mediators in the liver, and thus may exert a regulatory influence on Cyp1a1. To further elucidate the relationship between peroxisome proliferators, the inflammatory cascade, and *Cyp1a1*, TCDD-mediated induction of *Cyp1a1* was investigated in wild-type, IKK $\beta^{*l}$ , TNF1 $^{*l}$ , and TNF1 $^{-l}$  C57Bl/6 mice. Embryonic fibroblasts from IKK $\beta^{*l}$ . C57Bl/6 mice exhibit a 50% reduction in IKK activity and a 90% reduction in NF-kB DNA binding activity. Signalling through TNFr1 has been shown to be responsible for 85-90% of NF-KB DNA binding and transcriptional activity of an NF-κB reporter gene. Mice were treated with PPARα agonist Wy-14643 (100 mg/kg), 16 µg/kg TCDD, or both compounds. Liver Cyp1a1 protein levels and enzymatic activity were quantitated. Cyp1a1 protein levels and enzymatic activity were quantitated. Cyp1a1 protein levels and enzymatic activity were not significantly different in  $IKK\beta^{+/-}$  mice when compared to  $IKK\beta^{+/+}$  mice. In both  $IKK\beta^{+/-}$  and  $IKK\beta^{+/-}$  mice, addition of Wy-14643 alone did not induce Cyp1a1, and Wy-14643 did not affect the TCDD inducibility of Cyp1a1 protein or enzymatic activity. TCDD-mediated induction of Cyp1a1 protein and enzymatic activity were not altered in TNFr1\*/- and TNFr1\*/- mice when compared to TNFr1\*/- mice. Regardless of TNFr1 genotype, Wy-14643 alone did not induce Cyp1a1, and Wy-14643 did not affect the inducibility of Cyp1a1 protein or enzymatic activity by TCDD. This suggests that TCDD-mediated induction of Cyp1a1 is not affected by peroxisome proliferators or by a significant loss of NF-KB activity in vivo. (Supported by USPHS grant ES10337)

## 1672 EFFECT OF EPIGALLOCATECHIN GALLATE AND EPICATECHIN GALLATE ON CYP450 ISOFORMS IN THE MALE SWISS WEBSTER MOUSE.

M. G. Goodin and <u>R. J. Rosengren</u>. Pharmacology and Toxicology Department, University of Otago, Dunedin, New Zealand.

Epigallocatechin gallate (EGCG) is a potent cancer-preventative agent. Specifically, EGCG has been shown to inhibit prostate tumor growth in a male athymic nude mouse model. However, no mechanism for this action has been determined. Therefore, the effect of EGCG and epicatechin gallate (ECG) on enzymes relevant to both the development of prostate cancer and carcinogen bioactivation were evaluated in the male Swiss Webster mouse. Mice were dosed with EGCG or ECG (25 or 50 mg/kg, ip) for 7 days and cytosolic extract and microsomes were prepared on day 8. All treatments were well tolerated by the mice. However, after 5 days of EGCG (50 mg/kg) one mouse was euthanised because it appeared ill and lost 4 g of body weight. This mouse had severe hepatotoxicity as indicated by an ALT of 1995 IU/L and extensive histological evidence of hepatic necrosis. All other mice had normal weight gain and normal levels of ALT activity. Enzymatic results demonstrated that EGCG and ECG (50 mg/kg) decreased CYP1A catalytic activity and polypeptide levels, while CYP3A catalytic activity and polypeptide levels were increased in response to EGCG (50 mg/kg). Specifically, EGCG and ECG inhibited CYP1A catalytic activity by 43 and 29% while CYP3A catalytic activity was induced by 52%, compared to vehicle control (1.19 vs. 0.78 nmol/mg/min). ECG (25 and 50 mg/kg), but not EGCG, inhibited prostatic aromatase activity by 31% compared to vehicle control. Hepatic COMT remained unchanged following catechin treatment. In conclusion, EGCG and ECG may play a cancer-preventive role in prostate cancer due to the induction of CYP3A and inhibition of aromatase, respectively. However, the results with EGCG (50 mg/kg) are tempered by the fact that this dose can produce hepatotoxicity in susceptible mice. A similar hepatotoxic profile occurs in BALB/c mice. Interestingly, this effect is species-specific as high doses of EGCG are not hepatotoxic in male rats.

# 1673 ENDOGENOUS REGULATION OF CYP1A1 INDUCTION IN HEPA 1c1c7 CELLS IS MEDIATED BY CALCIUM-DEPENDENT ADHESION.

L. M. Van Pay<sup>1</sup>, M. A. Pickart<sup>2,3</sup>, C. R. Ivarie<sup>3</sup> and <u>B. Allen-Hoffmann<sup>1,2,3</sup></u>.

<sup>1</sup>Molecular and Environmental Toxicology, University of Wisconsin, Madison, WI,

<sup>2</sup>Biotechnology Training Program, University of Wisconsin, Madison, WI and

<sup>3</sup>Pathology and Laboratory Medicine, University of Wisconsin, Madison, WI.

Previous studies in our laboratory have shown that disruption of cell-cell and cell-substratum interactions in Hepa 1c1c7 cells leads to an AhR-dependent induction of CYP1A1 mRNA levels in the absence of xenobiotics. In an effort to identify suspension-sensitive regulatory elements we performed deletion analysis of the 5' region of the human CYP1A1 promoter. These studies revealed that the xenobiotic responsive elements and GC box are essential for suspension-induced transcription, while the negative regulatory element (NRE) did not appear to play a role in the suspension mediated response. To specifically disrupt cadherin-mediated cell-cell adhesion, cells were shifted from high to low calcium-containing media. Steady state levels of CYP1A1 mRNA increased in wild-type Hepa 1c1c7 cells following a cadherin-disrupting shift from 1.8 mM calcium media to 0.05 mM calcium media. Additionally we show that β-catenin, an intracellular adherens junction protein

that binds to cadherins, coimmunoprecipitates with the AhR in wild-type Hepa 1c1c7 cells. We determined the expression patterns of adherens junction proteins in Hepa 1c1c7 wild-type, Class I and Class II mutant cell lines. All three cell lines express comparable levels of N-cadherin and  $\beta$ -catenin, however the expression of  $\beta$ -catenin was greatly reduced in the Class I mutants as compared to the other two cell lines. These data suggest that cadherin-mediated cell-cell adhesion may function in the endogenous regulation of CYP1A1 gene expression in Hepa 1c1c7 cells.

## 1674 EFFECT OF THIABENDAZOLE ON RAT HEPATIC XENOBIOTIC METABOLISING ENZYME ACTIVITIES.

B. G. Lake, C. Meredith, M. P. Scott and R. J. Price. BIBRA International Ltd.,, Carshalton, Surrey, United Kingdom.

The aim of this study was to examine the effect of the anthelmintic agent and fungicide thiabendazole (TB) on some markers of rat hepatic xenobiotic metabolism. Male Sprague-Dawley rats were fed control diet or diets containing 102-5188 ppm TB for 28 days. As a positive control for induction of hepatic xenobiotic metabolism, rats were also fed diets containing 1457 and 10155 ppm butylated hydroxytoluene (BHT). Treatment with TB and BHT resulted in dose-dependent increases in relative liver weight. TB was found to be a mixed inducer of cytochrome P450 (CYP) forms in the CYP1A and CYP2B subfamilies. The administration of high doses of TB resulted in the induction of 7-ethoxyresorufin O-deethylase and 7-pentoxyresorufin O-depentylase activities and CYP1A2 and CYP2B1/2 apoprotein levels. Levels of hepatic CYP mRNAs were determined by real-time quantitative reverse transcription-polymerase chain reaction methodology. Treatment with 5188 ppm TB produced 169-, 25-, 41- and 25-fold increases, respectively, in CYP1A1, CYP1A2, CYP2B1 and CYP2B1/2 mRNA levels In contrast to TB, BHT was a CYP2B form inducer in rat liver, increasing 7-pentoxyresorufin O-depentylase activity and CYP2B1/2 apoprotein levels. Treatment with 10155 ppm BHT produced 3115- and 972-fold increases, respectively, in CYP2B1 and CYP2B1/2 mRNA levels, whereas CYP1A1 and CYP1A2 mRNA levels were increased <4-fold. Both TB and BHT induced GSH S-transferase (GST) activities towards a range of substrates. GST activity towards 1-chloro-2, 4-dinitrobenzene as substrate was induced 3.1- and 3.9 -fold, respectively, by treatment with 5188 ppm TB and 10155 ppm BHT. In addition, TB and BHT produced 248- and 102-fold increases in GSTP1 mRNA levels, whereas GSTT1 mRNA levels were only increased around 4-fold. In summary, these results demonstrate that TB induces both phase I and II xenobiotic metabolising enzymes in rat liver. (Supported by the UK Food Standards Agency).

# 1675 CYP2E1 GENOTYPE AND PHENOTYPE IN A POPULATION OCCUPATIONALLY EXPOSED TO VOLATILE ORGANIC CHEMICALS (VOCS).

A. Mendoza-Cantu<sup>1</sup>, F. Castorena-Torres<sup>1</sup>, M. Bermudez<sup>1</sup>, R. A. Reyes<sup>1</sup>, L. Lopez-Carrillo<sup>2</sup> and <u>A. Albores<sup>1</sup></u>. <sup>1</sup>Cinvestav-IPN, Mexico City, D.F., Mexico and <sup>2</sup>Instituto Nacional de Salud Publica, SS, Cuernavaca, Mor., Mexico.

VOCs effects were studied in 103 employees of two print workshops. Environmental toluene and xylene levels exceeded maximum exposure level (MEL). The mean toluene concentration in an 8 h increased 52% compared to concentrations at the beginning of the working shift, whereas xylene levels increased 90%. As for toluene, there is a significant relationships between the toluene in the environment/ urinary hypuric acid with lymphocytary mRNA. Another statisctically significant was the relationship between methyl hypuric acid and the 1-hydroxy-chlorzoxazona(1-OHCZ)/chlorzoxazona (CZ). Although polymorfism did not modify toluene, there is a trend suggesting that individuals showing the c1 allele of the RsaI/PstI, polymorphism are more responsive to toluene mediated mRNA icrese than those showing the allele c2. Our results suggest that VOCs regulate CYP2E1 at different levels, i.e., toluene directly regulates mRNA content whereas xylene increases enzyme activity mainly (Supported by: EC contract: ERB IC18-CT980341 and Conacyt project M0061-M9602).

## 1676 CYP1A2 GENO- AND PHENOTYPE IN A POPULATION OF THE COAL REGION IN NORTHERN MEXICO.

F. Castorena<sup>1</sup>, A. Mendoza-Cantu<sup>1</sup>, M. Bermudez<sup>1</sup>, L. Lopez-Carrillo<sup>2</sup>, J. E. Salinas-Moreno<sup>3</sup> and <u>A. Albores<sup>1</sup>. <sup>1</sup> Cinvestav-IPN, Mexico City, D.F., Mexico, <sup>2</sup> Instituto Nacional de Salud Publica, SS, Cuernavaca, Mor., Mexico and <sup>3</sup> Secretaria de Salud, Sabinas, Coah., Mexico.</u>

CYP1A2 regulation by polycyclic aromatic hydrocarbons (PAHs) and the polymorphism influence was investigated in 46 masculine volunteers in the Coal Regio of Northern Mexico. PAHs exposure was estimated by the urinary excretion of 1-hydroxy pyrene (1-OHP) and CYP1A2 phenotype was assessed by the caffeine meta-

bolic ratio (CMR) and CYP1A2 mRNA in peripheral lymphocytes. Genotype was evaluated in the promotor region (-2964) and Intron 1. A 1-OHP gradient was observed in the population studied. The genotype distribution was: for the intron 1 C/C (0), C/A (45) and A/A (55%), and for the promotor G/G (37.5), G/A (39.5) and A/A (23%), both distributions were in agreement to the Hardy-Weimberg equilibrium model, and showed that, according to the CMR, a greater enzyme activity was observed in the A/A individuals compared to C/A (p<0.001). No correlation was observed between polymorphism in the promotor region and the parameters evaluated. These results suggest that PAHs affect the CYP1A2 phenotype in individuals with an A/A polymorphism in the intron 1 (Supported by: EC contract: ERB IC18-CT980341 and Conacyt project M0061-M9602).

1677

EFFECT OF SOY DIET ON EXPRESSION OF ADRENAL CYTOCHROMES P450 (CYP) 1A1, 1B1, 11A, AND STEROIDOGENIC ACUTE REGULATORY PROTEIN (STAR) IN RATS AFTER ADMINISTRATION OF 7, 12-DIMETHYLBENZANTHRACENE (DMBA).

X. Fu<sup>1</sup>, B. Blaydes<sup>1</sup>, S. Cooper<sup>1</sup>, J. R. Latendresse<sup>2</sup>, L. Muskhelishvili<sup>2</sup>, L. J. Hennings<sup>2</sup> and B. Delclos<sup>1</sup>. <sup>1</sup> Biochemical Toxicology, NCTR, Jefferson, AR and <sup>2</sup> Pathology Associates International, Jefferson, AR.

CYP1A1 and CYP1B1 are important in DMBA bioactivation. Although dietary soy has been shown to modulate the induction of CYP1A1 and 1B1 by DMBA in rat liver and mammary, the effects of soy on DMBA adrenal toxicity and enzymes potentially related to this toxicity have not been thoroughly investigated. In this study, the effect of a soy-containing diet on mRNA expression of CYP1A1 and CYP1B1 as well as two enzymes involved in steroid hormone synthesis in the adrenal, CYP11A and StAR, were examined. In contrast to CYP1A1, but like CYP1B1, constitutive expression of CYP11A and StAR are high in rat adrenal cortex and regulated via cAMP. Female Sprague-Dawley rats were placed on either soy-containing NIH-31 diet or soy- and alfalfa-free 5K96 diet from postnatal day (PND) 21 until sacrifice. On the first day of diestrus when the animals were PND 50  $\pm$  5, rats received either an oral dose of 80 mg/kg DMBA or sesame oil, the vehicle, and sacrificed at 24 h after treatment. Serum was collected at necropsy and corticosterone levels were measured and found not to be altered by DMBA. DMBA-induced apoptotic changes in adrenal glands, confirmed by TUNEL assay and activation of caspase 3, were more apparent in rats fed NIH-31 diet. mRNA expression was analyzed by real time RT-PCR. In comparison to controls, rats treated with DMBA in both dietary groups had greatly induced adrenal CYP1A1 but significantly lower CYP1B1. DMBA treatment also caused significantly lower expression of CYP11A and StAR relative to vehicle controls only in rats fed NIH-31 diet. It appears that different mechanisms underlie regulation of CYP1A1 and CYP1B1 expression by DMBA in rat adrenal gland and that dietary soy may affect DMBA-induced apoptosis and enzyme expression in rat adrenal.

1678

ROLE OF CYTOCHROME P4501A2 IN THE METABOLIC ACTIVATION OF 3-METHYLCHOLANTHRENE TO GENOTOXIC METABOLITES THAT PREFERENTIALLY BIND TO CYP1A1 PROMOTER *IN VITRO* AND MODULATE CYP1A1 GENE EXPRESSION.

B. Moorthy<sup>1</sup>, K. Muthiah<sup>1</sup>, S. R. Kondraganti<sup>1</sup>, G. Zhou<sup>2</sup> and W. Jiang<sup>1</sup>.

<sup>1</sup>Pediatrics, Baylor College of Medicine, Houston, TX and <sup>2</sup>School of Rural Public Health, Texas A&M University system, Houston, TX.

Cytochrome P4501A (CYP1A) enzymes play important roles in the bioactivation of 3-methylcholanthrene (MC) to genotoxic metabolites. Here, we tested the hypothesis that CYP1A2 plays a role in the metabolism of MC to metabolites that may covalently bind to CYP1A1 promoter and modulate CYP1A1 gene expression. Liver microsomes (2 mg) from MC-treated female wild-type (C57BL/6J) (WT) mice or CYP1A2-null (KO) mice were incubated at 37 °C for 2 h with MC (10  $\mu \text{M})$  in the presence of NADPH and plasmid DNA containing human CYP1A1 promoter (pGL3-1A1) (50  $\mu$ g). The plasmid DNA was re-precipitated and DNA adducts were analyzed by  $^{32}$ P-postlabeling. MC, in the presence of WT or KO microsomes, induced formation of 5 adducts that were not seen in the absence of NADPH. The adduct levels were 3-fold lower in the presence of KO microsomes, suggesting that CYP1A2 played an important role in the bioactivation of MC. In order to determine if MC adducts were located on the CYP1A1 promoter, the 1.6 kb CYP1A1 promoter insert was released from the pGL3-1A1 construct by restriction enzyme digestion, followed by gel electrophoresis and elution of the promoter (1.6 kb) and vector (5.2 kb) fragments. Postlabeling analyses of the promoter and vector fragments revealed that 85% of the adducts were present in the promoter fragment, suggesting that the MC-DNA adducts were preferentially formed in the promoter region. Transient transfection of the adducted plasmids into rat hepatoma (H4IIE) cells for 16 h, followed by treatment of the cells with MC (1  $\mu$ M) for 8 h resulted in 35% lesser induction of reporter (luciferase) gene expression, compared to that observed when control plasmids were used in transfection experiments. In conclusion, our results suggest an important role for CYP1A2 in the formation of sequence-specific MC-DNA adducts, which in turn attenuate CYP1A1 gene expression. (Supported by NIH grant ES09132.)

ARSENITE DECREASES PHENOBARBITAL- AND RIFAMPICIN-MEDIATED INDUCTION OF CYP3A4 BY DIFFERENT MECHANISMS IN CULTURED HUMAN HEPATOCYTES.

T. L. Noreault<sup>1</sup>, V. E. Kostrubsky<sup>2</sup>, S. G. Wood<sup>3</sup>, R. C. Nichols<sup>3,6</sup>, S. C. Strom<sup>4</sup>, H. W. Trask<sup>3</sup>, <u>S. A. Wrighton<sup>5</sup></u>, J. M. Jacobs<sup>3</sup>, P. R. Sinclair<sup>3,1</sup> and <u>J. F. Sinclair<sup>3,1</sup> Pharmacology & Toxicology</u>, Dartmouth Medical School, Hanover, NH, <sup>2</sup>Department of Safety Sciences, Pfizer, Ann Arbor, MI, <sup>3</sup>Research, VA Medical Center, White River Junction, VT, <sup>4</sup>Pathology, University Pittsburgh Med. Ctr, Pittsburgh, PA, <sup>3</sup>Research Laboratories, Lilly, Indianapolis, IN and <sup>6</sup>Microbiology/Immunology, Dartmouth Medical School, Indianapolis, NH.

In rodents, the receptor CAR mediates the induction of CYP3A by phenobarbital (PB), while the receptor PXR mediates the induction of CYP3A by dexamethasone. In studies with reporter constructs, however, human PXR (hPXR) is responsive to PB. We have previously reported that, in cultured rat hepatocytes, arsenite decreases induction of CYP3A protein by dexamethasone and PB with little to no decrease in CYP3A mRNA. These findings indicate that arsenite acts by a post-transcriptional mechanism and does not alter the interaction of CAR or PXR to its ligands or cofactors. Here we investigated the effect of arsenite on induction of CYP3A4 by either rifampicin or PB in cultured human hepatocytes. In PB-treated cells, arsenite decreased CYP3A4 protein and metabolism of testosterone to 6beta-hydroxytestosterone, an activity associated with CYP3A. There was no significant decrease in CYP3A4 mRNA, similar to our findings for rat CYP3A. In contrast, in rifampicintreated cells, arsenite decreased induction of CYP3A4 mRNA in parallel with decreases in CYP3A4 protein and the formation of 6beta-testosterone. Since hPXR is responsive to rifampicin, the results suggest that hPXR is more sensitive to inhibition by arsenite than rat PXR. However, since induction of CYP3A4 mRNA by PB is not decreased by arsenite, human CAR may be less sensitive to arsenite than hPXR. Thus, PB may utilize the human CAR receptor to induce CYP3A when PXR is inhibited. We are currently investigating the effect of arsenite on expression of reporter constructs of CAR and PXR. This work was supported by NIH (ES010426).

EXPRESSION OF AH RECEPTOR, ARNT, CYP1A1, AND CYP1B1 IN RAT MAMMARY EPITHELIA *IN VITRO* IS EACH SUBSTANTIALLY ELEVATED BY SPECIFIC EXTRACELLULAR MATRIX INTERACTIONS THAT PRECEDE DUCTAL FORMATION.

M. L. Larsen<sup>1</sup>, R. S. Pollenz<sup>2</sup> and C. R. Jefcoate<sup>1</sup>. <sup>1</sup>Pharmacology, University of Wisconsin, Madison, WI and <sup>2</sup>Biology, University of South Florida, Tampa, FL.

Cytochrome P4501B1 (CYP1B1), the major constitutively expressed CYP in the rat mammary gland, is induced by Ah-receptor (AhR) ligands, while CYP1A1 is usually only expressed after such induction. Each form contributes to carcinogenic activation of polycyclic aromatic hydrocarbons (PAHs). CYP1B1, AhR, and Arnt were very weakly expressed in rat mammary epithelial cells (RMEC) when grown on plastic, even after AhR activation by TCDD. RMEC cultured on Matrigel (predominately laminin) or on a floating gel of collagen I demonstrated tubular organization and substantially increased basal CYP1B1 and induced CYP1A1 expression, in parallel with large increases in AhR and Arnt. Collagen I, collagen IV, and laminin, plated as thin films, were all unable to reproduce the tubular organization of RMEC or the increases in AhR, Arnt, or CYP expression. However, a thick, adherent collagen I bed recapitulated the substantial increases in AhR, Arnt, basal CYP1B1, and induced CYP1A1 expression, but without supporting tubulogenesis. These increases in protein expression were observed within  $\hat{24}h$  of  $\check{R}MEC$  dispersal on Matrigel, and substantially prior to tubulogenesis (3- to 5 days). Increases in AhR, Arnt, and CYP expression were closely paralleled by enhanced expression of beta-catenin and E-cadherin, components of cell-cell adhesion complexes. Synthetic peptides that selectively antagonize E-cadherin function and integrin-ECM interactions each reduced tubular formation without diminishing AhR, Arnt, and CYP expression. These data demonstrate that extracellular matrix surface adhesion interactions, which may also subsequently promote tubule morphogenesis, mediate AhR and Arnt expression, which, in turn, enhances CYP expression. Tubule morphology is not needed for this expression sequence and is more demanding on adhesion interactions.

ACTIVITIES OF CYP2E1 AND 1A2 IN PATIENTS WITH HEPATITIS C (HC) AND HC-ASSOCIATED PORPHYRIA CUTANEA TARDA (PCT/HC).

S. I. Shedlofsky<sup>1,3</sup>, R. T. Tosheva<sup>1</sup>, R. A. Blouin<sup>1</sup>, C. M. Charriez<sup>1</sup>, C. K. Hallberg<sup>2</sup> and K. Anderson<sup>2,3</sup>, <sup>1</sup>University of Kentucky, Lexington, KY, <sup>2</sup>University of Texas Med. Branch, Galveston, TX and <sup>3</sup>General Clinical Research Centers, Lexington, KY.

Liver injury in HC very likely involves increased hepatic oxidative stress with hepatic cytochromes P450 activities probably contributing to it. We report initial results on the activities of two P450 isoforms known to leak reactive oxygen, and other markers for oxidative stress, in patients with HC, PCT/HC and controls. METHODS: Chlorzoxazone and theophylline oral clearances were used as markers of CYP2E1 and 1A2, respectively; urines were collected for analysis of F2-isoprostanes; blood samples were collected for hyaluronic acid (HA) and procollagen propeptide III (PPIII). 24 patients with HC who had not been treated recently for their infection, 11 patients with PCT/HC, and 10 controls have been studied to date. Correlations were made between CYP 2E1 and 1A2 and histological activity and fibrosis scores, urinary F2-isoprostanes, HA and PPIII. For CYP1A2, smokers were analyzed separately from non-smokers. All PCT patients were smokers. RE-SULTS: CYP2E1 activities for HC patients with mild, moderate or severe histological injury were 5.28 +2.05(n=10), 3.43 +1.54(n=8) and 4.64+2.13(n=6) respectively and were not statistically significant. Results for CYP 1A2 activities in the above groups were divided in smokers and non-smokers and are as follows: mild 0.31 +0.16 (n=2), moderate 0.30 +0.07 (n=4) and severe 0.25 +0.03 (n=4) for nonsmokers and mild 0.45 +0.19 (n=8), moderate 0.90 +0.30 (n=4) and severe 0.69 +0.30 (n=2) for smokers. Results in patients with PCT/HC for both CYP1A2 and 2E1 were not statistically significant from HC or controls. Histological scores and levels of HA (r=0.347), PPIII (r=0.214) and F2-isoprostanes (r=0.048) show weak or low correlation. CONCLUSIONS: These preliminary results do not show good correlations between degree of liver injury and measures of oxidative stress in HC or PCT/HC. However, due to large variability in P450 activities, results from a larger number of subjects will be needed

1682

IDENTIFICATION OF CYP2E1-DEPENDENT GENES INVOLVED IN CARBON TETRACHLORIDE INDUCED LIVER INJURY: A MODEL FOR CHEMICAL TOXICITY MEDIATED BY FREE RADICALS.

S. Avasarala and S. Lee. *Biochemistry, The Chinese University of Hong Kong, Shatin, Hong Kong, Hong Kong.* Sponsor: <u>K. Chan</u>.

The hazardous effects of chemicals are of great concern and widely studied in an effort to determine the mechanisms underlying their toxicity and carcinogenicity. Chemicals such as carbon tetrachloride (CCl<sub>4</sub>) and acetaminophen induce liver injury through free radical mechanism. CCl<sub>4</sub> is considered as a prototype for better understanding of free radical mediated hepatotoxicity. The biochemical basis of CCl<sub>4</sub> induced lipid peroxidation has been well studied but molecular mechanism underlying this injury remain to be elucidated. The hepatotoxicity of CCl<sub>4</sub> is mainly mediated by cytochorme P4502E1 (CYP2E1) that belongs to P450 (P-450s) superfamily of hemoproteins, which carry out oxidative metabolism of many endogenous and xenobiotic chemicals. Previous studies in our laboratory demonstrated that mice, which lack CYP2E1 expression, were resistant to liver damage after i.p. administration of CCl<sub>4</sub> (1 ml/kg), thus indicating that CYP2E1 is the major factor involved in CCl4 induced liver injury. In order to depict the molecular mechanism underlying this event, CYP2E1-null mice were used as an in vivo model and fluorescent differential display (FDD) method was employed to identify CYP2E1-dependent genes. Approximately thirty-five differentially expressed FDD fragments have been excised, reamplified, subcloned and sequenced. The expression levels of genes related to metabolism of lipids, inflammatory response and hepatocyte damage were confirmed by northern blotting. Further characterization of these genes for their temporal and tissue expression may help us to identify their roles in CCl<sub>4</sub> induced hepatotoxicity thus giving clear insight into the molecular biology of free radical mediated liver injury. (Supported by a grant from the Research Grants Council of the HKSAR project No.CÜHK4135/01M).

## 1683 NEUROPROTECTIVE EFFECTS OF CYP2D6 OVEREXPRESSION IN DIFFERENTIATED PC12 CELLS.

R. D. Harbison<sup>1</sup>, M. Banasik<sup>1, 2</sup>, T. Stedeford<sup>1, 2</sup>, N. Matoh<sup>3</sup>, S. Tanaka<sup>3</sup>, M. Takehashi<sup>3</sup> and K. Ueda<sup>3, 1</sup>Department of Environmental and Occupational Health, University of South Florida, Tampa, FL, <sup>2</sup>Laboratory of Toxicology and Risk Assessment, Polish Academy of Sciences, Gliwice, Poland and <sup>3</sup>Laboratory of Molecular Clinical Chemistry, Institute for Chemical Research, Kyoto University, Uji, Japan.

Clonal pheochromocytoma cell lines overexpressing cytochrome P450 2D6 (CYP2D6) were established. CYP2D6 was localized in the endoplasmic reticulum, and its enzymatic activity in the microsomal fraction was confirmed by using high

performance liquid chromatography analysis with [guanidine-14C]debrisoquine as a substrate. Overexpression of CYP2D6 protected both actively dividing and differentiated cells against the toxic effects of 1-methyl-4-phenylpyridinium ion at the concentration range of 20 to 40 microM, as assessed by the 3-(4, 5-dimethylthiazol-2-yl)-2, 5-diphenyltetrazolium bromide assay. The production of reactive oxygen species in the mitochondria was suppressed. The cytotoxicity of 1-methyl-4-phenyl-1, 2, 3, 6-tetrahydropyridine was unchanged in both actively dividing and differentiated cells overexpressing CYP2D6 versus mock-transfected controls at concentrations up to 500 microM. These results suggest that the lowered enzyme activity of CYP2D6 in individuals, termed poor metabolizers may represent a risk factor from exposure to select neurotoxicants.

1684

EFFECT OF THE PROTOTYPICAL INDUCER RIFAMPICIN ON CYTOCHROME P450 3A INDUCTION IN LONG-TERM CULTURES OF HUMAN HEPATOCYTES.

C. M. Chandler, G. Zhang, R. Clark, C. L. Crespi and D. M. Stresser. Discovery Labware, BD Biosciences, Woburn, MA.

The demand for pharmacological and toxicological use of primary cultured human hepatocytes is increasing. However, high quality primary human hepatocytes suitable for these studies are available only in limited supply. The goal of this study was to examine if long-term cultures of hepatocytes are suitable for cytochrome P4503A induction studies. The use of long-term cultures would thus greatly increase the experimental window for induction studies, permit repeat experiments with material from the same donor and allow for a more efficient use of this scarce resource. Hepatocytes were isolated from livers of 5 donors and maintained in hepatocyte culture medium for different periods up to 4 - 9 weeks before culture quality had significantly deteriorated or became unresponsive to inducer. Morphological examination showed that cuboid shape of hepatocytes and monolayer appearance could be maintained during culture however, culture quality declined with time in culture as expected and varied between donors. CYP3A induction was studied weekly or bi-weekly using 20 mM rifampicin (RIF), a prototypical inducer for CYP3A4. After the final day of the three-day treatment, the activity of testosterone 6b-hydroxylase was determined. Treatment with RIF caused a minimum 7-fold and maximum 120-fold induction in testosterone 6b-hydroxylase activity, depending on donor or length of time in culture. In all five donors, RIF-induced CYP3A fold-induction at or near the final week in culture was comparable to that in the 1st week of culture. In general, the fold-induction response was higher after 2 weeks of culture due to a decreased basal level of CYP3A activity. Our results demonstrate that long-term cultures of human hepatocytes are suitable for CYP3A induction testing and that culture use within one week of isolation is not required.

## 1685 THE USE OF IMMORTALIZED HEPATOCYTES IN METABOLISM AND INDUCTION STUDIES.

K. C. Lyon, M. Czerwinski, P. Toren, M. Perry and <u>A. Parkinson</u>. *XenoTech LLC, Lenexa, KS*.

Ea1C-35 and Fa2N-4 are two SV40-immortalized human hepatocyte cell lines developed by Multicell Technologies (Warwick, RI). Czerwinski et al (Drug Metabolism Reviews 35, suppl 2, #462, 2003) has previously demonstrated that multiple cytochrome P450 (CYP) enzymes are inducible in the Fa2N-4 cells. In the current study, we investigated the CYP activity in vehicle and enzyme inducertreated cultures to characterize the function of the major nuclear receptor pathways in the two cell lines. Using LC/MS/MS methods, we demonstrated that both cell lines metabolize CYP-specific substrates for CYPs 1A2 (phenacetin), 2B6 (bupropion), 2C9 (diclofenac), 2C19 (S-mephenytoin), 2D6 (dextromethorphan) and 3A4 (midazolam). In addition, we examined the response of the cell lines to compounds that regulate enzyme induction through specific nuclear receptor pathways. Treatment of the Ea1C-35 and Fa2N-4 cells with aryl hydrocarbon receptor agonists including 3-methylcholanthrene, Bnaphthoflavone and omeprazole caused an increase in CYP1A2 activity. Likewise, dosing of Ea1C-35 and Fa2N-4 cells with pregnane X receptor agonists such as rifampin, hyperforin and ciglitazone caused an increase in CYP3A4 activity. In summary, these cell lines demonstrate hepatocyte-like CYP-mediated metabolism and induction through distinctive nuclear receptor pathways. The use of the cell lines present a promising alternative to primary cultures of human hepatocytes for evaluating both metabolite stability and enzyme induction of new chemical entities.

1686

VALIDATION OF POOLED CRYOPRESERVED HUMAN HEPATOCYTES AS A MODEL FOR METABOLISM STUDIES.

G. Zhang, C. M. Chandler, A. Dandeneau, C. L. Crespi and D. M. Stresser. Discovery Labware, BD Biosciences, Woburn, MA.

Primary human hepatocytes are one of the most important systems for xenobiotic metabolism and toxicity studies. However, the demand for fresh human hepatocytes far exceeds current supply. Cryopreserved human hepatocytes represent a con-

venient and biologically relevant model to mitigate this issue. The aim of the study was to validate a pool of cryopreserved human hepatocytes as a model for drug metabolism studies. Four lots of hepatocytes were selected based on previously characterized viability, P450 isoform- and uridine diphosphate glucuronosyltransferase (UGT)-activity. After enrichment of *vid*ole cells using a percoll purification, hepatocytes (0.5x106 cells/ml) were incubated with 25 uM 7-ethoxycourmarin (7-EC) in Williams Medium E in a 24-well plate for different times up to 240 minutes. The formation of 7-hydroxycoumarin (7-HC), and its glucuronide (7 HCG) and sulfate (7-HCS) were measured using HPLC. The cell *via*bility was monitored over the culture period by both trypan blue exclusion and the leakage of lactate dehydrogenase. Cell viability was well maintained during the entire 240 minute incubation period (essentially unchanged from initial 77% viability). Formation of all three metabolites (7-HC, 7HCG and 7-HCS) was linear with time of incubation except that 7-HCS was not detected at the first incubation time point (30 min). After 240 min of incubation, the total metabolism from the three metabolites was 11.6 nmol/106 cells, an average of 12.7 and 10.4 nmol/106 cells from two separate experiments. In other experiments, the metabolic stability of 10 compounds was studied and compared to literature values. Our results demonstrate the suitability of this pool for in vitro drug metabolism studies.

## THE ONTOGENY OF HEPATIC CYTOCHROME P450S IN SPRAGUE-DAWLEY RATS.

B. T. McPhail, S. Muralidhara and J. Bruckner. University of Georgia, Athens, GA.

Physiological and biochemical changes that occur as an infant grows have the potential to substantially alter the toxicokinetics and adverse effects of solvents, pesticides and other chemicals. Limited information is available on the ontogeny of P450s in both humans and rodents. The objective of our project was to thoroughly characterize the maturation of several hepatic P450s that are involved in the metabolic activation of halogenated solvents and in the inactivation of pyrethroid insecticides. Groups of Sprague-Dawley rats of mixed sexes, ranging in age from 5 to 60 days, were sacrificed. Livers were removed, homogenized, and the microsomes isolated for measurement of total P450 levels and p-nitrophenol hydrolyase (CYP2E1), ethoxyresorufin O-deethlyase (CYP1A1/2) and pentoxyresorufin Odeethylase (CYP2B1/2) activities. Activities of P450s were very low in the liver of neonatal rats, but increased substantially within the first 15 days of life. Twentyone-day-old pups exhibited maximal CYP2E1 activity of 2.75 nmol/mg protein. CYP2E1 diminished slightly by 30 days of age, but CYP1A1/2 activity rose dramatically (i.e., from 1000 to 6000 nmol/mg protein). CYP2B1/2 remained relatively constant, while total P450 levels gradually increased from birth to puberty. Our findings indicate that activities of CYP1A1/2, 2B1/2, and 2E1 in rats are very low at birth, rise to maximums that exceed adult levels by 20-30 days of age and then progressively diminish through sexual maturity.

### 1688

ORAL ADMINISTRATION OF BENZO(A) PYRENE IN THE INTACT MOUSE: DETOXICATION BY INDUCIBLE CYP1A1 IS MUCH MORE IMPORTANT THAN METABOLIC ACTIVATION.

D. W. Nebert, H. Dong, T. P. Dalton, M. L. Miller, S. Derkenne, C. Curran and S. Uno. Environmental Health and Center for Environmental Genetics, University of Cincinnati, Cincinnati, OH.

There is a general rule in pharmaceutical companies that, if any test drug coming through the pipeline shows induction of CYP1 proteins (i.e. AH receptor activation), it is immediately dropped for fear of its likelihood to cause cancer. Benzo[a]pyrene (BaP) must be metabolically activated to exert its toxic effects. Numerous studies performed in vitro and in cell culture systems have shown unequivocally that the CYP1A1 enzyme metabolically activates BaP into toxic and DNA-binding intermediates that are associated with mutations and cancer. We therefore sought to confirm the role of CYP1A1 in metabolic activation of BaP, comparing Cyp1a1(-/-) knockout with Cyp1a1(+/+) wild—type miceing oral BaP at doses of 125, 12.5 and 1.25 mg/kg/day. Cyp1a1(-/-) mice at the 125-mg dose die within 30 days whereas Cyp1a1(+/+) mice appeared healthy 1 year later. The rate of BaP clearance was 4-fold greater in wild-type than knockout mice. The cause of death in Cyp1a1(-/-) mice receiving oral BaP was immunotoxicity, including toxic chemical depression of the bone marrow; effects on the Cyp1a1(-/-) mouse's immune system were detected even at oral BaP doses of 12.5 and 1.25 mg/kg/day. DNA post-labeling studies demonstrated statistically significantly (P<0.0001) higher BaP-DNA adduct levels in Cyp1a1(-/-) than Cyp1a1(+/+) in liver, small intestine, spleen and marrow at the 125 and 12.5 mg/kg/day BaP doses, and in spleen even at the 1.25 mg/kg/day dosage. We conclude that, despite previous studies in vitro and in cell culture to the contrary, the present data indicate —in the intact animal——inducible CYP1A1 is much more important in detoxication and protection against oral BaP toxicity than in mice lacking CYP1A1. Whether the protection comes primarily from the liver, the GI tract, or something in the context of the immune system—remains to be determined.——Supported, in part, by NIH grants P30 ES06096, R01 ES06321 and R01 ES08147.

## ABILITY OF FLAVONOIDS IN ST. JOHN'S WORT TO DECREASE CYP1 ACTIVITIES.

A. M. Chaudhary and K. L. Willett. Pharmacology, The University of Mississippi, University, MS.

As with many available herbal preparations, components of St. John's wort are not completely characterized with respect to their interaction with drug metabolizing enzymes. CYP1B1 is a cytochrome P450 gene involved in metabolizing both polycyclic aromatic hydrocarbons and estradiol to potentially carcinogenic intermediates. CYP1B1 is also over expressed in human cancer cells. Finding compounds that inhibit CYP1B1-mediated metabolism is an important goal in cancer and chemoprevention research. In order to identify flavonoids that specifically inhibit recombinant CYP1B1 compared to CYP1A1, nine flavonoids were screened for their ability to inhibit ethoxyresorufin-O-deethylase (EROD) activity. Rutin, hyperoside, and homoeriodictoyl did not inhibit in either system whereas quercetrin, kaempferol, myrecetin and isoquercetin did not specifically inhibit CYP1B1 relative to CYP1A1. Quercetin (IC50s: 1A1= 4.6 µM; 1B1 = 3.25 µM) and amentoflavone (IC50s: 1A1= no inhibition; 1B1 = 4.2 µM) did exhibit some specificity of inhibition and were selected for further study in 22Rv1 prostate cancer cell. Prostate cancer is the most common cancer in US men and second leading cause of cancer death in men. While TCDD induced EROD activity (19 ± 1.8 pmol/mg/min), quercetin and amentoflavone alone did not induce activity relative to DMSO control treated cells. TCDD induced cells (1nM/24 hr) were then dosed with different concentrations (0.5-5 µM) of flavonoids. After 30 min, EROD assays were done. Relative to TCDD alone, quercetin inhibited EROD activity (IC50:  $3.74 \pm 0.3 \; \mu M)$  in dose dependent manner in 22Rv1 prostate cells. In contrast, amentoflavone did not inhibit EROD activity. In intact cells EROD is not CYP isoform specific. Therefore, qRT/RT PCR and western blots are being used to determine the relative inhibition of CYP1B1 and CYP1A1 in the prostate cells. By distinguishing relative roles of cytochrome P450s (specifically CYP1B1 vs. CYP1A1) in different human cancer cell lines, methodologies can be developed to provide better diagnostics and possibly new therapies against cancer formation. THEOPHYLLINE METABOLISM AND PHARMACOKINETICS IN CYP1A2(+/+) WILD-TYPE AND CYP1A2(-/-) KNOCKOUT MICE.

S. Derkenne, <u>C. Curran</u>, <u>T. P. Dalton</u>, <u>H. G. Shertzer</u> and <u>D. W. Nebert</u>. *University of Cincinnati, Cincinnati, OH*.

Theophylline is widely used in the treatment of chronic obstructive pulmonary diseases. Plasma pharmacokinetics and renal excretion of theophylline and its metabolites (1-methyl- and 1, 3-dimethyluric acid, 3-methylxanthine) were investigated in Cyp1a2(+/+) wild-type C57BL/6J and Cyp1a2(-/-) knockout mice (C57BL/6J). Following a single i.p. dose (8 mg/kg), urine was collected during the next 24 h and sequential blood samples were drawn. Some mice were treated with i.p. 2, 3, 7, 8tetrachlorodibenzo-p-dioxin (TCDD; 10 µg/kg) 24 h prior to theophylline administration. Plasma and urine concentrations of theophylline and its metabolites were determined by high-performance liquid chromatography. We confirmed that this dose of theophylline (8 mg/kg i.p.) gave linear pharmacokinetics by testing 4 doses. The half-life of theophylline elimination from blood was more than 4 times longer in Cyp1a2(-/-) than Cyp1a2(+/+) mice  $(172 \pm 33 \text{ vs } 40.4 \pm 8.8 \text{ min, mean } \pm \text{SD})$ and more than 10 times different after TCDD treatment (152  $\pm$  28 vs 13.5  $\pm$  5.0 min). Theophylline clearance was concomitantly 4 times slower in Cyp1a2(-/-) than Cyp1a2(+/+) mice  $(2.6 \pm 0.4 \text{ vs } 10 \pm 1.5 \text{ ml/min/kg})$  and more than 10 times different after TCDD treatment  $(3.4 \pm 0.94 \text{ vs } 32 \pm 7.7 \text{ ml/min/kg})$ . Thus, the total area under the plasma theophylline concentration-time curve (AUC) was 3 times larger in Cyp1a2(-/-) than in Cyp1a2(+/+) mice (2346 vs 794 mg min/ml); TCDD treatment increased this difference to 8-fold (2046 vs 255 mg min/ml). The urinary 1-methyluric acid is 8 times greater in Cyp1a2(-/-) mice after TCDD treatment (3.0  $\pm$  0.5 vs 0.37  $\pm$  0.10, percent of injected amount of drug); in contrast, there is little change in Cyp1a2(+/+) mice after TCDD treatment (17  $\pm$  1.6 vs  $15 \pm 4.2$ ). We conclude that CYP1A2 (which is TCDD-inducible) is the major enzyme metabolizing theophylline; there is a second enzyme, however, and it is TCDD-inducible and responsible for a small amount of 1-methyluric acid forma--Supported, in part, by NIH grants P30 ES06096, R01 ES06321 and R01 ES08147.

### 1691

DECREASED CYP1A1-DEPENDENT ENZYME ACTIVITY AND PROTEIN LEVELS IN HEPG2 CELLS EXPOSED TO BENZO(A)PYRENE IN THE PRESENCE OF 1-NITROPYRENE.

S. Cherng<sup>1, 2</sup>, S. Hsu<sup>3</sup>, J. Yang<sup>4</sup> and H. Lee<sup>1</sup>. <sup>1</sup>Institute of Toxicology, Chung Shan Medical University, Taichung, Taiwan, <sup>2</sup>Food Science and Nutrition, Hung Kuang University, Taichung, Taiwan, <sup>3</sup>Department of Education & Research, Taichung Veterans General Hospital, Taichung, Taiwan and <sup>4</sup>Department of Life Science, National Tsing Hua University, Hsinchu, Taiwan. Sponsor: P. Howard.

The genotoxicity of polycyclic aromatic hydrocarbons (PAHs) and nitrated PAHs may be influenced by interaction of the compounds at the level of enzyme activity. Limited information was available concerning the effect of 1-nitropyrene (1-NP) on benzo[a]pyrene (BaP)-induced genotoxicity in mammalian cells. In this study, the human ĥepatoma cell line HepG2 was simultaneously treated with 1-NP and BaP to investigate the effects of chemical interaction on the genotoxicity of this binary mixture. The BaP-DNA adduct levels, evaluated by 32P-postlabeling, decreased in the presence of added 1-NP in a dose-dependent manner. Our results showed that the inhibition of BaP-DNA adduct formation by 1-NP was due to decreased cytochrome P450 1A1 (CYP1A1)-linked aryl hydrocarbon hydroxylase activity. Furthermore, northern blot analysis showed that 1-NP slightly attenuated BaP-induced CYP1A1 mRNA expression, but western blot analysis revealed a large decrease in the level of CYP1A1 protein. Analysis of in vitro proteolysis demonstrated that the addition of 1-NP enhanced CYP1A1 protein degradation. The proteolysis of CYP1A1 protein was inhibited by the addition of an antioxidant, dithiothreitol. These findings suggested that a posttranslational mechanism is involved in loss of CYP1A1 protein, causing the decrease of BaP-DNA adduct levels in the presence of binary mixtures of 1-NP and BaP.

### 1692

ROLE OF MOUSE CYP2E1 IN THE O-HYDROXYLATION OF P-NITROPHENOL: COMPARISON OF ACTIVITIES IN *CYP2E1* (-/-) AND WILDTYPE MICE.

K. K. Wolf<sup>1</sup>, S. G. Wood<sup>3</sup>, J. L. Bement<sup>3</sup>, P. R. Sinclair<sup>3, 2, 1</sup>, S. A. Wrighton<sup>4</sup>, E. Jeffery<sup>5</sup>, F. J. Gonzalez<sup>6</sup> and J. F. Sinclair<sup>3, 2, 1</sup>. <sup>1</sup> Pharmacology and Toxicology, Dartmouth Medical School, Hanover, NH, <sup>2</sup> Biochemistry, Dartmouth Medical School, Hanover, NH, <sup>3</sup> VA Medical Center, White River Junction, VT, <sup>4</sup> Lilly Research Laboratories, Indianapolis, IN, <sup>5</sup> Food Science and Human Nutrition, University of Illinois, Urbana, IL and <sup>6</sup> Laboratory of Drug Metabolism/ Disposition, National Cancer Institute, Bethesda, MD.

Selective enzymatic activities are used to identify the role of an individual form of CYP in a particular biotransformation. p-Nitrophenol O-hydroxylation (PNPH) has been widely used as a measure of CYP2E1. However, rat and human forms of CYP3A have also been shown to catalyze this activity. In mice, the contribution of CYP3As and CYP2E1 to PNPH is not known. Here we compared hepatic microsomes from Cyp2e1 (-/-) and wild type mice to investigate the contribution of constitutive and alcohol-induced levels of murine CYP2E1 and CYP3A to PNPH. In untreated mice, hepatic levels of PNPH were much greater in wildtype mice compared to Cyp2e1 (-/-) mice, suggesting a major role of CYP2E1 in catalyzing PNPH. Hepatic levels of PNPH were not significantly different between males and females, even though females have dramatically higher levels of CYP3A. Treatment with ethanol in combination with isopentanol resulted in induction of CYP3A proteins in wildtype and knockout mice, and CYP2E1 protein in wildtype mice. The alcohol treatment increased PNPH in hepatic microsomes from wildtype mice but not from knockout mice. Our findings suggest that constitutive and alcohol-induced forms of mouse CYP3A have little to no role in PNPH. Therefore, in untreated and alcohol-treated mice, PNPH can be used as an unambiguous assay for CYP2E1.

### 1693 STUDY OF METABOLIC INTERACTIONS OF FIPRONIL AND SOME CYP3A4 SUBSTRATES.

J. Tang, A. Usmani, E. Hodgson and R. L. Rose. Environmental and Molecular Toxicology, North Carolina State University, Raleigh, NC.

Fipronil, a highly active and broad spectrum insecticide from the phenyl pyrazole family, is a potent disruptor of the ?-aminobutyric acid (GABA)-gated chloride channel in the insect central nervous system. It owes its insect selectivity to the fact that it is less potent in binding the GABA receptor in mammals. Since its discovery about a decade ago, fipronil has been used against a variety of agricultural, domestic and veterinary insect pests. Despite its wide range of use, however, mammalian metabolism of fipronil has not been extensively investigated. The human metabolism of fipronil has been studied in our laboratory using human liver microsomes (HLM) and cytochrome P450 (CYP) isoforms. CYP3A4 has been identified as the major enzyme catalyzing fipronil metabolism in human. Because of broad substrate specificity of CYP3A4, fipronil may interact with many other CYP3A4 substrates.

This study investigated metabolic interactions of fipronil with testosterone or diazepam, two other CYP3A4 substrates. Fipronil was incubated with testosterone or diazepam in HLM and metabolites were analyzed using HPLC. When 1.25, 5 or 20 ?M fipronil incubated with a serial concentrations of testosterone (0-200 ?M), activation of fipronil S-oxidation was observed using HLM as the enzyme source. Inhibition of testosterone 6?-hydroxylation was observed in HLM when incubating testosterone (4, 20, or 100 ?M) with fipronil (0-160 ?M). There were no significant effects of diazepam (0-400 ?M) on metabolism of fipronil (5, 20 or 80 ?M). However, when 6.25, 25 or 100 ?M concentrations of diazepam were incubated with fipronil (0-160 ?M), diazepam hydroxylation was not significantly affected although demethylation of diazepam was inhibited. These results demonstrate that fipronil has the potential to interact with other CYP3A4 substrates (Supported by NIOSH Grant OH07551-ECU).

#### 1694

N-DEALKYLATION OF N-ETHYL-N-(2-HYDROXYETHYL)PERFLUOROOCTANESULFONAMID E (N-ETFOSE) BY RAT LIVER MICROSOMES AND BY EXPRESSED RAT AND HUMAN CYTOCHROMES P450 (CYPS).

L. Xu<sup>1</sup>, A. S. Seacat<sup>2</sup>, J. L. Butenhoff<sup>2</sup> and M. W. Anders<sup>1</sup>. <sup>1</sup>Pharmacology and Physiology, University of Rochester, Rochester, NY and <sup>2</sup>3M Co., St. Paul, MN.

N-EtFOSE is a N-substituted perfluorooctanesulfonamide that is degraded to PFOS. Male rat hepatic microsomal fractions catalyze the NADPH-dependent dealkylation of N-EtFOSE to N-(2-hydroxyethyl)perfluorooctanesulfonamide (FOSE alcohol), which is dealkylated to perfluorooctanesulfonamide (FOSA). The nonselective CYP inhibitors 1-octylamine and 1-benzylimidazole and the NADPH-cytochrome P450 reductase inhibitor diphenyliodium chloride blocked the biotransformation of N-EtFOSE to FOSE alcohol, indicating a role for the CYPs. The objective of this study was to identify the major rat and human CYPs that catalyze the N-dealkylation of N-EtFOSE. Inhibition of N-dealkylase activity by several CYP isoform-selective inhibitors was first examined in rat hepatic microsomal fractions. The N-deethylation of N-EtFOSE was inhibited 90% by disulfiram (CYP2E1), 70% by furafylline (CYP1A2), orphenadrine and diphenhydramine (CYP2B1), and cimetidine (CYP2C11), and 55% by clotrimazole (rat CYP3A2). Studies with expressed rat CYPs showed that CYP3A2, CYP2C11, and CYP2B1 catalyzed the N-deethylation of N-EtFOSE at rates of 15.6, 14.7, and 6.6 pmol/min/nmol P450, respectively. Studies with expressed human CYPs showed that hCYP2C19, hCYP3A4, and hCYP3A5 catalyzed the N-deethylation of N-EtFOSE at rates of 267, 23.6, and 204 pmol/min/nmol P450, respectively. Incubation of FOSE alcohol with the same series of expressed rat and human CYPs showed that rat CYP2C11 and hCYP2C19 catalyzed the N-dealkylation of FOSE alcohol at rates of 0.69 and 1.55 nmol/min/nmol P450, respectively. Rat CYP3A2, CYP1A2, and CYP2B1 catalyzed the N-dealkylation of FOSE alcohol at rates of 98, 39, and 30 pmol/min/nmol P450, respectively. These results establish a role for rat CYP3A2, CYP2C11, and CYP2B1 and human hCYP2C19 hCYP3A4/5 in the biotransformation of N-EtFOSE and FOSE alcohol. (Supported in part by the 3M

### 1695 COMPARATIVE HEPATIC MICROSOMAL ENZYME STUDIES IN COMMERCIALLY RAISED GAMEBIRDS.

K. A. Cortright and <u>A. L. Craigmill</u>. Environmental Toxicology, University of California-Davis, Davis, CA.

Species differences in drug metabolism can affect therapeutic efficacy and residues in food animals. For example, Webb et al. (2000) has shown that it is safe to treat bobwhite quail with fenbendazole but the therapeutic index in this species is much lower than for other gamebird species. Using hepatic microsomes, we have characterized the kinetics of hepatic cytochrome P450 (CYP)1A and 3A-like activities in chicken, pheasant and quail, using the fluorescent substrates ethoxyresorufin and 7benzyloxy-(trifluoromethyl)-coumarin (BFC). Inhibition studies were also conducted with prototypical inhibitors of CYP1A2, furafylline, and CYP3A, ketoconazole and erythromycin. Pheasant had the highest ethoxyresorufin-O-deethylase (EROD) activity compared to chicken and quail, 418 versus 46.8 and 15.08 pmoles product/mg x min (quail pooled), respectively. The calculated IC50's for furafylline toward EROD activity were 39uM, 40uM and >100uM for bobwhite quail, chicken, and pheasant, respectively. Kinetic parameters for oxidation of BFC (a CYP3A-selective substrate) were estimated. The apparent Vmax in chicken, pheasant and bobwhite quail was 1628, 7915, and 28347 pmoles product/mg x min, respectively. The apparent Km was 5.0, 4.2 and 34.3uM in chicken, pheasant and bobwhite quail, respectively. The IC50's for ketoconazole inhibition of BFC (20uM) metabolism were 98uM, 100uM and >400uM for chicken, bobwhite quail and pheasant, respectively. Chicken and quail were similar to rats and sheep in their sensitivity to ketoconazole inhibition (IC50's 130 and 106uM, respectively), while pheasant was again much less sensitive. Erythromycin showed very minor inhibition at most inhibitor and substrate concentrations tested. At 2 uM BFC it increased metabolism in a dose-dependent manner in the pheasant and the quail, but not in the chicken. CYP1A and CYP3A metabolize the majority of therapeutic drugs. These species differences in metabolic capacity may be related to the greater sensitivity of bobwhite quail to fenbendazole.

## 1696 CYTOCHROME P450 ENZYME ACTIVITIES IN EMBRYONIC TURKEY LIVER.

C. E. Perrone<sup>1</sup>, L. Leung<sup>2</sup>, J. Kao<sup>2</sup>, H. Yasmeen<sup>2</sup>, G. L. Fisher<sup>2</sup> and <u>G. M. Williams<sup>1</sup></u>. <sup>1</sup>Pathology, New York Medical College, Valhalla, NY and <sup>2</sup>Drug Safety and Metabolism, Wyeth Research, Collegeville, PA.

Previous experiments in our laboratory showed that embryonic turkey liver has functional phase I and phase II biotransformation enzymes capable of bioactivation of selected pro-carcinogens (Toxicologist 72(S-1): 155, 2002). To further assess whether turkey embryos could be useful as a model to obtain data on chemical-induced toxicity and carcinogenicity with human relevance, we examined embryonic turkey liver microsomal fractions for activities of seven major human drug-metabolizing cytochrome P450s by fast-gradient liquid chromatography tandem mass spectrometry (LC-MS/MS) (Drug Metab. Dispos. 29(1): 23-29, 2001). Using a cocktail consisting of specific probes for human CYP450s (ethoxyresorufin [CYP1A2], coumarin [CYP2A6], taxol [CYP2C8], dicofenac [CYP2C9], Smephenytoin [CYP2C19], bufuralol [CYP2D6], and midazolam [CYP3A4]), we detected activities for all probes except for CYP1A2 and CYP2C19. Corresponding activities for CYP enzymes were similar in liver microsomes from control, phenobarbital (PB)- and 3-MC-treated turkey embryos, suggesting that induction had not occurred except for CYP1A2 activity which was only detected in 3-MC-treated embryos. The distribution of enzyme activities for the different substrates in embryonic turkey liver microsomes appeared to be quite similar to that in a pool of human liver microsomes determined in our laboratory. We conclude that embryonic turkey liver possesses P450 enzyme activities that can metabolize probes specific for different human P450 enzymes. Thus, turkey embryos could be utilized to assess potential chemical toxicity to humans.

1697

MODULATION OF HEPATIC AND PULMONARY CYTOCHROME P4501A1 EXPRESSION BY HYPEROXIA AND INHALED NITRIC OXIDE IN THE NEWBORN RAT: IMPLICATIONS FOR LUNG INJURY.

X. I. Couroucli, Y. Wei, W. Jiang, L. Evey and <u>B. Moorthy</u>. *Pediatrics, Baylor College of Medicine, Houston, TX*.

Inhaled nitric oxide (INO), in conjunction with supplemental oxygen, is used in the treatment of neonatal pulmonary hypertension associated with hypoxic respiratory failure. In this study, we tested the hypothesis that exposure of newborn rats to INO, hyperoxia or hyperoxia + INO would modulate expression of pulmonary and hepatic cytochrome P450 (CYP)1A1 isoform, in relation to acute lung injury. Newborn Fisher 344 rats were maintained in room air or exposed to INO (50 ppm), hyperoxia (> 95% oxygen), or hyperoxia + INO (20 or 50 ppm) for up to 168 h, and catalytic activities, apoprotein contents (western blotting), and mRNA levels (RT-PCR) of pulmonary and hepatic CYP1A1 were determined. Animals given hyperoxia + INO (20 or 50 ppm) were more susceptible to acute lung injury, as determined by lung weight/body weight ratios, than those exposed to hyperoxia or INO alone. Hyperoxic rats given 20 ppm INO displayed lesser lung injury than those exposed to 50 ppm INO. Hepatic and pulmonary CYP1A1 expression at the protein and mRNA level was significantly induced by hyperoxia or ÎNO for 48 h, compared to air-breathing controls, followed by decline at later time points. On the other hand, while no significant alteration in CYP1A1 expression was noticed in animals given hyperoxia + INO (20 or 50 ppm) for up to 48 h, CYP1A1 levels declined after 72-168 h of exposure. The decline of CYP1A1 induction was accompanied by increased lung injury. Immunohistochemical studies revealed localization of CYP1A1 expression in the epithelial and endothelial cells of the lung. In conclusion, our results suggest that modulation of CYP1A1 expression contributes to the development of acute lung injury by hyperoxia and INO, and that lower dose of INO in conjunction with hyperoxia may be beneficial to infants suffering from pulmonary hypertension. (Supported by NIH grant HL KO8 04333.)

1698

DECREASED ACETAMINOPHEN TOXICITY IN LUNG AND KIDNEY, BUT NOT NASAL MUCOSA, OF MICE WITH LIVER-SPECIFIC KNOCKOUT OF THE NADPH-CYTOCHROME P450 REDUCTASE GENE.

<u>I. Gu</u>, <u>H. Cui</u>, M. Behr, L. Zhang, Q. Zhang, Y. Weng, W. Yang and <u>X. Ding</u>. Wadsworth Center, New York State Department of Health, Albany, NY.

Acetaminophen (AP) overdose causes toxicity in liver and extrahepatic tissues. Although it is well established that cytochrome P450 (CYP) enzymes play a critical role in the metabolic activation of AP, it is not yet clear whether AP toxicity in ex-

trahepatic tissues depends on hepatic biotransformation. The aim of this study is to determine whether extrahepatic AP toxicity is altered in a mouse model with liverspecific deletion of the NADPH-cytochrome P450 reductase (CPR) gene. The liver CPR-knockout (null) and the wild-type (WT) mice were given a single i.p. injection of AP at 400 mg/kg, and blood samples were collected for determination of serum AP concentrations. Serum alanine aminotransferase and tissues histopathology for liver, lung, nose, and kidney were also determined. As expected, acute AP hepatotoxicity was observed in WT, but not the null mice. However, the null mice also had reduced toxicity in the nasal mucosa, lung, and kidney, although the anticipated decreases in hepatic AP metabolism would increase circulating AP levels in the null mice. Pharmacokinetic analysis indicated that AP clearance in the null mice was significantly faster than in the WT controls, which suggests occurrence of compensatory increases of other biotransformation enzymes that are active in AP metabolism in the null mice. Nevertheless, after increasing AP dose to 600 mg/kg in the null mice to maintain comparable circulating AP levels in the two strains, we still observed a reduced AP toxicity in the lung and kidney, but not in the nasal mucosa of the null mice. These results indicate that AP toxicity in the nasal mucosa is not dependent on hepatic metabolic activation, and that AP toxicity in the lung and the kidney may be at least partly caused by liver-derived AP metabolites.

1699

INJURY PATTERNS IN THE NASAL PASSAGE FROM INHALED NA ARE RELATED TO AIRFLOW PATTERNS AND IN SITU METABOLISM OF NA IN SPRAGUEDAWLEY RATS.

M. G. Lee<sup>1</sup>, S. Camacho<sup>2</sup>, A. R. Buckpitt<sup>2</sup> and C. G. Plopper<sup>1</sup>. <sup>1</sup>Department of Anatomy, Physiology, and Cell Biology, School of Veterinary Medicine, University of California, Davis, Davis, CA and <sup>2</sup>Department of Molecular Biosciences, School of Veterinary Medicine, University of California, Davis, Davis, CA.

Naphthalene (NA) is a bio-activated environmental cytotoxicant for rodent respiratory tract. In the rat nasal passage, NA injury was confined within the olfactory mucosa regardless of route of exposure. Since cell types of the olfactory mucosa are known to be phenotypically homogeneous, it was assumed their metabolic capacity was also homogeneous. However, only a limited region of the olfactory mucosa was injured by inhaled NA whereas injury from NA i.p. occurred across the olfactory mucosa. To test whether this characteristic injury pattern from inhaled NA is relevant to previous defined patterns of nasal airflow, male Sprague-Dawley rats were exposed to filtered air, 2 ppm NA, or 25 ppm NA for 4 h. Injury was assessed 24 h after exposure by high-resolution histopathology. The region where the highest nasal airflow exists was injured by either dose of NA without any significant differences in the degree of cellular injury. At 25 ppm, however, injury was spread across broader region of the olfactory mucosa. In an effort to identify the metabolic environment of the rat nasal passage, we performed immunohistochemistry against cytochrome P450 2F, the key enzyme for generating toxic metabolites of NA. Cytochrome P450 2F was present primarily within the olfactory mucosa in the nasal passage. Recently, companion studies revealed a high rate of NA metabolism in the olfactory mucosa (Km =  $84 \mu M$  and Vmax = 24 nmoles/nmole P450/min). Overall, this study demonstrated that the injury pattern associated with NA exposure in the rat nasal passage was correlated with nasal airflow patterns as well as in situ metabolism of NA. It is notable that we detected NA injury at 2 ppm NA for 4 h, a concentration which is much lower than the current OSHA standard for humans (10 ppm for 8 h time-weighted average (TWA)). Supported by NIEHS ES04311, ES06700 and ES05707.

1700

TARGETED DISRUPTION OF THE OLFACTORY MUCOSA-SPECIFIC CYP2G1 GENE: IMPACT ON ACETAMINOPHEN TOXICITY IN THE LATERAL NASAL GLAND, AND TISSUE-SELECTIVE EFFECTS ON CYP2A5 EXPRESSION.

H. Cui, X. Zhuo, J. Gu, M. Behr, P. Swiatek, Q. Zhang, Y. Xie, D. Collins and X. Ding. Wadsworth Center, New York State Department of Health, Albany, NY.

CYP2G1 is a cytochrome P450 monooxygenase expressed uniquely in the olfactory mucosa (OM). We have generated Cyp2g1-null mice to identify the roles of CYP2G1 in the biology and the tissue-specific toxicity of xenobiotic compounds in the nose. Homozygous Cyp2g1-null mice are *via*ble and fertile; they show no evidence of embryonic lethality, morphological abnormality, or developmental deficits; and they seem to have normal olfactory ability. However, OM microsomes from Cyp2g1-null mice were found to have significantly lower activities than microsomes from wild-type mice in the metabolism of testosterone and progesterone (-60% decrease), and in the metabolic activation of coumarin (>70% decrease). Unexpectedly, a significant reduction in the expression of the Cyp2a5 gene was found in the liver, the lateral nasal gland (LNG), and, to a lesser extent, the kidney of adult Cyp2g1-null mice. The loss of CYP2G1 expression, and the associated decrease in the hepatic expression of CYP2A5, did not decrease systemic clearance, extent of hepatotoxicity, or OM toxicity of acetaminophen (AP). However, the

LNG, which is the major site for the production of odorant binding proteins, was protected from AP (at 400 mg/kg) toxicity in the Cyp2g1-null mice. Paradoxically, the LNG did not have detectable CYP2G1, and the decrease in LNG CYP2A5 expression in the Cyp2g1-null mice was not accompanied by decreases in microsomal AP metabolism. We hypothesize that OM CYP2G1 (through a paracrine pathway) or LNG CYP2A5 may indirectly influence resistance of the LNG to chemical toxicity, possibly by regulating gene expression in the LNG through steroid hormones or other endogenous CYP substrates and their metabolites.

1701

MECHANISM-BASED INACTIVATION OF HUMAN PULMONARY CYTOCHROME P450 2F1 BY PNEUMOTOXIN 3-METHYLINDOLE.

J. S. Kartha, <u>K. W. Skordos</u>, D. L. Lanza and <u>G. S. Yost</u>. *Pharmacology and Toxicology, University Of Utah, Salt lake city, UT.* 

3-Methylindole (3-MI) is a pneumotoxin that requires P450-catalyzed metabolic activation (dehydrogenation), to an electrophilic methylene imine to elicit toxicity. Previous studies have shown that the human pulmonary cytochrome P450 2F1 enzyme and its goat analog, P450 2F3, selectively catalyze the dehydrogenation of 3-MI without the formation of any oxygenated metabolites. In addition, previous work with 2F1 have shown that concentrations of 3-MI above 300µM strongly inhibited formation of the dehydrogenated product, indicating that 3-MI could be a mechanism-based inhibitor of 2F1. The purpose of this study was to determine if 3-MI could inhibit 2F1 and 2F3 in a time- and concentration-dependent manner. In the presence of NADPH, P450 2F1 lost approximately 58 % of its 7-ethoxycoumarin O-deethylase activity following a 30 minute pre-incubation with 3-MI. Pre-incubations done with 3-MI in the absence of NADPH did not show comparable loss of activity. The kinetic constants for the inactivation of P450 2F1 by 3-MI were determined using the Kitz-Wilson plot. The concentration required for half-maximal inactivation KI, was found to be 49µM and the maximal rate of inactivation kinact was 0.01/min. The partition ratio, which is the number of 3-MI molecules metabolized per molecule of 2F1 inactivated, was approximately 280. Thus, 3-MI inactivated 2F1 slowly, but at a reasonably low concentration. Exogenous nucleophiles such as glutathione did not protect P450 2F1 from 3-MI mediated inactivation, suggesting that the reactive intermediate remained within the active site of the enzyme. Preliminary data show that 3-MI could be inhibiting the 7-ethoxy coumarin deethylase activity of 2F3 in a time- and concentration-dependent manner. In conclusion, this study presents evidence that 3-MI acts as a mechanism-based inhibitor of human CYP2F1, which may be the most important enzyme in the bioactivation of pneumotoxicants like 3-MI, or carcinogens like naphthalene, benzene and styrene. This research was supported by NHLBI grant HL13645.

1702

INVESTIGATION OF THE IRREVERSIBILITY OF CYP450 INHIBITION CAUSED BY M-XYLENE AND METABOLITES IN RAT LUNG AND NASAL MUCOSA.

A. Vaidyanathan and R. Schatz. Pharmacology Sciences., Northeastern University, Roston, MA

Xylene (XYL) is used as a solvent in paints, cleaning agents and gasoline. Exposure occurs primarily by inhalation. Due to the volatility and lipophilicity of the xylenes, the lung and nasal mucosa are primary target organs. m-XYL is oxidized via cytochrome P450 (CYP450) isozymes to 3-methylbenzyl alcohol (3-MBA) and subsequently to m-tolualdehyde (m-ALD). The major CYP450 isozymes involved in the metabolism of the xylenes in the lung and nasal mucosa (target tissues) include CYPs 2B, 2E1 and 4B1. m-XYL alters cytochrome CYP450 activity in an organ and isozyme specific manner. The purpose of this work was to determine if the interaction of the reactive metabolite of m-XYL, m-ALD, to CYP450 was reversible. To determine the role of m-ALD in m-XYL induced CYP inhibition in these respiratory tissues, hydrazine was used to adduct the unstable aldehyde intermediate and prevent it from binding to CYP450. There was a time-dependent inhibition by m-XYL and metabolites of CYPs 2B, 2E1 and 4B1 in the lung and nasal mucosa. CYP 2B, 2E1 and 4B1 inhibition caused by these compounds was not reversible upon overnight dialysis. The presence of hydrazine in preincubation mixtures prevented inhibition caused by m-XYL, 3-MBA or m-ALD of CYPs 2B, 2E1 and 4B1 in the lung and nasal mucosa. This irreversible binding by m-ALD may represent a mechanism by which xylene expresses its in vivo toxicity.

## 1703 TOXICOGENOMICS PROJECT IN JAPAN - OBJECTIVE AND PROPOSAL.

T. Urushidani<sup>1,2</sup>, J. Kanno<sup>1</sup>, T. Miyagishima<sup>2</sup> and T. Nagao<sup>3,2</sup>. <sup>1</sup>Cell. & Mol. Toxicol., National Institute of Health Sciences(NIHS), Tokyo, Japan, <sup>2</sup>Toxicogenomics Project, NIHS, Tokyo, Japan and <sup>3</sup>Director General, NIHS, Tokyo, Japan. Sponsor: <u>S.</u> Tsuda.

In the worldwide pharmaceutical market, the entry of new chemicals is decreasing in spite of the progress of technology in finding the seeds for new drugs. Many candidate drugs drop out in the stage of non-clinic and clinic. A considerable percent-

age of dropouts is due to toxicity. It was commonly recognized by the Japanese pharmaceutical industry and the government that predicting toxicity in the early stage of drug development was indispensable, and that the construction of a database based on toxicogenomics technology using it along with bioinformatics technology seemed to be the most effective plan. Along this line, The Ministry of Health Labor and Welfare, NIHS, and the working group of the Japan Pharmaceutical Manufacturers Association began to draft a research project where both the nation and private companies joined. The project, for the 5 years from 2002 to 2007, has just started. Half of the amount for the entire budget, about 5 billion yen, is from the national budget, while the remaining half is from the 17 companies which participated in the project within the Japan Pharmaceutical Manufacturers Association. The main features and advantages of the project are: 1) the quantification of "absolute content of mRNA per one cell" is attained by using the Affymetrix GeneChip, 2) of the total group of 150 chemicals including considerable number of "the drug of which clinical trial was terminated or of which marketing was ceased due to the fact that human toxicity emerged, even though the presence of toxicity was undetected or neglected in non-clinical tests", 3) various toxicological data with high quality have links to the gene expression data in the database, and 4) the bridging of the interspecies is considered. The final goal of the project is to construct a large-scale database of these chemicals on rats and to develop a system which will forecast the toxicity of new chemicals in the early stage of drug development. This paper reports the outline and the present state of the proj-

## 1704 USING TRANSCRIPT PROFILING FOR PREDICTIVE TOXICOLOGY: OPPORTUNITIES AND CHALLENGES.

R. A. Jolly, K. M. Goldstein, T. Wei, J. Colet, H. Gao, T. P. Ryan, <u>C. E. Thomas</u>, H. B. Harlow, K. Kramer, S. Patwardhan, S. T. Estrem and <u>J. L. Stevens</u>. *Exploratory Toxicology, Lilly Research Labs, Indianapolis, IN*.

The development predictive toxicology databases based on transcript profiles represents a promising application for microarrays in pharmaceutical safety assessment. In principle, a predictive toxicology database contains transcript profiles from model toxicants (training set) with known mechanisms of injury. The hypothesis is that the training set can be used to predict the biological properties of a novel chemical entity based on a tissue transcript profile alone. To test this hypothesis, male SD rats were treated with a single dose of five prototypical hepatotoxicants and sacrificed 4, 24, 48 and 168 hours post dose. A dose response was characterized using minimally or non-toxic dose (low dose) and a high dose that caused a discernable lesion. Transcript profiles were generated and evaluated in liver. Preliminary analysis using hierarchical clustering (HCS) and principle component analysis (PCA) of hepatic transcript profiles showed that distinct transcript classes were generated. To determine the predictive value of the data set, we used a supervised k nearest neighbor (kNN) analysis. High dose samples were categorized, a priori, as HEPATOTOXIC (HPTX); low dose and vehicle samples were categorized as NON- HEPATOTOXIC (N-HPTX). Samples were randomly divided into training and test sets. The training set samples were designated HPTX or N-HPTX based on clinical chemistry and histology results while samples in the test set were classified as HPTX or N-HPTX by kNN analysis. Prediction rates were assessed after one thousand randomized iterations. Accuracy was approximately 80% but was variable with high rates of false negatives noted. When early time points and low dose toxicant samples (these samples also showed fewer transcript changes) were excluded the prediction rates improved with a dramatic decrease in false negatives. Thus, the dramatic effects of dose and time on accuracy of prediction, highlight the limitations of this type of analysis.

## 1705 FORMULATION OF RNA PERFORMANCE STANDARDS FOR REGULATORY TOXICOGENOMIC STUDIES.

B. A. Rosenzweig<sup>1</sup>, E. Mansfield<sup>1</sup>, P. Pine<sup>1</sup>, F. D. Sistare<sup>1</sup>, J. C. Fuscoe<sup>2</sup> and K. Thompson<sup>1</sup>. <sup>1</sup>Division of Applied Pharmacology Research, CDER, USFDA, Laurel, MD and <sup>2</sup>Center for Functional Genomics, NCTR, USFDA, Jefferson, AR.

Genome-wide measurement of gene expression has the potential to be highly informative for non-clinical assessments of drug safety and action, but there is acknowledged variability among users and between platforms due to differences in probe sequence selection, protocol non-uniformity, and other issues associated with this technology. To enable regulatory reviewers to objectively evaluate the quality and content of gene expression data, it is important to identify performance characteristics of well-conducted microarray experiments. To this end, we have initiated a collaborative research project to test the feasibility and value of using a set of mixed tissue samples to evaluate the ability of different laboratories and microarray platforms to detect designed-in differences in gene expression between two complex biological samples. To construct the mixed tissue samples, total RNA was isolated from four tissues (brain, liver, kidney, and testis), pooled across sets of 8 male Sprague-Dawley rats, and assayed on Affymetrix RAE230A arrays. Probes for tis-

sue-selective genes that exhibited a range of expression levels and performed consistently across pools prepared from different animal shipments and sources were identified as potential benchmark calibration genes. Two samples composed of different defined proportions of total RNA from the four tissues were prepared and tested to assure consistent detection of benchmark gene expression at the input ratios. To establish which metrics are most informative for assessing expression array assay performance within a given platform, sets of mixed tissue samples will be evaluated at multiple sites, on Affymetrix, Agilent, and Amersham arrrays, and on an in-house spotted oligonucleotide array at NCTR. Incorporation of measures of assay performance, such as a mixed tissue standard, into toxicogenomic data submissions could help assure regulators that high quality data is being submitted to support a regulatory review.

## 1706 LASER MICRODISSECTION AND ITS APPLICATION IN TOXICOGENOMICS.

W. Hu, M. Taurino, M. Wojke, T. Monticello and Z. Jayyosi. Drug Safety Evaluation, Aventis Inc., Bridgewater, NJ.

Gene expression analysis using total RNA isolated from whole organs may not identify specific gene modulations attributed to toxicity related to individual cell type. When sampling whole organs, gene expression responses from the specific cellular site of injury may be 'diluted' with adjacent unaffected cell population. The goal of this study was to develop, validate, and utilize a reliable laser microdissection (LMD) technique for the isolation of RNA for cell-specific gene expression studies. The Leica AS LMD system was utilized to capture cells from cryosections (8mm thick) of rat kidney. Several variables were evaluated: 1) optimal RNA isolation protocol; 2) time from tissue slide preparation to LMD; and 3) optimal number of cell profiles. Several RNA isolation protocols were evaluated; optimal results (yield and purity) were obtained with the Qiagen RNeasy Micro kit. A time-course experiment (30 sec - 4 min) was performed to determine the maximal amount of time the sample is stable to permit light microscopic evaluation until LMD. Quality RNA was still present up to the 4 min post-cryosectioning time-point. Similar RNA quality was obtained from all sample sizes (500 to 40, 000 cells), and increasing amounts of RNA were obtained with increasing cell number. Upon validation results, the expressions of 14 differentially regulated genes were evaluated from RNA isolated from whole rat kidney or LMD-derived samples of specific regions using RT-PCR. Comparable gene expression levels were found from both samples indicating that LMD did not alter the gene expression profile within various cellular components. In addition, cell-specific RNA expression profiling, using the Affymetrix RGU34A chip, obtained by LMD, was performed to delineate the responses of proximal tubules affected by a kidney toxicant from the responses of adjacent non-affected cell types or control tissue; these responses were also compared to those obtained from the entire kidney. In conclusion, results from this study provided a full scope validation of LMD technique and its application in the field of toxicogenomics.

EXPRESSION ANALYSIS OF NOVEL BIOMARKERS OF NEPHROTOXICITY USING LASER CAPTURE MICRODISSECTION (LCM) AND IMMUNOHISTOCHEMISTRY (IHC).

<u>L. A. Obert</u><sup>2</sup>, <u>J. W. Davis</u><sup>1</sup>, F. Goodsaid<sup>1</sup>, K. Milford<sup>2</sup>, P. Louro<sup>2</sup>, M. Geraci<sup>2</sup>, R. J. Smith<sup>1</sup> and <u>I. Y. Rosenblum</u><sup>1</sup>. <sup>1</sup>Molecular Toxicology, Schering-Plough, Lafayette, NJ and <sup>2</sup>Pathology, Schering-Plough, Lafayette, NJ.

Previous studies have identified clusterin, osteopontin (OPN) and hepatitis A virus cellular receptor-1 (HAVcr-1), a homologue of kidney injury molecule-1 (KIM-1) as novel genomic markers of nephrotoxicity in cynomolgus monkeys. Those results provided the first data confirming gene expression changes associated with rodent nephrotoxicity in a non-human primate model. In order to further analyze these novel biomarkers LCM was employed to analyze their localized expression in kidneys of female cynomolgus monkeys dosed with the aminoglycoside antibiotic gentamicin (10 mg/kg) and/or everninomicin (30 or 60 mg/kg), an experimental oligosaccharide antibiotic, for seven days. Monkeys receiving both drugs demonstrated proximal tubular injury as early as Day 1, consistent with a potentiation of toxicity resulting from co-administration of both test articles. By Day 7, monkeys dosed with 60 mg/kg everninomicin alone developed similar lesions, while the group exposed to both compounds had more extensive tubular damage. Gene expression within LCM-selected regions correlated with whole tissue expression changes especially at the anatomical site of damage in the kidney. Cortical tubules were the primary site of HAVcr-1 expression changes. Clusterin and OPN were more uniformly expressed throughout the kidney; although there was a higher correlation between expression in the cortex and the whole tissue than in medullary tubules or glomeruli. The presence of these putative markers in the urine has been proposed as proteomics markers of nephrotoxicity in rodents and humans. IHC was used to analyze in situ protein expression of these markers. Preliminary IHC analyses have confirmed that protein expression correlated with whole tissue and LCM gene expression analysis. The results shown here provide evidence that candidate genomic biomarker expression was localized to specific anatomic locations using LCM and protein expression was confirmed by IHC.

## 1708 QUANTIFYING GENE EXPRESSION NETWORKS: IDENTIFYING NETWORK STRUCTURE.

T. Yamanaka<sup>1</sup>, H. Toyoshiba<sup>1</sup>, <u>N. Walker</u><sup>1</sup>, F. Parham<sup>1</sup>, <u>J. Martinez</u><sup>1</sup>, H. Sone<sup>1</sup> and <u>C. Portier</u><sup>1</sup>. <sup>1</sup>Laboratory of Computational Biology and Risk Analysis, National Institute of Environmental Health Sciences, Research Triangle Park, NC and <sup>2</sup>LCBRA, NIEHS, Research Triangle Park, NC.

Gene expression arrays have revolutionized biology by generating vast amount of data quantifying the level of mRNA expression. Consequently biology is currently undergoing a shift to an informative and quantitative science. One of the major unresolved issues in the analysis of gene expression data is the identification and quantification of gene regulatory networks. Several methods have been proposed for identifying gene networks. However, almost all of these don't fully incorporate statistical methods into the analyses in the sense that they fail to quantify the likelihood that the network is a gbesth network and the strength of the links between genes in the network. We present a new method for analyzing gene expression to infer genetic interactions. We use Bayesian networks as a mathematical tool. Our approach is based on a rigorous Bayesian statistical framework. The analytical approach we present uses the actual measured observations on gene expression and incorporates prior distributions for all parameters in the gene interaction network model. The method encompasses model selection theory in Bayesian regression to find gene network structures suitable for given datasets. By introducing rigorous statistical methods into the estimation problem for gene interaction networks, important issues such as the statistical power for identifying the correct model and the uncertainty in model parameters can be easily assessed. Computer simulations demonstrate that the proposed method is capable of extracting knowledge from datasets with a limited number of small replicates as is the current case for most microarray studies. This lack of experimental replication is a common issue when analyzing expression data. The performance of our algorithm is evaluated by a dataset from HPL1A lung airway epithelial cells after exposure to TCDD for 24 hours. We estimated a hypothetical network from this dataset and argue its validity both biologically and statistically.

#### 1709

ESTROGENICITY OF THE DIETARY INDOLE, 3, 3'-DIINDOLYLMETHANE, IN RAINBOW TROUT (ONCORHYNCHUS MYKISS).

S. C. Tilton and D. E. Williams. Environmental and Molecular Toxicology and The Marine and Freshwater Biomedical Sciences Center, Oregon State University,

Indole-3-carbinol (I3C) is a glucosinolate hydrolysis product from cruciferous vegetables that has been found to have chemoprotective effects in several animal models. However, I3C given long-term postinitiation modulates liver carcinogenesis similar to the actions of 17β-estradiol (E2) so that it promotes hepatic tumors in trout and rat models, but inhibits them in mice. 3, 3'-Diindolylmethane (DIM) is the major acid condensation product of I3C observed in the stomach after dietary consumption and in the liver after absorption. We have found DIM to be estrogenic in precision trout liver slices and bind to the estrogen receptor with an EC<sub>50</sub> of 110 µM and a relative binding affinity 17-fold higher than Î3C. Hepatic gene expression profiles were analyzed in juvenile rainbow trout fed dietary E2, DIM, I3C, β-naphthoflavone (a known cytochrome P450 inducer) or 0.2% DMSO vehicle for 12 days. Transcript profiles were compared between treatment groups and controls using custom Atlantic salmon cDNA arrays to determine the expression level of approximately 3700 genes, including 3119 unique Salmo salar elements and 438 Oncorhynchus mykiss elements (ESTs). Genes known to be controlled by E2, such as vitellogenin (VTG), vitelline envelope, and binding proteins were found to be upregulated by both DIM and E2 while other genes, such as those involved in the acute immune response, were downregulated. Gene expression correlated well with levels of hepatic zona radiata, VTG and CYP1A proteins measured in these fish. This data suggests that DIM is estrogenic in trout models and regulates gene expression similarly to E2 in vivo. Supported by NIH grant ES03850 and ES07060.

### 1710

ESTROGEN-INDUCED GENE EXPRESSION IN HUMAN UTERINE LEIOMYOMA AND NORMAL UTERINE SMOOTH MUSCLE CELL LINES.

C. Swartz<sup>1</sup>, <u>C. Afshari</u><sup>2</sup>, L. Yu<sup>1</sup>, K. Hall<sup>1</sup> and <u>D. Dixon</u><sup>1</sup>. <sup>1</sup>NIEHS, Research Triangle Park, NC and <sup>2</sup>Amgen, Thousand Oaks, CA.

Uterine leiomyomas are widely prevalent, yet benign reproductive tract neoplasms of women. Their growth, and perhaps development, are widely believed to be under the influence of steroid hormones (estrogen and progesterone) although the

exact mechanism of this influence remains unclear. Numerous growth factors, cytokines, and other signal transduction factors have been implicated as effectors in the pathogenesis of uterine leiomyoma, either as downstream components of hormone initiated pathways or as effectors on their own. Interactions between these various pathways have been difficult to establish. Global gene expression analysis platforms, such as cDNA microarray, provide a means for tracking activities of multiple pathways simultaneously. In this study, we used cDNA microarrays to identify genes and pathways involved in the response of uterine leiomyoma (UtLM) and normal uterine smooth muscle (UtSMC) cells to estrogen. UtLM and UtSMC cells were treated with 10<sup>-8</sup>M17β-estradiol or ethanol (vehicle control) for 24 hours and differential gene expression between treated and control cells was assessed through competitive hybridization to cDNA arrays using fluorescent labels. Expression changes for selected genes were confirmed by northern blot and either western blot or immunocytochemistry. IGF-1 was up-regulated in estrogen-treated UtLM cells. Also, two other genes that are potentially involved in the IĞF-1 pathway were differentially expressed. A-myb, a transcription factor which promotes cell cycle progression, was up-regulated, and MKP-1, a dual specificity phosphatase that dephosphorylates mitogen-activated kinase, was down-regulated. Of these three genes, only MKP-1 was differentially expressed (also down-regulated) in UtSMC cells. These results demonstrate some novel genes that may play a role in the growth of uterine leiomyoma and strengthen the case for involvement of the IGF-1 pathway in the response of uterine leiomyoma cells to estrogen.

## 1711 DIFFERENTIAL GENE EXPRESSION BY ANDROGENS AND ESTRADIOL BY MICROARRAY ANALYSIS IN THE LARGEMOUTH BASS (MICROPTERUS SALMOIDES).

J. L. Blum<sup>2</sup>, P. Larkin<sup>4</sup>, K. J. Kroll<sup>3</sup> and <u>N. D. Denslow<sup>1,3</sup>. <sup>1</sup>Biochemistry and Molecular Biology, University of Florida, Gainesville, FL, <sup>2</sup>Graduate Program in Pharmacology, University of Florida, Gainesville, FL, <sup>3</sup>Biotechnology Program, University of Florida, Gainesville, FL and <sup>4</sup>EcoArray, LLC, Alachua, FL.</u>

The purpose of this study was to compare the gene expression profiles between largemouth bass treated with estradiol, dihydrotestosterone, or 11-ketotestosterone by cDNA microarray. These steroid hormones principally produce their effects through interaction with their respective nuclear receptors, and in concert with other transcription factors, control gene expression. Genes were cloned using differential display, cDNA subtraction, or directed cloning methods. These genes were arrayed on nylon membranes and hybridized with radiolabeled liver cDNA from treated or control fish. The gene profiles for each of the treatments were distinct from one another suggesting that it will be possible to distinguish hormonally active agents in the environment that behave as androgens or estrogens. The genes that are most up-regulated by estradiol include genes involved in egg production such as three vitellogenins, two choriogenins, aspartic protease and protein disulfide isomerase. On the other hand, the androgens upregulate a different set of genes, including several ESTs. While vitellogenin 2 is upregulated by all treatments, the level of induction was 500 fold for estradiol but only 10-fold for dihydrotestorenone and 2-fold for 11-keto-testosterone. Other estrogen up-regulated genes were not induced by the androgens. In fact the EST clone 24-1 that was up-regulated by estradiol was down-regulated by the androgens. It may be important to have multiple biomarkers, or gene fingerprints, to clearly distinguish the classes of endocrine acting compounds in the environment.

# 1712 DOSE RESPONSE ANALYSIS OF FEMORAL CHANGES IN GENE EXPRESSION ELICITED BY ETHYNYL ESTRADIOL USING CDNA MICROARRAYS.

J. Burt<sup>1, 3</sup>, L. D. Burgoon<sup>2, 3</sup>, D. R. Boverhof<sup>1, 3</sup>, Y. Sun<sup>1, 3</sup> and <u>T. R. Zacharewski<sup>1, 3</sup>. <sup>1</sup>Biochemistry and Molecular Biology, Michigan State University, East Lansing, MI, <sup>2</sup>Pharmacology & Toxicology, Michigan State University, East Lansing, MI and <sup>3</sup>Institute of Environmental Toxicology, Michigan State University, East Lansing, MI.</u>

To investigate estrogenic effects on bone, changes in the global gene expression in femoral tissue were examined in immature, ovariectomized C57BL/6 mice treated with 17 $\alpha$ -ethynyl estradiol (EE), a synthetic, orally active estrogen. Mice were gavaged with 0.1, 1.0, 10, 100 or 250 µg/kg of EE or vehicle and femurs were harvested after 24 hours. cDNA microarrays representing 6376 clones (4858 unique genes) were used to compare gene expression profiles of EE treated animals to vehicle controls using a common reference design. This design results in two independent labelings per sample, with appropriate dye swaps, and 3 biological replicates were conducted. The data were normalized using a general linear mixed model (GLMM) and gene effects examined using a separate gene-specific GLMM. A list of 202 significant genes was compiled using a model-based t-statistic filtering approach with an absolute value t-score cut-off of 4.0 and a subset verified using real-time PCR. k-means clustering was performed and the data were best described with 6 separate clusters: the majority of the genes only being affected at the high doses of

EE. Among these genes, many are involved in transcriptional regulation, signal transduction and apoptosis. Of interest was the up-regulation of osteoprotogerin (OPG), a regulator of apoptosis. Previous studies have shown that OPG is estrogen responsive and *in silico* analysis identified two imperfect estrogen response elements in the region downstream of the transcriptional start site. Comparative analysis with liver dose response expression patterns found many pathways in common, including lipid metabolism and transport, and oxidative stress. These results corroborate previous reports that bone is responsive to estrogen and may provide insights into estrogen's role in maintaining bone homeostasis. Supported by ES011271

# 1713 THE USE OF GENE EXPRESSION PROFILING FOR IDENTIFYING POTENTIAL BIOMARKERS OF REPRODUCTIVE TOXICOLOGY.

L. Nelms<sup>1</sup>, R. E. Chapin<sup>2</sup>, B. Lu<sup>1</sup>, S. J. Curry<sup>2</sup>, M. B. Wilhelms<sup>3</sup>, M. R. Elwell<sup>3</sup>, D. Pelletier<sup>1</sup> and <u>M. P. Lawton<sup>1</sup>. <sup>1</sup>Molecular and Investigative Toxicology, Pfizer, Groton, CT, <sup>2</sup>Investigative Developmental Toxicology, Pfizer, Groton, CT and <sup>3</sup>Pathology, Pfizer, Groton, CT.</u>

More sensitive clinical markers of damage to the male reproductive system are needed. Testicular toxicity in rodents and other preclinical species is currently determined by a histologic evaluation of tissues from treated animals. In humans, an ejaculated sperm count has been the gold standard for many years, because sperm output is a direct result of spermatogenesis. However, sperm count has some drawbacks: it is highly variable across individuals and from one sample to another within a single individual, and it reflects damage that happened weeks or months previously. We are using emerging "omics" technologies to identify clinically relevant, "leading" biomarkers of testis toxicity. To find candidate biomarkers, rats were treated with well-described toxicants to produce varying degrees of testis damage. Serum was profiled by 2D gels (proteomics), urine by NMR (metabonomics), and various tissues (testis, prostate, liver, and whole blood) by gene expression profiling (genomics). For this communication, male Sprague-Dawley rats were dosed with the well-known testicular toxicant, 1, 3-dinitrobenzene (DNB) at 0, 2, 5, or 10 mg/kg/day, and samples collected after 2, 4, 7, and 10 days of treatment. The histologic lesions were as described previously: Sertoli vacuolization, and apoptosis of round spermatids and spermatocytes, followed by sloughing of dead and dying germ cells. The degree of these effects varied with dose and duration. Gene expression analysis using Affymetrix GeneChips also revealed changes that varied with time and dose. Experimental validation of candidate markers using a variety of techniques (in situ hybridization, RT-PCR, regulation by other compounds, etc.) will be described.

# 1714 EXPRESSION PROFILING THE HEPATIC RESPONSE OF RATS TREATED WITH FENOFIBRATE AND FIVE OTHER FIBRATE ANALOGUES.

P. D. Cornwell, A. T. De Souza and R. G. Ulrich. Molecular Profiling, Rosetta Inpharmatics, Merck Research Labs, Kirkland, WA.

Peroxisome proliferator-activated receptors (PPAR) are a group of nuclear receptors that mediate a variety of cellular functions. Fibrates (primarily PPAR agonists) are used clinically to treat dyslipidemias but cause peroxisome proliferation, hepatomegaly and hepatic tumors in rodents. The goal of this study was to identify the gene expression changes responsible for the acute effects (i.e. hepatomegaly) of fibrates in rats. Male CD rats were treated daily by oral gavage with multiple dose levels of fenofibrate and five other fibric acid analogues for up to two weeks. Only one compound caused any significant increase in serum ALT or AST activity; however, all six compounds caused hepatocellular hypertrophy and significant increases in liver mass: body mass ratios. Liver total RNA from compound treated and vehicle treated animals was hybridized to custom oligonucleotide arrays containing 22, 505 rat sequences. Time-matched pools of liver RNA from vehicle treated animals were used for the reference channel, and all hybridizations were performed in duplicate with the labeling fluors (Cy3 or Cy5) reversed in the second hybridization. Microarray expression profiling revealed that hepatic expression of 1288 genes was related to dose level or length of treatment of all six compounds and was correlated with grade of hepatocellular hypertrophy. Included in this list were changes in gene expression that were consistent with peroxisome proliferation; increased fatty acid transport; increased mitochondrial and peroxisomal  $\beta$ -oxidation; increased uptake of LDL-cholesterol; and decreased glucose uptake, gluconeogenesis and glycolysis. It is likely that these changes are related to the clinical benefits of fibrate drugs, including decreased serum triglycerides and LDL-cholesterol and increased serum HDL-cholesterol. The large number of genes whose expression is treatment and hepatomegaly related, and that have functions associated with the target effects of fibrates leads to the conclusion that hepatomegaly is the result of PPARα activation.

### 1715

GENE EXPRESSION PROFILE OF HEPATIC STEATOSIS IN PPAR $\alpha$ -DEFICIENT MOUSE LIVER AFTER EXPOSURE TO HYDRAZINE.

<u>V. E. Richards</u>, B. Chau and <u>C. A. McQueen</u>. *Pharmacology and Toxicology, University of Arizona, Tucson, AZ*.

Peroxisome proliferator activated receptors (PPAR) are members of the nuclear hormone receptor superfamily. Of the three identified isoforms ( $\alpha$ ,  $\beta/\delta$  and  $\gamma$ ), PPAR $\alpha$ is involved in the control of hepatic fatty acid and glucose metabolism. A deficiency of PPAR $\alpha$ -dependent  $\beta$ -oxidation of fatty acids causes disturbances in lipid and energy homeostasis and is critical in the pathological accumulation of lipids in the liver, referred to as steatosis. Steatosis has been reported as a toxicological endpoint of hydrazine (HD) exposure in rodents. HD is a metabolite of the tuberculostatic drug isoniazid, as well as an industrial compound. In C57Bl/6 mice, HD has been shown to induce the expression of genes regulated by PPARα, including Cyp4a14, Apoa5, Cpt and Hmgcs2. The present study was designed to determine the involvement of PPARα in HD-mediated steatosis. PPARα-deficient mice received an oral dose of HD (0-300 mg/kg). Using a cDNA microarray, hepatic gene expression profiles were investigated 24 hours after a sub-cytotoxic dose of 100 mg HD/kg. Data revealed induction of Prkcz, Apoa4, and Agpat3 and reduction in the expression of Lpl, Abca1, and Gpr68 in PPARα-deficient mice. These genes are reported to coordinate triglyceride-rich lipoprotein homeostasis. Twenty-four hours after 300 mg HD/kg histological studies showed dramatic hepatic lipid accumulation and macrovesicular degeneration in the deficient mice compared to the wildtype. Biochemical assessment revealed a dose-dependent elevation in alanine aminotransferase (ALT) activity and reduction in plasma cholesterol and triglyceride levels. These data suggest HD severely overwhelms the removal of hepatic lipids in PPARα-deficient mice. Moreover, the ability to alter the expression of PPARα-regulated genes is a critical hepatic response to HD. (Supported by R01 ES10047 and P30 ES6694).

#### 1716

EFFECT OF FURAN, CHLOROFORM, DI-(2-ETHYLHEXYL)PHTHALATE (DEHP) AND OXAZEPAM ON BIOMARKERS OF CELL CYCLING AND PROLIFERATION IN MOUSE LIVER.

C. Meredith<sup>1</sup>, M. P. Scott<sup>1</sup>, A. Barton<sup>2</sup>, R. J. Price<sup>1</sup>, T. R. Hupp<sup>3</sup>, <u>C. R. Elcombe<sup>2</sup></u> and <u>B. G. Lake<sup>1</sup></u>. <sup>1</sup>BIBRA International Ltd., Carshalton, Surrey, United Kingdom, <sup>2</sup>CXR Biosciences Ltd., Dundee, United Kingdom and <sup>3</sup>University of Dundee, Dundee, United Kingdom.

The aim of this study was to identify biomarkers of tumor formation by non-genotoxic agents in mouse liver. Male (oxazepam only) and female B6C3F1 mice were treated with both carcinogenic and non carcinogenic doses of the compounds. Mice were given corn oil (control) or the cytotoxins furan (1-15 mg/kg) and chloroform (238 and 437 mg/kg) by gavage 5 days per week for periods of 1, 5 and 26 days. Chloroform was also given in the drinking water at non carcinogenic doses of 200 and 1800 mg/l. Mice were fed control diet or diets containing the mitogens DEHP (30-6000 ppm) and oxazepam (2.5-2500 ppm) for periods of 1, 7 and 28 days. Both furan and chloroform (gavage only) produced dose-dependent hepatotoxicity (increased serum alanine aminotransferase). Treatment with DEHP induced hepatic peroxisome proliferation (palmitoyl-CoA oxidation) and oxazepam induced cytochrome P450-dependent enzymes. At necropsy, total RNA was extracted from liver samples and mRNA levels of selected genes (including c-fos, cmyc, cyclin D, Gadd45β, p53, bcl2) determined by real-time quantitative reverse transcription-polymerase chain reaction methodology. At day 26, carcinogenic doses of chloroform (238 and 437 mg/kg) produced significant 11 and 47 fold increases, respectively, in c-myc. The expression of c-myc was also increased by 4 and 15 mg/kg carcinogenic doses of furan, whereas at day 28 neither oxazepam nor DEHP produced significant effects. While carcinogenic doses of DEHP (6000 ppm) and oxazepam (2500 ppm) produced significant increases (10 and 24 fold, respectively) in Gadd45β expression, furan had no significant effect. Overall, certain genes may be useful biomarkers of non-genotoxic carcinogenesis in mouse liver. (Supported by UK Food Standards Agency).

## 1717 DI(2-ETHYLHEXYL) PHTHALATE INDUCED GENE EXPRESSION CHANGES.

<u>I. S. Wong</u>. Cell Biology & Neuroscience, Environmental Toxicology Program, University of California, Riverside, CA.

Increasing chemical use and population growth necessitates an understanding of how pollutants affect the environment, and human and animal health as well. This is particularly true with pollutants such as di(2-ethylhexyl) phthalate (DEHP), a peroxisome proliferator and a plasticizer ubiquitously present in the environment. The National Toxicology Program Center for the Evaluation of Risks to Human Reproduction (NTP CERHR) concluded that there is a serious concern for

DEHP's potential detrimental effects on male infant reproductive development. Despite the wide use and known adverse effects of DEHP, its mechanism(s) of reproductive toxicity are poorly understood. To begin to identify potential DEHP targeted pathways relevant to reproductive development, it is important to have a transcriptional profile of genes affected after exposure to DEHP. We did this by assaying gene expression changes in the liver and the testes of C57BL/6 mice after exposure to 1.0% dietary DEHP for 13 weeks using microarray technology. DEHP exposure resulted in the induction or suppression of myriad genes in the liver and the testes. In the liver several affected steroidogenic genes were identified: cyp2b9, cyp7b1, 11b-hydroxysteroid dehydrogenase (11bHSD), and 3b-hydroxysteroid dehydrogenase V (HSD3b5). Additionally, several key genes, either directly or indirectly involved in the development of the gonadal testes, were identified: vanin-1, prostaglandin D synthetase (PGDS), and oligodendrocyte-specific protein (OSP). Currently, detailed studies on selected genes are undertaken to ascertain dose- and time-dependence, and the dependence on the presence of a putative DEHP receptor peroxisome proliferator activated receptor a (PPARa). Taking the data collectively, we postulate that DEHP's mechanism of reproductive toxicity is in part due to its perturbation of genes necessary for important processes critical for proper reproductive development and function: steroid hormone metabolism and testes determination.

#### 1718

CHEMICAL GENOMICS ANALYSIS OF GENE EXPRESSION PROFILES TO HELP ELUCIDATE MOLECULAR MECHANISMS OF ANTI-BREAST CANCER AGENTS.

C. Yang<sup>1,3</sup>, P. Blower<sup>1</sup>, K. Cross<sup>1</sup>, G. Myatt<sup>1</sup>, J. Richards<sup>2</sup>, R. Brueggemeier<sup>2</sup> and J. Rathman<sup>3</sup>. <sup>1</sup>Leadscope, Inc., Columbus, OH, <sup>2</sup>College of Pharmacy, The Ohio State University, Columbus, OH and <sup>3</sup>Chemical Engineering, The Ohio State University, Columbus, OH. Sponsor: D. Johnson.

Throughput genomic studies are producing large databases of molecular information on cancers and other cell and tissue types. Hence, the opportunity to link these accumulating data to the drug discovery process becomes a real possibility. However, despite the introduction of a new paradigm and methodologies, this large amount of information and significant investment has not led to dramatic increases in productivity in drug discovery. To link the vast amount of genomics information to small molecule discovery, we have in the past correlated the gene expression profiles of NCI 60 cell lines to compound activity patterns of the same cell lines. The genes were classified using a gene hierarchy based on Gene Ontology Consortium. The gene families defined in the hierarchy function as biologically meaningful features for statistical gene mining. The chemical scaffolds were built by extracting common cores of the compounds responsible for the initial correlations with gene expression profiles. These compound scaffolds are used to probe the genes within certain pathways. The set of selected genes and the compounds provide a foundation for building hypotheses based on molecular mechanisms. In this paper, an experimental design to validate the informatics methodology is presented. The activities of the selected compounds were measured by IC50 and EC50 values for breast and colon cancer cell lines. Gene expressions were measured using Affymetrix U133 chips. Data mining results from this experiment will be tested by real time PCR to validate the molecular hypothesis of pairs of genes and compounds.

# 1719 IDENTIFICATION OF GENE EXPRESSION CHANGE AS A FUNCTION OF DOSE IN A MICROARRAY EXPERIMENT.

K. Dawson¹, J. E. Eckel¹, C. Gennings¹, D. Boverhof² and T. Zacharewski².³.⁴.¹ Biostatistics, VA Commonwealth University, Richmond, VA, ²Department of Biochemistry & Molecular Biology, Michigan State University, East Lansing, MI, ³Nation Food Safety & Toxicology Center, Michigan State University, East Lansing, MI and ⁴Institute for Environmental Toxicology, Michigan State University, East Lansing, MI.

Pattern recognition methods are described for cDNA microarray data from a doseresponse (D-R) study with immature ovariectomized C57BL/6 mice gavaged with ethynyl estradiol (0, 0.1, 1, 10, 100, and 250 ug/kg). In this study microarrays, representing 6, 528 cDNA clones, were used to assess hepatic changes in gene expression using the common reference design replicated in quadruplicate. A screening algorithm was applied to identify genes associated with change in expression level over dose. For each treatment, replication, and block, data were normalized using loess local regression within each dye swap. A D-R pattern was constructed for each gene by comparing mean responses between adjacent doses. Let  $E_{ij}$  denote the mean expression at the ith dose, i=1, 2, ..., 6 for the jth gene. When a t-test comparing  $E_{ij}$ ,  $E_{i+1,j}$  was significant, the pattern was classified as increasing  $(p_{ij}=1)$  based on the change in mean expression. Non-significant tests indicated no change  $(p_{ij}=0)$ . A pattern set  $p_i=(p_{1j},p_{2j},p_{3j},p_{4j},p_{5j})$  was then constructed for each gene. Over 80% of the genes fell into the pattern set (0,0,0,0,0)

indicating constant expression over all doses. Pattern set (-1, 0, 0, 0, 0), associated with a decrease in expression at 0.1 ug/kg which remained constant through higher doses, was associated with 6% of the genes. An increase in expression at 0.1 ug/kg, which then remained constant, was identified in 3% of genes. No change at doses < 250 ug/kg were observed in 1.8% of genes with 0.9% decreasing and 0.9% increasing at that dose. Without first defining forms for the D-R relationships, this algorithm can screen for any pattern in expression over increasing dose. Observed pattern sets are useful in suggesting functional forms for underlying D-R relationships. This work was supported by two grants (#T32 ES07334-01A1 and #R01-) from the NEIHS, NIH.

### 1720 NORMALIZATION OF MICROARRAY DOSE-RESPONSE DATA.

J. Eckel<sup>1</sup>, C. Gennings<sup>1</sup>, K. Dawson<sup>1</sup>, D. Boverhof<sup>2</sup> and <u>T. Zacharewski<sup>2</sup></u>.

<sup>1</sup>Department of Biostatistics, Virginia Commonwealth University, Richmond, VA and

<sup>2</sup>Department of Biochemistry & Molecular Biology, National Food Safety & Toxicology Center and Institute for Environmental Toxicology, Michigan State University, East Lansing, MI.

An important underlying assumption of any dose-response study is that the experimental conditions/subjects are similar across levels of the exposure variable, so that changes in the response variable can be attributed to exposure to the agent(s) under study. This assumption is often not valid in the analysis of microarray dose-response data due to experimental factors including differences in labeling or detection efficiencies, and systematic biases in the measured expression levels due to spot location, array or replication factors. Thus, normalization is an important initial step in the analysis of gene expression data where the objective is to balance the individual intensity levels across these experimental factors while maintaining the effect due to exposure to the agent under study. Various normalization strategies have been described in the literature including log centering, analysis of variance modeling, and lowess smoothing for removing intensity-dependent effects. We describe a method that incorporates many of these into a single strategy for use in a dose-response study using a spoke design with dye-swaps between vehicle and each dose group (termed a reference set). The motivation for our normalization strategy is to balance the effects due to dye, location and replication within each dose or vehicle group within each reference set while maintaining the mean within these groups. The method is demonstrated using data from a dose-response study of ethynyl estradiol (0, 0.1, 1, 10, 100, 250  $\mu$ g/kg) in liver tissue from immature ovariectomized C57/BL6 mice. In this study cDNA microarrys, representing 6, 528 cDNA clones, were used to assess hepatic changes in gene expression using the spoke design that was replicated in quadruplicate. The success of the normalization strategy is demonstrated via plots. This work was supported by two grants (#T32 ES07334-01A1 and #R01- ES011271) from the NEIHS, NIH.

# 1721 USE OF RAY DESIGNS IN EVIDENCE-BASED DECISIONS INVOLVING MIXTURES OF LARGE NUMBERS OF CHEMICALS.

C. Gennings, H. Carter, K. Fisher and R. Carchman. Solveritas, LLC, Richmond, VA.

The protection of human health from the adverse effects of cumulative and acute exposure to chemical mixtures is an important issue. The toxicity of a mixture depends in part on the toxicity of the components and how the components interact. In some cases the toxicity of an agent or mixture may be adjusted by selecting/changing industrial or environmental processes that produce the mixture and/or ameliorate the effect by pretreatment or antidote therapy. For example, a chlorination process and an ozonation process in disinfecting drinking water may result in different levels of disinfectant by-products in drinking water. In the case of combination therapy for exposure to nerve threat agents our methods can facilitate the selection of improved treatment. In general, for decision-makers to select/change these processes/treatments, it is important to identify whether or not the components of the mixture, including the unidentified fraction in complex mixtures, combine additively. Fixed-ratio ray designs, which may include the use of single chemical data in addition to data along mixture ray(s), are feasible designs in the analysis of mixtures with many components. Such designs permit a reduction in the amount of experimental effort when the region of interest can be restricted to exposure-relevant mixing ratios. We have developed statistical methodology based on these fixed-ratio ray designs that facilitate testing hypotheses of additivity along specified rays of interest for mixtures of many chemicals. The methods are illustrated with data from a lethality study (Solana et al (1990) Toxicology Applied Pharmacology 102:421-429) of soman exposure in guinea pigs when pretreated with physostigmine and azaprophen. The analysis suggests an antagonistic relationship between these two agents as the level of soman increases indicating azaprophen pretreatment is preferable to the combination in the dose range considered. Further, our methods allow for testing for interactions among subsets of the components in the mixture and for comparison across subpopulations of interest.

IMPROVED DETERMINATION OF REGENERATED SARIN (GB) IN MINIPIG AND HUMAN BLOOD BY GAS CHROMATOGRAPHY-CHEMICAL IONIZATION MASS SPECTROMETRY USING ISOTOPE DILUTION AND LARGE VOLUME INJECTION.

E. M. Jakubowski<sup>1</sup>, J. M. McGuire<sup>2</sup>, J. L. Edwards<sup>2</sup>, R. A. Evans<sup>2</sup>, S. W. Hulet<sup>1</sup>, B. J. Benton<sup>1</sup>, J. S. Forster<sup>1</sup>, D. C. Burnett<sup>1</sup>, W. T. Muse<sup>1</sup>, C. L. Crouse<sup>2</sup>, R. J. Mioduszewski<sup>1</sup> and <u>S. A. Thomson</u><sup>1</sup>. <sup>1</sup>Toxicology Team, Edgewood Chemical Biological Center, APG-Edgewood, MD and <sup>2</sup>Geo-Centers, APG-Edgewood, MD.

Recent developments to improve nerve agent biomarker techniques include a method for measuring fluoride regenerated isopropyl methylphosphonofluoridate (Sarin or GB) from human or animal plasma (M.Polhuijs, et al. Toxicol. Appl. Pharmacology, 146, 156-161, 1997). Our efforts extended the fluoride ion regeneration method to be able to determine GB in red blood cell and tissue samples using a gas chromatograph-flame photometric detector (GC-FPD) with a solid sorbent tube sample inlet. However this method is labor intensive and subject to interferences. To improve the analysis, a new GC method was developed that utilizes an autoinjector, a large volume injector port (LVI), positive ion ammonia chemical ionization detection in the SIM mode, and a hexadeuterated-GB stable isotope internal standard. Ethyl acetate extracts from spiked human whole blood samples and from blood/tissue of whole-body GB exposed minipigs were analyzed by the improved method. Results indicated that the method range was 10-5000 pg on column. The detection limit was 3 pg of GB on column despite the complexity of the red blood cell/tissue matrix. Conditions that needed to be optimized for the LVI included injection volume, initial temperature, pressure, and flow rate. Other solvents were evaluated such as methyl acetate, hexane, and methanol but were found to be problematic to the sample preparation or to the LVI. The red blood cell (RBC) fraction of spiked human blood yielded regenerated GB levels comparable to those seen in the plasma when spiked at ng/mL concentrations.

# 1723 THE INHALATION TOXICITY OF GB VAPOR IN RATS AS A FUNCTION OF EQUILIBRATION TIME FOR TEN MINUTE EXPOSURES.

J. S. Anthony<sup>1</sup>, M. V. Haley<sup>1</sup>, J. H. Manthei<sup>1</sup>, R. A. Way<sup>1</sup>, D. C. Burnett<sup>1</sup>, B. P. Gaviola<sup>1</sup>, D. R. Sommerville<sup>1</sup>, R. B. Crosier<sup>1</sup>, R. J. Mioduszewski<sup>1</sup>, S. A. Thomson<sup>1</sup>, C. L. Crouse<sup>2</sup> and K. L. Matson<sup>2</sup>. <sup>1</sup>Edgewood Chemical Biological Center, Department of the Army, Aberdeen Proving Ground, MD and <sup>2</sup>Geo-Centers Inc., Abingdon, MD.

Characterizing the toxicity of airborne exposures to chemical warfare agents requires sensitive, accurate and reliable analytical chemistry methods as well as adequate methods for generating and controlling the test atmosphere. In addition to concentration and exposure time, it is necessary to examine what effect the chamber equilibration time (t<sub>99</sub>) has on measured biological endpoints for shorter duration inhalation exposures (i.e. < 10 minutes). The  $t_{99}$  is defined as the time necessary for an exposure chamber to reach 99% of its experimental concentration. Once this value is reached, the chamber concentration will not rise more than an additional 1%, regardless of exposure time. MacFarland (1975) has suggested that for short-term dynamic exposures, exposure time (t) should be greater than (or equal to) 13(t<sub>99</sub>) (MacFarland's Rule). Although there is no problem in adhering to this guideline for longer exposures (e.g. 60 or 240 min), adherence is not practical for exposures of 10 min or less where chamber dynamics will only allow the  $t_{99}$  value be kept to a minimum. The present study examined dose-response (lethality) relationships for GB vapor in rats derived from 10-minute exposures with too values that do not adhere to MacFarland's Rule, i.e., 2.1, 5.2, or 8 minutes. It was generally concluded that differences in  $LCT_{50}$  values collected under the above  $t_{99}$  conditions were minimal and would not be considered statistically significant.

## 1724 CLINICAL SAFETY OF REACTIVE SKIN DECONTAMINATION LOTION (RSDL).

D. A. Tonucci<sup>1</sup>, S. Masaschi<sup>1</sup>, L. Lockhart<sup>1</sup>, M. Millward<sup>1</sup>, D. Liu<sup>2</sup>, R. Clawson<sup>2</sup>, V. Murphy<sup>3</sup>, P. O'Dell<sup>4</sup>, M. C. Lanouette<sup>5</sup>, T. Hayes<sup>6</sup> and <u>C. Sabourin<sup>6</sup>. <sup>1</sup> Hill Top Research, Cincinnati, OH, <sup>2</sup> Chemical Biological Medical Systems Project Management Office, Ft Detrick, MD, <sup>3</sup> MarCorSysCom, Quantico, VA, <sup>4</sup> O'Dell Engineering, Cambridge, ON, Canada, <sup>5</sup> Canadian Department of National Defense, Ottawa, ON, Canada and <sup>6</sup> Battelle, Columbus, OH.</u>

A clinical program was designed to assess the dermal safety of a new personal skin decontaminant system. Reactive Skin Decontamination Lotion (RSDL) is a liquid, reactive lotion which removes and destroys chemical warfare agents and toxins from the skin. The clinical program included: a 21-day cumulative dermal irritation study in 30 subjects, a Repeat Insult Patch Test (RIPT; Jordan/King modified Draize design) in 200 subjects and a photo-irritancy/allergenicity study in 30 subjects. For cumulative irritancy 25  $\mu L$  of RSDL applied to a 1 cm punch of sponge

applicator was patched occlusively for 21 consecutive days. Results from the study indicated that RSDL/applicator was of low irritancy potential versus the positive (0.5 M sodium lauryl sulphate) and negative (normal saline) controls. For allergenicity, 25 µL of RSDL/applicator punch was patched 9 times, with continuous exposure, for a 3-week induction phase followed by a 2-week rest period where subjects received no exposure to RSDL/applicator. A single challenge application at a naive site followed the rest period. RSDL/applicator was not allergenic in the RIPT as indicated by low erythema scores reported during the challenge phase. RSDL was tested for phototoxicity by comparing the skin reaction to a single exposure of RSDL/applicator with or without UVA/B exposure. Finally, photoallergenicity was determined for RSDL in a similar manner as in the RIPT with the exception that subjects were exposed to UV radiation after patch removal during induction and challenge. RSDL was found non phototoxic and non photoallergenic. The cumulative irritation, RIPT and phototox/photoallergy studies indicate that RSDL has a low risk for the development of dermal toxicity. Supported by RSDL/Foreign Comparative Testing Program and conducted under USAMRMC Contract No. DAMD17-99-D-0010.

## 1725 DETERMINATION OF RADIOPROTECTIVE EFFICACY OF GENISTEIN WHEN ADMINISTERED BEFORE OR AFTER IONIZING RADIATION.

M. R. Landauer and V. Srinivasan. Radiation Pathophysiology and Toxicology, Armed Forces Radiobiology Research Institute, Bethesda, MD.

At present there is no way to protect first-responders and remediation workers from the biomedical effects of ionizing radiation. Agents that can protect against ionizing radiation and that can be administered before radiation or shortly after irradiation would permit rescue workers to provide the services needed. In addition to their use against radiological terrorism, chemical radioprotectors have utility in clinical oncology and space travel. Soy phytoestrogens have been reported to have many beneficial health effects including a reduction in osteoporosis and some cancers. The most plentiful isoflavone from soybeans is genistein (4', 5, 7-tri-hydroxy-flavone). Genistein is an antioxidant and protein kinase inhibitor. In this study the radioprotective effects of genistein were evaluated in male CD2F1 mice. The traditional 30day survival endpoint for the evaluation of radioprotectors was used. Mice received a single subcutaneous injection of either vehicle or 5 mg genistein/mouse at 0.5, 1, or 24 hours before irradiation or 0.5 hours after irradiation. The radiation dose was 9.5 Gy at a dose rate of 0.6 Gy/minute from a cobalt-60 source. Of all the time points tested, genistein provided statistically significant radioprotective efficacy only when administered 24 hours before irradiation. The mechanism(s) for this protection are under investigation.

### 1726

SEIZURE/STATUS EPILEPTICUS AND ANIMAL TOXICITY INDUCED BY LITHIUM PILOCARPINE CLOSELY MIMICS HIGH-DOSE ORGANOPHOSPHATE EXPOSURE.

M. P. Nambiar<sup>1</sup>, L. M. Tetz<sup>1</sup> and R. K. Gordon<sup>1</sup>. <sup>1</sup>Biochemical Pharmacology, Walter Reed Army Institute of Research, Silver Spring, MD, <sup>2</sup>Biochemical pharmacology, WRIAR, Silver Spring, MD and <sup>3</sup>Biochemical Pharmacology, WRIAR, Silver Spring, MD.

In organophosphororus chemical warfare agent exposure, inhibition of neuronal AChE leads to excessive acetylcholine accumulation resulting in hypercholinergy and seizure. Prolonged and repeated seizure (status epilepticus, SE), leads to neuronal damage and neurobehavioral abnormalities. The series of events leading to neurodegeneration following organophosphate exposure are not understood. Thus, there is a requirement for drugs that can protect against OP induced SE and neuropathology. We have developed a rat lithium-pilocarpine animal model and radiotelemetry using bipotential probes to rapidly screen the efficacy of various new generation and next generation anti-epileptic drugs for protection against seizures/SE and the consequent neurobehavioral impairment. Administration of a single dose 220-240 mg/kg pilocarpine, ip, 24 h after 5 mEq lithium injection produce strong seizure/SE. Comparison of seizure/SE produced by lithium pilocarpine to nerve agent to published data of soman shows a close resemblance. The onset of EEG spike activity is observed at 4 min after administration and siezure episodes after 9 min that is followed by SE. Sensitivity regarding gender, quiet period after seizure, frequency, low frequency spikes, clonic jerks of the head & shoulder, repetitive episodes of facial and forelimb clonus, rearing on hind legs, weight loss, brief episodes straub tail, prominent fasciculation of the back and trunk and hunched posture after 24 h were comparable between pilocarpine model and soman exposure. Animal toxicity by survivability and brain histopathology were also similar between pilocarpine and high-dose soman exposure. These data suggest that a single dose injection of pilocarpine following lithium is reminiscent of chemical warfare agent exposure and can be used to rapidly screen potential drugs for post exposure

<sup>2</sup>Pharmacology, USAMRICD, Aberdeen Proving Ground, MD. Sponsor: J. Yourick.

highly toxic organophosphorate VX [O-ethyl (2(diisopropylamino)ethyl)methyl phosponothionate] is an irreversible inhibitor of the enzyme acetylcholinesterase (AChE). Prolonged inhibition of AChE increases endogenous levels of acetylcholine and is toxic at nerve synapses and neuromuscular junctions. We hypothesized that repeated low-level exposures to VX would affect genes associated with cell survival, neuronal plasticity and neuronal remodeling, including brain derived neurotrophic factor (BDNF). We examined the time course of expression of BDNF mRNA expression in mouse brain following repeated exposure (1/day for 5 days/wk for 2 wk) to low levels of VX (0.2 LD50 and 0.4 LD50). In situ hybridization analysis for BDNF mRNA expression showed that there was a significant elevation in BDNF mRNA expression in brain regions including the dentate gyrus, CA3, and CA1 (P<0.05) regions of the hippocampal formation, as well as in the piriform cortex, hypothalamus, amygdala and thalamus, 2 hr and 72 hr after the last 0.4 LD50 VX exposure. In addition, 0.2 LD50 VX increased BDNF expression in the piriform cortex and the dentate gyrus 2 hr, but not 72 hr, following the last VX exposure. The greater susceptibility of the piriform cortex and hippocampus to BDNF changes following low dose VX exposure is of interest since these two limbic regions are important for the generation and propagation of seizures. Whether increased BDNF in response to repeated low dose VX exposure is an adaptive response to prevent cellular damage, or is a precursor to impending brain damage, remains to be determined. If elevated BDNF is an adaptive response, exogenous BDNF may be a potential therapeutic target to reduce toxic effects of nerve agent exposure.

### 1728 LOW-LEVEL EFFECTS OF VX VAPOR EXPOSURE ON PUPIL SIZE IN RATS.

Thomson</u><sup>1</sup>. <sup>1</sup>US Army Edgewood Chemical Biological Command, Aberdeen Proving Ground, MD and <sup>2</sup>Geo-Centers, Inc., Gunpowder, MD

O-Ethyl S- [2-(diisopropylamino)ethyl] methylphosphonothioate (VX) can present an inhalation, ocular and dermal hazard in vapor or aerosol form. One of the first observable clinical signs of VX vapor exposure is miosis. Therefore, the objective of this study was to characterize the dose-response (miosis) relationship of VX vapor for acute whole-body exposures in rats. Effective dosages (concentration x time) resulting in miosis in 50% of the exposed rats (ECt50) were calculated for 10, 60 and 240- minute exposures. Rats were exposed to low levels of VX vapor in a 750-liter dynamic air flow inhalation chamber. Air-exposed rats served as sham controls. Pupil size changes were assessed with infrared pupillometry. Results indicate that the ECt50s for each exposure duration were not constant but increased with increasing exposure duration. The ECt50s were 1-2 orders of magnitude lower than the ECt50s of at least two other related organophosphorous (OP) compounds, sarin (GB) and cyclosarin (GF). At these concentrations there was no evidence of delayed miotic effects caused by additional inhalation, ocular or dermal penetration of VX.

A COMPARISON OF BASELINE CHOLINESTERASE LEVELS AND THE INHIBITORY RESPONSE TO PYRIDOSTIGMINE IN WHOLE BLOOD, PLASMA, AND RBCS FROM HUMANS AND SEVERAL NONHUMAN PRIMATE SPECIES.

N. A. Niemuth<sup>1</sup>, <u>C. T. Olson</u><sup>1</sup>, T. L. Hayes<sup>1</sup>, G. van der Zwaag<sup>1</sup>, C. Matthews<sup>1</sup>, D. E. Lenz<sup>2</sup> and I. Koplovitz<sup>2</sup>. <sup>1</sup>Medical Research and Evaluation Facility, Battelle Memorial Institute, Columbus, OH and <sup>2</sup>US Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, MD.

The purpose of this investigation was to compare baseline cholinesterase (ChE) levels and the response to the ChE inhibitor pyridostigmine (PB) in blood, plasma and packed RBCs from humans (HUM), Indian Rhesus (IRH), Chinese Rhesus (CRH), Cynomologus (CYN), and African Green (AFG) monkeys. Baseline ChE and AChE activities were measured in duplicate on a Hitachi 912 clinical analyser using the Boehringer Mannheim modification of the Ellman method. Blood was

spiked with PB to produce final concentrations of 15, 30, or 150 ng/ml. ChE inhibition was measured after approximately one hour. Baseline whole blood ChE levels were similar in IRH, CRH, CYN and AFG monkeys (5.3-6.0 University/mL), but were significantly less than the HUM level (8.4 University/mL). Plasma ChE levels were similar in HUM, IRH, CRH, and CYN (4.3-5.2 University/mL), but were significantly greater than in AFG monkeys (0.6 University/mL). RBC AChE levels were more variable between the individual species. These were highest in humans (10.3 University/ml) lowest in CYN (4.4 University/ml) and mid-level (6.3, 6.9 and 8.1 University/ml) in CRH, IHR, and AFG monkeys, respectively. All species exhibited a strong inhibitory response to PB. In whole blood, the dose-response trend was significantly steeper for AFG than HUM, IRH, CRH, and CYN. Otherwise, similar trends were observed for all species, despite differences in baseline ChE and AChE levels. These results indicate that baseline ChE and AChE, and the in vitro inhibitory response to PB differ among primate species; in particular, baseline plasma ChE and whole blood ChE inhibition measured in AG monkeys differed from other primate species.

#### 1730

LOCALIZATION OF SUBSTANCE P GENE EXPRESSION FOR EVALUATING PROTECTIVE COUNTERMEASURES AGAINST SULFUR MUSTARD.

S. L. Casbohm<sup>1</sup>, J. V. Rogers<sup>1</sup>, M. K. Stonerock<sup>1</sup>, J. L. Martin<sup>2</sup>, K. M. Ricketts-Kaminsky<sup>2</sup>, M. C. Babin<sup>1</sup>, R. P. Casillas<sup>1</sup> and C. L. Sabourin<sup>1</sup>. <sup>1</sup> Medical Research & Evaluation Facility, Battelle, Columbus, OH and <sup>2</sup>US Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, MD.

Sulfur mustard [bis(2-chloroethyl)sulfide; SM] is a chemical warfare agent that produces edema and blister formation with a severe inflammatory reaction. The neuropeptide Substance P (SP) contributes to skin inflammation. The mouse ear vesicant model for cutaneous SM injury has been used to evaluate pharmacological agents for countering SM injury. The vanilloid, olvanil has been shown to reduce SM-induced edema and mRNA expression of cytokines and chemokines, suggesting that blocking the inflammatory effects of SP may provide protection against SM-induced dermal injury. This study examined SP expression in skin exposed to SM. Mice were exposed topically to SM (0.16 mg) on the inner surface of the right ear, with or without olvanil pretreatment, and tissues were collected at 1, 10, 30, 60, and 360 min following SM exposure. SP mRNA was localized in skin using in situ hybridization. In naive skin, mRNA localization was associated with blood vessels and sebaceous glands. In SM-exposed samples, hybridization was also detected in perivascular dermal cells. SP protein expression was identified immunohistochemically in the ear skin of naive, SM-, olvanil/SM-, and vehicle-treated mice. For the inner surface of the ear, the mean number of SP-positive perivascular cells in the dermis of olvanil-treated/SM-exposed ears was significantly lower than that of SMexposed ears at both 60 and 360 min. In the outer surface of the ear, the mean number of SP-positive perivascular cells in the dermis of olvanil-treated/SM-exposed ears was significantly lower than that of SM-exposed ears at 360 min. These findings suggest that drugs targeting pro-inflammatory neuropeptides may reduce the severity of SM-induced cutaneous damage. Supported by the US Army Medical Research and Materiel Command under Contract No. DAMD17-99-D-0010, Task Order 0013.

#### 1731

PROTEOLYTIC CLEAVAGE AND COUNTER-IRRITATING EFFECT OF H2A HISTONE FRAGMENT AGAINST SULFUR MUSTARD-INDUCED SKIN LESIONS.

<u>University</u>, <u>Wormser</u> and B. Brodsky. *Institute of Life Sciences, The Hebrew University*, Jerusalem, Israel.

Skin exposure to sulfur mustard (SM), a potent chemical-warfare agent, results in erythema, edema, and blisters. Previous studies demonstrated the protective effect of topical iodine treatment against SM-induced skin damage. Iodine exerts its beneficial activity by induction of endogenous protective peptide, identified as 9 amino acids fragment of histone H2A. The anti-inflammatory/anti-vesicating activity of the peptide was evaluated by the mouse ear edema model. Intravenous administration of 0.1, 1 and 10 mg/kg of the peptide 5 min prior to SM exposure caused statistically significant reduction of 20%, 23% and 22%, respectively, in mouse ear swelling as compared to control animals injected with saline. The t1/2 of the peptide in mouse and human serum was 7 and 14 min, respectively. The degradation products were separated by HPLC and identified by mass spectra. Similar cleavage sites were observed for both human and mouse serum. It is suggested that the antidotal effect of the peptide might be of therapeutic value in protecting other sensitive tissues such as lung and bone marrow and in treatment of inflammation-associated disorders. (This study was supported by US Army Medical Research and Material Command under Cooperative Agreement DAMD17-03-2-0013.)

#### 1732

REDUCED SULFUR MUSTARD-INDUCED SKIN TOXICITY IN CYCLOOXYGENASE-2 KNOCKOUT AND CELECOXIB-TREATED MICE.

A. Nyska<sup>1</sup>, A. Sintov<sup>2</sup>, R. Langenbach<sup>3</sup>, B. Brodsky<sup>4</sup> and <u>University. Wormser</u><sup>4</sup>.

<sup>1</sup>Laboratory of Experimental Pathology, NIEHS, Research Triangle Park, NC,

<sup>3</sup>Laboratory of Molecular Carcinogenesis, NIEHS, Research Triangle Park, NC and <sup>4</sup>Institute of Life Sciences, The Hebrew University, Jerusalem, Israel.

Sulfur mustard (SM) is a potent vesicant which elicits inflammatory response upon skin exposure. To evaluate the role of COX-1 and COX-2 in SM-induced skin toxicity, we applied the agent to the ears of wildtype (WT), COX-1-deficient, and COX-2-deficient mice. In the latter, SM-induced ear swelling was significantly reduced as compared to WT. Quantitative histopathology revealed no epidermal ulceration in COX-2-deficient mice, whereas the WT showed some degree of severity in this parameter. COX-2-deficient mice showed significant reductions in severity of epidermal necrosis, acute inflammation and hemorrhage as compared to the WT mice. COX-1 deficiency resulted in significant exacerbation in severity of epidermal ulceration and epidermal necrosis as compared to WT strain. Post-exposure intraperitoneal injection of the selective COX-2 inhibitor celecoxib to normal mice resulted in significant reduction in ear swelling at intervals of 40 and 60 min between exposure and treatment. Histopathological evaluation showed significant reductions in subepidermal microblister formation and dermal necrosis as compared to the control group. Topical treatment with a combination of iodine, clobetasol and celecoxib at interval of 20 min between exposure and treatment resulted in significant reduction in ear toxicity. These findings may indicate that a) COX-2 participates in the early stages of SM-induced skin toxicity, b) COX-1 might exert some protective function against this chemical insult, c) topical preparation containing COX-2 inhibitor is effective in reducing SM-induced skin toxicity (This study was supported by US Army Medical Research and Material Command under Cooperative Agreement DAMD17-03-2-0013).

### 1733 GENE EXPRESSION IN MICE EXPOSED TO LOW AND HIGH LEVELS OF SULFUR MUSTARD.

J. V. Rogers<sup>1</sup>, Y. W. Choi<sup>1</sup>, R. C. Kiser<sup>1</sup>, <u>R. P. Casillas<sup>1</sup></u>, <u>M. C. Babin<sup>1</sup></u>, <u>J. J. Schlager</u> and <u>C. L. Sabourin<sup>1</sup></u>. <sup>1</sup>Medical Research & Evaluation Facility, Battelle Memorial Institute, Columbus, OH and <sup>2</sup>Pharmacology Division, US Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, MD.

Sulfur mustard [bis-(2-chloroethyl)-sulfide; SM] exposure leads to blister formation in skin of exposed individuals. This study examined SM-induced changes in gene expression using cDNA microarrays in skin from mice cutaneously exposed to SM. Ear skin from five mice, paired as SM-exposed right ear and vehicle control left ear at six dose levels (0.005, 0.01, 0.02, 0.04, 0.08, and 0.16 mg), was harvested at 24 h. Alterations in gene expression were analyzed using cDNA microarrays containing 1, 176 genes. Genes were selected on the basis of all mice (N=5) in the same dose group demonstrating a ≥2-fold increase or decrease in gene expression in SMexposed tissue compared to control skin at all six SM doses. When comparing skin exposed at all six SM doses with controls, a total of 19 genes within apoptosis, transcription factors, cell cycle, inflammation, and oncogenes and tumor suppressors categories were found to be up-regulated; no genes were down-regulated. A comparison of skin exposed to low (0.005 and 0.01 mg) and high (0.08 and 0.16 mg) doses of SM showed differences in the number and category of genes that were upor down-regulated. Low level SM primarily altered transcription factors and repressors as well as genes involved in the cell cycle (e.g., cdc25B; cyclins) and apoptosis (e.g., GADD45; TNF receptor ligands); whereas high level SM also altered genes related to cytokines, chemokines, growth factors and hormones (IL-1β, MCP-1, MIP-1α, and MIP-2). The results of this study provide a further understanding of the molecular responses to cutaneous SM exposure, and enable the identification of potential diagnostic markers and therapeutic targets for treating exposure to low and high levels of SM. Supported by the US Army Medical Research and Materiel Command under Contract No. DAMD17-99-D-0010, Task Order 0007.

### 1734

EFFECTS OF THE CHEMICAL WARFARE AGENT SULFUR MUSTARD ON OXIDATIVE METABOLISM IN CULTURED HUMAN EPIDERMAL KERATINOCYTES.

M. E. Martens. Biochemical Pharmacology Branch, US Army Medical Res. Inst. Chemical Defense, Aberdeen Proving Ground, MD. Sponsor: A. Brimfield.

Historically, the effects of sulfur mustard (2, 2'-dichlorodiethyl sulfide, SM) on the mitochondrial pathways involved in oxidation of various metabolic substrates have not been well-characterized. Therefore, we have examined the effects of SM on oxidative metabolism in cultured human epidermal keratinocytes (HEK). Our previous results have shown that, while the oxidation of glucose *via* the Krebs cycle is virtually absent in HEK, the rate of glutamine oxidation is sufficient for it to be a

significant source of energy in these cells. We also demonstrated that oxidation of glutamine and palmitic acid is inhibited by vesicating concentrations of SM (100 -500 mM). Between 8 - 24 hours after exposure the degree of inhibition at 500 mM SM was severe enough to suggest that irreversible mitochondrial damage had occurred. Here we report the results of time- and concentration-dependence studies of SM-induced inhibition of glutamine oxidation. In these studies, metabolic activity was determined by measuring the rate of 14CO2 production from 14C-glutamine. In controls and at all concentrations of SM used, 14CO2 production was linear between 0 - 18 hours. It then plateaued between 18 - 24 hours, suggesting depletion of one or more vital metabolites, so these data were disregarded when calculating respiratory rates. In these experiments, SM concentrations of 25, 50 and 100 mM had no effect on the metabolic rate, whereas significant inhibition was seen at both 200 and 300 mM SM (72% and 85% inhibited, respectively; P < 0.05). Although in our preliminary studies we did see inhibition at 100 mM SM, it was not as severe as that at 300 mM or higher. It may be that 100 mM is at or near a threshold value below which mitochondrial metabolism is not affected. This is similar to the threshold level (67 - 167 mM) we have reported for SM-induced NAD+ depletion and inhibition of anaerobic glycolysis. We concluded from these results that mitochondrial metabolic injury may play an important role in the development of SM-induced pathology.

1735

THE USE OF FLOW CYTOMETRY TO DETERMINE THE EFFECTS OF THE VESICATING AGENTS SULFUR MUSTARD (SM) AND LEWISITE (L) ON HUMAN T CELLS (CD3+).

H. L. Meier. BiochemPharmacology, USAMRICD, Aberdeen Proving Ground, MD. Sponsor: A. Brimfield.

It was learned from the casualties of the Iran-Iraq war that exposure to the vesicating agent SM caused a decrease in the number of circulating white blood cells (WBC). To understand the effects of the vesicant on the WBC, it was decided to study changes induced by vesicants on the subpopulations of leukocytes. Leukocytes were exposed to either SM or L, and the effects of these vesicating agents on CD3+ were investigated by flow cytometry. There were no detectable changes in size, density, or activation of cytotoxic pathways during the first 4 hrs after SM in CD3+, but there was a concentration (conc) dependent decrease in the percent of CD3+. At 24 hrs after SM exposure, CD3+ showed a steep increase in Annexin V+ (AV+) [marker of apoptosis] cells at 10µM SM but required higher conc of SM to demonstrate similar conversion of the CD3+ to Viaprobe (7-AAD+) and propidium iodide (PI+) [markers of necrosis]. L, on the other hand, caused no observable change in the percent of the CD3+ at any of the time points studied but caused increased binding of cytotoxic markers as early as 1 hr after L exposure. L caused a time- and conc-dependent increase in the binding of AV, 7-AAD, and PI to the exposed cells. At 1 and 4 hrs after L exposure, there was a large increase in AV+ cells, PI+ and 7-AAD+ cells at 100 μM L, but at 24 hrs post-exposure to L the large increase in the binding of these markers was at 10  $\mu \dot{M}$  . These findings were consistent with the findings that SM initially cause the activation of the apoptotic cell death pathway during the cells latent period. After the cell is depleted of energy at 4-8 hrs it converted to the necrotic pathway of cell death. However, cells exposed to L demonstrated no latent period and appeared to enter into the necrotic cell death pathway within the first hr after L exposure.

1736

THIODIGLYCOL METABOLISM BY ALCOHOL DEHYDROGENASE USING NMR: SYNTHETIC ROUTE TO THE METABOLIC INTERMEDIATE HYDROXYETHYLTHIOACETALDEHYDE.

A. A. Brimfield<sup>1</sup> and M. J. Novak<sup>2</sup>, <sup>1</sup>Biochemical Pharmacology, USAMRICD, Aberdeen Proving Ground, MD and <sup>2</sup>Chemistry, Florida Institute of Technology, Melbourne. FL.

In aqueous solution sulfur mustard (2, 2'-bis-chloroethyl sulfide) hydrolyzes to thiodiglycol (2, 2'-bis-hydroxyethyl sulfide, TDG). We demonstrated the metabolism of TDG in homogenates of human skin and by pure horse liver alcohol dehydrogenase (ADH) [J.Biochem. Molec. Toxicol.1998. 12:361] *in vitro* by monitoring NAD reduction at 340 nm. Following the enzymatic reaction by NMR we identified 2-hydroxyethylthioacetic acid as the end prodict of the two-step TDG oxidation [for conditions see The Toxicologist. 2002.66(1S):230 abst. 1128]. Based on the absence of a down field aldehyde signal, we concluded the intermediate aldehyde remained in the active site while a second molecule of NAD was reduced. Subsequent NMR studies indicat a transient peak at 3.42 ppm, suggesting the presence of the hydrated aldehyde intermediate. Here we report a synthetic route to this labile intermediate by diisobutyl aluminum hydride reduction of the monoprotected methyl ester of 2-hydroxyethylthioacetic acid (methyl 2-[t-butyldimethylsi-

lyloxy]ethylthioacetate) at -60 C° in toluene. The protective silyl group, used to prevent potential cyclization during reduction, was removed using tetrabutylammonium fluoride in tetrahydrofuran. NMR in duterochloroform exhibited signals at 9.4 ppm (*t*, J=3.3 Hz, CHO) and 2.3 ppm (*d*, J=3.3 Hz, RSCH<sub>2</sub>CHO). This compound will be used to confirm the identity of the peaks in the ADH NMR spectra.

1737

REAL-TIME CONCENTRATION AND RESPIRATORY MONITORING TO CONTROL PRESENTED DOSE IN AN AUTOMATED AEROSOL EXPOSURE SYSTEM.

J. M. Hartings<sup>1, 2</sup>, B. R. Goodenow<sup>2</sup> and <u>C. J. Roy<sup>2</sup></u>. <sup>1</sup>Biaera Technologies, Inc., Frederick, MD and <sup>2</sup>Department of Aerobiology and Product Evaluation, USAMRIID, Fort Detrick, MD.

Well-characterized aerosol systems are critical for toxicological and pharmacological studies involving inhaled materials. Accurate and precise delivery and subsequent measurement of an a priori determined inhaled dose is a determinative factor in identifying biological responses to inhaled materials. An automated bioaerosol exposure system (ABES) has been developed that utilizes real-time respiratory and aerosol concentration monitoring to control exposure duration and presented dose. Pressure fluctuations in the head-only exposure chamber, caused by the nonhuman primate pulmonary function, were used to determine respiratory rate, tidal volume, and minute volume. For each breath detected, the ABÊS software multiplied the measured tidal volume by the aerosol concentration as determined by Thermo Anderson MIE personalData RAM air sampling device to calculate a presented dose. ABES summed the doses from each breath and automatically terminated the exposure when the requisite presented dose was achieved. To validate this method, rhesus macaques (n = 9) were exposed to aerosolized staphylococcal enterotoxin B with a target presented dose of 220 µg/kg as part of an ongoing vaccine efficacy study. Aerosol samples were taken by using an all glass impinger (AGI) to compare the ABES determined presented dose to that from the in-use dose measurement technique. Animal weights ranged from 4.3 to 9.8 kg, respiratory minute volumes ranged from 1059 to 2800 ml, and average aerosol concentration ranged from 35.7 to 55.7  $\mu$ g/L. AGI sample analysis indicated a presented dose of 210  $\pm$  30  $\mu$ g/kg for all of the test subjects. These results indicate that this feedback-based, dose-metering algorithm of the ABES can successfully accommodate a wide range of experimental conditions and physiological parameters. The resulting precision and accuracy of delivering an a priori defined presented dose to non-human primates will isolate dose response as the primary determinant of biological outcomes.

1738

REAL-TIME DOSIMETRY INCORPORATES UNANTICIPATED RESPIRATORY CHANGES DURING SEB AEROSOL EXPOSURES WITH RHESUS MACAQUES.

C. J. Roy, B. R. Goodenow and J. M. Hartings. Aerobiology & Product Evaluation, USAMRIID, Fort Detrick, MD.

Staphyloccocal enterotoxin B (SEB) is a protein toxin derived from Staphyloccocus aureus and is considered a biological threat agent. When disseminated as an aerosol, SEB can cause a shock-like disease, inducing vascular leak and formation of pulmonary lesions as little as 24-48 hours after inhalation. Nonhuman primates are the animal model of choice in pathogenesis and vaccine efficacy studies because of the sensitivity of the species to the toxin. In an ongoing efficacy study, the use of realtime dosimetry function of the Automated Biaerosol Exposure System (ABES) was used to control the delivery of the SEB challenge dose. Six weeks after vaccination, Rhesus macaques (n=10) were challenged with aerosolized SEB (MMAD=1.0 µm,  $\sigma_{g} = 1.4$ ) at a target dose of 220 µg/kg ( $\approx 10 \text{ LD}_{50}$ s). A head-only configuration of the ABES in a class III safety cabinet was used in the exposures. Anesthetized (Telazol, 5-6 mg/kg) primates were allowed to breathe the requisite volume of atmosphere based on particle concentration to attain the predetermined dose rather than relying on a timed exposure based on predictive measures such as plethysmography. Time to reach the requisite dose was highly variable (mean  $\pm$  S.D. = 22:07  $\pm$ 8:04 mm:ss) and marked fluctuations in the respiratory parameters (tidal volume, TV; frequency, F) were observed in many of the animals. Linear regression analysis of the pulmonary data showed significant deviations (p<0.05) in the TV and F in 40 and 60% of the primates under study, respectively. Changes in respiratory function may have been a result of unanticipated acute pulmonary reactions to the aerosolized SEB or changes in the plane of anesthesia during the course of the procedure. In conclusion, the real-time dosimetry function supplied by the ABES platform during inhalation exposure proved useful in adapting to an unanticipated acute-phase changes in the respiratory patterns of the primates and improved accuracy (and overall precision) of the group target dose congruence in the challenge portion of this efficacy study.

### 1739

IMMUNE RESPONSE INDUCED BY AN EXPERIMENTAL MUCOSAL ADJUVANT ADMINISTERED WITH RECOMBINANT PROTECTIVE ANTIGEN (RPA) IN A GUINEA PIG CHALLENGE MODEL.

E. K. Leffel, B. R. Goodenow and C. J. Roy. Toxinology & Aerobiology, USAMRIID, Frederick, MD.

Bacillus anthracis, a spore-forming aerobic bacterium, is considered a biological threat agent when disseminated as an aerosol. The organism possesses three primary virulence factors, edema toxin (protective antigen + edema factor), lethal toxin (protective antigen + lethal factor) and a d-glutamyl polypeptide capsule. A recombinant protective antigen (rPA) vaccine was efficacious against aerosol challenge when administered by intramuscular injection (IM). This form of vaccination induces circulation of systemic IgG antibody, but has not been shown to induce mucosal immunity. In order to invoke mucosal immunity and reduce time to protection, target delivery of the vaccine to a mucosal surface, such as the nasal lining, is proposed. To test the alternative delivery of rPA, guinea pigs were vaccinated either intranasal (IN) or IM with 50 µg of rPA combined with the adjuvant CpG (CpGcontaining oligonucleotides). This vaccine preparation was compared to the standard adjuvant Alhydrogel<sup>TM</sup> (ALH). The vaccination was administered in a threedose schedule 28 days apart. Analysis of sera indicated higher circulating anti-rPA IgG in both the IM and IN groups. Analysis of bronchoaveolar lavage (BAL) fluid was used to detect an inflammatory response and production of s-IgA. Animals vaccinated with rPA-ALH or ALH alone were then challenged by aerosol to 200 LD<sub>50</sub> of B. anthracis (Ames strain). Results showed partial survival in the IM vaccinees (30%) compared to ALH controls (17%) and naïve controls (0%). Aerosol challenge is scheduled for the rPA-CpG groups. The preliminary results of this study suggest that the immune response observed in the IN-vaccinees indicative of protection when compared to the antibody levels present in the survivors vaccinated by injection.

### 1740

A NOVEL VACCINE DELIVERY SYSTEM THAT MINIMIZES ADVERSE EVENTS WHILE IMPROVING IMMUNE RESPONSE.

J. M. Blonder<sup>1</sup>, C. Coeshott<sup>1</sup>, E. Verderber<sup>1</sup>, A. Samaniego<sup>1</sup>, C. Tate<sup>1</sup>, K. Stone<sup>1</sup>, S. Smithson<sup>2</sup>, M. Westerink<sup>2</sup> and G. J. Rosenthal<sup>1</sup>. <sup>1</sup>Drug Development, RxKinetix, Inc., Louisville, CO and <sup>2</sup>Department of Medicine, Medical College of Ohio, Toledo, OH.

Given the rapid advances in vaccine engineering in the last decade, it is important that delivery systems for such agents are equally efficacious and amenable to widespread use. We recently developed a vaccine delivery system (F127/CpG) using Pluronic® F127 as a sustained release polymeric vehicle and a CpG motif as an adjuvant. F127/CpG has generated rapid, potent and durable antibody responses to protein antigens after a single injection in rodents. Presently, the safety of F127/CpG was examined to further establish its utility. Recombinant anthrax protective antigen (rPA) was formulated in F127/CpG and injected sc into mice. Potential adverse effects by rPA/F127/CpG were measured by following body weight gain, appearance of palpable nodules at the injection site, clinical chemistries, and blood cell differentials. Immune response was determined by measuring biologically active antibodies to rPA via a toxin neutralization assay. Mice treated with rPA/F127/CpG were compared to mice treated with either rPA in CpG, rPA in aluminum hydroxide (alum) as a traditional adjuvant/delivery system, or vehicles. Injection of rPA/F127/CpG caused no overt adverse effects when compared to the other rPA groups or vehicles. Over 10 weeks, the average body weight gain ranged from 3.2±1.4 g to 4.7±1.7 g. Reaction at the injection site was less pronounced in rPA/F127/CpG. Specifically, palpable nodules were observed in 1, 3, or 4 mice (out of 8) at 8 weeks and 0, 0, and 2 mice (out of 8) at 10 weeks for rPA/F127/CpG, rPA/CpG, or rPA/alum. Clinical chemistries and blood cell differentials did not vary among rPA or vehicle groups and were within normal ranges. Relative levels of neutralizing antibodies to anthrax toxin were 134, 104, and 42 for rPA/F127/CpG, rPA/CpG, or rPA/alum. These data demonstrate that injection of rPA in F127/CpG is well tolerated in mice and induces an improved immune response when compared to a more traditional vaccine system in which alum is utilized.

## 1741 DIFFERENTIAL SUSCEPTIBILITY OF MACROPHAGE CELL LINES TO BACILLUS ANTHRACIS (VOLLUM 1B).

B. W. Gutting, K. Gaske, R. Mackie, A. Slaterbeck, L. Sobota, A. Schilling and T. Buhr. *Naval Surface Warfare Center, Dahlgren, VA*.

Bacillus anthracis (BA) is the causative agent of anthrax disease. Macrophages (M $\phi$ ) play critical roles in bacterial infections. During infection, BA secretes several toxins that act on M $\phi$ s. One, lethal factor (LF), demonstrates specific cytotoxicity for M $\phi$ s and another, protective antigen (PA), aids in delivering LF to the cytosol. The ob-

jective of the present work was to examine the susceptibility of  $\ensuremath{\mathsf{M}} \varphi s$  for the Vollum 1B (LF+PA+) strain of BA. This work used RAW264, IC-21 and J774 Mφs. Cytotoxicity was determined using trypan blue (TB) exclusion, neutral red (NR) uptake, and lactate dehydrogenase (LDH) activity in the culture supernatant. With all M\$\psi\$s, outgrowth of vegetative BA was observed 8 hours after the addition of BA spores. RAW264 cells were the most sensitive to the toxic effects of BA; at 8 hours, a significant increase in LDH was detected (115 percent ↑ compared to control) and at 24 hours all RAW264 cells were dead (346 percent ↑ in LDH activity). Cytotoxicity of J774 Mφs could not be detected until 20 hours post infection using LDH activity (109 percent ↑ vs. control) and a significant decrease in NR uptake was detected at 21 hours (p<0.001). With RAW264 and J774 M\$\phi\_s\$, TB staining was detected at 12 and 15 hours, respectively. In studies using IC-21 M\$\phi\_s\$, no significant cell death using TB, NR or LDH could be detected up to 26 after the addition of BA spores, despite vegetative growth of BA in the culture for >18 hours. Neutralization studies were conducted using anti-LF and anti-PA antibody. Here, the addition of anti-PA, but not anti-LF, prevented RAW264 cell death. These data suggest that (i) M\$\phi\$ cell lines demonstrate differential susceptibility towards virulent BA, (ii) IC-21 cells do not undergo necrosis when co-cultured >18 hours with vegetative Vollum 1B, and (iii) the mechanism of RAW264 cell death is mediated, in part, by PA. A better understanding the mechanism of Mφ resistance or susceptibility to BA may lead to novel therapies for anthrax disease. (Supported by ONR)

## 1742 METHYLMERCURY CONTAMINATION IN FISH: HUMAN EXPOSURES AND RISK COMMUNICATION.

D. D. Petersen. NRMRL, USEPA, Cincinnati, OH.

Many people in America are at risk for methylmercury toxicity because of their consuption of contaminated fish. Often the health risks of various persistant bioaccumulating toxicants (PBTs) are underestimated because amplification in food chains results in toxic levels of contamination even though ambient levels in water bodies may be near detection limits. Two concerns have developed form this situation. First: many of the susceptible individuals are unaware of the risk, and second; there are few effective means of communicating the risk information to these individuals. Recent data shows that approximately 8% of American women bear methylmercury body burdens that are above thresholds for toxic symptoms in the developing fetus. Given the EPA reference dose of .1 mg/kg/day and can tuna with 17ug/can, the safe dose of tuna for a small child would be once every two weeks. A handbook for communicating this information has been prepared and will be diplayed.

# 1743 LINKING COMMUNITY OUTREACH AND EDUCATION WITH RESEARCH TO IMPROVE THE HEALTH OF A POPULATION.

C. G. Sumaya<sup>1</sup>, G. Carrillo<sup>2,1</sup>, <u>K. C. Donnelly<sup>2,1</sup></u> and J. A. Parrish<sup>2,1</sup>. <sup>1</sup> Center for Community Outreach and Education, Texas A& M University Center for Environmental and Rural Health, College Station, TX and <sup>2</sup> School of Rural Public Health, Texas A&M University System Health Science Center, College Station, TX.

The Community Outreach and Education Program (COEP) primarily focuses on translating the research findings of the Center for Environmental and Rural Health (CERH) and educating the rural communities of the Texas-Mexico border. A research project, "Estudio Por Ninos Saludables en Rio Bravo" was established through funds from a USEPA STAR grant and NIEHS Centers at Texas A& M and Rutgers Universities to investigate childhood exposure to pesticides. This research showed that children ages 6 to 48 months had a median exposure level to pesticides comparable to the 90th percentile from the CDC's NHANES study and that simple behavioral changes could drastically reduce potential exposures. The COEP's approach to reducing childhood exposures to pesticides was to conduct town meetings in Rio Bravo, TX to identify means of preventing children's exposure to pesticides. Local promotoras (community health workers) will be trained in pesticide and other environmental health problems affecting this population, in collaboration with the Laredo Health Department. The promotoras and colonia residents will receive a pre-intervention assessment prior to training and a post-intervention assessment after completion of the first training. This pilot program will include a bilingual environmental health curriculum to evaluate the effectiveness of the type of intervention used and an appropriate manner of delivery for this target population. The COEP is an important complement to research to expand communication in the target population and to evaluate the utility of preventive measures. Future plans include: expanding our bilingual curriculum to other environmentally related health issues and other geographic areas along the Texas-Mexico border and to link this program with Mexico health departments to reach communities on both sides of the Texas border.

#### 1744

## TRANSLATING CHILDREN'S ENVIRONMENTAL HEALTH RISK RESEARCH FOR COMMUNITIES.

C. H. Drew and E. M. Faustman. Institute for Risk Assessment and Risk Evaluation, University of Washington, Seattle, WA.

The Center for Child Environmental Health Risks Research at the University of Washington (CEHR) is working to understand the mechanisms defining children's susceptibility to pesticides and the potential for neurodevelopmental impacts. Researchers at CEHR focus on environmental, genetic, and developmental factors that determine susceptibility. Understanding where children spend their time is one emphasis for the Center. Researchers use environmental modeling and sampling, child activity patterns, and biological monitoring to better characterize the environmental and occupational "takehome exposure pathway" for children living on or near treated farmland. CEHR translates this research into a community-based research intervention project aimed at breaking the takehome pathway. A diverse community advisory board advises project staff about developing materials and intervention methods. Individual, group-based and community wide intervention activities have focused on overall child health risks. Community-wide events such as health fairs (n = 1200 individuals) were popular among the mostly Latino intervention community. They provided educational materials and items such as laundry detergent. Volunteers also teamed with professional health care workers to conduct smaller scale "home health parties" with families, friends and neighbors (n = 1000 events). Additionally, the project has developed a wide range of pesticide education materials for preschool and elementary students and for adults in citizenship and English as a second language classes. These include a Head Start curriculum for 3-4 year olds that teach pesticide safety with activities such as songs and puzzles. To date, over 18, 000 people have participated in more than 1800 events. (Supported by grants from the USEPA (R82688601), NIEHS (5PO1ES09601) and the Center for the Study and Improvement of Regulation).

ENVIROHEALTH CONNECTIONS: A COLLABORATIVE EXPLORATION OF THE ENVIRONMENT & HUMAN HEALTH.

C. Mutryn  $^1$ ,  $\underline{M}$ , A. Trush  $^2$  and G. P. Long  $^1$ .  $^1$  Maryland Public Television, Owings Mills, MD and  $^2$ JHU Bloomberg School of Public Health, Baltimore, MD.

A 7-year NIEHS-funded project to develop, implement, evaluate, & disseminate an innovative model for using environmental health science (EHS) as an integrative context for learning (EHSIC), focusing on enhancing Maryland middle & high school teacher & student awareness and knowledge of EHS and on improving overall student academic performance by developing high-quality, cutting edge interdisciplinary instructional materials/resources, based on Maryland State Standards, to be used by teachers to deliver EHS curricular content; enhancing their ability to develop & deliver interdisciplinary instruction based on EHS concepts, issues, & career opportunities and to develop skills students need to perform successfully in all academic subjects & on state-mandated standardized testing; and providing teachers & students with opportunities to interact with and learn from environmental health scientists. The project is unfolding in 3 phases: Development of Needed Curricular Materials & Enhancement of Teacher Capacity: Fall 2000 - Summer 2003; Implementation in Schools: Fall 2003 - Spring 2006; Evaluation & Dissemination of EHSIC Model: Fall 2005 - Spring 2007. Current studies & results at start of project Phase II: Completion of instructional video & interactive Breakingwebsite: EnviroMysteries: the http://enviromysteries.thinkport.org/ re: indoor air pollution & asthma; ongoing development of EHS topic lesson plans & Tech Tours for the MPT Thinkport education super site at www.thinkport.org; selection of 9 Collaborative Teaching Teams developing & implementing EHS/technology infused lessons & activities; establishment of an environmental health scientist Speakers Bureau with whom teachers & students can interact & learn; implementation of an annual 2-day Winter Colloquium, an annual statewide 4-day Summer Teacher Training Institute, and an EHSIC Electronic Learning Community at: http://www.cte.jhu.edu/ep/, providing dynamic professional development communications & resources for all educators participating in the project.

## 1746 DEVELOPMENT OF K-12 ENVIRONMENTAL HEALTH & SCIENCE (EH&S) CURRICULA.

J. A. Gorenstein, D. Cook, J. Rodriguez and R. Fuchs-Young. *Center for Research on Environmental Disease, UT M. D. Anderson Cancer Ctr., Smithville, TX.* Sponsor: C. Walker.

K-12 education increasingly employs the Internet as a source of scientific information, classroom activities and lessons. Accordingly, our Community Outreach & Education Program (COEP) develops web-based K-12 resources and curricula to inform students about mechanisms of environmental disease. The goal is to provide accurate information that promotes a better understanding of the impact of environmental disease.

ronmental factors and toxicants on human health, and encourages healthier lifestyle choices. Materials employ EH&S as an integrating context to stimulate comprehensive, inquiry-based and integrated learning across subjects, including science, language arts, history and math. Curricular materials are produced through the cooperative contributions of faculty scientists and K-12 teachers, who, respectively, provide scientific information and translate it into age-appropriate content. Curricula are piloted and evaluated in TX schools, revised as needed and distributed free-of-charge. These easily accessible curricula provide needed resources to under-funded school systems and over-extended teachers. Veggie-mon (veggiemon.org) is an EH&S website for 4-8 graders that presents lessons about causes and prevention of environmental disease through colorful and interactive characters and activities. The website includes sections on tobacco avoidance, UV exposure, diet and nutrition. Impact assessments (IRB approved) demonstrated that after viewing the website there was a significant increase in the number of students who could correctly identify environmental hazards that cause disease. SCREAM, a curriculum for high school students, investigates the interactions between environmental factors and genetics in determining cancer risk. Our most recent effort is a module for high school seniors and young adults that explores the Ethical, Legal and Social Implications (ELSI) of advancing genomic technologies that will generate data on disease susceptibility. All curricula are accompanied with teaching manuals and aids to facilitate their implementation into classroom lessons.

#### 1747 BUILDING CREDIBILITY IN K-12 EDUCATION.

H. Goeden<sup>1</sup>, P. Shubat<sup>1</sup>, L. Solem<sup>2</sup> and R. Skoglund<sup>3</sup>. <sup>1</sup>Minnesota Department of Health, St. Paul, MN, <sup>2</sup>Minnesota Pollution Control Agency, Duluth, MN and <sup>3</sup>3M, St. Paul, MN.

The Northland Chapter of the Society of Toxicology (NLSOT) has had an active education program for elementary and secondary schools (K-12) since 1999. The committee recently evaluated past experiences and expectations, resulting in a shift of focus. NLSOT now focuses on teachers and their needs instead of toxicologists, in particular bringing toxicologists to where teachers are already prepared to learn new concepts. In the first years of programming, NLSOT planned and implemented a training session for toxicologists to equip them as guest lecturers in classrooms. NLSOT inventoried resources by collecting and evaluating toxicology curriculum materials and surveying interest and skills of chapter members. In subsequent years NLSOT trained members to use Toxicology-in-a-Box<sup>TM</sup> and ToxRAP<sup>TM</sup>. The subcommittee researched teacher training and career development, and the barriers to introducing new materials into science curriculum. Over the course of three years, NLSOT found little sustained interest amongst NLSOT members in developing expertise in the K-12 classroom. NLSOT was also unable to attract teachers to attend time-intensive training in toxicology curricula. Based on successful interactions with 80 teachers at a multi-state science teachers association conference, NLSOT found that teachers who came to the conference were ready to discuss new curricula, accepted toxicology kits, attended lectures offered by toxicologists, and were interested in discussing the curricula which they developed on their own. Teaching tools developed and distributed by NLSOT included two types of seed germination and growth experiments that illustrate principles of doseresponse, a lecture on toxicological principles, and a lecture on classroom resources for teaching toxicology principles. As a result of this evaluation, NLSOT has set a goal of increasing science teachers' familiarity with SOT and toxicology concepts by participating in venues where teachers are seeking curriculum enrichment, such as annual meetings of science teachers associations.

## 1748 THE AMBIENT PROJECT: HIGH SCHOOL ENVIRONMENTAL HEALTH SCIENCES CURRICULUM.

L. Pitman<sup>1, 2</sup>, L. E. Fleming<sup>1</sup>, T. Pitman<sup>1, 4</sup>, W. Stephan<sup>1</sup>, H. Davis<sup>1</sup> and K. Goodman<sup>1</sup>. <sup>1</sup>NIEHS MFBS Center, Rosenstiel School of Marine and Atmospheric Sciences, University of Miami, Miami, FL, <sup>2</sup>Educational Specialists, Miami Dade County Public Schools, Miami, FL, <sup>3</sup>Epidemiology, Miami Dade County Public Health Department, Miami, FL and <sup>4</sup>Chemistry, Florida International University (FIU), Miami, FL. Sponsor: L. O'Fallon.

The AMBIENT Project (Atmospheric and Marine-Based Interdisciplinary Environmental Health Training) is environmental health curriculum targeted at high school teachers. AMBIENT facilitates involvement of teachers and students with research scientists and community members in an interdisciplinary approach to learning about their local and global environmental health science issues. Funded by National Institute of Environmental Health Sciences (NIEHS), the AMBIENT curriculum is based on four environmental themes with associated environmental health issues of: air (asthma), water (microbes), soil (lead), and food (foodborne illness & nutrition), as well as modules in toxicology and ethics. Each module integrates language arts (creative writing and critical reading) with math, science and mapping, and ends in a culminating experience (ie. debate or role play). The problem-based learning approach uses real-life scenarios and data. All the modules (including individual stand-alone activities) can be downloaded from the AMBIENT

Website at www.rsmas.miami.edu/groups/niehs/ambient/. At summer workshops, high school teachers work in interdisciplinary groups to enhance their own understanding of environmental health sciences and ethical issues. An outside evaluator has documented the creation and implementation of the AMBIENT curriculum with the teachers and high school students in their classrooms. Evaluation has shown significant increases in environmental health knowledge among AMBIENT teachers and students after using the curriculum, as well as actual curriculum implementation in Miami-Dade County Public Schools often crowded and highly diverse inner city high school classrooms. Future work involves the dissemination of AMBIENT, as well as the creation of additional modules with educator, community and scientific partners.

AN INTERDISCIPLINARY, ENVIRONMENTAL HEALTH-BASED APPROACH TO IMPROVING SCIENCE LEARNING BY ELEMENTARY TEACHERS AND STUDENTS.

N. Moreno, B. Tharp and P. Cutler. Center for Educational Outreach, Baylor College of Medicine, Houston, TX. Sponsor: L. O'Fallon.

The National Science Education Standards emphasize the need for improved science teaching and learning throughout grades K-12. Teacher content knowledge, appropriate teaching approaches and the use of standards-aligned curricula all have been identified as essential for effective science instruction. At the same time, the Standards emphasize the importance of connecting student learning to the real world. The Environment as a Context for Opportunities in Schools (ECOS) project in Houston, Texas is piloting an integrated approach to science teaching in elementary schools built around environmental health themes. The ECOS project uses the interdisciplinary My Health My World educational program (developed with funding from NIEHS and NCRR) as the backbone of a integrated instructional program that weaves together science, health, mathematics and reading/language arts. At the same time, the project aims to improve teacher practice through intensive summer and year-round professional development on content and teaching strategies. The ECOS project has developed and evaluated supplementary mathematics and reading materials, Spanish language components, a teacher professional development program on environmental health and new teaching units for students in grades K-2. Field tests of new materials indicated high levels of teacher satisfaction with the content and instructional approaches. In addition, teachers reported development of language arts and science skills by students. Teacher professional development provided by the project led to statistically significant increases in teacher content knowledge on topics related to environmental health and in teacher science teaching efficacy beliefs. Initial classroom observations of teachers suggest that the project is promoting interactive, inquiry teaching behaviors by teachers. The ECOS project is funded by grant number R25 ES010698 from NIEHS.

## 1750 PROBLEM-BASED LEARNING FOR ENVIRONMENTAL HEALTH.

E. Henry<sup>1</sup>, D. G. Markowitz<sup>1</sup>, P. Braus<sup>2</sup>, P. Debes<sup>1</sup>, K. Hart<sup>2</sup>, D. Hursh<sup>3</sup> and C. Martina<sup>3</sup>. Environmental Medicine, University of Rochester, Rochester, NY, <sup>2</sup>Community and Preventive Medicine, University of Rochester, Rochester, NY and <sup>3</sup>Warner Graduate School of Eudcation and Human Development, University of Rochester, Rochester, NY.

The My Environment, My Health, My Choices project offers teachers the opportunity to develop curricula to address environmental health topics in science and non-science subjects. This project involves 3-member teams, composed of science and non-science teachers, from public and private urban, rural, and suburban middle and high schools from the Rochester, New York area. Each team develops curriculum units using a problem-based learning (PBL) format to focus on a local environmental health issue. Evaluation of 4 teams participating in Phase I of this 7-year project allowed us to identify program successes and issues of concern, and enabled us to re-structure certain aspects of our program design. The evaluation included surveys, focus groups, interviews and classroom observation. Our evaluation indicated the need to overcome the difficulty in finding common curriculum planning time, meet challenges of interdisciplinary teaching within the current school structure, and solve teacher concerns about using a PBL curriculum in courses with standardized testing and state-required curricula. We also noted the need for clarity of goals and outcomes for the teachers. As a result of the evaluation, we modified certain aspects of the program, including implementing a more rigorous process to select teachers who are open to changing their classroom routine and who have strong administrative support for their participation in this project. The initial week-long training for teachers was altered from a predominantly lecture format to a hands-on workshop in which teachers participated in PBL exercises and used a curriculum development template to write initial drafts of their units. We also provided teachers will examples of how to use environmental health lessons to meet educational standards. We are currently evaluating 7 teams in Phase II of the project to assess the success of the changes that we made.

## 1751 DEVELOPMENT AND ASSESSMENT OF AN ONLINE, UNDERGRADUATE INTRODUCTION TO TOXICOLOGY COURSE.

K. L. Willett<sup>1</sup> and A. S. Bouldin<sup>2</sup>. <sup>1</sup>Pharmacology and Environmental Toxicology, University of Mississippi, University, MS and <sup>2</sup>Pharmacy Administration, The University of Mississippi, University, MS.

Introduction to Toxicology has been an elective course for honors pharmacy students and a required course for forensic chemistry majors at The University of Mississippi for a number of years. In order to increase the options available to students, this course was developed and delivered via an online format for two semesters. The course was administered through the existing Ole Miss Online structure (using Blackboard) and was divided into two blocks, each utilizing a different textbook. The first half of the course (Lectures 1-14) introduced the basic concepts and principles of toxicology while the second half was more focused on aspects of forensic toxicology including the signs, symptoms, toxicities and analytical detection methods associated with drugs of abuse (Lectures 15-28). Each week the students were responsible for viewing two or three PowerPoint presentations that supplemented their assigned online and text reading. "Lecture" was provided by voice audio that was prerecorded to explain the material on each slide. An expanded course evaluation was developed to assess student attitudes and perceptions of the online version of the course, along with perceived comparisons between online and traditional environments. A primary advantage of the online format as perceived by the students was working at a time of their own choosing; yet managing that time and "keeping up" was reported as being difficult. Most students (72%) did believe that they saved time by taking this course online (responding with a 1 or a 2 on a 5point Likert-type scale). Additionally, no student perceived that he/she missed any content by taking the course online. Current and potential challenges associated with this teaching format along with changes that may be implemented in future versions of the course will be presented.

#### 1752

CHARACTERIZING THE UNCERTAINTIES IN SCREENING AND ASSESSING RISKS TO CHEMICALS THAT DECREASE THYROID HORMONE CONCENTRATIONS.

M. J. DeVito and K. M. Crofton. ORD/NHEERL/ETD, USEPA, Research Triangle Park, NC.

A variety of chemicals alter thyroid hormones (THs) in rodents. The importance of THs during neurodevelopment, suggest that these chemicals would likely be developmental neurotoxicants. Several levels of uncertainty impact our understanding of the point of departure, mode-of-action and mechanism-of-action of xenobiotics that alter THs. Humans appear more sensitive than rodents to alterations in THs during development. In rodents, neurodevelopment toxicity may require large decreases in thyroxine (T4) concentrations (>50%). In humans, decreased IQs were observed in offspring of women subclinically hypothyroid during the first trimester with serum T4 levels decreased only 25 - 30%. The potentially greater human sensitivity to TH decreases could impact an assessment of the point of departure and the development of regulatory exposure limits. A second uncertainty is the impact of species differences in the pharmacokinetics of THs. In rodents, the serum halflife of T4 is on the order of hours whereas in humans it is 4-7 days. In humans, serum is a major storage pool for thyroid hormones. In rodents, the major storage pool is the thyroid gland. In rats, glucuronidation is a major deactivation pathway while in humans, deiodination and sulfation is more important. These differences may result in altered sensitivity to environmental chemicals. Another uncertainty is species differences due to altered sensitivity to the mechanisms of action of xenobiotics; e.g., induction of UDPGT, which increases elimination of THs, is mediated in part by CAR and PXR pathways. There are species differences in the structure activity relationship for activation of these pathways that could lead to altered species sensitivity to xenobiotics. Present mammalian screens for chemicals that thyrotoxic xenobiotics do not consider these potential species differences. Development of alternative screens that could also assess these species differences could aid in our ability to screen and assess thyrotoxic chemicals. (This abstract does not represent USÉPA policy.)

## 1753 ESTABLISHING A SAFE DOSE FOR PERCHLORATE BASED ON HUMAN EVIDENCE OF A NO EFFECT LEVEL.

R. C. Pleus<sup>1</sup>. <sup>1</sup>Intertox, Seattle, WA and <sup>2</sup>Pharmacology, UNMC, Omaha, NE.

The pharmacology of perchlorate is well understood. Perchlorate acts by competitively inhibiting iodide uptake at the sodium iodide symporter in the thyroid, which is the basis of its use as a medication. The medical and toxicological aspects

of perchlorate are well known and have been extensively reviewed (Wolff 1998; Goodman 2003). Traditionally toxicologists test chemicals by looking for clear indications of adverse effects in laboratory animals. Such indications might include tumors, hyperplasia, microscopic lesions, and structural abnormalities. Once adverse effects have been characterized, toxicological testing evolves by lowering the exposure dose in order to define a no-observable-adverse-effect level (NOAEL) or failing that, a lowest-observable-adverse-effect level (LOAEL). When these doses are established, uncertainty factors are applied to establish safe values for human exposure. However, when the pharmacology of an agent is known, this knowledge can be used to establish with virtual certainty a lower bound other than zero for a safe exposure level. Identifying the threshold of a precursor to a precursor to a possible adverse effect in humans logically increases both precision and *certainty*, and thus overcomes the limitations of the traditional uncertainty factor approach. For perchlorate, iodide uptake is the initial step (precursor) of the biochemical pathway that could lead to a clinically significant reduction in circulating thyroid hormones (TH). Such a change in TH could lead to developmental deficits in the fetus, the accepted population of concern. Greer et al. (2002) measured a no-observed-effect level (NOEL) of 0.007 mg/kg-day and estimated a true no-effect level (NEL) of 0.005 to 0.006 mg/kg-day for inhibition of radioiodine uptake (RAIU) by perchlorate in men and women. Apart from being an inherently safe dose, the estimated NEL provides a plausible lower bound for a reference dose derived from traditional animal toxicology studies. Further, the NEL has inherently greater precision than a NOAEL or LOAEL and this precision should be reflected when choosing values for uncertainty factors.

## 1754 EXPOSURE ASSESSMENT FOR PERCHLORATE IN DRINKING WATER.

D. Proctor<sup>1</sup>, E. Cohen<sup>1</sup>, H. Leung<sup>1</sup>, S. Hays<sup>1</sup>, L. Barraj<sup>1</sup> and <u>A. Madl</u><sup>2</sup>. *Exponent, Irvine, CA and* <sup>2</sup>*ChemRisk, San Francisco, CA*.

Perchlorate is a public health issue of recent interest because it has been found at low levels in the drinking water used by millions of Americans. High level exposure to perchlorate inhibits thyroidal iodide uptake, and disruption of thyroid function can result in neurological effects. Monitoring conducted in California indicates that perchlorate has been measured in approximately 8% of the drinking water supplies, and 60% of those sources contain less than 10 ppb. Preliminary data has suggested that perchlorate can accumulate in leafy vegetables. Further, it has been found in cows milk and human breast milk. Assuming 10 ppb of perchlorate in drinking and irrigation water supplies, we evaluated the potential perchlorate exposure from a variety of scenarios: 1) ingestion of water and water based drinks (e.g., coffee) for the total US population, children age 1-6 years, and women of childbearing age, 2) mothers milk ingestion for a nursing neonate, 3) lettuce ingestion among childbearing age women, which considered recent data regarding perchlorate accumulation in lettuce, and 4) total water intake from all food and drink sources (e.g., moisture in produce, soda, dairy, etc). For the neonate evaluation, we used a simple pharmacokinetic model to estimate steady-state perchlorate levels in the milk of lactating mothers. For all other scenarios, consumption data from the USDA was used to estimate ingestion at the 50th and 90th percentiles. Nutrient recipes were used to translate the foods as consumed into various nutrients, including moisture (water). The bodyweight-adjusted doses at the 50th percentile ranged from 0.00003 mg/kg-day (nursing neonate and lettuce ingestion) to 0.001 mg/kg-day for the total water intake (direct, indirect and foodbased) for women age 18 to 40 years. Exposures at the 90th percentile were approximately 2.5-times higher. These estimates are preliminary and based on conservative simplistic exposure assumptions. The estimated doses are all lower than those that have been shown to affect thyroidal iodine uptake among humans, a precursor to know adverse effects.

## 1755 DERIVATION OF A RFD FOR PERCHLORATE: IDENTIFING A CRITICAL HEALTH ENDPOINT AND THE MOST SENSITIVE SUBPOPULATION.

<u>A. Madl<sup>2</sup></u>, <u>D. Proctor<sup>1</sup></u>, <u>H. Leung<sup>1</sup></u>, E. Goswami<sup>1</sup>, S. Hays<sup>1</sup> and <u>E. Cohen<sup>1</sup></u>. <sup>1</sup>Exponent, Irvine, CA and <sup>2</sup>ChemRisk, San Francisco, CA.

Perchlorate (ClO4-) is a drinking water contaminant and is known to inhibit of thyroidal iodide uptake. While environmental agencies have proposed a RfD for ClO4-, their approaches and reliance on human versus animal experimental data differ. A critical evaluation of the human scientific literature was conducted to identify a critical endpoint for the derivation of a RfD for ClO4- and clearly define possible sensitive subgroups for exposure and uncertainty assessments. Numerous studies have evaluated the effects of ClO4- in humans in medical, community, occupational and experimental settings. Based on our assessment, it was concluded that a decrease in thyroidal iodide uptake is the most sensitive effect of ClO4- and the Greer et al. (2002) study is the most appropriate for deriving a RfD. There are clear differences in thyroid function between the human fetus, neonate and adult. It was concluded from our evaluation that the developing neonate would be most

susceptible to the effects of ClO4-. The basis for this conclusion is that during gestation, fetal development is dependent on and protected by transfer of maternal thyroid hormones and as long as maternal thyroid iodide uptake and hormone levels are maintained, normal fetal development would be expected. Following birth, the neonate is dependent on its own production of thyroid hormone with iodide supply originating from maternal breast milk. Iodide uptake in the neonatal thyroid and iodide levels in breast milk should be maintained at normal levels for normal neurodevelopment to occur in the infant. Dietary iodide intake in the US was concluded to be sufficient to prevent thyroid changes, precluding pregnant women as a sensitive subgroup. Thus, it appears that derivation of a RfD ClO4- based on protection against inhibition of thyroidal iodide uptake, the first step in the production of thyroid hormones, would prevent adverse effects during fetal and neonatal development. Exposure and uncertainty assessments will focus on the developing neonate as the most sensitive subgroup.

## 1756 SCIENTIFIC RATIONALE FOR THE DERIVATION OF A REFERENCE DOSE (RFD) FOR PERCHLORATE.

H. Leung<sup>1</sup>, D. Proctor<sup>1</sup>, A. Madl<sup>2</sup>, S. Hays<sup>1</sup> and E. Cohen<sup>1</sup>. <sup>1</sup>Exponent, Irvine, CA and <sup>2</sup>ChemRisk, San Francisco, CA.

Perchlorate (ClO4-), a contaminant in drinking water, inhibits thyroidal iodide (I-) uptake and may disrupt the production of thyroid hormones (TH) leading to thyroid dysfunctions and other neurological deficits. Pregnant women, fetuses, neonates and people with I- deficiency or compromised TH status may be especially at risk. Governmental agencies have used various methods to draft risk assessments for ClO4-, producing disparate results. We have critically reviewed the rationale for the most appropriate approach to derive a RfD for ClO4-. The major conclusions are: (1) I- uptake inhibition is a precursor to TH level perturbation, which in turn is a precursor to thyroid dysfunction. A health risk assessment for ClO4- must recognize that I- uptake inhibition is not a genuine adverse effect; (2) Human dose-effect data are available, and are preferable to animal data in order to avoid the uncertainties of interspecies extrapolation; (3) Controlled human volunteer studies offer more reliable exposure information and are preferable to other epidemiological and community studies. (4) The benchmark dose methodology is recommended for dose-response assessment and the benchmark dose effect level (BMDL) corresponding to one standard deviation from the mean of the control population should be used; (5) As the half-life of perchlorate in humans is moderate (8 h), allowing steady state level to be readily attained, no adjustment factor is needed for extrapolating I- uptake inhibition data from less than chronic exposure; (6) Many surveys have shown that the dietary I- intake is sufficient in the US population and very few women are I- deficient; (7) There is evidence that person-toperson variation, including those individuals at sensitive developmental life stages, is less than 3 fold. On the basis of these considerations, we have derived a BMDL of 0.0126 mg/kg-d based on the thyroidal I- uptake inhibition data in the Greer et al. (2002) study (Environment Health Perspect. 110:927). We applied an overall uncertainty factor of 3 to arrive at a tentative RfD of 0.0042 mg/kg-d.

### 1757 USE OF HUMAN AND ANIMAL PBPK MODELS IN RISK ASSESSMENT FOR PERCHLORATE.

D. R. Mattie<sup>1</sup>, T. R. Sterner<sup>2</sup>, E. A. Merrill<sup>3</sup>, R. A. Clewell<sup>3</sup>, Q. Zhao<sup>4</sup>, J. E. Strawson<sup>4</sup> and M. L. Dourson<sup>4</sup>. <sup>1</sup>AFRL, Wright-Patterson AFB, OH, <sup>2</sup>OpTech, Dayton, OH, <sup>3</sup>Geo-Centers, Wright-Patterson AFB, OH and <sup>4</sup>Toxicology Excellence for Risk Assessment (TERA), Cincinnati, OH.

Perchlorate has been used as a solid rocket propellant and ignitable source in munitions for many years. Recently, it has been found in surface and ground waters of multiple environmental sites, especially in the western United States. The primary effect of this chemical is inhibition of iodide uptake by the thyroid. Sufficient inhibition over time results in a depression of thyroid hormone formation and subsequent compensatory increase of thyroid stimulating hormone (TSH). The most sensitive measure of thyroid function disruption is iodide uptake inhibition and the most sensitive population in humans is likely to be the fetus. However there are no quantitative dose-response toxicity data available for the fetus in either animals or humans. To assist in addressing this issue, perchlorate physiologically based pharmacokinetic (PBPK) models were developed for rats at different life stages including the normal adult, pregnant female and fetus, and lactating female and neonate. In addition, a PBPK model for adult humans was also developed. These PBPK models were verified using iodide uptake inhibition studies in rats and humans. Effective doses for iodide inhibition in rats and humans at different life stages were estimated. Results indicated that the fetus is the most sensitive life stage for iodide uptake inhibition. By applying the ratio of predicted effective doses between adult rats and humans to those predicted for rats of different life stages, an effective dose of 0.006 mg/kg/day can be estimated for 5% iodide uptake inhibition in the human fetus. By using this effective dose in human fetus as the point-of-departure, a risk estimate for perchlorate of 0.002 mg/kg/day can be developed by applying an uncertainty factor of 3 fold to account for intraspecies variation. This new risk level confirms the previously proposed value of 0.002 mg/kg/day determined by other

CAPTURING AND MODELING HUMAN
INTERINDIVIDUAL DIFFERENCES FOR HEALTH RISK
ASSESSMENT: HEPATIC BIOACTIVATION OF
CHIOROFORM

J. C. Lipscomb<sup>1</sup>, J. T. Du<sup>2</sup>, J. C. Swartout<sup>1</sup>, D. A. Mahle<sup>3</sup>, J. E. Snawder<sup>4</sup> and G. L. Kedderis<sup>5</sup>. <sup>1</sup>ORD/NCEA, USEPA, Cincinnati, OH, <sup>2</sup>OW/HECD, USEPA, Washington, DC, <sup>3</sup>Man Tech Environmental Tech Inc., Wright-Patterson AFB, OH, <sup>4</sup>Taft Lab., CDC/NIOSH, Cincinnati, OH and <sup>5</sup>Independent Consultant, Chapel Hill, NC.

Chloroform (CF) is a volatile drinking water contaminant. Risks via the oral, but not inhalation route have been estimated. This study was conducted to adjust inhalation dosimetry between animals and humans and assess the impact of variability in some factors which may predispose humans to toxicity. CF partition coefficients were determined in tissues from young and mature rats, and in blood from adult and pediatric patients. CF metabolic rate constants and hepatic CYP2E1 protein concentrations were determined in liver tissue from adult rats and human adult and child organ donors. Vmax was extrapolated to intact tissue and scaled to body weight. The distribution of hepatic blood flow (HBF) as percent of cardiac output was determined from a total of 59 published individual values in human adults. These data were incorporated into physiologically based pharmacokinetic (PBPK) models constructed for mice; rats; and human adults, preadolescents and infants. Because of the relevance of the inhalation reference concentration to chronic, lifetime exposures, constant exposure to CF was simulated until steady state was reached rather than simulating intermittent exposure scenarios. Toxicity studies with mice demonstrate a duration-adjusted NOAEL (liver effects) of 0.9 ppm CF. Simulations indicated that the human equivalent exposure concentration, based on hepatic CF metabolism, was approximately 6 ppm. Among adults, increases in CYP2E1 content and activity, blood:air partitioning, and HBF produced approximately 1, 4 and 17% increases in CF metabolism, respectively. Children converted as much as 34% more CF to metabolites than equivalently exposed adults. These findings will be useful in determining the magnitude of PK variability in the risk relevant PK outcomes between species and among humans.

1759

THE CONTRIBUTION OF PHARMACOKINETIC VARIABILITY TO VARIABILITY IN HEPATIC LABELING INDEX DATA FROM B6C3F1 MICE EXPOSED TO CHLOROFORM.

C. Tan and R. Conolly. CIIT Centers for Health Research, Research Triangle Park, NC

We have extended a PBPK model for chloroform to describe a plausible mechanism of hepatic cell killing and regenerative proliferation (Toxicol. Sciences. 75, 192-200, 2003). The resulting PBPK/PD model simulates labeling index (LI) data. A Monte Carlo implementation of the PBPK model (Regul. Toxicol. Pharmacology 2, 144-155, 2000) provides an opportunity to examine the role of PK variability in the LI data. We used this approach with a hepatic LI data set where female B6C3F1 mice inhaled chloroform for 7 consecutive days at various combinations of duration and concentration (Toxicol. Sciences. 66, 201-208, 2002). Our analysis is showed that variability in the parameters of the PBPK model accounted for most of the variability in the LI data. LI variability was slightly under predicted when the LI was close to its control level (e.g., measured: control, 0.55  $\pm$  0.26, 30 ppm for 2 h/day,  $1.5 \pm 1.23$ ; simulated:  $1.10 \pm 1.12$ ). For exposures that led to larger increases in LI (e.g., LIs from 2.82 to 19.92), Monte Carlo-predicted PK variability accounted for all of the variability in measured LI. Under prediction of LI variability for small changes in LI may reflect the implementation of the Monte Carlo model or uncertainties associated with experimental measurement of LI. While contribution from variability in the PD cannot be ruled out, this result suggests that PK variability is a major determinant of variability in LI data from chloroform-exposed female B6C3F1 mice. We plan to extend these analyses to male mice and to male and female rats with the goal of better understanding the role of PK variability in variability of LI data. This understanding will guide the eventual scale-up of the PBPK/PD model to humans.

1760

A TRIAL OF TOXICOGENOMIC ANALYSIS OF HUMAN UMBILICAL CORDS FOR DEVELOPING A NEW RISK ASSESSMENT METHOD OF FETAL EXPOSURE TO MULTIPLE CHEMICALS.

M. Komiyama<sup>1,2</sup> and C. Mori<sup>1,3</sup>. <sup>1</sup>Bioenvironmental Medicine, Chiba University, Chiba, Japan, <sup>2</sup>Center for Environment, Health and Field Sciences, Chiba University, Kashiwa, Japan and <sup>3</sup>Core Research for Evolutional Sciences. and Technol. (CREST), Japan Sciences. and Technol. Corporation (JST), Kawaguchi, Japan.

It has been shown that human fetuses are exposed to multiple chemicals including endocrine disruptors. Since there is anxiety that these multiple chemical exposures may cause delayed long-term effects, it is necessary to establish a new evaluation method of health risk derived from exposure to multiple chemicals during fetal period. We are attempting to apply toxicogenomic analysis of human umbilical cords to the future risk assessment. In this study, we analyzed relationship between concentrations of persistent chemicals and gene expression patterns in umbilical cords of 9 Japanese newborns. In the concentration of the chemicals, significant correlations were observed between total polychlorinated biphenyls and many of other chemicals. Gene expression in each umbilical cord was examined by cDNA microarrays, using cultured human umbilical vein endothelial cells as reference. Expression profiles of the umbilical cords were analyzed by principal components analysis and hierarchical cluster analysis, and compared with chemical concentration profiles. The expression profiles of highly exposed umbilical cords were different from those of umbilical cords with lower exposure levels. However, there was an exceptional case. In the exceptional umbilical cord, total concentration of the chemicals was lowest, but its gene expression profile was quite similar to those of the umbilical cords with higher total chemical concentration levels. These results suggest that gene expression profile of umbilical cord can be used for evaluation of exposure levels at fetal period. Moreover, it might be useful to detect potential high risk group, because both of actually higher exposure level and genetically higher susceptibility of an individual to multiple chemicals might be regarded as higher health risk to the individual.

1761

APPLICATION OF A PBPK MODEL TO AID IN UNDERSTANDING THE RELATIVE POTENCIES (REPS) OF DIOXIN-LIKE CHEMICALS.

L. S. Birnbaum<sup>1</sup>, C. Emond<sup>2</sup> and M. J. DeVito<sup>1</sup>. <sup>1</sup>ORD/NHEERL/ETD, USEPA, Research Triangle Park, NC and <sup>2</sup>NRC, NAS, Washington, DC.

The TEF methodology is a relative potency scheme used in risk assessments for dioxin-like chemicals to derive the TCDD equivalents of a mixture. TEF values were assigned to chemicals by an expert panel based on a review of all available data. A criticism of this method is the large range, over 1000-fold, in the REPs for some dioxin-like congeners. One reason for this variability could be experimental design. The aim of this study is to apply a PBPK model to examine the impact of study designs used to estimate REPs. A PBPK model developed for TCDD in rats was used to simulate experimental studies of model dioxin-like chemicals. CYP1A2 induction is by described an Ah receptor-mediated mechanism. Model outputs for CYP1A2 induction were used to estimate REPs. Acute and subchronic exposure conditions were simulated. In the acute simulations, the model was run for up to 14 days post exposure. Subchronic exposures were simulated for 90 days. In order to simulate a variety of dioxin-like chemicals, the AhR affinity was varied (10-1 to 10-4 nmol/ml) and the elimination rate (Kel) was increased by 10 and 20 fold compared to the TCDD. Dose response simulations were run and ED50s for predicted CYP1A2 induction were estimated for each simulation. The REP was calculated as the ratio of the ED50s for model chemical vs. TCDD simulations. When only the AhR affinity is varied, study design had no impact on the estimate of the REP. Study design significantly affected the estimate of the REP when Kel was varied. The REP varied by 100 fold when Kel was increased 20-fold depending on the study design. The present study demonstrates the utility of PBPK models when applied to the TEF methodology. If sufficient data on AhR binding and pharmacokinetics in humans were available for a particular congener, it would be possible to use these models to estimate human TEF values. (This abstract does not represent USEPA policy. Funded by in part by a cooperative agreement with NRC and EPA (CR 828790)).

1762

DERIVATION OF A RANGE OF INTERIM INHALATION CANCER SLOPE FACTORS FOR TCE USING PHYSIOLOGICALLY BASED PHARMACOKINETIC MODELING.

L. Yost<sup>1,3</sup>, J. F. Greene<sup>1,2</sup>, S. M. Hays<sup>1,5</sup>, M. Kelsh<sup>1,4</sup> and P. Sheehan<sup>1,2</sup>.

<sup>1</sup>Exponent, Menlo Park, CA, <sup>2</sup>Health Risk, Exponent, Oakland, CA, <sup>3</sup>Health Risk, Exponent, Bellevue, WA, <sup>4</sup>Health, Exponent, Menlo Park, CA and <sup>5</sup>Health Risk, Exponent, Boulder, CO.

Widespread use of trichloroethene (TCE) as a solvent and its relative stability has resulted in it being one of the most frequently detected groundwater contaminants in the United States. Although extensively studied, derivation of a cancer slope factor (CSF) representative of potential human health risk remains controversial and the recent EPA re-assessment of TCE did not identify an inhalation CSF. Both animal and human data are suggestive of a threshold for cancer. However, the absence of a consensus on the mechanism(s) of action complicates implementation of a threshold approach. Animal models demonstrate high species, strain, sex, and route of exposure specificity, with carcinogenicity, if it occurs at all, typically seen following cellular damage. The epidemiological studies of TCE inhalation and carcinogenicity in workers are largely negative. For those few studies reporting significant increases in cancer, there are substantial study design problems and a lack of quan-

titative information on worker exposures. This paper performs a weight-of-evidence analysis of the epidemiological and animal studies to identify the most appropriate studies, endpoints, and approaches to dose-response modeling. The most appropriate inhalation data for derivation of a CSF were the mouse liver tumor data reported by Maltoni (1988). A range of inhalation CSFs was derived based on inhaled doses of TCE, as well as several internal dose measures, derived using a physiologically based pharmacokinetic model (Clewell et al. 2000). The upper end of the resulting estimates is similar to the interim value of 0.007 (mg/kg-day)-1 established by the California Office of Environmental Health Hazard Assessment and the range provides a reasonable basis for risk management decisions. Future studies will help to refine these estimates.

# 1763 ISSUES IN THE VALIDATION OF PBPK MODELS FOR RISK ASSESSMENT: AN EXAMPLE WITH PERCHLOROETHYLENE.

J. Kester<sup>2</sup>, R. Gentry<sup>1</sup> and H. Clewell<sup>1</sup>. <sup>1</sup>ENVIRON Health Sciences Institute, Ruston, LA and <sup>2</sup>ENVIRON Health Sciences Institute, St. Louis, MO.

There has been growing use of physiologically based pharmacokinetic (PBPK) models to perform the dosimetry for human health toxicity and risk assessments. One of the more problematic aspects of the application of a particular PBPK model in such cases is the determination of whether the model has been adequately validated to provide confidence in the extrapolations performed with it. A number of PBPK models have been developed for perchloroethylene (PCE), differing primarily in the parameters estimated for metabolism. All of the models provide reasonably accurate simulations of some kinetic data for PCE in mice and humans, and could therefore be considered, to some extent, validated. However, extrapolation of animal-based cancer potency estimates for PCE to humans is critically dependent on the prediction of human metabolism at low environmental exposures. Recent data (Volkel et al. 1998) on the urinary excretion of TCA, the major metabolite of PCE, at relatively low exposure concentrations (10 to 40 ppm), made it possible to compare the high- to low-dose extrapolation capability of the various published models. We found that the model of Gearhart et al. (1993), which is the only model to include a description of TCA kinetics, gave the closest predictions of the urinary excretion observed in the low-concentration exposures (within a factor of 2). Other models overestimated metabolite excretion in this study by 5- to 15-fold. Cancer risk estimates for PCE based on liver tumors in mice in the NTP study were estimated with the Gearhart et al. (1993) model, using lifetime average daily amount metabolized per volume liver as the dose metric. Assuming pharmacodynamic equivalence of mice and humans, the resulting inhalation risk estimate for lifetime exposure to PERC at one microgram per cubic meter was 0.38 per million. The corresponding risk for oral exposure at one milligram per kilogram per day was 0.00293.

PREDICTION OF BIOLOGIC PARTITION COEFFICIENTS AND BINDING AFFINITIES USING STRUCTURE ACTIVITY RELATIONSHIPS (SAR) MODELS.

M. Mumtaz<sup>1</sup>, H. A. El-Masri<sup>1</sup>, D. Hawkins<sup>2</sup>, D. Mills<sup>3</sup> and S. Basak<sup>3</sup>.

<sup>1</sup>Computational Toxicology Laboratory/Division of Toxicology, ATSDR, Atlanta, GA, 
<sup>2</sup>School of Statistics, University of Minnesota, Minneapolis, MN and <sup>3</sup>Natural 
Resources Research Institute, University of Minnesota Duluth, Duluth, MN.

For some contaminants, toxicological data are usually not sufficient to evaluate toxic effects and conduct health risk assessments. In such cases, until appropriate data become available, ATSDR and other federal agencies often recommend the use of surrogate values obtained from computational tools such as structure activity relationship (SAR) techniques and physiologically based pharmacokinetic (PBPK) modeling. In an ongoing effort to develop alternative toxicity assessment methods, we have applied SAR to compute: 1) tissue:air partition coefficients, including fat:air, liver:air, and muscle:air, for a group of 46 low molecular weight volatile organic compounds (VOCs); 2) blood:air partition coefficients for a set of 39 VOCs; and 3) aryl hydrocarbon (Ah) receptor binding affinity for a set of 34 dibenzofurans using SAR calculations based on theoretical molecular descriptors. These descriptors consisted of four classes based on increased level of complexity and computational demand such as topostructural (TS), topochemical (TC), geometrical (3D) and quantum chemical (QC). Experimental vs. predicted blood:air partition coefficients utilizing only the TC descriptors for some common contaminants were as follows: benzene, 2.88 vs. 2.50; chloroform, 3.04 vs. 3.32; n-hexane, 0.83 vs. 1.28; and toluene, 2.89 vs. 3.38. The results indicate that the cross-validated variance coefficients ( $R^2_{cv}$ ) values when using TS, TC, and 3D descriptors are -0.05, 0.94, and 0.07, respectively. The  $R^2_{cv}$  for TS+TC+3D combined is 0.94 which shows no improvement over the TC descriptors alone. In conclusion, (1) structure based models using simple descriptors adequately predict toxicological characteristics of some environmental contaminants, and (2) development of extensive or complex descriptors and models might not enhance this capability.

#### 1765

ANALYSIS OF AN INTERACTION THRESHOLD IN DRUG/CHEMICAL MIXTURES ALONG A FIXED-RATIO RAY

A. Hamm<sup>1</sup>, C. Gennings<sup>1, 2</sup>, H. Carter<sup>1, 2</sup> and <u>R. Carchman</u><sup>2</sup>. <sup>1</sup>Biostatistics, Virginia Commonwealth University, Richmond, VA and <sup>2</sup>Solveritas, LLC, Richmond, VA

Human exposure to drug/chemical mixtures can result from therapeutic interventions or environmental sources. Of interest is the interaction that may occur among the components of these mixtures. Since interaction can be dose-dependent, it is important to determine exposure levels to either exploit the benefits of the interaction in a therapeutic application or to avoid the effect of the interaction in the case of an environmental risk assessment. As a result of the dose-dependent nature of interactions, it follows that there are regions of additivity and regions of interaction with an unknown boundary separating the two regions. As the number of mixture components increases, the experimental effort required to support the estimation of the boundary becomes impractical. Fixed-ratio ray designs can be used to detect interactions among the components of the mixture. Along each fixed-ratio ray, the interaction threshold boundary is a point on the ray. We developed dose-response models for fixed-ratio ray designs that allow the estimation of the location of the interaction threshold for each mixture ray. Methods were developed to analyze the effect of selected subsets of mixture components on interactions and the location of the interaction threshold for each ray. These methods are illustrated with a neurotoxicity study (endpoint: motor activity) of a mixture of five pesticides (acephate, diazinon, chlorpyrifos, malathion, and dimethoate). Results indicate that on the 'full' five-pesticide ray, there was evidence of the existence of an interaction across the ray. However, when malathion was removed and the remaining four pesticides occurred at the same relative proportions on a 'reduced' ray, an interaction threshold of about 8 mg/kg was estimated, indicating additivity below and synergy above this dose. (The project described was partially supported by a grant (#T32-ES07334-01A1) from the NIEHS, NIH)

#### 1766

D-OPTIMAL EXPERIMENTAL DESIGNS TO TEST FOR DEPARTURE FROM ADDITIVITY IN A FIXED-RATIO RAY MIXTURE.

T. Coffey¹, L. Stork¹, C. Gennings¹, W. H. Carter¹, J. E. Simmons² and D. W. Herr². ¹Biostatistics, Virginia Commonwealth University, Richmond, VA and ²ORD/NHEERL, USEPA, Research Triangle Park, NC.

Risk assessors are becoming increasingly aware of the importance of assessing interactions between chemicals in a mixture. Most traditional designs for evaluating interactions are prohibitive when the number of chemicals in the mixture is large. However, evaluation of interactions with many chemicals is becoming easier through recent advances in statistically-based experimental design. Using a fixedratio mixture ray with chemicals in relevant proportions results in an economical design that allows estimation of additivity and interaction for a mixture of interest. This methodology is easily extended to a mixture with a large number of chemicals. Using this methodology, optimal experimental conditions can be chosen that increase the power of detecting a departure from additivity. Although these designs are well known for linear models, optimal designs for nonlinear threshold models have had few applications in toxicology. A D-optimal criterion that minimizes the variances of the parameters of a nonlinear threshold model was used to create an optimal design for a fixed-ratio mixture ray. For a fixed sample size, this design selects the experimental doses and number of observations per dose level that result in minimum variance of the model parameters and increased power to detect departures from additivity. A related design that utilizes a D-optimality criterion is also presented that results in minimum variance when some mixture data are available but additional doses are desired. An optimal design for both scenarios is illustrated using data collected on a 2:1 ratio (chlorpyrifos:carbaryl) mixture experiment. For this example, the optimal designs for the nonlinear threshold model depend on prior specification of a dose threshold. Supported by T32 ES07334-01A1 (NIEHS, NIH) and CR-828-11401 (USEPA). This is an abstract of a proposed presentation and does not necessarily reflect EPA policy or the official views of the NIEHS, NIH.

## 1767 ANALYSIS OF AN INTERACTION THRESHOLD IN A MIXTURE OF DRUGS AND/OR CHEMICALS.

H. Carter<sup>1, 2</sup>, A. Hamm<sup>1</sup>, C. Gennings<sup>1, 2</sup> and <u>R. Carchman</u><sup>2</sup>. <sup>1</sup>Biostatistics, Virginia Commonwealth University, Richmond, VA and <sup>2</sup>Solveritas, LLC, Richmond, VA.

In mixtures toxicology, risk assessors often make a default assumption that additivity is present at lower concentrations of mixture exposures and that interactions occur at higher mixture concentrations. This assumption is consistent with the concept of an interaction threshold, i.e., the boundary between the region of additivity and the region of interaction. We have developed methodology that permits the estimation of the boundary that defines these regions. The methodology is illustrated

with a two-component mixture of ethanol and chloral hydrate in a study of righting reflex in mice. Using our methods, a region of synergy is found in the low ethanol and high chloral hydrate dose combination region; departure from additivity was not found in the low dose region of chloral hydrate over all levels of ethanol. Results obtained from the application of our methodology to a smaller, independent dataset were confirmed by the results obtained in the much larger study conducted by Gessner and Cabana (1970; Journal of Pharmacology and Experimental Therapeutics 156, 602-5) for the ED50 contour of the mixture. Our methodology allows for the interaction threshold boundary to range over response levels. In the analysis of the chloral hydrate/ethanol data, our approach suggests evidence of an interaction at response rates as low as the 5% in the high chloral hydrate and low ethanol dose combination region. At and below the 1% level of response there was no indication of departure from additivity. Theoretically, our approach is not limited by the number of components in the mixture. The project described was partially supported by a grant (#T32 ES07334-01A1) from the NIEHS, NIH.

<sup>2</sup>ORD/NHEERL, USEPA, Research Triangle Park, NC.

Detecting and characterizing interactions among chemicals is an important environmental issue. This study was conducted to test for the existence of a significant departure from additivity for a mixture of two cholinesterase (ChE)-inhibiting pesticides: chlorpyrifos (CPF), an organophosphate; and carbaryl (CARB), a carbamate. The effects of CPF and CARB on ChE activity in the brain, plasma, and red blood cells of male Long Evans rats were evaluated using single chemical dose-response curves (CPF: 0, 3, 10, 20, 30 and 50 mg/kg; CARB: 0, 10, 30, 50, 100 and 175 mg/kg; po; 5 rats per group) and a 2:1 (CPF:CARB) mixing ratio (total dose: 0, 28 and 35 mg/kg; 6 rats per group) evaluated at the time of near maximal ChE inhibition by the mixture (4 h after dosing). Nonlinear additivity models estimated from the single chemical data were fit for each outcome. Nonlinear mixture models estimated from the mixture data were compared to that predicted using the additivity model along the 2:1 mixture ray. A significant difference between the mixture and additivity models is considered evidence of interaction. A significant dose-response effect was detected for the single chemical and mixture data. Using a likelihood ratio test, departure from additivity was not detected for any of the three endpoints. While the additivity model was estimated from data in the active range of the dose-response curves, the mixture data included only two doses above control, which were generally near optimal effect. Hence, generalizing these conclusions to the low-dose region of the mixture ray should be made with caution. For further investigation, the existing data are useful in determining an optimal design associated with maximum power for detecting interactions. Supported by T32 ES07334-01A1 (NIEHS, NIH) and CR-828-11401 (USEPA). This is an abstract of a proposed presentation and does not necessarily reflect EPA policy.

## 1769 RISK ASSESSMENT FOR MALE REPRODUCTIVE TOXICANTS.

I. Mangelsdorf<sup>1</sup>, J. Buschmann<sup>1</sup> and B. Orthen<sup>2</sup>. <sup>1</sup>Chemical Risk Assessment, Fraunhofer Institute of Toxicology and Experimental Medicine, Hannover, Germany and <sup>2</sup>Federal Institute for Occupational Safety and Health, Dortmund, Germany. Sponsor: <u>H. Muhle</u>.

In recent years, publications related to an apparent decline in male sperm quality and concerns with the potential effects of environmental estrogens have led to an increased awareness of potential effects on male fertility. The majority of the information concerning reproductive toxicants comes from animal reproduction studies. However, there is concern that mating trials are too insensitive to assess effects on spermatogenesis and epididymal functioning because of the vast excess of spermatozoa ejaculated in rodents but not in humans. A literature review was conducted, to assess the sensitivity of different endpoints of male reproductive toxicity in laboratory animals and their predictivity for the human situation. Of the endpoints indicating reproductive toxicity in animal studies, fertility was indeed a very insensitive parameter. The most sensitive endpoint was histopathology of the testes. Using refined histopathology, effects could be detected as early as after four weeks treatment. Other sensitive endpoints were the weights of reproductive organs, including accessory glands, i.e., testis, epididymis, prostate, and of the seminal vesicle, as well as sperm count, sperm morphology and sperm motility. Sperm motility was found to be in some cases more sensitive than histopathology. In most cases, not only one

but several endpoints were affected at one dose level. Humans were generally not more susceptible to reproductive toxicants than laboratory animals. In conclusion, with respect to hazard identification, it is possible to detect adverse effects on male reproduction in a standard subacute study with concentrations that produce significant general toxicity. If effects indicating male reproductive toxicity are found, for the risk assessment the NOAEL has to be determined by testing specific sensitive parameters within a subacute or preferably subchronic toxicity study. Mating of the animals would then be only be needed to detect influences on mating behavior.

1770

APPROACHES FOR CONVERTING ADULT DOSE TO CHILDREN OF VARIOUS AGE GROUPS: RELEVANCE FOR THE RISK ASSESSMENT OF ENVIRONMENTAL CHEMICALS.

D. Gohore Bi and <u>K. Krishnan</u>. Occupational and Environmental Health, Universite de Montreal, Montreal, QC, Canada.

Several approaches for converting the adult dose of pharmaceutical products for children of different ages are found in the clinical and biomedical literature. These are potentially useful in the context of health risk assessment, for conducting adult to child extrapolation of external dose of chemicals in the environment. The aim of this work was to analyse and compare various approaches available in the biomedical field for converting oral dose (mg/kg/d) of non-volatile chemicals from adults (A) to children of various age groups (newborn (N), infant (I), preschool (P) and highschool (H)). After a systematic literature review, the following methods were identified: Young's rule (I), Clark's rule (II), Fried's rule (III), body surface adjustment (IV) and pharmacokinetic approaches (V). Method I, based on age of children, yielded an adult/child dose conversion factor (A/C) of 8.73, 2.75, 1.3, 0.99 and 1.06, respectively, for the N, I, P and H groups. Method II, based on body weight, yielded an A/C of 1 for all age groups, since the dose in terms of mg/kg/d was identical in all groups. Method III, recommended only for application to N and I groups based on an empirical formula, yielded A/C of 9 and 3, respectively. Method IV, facilitating dose calculations based on body surface differences, yielded A/C of 0.41, 0.49, 0.55, 0.75 respectively for N, I, P and H groups. Method V, which represents either steady-state algorithms or compartmental models, yielded varying Â/C factors as a function of the age-dependent clearance and volume of distrbution, and these factors appear to be, in several cases, lower than those given by the above empirical approaches (particularly Methods I-III). This work represents an initial attempt to evaluate the usefulness of existing methods for conducting adult-children conversion of exposure doses of environmental chemicals for risk assessment purposes. Overall, the use of pharmacokinetic models should be sought instead of the empirical formulae for conducting adult-children dose extrapola-

BENCHMARK DOSE MODELING OF MERCURY-INDUCED ACUTE RENAL FAILURE IN SPRAGUE-DAWLEY RATS WITH RENAL INSUFFICIENCY COMPARED TO HEALTHY CONTROLS.

R. Brown, E. F. Madden, M. E. Stratmeyer and P. L. Goering. CDRH, USFDA, Rockville. MD.

Experimentally induced renal insufficiency (RI) increases the sensitivity of rodents to the adverse effects of a subsequently administered nephrotoxic agent. Since patients with renal insufficiency are at increased risk of developing acute renal failure (ARF) following exposure to nephrotoxic compounds, compared to healthy individuals, the use of animal models of renal insufficiency improves the clinical relevance of toxicity test results used for the risk assessment of nephrotoxic compounds released from medical device materials. Benchmark dose modeling was used to quantify the magnitude of the increased sensitivity in male Sprague-Dawley rats, compared to healthy controls, following iv injection of mercuric chloride (HgCl2). RI was induced by 3 daily sc injections of gentamicin (250 mg/kg). HgCl2 (0.025 to 0.5 mg/kg) was administered on Day 4. Healthy control animals received sc saline x 3 days followed by HgCl2 on Day 4. Blood was collected for analysis in anesthetized rats 24 hours after HgCl2 injection. The dose-response relationship is based on the number of animals in ARF, defined as 2x the mean value of BUN in healthy, non-mercury exposed animals. BMD50[control]/BMDL50[RI] ratios for mercury-induced ARF were in the range of 3-14, with only one dose ratio > 10 (for the BMD50[control]/BMDL50[RI] ratio derived from results obtained with the log-logistic dose-response model). Assuming a similar increased sensitivity exists for patients with RI exposed to mercury or other nephrotoxic agents, compared to healthy persons, these results suggest that the default uncertainty factor of 10 used in noncancer risk assessment to account for interindividual variability in a population response to a given dose of a compound is adequately protective in most cases.

#### 1772

ESTIMATION OF THE MAGNITUDE OF THE PHARMACOKINETIC COMPONENT OF THE INTERINDIVIDUAL VARIABILITY FACTOR USING A PROBABILITY BOUNDS APPROACH.

A. Nong and <u>K. Krishnan</u>. Occupational and Environmental Health, Universite de Montreal, Montreal, QC, Canada.

The pharmacokinetic (PK) component of the interindividual variability factor (IVF) used in the derivation of reference concentrations (RfCs) of systemically-acting volatile organic chemicals (VOCs) has been estimated using Monte Carlo approaches and PBPK models. Since the RfC derivation considers continuous lifetime human exposure to VOCs in the environment, algorithms to compute steady-state blood concentrations (SS-BC) can be used to derive the IVF-PK. In this context, probability bounds (P-bounds) approach is also potentially useful for computing an interval of a probability distribution value of SS-BC from knowledge of population distribution of input parameters. The objective of this study was therefore to estimate IVF-PK using the P-bounds approach along with an algorithm for calculating SS-BC of VOCs. The existing steady-state algorithm, derived from physiological pharmacokinetic models, was re-written such that SS-BC could be related, without any interdependence, to the following input parameters: pulmonary ventilation scaled to body weight (Qpc), ventilation/perfusion ratio (VP), hepatic blood flow as a fraction of cardiac output (Qlc), intrinsic metabolic clearance (Cl) and blood:air partition coefficient (Pb). The IVF was calculated from the P-bounds of SS-BC corresponding to the 50th and 95th percentiles. Following the specification of population distributions of parameters (Qpc: normal, VP: lognormal, Qlc: normal, Cl: lognormal, Pb: normal) in RAMAS Risk Calc® software version 3.0 (Applied Biomathematics, Setauket, NY), the P-bounds estimates of SS-BC of toluene (TOL), styrene (STY), 1-4-dioxane (DIO), and chloroform (CHM) were obtained for low level exposures (1 ppm). The IVF intervals based on these results for TOL, STY, DIO and CHM were 1.6-1.9, 2.0-2.6, 1.8-2.3, and 1.4-1.6, respectively. The use of P-bounds method along with steady-state algorithms, as done in this study for the first time, is a scientifically-sound and practical way of computing IVF for systemically-acting VOCs.

#### 1773

LACK OF SUBCHRONIC TOXICITY OF TRICHLOROETHYLENE ADMINISTERED VIA AQUEOUS GAVAGE TO MICE.

P. S. Palkar<sup>1</sup>, S. S. Anand<sup>1</sup>, M. M. Mumtaz<sup>2</sup> and H. M. Mehendale<sup>1</sup>.

<sup>1</sup>Department of Toxicology, University of Louisiana, Monroe, Monroe, LA and <sup>2</sup>ATSDR, Atlanta, GA.

The present work is a part of an ongoing project to study potential subchronic interactive toxicity of common water contaminants such as trichloroethylene (TCE), perchloroethylene, chloroform and trichloroacetic acid. The specific objective of this work was to examine the effects of TCE alone. Male Swiss Webster mice received TCE (200, 400, 500 mg/kg/d chosen from preliminary acute and subchronic lethality studies) in an aqueous emulsion of Alkamul EL-620 (0.3 ml/mouse) by oral gavage for 30 days (d). A single administration of 2500 and 1500 mg TCE/kg resulted in 100 and 80% mortality, respectively. Repeated administration of 750 mg TCE/kg led to 100% lethality between 3 to 5 d whereas, repeated administration of 600 mg TCE/kg led to 20% mortality between 5 to 7 d in the absence of any significant liver or kidney injury, suggesting that deaths might be due to extrahepatic and extrarenal effects, possibly by CNS toxicity. The dose range of 200 to 500 mg TCE/kg for 30 d did not cause any mortality. Liver injury was measured by ALT on 7, 15, 21, 30 d, and at 24, 48, 72 h after the last exposure (30 d) and by histopathology (H&E - stained liver sections) on 30 d. Liver tissue repair was assessed by [3H]-thymidine incorporation into hepatonuclear DNA and by PCNA at 0 and 30 d. BUN was measured to assess kidney injury on 7, 15, 21, 30 d, and at 24, 48, 72 h after the last exposure (30 d). ALT or BUN levels were not significantly increased over the time course except for marginal increase in ALT on 21 d and at 48 h after the last exposure. Histopathology and PCNA findings were consistent with the biochemical end points. Hepatic microsomal CYP2E1 protein measured by Western blotting on 0 and 30 d was unaltered by TCE in the present study. Hepatic glutathione measured on 0 and 30 d was unchanged by TCE. These biochemical findings are consistent with lack of hepatic damage after subchronic exposure to TCE. The effects of TCE in combination with other water contaminants remain to be explored (supported by ATSDR U61/ATD 681482).

#### 1774

OCCUPATIONAL EXPOSURE TO AIRBORNE QUATERNARY AMMONIUM CHLORIDE DISINFECTANTS: MARGIN OF EXPOSURE ANALYSIS.

J. D. Hamilton, S. S. Willems and <u>D. A. Daggett</u>. Global Product Safety, Johnson Diversey, Inc., Sturtevant, WI.

Institutional and Industrial (I&I) disinfectants are generally sold as concentrated liquids that require controlled dilution with water prior to use. The USEPA has traditionally required respiratory protective equipment for quaternary ammonium

chloride (quat) disinfectant concentrates and use solutions based on the outcome of acute inhalation toxicity studies. To determine whether respiratory protection is warranted, an inhalation exposure assessment was conducted by JohnsonDiversey based on an established Unit Exposure (UE) method to characterize exposure to the quats n-alkyl dimethyl benzyl ammonium chloride and didecyl dimethyl ammonium chloride. The UE method was derived from analysis of inhalation exposure monitoring data collected from biocide application studies. The UE method calculates a dose in mg/kg/day based on the concentration of active ingredient in the product and the application method. Using a worse-case scenario assumption that the disinfectant is applied as a concentrate (i.e., not diluted 1:256), inhalation exposure to quat according to the UE method was estimated to be 3.4 x 10<sup>-6</sup> mg/kg/day. A Margin of Exposure (MOE) approach was used to investigate the potential risk associated with the UE estimate. MOE values of 100 or above are typically associated with no unreasonable risk for adverse effects. Using the lowest EPAaccepted NOAEL of 3 mg/kg/day for the quat active ingredient, the MOE value calculated here was 8 x 10<sup>3</sup>. To further explore potential exposures to quat during use of an I&I disinfectant, a chamber exposure assessment was conducted by spraying 389.7 grams of undiluted disinfectant into a 10.8 m<sup>3</sup> test chamber with the ventilation turned off. Airborne quat was not detected in the study (with a limit of detection of 2 mg/m<sup>3</sup>). It was concluded that exposure to quat concentrates presents no known unreasonable risk for adverse effects by inhalation, and respiratory protection during use is not warranted.

#### 1775

ASSESSMENT OF RESPIRATORY ENDPOINTS RESULTING FROM NICKEL EXPOSURE: DERIVATION OF MINIMAL RISK LEVELS.

H. Abadin<sup>1</sup>, L. Ingerman<sup>2</sup>, S. Wilbur<sup>1</sup> and M. Fay<sup>1</sup>. <sup>1</sup>Agency for Toxic Substances and Disease Registry, Atlanta, GA and <sup>2</sup>Environmental Science Center, Syracuse Research Corp, Syracuse, NY. Sponsor: P. McGinnis.

The respiratory tract is the most sensitive target of nickel toxicity following inhalation exposure. This is supported by a number of short- and longer-term studies in rats and mice. A series of National Toxicology Program (NTP) reports identified no-adverse-effect levels (NOAELs) in rats exposed to nickel sulfate, nickel subsulfide, and nickel oxide. Of the three compounds, nickel sulfate was the most toxic, likely due to its solubility. The Agency for Toxic Substances and Disease Registry (ATSDR) released a toxicological profile for nickel in 1997 that included minimal risk levels (MRLs) derived using the rat data from the NTP study. An update to the 1997 profile was developed and released in October 2003. As a result, the database for nickel was updated and the MRLs for nickel were re-examined. The re-assessment utilized the same NTP study that identified NOAELs of 0.06 mg/m<sup>3</sup> and 0.03 mg/m<sup>3</sup> in rats exposed for 13 weeks and 2 years, respectively. The key findings at higher doses were chronic lung inflammation, atrophy of the olfactory epithelium, and fibrosis. Minimal alveolar macrophage hyperplasia was observed at all doses, but was not considered adverse at the lower doses. When lung effects consisted only of the alveolar macrophage hyperplasia, the incidence and severity was not significantly different from controls. Thus, this effect was not believed to compromise lung function at those exposure levels, but was considered part of the normal physiologic response to inhaled particles. The resulting intermediate- and chronic-duration MRLs were 0.2 ug/m<sup>3</sup> and 0.09 ug/m<sup>3</sup>, respectively.

#### 1776

DOSE-RESPONSE ANALYSIS OF COMBINED DATA FROM CLINICAL TRIALS: A CASE STUDY OF DATA ANALYSIS FOR SYSTEMIC CONTACT DERMATITIS IN A SENSITIZED POPULATION.

Q. Zhao¹, L. Haber¹ and A. Bathija². ¹ TERA, Cincinnati, OH and ² USEPA, Washington, DC.

Human data are always of the greatest value in risk assessment; however, we often do not have the luxury of a rich human data set suitable for dose response analysis. For data from experimental clinical studies, it is often difficult to establish a clear NOAEL based on the individual studies, due to the small size of the groups tested, the wide variability among individuals, and limited doses tested in each experiment. Here, we present a dose-response analysis of data from multiple clinical studies on systemic contact dermatitis in sensitized subjects who were challenged with oral soluble nickel doses, by using a meta analysis technique to control these shortcomings. The data from a total of 12 studies with a total sample size of 300 subjects were used in the meta analysis, and the combined data provide responses over a wide dose range (0.45 ~ 5.6 mg). Our analysis estimated that the ED05 (the dose estimated to cause an extra risk of 5%) and the ED10 in the sensitized population are 0.559 mg and 0.914 mg, respectively; the corresponding daily doses are 8.0 x 10-3 and 1.3 x 10-2 mg/kg-day, respectively, assuming a 70 kg body weight. By using this technique, we are able to provide a dose-response analysis for data which normally would not have been considered suitable for dose-response assessment. The opinions expressed are those of the authors and do not reflect USEPA policy.

THE ATSDR CHRONIC ORAL MINIMAL RISK LEVEL (MRI.) FOR FILIORIDE

L. Ingerman<sup>1</sup>, C. Tylenda<sup>2</sup> and <u>D. Jones<sup>2</sup></u>. <sup>1</sup>Environmental Science Center, Syracuse Research Corp, Saratoga Springs, NY and <sup>2</sup>ATSDR, Atlanta, GA.

ATSDR is currently updating its Toxicological Profile for Fluorine, Hydrogen Fluoride, and Fluorides. Numerous municipalities have implemented fluoridation programs to decrease the prevalence of dental caries in children. The US Department of Health and Human Services has recommended a drinking water fluoride concentration of 0.7-1.2 ppm. A number of community-based studies have examined potential health effects associated with this fluoride concentration, but study results have been variable. The primary target of fluoride toxicity following chronic oral exposure is the skeletal system. ATSDR has derived a chronic-duration oral MRL for fluorides based on adverse bone effects. A chronic-duration MRL is an estimate of daily exposure to a substance that is likely to be without appreciable risk of adverse effects over a period of 1 year or more. A number of epidemiology studies of populations exposed to 1 ppm fluoride (0.03 mg/kg/day) have found increases, decreases, or no effect on hip fracture rates among older women. Studies evaluating exposure to higher doses have consistently found significant increases in the risk of nonvertebral fractures, particularly hip fractures. The MRL derivation was based on a study of older residents of 6 communities in China exposed to differing levels of fluoride in drinking water (Li et al. 2001). This study considered other potential sources of fluoride and used communities with similar calcium intakes. A significant increase in the prevalence of hip fractures was observed in the community exposed to 4.32-7.97 ppm (average total fluoride intake of 0.25 mg/kg/day), but not in the community exposed to 2.62-3.56 ppm (0.15 mg/kg/day); the community with a fluoride level of 1.0-1.06 ppm (0.055 mg/kg/day) was used as the comparison group. In accordance with established procedure, the NOAEL of 0.15 mg/kg/day was divided by an uncertainty factor of 3 to account for human variability to derive the MRL of 0.05 mg/kg/day.

#### 1778 UPDATING THE FREE CYANIDE RFD.

L. T. Haber<sup>1</sup>, B. R. Stern<sup>2</sup>, Q. Zhao<sup>1</sup>, J. Strawson<sup>1</sup> and N. Chiu<sup>3</sup>. <sup>1</sup>TERA, Cincinnati, OH, <sup>2</sup>B.R. Stern Associates, Alexandria, VA and <sup>3</sup>USEPA, Washington, DC

Cyanide is used in a number of industrial processes, including mining, metallurgy, manufacturing, and photography, because of its ability to form stable complexes with a range of metals. These multiple forms of cyanide have significant differences in toxicity due to their different ability to liberate the CN- moiety. Some cyanide complexes have little or no bioavailability. Cyanide or cyanogenic compounds (ones that are metabolized to cyanide) are found in many foods; smoking can also be a significant source of cyanide. The previous free cyanide RfD was developed in 1985, based on thyroid and nervous system effects at a LOAEL of 30 mg CN/kgday, and a NOAEL in a separate study of 10.9 mg/kg-day. This RfD has been updated in light of new studies. In particular, a subchronic study conducted with sodium cyanide in drinking water evaluated a range of endpoints at daily doses up to 12.5 mg/kg-day in rats and 28.8 mg CN/kg-day in mice (NTP, 1993). This study found no histopathological evidence of damage to the thyroid or nervous system, although thyroid hormone levels were not evaluated. However, there were several dose-related decreases in male reproductive parameters. Decreased caudal epididymis weight was not supported by a decrease in spermatazoa count, but decreased testis weight at the high dose in rats was supported by decreased spermatid count. BMDLs based on different toxic effect endpoints were derived. The RfD was derived including uncertainty factors for interspecies differences and to protect sensitive populations. In addition, an endpoint-by-endpoint analysis was used for determination of the appropriate composite uncertainty factor for subchronic to chronic extrapolation and for database uncertainties, taking into account the lack of progression seen with various endpoints and for related compounds, and the potential for neurodevelopmental effects secondary to thyroid effects. Disclaimer: The opinions and conclusions expressed in this abstract are those of the authors and do not necessarily reflect those of the USEPA.

DEVELOPMENT OF PROVISIONAL TOXICITY VALUES FOR COBALT. H CHOUDHURY. NATIONAL CENTER FOR ENVIRONMENTAL ASSESSMENT, OFFICE OF RESEARCH AND DEVELOPMENT, USEPA, CINCINNATI, OH.

H. Choudhury. ORD, NCEA, USEPA, Cincinnati, OH.

USEPA, in the absence of toxicity values on the IRIS, develops peer reviewed provisional toxicity values in support of superfund site assessments. Cobalt is known to have a nutritional function as a vital component of vitamin B12. However, there is no evidence that the intake of cobalt is limiting in the human diet which ranges

from 1E-2 to 1E-4mg/kg-day, and therefore no Recommended Daily Allowance has been set by the National Research Council. Human data have been suggestive of a possible association between exposure to cobalt and respiratory tumors. Chronic studies have demonstrated the carcinogenic potential of inhaled cobalt in rats and mice, with alveolar and bronchial tumors being the most prevalent. The precise mechanism of cobalt-induced carcinogenicity has not been fully determined. Evidence indicates that cobalt is capable of eliciting genotoxic effects. The most likely mechanism for the carcinogenic effects of cobalt involves the generation of cobalt-induced oxidative stress. In accordance with the proposed Guidelines for Carcinogenic Risk Assessment (USEPA, January 2001), cobalt is likely to be carcinogenic to humans, and under the 1986 Guidelines, cobalt is classified as group B1. Using the default linear dose-response model, a provisional inhalation unit risk of 2.8E-3 (ug Co/cu.m)-1 was derived for cobalt, based on increased incidence of respiratory tumors in B6C3F1 mice. Data were inadequate to derive an oral slope factor for cobalt. Using polycythemia in humans as a sensitive indicator of cobalt deficiency, an RfD of 2E-2 mg/kg-day has been derived by applying an uncertainty factor of 10 to the LOAEL, for hematological effects in anemic patients (factor of 3- for LOAEL and 3- for database deficiency). (This abstract does not necessarily reflect USEPA Policy.)

THE IMPORTANCE OF CONSIDERATION OF MODE OF ACTION DATA IN NON-CANCER RISK ASSESSMENT: THE CASE OF ETHYLENE CYANOHYDRIN.

M. Osier and M. Odin. Syracuse Research Corporation, Syracuse, NY.

Consideration of mode of action is of critical importance in the evaluation of the toxic effects of a chemical. While an emphasis on mode of action is evident in recent thinking regarding cancer risk assessment, it is also important when considering noncancer effects. Derivation of a provisional RfD for ethylene cyanohydrin provides an excellent practical example of the role that understanding of mode of action can have in noncancer risk assessment. No chronic oral studies of ethylene cyanohydrin toxicity have been reported. Of the three subchronic studies, one examined only a single endpoint and another reported only group and failed to report statistical analysis of the data; as such, neither study provides a sufficiently detailed evaluation of ethylene cyanohydrin toxicity to allow for the derivation of an RfD. The third study evaluated a broad spectrum of endpoints in a single species. The study only reported slight, statistically significant changes in the absolute weights of the heart and brain. A lack of more clearly toxic effects would generally be of concern when attempting to derive an RfD, perhaps even resulting in no number being derived. However, consideration of a proposed mechanism of action for ethylene cyanohydrin, in situ generation of cyanide, identified the brain and the heart, both of which are very sensitive to changes in cellular energy status, as potentially sensitive targets of ethylene cyanohydrin toxicity. With this consideration in mind, subtle, statistically significant changes in organ weights of these sensitive targets were considered to be toxicologically relevant, and NOAEL and LOAEL values were identified from the study and used in the derivation of an RfD. (This abstract does not necessarily reflect EPA policy).

1781 LACK OF EFFECTS OF 1439 MHZ ELECTROMAGNETIC NEAR FIELD EXPOSURE ON THE BLOOD-BRAIN BARRIER IN IMMATURE AND YOUNG RATS.

M. Kuribayashi<sup>1,4</sup>, J. Wang<sup>2</sup>, O. Fujiwara<sup>2</sup>, Y. Doi<sup>3</sup>, K. Nabae<sup>3</sup>, S. Tamano<sup>3</sup>, T. Ogiso<sup>1</sup>, M. Asamoto<sup>1</sup> and <u>T. Shirai</u><sup>1</sup>. <sup>1</sup>Experimental Pathology and Tumor Biology, Nagoya City University Graduate School of Medical Sciences, Nagoya, Japan, <sup>2</sup>Electrical and Computer Engineering, Nagoya Institute of Technology, Nagoya, Japan, <sup>3</sup>Daiyu-kai Institute of Medical Science, Nagoya, Japan and <sup>4</sup>Ono Pharmaceutical Co. Ltd., Safety Research, Fukui, Japan.

The use of cellular phones has been spreading rapidly all over the world and the potential risk of electromagnetic near-fields (EMFs) from their antennae to human health, especially with respect to disturbance of the blood-brain barrier (BBB), is a source of concern. In the present study, we performed experiments to explore whether EMF exposure causes any damage to the BBB in rats with ages equivalent to the time of BBB genesis (4-weeks-old) and the teenage (10-weeks-old) period. For this purpose, alteration of BBB-related genes, such as those encoding p-glycoprotein, aquaporin-4 and claudin-5, was assessed by immunohistochemistry and quantitative RT-PCR in the brain. First, we verified that expression of the 3 genes is influenced by 1, 3-dinitrobenzene (DNB), a chemical reported to destroy the BBB, and then we performed an EMF exposure experiment with 0, 2.0 and 6.0 W/kg brain-average specific absorption rates at 1.5 GHz for 90 min/day for 1 or 2 weeks. Vascular permeability was also investigated using dye-transfer technique by FITC-

dextran and albumin immunohistochemistry. As a result, expression of the 3 genes was found to be clearly decreased after administration of DNB as a positive control, when compared with the control values. However, there were no biologically meaningful differences with the EMF at any exposure level at either age. Vascular permeability, monitored with reference to transfer of FITC-dextran, was not affected by EMF exposure. Furthermore, albumin leakage from capillary blood vessels to brain parenchymal tissue was detected in the brains of rats receiving DNB, although there was no change with EMF exposure. Thus, these findings suggest that local exposure to 1.5 GHz EMF exerts no adverse effects on the BBB in immature and young rats.

## 1782 RESULTS OF SCREENING TESTS ON RE-REFINED MINERAL OILS DERIVED FROM USED OILS.

W. Dalbey, R. McKee, S. Hong, M. Amoruso and J. Freeman. ExxonMobil Biomedical Sciences, Inc., Annandale, NJ.

Used or waste lubricating oils (such as used engine oils) are sometimes re-refined to produce base stocks for use in finished lubricant products or other applications. Engine oils, particularly from passenger cars, accumulate potentially carcinogenic polycyclic aromatic compounds (PACs) during use. The PACs may not be completely removed during re-refining. The presence of biologically active PACs was assessed in re-refined oils using method ASTM E 1687-95, a modification of the Ames test. A mutagenicity index (MI, or the slope of a linear dose-response) less than 1.0 in this assay indicates a high probability that the oil would be noncarcinogenic in skin-painting bioassays. Among 130 samples of re-refined oils tested in this assay since 1985, >20% had MI >1.0, compared to no MI >0.8 among 53 currently marketed virgin base oils as recently reported by major producers. Directionally, used oils re-refined by hydrotreating had lower MI values than the non-hydrotreated samples, but both had MI values higher than virgin base oils. Data from analysis for PACs are limited. Analyses of specific PACs have typically not been useful as a screening method, but directionally PACs among re-refined oils with MI <1.0 were higher than in virgin base oils. Skin-painting tests in mice were performed on 5 re-refined oils, all having MI values <1.0 and relatively low PAC content. None caused skin tumors in the skin-painting assay. Contamination with PCBs and metals also continues to be an area of concern based on historical and recent data. Due in part to potential health effects, the use in finished lubricants of re-refined oils without severe processing and appropriate feed quality controls should generally be discouraged.

## AN EMPIRICAL EVALUATION OF THE CANCER POTENCY OF DIOXIN TOXIC EQUIVALENTS (TEQs) IN FOUR PCB MIXTURES.

R. E. Keenan<sup>1</sup>, J. M. Hamblen<sup>1</sup>, J. B. Silkworth<sup>2</sup>, M. N. Gray<sup>1</sup>, P. O. Gwinn<sup>1</sup> and S. B. Hamilton<sup>3</sup>. <sup>1</sup>AMEC Earth & Environmental, Portland, ME, <sup>2</sup>Global Research Center, General Electric Co., Niskayuna, NY and <sup>3</sup>Environmental Programs, General Electric Co., Fairfield, CT.

In 1996, the USEPA evaluated PCB cancer risks by reviewing both human epidemiology and animal bioassay data on PCB mixtures and developed a range of cancer slope factors (CSFs), based on animal models, for use in risk assessments of PCBs. In 2000, USEPA released its revised draft Dioxin Reassessment, which uses a toxic equivalency method to relate the cancer potency of the designated dioxinlike chemicals, including dioxin-like PCB congeners, to the cancer potency of 2, 3, 7, 8-tetrachlorodibenzo-p-dioxin (TCDD) and to estimate the potency of mixtures containing those congeners. The current study was conducted to evaluate the application of the toxic equivalency approach in estimating the cancer potency of PCBs. The dose-response assessment was based on the results of 2-year cancer bioassays in which female Sprague-Dawley (SD) rats were fed TCDD or one of four PCB mixtures (Aroclors 1016, 1242, 1254, and 1260) with varying degrees of chlorination. Using EPA benchmark dose software, a rodent cancer slope factor (CSF) was determined for TCDD and for the dioxin toxic equivalent (TEQ) component of each PCB mixture. A basic precept of the toxic equivalency method is that a given dose of TEQ has equal biological potency irrespective of the chemical mixture from whence it came. If the tenet is correct, then every CSF determined in this way should be approximately equal to each other and to that of TCDD. CSFs of 9600, 220000, 16000, 8900, and 50000 per mg/kg-d were generated for TCDD and for TEQ components in Aroclors 1016, 1242, 1254, and 1260, respectively. The current study revealed that the TEQ CSFs varied by a factor of 24 across the range of PCB mixtures tested and, therefore, were not equal to the potency of TCDD. These results indicate that there is considerable uncertainty associated with the use of the dioxin toxic equivalency method for characterizing the cancer potency of PCB mixtures.

ESTIMATION OF A NO OBSERVED EFFECT LEVEL FOR 2, 4-DIANIMOTOLUENE, A GENOTOXIC LIVER CARCINOGEN, IN A 16-WEEK FEEDING STUDY USING MALE F344 RATS

N. IAMI<sup>1</sup>, T. ICHIHARA<sup>1</sup>, H. YOSHINO<sup>1</sup>, H. WANIBUCHI<sup>2</sup>, K. MORIMURA<sup>2</sup>, A. HAGIWARA<sup>1</sup> and <u>S. FUKUSHIMA<sup>2</sup></u>. <sup>1</sup>Daiyu-kai Institute of Medical Science, Ichinomiya, Japan and <sup>2</sup>Department of Pathology, Osaka City University Medical School, Osaka, Japan.

The carcinogenic potential of 2, 4-diaminotoluene(2, 4-DAT) at very low doses was evaluated in male F344 rats. Groups of 90 or 30 animals (21-day old at commencement) were given 0 (as control), 0.001, 0.01, 0.1, 1, 10, 100 and 300 ppm 2, 4-DAT in their diet for 16 weeks. Marked retardation of body weight increase was found in 300 ppm 2, 4-DAT group, but not in animals fed a diet containing less than 100 ppm. No adverse effects were found in terms of survival and clinical sign. Administration of a dietary concentration of 300 ppm to rats caused prominent elevation of liver weight, serum glucose (GLU), total cholesterol (T-CHO), phospholipid (PL) and triglyceride(TG), and quantitative values of gluthathioneS-transferase placental from (GST-P) positive hepatocytic foci, which are preneoplastic lesion. Significant increased liver weight was also noted in rats fed 100 ppm 2, 4-DAT, but not with doses of 10 ppm 2, 4-DAT or less. Quantitative values for GST-P positive foci were significantly increased in 100 ppm groups, but at10 ppm and lower there were no differences from controls. Thus, a no-observed effect level of 2, 4-DAT was estimated to be 10 ppm (0.654 mg/kg/day) under the present experimental conditions.

#### 1785

BENCHMARK DOSE ANALYSIS OF PAPILLOMA INDUCTION IN THE SKIN OF TG.AC MICE FOLLOWING ORAL OR DERMAL EXPOSURE TO 2, 3, 7, 8-TETRACHLORODIBENZO-P-DIOXIN.

M. E. Wyde<sup>1</sup>, <u>A. Braen<sup>2</sup></u>, <u>M. R. Hejtmancik<sup>3</sup></u>, J. D. Johnson<sup>3</sup>, <u>A. F. Fuciarelli<sup>4</sup></u>, M. K. Vallant<sup>1</sup>, <u>J. R. Bucher<sup>1</sup> and N. J. Walker<sup>1</sup>. <sup>1</sup>NIEHS, Research Triangle Park, NC, <sup>2</sup>Hoffman-La Roche, Nutley, NJ, <sup>3</sup>Battelle, Columbus, OH and <sup>4</sup>Battelle, Richland, WA.</u>

The Tg.AC transgenic mouse develops epidermal papillomas in response to some non-genotoxic and complete carcinogens. 2, 3, 7, 8-Tetrachlorodibenzo-p-dioxin (TCDD), a multi-site rodent carcinogen, induces the formation of papillomas in the skin of Tg.AC mice. To evaluate the dose-response relationship for TCDD-induced papilloma formation by the dermal and oral routes of administration, female Tg.AC mice were exposed dermally to TCDD at 0, 5, 17, 36, 76, 121, 166, 355 or 760 ng/kg or by gavage to 0, 105, 450, or 1250 ng/kg for 26 weeks. The number of mice with papillomas increased in a dose-dependent manner by both routes. The skin concentration of TCDD was higher with increased doses of TCDD, demonstrating a linear relationship between administered dose and internal dose at the target site. Papilloma incidence was used to calculate Benchmark Dose for an effective dose resulting in a 10% increase over background (ED10). Papilloma response was lower in mice receiving TCDD by gavage than by dermal exposure. The estimated ED10 for increased papilloma incidence by TCDD using average daily doses and an empirical log-logistic model was 333 ng/kg by gavage and 3.90 ng/kg by dermal exposure. The slope of the dose-response curve for the incidence of papillomas with respect to skin concentrations of TCDD was steeper and the incidence of papillomas higher in mice receiving TCDD by dermal exposure than by gavage. The estimated ED10 for papilloma incidence with respect to mean skin TCDD concentrations at the end of the study was 320 pg/g by dermal exposure and 2710 pg/g by gavage using log-probit and log-logistic models, respectively. These studies demonstrate that papilloma formation in Tg.AC mice is more responsive to TCDD by dermal exposure than by gavage. These differences likely reflect pharmacokinetic and pharmacodynamic differences in the delivery of TCDD to the skin via the two routes of exposure.

#### 1786

COMPARISON OF RISK ASSESSMENT METHODS FOR POLYCYCLIC AROMATIC HYDROCARBON (PAH) MIXTURES IN AIR.

H. I. Williams<sup>1</sup>, A. Wiman<sup>1</sup>, <u>C. A. Williams</u><sup>1</sup>, C. Stineman<sup>2</sup> and T. Husain<sup>3</sup>. <sup>1</sup>Ecology and Environment, Inc., Tallahassee, FL, <sup>2</sup>Ecology and Environment, Inc., Chicago, IL and <sup>3</sup>Faculty of Engineering, Memorial University of Newfoundland, St. Johns NF Canada

Polycyclic aromatic hydrocarbons (PAH) are common environmental contaminants formed by incomplete combustion of organic material. Generally, when PAH mixtures in the environment are analyzed, the concentrations of 16 individual PAH are measured, 7 of which are considered probable human carcinogens by the USEPA (EPA). PAH mixtures usually include hundreds of compounds, not just the 16 that are typically measured. EPA currently uses the relative potency approach to

assess the carcinogenic risk posed by PAH mixtures. The concentrations of the 7 carcinogenic PAH are measured, their cancer potencies are estimated relative to benzo(a)pyrene (BaP), and then risk is estimated by summing the risks from individual PAH. However, the World Health Organization (WHO) and other regulatory agencies recommend a different approach, termed the surrogate method, which is intended to estimate risk posed by an entire PAH mixture. The surrogate method assumes that the potency of a PAH mixture is proportional to its BaP content. The cancer potency of a mixture is expressed in terms of its BaP content, using BaP as a surrogate for the entire mixture. The risk posed by an unknown PAH mixture is estimated by comparing its BaP content to that of well studied PAH mixtures with established cancer potencies. This study compares the risk estimates obtained by applying these two methods to real world data. Concentrations of 16 individual PAH were measured in respirable particulate matter (PM 10) samples collected at two locations downwind from the 1991 Kuwaiti oil fires over the duration of the fires. For this mixture, the surrogate method gave risk estimates  $6\ \mathrm{to}\ 7$ times higher than the relative potency method currently used by the EPA. Reasons for the differences in results using the two methods are discussed.

## 1787 UPDATED CANCER RISK ASSESSMENT OF ACRYLONITRILE.

C. R. Kirman<sup>1</sup>, M. Gargas<sup>2</sup>, J. Klaunig<sup>3</sup>, J. Collins<sup>4</sup>, T. Starr<sup>5</sup>, D. Strother<sup>6</sup> and R. Deskin<sup>7</sup>. <sup>1</sup>The Sapphire Group, Beachwood, OH, <sup>2</sup>The Sapphire Group, Dayton, OH, <sup>3</sup>Indiana University, Indianapolis, IN, <sup>4</sup>Dow Chemical Company, Midland, MI, <sup>5</sup>TBS Associates, Raleigh, NC, <sup>6</sup>BP Chemical, Arlington, VA and <sup>7</sup>Cytec Industries, West Paterson, NJ.

The database to support cancer risk assessment for acrylonitrile (AN) has been greatly improved over the past 20 years and includes robust epidemiological data, bioassay data from two rodent species, animal and human PBPK models, and extensive mechanistic data. A cancer dose-response assessment was conducted for AN using this information. Consideration of the cancer weight of evidence for AN is complicated by the fact that the toxicological and epidemiological databases provide conflicting evidence. Animal studies indicate that AN is carcinogenic in multiple tissues in rats and mice. In workers, however, a number of large epidemiology studies, including those with well-documented exposure information, indicate no evidence of a causal association between AN exposure and cancer mortality of any type. The epidemiology data cover the full range of past worker exposures, including early industry exposures (1940s-1978) that are far higher than occur today and that approach levels found to be tumorigenic in animals. A dose-response assessment was prepared based upon the most sensitive animal tumor site and species (rat brain). Recent mechanistic studies for AN-induced brain tumors in rats strongly implicate a role for oxidative stress due to an oxidative metabolite of AN (2-cyanoethylene oxide or CEO, cyanide), but do not rule out a potential role for direct genotoxicity for CEO. A PBPK model was used to support the dose-response assessment. Internal doses were predicted for 12 data sets which were pooled together to provide a characterization of the dose-response relationship for brain tumors in the rat. Based upon the weight of evidence provided by the mechanistic studies the cancer dose-response assessment for AN-induced brain tumors in the rat was performed using nonlinear methods. The range of well studied human exposures was employed to add further perspective about appropriate margins of exposure.

## 1788 NEW DATA AND GUIDELINES SUPPORT A REVISED CANCER RISK ASSESSMENT FOR ACRYLAMIDE.

P. R. McClure<sup>1</sup>, D. W. Wohlers<sup>1</sup> and <u>R. S. DeWoskin</u><sup>2</sup>. <sup>1</sup>Environmental Science Center, Syracuse Research Corporation, Syracuse, NY and <sup>2</sup>National Center for Environmental Assessment, USEPA, Research Triangle Park, NC.

Since EPA last assessed acrylamide carcinogenicity in 1988, new cancer and modeof-action (MOA) data and new EPA guidelines (1999) for cancer risk assessment have been released. The 1988 assessment classified acrylamide as a probable human carcinogen, and derived an oral cancer slope factor based on an analysis of the results from a 2-year drinking water study in F344 rats with pooled incidence data for tumors in CNS, oral cavity, and thyroid tumors (both sexes); mammary gland and uterine tumors (females); and tunica vaginalis mesotheliomas (TVMs; males). This study had abnormally high CNS and oral cavity tumors in control males, and possible complications from a viral infection. A new cancer bioassay was subsequently conducted with a larger number of rats (increased statistical power), and dose spacings that improved the characterization of the dose-response relationship. The newer study results corroborated the acrylamide-induced thyroid tumors, mammary gland tumors, and TVMs, but not the previously observed CNS, uterine, and oral tumors, indicating that these tumors that were observed in the earlier study may not have been directly related to acrylamide exposure. Based on the more recent tumor data, and in accordance with the 1999 cancer guidelines, benchmark doses were calculated as points of departure for the low-dose cancer risk assessment (e.g., LED10, the lower bound on the 10 percent effect level), and a linear extrapolation to the origin was derived based on a genotoxic MOA. Although a nongenotoxic MOA (and potential nonlinear dose-response relationships) has been hypothesized for acrylamide-induced thyroid tumors, mammary gland tumors, and TVMs in rats, the supporting evidence is weak for some of the tumor types, and there is good evidence for acrylamide's genotoxic potential. In summary, application of the revised cancer guidelines and incorporation of new data provide a more scientifically defensible cancer slope factor. [This abstract does not necessarily reflect EPA policy.]

### 1789 AVAILABLE TOXICITY DATA ON ALTERNATIVE DRY CLEANING CHEMICALS.

J. F. Collins, A. G. Salmon, J. D. Budroe, M. A. Marty and G. V. Alexeeff. CalEPA/OEHHA, Oakland, CA.

Concerns about the carcinogenicity of perchloroethylene (perc; tetrachloroethylene) led to the introduction of alternatives in dry cleaning. The South Coast Air Quality Management District has proposed its elimination in dry cleaning by 2020; the State legislature is considering elimination by 2013. Available toxicity data on four proposed alternatives, already in use in some areas, have been reviewed. (1) Cyclic siloxanes. Preliminary results with decamethylcyclopentasiloxane (D5) indicated that inhalation of 160 ppm for 12 or 24 months by female rats led to endometrial adenocarcinomas. Octamethylcyclotetrasiloxane (D4) is estrogenic. D5 (log Kow = 5.2) and D4 are bioconcentrated. (2) In a two-year inhalation study by NTP, propylene glycol tert-butyl ether resulted in neoplastic and non-neoplastic lesions of the liver in male and female mice. Rats showed hyaline degeneration of olfactory epithelium in both sexes, and basophilic liver foci and kidney lesions in males. (3) 1-bromopropane (BP), a non-ozone depleting chemical, is a neurotoxicant and a reproductive toxicant. The NTP is currently conducting a two year inhalation bioassay of BP. (4) Other alternatives are based on mineral spirits, which can cause neurotoxicity. One formulation also contains 5% fluorocarbons, mainly ethyl perfluoroisobutyl ether and ethyl perfluorobutyl ether. Additional information is needed on the environmental persistence of these chemicals. All these alternatives have some toxicity, which, in addition to environmental fate data, must be considered before they are widely substituted for perc. Health protective values for chronic inhalation exposure have been estimated as 700 µg/m<sup>3</sup> for D5, 200 µg/m<sup>3</sup> for propylene glycol tert-butyl ether, 1.1 mg/m<sup>3</sup> for 1-propyl bromide, 1.2 mg/m<sup>3</sup> for the C10 and C11 isoparaffins in mineral spirits, and 19 mg/m<sup>3</sup> for HFE-7200. In addition an inhalation unit risk for cancer of 5.2 x  $10^{-7} \, (\mu g/m^3)^{-1}$  was estimated for propylene glycol tert-butyl ether.

## 1790 RFD AND CANCER ASSESSMENT FOR DICHLOROACETIC ACID (DCA).

J. M. Donohue<sup>1</sup>, H. Galal-Gorchev<sup>1</sup>, K. B. Altschuler<sup>2</sup> and W. Brattin<sup>3</sup>. <sup>1</sup>Health and Ecological Criteria Department, USEPA, Washington DC, DC, <sup>2</sup>ICF Consulting Inc., Fairfax, VA and <sup>3</sup>Syracuse Research Corp., Denver, CO. Sponsor: E. Ohanian.

The Environmental Protection Agency released a Reference Dose (RfD) and quantitative cancer assessment on the Integrated Risk Information System (IRIS) for the disinfection by-product, DCA in September, 2003. The reference dose was derived from a study in male and female dogs given doses of 0, 12.5, 39.5, or 72 mg/kg/day in gelatin capsules for a 90-day period (Cicmanec et al., 1991). Changes in testicular histopathology, mild vacuolization of the cerebral and cerebellar myelinated nerves, and increases in liver weight were observed at the lowest dose tested and increased in severity with increasing doses. An uncertainty factor of 3, 000 was applied to the LOAEL to derive an RFD of 0.004 mg/kg/day. IRIS (1996) had previously categorized DCA as a probable human (B2) carcinogen but had not quantified the dose-response. The DCA IRIS summary was updated to provide the quantitative data for cancer and a weight-of-evidence determination that the data are sufficient to conclude that DCA is a likely human carcinogen that lacks a cohesive mode of action. Support for this conclusion is provided by: a number of independent studies reporting consistently positive results at roughly comparable doses; site concordance for tumor formation between two species; clear evidence of a doseresponse relationship; and apparent development of tumors from more than one hepatic cell line. A recent drinking water study of the tumorigenicity of DCA in mice (De Angelo et al., 1999) provided the dose response information which was used to derive an oral cancer slope factor of 0.05 per mg/kg/day and a drinking water unit risk of 1.4 E-3/mg/L. [The opinions expressed represent those of the authors and do not necessarily reflect the opinions of the USEPA.]

## 1791 CHILDRENS HEALTH BENEFITS FROM REDUCTIONS IN CRITERIA AIR POLLUTION CONCENTRATIONS.

E. Wong<sup>1</sup>, <u>I. Gohlke<sup>1</sup></u>, W. Griffith<sup>1</sup>, S. Farrow<sup>2</sup> and <u>E. M. Faustman<sup>1,2</sup></u>. <sup>1</sup>Institute for Risk Analysis and Risk Communication, Department Environ Occup Health Sciences, University of Washington, Seattle, WA and <sup>2</sup>Engr Public Policy, Carnegie Mellon University, Pittsburgh, PA.

Benefit-cost analyses of environmental legislations are increasingly required, and evaluations of controlling criteria air pollutants have used health risk assessment methodologies. Children are significantly impacted by improved air quality, yet key

environmental health policy analyses have not focused upon effects in children. A meta-analysis approach examined the hypothesis that child-specific health impacts, both in number of cases and economic benefits, due to the US Clean Air Act would be similar to health benefits for adults. For only five endpoints were estimates of both reductions in cases and economic benefit able to be calculated using risk assessment methodologies. For concentration reductions predicted to occur by 2010, we estimate 200 (90% CI: 50, 300) fewer expected cases of postneonatal mortality, 10, 000 (4000, 20 000) fewer asthma hospitalizations with estimated benefits of \$20-46 million (\$1990) and 40, 000 (10 000, 70 000) less emergency room visits with estimated benefits of \$1.3-5.8 million in children 1-16 years, 20 (10, 20) million school absences avoided by children 6-11 with estimated benefits of \$0.7-1.8 billion, and 10, 000 (-20 000, 70 000) fewer low birth weight infants with estimated benefits of \$230 million. Inclusion of this limited child-specific data resulted in an additional \$1-2 billion (\$1990) to the \$8 billion in health benefits estimated from decreased adult morbidity, and an additional \$600 million compared to the \$100 billion from decreased mortality. These estimates highlight the need for increased consideration of health effects in children including improved mechanistic information relating environment to health effects in children, additional life-stage information for susceptible populations, and improved health economics information for children. Funded by Center for the Study and Improvement of Regulation at Carnegie Mellon University/University. WA and EPA /NIEHS (EPA-R826886, NIEHS 1P01 ES09601).

## 1792 DRINKING WATER ECONOMIC ANALYSIS (EA): THE ARSENIC CESSATION LAG MODEL.

A. E. Schulman<sup>1</sup>, M. Manibusan<sup>3</sup>, C. O. Abernathy<sup>2</sup>, M. Messner<sup>3</sup>, S. Qian<sup>4</sup> and D. Gaylor<sup>4</sup>. <sup>1</sup>OECA/OC, USEPA, Washington, DC, <sup>2</sup>OW/OST, USEPA, Washington, DC, <sup>3</sup>OW/OGWDW, USEPA, Washington, DC and <sup>4</sup>Sciences International, Alexandria, VA.

The 1996 Safe Drinking Water Act Amendments require an EA for all regulations. The EA examines treatment and analytical costs and public health benefits. Included in the public health benefits section is a cancer latency analysis to account for decreased future cancer risk after current exposure reduction. If public health benefits are discounted due to disease developmental latency, then credit should also be applied to acknowledge the proportional health benefits accrued from immediate exposure reduction. A mathematical model is required to describe the cessation lag, or in other words, how the attributable cancer case rate moves from its current assumed steady state toward its new lower limit. To that end, we used the available Arsenic data in an attempt to model a chemical-specific cessation lag. Due to the lack of sufficient data for Arsenic, we decided to use data on smoking from Hrubec and McLaughlin (1997) to model the rate at which the new limit is approached. Key assumptions in this comparison include: 1. the mode(s) of action is/are similar, and 2. the specific cessation lag for lung cancer due to smoking approximates that for all cancers associated with ingested arsenic exposure. This model approximates that at 2, 10 and 20 years post-exposure reduction of As exposures in drinking water from 50 ppb to 10 ppb, there is a corresponding 41%, 83% and 90% maximum reduction in lung cancer risk, respectively. This model can be applied to other exposure reduction situations when relative risks are known for individuals at both high (pre-regulation) and low (post-regulation) exposure conditions. [The opinions expressed in this abstract are those of the authors and not necessarily those of USEPA.]

#### 1793

INFLUENCE OF THE NATIONAL RESEARCH COUNCIL (NRC) REPORT <u>ARSENIC IN DRINKING WATER: 2001 UPDATE</u> ON THE DERIVATION OF THE CANCER SLOPE FACTOR FOR INORGANIC ARSENIC.

T. McMahon<sup>1</sup>, C. Abernathy<sup>2</sup>, J. Chen<sup>1</sup> and <u>I. S. Dooley<sup>2</sup></u>. <sup>1</sup>OPP, USEPA, Washington D.C., DC and <sup>2</sup>OW, USEPA, Washington D.C., DC.

Several EPA program offices are involved in regulation of inorganic arsenic due to its presence in the environment, e.g., water, and in various pesticides, including CCA (chromated copper arsenate), a widely used wood preservative. In 1996, USEPA charged the NRC with reviewing EPA's characterization of potential human risks from ingestion of inorganic arsenic in drinking water, the available data on carcinogenic and non-carcinogenic effects of ingested inorganic arsenic, the data on metabolism, kinetics, and mode(s) of action of inorganic arsenic, and research needs to fill data gaps. EPA applied many of the recommendations from the resulting 1999 NRC report in the January 2001 regulation for arsenic in drinking water. In March 2001, USEPA charged the NRC to review the EPA risk analysis with respect to model choice, exposure estimates, and population differences in light of new information from studies published since the 1999 NRC report The resulting 2001 report by the NRC made specific recommendations to EPA with respect to the assumptions and models used by EPA supporting the risk analysis for inorganic arsenic. As a result of the 2001 NRC report, the Office of Pesticide

Programs (OPP) formed an intra-Agency workgroup charged with examining the NRC recommendations and their potential influence on regulation of inorganic arsenic by the various program offices. For OPP as well as for future updates to the EPA's Integrated Risk Information System (IRIS) for inorganic arsenic, the current recommendations of the NRC as published would increase the cancer potency factor for inorganic arsenic by a minimum of 3-fold from the current value of 1.5 E +0. The workgroup is examining the NRC recommendations for any further potential regulatory influence.

#### 1794

EVIDENCE FROM EPIDEMIOLOGICAL AND MODE OF ACTION STUDIES SUPPORT A NONLINEAR DOSE-RESPONSE RELATIONSHIP FOR ARSENIC-INDUCED CARCINOGENESIS.

A. Schoen<sup>1</sup>, <u>B. Beck</u><sup>1</sup>, <u>R. Sharma</u><sup>2</sup> and E. Dube<sup>1</sup>. <sup>1</sup> Gradient Corporation, Cambridge, MA and <sup>2</sup> Arch Chemicals, Inc., Norwalk, CT.

Recent risk assessments for arsenic conducted by both the USEPA (USEPA) and the National Research Council (NRC) have assumed a linear dose response for arsenic-induced carcinogenesis. In this presentation, we evaluate both epidemiological and mechanistic evidence and conclude that the dose-response for arsenic is likely to be nonlinear at low doses and unlikely to be of toxicological concern at levels commonly found in the US. While epidemiological studies of populations outside the US demonstrate that arsenic concentrations greater than several hundred mg/L are associated with cancer, studies in the US of populations exposed to elevated concentrations of arsenic in drinking water do not provide evidence of a doseresponse relationship between arsenic and increased cancer. We reviewed several proposed mechanisms of arsenic-induced carcinogenesis, including generation of oxidative stress, perturbation of DNA methylation patterns, inhibition of DNA repair, and modulation of signal transduction pathway. All of these mechanisms are consistent with a nonlinear (specifically sublinear) dose response relationship for arsenic. It is probable that these mechanisms do not act in isolation, but overlap, and contribute to the complex nature of arsenic-related cancers. Arsenic's toxicity can also be modulated by nutritional factors. Diets adequate in methyl donor groups (i.e., choline or methionine), selenium, and antioxidants (as is typical of the US diet) can mitigate arsenic's toxicity. Based on a consideration of arsenic's plausible mechanisms, modulation by nutritional factors, and of evidence from epidemiological studies, we recommend the use of non-linear methods, either via biologically based modeling or use of a margin-of-exposure analysis, to characterize arsenic cancer risks.

#### 1795 HORMESIS DATABASE.

R. R. Blain and <u>E. J. Calabrese</u>. Environmental Health Sciences, University of Massachusetts, Amherst, MA.

Until recent years, the concept of hormesis (i.e., low dose stimulation, high dose inhibition) has generally been overlooked by the scientific community. In an attempt to examine the occurrence and generalizability of the hormetic curve, two separate databases have been developed. The first is a relational retrieval database (i.e., Retrieval Hormesis Database). This database permits an evaluation of studies over numerous parameters, including the type and quality of the studies as well as the physical/chemical properties of the agents. The information obtained from the approximately 5500 dose-responses entered indicates the generalizability of the ĥormetic response across models (e.g., plant, animal, bacteria), in vitro and in vivo study designs, with many different chemicals, and across many different endpoints (e.g., growth, metabolism, immune response). While the database was originally designed to assess the hypothesis concerning whether hormesis was a demonstrable phenomenon that was reproducible, the database has not only provided a means to affirmatively address this question but to also permit significant insight into the nature of the dose response in the sub-NOAEL zone and its broad-based generalizability. The second database was designed specifically to address the frequency of hormesis in the toxicological literature (i.e., Hormesis-Frequency Database). This database demonstrated that 40% of the dose-responses that fit the rigorous entry criteria followed a hormetic response. Pro and cons of each database and the information they can provide will be part of the poster session

#### 1796

AN EXPANDING WEB RESOURCE ON COMPARATIVE RISK INFORMATION: THE INTERNATIONAL TOXICITY ESTIMATES FOR RISK (ITER) DATABASE JOINS THE NATIONAL LIBRARY OF MEDICINE'S (NLM) TOXNET SYSTEM.

A. Wullenweber<sup>1</sup>, <u>P. Wexler</u><sup>2</sup> and <u>M. Dourson</u><sup>1</sup>. <sup>1</sup>TERA, Cincinnati, OH and <sup>2</sup>NLM, Bethesda, MD.

Among the many limitations of using risk values to assess overall chemical risks is the over-reliance on data from one or another particular organization. Since 1996, Toxicology Excellence for Risk Assessment (TERA), through its ITER database, has

extended the horizon for risk assessors by presenting risk data from a variety of authoritative groups worldwide. Presented in tabular format for easy comparison, and enhanced with a synopsis explaining differences in data, ITER provides key risk data and/or cancer classifications from the Agency for Toxic Substances and Disease Registry, Health Canada, International Agency for Research on Cancer, National Institute of Public Health and the Environment (RIVM, The Netherlands), USEPA (EPA), and independent parties. Operational for nearly 20 years, the TOXNET system, a product of NLM, consolidates a variety of bibliographic, factual, nomenclature and other information related to potentially toxic chemicals and other agents. Among its files are the scientifically peer reviewed Hazardous Substances Data Bank (HSDB), TOXLINE, USEPA's Integrated Risk Information System (IRIS), the National Cancer Institute's Chemical Carcinogenesis Research Information System (CCRIS), and the ChemIDplus database. NLM supplements these with a variety of other online resources and tools in toxicology and environmental health, for the professional and public. The recent addition of ITER to TOXNET has benefited both and resulted in an enhanced risk resource. For example, as part of TOXNET, ITER can now be searched by chemical synonym and via free text. Multi-file searching allows a single query to be run against multiple toxicological databases, including ITER, and links to TOXLINE allow users to obtain current literature references and abstracts on ITER chemicals. Meanwhile, ITER has strengthened and broadened TOXNET's data in support of risk assessment by its incorporation of sound risk values from highly regarded national and international organizations.

1797

NATO WORKSHOP ON COMPARATIVE RISK ASSESSMENT AND ENVIRONMENTAL MANAGEMENT: SUMMARY AND CURRENT TRENDS.

I. Linkov. ICF Consulting, Lexington, MA.

Site contamination and disturbance by industrial development operations requires management decisions that weigh the benefits of remedial alternatives against the risks and disruptions associated with its implementation. In particular, a framework is needed that integrates risk assessment and engineering options, generates performance standards, compares options for risk reduction, communicates uncertainty, and effectively allows reiteration of the decision-making process. Comparative Risk Assessment (CRA) is emerging as a methodology with much promise in these areas; it can be applied to facilitate decision-making when various possible activities compete for limited resources. The CRA framework may be an especially valuable tool for prioritization of remediation efforts and for making choices among various environmental policies specific to oil industry operations. The goal of the North Atlantic Treaty Organization (NATO) workshop on CRA (October, 2002) was to review recently developed concepts and mechanics of CRA, assign them to a quantitative analytical framework, and use CRA to help decisionmakers choose among various environmental policies. This talk summarizes presentations and discussions on the use of CRA to provide the scientific basis for selection environmentally sound and cost-efficient policies, strategies, and solutions to environmental challenges. This workshop was supported by the Society of Toxicology.

## 1798 SCREENING TOOLS FOR CONTEXT-BASED DECISION-MAKING.

I. Walls and . ILSI RSI Expert Panel. Risk Science Institute, International Life Sciences Institute, Washington, DC. Sponsor: P. Fenner-Crisp.

When predicting toxicity, ideally all relevant information is available on (a) the potentially toxic agent; (b) the host species of interest; (c) the exposure scenario; (d) the dose at which exposure occurs. Typically, complete information is not available, so a decision must be made using less-than-ideal data. Screening tools are developed for predicting toxicity of chemicals in the absence of a comprehensive dataset on the toxicology of a chemical. The ILSI Risk Science Institute established an Expert Panel to develop a framework for evaluating the utility and application of screening tools for decision-making. The framework includes: 1. Problem formulation. 2. Identify tools to address specific questions (e.g., literature, databases, research studies) 3. Develop a plan on how to proceed 4. List assumptions and caveats 5. Assess degree of confidence in plan to address questions 6. Make "Context-Based" decision 7. Evaluate Decision In problem formulation, an important concept is recognition that a very specific question should be asked, including the context (e.g., health issues, exposure and host factors) in which the question is posed. For example, one might ask, "We have found agent X in drinking water. Is it safe for the population to drink this water or should we recommend that they drink bottle water?" Once a specific question has been posed, the user can assess the tools available to address the question. The Expert Panel is identifying criteria for determining the appropriate screening tool. The choice of tool will depend on the question and the level of uncertainty that may be appropriate for the context. For example, it may be important to have a rapid result, or it may be important to have a high degree of confidence in your answer. The framework is iterative, in that users may refine the

question as they proceed. Case studies are being developed to illustrate how the framework can be used effectively to address specific questions for cancer and non-cancer endpoints.

1799

COMPARATIVE APPROACHES TO PRIORITY SELECTION OF CHEMICALS FOR TOXICITY ASSESSMENT/REASSESSMENT: IMPLICATIONS FOR PUBLIC HEALTH PROTECTION.

<u>B. R. Stern</u> and <u>P. McGinnis</u><sup>2</sup>. <sup>1</sup>BR Stern and Associates, Annandale, VA and <sup>2</sup>Syracuse Research Corporation, Philadelphia, PA.

Only a small subset of the hundreds of thousands of chemicals in commerce, and their byproducts, have been evaluted for potential toxicity to humans and ecological organisms, raising concerns that public health is not adequately protected by regulatory agencies. This study compares and contrasts the approaches taken by state, federal, and international agencies to nominating and selecting chemicals for priority assessment/reassessment. Five US state agencies, four US federal agencies, three countries (Canada, Netherlands, Germany) and five international organizations (EU/ECB, IARC, IPCS, WHO, JEFCA) are compared with regard to (1)criteria utilized for chemical priority selection; (2)methodologies/processes used to perform the selection; (3)throughput; (4)transparency and stakeholder input; and (5) resource utilization. The results show that there is a continuum of prioritization schemes, from those that are health-based and incorporate only direct and indirect (surrogate) measures of public health impacts to those that include mainly surrogate measures of public health impact (eg, legislative mandates) and simple indicators of economic impact (eg, production volume). Methodologies range from those that are qualitative and subjective with minimal stratification ranking schemes, to those that are highly quantitative, with alogrithms for scoring and ranking. The degree of transparency and stakeholder input is also highly variable; some processes are informal and less transparent whereas others involve numerous levels of formal review and public comment. The more comprehensive the process, the greater the cost and time impacts. Interestingly, throughput is not greatly altered by the complexity of the process and thus public health is likely to be underprotected. Several recommendations are made to improve the process in the US and include harmonization of approaches among state and federal agencies, and use of external advisory panels to review data and and prioritize chemicals for review.

1800

STATUS OF HEALTH ENDPOINTS SUBMISSIONS IN THE USEPA HIGH PRODUCTION VOLUME (HPV) CHEMICAL CHALLENGE PROGRAM.

J. Tao, R. Hefter, R. Northrop, L. Scarano, M. Sonawane, A. Benson and <u>D. Sawhney</u>. *USEPA, Washington DC, DC.* 

The USEPA HPV Challenge Program was initiated in 1998 to encourage the chemical industry to voluntarily submit basic hazard information on all US High Production Volume chemicals. In response, 334 chemical companies committed to provide the public with health and environmental effects information on 2, 165 HPVs. EPA's goal for the HPV program is to have at least one adequate study for each identified health effect endpoint in order to perform a screening level hazard assessment. To minimize the testing burden, USEPA encouraged manufacturers to group chemicals as a category where appropriate based on similar structures and/or toxicological and other properties. EPA had received approximately 245 submissions for 1, 125 chemicals (95 categories and 150 single chemicals) and 213 of EPA's responses have been posted on the EPA website. Of the reviewed submissions, 59 have at least one adequate study on all endpoints, and 102 have adequate data for one or more endpoints, but not for all. For sixty-two out of the 102 submissions, manufacturers proposed new testing for one or more endpoints, and proposed testing on all endpoints for 4 submission. For 5 submissions, USEPA agreed with manufacturers not to do any new testing because of the physicochemical properties of the chemicals, and in 11 other submissions, USEPA agreed that reduced testing was appropriate. EPA was unable to evaluate completely 31 other submissions, and in those cases either requested additional information or returned the submission to the submitter(s). Finally, no action was required on one submission because production has ceased. Once screening level data have been obtained, USEPA will prioritize the chemicals to determine whether more in-depth information is needed to adequately address potential hazards. The views expressed are those of the authors and do not represent EPA policy.

1801 USING ANIMAL AND HUMAN MODE OF ACTION INFORMATION IN ASSESSING HUMAN RISK: A FRAMEWORK FOR ANALYSIS.

P. A. Fenner-Crisp and . ILSI RSI Human Relevance Work Group. Risk Science Institute, International Life Sciences Institute, Washington, DC.

In late 2003, the International Life Sciences Institute's Risk Science Institute (ILSI RSI) published the product of a two-year effort on using animal and human mode of action (MOA) information to generate a framework for evaluating the human

relevance of non-genotoxic carcinogens. That report presents a case study analysis of six MOAs that led to development of a four-part Human Relevance Framework (HRF) for systematic and transparent analysis of MOA data and information. The HRF features a "concordance" analysis of MOA information from both animal and human sources, with a focus on determining the appropriate role for the animal MOA information in human risk assessment. With MOA information increasingly available for risk assessment purposes, the sponsors of this project, the USEPA and Health Canada, asked ILSI RSI to evaluate the utility and applicability of the new HRF for a broader set of endpoints, including mutagenicity as it relates to carcinogenicity and endpoints other than cancer. The RSI Working Group, including some participants from the original project, is testing the HRF with ten new case studies representing developmental effects, male reproductive effects, neurotoxic effects, and renal toxicity. The Workgroup also is examining the HRF's applicability to mutagenic carcinogens. The MOAs analyzed include chemically-induced alterations in thyroid homeostasis associated with hearing loss, disruption in brain cell replication associated with behavioral effects, and decreased fetal Leydig cell testosterone production associated with abnormal Wolffian duct system development.

## 1802 CATEGORY APPROACH IN THE USEPA HIGH PRODUCTION VOLUME CHALLENGE PROGRAM.

L. Scarano, R. Hefter, R. Northrop, M. Sonawane, J. Tao, A. Benson and  $\underline{D}$ . Sawhney. USEPA, Washington DC, DC.

In 1998, the USEPA High Production Volume (HPV) Chemical Challenge Program began to develop a new approach to acquire basic hazard data on HPV chemicals. The Challenge Program encouraged the US chemical industry to voluntarily provide basic hazard data and make it publicly available. In response, 334 chemical companies committed to provide the public with health and environmental effects information on 2, 165 HPV chemicals. Traditionally, testing is done on individual chemicals. In the Challenge Program, USEPA encouraged manufacturers to consider testing groups of related chemicals using a category approach. Categories of chemicals have similar structures and/or properties. In general, principles of structure-activity relationships are considered by EPA to be appropriate for developing a category. In an ideal category, tests performed on one or more members can be used to read across to other, untested category members. This approach saves time, money and animals because complete testing of every chemical in an appropriate category may not be necessary. EPA received the first submission in the Challenge Program in April 2000. To date, about 90% of the chemicals (975 out of 1125) submitted in the Challenge Program are category members. The number of chemicals in a given category submission has ranged from 3 to over 150. Upon review of the submissions, USEPA believes some categories are more appropriate than others. The outcome of the proposed testing of category members is the ultimate test for whether a category proposal is reasonable. EPA and others' comments are posted on the EPA website and is now beginning to receive industry responses to comments and/or the results of testing for proposed category submissions. This presentation will discuss (1) the adequacy of completed categories to date; (2) using the test results for possible future risk assessment purposes; and (3) the future use of categories in other EPA programs. The views expressed are those of the authors and do not represent EPA policy.

## 1803 ESTIMATING SEVERITY FOR DEVELOPMENT OF THE CONTAMINANT CANDIDATE LIST (CCL).

A. M. Mahfouz<sup>1</sup>, J. Donohue<sup>1</sup>, N. Chiu<sup>1</sup>, J. Du<sup>1</sup>, O. Conerly<sup>1</sup>, <u>C. O. Abernathy</u><sup>1</sup>, B. Ambika<sup>1</sup>, S. Kueberuwa<sup>1</sup> and W. Mendez<sup>2</sup>. <sup>1</sup>Office of Water, USEPA, Washington, DC and <sup>2</sup>ICF Consulting, Fairfax, VA.

In compliance with the 1996 Amendment to the SDWA, OW developed a process to select contaminants in drinking water for possible future regulations. In March 1998, USEPA published the first Contaminant Candidates List (CCL) and asked the National Academy of Sciences (NAS) to peer review the process used in developing this list. The NAS's National Research Council (NRC), provided its recommendation in its 2001 publication entitled "Classifying Drinking Water Contaminants for Regulatory Consideration". At the present time EPA is testing the use of the process recommended by the NRC to develop future CCLs. Five attributes (potency, severity, prevalence, magnitude, persistence/mobility) were recommended by the NRC to select the CCL from a group of initially screened contaminants referred to as the Pre-CCL. The NRC report included a scoring scale for severity which served as a starting point for the EPA work. The NRC scoring protocol was refined through several cycles of testing against data on chemicals with potential to be on the Pre-CCL and then refining the severity scale based on the test results. The metric selected to provide the severity data was the critical effect associated with the parameter selected for scoring potency (RfD, LOAEL, etc). For one phase of testing the severity scoring protocol, the first 100 chemicals on IRIS were used as a data source for critical effects. The critical effects were scored against a nine point severity scale and binned by score. This permitted a detailed evaluation of the scoring scale. For some chemicals, the critical effect given in the IRIS database was found to be ambiguous, others had several critical effects listed and others had none. This required further refinement of the severity scoring protocol. Some issues are still under consideration in scoring severity; these include concerns about sensitive population, concerns about chemicals with extensive data gaps, and testing the severity scores in conjunction with the other attribute scores in several CCL prototype decision algorithms.

## 1804 ESTIMATING POTENCY FOR DEVELOPMENT OF THE CONTAMINANT CANDIDATE LIST (CCL).

<u>G. Blumenthal</u><sup>2</sup>, J. M. Donohue<sup>1</sup>, O. Conerly<sup>1</sup>, K. Sullivan<sup>2</sup>, <u>A. Mahfouz</u><sup>1</sup>, J. <u>Du</u><sup>1</sup>, S. Kueberuwa<sup>1</sup>, <u>C. Abernathy</u><sup>1</sup>, N. Chiu<sup>1</sup> and A. Bathija<sup>1</sup>. <sup>1</sup> Health and Ecological Criteria Department, USEPA, Washington, DC and <sup>2</sup>ICF Consulting Inc., Fairfax, VA.

The 1996 Safe Drinking Water Act requires EPA to develop a list of contaminants with potential for regulation on a five-year cycle, and to make regulatory determinations from each list three years after its publication. EPA requested assistance from the National Research Council (NRC) of the National Academy of Sciences in providing suggestions for a comprehensive, transparent process of selecting contaminants for inclusion on the CCL. The NRC recommendations were published in 2001. They provided a framework for the process in which a Pre-CCL is initially selected from the universe of contaminants of concern. The CCL is chosen from the Pre-CCL using a computerized decision algorithm and scored attributes for health effects (potency, severity) and occurrence (prevalence, magnitude, persistence and mobility). EPA has developed and tested an approach for scoring the noncancer potencies of Pre-CCL chemicals using as input parameters several QSARgenerated or measured toxicological values [reference dose (RfD), No-Observed-Adverse-Effect-Level (NOAEL), Lowest-Observed-Adverse-Effect-Level (LOAEL), LD50]. The scoring for each parameter was calibrated based on data from a learning set of known drinking water contaminants. The distribution of the RfD, NOAEL, LOAEL, and LD50 values for the learning set chemicals was examined and found to be roughly log-normal. The log-based distribution was mapped onto a ten point scoring scale by equating a value of 5 on the scale to the modal value in the distribution resulting in an set of equations that can be used to score each type of potency input. Scores were fairly consistent across related inputs for individual chemicals. Agreement was weakest for the weakly toxic chemicals in the example data sets. [The opinions expressed represent those of the authors and do not necessarily reflect the opinions of the USEPA.]

## 1805 THE USEPA CONTAMINANT CANDIDATE LIST(CCL) DEVELOPMENT PROCESS.

O. D. Conerly<sup>1</sup>, <u>C. Abernathy</u><sup>1</sup>, A. Bathija<sup>1</sup>, N. Chiu<sup>1</sup>, J. Donohue<sup>1</sup>, <u>J. Du</u><sup>1</sup>, S. Kueberuwa<sup>1</sup>, <u>A. Mahfouz</u><sup>1</sup> and W. Mendez<sup>2</sup>. <sup>1</sup>Office of Water, USEPA, Washington, DC and <sup>2</sup>ICF Consulting, Fairfax, VA.

The Safe Drinking Water Act Amendment of 1996 requires the United States Environmental Protection Agency (USEPA) to develop a list of contaminants(CCL) every 5 years to assist in priority-setting efforts for the drinking water program. From each list, the Agency is required to make regulatory determinations for at least 5 contaminants 3 years after its publication. The first CCL (1998) was criticized by some stakeholders for not considering a wider range of chemical and microbial contaminants. Accordingly, USEPA requested assistance from the National Research Council (NRC) to develop a prioritization process that would consider all potential drinking water contaminants. In response to USEPA, NRC published a series of reports. The most recent and final report, Classifying Drinking Water Contaminants for Regulatory Consideration, recommends that the Agency develop the CCL using two steps. The process would begin with a universe of potential and known drinking water contaminants. Using screening and expert judgment, this universe would be reduced to a preliminary CCL (PČCL). The CCL would be selected from the PCCL using a prototype classification algorithm in conjunction with expert judgment. To evaluate the feasibility of the NRC suggestions, USEPA formed and has been actively working with an advisory group under the National Drinking Water Advisory Council (NDWAC). The workgroup consists of a diverse group of representatives from academia, water utilities, State governments and environmental interest groups. Recommendations from the working group are expected in early 2004. [The opinions expressed in this abstract are those of the authors and not necessarily those of USEPA.]

## 1806 A CRITICAL LOOK AT THE EU DRINKING WATER PARAMETRIC VALUE AND ITS USE AS AN INDICATOR OF HEALTH RISK.

E. R. Nestmann, L. A. Haighton, E. Cheng and R. A. Halford. CANTOX HEALTH SCIENCE INTERNATIONAL, Mississauga, ON, Canada.

The EU drinking water parametric value for pesticides of 0.1 ppb is based largely on the precautionary principle and technological considerations rather than toxicity or risk. Problems can arise when any pesticide present at levels above 0.1 ppb is misinterpreted as being a definitive health risk. Clauses in the EU directive stating: "in

the event of non-compliance..member states shall consider whether that non-compliance poses any risk to human health" and "consumers are notified except where the competent authorities consider the non-compliance with the parametric value to be trivial" are often overlooked. For this risk assessment, WHO health based GVs were evaluated and compared to the arbitrary EU value for over 40 chemicals. The WHO values were higher than the EU value, by as much as 3000 times. The pesticides were prioritized on the basis of margin of difference between the WHO and EU value. Exposures from drinking water with pesticides at a level of 0.1 ppb (about 0.003 microgram/kg/day) were also compared to ADIs; exposures of 0.003 microgram/kg/day represent 0.003% of the ADI for bentazone. This assessment provides much needed perspective as to which pesticides would constitute a real health concern if the EU value is exceeded, and which would not. Another problem with the EU parametric value has been its misuse for beverages. Recently, a localized populace became outraged by claims from an NGO that their beverages contained pesticides. Although tests commissioned by their government indicated that the NGO results were inaccurate, the controversy continued. At the root of the conflict was the use of the EU parametric value as an indicator of danger. It is inappropriate to use the EU limit for beverages for a number of reasons such as technological difficulties in measuring pesticides at such a low level, differences in consumption, and use of ingredients, other than water, that may have individual pesticide tolerances. The recent controversy indicates that activists can initiate social unrest by such misapplication of the EU value.

#### 1807

PRINCIPLES AND PRACTICES FOR DIRECT DOSING OF PRE-WEANING MAMMALS IN TOXICITY TESTING AND RESEARCH.

T. Zoctis and . ILSI RSI Working Group. Risk Science Institute, International Life Sciences Institute, Washington, DC.

Most standardized toxicology testing protocols recommend the use of adult animals to characterize hazards. However, children represent a unique segment of the population, for which adult animal models may not be predictive. Indirect exposure of a developing animal via maternal milk is assumed to occur in developmental toxicology studies that include a lactation phase, but it is seldom measured directly. Direct dosing is defined as the administration of a test substance directly to a pre-weaning mammal. The ILSI RSI working group developed a handbook on how to undertake direct dosing laboratory studies on pre-weaning mammals. When designing the protocol, several issues must be considered, including selection of the test species, the route of administration, dose levels and the timing of doses. Test species discussed included rodents, rabbits, canines, swine and non-human primates. Knowledge of the maturational status of the test species and information on critical windows of development are important in creating a valid study design. Most common routes of administration (e.g., oral, inhalation, injection) for direct dosing are possible with typical laboratory species; however, some adjustments may be necessary due to practical considerations. Care must be taken in the selection of dose levels for the pre-weaning mammal; it may be necessary to conduct a preliminary dose range finding study to determine appropriate dose levels. Information on pharmacokinetics in young animals versus adults and in the test species versus humans can be useful. The conduct of the study and the interpretation of the data might also be influenced by stress on the pre-weaning mammal that can result from interruption of normal maternal care, or from handling and dosing procedures. Ultimately, the success of the study will depend upon careful preparation, including thorough training of the technical staff.

#### 1808

VALIDATION OF THE HUMAN EPIDERMIS MODEL SKINETHIC FOR SKIN CORROSION TESTING ACCORDING TO NEW OECD TEST GUIDELINE 431.

M. Liebsch<sup>1</sup>, H. Kandarova<sup>1</sup>, H. Spielmann<sup>1</sup>, R. Guest<sup>2</sup>, A. Whittingham<sup>2</sup>, N. Warren<sup>2</sup>, A. O. Gamer<sup>3</sup>, T. Kaufmann<sup>3</sup>, M. Remmele<sup>3</sup> and B. De Wever<sup>4</sup>.

<sup>1</sup>ZEBET, Federal Institute for Risk Assessment (BfR), Berlin, Germany, <sup>2</sup>Safepharm Laboratories, Derby, United Kingdom, <sup>3</sup>Toxikologie Z470, BASF AG, Ludwigshafen, Germany and <sup>4</sup>Skinethic Laboratories, Nice, France. Sponsor: A. Goldberg.

Reconstituted human skin models are increasingly investigated for their usability in toxicological hazard identification/safety testing, because primary cells in an organotypic structure with a functional stratum corneum allow for *in vitro* test designs modeling bioavailability. Moreover, variability of results is lower than observed with human skin. However, skin models will only be accepted for industrial and regulatory use if they are at the same time predictive, reproducible and available. While promising predictivity and reproducibility have been shown in validation studies, availability has been a problem: commercially produced skin models went off the market, and with them the validated tests disappeared. The availability issue can be solved if studies prove that robust test protocols applied to various skin models reveal comparable results. When the EPISKIN skin corrosion test validated by ECVAM became unavailable (Fentem et al. Toxicol. *In Vitro* 12, 483-524, 1998) a "catch-up-validation" with the model EpiDerm revealed almost identical results (Liebsch et al. ATLA 28, 371-401, 2000). Therefore, the new OECD Test

Guideline 431 "In Vitro Skin Corrosion: Human Skin Model Test" defines general and functional skin model conditions, including reference chemicals that need to be correctly classified before a new skin model is used in the context of TG 431. In the summer of 2003, ZEBET tested several chemicals from the ECVAM validation trial, applying the validated EpiDerm skin corrosion test protocol to the SkinEthic model and obtained identical results. In November/December 2003 a blind trial will be performed in which ZEBET, Safepharm and BASF will re-test the reference chemicals specified in OECD TG 431. Data on reproducibility between laboratories and over time, as well as predictions obtained will be presented.

## 1809 WELFARE-ENHANCED CAGE DESIGN FOR PRIMATE TOXICOLOGY STUDIES.

J. Hedley and S. Grainger. Covance Laboratories Ltd., Harrogate, United Kingdom. Sponsor: D. Everett.

Non-human primates have been utilised in the performance of regulatory toxicology studies for many years with one of the more common species of choice being the Cynomolgus Macaque (Macaca fascicularis). The current standards of care and welfare afforded to these animals reflect the increasing awareness of the necessity to address their social and environmental needs. It is now widely recognised that the provision of social and environmental stimuli in a caging environment, that supports and encourages the animals in demonstrating their natural behaviour patterns, has a positive effect on their health and well being. It can therefore be argued that such benefits to the animal will enhance the scientific integrity of any experimental work in which they are involved. In 2001 plans were drawn up for the design and construction of a purpose built primate facility, the principal function of which was to support the conduct of regulatory toxicology studies utilising the Cynomolgus Macaque. The facility would house primates in bespoke caging designed to satisfy the social and environmental needs of the animals, so far as reasonably practicable, whilst maintaining sufficient restrictions to facilitate the performance of routine daily experimental procedures. It was necessary that any caging would exceed guidance for the housing of non-human primates as specified within Home Office Code of Practice (Animals (Scientific Procedures) Act 1986), and satisfy draft recommendations for the revision of Appendix A of the European Convention (ETS 123). Over the following 18 months cage designs and prototypes were assessed and refined. Modifications were made where necessary and long-term trials were undertaken with large groups of animals. The result was a caging system that supports the social requirements of the animal, affords environmental stimuli in various forms and enhances the conduct of the experimental work for which the animals are intended.

#### 1810

DO PRECLINICAL STUDIES IN PREADOLESCENT ANIMALS PREDICT CLINICAL TOXICITY?-LANSOPRAZOLE (A PROTON PUMP INHIBITOR) AS A CASE EXAMPLE-.

A. Youssef. TAP Pharmaceutical Products Inc., Lake Forest, IL.

The reference standard in treating adults with acid-related disorders, are increasingly being used in children despite limited pediatric safety and pharmacokinetics data. Proton pump inhibitors, similar to more than 60% of all pharmaceutical products, are metabolized by CYP3A4. The new FDA guidance on "Non Clinical Safety Evaluation of Pediatric Drug Products" expects the conduct of juvenile preclinical studies as a method to predict/evaluate the toxicity and pharmacokinetics prior to clinical studies. However, this guidance does not address clearly the difference between humans and animal models in the growth and development of the stomach as a target organ. Furthermore, the impact of the difference in ontogeny of CYP enzymes and their subtypes, between animals and humans, lakes emphasis. A case study using preadolescent animal models will be discussed. Discussion of some differences in the ontogeny and the subtypes of CYP between rats and humans which impacts the validity of the rat as a model was published (Youssef et al., 2003). The ontogeny of the enterochromaffin-like cells (target cells for proton pump inhibitors) in the stomach between rodents and humans will be discussed. Additional information from a 13 week study in the preadolescent dog model using lansorprazole will be provided. The learned lessons and recommendations based on using the dog and rat preadolescent models to predict the toxicity and pharmacokinetics in pediatrics, will be presented.

## 1811 ICCVAM PROCESS FOR NOMINATION AND SUBMISSION OF NEW, REVISED, AND ALTERNATIVE TEST METHODS.

L. M. Schechtman<sup>1</sup>, W. S. Stokes<sup>2</sup>, M. L. Wind<sup>3</sup>, B. C. Blackard<sup>2, 4</sup> and <u>R. R. Tice<sup>2, 4, 1</sup>NCTR</u>, USFDA, Rockville, MD, <sup>2</sup>NICEATM, NIEHS, Research Triangle Park, NC, <sup>3</sup>DHS, CPSC, Bethesda, MD and <sup>4</sup>NICEATM, ILS. Inc., Research Triangle Park, NC.

The Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM) coordinates (a) the technical evaluation of new, revised and alternative test methods of Federal agency interest, and (b) cross-agency issues relat-

ing to the validation, acceptance and national and international harmonization of toxicological test methods. ICCVAM recently developed and adopted a process by which test method nominations and submissions are considered and prioritized for review and evaluation. Prioritization of proposed test methods is based on several criteria, including: the applicability of the method to regulatory testing needs; the extent of anticipated use by one or more agencies; the level of multi-agency interest; the potential for the method to reduce, refine or replace animal use; the prospect of the test method to provide improved prediction of adverse health or environmental effects compared to current test methods accepted by regulatory agencies; and the extent to which the test method affords other advantages, such as reduced time or cost. The newly revised ICCVAM Guidelines for the Nomination and Submission of New, Revised, and Alternative Test Methods describe: 1) the ICCVAM nomination and submission process, 2) the information that should be provided in a test method submission or nomination and an outline for organizing the necessary information; and 3) the ICCVAM process for developing performance standards, which communicate the basis on which a validated and accepted test method has been determined to have sufficient accuracy and reliability for a specific testing purpose. Test method submitters/ nominators are encouraged to utilize these Guidelines and communicate with NICEATM and ICCVAM during the preparation of test method submissions and nominations. These Guidelines are expected to facilitate the preparation of test method submissions and nominations and their consideration by ICCVAM. ILS staff supported by NIEHS Contract NO1-ES-35504.

## THE ICCVAM/NICEATM PROCESS FOR DEVELOPING TEST METHOD PERFORMANCE STANDARDS.

W. S. Stokes<sup>1</sup>, L. M. Schechtman<sup>2</sup>, A. Rispin<sup>3</sup>, R. N. Hill<sup>3</sup>, K. Hamernik<sup>3</sup>, B. C. Blackard<sup>1,4</sup> and <u>R. R. Tice<sup>1,4,1</sup> NICEATM</u>, NIEHS, Research Triangle Park, NC, <sup>2</sup>NCTR, USFDA, Rockville, MD, <sup>3</sup>OPPTS, USEPA, Washington, DC and <sup>4</sup>ILS, Inc., Research Triangle Park, NC.

Test methods proposed for regulatory testing should routinely undergo validation studies to assess their reliability and relevance for specific applications. Regulatory agencies can then determine if the test method is sufficiently accurate and reliable to be accepted for a proposed specific use. The Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM) has established a process for developing and using performance standards (PS) to evaluate the acceptability of proposed test methods that are based on similar scientific principles and that measure or predict the same biological or toxic effect as an accepted test method. ICCVAM defined the three critical components of PS as: (1) essential test method components, i.e. the requisite structural, functional, and procedural elements of a validated test method that should be included in the protocol of a proposed mechanistically and functionally similar test method; (2) a minimum list of reference chemicals, which is used to assess the accuracy and reliability of the analogous test method; and (3) comparable accuracy and reliability values that should be achieved by the proposed test method when evaluated using the minimum list of reference chemicals. The ICCVAM also established a process for developing and recommending PS during future test method evaluations. NICEATM and an ICC-VAM working group will develop proposed test method specific PS, which will be made available for public comment. An independent peer review panel will review the proposed PS for completeness and appropriateness as a part of the panels evaluation of the proposed test method. ICCVAM will then finalize and forward recommended PS together with test method recommendations to Federal agencies and make these available to the public. The availability of PS is expected to facilitate the development and validation of improved test methods that are similar to previously accepted methods. ILS staff supported by NIEHS contract NO1-ES-35504.

## 1813 RISK MANAGEMENT UNDER REACH - THE NEW EUROPEAN CHEMICALS POLICY.

T. Petry, A. Conrad and T. Golojuch. The Weinberggroup LLC, Brussels, Belgium.

In autumn 2003, the European Commission proposed a first draft of its new chemicals legislation, known as REACH (Registration, Evaluation and Authorisation of Chemicals.) It represents a major overhaul on management of risks associated with chemicals within the European Union (EU). This draft is the result of a complex series of discussions and negotiations between scientists, policy maker and politicians, individual Member States, the chemical manufacturers and downstream users of chemicals as well as non-governmental organizations. At its core, REACH will require producers and users of chemical substances to register these uses in a volumetriggered system. Submission of chemical assessment reports containing information on the hazards, exposures and risks associated with the uses of the chemical substances for review by governmentally-appointed expert committees will be required. Chemicals deemed hazardous, e.g., substances said to be Category 1 or 2 carcinogens, mutagens or toxic to the reproductive system according to the EU

Dangerous Substances Directive 67/548/EEC, will trigger a complex review and authorisation procedure. As it stands, authorisation will also be required for substances considered to be *of concern* such as endocrine disrupters or substances that are persistent, bioaccumulative and toxic. In the authorisation process, an expert panel within a newly established EU chemicals agency will be expected to utilize scientific and socioeconomic data and information in their decision on the authorisation of uses of substances of concern. The results of a study to characterize the specific data requirements and the process of risk management in this emerging legislation will be reported. Specific consideration will be given to ill-defined areas under the proposed authorisation scheme. An effective approach that aims at putting risk into context to assure that politically driven risk management programs recognize the required balance between risk of use against risk of loss of the substance in achieving sustainability in the EU will be discussed.

## 1814 REGULATION OF VETERINARY ANTIMICROBIAL DRUG RESIDUES IN FOOD: FDA AND VICH APPROACHES.

A. H. Fernandez. CVM, USFDA, Rockville, MD.

The effect of antimicrobial drug residues in food on the human intestinal flora has been a FDA concern for more than a decade. Based on conclusions from international meetings and results from FDA sponsored research, the Center for Veterinary Medicine has been assessing the human food safety of antimicrobial drug residues based on adverse effects on human intestinal flora in the last 7-8 years. A guidance document (Guidance #52) for addressing this issue was published in January of 1996 and a modified guidance in October of 2003. Because of the international concern about the effect of antimicrobial residues in food on the human intestinal flora, the International Cooperation on Harmonization of Technical Requirements for Registration of Veterinary Medicinal Products (VICH) charged a Task Force to harmonize regulatory requirements for this area and recommend testing methods for assessing the effect of antimicrobial drug residues on endpoints of human health concern. The VICH guideline GL #36 is currently at the later stages of the VICH process. Both the FDA and VICH documents request that sponsors first address the need for a microbiological ADI following a pathway approach. This approach assesses the activity of the drug and/or its metabolites on relevant human intestinal bacteria and the concentration of residues that remain microbiologically active in the human colon after ingestion of food containing these residues. The no-observed effect level (NOEL) should be determined for the adverse effects that have been linked to public health concern: development of resistant bacteria and disruption of the colonization barrier of the flora. If necessary, both guidelines recommend using in vitro or in vivo test systems for determining NOELs for these endpoints. Specific test systems are discussed for each endpoint only in the VICH guideline. In addition, the VICH guideline recommends procedures for deriving an ADI using data from these methods. It also includes a glossary of terminology and appendices recommending future areas of research and statistical procedues to be used for data evaluation.

## 1815 VICH HUMAN FOOD SAFETY GUIDELINES: PROGRESS REPORT.

L. T. Mulligan. *Human Food Safety, USFDA/CVM, Rockville, MD.* Sponsor: <u>A. Fernandez</u>.

VICH (International Cooperation on Harmonization of Technical Requirements for Resgistration of Veterinary Medicinal Products) was established in 1996 and patterned after ICH, the human drug international harmonization process. VICH has nine Working Groups charged with harmonizing technical requirements for the registration of veterinary products in the participating regions: The European Union, Japan, USA, Australia/New Zealand, and Canada. The Safety Working Group (SWG) was established in 1997 and mandated to determine the complete package of toxicological studies needed to establish an Acceptable Daily Intake (ADI) for residues of veterinary drugs. The SWG had its last meeting in the USA in December of 2003. To date, they have completed eight guidelines. These consist of "General Approach to Testing Guideline" containing the overall toxicological requirements for human food safety and seven other specific guidelines. The specific guidelines include genotoxicity, reproductive toxicity, developmental toxicity, repeat-dose toxicity (90-day and chronic studies), carcinogenicity, and effects of drug residues on human intestinal flora. The guidelines are either new or based on ICH or OECD guidelines. Following implementation, the guidelines will replace the present guidelines and may require major changes in veterinary drug regulation in the regions. The purpose of this presentation is to review the VICH guidelines and emphasize significant changes that will impact the current veterinary drug regulatory process.

### EVALUATION OF ACUTE DRUG-INDUCED VASCULAR INJURY BIOMARKERS.

C. Louden<sup>1</sup>, D. Brott<sup>1</sup>, L. Foster-Brown<sup>1</sup>, S. Gould<sup>2</sup>, H. Jones<sup>2</sup>, H. Prior<sup>2</sup>, J. Valentin<sup>2</sup>, G. Evans<sup>2</sup>, S. Bjurstrom<sup>3</sup>, K. Kenne<sup>3</sup>, I. Schuppe-Koistinen<sup>3</sup> and G. Betton<sup>2</sup>. <sup>1</sup>Safety Assessment - US, AstraZeneca Pharmaceutical, Wilmington, DE, <sup>2</sup>Safety Assessment - UK, AstraZeneca Pharmaceuticals, Alderley Park, United Kingdom and <sup>3</sup>Safety Assessment - Sweden, AstraZeneca Pharmaceuticals, Sodertalje, Sweden. Sponsor: P. Ciaccio.

The unavailability of non-invasive diagnostic markers for drug-induced vascular injury is of concern to the pharmaceutical industry. Therefore, the discovery and validation of potential markers with clinical applicability would add great value to risk assessment and risk management and hence expedite the drug development process. However, validation of potential biomarkers is complicated by the fact that vascular wall biology is complex and comparing responses across species is challenging. In an attempt to identify markers of drug-induced vascular injury, we hypothesized that assessment and evaluation of endothelial cells, sub endothelial collagen, medial smooth muscle cells, adventitial fibroblasts, and/or circulating elements of the blood should yield potentially useful diagnostic markers. In a preliminary study, we evaluated markers of tissue injury, coagulation cascade, acute inflammation and cellular adhesion molecules in serum and/or plasma from dogs treated with an endothelin receptor antagonist ZD1611. In addition, protein expression in the right coronary artery, from control and treated dogs, was evaluated using immunohistochemistry and proteomics. Our results show a clear increase in circulating vWF in treated dogs as early as 3 hours post-dosing, this effect was sustained for 12 hours and returned to baseline at 24 hours post-dosing. This finding is of interest since vWF is frequently used as a diagnostic marker of vascular integrity in humans. The other serum and plasma biomarkers evaluated, including routine hematology and chemistry, were not altered post-dosing. However, immunohistochemistry showed the specific loss of Caveolin-1 expression within the lesions. These data suggest that vWF is a potential bridging biomarker of acute drug-induced vascular injury and that acute lesions have a loss of Cav-1 expression.

## 1817 ROLE OF CAVEOLIN-1 IN DRUG-INDUCED VASCULAR INJURY.

D. Brott<sup>1</sup>, A. Katein<sup>1</sup>, L. Foster-Brown<sup>1</sup>, J. Morelli<sup>1</sup>, G. Evans<sup>2</sup>, H. Jones<sup>2</sup>, S. Gould<sup>2</sup>, G. Betton<sup>2</sup>, S. Bjurstrom<sup>3</sup>, H. Prior<sup>2</sup>, J. Valentin<sup>2</sup> and C. Louden<sup>1</sup>.

In toxicology studies, drug-induced vascular lesions in rats and dogs is an issue of major concern because there are no obvious predictive biomarkers for pre-clinical or clinical monitoring and there is an intellectual gap in our knowledge and understanding of the pathogenesis of these lesions. There is strong evidence suggesting localized vasodilation, inability of the vasculature to maintain tone and alterations in regional myocardial blood flow are critical events in the development of drug-induced arterial lesions in dogs. While vasodilation and increased shear stress appear to play a role in drug-induced vascular injury, the exact mechanism of smooth muscle cell (SMC) and endothelial cell (EC) injury/death is unknown. In acute druginduced vascular injury, we observed early decreases and/or loss of caveolin-1 (cav1) expression. Since cav1 is expressed on both SMC and EC, the primary targets of vascular injury, and based on location and function we hypothesized that cav1 could play an important role in the mechanism of drug-induced vascular injury as well as be a mechanistically linked diagnostic marker of vascular integrity. Therefore, we attempted to develop an in vitro system to study the mechanism of drug-induced vascular toxicity and determine if loss of cav1 precedes cell death. In our initial studies we used a rat, embryonic, aortic smooth muscle cell line (A10) and IBMX as our test compound. IBMX was selected because it is a broad-spectrum phosphodiesterase inhibitor (PDE) and inhibition of PDE type IV can cause mesenteric arterial lesions in the rat. Our preliminary results show that IBMX caused loss of cav1 in a dose-dependent manner in A10 cells and furthermore, the loss of cav1 preceded apoptosis. Minoxidil had similar but less pronounced effects with A10 cells. These data suggest that cav1 may be playing an important role in the initiation of drug-induced vascular injury in rats and dogs.

NOVEL TECHNIQUES FOR ISOLATION AND CHARACTERIZATION OF ENDOTHELIAL CELLS AND VASCULAR SMOOTH MUSCLE CELLS FROM CANINE CORONARY ARTERIES.

X. Yu<sup>1</sup>, M. K. Dame<sup>2</sup>, R. Garrido<sup>1</sup>, D. Stump<sup>1</sup>, W. Bobrowski<sup>1</sup>, J. E. McDuffie<sup>1</sup>, J. Varani<sup>2</sup> and M. A. Albassam<sup>1</sup>. <sup>1</sup>Worldwide Safety Sciences, Pfizer Global Research & Development, Ann Arbor, MI and <sup>2</sup>Pathology, University of Michigan, Ann Arbor, MI. Sponsor: A. Brown.

Beagle dogs are commonly used in drug safety studies. The morphological changes of endothelial cells (EC) and vascular smooth muscle cells (VSMC) were observed in drug-induced vascular injury. The ability to isolate and characterize pure EC and

VSMC cultures could prove useful in the investigation of compound-evoked vascular cell responses. EC and VSMC cultures from canine coronary arteries are not commercially available and the methods for isolating these cells have not been published. This work was initiated to establish novel methods for isolation of pure ECs and VSMC from Beagle dog coronary arteries. For isolation of ECs, different periods of enzyme incubation time (10-40 minutes) were performed. The ECs collected following 10-minute enzyme incubation were found to have the highest purity. The EC cultures were characterized by uptake of Dil-Ac-LDL, immunocytochemical staining for von Willibrand factor and by transmission electron microscopy (TEM). Multi-stage enzyme digestion (30 minutes to 2 hours) was performed to isolate VSMC. The VSMC collected following three consecutive 30minute enzyme incubation/wash periods were found to have the highest purity. The VSMC cultures were characterized by immunocytochemical staining for smooth muscle a-actin and by TEM. The VSMC cultures failed to stain for von Willibrand factor (an endothelial cell marker) or basic fibroblast growth factor (a fibroblast cell marker), suggesting that the VSMC isolates were pure. Pure canine coronary EC and VSMC cultures may serve as in vitro models for investigating compound-evoked cell-specific signal transduction.

### 1819 ENDOTHELIN-1 AND VASCULAR TOXICITY OF HIV COCKTAILS.

V. Y. Hebert, B. Crenshaw, R. L. Romanoff, V. P. Ekshyyan and T. R. Dugas. *Pharmacology, LSU Health Sciences Center, Shreveport, LA.* Sponsor: <u>K. McMartin</u>.

Pulmonary arterial hypertension (PAH) is a progressive disease of the pulmonary vasculature involving vascular smooth muscle cell (VSMC) proliferation, vasoconstriction, right ventricular hypertrophy, and eventually, right heart failure and death. The incidence of PAH in the general population is ~1:200, 000, however, the incidence of HIV-associated PAH is 1:200. Further, while conventional HIV therapy with NRTIs (nucleoside reverse transcriptase inhibitors) leads to regression of PAH, the more aggressive Highly Active Antiretroviral Therapy (HAART, two NRTIs plus a protease inhibitor) increases the incidence of HIV-associated PAH as much as 2-fold. Though there are relatively few models for PAH, previous reports indicate the disease can be initiated by endothelial injury and release of the mitogen ET-1. ET-1, in turn, stimulates VSMC proliferation. To determine whether HAART exacerbates endothelial cell injury and release of cytokines like ET-1, we treated human umbilical vein endothelial cells with micromolar amounts of AZT, the protease inhibitor indinavir, or AZT plus indinavir, and measured cell viability, respiration, ATP, and ET-1 release. Both AZT and indinavir induced marked decreases in cellular oxygen uptake and ATP production, as well as increases in nitric oxide and ET-1 release. Though the drugs had no apparent effect on proliferation in VSMC alone, in cocultures of VSMC plus endothelial cells, the drugs increased proliferation of both endothelial cells and VSMC. Finally, when cocultures of endothelial cells and VSMC were treated with selective antagonists for  ${\rm ET_A}$  and  ${\rm ET_B}$  receptors, HAART-induced VSMC proliferation was attenuated. We thus hypothesize that HIV drug cocktails exacerbate HIV-associated PAH by inducing endothelial mitochondrial dysfunction, in turn stimulating the release of ET-1, and ultimately, VSMC proliferation.

#### 1820

POTENTIAL MARKERS OF ACUTE CORONARY ARTERY INJURY IN DOGS FOLLOWING ADMINISTRATION OF CI-1034, AN ENDOTHELIN A RECEPTOR ANTAGONIST.

E. McDuffie, X. Yu, Y. Song and M. Albassam. Worldwide Safety Sciences, Pfizer Global Research & Development, Ann Arbor, MI. Sponsor: A. Brown.

The objective of this study was to investigate potential markers for coronary vascular injury evoked by CI-1034, a selective nonpeptide endothelin A receptor antagonist. CI-1034 was administrated to male beagle dogs intravenously (iv) for 4 days. Treated groups consisting of 5 animals received CI-1034 at 120 mg/kg (iv) in bolus. Control animals (n=3) received the vehicle only. Animals were sacrificed on day 5; one treated animal was sacrificed on day 4 due to moribundity. Macroscopically, drug-related effects including hemorrhage were observed in the extramural coronary groove and atrium in the treated animals. Histologically, coronary changes were noted in the treated animals and characterized by medial hemorrhage and necrosis, and mixed inflammatory-cell infiltrates in the intima, media and adventitia. Immunohistochemistry (IHC) staining indicated increases in expression of inducible nitric oxide synthase (iNOS) and cleaved caspase 3 (a marker of apoptosis) in the coronary arteries from the treated group. Similar levels of expression of endothelial nitric oxide synthase (eNOS) in both control and treated animals were noted by IHC. Colorimetric assay showed increased levels of nitrite and nitrate (markers for accumulation of nitric oxide production) in both serum and urine from the treated animals only. Increased levels of pro-inflammatory cytokine, interleukin-6 (IL-6) and acute phase proteins, fibrinogen and serum amyloid A (SAA), were detected by enzyme-linked immunosorbent assay (ELISA) in the blood from CI-1034-treated animals. These findings suggest that CI-1034-evoked acute coronary artery injury involves activation of iNOS and apoptosis; increased levels of IL-6, fibrinogen and SAA may serve as markers of acute drug-induced coronary artery injury.

#### 1821

AN EXPERIMENTAL PDE IV INHIBITOR-INDUCED VASCULAR INJURY (VI) ASSOCIATED WITH INCREASED MAST CELL DEGRANULATION AND ELEVATED SERUM LEVELS OF ACUTE-PHASE PROTEINS IN SPRAGUE-DAWLEY RATS.

J. Zhang<sup>1</sup>, R. Honchel<sup>1</sup>, J. L. Weaver<sup>1</sup>, A. Knapton<sup>1</sup>, <u>E. H. Herman</u><sup>1</sup>, F. M. Goodsaid<sup>2</sup>, <u>J. W. Davis II</u><sup>2</sup>, <u>I. Y. Rosenblum</u><sup>2</sup> and <u>F. D. Sistare</u><sup>1</sup>. <sup>1</sup>Division of Applied Pharmacology Research, Center For Drug Evaluation and Research, USFDA, Laurel, MD and <sup>2</sup>Toxicology, Schering-Plough Research Institute, Lafayette, NJ.

Evaluation of drug-induced VI has been hampered by a lack of early clinical signs and accessible biomarkers. As part of an ongoing effort to establish a rat model of drug-induced VI, rats were gavaged with an experimental PDE IV inhibitor at doses of 3 to 160 mg/kg/day (mkd) for 1 to 9 days and sacrificed 24 hr after the last dose. Doses of 6 mkd and higher resulted in systemic toxicity. Vascular lesion development appeared to be both time- and dose-dependent. A semiquantitative scale (0 to 5+) was used to grade mesenteric vascular lesions. Lesions increased in both incidence and severity from 0.6+ to 4.7+ following three doses of 3, 6, or 40 mkd. Similar lesions and scores were observed following 9 doses of 3 mkd (1.2+) or 7 doses of 9 mkd (3.0+). In mesenteric vasculature, the compound induced arteriolar fibrinoid necrosis, arterial hemorrhage and necrosis, and perivascular inflammation, accompanied by endothelial cell (EC) activation, mast cell degranulation, increased nitrotyrosine formation on EC, and apoptosis of EC and smooth muscle cells. VI correlated well with the extent of neutrophilia, lymphopenia, and increased serum levels of haptoglobin and α1-acid glycoprotein at all time points. Increased serum IL-6 was seen only at early time points. The pathologic findings suggest that mechanisms responsible for the VI might involve peroxynitrite-mediated damage to EC and a concurrent activation of certain immune system components. Further work is required to refine the model and elucidate the pathogenesis of VI. We are evaluating additional blood-based biomarkers to identify drug-induced VI and differentiate it from inflammation. A more specific biomarker panel will be critical to expand our capabilities in safety monitoring of preclinical or clinical studies with PDE inhibitors.

## 1822 ESTABLISHMENT OF AN *IN VITRO* METHOD FOR ASSESSMENT OF DRUG-INDUCED VASCULITIS.

Y. Zhou<sup>1</sup>, H. Yamada<sup>1</sup>, <u>I. Horii</u><sup>1</sup> and K. Suzuki<sup>2</sup>. <sup>1</sup>Worldwide Safety Sciences, Pfizer Global Research & Development, Nagoya Laboratories, Pfizer Inc., Nagoya, Japan and <sup>2</sup>Department of Molecular Pathobiology, Mie University School of Medicine, Tsu, Japan.

[Purpose] Vasculitis has been shown to cause injury of organs such as liver, heart, kidney in both preclinical toxicity studies and clinical studies. Recently, several drugs were reported to be associated with a high incidence of vasculitis. This indicates the importance of establishing a system for assessing drug-induced vasculitis during early phase evaluation of candidate drugs. In this study, we established an in vitro, low bulk rapid vasculitis assessment method using cultured human umbilicalvein endothelial cells (HUVECs). We verified the correlation between data obtained from the in vitro method with that obtained from in vivo studies using animals. [Methods] Cultured HUVECs were exposed for 3, 6 and 24 h to varying concentrations of the vasculitis-inducing drugs, Siguazodan (PDE III inhibitor) and Fenoldopam (5-HT2 and dopamine DA1 agonist). The degree of HUVECs injury was evaluated by determining the concentrations of the following molecular markers of coagulation/fibrinolysis in the culture medium using ELISA: von Willebrand factor (vWF), tissue type plasminogen activator/plasminogen activator inhibitor-1 complex, and soluble intercellular adhesion molecule-1 and TNF-a. Morphological changes in HUVECs and the expression of vWF in HUVEC cytoplasm, platelet endothelial cell adhesion molecule-1 and tissue factor on the cell membrane were determined by immunostaining. [Results & Conclusion] When HUVECs were exposed to the above vasculitis-inducing drugs, vasculitis-related markers were increased in the culture medium, functional molecules were expressed on the cell membrane, and cell morphological changes were observed in a dose-dependent fashion. The dose of drugs that induced remarkable changes in HUVECs was in the same range as concentrations of animal (dog and rat) plasma from in vivo studies. These findings suggest that this method may be useful for evaluating and screening drug candidates induced the vascular endothelium injury.

#### 1823

USE OF A NON-INVASIVE TELEMETRY SYSTEM (EMKA) FOR FUNCTIONAL CARDIOVASCULAR ENDPOINTS IN TOXICOLOGY STUDIES.

H. Prior<sup>1</sup>, D. Hunter<sup>1</sup>, J. Schofield<sup>1</sup>, K. Gracie<sup>1</sup>, J. Moors<sup>1</sup>, K. Philp<sup>1</sup>, P. Carter<sup>2</sup>, J. Valentin<sup>1</sup> and <u>T. Hammond</u><sup>2</sup>. <sup>1</sup> Safety Pharmacology, AstraZeneca UK Ltd., Macclesfield, Cheshire, United Kingdom and <sup>2</sup> Safety Assessment UK, AstraZeneca UK Ltd., Macclesfield, Cheshire, United Kingdom.

Introduction: Inclusion of ECGs in toxicology studies has conventionally been at snap-shot time-points, with restrained dogs in slings, which can lead to stress and heart rates above the normal resting values. This can mean that the sensitivity of the system is reduced for the detection of effects of test compounds on ECG parameters, in particular QT interval. New technological advances in non-invasive telemetry systems permit inclusion of longer-term, higher quality measurements, thus improving the detection of such effects. Objectives: To demonstrate the value of including non-invasive ECG recordings in a dog toxicology study. Methods: 30 dogs on a one month oral toxicity study had ECGs recorded for up to 22 hours, using external skin electrodes (EMKA technologies, France) on Days -5, 2, 7, 14, 21 and 27, in order to investigate suspected QT prolongation effects identified in a previous single dose and 7 day Safety Pharmacology (SP) telemetry study. All other measurements (toxicokinetics, clinical pathology, pathology) were as normal for this type of regulatory study, but are not discussed within the context of this abstract. Results: Inclusion of these recordings eliminated the need for a separate follow-up SP study, since the data from the control animals and four dose levels of compound (3M/3F per group) produced a clear dose- and time-related effect on QT interval. Conclusions: Inclusion of cardiovascular SP end-points within toxicology studies can therefore be advantageous from an animal welfare, data quality, compound requirement and resource perspective.

#### 1824

A METHOD FOR THE LONG TERM MONITORING OF CARDIOVASCULAR AND RESPIRATORY FUNCTION IN THE WISTAR RAT.

N. McMahon<sup>1</sup>, A. Robinson<sup>1</sup>, E. Martel<sup>2</sup> and J. Valentin<sup>1</sup>. <sup>1</sup>Safety Pharmacology, Safety Assessment, AstraZeneca R&D, Macclesfield, Cheshire, United Kingdom and <sup>2</sup>CERB, Baugy, France. Sponsor: T. Hammond.

The development and utility of pharmaceutical agents may be limited by cardio-and/or respiratory toxicity. We present a method for simultaneous evaluation of functional cardiovascular and respiratory effects. Five male and five female Wistar rats, approximately 9 weeks old, weighing 294-330g were chronically implanted under anaesthesia with a DSI telemetry implant (TL11M2-C50-PXT) 2 weeks before study. While on study rats received daily oral doses of 1% carboxymethylcellulose and 0.1% Tween80. Respiratory and cardiovascular data was collected pre-dose and for 4 and 24 hours post-dose, respectively, on Days 1, 14, 28, 63, 91, 126, 154 and 182. This was achieved by placing a conscious unrestrained rat in a whole-body plethysmography chamber (EMKA, PLY/UN2P) residing on top of a telemetry receiver 30 minutes prior to dosing and for 4 hours post-dose, after which time it was returned to its home cage on top of the same receiver. In this configuration cardio-vascular parameters (systolic and diastolic blood pressures and heart rate) and respiratory parameters (rate, peak inspiratory and expiratory flows, inspiration and expiration times, tidal volume, minute volume and index of airway resistance PenH) were simultaneously acquired. Respiratory data was acquired from at least 3 rats/sex to Day 182 and cardiovascular data from at least 3 rats/sex to Day 63. We have shown that using combined telemetry and plethysmography techniques, cardiovascular and respiratory function can be successfully studied for up to 2 and 6 months, respectively. This approach may be used investigate acute and chronic effects of pharmaceutical agents on the cardiovascular and respiratory systems and their interactions. This type of study can be performed independently or as part of a toxicology study using satellite groups. Furthermore, there is the potential for reuse.

#### 1825

ASSESSMENT OF QT INTERVAL PROLONGATION USING A TELEMETRY SYSTEM IN CONSCIOUS GUINEA PIGS.

T. Harada, M. Shiotani, J. Abe, M. Nagata, Y. Hamada and I. Horii. *PGRD Nagoya Lab., Pfizer Inc., Taketoyo, Aichi, Japan.* Sponsor: <u>M. Kurata</u>.

Prolongation of QT interval is an important safety issue because it may be associated with life-threatening ventricular arrhythmias such as torsades de pointes. However, since distribution of cardiac ion channel in humans differs from that in animals, it is essential to use the most appropriate animal species to be able to assess the risk for a cardiac event induced by a novel agent in humans. Although isolated papillary muscles from guinea pigs are currently used to evaluate the action potential duration (APD) because of the similarity of the ionic currents in ventricular myocytes between humans and guinea pigs, the evaluation of the QT interval in conscious guinea pigs has not been established as yet. In this study, we focused on

the technical and scientific validation of *in vivo* measurement of the QT interval in conscious guinea pigs. Transmitters were implanted subcutaneously in male Hartley guinea pigs and a telemetry system was used to record and analyze ECGs. ECGs were recorded 24 hours before and after treatment with d, l-sotalol (SOT, 40 mg/kg, i.v.) and astemizole (ATZ, 30 mg/kg, p.o.) to compare the QT/RR plots between pre- and post-dosing. Thus, a well-defined T wave was continuously recorded in this study. ATZ and SOT produced the QT interval prolongation, and it was more obvious at lower heart rate. SOT also produced marked bradycardia 0-2 hours after the dosing. APDs were also prolonged in isolated guinea pig papillary muscles as assessed using a microelectrode technique. The results of the present study coincided with those of other studies on drug-induced QT prolongation, and clarified the timecourse of QT changes in guinea pigs. Therefore, it is suggested that, in the early stage of drug development, the telemetry system is a useful tool to examine cardiac electrophysiology in guinea pigs in vivo, especially regarding the evaluation of the QT interval. In addition, simultaneous evaluation in vivo and in vitro would increase the reliability of the risk assessment of QT prolongation.

#### 1826

COMPARISONS OF HOLTER AND TELEMETRIC ECG MONITORING FOR EVALUATION OF QT INTERVALS IN CYNOMOLGUS MONKEYS.

S. kitani, K. Sakamoto, N. Muto, M. Nomura and W. Tierney. Ina Research Inc., Nishiminowa, Ina, Nagano, Japan.

Telemetric ECG monitoring is an invasive procedure, whereas Holter monitoring is not. Analysis of QT intervals has been generally thought to be difficult by Holter monitoringDWe established an improved method of Holter monitoring method using animals acclimated to experimental procedures. ECG parameters including R-R intervals, PR, QRS and QT intervals recorded by these 2 methods were compared in cynomolgus monkeys dosed orally with sotalol hydrochloride, an antiarrythmic agent. Three male cynomolgus monkeys, 4-6 years of age weighing 4-8 kg, from INA RESEARCH PHILIPPINES, INC. were used in this study. Initially, telemetric ECG recordings were conducted, followed by Holter ECG monitoring after an approximately 2-month rest and recovery period. Electrodes were inserted into the subcutis for telemetric monitoring and placed on the shaved skin surface for Holter monitoring, both at the right subclavian and the left abdominal areas. Animals were dosed with sotalol hydrochloride orally at 5 mg/kg. ECGs were recorded from 1 hour pre-dosing until 24 hours post-dosing. Mean heart rates were 103 and 97 times/min in Holter and telemetric ECGs, respectively. Prolongation of QT intervals peaked 1-2 hours post-dosing in both methods and QT intervals were clearly prolonged by 141% and 149% in Holter and telemetry ECGs, respectively, compared to the pretreatment values. Comparable results were obtained by both telemetric and Holter monitoring. Telemetric ECG recordings are routinely employed to conduct QT intervals evaluations in conscious, unrestrained animals. Similarly, evaluation of drugs for prolongation of QT intervals can be detected by Holter monitoring. The results of this study indicate that simple non-invasive Holter ECG monitoring may be available and practical in routine safety evaluations of pharmaceuticals.

## 1827 COMPARISONS OF NON-INVASIVE VERSUS INVASIVE DOG TELEMETRY.

H. Prior<sup>1</sup>, D. Hunter<sup>1</sup>, S. Jason<sup>1</sup>, K. Gracie<sup>1</sup>, J. Moors<sup>1</sup>, K. Philp<sup>1</sup>, J. Valentin<sup>1</sup> and T. Hammond<sup>2</sup>. <sup>1</sup>Safety Pharmacology, AstraZeneca UK Ltd., Macclesfield, Cheshire, United Kingdom and <sup>2</sup>Safety Assessment UK, AstraZeneca UK Ltd., Macclesfield, Cheshire, United Kingdom.

Introduction: Conscious dog telemetry is routinely used for in vivo cardiovascular Safety Pharmacology (SP) studies (ICHS7A guidelines), generally involving invasive surgery to position the telemetry implants. Therefore, colonies of dogs are generally required for long-term use on these studies. Advances in non-invasive telemetry systems may allow additional methodologies to be used, without prior surgical intervention. This allows dogs to be used from stock, or within toxicology studies. Objectives: To evaluate two different telemetry systems; invasive DSI® telemetry (analysis via Notocord HEMv3.4), and non-invasive external ECG telemetry (EMKA Technologies, France, data capture and analysis via IOXv1.7.0 and ECG Autov1.5.7). Methods: Dogs were allowed at least a 2 week recovery period from implantation of TL11M2-D70-PCT transmitters (ECG electrodes in a lead II configuration). For the non-invasive methodology, dogs had external skin electrodes attached in a lead II position, which were held in place by a jacket holding the battery and transmitter. ECG recordings were made from six, male Alderley Park beagle dogs (10-14 kg) using both DSI® and EMKA technologies, simultaneously. Dogs were recorded for 1 hour pre-dose then 6 hours post-dose under control conditions, then following ascending oral doses of  $(\pm)$ sotalol at intervals of 1-2 days. Results: Correlation in data (HR, PR, QT) produced by the 2 systems was within  $\pm5\%$  expected, except for QRS duration. Similar increases in QTC (Van de Waters formula) were apparent using both systems, peaking at 10.4, 13.5 and 17.8% (DSI), or 8.9, 11.5 and 14% from control (EMKA; 4, 8, and 16 mg/kg, respectively). Conclusions: The EMKA system is complementary to DSI. This allows inclusion of quality measurements of SP endpoints in toxicology studies, thus reducing animal usage and compound requirements, by reducing the need for separate SP studies.

## 1828 SIMULTANEOUS CARDIOVASCULAR AND PULMONARY STUDIES IN MONKEYS AND DOGS.

C. R. Hassler. Safety Pharmacology, Battelle, Columbus, OH. Sponsor: M. Brooker.

S7A cardiovascular (CV) and pulmonary (PUL) safety pharmacology studies are most frequently performed in different species and/or different animal models instead of being simultaneously performed in the same animal. When simultaneous CV and PUL measurements are used, it is of interest to ascertain the cardiovascular alterations imposed upon the animal model by the restraint required for the pulmonary measurements. Cardiovascular responses in appropriately trained dogs and monkeys were compared between restraint for pulmonary function and normal cage housing conditions. Restraint slings and restraint chairs were used for dogs and monkeys respectively. Pulmonary flows were collected via head dome and pneumotach. Monkeys were placed in isolation boxes. Animals were instrumented via implanted telemetry for blood pressure, heart rate and ECG. Trained groups of dogs (N=17) and monkeys (N=21) were evaluated up to 7 hours both restrained and unrestrained. Sling restraint/PUL in dogs increased blood pressures 8% and decreased heart rate 6%. Chair restraint/PUL in monkeys increased blood pressures 14% and increased heart rate 22%. Properly conditioned dogs and monkeys may be restrained for pulmonary function determinations with only minor alteration of CV parameters. Restrained-to-home cage differences were nominally 15% or less except for monkey heart rates which were 22% higher during restraint. These CV differences for the restraint conditions used are unlikely to alter the CV conclusions that would be derived from this data. However, these differences in measured parameters require that the CV data be compared to similarly restrained animals. Dogs, especially females, are more amenable to the restraint process and can be readily trained to accept the presence of humans in the experimental room. However, monkeys must be isolated from human contact. Appropriate restraint environment and adequate conditioning are key to the successful implementation of simultaneous CV/PUL collection.

# 1829 ECG CHANGES DURING INHALATION OF DILUTED ENGINE EMISSIONS IN A RAT MODEL OF MYOCARDIAL INFARCTION (MI).

J. MORIN<sup>1</sup>, S. LORIOT<sup>1</sup>, F. ANSELME<sup>2</sup>, A. CHAGROUI<sup>1</sup>, J. HENRY<sup>1</sup> and F. DIONNET<sup>3</sup>. <sup>1</sup>E9920, INSERM, ROUEN, France, <sup>2</sup>Cardiology Unit, CHRU Rouen, Rouen, France and <sup>3</sup>CERTAM, Saint Etienne du Rouvray, France. Sponsor: R. FORSTER

We developed a MI rat model for investigating the cardiac effects of inhaled diluted Diesel engine emissions as a representative surrogate for urban atmospheric pollution. Methods: Left ventricular MI was induced in 12 wistar rats by left coronary artery ligation. 2 months after surgery, rats were implanted with TA-F40 (DSÍ) transmitter for ECG lead II telemetry monitoring. ECG analysis was performed using ECG-Auto software (EMKA France), allowing direct automatic quantitation of arrhythmic events. 3 hour inhalation exposure periods of conscious unrestraint rats (6 rats per group) to a continuous flow of diluted Diesel engine emissions (Particulate Matter 0.5 mg/m3, mean aerodynamic diameter 90nm, CO 10 ppm, NOx 10 ppm)were performed. Results : No significant alteration of ECG but a slight sinusal tachycardia and decrease in HRV were observed in non MI rats exposed to exhausts. In non exposed MI rats, increased QT duration by 20-30 ms and a slight bradycardia (-20-30 bpm) and polymorphic ventricular extrasystoles (PVES) were observed, with preserved RR variability. In Exhaust exposed MI rats, a slight tachycardia (+ 40-50 bpm), frequent arrhythmia was observed consisting in increased PVES (x3times more), episodes of unsustained ventricular tachycardia (UVT) (3 to 6 consecutive beats), of sustained VT (SVT) (over 50 consecutive beats > 550 bpm)and of bigeminy. Bigeminy and VT episodes were not observed in non exposed MI rats. The induction of these arrhythmic events was rapid (within 20 min) for increase in PVES, by approx 2h for unsustained VT episodes, and by approx 4h for sustained VT episodes. Return to basal situation was observed within 12 to 24h after exposure termination. Conclusion : Upon exposure to combustion aerosols, MI rats exhibit marked ECG changes whereas sham controls do not. This model will facilitate the experimental study of outcomes and mechanisms associated with ambient air pollution-related increases in cardiorespiratory morbidity, as identified epidemiologically.

#### 1830

THE CARDIOVASCULAR EFFECTS OF CLINICALLY RELEVANT DOSES OF D, L-SOTALOL AND VERAPAMIL, OBSERVED AFTER ACUTE ORAL ADMINISTRATION TO CONSCIOUS, TELEMETERED CYNOMOLGUS MONKEYS.

P. L. Munt, D. J. Beard, P. H. Davies, C. Winfield, J. J. Daniels, R. Brammer and F. Sannajust. *Huntingdon Life Sciences, Huntingdon, Cambridgeshire, United Kingdom.* Sponsor: C. Hardy.

Clinically recommended daily doses extend to 320 mg for d, l-sotalol and 480 mg for verapamil, which are respectively 6 mg/kg and 10 mg/kg, assuming a bodyweight of 50 kg. The effects of acute oral administration of 5 and 10 mg/kg of each compound were examined on blood pressure (BP), heart rate (HR) and ECG in 5 conscious telemetered monkeys. BP, HR and ECG were continuously measured before and up to 24 hours after dosing, the data being collected and analysed using a DSI /Gould Po-Ne-Mah data system. The QT intervals were corrected for HR using a linear regression analysis (QTcR). In comparison with vehicle (water), d, lsotalol at 5 and 10 mg/kg significantly (p<0.01) reduced HR and increased QT. A significant (p<0.01) prolongation in QTcR was observed at 10 mg/kg with maximal effect observed during 1.5 to 4 hours post-dose. Responses of BP to these treatments were minimal reductions. Verapamil induced a non dose-dependent reduction in QTcR over the 4 to 12 hour post-dose period, which was significant at both dose levels (p<0.05), 12 hours post-dose. At 10 mg/kg, verapamil produced a moderate but non-significant reduction in heart rate and slight reduction in blood pressure. We found that, in telemetered cynomolgus monkeys, oral doses of 5 and 10 mg/kg of d, l-sotalol and verapamil induced changes in QT, as indicated by the corrected QT (QTcR) that were consistent with clinically reported effects. The cynomolgus monkey is therefore considered a suitable and predictive species for detection of potential QT changes.

#### 1831

VALIDATION FOR QT PROLONGATION IN CONSCIOUS CYNOMOLGUS MONKEYS ADMINISTERED SOTALOL VIA NASOGASTRIC ROUTE.

M. miyamoto, <u>C. M. Kelly</u> and S. J. Gosselin. *Huntingdon Life Sciences, East Millstone, NJ.* 

The purpose of this study was to evaluate the DSI (Data Sciences, St. Paul, MN) telemetry system in our Testing Facility environment with an agent known to cause QT prolongation in cynomolgus monkeys. Under general anesthesia, telemetry transmitters were implanted in 8 adult cynomolgus monkeys (4 /sex). Pretest data were collected for a 48 hour period prior to initiation of dosing. Sotalol was administered by nasogastric gavage in a dose escalation regimen at 0, 4, 8, and 16 mg/kg, respectively. Data were collected every 15 minutes for 2 hours prior to dosing and every 30 minutes for 24 hours following each dose. The effect of sotalol on QT interval was assessed by several methods including QTca (regression analysis of QT on RR interval for each animal from the pre-treatment data), % and absolute QT and QTc change from baseline, comparison of absolute QT with similar HR, and QT:HR outlier analysis. For statistical analysis, data were averaged over the following time periods: 0 to 3 hours, 3 to 6 hours, 6 to 12 hours and 12 to 24 hours. Baseline was defined as the mean of all measurements in the 2 hours prior to dosing. Analysis of covariance for repeated measures with treatment, animal and time period as factors and baseline as a covariate was used to test whether treatment effects varied during the above time intervals. Treatments were compared to control using Williams' test, and for time intervals, each sex was also analyzed separately. The peak effect of sotalol on QT prolongation occurred between 0-3 hours, and the degree of QT prolongation was dose-related in males only. However, the peak effect of sotalol on QTc was dose-related between 0 and 3 hour in both sexes. QT intervals were prolonged when compared with similar HR between 0 to 6 hours in both sexes. The number of outliers were dose related at 0-3 hours in both sexes. In conclusion, we have demonstrated the suitability of using DSI telemetry systems in cynomolgus monkeys to detect changes in QT interval in our Testing Facility envi-

TRIANGULATION, REVERSE-USE-DEPENDENCE AND INSTABILITY DISTINGUISH THE PROARRHYTHMIC POTENTIAL OF DRUGS IN A PACED ISOLATED LANGENDORFF RABBIT HEART.

J. Valentin<sup>1</sup>, K. Gracie<sup>1</sup>, S. Palethorpe<sup>1</sup>, <u>T. Hammond</u><sup>1</sup> and L. Hondeghem<sup>2</sup>.

<sup>1</sup>Safety Pharmacology, Safety Assessment, AstraZeneca R&D, Macclesfield, Cheshire, United Kingdom and <sup>2</sup>Hondeghem Pharmaceutical Consulting, Oostende, Belgium.

QT is used as a surrogate marker for a rare but potentially fatal ventricular arrhythmia known as Torsades de Pointes (TdP). However the clear link between QT prolongation and the proarrhythmic risk has not been demonstrated. To evaluate the effects of 36 clinically-relevant drugs in an automated *in vitro* proarrhythmia model

using electrophysiological techniques<sup>1</sup>. Monophasic action potentials were recorded from paced Langendorff-perfused female adult rabbit hearts. Parameters evaluated included action potential duration (APD $_{60}$ ), Triangulation (T), Reverse-use-dependence (R) and Instability (I; TRIad). Thirty-six drugs covering the entire range of torsadogenic propensity<sup>2</sup> were evaluated at concentrations encompassing and exceeding the effective free therapeutic plasma concentration (EFTPC). Compounds were correctly identified and categorized according to their clinically recognised proarrhythmic risk. Briefly, antiarrhythmics which have Ikr block as a primary pharmacodynamic mechanism concentration-dependently increased APD and TRIad within or at low multiples of the EFTPC. Drugs for which there have been no incidences reported or only isolated reports of TdP in humans, showed no change in TRIad with or without APD<sub>60</sub> prolongation at high multiples of EFTPC. Drugs for which numerous cases of TdP have been reported (including those suspended or withdrawn from markets) showed increases of elements of TRIad with complex concentration-response relationships relative to the EFTPC. This automated proarrhythmic model and the use of TRIad analysis, accurately distinguishes between drugs associated with proarrhythmia and those free from proarrhythmic risk. We conclude that this model provides unique and valuable information, which, when coupled to existing models, helps to establish an in-depth integrated risk assessment. 1. Hondeghem, LM et al., 2001. THE INTERACTION OF SEROTONERGIC AND DOPAMINERGIC SYSTEMS IN THE DEVELOPING RAT AFTER NEONATAL COCAINE EXPOSURE.

T. B. Summavielle<sup>1, 2</sup>, C. J. Alves<sup>1</sup>, A. Magalhaes<sup>1</sup>, L. de Sousa<sup>1</sup> and M. A. Tavares<sup>3, 1</sup>. <sup>1</sup>Neurobehavior, Institute for Molecular and Cellular Biology, Porto, Portugal, <sup>2</sup>Biomedical Sciences, Allied Health Sciences School of Porto, Porto, Portugal and <sup>3</sup>Institute of Anatomy, Medical School, University of Porto, Porto, Portugal. Sponsor: <u>S. Ali</u>.

Exposure to cocaine in the adult rat is known to increase serotonin (5-HT) release in the ventral mesencephalon (VTA-SN), nucleus accumbens (ACCB) and striatum (STR), while decreasing cell firing in the raphe nuclei (RN). It was suggested that cocaine acts on the dopaminergic system through a 5-HT-DA interaction, regulating dopamine (DA) action in the ACCB and STR. This interaction would begin in the RN and could modulate cocaine-induced behavioral dysfunctions. Neonatal cocaine is well known to affect the development of both DA and 5-HT systems. Here, we have studied the effects of prolonged neonatal cocaine in the RN, VTA-SN, STR and ACCB, throughout the development of these two systems. Male and female Wistar rats were injected s.c., from postnatal day 1 (PND1) to PND30 with cocaine hydrochloride in two daily doses at 15 mg/kg/day. Control animals were given isovolumetric saline. On PND14, 21 and 30, open-field behavioral tests were conducted to evaluate changes in motor activity. At the same time, rats from at least three different litters (N=6-9 per gender) were sacrificed and brains dissected for determination of DA and 5-HT in the RN, VTA-SN, ACCB and STR, by high performance liquid chromatography with electrochemical detection (HPLC-EC). Significantly increased DA and 5-HT levels were observed in all regions on PND14 and 21, but not on PND30. In both cocaine exposed male and female pups, there was a clear parallelism between levels of 5-HT and DA in all assessed regions, except in the ACCB. In accordance, exploratory and global locomotor actives were seen to increase in both genders on PND14, and decrease on PND30. Therefore, we suggest that, as in the mature, also in the developing rat, cocaine acts on the dopaminergic system through 5-HT-DA interaction in the neural pathways.

ROLE OF ENVIRONMENT IN FETAL BASIS FOR ADULT DISEASES: DEVELOPMENT OF AN ANIMAL MODEL FOR NEURODEGENERATION (ND). AE AHMED, S. JACOB AND G. CAMPBELL, DEPARTMENT OF PATHOLOGY, THE UNIVERSITY OF TEXAS MEDICAL BRANCH, GALVESTON, TEXAS 77550-0609.

A. E. Ahmed. Pathology, UTMB, Galveston, TX.

Nearly every human disease has an environmental component. Fetuses are sensitive to environmental insults and developmental exposure may have a far more detrimental effects in the etio-pathology of fetal and adult diseases. Knowledge of the mechanisms of how environmental insults program fetuses for adult diseases is scanty. Our objective is to develop an animal model to examine the role of drinking water disinfectant byproducts (DBP) in fetal basis for adult ND. Pregnant mice, at day 6 of gestation (GD 6), received a daily oral dose of chloroacetonitrile (CAN, 25 mg/kg), a member of the haloacetonitrile (HAN) group of DBP. At GD 12, two groups were injected with 2-14C-CAN (333 mCi /kg, i.v.) and sacrificed at 1 and 24 h after treatment. Fetal brain uptake of CAN was examined using quantitative in situ whole-body autoradiography. The remaining animals continued treatment

until GD18. One treated group and its control were anesthetized and fetal brains were extracted for quantitation of oxidative stress (OS) markers. The other group and its control were anesthetized, perfused and fetal brains were prepared for histological examinations for ND. The results indicate a) rapid placental transfer, fetal brain uptake and retention of 2-14C-CAN/ metabolites in cerebral cortex and hippocampus, b) CAN uptake in fetal brain induced OS as indicated by decreased GSH/GSSG (4 folds), increased lipid per-oxidation (1.3 folds), and oxidative DNA damage (1.3 folds), c) Significant increase in apoptotic ND in treated fetal brains as detected by DeOlmos cupric silver staining in the cortical regions, and increased immunohistochemical labeling (TUNEL) of apoptotic nuclei in the cortex and choroid plexuses. In conclusion, CAN, following *in utero* exposure, crossed the placenta and fetal blood brain barriers and induced OS that triggered apoptotic ND in fetal brain. Future development of this model will explore the molecular biological mechanisms of these events and its impact on offspring.

## 1835 DELTAMETHRIN-INDUCED DELAYS IN BEHAVIORAL DEVELOPMENT.

M. A. Cheh<sup>1</sup>, L. Michna<sup>2</sup>, A. W. Kusnecov<sup>3</sup> and G. C. Wagner<sup>3</sup>. <sup>1</sup>Neuroscience, Rutgers University, New Brunswick, NJ, <sup>2</sup>Toxicology, Rutgers University, New Brunswick, NJ and <sup>3</sup>Psychology, Rutgers University, New Brunswick, NJ. Sponsor: <u>K.</u> Reuhl.

Deltamethrin (DM) is a commonly used insecticide purportedly having low acute mammalian toxicity. Here we show that prenatal exposure to DM delays the development of cerebellar-dependent skills in BALB/c mice. Pregnant mice were administered DM (10 mg/kg sc) or vehicle on embryonic day 13 (E13). Neonates were subsequently exposed to DM at the same dose or vehicle on postnatal day 14 (P14) (in a 2 X 4 design). The pups of treated dams showed no difference in their ability to surface right (P5-9). However, male E13-treated pups showed a delay in the maturation of the mid-air righting reflex and an impairment in their grip strength (P13-P19) while female pups were unaffected. Treatment with DM on P14 did not cause disruption of skill ontogeny or an exacerbation of the delay observed following E13 treatment. This is consistent with neurochemical analaysis of pups exposed to DM (10 mg/kg sc) or vehicle on P7 and P14. HPLC revealed no changes in striatal or cerebellar dopamine, serotonin, or their metabolites 2 hours after acute treatment with DM compared to age-matched vehicle-treated pups. In addition, acute exposure of adult Ĉ57/BLJ6 mice to DM (9 mg/kg) did not alter levels of dopamine, serotonin, or their metabolites in the striatum, hypothalamus, or frontal cortex at 1, 12, 24, or 72 hours following exposure. These observations indicate that prenatal exposure to low doses of DM alters behavioral development of males in a manner that appears to be independent of brain monoamines. ## 1836 EXPLORING A FISH MODEL OF DEVELOPMENTAL ETHANOL NEUROTOXICITY.

S. Oxendine<sup>1, 2</sup>, <u>S. Padilla</u> and <u>D. E. Hinton</u> <sup>1</sup> · <sup>1</sup> Neurotox. Division, USEPA, Research Triangle Park, NC, <sup>2</sup> Curr. in Toxico., UNC-CH, Chapel Hill, NC and <sup>3</sup> Nicholas School of the Environment, Duke University, Durham, NC.

Rapid methods are needed for screening chemicals for potential toxicity to the developing nervous system. Methods are also needed that isolate the developing organism without confounding factors surrounding maternal detoxification or other influences. To meet these needs, we are assessing developmental neurotoxicity using Japanese medaka fish (Oryzias latipes) as an alternative animal model. Early life stage toxicity tests in fish may serve as developmental toxicity screens for evaluating the effects of chemical exposures. Ethanol is a well-documented mammalian neurotoxicant that produces craniofacial abnormalities, optic impairment, and cognitive deficits in individuals exposed during development. In the first study, pre-hatch medaka embryos were treated with 0.5 to 5.0% ethanol in embryo rearing medium at 26°C (n=10 per group). Treatment and observation of embryos began 24 hours after fertilization and continued for up to two weeks (day nine is the normal hatching day). Ethanol concentrations at or above 3% were lethal to embryos. A second study was designed to determine how the timing of ethanol exposure affects developmental toxicity. Medaka embryos were treated with 1% ethanol during three distinct periods of development (days1-3, 4-6, or 7-9 post fertilization) to determine potential windows of vulnerability. Whereas treatment during 7-9 days post fertilization tended to delay hatching, treatment during days 1-3 produced more abnormal embryos, suggesting that this stage represents a period of heightened sensitivity to ethanol. These results suggest that the medaka fish may serve as a useful alternative model for assessing neurotoxic potential during development. This is an abstract of a proposed presentation and does not imply Agency policy. \*S. Oxendine is funded by the Minority Neuroscience Fellowship Program

DOPAMINE TRANSPORTER AND VESICULAR MONOAMINE TRANSPORTER LEVELS ARE INCREASED BY PERINATAL HEPTACHLOR EXPOSURE.

W. M. Caudle, J. R. Richardson, E. D. Dean, M. Z. Wang and G. W. Miller. Center for Neurodegenerative Disease, Rollins School of Public Health, Emory University, Atlanta, GA.

Heptachlor, a chlorinated cyclodiene insecticide, was a widely used pesticide for many years until it was banned in the late 1970s. In the early 1980s residents in Hawaii were exposed to high levels in the milk supply from contaminated dairy cattle, raising the concern that the offspring of women exposed to heptachlor may have been adversely affected. Previous studies have shown that gestational exposure of rats to 4.2 or 8.4 mg/kg/day from gestation day (GD)10 through GD21 results in increased levels of the dopamine transporter (DAT) in the offspring on postnatal days (PND) 10 and 22. In this study, we sought to determine the effects of longerterm lower level to exposure to heptachlor on DAT, and two other crucial components of the dopaminergic system, the vesicular monoamine transporter 2 (VMAT2) and tyrosine hydroxylase (TH). Female C57BL/6J mice received 0 or 3 mg/kg heptachlor in peanut butter every 3 days for 2 weeks prior to breeding. Treatment continued on the same schedule throughout gestation and lactation until the offspring were weaned on postnatal day (PND) 21. On PND 28, mice were sacrificed and the striatum was removed and frozen on dry ice for determina-tion of monoamine levels by HPLC and dopaminergic markers by western blotting. Perinatal exposure to heptachlor resulted in no overt toxicity to either the dams or the offspring. Striatal levels of dopamine and its metabolites, DOPAC and HVA, were similarly unaffected by treatment. However, DAT levels were increased 2.1 fold. VMAT2 levels and TH levels were also increased by 1.7 and 1.3 fold, respectively. Since increased levels of DAT appear to predict susceptibility of brain regions to Parkinsons disease (PD) and organochlorine insecticides have been linked with increased risk for PD, these results suggest that alterations of the dopaminergic system by perinatal exposure to heptachlor may increase susceptibility to PD. (Supported by ES-012315).

#### 1838

EFFICACY OF *IN VITRO* CARBOXYLESTERASE DETOXICATION OF ORGANOPHOSPHATES IN ADULT AND JUVENILE RAT LIVER AND SERUM.

J. T. Pittman<sup>1</sup>, C. A. Moore<sup>1</sup>, E. B. Shows<sup>1</sup>, H. H. Chambers<sup>2</sup>, J. L. Wagner<sup>1</sup> and J. E. Chambers<sup>1</sup>. <sup>1</sup>College of Veterinary Medicine, Mississippi State University, Mississippi State, MS and <sup>2</sup>Department of Entomology, Mississippi State University, Mississippi State, MS.

Juvenile animals are more vulnerable than adults to the acute toxicity of organophosphorus (OP) insecticides. Acute toxicity levels are strongly related to the presence and the efficiency of specific detoxication mechanisms, primarily several protective esterases such as carboxylesterases (CbxE). The in vitro sensitivities of liver [adult, postnatal day (PND) 12, and PND1] and serum [adult and PND 12] CbxE were determined for the active metabolites (oxons) of a group of OP insecticides (e.g. paraoxon, chlorpyrifos-oxon), to investigate age-related differences in toxicity. In addition, the effect of tissue concentration on the in vitro potency of the CbxE inhibitors was investigated. CbxE activity was assessed spectrophotometrically using 4-nitrophenyl valerate as the substrate. The assessment of the protective capabilities of CbxE for each oxon, in each age group, was based on IC50 values, calculated by linear regression. All oxons showed higher IC50 values for high tissue concentration compared to low concentration, reflecting the higher number of CbxE molecules present. The oxons tested showed a variable range of IC50 values for both liver and serum for each age group. Of the compounds tested, chlorpyrifos-oxon (Cpxn) had the lowest IC50 for both liver and serum in all ages, reflecting the high sensitivity of CbxE for Cpxn. IC50s were higher in serum than liver in most cases. Generally, for all of the OP compounds tested in both liver and serum, the IC50 for each age group increased with increasing age which may reflect the higher CbxE levels in adult tissue. These data indicate that the stoichiometric detoxication efficiency of CbxE is compound-specific as well as age-dependent, and it is of paramount importance to consider comparable tissue or enzyme concentrations when making comparisons of potency among compounds. (Supported by NIH R01 ES011287)

#### 1839

EFFECTS OF EARLY POSTNATAL ORAL EXPOSURE TO CHLORPYRIFOS AND METHYL PARATHION ON CHOLINE ACETYLTRANSFERASE IN REGIONS OF THE RAT BRAIN.

J. A. Dobbs, M. B. Dail, <u>R. L. Carr</u>, <u>E. C. Meek</u> and <u>J. E. Chambers</u>. *Center for Environmental Health Sciences, Mississippi State University, Mississippi State, MS*.

The effects of early postnatal exposure to the commonly used organophosphorus insecticides chlorpyrifos (CPS), a diethyl phosphorothionate, and methyl parathion (MPS), a dimethyl phosphorothionate, on choline acetyltransferase (ChAT) activ-

ity in regions of the developing rat brain were investigated. Using an incremental dosing regimen, postnatal rats were orally gavaged daily with either corn oil or chlorpyrifos at a low dose of 1 mg/kg from postnatal day (PND) 1 to 21; a medium dose of 1mg/kg from PND 1-5, 2mg/kg from PND 6-13, and 4mg/kg from PND 14-21; a high dose of 1.5mg/kg from PND 1-5, 3mg/kg from PND 6-13, and 6mg/kg from PND 14-21, or methyl parathion at a low dose of 0.2mg/kg from PND 1-21; a medium dose of 0.2mg/kg from PND 1-5, 0.4mg/kg from PND 6-13, and 0.6mg/kg from PND 14-21; a high dose of 0.3mg/kg from PND 1-5, 0.6mg/kg from PND 6-13, and 0.9mg/kg from PND 14-21. Exposures to insecticides did not produce signs of overt toxicity as indicated by no adverse effects on weight gain. Cholinesterase (ChE) activity was measured spectrophotometrically. Animals displayed a range of 10-50% brain ChE inhibition on PND 21, 10-40% at PND 30 and 10-30% at PND 40. Pups were sacrificed on postnatal days 25, 30 and 40 for the radioenzymatic microdetermination of ChAT activity in the hippocampus and medulla/pons. Pups exposed to low doses of MPS exhibited an increase in hippocampal ChAT activity in all age groups. In medulla/pons of MPS treated rats, significant increases were seen in the high dose group at PND 30, and in the low and medium dose groups at PND 40. Within the CPS treatments, the medulla/pons of the high dose animals at PND 40 was significantly higher than controls. Cerebral cortex and corpus striatum are currently under investigation following the same protocol. (Supported by NIH R01 ES 10386).

### 1840

HUMAN LIVER CARBOXYLESTERASE DURING POSTNATAL MATURATION AND ITS SENSITIVITY TO CHLORPYRIFOS OXON.

C. Pope<sup>1</sup>, S. Karanth<sup>1</sup>, J. Liu<sup>1</sup>, J. Shaikh<sup>1</sup> and B. Yan<sup>2</sup>. <sup>1</sup>Physiol Sciences, Oklahoma State University, Stillwater, OK and <sup>2</sup>Biomed Sciences, University Rhode Island, Kingston, RI.

Age-related expression of carboxylesterase activity in laboratory animals has been correlated with differential sensitivity to organophosphorus insecticides including chlorpyrifos. We compared human liver carboxylesterase activity (using p-nitrophenyl acetate as substrate) in samples from infants of 2, 3, 4, 8 and 24 months of age and adults (20 and 21 years of age). Liver S9 fractions were obtained from XenoTech (Lenexa, KS) with information on patient demographics and microsomal enzyme activities. The rank order of carboxylesterase activity in the age groups was determined (2 mo<3 mo<20 yr<24 mo<4 mo<21 yr<8 mo). Carboxylesterase activity across samples was highly correlated with microsomal cytochrome b5 (Spearman r=0.93, p=0.007) and testosterone 6β-hydroxylation (r=0.96, p=0.003) but was not correlated with other microsomal activities (total cytochrome P450, coumarin 7-hydroxylation, 7-ethoxyresorufin O-dealkylation). Proteins (3 µg) of each sample were separated and blotted using antibodies against recombinant rat hydrolase S (HS) and human carboxylesterase (HCE) types 1, 2 and 3. Relatively similar levels of HS and HCE-1 (ranges: 19.1-28.3, 17-28.2 units, respectively) were noted across age groups except for the 2 mo sample (0.8, 8.5 units). Generally lower HCE-2 levels were noted in these same samples (3.6-20.1 units), but with the lowest level (1.5 units) again noted in the 2 mo sample. Within the 3 mo-21 yr subset, no correlation between age and expression of either HS, HCE-1 or HCE-2 was noted. HCE-3 was not detected in any fractions. Aliquots were preincubated (30 min, 37°C) with a range of chlorpyrifos oxon concentrations to evaluate in vitro sensitivity. No significant differences in IC50 values were obtained in 3 mo-21 yr samples (range: 1.42-2.12 nM), while IC50 was significantly lower in the 2 mo sample (0.5 nM). While preliminary, these results suggest that liver carboxylesterase expression or sensitivity to chlorpyrifos oxon changes little during postnatal maturation after about 3 months of age.

EFFECTS OF PERINATAL EXPOSURE TO PCB 153 ON THE BRAIN NEUROTRANSMITTERS OF OFFSPRING RATS

T. Honma, M. Miyagawa, M. Suda, R. Wang, K. Kobayashi and S. Sekiguchi. Department of Health Effects Research, National Institute of Industrial Health, Kawasaki, Japan. Sponsor: M. Chiba.

Different types of toxicity of PCBs have been investigated. Some reports have suggested that exposure to PCB mixtures at perinatal period may affect the development of the central nervous system both in humans and animals, however, developmental neurotoxicity of each congener remains still unclarified. To investigate the effects of *in utero* exposure to PCB 153 (2, 2', 4, 4', 5, 5'-hexachlorobiphenyl), a representative non-planar PCB congener, on hormonal and neurobehavioral development in the offspring of rats, pregnant CD (SD) IGS rats were given PCB 153 (0, 16, 64 mg/kg/day) orally on gestation day 10 (GD 10) to day 16 (GD 16). Offspring rats were examined at different weeks of age regarding the effects of PCB 153 on (1) endocrine system (thyroid and testis), (2) brain neuroactive substances, and (3) cognitive functions (learning and memory). In this paper, we described the effects of PCB 153 on the brain contents of neuroactive monoamines of the off-

spring. PCB exposure did not produce any significant effects on body weights of dams during gestation and lactation. No dose-dependent changes in body weights, body length, and organ weights in offspring were observed. On post natal day (PND) 7, 21, and 42, serotonin (5HT) and its metabolites, 5-hydroxyindoleacetic acid content of the brain of male rats increased in a dose-dependent manner. Dopamine (DA) and its metabolites, 3, 4-dihydroxyphenylacetic acid and homovanillic acid, increased in the male brain on PND 7 and 42. These results indicate that 5HT and DA release from the nerve terminals was increased. The activity of 5HT and DA neurons in the male brain may be elevated in some limited situations following perinatal exposure to PCB 153. These results suggest that the exposure to relatively high dose of PCB 153 at the early stage of life alters the cerebral neurotransmission in the offspring rats.

PERINATAL EXPOSURE TO DELTAMETHRIN ALTERS DOPAMINERGIC NEUROCHEMISTRY IN THE DEVELOPING MOUSE BRAIN.

J. R. Richardson, W. M. Caudle, E. D. Dean, M. Z. Wang and G. W. Miller. Center for Neurodegenerative Disease, Rollins School of Public Health, Emory University, Atlanta, GA.

During the last decade there has been increasing concern that children are not adequately protected from the adverse effects of pesticides. Because of this concern, many pesticides have had their uses restricted or banned. In their place, pyrethroids have become one of the pesticides of choice because they are environmentally labile and generally exhibit low mammalian toxicity. Recently, it has been shown that deltamethrin (DM), a widely used type II pyrethroid, may exert specific effects on the nigrostriatal dopaminergic system by altering striatal dopamine uptake and dopamine transporter (DAT) levels in adult mice. In this study, we sought to determine whether perinatal exposure to low levels of DM would alter dopaminergic neurochemistry in the developing mouse brain. Female C57BL/6J mice received 0 or 3 mg/kg DM in peanut butter every 3 days for 2 weeks prior to breeding. Treatment continued on the same schedule throughout gestation and lactation until the offspring were weaned on postnatal day (PND) 21. On PND 28, mice were sacrificed and the striatum was removed and frozen on dry ice for determination of monoamine levels by HPLC and dopaminergic markers by western blotting. Perinatal exposure to DM elicited no overt toxicity to either the dams or the offspring. Striatal levels of dopamine or its metabolites, DOPAC and HVA, were not affected by treatment. However, levels of the dopamine transporter (DAT) were increased by 1.9 fold, similar to that seen in adult animals exposed to higher dosages of DM. In addition, we determined the levels of the vesicular monoamine transporter 2 (VMAT2) and tyrosine hydroxylase (TH), two additional markers of dopaminergic neurons. Striatal VMAT2 levels were increased by 1.7 fold and TH levels were increased by 1.5 fold in the offspring of DM treated animals. Taken in concert, these data suggest that the developing dopaminergic system is particularly sensitive to alterations induced by low level exposure to DM during the perinatal period. METHAMPHETAMINE-INITIATED
NEURODEVELOPMENTAL DEFICITS ARE ENHANCED
IN OXOGUANINE GLYCOSYLASE 1 (OGG1) KNOCKOUT
MICE.

A. W. Wong<sup>1</sup>, W. Jeng<sup>1</sup> and P. G. Wells<sup>1, 2</sup>. <sup>1</sup>Faculty of Pharmacy, University of Toronto, Toronto, ON, Canada and <sup>2</sup>Department of Pharmacology, University of Toronto, Toronto, ON, Canada.

Teratogenesis may involve oxidative DNA damage, in particular the lesion 8-oxoguanine (8-oxoG), which in mammals is repaired by oxoguanine glycosylase 1 (Ogg1). We have shown that in utero exposure to methamphetamine (METH) on gestational day (GD) 17 enhances DNA oxidation in CD-1 fetal mouse brain, and causes permanent postnatal motor coordination deficits [Toxicologist 72(S-1): 342 (No. 1661), 2003]. Also, ogg1 knockout mice are more susceptible to METH-enhanced 8-oxoG levels in the fetal brain [Toxicologist 72(S-1): 342 (No. 1663), 2003]. Here we used ogg1 knockout mice to investigate the developmental roles of 8-oxoG and Ogg1 in the respective initiation of and risk for METH-initiated neurodevelopmental anomalies following in utero exposure. METH (40 mg/kg) or its saline vehicle was administered on GD 17 to pregnant heterozygous (+/-) ogg1-deficient females (mated to ogg1 +/- males). Beginning at 6 weeks after birth, the offspring were tested for motor coordination using the rotarod apparatus. Female ogg1 homozygous null (-/-) offspring exposed in utero to METH had enhanced coordination deficits compared to saline-exposed controls of the same genotype at 6, 8, 10 and 12 weeks (p=0.03, p<0.001, p=0.008 and p=0.04, respectively). Longterm deficits were also observed in female -/- offspring compared to wild type (+/+)littermates at 8, 10 and 12 weeks (p<0.001, p<0.01 and p=0.005, respectively), and compared to +/- littermates at 6 and 8 weeks (p=0.02 and p=0.05, respectively).

Exposure to METH in male -/- mice resulted in enhanced coordination deficits compared to saline -/- controls at 6 and 8 weeks (p<0.05). This is the first evidence of postnatal motor coordination impairment in drug-exposed mice fetuses lacking Ogg1, indicating that 8-oxoG constitutes an embryopathic molecular lesion, and that functional DNA repair in the fetus may be important in protecting against METH-initiated neurodevelopmental deficits. (Support: Canadian Institutes of Health Research; SOT Covance Fellowship [WJ])

## 1844 INCREASED METHAMPHETAMINE-ENHANCED DNA OXIDATION IN FETAL BRAIN OF *COCKAYNE SYNDROME B (CSB)* KNOCKOUT MICE.

T. J. Preston<sup>1</sup>, <u>P. G. Wells<sup>1, 2</sup></u>, <u>W. Jeng<sup>1</sup> and <u>A. W. Wong<sup>1</sup>. <sup>1</sup> Faculty of Pharmacy, University of Toronto, Toronto, ON, Canada and <sup>2</sup>Department of Pharmacology, University of Toronto, Toronto, ON, Canada.</u></u>

Repair of 8-oxoguanine (8-oxoG), a form of oxidative DNA damage, on the nontranscribed strand of DNA is primarily catalyzed by oxoguanine glycosylase 1 (Ogg1). However, 8-oxoG in actively transcribed DNA is repaired via the transcription-coupled repair (TCR) pathway, catalyzed by the Cockayne Syndrome B (CSB) protein. We have shown that knockout mice deficient in Ogg1 have enhanced levels of DNA damage to the fetal brain following in utero exposure to the neurotoxic drug methamphetamine (METH) on gestational day (GD) 17 [Toxicologist 72(S-1): 342 (No. 1663), 2003]. Here we used CSB knockout mice to investigate the developmental role of CSB in repairing METH-initiated fetal DNA oxidation following in utero exposure. METH (40 mg/kg) or its saline vehicle was administered on GD 17 to pregnant heterozygous (+/-) CSB-deficient females (mated to *CSB+/-* males). Dams were sacrificed 4 hr later, and fetal brains were isolated and analyzed for oxidative DNA damage, determined by 8-oxoG formation. In fetal brain, no significant differences were observed in DNA oxidation among saline-exposed wild type (+/+) CSB-normal, or +/- or homozygous null (-/-) CSBdeficient fetuses. However, with METH exposure, there was a 40% increase in 8oxoG levels in -/- CSB-deficient fetuses compared to +/+ CSB-normal littermates (p<0.05). DNA oxidation also was elevated in fetal brain from METH-exposed +/fetuses compared to saline-exposed controls of the same genotype (p<0.05), and in METH-exposed -/- fetal brains compared to saline-exposed -/- controls (p=0.001). This is the first evidence of increased DNA oxidation in drug-exposed fetuses lacking CSB, and suggests that in addition to Ogg1, CSB and the TCR pathway may contribute in protecting against METH-initiated developmental neurotoxicity. ## 1845 EFFECTS OF LOW DOSE PERINATAL VINCLOZOLIN EXPOSURE ON A BATTERY OF ANDROGEN-MEDIATED BEHAVIORS.

N. W. Colbert, J. B. Concannon and <u>V. P. Markowski</u>. Environmental Toxicology Center, University of Southern Maine, Portland, ME.

Vinclozolin (Vz) is a fungicide applied to industrial landscapes, golf turf, and foods intended for human consumption. Health concerns have arisen because metabolites of Vz bind to the androgen receptor, alter the expression of androgen-responsive genes and disrupt the development of male reproductive organs. Since androgens are also responsible for sex differentiation in the CNS, Vz could permanently affect sex-specific behaviors. Pregnant Long-Evans rats were administered 0, 1.5, 3, 6, or 12mg/kg Vz p.o. from gestation day 14 to postnatal day (PND) 3. Endpoints following parturition including pups per litter, sex ratio, mortality, male nipple retention, anogenital distance, and body weight throughout the preweaning period were not affected. Although we did not observe gross maternal or neonatal toxicity, Vz affected a number of behaviors in juvenile and adult male offspring. Two sexdifferentiated functions were examined in immature males and females: social play behavior on PND22 and PND34 and the corticosterone stress response on PND34. In adult males, ex copula penile erections and copulatory behavior was also examined. During play behavior, males performed more of the target behaviors than females regardless of age. Although there were no exposure effects in PND22 offspring, the PND34 males showed evidence of dose-related demasculinization. In the stress procedure, female offspring responded to restraint with significantly higher plasma corticosterone compared to males. There was also a significant main effect of Vz exposure, although the relationship was complex and nonlinear. Adult males in each of the Vz dose groups produced significantly fewer erections than controls during ex copula tests. Low intensity erections, characterized by distension of the glans and tumescence of the base, were the most sensitive to exposure. As a consequence of Vz effects on social and erectile behaviors, exposed males showed numerous copulatory deficits during group mating and subsequently sired fewer offspring.

### AGE-DEPENDENT INCREASES IN MDMA-MEDIATED DOPAMINERGIC NEUROTOXICITY IN MICE.

M. E. Reveron<sup>1</sup>, G. V. Erives<sup>2</sup>, S. S. Lau<sup>2</sup> and T. J. Monks<sup>2</sup>. <sup>1</sup>Division of Pharmacology and Toxicol., University of Texas at Austin, Austin, TX and <sup>2</sup>Department of Pharmacology and Toxicol., University of Arizona Health Sciences Center, Tucson, AZ.

3, 4-Methylenedioxyamphetamine (MDA) and 3, 4-methylenedioxymethamphetamine (MDMA, ecstasy) are ring-substituted amphetamine derivatives with stimulant and hallucinogenic properties. The recreational use of these amphetamines, especially MDMA, is prevalent despite warnings of irreversible damage to the central nervous system. In rats and non-humans primates, MDMA elicits chronic damage to the serotonergic system, whereas in mice it causes long-term damage to the dopamine (DA) system. Although the extent of MDMA-mediated serotonergic neurotoxicity in rats is age-dependent, little is known of the factors regulating MDMA-mediated dopaminergic neurotoxicity in mice. We therefore examined the age-dependent MDMA-mediated dopaminergic toxicity in C57B1/6J mice (5 and 11 weeks old). Mice were treated with (+)-MDMA (20mg/kg, sc.) every two hours, for a total of four injections. MDMA elevates core body temperature, which appears to play an important role in MDMA-induced neurotoxicity, and increases in rectal temperature of 0.9°C and 2.1°C were observed in mice aged 5 and 11 weeks respectively. Significant reductions in striatal DA (87% decrease) concentrations, and its metabolites, homovanillic acid, and 3, 4-dihydroxyphenylacetic acid, were found in older mice, with reductions in DA of only 24% in the younger mice. Immunoblot analysis of the dopamine transporter, the vesicular monoamine transporter 2, and tyrosine hydroxylase revealed significant reductions of 70%, 19%, and 58% respectively in the older mice. Significant reductions in dopamine transporter expression (26%) also occurred in the younger mice. Interestingly, we documented a mild but significant (22%) decrease in striatal serotonin (5-HT) concentrations in the older mice. We conclude that age plays an important role in determining the magnitude of MDMA-mediated neurotoxicity in mice, and perhaps in determining the selectivity of the toxicity (DA vs 5-HT).

# 1847 THE EFFECT OF ACUTE ETHANOL EXPOSURE ON OXIDATIVE STRESS AND CASPASE-3 ACTIVE SUBUNIT EXPRESSION IN POSTNATAL DAY 4 RAT CEREBELLUM.

K. H. Horn<sup>1</sup>, L. M. Kamendulis<sup>2</sup>, C. R. Goodlett<sup>3, 1</sup> and J. E. Klaunig<sup>2, 1</sup>.

Microencephaly, a hallmark feature for the clinical diagnosis for Fetal Alcohol Spectrum Disorder results from the loss of cell populations within the CNS. Oxidative stress leading to apoptosis has been suggested as a potential mechanism underlying ethanol-induced cell death. Recent in vitro work demonstrated protection against ethanol-induced cerebellar granule cell loss following antioxidant supplementation. In addition, catalase activity was increased in the cerebellum 6- and 12-hours after ethanol exposure to postnatal day 4 (PD4) rat pups. In this study, we investigated ethanol's ability to decrease total antioxidant capability (TAC), increase reactive oxygen species (ROS), and increase capase-3 active subunit expression following ethanol exposure on PD4. Long Evans rat pups were matched for sex and rats within each pair received either milk intubations or 5.25g/kg ethanol (11.9% (v/v) solution in milk) in 2 intubations, 2 hours apart. Cerebellar tissue was collected and TAC, ROS, or caspase-3 active subunit expression was measured. Results indicated that a single ethanol exposure on PD4 had no effects on TAC. In contrast, ethanol treatment caused significant increases in cerebellar ROS levels [F(1, 24)=4.939, p<0.05] 12 hours after the initial intubation (t(10)=2.564, p<0.05). In addition, caspase-3 active subunit expression was significantly increased following ethanol exposure on PD4 [F(1, 25)=19.817, p<0.01], with post hoc analyses indicating significant increases at the 8- and 12-hour time points (p<0.05). These data, in conjunction with our previous findings that ethanol exposure increases catalase activity, suggest that oxidative stress may contribute to ethanol-induced cell loss within this model.

POLYAROMATIC HYDROCARBON MIXTURE EFFECTS ON CENTRAL NERVOUS SYSTEM DEVELOPMENT, PLASTICITY, AND BEHAVIOR.

D. B. Hood, D. D. Wormley, T. Nayyar, J. Wu, T. Tu and S. Johnson. pharmacology, meharry medical college, Nashville, TN.

Environmental contaminants within the polyaromatic hydrocarbon class have been shown to cross the placenta, and by doing so, the fetus is exposed to the contaminant body burden of the mother. Consequently, a gestational exposure to environmental contaminant polyaromatic hydrocarbons may result in increased adverse
