Abstract

The objective biomization method developed by Prentice *et al.* (1996) for Europe was extended using modern pollen samples from Beringia and then applied to fossil pollen data to reconstruct palaeovegetation patterns at 6000 and 18,000 ^{14}C yr BP.

The predicted modern distribution of tundra, taiga and cool conifer forests in Alaska and north-western Canada generally corresponds well to actual vegetation patterns, although sites in regions characterized today by a mosaic of forest and tundra vegetation tend to be preferentially assigned to tundra. Siberian larch forests are delimited less well, probably due to the extreme under-representation of *Larix* in pollen spectra.

The biome distribution across Beringia at 6000 ^{14}C yr BP was broadly similar to today, with little change in the northern forest limit, except for a possible northward advance in the Mackenzie delta region. The western forest limit in Alaska was probably east of its modern position.

At 18,000 ^{14}C yr BP the whole of Beringia was covered by tundra. However, the importance of the various plant functional types varied from site to site, supporting the idea that the vegetation cover was a mosaic of different tundra types.

INTRODUCTION

The northern high latitudes play a crucial role in the climate system. High-latitude climates are especially sensitive to major changes in boundary conditions, such as solar radiation and concentrations of greenhouse gases (Bartlein *et al.*, 1992; Watson *et al.*, 1998). This sensitivity is viewed primarily as the result of strong albedo feedback associated with changes in snow and sea-ice cover (Kutzbach & Gallimore, 1988; TEMPO, 1996; Washington & Meehl, 1996). Another potentially powerful climatic feedback is related to changes in the composition and distribution of high-latitude vegetation, particularly the location of the forest–tundra boundary, which acts in synergy with the sea-ice feedback to amplify climatic warming or cooling (Foley *et al.*, 1994; Melillo *et al.*, 1996; TEMPO, 1996; Texier *et al.*, 1997). Records of past large-scale vegetation changes in the Arctic and sub-Arctic are therefore important for testing the performance of: (1) atmospheric general circulation models (AGCMs) in a key region and (2) coupled models that attempt to include physical interactions among the atmosphere, oceans and vegetation (Foley *et al.*, 1998; Kubatzki *et al.*, 1998).

High-quality late-Quaternary palaeovegetation records are relatively scarce in many parts of the far north due to a complex glacial history, the discontinuous nature of non-lacustrine deposits, low lacustrine sedimentation rates, low pollen productivity, and the logistical challenges of working in remote areas (Lamb & Edwards, 1988). However, Beringia (north-western Canada, Alaska and north-eastern Russia) is relatively well studied; for decades there has been broad interdisciplinary interest in the biologically critical 'Bering Land Bridge' that linked Asia and North America (Hopkins, 1967; Hopkins *et al.*, 1982; West, 1997). Furthermore, Beringia was largely unglaciated during the Quaternary and has several continuous records extending to and beyond the last glacial maximum. Thus, palaeoecological records from Beringia can make an important contribution to understanding the dynamics of climate in the Arctic.

The link between vegetation and climate at large spatial scales has encouraged the development of global vegetation models (e.g. Prentice *et al.*, 1992; VEMAP Members, 1995; Haxeltine & Prentice, 1996; Neilson *et al.*, 1998) which can be used to translate the output of AGCMs into maps of present (potential), future, or past vegetation (e.g. Prentice *et al.*, 1992; Harrison *et al.*, 1995; VEMAP Members, 1995; Harrison *et al.*, 1998; Kutzbach *et al.*, 1998; Neilson *et al.*, 1998). The simulated vegetation distribution can be compared with modern vegetation maps (e.g. Prentice *et al.*, 1992) or, in the case of past vegetation, reconstructions based on pollen and plant-macrofossil data (e.g. Harrison *et al.*, 1998; Jolly *et al.*, 1998). For this to be done effectively requires that palaeovegetation data are organized in a way that is compatible with model output. The aim of the BIOME 6000 project (Prentice & Webb, 1998) is to translate fossil pollen assemblages into a form that allows such direct data-model comparison. In the method devised by Prentice *et al.* (1996) pollen taxa are assigned to one or more plant functional types (PFTs), which may then be combined to define biomes according to an explicit algorithm; the resultant biome assignments can be compared with biomes simulated by the vegetation model. The biomization method has been tested and applied in a number of different regions (e.g. Prentice *et al.*, 1996; Jolly *et al.*, 1998; Prentice *et al.*, 1998; Tarasov *et al.*, 1998; Yu *et al.*, 1998; other articles in this issue), and it appears to provide robust results across a wide range of climates and vegetation types.

In this paper we apply the biomization method (Prentice *et al.*, 1996) to reconstruct the biomes across Beringia for 0, 6000, and 18,000 ^{14}C yr BP, and discuss the implications of the results for our understanding of vegetation and climate changes in this region.

STUDY REGION

Beringia (here defined as the area between 130°W and 125°E, and from 53° to 75°N), extends westward from the lower Mackenzie Valley in Canada to the Verkhoyansk Range of eastern Siberia, and from the New Siberian Islands of the Russian Arctic to the Pacific Rim. The topography of eastern Beringia (Alaska and north-western Canada) is dominated by the generally east–west trending Brooks Range in the north and the Alaska, Wrangell-St. Elias, and Coast Ranges in the south. Interior Alaska is a region of large tectonic basins and extensive uplands, with the Yukon-Kuskokwim lowland lying to the south-west. Far northern Alaska is characterized by the Arctic coastal plain. Uplands dominate most of north-western Canada, with the exception of the lower Mackenzie region and the Toktoyuktok Peninsula. Western Beringia (north-east Siberia) is topographically complex. The upper Indigirka and Kolyma drainages, and Kamchatka, are mountainous; the Chukchi and Koryak Uplands dominate the eastern part of the region. However, extensive lowlands occupy the northern coastal plain (Yana-Indigirka-Kolyma lowland) and south-eastern Chukotka (Anadyr Penzhina lowland). Although areas of eastern Beringia bordered the continental and cordilleran ice sheets, much of Beringia remained ice-free during the last glacial maximum (Hamilton & Thorson, 1983; Porter *et al.*, 1983; Ananyeyev *et al.*, 1993). The most extensive glaciation was of the southern mountains and adjacent lowland of south-central

Alaska. Glaciers were restricted to valleys in the mountainous areas of western Beringia and the Brooks Range of northern Alaska.

Modern regional climate

Beringia is not as geographically coherent as its recent common history might imply. Climate (and vegetation) vary considerably across the region today—and presumably have done so in the past. Winter climate is influenced by variations of the East-Asian mid-tropospheric trough-ridge system. A strong upper-level trough is centred south of Beringia off eastern China and traverses through central Canada (Harman, 1991). North of the trough, in western Beringia, the Siberian surface high pressure system is prominent due to intensive radiational cooling (Lydolph, 1977) and creates a cold, north-westerly flow into north-east Asia, thus greatly restricting maritime influence (Mock *et al.*, 1998). January temperatures range from below −40 °C in the interior valleys to around −17 °C along the eastern Siberian coast (WMO, 1979, 1981). Another cold-core high occurs over north-western Canada. January temperatures are *c.* −30 °C in north-eastern Alaska and *c.* −15 °C along the south-west Alaskan coast.

High solar radiation explains much of the summer peak in the annual temperature cycle, although subtropical high pressure systems that dominate the mid-latitudes advect warm air from the south into both eastern and western Beringia during the summer (Mock *et al.*, 1998). Over western Beringia, average July temperatures are somewhat warmer along the eastern coast (*c.* 12 °C) compared with inland and farther north (*c.* 5–10 °C), because the East Asian trough is often centred over eastern Siberia bringing relatively cold air from the north (Moritz, 1979; Mock *et al.*, 1998). Average July temperatures for eastern Beringia generally exhibit a north-south gradient of increasing temperature (5–15 °C; WMO, 1979, 1981), but some west-east gradients exist due to the influence of the Bering Sea. The highest temperatures occur in the eastern interior of Alaska.

Precipitation across Beringia is low during winter; many locations receive < 25 mm on average during January (WMO, 1979, 1981). Higher precipitation in south-eastern Russia results from occasional winter storms that move up the coastline from China (Terada & Hanzawa, 1984). The Aleutian low causes high precipitation in southern coastal Alaska, as moist air masses are uplifted over coastal mountain ranges (Hare & Hay, 1974; Mock, 1996). Over most of Beringia, precipitation exhibits a mid-to-late summer maximum as the East Asian trough steers mid-latitude cyclones through the region. Lydolph (1977) suggested that the onshore flow of moisture into south-eastern Russia resembles a variation of the Asian summer monsoon, although its effects are mostly limited to south of the Okhotsk Sea. Mid-latitude cyclones that originate in the lee of Mongolian mountain ranges occasionally transport monsoonal moisture farther north into Siberia (Chen *et al.*, 1991). Average July precipitation exhibits a general north-south gradient in western Beringia, with values varying from 50 to 100 mm, and in eastern Beringia is generally *c.* 80 mm.

Modern vegetation patterns

The modern Beringian vegetation grades from tundra in the far north and areas bordering the Chukchi and Beaufort Seas, to forest in the continental interiors and the southern coastal regions (Fig. 1b). In eastern Beringia, northern coastal lowlands are characterized by graminoid tundra (*Carex* and *Eriophorum* spp.). Inland, on interfluves and at intermediate elevations, dwarf-birch/heath/willow tundras (*Betula glandulosa*, *B. nana* (*sensu lato*), *Vaccinium* spp., *Ledum* spp., *Salix* spp.) occur, with alder (*Alnus crispa*) locally abundant. The tundra of coastal western Alaska is characterized by grass-herb communities with *Salix*. Alpine tundra of variable composition occurs above 600–800 m. The interior boreal forest of Alaska-Yukon is dominated by spruce (*Picea glauca*, *P. mariana*) and successional hardwoods (*Populus* and *Betula* spp.). The northern forest limit closely follows the southern flanks of the Brooks Range in Alaska and lies just south of the coast in north-western Canada; the forest-tundra margin is relatively abrupt compared with that further east in Canada, but local tree distribution tends to be dependent on substrate and topography. A topographically controlled mosaic of forest and tundra also occurs in the Alaska Range. Westward, spruce becomes progressively more confined to river valleys and occurs predominantly as gallery forest at its western limits. Cool conifer forests, dominated by Sitka spruce (*Picea sitchensis*) and hemlock (*Tsuga heterophylla*, *T. mertensiana*), occur along the coast of south-central and south-eastern Alaska from the Kenai Peninsula eastwards. In the mountainous south-east of the region, subalpine fir (*Abies lasiocarpa*) and lodgepole pine (*Pinus contorta*) are important forest constituents.

Extensive shrub and herb tundra occurs in the northern and eastern parts of western Beringia. On Wrangel Island and the New Siberian Islands, graminoids, mosses and forbs predominate at lower elevations, and fell field occupies mid-elevations and exposed slopes (Yurtsev, 1974; Aleksandrova, 1977). Northern and eastern coastal areas of the mainland are dominated by a graminoid-*Artemisia* tundra with prostrate *Salix* and occasional *Betula exilis*. Lowlands along the Okhotsk Sea coast support wet graminoid-*Salix*-Ericales tundra. A mosaic of tundra types characterize the Chukchi uplands, the Chukchi Peninsula and the Anadyr-Penzhina lowland. *Betula exilis*, *B. middendorfii*, *Alnus fruticosa*, *Salix* spp. and various ericads occur widely, except at high elevations (Kozhevnikov, 1989). *Pinus pumila* is an abundant shrub in southern areas of Chukotka at low- to mid-elevations. An open *Larix dahurica* forest dominates low- to mid-elevation sites over most of the Kolyma and Indigirka drainage basins. The understory contains *P. pumila*, *B. exilis*, *B. middendorfii*, *Salix* spp., ericads and fruticose lichens. *Chosenia arbutifolia* and *Populus suaveolens* grow along floodplains. In the forest, *A. fruticosa* is restricted to stream valleys and mid-elevations with poorly developed soils (Khokhryakov, 1985). *Picea obovata* is restricted to a small disjunct population near Magadan. Areas of steppe are found in the upper Indigirka and upper Yana basins. Small areas of steppe also occur in the Kolyma basin and Chukotka, mostly restricted to warm,

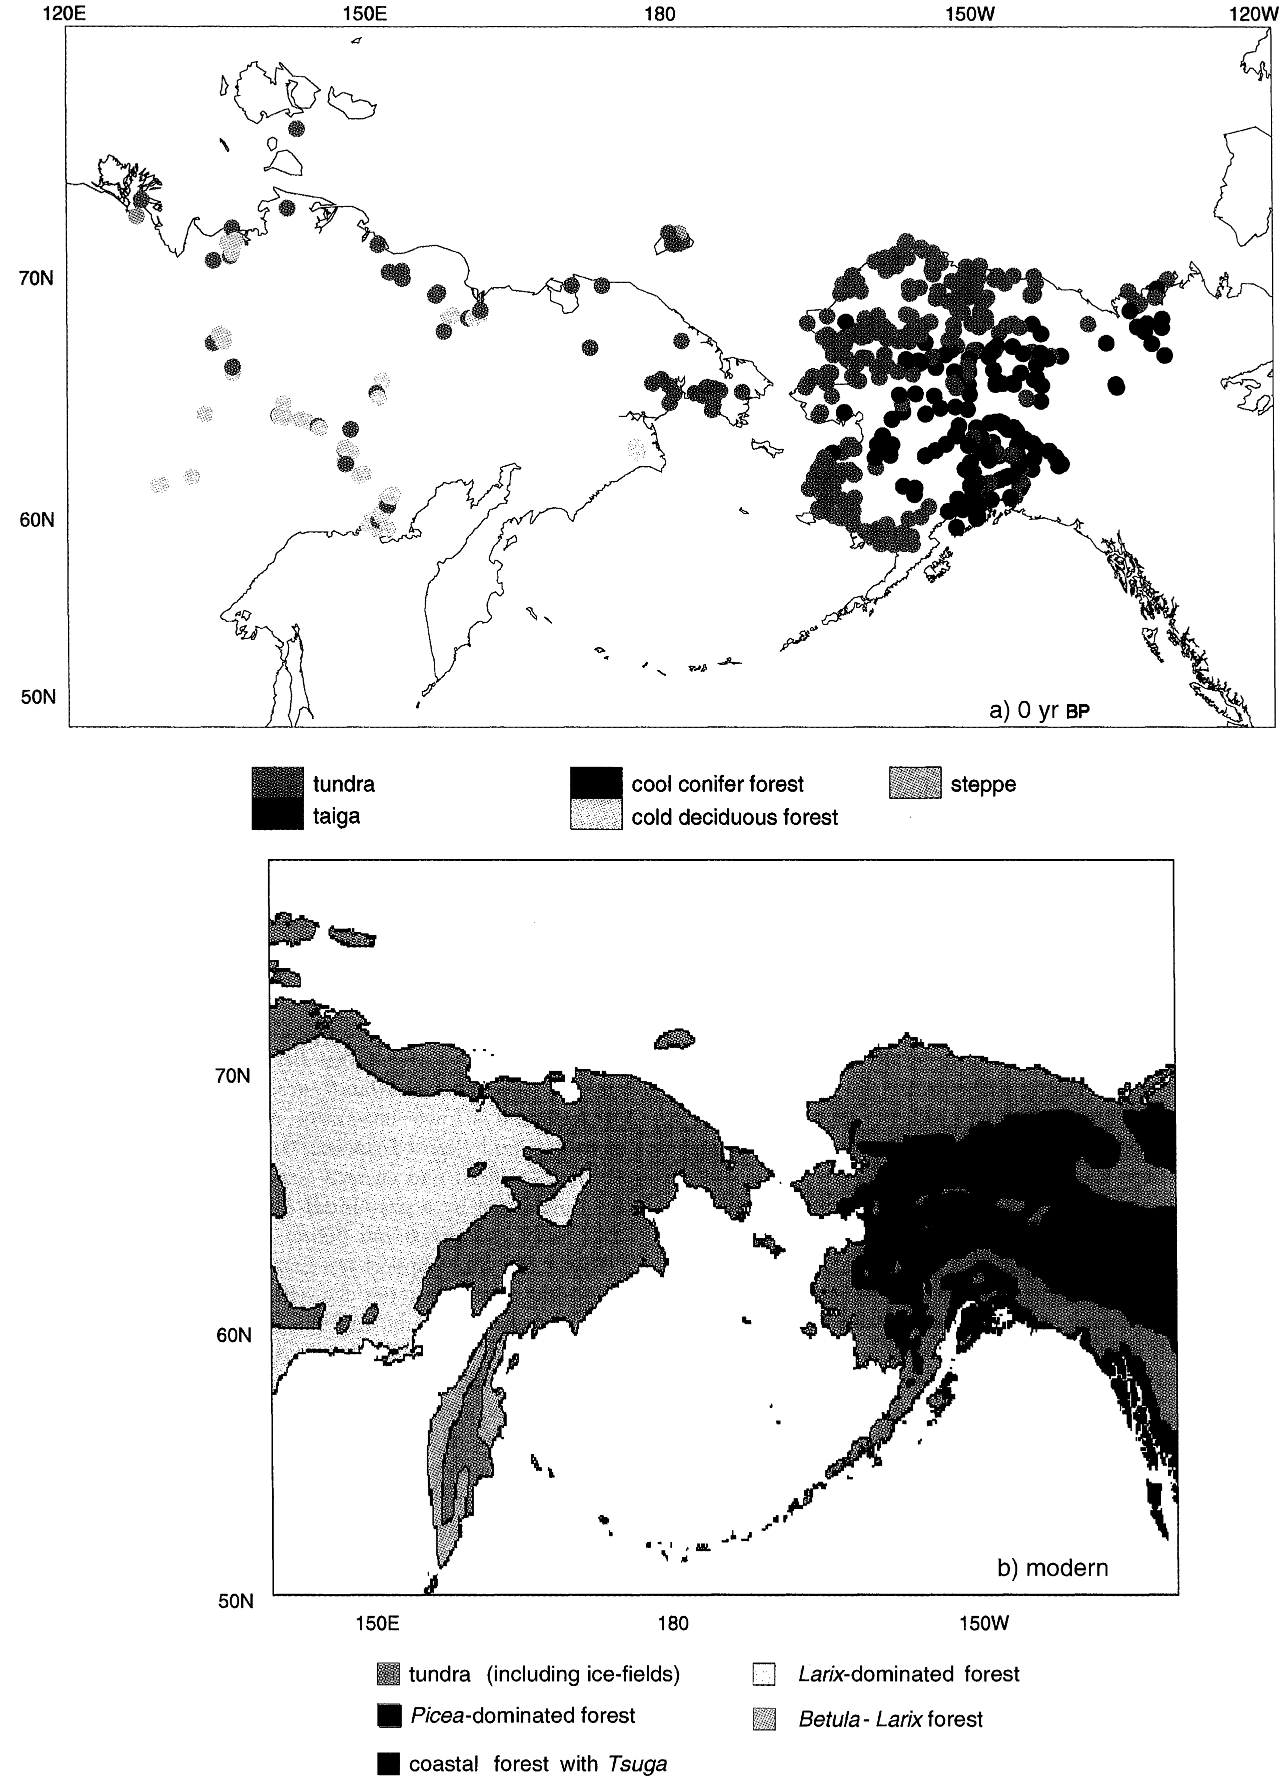

Figure 1 Modern biomes (a) reconstructed from surface pollen data, compared with (b) modern vegetation as reconstructed from data in Viereck *et al.* (1992), Ritchie (1984b), Anonymous (1990) and field descriptions by the investigators. In cases where multiple samples from a site yielded different biome reconstructions, all the alternatives are plotted; otherwise, each site is represented by a single reconstruction.

south-facing slopes (Yurtsev, 1982). Forests dominated by *Betula ermani* and *Larix kurilensis* cover much of Kamchatka at low- and mid-elevations. The vegetation of the northern part of Sakhalin Island is predominantly mixed forest of *Picea jezoensis* and *Abies sachalinensi*. On the mainland coast to the east, the upland forest of the lower Amur region is a mix of *Abies nephrolepsis*, *Picea ajanensis* and broadleaved trees.

Palaeoecological records

Palaeoenvironmental records from Beringia cover the last glacial maximum, the subsequent deglaciation, and the Holocene. In eastern Beringia there is a relatively good coverage of modern and fossil pollen sites (see reviews in Ager, 1983; Ritchie, 1984a, 1987; Ager & Brubaker, 1985; Barnosky *et al.*, 1987; Lamb & Edwards, 1988; Anderson & Brubaker, 1993, 1994; Edwards & Barker, 1994). Western Beringa is less extensively covered, but recent work (e.g. Lozhkin *et al.*, 1993; Anderson & Lozhkin, 1995; Lozhkin & Anderson, 1995) has added considerably to the vegetation records of this region.

DATA AND METHODS

Modern pollen and vegetation data

We assembled the raw pollen counts from 445 modern pollen samples from 411 sites in eastern Beringia (Table 1). Most samples (90%) were derived from surficial lake sediments or lacustrine sediment core tops; the rest were from peat, moss polsters or alluvium. For western Beringia (Table 2) we obtained a total of 238 samples from 92 different localities; 55 samples are from unpublished original pollen counts, the others are digitized from percentage data published in the literature. Most of the western Beringian samples were from moss polsters, peat, alluvium or soil; the others (17%) were surficial lake sediments. In Russia, the nature of the pollen sum varies among authors (e.g. arboreal sum, non-arboreal sum, sum of pollen and spores). We only used data from those publications in which the nature of the pollen sum was described, so it was possible to back-calculate pollen counts using an arbitrary sum.

A map of modern vegetation (Fig. 1b) was made using the maps and descriptions in Viereck *et al.* (1992), Ritchie (1984b), Anonymous (1990) and from the personal knowledge of the investigators.

Pollen data for 6000 and 18,000 ^{14}C yr BP

The fossil pollen data were derived from both published and unpublished sources. Most of the data were obtained as raw counts via the North American Pollen Database (NAPD) and the PALE Pollen Database (PPD). Some published pollen diagrams were digitized and are represented by percentage data only. Most of the records come from lake-sediment sections, the rest from peat sections or other deposits. For 6000 ^{14}C yr BP we used 92 pollen spectra from 79 sites in eastern Beringia (Table 3) and 24 spectra from 22 sites in western Beringia (Table 4). Data for 18,000 ^{14}C yr BP were available for 11 dated Beringian sites, 3 of which are from western Beringia (see Tables 3 and 4).

For each site, we used the pollen spectrum nearest to 6000 or 18,000 ^{14}C yr BP, within a $\pm$500-year window. In one western Beringian site (Elikchan: Lozhkin & Anderson, 1995), a sample just outside the 6000 $\pm$ 500 yr BP time window was selected because the site was considered too important geographically to omit. All sites are radiocarbon-dated, and virtually all the samples were defined by interpolation from an age model (in a few cases the sample was derived by a short extrapolation). In cases when multiple age models would have resulted in the selection of different samples, we biomised all the samples. This exercise showed that the choice of different age models had no effect on the reconstructed biome, except in a very few cases. In cases where the choice of age model resulted in the reconstruction of different biomes, all of the alternative reconstructions are plotted on the final maps.

Biomization procedure

The biomization procedure has been described in detail by Prentice *et al.* (1996). Pollen taxa are assigned to one or more plant functional types (PFTs), according to the structural and functional features of the constituent species, e.g. stature, phenology, leaf type, and bioclimatic tolerances. Each biome is defined by a set of characteristic PFTs that is based on both bioclimatic considerations and observed ranges of the PFTs. Combining the taxa to PFT, and the PFT to biome, allocations allows a biome-taxon matrix to be constructed. Using a fuzzy logic approach, each individual pollen spectrum is assumed to have a degree of affinity with each biome, which can be expressed numerically. The biome with the highest affinity score is then selected as the one corresponding to the pollen spectrum. In cases where the highest affinity score for two or more biomes is equal, a tie-breaking rule is applied to determine which biome is attributed to the sample, following Prentice *et al.* (1996).

Following Tarasov *et al.* (1998), we included all terrestrial pollen taxa, except those that are obvious exotics to the region and a few minor taxa with obscure biologies. The motivation for doing this is that treeless biomes such as tundra may be better identified palynologically if a suite of minor taxa are included; otherwise relatively high levels of pollen of forest taxa may distort the tundra signal and resultant assignments in the biomization procedure. Spores of the lower vascular plants and mosses were excluded because their abundances can fluctuate dramatically as a result of changing sediment influx due to changes in subaerial erosion even when their representation in the catchment vegetation is unchanged. Aquatic taxa were also excluded as they do not reflect terrestrial vegetation. The cold deciduous forest of north-east Siberia is dominated by *Larix*, which is very poorly represented in both modern and fossil pollen assemblages; *Larix* may not be represented in a modern pollen sample even when locally present. We applied a weighting ($\times$20) to occurrences of *Larix* in individual pollen spectra, in order to maximize the chance of reconstructing cold deciduous forest when it

Table 1 Characteristics of the surface pollen sample sites from Alaska and north-western Canada. Longitude is expressed by the standard convention, with + for °E and – for °W. For mapping purposes, some sites (indicated by ‡) which are very close to one another have been displaced slightly.

Table 2 Characteristics of the surface pollen samples sites from Siberia. Longitude is expressed by the standard convention, with + for °E and – for °W. For mapping purposes, some sites (indicated by ‡) which are very close to one another have been displaced slightly.

Table 3 Characteristics of the 6000 and 18,000 ^{14}C yr BP pollen sites from Alaska and north-western Canada. Longitude is expressed by the standard convention, with + for °E and – for °W. Dating control (DC) codes are based on the COHMAP dating control scheme (Webb, 1985; Yu & Harrison, 1995). For sites with continuous sedimentation (indicated by a C after the numeric code), the dating control is based on bracketing dates where 1 indicates that both dates are within 2000 years of the selected interval, 2 indicates one date within 2000 years and the other within 4000 years, 3 indicates both within 4000 years, 4 indicates one date within 4000 years and the other within 6000 years, 5 indicates both dates within 6000 years, 6 indicates one date within 6000 years and the other within 8000 years, and 7 indicates bracketing dates more than 8000 years from the selected interval. For sites with discontinuous sedimentation (indicated by D after the numeric code), 1 indicates a date within 250 years of the selected interval, 2 a date within 500 years, 3 a date within 750 years, 4 a date within 1000 years, 5 a date within 1500 years, 6 a date within 2000 years, and 7 a date more than 2000 years from the selected interval. For mapping purposes, some sites (indicated by ‡) which are very close to one another have been displaced slightly.

was probably present. The value of × 20 was selected after consideration of several biomizations of both the modern surface samples and the fossil pollen samples using different weighting factors (× 1, × 10, × 20).

We initially adopted the pollen-to-PFT assignment defined for Europe by Prentice *et al.* (1996) and subsequently modified for Mongolia and the Former Soviet Union west of ≈ 130°E by Tarasov *et al.* (1998). We defined six new PFTs: arctic/alpine forb (af: e.g. *Circea alpina*), arctic heath (ah: e.g. *Cassiope*), boreal forb (bf: e.g. *Linnaea*), boreal summergreen conifer (bsc: e.g. *Larix*), dry tundra forb (dtf: e.g. *Androsace*) and xeric forb (xf: e.g. Chenopodiaceae, Polygonaceae). The boreal forbs are too widely distributed to have diagnostic value; this PFT is therefore not assigned to biomes and is excluded from subsequent steps in the biomization procedure. The 'cold desert' biome to which xeric forbs contributed was not intended to be comparable to 'desert' as defined by Tarasov *et al.* (2000). It is rather a possible biome within the 'no-analogue' tundra vegetation of Beringia at the last glacial maximum (Hopkins, 1967; Cwynar & Ritchie, 1980; Anderson *et al.*, 1989).

Pollen taxa were assigned to one or more of the defined PFTs based on our knowledge of the modern ecology and biology of individual species. Arboreal and shrub forms of *Betula* and *Alnus* are placed in the appropriate PFTs if they were distinguished palynologically. *Pinus* and *Pinus* (Haploxylon) in samples from Alaska were classified as eurythermic conifers (ec). However, in Siberia, these taxa were classified as cool-boreal conifer shrubs (cbc) because *Pinus pumila* is the only representative of the genus present in this region. Table 5 shows the assignment of pollen taxa to the PFTs used in the Beringian biomization.

The steppe forb PFT includes taxa that are known from azonal grasslands in Beringia today (Yurtsev, 1981). Several of these taxa (e.g. *Anemone*, *Galium*) are also assigned to the tundra forb PFT. Although *Artemisia* occurs today in tundra regions, it was classified as a steppe forb in this biomization for consistency with the treatment of *Artemisia* in the biomizations of Europe (Prentice *et al.*, 1996), other regions of North America (Thompson & Anderson, 2000; Williams *et al.*, 2000) and China (Yu *et al.*, 2000). An experiment in which *Artemisia* was classified as both a steppe forb and an arctic/alpine forb showed that this decision did not adversely affect the modern biomization of Beringia.

Seven biomes could potentially occur in Beringia: tundra, steppe, cold desert (characterized by xeric forbs), cold deciduous forest (*Larix* and hardwoods), cold mixed forest (hardwoods, *Abies*, *Tsuga* and *Pinus*), taiga (characterized by *Picea*), and cool conifer forest (characterized by *Tsuga*). Table 6 shows the defined composition of each biome in terms of PFTs. In the case of tie-breaks, biomes were assigned in the order they appear in Table 6. The PFT definitions, the assignments of individual pollen taxa to PFTs, and the assignments of PFTs to biomes are broadly consistent with the definitions used in adjacent regions of North America by Williams *et al.* (2000) and Thompson & Anderson (2000).

Table 6 Assignment of plant functional types (PFTs) to biomes in Beringia.

Biome	Code	Plant functional types
tundra	TUND	aa, ab, af, ah, cbc, dtf, g, h, s
cold deciduous forest	CLDE	ab, bs, bsc, bts, cbc, ec, h
taiga	TAIG	ab, bec, bs, bsc, bts, ec, h
cold mixed forest	CLMX	ab, bs, ctc, ec, h
cool conifer forest	COCO	ab, bec, bs, ctc, ec, h
cold desert	DESE	xf
steppe	STEP	g, sf

RESULTS

Predicted vs. observed modern biomes

The pollen-derived biome map (Fig. 1a) shows patterns which correspond well to observed patterns in vegetation distribution (Fig. 1b) in eastern Beringia. In particular, the map accurately captures the modern position of both the northern and western boundary of the taiga, and the occurrence of cool conifer forest along the coast of south-central Alaska. Two sites in North America (S338, S353) beyond the observed northern limit of the coastal cool conifer forest are misclassified. This apparently reflects the presence of low percentages of *Tsuga* pollen, probably derived by long-distance transport from the south. Sites in regions of eastern Beringia characterized today by a mosaic of tundra and taiga vegetation tend to be preferentially assigned to tundra. However, moss-polster samples from this zone are more likely to correctly reflect the local presence of gallery forest (e.g. two samples from gallery forest, from the Noatak River and Seward Peninsula, are classified as taiga).

Vegetation patterns in western Beringia are captured less well in the biome maps, but there is a broad-scale agreement. The Chukotkan tundra is well delimited, but the extent of cold deciduous forest in north-east Siberia is underestimated. This probably reflects the fact that *Larix*, one of the dominant tree species in this type of forest, is systematically under-represented in the pollen spectra. As in eastern Beringia, open forest areas are often classified as tundra.

Mid-Holocene biomes

The reconstructed distribution of biomes across Beringia at 6000 ^{14}C yr BP (Fig. 2a) is similar to the modern distribution. There is almost no change in the northern position of the tundra/taiga boundary in Alaska, although taiga is indicated north of its modern limit in the Mackenzie Delta region. There are insufficient data to delimit accurately the western limit of taiga in Alaska. However, the reconstruction of tundra vegetation at a number of sites within the modern taiga zone suggests the forest cover in the western interior was more discontinuous than it is today. Tundra characterizes the southern coastal region of Alaska rather than cool conifer forest, which is shown only in the far south-east of Alaska. The extent of tundra in Chukotka and coastal Kamchatka at

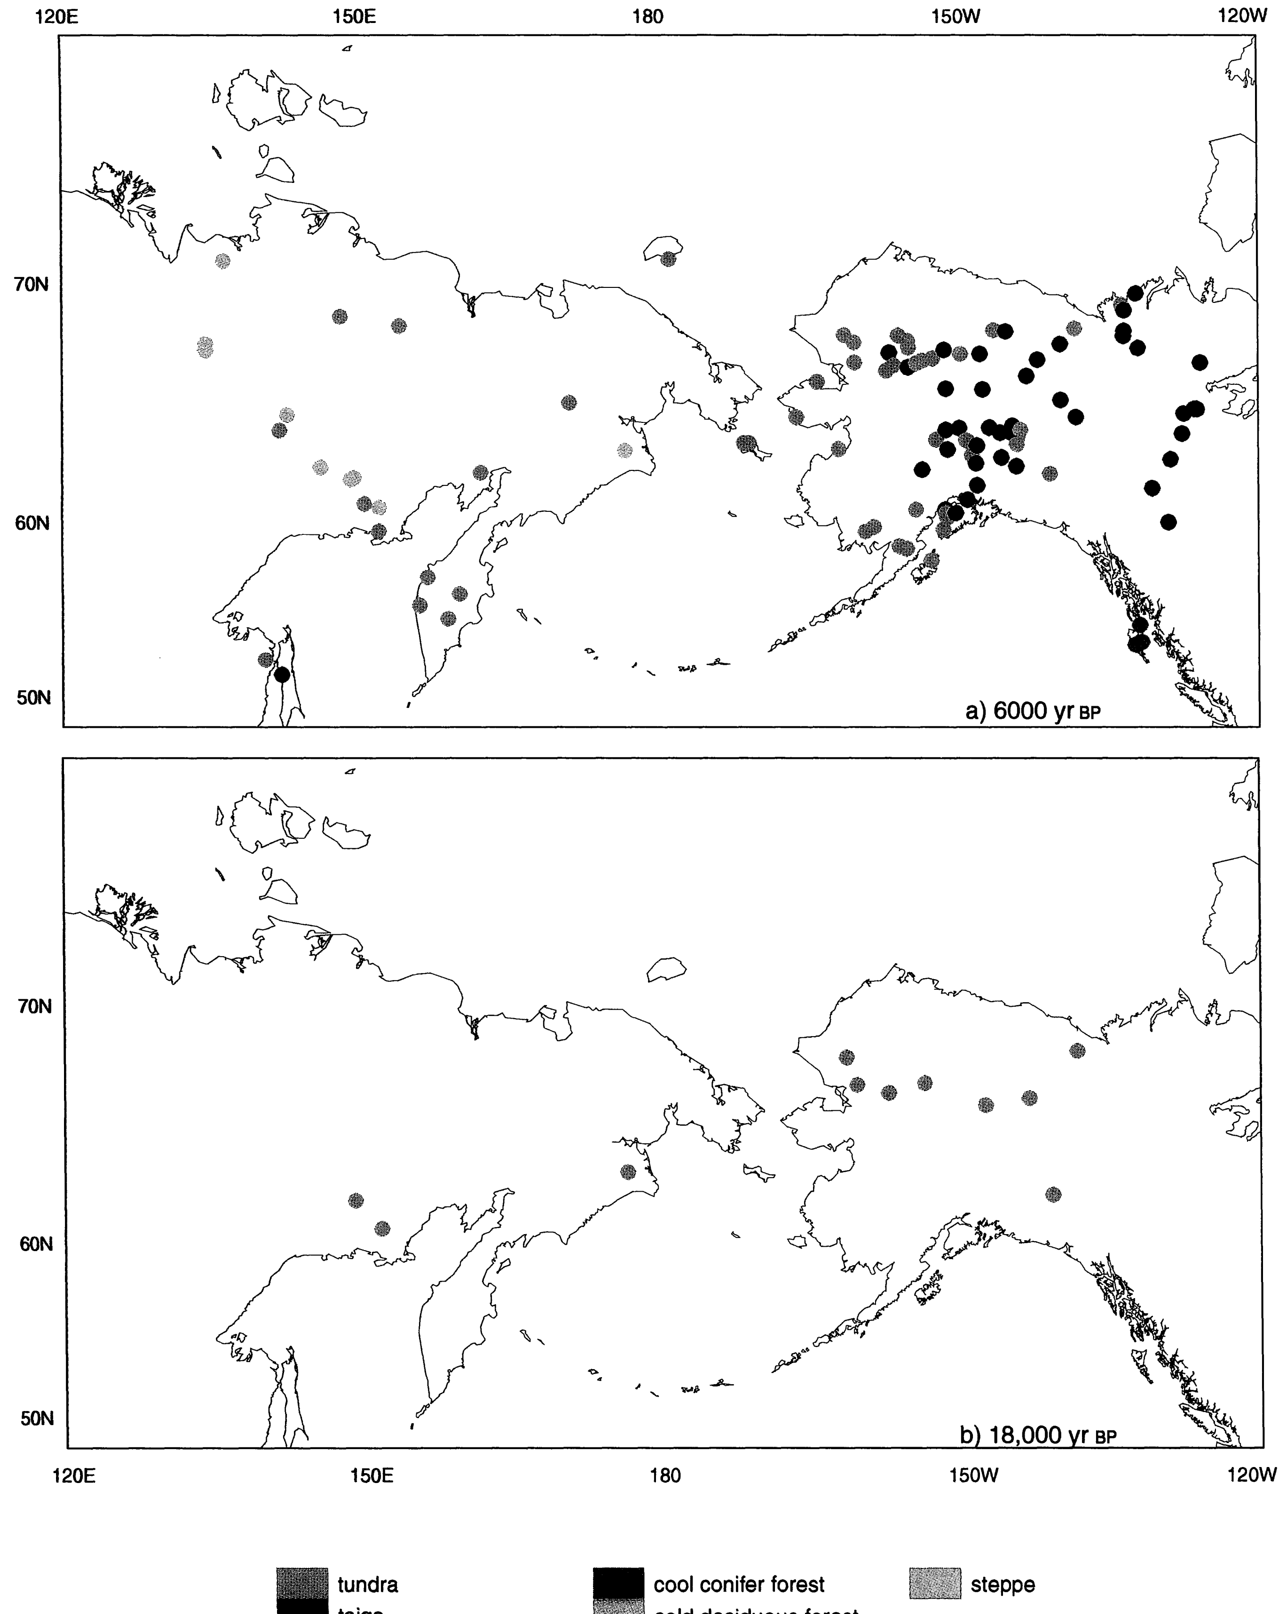

Figure 2 Biomes reconstructed from fossil pollen data at (a) 6000 ^{14}C yr BP and (b) 18,000 ^{14}C yr BP.

Table 7 Percentage contribution of different plant functional types (PFTs), derived from the biomization procedure, in LGM pollen samples from Beringia. The PFT codes are defined in Table 5. PFTs contributing to the tundra biome are listed first.

6000 ^{14}C yr BP is similar to today. Given the problem of *Larix* representation in the pollen record, the reconstruction of tundra in areas of the Yana-Indigirka-Kolyma lowland cannot be interpreted as reliably indicating a southward shift in the northern limit of cold deciduous forest in western Siberia at 6000 ^{14}C yr BP. In accord with other interpretations of the data, our reconstructions provide no evidence of an expansion of other biomes (e.g. taiga or cold mixed forest) into the region occupied today by cold deciduous forest.

Last glacial maximum biomes

In contrast to the situation at 6000 ^{14}C yr BP, the predicted distribution of biomes at 18,000 ^{14}C yr BP was very different from today. The biome map for 18,000 ^{14}C yr BP (Fig. 2b) shows tundra across the whole of Beringia. However, the importance of component tundra PFTs differs from region to region (Table 7). For example, at Kaiyak Lake (Anderson, 1985) steppe forbs (sf) are strongly represented, whereas at Sands of Time Lake (Lamb & Edwards, 1988) the xeric forb (xf) PFT is quite prominent, and at Jack London, Magadan (Lozhkin *et al.*, 1993) shrub and heath PFTs (aa, h, bs) are important.

DISCUSSION AND CONCLUSIONS

The biomization method

The biomization method appears to capture the broad-scale features of the modern vegetation patterns across Beringia reasonably well, except that it fails to predict the observed extent of the *Larix*-dominated cold deciduous forest in western Beringia. Correctly defining the limits of *Larix*-dominated forest from pollen data is difficult because of the poor representation of *Larix* in the pollen record. Although our use of a weighting factor for *Larix* increases the number of sites correctly assigned to cold deciduous forest, weighting is only effective when *Larix* pollen is actually present in a sample. One possible solution to this problem would be to average the pollen spectra of several samples within a specified window (e.g. 6000 ± 500 yr) and use this composite spectrum for biomization. Such an approach would enhance the representation of *Larix* because, although not present in every sample, *Larix* pollen tends to be present in some samples within a broader time series. An alternative approach might be to use macrofossil records in conjunction with the pollen data from a given site.

Vegetation and climate of Beringia at 6000 ^{14}C yr BP

The biome map (Fig. 2a) shows that northern treeline in western Beringia and Alaska was similar to present at 6000 ^{14}C yr BP. In northern Alaska, there is no macrofossil evidence that *Picea* occurred further north than today at any stage during the Holocene (Hopkins *et al.*, 1981) and the pollen record has consistently been interpreted as showing that the position of northern treeline in this region was similar to today (e.g. Brubaker *et al.*, 1983; Anderson, 1985, 1988). The biomised data, although somewhat noisy, indicate that treeline was further north than today in the lower Mackenzie-Tuktoyaktuk region. There was a treeline advance in north-western Canada in the early Holocene, and dated macrofossils show that *Picea* grew north of its modern limit as late as 6000 ^{14}C yr BP (Ritchie & Hare, 1971; Ritchie *et al.*, 1983; Spear, 1983; Ritchie, 1984a). Our data appear to reflect the waning stages of this early Holocene treeline advance, and underscore differences in treeline response between Alaska and the easternmost part of the Beringian region. Macrofossil evidence also suggests that treeline was further north in western Beringia during the early Holocene (Khotinskiy, 1984), but it is not possible to detect any residual treeline extension from the biome map for 6000 ^{14}C yr BP. Biome reconstructions for other regions of the Arctic (e.g. Prentice *et al.*, 1996; Texier *et al.*, 1997; Tarasov *et al.*, 1998) indicate that treeline was considerably further north than today, with the greatest northward shift (of up to 200–300 km) in central Siberia. Arctic tree line extensions during the mid-Holocene have been interpreted as indicating increased growing-season warmth as a result of orbitally induced insolation changes (e.g. TEMPO, 1996; Prentice *et al.*, 2000). Our reconstructions demonstrate that there was a strong regionalization to this circum-polar warming. They suggest that other, indirect responses to orbital forcing (e.g. variations in the East Asian trough-ridge system or changes in circulation in the Arctic Ocean) may have played an important role in determining Arctic regional climates during the mid-Holocene (see Ritchie & Hare, 1971). MacDonald *et al.* (1993) also noted the apparent asymmetry of Holocene treeline extensions. This asymmetry has not been seen in climate model simulations to date (e.g. TEMPO, 1996; Harrison *et al.*, 1998; Joussaume *et al.*, 1998).

There are insufficient data to delimit accurately the western limit of taiga in Alaska at 6000 ^{14}C yr BP. However, the mixture of tundra and taiga in the central and western interior of Alaska, which we interpret as indicating that the forest cover was less complete than today, is consistent with data that indicate that the westward spread of *Picea* was not completed until after 6000 ^{14}C yr BP (Anderson & Brubaker, 1994; Edwards & Barker, 1994; Hu *et al.*, 1996).

The presence of tundra in southern coastal Alaska, in contrast to today's cool conifer forest, may indicate that winters were colder than present and exceeded the tolerances of *Tsuga* and *Picea sitchensis*, although some factor other than winter cold must also have limited the spread of *P. glauca* and *P. mariana* to the coast (Lozhkin *et al.*, 1993). The westward limitation of *Picea* in Alaska may reflect an enhanced east–west summer temperature gradient, with advection due to a strong Pacific subtropical high causing a relative cooling of the Alaskan coast and adjacent regions (see e.g. Ritchie & Hare, 1971; Mock *et al.*, 1998).

There is no evidence that the cold deciduous forests of western Beringia were less extensive at 6000 ^{14}C yr BP than they are today. Cold deciduous forests are confined to regions where the winter temperatures exceed the limits for the growth of boreal evergreen conifers (Prentice *et al.*, 1992). Thus, the fact that biomes such as taiga, cool conifer, or cold mixed forests do not encroach on the cold deciduous forest zone in western Beringia indicates that winters were not significantly warmer than today. This climatic interpretation is consistent with evidence from Japan (Takahara *et al.*, 2000).

Vegetation and climate of Beringia at the last glacial maximum

Our reconstructions show that Beringia was covered by tundra vegetation at the last glacial maximum. The occurrence of tundra across Beringia at the LGM is consistent with a significant, and most likely year-round, cooling. A large cooling is also implied by the biome reconstructions in adjacent regions of western Siberia (Tarasov *et al.*, 2000), northern China (Yu *et al.*, 2000) and Japan (Takahara *et al.*, 2000). Such a cooling suggests that the southerly flow along the western edge of the North American ice sheet that is observed in many palaeoclimatic simulations (e.g. Broccoli & Manabe, 1987; Kutzbach *et al.*, 1993; Kutzbach *et al.*, 1998) did not result in significant warming in Beringia, nor did it lead to significantly warmer conditions in Beringia than in adjacent regions. Differences in the relative abundance of PFTs from site to site support the widely accepted idea that the vegetation of Beringia was a mosaic of different tundra types (Ritchie & Cwynar, 1982; Schweger, 1982). A more detailed subdivision of tundra, based on an analysis of the modern physiologic and bioclimatic limits of Arctic PFTs, would be helpful in order to analyse the climatic implications of variation in tundra vegetation types across Beringia.

ACKNOWLEDGMENTS

The biomization described here was begun at the BIOME 6000 regional workshop for Beringia and Japan (October 15th-29th 1997, Lund, Sweden), which was funded by the International Geosphere-Biosphere Programme (IGBP) through the IGBP Data and Information System (IGBP-DIS), the Global Analysis, Interpretation and Modelling (IGBP-GAIM) task force, and the PAst Global changES (IGBP-PAGES) core project. We thank Ben Smith for making the BIOMISE program available to us, Matt Duvall (PARCS Data Coordinator) and F. Dobos for assistance with data compilation, Colin Prentice for advice on biomization techniques, Dave Murray, Skip Walker, Volodya Razzhivin and Nadja Matveyeva for discussions about Arctic plant functional types, and Colin Prentice and Patrick Bartlein for reviews of an earlier draft of the manuscript. The North American Pollen Database can be accessed at http://www.museum.state.il.us/research/napd/ and the PARCS database at http://www.ngdc.noaa.gov/paleo/parcs/. This paper is a contribution to the PALE/PARCS initiative, to BIOME 6000, to TEMPO (Testing Earth system Models with Paleoenvironmental Observations) and to the Palaeoclimate Modelling Intercomparison Project (PMIP).

BIOSKETCH

The Paleoclimates from Arctic Lakes and Estuaries (PALE) initiative, which is now part of the Paleoenvironmental Arctic Sciences (PARCS) initiative, was established in 1992 and is supported by the US National Science Foundation (PARCS, 1999). The initiative has as a goal the collection of arctic and subarctic palaeoenvironmental datasets for data-model comparison. Pollen and macrofossil data, and biome reconstructions made using these data, are one component of the PALE data base. The PARCS steering committee is co-chaired by Mary Edwards (Department of Geography, NTNU, Trondheim) and Michael Retelle (Department of Geology, Bates College, Lewiston). Matt Duvall (Quaternary Research Center, University of Washington, Seattle) is the PARCS Data Coordinator. More information about the PARCS initiative can be accessed via http://www.ngdc.noaa.gov/paleo/parcs/.
