Hydrogeology and Analysis of Aquifer Characteristics in West-Central Pinellas County, Florida

By James C. Broska *and* Holly L. Barnette

ABSTRACT

The U.S. Geological Survey, in cooperation with Pinellas County, Florida, conducted an investigation to describe the hydrogeology and analyze the aquifer characteristics in west-central Pinellas County. A production test well and four monitor wells were constructed in Pinellas County at Walsingham Park during 1996-97. Water-quality sampling, static and dynamic borehole geophysical surveys, and hydraulic tests were conducted at the wells to delineate the hydrogeology at Walsingham Park. A 9-day aquifer test was conducted to determine the hydraulic characteristics of the aquifer system and observe the changes in water quality due to pumping.

A numerical model was constructed to simulate the aquifer test and calculate values for hydraulic conductivity and storage coefficient for permeable zones and confining units at Walsingham Park. Final calibrated values for hydraulic conductivity for the different permeable zones and confining units at the test site were 18 feet per day for Upper Zone A, 750 feet per day for Lower Zone A, 1 foot per day for Zone B, $1x10^{-4}$ feet per day for the intermediate confining unit, and 10 feet per day for the semiconfining unit separating Upper Zone A and Lower Zone A. Final calibrated values for storage coefficient were $3.1x10^{-4}$ for Upper Zone A, $8.6x10^{-5}$ for Lower Zone A, $2.6x10^{-5}$ for Zone B, $3.1x10^{-4}$ for the intermediate confining unit, and $4.3x10^{-5}$ for the semiconfining unit separating Upper Zone A and Lower Zone A. Estimates of transmissivity for Upper Zone A and Lower Zone A were about 2,500 and 37,500 feet squared per day, respectively.

INTRODUCTION

Pinellas County, located in west-central Florida, has limited potable water supplies and is dependent on water delivered from Tampa Bay Water (formerly called the West Coast Regional Water Supply Authority) which withdraws water from neighboring inland counties to meet the water demands of a large population. Although the population of Pinellas County has not increased significantly since 1990, during the period from 1970 to 1990 the population of Pinellas County increased from 552,329 to 851,659 (University of Florida, 1991). In 1990, the county received a total of 78 Mgal/d of water from Hillsborough and Pasco Counties (Marella, 1992). To alleviate some of the demand for this delivered water, Pinellas County is exploring the possibility of using the brackish-water resources within the Upper Floridan aquifer underlying the county.

Brackish waters (water with dissolved-solids concentrations between 1,000 and 10,000 mg/L) are found in the Upper Floridan aquifer at depths ranging from about 100 to 400 ft below land surface in central Pinellas County (Cherry and others, 1970). The development of these brackish-water resources through low-pressure reverse osmosis could provide a source of potable water. Low-pressure reverse osmosis is a process of forcing water through a membrane to remove dissolved solids, thus purifying the water; however, the process is economically practical only when dissolved-solids concentrations are less than 7,000 mg/L (D. Slonena, Pinellas County Utilities, written commun., 1998).

A production test well and four monitor wells were constructed in 1996-97 at Walsingham Park in west-central Pinellas County. The wells were subjected to various geologic investigation methods to determine the hydrogeology at the test site and the viability of brackish-water development in the area.

Purpose and Scope

This report presents the results of a study by the U.S. Geological Survey (USGS), in cooperation with Pinellas County, to evaluate the brackish-water resources underlying the Walsingham Park study area in west-central Pinellas County. Results from the field investigation and numerical simulation to determine aquifer characteristics at the Walsingham Park test site could provide valuable information for future development of brackish water in Pinellas County and in other coastal counties in west-central Florida. The report includes: descriptions of the hydrogeologic framework of the study site, hydraulic characteristics of the aquifer system, and description of the ground-water quality.

The objectives of this report are to 1.) describe the hydrogeology at the test site, and 2.) evaluate an aquifer test conducted in the Upper Floridan aquifer at the test site.

Description of the Study Area

Pinellas County is a peninsula in west-central Florida bounded by Tampa Bay to the east and the Gulf of Mexico to the west (fig. 1). The county is part of the Gulf Coastal Lowlands physiographic region described by White (1970) which consists of low angle scarps and terraces formed during several Pleistocene sea-level stands. The climate of Pinellas County is subtropical with an average rainfall of 53 inches per year (in/yr). Most rainfall occurs during the summer months between June and September (Causseaux and Fretwell, 1983). Land surface elevation at the Walsingham Park test site is about 55 ft above sea level.

HYDROGEOLOGIC FRAMEWORK

The geology of Florida consists of a pre-Mesozoic igneous and metamorphic basement and an overlying thick sequence of sedimentary units deposited during transgressive and regressive episodes (Heath and Smith, 1954). The hydrogeologic framework underlying the study area consists of Eocene or younger-age rocks and makes up the surficial aquifer system, the intermediate confining unit, and the Floridan aquifer system (fig. 2). This multilayered system consists of several permeable zones interbedded with zones of variable permeability that function as either confining units or semiconfining units. A semiconfin-

ing unit in this report refers to lower-permeability carbonate units that do not produce large quantities of water to wells when pumped (Knochenmus and Swenson, 1996). The hydrogeologic information compiled from wells at the test site was correlated with hydrogeologic information from previous studies in west-central Pinellas County. A generalized hydrogeologic section, oriented north-south, was constructed from natural-gamma geophysical logs (fig. 3).

Surficial Aquifer System

The surficial aquifer system (SAS) in Pinellas County is the shallowest water-bearing formation in the study area and consists of undifferentiated sands and clays which change in composition laterally and vertically (Causseaux, 1985). The post-Miocene age surface deposits in Pinellas County lie unconformably above the Hawthorn Group. Surface deposits are characterized by a base of marginal marine beds overlain by sandy, marine terrace deposits and capped by aeolian sand deposits. The thickness of the SAS, which ranges from a few feet to 50 ft, restricts the amount of potable water the aquifer supplies; however, the non-potable water is utilized for irrigation (Gilboy, 1985). The SAS at the Walsingham Park site is about 35 ft thick. Throughout Pinellas County, the water table is less than 15 ft below land surface during dry periods and close to land surface during wet periods. Precipitation is the main source of recharge.

Hydraulic properties of the SAS are highly variable due to the diversity in physical characteristics of the sediments. Grain size, sorting, and thickness vary throughout the system and greatly influence the permeability and porosity of the system. Values for specific yield range from 0.1 to 0.35 (Causseaux, 1985). Horizontal hydraulic conductivity is estimated to range from 13 to 33 ft/d (Cherry and Brown, 1974; Sinclair, 1974) and vertical hydraulic conductivity is estimated to range from 0.36 to 13 ft/d (Sinclair, 1974; Hutchinson and Stewart, 1978).

Intermediate Confining Unit

The surficial and Floridan aquifer systems are separated by the low-permeability intermediate confining unit (ICU). The ICU occurs within the upper Miocene undifferentiated Arcadia Formation of the Hawthorn Group. The formation consists of interbedded quartz sands, clays, and carbonates. The clay beds in the Arcadia Formation act as confining beds
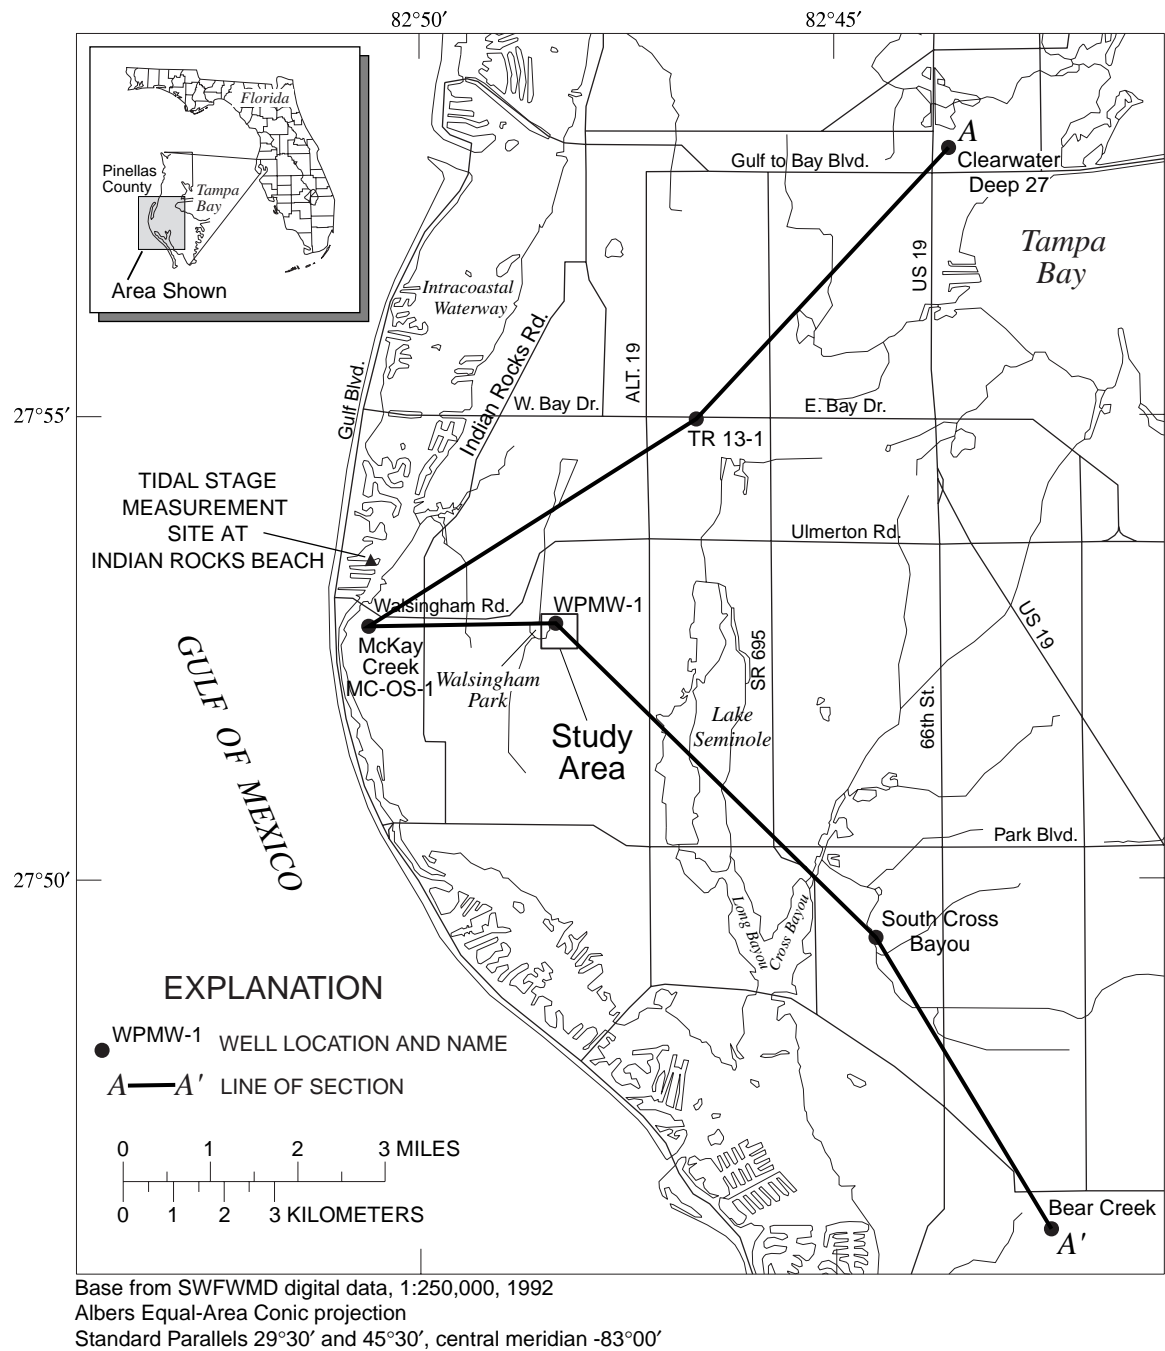

Figure 1. Location of the study area in west-central Pinellas County, well names, and hydrogeologic section *A-A'.*

throughout Pinellas County (Heath and Smith, 1954). The thickness of the ICU averages about 90 ft and ranges from 50 to 140 ft. At the Walsingham Park site, the ICU is about 100 ft thick. Due to the heterogeneous nature of the unit, a wide range of hydraulic properties has been reported. Vertical hydraulic conductivity for the ICU ranges from 1.3×10^{-4} to 6.9×10^{-3} ft/d (Sinclair, 1974; Black, Crow and Eidness, Inc., 1978). Leakance values reported in previous investigations range from 1×10^{-5} to 1.5×10^{-2} (ft/d)/ft (Black, Crow and Eidness, Inc., 1978; Seaburn and Robertson, Inc., 1983; Brown and Associates, Inc., 1986).

Floridan Aquifer System

The Floridan aquifer system consists of limestones and dolomites and includes the Upper Floridan aquifer, the middle confining unit, and the Lower Floridan aquifer. The Upper Floridan aquifer in Pinellas County is composed of the Avon Park Formation, the Ocala Limestone, the Suwannee Limestone, and the Tampa Member of the Arcadia Formation (fig. 2). The Avon Park Formation consists of marine limestones interbedded with dolostones. The limestones are predominantly well indurated packstones which are highly fossiliferous. Overlying the Avon Park Formation is the Ocala Limestone. The Ocala Limestone consists of moderately indurated grainstones and packstones. The foraminiferal limestones in the unit commonly contain benthic foraminifera, bryozoan, echinoid, and mollusk fossils. The Ocala Limestone has a gradational contact with the overlying Suwannee Limestone. The Suwannee Limestone is predominantly foraminiferal packstone to grainstone with abundant mollusk and microfaunal remains (Miller, 1986). Overlying the Suwannee Limestone is the Tampa Member of the Arcadia Formation, which is the lower Miocene unit of the Hawthorn Group (Miller, 1986). The Tampa Member lies unconformably on the Suwannee Limestone and consists of limestone with dolostone, sands, and clays present in minor amounts. Mollusks, foraminifera, and algae are the common fossil molds present in the unit. The unit varies from mudstones to packstones, but is predominately wackestones.

In Pinellas County, the Upper Floridan aquifer is subdivided into four permeable zones generally separated by semiconfining units as defined by Hickey (1982). The zones are labeled alphabetically with increasing depth from A to D. The focus of this report is the uppermost part of the Upper Floridan aquifer, specifically the Tampa Member of the Arcadia Formation of the Hawthorn Group (Zone A) and the Suwannee Limestone (Zones A and B) because these are the only zones that contain brackish water at concentrations suitable for low-pressure reverse osmosis. Further discussions will be restricted to Zones A and B.

Zone A

Zone A, the shallowest and freshest permeable zone in the Upper Floridan aquifer, is made up of the Tampa Member and the upper part of the Suwannee Limestone. In Pinellas County, the thickness of Zone A averages 180 ft and ranges from approximately 115 to 250 ft. Reported transmissivities for Zone A throughout Pinellas County range from 10,000 to 40,000 ft^2/d (Hickey, 1982; Seaburn and Robertson, Inc., 1983; Brown and Associates, Inc., 1986). Values for storativity range from 4×10^{-4} to 8×10^{-4} (Hickey, 1982). Hickey (1982) divided Zone A into Upper Zone A (UZA) and Lower Zone A (LZA), separated by a discontinuous semiconfining unit. At the Walsingham Park site, a 25-ft thick semiconfining unit consisting of an abundance of marine clay separates the 140 ft thick UZA from LZA, which is about 50 ft thick (fig. 2).

Zone B

In Pinellas County, Zone B underlies Zone A. Thickness of Zone B averages about 150 ft and ranges from about 125 to 170 ft. The upper part of Zone B functions as a semiconfining unit in some parts of Pinellas County and is considered a nonproducing zone in these areas (Hickey, 1982; Knochenmus and Swenson, 1996). Reported hydraulic properties for this sequence are 1.3×10^{-3} to 2 ft/d for vertical hydraulic conductivity, 0.1 ft/d for horizontal hydraulic conductivity, and 7×10^{-3} (ft/d)/ft for leakance (Hickey, 1982; Seaburn and Robertson, Inc., 1983; and Brown and Associates, Inc., 1986). The lower part of Zone B is more permeable and is comprised of the lower part of the Suwannee Limestone. Thickness of this section of Zone B averages about 62 ft and ranges from 50 to 75 ft. Transmissivity estimates by Hickey (1982) suggest a value of about 5,000 ft^2/d. At the study site, Zone B was encountered between 350 and 547 ft below land surface. However, no apparent changes in permeability in the upper and lower parts of Zone B could be determined during drilling.

Delineation of Hydrogeologic Units Underlying the Study Area

The delineation of hydrogeologic units and their associated hydraulic properties at the Walsingham Park test site was accomplished through the collection and interpretation of lithologic and stratigraphic data, water-quality data, borehole geophysical data, and hydraulic data. During the well construction, rock core description, discrete water-quality sampling, borehole geophysical logging, and specific capacity tests were performed. Upon completion of the well construction, a 9-day aquifer test was performed. In total, one test production well 3 and four monitor wells were installed at the test site (fig. 4).
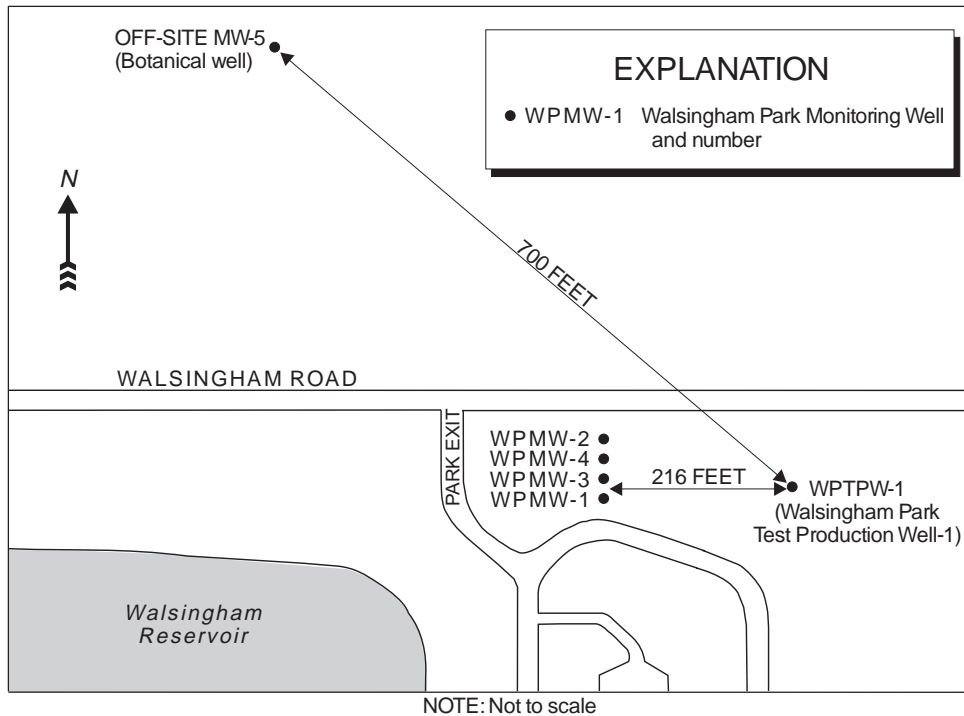

Figure 4. Walsingham Park test site, including location of wells drilled during the field investigation, and location of off-site monitor well (general location is shown in fig. 1).

A production test well and four monitor wells were drilled by using a dual-wall reverse-circulation rotary drilling method. With this drilling method, pressurized air is forced down between the inner and outer barrels of the drilling stem. Rock and/or sediment is cut by the drill bit, and core samples rise to land surface through the inner barrel. The first well drilled was originally designed to function as a deep exploratory well and was drilled to a depth of 547 ft. This well was drilled to define the geology, water quality, and vertical distribution of producing zones and confining units at the test site. Data collected from the deep exploratory well were used to determine the total depths and casing depths of the test production well and monitor wells. After drilling and data collection, the deep exploratory well was backplugged to a depth of 266 ft and converted into the Walsingham Park UZA monitor well 1 (WPMW-1). The WPMW-1 and all other monitor wells were constructed to monitor a specific producing zone or lower permeability unit to evaluate the responses of various zones to pumping. The other wells drilled as part of this study are hereafter referred to as the test production well 1 (WPTPW-1), the LZA brackish-water monitor well 2 (WPMW-2), the intermediate confining unit monitor well 3 (WPMW-3),

and the surficial aquifer system monitor well 4 (WPMW-4). Total depths and casing depths of all the wells constructed during this study are provided in figure 5.

Water-Quality Sampling

Water-quality samples were collected by the USGS and Pinellas County personnel during drilling of WPMW-1 to determine vertical distribution of water quality at the site. Water samples were collected at discrete intervals every 10 ft during drilling and tested onsite for specific conductance, temperature, and pH. When abrupt changes in field measurements occurred, water samples were collected and analyzed for major ions and physical properties at the Pinellas County Utilities laboratory. A vertical water-quality profile showing variations in dissolved solids with depth during drilling of WPMW-1 is presented in figure 6. As illustrated, the dissolved-solids concentration begins increasing approximately 350 ft below land surface. Although some water samples collected between 360 and 425 ft below land surface contained a lower concentration of dissolved solids, this anomaly may have been caused by drilling constraints as water samples were collected over a period of 3 consecutive days.

Figure 5. Generalized section view of casing depths and final depths of wells at the Walsingham Park test site.
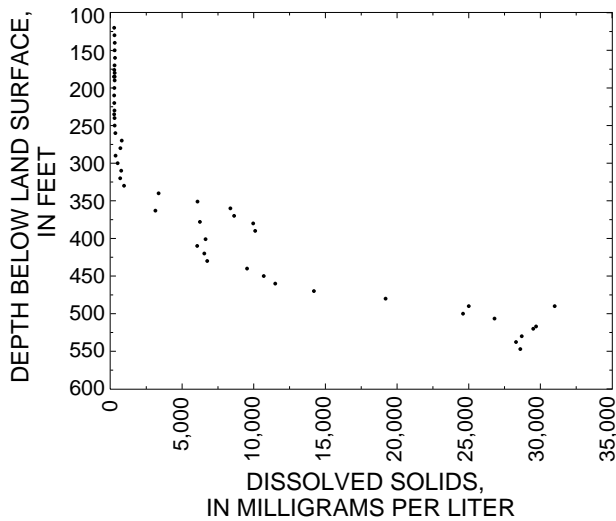

Figure 6. Relation of dissolved solids and depth from water samples collected during drilling of Walsingham Park deep exploratory well (WPMW-1).

Figure 7. Relation between dissolved solids and specific conductance of selected water samples collected during drilling of Walsingham Park deep exploratory well (WPMW-1).

The freshening of water samples between drilling days may have been the result of mixing of waters in the borehole. However, previous investigations in northern Pinellas County have shown that layering of water with higher dissolved-solids concentrations can occur over water with lower dissolved-solids concentrations (Knochenmus and Swenson, 1996). The nature of this water-quality anomaly at the Walsingham Park test site could not be determined upon completion of drilling.

Additionally, selected samples were used to show the correlation between specific conductance and dissolved-solids concentrations for ground water representative of the study site (fig. 7). The linear regression closely fits a straight line with a correlation coefficient (r) of 0.997. The correlation of the two parameters was later used to estimate changes in dissolved-solids concentration under pumping conditions; however, the relation of dissolved solids to specific conductance would not be constant for the entire range of samples (Hem, 1985). As figure 7 illustrates, the slope of the linear regression is different for specific ranges of conductance values. Changes in water quality that occurred during hydraulic testing are discussed further in the aquifer test section of this report.

Geophysical Logging

Borehole geophysical logging was used to delineate hydrogeologic units, flow zones, and water-quality changes at the test site. Geophysical logs were collected by a Pinellas County contractor under static and pumping conditions on WPMW-1. A lithologic log from WPMW-1 was also compiled during drilling.

Logs collected during static conditions included caliper, natural-gamma radiation, fluid resistivity, and fluid temperature. Logs collected under pumping conditions included ascending and descending flow meter with the pump placed 120 ft below land surface. A schematic of the geophysical logs collected from WPMW-1 is shown in figure 8.

Interpretations of the geophysical logs in conjunction with the lithologic log were used to determine the distribution of flow zones and semiconfining units. Natural-gamma radiation logs are used to delineate clay and phosphate-bearing deposits by recording the naturally occurring radiation coming from the formation adjacent to the borehole. The natural-gamma log, when correlated with the WPMW-1 lithologic log, confirmed the presence of clay and phosphate deposits from 35 to 135 ft below land surface. This sequence corresponded to the ICU at the study site. The decrease in the natural-gamma values at about 340 ft below land surface indicates a region of low phosphate content within the Suwannee Limestone.

Flow logs measured under pumping conditions are used in conjunction with caliper logs to delineate flow zones. Within a relatively uniform borehole diameter, an increase in counts per second indicates an increase in fluid velocity, thus an increase in flow. The flow meter logs collected at WPMW-1 indicate the presence of a major flow zone from around 300 to 350 ft below land surface, corresponding to LZA.

Figure 8. Geophysical logs of Walsingham Park deep exploratory well (WPMW-1).

Fluid resistivity and temperature logs are used to identify zones of water-quality change. The fluid resistivity and fluid temperature logs indicate a rapid water-quality change approximately 350 ft below land surface as fluid resistivity decreases and fluid temperature increases. The change in water quality at 350 ft below land surface was noted in the water-quality profile developed from water samples taken during drilling. However, unlike the water-quality profile, neither the fluid resistivity nor temperature logs suggest a freshening of water from 360 ft below land surface to the lowest extent of the logs at about 415 ft below land surface (fig. 8).

Specific-Capacity Tests

Specific-capacity tests were performed on WPMW-1 to evaluate the various hydrogeologic units at the study site. Water-level data, collected under a range of pumping rates, were analyzed to estimate hydraulic parameters of the system. Specific-capacity tests measure well yield per unit of drawdown for specific intervals of individual hydrogeologic units. Results were used to estimate hydraulic properties of specific intervals, locate permeable zones, and determine the well and casing depths of the monitor and production wells. In addition to specific-capacity tests, packer tests were performed upon completion of WPMW-1 (prior to backplugging) to further identify permeable zones at the site. Transmissivity and hydraulic conductivity values, estimated from specific-capacity and packer tests performed on the deep exploratory well (WPMW-1), are listed in table 1.

The values were estimated by applying specific-capacity and packer-test data to empirical equations developed from the modified Jacob nonequilibrium equation for a single-well test (Driscoll, 1986, p. 1021). Due to the difficulty in placing packers in the borehole and leakage problems detected around the packers, confidence in the packer-test data was low for determining hydraulic parameters. However, UZA from about 135 to 270 ft below land surface and LZA from about 300 to 350 ft below land surface were determined to be the primary flow zones contributing ground water to the wells. Although LZA had a higher specific capacity, it was located directly above a highly mineralized water-quality zone. Therefore, UZA was more suitable for a longer-term aquifer test.

Aquifer Test

A 9-day aquifer test was conducted at the test site from July 29 to August 7, 1997, to estimate the hydraulic parameters of Zone A and determine changes in water quality due to long-term pumping. The four onsite and one offsite monitor wells were used to observe responses in various zones to pumping from UZA at WPTPW-1. Background water-level data collected before and after pumping showed that head differences between zones at the test site reflected a downward head gradient (fig. 9). At the onset of the aquifer test, the water level in the SAS monitor (WPMW-4) was about 2.5 ft above the water level in the ICU monitor (WPMW-3), whereas the water level in the ICU monitor was more than 36 ft higher than the water level in the UZA monitor (WPMW-1). Moreover, the water level in the UZA monitor was 0.15 ft higher than the water level in the LZA monitor (WPMW-2). The test production well (WPTPW-1) was pumped at a rate of 220 gal/min for the length of the test. After the initiation of pumping, responses were noted for the various monitor wells. WPMW-1 responded immediately with a lowering of water level in the first minute of pumping. WPMW-2 also responded quickly with the first drawdown noted after 4 minutes of pumping. Contrasting the changes in water levels at these two wells, the water level in WPMW-1 decreased by 1.0 ft, whereas the water level in WPMW-2 decreased by 0.02 ft after 4 minutes of pumping. Furthermore, a "reverse water-level fluctuation" (Andreasen and

Figure 9. Water levels in all monitor wells before, during, and after the 9-day aquifer test.

Brookhart, 1963) was observed in the ICU monitor well WPMW-3. The water level in the ICU began to rise immediately after pumping began and declined when pumping ended (fig. 9). A possible explanation for this occurrence is that the release of water from compressive storage produced by pumping in UZA caused a reduction in aquifer volume of UZA, which in turn caused both horizontal and vertical deformations in the overlying ICU. These deformations of the ICU subsequently induced the measured water-level rise. This phenomenon has been documented and is often referred to as the Noordbergum Effect (Hsieh, 1996). No response due to pumping was denoted in the surficial aquifer system monitor well WPMW-4. Although water levels were monitored in the five wells for the duration of the test, drawdowns reached steady-state within the first 3 hours of pumping when tidal effects began to interfere with drawdown measurements (fig. 9).

Water-quality data were collected for the duration of the 9-day aquifer test. Specific conductance probes were placed in WPMW-1 and WPMW-2 at depths of 250 ft and 330 ft, respectively. Discharge water from WPTPW-1 was monitored hourly for specific conductance for the duration of the aquifer test. The changes in specific conductance measured during the test are shown in figure 10. Interestingly, water-quality changes noted in the UZA and the LZA monitor wells exhibited opposite trends. By using the relation between dissolved solids and specific conductance developed earlier (fig. 7), an inference can be made regarding the changes in dissolved solids concentrations during the aquifer test. The specific conductance in WPMW-1 in UZA increased from about 1,050 to 1,600 µS/cm corresponding to an increase in dissolved- solids concentration of about 372 mg/L. By contrast, the specific conductance in WPMW-2 in LZA decreased from about 11,900 to 11,200 µS/cm corresponding to a decrease in dissolved-solids concentrations of about 440 mg/L over the 9 days of the test. The specific conductance of the composite sample collected from WPTPW-1 increased from 470 to 488 µS/cm. Although this slight increase in measured specific conductance can be considered to be within the error of measurement of the conductance probe, the data showed a consistent trend (fig. 10).

The opposite trends in water-quality changes noted between the UZA and the LZA monitor wells during the 9-day aquifer test are difficult to explain.

The upward hydraulic gradient between LZA and UZA induced during the aquifer test may have resulted in upward movement of more saline water. However, the freshening of water in the LZA monitor well (WPMW-2) during the aquifer test is anomalous. As figure 10 illustrates, the rate of change of measured specific conductance appears to decrease from the time pumping began. It is possible that mineralized water may have invaded LZA during drilling of the deep exploratory well and may have evacuated LZA during the aquifer test, thus returning to native conditions. Since the aquifer test lasted only 9 days, no data are available to determine the specific conductance values at longer pumping times.

Data and the results of the aquifer test are on file and available at the USGS Tampa office. Because analytical methods are constrained by limitations in the simplification of a flow system into one- or two-dimensional flow, the 9-day aquifer test was analyzed by using numerical methods. Numerical methods can simultaneously calculate changes in head and advective transport in a variable-density flow system for multiple observation points.

ANALYSIS OF AQUIFER CHARACTERISTICS

A numerical modeling approach was used to simulate the effects of pumping the variable-density ground-water flow system at the test site. The model was constructed to simulate the 9-day aquifer test conducted at the site and to refine estimates of hydraulic parameters such as hydraulic conductivity and storage coefficient determined from specific-capacity tests and previous investigations.

Numerical Methods

The USGS computer code HST3D (Kipp, 1987) was used to solve the equation for ground-water flow and solute transport using backward-in-space and backward-in-time finite-difference approximation methods. Mass-fractional concentrations and total fluid pressures were simulated using the model. The reader is referred to the original report that documents the computer code (Kipp, 1987) for a complete discussion of the numerical methods and model code.
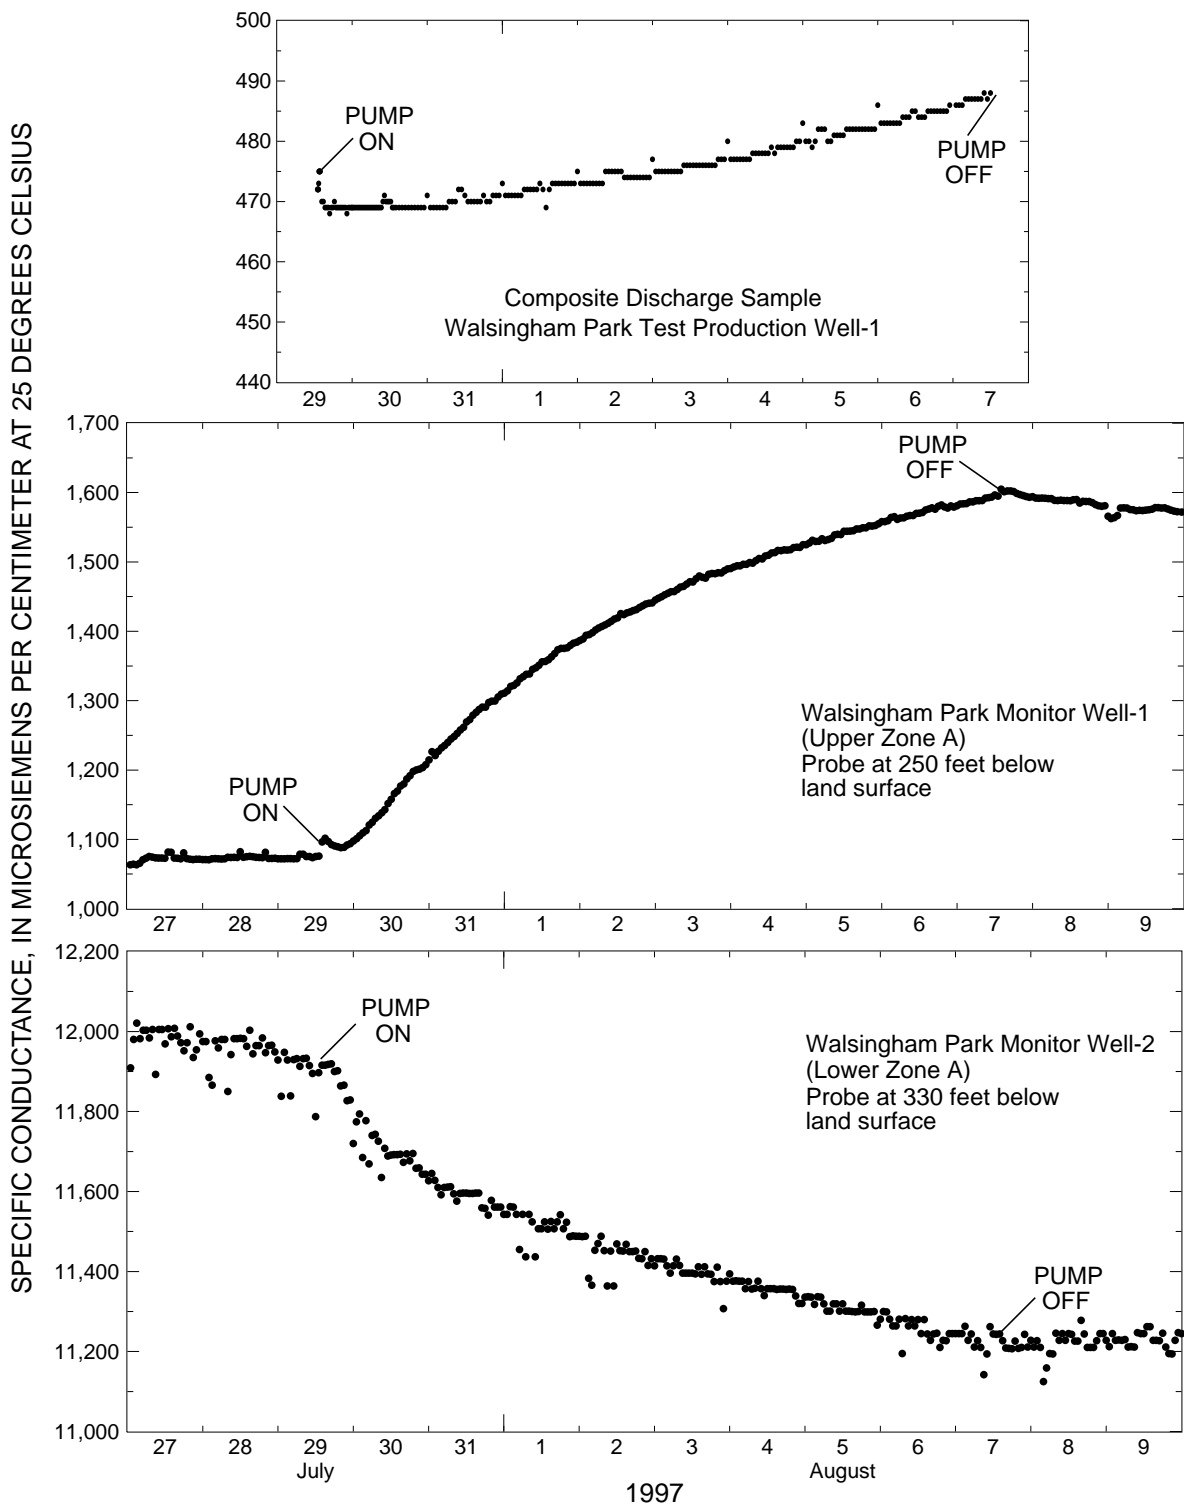

Figure 10. Changes in specific conductance during the 9-day aquifer test at Walsingham Park Test Production Well and Walsingham Park Monitor Wells 1 and 2.

Conceptual Model

The hydrogeologic system of the study area is conceptualized as a multilayered aquifer system encompassing various permeable zones separated by confining and semiconfining units extending from the surficial aquifer system downward through the Suwannee Limestone of the Upper Floridan aquifer (fig. 2). Ground-water flow is considered to be lateral in permeable zones and vertical in confining and semiconfining zones. Ground-water quality changes from fresh to saline with depth as ground water becomes increasingly dense with higher concentrations of dissolved solids. Several assumptions were made regarding the conceptualized hydrogeologic system to effectuate numerical simulation:

1. The aquifer system is assumed to act as an equivalent porous medium,
2. All aquifer layers are homogeneous and isotropic,
3. Initial conditions are hydrostatic,
4. Initial fluid density is constant in each model row, and
5. The water-quality profile is laterally homogeneous for the entire model area.

Design of Numerical Model

The numerical model subdivides the conceptualized hydrogeologic system from the ICU through Zone B at the test site into an organized network of grid blocks, each with assigned fluid and matrix properties representing a 500-ft thick section underlying the test site. The model was constructed by using a cylindrical-coordinate grid of 124 columns and 12 rows (fig. 11), and was designed to simulate the responses of UZA and LZA to brackish-water development. The columns are variable in width with radial spacing expanding logarithmically from 0.3 ft at the test production well up to a maximum width of 328 ft extending out to 11,500 ft. Radial widths extending to 12,500 and 14,500 ft were also simulated, but the additional simulation area in the horizontal direction had no affect on model results. The 12 model rows were grouped together as five distinct hydrogeologic layers. Layer 1 corresponds to model rows 1-3, is 175 ft thick, and represents Zone B of the Upper Floridan aquifer. Layer 2 corresponds to model rows 4 and 5, is 50 ft thick, and represents LZA of the Upper Floridan aquifer. Layer 3 corresponds to model row 6 and represents a discrete, 25-ft section within Zone A with an increased occurrence of green clays. This section was modeled to determine the hydraulic properties of the unit separating UZA and LZA. Layer 4 corresponds to model rows 7-9, is 150 ft thick, and represents UZA of the Upper Floridan aquifer. Layer 5 corresponds to model rows 10-12, is 100 ft thick, and represents the ICU.

Initial and Boundary Conditions

Initial conditions refer to pressure and fluid property distributions established prior to the initiation of the model simulation. Hydrostatic conditions are established in HST3D from a distribution of dissolved solids and fluid densities for each model row. Values for dissolved-solids concentrations and fluid densities, based on water-quality parameters defined from samples taken during drilling, were used to establish initial conditions (table 2). The model calculates the starting fluid pressures based on the user-specified fluid property distribution for all model rows as well as at model boundaries. Under these hydrostatic conditions, the aquifer response to pumping is determined by model simulated changes in pressure relative to the initial hydrostatic conditions (Anderson and Woessner, 1992).

Boundary conditions delimit the model domain by constraining the lateral and vertical extent of the simulated flow system at the model periphery. The inner cylindrical boundary represents the production well and was defined by allocating well information to the various rows that represent the open-hole interval of the pumped well. Model rows not open to the production well were assigned a no-flow condition, whereas the outer cylindrical boundary was defined as a specified-pressure condition (fig. 11). The assigned pressure distribution along the vertical plane of the outer boundary was calculated by using water-level and dissolved-solids concentration data obtained during drilling of the test production well. The lower model boundary was defined as a specified-pressure boundary equivalent to the pressure exerted by a column of stratified saltwater and freshwater in the overlying strata determined from the density of water samples acquired during drilling (fig. 11). The outer and lower specified-boundaries were used to simulate an infinitely extensive aquifer while eliminating the modeling of indefinite regions outside the study area. The upper model boundary was assigned a no-flow boundary coinciding with the top of the ICU. Because no drawdown occurred in either the SAS or the ICU monitor wells during the aquifer test, a no-flow boundary condition at the top of the ICU was deemed appropriate. However, row 11 (corresponding to the

Table 2. Values for model parameters used to establish initial conditions and values for calibrated model parameters

[lb/ft^3, pound per cubic foot; mg/L, milligrams per liter; ft^2, feet squared; ft/d, feet per day]

Hydrogeologic unit	Initial conditions		Calibrated model		
	Density (lb/ft^3)	Scaled-solute mass fraction / dissolved solids (mg/L)	Intrinsic permeability (ft^2) / hydraulic conductivity (ft/d)	Storage coefficient	Effective porosity (percent)
Intermediate confining unit	62.38	0.0089 / 250	3.9×10^{-15} / 0.0001	3.1×10^{-4}	35
Upper Zone A	62.38	0.0098 / 275	7.0×10^{-11} / 18	2.6×10^{-4}	30
Semiconfining unit	62.41	0.0250 / 700	3.9×10^{-11} / 10	4.3×10^{-5}	35
Lower Zone A[a] (Row 6)	62.61	0.1786 / 5,000	2.9×10^{-9} / 750	8.6×10^{-5}	30
Lower Zone A (Row 5)	62.72	0.2679 / 7,500	2.9×10^{-9} / 750	8.6×10^{-5}	30
Zone B	63.65	1.0 / 28,000	3.9×10^{-12} / 1	2.6×10^{-5}	30

[a] Input parameters varied between the two rows representing Lower Zone A.

open-hole interval of WPMW-3) was used as an indictor for the upper limit of hydraulic parameters that would simulate a no-response condition in the ICU. Although the lack of a drawdown in the ICU made it impossible to accurately estimate hydraulic properties of the unit, model parameters in rows representing the ICU were adjusted to eliminate drawdown during the simulation.

Model Parameters

Model parameters including bulk matrix properties, fluid properties, and well information were defined for the five hydrogeologic units simulated (table 2). Although some adjustments were made to the parameters during calibration, initial values were carefully selected based on data collected during this investigation and previous studies (Hickey, 1982, 1989; Knochenmus and Swenson, 1996; Yobbi, 1996). Each model parameter is discussed in detail below:

1. *Bulk matrix properties.*—Bulk matrix properties include effective porosity, hydraulic conductivity (as a function of intrinsic permeability), storage coefficient (as a function of matrix compressibility), and dispersivity. Bulk matrix properties (except dispersivity) for each hydrogeologic layer are listed in table 2. Because values of dispersivity are poorly known within the study area, a conservative approach was used by setting longitudinal and transverse dispersivity to zero.

2. *Fluid properties.*—Fluid properties include viscosity, density, compressibility, temperature, and dissolved-solids concentration. Dissolved-solids concentration is expressed as a scaled-solute mass fraction ranging from 0 to 1 in HST3D. A value of 0 represents pure freshwater whereas a value of 1 represents water with the highest dissolved-solids concentration (28,000 mg/L) in the model. Values for density and dissolved solids for each hydrogeologic layer are summarized in table 2. Fluid viscosity was held constant for the entire model at 1.0×10^{-3} centipoise. Likewise, fluid temperature and fluid compressibility were held constant with values of 77 $^{\circ}$F, and 3.03×10^{-6} in^2/lb, respectively.

3. *Well information.*—Well information needed for model input includes the withdrawal rate of the pumping well and is distributed equally over the three rows representing the pumped zone. The test production well open to UZA was simulated in model rows 7-9. The simulated pumpage was discretized with a constant withdrawal rate assigned to each of the three rows. The total pumpage assigned for all three rows for the aquifer test simulation equaled 220 gal/min. Pumpage was varied thereafter from 200 to 700 gal/min during the brackish-water development simulations.

Simulation of Aquifer Test

Numerical analysis of the 9-day aquifer test data provided a method for calculating hydraulic properties of various hydrogeologic units at the test site. The numerical model was calibrated by simulating the aquifer system's response to pumping UZA during the aquifer test. The model analysis of the 9-day aquifer test consisted of meeting two calibration objectives within acceptable limits: (1) simulate the drawdown and recovery of water levels in selected wells measured during the test, and (2) simulate the overall response of the system to pumping.

The first objective involved matching the initial drawdown part of the aquifer test. The initial 139 minutes of the aquifer test was used because nearly all drawdown effects occurred during this time and monitor well drawdowns could be separated from tidal effects. Tidal effect corrections were made by calculating the tidal efficiency for the monitor zone and adjusting drawdown and recovery data accordingly. Tidal efficiency is the ratio of the water-level amplitude measured in a well to the oceanic tidal amplitude (Ferris and others, 1962). Tidal data were collected at a gage located on the intracoastal waterway at Indian Rocks Beach, 2 mi west of the study site (fig. 1). The calculated tidal efficiency for Zone A averaged 10 percent for ebbing tides and 16 percent for flooding tides. After tidal corrections were made to the observed data, the corrected drawdowns were compared to simulated drawdowns.

Model parameters were adjusted until a reasonable match was derived where simulated drawdowns closely paralleled the observed drawdowns. A reasonable match was considered less than 0.10 ft difference between simulated and observed drawdown data. Final calibrated values for hydraulic conductivity were 18 ft/d for UZA, 750 ft/d for LZA, 1 ft/d for Zone B, 1×10^{-4} ft/d for the ICU, and 10 ft/d for the semiconfining unit separating UZA and LZA. Final calibrated values for storage coefficient were 3.1×10^{-4} for UZA, 8.6×10^{-5} for LZA, 2.6×10^{-5} for Zone B, 3.1×10^{-4} for the ICU, and 4.3×10^{-5} for the semiconfining unit separating UZA and LZA. Calibrated model parameters were further checked by comparing the observed recovery data of the aquifer test to the simulated recovery water levels (fig. 12). Values of the corrected, observed drawdown and recovery and simulated values are provided in table 3.

Table 3. Simulated and corrected observed drawdown and recovery for selected monitor wells during the 9-day aquifer test

[UZA, upper zone A; LZA, lower zone A; NA, data not available; all values are in feet]

Zone and well	Corrected observed drawdown[a]	Simulated drawdown	Corrected observed recovery[b]	Simu- lated recovery
UZA WPMW-1	2.69	2.66	2.79	2.66
LZA WPMW-2	0.29	0.30	0.36	0.31
UZA Botanical Well	NA	0.59	0.54	0.60

[a]Corrected drawdown for first 139 minutes of pumping.
[b]Corrected recovery for first 136 minutes of recovery in WPMW-1 and Botanical Well, and first 192 minutes of recovery in WPMW-2.

The second objective involved matching the long-term pattern of drawdown and recovery for the length of the 9-day aquifer test. As figure 9 shows, after the initial 139 minutes of pumping, observed drawdowns stabilized (excluding tidal effects) for the remainder of the 9-day test until the pump was turned off and recovery effects occurred. A reasonable match was accomplished when simulated drawdowns functioned in a similar fashion with drawdowns decreasing after the initial drop in water levels and stabilizing throughout the simulation until the recovery part of the test (fig. 13). It should be noted that the simulated hydrographs are superimposed over the uncorrected field hydrographs. No attempt was made to simulate the variations in water levels due to tidal effects.

Sensitivity Analysis

Sensitivity analysis was used to determine the effect of each parameter on the calibrated model results. Input parameters were individually varied over a reasonable range of values to determine the sensitivity of the model to that particular parameter over the entire simulation period. Ranges were based on values from previous investigations discussed in the hydrogeologic framework section of this report. Changes in certain parameters had no effect on the model, whereas others noticeably affected the model results. For example, a one order of magnitude increase and decrease in the value of matrix compressibility in model rows representing both UZA and LZA had no effect on the model results. Furthermore, a one order of magnitude increase and decrease in the intrinsic permeability of model rows representing the ICU had
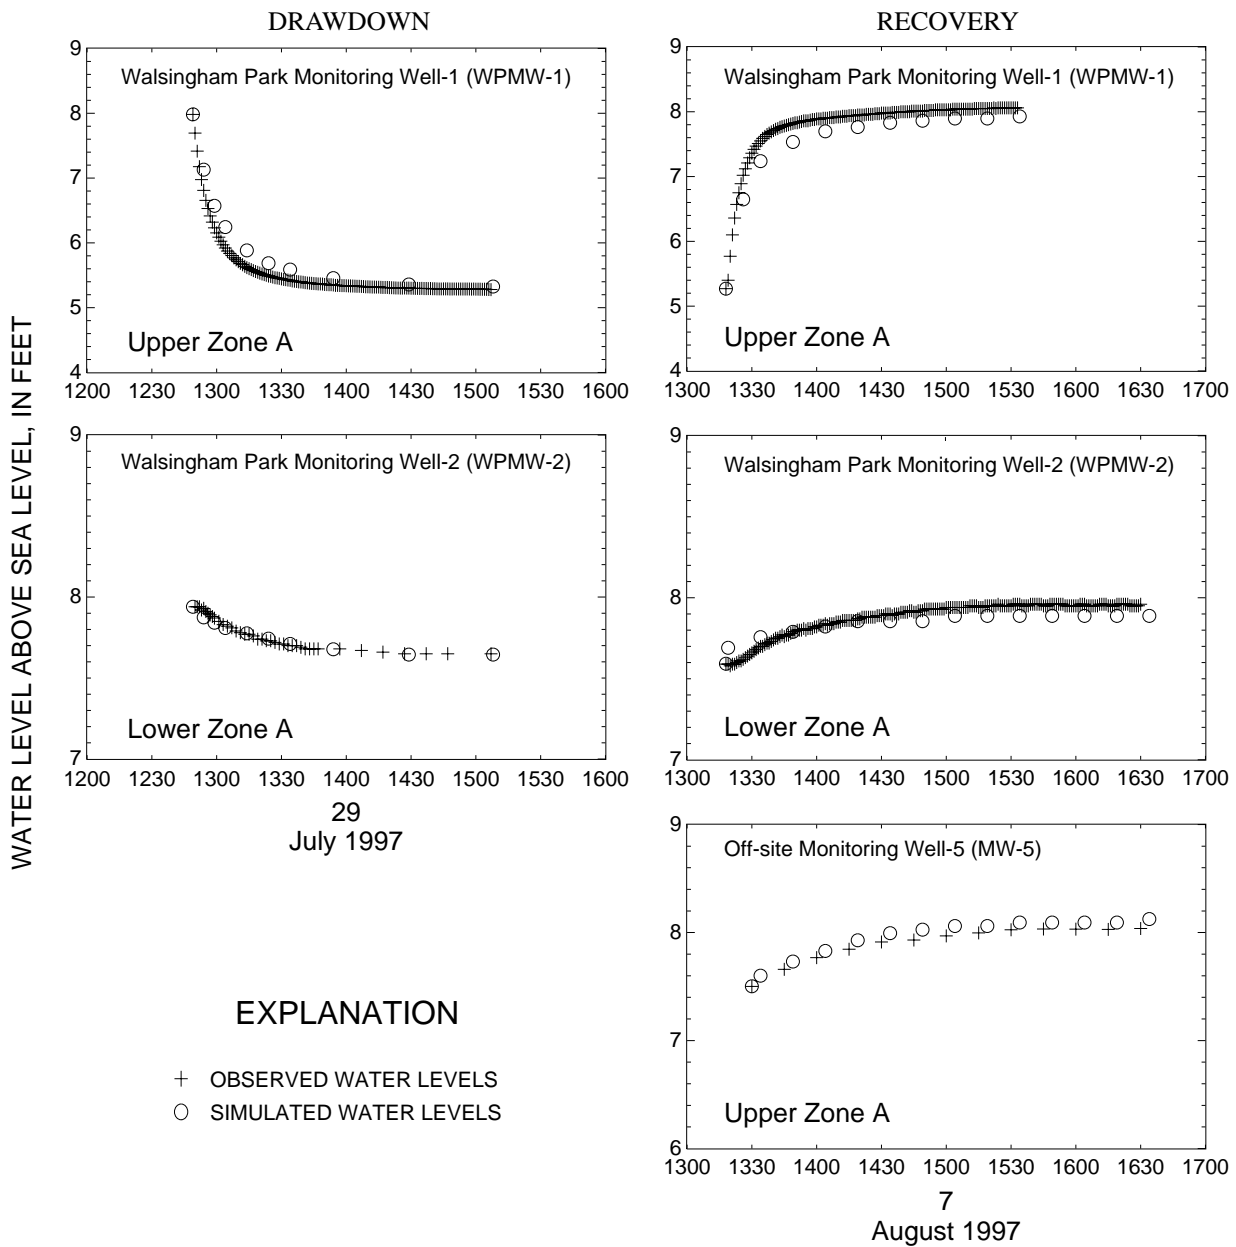

Figure 12. Simulated and observed water levels during drawdown and recovery periods at selected wells during the 9-day aquifer test.

no effect on the model results. Conversely, the largest changes to the model results occurred from changes in intrinsic permeability values assigned to both UZA and LZA (figs. 14a thru 14d). Model rows representing UZA were increased and decreased by one order of magnitude, whereas model rows representing LZA were changed by a factor of 2 and 0.5. Additionally, the value of matrix compressibility assigned to model rows representing the ICU were increased and decreased by one order of magnitude (figs. 14e and 14f). An increase in the matrix compressibility of the ICU resulted in a slight response in only UZA. Furthermore, this response occurs in the early part of the drawdown graph, but the overall magnitude of drawdown in UZA did not change. The model was generally sensitive to changes of intrinsic permeability and insensitive to changes of matrix compressibility; therefore, more confidence was placed on estimates of transmissivity than on estimates of storativity.

Model Limitations

Results from model simulations outlined in this report are approximations of the actual hydrogeologic system. Confidence in model results is dependent on the assumptions outlined earlier in this report and the extent that the hydrogeologic system is simplified for mathematical representation. Simplification of the conceptual model is necessary to simulate a very complex natural system; however, the extent to which the system is simplified represents a source of error in model results. The major limiting factor in the model simulations is that the hydrogeologic system was simulated as a five-layered system with isotropic, homogeneous, and porous-medium individual layers. The actual hydrogeologic system may, however, be anisotropic, heterogeneous, and possess properties of secondary porosity due to dissolution and fracturing. Although alternate combinations of model parameters may provide similar results to those outlined in this report, the model incorporated the best estimates of the unknown parameters, the local geology, and hydrologic conditions.

SUMMARY

This report presents the results of a study to evaluate the brackish-water resources in the Upper Floridan aquifer underlying west-central Pinellas County, Florida. A production test well and four monitor wells were constructed at a location in Walsingham Park in 1996-97. The wells were sampled for water-quality parameters and investigated using borehole geophysical methods and hydraulic testing. The data collected were analyzed by using numerical techniques to delineate the hydrogeologic framework at the test site.

Collected data indicate that a multilayered aquifer system consisting of two permeable zones underlies Walsingham Park. One zone extends from about 135 to 275 ft below land surface and corresponds to UZA of the Upper Floridan aquifer. Another permeable zone extends from about 300 to 350 ft below land surface and corresponds to LZA of the Upper Floridan aquifer. Analysis of water-quality data indicates that LZA may not provide water of consistent quality because of rapidly increasing dissolved-solids concentrations occurring around 350 ft below land surface. UZA was deemed more appropriate for production pumping and was tested during a 9-day aquifer test.

A numerical model was developed to simulate the 9-day aquifer test performed at the Walsingham Park test site. The model was calibrated to the drawdown and recovery water levels of selected monitor wells at the test site. Final calibrated values for hydraulic conductivity were 18 ft/d for UZA, 750 ft/d for LZA, 1 ft/d for Zone B, 1×10^{-4} ft/d for the ICU, and 10 ft/d for the semiconfining unit separating UZA and LZA. Final calibrated values for storage coefficient were 3.1×10^{-4} for UZA, 8.6×10^{-5} for LZA, 2.6×10^{-5} for Zone B, 3.1×10^{-4} for the ICU, and 4.3×10^{-5} for the semiconfining unit separating UZA and LZA.
