

Review of the National Ambient Air Quality Standards for Ozone:

Policy Assessment of Scientific and Technical Information

OAQPS Staff Paper – Second Draft

EPA-452/D-05-002
July 2006

Review of the National Ambient Air Quality Standards for Ozone:

Policy Assessment of Scientific and Technical Information

OAQPS Staff Paper – Second Draft

U.S. Environmental Protection Agency
Office of Air Quality Planning and Standards
Research Triangle Park, North Carolina

DISCLAIMER

This document has been reviewed by the Office of Air Quality Planning and Standards (OAQPS), U.S. Environmental Protection Agency (EPA), and approved for publication. This second draft OAQPS Staff Paper contains the initial conclusions of the staff of the OAQPS and does not necessarily represent those of the EPA. Mention of trade names or commercial products is not intended to constitute endorsement or recommendation for use.

TABLE OF CONTENTS

List of Figures	xii
1. INTRODUCTION.....	1-1
1.1 PURPOSE.....	1-1
1.2 BACKGROUND	1-2
1.2.1 Legislative Requirements.....	1-2
1.2.2 History of Ozone NAAQS Reviews	1-3
1.2.3 Litigation Related to the 1997 Ozone Standards	1-5
1.2.4 Current Ozone NAAQS Review	1-5
1.3 GENERAL APPROACH AND ORGANIZATION OF THE DOCUMENT	1-6
REFERENCES	1-9
2. AIR QUALITY CHARACTERIZATION	2-1
2.1 INTRODUCTION	2-1
2.2 CHEMICAL AND PHYSICAL PROPERTIES, FORMATION, AND TRANSPORT	
2-1	
2.2.1 Chemical and Physical Properties.....	2-1
2.2.2 Formation.....	2-2
2.2.3 Transport.....	2-2
2.2.4 Precursors, Sources and Emissions.....	2-5
2.2.5 Tropospheric vs. Stratospheric Ozone	2-5
2.2.6 Relationship of Ozone to Photochemical Oxidants	2-8
2.3 DATA SOURCES	2-8
2.3.1 Air Quality System (AQS).....	2-10
2.3.2 CASTNET.....	2-10
2.4 OZONE MONITORING METHODS AND DATA QUALITY	2-11
2.5 CHARACTERIZATION OF GROUND-LEVEL OZONE CONCENTRATIONS	2-14
2.5.1 Metrics	2-14
2.5.2 Spatial Variability	2-15
2.5.2.1 Comparison of 1-hr, 8-hr, and 24-hr Ozone Metrics	2-15

2.5.2.2	8-Hour and 1-Hour Statistics	2-15
2.5.2.3	Cumulative Concentration-Weighted Statistics	2-21
2.5.3	Temporal Variability	2-21
2.5.3.1	Long Term Variability – Trends	2-21
2.5.3.2	Short Term Variability – Annual	2-30
2.5.3.3	Seasonal Variability	2-30
2.5.3.4	Short Term Variability – Diurnal	2-33
2.6	CHARACTERIZATION OF OZONE EPISODES	2-41
2.7	POLICY RELEVANT BACKGROUND LEVELS	2-46
	REFERENCES	2-48

3. POLICY-RELEVANT ASSESSMENT OF HEALTH EFFECTS EVIDENCE 3-1

3.1	INTRODUCTION	3-1
3.2	MECHANISMS OF TOXICITY	3-3
3.3	NATURE OF EFFECTS	3-3
3.3.1	Morbidity	3-4
3.3.1.1	Effects on the Respiratory System from Short-term Exposures	3-4
3.3.1.2	Effects on the Respiratory System from Long-term Exposures	3-17
3.3.1.3	Effects on the Cardiovascular System	3-23
3.3.2	Premature Mortality	3-24
3.3.2.1	Mortality and Short-term O ₃ Exposure	3-25
3.3.2.2	Mortality and Long-term O ₃ Exposure	3-30
3.3.3	Ozone Effects on UV-B Flux	3-32
3.3.4	Summary	3-33
3.4	ASSESSMENT OF EVIDENCE FROM EPIDEMIOLOGICAL STUDIES	3-33
3.4.1	Strength of Associations	3-35
3.4.2	Robustness of Associations	3-35
3.4.2.1	Exposure Error	3-35
3.4.2.2	Confounding by Copollutants	3-38
3.4.2.3	Model Specification	3-40
3.4.3	Consistency	3-41
3.4.4	Lag Structure in Short-term Exposure Studies	3-41
3.4.5	Concentration-Response Relationships and Potential Thresholds	3-42

3.5	BIOLOGICAL PLAUSIBILITY AND COHERENCE OF EVIDENCE	3-46
3.5.1	Animal-to-Human Extrapolation Issues	3-46
3.5.2	Coherence and Plausibility of Short-term Effects on the Respiratory System	3-51
3.5.3	Coherence and Plausibility of Effects on the Cardiovascular System	3-54
3.5.4	Coherence and Plausibility of Effects Related to Long-Term O ₃ Exposure	3-56
3.5.5	Coherence and Plausibility of Mortality-Related Health Endpoints	3-57
3.6	OZONE-RELATED IMPACTS ON PUBLIC HEALTH	3-58
3.6.1	Factors which Modify Responsiveness to Ozone	3-59
3.6.2	Susceptible Population Groups	3-60
3.6.2.1	Active People	3-60
3.6.2.2	People with Lung Disease	3-62
3.6.2.3	Children and Older Adults	3-65
3.6.2.4	People with Increased Responsiveness to Ozone	3-66
3.6.2.5	Other Population Groups	3-67
3.6.3	What Constitutes an Adverse Health Impact from Ozone Exposure?	3-67
3.6.4	Estimation of Potential Numbers of People in At-Risk Susceptible Population Groups in the United States	3-73
3.7	SUMMARY AND CONCLUSIONS FOR OZONE HEALTH EFFECTS	3-74
3.7.1	Respiratory Morbidity Effects of Short-term Exposures to Ozone	3-75
3.7.2	Cardiovascular Morbidity Effects of Short-term Exposures to Ozone	3-78
3.7.3	Mortality-Related Effects of Short-term Exposures to Ozone	3-79
3.7.4	Health Effects of Repeated Short-term Exposures to Ozone	3-80
3.7.5	Confidence in Various Health Outcomes Associated with Short-term Exposures to Ozone	3-80
3.7.6	Health Effects of Long-term Exposures to Ozone	3-83
3.7.7	Health Effects of Pollutant Mixtures Containing Ozone	3-83
3.7.8	Populations at Risk/Susceptibility Factors Associated with Ozone Exposure	3-84
	REFERENCES	3-87

4. CHARACTERIZATION OF HUMAN EXPOSURE TO OZONE 4-1

4.1	INTRODUCTION	4-1
4.2	OZONE EXPOSURE STUDIES	4-2
4.2.1	Exposure Concepts and Definitions.....	4-2
4.2.2	Monitoring Equipment Considerations.....	4-3
4.2.3	Personal Ozone Exposure Assessment Studies.....	4-4
4.2.4	Microenvironmental Studies.....	4-5
4.3	EXPOSURE MODELING.....	4-6
4.3.1	The APEX Model	4-6
4.3.2	Key Algorithms.....	4-11
4.3.3	Model Output.....	4-12
4.3.4	Limitations of the Model	4-13
4.3.4.1	Estimation of Ambient Air Quality.....	4-14
4.3.4.2	Estimation of Concentrations in Indoor Microenvironments	4-14
4.3.4.3	Air Exchange Processes.....	4-15
4.3.4.4	Deposition Processes	4-15
4.3.4.5	Chemical Reaction Processes	4-16
4.3.4.6	Characterization of Population Demographics and Activity Patterns	4-16
4.3.4.7	Modeling Physiological Processes.....	4-17
4.4	SCOPE OF EXPOSURE ASSESSMENT.....	4-18
4.4.1	Selection of Urban Areas to be Modeled.....	4-18
4.4.2	Time Periods Modeled.....	4-18
4.4.3	Populations Modeled	4-19
4.5	INPUTS TO THE EXPOSURE MODEL.....	4-20
4.5.1	Population Demographics.....	4-20
4.5.2	Population Commuting Patterns	4-21
4.5.3	Human Activity Data	4-21
4.5.4	Physiological Data	4-24
4.5.5	Microenvironments Modeled.....	4-24
4.5.5.1	Air Exchange Rates for Indoor Residential Environments.....	4-25
4.5.5.2	AER Distributions for Other Indoor Environments.....	4-26
4.5.5.3	Proximity and Penetration Factors For Outdoors and In-vehicle	4-26
4.5.5.4	Ozone Decay and Deposition Rates.....	4-27
4.5.6	Meteorological Data.....	4-27
4.5.7	Ambient Ozone Concentrations.....	4-27
4.5.8	Modeling Alternative Standards	4-28

4.6	EXPOSURE ASSESSMENT RESULTS	4-29
4.6.1	Comparison With Exposure Estimates From the Prior Review.....	4-42
4.6.2	Summary of Sensitivity, Uncertainty, and Evaluation Analyses.....	4-44
4.6.2.1	Sensitivity Analyses.....	4-44
4.6.2.2	Uncertainty Analyses.....	4-46
4.6.2.3	Model Evaluation.....	4-46
	REFERENCES	4-48
5.	CHARACTERIZATION OF HEALTH RISKS.....	5-1
5.1	INTRODUCTION	5-1
5.1.1	Overview of Risk Assessment From Last Review	5-2
5.1.2	Development of Approach for Current Risk Assessment.....	5-2
5.2	SCOPE OF OZONE HEALTH RISK ASSESSMENT.....	5-4
5.2.1	Selection of Health Endpoint Categories.....	5-6
5.2.2	Selection of Study Areas.....	5-8
5.2.3	Air Quality Considerations	5-9
5.3	COMPONENTS OF THE RISK MODEL	5-11
5.3.1	Assessment of Risk Based on Controlled Human Exposure Studies	5-11
5.3.1.1	General Approach	5-11
5.3.1.2	Exposure Estimates.....	5-14
5.3.1.3	Exposure-Response Functions.....	5-15
5.3.1.4	Characterizing Uncertainty and Variability	5-16
5.3.2	Assessment of Risk Based on Epidemiological Studies.....	5-22
5.3.2.1	General Approach	5-22
5.3.2.2	Air Quality Considerations	5-25
5.3.2.3	Concentration-Response Functions	5-26
5.3.2.4	Baseline Health Effects Incidence and Population Estimates.....	5-29
5.3.2.5	Characterizing Uncertainty and Variability	5-30
5.4	OZONE RISK ESTIMATES.....	5-38
5.4.1	Recent Air Quality	5-38
5.4.2	Just Meeting Current and Alternative Ozone Standards.....	5-56
5.4.3	Comparison with Risk Estimates from Prior Review.....	5-69
5.4.4	Key Observations.....	5-72

7. POLICY-RELEVANT ASSESSMENT OF WELFARE EFFECTS EVIDENCE.. 7-1

7.1	INTRODUCTION	7-1
7.2	MECHANISMS GOVERNING PLANT RESPONSE TO OZONE	7-2
7.2.1	Ozone Uptake: Canopy, Plant and Leaf.....	7-3
7.2.2	Cellular to Systemic Response.....	7-4
7.2.3	Compensation and Detoxification.....	7-4
7.2.4	Changes to Plant Metabolism	7-5
7.2.5	Plant Response to Chronic/Long-term Exposures	7-6
7.3	NATURE OF EFFECTS ON VEGETATION	7-6
7.3.1	Vegetation Effects Endpoints	7-7
7.4	IMPACTS ON PUBLIC WELFARE	7-9
7.4.1	What Constitutes an Adverse Vegetation Impact from Ozone Exposure?	7-10
7.4.2	Factors That Modify Functional and Growth Response	7-10
7.4.2.1	Genetics.....	7-11
7.4.2.2	Biological Factors	7-11
7.4.2.3	Physical Factors	7-13
7.4.2.4	Chemical Factors	7-13
7.5	CHARACTERIZATION OF VEGETATION EXPOSURES TO OZONE.....	7-15
7.5.1	Key Considerations in Vegetation Exposure Characterization.....	7-15
7.5.2	Monitor Networks: National Coverage.....	7-22
7.5.3	Community Multi-scale Air Quality Model (CMAQ).....	7-26
7.5.4	Generation of Potential Ozone Exposure Surfaces (POES)	7-26
7.6	CHARACTERIZATION OF VEGETATION RISKS	7-38
7.6.1	Scope of Vegetation Risk Assessment.....	7-38
7.6.2	Characterization of Crop Risks and Associated Economic Benefits	7-40
7.6.2.1	Exposure Methodologies Used in Vegetation Research.....	7-40
7.6.2.2	Basis for C-R Functions.....	7-42
7.6.2.3	Considerations for Exposures at Crop Canopy Height	7-47
7.6.2.4	Quantifiable Risk of Yield Loss In Select Commodity, Fruit and Vegetable Crops	7-48
7.6.2.5	Economic Benefits Assessment – AGSIM	7-51
7.6.3	Tree Risk Assessments	7-55
7.6.3.1	Quantifiable Risk of Biomass Loss In Select Tree Seedling Species	7-55
7.6.3.2	Foliar Injury Incidence.....	7-58

7.6.3.3	Modeled Mature Tree Growth Response: Eastern and Western Species Case Studies.....	7-63
7.7	QUALITATIVE RISK: ECOSYSTEM CONDITION, FUNCTION AND SERVICES	7-68
7.7.1	Evidence of Potential Ozone Alteration of Ecosystem Structure and Function	7-71
7.7.2	Effects on Ecosystem Products and Services.....	7-72
7.7.2.1	Carbon Sequestration.....	7-72
	REFERENCES	7-74
8.	STAFF CONCLUSIONS ON SECONDARY OZONE NAAQS.....	8-1
8.1	INTRODUCTION	8-1
8.2	APPROACH	8-2
8.3	SECONDARY O ₃ STANDARD	8-4
8.3.1	Background.....	8-4
8.3.2	Adequacy of Current O ₃ Standard	8-4
8.3.2.1	Considerations Based on Vegetation Effects Evidence.....	8-5
8.3.2.2	Pollutant Indicator.....	8-7
8.3.2.3	Averaging Times.....	8-7
8.3.2.4	Form of the Standard	8-8
8.3.2.5	Level of the Standard.....	8-11
8.4	ALTERNATIVE SECONDARY STANDARD OPTIONS FOR CONSIDERATION ..	8-13
8.5	SUMMARY OF KEY UNCERTAINTIES AND RESEARCH RECOMMENDATIONS RELATED TO SETTING SECONDARY O ₃ STANDARDS	8-14

2-1	NO _x Emission Sources, 1970-2004	2-3
2-2	VOC Emission Sources, 1970-2004	2-6
2-3	Relationship between Precision of 1-hour Ozone Data and Corresponding Standard Deviation of 8-hour Design Values	2-13
3-1	Acute O ₃ -induced Physiological and Biochemical Changes in Humans and Animals	3-50
3-2	Gradation of Individual Responses to Short-Term Ozone Exposure in Healthy Persons	3-71
3-3	Gradation of Individual Responses to Short-Term Ozone Exposure in Persons with Impaired Respiratory Systems	3-72
3-4	Summary of Ozone-Induced Respiratory Health Effects from Clinical Studies	3-79
4-1	Exertion levels in terms of equivalent ventilation rates (liters/min-m ²)	4-12
4-2	Urban areas and time periods modeled	4-18
4-3	Population coverage of modeled areas (2002 analysis)	4-20
4-4	Studies in CHAD used in this analysis	4-23
4-5	Microenvironments Modeled	4-24
4-6	Alternative 8-hour ozone standard scenarios	4-28
4-7	2002-2004 8-hour ozone design values for the modeled areas	4-29
4-8	Counts of children (ages 5-18) with one or more 8-hour ozone exposures above 0.07 ppm-8hr, concomitant with moderate or greater exertion, for 2002	4-32
4-9	Counts of children (ages 5-18) with three or more 8-hour ozone exposures above 0.07 ppm-8hr, concomitant with moderate or greater exertion, for 2002	4-32
4-10	Comparison of exposure modeling between the current and the 1997 reviews	4-42
4-11	Comparison of exposure modeling results for the 84/3 standard between the current and the 1997 reviews (Houston) ¹	4-43
4-12	Comparison of exposure modeling results for the 84/3 standard between the current and the 1997 reviews (Houston, Los Angeles, New York, Philadelphia, St. Louis, and Washington combined) ¹	4-43
4-13	Sensitivity to activity database: counts of children (ages 5-18) with any or three or more 8-hour ozone exposures above 0.07 ppm-8hr concomitant with moderate or greater exertion	4-44
4-14	Sensitivity to longitudinal activity pattern algorithm: counts of Boston (2002 base case) population groups with any or three or more 8-hour ozone exposures above 0.07 ppm-8hr concomitant with moderate or greater exertion	4-45
4-15	Sensitivity to ozone decay rate: counts of children (ages 5-18) with any or three or more 8-hour ozone exposures above 0.07 ppm-8hr concomitant with moderate or greater exertion	4-45

4-16	Sensitivity to proximity factor: counts of children (ages 5-18) with any or three or more 8-hour ozone exposures above 0.07 ppm-8hr concomitant with moderate or greater exertion	4-46
4-17	Sensitivity to air exchange rate: counts of children (ages 5-18) with any or three or more 8-hour ozone exposures above 0.07 ppm concomitant with moderate or greater exertion	4-46
5-1	Locations and Health Endpoints Included in the O ₃ Risk Assessment Based on Epidemiological Studies	5-28
5-2	Relevant Population Sizes for O ₃ Risk Assessment Locations.....	5-31
5-3	Baseline Mortality Rates (per 100,000 Population) Used in the O ₃ Risk Assessment ..	5-32
5-4	Baseline Rates for Hospital Admissions Used in the O ₃ Risk Assessment	5-33
5-5	Comparison of Number and Percent of Active School Age Children Estimated to Experience Lung Function Responses Associated with 8-Hour Ozone Exposure While Engaged in Moderate Exertion for Location Specific O ₃ Seasons*	5-40
5-6	Comparison of Number and Percent of Occurrences of Lung Function Responses Among Active School Age Children Associated with 8-Hour O ₃ Exposure While Engaged in Moderate Exertion for Location Specific O ₃ Seasons	5-44
5-7	Estimated Respiratory Symptoms Associated with Recent (April - September, 2004) O ₃ Concentrations Above Background in Boston, MA	5-47
5-8	Estimated Respiratory Symptoms Associated with Recent (April - September, 2002) O ₃ Concentrations Above Background in Boston, MA	5-48
5-9	Estimated Hospital Admissions Associated with Recent (April - September, 2004) O ₃ Concentrations in NY, NY.....	5-50
5-10	Estimated Hospital Admissions Associated with Recent (April - September, 2002) O ₃ Concentrations in NY, NY.....	5-50
5-11	Estimated Non-Accidental Mortality Associated with Recent (April - September, 2004) Ozone Concentrations.....	5-51
5-12	Estimated Non-Accidental Mortality Associated with Recent (April - September, 2002) O ₃ Concentrations	5-53
7-1a	Evaluation statistics for the 3 month 12-hr SUM06 interpolations of the Eastern and Western US domains. NMB is Normalized Mean Bias, NME is Normalized Mean Error, AMB is Absolute Mean Bias and AME is Absolute Mean Error. Explanation of these metrics are given in the text.....	7-33
7-1b	Evaluation statistics for the 3 month 12-hr W126 interpolations of the Eastern and Western US domains	7-33
7-2	Air quality and soybean yield loss data from the SOYFACE experiment in Illinois.....	7-46
7-3	Agricultural model results	7-54
7-4	Percentage and number of counties with visible foliar injury and without injury (none) below various standard levels for the years 2001-2004. Each county had an O ₃ monitor and a USDA forest service FIA plot tracking visible foliar injury due to O ₃ exposure.	7-62

7-5 Relative increase in total annual tree biomass growth, simulated with the TREGRO model, if the level current and alternative standards are met. 7-66

1. INTRODUCTION

1.1 PURPOSE

This second draft Staff Paper, prepared by staff in the U.S. Environmental Protection Agency's (EPA) Office of Air Quality Planning and Standards (OAQPS), evaluates the policy implications of the key studies and scientific information contained in the final document, *Air Quality Criteria for Ozone and Related Photochemical Oxidants* (USEPA, 2006; henceforth referred to as the CD), prepared by EPA's National Center for Environmental Assessment (NCEA). This second draft Staff Paper also presents and interprets results from several analyses (e.g., air quality analyses, human exposure analyses, and human health risk assessments) and discusses an environmental assessment of vegetation-related impacts. We believe that these analyses should be considered in EPA's current review of the national ambient air quality standards (NAAQS) for ozone (O₃). This second draft Staff Paper presents conclusions and identifies options that we believe are appropriate for the Administrator to consider concerning whether, and if so how, to revise the primary (health-based) and secondary (welfare-based) O₃ NAAQS.

The policy assessment to be presented in the final version of this draft Staff Paper is intended to help "bridge the gap" between the scientific assessment contained in the CD and the judgments required of the EPA Administrator in determining whether it is appropriate to revise the NAAQS for O₃. Emphasis will be placed on identifying those conclusions and uncertainties in the available scientific literature that the staff believes should be considered in selecting an indicator, averaging times, forms¹, and levels for the primary (health-based) and secondary (welfare-based) standards, which must be considered collectively in evaluating the health and welfare protection afforded by O₃ standards. The final Staff Paper will evaluate the policy implications of the key studies and scientific information contained in the CD, identify the critical elements that EPA believes should be considered in the current review of the NAAQS for O₃, and present factors relevant to the evaluation of current primary and secondary O₃ NAAQS, as well as conclusions and identification of options for the Administrator to consider.

This second draft Staff Paper is being provided to CASAC and the public for review at a meeting planned for August 24-25, 2006. Following that meeting, we will complete revision of the human exposure analyses, health risk assessment and environmental assessment of

¹ The "form" of a standard defines the air quality statistic that is to be compared to the level of the standard in determining whether an area attains the standard.

1 vegetation-related impacts. Taking into account these revised analyses and CASAC and public
2 comments, we will prepare a final Staff Paper, based on the CD, and will make that final
3 document available to CASAC and the public in early Fall 2006.

4 While this draft Staff Paper should be of use to all parties interested in the O₃ NAAQS
5 review, it is written with an expectation that the reader has some familiarity with the technical
6 discussions contained in the CD.

7 **1.2 BACKGROUND**

8 **1.2.1 Legislative Requirements**

9 Two sections of the Clean Air Act (Act) govern the establishment and revision of the
10 NAAQS. Section 108 (42 U.S.C. 7408) directs the Administrator to identify and list “air
11 pollutants” that “in his judgment, may reasonably be anticipated to endanger public health and
12 welfare” and whose “presence . . . in the ambient air results from numerous or diverse mobile or
13 stationary sources” and, if listed, to issue air quality criteria for them. These air quality criteria
14 are intended to “accurately reflect the latest scientific knowledge useful in indicating the kind
15 and extent of identifiable effects on public health or welfare which may be expected from the
16 presence of [a] pollutant in ambient air”

17 Section 109 (42 U.S.C. 7409) directs the Administrator to propose and promulgate
18 “primary” and “secondary” NAAQS for pollutants identified under section 108. Section
19 109(b)(1) defines a primary standard as one “the attainment and maintenance of which in the
20 judgment of the Administrator, based on such criteria and allowing an adequate margin of safety,
21 are requisite to protect the public health.”² A secondary standard, as defined in Section
22 109(b)(2), must “specify a level of air quality the attainment and maintenance of which, in the
23 judgment of the Administrator, based on such criteria, is requisite to protect the public welfare
24 from any known or anticipated adverse effects associated with the presence of [the] pollutant in
25 the ambient air.”³

26 In setting standards that are “requisite” to protect public health and welfare, as provided
27 in section 109(b), EPA’s task is to establish standards that are neither more nor less stringent

² The legislative history of section 109 indicates that a primary standard is to be set at “the maximum permissible ambient air level . . . which will protect the health of any [sensitive] group of the population,” and that for this purpose “reference should be made to a representative sample of persons comprising the sensitive group rather than to a single person in such a group”. [S. Rep. No. 91-1196, 91st Cong., 2d Sess. 10 (1970)].

³ Welfare effects as defined in section 302(h) [42 U.S.C. 7602(h)] include, but are not limited to, “effects on soils, water, crops, vegetation, man-made materials, animals, wildlife, weather, visibility and climate, damage to and deterioration of property, and hazards to transportation, as well as effects on economic values and on personal comfort and well-being.”

1 than necessary for these purposes. In so doing, EPA may not consider the costs of implementing
2 the standards. See generally *Whitman v. American Trucking Associations*, 531 U.S. 457, 464,
3 475-76 (2001).

4 The requirement that primary standards include an adequate margin of safety was
5 intended to address uncertainties associated with inconclusive scientific and technical
6 information available at the time of standard setting. It was also intended to provide a reasonable
7 degree of protection against hazards that research has not yet identified. *Lead Industries*
8 *Association v. EPA*, 647 F.2d 1130, 1154 (D.C. Cir 1980), cert. denied, 101 S. Ct. 621 (1980);
9 *American Petroleum Institute v. Costle*, 665 F.2d 1176, 1186 (D.C. Cir. 1981), cert. denied, 102
10 S.Ct. 1737 (1982). Both kinds of uncertainties are components of the risk associated with
11 pollution at levels below those at which human health effects can be said to occur with
12 reasonable scientific certainty. Thus, in selecting primary standards that include an adequate
13 margin of safety, the Administrator is seeking not only to prevent pollution levels that have been
14 demonstrated to be harmful but also to prevent lower pollutant levels that may pose an
15 unacceptable risk of harm, even if the risk is not precisely identified as to nature or degree.

16 In selecting a margin of safety, the EPA considers such factors as the nature and severity
17 of the health effects, the size of the sensitive population(s) at risk, and the kind and degree of the
18 uncertainties that must be addressed. The selection of any particular approach to providing an
19 adequate margin of safety is a policy choice left specifically to the Administrator's judgment.
20 *Lead Industries Association v. EPA*, supra, 647 F.2d at 1161-62.

21 Section 109(d)(1) of the Act requires that "not later than December 31, 1980, and at 5-
22 year intervals thereafter, the Administrator shall complete a thorough review of the criteria
23 published under section 108 and the national ambient air quality standards . . . and shall make
24 such revisions in such criteria and standards and promulgate such new standards as may be
25 appropriate" Section 109(d)(2) requires that an independent scientific review committee
26 "shall complete a review of the criteria . . . and the national primary and secondary ambient air
27 quality standards . . . and shall recommend to the Administrator any new . . . standards and
28 revisions of existing criteria and standards as may be appropriate" Since the early 1980's,
29 this independent review function has been performed by the Clean Air Scientific Advisory
30 Committee (CASAC), a standing committee of EPA's Science Advisory Board.

31 **1.2.2 History of Ozone NAAQS Reviews**

32 Tropospheric (ground-level) O₃ is formed from biogenic precursor emissions and as a
33 result of anthropogenic precursor emissions. Naturally occurring O₃ in the troposphere can result
34 from biogenic organic precursors reacting with naturally occurring nitrogen oxides (NO_x) and by
35 stratospheric O₃ intrusion into the troposphere. Anthropogenic precursors of O₃, specifically

1 NO_x and volatile organic compounds (VOC), originate from a wide variety of stationary and
2 mobile sources. Ambient O₃ concentrations produced by these emissions are directly affected by
3 temperature, solar radiation, wind speed and other meteorological factors.

4 The EPA initially established primary and secondary NAAQS for photochemical
5 oxidants on April 30, 1971 (36 FR 8186). Both primary and secondary standards were set at an
6 hourly average of 0.08 parts per million (ppm), total photochemical oxidants, not to be exceeded
7 more than one hour per year.

8 On February 8, 1979, EPA completed its first periodic review of the criteria and
9 standards for O₃ and other photochemical oxidants (44 FR 8202). In that action, EPA made
10 significant revisions to the original standard: the level of the primary and secondary NAAQS
11 was changed to 0.12 ppm; the indicator was changed to O₃; and the form of the standards was
12 changed to be based on the expected number of days per calendar year with a maximum hourly
13 average concentration above 0.12 ppm (i.e., attainment of the standard occurs when that number
14 is equal to or less than one).

15 On March 9, 1993, EPA concluded its second periodic review of the criteria and
16 standards for O₃ by deciding that revisions to the O₃ NAAQS were not warranted at that time (58
17 FR 13008). The timing of this decision was required by a court order issued to resolve a lawsuit
18 filed to compel EPA to complete its review of the criteria and standards for O₃ in accordance
19 with the Act. This decision reflected EPA's review of relevant scientific and other information
20 assembled since the last review, as contained in the 1986 O₃ CD (USEPA, 1986), its Supplement
21 (USEPA, 1992) and the 1989 O₃ Staff Paper (USEPA, 1989), although it did not take into
22 consideration a large number of studies on the health and welfare effects of O₃ published since
23 the literature was last assessed in the O₃ Supplement. The final decision emphasized the
24 Administrator's intention to proceed as rapidly as possible with the next periodic review of the
25 air quality criteria and standards to consider the more recent information.

26 Under a court-ordered schedule and a highly accelerated review process, EPA completed
27 its third review of the O₃ NAAQS on July 18, 1997, based on the 1996 O₃ CD (USEPA, 1996a)
28 and 1996 O₃ Staff Paper (USEPA, 1996b). EPA revised the primary and secondary O₃ standards
29 on the basis of the then latest scientific evidence linking exposures to ambient O₃ to adverse
30 health and welfare effects at levels allowed by the 1-hr average standards (62 FR 38856). The
31 O₃ standards were revised by replacing the existing primary 1-hr average standard with an 8-hr
32 average O₃ standard set at a level of 0.08 ppm. The form of the primary standard was changed to
33 the annual fourth-highest daily maximum 8-hr average concentration, averaged over three years.
34 The secondary O₃ standard was changed by making it identical in all respects to the revised
35 primary standard.

1 **1.2.3 Litigation Related to the 1997 Ozone Standards**

2 Following promulgation of the revised O₃ NAAQS, petitions for review were filed
3 addressing a broad range of issues. On May 14, 1999, in response to those challenges, the U.S.
4 Court of Appeals for the District of Columbia Circuit (D.C. Circuit) remanded the O₃ NAAQS to
5 EPA, finding that section 109 of the Act, as interpreted by EPA, effected an unconstitutional
6 delegation of legislative authority.⁵ In addition, the D.C. Circuit Court directed that EPA should
7 consider the potential beneficial health effects of O₃ pollution in shielding the public from the
8 effects of solar ultraviolet (UV) radiation, as well as the adverse health effects.

9 EPA petitioned the U.S. Supreme Court for certiorari on the constitutional issue but did
10 not request review of the D.C. Circuit ruling regarding its obligation to consider the potential
11 beneficial health effects of O₃. On February 27, 2001, the U.S. Supreme Court unanimously
12 reversed the judgment of the D.C. Circuit on the constitutional issue, holding that section 109 of
13 the CAA does not delegate legislative power to the EPA in contravention of the Constitution, and
14 remanded the case to the D.C. Circuit Court to consider those challenges to the O₃ NAAQS that
15 had not been addressed by that Court's earlier decisions.⁶ On March 26, 2002, the D.C. Circuit
16 Court issued its final decision, finding the 1997 O₃ NAAQS to be "neither arbitrary nor
17 capricious," and denying the remaining petitions for review.⁷

18 In response to the D.C. Circuit's remand to consider the potential beneficial health
19 effects of O₃ pollution in shielding the public from the effects of solar (UV) radiation, On
20 November 14, 2001, EPA proposed to leave the 1997 8-hr NAAQS unchanged (66 FR 52768).
21 After considering public comment on the proposed decision, EPA reaffirmed the 8-hr O₃
22 NAAQS set in 1997 (68 FR 614). Finally, on April 30, 2004, EPA announced the decision to
23 make the 1-hr O₃ NAAQS no longer applicable to areas one year after the effective date of the
24 designation of those areas for the 8-hr NAAQS (69 FR 23966). For most areas the date that the
25 1-hr NAAQS no longer applied was June 15, 2005. (See 40 CFR 50.9 for details.)

26 **1.2.4 Current Ozone NAAQS Review**

27 EPA initiated the current NAAQS review in September 2000 with a call for information
28 (65 FR 57810). A project work plan (USEPA, 2002) for the preparation of the CD was released
29 in November 2002 for CASAC and public review. EPA held a series of workshops in mid-2003
30 on several draft chapters of the CD to obtain broad input from the relevant scientific

⁵ *American Trucking Associations v. EPA*, 175 F.3d 1027 (D.C. Cir., 1999)

⁶ *Whitman v. American Trucking Associations*, 531 U.S. 457 (2001)

⁷ *American Trucking Associations v. EPA*, 283 F.3d 355, (D.C. Cir. 2002)

1 communities. These workshops helped to inform the preparation of the first draft CD (EPA,
2 2005a), which was released for CASAC and public review on January 31, 2005.

3 During the process of preparing the first draft CD, NCEA revised the planned format of
4 the CD described in the 2002 work plan. These revisions were made as part of a collaborative
5 effort with OAQPS staff to modify the review process so as to enhance the Agency's ability to
6 meet this and future NAAQS review schedules. As described in Chapter 1 of the first draft CD,
7 emphasis is placed on interpretative evaluation and integration of evidence in the main body of
8 the document, with more detailed descriptions of individual studies being provided in a series of
9 accompanying annexes. This change is intended to streamline the document so as to facilitate
10 timely CASAC and public review and to focus more clearly on issues most relevant to the policy
11 decisions to be made by the Administrator. The modified review process envisions that key
12 policy-relevant issues will be identified earlier in the review process through enhanced
13 collaboration between NCEA and OAQPS, leading to a more efficient linkage between the CD
14 and the Staff Paper. At the CASAC meeting held on May 4-5, 2005, to review the first draft CD,
15 this new format for the CD was met with general approval of CASAC and the public. A second
16 draft CD (EPA, 2005b) was released for CASAC and public review on August 31, 2005, and the
17 final CD was released in March 2006. In a June 8, 2006 letter to the Administrator, CASAC
18 offered additional advice to the Agency concerning Chapter 8 of the final CD (Integrative
19 Synthesis) to help inform this second draft Staff Paper (Henderson, 2006).

20 .
21 The schedule for completion of this review is governed by a consent decree resolving a
22 lawsuit filed in March 2003 by a group of plaintiffs representing national environmental
23 organizations, alleging that EPA had failed to complete the current review within the period
24 provided by statute. *American Lung Association v. Whitman* (No. 1:03CV00778, D.D.C. 2003).
25 The modified consent decree that now governs this review, entered by the court on December 16,
26 2004, provides that EPA will sign for publication notices of proposed and final rulemaking
27 concerning its review of the O₃ NAAQS no later than March 28, 2007 and December 19, 2007,
28 respectively. A series of interim target dates are designed to ensure that these deadlines will be
29 met, including release of a second draft Staff Paper by July 2006, followed by CASAC and
30 public review by August 2006, with completion of a final Staff Paper by early Fall 2006.

31 **1.3 GENERAL APPROACH AND ORGANIZATION OF THE DOCUMENT**

32 The policy assessment in this second draft Staff Paper is based on staff's evaluation of
33 the policy implications of the scientific evidence contained in the CD and results of quantitative
34 analyses based on that evidence. Taken together, this information informs conclusions and
35 identification of options on certain elements of the O₃ standards under review. While the CD

1 focuses on new scientific information available since the last review, it appropriately integrates
2 that information with scientific criteria from previous reviews. The quantitative analyses
3 presented in this second draft Staff Paper (and described in more detail in technical support
4 documents) are based on the most recently available air quality information, so as to provide
5 current characterizations of O₃ air quality patterns and estimated health and environmental risks
6 related to exposure to ambient O₃ concentrations.

7 Following this introductory chapter, this draft Staff Paper is organized into three main
8 parts: the characterization of ambient O₃ air quality data; O₃-related health effects and primary
9 O₃ NAAQS; and O₃-related welfare effects and secondary O₃ NAAQS. The content of these
10 parts is discussed more fully below.

11 The characterization of ambient O₃ and related photochemical oxidants is presented in
12 Chapter 2 and includes information on O₃ properties, current O₃ air quality patterns, historic
13 trends, and background levels. This chapter provides a frame of reference for subsequent
14 discussion of current and alternative O₃ NAAQS and alternative forms of O₃ standards.

15 Chapters 3 through 6 comprise the second main part of this draft Staff Paper dealing with
16 human health and primary standards. Chapter 3 presents an overview of key policy-relevant
17 health effects evidence, major health-related conclusions from the CD, and an examination of
18 issues related to the quantitative assessment of evidence from controlled human exposure and
19 epidemiological studies. Chapters 4 and 5 describe the scope and methods used in conducting
20 human exposure and health risk assessments and present results from those assessments.
21 Chapter 6 includes a discussion of the adequacy of the current primary standard and identifies
22 alternative primary standards that we believe are appropriate for the Administrator to consider.

23 Chapters 7 and 8 comprise the third main part of this draft Staff Paper. Chapter 7
24 presents a policy-relevant assessment of O₃ welfare effects evidence and discusses the scope and
25 methods that we have used in conducting vegetation-related exposure and risk assessments.
26 Chapter 8 includes a discussion of the adequacy of the current secondary standard and identifies
27 alternative secondary standards that we believe are appropriate for the Administrator to consider.

28 The conclusions and identification of options presented in this second draft Staff Paper
29 are informed by comments received from CASAC and the public in their reviews of the first
30 draft Staff Paper as well as CASAC's additional advice concerning the final CD. The final Staff
31 Paper will be informed by further comments received from CASAC and the public in their
32 review of this second draft Staff Paper. The final Staff Paper will take into account the scientific
33 evidence reviewed in the final CD and will include: 1) the results of comparative air quality
34 analyses, human exposure and health risk assessments, and vegetation-related environmental
35 assessments; 2) the overall evaluation of the adequacy of the current primary and secondary
36 NAAQS; and 3) conclusions and identification of options that we believe are appropriate for the

1 Administrator to consider concerning whether and if so how to revise the O₃ NAAQS to address
2 public health and welfare effects associated with exposure to O₃ and related photochemical
3 oxidants.

2. AIR QUALITY CHARACTERIZATION

2.1 INTRODUCTION

This chapter generally characterizes ambient ozone (O₃) and related photochemical oxidants in terms of measurement methods, recent concentrations and trends, relationships between different air quality indicators, and estimates of policy-relevant background. This information is useful for interpreting the available exposure, health, and welfare effects information, and for evaluating the adequacy of the current primary and secondary standards for O₃ and developing options for alternative standards. The information presented in this chapter was drawn from the Criteria Document (CD) and additional analyses of data from various O₃ monitoring networks.

This chapter particularly focuses on 1-hr, 8-hr, and 24-hr average concentrations metrics in characterizing urban O₃ air quality because these are the metrics most frequently used in the health effect studies discussed in the CD and Chapter 3 of this Staff Paper. For the vegetation exposure and risk assessment discussed in Chapter 7 of this Staff Paper, both the current secondary standard 8-hr. metric and the cumulative, concentration-weighted metric, SUM06, are used.

2.2 CHEMICAL AND PHYSICAL PROPERTIES, FORMATION, AND TRANSPORT

2.2.1 Chemical and Physical Properties

Ozone and other oxidants form mainly by chemical reactions in the atmosphere involving two classes of precursor pollutants, volatile organic compounds or VOCs and nitrogen oxides (NO_x) in the presence of sunlight. Ozone is, therefore, a secondary pollutant. Carbon monoxide (CO) can have a limited impact on O₃ formation in urban areas. The formation of O₃, other oxidants, and oxidation products from these precursors is a complex process involving many factors: the intensity and spectral distribution of sunlight; atmospheric mixing and processing on cloud and aerosol particles; the concentrations of the precursors in ambient air; and the rates of chemical reactions of the precursors. A more detailed discussion of these processes can be found in Chapter 2 of Volume 1 of Air Quality Criteria for Ozone and Related Photochemical Oxidants (CD, pp.2-1 – 29).

The effects of sunlight on O₃ formation, aside from the role of solar radiation in meteorological processes, depend on its intensity and its spectral distribution. Intensity varies diurnally, seasonally, and with latitude, but the effect of latitude is strongest in the winter. Ultraviolet radiation from the sun plays a key role in initiating the photochemical processes leading to O₃ formation and affects individual photolytic reaction steps. However, there is little

1 empirical evidence in the literature, directly linking day-to-day variations in observed surface
2 UV radiation levels with variations in tropospheric O₃ levels (CD, p.AX2-90).

3 **2.2.2 Formation**

4 The chemical formation of O₃ in the troposphere results from the oxidation of nitric oxide
5 (NO) to nitrogen dioxide (NO₂) by organic (RO₂) or hydro-peroxy (HO₂) radicals. Photolysis
6 (the chemical process of breaking down molecules into smaller units through the absorption of
7 light) of NO₂ yields NO and a ground-state oxygen atom, O(³P), which then reacts with
8 molecular oxygen to form ozone (CD, p.2-2).

9 In urban areas, both biogenic and anthropogenic VOCs are important for O₃ formation. In
10 non-urban, vegetated areas, biogenic VOCs emitted from vegetation tend to be the most
11 important. In the remote troposphere, CH₄ and CO are the main carbon-containing precursors to
12 O₃ formation. In coastal environments and other selected environments, atomic Cl and Br
13 radicals can also initiate the oxidation of VOCs (CD, p.2-2 and 2-3).

14 Oxidized nitrogen compounds are emitted to the atmosphere mainly as NO which is
15 oxidized to NO₂ which subsequently can be reduced back to NO. Consequently, NO and NO₂ are
16 often grouped together into their own family called NO_x (CD, p.2-3). NO_x is considered a good
17 surrogate for NO_y and, thus, is commonly monitored and reported (see Table 2-1). Oxidized
18 nitrogen containing compounds are essential to the formation of O₃ in the air. There are a large
19 number of oxidized nitrogen containing compounds in the atmosphere including NO, NO₂, NO₃,
20 HNO₂, HNO₃, N₂O₅, HNO₄, PAN and its homologues, other organic nitrates and particulate
21 nitrate. Collectively these species are referred to as NO_y.

22 **2.2.3 Transport**

23 The transport of O₃ and other secondary pollutants is determined by meteorological and
24 chemical processes extending typically over spatial scales of several hundred kilometers (e.g.,
25 Civerolo et al., 2003; Rao et al., 2003). An analysis of the output of regional model studies
26 conducted by Kasibhatla and Chameides (2000) suggests that O₃ can be transported over a few
27 thousand kilometers in the upper boundary layer of the eastern half of the United States during
28 specific O₃ episodes. Convection is capable of transporting O₃ and its precursors vertically
29 through the troposphere as shown in Annex AX2.3.2 of the CD. Nocturnal low-level jets (LLJs)
30 can also transport pollutants hundreds of kilometers over the mid-Atlantic region, the central
31 U.S. and California (Zhang et al., 2001). Turbulence associated with LLJs can bring these
32 pollutants to the surface and result in secondary O₃ maxima in the early morning in many
33 locations. However, the presence of mountain barriers can limit both horizontal and vertical

1 dispersion such as observed in Los Angeles and Mexico City and will resulting in a greater
2 frequency and duration of days with high O₃ concentrations (CD, p.2-10).

3 **2.2.4 Precursors, Sources and Emissions**

4 Although there are direct sources of O₃ (electrical discharges, lightning), ambient O₃
5 pollution problems are generally acknowledged to result from the secondary formation of O₃ via
6 the processes described in section 2.2.1.

7 Table 2-2 (see <http://www.epa.gov/airtrends/econ-emissions.html>) lists the main sources
8 of VOC emissions from 1970-2004. The categories in the table are self explanatory with the
9 exception of the fires and miscellaneous categories. The fires category includes both wild fires
10 and prescribed burns. The miscellaneous category includes mainly structural fires and sources
11 from agricultural activities. One category not in either table is biogenic emissions. Biogenic
12 emissions are an important factor on warm to hot days in heavily vegetated areas. As can be
13 seen in the table, highway vehicles have been the single largest source of VOC emissions over
14 the years ranging from about 49% of total emissions in 1970 to about 27% of total emissions in
15 2004. Starting in 2001, solvent use and highway vehicles were the two main sources of VOCs
16 with roughly equal contributions to the total emissions.

17 Table 2-1 contains the same emission information but for NO_x emissions. Again,
18 highway vehicles are the single largest source of NO_x emissions over the years ranging from
19 about 47% of total emissions in 1970 to about 37% of total emissions in 2004.

20 **2.2.5 Tropospheric vs. Stratospheric Ozone**

21 The atmosphere can be divided into several distinct vertical layers, based primarily on the
22 major mechanisms by which they are heated and cooled. The lowest major layer is the
23 troposphere, which extends from the earth's surface to about 8 km above the surface in polar
24 regions and to about 16 km above the surface in tropical regions. The planetary boundary layer
25 (PBL) is the lower sub-layer of the troposphere, extending from the surface to about 1 or 2 km,
26 and is most strongly affected by surface conditions. The stratosphere extends from the top of the
27 troposphere, to about 50 km in altitude. The emphasis in this chapter is placed on concentrations
28 of O₃ occurring in the lower troposphere, in particular in the PBL (CD, p.2-1).

29 In urban environments, the rate of O₃ formation is sensitive to the rate of photolysis of
30 several species including H₂CO, H₂O₂, O₃, and especially NO₂. Monte Carlo calculations suggest
31 that model simulations of photochemical O₃ production are most sensitive to uncertainty in the
32 photolysis rate coefficient for NO₂ (CD, p.AX2-90).

2.2.6 Relationship of Ozone to Photochemical Oxidants

Photochemical oxidants are strongly oxidizing compounds, which are the primary constituents of photochemical smog. The photochemical oxidants found in ambient air in the highest concentrations are O₃ and nitrogen dioxide (NO₂). Other oxidants, such as hydrogen peroxide (H₂O₂) and peroxyacylnitrates (PANs) are produced in much smaller quantities than O₃. In 1971, EPA promulgated NAAQS to protect the public health and welfare from adverse effects of photochemical oxidants, at that time, defined on the basis of commercially available measurement methodology. After 1971, however, O₃-specific commercial analytical methods became available, as did information on the concentrations and effects of the related non-O₃ photochemical oxidants. As a result, the indicator or chemical designation of the standards was changed in 1979 from photochemical oxidants to O₃. As discussed in Chapter 3, use of O₃ for this NAAQS has served as a surrogate or indicator for the health effects associated with the overall photochemical oxidant mix, including O₃-related effects. However, it is virtually impossible to quantify in a practical manner the aggregate effects of photochemical oxidants that generally exist in concentrations not measurable with routine technologies, and are fundamentally intertwined with O₃ atmospheric chemistry. Ambient O₃ can be measured reliably and has been associated independently with health outcomes, and therefore has the attributes of being both a reasonable and practical indicator of the ambient mix of photochemical oxidants.

2.3 DATA SOURCES

Two main sources of monitoring data were used for this assessment, the state-supplied data from various types of monitors housed in the Air Quality System (AQS) data base (which includes National Park Service monitors) and the Clean Air Status and Trends Network (CASTNET). The vegetation exposure analysis also uses an enhanced Veroni Neighborhood Average (eVNA) spatial interpolation technique to combine 2001 monitor data from both AQS and CASTNET with 2001 modeled data from the Community Multi-scale Air Quality (CMAQ) model. This interpolated surface is used to fill in the gaps left by a sparse rural monitoring network in the western United States.

Air quality models are often used to simulate the formation, transport, and decay of air pollution. The CMAQ modeling system is a comprehensive three-dimensional grid-based Eulerian air quality model designed to estimate O₃ and particulate concentrations and deposition over large spatial scales (Dennis et al., 1996; Byun and Ching, 1999). The CMAQ model is a publicly available, widely-used, peer-reviewed, state-of-the-science model consisting of a number of science attributes that are critical for simulating the oxidant precursors and nonlinear

2 Figure 2-1. Locations of Ozone Monitors from AQS and CASTNET

1 organic and inorganic chemical relationships associated with the formation of O₃, as well as
2 sulfate, nitrate, and organic aerosols.

3 For this Staff Paper, the three most recent years of reported and certified data available in
4 AQS was 2002-2004. The 2005 data would not be certified until July 1, 2006.

5 **2.3.1 Air Quality System (AQS)**

6 EPA's ambient air quality surveillance regulations are found at 40 CFR Part 58. Section
7 58.20 requires States to provide for the establishment of air quality surveillance systems in their
8 State Implementation Plans (SIP). The air quality surveillance system consists of a network of
9 monitoring stations designated as State and Local Air Monitoring Stations (SLAMS), which
10 measure ambient concentrations of those pollutants for which standards have been established in
11 40 CFR Part 50. SLAMS, National Air Monitoring Stations (NAMS), which are a subset of
12 SLAMS, and Photochemical Assessment Monitoring Stations (PAMS) must meet the
13 requirements of 40 CFR Part 58, Appendices A (Quality Assurance Requirements), C (Ambient
14 Air Quality Monitoring Methodology), D (Network Design Criteria), and E (Probe and Path
15 Siting Criteria).

16 The Air Quality System (AQS) is EPA's repository of ambient air quality data. AQS
17 stores data from over 10,000 monitors; 5000 of which are currently active. Of these, over 3000
18 measure and report O₃ concentration data (See Figure 2-1). These monitors make up the
19 SLAMS, PAMS, NAMS, and other special purpose monitors used and operated by the States.
20 AQS also contains meteorological data, descriptive information about each monitoring station
21 (including its geographic location and its operator), and data quality assurance/quality control
22 information. The Office of Air Quality Planning and Standards (OAQPS) and other AQS users
23 rely upon the data system to assess air quality, assist in Attainment/Non-Attainment
24 designations, evaluate State Implementation Plans for Non-Attainment Areas, perform modeling
25 for permit review analysis, and other air quality management functions. AQS information is also
26 used to prepare reports for Congress as mandated by the Clean Air Act (see
27 <http://www.epa.gov/ttn/airs/airsaqs/sysoverview.htm>).

28 The NAMS/PAMS/SLAMS O₃ monitor network achieved an overall average bias (upper
29 bound) of 0.2% and an overall mean precision of 3% for 2002. If special purpose and other O₃
30 monitors are also included the average upper bounds of bias and precision were 0.4% and 2.9%
31 respectively (U.S. EPA 2004a).

32 **2.3.2 CASTNET**

33 CASTNET is the nation's primary source for data on dry acidic deposition and rural,
34 ground-level O₃. Operating since 1987, CASTNET is used in conjunction with other national

1 monitoring networks to provide information for evaluating the effectiveness of national emission
2 control strategies. CASTNET consists of over 80 sites across the eastern and western United
3 States (see Figure 2-1) and is cooperatively operated and funded with the National Park Service.
4 In 1986, EPA established the National Dry Deposition Network (NDDN) to obtain field data on
5 rural deposition patterns and trends at different locations throughout the United States. The
6 network consisted of 50 monitoring sites that derived dry deposition data based on measured air
7 pollutant concentrations and modeled dry deposition velocities estimated from meteorology, land
8 use, and site characteristic data. In 1990, amendments to the Clean Air Act necessitated a long-
9 term, national program to monitor the status and trends of air pollutant emissions, ambient air
10 quality, and pollutant deposition. In response, EPA, in cooperation with the National Oceanic
11 Atmospheric Administration (NOAA), created CASTNET from NDDN. In terms of data quality,
12 CASTNET achieved 98% to 99% of all precision and accuracy audits being within the $\pm 10\%$
13 criteria for both precision and accuracy. Overall, CASTNET O₃ monitors are stable and show
14 only very small variation (U.S. EPA 2003, p.22).

15 **2.4 OZONE MONITORING METHODS AND DATA QUALITY**

16 **2.4.1 Ozone Monitoring Methods**

17 Ozone monitoring is conducted almost exclusively with UV absorption spectrometry with
18 commercial short path instruments, a method that has been thoroughly evaluated in clean air. The
19 ultimate reference method is a relatively long-path UV absorption instrument maintained under
20 carefully controlled conditions at the National Institute of Standards and Technology (NIST)
21 (CD, p.2-22).

22 Several reports in the reviewed scientific literature have investigated interferences in O₃
23 detection via UV radiation absorption and chemiluminescence. These include the effects of
24 water vapor, VOC's, aromatic compounds and their oxidation products, and other organic and
25 inorganic compounds. Water vapor had no significant impact on UV absorption-based
26 instruments, but could cause a positive interference of up to 9% in chemiluminescence-based
27 detectors at high humidities (dew point of 24° C). Aromatic compounds and their oxidation
28 products were found to generate a positive but small interference in the UV absorption
29 instruments. However, when the results are applied to ambient concentrations of toluene and
30 NO_x, the effect appears to be very minor (about 3 percent under the study conditions). Other
31 organic and inorganic compounds displayed interferences, but not at levels likely to interfere
32 with accurate determination of O₃ in an urban environment. The possibility for substantive
33 interferences in O₃ detection exists, but such interferences have not been observed even in urban
34 plumes (CD, p.2-25).

1 Ozone is also measured by differential optical absorption spectroscopy (DOAS) at a
2 variety of wavelengths in the UV and visible parts of the spectrum. Comparisons of DOAS
3 results to those from a UV absorption instrument showed good agreement on the order of 10%.
4 Researchers have reported a positive interference due to an unidentified absorber in the 279 to
5 289 nm spectral region used by many commercial short-path DOAS systems for the
6 measurement of O₃. Results of that study suggest that compounds from wood burning, used for
7 domestic heating, may be responsible (CD, p.AX2-149).

8 9 **2.4.2 Effect of Measurement Precision on 8 hour Ozone Averages**

10 For 2002 to 2004, the average precision in the collected O₃ measurements was
11 approximately 3%. This means, for example, that a 1-hr measured concentration of 100 ppb
12 could be between 97 ppb and 103 ppb. Staff conducted an analysis to determine the precision of
13 an 8-hr averaged O₃ concentration (Cox and Camalier, 2006). Daily maximum 8-hr O₃ values
14 were simulated using a Weibull distribution to yield a “true” three-year averaged O₃ design value
15 without the influence of measurement error.

16 Utilizing site specific precision data from 900 O₃ monitors for the 2002 through 2004 O₃
17 seasons, a second set of 8-hr O₃ concentrations was generated to incorporate the precision data
18 from the O₃ monitoring network to account for instrument measurement error. The result was a
19 value which reflected the “true” O₃ design value plus measurement error. The difference
20 between the value with measurement error and the “true value” reflects the impact of the
21 instrument measurement error on the calculated 8-hr design value.

22 The exercise was repeated 1000 times and the differences between the two previously
23 described design values were summarized. Table 2-3 shows the results of the analysis. The
24 percentiles presented in the table reflect the percentage of sites at or below the corresponding 1-
25 hour precision value. The table shows that even at a precision of approximately 4.5% of which
26 95% of the O₃ sites are at or below, the standard deviation of the difference between the 8-hr
27 design values is less than 1 ppb.

28 A second exercise was performed to incorporate systematic bias error which includes the
29 instrument drift, noise, precision and calibration error associated with the UV absorption method.
30 It was assumed that each 8-hr measurement was subjected to this randomly occurring bias which
31 had an average of zero and a standard deviation of approximately 4 ppb. The mean and standard
32 deviation utilized for the simulation were believed to be reasonable estimates for monitors
33 operating under normal conditions. The results of this exercise show that assuming a random
34 bias of 4 ppb produced an uncertainty in the 8-hr design value of approximately 1.3 ppb.

35 It should be noted that the above estimate does not account for potential interferences
36 known to exist with the UV absorption method “due to positive interference by a number of

1 **Table 2-3. Relationship between Precision of 1-hour Ozone Data and Corresponding Standard Deviation of 8-hour Design**
 2 **Values**

Precision of 1- hour ozone value (%)	Nationwide Percentile	Standard Deviation of Difference in DV's (ppb)
1.63	25	0.27
2.22	50	0.34
2.97	75	0.45
3.89	90	0.57
4.52	95	0.63

1 organic compounds, mainly those produced during the oxidation of aromatic hydrocarbons and
2 some primary compounds such as styrene and naphthalene.” These observations, however, were
3 made during studies in Mexico City and a smog chamber where concentrations of these types of
4 compounds were many times higher than are typically found at ambient air monitoring sites in
5 the United States (CD, p.AX2-148).
6

7 **2.5 CHARACTERIZATION OF GROUND-LEVEL OZONE CONCENTRATIONS**

8 **2.5.1 Metrics**

9 This section characterizes ground level O₃ concentrations based on several metrics. Two
10 daily maximum statistics, 1-hr and 8-hr averages, and one daily average statistic in the form of a
11 24-hr concentration, and one cumulative concentration weighted statistic, the SUM06, are
12 summarized to show how O₃ varies over space and time. The 1-hr and 8-hr daily maximum
13 averaging times reflect the former and current O₃ standards, and much of the health effects
14 literature for O₃ has focused on effects associated with these averaging times. The 24-hr daily
15 average has been used for several personal exposure studies (CD, pp.3-72 – 74). The SUM06
16 has been used frequently in the scientific literature and CD in studying and assessing the
17 relationship between O₃ exposures and adverse effects on vegetation. The daily maximum 8-hr
18 values are found by first calculating running or moving 8-hr values for all 24 hours in a day (for
19 example, averaging the 1-hr concentrations from 1:00am to 8:00 am, then average the 1-hr
20 values from 2:00am to 9:00 am, etc.). Then the maximum value for each day is found (note that
21 any 8-hr time period that starts in a day is assigned to that day). On an annual basis, the fourth
22 highest of these values is summarized. The daily maximum 1-hr statistic is the maximum value
23 of all 1-hr values in a day. On an annual basis, the second highest of these values in a year is
24 summarized. The 24-hr average is a mean of the 24 individual hourly concentrations measured
25 from midnight to midnight. The maximum, 3 month, 12 hour SUM06 statistic is calculated by
26 cumulating all 1-hr values greater than or equal to 0.06ppm that occur during the 12 hour daytime
27 window (8:00am to 8:00pm Local Standard Time) for each month of the O₃ monitoring season
28 and then finding the largest consecutive 3-month sum of these values in an O₃ monitoring season
29 according to the secondary standard proposed in 1996 (61 FR Dec 13, 1996), but not adopted in
30 1997 (62 FR Jul 18, 1997). The SUM06 has a weighting function that is 0 when
31 the concentration is less than 0.06 and is 1.0 when the concentration is greater than or equal to
32 0.06.

2.5.2 Spatial Variability

This section characterizes the spatial variability of O₃ based on all the metrics discussed above. Spatial variability is based on maps displaying county levels of the various metrics. In this way different levels of O₃ for different areas of the country are displayed.

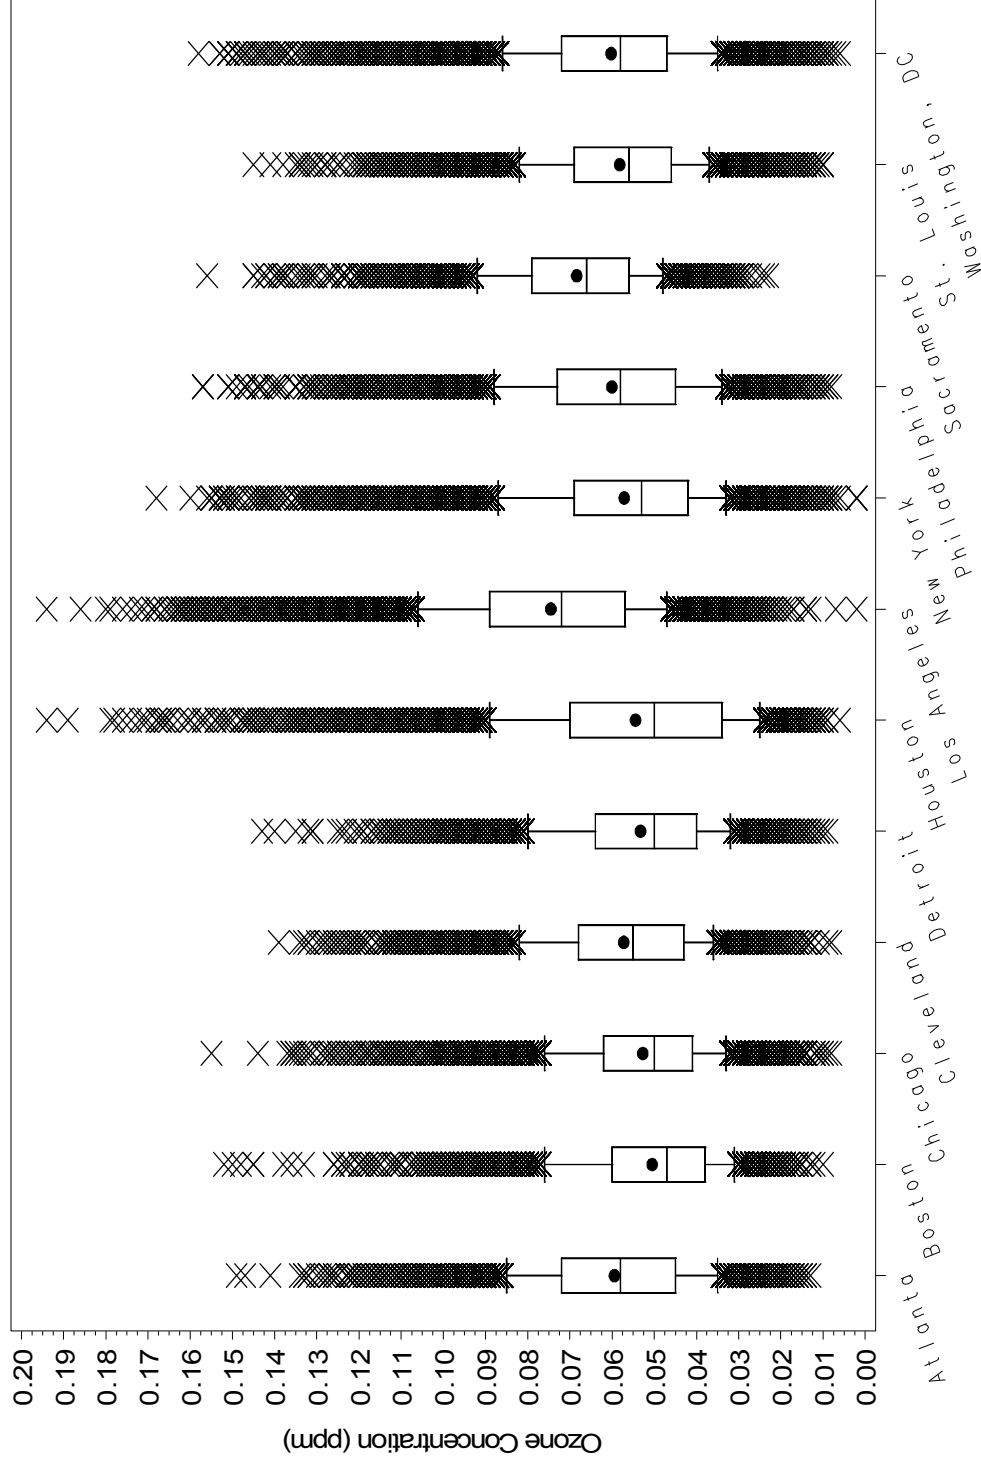

2.5.2.1 Comparison of 1-hr, 8-hr, and 24-hr Ozone Metrics

Figures 2-2 to 2-4 show the distributions for measured 1-hr, 8-hr, and 24-hour daily average ozone concentrations for 12 major urban areas in the United States. The Los Angeles area clearly has a distribution which is different from the other 11 cities in that the hourly concentration interquartile range is within 0.057 to 0.089 ppm as opposed to the next highest interquartile range of Sacramento where 50% of the hourly concentrations lie between 0.056 and 0.079 ppm. In comparison, Houston which also has several 1-hr concentrations greater than 0.125 ppm has a lower interquartile range of 0.034 to 0.07 ppm with 10% of its hourly values greater than 0.089 ppm as opposed to approximately 0.106 ppm for Los Angeles. Houston also has a larger interquartile range of 0.036 ppm when compared to the average of the remaining 11 cities of 0.025 ppm. This trend is also observed in the 8-hr averaged concentrations. The remaining 9 cities all exhibit similar distributions to one another for the 1-hr and 8-hr metrics.

When examining the 24-hour daily averaged concentration distributions, the nine cities which had similar distributions for the 1-hr and 8-hr concentrations still exhibit the same similarity. However, Houston shows a lower 75th percentile than the other cities with areas like Cleveland, Philadelphia and New York having higher distributions. The lower 24 hour concentrations in Houston indicate a wider range between the daily ozone minima and maxima unlike an area like Cleveland, which has a higher interquartile range. This implies higher overall background concentrations, possibly caused by transport from other major urban areas.

2.5.2.2 8-Hour and 1-Hour Statistics

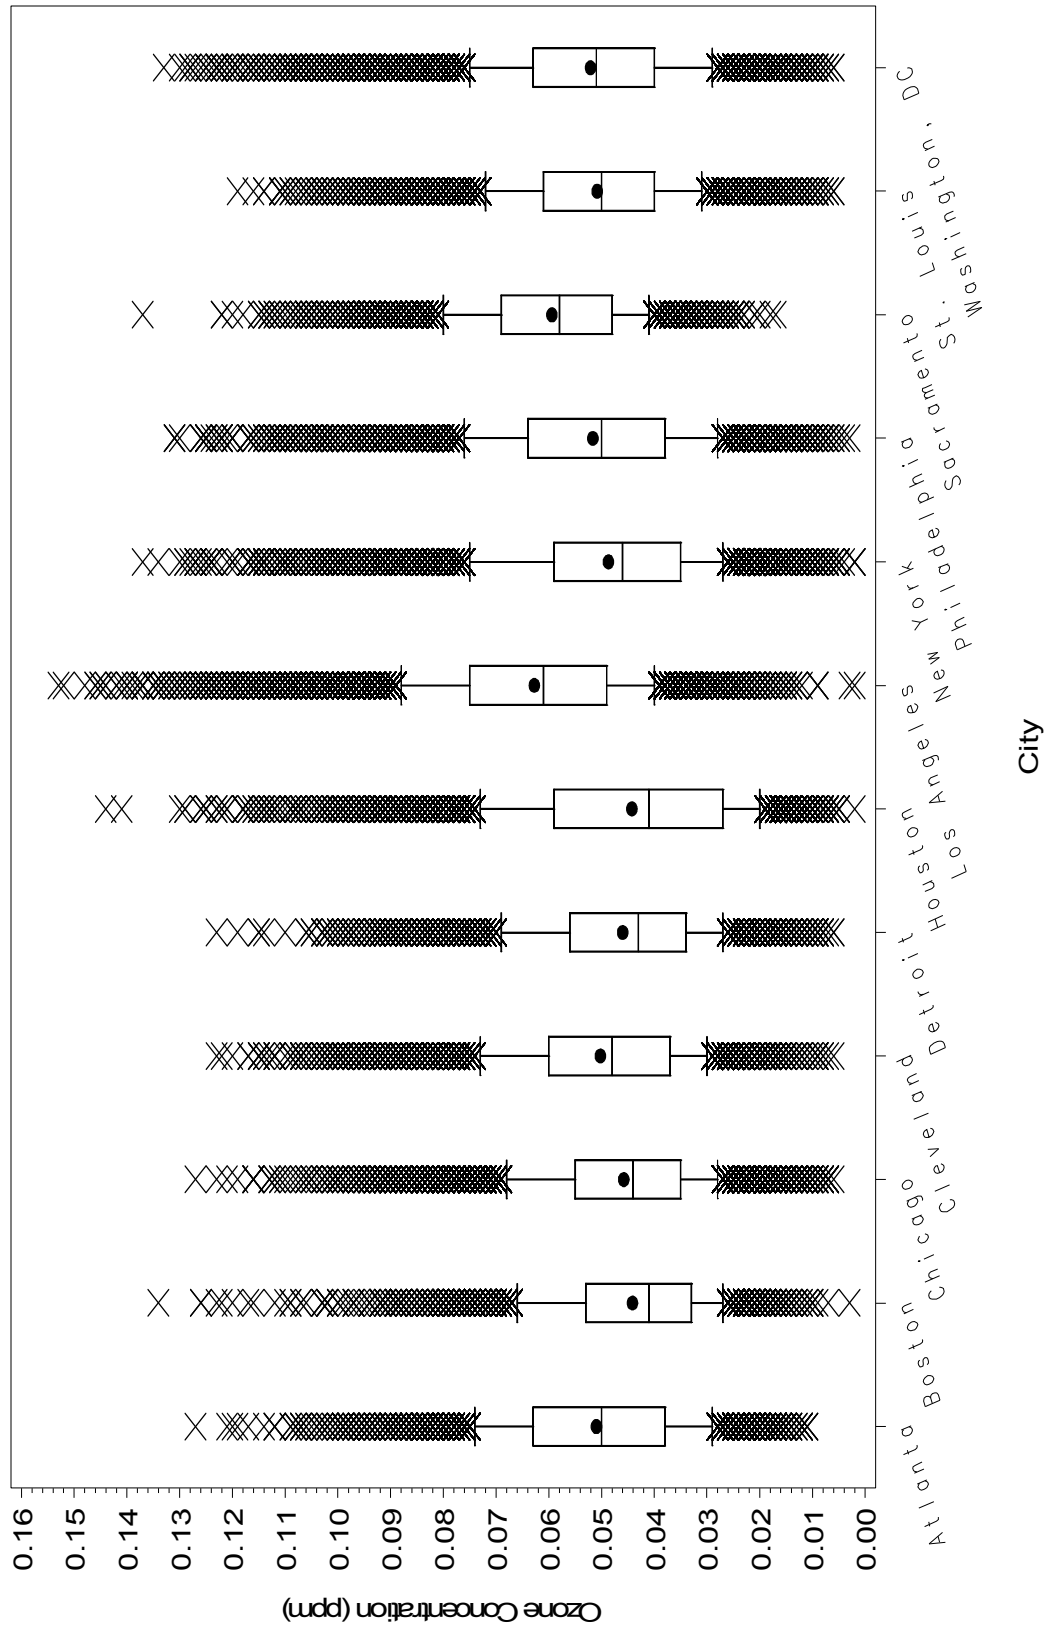

High 8-hr average O₃ concentrations tend to occur near larger urban areas exhibiting similar patterns as corresponding 1-hr concentrations (see Figure 2-5). Elevated 8-hr levels occurring in smaller urban and non-urban areas are most likely caused by transport (see Figure 2-6). Higher 8-hr O₃ levels observed in smaller urban and non-urban areas are most obvious at the end of the northeast corridor (the highly urbanized area running from Washington, DC to Boston, MA), North-central New York, and the Northern coast of Lake Michigan. Some of the highest levels occur not in California but in Texas, some counties in the Northeast Corridor, and isolated counties in the East (see Figure 2-6) (Fitz-Simons, et al., 2005). The highest 1-hr levels occur in California. (Fitz-Simons, et al., 2005).

2.5.2.3 Cumulative Concentration-Weighted Statistics

The highest SUM06 levels in 2001 (most of the analyses in Chapter 7 center on 2001 data) occurred in most of the agricultural areas of California. When the data were from CASTNET sites, more purely rural counties showed higher values (See Figure 2-7, 2-8). (Fitz-Simons, et al., 2005). The SUM06 values experienced a sharp decline in 2004 when compared to 2002 primarily in the eastern part of the United States (See Figure 2-9, 2-10). Although there were reductions in the West, the decreases in the East were more substantial. The overall reductions across the country could possibly be due to lower temperatures experienced during the O₃ season. However, the eastern half of the country was also subject to the emission control requirements implemented under the NO_x SIP Call which occurred after 2002. The improvements seen in 2004 for the East are most likely due to a combination of cooler weather and the emission reductions from the NO_x SIP Call.

2.5.3 Temporal Variability

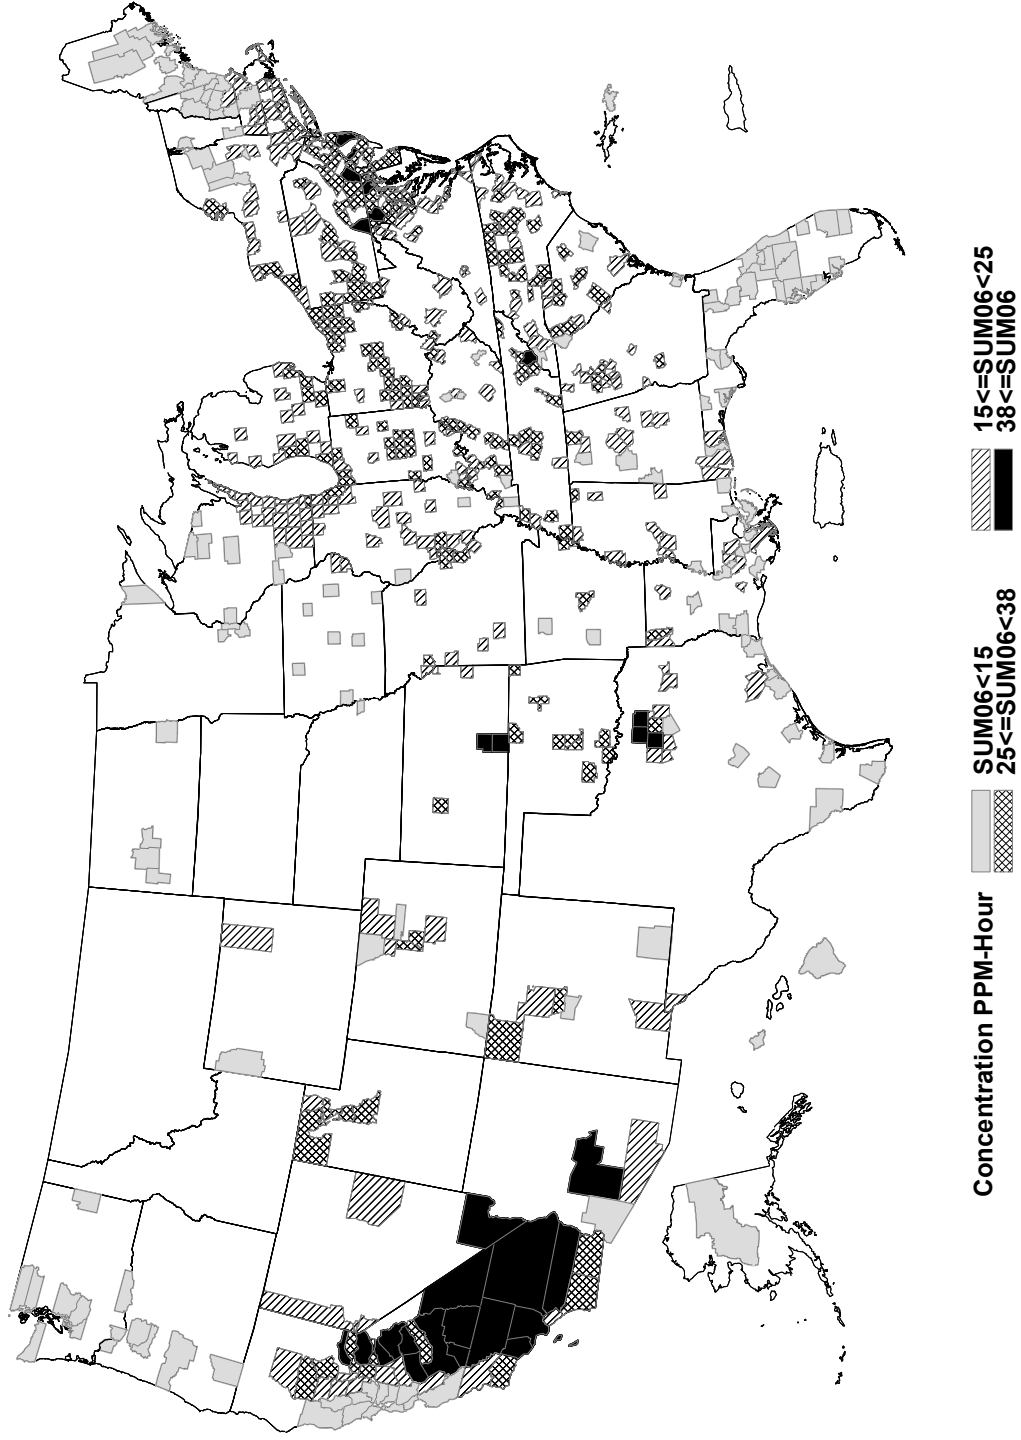

Temporal variability consists of several time frames when considering characterization of ground level air quality data. Multi-year variability characterizes long term variability or year to year variability. Trends usually provide evidence on whether or not a situation is getting better or worse over time. For the purposes of displaying long term trends, the data from both AQS and CASTNET are screened for temporally consistent data (only data from sites that meet a data completeness criteria of 12 complete years out of 15 and no gaps of more than 3 consecutive years are included). Seasonal variability characterizes month to month variability to demonstrate when in the year the highest concentrations occur. Diurnal variability characterizes hour-to-hour changes demonstrating when, in the day, the highest concentrations occur (Fitz-Simons, et al., 2005).

2.5.3.1 Long Term Variability – Trends

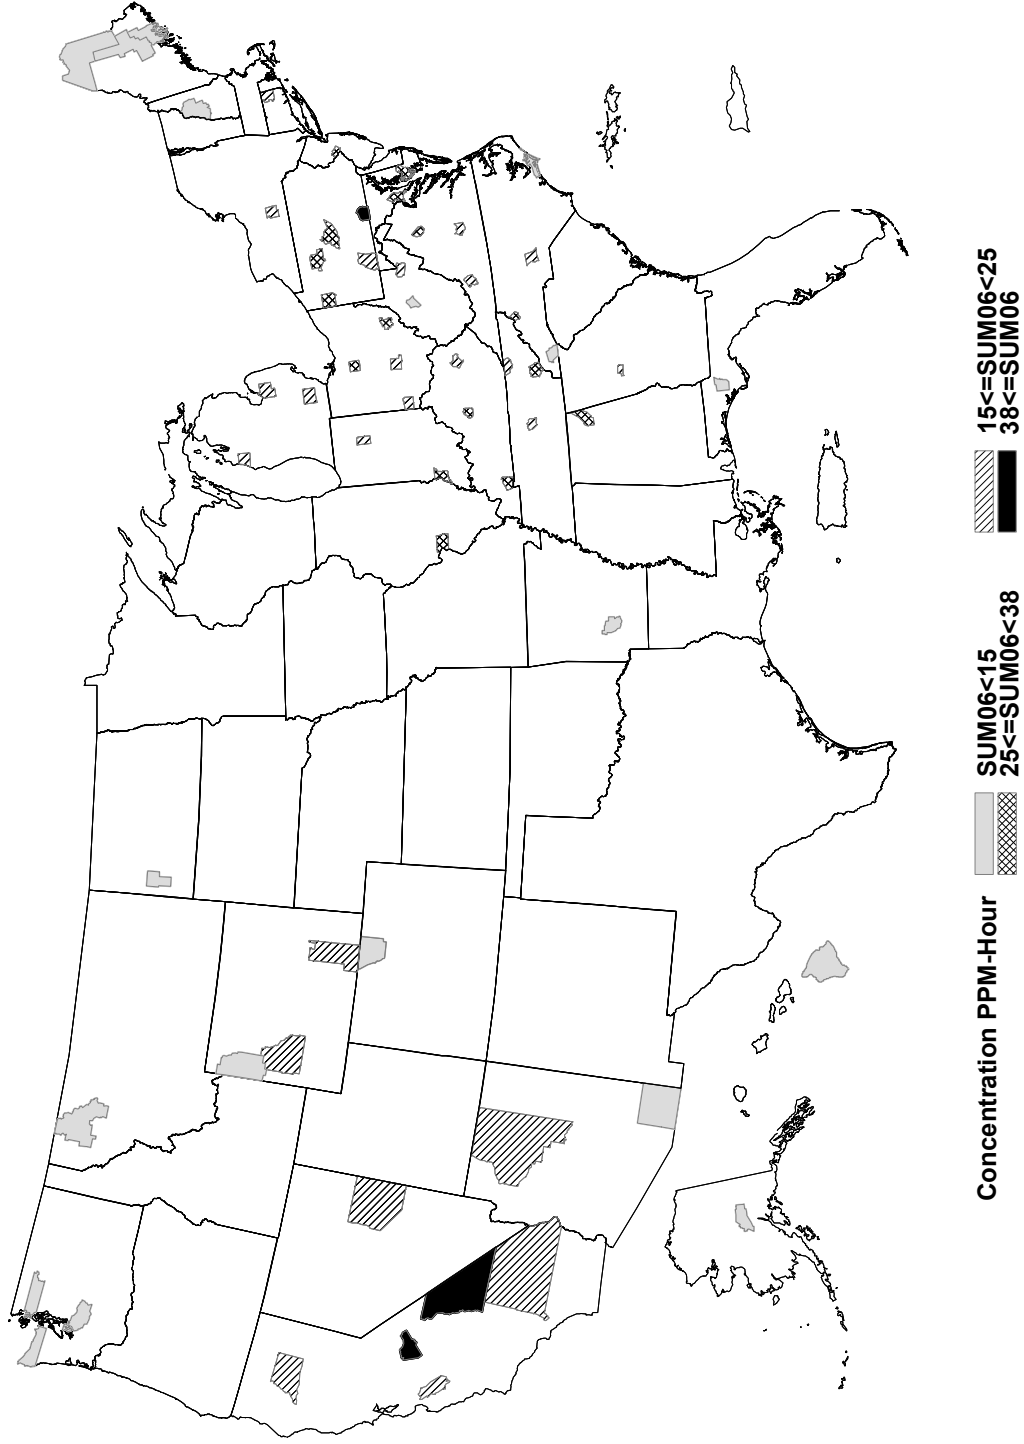

Long term, nationwide trends for 8-hr O₃ values are presented in Figures 2-11 and 2-12. Figure 2-11 presents data from sites in the AQS that meet trends criteria and have locations described as Urban and Center City. Figure 2-12 presents data from CASTNET which are rural locations.

The rural and urban trends are similar, but the urban trends have more data and more variation. The rural means are slightly lower than the urban means; however the largest urban concentrations are much higher than the largest rural concentrations (Fitz-Simons, et al., 2005).

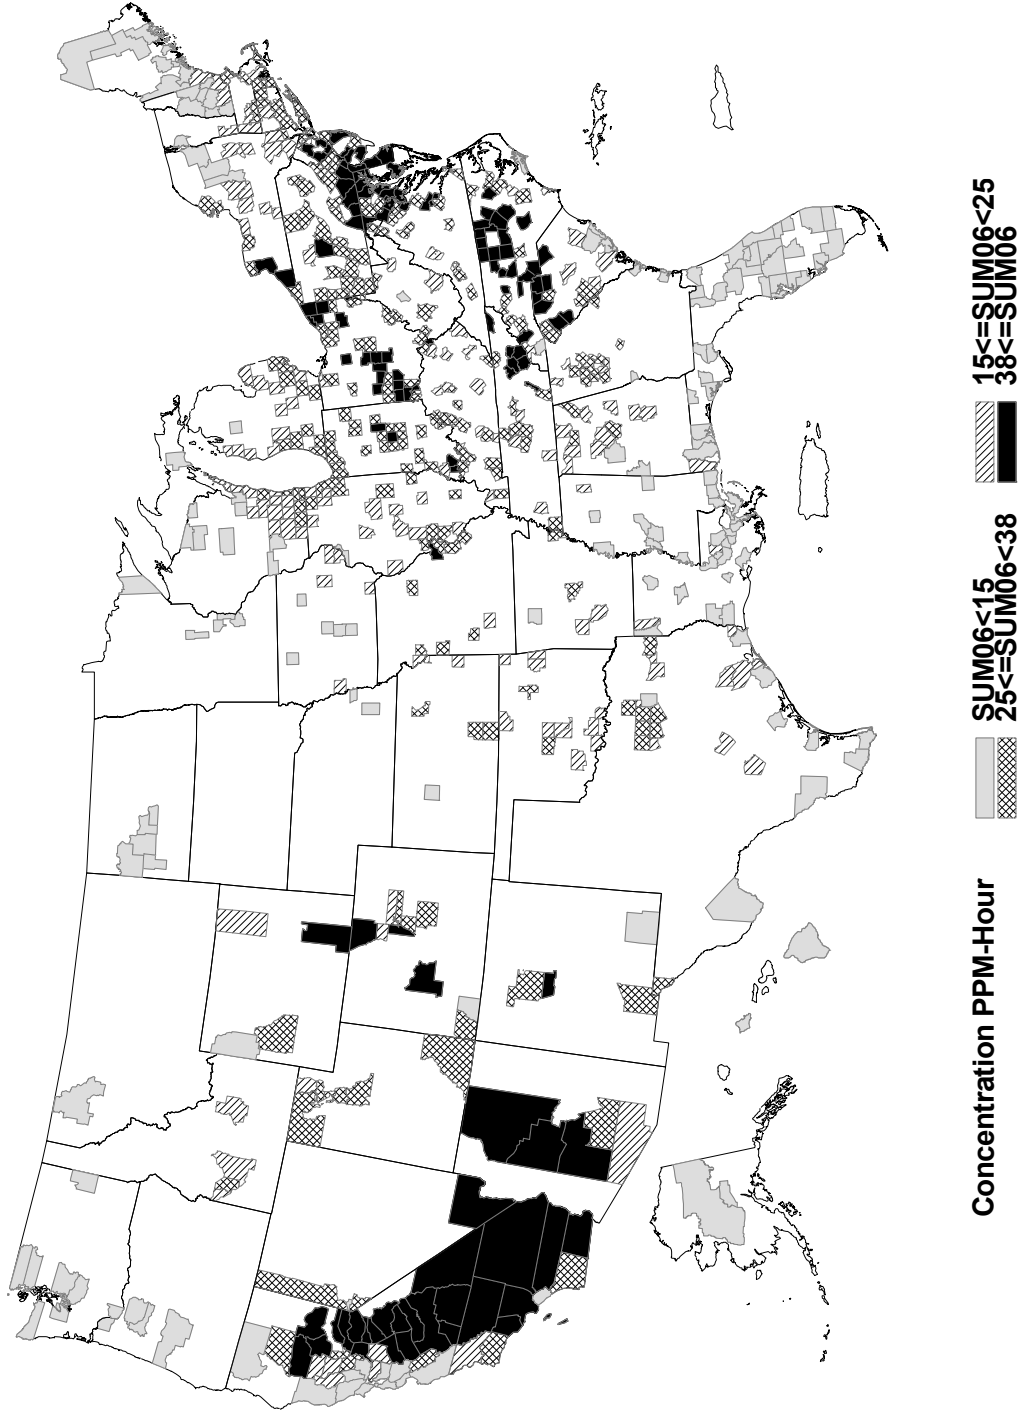

Long term trends for 1-hr O₃ values are presented in Figures 2-13 and 2-14. Figure 2-13 presents data from sites in the AQS that meet trends criteria and have locations described as Urban and Center City. Figure 2-14 presents data from CASTNET which are rural locations. As with the 8-hr data, the 1-hr urban trends and rural trends are similar, but urban have more data

1 and more variation. The 1-hr means for the urban trends are higher than the means for the rural
2 trends. This difference is more pronounced than in the 8-hr trends (Fitz-Simons, et al., 2005).

3 The long term trends for both 1-hr and 8-hr O₃ data are similar. The 8-hr concentrations
4 are lower, but the trends are basically parallel. The highest means occur in 1990,1991,1995,
5 1998 and 2002. The highest extreme values are clearly in the 1990s. In many cases, short term
6 variation (3 years or less) is associated with meteorological conditions that are generally more or
7 less conducive to O₃ formation in a particular year. One high year between two low years or one
8 low year between two higher years are examples of this 3 years or less variation (see Evaluating
9 Ozone Control Programs in the Eastern United States: NO_x p.17, U.S. EPA, 2005b).

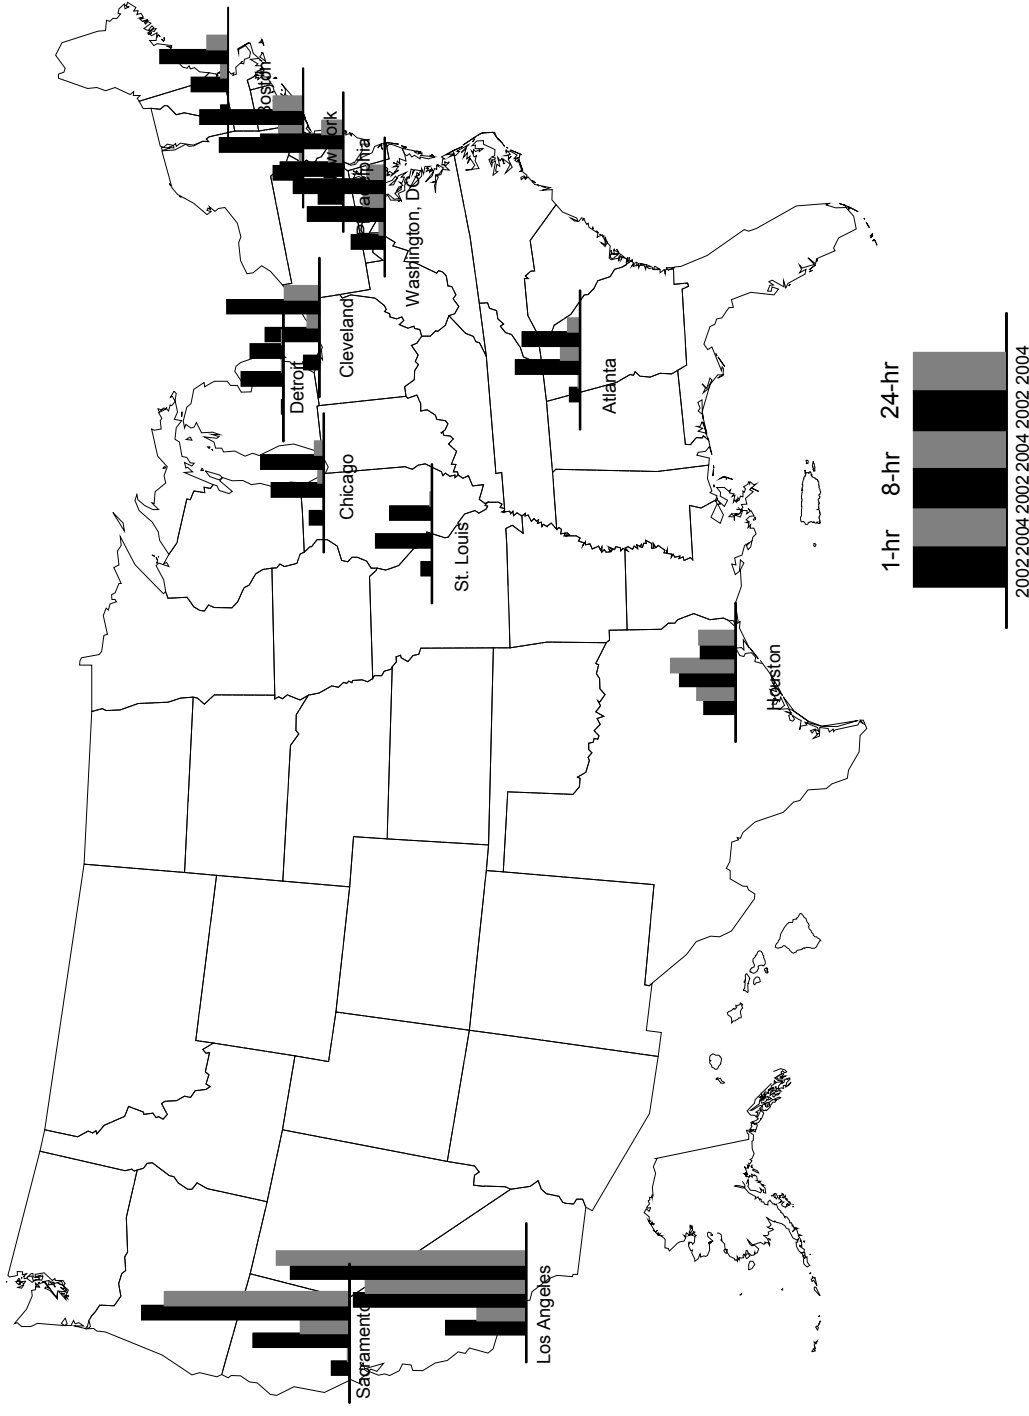

10 **2.5.3.2 Short Term Variability – Annual**

11 Figure 2-15 shows a map of the number of exceedance days for 2002 and 2004 at 12
12 urban locations in the United States. Each grouping of two bars represents the number of
13 exceedance days for 1-hr, 8-hr averaged and 24-hr averaged ozone concentrations. The 1-hr
14 measured concentrations were compared to the previous 1-hr ozone standard of 0.12 ppm , 8
15 hour averaged concentrations were compared to the current ozone standard of 0.08 ppm and the
16 average 24 hour concentrations were compared to 0.055 ppm which is the 95th percentile for 24
17 hour ozone concentrations across the United States for 2002 through 2004. The data show that
18 in all sites in the Midwest and the East, ozone concentrations were down dramatically in 2004
19 when compared to 2002. This is due in part to the fact that 2004 was much cooler than 2002, but
20 also reflects the improvement in air quality due to NO_x emission reductions in 2003 and 2004
21 due to the NO_x SIP Call, which concentrated on reducing NO_x in the eastern part of the country,
22 thereby reducing peak O₃ concentrations (U.S. EPA, 2005b). However, Houston, Los Angeles
23 and Sacramento which were not included in NO_x SIP Call did not see these declines. The
24 number of 8-hr exceedance days actually increased for Houston while remaining around the
25 same in Los Angeles. The number of days greater than 0.055 ppm for the 24 hour averaged
26 concentrations remained around the same or was slightly higher for 2004 than 2002 for all three
27 cities west of the Mississippi River.

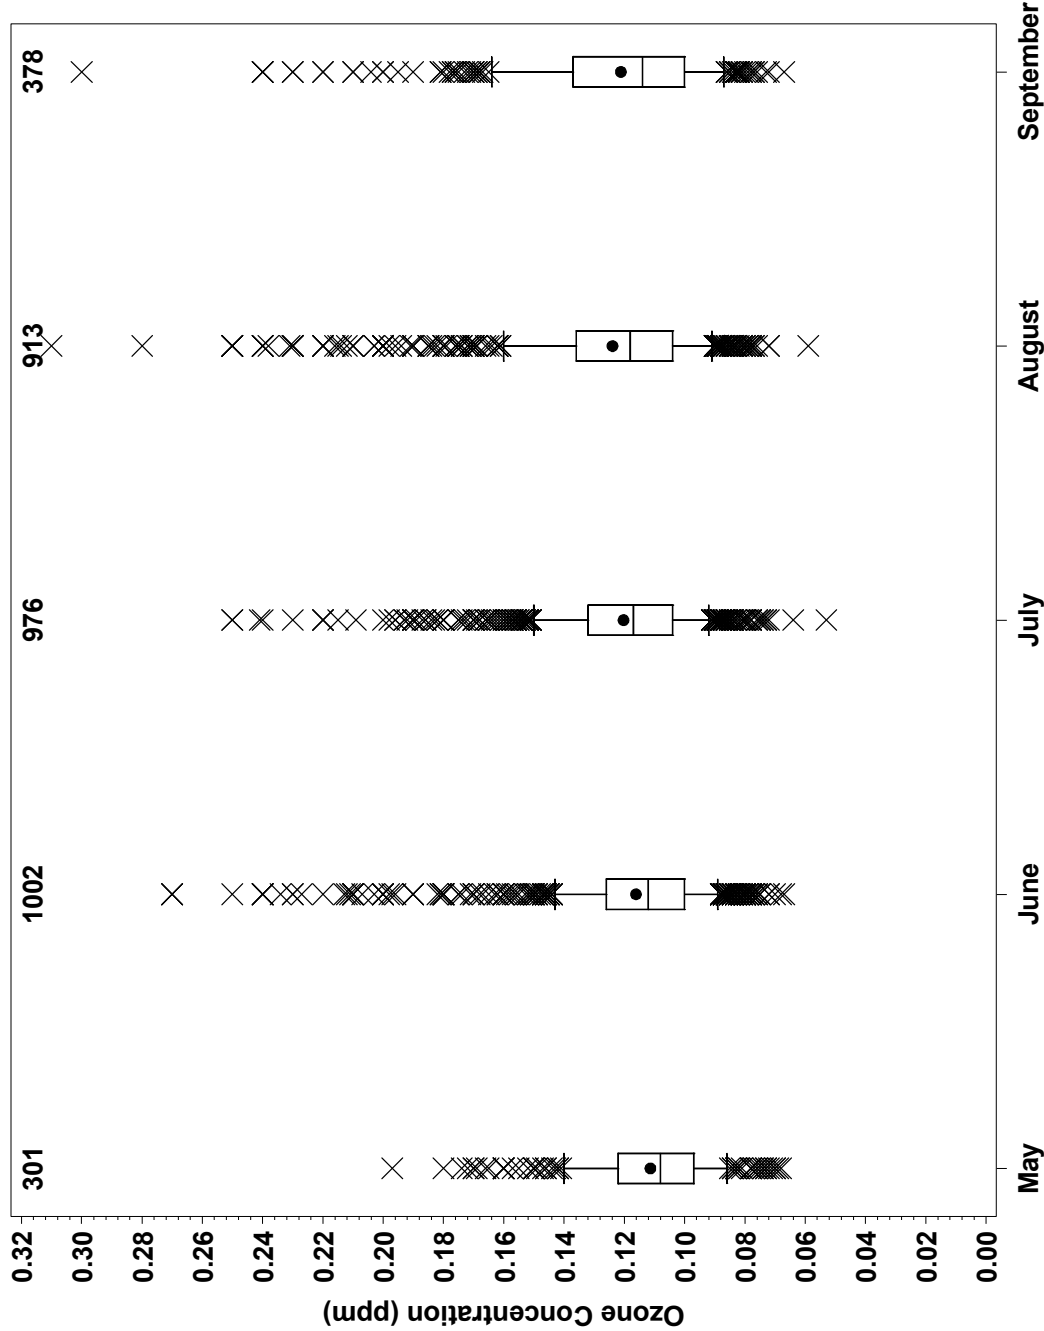

28 **2.5.3.3 Seasonal Variability**

29 Monthly statistics are the best method to characterize seasonal variation in O₃
30 concentrations. However in many areas, monitors are not active during cooler months. As a
31 result, data from May through September are the only universally available data for all monitors.
32 Although this is a limited characterization of seasonal variability, it is consistent across the entire
33 national network.

34 Figure 2-16 shows box-plots of all 2004 data from May through September for the
35 second highest daily 1-hr maximums. The center of the distribution shows a slight, steady

5 Data Source: AQS

1 increase from May to September while the extreme values show a more pronounced but more
2 variable increase for the same period (Fitz-Simons, et al., 2005).

3 Figure 2-17 shows box-plots of all 2004 data from May through September for the fourth
4 highest daily 8-hr maximums. The center of the distribution and the extremes show a slight,
5 steady increase from May to July followed by a slight decrease from July through September
6 (Fitz-Simons, et al., 2005).

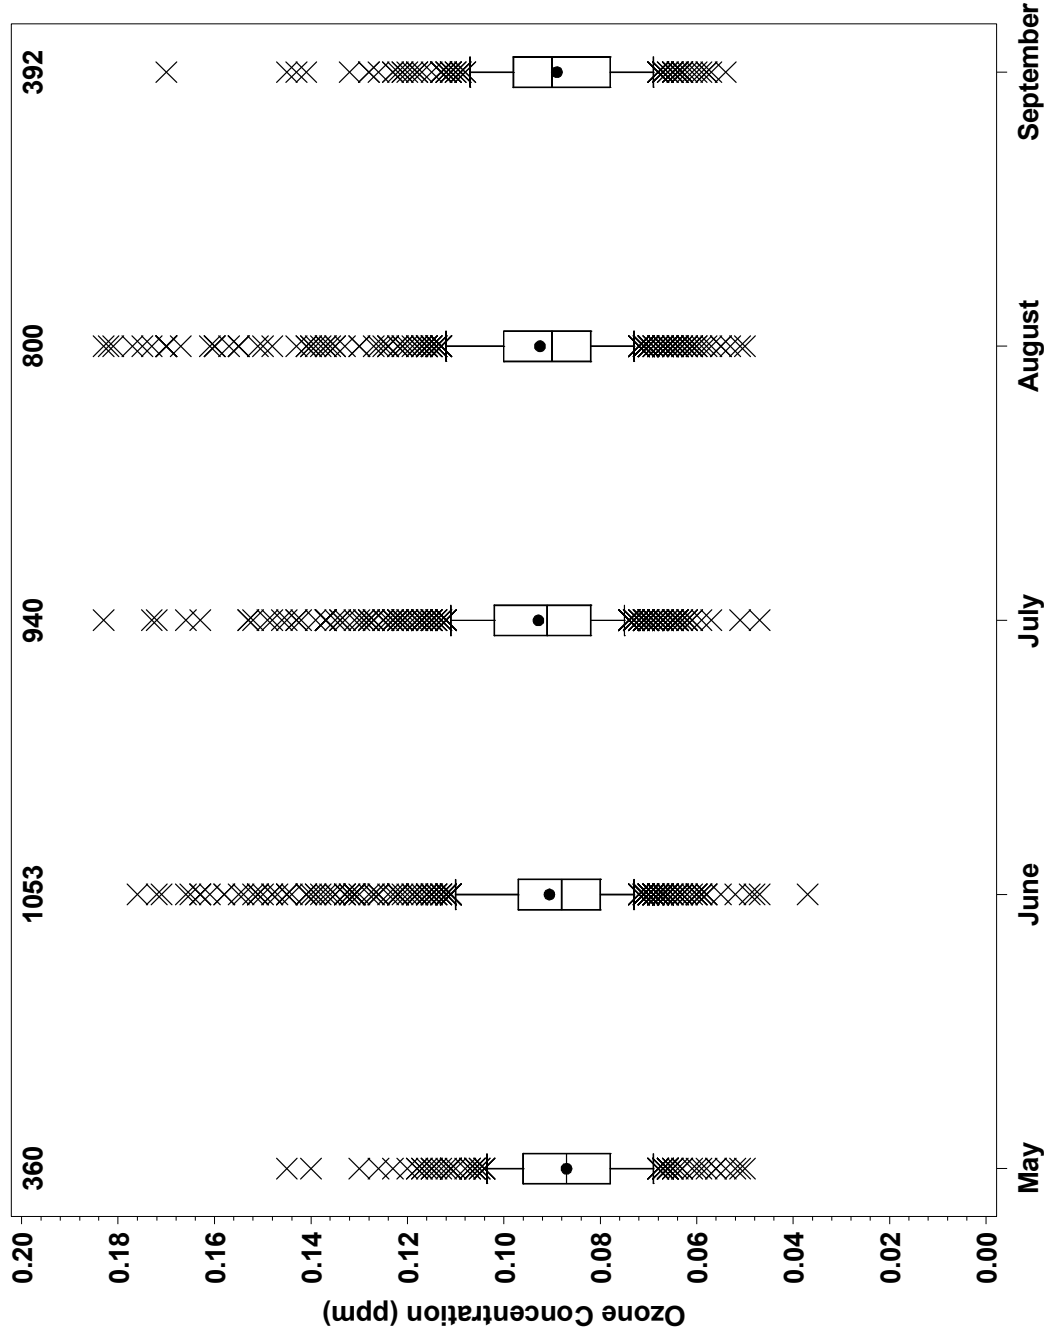

7 **2.5.3.4 Short Term Variability – Diurnal**

8 The daily cycles of human activity and the solar phase drive the hour-to-hour daily cycle
9 seen in ground level O₃ concentrations. The daily 1-hr peak levels generally occur in the
10 afternoon with the lowest concentration occurring in the early morning. However, on any given
11 day when conditions are right, this phase can be reversed with the highest values occurring at
12 night or early morning. Ozone transport can also effect at what time peaks can occur. For
13 example, some sites in Maine peak late in the evening due to transport.

14 In order to examine diurnal patterns, box-plots summarize 1-hr values and 8-hr for each
15 hour in the day. The most recently available data, 2004, was used to generate all the box-plots.
16 Figure 2-18 summarizes 1-hr data from AQS that was classified as urban and center city. The
17 pattern is similar for both weekend and week day data. The pattern of the center of the
18 distribution of values shows a smooth sinusoidal portion of the curve from 6:00AM until 8:00PM
19 and reaches a peak at 1:00 PM to 3:00 PM. Then the pattern alters to a gradual decrease from
20 9:00 PM to 6:00AM (Fitz-Simons, et al., 2005).

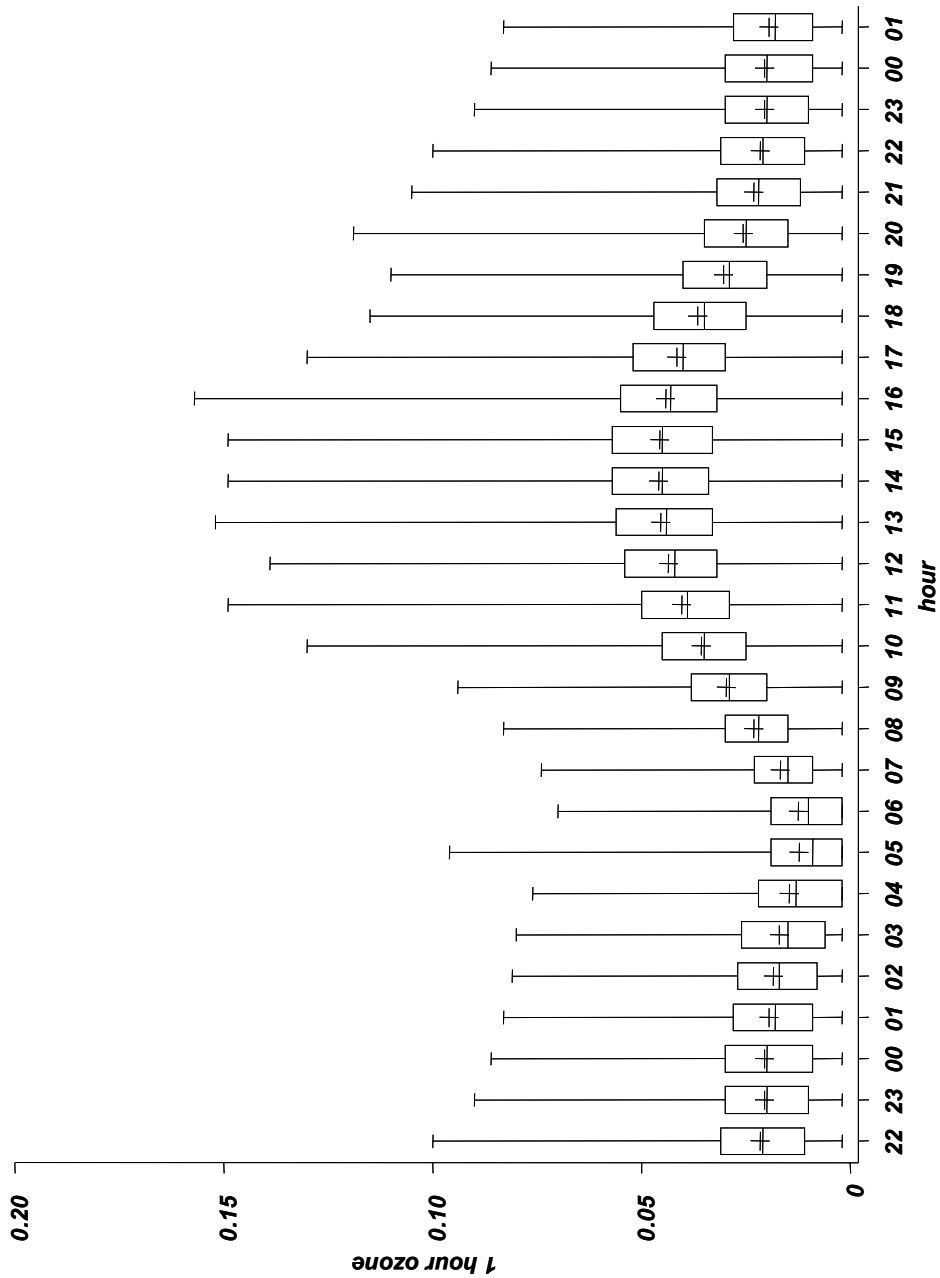

21 Figure 2-19 shows the same set of summaries for 8-hr data. 8-hr values run from 0 to 23
22 hours. Hour1 is the average of 1-hr values from 1 to 8 while hour 2 is the average of hours 2 to 9
23 and so on. The main difference between the 1-hr data and the 8-hr data is that the 8-hr data
24 exhibit a smoother sinusoidal pattern throughout the day with a peak for the center of the
25 distribution occurring at 10:00 AM or 11:00 AM and a minimum at about 12:00 midnight. The
26 week end pattern is similar to the week day pattern (Fitz-Simons, et al., 2005).

27 Figures 2-20 through 2-23 summarize 1-hr and 8-hr data from CASTNET sites which are
28 considered rural. Several differences are noted here. The patterns for the center of the
29 distribution are similar to the patterns for the urban sites. The largest values of the 1-hr data
30 exhibit no pattern but the largest values for the 8-hr data have a discernable pattern that differs
31 from the patterns for the values in the center of the distribution. The weekday pattern for the
32 highest values, shown in figure 2-22, has a smooth sinusoidal pattern but reaches 2 peaks in the
33 day (12:00 midnight and 12:00 noon). The weekend pattern, shown in figure 2-23, also shows a
34 pronounced peak in the afternoon at about 1:00 PM which occurs about 2 hours after the peak for
35 the values in the center of the distribution (Fitz-Simons, et al., 2005).

2.6 CHARACTERIZATION OF OZONE EPISODES

Major episodes of high O₃ concentrations in the eastern United States are associated with slow moving, high pressure systems. High pressure systems during the warmer seasons are associated with the sinking of air, resulting in warm, generally cloudless skies, with light winds. These conditions result in the development of stable air masses near the surface which inhibit the vertical mixing of O₃ precursors. The combination of inhibited limited vertical mixing and light winds minimizes the dispersal of pollutants emitted in urban areas, allowing their concentrations to build up. Photochemical activity involving these precursors is also enhanced because of higher temperatures and the availability of sunlight. Downward entrainment of overnight transported ozone and precursors trapped aloft begins on the following day as the PBL starts growing. In the eastern United States, high O₃ concentrations during an episode can extend over hundreds of thousands of square kilometers for several days.

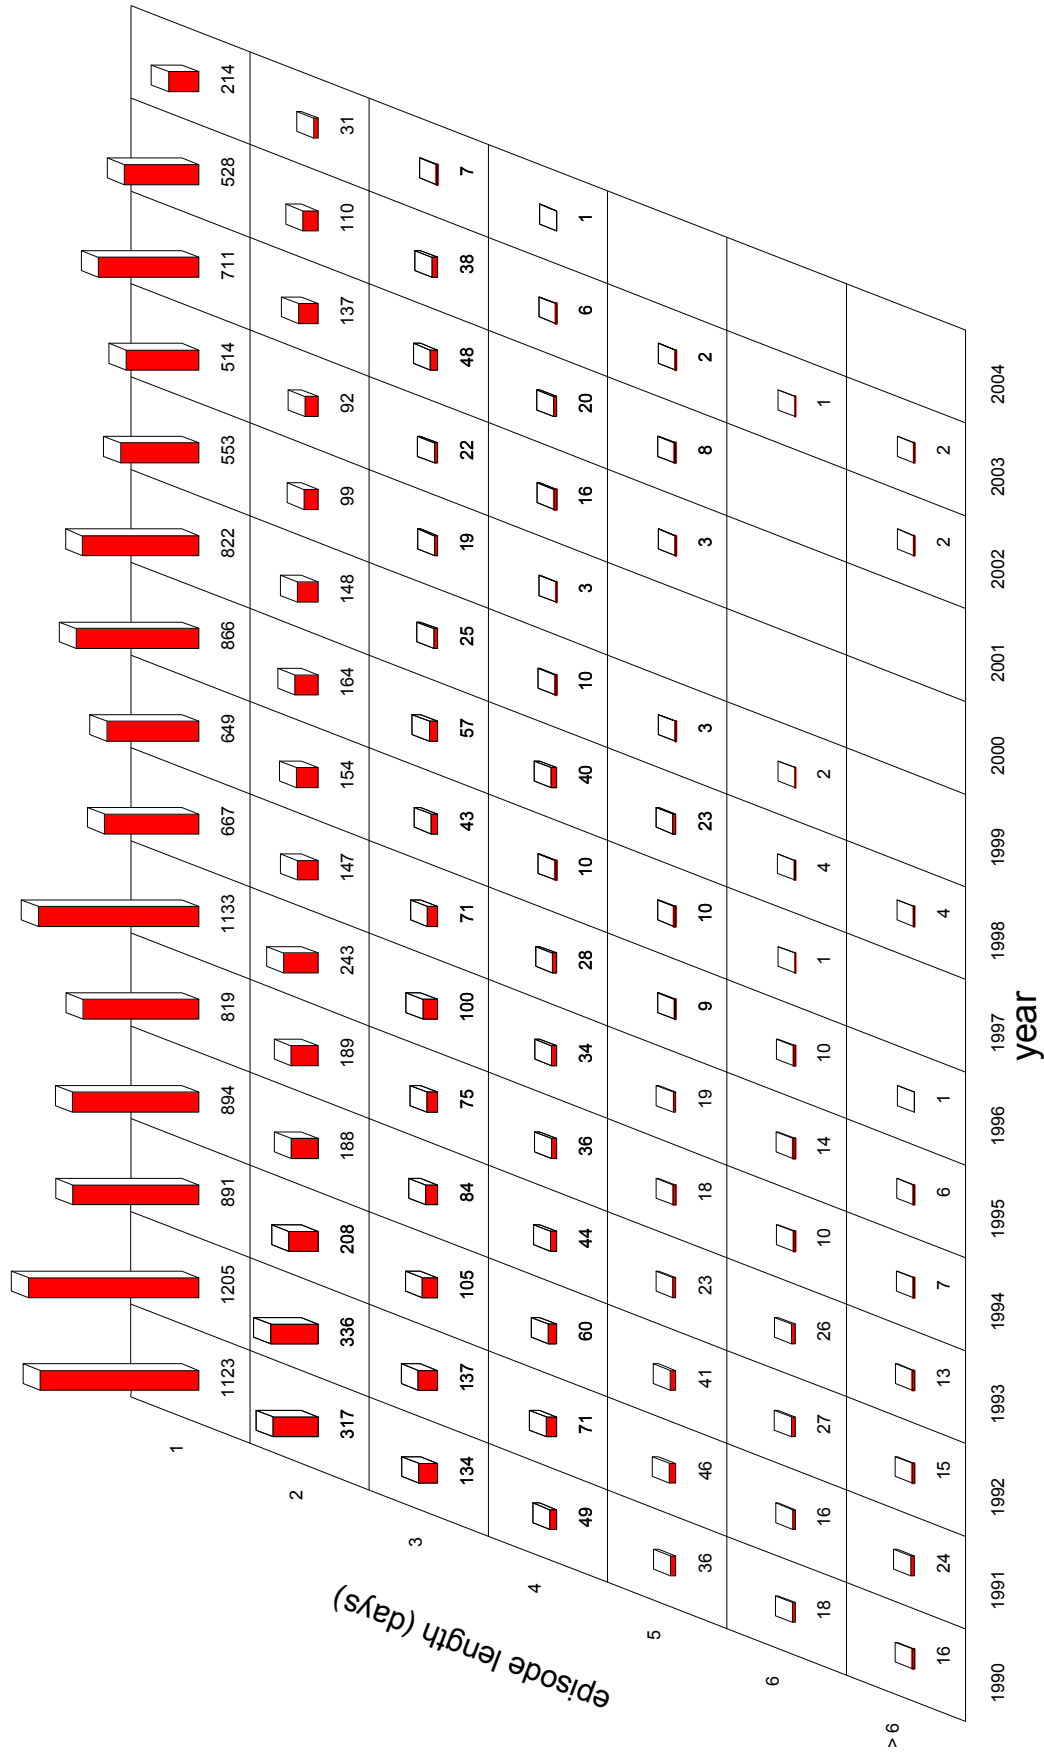

Episodes have two main characteristics, the concentration level reached and the length of time that this level is reached in consecutive days. The following discussion addresses how these characteristics of episodes have varied through both space and time.

Numbers of episodes defined by daily maximum 1-hr O₃ concentrations reaching a level of 0.12ppm for 1 day generally follow the long term trend of central values (means or medians) of the 1-hr O₃ data (See Figures 2-13 and 2-24). As the length of these episodes increases, the frequency of these episodes decreases. In the most recent years (1997-2004) episodes lasting 5 days or more often have not occurred at all (Fitz-Simons, et al., 2005). For this we conclude that control strategies have been reducing peak 1-hr O₃ across major urban areas.

Numbers of episodes defined by daily maximum 8-hr O₃ concentrations reaching a level of 0.08ppm for 1 day generally follow the long term trend of central values of the 8-hr O₃ data (See Figures 2-11 and 2-25). As the length of these episodes increase, the frequency of these episodes decreases. However, some of the longer episodes (6 days or more) continue to occur at this level even in the most recent years. In fact the episode must be defined by a level of 0.10 ppm before these longer episodes disappear in the most recent years (Fitz-Simons, et al., 2005).

As episode length and level increase for both 1-hr and 8-hr O₃ data the frequency decreases (Figure 2-26 and 2-27). The longer periods and higher levels disappear altogether in the period from 2000-2004 (Fitz-Simons, et al., 2005).

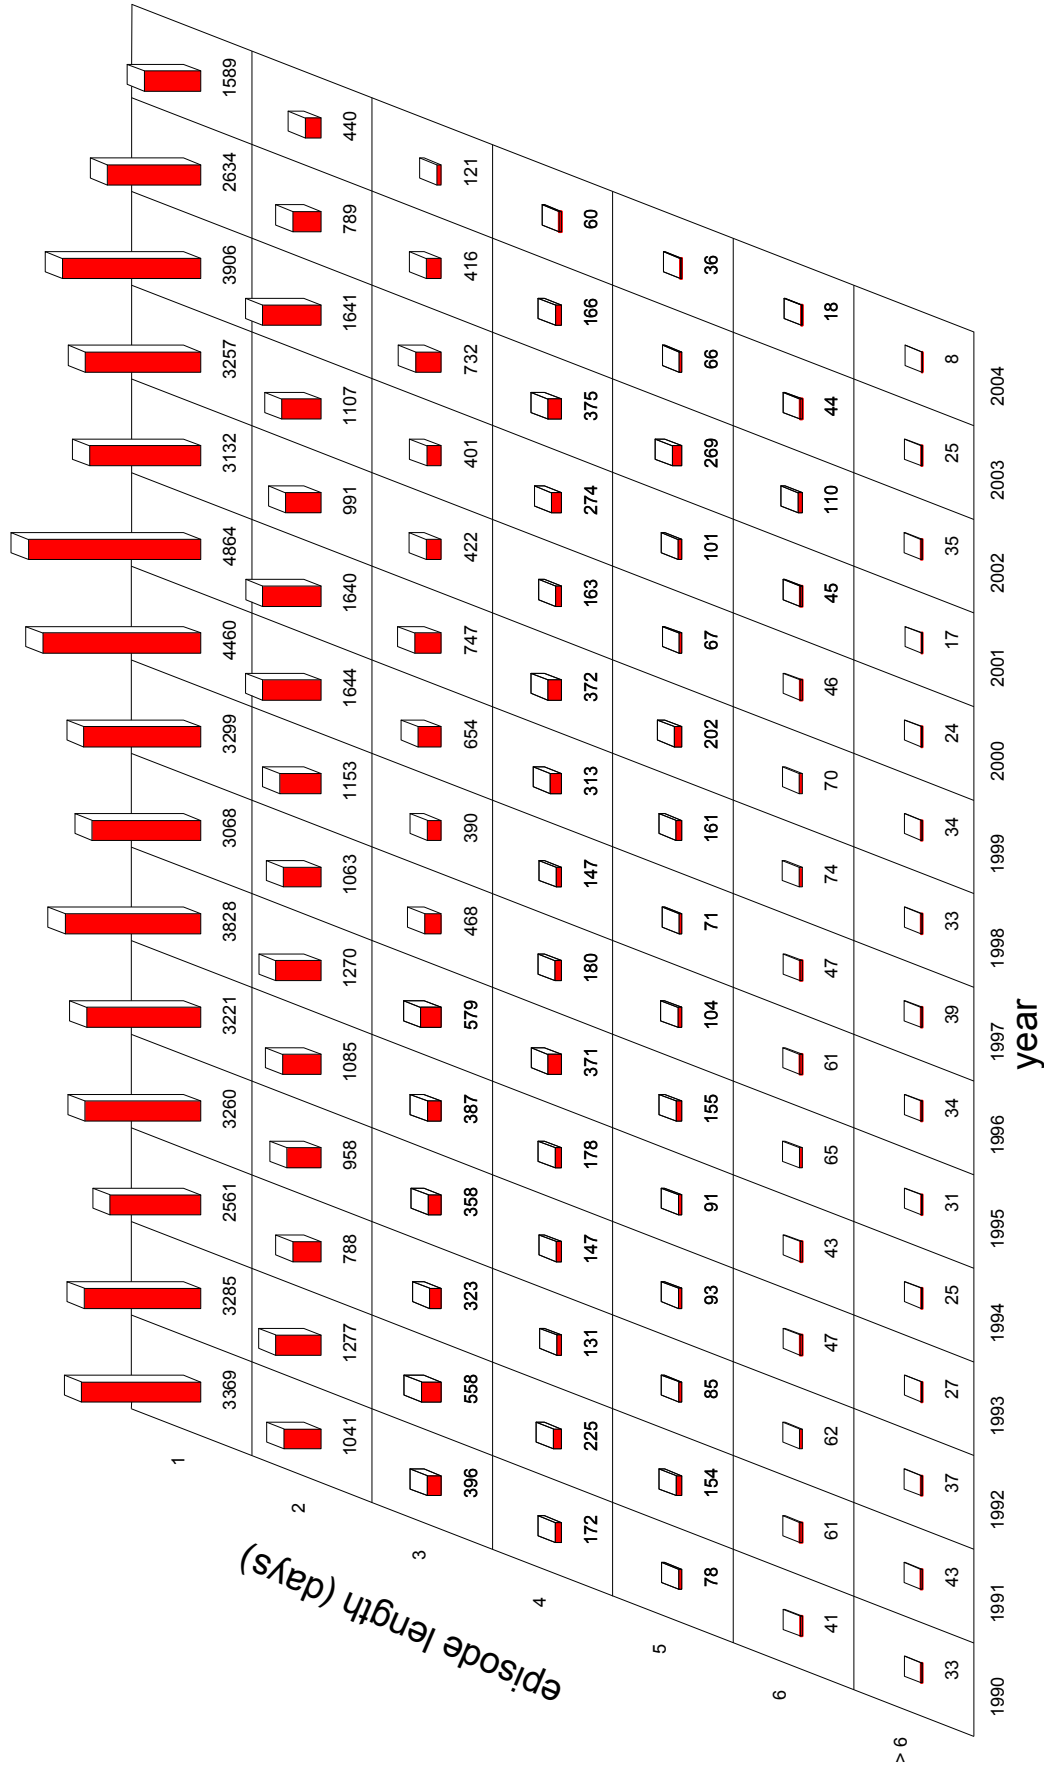

One final aspect of episodes to examine is the return time or the number of days between episodes. Looking at the intervals between episodes of 0.08ppm for 8-hr data, the most prevalent gap length in days is 1 day. There is a slight peak again at 4 days followed by a gradual decrease in frequency as the gap-length increases (see Figure 2-28). Looking at the same data for episodes of 0.12ppm, it appears that some periodicities appear at 1 day, 5-6 days, 21 days, and

1 33-34 days. The frequencies for these episodes are so small compared to frequencies lower level
2 episodes that these indications should not be considered real or significant indications of
3 periodicities. The 1-hr O₃ data exhibit much the same lack of periodicity as the 8-hr data (Fitz-
4 Simons, et al., 2005).

5 **2.7 POLICY RELEVANT BACKGROUND LEVELS**

6 For purposes of this document, background or policy relevant background (PRB) O₃ is
7 defined as the distribution of O₃ concentrations that would be observed in the U.S. in the absence
8 of anthropogenic (man-made) emissions of precursor emissions (e.g., VOC, NO_x, and CO) in the
9 U.S., Canada, and Mexico. This is referred to as policy-relevant background, since this
10 definition of background facilitates separating pollution levels that can be controlled by U.S.
11 regulations (or through international agreements with neighboring countries) from levels that are
12 not generally controllable in this manner. As defined here, PRB includes (1) O₃ in the U.S. from
13 natural sources of emissions in the U.S., Canada, and Mexico and (2) O₃ in the U.S. from the
14 transport of O₃ or the transport of emissions from both natural and man-made sources, from
15 outside of the U.S. and its neighboring countries. As discussed in Chapter 5 of this Staff Paper,
16 PRB concentrations enter into the assessments of risk to human health.

17 Contributions to PRB levels of O₃ include: photochemical interactions involving natural
18 emissions of VOCs, NO_x, and CO; the long-range transport of O₃ and its precursors from outside
19 North America; and stratospheric-tropospheric exchange (STE). Processes involved in STE are
20 described in detail in Annex AX2.3 of the CD. Natural sources of O₃ precursors include biogenic
21 emissions, wildfires, and lightning. Biogenic emissions from agricultural activities are not
22 considered in the formation of PRB (CD, p.AX2-145).

23 As a result of long-range transport from anthropogenic source regions within North
24 America, estimates of PRB O₃ concentrations cannot be derived solely from measurements of
25 O₃, and must be based on modeling. The global photochemical transport model GEOS-CHEM
26 (Fiore et al., 2003) has been applied to estimate PRB O₃ concentrations across the U.S. (U.S.
27 EPA, 2005a, AX3-131). The CD refers to a number of GEOS-Chem publications (Bey et al.,
28 2001; Liu et al., 2002; Martin et al., 2002; Fusco and Logan, 2003; Li et al., 2002, 2005),
29 summarizing their conclusions as "results indicate no significant bias, and agreement to generally
30 within 5 ppbv for monthly mean concentrations at different altitudes." The CD goes on to
31 review detailed evaluations of GEOS-Chem with ozone observations at U.S. surface sites (Fiore
32 et al., 2002, 2003), comparisons of GEOS-Chem and MOZART global models with observations
33 (Goldstein et al., 2004), and note that "several other papers have evaluated the GEOS-Chem
34 simulation for surface ozone and its precursors over the United States." Summarizing their

1 assessment of the validity of the GEOS-Chem model, the CD states "in conclusion, we estimate
2 that the PRB ozone values reported by Fiore et al. (2003) for afternoon surface air over the
3 United States are likely 10 ppbv too high in the southeast in summer, and accurate within 5 ppbv
4 in other regions and seasons."

5 The GEOS-Chem model shows that PRB O₃ concentrations are a function of season,
6 altitude and total surface O₃ concentration. PRB O₃ concentrations at the surface are generally
7 predicted to be in the range of 0.015 to 0.035 ppm in the afternoon, and they decline under
8 conditions conducive to O₃ episodes. They are highest during spring and decline into summer.
9 Higher values tend to occur at higher elevations during spring due to contributions from
10 hemispheric pollution and stratospheric intrusions. The stratospheric contribution to surface O₃ is
11 typically well below 0.020 ppm and only rarely elevate O₃ concentrations at low-altitude sites
12 and only slightly more often elevate them at high-altitude sites (U.S. EPA, 2005a, AX3-148).

13 The exposure and health risk analyses described in Chapter 4 and 5 use estimates of PRB
14 based on runs of the GEOS-CHEM model applied for the 2001 warm season (i.e., April to
15 September). The GEOS-CHEM data consist of gridded values with latitude running from 12° to
16 80 ° in 2 ° steps and longitude running from -177.5 ° to -47.5° in 2.5 ° steps. These data are
17 hourly values which have been used to create daily diurnal profiles which are fixed for each day
18 of each month during the O₃ season. The model estimated the PRB and total O₃ concentrations
19 at each grid point. The PRB estimates from the grid nearest each of the 12 urban areas included
20 in the exposure and risk analyses has been used to estimate PRB in each of these areas.
21 Appendix 2A provides plots of the PRB estimates by month for each of the 12 urban areas.

3. POLICY-RELEVANT ASSESSMENT OF HEALTH EFFECTS EVIDENCE

3.1 INTRODUCTION

This chapter assesses key policy-relevant information on the known and potential health effects associated with exposure to ambient O₃, alone and in combination with other pollutants that are routinely present in ambient air. This assessment focuses specifically on the health effects evidence evaluated in Chapters 4 through 7 of the CD with particular emphasis on the integrative synthesis presented in Chapter 8. That integrative synthesis focuses on integrating newly available scientific information with that available from the last review, as well as integrating information from various disciplines, to address a set of issues central to the assessment of scientific information upon which this review of the O₃ NAAQS is based. This chapter also addresses key issues relevant to quantitative assessment of controlled-human exposure and epidemiological evidence, to provide a foundation for the quantitative human exposure and health risk assessments presented below in Chapters 4 and 5. Those quantitative assessments, together with this evidence-based assessment, provide the foundation for the development of staff conclusions and identification of options for consideration related to primary standards for O₃ presented below in Chapter 6.

The decision in the last review focused primarily on evidence from short-term and prolonged controlled-exposure studies reporting lung function decrements, respiratory symptoms, and respiratory inflammation in humans, as well as epidemiology studies reporting excess hospital admissions and emergency department (ED) visits for respiratory causes. The CD prepared for this review emphasizes a large number of epidemiological studies published since the last review with these and additional health endpoints, including acute and chronic health effects of O₃ for premature mortality, enhanced respiratory symptoms and lung function decrements in asthmatic individuals, school absences, and ED visits for respiratory causes. It also emphasizes important new information from toxicology, dosimetry, and controlled human exposure studies.

As discussed in more detail below (section 3.3), highlights of the new evidence include:

- New controlled human-exposure studies have examined whether lung function decrements are observed in healthy adults under moderate exertion for 6.6 hr exposures to levels as low as 0.04 ppm.
- New controlled human-exposure studies offer evidence of increased airway responsiveness to allergens in subjects with allergic asthma and allergic rhinitis exposed to O₃.

- 1 • Numerous controlled human-exposure studies have reported indicators of O₃-induced
2 inflammatory response in both the upper respiratory tract (URT) and lower respiratory
3 tract (LRT), while other studies have shown significant changes in host defense
4 capability following O₃ exposure of healthy young adults.
- 5 • Animal toxicology studies provide new information regarding mechanisms of action,
6 increased susceptibility to respiratory infection, and the biological plausibility of acute
7 effects and chronic, irreversible respiratory damage.
- 8 • Numerous acute exposure epidemiological studies published during the past decade
9 offer added evidence of ambient O₃-related lung function decrements and respiratory
10 symptoms in exercising healthy subjects and asthmatic subjects, as well as evidence on
11 new health endpoints, such as the relationships between ambient O₃ concentrations and
12 school absenteeism and between ambient O₃ and cardiac physiologic endpoints.
- 13 • Several new studies have been published over the last decade examining the temporal
14 associations between O₃ exposures and ED visits for respiratory diseases and on
15 respiratory-related hospital admissions.
- 16 ▪ Newly available, large multicity studies, designed specifically to examine the effects of
17 acute exposure to PM and O₃ on mortality, provide much more robust and credible
18 information than was available in the last review. The results from two key studies
19 carried out in 95 U.S. communities (U.S. National Morbidity, Mortality Air Pollution
20 Study [NMMAPS]) and in 23 European cities (Air Pollution and Health: European
21 Approach [APHEA]) reported positive and significant O₃ effect estimates for all cause
22 (nonaccidental) mortality.
- 23 • In a recent study, Bell et al. (2006) applied several statistical models to data on air
24 pollution, weather, and mortality for the 98 NMMAPS communities to evaluate
25 whether a threshold level exists for premature mortality. The results indicate that even
26 low levels of tropospheric O₃ are associated with premature mortality.
- 27 • Three recent meta-analyses evaluated potential sources of heterogeneity in O₃-mortality
28 associations, and these studies provide evidence of a robust association between
29 ambient O₃ and mortality, especially for the warm O₃ season.

30
31 Section 3.2 provides an overview of mechanisms of toxicity, with more detailed discussion
32 in Appendix 3A. Section 3.3 summarizes the nature of effects induced by O₃ exposure or
33 associated with exposure to O₃, alone and in combination with other pollutants, drawing on
34 information in Chapters 5-8 of the CD. Section 3.4 summarizes conclusions and judgments from
35 the CD's integrative assessment of the epidemiological evidence regarding the extent to which
36 causal inferences can be made about observed associations between health endpoints and
37 exposure to O₃, and discusses key issues related to quantitative risk assessment based on such
38 evidence. Section 3.5 discusses biological plausibility and coherence of evidence for O₃-related
39 adverse health effects, including short-term respiratory effects, short-term cardiovascular effects,

1 long-term health effects, and mortality-related health endpoint. Drawing from the CD's
2 integrative synthesis, section 3.6 discusses factors that modify responsiveness to O₃; potentially
3 susceptible and vulnerable populations groups; and public health impacts of exposure to ambient
4 O₃. Finally, section 3.7, summarizes key policy-relevant conclusions from the CD about O₃-
5 related health effects, in the context of a discussion of issues related to our confidence in and the
6 utility of the underlying evidence.

7 **3.2 MECHANISMS OF TOXICITY**

8 Evidence is covered in Chapters 5 and 6 of the CD on possible mechanisms by which
9 exposure to O₃ may result in acute and chronic health effects. While most of the available
10 evidence addresses mechanisms for O₃, we recognize that O₃ serves as an indicator for the total
11 photochemical oxidant mixture found in the ambient air, which includes various reactive oxidant
12 species (ROS). Some effects may be caused by one or more components in the overall pollutant
13 mix, either separately or in combination with O₃. Evidence from dosimetry, toxicology, and
14 human exposure studies has contributed to an understanding of the mechanisms that help to
15 explain the biological plausibility and coherence of evidence for O₃-induced respiratory health
16 effects reported in epidemiological studies. In the past, however, little information was available
17 to help explain potential biological mechanisms which linked O₃ exposure to premature mortality
18 or cardiovascular effects. More recently, however, an emerging body of animal toxicology
19 evidence is beginning to suggest mechanisms that may mediate acute O₃ cardiovascular effects.

20 Scientific evidence discussed in the CD (section 5.2) indicates that reactions with lipids
21 and antioxidants are the initial step in mediating deleterious health effects of O₃. There is
22 subsequent activation of a cascade of events starting with inflammation, altered permeability of
23 the epithelial barrier, impaired clearance mechanisms (including host defense), and pulmonary
24 structural alterations that potentially exacerbate a preexisting disease status. According to the
25 CD, the scientific evidence is still lacking for clearly establishing a role for one or a group of
26 mechanistic pathways underlying O₃ health effects observed in epidemiological studies.
27 Appendix 3A provides a further discussion of mechanisms of toxicity.

28 **3.3 NATURE OF EFFECTS**

29 The CD provides new evidence that notably enhances our understanding of short-term
30 exposure effects, including effects on lung function, symptom, and inflammatory effects reported
31 in controlled exposure studies. These studies support and extend the findings of the previous
32 CD. There is also a significant body of new epidemiological evidence of associations between
33 short-term exposure to O₃ and effects such as premature mortality, hospital admissions and ED

1 visits for respiratory (e.g., asthma) causes. Key epidemiological and human controlled exposure
2 studies are summarized in Appendices 3B and 3C, respectively.

3 The following discussions of O₃-related health effects are based on scientific evidence
4 critically reviewed in chapters 5, 6, and 7 of the CD, as well as the CD's integration of scientific
5 evidence contained in Chapter 8. In addition, these health effects discussions rely on the more
6 detailed information and tables presented in the CD's annexes AX5, AX6, and AX7.

7 Conclusions drawn about O₃-related health effects depend on the full body of evidence from
8 controlled-exposure human, epidemiological and toxicological data contained in the CD.

9 Section 3.3.1 focuses on a broad array of morbidity effects, including both acute and chronic
10 exposures. Section 3.3.2 focuses on the expanded body of evidence on associations between
11 acute O₃ exposure and mortality, as well as the more limited evidence on chronic O₃ exposures
12 and mortality.

13 **3.3.1 Morbidity**

14 This section summarizes scientific information contained in the CD on respiratory and
15 cardiovascular effects associated with exposure to O₃. Evidence of O₃-related hospital
16 admissions and ED visits is discussed in section 3.3.1.1, followed by discussion of the effects of
17 short-term and long-term exposure to O₃ on the respiratory system in sections 3.3.1.2 and 3.3.1.3,
18 and O₃-related cardiovascular effects in section 3.3.1.4.

19 **3.3.1.1 Effects on the Respiratory System from Short-term Exposures**

20 Short-term exposures to O₃ have been reported to induce a wide variety of respiratory
21 health effects. These effects include a range of effects, such as morphological changes in the
22 respiratory tract, pulmonary function decrements, respiratory symptoms, respiratory
23 inflammation, increased airway responsiveness, changes in host defense capability, acute
24 morphological effects, increased ED visits and hospital admissions, and effects on exercise
25 performance. Short-term O₃ exposure has also been associated with increases in restricted
26 activity days and school absences but evidence is limited for these effects.

27 **3.3.1.1.1 Pulmonary Function Decrement, Respiratory Symptoms, and Asthma** 28 **Medication Use**

29 A very large literature base of studies published prior to 1996, which investigated the
30 health effects on the respiratory system from short-term O₃ exposures, was reviewed in the 1986
31 and 1996 CDs (U.S. Environmental Protection Agency, 1986, 1996). In the last review, the
32 lowest O₃ concentration at which statistically significant reductions in forced vital capacity
33 (FVC) and forced expiratory volume in 1 second (FEV₁) had been reported in sedentary subjects
34 was 0.5 ppm (CD, p 6-3). During exercise, spirometric and symptomatic responses were
35 observed at much lower O₃ exposures. When minute ventilation was considerably increased by

1 continuous exercise (CE) during O₃ exposures lasting 2 hr or less at ≥ 0.12 ppm, healthy subjects
2 generally experienced decreases in FEV₁, FVC, total lung capacity (TLC), inspiratory capacity
3 (IC), mean forced expiratory flow from 25% to 75% of FVC (FEF₂₅₋₇₅), and tidal volume (V_T);
4 increases in specific airway resistance (sRaw), breathing frequency (f_B), and airway
5 responsiveness; and symptoms such as cough, pain on deep inspiration, shortness of breath,
6 throat irritation, and wheezing. When exposures were increased to 4- to 8-hr in duration,
7 statistically significant spirometric and symptom responses were reported at O₃ concentrations as
8 low as 0.08 ppm and at lower minute ventilation (i.e., moderate rather than high level exercise)
9 than the shorter duration studies (CD, p. 6-6).

10 The most important observations drawn from studies reviewed in the 1996 CD were that:
11 (1) young healthy adults exposed to O₃ concentrations ≥ 0.08 ppm develop significant,
12 reversible, transient decrements in pulmonary function if minute ventilation or duration of
13 exposure is increased sufficiently, (2) children experience similar spirometric responses but
14 lesser symptoms from O₃ exposure relative to young adults, (3) O₃-induced spirometric
15 responses are decreased in the elderly relative to young adults, (4) there is a large degree of
16 intersubject variability in physiologic and symptomatic responses to O₃ but responses tend to be
17 reproducible within a given individual over a period of several months, and (5) subjects exposed
18 repeatedly to O₃ for several days show an attenuation of response upon successive exposures.
19 This attenuation is lost after about a week without exposure (CD, p. 6-2).

20 Since 1996, there have been a number of studies published investigating spirometric and
21 symptomatic responses, and they generally support the observations previously drawn. Recent
22 studies for acute exposures of 1 to 2 hr and 6 to 8 hr in duration are summarized in Table AX6-1
23 of the CD (p. AX6-5 to AX 6-7) and reproduced here as Table 3C-1 in Appendix 3C. Among
24 the more important of the recent studies was McDonnell et al. (1997) which examined reported
25 changes in FEV₁ in 485 white males (ages 18-36) exposed for 2 hr to O₃ concentrations from as
26 low as 0.08 ppm up to 0.40 ppm, at rest or with intermittent exercise (IE). Decrements in FEV₁
27 were modeled by sigmoid-shaped curve as a function of subject age, O₃ concentration, minute
28 ventilation, and duration of exposure. In another study, Ultman et al. (2004) found that exposing
29 60 young, healthy subjects to 0.25 ppm O₃ for 1 hr with continuous exercise produced
30 considerable intersubject variability in FEV₁ decrements ranging from 4% improvement to a
31 56% decrement, which was consistent with findings in the 1996 CD. One third of subjects had
32 FEV₁ decrements > 15% and 7% had decrements > 40%. Foster et al. (1993, 1997) examined the
33 effects of O₃ on ventilation distribution and reported results suggesting a prolonged O₃ effect on
34 the small airways and ventilation distribution (CD, p. 6-5).

35 For prolonged exposures (4 to 8 hr) in the range of 0.08 to 0.16 ppm O₃ using moderate
36 quasi-continuous exercise (QCE; 50 min exercise [minute ventilation of 35 to 40 L/min] and 10

1 min rest per hr), several pre- and post-1996 studies (Folinsbee et al., 1988; Folinsbee et al., 1994;
2 Horstman et al., 1990; Adams, 2002, 2003, 2006) have reported statistically significant
3 spirometric responses and increased symptoms in healthy adults with increasing duration of
4 exposure, O₃ concentration, and minute ventilation. Based on review of several prolonged
5 exposure studies, the CD (p. 6-6) concluded that FEV₁ decrements are a function of minute
6 ventilation in 6.6 hr exposure studies and that data from recent studies do not support the
7 contention that minute ventilation should be normalized to BSA for adults. Triangular exposure
8 studies (Hazucha et al., 1992; Adams 2003, 2006) suggest that, depending upon the profile of the
9 exposure, the triangular exposure, which may reflect the pattern of ambient exposures in some
10 locations, can potentially lead to greater FEV₁ decrements than square wave exposures when the
11 overall O₃ doses are equal (CD, p. 6-10), suggesting that peak exposures are important in terms
12 of O₃ toxicology.

13 McDonnell (1996) and Adams (2002, 2006) used data from a series of studies to
14 investigate the frequency distributions of FEV₁ decrements following 6.6 hr exposures and found
15 that average FEV₁ responses were relatively small (between 5 and 10 %) at 0.08 ppm O₃ (CD, p.
16 8-17). However, about 18% of the exposed subjects had moderate functional decrements (10 to
17 20%), and about 8% experienced large decrements (>20%). Figure 3-1A,B,C (CD, Figures 8-
18 1A,B and 8-2, pp. 8-17 and 8-19) demonstrates that while average responses may appear small
19 and insignificant, some individuals can experience much more significant and severe effects that
20 may be clinically significant. The FEV₁ responses illustrated in this figure were not corrected for
21 the effect of exercise in clear air. When that is done for the Adams (2002, 2006) data, the
22 percentage of subjects experiencing $\geq 10\%$ FEV₁ decrements changes to 7%, 7% and 23% at O₃
23 concentrations of 0.04, 0.06 and 0.08 ppm, respectively in a set of studies conducted in southern
24 California (CD, p. 8-18). The development of these effects is time-dependent during both
25 exposure and recovery periods, with great overlap for development and disappearance of the
26 effects. In healthy human subjects exposed to typical ambient O₃ levels near 0.12 ppm,
27 spirometric responses largely resolve within 4 to 6 hr postexposure, but cellular effects persist
28 for about 24 hr. In these healthy subjects, small residual lung function effects are almost
29 completely gone within 24 hr, while in hyperresponsive subjects, recovery can take as much as
30 48 hr to return to baseline. The majority of these responses are attenuated after repeated
31 exposure, but such attenuation to O₃ is lost one week postexposure (CD, p. 8-19).

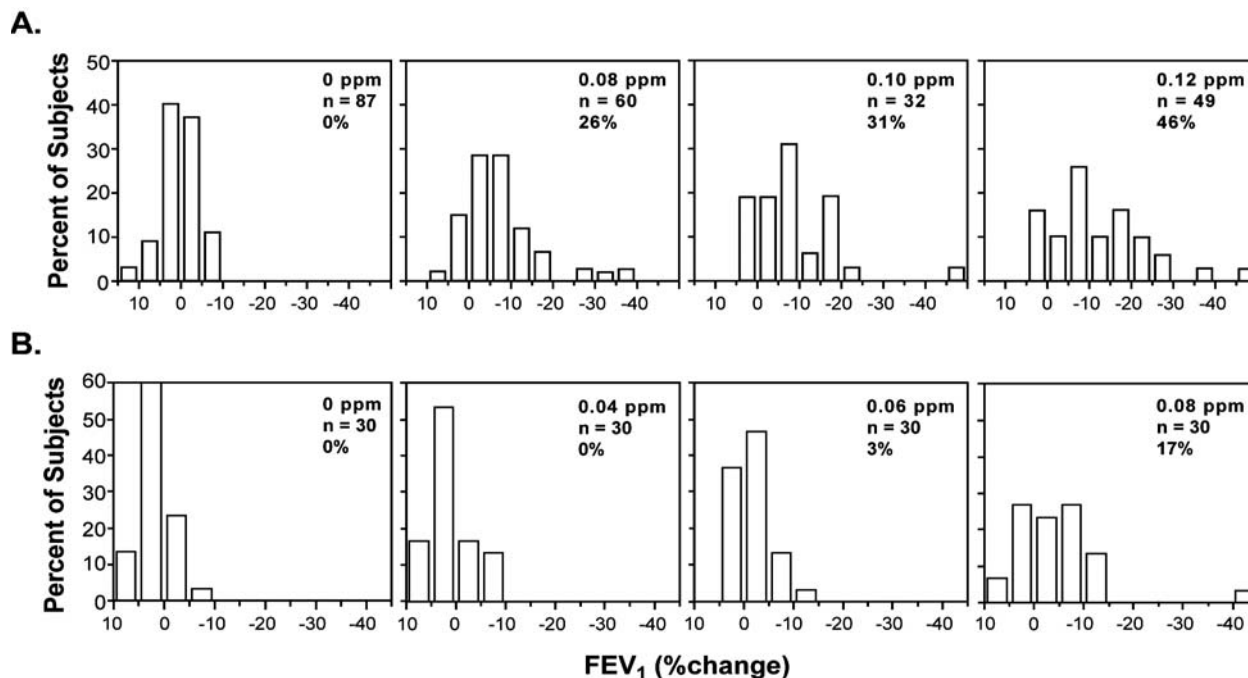

Figure 3-1A and B. Frequency distributions of FEV₁ changes following 6.6-h exposures to a constant concentration of O₃ or filtered air. Note that the percentage in each panel indicates the portion of subjects tested having FEV₁ decrements in excess of 10%.

Source: Panel A, McDonnell (1996); Panel B, Adams (2002, 2006), pre- and post-FEV₁ data for each subject provided by author.

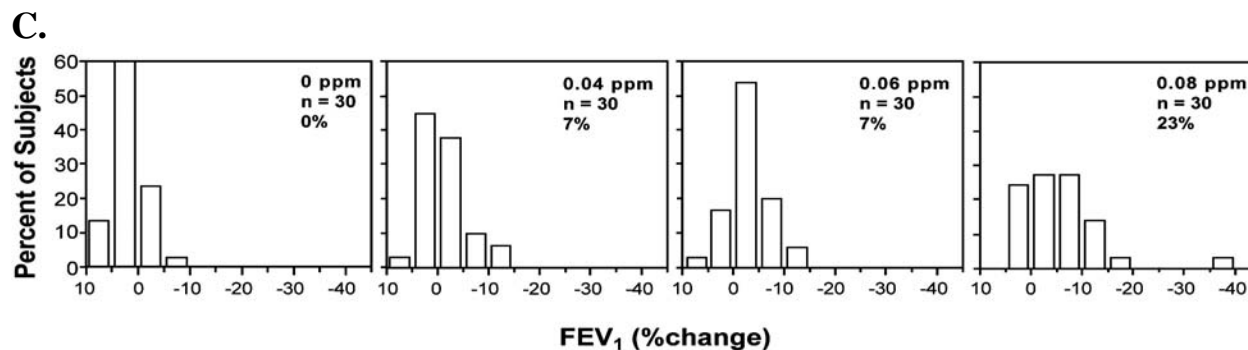

Figure 3-1C. Frequency distributions of FEV₁ changes following 6.6-h exposures to a constant concentration of O₃ or filtered air. The FEV₁ changes following O₃ exposures have been corrected for filtered air responses, i.e., they are O₃-induced FEV₁ changes. Note that the percentage in each panel indicates the portion of subjects tested having FEV₁ decrements in excess of 10%.

1 A relatively large number of field studies investigating the effects of ambient O₃
2 concentrations, in combination with other air pollutants, on lung function decrements and
3 respiratory symptoms have been published since 1996 (see CD, sections 7.2.3, 7.2.4, and
4 8.4.4.1). These newer studies support the major findings of the 1996 CD that lung function
5 changes, as measured by decrements in FEV₁ or peak expiratory flow (PEF), and respiratory
6 symptoms in healthy adults and asthmatic children are closely correlated to ambient O₃
7 concentrations. Pre-1996 field studies focused primarily on children attending summer camps
8 and found O₃-related impacts on measures of lung function, but not respiratory symptoms, in
9 healthy children. The newer studies have expanded into looking at O₃-related effects on outdoor
10 workers, athletes, the elderly, hikers, school children, and asthmatics. Collectively, these studies
11 confirm and extend clinical observations that prolonged exposure periods, combined with
12 elevated levels of exertion or exercise, may magnify the effect of O₃ on lung function. The most
13 representative data come from the hiker study (Korrick et al., 1998), which provided outcome
14 measures stratified by several factors (e.g., gender, age, smoking status, presence of asthma)
15 within a population capable of more than normal exertion. In this study, lung function was
16 measured before and after hiking, and both ambient and personal O₃ exposure measurements
17 were made. Decreased lung function was associated with O₃ exposure, with the greatest effect
18 estimates reported for the subgroup that reported having asthma or wheezing, and for those who
19 hiked for longer periods of time, thus increasing the exposure period (CD, p. 7-36).

20 Asthma panel studies, conducted both in the U.S. and in other countries, have reported
21 that decrements in PEF are associated with O₃ exposures among asthmatic and healthy persons
22 (CD, sections 7.2.3.2 and 8.4.4.1). One large U.S. multicity study (Mortimer et al., 2002)
23 examined O₃-related changes in PEF in 846 asthmatic children from 8 urban areas and reported
24 that the incidence of $\geq 10\%$ decrements in morning PEF are associated with a 30 ppb increase in
25 8-hr average O₃ for a 5-day cumulative lag, suggesting that O₃ exposure may be associated with
26 clinically significant changes in PEF in asthmatic children; however, no associations were
27 reported with evening PEF (CD, p. 7-40). The authors also reported that the associations
28 reported with morning PEF remained statistically significant when days with 8-hr O₃
29 concentrations above 80 ppb were excluded (CD, p. 7-43). Two studies (Romieu et al., 1996,
30 1997) carried out simultaneously in northern and southwestern Mexico City with mildly
31 asthmatic school children reported statistically significant O₃-related reductions in PEF, with
32 variations in effect depending on lag time and time of day. While several studies (Gielen et al.,
33 1997; Jalaludin et al., 2000; Ross et al., 2002; Thurston et al., 1997) report statistically
34 significant associations between O₃ exposure and reduced PEF in asthmatics, other studies
35 (Hilterman et al., 1998; Delfino et al., 1997a) did not, possibly due to very low levels of O₃.

1 Collectively, however, these studies indicate that O₃ may be associated with declines in lung
2 function in asthmatic individuals (CD, p. 7-40 to 7-43).

3 Mortimer et al. (2002) discussed biological mechanisms for delayed effects on pulmonary
4 function, which included increased bronchial reactivity secondary to airway inflammation
5 associated with irritant exposure (CD, p. 7-43). Animal toxicological and human chamber
6 studies (CD, Chapters 5 and 6) provide supporting evidence that exposure to O₃ may augment
7 cellular infiltration and cellular activation, enhance release of cytotoxic inflammatory mediators,
8 and alter membrane permeability (CD, p.7-44). In most laboratory animals studied, biochemical
9 markers of lung injury and associated morphological changes were not found to be attenuated,
10 even though at similar exposures pulmonary function changes might be attenuated.

11 Most of the panel studies which have investigated associations between O₃ exposure and
12 respiratory symptoms or increased use of asthma medication are focused on asthmatic children
13 (CD, sections 7.2.4 and 8.4.4.1). Two large U.S. studies (Mortimer et al., 2002; Gent et al.,
14 2003), as well as several smaller U.S. (Delfino et al., 2003; Just et al., 2002; Newhouse et al.,
15 2004; Romieu et al., 1996, 1997; Ross et al., 2002; Thurston et al., 1997) and international
16 studies (Hilterman et al., 1998; Desqueyroux et al., 2002a,b), have reported fairly robust
17 associations between ambient O₃ concentrations and daily symptoms/asthma medication use,
18 even after adjustment for copollutants.

19 The National Cooperative Inner-City Asthma Study (NCICAS) reported morning
20 symptoms in 846 asthmatic children from 8 U.S. urban areas to be most strongly associated with
21 a cumulative 1- to 4-day lag of O₃ concentrations (Mortimer et al., 2002). The NCICAS used
22 standard protocols that included instructing caretakers of the subjects to record symptoms in the
23 daily diary by observing or asking the child (Mitchell et al., 1997). Symptoms reported included
24 cough, chest tightness, and wheeze. In the analysis pooling individual subject data from all eight
25 cities, the odds ratio for the incidence of symptoms was 1.35 (95% CI: 1.04, 1.69) per 30 ppb
26 increase in 8-hr avg O₃ (10 a.m.-6 p.m.). The mean 8-hr avg O₃ was 48 ppb across the 8 cities.
27 Excluding days when 8-hr avg O₃ was greater than 80 ppb (less than 5% of days), the odds ratio
28 was 1.37 (95% CI: 1.02, 1.82) for incidence of morning symptoms

29 Gent and colleagues (2003) followed 271 asthmatic children under age 12 and living in
30 southern New England for 6 months (April through September) in a diary study of daily
31 symptoms in relation to O₃ and PM_{2.5}. Mean 1-hr max O₃ and 8-hr max O₃ concentrations were
32 58.6 ppb (SD 19.0) and 51.3 ppb (SD 15.5), respectively. The data were analyzed for two
33 separate groups of subjects, 130 who used maintenance asthma medications during the follow-up
34 period and 141 who did not. The need for regular medication was considered to be a proxy for
35 more severe asthma. Not taking any medication on a regular basis and not needing to use a
36 bronchodilator would suggest the presence of very mild asthma. Effects of 1-day lag O₃ were

1 observed on a variety of respiratory symptoms only in the medication user group. Both daily 1-
2 hr max and 8-hr max O₃ concentrations were similarly related to symptoms such as chest
3 tightness and shortness of breath. Effects of O₃, but not PM_{2.5}, remained significant and even
4 increased in magnitude in two-pollutant models. Some of the associations were noted at 1-hr
5 max O₃ levels below 60 ppb. In contrast, no effects were observed among asthmatics not using
6 maintenance medication. In terms of person days of follow-up, this is one of the larger studies
7 currently available that address symptom outcomes in relation to O₃, and provides supportive
8 evidence for effects of O₃ independent of PM_{2.5}. Study limitations include limited control for
9 meteorological factors and the post-hoc nature of the population stratification by medication use
10 (CD, p. 7-53).

11 The multicities study by Mortimer et al. (2002), which provides an asthmatic population
12 most representative of the United States, and several single-city studies indicate a robust
13 association of O₃ concentrations with respiratory symptoms and increased medication use in
14 asthmatics. While there are a number of well-conducted, albeit relatively smaller, studies which
15 showed only limited or a lack of evidence for symptom increases associated with O₃ exposure,
16 these studies had less statistical power and/or were conducted in areas with relatively low O₃
17 levels (CD, p. 7-54). The CD (p. 7-55) concludes that the asthma panel studies, as a group, and
18 the NCICAS in particular, indicate a positive association between ambient concentrations and
19 respiratory symptoms and increased medication use in asthmatics. The evidence has continued
20 to expand since 1996 and now is considered to be much stronger than in the previous review of
21 the O₃ primary standard.

22 The association between school absenteeism and ambient O₃ concentrations was assessed
23 in three relatively large field studies (CD, section 7.2.6). Chen et al. (2000) examined daily
24 school absenteeism in 27,793 elementary school students in Nevada over a 2-year period (after
25 adjusting for PM₁₀ and CO concentrations) found that ambient O₃ concentrations were associated
26 with 10.41% excess rate of school absences per 40 ppb increase in 1-hr max O₃. Gilliland et al.
27 (2001) studied O₃-related absences among 1,933 4th grade students in 12 southern California
28 communities and found significant associations between 30-day distributed lag of 8-hr average
29 O₃ concentrations and all absence categories, particularly for respiratory causes. Neither PM₁₀
30 nor NO₂ were associated with any respiratory or nonrespiratory illness-related absences in single
31 pollutant models. The CD concludes that these studies of school absences suggest that ambient
32 O₃ concentrations, accumulated over two to four weeks, may be associated with school
33 absenteeism, particularly illness-related absences, but further replication is needed before firm
34 conclusions can be reached regarding the effect of O₃ on school absences (CD, p. 7-60).

3.3.1.1.2 Airway Responsiveness

Airway hyperresponsiveness (AHR), also known as bronchial hyperreactivity, refers to a condition in which the propensity for the airways to bronchoconstrict due to a variety of stimuli (e.g., exposure to cold air, allergens, or exercise) becomes augmented (CD, section 6.8). This condition is typically quantified by measuring the decrement in pulmonary function (e.g., spirometry or plethysmography) after inhalation exposure to specific (e.g., antigen, allergen) or nonspecific (e.g., methacholine, histamine) bronchoconstrictor stimuli. Exposure to O₃ causes an increase in nonspecific airway responsiveness as indicated by a reduction in the concentration of methacholine or histamine required to produce a given reduction in FEV₁ or increase in SRaw. Increased airway responsiveness is an important consequence of exposure to O₃ because its presence means that the airways are predisposed to narrowing on inhalation of various stimuli, such as specific allergens, cold air or SO₂ (CD, p. 8-21). Significant, clinically relevant decreases in pulmonary function have been observed in early phase allergen response in subjects with rhinitis after consecutive (4-day) exposure to 0.125 ppm O₃ (Holz et al., 2002). Similar increased airway responsiveness in asthmatics to house dust mite antigen 16 to 18 hrs after exposure to a single dose of O₃ (0.16 ppm for 7.6 hrs) was observed. These observations suggest that O₃ exposure may be a clinically important factor that can exacerbate the response to ambient bronchoconstrictor substances in individuals with preexisting allergic asthma and that O₃'s influence may have an immediate impact on asthmatics as well as contribute to effects that persist for longer periods (CD, p. 8-21).

An important aspect of increased airway responsiveness after O₃ exposure is that it represents a plausible link between O₃ exposure and increased hospital admissions. Kreit et al. (1989) found that O₃ can induce increased airway responsiveness in asthmatic subjects to O₃, who typically have increased airway responsiveness at baseline. A subsequent study (Jorres et al., 1996) suggested an increase in specific (i.e., allergen-induced) airway reactivity in subjects with allergic asthma, and to a lesser extent in subjects with allergic rhinitis after exposure to 0.25 ppm O₃ for 3 hrs; other studies (Molfino et al., 1991; Kehrl et al., 1999) reported similar results. According to one study (Folinsbee and Hazucha, 2000), changes in airway responsiveness after O₃ exposure resolve more slowly than changes in FEV₁ or respiratory symptoms. Other studies of repeated exposure to O₃ suggest that changes in airway responsiveness tend to be somewhat less affected by attenuation with consecutive exposures than changes in FEV₁ (Dimeo et al., 1981; Folinsbee et al., 1994; Gong et al., 1997a; Kulle et al., 1982) (CD, p. 6-31).

An extensive laboratory animal data base exploring the effects of acute, long-term, and repeated exposure to O₃ indicates that induction of AHR occurs at relatively high (≥ 1 ppm) O₃ concentrations (p. 8-21). These studies provide clues to the roles of physiological and biochemical components involved in this process, but caution should be exercised in interpreting

1 these results, as different mechanisms may be involved in mediating high- and low-dose
2 responses. As observed in humans, the acute changes in AHR do not persist after long-term
3 exposure of animals exposed to near-ambient concentrations of O₃, and attenuation has been
4 reported. In addition, dosimetric adjustments potentially could be made to allow better
5 estimation of levels that would be relevant to human exposure effect levels.

6 The CD concludes that O₃ exposure is linked with increased AHR (CD, section 6.8).
7 Both human and animal studies indicate that airway responses are not associated with
8 inflammation, but they do suggest a likely role for neuronal involvement (CD, p. 8-21). Increases
9 in AHR do not appear to be strongly associated with decrements in lung function or increases in
10 symptoms (CD, p. 6-31).

11 **3.3.1.1.3 Respiratory Inflammation and Permeability**

12 Based on evidence from the previous review, acute inflammatory responses in the lung
13 have been observed subsequent to 6.6 hr O₃ exposures to the lowest tested level of 0.08 ppm in
14 healthy adults. Some studies suggest that inflammatory responses may be detected in some
15 individuals following O₃ exposures in the absence of O₃-induced pulmonary decrements in those
16 subjects. Short-term exposures to O₃ also can cause increased permeability in the lungs of
17 humans and experimental animals (CD, sections 5.2.3, 6.9, 7.2.5 and 8.4.3). Not only are the
18 newer findings consistent with the previous review, but also there is better evidence about the
19 physiological mechanisms by which O₃ causes these effects.

20 Lung inflammation and increased permeability, which are distinct events controlled by
21 different mechanisms, are two well characterized effects of O₃ exposure observed in all species
22 studied. Disruption of the lung barrier leads to leakage of serum proteins, influx of
23 polymorphonuclear leukocytes (PMNs), release of bioactive mediators, and movement of
24 compounds from the airspaces into the blood.

25 In the animal toxicological studies discussed in the CD (Chapter 5), the lowest O₃
26 concentration that induced inflammation in the mouse lung was 0.11 ppm for 24 hr exposures.
27 Shorter exposures of 8 hours required concentrations of 0.26 ppm to induce epithelial
28 permeability though there was no effect on inflammation. The lowest O₃ concentration that
29 affected epithelial permeability or inflammation in the rat was 0.5 ppm for a 3 hr exposure or
30 0.12 ppm for 6 hr (CD, p. 8-23). After acute exposures, the influence of the duration of exposure
31 increases as the concentration of O₃ increases; however, dosimetric adjustments would need to be
32 done before one can compare levels. The exact role of inflammation in causation of lung disease
33 is not known; nor is the relationship between inflammation and lung function (CD, p. 5-23).

34 A number of human O₃-exposure studies have analyzed bronchoalveolar lavage (BAL)
35 and nasal lavage (NL) fluids and cells for markers of inflammation and lung damage. These
36 studies are summarized in the CD (Annex AX6, Tables AX6-12 and AX6-13). Increased lung

1 inflammation is demonstrated by the presence of neutrophils (PMNs) found in BAL fluid in the
2 lungs, which has long been accepted as a hallmark of inflammation. It is apparent, however, that
3 inflammation within airway tissues may persist beyond the point that inflammatory cells are
4 found in the BAL fluid. Soluble mediators of inflammation, such as cytokines and arachidonic
5 acid metabolites have been measured in the BAL fluid of humans exposed to O₃. In addition to
6 their role in inflammation, many of these compounds have bronchoconstrictive properties and
7 may be involved in increased airway responsiveness following O₃ exposure (CD, p. 6-31, p. 8-
8 22). An in vitro study of epithelial cells from nonatopic and atopic asthmatics exposed to 0.01 to
9 0.10 ppm O₃ showed significantly increased permeability compared to cells from normal
10 persons. This indicates a potentially inherent susceptibility of cells from asthmatic individuals
11 for O₃-induced permeability.

12 In the 1996 CD, assessment of human exposure studies indicated that a single, acute (1 to
13 4 hrs) O₃ exposure (0.2 to 0.6 ppm) of subjects engaged in moderate to heavy exercise could
14 induce a number of cellular and biochemical changes suggestive of pulmonary inflammation and
15 lung permeability (CD, p. 8-22). These changes persisted for at least 18 hrs. Graham and Koren
16 (1990) compared inflammatory mediators present in NL and BAL fluids of humans exposed to
17 0.4 ppm O₃ for 2 hrs and found similar increases in PMNs in both fluids, suggesting a qualitative
18 correlation between inflammatory changes in the lower airways (BAL) and upper respiratory
19 tract (NL). Acute airway inflammation was shown in Devlin et al. (1990) to occur among adults
20 exposed to 0.08 ppm O₃ for 6.6 hr with exercise, and McBride et al. (1994) reported that
21 asthmatic subjects were more sensitive than non-asthmatics to upper airway inflammation for O₃
22 exposures (0.24 ppm, 1.5 hr, with light IE) that did not affect pulmonary function (CD, p. 6-33).

23 Since 1996, a substantial number of human exposure studies have been published which
24 have provided important new information on lung inflammation and epithelial permeability.
25 Mudway and Kelly (2004) examined O₃-induced inflammatory responses and epithelial
26 permeability with a meta-analysis of 21 controlled human exposure studies and showed that
27 PMN influx in healthy subjects is associated with total O₃ dose (product of O₃ concentration,
28 exposure duration, and minute ventilation) (CD, p. 6-34). Results of the analysis suggest that the
29 time course for inflammatory responses (including recruitment of neutrophils and other soluble
30 mediators) is not clearly established, but differential attenuation profiles for many of these
31 parameters are evident (CD, p. 8-22).

32 A number of studies (Peden et al., 1997; Scannell et al., 1996; Hilterman et al., 1999;
33 Bosson et al., 2003) have provided evidence suggesting that asthmatics show greater
34 inflammatory response than healthy subjects when exposed to similar O₃ levels (CD, section
35 6.9). Markers from BAL fluid following both 2-hr (Devlin et al., 1997) and 4-hr (Christian et al.,
36 1998; Jorres et al., 2000) O₃ exposures repeated up to 5 days indicate that there is ongoing

1 cellular damage irrespective of attenuation of some cellular inflammatory responses of the
2 airways, pulmonary function, and symptom responses (CD, p. 8-22).

3 The CD (p. 8-24) concludes that interaction of O₃ with lipid constituents of epithelial
4 lining fluid (ELF) and cell membranes and the induction of oxidative stress is implicated in
5 injury and inflammation. Alterations in the expression of cytokines, chemokines, and adhesion
6 molecules, indicative of an ongoing oxidative stress response, as well as injury repair and
7 regeneration processes, have been reported in animal toxicology and human in vitro studies
8 evaluating biochemical mediators implicated in injury and inflammation. While antioxidants in
9 ELF confer some protection, O₃ reactivity is not eliminated at environmentally relevant
10 exposures. Further, antioxidant reactivity with O₃ is both species-specific and dose-dependent
11 (CD, p. 8-24).

12 **3.3.1.1.4 Changes in Host Defense Capability**

13 As discussed in the CD (sections 5.2.2, 6.9.6, and 8.4.2), short-term exposures to O₃ have
14 been shown to impair host defense capabilities in both humans and experimental animals by
15 depressing alveolar macrophage (AM) functions and by altering the mucociliary clearance of
16 inhaled particles and microbes. Short-term O₃ exposures also interfere with the clearance
17 process by accelerating clearance for low doses and slowing clearance for high doses. Animal
18 toxicological studies have reported that acute O₃ exposures suppress alveolar phagocytes and
19 immune functions. Dysfunction of host defenses and subsequent increased susceptibility to
20 bacterial lung infection in laboratory animals has been induced by short-term exposures to O₃
21 levels as low as 0.08 ppm (CD, p. 8-26).

22 Changes in antibacterial defenses are dependent on exposure regimens, species and strain
23 of lab animals, species of bacteria, and age of the animals used. Acute O₃-induced suppression
24 of alveolar phagocytosis and immune function in experimental animals appeared to be transient
25 and attenuated with continuous or repeated exposures. Ozone exposure has also been shown to
26 interfere with AM-mediated clearance in the respiratory region of the lung and with mucociliary
27 clearance of the tracheobronchial airways. These interferences with clearance are dose
28 dependent, with low doses accelerating clearance and high doses slowing the process (CD, p. 8-
29 26).

30 A single controlled human exposure study (Devlin et al., 1991) reviewed in the 1996 CD
31 reported that exposure to 0.08 to 0.10 ppm O₃ for 6.6 hrs (with moderate exercise) induced
32 decrements in the ability of AMs to phagocytose microorganisms; several other human studies
33 reported similar effects but with higher exposure concentrations (CD, p. 8-26). Integrating the
34 recent study results with evidence available in the 1996 CD, the CD concludes that available
35 evidence indicates that short-term O₃ exposures have the potential to impair host defenses,
36 primarily by interfering with AM function. Any impairment in AM function may lead to

1 decreased clearance of microorganisms or nonviable particles. Compromised AM functions in
2 asthmatics may increase their susceptibility to other O₃ effects, the effects of particles, and
3 respiratory infections (CD, p. 8-26).

4 **3.3.1.1.5 Morphological Effects**

5 The 1996 CD found that short-term O₃ exposures cause similar alterations in lung
6 morphology in all laboratory animal species studied, including primates. Cells in the
7 centriacinar region (CAR) of the lung (the segment between the last conducting airway and the
8 gas exchange region) have been recognized as a primary target of O₃-induced damage (epithelial
9 cell necrosis and remodeling of respiratory bronchioles), possibly because epithelium in this
10 region receives the greatest dose of O₃ delivered to the lower respiratory tract. Following
11 chronic O₃ exposure, structural changes have been observed in the CAR, the region typically
12 affected in most chronic airway diseases of the human lung (CD, p. 8-24).

13 Ciliated cells in the nasal cavity and airways, as well as Type I cells in the gas-exchange
14 region, are also identified as targets. While short-term O₃ exposures can cause structural changes
15 such as fibrosis in the CAR, these changes appear to be transient with recovery time after
16 exposure, depending on species and O₃ dose. The potential impacts of repeated short-term and
17 chronic morphological effects of O₃ exposure are discussed later in section 3.3.1.2.5.

18 Recent studies continue to show that short-term and sub-chronic exposures to O₃ cause
19 similar alterations in lung structure in a variety of experimental animal species, at concentrations
20 of 0.15 ppm in rats and even lower concentrations in primates (CD, section 5.2.4.). Recent work
21 has shown that a topical anti-inflammatory corticosteroid can prevent these effects in nasal
22 epithelia, while exposure to bacterial endotoxin can potentiate effects. Ozone-induced fibrotic
23 changes in the CAR are maximal at 3 days of exposure and recover 3 days post-exposure with
24 exposures of 0.2 ppm O₃ in rodents. One study has demonstrated variability of local O₃ dose and
25 subsequent injury in the respiratory tract due to depletion of glutathione (GSH). The proximal
26 respiratory bronchiole receives the most acute epithelial injury from exposures \leq 1 ppm, while
27 metabolic effects were greatest in the distal bronchioles and minor daughter airways (CD, p. 5-
28 38).

29 Based on evidence from animal toxicological studies, short-term and sub-chronic
30 exposures to O₃ can cause morphological changes in the respiratory systems, particularly in the
31 CAR, of a number of laboratory animal species (CD, section 5.2.4).

32 **3.3.1.1.6 Emergency Department Visits/Hospital Admissions for Respiratory** 33 **Causes**

34 The 1996 CD evaluated ED visits and hospital admissions as possible outcomes
35 following exposure to O₃ (CD, section 7.3). The evidence was limited for ED visits, but results
36 of several studies generally indicated that short-term exposures to O₃ were associated with

1 respiratory ED visits. The strongest and most consistent evidence, both below and above 0.12
2 ppm 1-hr max O₃, was found in the group of studies which investigated summertime daily
3 hospital admissions for respiratory causes in different eastern North American cities. These
4 studies were consistent in demonstrating that ambient O₃ levels were associated with increased
5 hospital admissions and accounted for about one to three excess respiratory hospital admissions
6 per million persons with each 100 ppb increase in 1-hr max O₃, with adjustment for possible
7 confounding effects of temperature and copollutants. Overall, the 1996 CD concluded that there
8 was strong evidence that ambient O₃ exposures can cause significant exacerbations of preexisting
9 respiratory disease in the general public (CD, p. 7-66). Excess respiratory-related hospital
10 admissions associated with O₃ exposures for the New York City area (based on Thurston et al.,
11 1992) were included in the quantitative risk assessment in the prior review and are included in
12 the current assessment along with estimates for respiratory-related hospital admissions in
13 Cleveland, Detroit, and Los Angeles based on more recent studies (see Chapter 5). Significant
14 uncertainties and the difficulty of obtaining reliable baseline incidence numbers resulted in ED
15 visits not being used in the quantitative risk assessment conducted in the last O₃ NAAQS review.

16 In the past decade, a number of studies have examined the temporal being used in the
17 quantitative risk assessment conducted in the last O₃ NAAQS review.associations between O₃
18 exposures and ED visits for respiratory causes (CD, section 7.3.2). These studies are
19 summarized in the CD (Table AX7-3, Chapter 7 Annex). Respiratory causes for ED visits
20 include asthma, bronchitis, emphysema, pneumonia, and other upper and lower respiratory
21 infections, such as influenza, but asthma visits typically dominate the daily incidence counts.
22 Among studies with adequate controls for seasonal patterns, many reported at least one
23 significant positive association involving O₃. These studies examined ED visits for total
24 respiratory complaints (Delfino et al., 1997b, 1998b; Hernandez-Garduno et al., 1997; Ilabaca et
25 al., 1999; Lin et al., 1999), asthma (Friedman et al., 2001; Jaffe et al., 2003; Stieb et al., 1996;
26 Tenias et al., 1998; Tobias et al., 1999 ; Tolbert et al., 2000 ; Weisel et al., 2002), and COPD
27 (Tenias et al., 2002).

28 Figure 7-8 (CD, p. 7-68) provides effect estimates for associations between ED visits for
29 asthma and short-term O₃ exposures. In general, O₃ effect estimates from summer only analyses
30 tended to be positive and larger compared to results from cool season or all year analyses (CD, p.
31 7-67). Several of the studies reported significant associations between O₃ concentrations and ED
32 visits for respiratory causes. However, inconsistencies were observed which were at least
33 partially attributable to differences in model specifications and analysis approach among various
34 studies. For example, ambient O₃ concentrations, length of the study period, and statistical
35 methods used to control confounding by seasonal patterns and copollutants appear to affect the
36 observed O₃ effect on ED visits. Thus, the CD (p. 7-71) has concluded that stratified analyses by

1 season generally supported a positive association between O₃ concentrations and ED visits for
2 asthma in the warm season.

3 Unscheduled hospital admissions occur in response to unanticipated disease
4 exacerbations and are more likely to be affected by environmental factors, such as high O₃ levels.
5 Thus, hospital admissions studies focus specifically on unscheduled admissions. Results of a
6 fairly large number of these studies published during the past decade are summarized in Table
7 AX7-4 (CD, Chapter 7 Annex). As a group, these hospital admissions studies tend to be larger
8 geographically and temporally than the ED visit studies and provide results that are generally
9 more consistent. The largest and most significant associations of respiratory hospital admissions
10 with O₃ concentrations were observed using short lag periods, in particular for a 0-day lag (same
11 day exposure) and a 1-day lag (previous day exposure). Most studies in the United States and
12 Canada indicated positive, statistically significant associations between ambient O₃
13 concentrations and respiratory hospital admissions in the warm season, including studies with
14 98th percentile 8-hr maximum O₃ levels as low as about 50 ppb. However, not all studies found
15 a statistically significant relationship with O₃, possibly because of insufficient power and/or very
16 low ambient O₃ levels. Analyses for confounding using multipollutant regression models suggest
17 that copollutants generally do not confound the association between O₃ and respiratory
18 hospitalizations. Ozone effect estimates were robust to PM adjustment in all-year and warm-
19 season only data.

20 Overall, the CD concludes that positive and robust associations were found between
21 ambient O₃ concentrations and various respiratory disease hospitalization outcomes, when
22 focusing particularly on results of warm-season analyses. Recent studies also generally
23 supported a positive association between O₃ concentrations and ED visits for asthma during the
24 warm season (CD, p. 7-175). These observations are strongly supported by the human clinical,
25 animal toxicologic, and epidemiologic evidence for lung function decrements, increased
26 respiratory symptoms, airway inflammation, and increased airway responsiveness. Taken
27 together, the overall evidence supports a causal relationship between acute ambient O₃ exposures
28 and increased respiratory morbidity outcomes resulting in increased ED visits and
29 hospitalizations during the warm season (CD, p. 8-77).

30 **3.3.1.1.7 Effects on Exercise Performance**

31 The effects of O₃ exposure on exercise performance of healthy individuals have been
32 investigated in a number of controlled exposure studies (CD, section 6.7). Several studies
33 discussed in the 1996 CD reported that endurance exercise performance and VO_{2max} may be
34 limited by acute exposure to O₃. Other studies found that significant reductions in maximal
35 endurance exercise performance may occur in well-conditioned athletes while they perform CE
36 (V_E > 80 L/min) for 1 hr at O₃ concentrations ≥ 0.18 ppm. There are no new studies available in

1 the CD. Thus, as in the 1996 CD, the CD concludes that reports from studies of O₃ exposure
2 during high-intensity exercise indicate that breathing discomfort associated with maximal
3 ventilation may be an important factor in limiting exercise performance in some, but not all,
4 subjects (CD, p. 6-30).

5 **3.3.1.2 Effects on the Respiratory System from Long-term Exposures**

6 The 1996 CD concluded that there was insufficient evidence from the limited number of
7 studies to determine whether long-term O₃ exposures resulted in chronic health effects at
8 ambient levels observed in the U.S. However, the aggregate evidence suggested that O₃
9 exposure, along with other environmental factors, could be responsible for health effects in
10 exposed populations (CD, section 7.5). Animal toxicological studies carried out in the 1980's
11 and 1990's demonstrated that long-term exposures can result in a variety of morphological
12 effects, including permanent changes in the small airways of the lungs, including remodeling of
13 the distal airways and CAR and deposition of collagen, possibly representing fibrotic changes.
14 These changes result from the damage and repair processes that occur with repeated exposure.
15 Fibrotic changes were also found to persist after months of exposure providing a potential
16 pathophysiologic basis for changes in airway function observed in children in some recent
17 epidemiological studies. It appears that variable seasonal ambient patterns of exposure may be
18 of greater concern than continuous daily exposures.

19 This section reviews studies published since 1996 in which health effects were assessed
20 for O₃ exposures lasting from weeks to several years. Summaries of recent morphological
21 effects studies of subchronic and chronic exposures are listed in Table AX5-10 (CD, Annex
22 AX5). Summaries of recent morbidity effects epidemiological studies of long-term exposure are
23 listed in Table AX7-6 (CD, Annex AX7).

24 **3.3.1.2.1 Seasonal Ozone Effects on Lung Function**

25 It is well documented in controlled human exposure and field studies that daily multi-
26 hour exposures to O₃ produce transient declines in lung function; however, lung function effects
27 of repeated exposures to O₃ over extended periods are far less studied. Several studies published
28 since 1996 have investigated lung function changes over seasonal time periods (CD, section
29 7.5.3). One large, three-year study (Frischer et al., 1999) collected repeated lung function
30 measurements in 1,150 young, Austrian school children and reported that there was an
31 association between growth-related increases in lung function over the summer season and
32 seasonal mean O₃ levels. Mean summertime 24-hr avg O₃ concentrations ranged from 32.5 to
33 37.3 ppb during the three summers. Growth-related increases in lung function over the summer
34 season were reduced in relation to seasonal mean O₃. It was cautioned that it was difficult to
35 attribute the reported effects to O₃ alone independently of copollutants (CD, p. 7-113). A one-

1 year extension of this study by Horak et al. (2002a,b) confirmed the results that seasonal mean
2 O₃ levels are associated with a negative effect on increases in lung function in children. A study
3 (Kopp et al., 2000) of 797 children in Austria and southwestern Germany reported smaller
4 increases in lung function in children exposed to higher levels of ambient O₃ (mean O₃
5 concentration of 44 to 52 ppb) compared to children living in areas with lower ambient O₃ levels
6 (25 to 33 ppb). Another Austrian study (Ihorst et al., 2000) of 2,153 young children found
7 significantly lower FVC and FEV₁ increases associated with higher O₃ exposures in the summer
8 but not in the winter. A pilot study (Kinney and Lippmann, 2000) of 72 young adult, military
9 academy students provided results that are consistent with a seasonal decline in lung function
10 that may be due, in part, to O₃ exposures. According to the CD (p. 7-114), these studies
11 collectively indicate that seasonal O₃ exposure is associated with smaller growth-related
12 increases in lung function in children than they would have experienced living in clean air and
13 that there is some limited evidence that seasonal O₃ also may affect lung function in young
14 adults, although uncertainty about the role of copollutants makes it difficult to attribute the
15 effects to O₃ alone.

16 **3.3.1.2.2 *Reduced Baseline Lung Function and Respiratory Symptoms***

17 Lung capacity grows during childhood and adolescence as body size increases, reaches a
18 maximum during the twenties, and then begins to decline steadily and progressively with age.
19 Long-term exposure to air pollution has long been thought to contribute to slower growth in lung
20 capacity, diminished maximally attained capacity, and/or more rapid decline in lung capacity
21 with age (CD, section 7.5.4). Toxicological findings evaluated in the 1996 CD demonstrated that
22 repeated daily exposure of rats to an episodic profile of O₃ caused small, but significant,
23 decrements in growth-related lung function that were consistent with early indicators of focal
24 fibrogenesis in the proximal alveolar region, without overt fibrosis (CD, section 5.2.5.2).
25 Because O₃ is a strong respiratory irritant and has been shown to cause inflammation and
26 restructuring of the respiratory airways, it is plausible that long-term O₃ exposures might have a
27 negative impact on baseline lung function, particularly during childhood when these exposures
28 might have long-term risks. As noted in the current CD, however, no recent toxicological studies
29 have been published on effects of chronic O₃ exposure.

30 Several epidemiological studies published since 1996 have examined the relationship
31 between growth-related lung function and long-term O₃ exposure. The most extensive and
32 robust study of respiratory effects in relation to long-term air pollution exposures among children
33 in the U.S. is the Children's Health Study carried out in 12 communities of southern California
34 starting in 1993 (Avol et al., 2001; Gauderman et al., 2000, 2002, 2004a,b; Peters et al.,
35 1999a,b). One study (Peters et al., 1999a) examined the relationship between long-term O₃
36 exposures and self reports of respiratory symptoms and asthma in a cross sectional analysis and

1 found a limited relationship between outcomes of current asthma, bronchitis, cough and wheeze
2 and a 40 ppb increase in 1-hr max O₃ (CD, p. 7-115). Another analysis (Peters et al., 1999b)
3 examined the relationship between growth-related lung function at baseline and levels of air
4 pollution in the community and reported evidence that annual mean O₃ levels were associated
5 with decreases in FVC, FEV₁, PEF and FEF₂₅₋₇₅ (the latter two being statistically significant)
6 among females but not males (CD, p. 7-116). In a separate study (Gauderman et al., 2000) of 4th,
7 7th, and 10th grade students, a longitudinal analysis of growth-related lung function over four
8 years found no association with O₃ exposure. Subsequent studies by the same group
9 (Gauderman et al., 2002, 2004a,b) led the authors to conclude that results provide little evidence
10 that ambient O₃ at current levels is associated with chronic deficits in the rate of increase in
11 growth-related lung function in children (CD, p. 7-116 to 7-118). Avol et al. (2001) examined
12 children who had moved from participating communities in southern California to other states
13 with improved air quality and found, with the exception of FEV₁, the O₃ effect estimates for all
14 other spirometric parameters were negative, but the associations were not as strong as those
15 observed for PM₁₀ (CD, p. 7-116). Collectively, the results of these reports from the children's
16 health cohorts provide little evidence for impact of long-term O₃ exposures on smaller increases
17 in growth-related lung function (CD, p. 7-116).

18 Evidence for a significant relationship between long-term O₃ exposures and decrements
19 in maximally attained lung function was reported in a nationwide study of first year Yale
20 students (CD, p. 7-120). Males had much larger effect estimates than females, which might
21 reflect higher outdoor activity levels and correspondingly higher O₃ exposures during childhood.
22 A similar study (Kunzli et al., 1997; Tager et al., 1998) of college freshmen at University of
23 California at Berkeley also reported significant effects of long-term O₃ exposures on lung
24 function (CD, p. 7-121). In a comparison of students whose city of origin was either Los
25 Angeles or San Francisco, long-term O₃ exposures were associated with significant changes in
26 mid- and end-expiratory flow measures, which could be considered early indicators for
27 pathologic changes that might progress to COPD.

28 In summary, recent publications from the southern California children's cohort study
29 provide no evidence for an association between long-term O₃ exposure and lung function in
30 children (CD, p. 7-118), while limited evidence is available from studies of adults and college
31 students suggest that long-term O₃ exposure may affect lung function or respiratory symptoms
32 (CD, pp. 7-120, 7-121). Overall, the CD concluded that this body of evidence was inconclusive
33 for effects of long-term O₃ exposure on respiratory symptoms or lung function (CD, p. 7-175).

34 **3.3.1.2.3 Long-term O₃ Exposure and Respiratory Inflammation**

35 As noted above in section 3.3.1.1.3 and in the CD (Chapter 6), chamber studies of
36 exercising humans exposed to O₃ for 2 to 6.6 hrs have demonstrated inflammation in the lungs,

1 including the alveolar region where gas exchange takes place. The potential long-term
2 significance of short-term exposures to O₃ is that they can result in the release of reactive
3 substances from inflammatory cells that can damage the sensitive cells lining the lungs. Over
4 time repeated inflammation can lead to permanent lung damage and restructuring of the small
5 airways and alveoli. Also, since inflammation is a hallmark characteristic of asthma, there is the
6 possibility that O₃-induced inflammation may exacerbate existing asthma or contribute to the
7 development of asthma in genetically predisposed individuals (CD, section 7.5.5).

8 For subchronic exposures of animals, permeability changes are transient (and species-
9 dependent) and return to control levels even with continuing exposure. For long-term O₃
10 exposures, persistent O₃-induced inflammation plays an important role in alterations of lung
11 structure and function. Significant remodeling of the epithelium and underlying connective
12 tissues in distal airways have been reported in rats exposed to 0.25 ppm O₃ (12 hr/day for 6
13 weeks) and in monkeys exposed to 0.2 ppm O₃ (8 hr/day for 90 days)(CD, p. 8-23).

14 In one epidemiological field study (Kinney et al., 1996), BAL fluids were taken in the
15 summer and winter from a group of joggers in New York and were compared for evidence of
16 acute inflammation and of enhanced cell damage (CD, p. 7-122). The mean 1-hr max
17 concentrations for a 3-month period were 58 ppb (max 110 ppb) in the summer and 32 ppb (max
18 64 ppb) in the winter. There was little evidence of acute inflammation in the summer BAL fluids
19 compared to winter, but there was evidence of enhanced cell damage. This suggests that even
20 though inflammation may diminish over the summer, cell damage may be continuing. A cross-
21 sectional cohort study (Calderon-Garciduenas et al., 1995) conducted in Mexico City provides
22 evidence of inflammation and genetic damage to cells in the nasal passages of children
23 chronically exposed to O₃ and other air pollutants (CD, p. 7-123). In Mexico City, the 1-hr avg
24 O₃ concentrations exceeded 120 ppb for 4.4 hr/day. Significantly higher DNA damage was
25 reported in children living in Mexico City compared to nonurban children and in older compared
26 to younger children. Another marker of inflammation, urinary eosinophils, was analyzed in an
27 Austrian school children study (Frischer et al., 2001), and it was reported that O₃ exposure (mean
28 30 day avg O₃ concentration before sample collection was 31.6 ppb) was significantly associated
29 with eosinophil inflammation (CD, p. 7-122).

30 In assessing these studies, the CD (p. 7-123) concluded that specific attribution of these
31 adverse respiratory and genotoxic effects to O₃ is difficult given the complex mixture in ambient
32 air, although inflammatory changes like eosinophil levels observed in the Austrian study would
33 be consistent with known effects of O₃.

34 **3.3.1.2.4 Risk of Asthma Development**

35 There have been a few studies investigating associations between long-term O₃ exposures
36 and the onset of new cases of asthma (CD, section 7.5.6). The Adventist Health and Smog

1 (AHSMOG) study cohort of 3,914 was drawn from nonsmoking, non-Hispanic white adult
2 Seventh Day Adventists living in California (Greer et al., 1993; McDonnell et al., 1999).
3 Subjects were surveyed in 1977, 1987, and 1992. During the ten-year follow-up in 1987, it was
4 reported that the incidence of new asthma was 2.1% for males and 2.2% for females (Greer et al.,
5 1993). A statistically significant relative risk of 3.12 (95% CI: 1.16, 5.85) per 10 ppb increase in
6 annual mean O₃ was observed in males, compared to a nonsignificant relative risk of 0.94 (95%
7 CI: 0.65, 1.34) in females. In the 15-year follow-up in 1992, it was reported that 3.2% of eligible
8 males and 4.3% of eligible females had developed adult asthma (McDonnell et al., 1999). For
9 males, the relative risk of developing asthma was 2.27 (95% CI: 1.03, 4.87) per 30 ppb increase
10 in 8-hr average O₃, but there was no evidence of an association in females. The lack of an
11 association in females does not necessarily mean there is no effect but may be due to differences
12 in time-activity patterns in males and females, which could lead to greater misclassification of
13 exposure in females. Consistency of results in the two studies with different follow-up times
14 provides supportive evidence of an association between long-term O₃ exposure and asthma
15 incidence in adult males; however, representativeness of this cohort to the general U.S.
16 population may be limited (CD, p. 7-125).

17 In a similar study (McConnell et al., 2002) of incident asthma among children (ages 9 to
18 16 at enrollment), annual surveys of 3,535 children initially without asthma were used to identify
19 new-onset asthma cases as part of the Children's Health Study. Six high-O₃ (75.4 ppb mean 1-hr
20 max over four years) and six low-O₃ (50.1 ppb, mean 1-hr max) communities were identified
21 where the children resided. There were 265 children who reported new-onset asthma during the
22 follow-up period. Although asthma risk was no higher for all residents of the six high-O₃ versus
23 six low-O₃ communities, asthma risk was 3.3 times greater for children who played three or more
24 sports as compared with children who played no sports within the high-O₃ communities. This
25 association was absent in the communities with lower O₃ concentrations. No other pollutants
26 were found to be associated with new-onset asthma (CD, p. 7-125)

27 Playing sports may result in extended outdoor activity and exposure occurring during
28 periods when O₃ levels are higher. The sports activities would cause an increased ventilation
29 rate, thus resulting in increased O₃ dose. It should be noted, however, that the results of the
30 Children's Health Study (McConnell et al., 2002) were based on a small number (20 in high-O₃
31 areas and 9 in low- O₃ areas) of new-onset asthma cases among children who played three or
32 more sports (CD, p. 7-125). Future replication of these findings in other cohorts would help
33 determine whether a causal interpretation is appropriate.

34 **3.3.1.2.5 Morphological Effects**

35 In animal toxicology studies, the progression of morphological effects reported during
36 and after a chronic exposure in the range of 0.5 to 1.0 ppm O₃ is complex, with inflammation

1 peaking over the first few days of exposure, then dropping, then plateauing, and finally, largely
2 disappearing (CD, section 5.2.4.4). By contrast, fibrotic changes in the tissue increase very
3 slowly over months of exposure, and, after exposure ceases, the changes sometimes persist or
4 increase. Epithelial hyperplasia peaks soon after the inflammatory response but is usually
5 maintained in both the nose and lungs with continuous exposure. Epithelial
6 hyperplasia/metaplasia also does not repair after the end of exposure. Patterns of exposure in
7 this same concentration range determine effects, with 18 months of daily exposure, causing less
8 morphologic damage than exposures on alternating months. This is important as environmental
9 O₃ exposure is typically seasonal. Long-term studies of Plopper and colleagues (Evans et al.,
10 2003; Schelegle et al., 2003; Chen et al., 2003; Plopper and Fanucchi, 2000) investigated infant
11 rhesus monkeys exposed to simulated, seasonal O₃ (0.5 ppm, 8 hrs/day for 5 days, every 14 days
12 for 11 episodes) and demonstrated: 1) remodeling in the distal airways, 2) abnormalities in
13 tracheal basement membrane; 3) eosinophil accumulation in conducting airways; and 4)
14 decrements in airway innervation (CD, p. 5-45). As with other effects, these findings advance
15 earlier information regarding possible injury-repair processes occurring with long-term O₃
16 exposures suggesting that these processes are only partially reversible and may progress
17 following cessation of O₃ exposure and may lead to nonreversible structural damage to lung
18 tissue; however, there is still too much uncertainty to quantitatively extrapolate these levels to
19 human effect levels at this time (CD, p. 8-25).

20 **3.3.1.2.6 Summary**

21 In the past decade, important new longitudinal studies have examined the effect of
22 chronic O₃ exposure on respiratory health outcomes. Evidence from recent long-term morbidity
23 studies have suggested in some cases that chronic exposure to O₃ may be associated with
24 seasonal declines in lung function, increases in inflammation, and development of asthma in
25 children and adults. Seasonal decrements or smaller increases in lung function measures have
26 been reported in several studies; however, it remains uncertain to what extent these changes are
27 transient. While there is supportive evidence from animal studies involving chronic exposures,
28 large uncertainties still remain as to whether current ambient levels and exposure patterns might
29 cause these same effects in human populations. The CD also concludes that epidemiological
30 studies of new asthma development and longer-term lung function declines remain inconclusive
31 at present (CD, p. 7-134).

32 **3.3.1.3 Effects on the Cardiovascular System**

33 At the time of the 1997 review, the possibility of O₃-induced cardiovascular effects was a
34 largely unrecognized issue. Since then, evidence has emerged that provides plausibility for how
35 O₃ exposures could exert cardiovascular system effects. This includes direct effects such as O₃-

1 induced release from lung epithelial cells of platelet activating factor (PAF) that may contribute
2 to blood clot formation that would increase the risk of serious cardiovascular outcomes (e.g.,
3 heart attack, stroke, mortality). Also, interactions of O₃ with surfactant components in epithelial
4 lining fluid of the lung results in production of oxysterols and reactive oxygen species that may
5 exhibit PAF-like activity contributing to clotting and also may exert cytotoxic effects on lung
6 and heart muscle cells. Other possible mechanisms may involve O₃-induced secretions of
7 vasoconstrictive substances and/or effects on neuronal reflexes that may result in increased
8 arterial blood pressure and/or altered electrophysiologic control of heart rate or rhythm. Some
9 animal toxicology studies have shown O₃-induced decreases in heart rate, mean arterial pressure,
10 and core temperature. The only controlled human exposure study that evaluated effects of O₃
11 exposure on cardiovascular health outcomes found no significant O₃-induced differences in
12 ECG, heart rate, or blood pressure in healthy or hypertensive subjects, but did observe a
13 significant O₃-induced increase the alveolar-to-arterial PO₂ gradient in both groups resulting in
14 an overall increase in myocardial work and impairment in pulmonary gas exchange.

15 Epidemiologic panel and field studies that examined associations between O₃ and various
16 cardiac physiologic endpoints have yielded limited evidence suggestive of a potential association
17 between acute O₃ exposure and altered heart rate variability, ventricular arrhythmias, and
18 incidence of heart attacks. A number of epidemiological studies have also reported associations
19 between short-term exposures and hospitalization for cardiovascular diseases. As shown in
20 Figure 7-13 of the CD, many of the studies reported negative or inconsistent associations. Some
21 other studies, especially those that examined the relationship when O₃ exposures were higher,
22 have found robust positive associations between O₃ and cardiovascular hospital admissions (CD,
23 p. 7-82). For example, one study reported a positive association between O₃ and cardiovascular
24 hospital admissions in Toronto, Canada in a summer-only analysis (mean 1-hr max O₃ of 41.2
25 ppb). The results were robust to adjustment for various PM indices, whereas the PM effects
26 diminished when adjusting for gaseous pollutants. Other studies stratified their analysis by
27 temperature, i.e., by warm days (≥ 20 °C) versus cool days (< 20 °C). Several analyses using
28 warm days consistently produced positive associations.

29 The epidemiologic evidence for cardiovascular morbidity is much more mixed than for
30 respiratory morbidity, with only one of several U.S./Canadian studies showing statistically
31 significant positive associations of cardiovascular hospitalizations with warm-season O₃
32 concentrations. Most of the available European and Australian studies (all of which conducted
33 all-year O₃ analyses) did not find an association between short-term O₃ concentrations and
34 cardiovascular hospitalizations. Overall, the currently available evidence is inconclusive
35 regarding an association between cardiovascular hospital admissions and ambient O₃ exposure
36 (CD, p. 7-83)

1 Based on the evidence from animal toxicology, human controlled exposure, and
2 epidemiologic studies, the CD concludes that this generally limited body of evidence is highly
3 suggestive that O₃ can directly and/or indirectly contribute to cardiovascular-related morbidity,
4 but that much needs to be done to more fully substantiate links between ambient O₃ exposures
5 and adverse cardiovascular outcomes (CD, p. 8-77).

6 **3.3.2 Premature Mortality**

7 There were only a limited number of studies which examined the relationship between O₃
8 and mortality available for review in the 1996 CD. Some studies suggested that mortality was
9 associated with short-term exposure to O₃, but conclusions could not be drawn regarding such
10 associations (CD, p. 84). Numerous recent studies have provided new and more substantial
11 evidence supporting such an association, as discussed below in section 3.3.2.1.

12 At the time of the last review, little epidemiological evidence was available on potential
13 associations between long-term exposure to O₃ and mortality. Among the recent studies are
14 some that have evaluated this relationship, and these newer studies still provide limited, if any,
15 evidence for an association between chronic O₃ exposure and mortality, as described in section
16 3.3.2.2.

17 **3.3.2.1 Mortality and Short-term O₃ Exposure**

18 The 1996 CD concluded that an association between daily mortality and O₃ concentration
19 for areas with high O₃ levels (e.g., Los Angeles) was suggested. However, due to a very limited
20 number of studies available at that time, there was insufficient evidence to conclude that the
21 observed association was likely causal, and thus the possibility that O₃ exposure may be
22 associated with mortality was not relied upon in the 1997 decision on the O₃ primary standard.

23 The 2006 CD includes results from numerous epidemiological analyses of the
24 relationship between O₃ and mortality. Key findings are available from multi-city time-series
25 studies that report associations between O₃ and mortality. These studies include analyses using
26 data from 90 U.S. cities in the National Mortality, Morbidity and Air Pollution (NMMAPS)
27 study and from 95 U.S. cities in an extension to the NMMAPS analyses (Samet et al., 2000,
28 reanalyzed in Dominici, 2003) and further analyses (Bell et al., 2004) using a subset of 19 U.S.
29 cities and focusing on cause-specific mortality associations (Huang et al., 2005). An additional
30 study (Schwartz, 2005) used case-crossover design and data from 14 U.S. cities to further
31 investigate the influence of adjustment for weather variables in the O₃-mortality relationship
32 (CD, p. 8-38). Finally, results are available from a European study, Air Pollution and Health: a
33 European Approach (APHEA), an analysis using data from 23 cities (Gryparis et al., 2004) and 4
34 cities (Toulomi et al., 1997) (CD, p. 7-93).

1 The original 90-city NMMAPS analysis, with data from 1987 to 1994, was primarily
2 focused on investigating effects of PM₁₀ on mortality. A significant association was reported
3 between mortality and 24-hr average O₃ concentrations during the warm season, but the
4 association was not significant in analyses for the full year (Samet et al., 2000) (CD, Figure 7-19;
5 p. 7-92). This is because the estimate using all available data was about half that for the
6 summer-only data at a lag of 1-day. The extended NMMAPS analysis included data from 95
7 U.S. cities and included an additional 6 years of data, from 1987-2000 (Bell et al., 2004), and
8 significant associations were reported between O₃ and mortality. The effect estimate for
9 increased mortality was 0.5% per 24-hr average O₃ measured on the same day (20 ppb change;
10 95% PI: 0.24, 0.78), and 1.04% per 24-hr average O₃ in a 7-day distributed lag model (20 ppb
11 change; 95% PI: 0.54, 1.55) (CD, p. 7-88). In analyses using only data from the warm season,
12 the results were not significantly different from the full-year results; the effect estimate for
13 increased mortality was 0.44% per 24-hr average O₃ measured on the same day (20 ppb change;
14 95% PI: 0.14, 0.74), and 0.78% per 24-hr average O₃ in a 7-day distributed lag model (20 ppb
15 change; 95% PI: 0.26, 1.30). The authors also report that O₃-mortality associations were robust
16 to adjustment for PM (CD, p. 7-97).

17 Using a subset of the NMMAPS data set, another study focused on associations between
18 cardiopulmonary mortality and O₃ exposure (24-hr avg) during the summer season only. The
19 authors report a 1.47% increase per 20 ppb change in O₃ concentration measured on the same
20 day (95% PI: 0.54, 2.39) and a 2.52% increase per 20 ppb change in O₃ concentration using a 7-
21 day distributed lag model (95% PI: 0.94, 4.10)(CD, p. 7-92). These findings suggest that the
22 effect of O₃ on mortality is immediate but also persists for several days.

23 As discussed below in section 3.4, assessment of confounding by weather, especially
24 temperature, is complicated by the fact that higher temperatures are associated with the increased
25 photochemical activities that are important for O₃ formation. Using a case-crossover study
26 design, another study assessed associations between daily maximum concentrations and
27 mortality, matching case and control periods by temperature, and using data only from the warm
28 season. The reported effect estimate of 0.92% change in mortality per 40 ppb O₃ (1-hr max, 95%
29 PI: 0.06, 1.80) was similar to time-series analysis results with adjustment for temperature (0.76%
30 per 40 ppb O₃, 95% PI, 0.13, 1.40), suggesting that associations between O₃ and mortality are not
31 sensitive to the adjustment methods for temperature (CD, p. 7-93).

32 An initial publication from APHEA, a European multi-city study, reported statistically
33 significant associations between daily maximum O₃ concentrations and mortality, with an effect
34 estimate of a 4.5% increase in mortality per 40 ppb O₃ (95% CI: 1.6, 7.7) in four cities (Toulomi
35 et al., 1997). An extended analysis was done using data from 23 cities throughout Europe
36 (Gryparis et al., 2004). In this report, a positive but not statistically significant association was

1 found between mortality and 1-hr daily maximum O₃ in a full year analysis (CD, p. 7-93).
2 Gryparis et al. (2004) noted that there was a considerable seasonal difference in the O₃ effect on
3 mortality; thus, the small effect for the all-year data might be attributable to inadequate
4 adjustment for confounding by seasonality. Focusing on analyses using summer measurements,
5 the authors report statistically significant associations with total mortality [1.8% increase per 30
6 ppb 8-hr O₃ (95% CI: 0.8, 2.9)], cardiovascular mortality [2.7% increase per 30 ppb 8-hr O₃
7 (95% CI: 1.2, 4.3)] and with respiratory mortality (6.8% increase per 30 ppb 8-hr O₃, 95% CI:
8 4.5, 9.2) (CD, p. 7-93, 7-99).

9 Two of the recent multi-city mortality studies (Bell et al., 2004; Gryparis et al., 2004)
10 have also reported associations for multiple averaging times (CD, p. 8-38). Bell and colleagues
11 (2004) reported associations between mortality and 1-hr daily max, 8-hr daily max and 24-hr avg
12 O₃ concentrations. Effect estimates for associations with 1-hr O₃ was slightly larger than that
13 reported for 8-hr O₃ concentrations, and both were distinctly larger than the association with 24-
14 hr avg O₃, but the effect estimates did not differ statistically. The APHEA study (Gryparis et al.,
15 2004) also reported effect estimates that were slightly larger with 1-hr than with 8-hr O₃
16 concentrations, but not significantly so.

17 Numerous single-city analyses have also reported associations between mortality and
18 short-term O₃ exposure, especially for those analyses using warm season data. As shown in
19 Figure 7-18 of the CD, the results of recent publications show a pattern of positive, often
20 statistically significant associations between short-term O₃ exposure and mortality during the
21 warm season (CD, p. 7-91). For example, statistically significant associations were reported in
22 southern California (Ostro et al., 1995), Philadelphia (Moolgavkar et al., 1995), Dallas (Gamble
23 et al., 1998), and Vancouver (Vedal et al., 2003), as well as numerous studies conducted in other
24 countries. However, no evidence of an association was seen in a study conducted in Pittsburgh
25 (Chock et al., 2000). In considering results from year-round analyses, there remains a pattern of
26 positive results but the findings are less consistent. For example, statistically significant
27 associations were reported in Philadelphia (Moolgavkar et al., 1995) and Dallas (Gamble et al.,
28 1998), while positive but not statistically significant associations were reported in Detroit
29 (Lippmann et al., 2000, reanalyzed in Ito, 2003), San Jose (Fairley, 1999, reanalyzed Fairley,
30 2003), and Atlanta (Klemm et al., 2004). No evidence for associations was reported in Los
31 Angeles (Kinney et al., 1995), Coachella Valley (Ostro et al., 2003), and St. Louis and Eastern
32 Tennessee (Dockery et al., 1992). In most single-city analyses, effect estimates were not
33 substantially changed with adjustment for PM (CD Figure 7-19, p. 7-92).

34 In addition, several meta-analyses have been conducted on the relationship between O₃
35 and mortality. As described in section 7.4.4 of the CD, these analyses reported fairly consistent
36 and positive combined effect estimates ranging from 1.5 to 2.5% increase in mortality for a

1 standardized change in O₃ (CD, Figure 7-20, p. 7-95). Three recent meta-analyses evaluated
2 potential sources of heterogeneity in O₃-mortality associations (Bell et al., 2005; Ito et al., 2005;
3 Levy et al., 2005). The CD (p. 7-96) observes common findings across all three analyses, in that
4 all reported that effect estimates were larger in warm season analyses, reanalysis of results using
5 default GAM criteria did not change the effect estimates, and there was no strong evidence of
6 confounding by PM (CD, p. 7-97). Bell et al. (2005) and Ito et al. (2005) both provided
7 suggestive evidence of publication bias, but O₃-mortality associations remained after accounting
8 for that potential bias. The CD (7-97) concludes that the “positive O₃ effects estimates, along
9 with the sensitivity analyses in these three meta-analyses, provide evidence of a robust
10 association between ambient O₃ and mortality.”

11 For standardized increments, effect estimates range from 0.5 to 2.5% increases in
12 mortality in the multi-city studies and from 0.5 to 5% in single-city studies. For most studies
13 that conducted season-specific analyses, effects were larger and more precise in warm-season
14 analyses (CD, p. 7-97).

15 In the CD (p. 7-101), Figure 7-22 shows the O₃ risk estimates with and without
16 adjustment for PM indices using all-year data in studies that conducted two-pollutant analyses.
17 Approximately half of the O₃ risk estimates increased slightly, whereas the other half decreased
18 slightly with the inclusion of PM in the models. In general, the O₃-mortality risk estimates were
19 robust to adjustment for PM in the models, with the exception of Los Angeles, CA data with
20 PM₁₀ (Kinney et al., 1995) and Mexico City data with TSP (Borja-Aburto et al., 1997). The U.S.
21 95 communities study (Bell et al., 2004) examined the sensitivity of acute O₃-mortality effects to
22 potential confounding by PM₁₀ (CD, 7-100). Restricting analysis to days when both O₃ and PM₁₀
23 data were available, the community-specific O₃-mortality effect estimates as well as the national
24 average results indicated that O₃ was robust to adjustment for PM₁₀ (Bell et al., 2004).

25 Several O₃-mortality studies examined the effect of confounding by PM indices in
26 different seasons (CD, p. 7-102, Figure 7-23). In analyses using all-year data and warm-season
27 only data, O₃ effect estimates were once again fairly robust to adjustment for PM indices, with
28 values showing both slight increases and decreases with the inclusion of PM in the model. In the
29 analyses using cool season data only, the O₃ effect estimates all increased slightly with the
30 adjustment of PM indices, although none reached statistical significance.

31 The three recent meta-analyses (Bell et al., 2005; Ito et al., 2005; Levy et al., 2005) all
32 examined the influence of PM on O₃ risk estimates. No substantial influence was observed in
33 any of these studies. In the analysis by Bell et al. (2005), the combined estimate without PM
34 adjustment was 1.7% (95% PI: 1.10, 2.37) from 41 estimates, and the combined estimate with
35 PM adjustment was 1.95% (95% PI: 1.06, 4.00) from 11 estimates per 20 ppb increase in 24-hr
36 avg O₃. In the meta-analysis of 15 cities (Ito et al., 2005), the combined estimate was 1.6%

1 (95% PI: 1.1, 2.2) and 1.5% (95% PI: 0.8, 2.2) per 20 ppb in 24-hr avg O₃ without and with PM
2 adjustment, respectively (CD, p. 7-103). The additional time-series analysis of six cities by Ito et
3 al. (2005) found that the influence of PM by season varied across alternative weather models but
4 was never substantial. Levy et al. (2005) examined the regression relationships between O₃ and
5 PM indices (PM₁₀ and PM_{2.5}) with O₃-mortality effect estimates for all year and by season.
6 Positive slopes, which might indicate potential confounding, were observed for PM_{2.5} on O₃
7 effect estimates in the summer and all-year periods, but the relationships were weak. The effect
8 of one causal variable (i.e., O₃) is expected to be overestimated when a second causal variable
9 (e.g., PM) is excluded from the analysis, if the two variables are positively correlated and act in
10 the same direction. However, the results from these meta-analyses, as well as several single- and
11 multiple-city studies, indicate that copollutants generally do not appear to substantially confound
12 the association between O₃ and mortality (CD, p. 7-103).

13 Finally, from those studies that included assessment of associations with specific causes
14 of death, it appears that effect estimates for associations with cardiovascular mortality are larger
15 than those for total mortality; effect estimates for respiratory mortality are less consistent in size,
16 possibly due to reduced statistical power in this subcategory of mortality (CD, p. 7-108). In
17 addition to all-cause mortality, several studies examined broad underlying causes of mortality,
18 such as cardiovascular and respiratory causes. The U.S. 95 communities study (1987-2000)
19 analyzed O₃ effect estimates from cardiovascular and respiratory mortality. The analysis by Bell
20 et al. (2005) used all available data, which included all-year data from 55 communities and
21 warm-season only data from 40 communities. The national average estimate from the
22 constrained distributed lag model was slightly greater for cardiopulmonary deaths than deaths
23 from all causes, with an excess risk of 1.28% (95% PI: 0.62, 1.97) compared to 1.04% (95% PI:
24 0.54, 1.55) per 20 ppb increase in 24-hr avg O₃ in the preceding week.

25 A related study (Huang et al., 2005) examined O₃ effects on cardiopulmonary mortality
26 during the summers (June to September) of 1987 to 1994 in 19 large U.S. cities from the
27 NMMAPS database. Figure 7-24 in the CD (p. 7-104), presents the Bayesian city-specific and
28 overall average O₃ effect estimates for cardiopulmonary mortality per 20 ppb increase in 24-hr
29 avg O₃ from a constrained 7-day distributed lag model. The O₃ effect estimate was 2.52% (95%
30 PI: 0.94, 4.10) excess risk in cardiopulmonary mortality per 20 ppb increase in 24-hr avg O₃ in
31 the preceding week for the combined analysis of all cities. For analyses of summer data,
32 confounding of the O₃ effect by PM is of concern as daily variations in O₃ may be correlated to
33 PM during the summer months. Huang et al. (2005) observed that when PM₁₀ was included in
34 the model, the O₃ effect estimate, on average, remained positive and significant. As PM₁₀
35 measurements were available only every 1 to 6 days, only single-day lags were examined. At a
36 0-day lag, O₃ was associated with a 1.47% (95% PI: 0.54, 2.39) excess risk versus a 1.49% (95%

1 PI: 0.66, 3.47) excess risk in cardiopulmonary mortality in the O₃-only model and after
2 adjustment for PM₁₀, respectively. The slight sensitivity of the O₃ health effects to the inclusion
3 of PM₁₀ in the model may indicate a true confounding effect. However, as only the days with
4 PM₁₀ data available were included in the analysis, the lack of significance is likely attributable to
5 higher statistical uncertainty due to the lack of daily PM₁₀ measurements (CD, p. 7-105).

6 Figure 7-25 in the CD (p., 7-106), presents effect estimates for associations between O₃
7 and cardiovascular mortality for all-year and warm-season analyses. All studies, with the
8 exception of Ponka et al. (1998), showed positive associations between O₃ and cardiovascular
9 mortality (CD, p. 7-105). As with all-cause mortality, there appears to be heterogeneity in the
10 effect estimates across studies. The cardiovascular mortality estimate from one meta-analysis
11 appears to be close to the mode of the effect estimates from the various studies, as shown in
12 Figure 7-25, in the CD (p. 7-105). This is expected, given that many of these studies were also
13 included in the meta-analysis. This study observed that the posterior mean estimate for
14 cardiovascular causes (2.23% excess risk per 20 ppb increase in 24-hr avg O₃ from 25 estimates)
15 was slightly larger than that for total mortality (1.75% excess risk from 41 estimates). However,
16 since cardiovascular deaths account for the largest fraction (over 40%) of total deaths, it is not
17 surprising that the risk estimates for cardiovascular mortality are somewhat similar to those from
18 all-cause mortality. Overall, the cardiovascular mortality risk estimates in the current literature
19 show consistently positive associations with some heterogeneity (most estimates fall within the
20 range of 1 to 8% per 40 ppb increase in 1-hr avg O₃ (CD, p. 7-107).

21 Several studies observed that the risk estimates for the respiratory category were larger
22 than the cardiovascular and total nonaccidental categories (Anderson et al., 1996; Gouveia and
23 Fletcher, 2000b; Gryparis et al., 2004; Zmirou et al., 1998). The apparent inconsistencies across
24 studies may be due in part to the differences in model specifications, but they may also reflect
25 the lower statistical power associated with the smaller daily counts of the respiratory category
26 (usually accounting for less than 10% of total deaths) compared to the larger daily counts for the
27 cardiovascular category (approximately 40 to 50% of total deaths). Thus, an examination of the
28 differences in risk estimates across specific causes requires a large population and/or a long
29 period of data collection. In one meta-analysis (Bell et al., 2005), which combined 23 estimates
30 from 17 studies for respiratory mortality, the effect estimate for respiratory causes was smaller
31 (0.94% excess risk per 20 ppb increase in 24-hr avg O₃) compared to the estimates for total
32 mortality (1.75% excess risk) and cardiovascular mortality (2.23% excess risk) (CD, p. 7-107).

33 In summary, several single-city studies observed positive associations between ambient
34 O₃ concentrations and cardiovascular mortality. In addition, a meta-analysis that examined
35 specific causes of mortality found that the cardiovascular mortality risk estimates were higher
36 than those for total mortality. The findings regarding the effect size for respiratory mortality

1 have been less consistent, possibly because of lower statistical power in this subcategory of
2 mortality. The CD finds that the results from U.S. multi-city time-series studies, along with the
3 meta-analyses, provide strong evidence for associations between short-term O₃ exposure and
4 mortality (CD, p. 7-84). The results of these analyses show that the effects of ozone on mortality
5 are generally robust to confounding by copollutants (CD, p. 7-149, 8-54). For cardiovascular
6 mortality, the CD reports that effect estimates are consistently positive, and are more likely to be
7 larger and statistically significant in the warm season analyses (CD, p. 7-108, Figure 7-22). The
8 findings regarding the effects size for respiratory mortality are less consistent, possibly due to
9 lower statistical power in this group (CD, p. 7-94). Overall, the CD concludes that these findings
10 suggest a likely causal association between short-term O₃ exposure and mortality particularly in
11 the warm season (CD, p. 8-78).

12 **3.3.2.2 Mortality and Long-term O₃ Exposure**

13 Little evidence was available in the last review on the potential for associations between
14 mortality and long-term exposure to O₃. In the Harvard Six City prospective cohort analysis, the
15 authors report that mortality was not associated with long-term exposure to O₃ (Dockery et al.,
16 1993). The authors note that the range of O₃ concentrations across the six cities was small (19.7
17 to 28.0 ppb in average 24-hr concentrations over the 7-year study period), which may have
18 limited the power of the study to detect associations between mortality and O₃ levels (CD, p. 7-
19 127).

20 As discussed in section 7.5.8 of the CD, in this review there are results available from
21 three prospective cohort studies: the American Cancer Society (ACS) study, the Adventist
22 Health and Smog (AHSMOG) study, and the U.S. Veterans Cohort study. In addition, a major
23 reanalysis report includes evaluation of data from the Harvard Six City cohort study (Krewski et
24 al., 2000). This reanalysis also includes additional evaluation of data from the initial ACS cohort
25 study report that had only reported results of associations between mortality and long-term
26 exposure to fine particles and sulfates (Pope et al., 1995).¹

27 In this reanalysis of data from the previous Harvard Six City prospective cohort study,
28 the investigators replicated and validated the findings of the original studies, and the report
29 included additional quantitative results beyond those available in the original report (Krewski et
30 al., 2000). In the reanalysis of data from the Harvard Six Cities study, the effect estimate for the
31 association between long-term O₃ concentrations (8.3 ppb between the highest and lowest
32 concentrations in the cities) and mortality was negative and nearly statistically significant
33 (relative risk = 0.87, 95% CI: 0.76, 1.00).

¹ This reanalysis report and the original prospective cohort study findings are discussed in more detail in section 8.2.3 in *Air Quality Criteria for Particulate Matter* (EPA, 2004).

1 The ACS study is based on health data from a large prospective cohort of approximately
2 500,000 adults and air quality data from about 150 U.S. cities. The initial report (Pope et al.,
3 1995) focused on associations with fine particles and sulfates, for which significant associations
4 had been reported in the earlier Harvard Six Cities study (Dockery et al., 1993). As part of the
5 major reanalysis of these data, results for associations with other air pollutants were also
6 reported, and the authors report that no significant associations were found with O₃. However,
7 results of seasonal analyses show a small positive association between long-term O₃
8 concentrations in the warm months (April-September) with a relative risk of 1.02 for all-cause
9 mortality (95% CI: 0.96-1.07) and a stronger association was reported for cardiopulmonary
10 mortality (relative risk=1.08, 95% CI: 1.01, 1.16) (Krewski et al., 2000, p. 174). For some
11 specifications of O₃ exposure in the ACS study, there was an effect in the warm quarter, as there
12 was in the reanalysis of the Harvard Six Cities study.

13 The ACS II study (Pope et al., 2002) reported results of associations with an extended
14 data base; the mortality records for the cohort had been updated to include 16 years of follow-up
15 (compared with 8 years in the first report) and more recent air quality data were included in the
16 analyses. Results are presented for full-year analyses, and show no evidence for a significant
17 association between long-term exposure to O₃ and mortality. As shown in Figure 7-27 of the
18 CD, the effect estimates are near zero and sometimes negative (though not statistically
19 significant) for associations between long-term O₃ exposure and all-cause, cardiopulmonary, and
20 lung cancer mortality (CD, p. 7-128).

21 The Adventist Health and Smog (AHSMOG) cohort includes about 6,000 adults living in
22 California. In two studies from this cohort, a significant association has been reported between
23 long-term O₃ exposure and increased risk of lung cancer mortality among males only (Beeson et
24 al., 1998; Abbey et al., 1999). No significant associations were reported between long-term O₃
25 exposure and mortality from all causes or cardiopulmonary causes. Due to the small numbers of
26 lung cancer deaths (12 for males, 18 for females) and the precision of the effect estimate (i.e., the
27 wide confidence intervals), the CD raised concerns about the plausibility of the reported
28 association with lung cancer (CD, p. 7-130).

29 The U.S. Veterans Cohort study (Lipfert et al., 2000b, 2003) of approximately 50,000
30 middle-aged males diagnosed with hypertension, reported some positive associations between
31 mortality and peak O₃ exposures (95th percentile level for several years of data). The analysis
32 included numerous analyses using subsets of exposure and mortality follow-up periods which
33 spanned the years 1960 to 1996. In the results of analyses using deaths and O₃ exposure
34 estimates concurrently across the study period, there were positive, statistically significant
35 associations between peak O₃ and mortality, with a 9.4% excess risk (95% CI: 0.4, 18.4) per
36 mean 95% percentile O₃ (CD, p. 7-129).

1 Thus, the results from all-year analyses in the Harvard Six Cities and ACS cohorts
2 provide no evidence for associations between long-term O₃ exposure and mortality, though the
3 warm-season results in the reanalysis of the ACS cohort study suggest a potential association.
4 Imprecise and inconclusive associations were reported in analyses for the AHSMOG cohort
5 study. Significant associations between long-term O₃ exposure and mortality were only reported
6 for the Veterans cohort study; while this study used an indicator of peak O₃ concentrations, the
7 cohort is also a rather specific subgroup of the U.S. population. Overall, the CD concludes that
8 consistent associations have not been reported between long-term O₃ exposure and all-cause,
9 cardiopulmonary or lung cancer mortality (CD, p. 7-130).

10 **3.3.3 Ozone Effects on UV-B Flux**

11 The CD (Chapter 10) provides a thorough analysis of the current understanding of the
12 relationship between reducing tropospheric O₃ concentrations and the potential impact these
13 reductions might have on increasing UV-B surface fluxes and indirectly contributing to increased
14 UV-B related health effects. It is clear that there are many factors that influence UV-B radiation
15 penetration to the earth's surface, including cloud cover, surface albedo, PM concentration and
16 composition, and gas phase pollution. A risk assessment of UV-B related health effects would
17 need to take into account human habits, such as outdoor activities, dress and skin care. However,
18 little is known about the impact of these factors on individual exposure to UV-B, and detailed
19 information does not exist regarding type (e.g., peak or cumulative) and time period (e.g.,
20 childhood, lifetime, current) of exposure, wavelength dependency of biological responses, and
21 interindividual variability in UV-B resistance. In fact there have been recent reports indicating
22 the necessity of UV-B in producing vitamin D, suggesting that increased risks of human disease
23 due to slight excess UV-B exposure may be offset by the benefits of enhanced vitamin D
24 production. However, as with other impacts of UV-B on human health, this beneficial effect of
25 UV-B radiation has not been studied in sufficient detail to allow for a credible health benefits or
26 risk assessment. The CD (p. 10-38) concluded that the effects of changes in surface-level O₃
27 concentrations on UV-induced health effects cannot be critically assessed given the significant
28 uncertainties summarized above.

29 **3.3.4 Summary**

30 The CD (Chapters 4-8) summarizes and assesses substantial new evidence which builds
31 upon what was previously known about the health effects of O₃. The new information supports
32 previous findings that short-term O₃ is associated with lung function decrements and respiratory
33 symptoms, as well as numerous more subtle effects on the respiratory system such as
34 morphological changes and altered host defense mechanisms. Short-term O₃ exposure has also

1 been associated with hospital admissions for respiratory causes in numerous new studies that
2 further confirm the findings evaluated in the 1996 CD. The CD reports that warm-season studies
3 show evidence for positive and robust associations between ambient O₃ concentrations and
4 respiratory hospital admissions, respiratory symptoms and lung function effects in asthmatic
5 children, and positive but less conclusive evidence for associations with respiratory ED visits
6 (CD, p. 7-175).

7 Some new studies have suggested associations between increased incidence of asthma or
8 reduced lung function and long-term exposure to elevated ambient O₃ levels. The findings of
9 this small group of studies are inconsistent, however, and the CD concludes that the evidence for
10 this group of associations is inconclusive (CD, p. 7-175).

11 A new body of studies has suggested associations between short-term O₃ exposure and
12 effects on the cardiovascular system, including changes in heart rate variability, cardiac
13 arrhythmia, incidence of MI and hospitalization for cardiovascular diseases. The CD finds this
14 body of evidence to be limited but supportive of potential effects of O₃ on the cardiovascular
15 system (CD, p. 7-175).

16 A major area where new information presented in the CD has significantly expanded our
17 knowledge on health effects is evidence of an elevated risk of mortality associated with acute
18 exposure to O₃, especially in the summer or warm season when O₃ levels are typically high.
19 Results from recent large U.S. multicity time-series studies and meta-analyses provide the
20 strongest evidence for associations between short-term O₃ exposure and mortality (CD, p. 7-
21 175). The risk estimates shown are consistent across studies and robust to control for potential
22 confounders. This overall body of evidence is highly suggestive that O₃ directly or indirectly
23 contributes to nonaccidental and cardiopulmonary-related mortality, but additional research is
24 needed to more fully establish underlying mechanisms by which such effects occur (CD, p. 8-
25 78).

26 **3.4 ASSESSMENT OF EVIDENCE FROM EPIDEMIOLOGICAL STUDIES**

27 In Chapter 8, the CD assesses the new health evidence, integrating findings from
28 experimental (e.g., toxicological, dosimetric and controlled human exposure) and
29 epidemiological studies, to make judgments about the extent to which causal inferences can be
30 made about observed associations between health endpoints and exposure to O₃. Section 8.4.4.3
31 of the CD indicates that *strength* of epidemiologic evidence (including the magnitude and
32 precision of reported O₃ effect estimates and their statistical significance), *consistency* of effects
33 associations (looking across results of multiple- and single-city studies conducted by different
34 investigators in different places and times), and *robustness* of epidemiological associations (i.e.,

1 stability in the effect estimates after considering a number of factors) are all important in forming
2 judgments as to the likely causal significance of observed associations (CD, p. 8-40).

3 In evaluating the evidence from epidemiological studies in sections 7.1.3 and 8.4.4.3, the
4 CD focuses on well-recognized criteria, including: (1) the *strength* of reported associations,
5 including the magnitude and precision of reported effect estimates and their statistical
6 significance; (2) the *robustness* of reported associations, or stability in the effect estimates after
7 considering factors such as alternative models and model specification, potential confounding by
8 co-pollutants, as issues related to the consequences of exposure measurement error; and (3) the
9 *consistency* of the effects associations as observed by looking across results of multi-le- and
10 single-city studies conducted by different investigators in different places and time (CD, p. 8-40).
11 Integrating more broadly across epidemiological and experimental evidence, the CD also focuses
12 on the *coherence* and *plausibility* of observed O₃-related health effects to reach judgments about
13 causality (CD, section 8.6).

14 Subsequent to the final CD being published, CASAC sent a letter to the Administrator
15 (Henderson, 2006) providing additional advice on some key issues in order to inform specifically
16 the preparation of this draft Staff Paper specifically and the review of the O₃ NAAQS in general.
17 The issues related to assessment of epidemiological studies are addressed in this section and
18 more generally in section 3.5, and include the general issue of the utility of time-series
19 epidemiological studies in assessing the risks from exposure to O₃ and other criteria pollutants,
20 as well as related issues about exposure measurement error in O₃ mortality time-series studies
21 and O₃ as a surrogate for the broader mix of photochemical oxidant pollution in time-series
22 studies. Implications of these issues for staff conclusions about the adequacy of the current O₃
23 NAAQS and the identification of options for consideration will be considered below in Chapter
24 6.

25 The following discussion summarizes the conclusions and judgments from the CD's
26 summary of epidemiologic evidence and integrative assessment, focusing in particular on
27 discussions of strength, robustness, and consistency in the epidemiological evidence; judgments
28 in the CD about coherence and plausibility are summarized below in section 3.5. This section
29 also addresses issues related to lag periods between O₃ ambient exposure levels and health
30 outcomes, the nature of O₃-health effect concentration-response relationships, and the assessment
31 of air pollutant mixtures containing O₃ in time-series epidemiological studies.

32 **3.4.1 Strength of Associations**

33 The strength of associations most directly refers to the magnitude of the reported relative
34 risk estimates. Taking a broader view, the CD draws upon the criteria summarized in a recent
35 report from the U.S. Surgeon General, which define strength of an association as “the magnitude

1 of the association and its statistical strength” which includes assessment of both effect estimate
2 size and precision, which is related to the statistical power of the study (CDC, 2004). In general,
3 when associations are strong in terms of yielding large relative risk estimates, it is less likely that
4 the association could be completely accounted for by a potential confounder or some other
5 source of bias (CDC, 2004). With associations that yield small relative risk estimates it is
6 especially important to consider potential confounding and other factors in assessing causality.

7 Effect estimates between O₃ and many health outcomes are generally small in size
8 and could thus be characterized as weak. For example, effect estimates for associations with
9 mortality generally range from 0.5 to 5% increases per 40 ppb increase in 1-hr max O₃ or
10 equivalent, whereas associations for hospitalization range up to 50% increases per standardized
11 O₃ increment. The CD particularly notes that there are several multicity studies for associations
12 between short-term O₃ exposure and mortality or morbidity that, although small in size, have
13 great precision due to the statistical power of the studies, concluding that such associations are
14 strong relative to the precision of the studies (CD, p.8-40). That is, the associations were strong
15 enough to have been reliably measured by the studies such that many of the associations can be
16 distinguished from the null hypothesis with statistical confidence.

17 **3.4.2 Robustness of Associations**

18 Factors considered in assessing *robustness* include impact of exposure error, potential
19 confounding by copollutants, and alternative models and model specifications, as evaluated in
20 the CD (sections 7.1.3 and 8.4.4.3) and discussed below.

21 **3.4.2.1 Exposure Error**

22 In time-series epidemiological studies, concentrations measured at ambient monitoring
23 stations are generally used to represent a community’s exposure to ambient O₃. For time-series
24 studies, the emphasis is on the temporal (e.g., daily or hourly) changes in ambient O₃. In cohort
25 or cross-sectional studies, air quality data averaged over a period of months to years are used as
26 indicators of a community’s long-term exposure to ambient O₃ and other pollutants. In both
27 types of analyses, exposure error is an important consideration, as actual exposures to individuals
28 in the population will vary across the community. As described in the CD, there are few sources
29 of O₃ exposure for most people other than ambient air; potential indoor sources of O₃ include
30 office equipment, air cleaners, and small electric motors (CD, p. 7-6). Exposure to ambient O₃
31 for individuals is influenced by factors related to the infiltration of O₃ into buildings, air
32 exchange rate, indoor circulation rate, and O₃ removal processes, as well as the time spent out of
33 doors by the individuals, particularly for those individuals who engage in exercise or other
34 activities which induce increased respiration (e.g., sports, construction work).

1 In a study describing the relationships between panel studies and time-series studies,
2 Sheppard (2005) noted that non-ambient exposures varied across individuals and were not likely
3 to have strong temporal correlations, whereas ambient concentrations across individuals should
4 be highly correlated. In the case of O₃, there are limited non-ambient sources, thus, the non-
5 ambient sources are likely to be independent of the ambient sources. A related simulation study
6 by Sheppard et al. (2005) examining non-reactive pollutants found no noticeable difference
7 between effects estimates using either total personal exposure or ambient concentration data
8 when non-ambient sources exposures were independent of ambient source exposures in times
9 series studies. Since O₃ is a reactive pollutant, an additional assumption needs to be made in
10 applying these conclusions to O₃, i.e., that its chemical reactivity does not induce strong temporal
11 correlations.

12 The seasonal variation of personal behaviors and building ventilation practices can
13 modify exposure, thereby obscuring the relationship between personal exposures and ambient
14 concentrations. In addition, that relationship may be affected by temperature. For example, high
15 temperatures may increase air conditioning use, which can reduce O₃ penetration indoors, further
16 complicating the role of temperature as a confounder of O₃ health effects. It should be noted that
17 the pattern of exposure misclassification error and the influence of confounders may differ across
18 the outcomes of interest as well as in susceptible populations. Those who suffer from chronic
19 cardiovascular or respiratory conditions may tend to protect themselves more from
20 environmental threats by reducing their exposure to both O₃ and its confounders, such as high
21 temperature and PM, than those who are healthy.

22 The CD discusses the potential influence of exposure error on epidemiological study
23 results in section 7.1.3.1. Three components to exposure measurement error are outlined: (1) the
24 use of average population rather than individual exposure data; (2) the difference between
25 average personal ambient exposure and ambient concentrations at central monitoring sites; and
26 (3) the difference between true and measured ambient concentrations (CD, p. 7-7). These
27 components are expected to have different effects, with the first and third likely not causing bias
28 in a particular direction (“nondifferential error”) but increasing the standard error, while the
29 second component may result in downward bias, or attenuation of the risk estimate (CD, pp. 7-7
30 to 7-8).

31 Some recent studies have evaluated the impact of exposure measurements error on O₃
32 effect estimates. Navidi et al. (1999) used data from a children’s cohort study to compare effect
33 estimates from a simulated “true” exposure level to results of analyses from O₃ exposures
34 determined by several methods. The results indicated that the use of O₃ exposures from personal
35 sampling or microenvironmental approaches is associated with nondifferential error in O₃ effect
36 estimates, compared with effect estimates from “true” exposures. However, O₃ exposures based

1 on the use of ambient monitoring data overestimates the individual's O₃ exposure and thus
2 generally results in O₃ effect estimates that are biased downward (CD, p. 7-8). Similarly, Zidek
3 (1997) noted that a statistical analysis must balance bias and imprecision (error variance). For
4 example, in a reanalysis of a study by Burnett et al. (1994) on the acute respiratory effects of
5 ambient air pollution, Zidek et al. (1998) noted that accounting for measurement error, as well as
6 making a few additional changes to the analysis, resulted in qualitatively similar conclusions, but
7 the effects estimates were considerably larger in magnitude (CD, p. 7-8).

8 In addition to overestimation of exposure and the resulting underestimation of effects, the
9 use of ambient O₃ concentrations may obscure the presence of thresholds in epidemiologic
10 studies (CD p. 7-9). Brauer et al. (2002) concluded that surrogate measures of exposure, such as
11 those from centrally located ambient monitors, that were not highly correlated with personal
12 exposures obscured the presence of thresholds in epidemiologic studies at the population level,
13 even if a common threshold exists for individuals within the population.

14 As discussed in the CD Section 3.9, O₃ concentrations measured at central ambient
15 monitoring sites may explain, at least partially, the variance in individual exposures; however,
16 this relationship is influenced by other factors such as air exchange rates in housing and time
17 spent outdoors which may vary from city to city. Other studies conducted in various cities
18 observed that the daily averaged personal O₃ exposures from the population were well correlated
19 with ambient O₃ concentrations, although substantial variability existed among the personal
20 measurements. Thus, there is supportive evidence that ambient O₃ concentrations from central
21 monitors may serve as valid surrogate measures for mean personal exposures experienced by the
22 population, which is of the most relevance for time-series studies. This is especially true for
23 respiratory hospital admission studies, for which much of the response is attributable to O₃
24 effects on people with asthma. Ambient monitors are more likely to correlate reasonably well
25 with the personal exposures of children, who spend more time outdoors in the warm season and
26 who are also more likely to have asthma than adults. Conversely, there is some concern about
27 the extent to which ambient concentrations are representative of personal O₃ exposures of
28 another particularly susceptible group of individuals, the debilitated elderly, and what impact that
29 may have on mortality and hospitalization time-series studies. The correlation between ambient
30 concentrations and personal exposure measurements has not been examined in this population.
31 A better understanding of the relationship between ambient concentrations and personal
32 exposures, as well as of the other factors that affect relationship will improve the interpretation
33 of concentration-population health response associations observed with ambient O₃
34 concentrations.

35 Existing epidemiologic models may not fully take into consideration all of the
36 biologically relevant exposure history or reflect the complexities of all of the underlying

1 biological processes. As discussed in the CD, Section 3.9, using ambient concentrations to
2 determine exposure generally overestimates true personal O₃ exposures by approximately 2- to
3 4-fold in available studies, resulting in biased descriptions of underlying concentration-response
4 relationships and attenuated risk estimates. The implication is that the effects being estimated
5 occur at fairly low exposures and the potency of O₃ is greater than these effects estimates
6 indicate. As very few studies evaluating O₃ health effects with personal O₃ exposure
7 measurements exist in the literature, effect estimates determined from ambient O₃ concentrations
8 must be evaluated and used with caution to assess the health risks of O₃. Until more data on
9 personal O₃ exposure becomes available, the use of routinely monitored ambient O₃
10 concentrations as a surrogate for personal exposures is not generally expected to change the
11 principal conclusions from O₃ epidemiologic studies. Thus, the CD concludes that “there is
12 supportive evidence that ambient O₃ concentrations from central monitors may serve as surrogate
13 measures for mean personal O₃ exposures experienced by the population, which is of most
14 relevance to time-series studies” (CD, p. 7-9). Therefore, population health risk estimates
15 derived using ambient O₃ levels from currently available observational studies, with appropriate
16 caveats about personal exposure considerations, remain useful.

17 In using epidemiological study results for quantification of health risks for certain health
18 outcomes, staff recognizes that the risk estimates may be underestimating true public health risk.
19 However, staff observes that the use of risk estimates for comparing relative risk reductions
20 between alternative O₃ standards considered in the risk assessment is less likely to suffer from
21 this concern. In addition, as discussed in Chapter 5, staff has conducted an exposure assessment
22 in conjunction with a portion of the health risk assessment that incorporates estimated population
23 exposures in developing risk estimates for health outcomes based on controlled human exposure
24 studies.

25 **3.4.2.2 Confounding by Copollutants**

26 Confounding occurs when a health effect that is caused by one risk factor is attributed to
27 another variable that is correlated with the causal risk factor; epidemiological analyses attempt to
28 adjust or control for potential confounders. Copollutants (e.g., PM, CO, SO₂ and NO₂) can meet
29 the criteria for potential confounding in O₃-health associations if they are potential risk factors
30 for the health effect under study and are correlated with O₃. Effect modifiers include variables
31 that may influence the health response to the pollutant exposure (e.g., co-pollutants, individual
32 susceptibility, smoking or age). Both are important considerations for evaluating effects in a
33 mixture of pollutants, but for confounding, the emphasis is on controlling or adjusting for
34 potential confounders in estimating the effects of one pollutant, while the emphasis for effect
35 modification is on identifying and assessing the level of effect modification.

1 The CD observes that O₃ is generally not highly correlated with other criteria pollutants
2 (e.g., PM₁₀, CO, SO₂ and NO₂), but may be more highly correlated with secondary fine particles,
3 especially during the summer months (CD, p. 7-148). In addition, the correlation between O₃
4 and other pollutants may vary across seasons, since O₃ concentrations are generally higher in the
5 summer months. This may lead to negative correlations between O₃ and other pollutants during
6 the cooler months, but positive associations between O₃ and pollutants such as fine particles
7 during the warmer months (CD, p. 7-17). Thus, the CD pays particular attention to the results of
8 season-specific analyses and studies that assess effects of PM in potential confounding of O₃-
9 health relationships in its discussions in section 7.6.4.

10 Multipollutant models are commonly used to assess potential confounding in
11 epidemiological studies. As discussed in the CD, the limitations to the use of multipollutant
12 models include the difficulty in interpreting results where the copollutants are highly colinear, or
13 where correlations between pollutants change by season (CD, p. 7-150). This is particularly the
14 situation where O₃ and a copollutant, such as sulfates, are formed under the same atmospheric
15 condition; in such cases multipollutant models would produce unstable and possibly misleading
16 results (CD, p. 7-152).

17 For mortality, the results from numerous multi-city and single-city studies are shown in
18 Figure 7-22 of the CD. These results indicate that O₃-mortality associations do not appear to be
19 substantially changed in multipollutant models including PM₁₀ or PM_{2.5} (CD, p. 7-88). Focusing
20 on results of warm season analyses, Figure 7-23 of the CD shows effect estimates for O₃-
21 mortality associations that are fairly robust to adjustment for PM in multipollutant models (CD,
22 p. 7-90). In general, based on results from several single- and multiple-city studies, and on
23 recent meta-analyses, the CD (p. 7-103) concludes that “copollutants generally do not appear to
24 substantially confound the association between O₃ and mortality.”

25 Similarly, multipollutant models are presented for associations between short-term O₃
26 exposures and respiratory hospitalization in Figure 7-12 of the CD; the CD concludes that
27 copollutants generally do not confound the relationship between O₃ and respiratory
28 hospitalization (CD, p. 7-70, 7-71). Multipollutant models were not used as commonly in studies
29 of relationships between respiratory symptoms or lung function with O₃, but the CD reports that
30 results of available analyses indicate that such associations generally were robust to adjustment
31 for PM_{2.5} (CD, p. 7-134). For various co-pollutant models, in a large multicity study of
32 asthmatic children (Mortimer et al., 2002), the O₃ effect was attenuated, but there was still a
33 positive association. In Gent et al. (2003), effects of O₃, but not PM_{2.5}, remained statistically
34 significant and even increased in magnitude in two-pollutant models (CD, p. 7-53).

35 Considering this body of studies, the CD concludes: “Multipollutant regression analyses
36 indicated that O₃ risk estimates, in general, were not sensitive to the inclusion of copollutants,

1 including PM_{2.5} and sulfate. These results suggest that the effects of O₃ on respiratory health
2 outcomes appear to be robust and independent of the effects of other copollutants (CD, p. 7-
3 154).” We use the results of single-pollutant model results in presentation of results in this
4 chapter and in quantitative risk assessments conducted as part of this review (see Chapter 5) for
5 purposes of comparing results from different studies. However, we also include the use of multi-
6 pollutant model results in presenting risk estimates, when available, to more completely
7 characterize the quantitative health risks associated with ambient O₃ levels.

8 **3.4.2.3 Model Specification**

9 The CD observes that one challenge of time-series epidemiological analysis is assessing
10 the relationship between O₃ and health outcomes while avoiding bias due to confounding by
11 other time-varying factors, particularly seasonal trends and weather variables. (CD, p. 7-12)
12 These variables are of particular interest because O₃ concentrations have a well-characterized
13 seasonal pattern (see Chapter 2) and are also highly correlated with changes in temperature.
14 Thus it can be difficult to distinguish whether effects are associated with O₃ or with seasonal or
15 weather variables in statistical analyses.

16 Section 7.1.3.4 of the CD discusses statistical modeling approaches that have been used
17 to adjust for time-varying factors, highlighting a series of analyses that were done in a Health
18 Effects Institute-funded reanalysis of numerous time-series studies. While the focus of these
19 reanalyses was on associations with PM, a number of investigators also examined the sensitivity
20 of O₃ coefficients to the extent of adjustment for temporal trends and weather factors. In
21 addition, several recent studies, including U.S. multi-city studies (Bell et al., 2005; Huang et al.,
22 2005; Schwartz et al., 2005) and a meta-analysis study (Ito et al., 2005), evaluated the effect of
23 model specification on O₃-mortality associations (CD, p. 7-14). As discussed in the CD (section
24 7.6.3.1), these studies generally report that associations reported with O₃ are not substantially
25 changed with alternative modeling strategies for adjusting for temporal trends and meteorologic
26 effects. However, significant confounding can occur when strong seasonal cycles are present,
27 suggesting that season-specific results are more generally robust than year-round results in such
28 cases. The CD concludes that “seasonal dependence of O₃-mortality effects complicates
29 interpretation of O₃ risk estimates calculated from year-round data without adequate adjustment
30 of temporal trends” (CD, p. 7-99), and that more work is needed in this area to reduce the
31 uncertainty involved in the epidemiologic interpretation of O₃ effect estimates (CD, p. 7-141).

32 A number of epidemiological studies have conducted season-specific analyses, as
33 discussed in section 7.6.3.2 of the CD. As observed above in section 3.3, such studies have
34 generally reported stronger and more precise effect estimates for O₃ associations in the warm
35 season than in analyses conducted in the cool seasons or over the full year. For assessing

1 relationships between O₃ and health outcomes, the CD highlights several reasons to focus on
2 warm season analyses: (1) the seasonal nature of O₃ concentrations; (2) the relationship between
3 O₃ formation and temperature; (3) correlations between other pollutants, particularly fine
4 particles, and O₃ variations across seasons in some areas; and (4) factors affecting exposure to
5 ambient O₃, such as air conditioning use, varies seasonally in most areas of the U.S.. We have
6 therefore focused on epidemiological findings from warm season analyses, where available, for
7 qualitative assessments and for the quantitative risk assessment discussed in Chapter 5.

8 **3.4.3 Consistency**

9 Consistency refers to the persistent finding of an association between exposure and
10 outcome in multiple studies of adequate power in different persons, places, circumstances and
11 times (CDC, 2004). In considering results from multicity studies and single-city studies in
12 different areas, the CD observes general consistency in effects of short-term O₃ exposure on
13 mortality, respiratory hospitalization and other respiratory health outcomes (CD, p. 8-41). The
14 variations in effects that are observed may be attributable to differences in relative personal
15 exposure to O₃, as well as varying concentrations and composition of copollutants present in
16 different regions. Thus, the CD concludes that “consideration of consistency or heterogeneity of
17 effects is appropriately understood as an evaluation of the similarity or general concordance of
18 results, rather than an expectation of finding quantitative results with a very narrow range” (CD,
19 p.8-41).

20 **3.4.4 Lag Structure in Short-term Exposure Studies**

21 In the short-term exposure epidemiological studies, many investigators have tested
22 associations for a range of lag periods between the health outcome and O₃ concentration (see
23 CD, sections 7.1.3.3). The CD observes that the selection of an appropriate lag period can
24 depend on the health outcome under study. For example, if cough is resulting from the irritant
25 action of O₃, that would be expected to occur with a short lag time; however, exacerbation of
26 asthma through an inflammatory response might occur up to several days after initial exposure
27 (CD, p. 7-12). For both mortality and respiratory hospital admissions, the CD reports that most
28 significant associations between O₃ and mortality were observed with O₃ measured on the same
29 day or a 1-day lag period in studies using individual lag periods (CD, p. 7-14). In U.S. multi-city
30 studies, larger effect estimate sizes were reported for the O₃-mortality relationship with the
31 distributed lag structure (CD, p. 7-88). Field studies of lung function or respiratory symptoms
32 reported associations with O₃ across a range of lag periods from the exposure on the same day to
33 exposures averaged over several days (CD, Sections 7.2.3 and 7.2.4). Cardiovascular effects
34 appeared to be associated with O₃ at shorter lag periods; cardiovascular health outcomes such as

1 changes in cardiac autonomic control were associated with O₃ measured on the same day (CD,
2 section 7.2.7.1). In addition, Peters et al. (2001) reported a positive but not statistically
3 significant association between myocardial infarction onset and O₃ with very short lag times of
4 1- to 4 hr (CD, p. 7-64).

5 In focusing on an effect estimate reported for any individual lag period, the CD observes
6 that it is important to consider the pattern of results across the series of lag periods. If there is an
7 apparent pattern of results across the different lags, then selecting the single-day lag with the
8 largest effect from a series of positive associations is likely to underestimate the overall effect
9 size, since single-day lag effect estimates do not fully capture the risk that may be distributed
10 over adjacent or other days (CD, p. 7-13). However, if the reported effect estimates vary
11 substantially across lag periods, any result for a single day may well be biased (CD, p. 7-14). If
12 the effect of O₃ on health outcomes persists over several days, distributed lag model results can
13 provide more accurate effect estimates for quantitative assessment than an effect estimate for a
14 single lag period (CD, p. 7-12). Conversely, if the underlying O₃-health relationship is truly an
15 acute effect, then a distributed lag model would likely result in a reduced effect estimate size that
16 may underestimate the effect (CD, p. 7-12).

17 On this basis, the CD focuses on effect estimates from models using 0- or 1-day lag
18 periods, with some consideration of multi-day lag effects (CD, p. 7-14). For quantitative
19 assessments, we conclude that it is appropriate to use results from lag period analyses consistent
20 with those reported in the CD, focusing on single day lag periods of 0-1 days for associations
21 with mortality or respiratory hospitalization, depending on availability of results (CD, p. 7-14).
22 When available, distributed lag model results also have been used in the quantitative risk
23 assessment. However, for those few studies that show inconsistent patterns, the use of single-
24 day lag results is not appropriate for inclusion in the quantitative assessment.

25 **3.4.5 Concentration-Response Relationships and Potential Thresholds**

26 It has been recognized that it is reasonable to expect that there likely are biological
27 thresholds for different health effects in individuals or groups of individuals with similar innate
28 characteristics and health status. For O₃ exposure, individual thresholds would presumably vary
29 substantially from person to person due to individual differences in genetic susceptibility, pre-
30 existing disease conditions and possibly individual risk factors such as diet or exercise levels
31 (and could even vary from one time to another for a given person). Thus, it would be difficult to
32 detect a distinct threshold at the population level, below which no individual would experience a
33 given effect, especially if some members of a population are unusually sensitive even down to
34 very low concentrations (U.S. EPA, 2004, p. 9-43, 9-44).

1 Some studies have tested associations between O₃ and health outcomes after removal of
2 days with higher O₃ levels from the data set; such analyses do not necessarily indicate the
3 presence or absence of a threshold, but provide some information on whether the relationship is
4 found using only lower-concentration data. For example, using data from 95 U.S. cities, Bell et
5 al. (2004) found that the effect estimate for an association between short-term O₃ exposure and
6 mortality was little changed when days exceeding 60 ppb (24-hr average) were excluded in the
7 analysis (CD, p. 8-43). Using data from 8 U.S. cities, Mortimer and colleagues (2002) also
8 reported that associations between O₃ and both lung function and respiratory symptoms remained
9 statistically significant and of the same or greater magnitude in effect size when concentrations
10 greater than 80 ppb (8-hr avg) were excluded (CD, p. 7-46). Several single-city studies are also
11 summarized in section 7.6.5 of the CD that report similar findings of associations that remain or
12 are increased in magnitude and statistical significance when data at the upper end of the
13 concentration range are removed.

14 Other time-series epidemiological studies have used statistical modeling approaches to
15 evaluate whether thresholds exist in associations between short-term O₃ exposure and mortality.
16 As discussed in section 7.6.5 of the CD, one European multi-city study included evaluation of
17 the shape of the concentration-response curve, and observed no deviation from a linear function
18 across the range of O₃ measurements from the study (Gryparis et al., 2004; CD p. 7-154).
19 Several single-city studies also observed a monotonic increase in associations between O₃ and
20 morbidity that suggest that no population threshold exists (CD, p. 7-159).

21 On the other hand, a study in Korea used several different modeling approaches and
22 reported that a threshold model provided the best fit for the data. The results suggested a
23 potential threshold level of about 45 ppb (1-hr maximum concentration; < 35 ppb, 8-hr avg) for
24 an association between mortality and short-term O₃ exposure during the summer months (Kim et
25 al., 2004; CD, p. 8-43). The authors reported larger effect estimates for the association for data
26 above the potential threshold level, suggesting that an O₃-mortality association might be
27 underestimated in the non-threshold model. A threshold analysis recently reported by Bell et al.
28 (2006) for 98 U.S. communities, including the same 95 communities in Bell et al. (2004),
29 indicated that if a population threshold existed for mortality, it would likely fall below a 24-h
30 average O₃ concentration of 15 ppb (< 25 ppb, 8-hr avg). In addition, Burnett and colleagues
31 (1997) plotted the relationships between air pollutant concentrations and both respiratory and
32 cardiovascular hospitalization, and it appears in these results that the associations with O₃ are
33 found in the concentration range above about 30 ppb (1-hr maximum; < 25 ppb, 8-hr avg).

34 Vedal and colleagues (2003) reported a significant association between O₃ and mortality
35 in British Columbia where O₃ concentrations were quite low (mean concentration of 27.3 ppb).
36 The authors did not specifically test for threshold levels, but the fact that the association was

1 found in an area with such low O₃ concentrations suggests that any potential threshold level
2 would be quite low in this data set.

3 In summary, the CD finds that, taken together, the available evidence from toxicological,
4 clinical and epidemiological studies suggests that no clear conclusion can now be reached with
5 regard to possible threshold levels for O₃-related effects (CD, p. 8-44). Further, recognizing that
6 limitations in epidemiological studies make discerning thresholds in populations difficult, the
7 evidence suggests that if a population threshold level does exist, it is likely near the lower limit
8 of ambient O₃ concentrations in the U.S. (CD, p. 8-44). We recognize, however, the possibility
9 that thresholds for individuals may exist in reported associations at fairly low levels within the
10 range of air quality observed in the studies but not be detectable as population thresholds in
11 epidemiological analyses. Based on the CD's conclusions, we judge that there is insufficient
12 evidence to support use of potential threshold levels in quantitative risk assessments and that it is
13 appropriate to estimate risks within the range of air quality concentrations down to estimated
14 policy-relevant background level.

15 **3.4.7 Health Effects of Pollutant Mixtures Containing O₃**

16 The potential for O₃-related enhancements of PM formation, particle uptake, and
17 exacerbation of PM-induced cardiovascular effects underscores the importance of considering
18 contributions of O₃ interactions with other often co-occurring air pollutants to health effects due
19 to O₃-containing pollutant mixes. Chapters 4, 5, and 6 of the CD provide a discussion of
20 experimental studies that evaluate interactions of O₃ with other co-occurring pollutants. Some
21 examples of important pollutant mixture effects noted there are highlighted below.

22 In Chapter 4, the CD noted some important interactive effects of coexposures to O₃, and
23 NO₂ and SO₂, two other common gaseous copollutants found in ambient air mixes. A study by
24 Rigas et al. (1997) showed that continuous exposure of healthy human adults to SO₂ or to NO₂
25 increased inhaled bolus O₃ absorption, while continuous exposure to O₃ alone decreased bolus
26 absorption of O₃. This suggests enhancement of O₃ uptake by NO₂ or SO₂ coexposure in ambient
27 air mixes. Another study by Jenkins et al. (1999) showed that asthmatics exhibited enhanced
28 airway responsiveness to house dust mite following exposures to O₃, NO₂, and the combination
29 of the two gases (CD, Chapter 6). Spirometric responses, however, were impaired only by O₃
30 and O₃+NO₂ at higher concentrations. On the other hand, animal toxicology studies (CD,
31 Chapter 5) that evaluated exposures to O₃ in mixture with NO₂, formaldehyde, and PM
32 demonstrated additive, synergistic or antagonistic effects, depending on the exposure regimen
33 and the specific health endpoints evaluated.

34 Several studies have demonstrated the enhancement by O₃ exposure of various respiratory
35 responses of sensitive individuals to allergens. For example, Peden et al. (1995) showed O₃-
36 induced increased response to nasal allergen challenge among allergic asthmatic subjects, and

1 Michelson et al. (1999) showed promotion by 0.4 ppm O₃ exposure of inflammatory cell influx
2 in response to nasal allergen challenge in asymptomatic dust-mite sensitive asthmatics. In
3 addition, Jörres et al. (1996) demonstrated enhancement by 0.25 ppm O₃ exposure of airway
4 responsiveness in mildly allergic asthmatics that was increased in response to an individual's
5 historical allergen (grass and birch pollen, house dust mite, animal dander). These results were
6 further extended by Holz et al. (2002) who showed that repeated daily exposure to 0.125 ppm O₃
7 for 4 days exacerbated lung function decrements (e.g., decreased FEV₁) in response to bronchial
8 allergen challenges among subjects with preexisting allergic airway disease, with or without
9 asthma (see Chapter 6 of the CD). This suggests that O₃ exposure can place allergic people who
10 do not have asthma, as well as people who do have asthma, at increased risk for allergic
11 respiratory effects. Consistent with and supporting the above findings are animal toxicology
12 studies reviewed in detail by Harkema and Wagner (2005), which indicate that (a) O₃-induced
13 epithelial and inflammatory responses in laboratory rodents are markedly enhanced by
14 coexposure to inhaled biogenic substances (e.g., bacterial endotoxin or ovalbumin, an
15 experimental aeroallergen) and (b) adverse airway effects of biogenic substances can be
16 exacerbated by coexposure to O₃.

17 Also of much note is a newly emerging literature which indicates that O₃ can modify the
18 biological potency of certain types of ambient PM, as shown by experimental tests. For
19 example, as described in the CD, Section 5.4.2, the reaction of diesel PM with 0.1 ppm O₃ for 48
20 hr increased the potency (compared to non-exposed or air-exposed diesel PM) to induce
21 neutrophil influx, total protein, and LDH in lung lavage fluid in response to intratracheal PM
22 instillation in rats (Madden et al., 2000). However, the potency of carbon black particles was not
23 enhanced by exposure to O₃, suggesting that O₃ reaction with organic components of the diesel
24 PM were responsible for the observed increased diesel PM effects.

25 Potential interaction of O₃ with fine PM in aged rats was examined by Kleinman et al.
26 (2000). In this study the effects of fine PM containing two common toxic constituents,
27 ammonium bisulfate (ABS, 0.3 μm 70 μg/m³) and elemental carbon (C, 0.3 μm 50 μg/m³) and a
28 mixture (ABS + C) with 0.2 ppm O₃ was evaluated on aged rat lung structure and macrophage
29 function. Exposures of O₃, elemental carbon or ABS alone did not cause significant lung injury,
30 lung tissue collagen content or respiratory burst activity. On the other hand, mixtures (ABS + C
31 + O₃) caused significant lung injury as assessed by increased cell proliferation response in lung
32 epithelial and interstitial cells, loss of lung tissue collagen and increase in respiratory burst and
33 phagocytic activity.

34 The majority of toxicological studies discussed in the CD evaluated effects of individual
35 pollutants or simple mixtures of the constituents of urban smog mixtures, and these toxicology
36 studies may not fully explain epidemiologic findings that have increasingly shown ambient O₃,

1 other gaseous pollutants, and/or PM to be associated with various health effects at relatively low
2 concentrations. In a recent report, Sexton et al (2004) utilized “smog chambers”, i.e.,
3 environmental irradiation chambers to generate synthetic photochemical oxidants mixtures
4 similar to urban smog, and studied the toxicity of such mixtures on the inflammatory response of
5 A549 cells in an in vitro exposure system. In this preliminary study, the authors found the
6 simulated urban photochemical oxidant mixture generated with the addition of O₃ to have
7 enhanced toxicity (as assessed by the expression of IL-8 mRNA). Additional toxicology studies
8 using similar realistic air pollution smog mixtures in the future may provide more relevant
9 biological understanding for the potential interactions that occur in the ambient air among
10 various pollutants.

11 All of the above types of interactive effects of O₃ with other co-occurring gaseous and
12 nongaseous viable and nonviable PM components of ambient air mixes argue for not only being
13 concerned about direct effects of O₃ acting alone, but also the need for viewing O₃ as a surrogate
14 indicator for air pollution mixes which may enhance risk of adverse effects due to O₃ acting in
15 combination with other pollutants. Viewed from this perspective, those epidemiologic findings
16 of morbidity and mortality associations, with ambient O₃ concentrations extending to
17 concentrations below 0.08 ppm, become more understandable and plausible.

18 **3.5 BIOLOGICAL PLAUSIBILITY AND COHERENCE OF EVIDENCE**

19 This section summarizes material contained in section 8.4.3 and section 8.6 of the CD,
20 which integrates epidemiological studies with mechanistic information from controlled human
21 exposure studies and animal toxicological studies to draw conclusions regarding the coherence of
22 evidence and biological plausibility of O₃-related health effects. For its assessment, the CD’s
23 discussion draws from epidemiological evidence on a range of relevant health endpoints (from
24 cardiopulmonary and physiological changes to morbidity and mortality) and assessment of
25 available toxicological and biochemical evidence on potential plausible causal relationships for
26 the observed epidemiological associations (CD, p. 8-45).

27 **3.5.1 Animal-to-Human Extrapolation Issues**

28 Table 3-1 (Table 8-1, CD, p. 8-29) summarizes physiological and biochemical
29 observations which represent the knowledge base available from toxicological studies in humans
30 and animals that support conclusions drawn about biological alterations that cause acute O₃-
31 induced health effects. Table 3-1 was based upon experimental data (contained in CD Chapters
32 5 and 6, as well as the chapter annexes), which used environmentally relevant exposure
33 regimens. Although most of the acute O₃-induced biological alterations are transient and
34 attenuate over time, this does not mean that injury at the cellular and tissue level does not

1 continue. Most inflammatory markers (e.g., PMN influx) attenuate after 5 days of exposure, but
2 markers of cell damage (e.g., LDH enzyme activity) do not attenuate and continue to increase.
3 Also, the time-line for resolution of many of the physiological and biological parameters
4 presented in Figure 3-2 (Figure 8-3, CD, p. 8-30) differ for healthy human subjects and those
5 with underlying cardiopulmonary diseases. The CD further notes that alterations in acute O₃-
6 induced cellular and molecular changes observed in human airway epithelium evolve over time,
7 as depicted in Figure 3-3 (Figure 8-4, CD, p. 8-31), and that the knowledge of this profile is
8 important in assessing biological plausibility to integrate across evidence of various health
9 endpoints.

10 The similarities in physiological, biochemical and pathological processes between
11 humans and many animal species are due to the high level of genome sequence homology that
12 exists across species (CD, p. 8-28). It is this homology that supports the use of knowledge
13 gained on initiation, progression, and treatment regimes for disease processes across species,
14 especially on the acute O₃-induced effects in the respiratory tracts of humans and various animal
15 species, as depicted in CD Table 3-1 and Figures 3-2 and 3-3. The similarities observed in
16 human and rat respiratory system effects (e.g., in spirometry, ventilatory response, host defense),
17 attenuation, and at higher levels of cellular organization (e.g., neutrophilic inflammation,
18 macrophage phagocytosis processes) lend support to animal-to-human extrapolation. This is
19 particularly important in collecting information that would not be possible to gather in human
20 exposure or epidemiological studies but may corroborate data from both types of studies.

21 Quantitative extrapolation requires a combination of dosimetry, end point homology, and
22 species sensitivity. Although uncertainties continue to exist, animal-to-human extrapolation can
23 be done for a number of health endpoints with sufficient accuracy to be useful in evaluating the
24 potential for human health effects. For example, the amount of protein in lavage fluid shows a
25 striking relationship when interspecies dosimetric adjustments are applied to the individual
26 species and exposure studies. One study (Hatch et al., 1994) of inflammatory markers suggests
27 that a 2 ppm O₃ exposure in sedentary rats approximates a 0.4 ppm exposure in exercising
28 humans (i.e., if one considers the dosimetry, the sensitivities of rats and humans are consistent).
29 This supports the use of some animal data collected at higher O₃ exposures to help understand
30 molecular changes in acutely exposed humans (CD, 8-31). Also of importance are the chronic
31 exposure studies (12 to 24 months) reporting lesions in animals caused by long-term O₃
32 exposures that may analogously occur in humans with long-term (months, years) exposure to
33 relatively high levels of O₃. However, specific exposure patterns of O₃ concentrations that could
34 produce comparable alterations in human lungs remain to be substantiated (CD, p. 8-32).

Table 3-1. Acute O₃-induced Physiological and Biochemical Changes in Human and Animals

Physiological/Biochemical Alterations	Human Exposure Studies^{1,2}	Animal Toxicology Studies^{3,4}
Pulmonary Function:	↓ FEV ₁ ↑ Frequency of breathing (rapid, shallow) ↓ FVC (cough, breathing discomfort, throat irritation, wheezing) Mild bronchoconstriction	↑ Frequency of breathing (rapid, shallow) ↓ FVC
Airway Responsiveness:	↑ (neuronal involvement) Change in lung resistance	↑ (vagal mediation) Change in lung resistance
Inflammation:	Yes ↑ inflammatory mediators	Yes ↑ inflammatory mediators
Reactive Oxygen Species:	↑	↑
Host Defense:	↑ particle clearance ↑ permeability ↓ AM phagocytosis	↑ particle clearance ↑ permeability ↓ clearance of bacteria ↑ severity of infection ↑ mortality & morbidity
Lung Injury: Morphology:	Yes	Yes
Susceptibility:	Age, Interindividual variability Disease status Polymorphism in certain genes being recognized	Species-specific differences Genetic basis for susceptibility indicated
Cardiovascular Changes:	Impairment in arterial O ₂ transfer Ventilation-perfusion mismatch (suggesting potential arterial vasoconstriction) ↑ rate pressure product ⁵ ↑ myocardial work ⁵	Heart rate ↓ core body temperature ↑ atrial natriuretic factor Role for platelet activity factor (PAF) indicated Increased pulmonary vascular resistance

¹ Controlled chamber exposure studies in human volunteers were carried out for a duration of 1 to 6.6 h with O₃ concentration in the range of 0.08-0.40 ppm with intermittent exercise.

² Data on some of the biochemical parameters were obtained from in vitro studies using cells recovered from BALF.

³ Responses were observed in animal toxicology studies with exposure for a duration of 2 to 72 h with O₃ concentration in the range of 0.1 to 2.0 ppm.

⁴ Various species (mice, rat, guinea pigs and rabbit) and strains.

⁵ In hypertensive subjects.

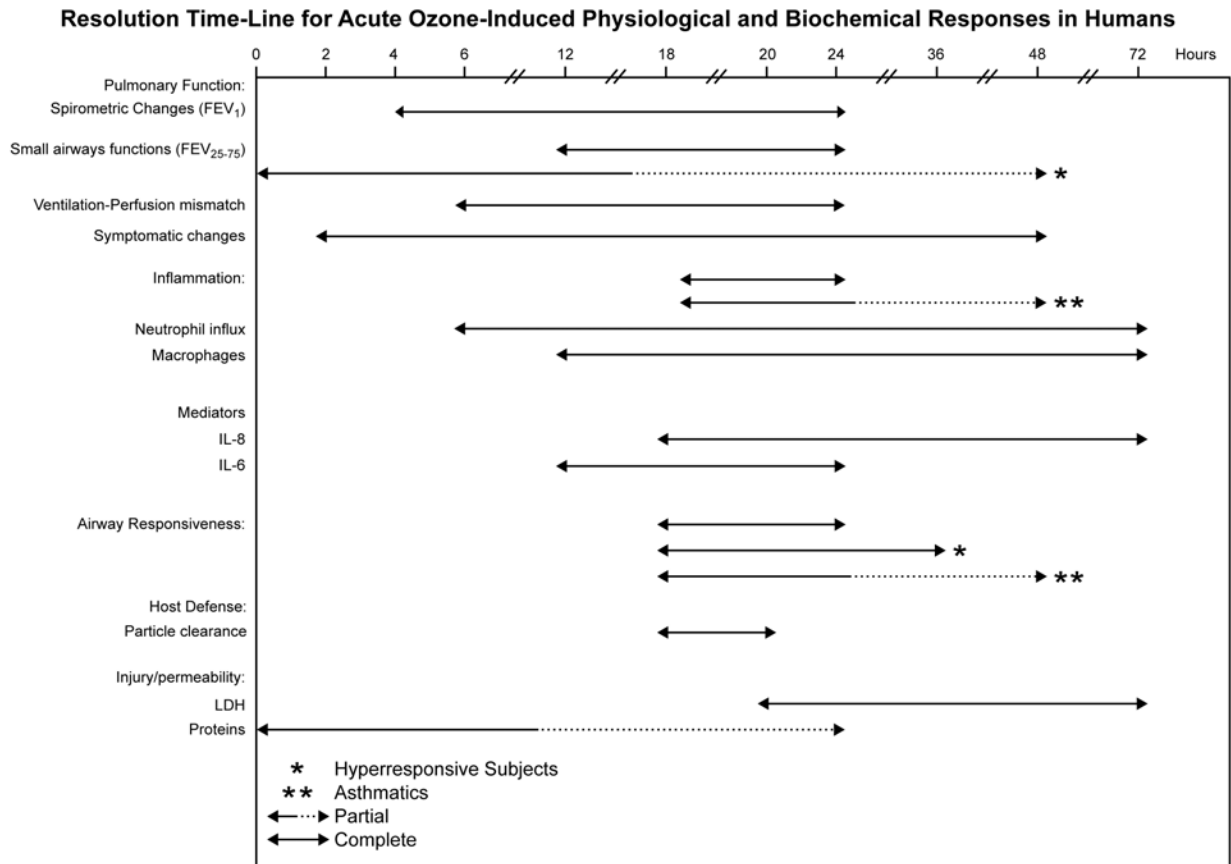

Figure 3-2. Resolution time-line for the respiratory, physiological, and biochemical parameters are derived from studies reported in the CD, Chapter 6 and Chapter 6 Annex.

Postulated Cellular and Molecular Changes in Human Airway Cells In Response to Acute Exposure to Ozone

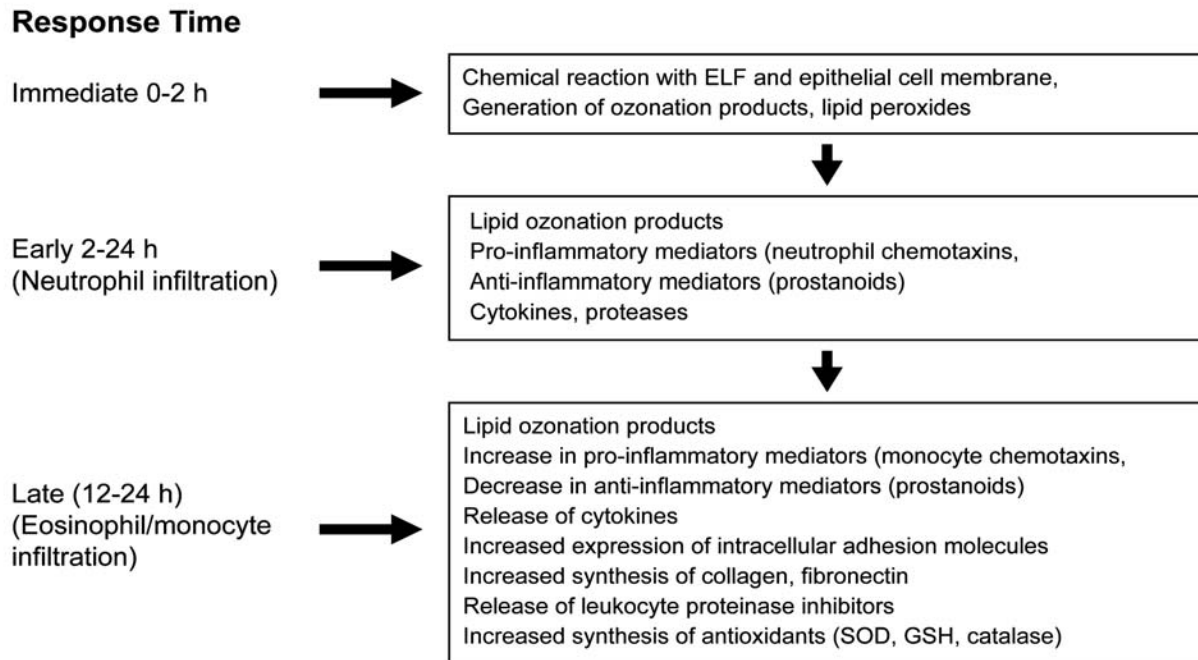

Figure 3-3. Acute (1-8 h) O₃ exposure-induced cellular and molecular changes and timelines for their resolution depicted here are derived from the data reported in Leikauf et al. (1995) and Mudway and Kelly (2000)3-4. Acute (1-8 h) O₃ exposure-induced cellular and molecular changes and timelines for their resolution depicted here are derived from the data reported in Leikauf et al. (1995) and Mudway and Kelly (2000).

3.5.2 Coherence and Plausibility of Short-term Effects on the Respiratory System

Acute respiratory morbidity effects that have been associated with short-term exposure to O₃ include such health endpoints as decrements in lung function, increased airway responsiveness, airway inflammation, epithelial injury, immune system effects, ED visits for respiratory diseases, and hospitalization due to respiratory illness

Recent epidemiological studies have supported evidence available in the previous O₃ NAAQS review on associations between ambient O₃ exposure and decline in lung function for children. Earlier observations that children and asthmatic individuals are particularly susceptible to ambient O₃ are supported by a meta-analysis (Kinney et al., 1996) of summer camp studies. The CD (p. 8-34) concludes that exposure to ambient O₃ has a significant effect on lung function, is associated with increased respiratory symptoms and medication use, particularly in asthmatics.

Short-term exposure to O₃ has also been associated with more severe morbidity endpoints, such as ED visits and hospital admissions for respiratory cases, including specific respiratory illness (e.g., asthma) (CD, sections 7.3.2 and 7.3.3). In addition, a few epidemiological studies have reported positive associations between short-term O₃ exposure and respiratory mortality, though the associations are not generally statistically significant, possibly due to a lack of statistical power for this mortality subcategory (CD, p. 7-109).

Considering the evidence from epidemiological studies, the results described above provide evidence for coherence in O₃-related effects on the respiratory system. Effect estimates from U.S. and Canadian studies are shown in Figure 3-4, where it can be seen that mostly positive associations have been reported with respiratory effects ranging from respiratory symptoms, such as cough or wheeze, to hospitalization for various respiratory diseases, and there is suggestive evidence for associations with respiratory mortality. Many of the reported associations are statistically significant.

Considering also evidence from toxicological, chamber, and field studies, the CD (section 8.6) discusses biological plausibility and coherence of evidence for acute O₃-induced respiratory health effects. Inhalation of O₃ for several hours while subjects are physically active can elicit both acute adverse pathophysiological changes and subjective respiratory tract symptoms (CD, section 8.4.2). Acute pulmonary responses observed in healthy humans exposed to O₃ at ambient concentrations include: decreased inspiratory capacity; mild bronchoconstriction; rapid, shallow breathing during exercise; subjective symptoms of tracheobronchial airway irritation, including cough and pain on deep inspiration; decreases in measures of lung function (e.g., FVC and FEV₁); and increased airway resistance (SR_{aw}). The severity of symptoms and magnitude of response depends on inhaled dose, individual O₃ sensitivity, and the degree of attenuation or

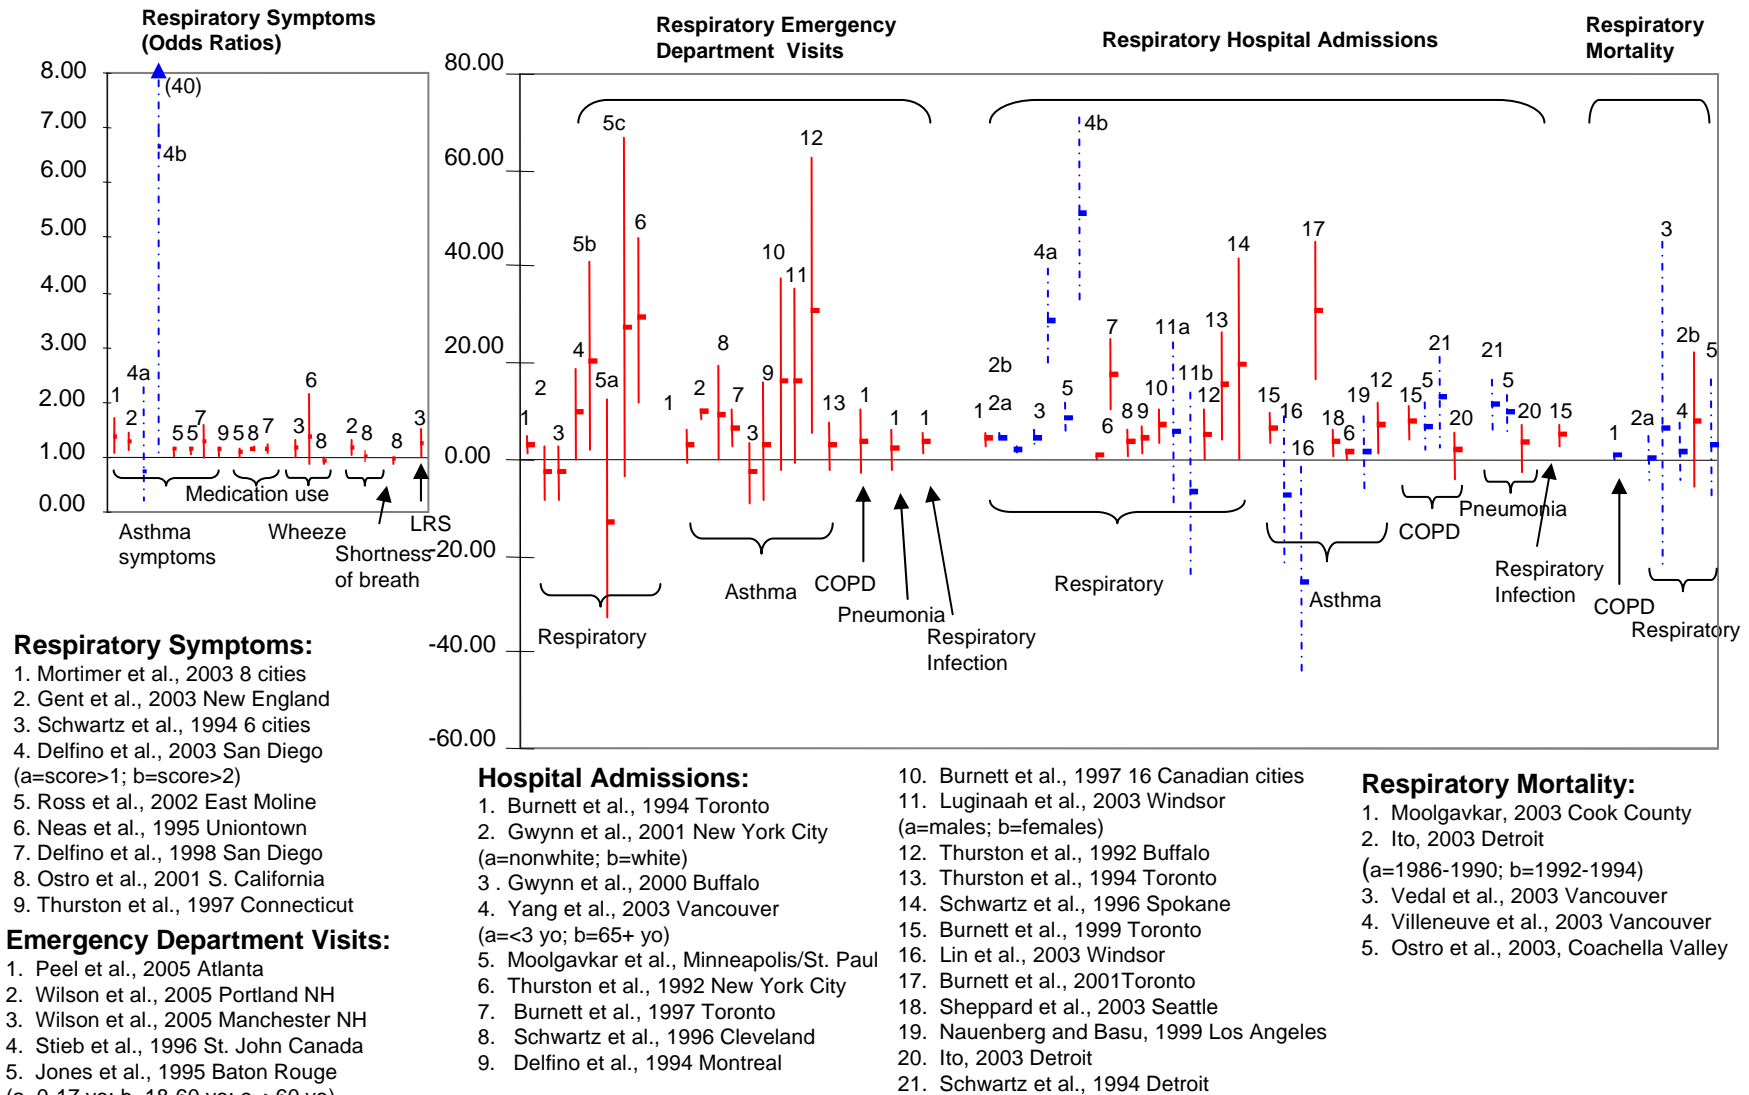

Figure 3-4. Effect estimates (with 95% confidence intervals) for associations between short-term ozone exposure and respiratory health outcomes.

Effect estimates expressed as odds ratios for associations with respiratory symptoms and % increase for other outcomes, per standardized increments: 20 ppb for 24-hr O₃, 30 ppb for 8-hr O₃, and 40 ppb for 1-hr O₃, presented in order of decreasing statistical power from left to right in each category. Dotted line (blue) indicates all year analyses; solid line (red) indicates warm season results. LRS=lower respiratory symptoms; COPD=chronic obstructive pulmonary disease

1 enhancement of response resulting from previous O₃ exposures. Lung function studies of several
2 animal species acutely exposed to relatively low O₃ levels (0.25 to 0.4 ppm) show responses
3 similar to those observed in humans, including increased breathing frequency, decreased tidal
4 volume, increased resistance, and decreased FVC. Alterations in breathing pattern return to
5 normal within hours of exposure, and attenuation in functional responses following repeated O₃
6 exposures is similar to those observed in humans.

7 Physiological and biochemical alterations investigated in controlled human
8 exposure and animal toxicology studies tend to support certain hypotheses of underlying
9 pathological mechanisms which lead to the development of respiratory-related effects reported in
10 epidemiology studies (e.g., increased hospitalization and medication use). Some of these are:
11 (a) decrements in lung function, (b) bronchoconstriction, (c) increased airway responsiveness, (d)
12 airway inflammation, (e) epithelial injury, (f) immune system activation, (g) host defense
13 impairment, and sensitivity of individuals, such as age, genetic susceptibility, and the degree of
14 attenuation present due to prior exposures. The time sequence, magnitude, and overlap of these
15 complex events, both in terms of development and recovery (as depicted in Figures 3-2 and 3-3),
16 illustrate the inherent difficulty of interpreting the biological plausibility of O₃-induced
17 cardiopulmonary health effects (CD, p. 8-48).

18 The interaction of O₃ with airway epithelial cell membranes and epithelial lining fluid
19 (ELF) to form lipid ozonation products and ROS is supported by numerous human, animal and in
20 vitro studies. Ozonation products and ROS initiate a cascade of events that lead to oxidative
21 stress, injury, inflammation, airway epithelial damage and increased epithelial damage and
22 increased alveolar permeability to vascular fluids. Repeated respiratory inflammation can lead to
23 a chronic inflammatory state with altered lung structure and lung function and may lead to
24 chronic respiratory diseases such as fibrosis and emphysema (CD, section 8.6.2). Continued
25 respiratory inflammation also can alter the ability to respond to infectious agents, allergens and
26 toxins. Acute inflammatory responses to O₃ are well documented, and lung injury can become
27 apparent within 3 hr after exposure in humans. Ozone-induced lung injury and subsequent
28 disruption of the airway epithelial barrier has been implicated in increased mucociliary clearance
29 of particles in human subjects.

30 Taken together, the CD concludes that the evidence from experimental human and animal
31 toxicology studies indicates that acute O₃ exposure is causally associated with respiratory system
32 effects, including O₃-induced pulmonary function decrements, respiratory symptoms, lung
33 inflammation, and increased lung permeability, airway hyperresponsiveness, increased uptake of
34 nonviable and viable particles, and consequent increased susceptibility to PM-related toxic
35 effects and respiratory infections (CD, p. 8-48).

3.5.3 Coherence and Plausibility of Effects on the Cardiovascular System

Only a few experimental studies of animals and humans have evaluated possible mechanisms or physiological pathways by which acute O₃ exposures may induce cardiovascular system effects. Ozone induces lung injury, inflammation, and impaired mucociliary clearance, with a host of associated biochemical changes all leading to increased lung epithelial permeability. As discussed in Section 3.2.2, the generation of lipid ozonation products and reactive oxygen species in lung tissues can influence pulmonary hemodynamics, and ultimately the cardiovascular system.

Other potential mechanisms by which O₃ exposure may be associated with cardiovascular disease outcomes have been described. Laboratory animals exposed to relatively high O₃ concentrations (≥ 0.5 ppm) demonstrate tissue edema in the heart and lungs. Ozone-induced changes in heart rate, edema of heart tissue, and increased tissue and serum levels of ANF found with 8-h 0.5 ppm O₃ exposure in animal toxicology studies (Vesely et al., 1994a,b,c) also raise the possibility of potential cardiovascular effects of acute ambient O₃ exposures

Animal toxicology studies have found both transient and persistent ventilatory responses with and without progressive decrease in heart rate (Arito et al., 1997). Observations of O₃-induced vasoconstriction in a controlled human exposure study by Brook et al. (2002) suggests another possible mechanism for O₃-related exacerbations of preexisting cardiovascular disease. One controlled human study (Gong et al., 1998) evaluated potential cardiovascular health effects of O₃ exposure. The overall results did not indicate acute cardiovascular effects of O₃ in either the hypertensive or control subjects. The authors observed an increase in rate-pressure product and heart rate, a decrement for FEV₁, and a >10 mm Hg increase in the alveolar/arterial pressure difference for O₂ following O₃ exposure. The mechanism for the decrease in arterial oxygen (O₂) tension study could be due to an O₃-induced ventilation-perfusion mismatch. Foster et al. (1993) demonstrated that even in relatively young healthy adults, O₃ exposure can cause ventilation to shift away from the well-perfused basal lung. This effect of O₃ on ventilation distribution may persist beyond 24-hr post-exposure (Foster et al., 1997). These findings suggest that O₃ may exert cardiovascular effects indirectly by impairing alveolar-arterial O₂ transfer and potentially reducing O₂ supply to the myocardium. Ozone exposure may increase myocardial work and impair pulmonary gas exchange to a degree that could perhaps be clinically important in persons with significant preexisting cardiovascular impairment.

As noted in Section 3.3.1.3, a limited number of new epidemiological studies have reported associations between short-term O₃ exposure and effects on the cardiovascular system. Among these studies, three were population-based and involved relatively large cohorts. Two studies, the ARIC (Liao et al., 2004) and the NAS (Parks et al., 2005) evaluated associations between O₃ and HRV. The other study, MONICA (Ruidavets et al., 2005) evaluated the

1 association between O₃ levels and the relative risk of MI. Such studies may offer more
2 informative results based on their large subject-pool and design. Results from these three studies
3 were suggestive of an association between O₃ exposure and the cardiovascular endpoints studies.
4 In other recent studies on incidence of myocardial infarction and some more subtle
5 cardiovascular health endpoints, such as changes in heart rate variability or cardiac arrhythmia,
6 some but not all studies reported associations with short-term exposure to O₃ (CD, section
7 7.2.7.1). From these studies, the CD concludes that the “current evidence is rather limited but
8 suggestive of a potential effect on HRV, ventricular arrhythmias, and MI incidence” (CD, p. 7-
9 65).

10 An increasing number of studies have evaluated the association between O₃ exposure and
11 cardiovascular hospital admissions. As shown in Figure 7-13 and discussed in section 7.3.4 of
12 the CD, many reported negative or inconsistent associations, whereas other studies, especially
13 those that examined the relationship when O₃ exposures were higher, have found positive and
14 robust associations between O₃ and cardiovascular hospital admissions. The CD finds that the
15 overall evidence from these studies remains inconclusive regarding the effect of O₃ on
16 cardiovascular hospitalizations (CD, p. 7-83).

17 The CD notes that the suggestive positive epidemiologic findings of O₃ exposure on
18 cardiac autonomic control, including effects on HRV, ventricular arrhythmias and MI, and
19 reported associations between O₃ exposure and cardiovascular hospitalizations in the warm
20 season gain credibility and scientific support from the results of experimental animal toxicology
21 and human clinical studies, which are indicative of plausible pathways by which O₃ may exert
22 cardiovascular effects (CD, Section 8.6.1).

23 **3.5.4 Coherence and Plausibility of Effects Related to Long-Term O₃ Exposure**

24 As discussed in section 8.6.2 of the CD, previous epidemiological studies have provided
25 only inconclusive evidence for either mortality or morbidity effects of long-term O₃ exposure.
26 The CD observes that the inconsistency in findings may be due to a lack of precise exposure
27 information, the possibility of selection bias, and the difficulty of controlling for confounders
28 (CD, p. 8-50). Several new longitudinal epidemiology studies have evaluated associations
29 between long-term O₃ exposures and morbidity and mortality and suggest that these long-term
30 exposures may be related to changes in lung function in children; however, little evidence is
31 available to support a relationship between chronic O₃ exposure and mortality or lung cancer
32 incidence (CD, p. 8-50).

33 Although human chamber studies have not evaluated effects with long-term exposures to
34 O₃, there is some evidence available from toxicological studies. While early animal toxicology
35 studies of long-term O₃ exposures were conducted using continuous exposures, more recent

1 studies have focused on exposures which mimic diurnal and seasonal patterns and more realistic
2 O₃ exposure levels (CD, p. 8-50). Studies of monkeys that compared these two exposure
3 scenarios found increased airway pathology only with the latter design. Persistent and
4 irreversible effects reported in chronic animal toxicology studies suggest that additional
5 complementary human data are needed from epidemiologic studies (CD, p. 8-50).

6 A long-term study of infant rhesus monkeys exposed to simulated seasonal O₃ (0.5 ppm ,
7 8 hr/day for 5 days every 14 days for 11 episodes) reported remodeling of the distal airways,
8 abnormalities in tracheal basement membrane, accumulation of eosinophils in conducting
9 airways, and decrements in airway innervation. Another long-term exposure study of monkeys
10 exposed to 0.61 ppm O₃ for a year and studies of rats exposed for 20 months (0.5-1.0 ppm O₃ for
11 6 hr/day) reported increased deposition of collagen and thickening of the CAR, suggestive of
12 irreversible long-term O₃ impacts on the lungs. Although some earlier seasonal exposure studies
13 of rats reported small, but significant, decrements in lung function consistent with focal
14 fibrogenesis in the proximal alveolar region, other chronic exposure studies with exposures of
15 0.5 to 1.0 ppm O₃ report epithelial hyperplasia that disappears in a few days. At this time,
16 however, there is little evidence from human studies for long-term O₃-induced effects on lung
17 function .

18 The CD (p. 8-51) concludes that evidence from animal toxicology studies strongly
19 suggests that chronic O₃ exposure is capable of damaging the distal airways and proximal alveoli,
20 resulting in lung tissue remodeling leading to apparent irreversible changes. Such structural
21 changes and compromised pulmonary function caused by persistent inflammation may
22 exacerbate the progression and development of chronic lung disease. Together with the limited
23 evidence available from epidemiological studies, these findings offer some insight into potential
24 biological mechanisms for suggested associations between long-term or seasonal exposures to O₃
25 and reduced lung function development in children which have been observed in epidemiologic
26 studies (CD, p. 8-51).

27 **3.5.5 Coherence and Plausibility of Mortality-Related Health Endpoints**

28 An extensive epidemiological literature on air pollution related mortality risk estimates
29 from the U.S., Canada, and Europe is discussed in the CD (sections 7.4 and 8.6.3). These single-
30 and multi-city mortality studies coupled with meta-analyses generally indicate associations
31 between acute O₃ exposure and elevated risk for all-cause mortality, even after adjustment for the
32 influence of season and PM. Several single-city studies that specifically evaluated the
33 relationship between O₃ exposure and cardiopulmonary mortality also reported results suggestive
34 of a positive association (CD, p. 8-51). These mortality studies suggest a pattern of effects for
35 causality that have biologically plausible explanations, but our knowledge regarding potential

1 underlying mechanisms is very limited at this time and requires further research. Most of the
2 physiological and biochemical parameters investigated in human and animal studies suggest that
3 O₃-induced biochemical effects are relatively transient and attenuate over time. The CD (p. 8-
4 52) hypothesizes a generic pathway of O₃-induced lung damage, potentially involving oxidative
5 lung damage with subsequent inflammation and/or decline in lung function leading to respiratory
6 distress in some sensitive population groups (e.g., asthmatics), or other plausible pathways noted
7 below that may lead to O₃-related contributions to cardiovascular effects that ultimately increase
8 risk of mortality.

9 The third National Health and Nutrition Examination Follow-up data analysis indicates
10 that about 20% of the adult population has reduced FEV₁ values, suggesting impaired lung
11 function. Most of these individuals have COPD, asthma or fibrotic lung disease (Manino et al.,
12 2003), which are associated with persistent low-grade inflammation. Furthermore, patients with
13 COPD are at increased risk for cardiovascular disease, and lung disease with underlying
14 inflammation may be linked to low-grade systemic inflammation associated with atherosclerosis,
15 independent of cigarette smoking (CD, p. 8-52). Lung function decrements in persons with
16 cardiopulmonary disease have been associated with inflammatory markers, such as C-reactive
17 protein (CRP) in the blood. At a population level it has been found that individuals with the
18 lowest FEV₁ values have the highest levels of CRP, and those with the highest FEV₁ values have
19 the lowest CRP levels (Manino et al., 2003; Sin and Man, 2003). This complex series of
20 physiological and biochemical reactions following O₃ exposure may tilt the biological
21 homeostasis mechanisms which could lead to adverse health effects in people with compromised
22 cardiopulmonary systems.

23 Of much interest are several other types of newly available data that support reasonable
24 hypotheses that may help to explain the findings of O₃-related increases in cardiovascular
25 mortality observed in some epidemiological studies. These include the direct effect of O₃ on
26 increasing PAF in lung tissue that can then enter the general circulation and possibly contribute
27 to increased risk of blood clot formation and the consequent increased risk of MI,
28 cerebrovascular events (stroke), or associated cardiovascular-related mortality. Ozone reactions
29 with cholesterol in lung surfactant to form epoxides and oxysterols that are cytotoxic to lung and
30 heart muscles and that contribute to atherosclerotic plaque formation in arterial walls represent
31 another potential pathway. Stimulation of airway irritant receptors may lead to increases in
32 tissue and serum levels of ANF, changes in heart rate, and edema of heart tissue. A few new
33 field and panel studies of human adults have reported associations between ambient O₃
34 concentrations and changes in cardiac autonomic control (e.g., HRV, ventricular arrhythmias,
35 and MI). These represent plausible pathways that may lead to O₃-related contributions to
36 cardiovascular effects that ultimately increase the risk of mortality.

1 In addition, O₃-induced increases in lung permeability allow more ready entry for inhaled
2 PM into the blood stream, and O₃ exposure would increase the risk of PM-related cardiovascular
3 effects. Furthermore, increased ambient O₃ levels contribute to ultrafine PM formation in the
4 ambient air and indoor environments. Thus, the contributions of elevated ambient O₃
5 concentrations to ultrafine PM formation and human exposure, along with the enhanced uptake
6 of inhaled fine particles, consequently contribute to exacerbation of PM-induced cardiovascular
7 effects in addition to those more directly induced by O₃ (CD, p. 8-53).

8 **3.6 OZONE-RELATED IMPACTS ON PUBLIC HEALTH**

9 The following discussion draws from section 8.7 of the CD to characterize factors which
10 modify responsiveness to O₃, subpopulations potentially at risk for O₃-related health effects, and
11 potential public health impacts associated with exposure to ambient O₃. Providing appropriate
12 protection of public health requires that a distinction be made between those effects that are
13 considered adverse health effects and those that are not adverse. What constitutes an adverse
14 health effect depends not only on the type and magnitude of effect but also on the population
15 group being affected. While some changes in healthy individuals would not be considered
16 adverse, similar changes in susceptible individuals would be seen as adverse. In order to
17 estimate the potential public health impact, it is important to consider both the susceptible
18 subpopulations for O₃ exposure and the definition of adversity for O₃ health effects.

19 **3.6.1 Factors which Modify Responsiveness to Ozone**

20 There are numerous factors which can modify individual responsiveness to O₃. These
21 include: influence of physical activity; age; gender and hormonal influences; racial, ethnic and
22 socioeconomic status (SES) factors; environmental factors; and oxidant-antioxidant balance.
23 These factors are discussed in more detail in section 6.5 of the CD.

24 It is well established that physical activity increases an individual's minute ventilation
25 and will thus increase the dose of O₃ inhaled (CD, section 6.5.4). Increased physical activity
26 results in deeper penetration of O₃ into more peripheral regions of the lungs, which are more
27 sensitive to acute O₃ response and injury. This will result in greater lung function decrements for
28 acute exposures of individuals during increased physical activity. Research has shown that
29 respiratory effects are observed at lower O₃ concentrations if the level of exertion is increased
30 and/or duration of exposure and exertion are extended. Predicted O₃-induced decrements in lung
31 function have been shown to be a function of exposure duration and exercise level for healthy,
32 young adults (McDonnell et al., 1997)

33 Most of the studies investigating the influence of age have used lung function decrements
34 and symptoms as measures of response. For healthy adults, lung function and symptom

1 responses to O₃ decline as age increases. The rate of decline in O₃ responsiveness appears
2 greater in those 18 to 35 years old compared to those 35 to 55 years old, while there is very little
3 change after age 55. In one study (Seal et al., 1996) analyzing a large data set, a 5.4% decrement
4 in FEV₁ was estimated for 20 year old individuals exposed to 0.12 ppm O₃, whereas similar
5 exposure of 35 year old individuals were estimated to have a 2.6% decrement. While healthy
6 children tend not to report respiratory symptoms when exposed to low levels of O₃, for subjects
7 18 to 36 years old symptom responses induced by O₃ tend to decrease with increasing age
8 (McDonnell et al., 1999).

9 Limited evidence of gender differences in response to O₃ exposure has suggested that
10 females may be predisposed to a greater susceptibility to O₃. Lower plasma and NL fluid levels
11 of the most prevalent antioxidant, uric acid, in females relative to males may be a contributing
12 factor (Housley et al., 1996). Consequently, reduced removal of O₃ in the upper airways may
13 promote deeper penetration. However, most of the evidence on gender differences appears to be
14 equivocal, with one study (Hazucha et al., 2003) suggesting that physiological responses of
15 young healthy males and females may be comparable (CD, section 6.5.2).

16 A few studies have suggested that ethnic minorities might be more responsive to O₃ than
17 Caucasian population groups (CD, section 6.5.3). This may be more the result of a lack of
18 adequate health care and socioeconomic status than any differences in sensitivity to O₃. The
19 limited data available, which have investigated the influence of race, ethnic or other related
20 factors on responsiveness to O₃, prevent drawing any clear conclusions at this time.

21 Few human studies have examined the potential influence of environmental factors such
22 as the sensitivity of individuals who voluntarily smoke tobacco (i.e., smokers) and the effect of
23 high temperatures. New controlled human exposure studies have confirmed that smokers are
24 less responsive to O₃ than nonsmokers; however, time course of development and recovery of
25 these effects, as well as reproducibility, was not different from nonsmokers (CD, section 6.5.5).
26 Influence of ambient temperature on pulmonary effects induced by O₃ has been studied very
27 little, but additive effects of heat and O₃ exposure have been reported.

28 Antioxidants, which scavenge free radicals and limit lipid peroxidation in the ELF, are
29 the first line of defense against oxidative stress. Ozone exposure leads to absorption of O₃ in the
30 ELF with subsequent depletion of ELF antioxidant level in the nasal ELF, but concentration and
31 antioxidant enzyme activity in ELF or plasma don't appear related to O₃ responsiveness (CD,
32 section 6.5.6). Controlled studies of the protective effects of dietary antioxidant supplements
33 have shown some protective effects of lung function but not of subjective symptoms or
34 inflammatory response. Dietary antioxidant supplements have provided some protection to
35 asthmatics by attenuating post-exposure airway hyperresponsiveness. Animal studies have also
36 supported the protective effects of ELF antioxidants.

1 **3.6.2 Susceptible Population Groups**

2 Several characteristics that may increase the extent to which a population group shows
3 sensitivity to O₃ have been discussed in the CD, in the sections on clinical studies in Chapter 6,
4 epidemiological studies in Chapter 7, and in the integrated assessment in Chapter 8; this section
5 will draw on all of these. The characteristics that likely increase susceptibility to O₃ are based
6 on: (1) activity patterns; (2) lung disease; (3) age; and (4) biological responsiveness to O₃.
7 Other groups that might have enhanced sensitivity to O₃, but for which there is currently very
8 little evidence, include: people with heart disease; groups based on race, gender and
9 socioeconomic status; and those with nutritional deficiencies.

10 **3.6.2.1 Active People**

11 A large group of individuals at risk from O₃ exposure consists of outdoor workers and
12 children, adolescents, and adults who engage in outdoor activities involving exertion or exercise
13 during summer daylight hours when ambient O₃ concentrations tend to be higher. This
14 conclusion is based on a large number of controlled-exposure human studies which have been
15 conducted with healthy children and adults and those with preexisting respiratory diseases (CD,
16 sections 6.2 and 6.3). These studies show a clear O₃ exposure-response relationship with
17 increasing spirometric and symptomatic response as exercise level increases. Furthermore, O₃-
18 induced response increases as time of exposure increases. Studies of outdoor workers and others
19 who participate in outdoor activities indicate that extended exposures to O₃ at elevated exertion
20 levels can produce marked effects on lung function.

21 The effects of O₃ on the respiratory health of outdoor workers and others who participate
22 in outdoor activities have been investigated in several recent epidemiologic studies. These
23 individuals may experience increased vulnerability for O₃ health effects, because they are
24 typically exposed to high doses of O₃ as they spend long hours outdoors often at elevated
25 exertion levels. In a group of berry pickers in Fraser Valley, Canada, large decrements in lung
26 function (~5% decrease in FEV₁ per 40 ppb increase in 1-hr max O₃) were associated with acute
27 exposure to O₃ (Brauer et al., 1996). The mean ambient 1-hr max O₃ was 40.3 ppb (SD 15.2)
28 over the study period of June to August 1993. The berry pickers worked outdoors for an average
29 of 11 hr at elevated heart rates (on average, 36% higher than resting levels). These results
30 indicate that extended exposures to O₃ at elevated exertion levels can produce marked effects on
31 lung function among outdoor workers.

32 Höppe et al. (1995) examined forestry workers for O₃-related changes in pulmonary
33 function in Munich, Germany. Ventilation rates, estimated from their average activity levels,
34 were elevated. When comparisons were made between high O₃ days (mean ½-hr max O₃ of 64
35 ppb) and low O₃ days (mean ½-hr max O₃ of 32 ppb), 59% of the forestry workers experienced a
36 notable decrement in lung function (i.e., at least a 20% increase in specific airway resistance or

1 at least a 10% decrease in FEV₁, FVC, or PEF) on high O₃ days. None experienced improved
2 lung function. This study also examined athletes following a 2-hr outdoor training period in the
3 afternoon yielding a ventilation rate double the estimate for the forestry workers. Though a
4 significant association between ambient O₃ levels and decrements in FEV₁ was observed overall,
5 a smaller percentage of the athletes (14%) experienced a notable decrement in lung function on
6 high O₃ days compared to the forestry workers; and 19% of the athletes actually showed an
7 improvement.

8 A large field study by Korrick et al. (1998) examined the effects of multi-hour O₃
9 exposures (on average, 8 hr) on adults hiking outdoors on Mount Washington, in NH. The mean
10 of the hourly O₃ concentrations during the hike was 40 ppb (range 21-74). After the hike, all
11 subjects combined experienced a relatively small mean decline in FEV₁ (1.5% decrease per 30
12 ppb increase in mean hourly O₃ concentrations) during the hike. Ozone-related changes in lung
13 function parameters were estimated. Stratifying the data by hiking duration indicated that
14 individuals who hiked 8 to 12 hr experienced a >2-fold decline in FEV₁ versus those only hiking
15 2 to 8 hr.

16 Results from the above field studies are consistent with those from earlier summer camp
17 studies (Avol et al., 1990; Higgins et al., 1990; Raizenne et al., 1987, 1989; Spektor et al., 1988,
18 1991), which also observed strong associations between acute O₃ exposure and decrements in
19 lung function among children who spent long hours outdoors. In a recent analysis by the
20 Southern California Children's Health Study, a total of 3,535 initially nonasthmatic children
21 (ages 9 to 16 years at enrollment) were followed for up to 5 years to identify new-onset asthma
22 cases associated with higher long-term ambient O₃ concentrations (McConnell et al., 2002).
23 Communities were stratified by pollution levels, with six high-O₃ communities (mean 1-hr
24 max O₃ of 75.4 ppb [SD 6.8] over four years) and six low-O₃ communities (mean 50.1 ppb
25 [SD 11.0]). In the combined analysis using all children, asthma risk was not found to be higher
26 for residents of the six high-O₃ communities versus those from the six low-O₃ communities.
27 However, within the high-O₃ communities, asthma risk was more than 3 times greater for
28 children who played three or more sports versus those who played no sports, an association not
29 observed in the low-O₃ communities. Therefore, among children repeatedly exposed to higher
30 O₃ levels, increased exertion outdoors (and resulting increased O₃ dose) was associated with
31 excess asthma risk.

32 These field studies with subjects at elevated exertion levels support the extensive
33 evidence derived from controlled human exposure studies. The majority of human chamber
34 studies have examined the effects of O₃ exposure in subjects performing continuous or
35 intermittent exercise for variable periods of time. Significant O₃-induced respiratory responses
36 have been observed in clinical studies of exercising individuals. The epidemiologic studies

1 discussed above also indicate that prolonged exposure periods, combined with elevated levels of
2 exertion or exercise, may magnify O₃ effects on lung function. Thus, outdoor workers and others
3 who participate in higher exertion activities outdoors during the time of day when high peak O₃
4 concentrations occur appear to be particularly vulnerable to O₃ effects on respiratory health.
5 Although these studies show a wide variability of response and sensitivity among subjects and
6 the factors contributing to this variability continue to be incompletely understood, the effect of
7 increased exertion is consistent.

8 **3.6.2.2 People with Lung Disease**

9 People with preexisting pulmonary disease are likely to be among those at increased risk
10 from O₃ exposure. Altered physiological, morphological and biochemical states typical of
11 respiratory diseases like asthma, COPD and chronic bronchitis may render people sensitive to
12 additional oxidative burden induced by O₃ exposure. The new results from controlled exposure
13 and epidemiologic studies continue to indicate that asthmatics are a sensitive subpopulation for
14 O₃ health effects.

15 A number of epidemiological studies have been conducted using asthmatic study
16 populations. The majority of epidemiological panel studies that evaluated respiratory symptoms
17 and medication use related to O₃ exposures focused on children. These studies suggest that O₃
18 exposure may be associated with increased respiratory symptoms and medication use in children
19 with asthma. Other reported effects include respiratory symptoms, lung function decrements,
20 and ED visits, as discussed in the CD (section 7.6.7.1). Strong evidence from a large multi-city
21 study (Mortimer et al., 2002), along with support from several single-city studies suggest that O₃
22 exposure may be associated with increased respiratory symptoms and medication use in children
23 with asthma. With regard to ambient O₃ levels and increased hospital admissions and ED visits
24 for asthma and other respiratory causes, strong and consistent evidence establishes a correlation
25 between O₃ exposure and increased exacerbations of preexisting respiratory disease for 1-hr
26 maximum O₃ concentrations <0.12 ppm. Several hospital admission and ED visit studies in the
27 U.S. (Peel et al., 2005), Canada (Burnett et al., 1997a; Anderson et al., 1997), and Europe
28 (Anderson et al., 1997) have reported positive associations between increase in O₃ and increased
29 risk of ED visits and hospital admissions, especially during the warm season.

30 Several clinical studies reviewed in the 1996 CD on atopic and asthmatic subjects had
31 suggested but not clearly demonstrated enhanced responsiveness to acute O₃ exposure compared
32 to healthy subjects. The majority of the newer studies reviewed in Chapter 6 of the CD indicate
33 that asthmatics are as sensitive as, if not more sensitive than, normal subjects in manifesting
34 induced pulmonary function decrements.

1 Ozone-induced increases in neutrophils, protein, and IL-8 were found to be significantly
2 higher in the BAL fluid from asthmatics compared to healthy subjects, suggesting mechanisms
3 for the increased sensitivity of asthmatics. Similarly, subjects with allergic asthma exhibited
4 increased airway responsiveness to inhaled allergens upon acute O₃ exposure. Asthmatics
5 present a differential response profile for cellular, molecular, and biochemical parameters (CD,
6 Figure 8-1) that are altered in response to acute O₃ exposure. Increases in O₃-induced
7 nonspecific airway responsiveness incidence and duration could have important clinical
8 implications for asthmatics.

9 Bronchial constriction following provocation with allergens presents a two-phase
10 response. The early response is mediated by release of histamine and leukotrienes that leads to
11 contraction of smooth muscle cells in the bronchi, narrowing the lumen and decreasing the
12 airflow. In asthmatics, these mediators also cause accumulation of eosinophils, followed by
13 production of mucus and a late-phase bronchial constriction and reduced airflow. Holz et al.
14 (2002) reported an early phase response in subjects with rhinitis after a consecutive 4-day
15 exposure to 0.125 ppm O₃ that resulted in a clinically relevant (>20%) decrease in FEV₁.
16 Allergen challenge in mild asthmatics 24 hr postexposure to 0.27 ppm O₃ for 2 hr resulted in
17 significantly increased eosinophil counts in BALF compared to healthy subjects (Vagaggini et
18 al., 2002). Epithelial cells from mucosal biopsies of allergic asthmatics indicated significant
19 increases in the expression of IL-5, IL-8 and GM-CSF, suggesting increased neutrophilic
20 inflammation compared to healthy subjects (Bosson et al., 2003).

21 Several human exposure studies have shown differences between asthmatics and healthy
22 human subjects with regard to PMN influx in BAL fluid. In vitro studies (Schierhorn et al.,
23 1999) of nasal mucosal biopsies from atopic and nonatopic subjects exposed to 0.1 ppm O₃ found
24 significant differences in release of IL-4, IL-6, IL-8, and *TNF-α*. Another study by Schierhorn et
25 al. (2002) found significant differences in the O₃-induced release of the neuropeptides neurokinin
26 A and substance P for allergic patients in comparison to nonallergic controls, suggesting
27 increased activation of sensory nerves by O₃ in the allergic tissues. Another study by Bayram et
28 al. (2002) using in vitro culture of bronchial epithelial cells recovered from atopic and nonatopic
29 asthmatics also found significant increases in epithelial permeability in response to O₃ exposure.
30 In addition, some controlled human O₃ exposure studies in asthmatics (Hiltermann et al., 1999;
31 Scannell et al., 1996) reported increased secretion of IL-8, suggesting increased neutrophilic
32 inflammation. Two studies (Jörres et al., 1996; Holz et al., 2002) observed increased airway
33 responsiveness to repeated daily O₃ exposure to bronchial allergen challenge in subjects with
34 preexisting allergic airway disease.

35 Newly available reports from controlled human exposure studies (see Chapter 6 in the
36 CD) utilized subjects with preexisting cardiopulmonary diseases such as COPD, asthma, allergic

1 rhinitis, and hypertension. The data generated from these studies that evaluated pulmonary
2 function changes in spirometry did not find clear differences between filtered air and O₃ exposure
3 in COPD and asthmatic subjects. However, the new data on airway responsiveness,
4 inflammation, and various molecular markers of inflammation and bronchoconstriction indicate
5 that people with atopic asthma and allergic rhinitis comprise susceptible groups for O₃-induced
6 adverse health effects.

7 Although controlled human exposure studies have not found evidence of larger
8 spirometric changes in people with COPD relative to healthy subjects, this may be due to the fact
9 that most people with COPD are older adults who would not be expected to have such changes
10 based on their age. However, in Section 8.7.1, the CD notes that new epidemiological evidence
11 indicates that people with COPD may be more likely to experience other effects, including
12 emergency room visits, hospital admissions, or premature mortality. For example, results from
13 an analysis of five European cities indicated strong and consistent O₃ effects on unscheduled
14 respiratory hospital admissions, including COPD (Anderson et al., 1997). Also, an analysis of a
15 9-year data set for the whole population of the Netherlands provided risk estimates for more
16 specific causes of mortality, including COPD (Hoek et al., 2000, 2001; reanalysis Hoek, 2003); a
17 positive, but nonsignificant, excess risk of COPD-related mortality was found to be associated
18 with short-term O₃ concentrations. Moreover, as indicated by Gong et al. (1998), the effects of
19 O₃ exposure on alveolar-arterial oxygen gradients may be more pronounced in patients with
20 preexisting obstructive lung diseases. Relative to healthy elderly subjects, COPD patients have
21 reduced gas exchange and low SaO₂. Any inflammatory or edematous responses due to O₃
22 delivered to the well-ventilated regions of the COPD lung could further inhibit gas exchange and
23 reduce oxygen saturation. In addition, O₃-induced vasoconstriction could also acutely induce
24 pulmonary hypertension. Inducing pulmonary vasoconstriction and hypertension in these
25 patients would perhaps worsen their condition, especially if their right ventricular function was
26 already compromised (CD, Section 6.10).

27 **3.6.2.3 Children and Older Adults**

28 Supporting evidence exists for heterogeneity in the effects of O₃ by age. As discussed in
29 section 6.5.1 of the CD, children, adolescents, and young adults (<18 yrs of age) appear, on
30 average, to have nearly equivalent spirometric responses to O₃, but have greater responses than
31 middle-aged and older adults when exposed to comparable O₃ doses. Symptomatic responses to
32 O₃ exposure, however, do not appear to occur in healthy children, but are observed in asthmatic
33 children, particularly those who use maintenance medications. For adults (>17 yrs of age)
34 symptoms gradually decrease with increasing age. In contrast to young adults, the diminished
35 symptomatic responses in children and symptomatic and spirometric responses in the elderly
36 may put them at an increased risk for continued exposure.

1 As described in the section 7.6.7.2 of the CD, many epidemiological field studies focused
2 on the effect of O₃ on the respiratory health of school children. In general, children experienced
3 decrements in pulmonary function parameters, including PEF, FEV₁, and FVC. Increases in
4 respiratory symptoms and asthma medication use were also observed in asthmatic children. In
5 one German study, children with and without asthma were found to be particularly susceptible to
6 O₃ effects on lung function. Approximately 20% of the children, both with and without asthma,
7 experienced a greater than 10% change in FEV₁, compared to only 5% of the elderly population
8 and athletes (Höppe et al., 2003).

9 The American Academy of Pediatrics (2004) notes that children and infants are among
10 the population groups most susceptible to many air pollutants, including O₃. This is in part
11 because their lungs are still developing. For example, eighty percent of alveoli are formed after
12 birth, and changes in lung development continue through adolescence (Dietert et al., 2000).
13 Children are also likely to spend more time outdoors than adults do, which results in increased
14 exposure to air pollutants (Wiley et al., 1991a,b). Moreover, children have high minute
15 ventilation rates and high levels of physical activity which also increases their dose (Plunkett et
16 al., 1992).

17 Several mortality studies have investigated age-related differences in O₃ effects. Among
18 the studies that observed positive associations between O₃ and mortality, a comparison of all age
19 or younger age (≤ 65 years of age) O₃-mortality effect estimates to that of the elderly population
20 (>65 years) indicates that, in general, the elderly population is more susceptible to O₃ effects
21 (Borja-Aburto et al. 1997; Bremner et al., 1999; Gouveia and Fletcher 2000b; O'Neill et al.,
22 2004; Simpson et al., 1997; Sartor et al., 1995; Sunyer et al., 2002). For example, a study by
23 Gouveia and Fletcher (2000b) examined the O₃-mortality effect by age in São Paulo, Brazil.
24 Among all ages, O₃ was associated with a 0.6% excess risk in all cause mortality per 40 ppb
25 increase in 1-hr max O₃. In comparison, in the elderly population, the O₃-mortality risk estimate
26 was nearly threefold greater, at 1.7%. Similarly, a Mexico City study found that O₃-mortality
27 effect estimates were 1.3% and 2.8% per 20 ppb increase in 24-hr average O₃ concentration in all
28 ages and the elderly, respectively (O'Neill et al., 2004).

29 The meta-analysis by Bell et al. (2005) found a larger effect estimate for the elderly
30 (2.92% per 20 ppb increase in 24-hr average O₃) than for all ages (1.75%). In the large U.S. 95
31 communities study (Bell et al., 2004), effect estimates were slightly higher for those aged 65 to
32 74 years, 1.40% excess risk per 20 ppb increase in 24-hr average O₃, compared to individuals
33 less than 65 years and 75 years or greater, 1.00% and 1.04%, respectively, using a constrained
34 distributed 7-day lag model. Bell et al. (2004) note that despite similar effects estimates, the
35 absolute effect of O₃ is substantially greater in the elderly population due to the higher
36 underlying mortality rates, which lead to a larger number of extra deaths for the elderly
37 compared to the general population. The CD concludes that the elderly population (>65 years of
38 age) appear to be at greater risk of O₃-related mortality and hospitalizations compared to all ages
39 or younger populations (CD, p. 7-177).

1 The CD notes that, collectively, there is supporting evidence of age-related differences in
2 susceptibility to O₃ health effects. The elderly population (>65 years of age) appear to be at
3 increased risk of O₃-related mortality and hospitalizations, and children (<18 years of age)
4 experience other potentially adverse respiratory health outcomes with increased O₃ exposure
5 (CD, section 7.6.7.2).

6 **3.6.2.4 People with Increased Responsiveness to Ozone**

7 Biochemical and molecular parameters extensively evaluated in animal toxicology and
8 controlled human exposure experiments were used to identify specific loci on the chromosomes
9 and, in some cases, to relate the differential expression of specific genes to biochemical and
10 physiological differences observed among these species. Utilizing O₃-sensitive and O₃-resistant
11 species, it has been possible to identify the involvement of AHR and inflammation processes in
12 O₃ susceptibility. However, most of these studies were carried out using relatively high doses of
13 O₃, making the relevance of these studies questionable in human health effects assessment. The
14 molecular parameters identified in these studies may serve as useful biomarkers with the
15 availability of suitable technologies and, ultimately, can likely be integrated with
16 epidemiological studies. Interindividual differences in O₃ responsiveness have been observed
17 across a spectrum of symptoms and lung function responses but do not yet allow identification of
18 important underlying factors, except a significant role for age.

19 **3.6.2.5 Other Population Groups**

20 There is limited, new evidence supporting associations between short-term O₃ exposures
21 and a range of effects on the cardiovascular system. Some but not all, epidemiological studies
22 have reported associations between short-term O₃ exposures and the incidence of myocardial
23 infarction and more subtle cardiovascular health endpoints, such as changes in heart rate
24 variability and cardiac arrhythmia. Others have reported associations with hospitalization or ED
25 visits for cardiovascular diseases, although the results across the studies are not consistent.
26 Studies also report associations between short-term O₃ exposure and mortality from
27 cardiovascular or cardiopulmonary causes. Based on epidemiological study results, the CD
28 concludes that the current evidence from field studies is rather limited but supportive of a
29 potential effect of short-term O₃ exposure and heart rate variability, cardiac arrhythmia and
30 incidence of myocardial infarction (CD, p. 7-66). In the CD's evaluation of studies of hospital
31 admissions for cardiovascular disease (CD, section 7.3.4), it is concluded that evidence from this
32 growing group of studies is generally inconsistent but is suggestive of an association with O₃ in
33 studies conducted during the warm season (CD, p. 7-83). This body of evidence suggests that
34 people with heart disease may be at increased risk from short-term exposures to O₃; however,
35 more evidence is needed to conclude that people with heart disease are a susceptible population.

36 Other groups that might have enhanced sensitivity to O₃, but for which there is currently
37 very little evidence, include groups based on race, gender and socioeconomic status, and those

1 with nutritional deficiencies, as discussed above in section 3.6.1 about factors which modify
2 responsiveness to O₃, above.

3 **3.6.3 What Constitutes an Adverse Health Impact from Ozone Exposure?**

4 In making judgments as to when various O₃-related effects become regarded as adverse
5 to the health of individuals, in previous NAAQS reviews staff has relied upon the guidelines
6 published by the American Thoracic Society (ATS) and the advice of CASAC. While
7 recognizing that perceptions of “medical significance” and “normal activity” may differ among
8 physicians, lung physiologists and experimental subjects, the ATS (1985) defined adverse
9 respiratory health effects as “medically significant physiologic changes generally evidenced by
10 one or more of the following: (1) interference with the normal activity of the affected person or
11 persons, (2) episodic respiratory illness, (3) incapacitating illness, (4) permanent respiratory
12 injury, and/or (5) progressive respiratory dysfunction.”

13 During the 1997 review, it was concluded that there was evidence of causal associations
14 from controlled human exposure studies for effects in the first of these five ATS-defined
15 categories, evidence of statistically significant associations from epidemiological studies for
16 effects in the second and third categories, and evidence from animal toxicology studies, which
17 could be extrapolated to humans only with a significant degree of uncertainty, for the last two
18 categories. For the current review, the evidence of O₃-related effects is stronger across all the
19 categories. For ethical reasons, clear causal evidence from controlled human exposure studies
20 still covers only effects in the first category. However, for this review there are results from
21 epidemiological studies, upon which to base judgments about adversity, for effects in all of the
22 categories. Statistically significant and robust associations have been reported in epidemiology
23 studies falling into the second and third categories. These more serious effects include
24 respiratory illness that may require medication (e.g., asthma), but not necessarily hospitalization,
25 as well as respiratory hospital admissions. Less conclusive, but still positive associations have
26 been reported for school absences, ED visits for respiratory causes, and cardiovascular hospital
27 admissions. Human health effects for which associations have been suggested through evidence
28 from epidemiological and animal toxicology studies, but have not been conclusively
29 demonstrated still fall primarily into the last two categories. In the last review of the O₃
30 standard, evidence for these more serious effects came from studies of effects in laboratory
31 animals, and could be extrapolated to humans only with a significant degree of uncertainty.
32 Evidence from animal studies evaluated in this CD strongly suggests that O₃ is capable of
33 damaging the distal airways and proximal alveoli, resulting in lung tissue remodeling leading to
34 apparently irreversible changes. Recent advancements of dosimetry modeling also provide a
35 better basis for extrapolation from animals to humans. Information from epidemiological studies

1 provides supporting, but limited evidence of irreversible respiratory effects in humans (as
2 described in section 6.3.3.2 below). Moreover, the CD concludes that the findings from single-
3 city and multi-city time-series epidemiology studies and meta-analyses of these epidemiology
4 studies support a likely causal association between short-term O₃ exposure and mortality
5 particularly in the warm season.

6 While O₃ has been associated with effects that are clearly adverse, application of these
7 guidelines, in particular to the least serious category of effects related to ambient O₃ exposures,
8 involves judgments about which medical experts on the CASAC panel and public commenters
9 have in the past expressed diverse views. To help frame such judgments, we have defined
10 gradations of individual functional responses (e.g., decrements in FEV₁ and airway
11 responsiveness) and symptomatic responses (e.g., cough, chest pain, wheeze), together with
12 judgments as to the potential impact on individuals experiencing varying degrees of severity of
13 these responses, that have been used in previous NAAQS reviews. These gradations and impacts
14 are summarized in Tables 3-2 and 3-3.

15 For active healthy people, moderate levels of functional responses (e.g., FEV₁
16 decrements of $\geq 10\%$ but $< 20\%$, lasting up to 24 hrs) and/or moderate symptomatic responses
17 (e.g., frequent spontaneous cough, marked discomfort on exercise or deep breath, lasting up to
18 24 hrs) would likely interfere with normal activity for relatively few sensitive individuals;
19 whereas large functional responses (e.g., FEV₁ decrements $\geq 20\%$, lasting longer than 24 hrs)
20 and/or severe symptomatic responses (e.g., persistent uncontrollable cough, severe discomfort on
21 exercise or deep breath, lasting longer than 24 hrs) would likely interfere with normal activities
22 for many sensitive individuals and therefore would be considered adverse under ATS guidelines.
23 However, for people with lung disease, even moderate functional (e.g., FEV₁ decrements $\geq 10\%$
24 but $< 20\%$, lasting up to 24 hrs) or symptomatic responses (e.g., frequent spontaneous cough,
25 marked discomfort on exercise or with deep breath, wheeze accompanied by shortness of breath,
26 lasting up to 24 hrs) would likely interfere with normal activity for many individuals, and would
27 likely result in additional and more frequent use of medication. For people with lung disease,
28 large functional responses (e.g., FEV₁ decrements $\geq 20\%$, lasting longer than 24 hrs) and/or
29 severe symptomatic responses (e.g., persistent uncontrollable cough, severe discomfort on
30 exercise or deep breath, persistent wheeze accompanied by shortness of breath, lasting longer
31 than 24 hrs) would likely interfere with normal activity for most individuals and would increase
32 the likelihood that these individuals would seek medical treatment or go to an ED for relief.

33 In judging the extent to which these impacts represent effects that should be regarded as
34 adverse to the health status of individuals, an additional factor that has been considered in
35 previous NAAQS reviews is whether such effects are experienced repeatedly during the course
36 of a year or only on a single occasion. While some experts would judge single occurrences of

Table 3-2. Gradation of Individual Responses to Short-Term Ozone Exposure in Healthy Persons¹

Functional Response	None	Small	Moderate	Large
FEV ₁	Within normal range ($\pm 3\%$)	Decrements of 3 to $\leq 10\%$	Decrements of >10 but $<20\%$	Decrements of $\geq 20\%$
Nonspecific bronchial responsiveness ²	Within normal range	Increases of $<100\%$	Increases of $\leq 300\%$	Increases of $>300\%$
Duration of response	None	<4 hrs	>4 hrs but ≤ 24 hrs	>24 hrs
Symptom Response	Normal	Mild	Moderate	Severe
Cough	Infrequent cough	Cough with deep breath	Frequent spontaneous cough	Persistent uncontrollable cough
Chest pain	None	Discomfort just noticeable on exercise or deep breath	Marked discomfort on exercise or deep breath	Severe discomfort on exercise or deep breath
Duration of response	None	<4 hrs	>4 hrs but ≤ 24 hrs	>24 hrs
Impact of Responses	Normal	Normal	Mild	Moderate
Interference with normal activity	None	None	A few sensitive individuals choose to limit activity	Many sensitive individuals choose to limit activity

¹ This table is reproduced from the 1996 O₃ AQCD (Table 9-1, page 9-24) (U.S. Environmental Protection Agency, 1996).

² An increase in nonspecific bronchial responsiveness of 100% is equivalent to a 50% decrease in PD₂₀ or PD₁₀₀.

Table 3-3. Gradation of Individual Responses to Short-Term Ozone Exposure in Persons with Impaired Respiratory Systems

Functional Response	None	Small	Moderate	Large
FEV ₁ change	Decrements of <3%	Decrements of 3 to ≤10%	Decrements of >10 but <20%	Decrements of ≥20%
Nonspecific bronchial responsiveness ³	Within normal range	Increases of <100%	Increases of ≤300%	Increases of >300%
Airway resistance (SRaw)	Within normal range (±20%)	SRaw increased <100%	SRaw increased up to 200% or up to 15 cm H ₂ O/s	SRaw increased >200% or more than 15 cm H ₂ O/s
Duration of response	None	<4 hr	>4 hr but ≤24 hr	>24 hr
Symptom Response	Normal	Mild	Moderate	Severe
Wheeze	None	With otherwise normal breathing	With shortness of breath	Persistent with shortness of breath
Cough	Infrequent cough	Cough with deep breath	Frequent spontaneous cough	Persistent uncontrollable cough
Chest pain	None	Discomfort just noticeable on exercise or deep breath	Marked discomfort on exercise or deep breath	Severe discomfort on exercise or deep breath
Duration of response	None	< 4 hr	>4 hr but ≤24 hr	>24 hr
Impact of Responses	Normal	Mild	Moderate	Severe
Interference with normal activity	None	Few individuals choose to limit activity	Many individuals choose to limit activity	Most individuals choose to limit activity
Medical treatment	No change	Normal medication as needed	Increased frequency of medication use or additional medication	Physician or emergency room visit

³ An increase in nonspecific bronchial responsiveness of 100% is equivalent to a 50% decrease in PD₂₀ or PD₁₀₀.

1 moderate responses to be a “nuisance,” especially for healthy individuals, a more general
2 consensus view of the adversity of such moderate responses emerges as the frequency of
3 occurrence increases. Thus it has been judged that repeated occurrences of moderate responses,
4 even in otherwise healthy individuals, may be considered to be adverse since they could well set
5 the stage for more serious illness (61 FR 65723). The CASAC panel in the last review expressed
6 a consensus view that these “criteria for the determination of an adverse physiological response
7 was reasonable” (Wolff, 1995b).

8 In 2000, the American Thoracic Society (ATS) published an official statement on “What
9 Constitutes an Adverse Health Effect of Air Pollution?” (ATS, 2000), which updated its earlier
10 guidance (ATS, 1985). The revised guidance was intended to address new investigative
11 approaches used to identify the effects of air pollution, and to reflect the concern for the impacts
12 of air pollution on specific groups that had been expressed through the environmental justice
13 movement.

14 The new guidance builds upon and expands the 1985 definition of adversity in several
15 ways. There is an increased focus on quality of life measures as indicators of adversity. There is
16 also a more specific consideration of population risk. Exposure to air pollution that increases the
17 risk of an adverse effect to the entire population is adverse, even though it may not increase the
18 risk of any individual to an unacceptable level. For example, a population of asthmatics could
19 have a distribution of lung function such that no individual has a level associated with significant
20 impairment. Exposure to air pollution could shift the distribution to lower levels that still do not
21 bring any individual to a level that is associated with clinically relevant effects. However, this
22 would be considered to be adverse because individuals within the population would have
23 diminished reserve function, and therefore would be at increased risk if affected by another
24 agent.

25 Of the various effects of O₃ exposure that have been studied, many would meet the ATS
26 definition of adversity. Such effects include, for example, any detectible level of permanent lung
27 function loss attributable to air pollution, including both reductions in lung growth or
28 acceleration of the age-related decline of lung function; exacerbations of disease in individuals
29 with chronic cardiopulmonary diseases; reversible loss of lung function in combination with the
30 presence of symptoms; as well as more serious effects such as those requiring medical care
31 including hospitalization and, obviously, mortality.

32 As discussed above, relatively small, reversible declines in lung function parameters may
33 be of questionable significance in healthy people. However, a 5 to 15 % change in FEV₁ is
34 considered to have clinical importance to asthma morbidity (ATS 1991; Lebowitz et al. 1987;
35 Lippmann, 1988). The National Institutes of Health (1997) has stated that a PEF below 80% of a
36 person’s personal best indicates a need for continued medication use in asthmatics. In Mortimer

1 et al. (2002), O₃ was associated with increased incidence of $\geq 10\%$ declines in morning PEF as
2 well as morning symptoms, suggesting that O₃ exposure may have clinically significant effects
3 on asthmatic children.

4 Reflecting new investigative approaches, the ATS statement describes the potential
5 usefulness of research into the genetic basis for disease, including responses to environmental
6 agents that will provide insights into the mechanistic basis for susceptibility, and provide
7 markers of risk status. Likewise biomarkers, that are indicators of exposure, effect or
8 susceptibility, may someday be useful in defining the point at which a response should be
9 equated with an adverse effect. Based on concern for segments of the population that may be
10 disproportionately exposed to environmental contaminants, or have other factors that may
11 increase susceptibility (e.g., genetic or nutritional factors), there was a call for increased research
12 in these areas.

13 Overall, the new guidance does not fundamentally change the approach previously taken
14 to define adversity, nor does it suggest a need at this time to change the structure or content of
15 the tables describing gradation of severity and adversity of effects in Tables 3-2 or 3-3 above.

16 **3.6.4 Estimation of Potential Numbers of People in At-Risk Susceptible** 17 **Population Groups in the United States**

18 Although O₃-related health risk estimates may appear to be numerically small, their
19 significance from an overall public health perspective is affected by the large numbers of
20 individuals in potential risk groups. Several subpopulations may be identified as having
21 increased susceptibility or vulnerability to adverse health effects from O₃, including: older adults,
22 children, individuals with preexisting pulmonary disease, and those with higher exposure levels,
23 such as outdoor workers.

24 One consideration in the assessment of potential public health impacts is the size of
25 various population groups that may be at increased risk for health effects associated with O₃-
26 related air pollution exposure. Table 8-4 in the CD summarizes information on the prevalence of
27 chronic respiratory conditions in the U.S. population in 2002 and 2003 (Dey and Bloom, 2005;
28 Lethbridge-Çejku et al., 2004). Individuals with preexisting cardiopulmonary disease constitute
29 a fairly large proportion of the population, with tens of millions of people included in each
30 disease category. Of most concern here are those individuals with preexisting respiratory
31 conditions, with approximately 11% of U.S. adults and 13% of children having been diagnosed
32 with asthma and 6% of adults having COPD (chronic bronchitis and/or emphysema). Table 8-5
33 in the CD provides further information on the number of various specific respiratory conditions
34 per 100 persons by age among the U.S. population during the mid-1990s. Asthma prevalence
35 tends to be higher in children than adults.

1 In addition, subpopulations based on age group also comprise substantial segments of the
2 population that may be potentially at risk for O₃-related health impacts. Based on U.S. census
3 data from 2003, about 26% of the U.S. population are under 18 years of age and 12% are 65
4 years of age or older. Hence, large proportions of the U.S. population are included in age groups
5 that are considered likely to have increased susceptibility and vulnerability for health effects
6 from ambient O₃ exposure.

7 The health statistics data illustrate what is known as the “pyramid” of effects. At the top
8 of the pyramid, there are approximately 2.5 millions deaths from all causes per year in the U.S.
9 population, with about 100,000 deaths from chronic lower respiratory diseases (Kochanek et al.,
10 2004). For respiratory health diseases, there are nearly 4 million hospital discharges per year
11 (DeFrances et al., 2005), 14 million ED visits (McCaig and Burt, 2005), 112 million ambulatory
12 care visits (Woodwell and Cherry, 2004), and an estimated 700 million restricted activity days
13 per year due to respiratory conditions (Adams et al., 1999). Combining small risk estimates with
14 relatively large baseline levels of health outcomes can result in quite large public health impacts.
15 Thus, even a small percentage reduction in O₃ health impacts on cardiopulmonary diseases would
16 reflect a large number of avoided cases.

17 Another key input for public health impact assessment is the range of concentration
18 response functions for various health outcomes. Epidemiologic studies have reported
19 associations between short-term exposure to O₃ with mortality, hospitalizations for pulmonary
20 diseases, ED visits for asthma, reduced lung function, and incidence of respiratory symptoms.
21 Effect estimates for morbidity responses to short-term changes in O₃ tend to be larger and more
22 variable in magnitude than those for mortality.

23 In addition to attribution of risks for various health outcomes related to O₃ and other
24 copollutants, important considerations in assessing the impact of O₃ on public health include the
25 size of population groups at risk, as well as the concentration-response relationship and potential
26 identification of threshold levels. Taken together, based on the above information, it can be
27 concluded that exposure to ambient O₃ likely has a significant impact on public health in the U.S.

28 **3.7 SUMMARY AND CONCLUSIONS FOR OZONE HEALTH EFFECTS**

29 Based on dosimetric, experimental, and epidemiological evidence assessed in the 1996
30 CD, a set of findings and conclusions were drawn regarding potential health effects of O₃
31 exposure as of 1996. These conclusions are integrated into the Summary and Conclusions for
32 Ozone Health Effects in the 2006 CD (section 8.8). (The revised CD will be referred to as the
33 “2006 CD” in this section to be more easily distinguished from the “1996 CD.”) Section 8.8 of
34 the 2006 CD also has summarized the main conclusions derived from the integrated analysis of

1 animal toxicology (2006 CD, Chapter 5), human experimental (2006 CD, Chapter 6) and
2 epidemiological (2006 CD, Chapter 7) studies that evaluated evidence of health effects
3 associated with short-term, prolonged, and long-term exposures to O₃ alone or in combination
4 with other pollutants commonly found in the ambient air. This section summarizes conclusions
5 drawn from section 8.8 of the 2006 CD with respect to the health effects associated with
6 exposure to O₃ that are most relevant to our assessment of the adequacy of the current primary
7 O₃ standard and the identification of options to consider concerning potential alternative
8 standards to protect public health with an adequate margin of safety.

9 **3.7.1 Respiratory Morbidity Effects of Short-term Exposures to Ozone**

10 In the 1996 CD, it was concluded from assessment of controlled human exposure studies
11 that short-term O₃ exposures to O₃ concentrations of ≥ 0.08 ppm for 6.6 to 8 hr under moderate
12 exertion and ≥ 0.12 ppm for 1 hr under heavy exertion cause decrements in lung function in
13 children and increased lung function and respiratory symptoms in healthy adults and asthmatic
14 individuals exposed (2006 CD, p. 8-73). Lung inflammatory responses have been observed in
15 healthy human adults following 6.6 hr O₃ exposures as low as 0.08 ppm (2006 CD, p. 8-75).
16 Changes in lung function, respiratory symptoms, and lung inflammatory responses occur as a
17 function of exposure concentration, duration, and level of exertion. Such experimentally
18 demonstrated effects were consistent with and helped support the plausibility of epidemiological
19 findings assessed in the 1996 CD regarding daily hospital admissions and ED visits for
20 respiratory causes.

21 The 1996 CD concluded that group mean data from numerous controlled human exposure
22 and field studies of healthy subjects (18 to 45 years of age) exposed for 1 to 3 hr indicate that, in
23 general, statistically significant pulmonary function decrements beyond the range of normal
24 measurement variability (e.g., 3 to 5% for FEV₁) occur

- 25 • at >0.12 ppm O₃ with very heavy exercise (competitive running).
- 26 • at >0.18 ppm O₃ with heavy exercise (easy jogging),
- 27 • at >0.30 ppm O₃ with moderate exercise (brisk walking),
- 28 • at >0.37 ppm O₃ with light exercise (slow walking), and
- 29 • at >0.50 ppm O₃ when at rest.

30 Small group mean changes (e.g., $<5\%$) in FEV₁ have been observed in healthy young
31 adults at levels as low as 0.12 ppm O₃ for 1 to 3 hr exposure periods. Also, lung function
32 decrements have been observed in children and adolescents at concentrations of 0.12 and 0.14
33 ppm O₃ with heavy exercise. Some individuals within a study may experience FEV₁ decrements
34 in excess of 15% under these conditions, even when group mean decrements are less than 5%.

1 For exposures of healthy, young adult subjects performing moderate exercise during
2 longer duration exposures (6 to 8 hr), 5% group mean decrements in FEV₁ were observed at

- 3 • 0.08 ppm after O₃ 5.6 hr,
- 4 • 0.10 ppm after O₃ 4.6 hr, and
- 5 • 0.12 ppm after O₃ 3 hr.

6 For these same subjects, 10% group mean FEV₁ decrements were observed at 0.12 ppm O₃ after
7 5.6 and 6.6 hr. As in the shorter duration studies, some individuals experience changes larger
8 than those represented by group mean changes.

9 The 2006 CD (section 8.8) concludes that newer meta-analyses confirmed interindividual
10 differences in lung function decrements reported in the 1996 CD. Age-specific differences in
11 lung function responses were also observed. Spirometric responses (due to decrements in lung
12 function) in healthy adults exposed to near ambient O₃ levels typically resolve to near baseline
13 within 4-6 hr. Meta-analyses of four controlled human exposure studies (two new and two
14 assessed in the 1996 CD) reporting the effects of prolonged (6.6 hr) exposures to 0.08 ppm O₃
15 during moderate exertion on lung function in young healthy adults (M=90, F=30; mean age 23
16 years) indicate an absolute FEV₁ decrease of 6%, whereas FEV₁ increased by 1% following fresh
17 air exposures. Newer studies from Adams (2002, 2006), as illustrated earlier in Figure 3-1B,
18 demonstrate notable interindividual variability for O₃ exposure concentrations of 0.04, 0.06 and
19 0.08 ppm. In these studies, following a continuous exposure to 0.08 ppm O₃ during intermittent,
20 moderate exertion, the group mean FEV₁ decrement was 5%, but 17 % of subjects had
21 FEV₁ decrements of 10% or more. Following exposure to 0.06 ppm O₃, the group mean FEV₁
22 decrement was less than 2%, but five subjects had greater than 5% FEV₁ decrements, with only
23 one experiencing this magnitude of effect when exposed to filtered air (2006 CD, p. 8-18). A
24 few controlled human exposure studies (Adams, 2003; 2006; Hazucha et al., 1992) investigated a
25 triangular exposure pattern at O₃ concentrations that had 6.6 to 8-hr averages between 0.08 and
26 0.12 ppm in order to more closely mimic typical ambient O₃ exposure patterns. Greater overall
27 FEV₁ decrements were observed with triangular exposures compared to the constant or square-
28 wave exposures. Furthermore, peak FEV₁ decrements observed during triangular exposures
29 were greater than those observed during square-wave patterns. At a lower average O₃
30 concentration of 0.06 ppm, no temporal (i.e., hour by hour responses) differences were observed
31 in FEV₁ decrements between square-wave and triangular exposure patterns. Results of these
32 studies suggest the potential for somewhat greater effects on lung function in ambient O₃
33 exposure scenarios that typically involve gradually increasing daily exposure up to a peak in the
34 late afternoon and a subsequent gradual decline (2006 CD, p. 8-19). The quantitative risk
35 assessment, discussed below in Chapter 5, provides estimates addressing what percentage of

1 active school age children are estimated to experience FEV₁ decrements greater than or equal to
2 10, 15, and 20% after 8-hr exposures to O₃ while engaged in moderate exertion.

3 Decrements in lung function associated with ambient O₃ levels have also been found in
4 children attending summer camps in southern Ontario, Canada, in the northeastern U.S., and in
5 southern California (2006 CD, p. 8-74). Meta-analyses indicate that a 0.50-mL decrease in FEV₁
6 is associated with a 1 ppb increase in O₃ concentration. For preadolescent children exposed to
7 120 ppb (0.12 ppm) ambient O₃, this amounts to an average decrement of 2.4 to 3.0% in FEV₁.
8 Similar responses are reported for exercising children and adolescents exposed to O₃ in ambient
9 air or O₃ in purified air for 1-2 hours.

10 The 1996 CD concluded that an increase in the incidence of cough has been reported at O₃
11 concentrations as low as 0.12 ppm in healthy adults during 1 to 3 hr of exposure with very heavy
12 exercise. Other respiratory symptoms, such as pain on deep inspiration, shortness of breath, and
13 lower respiratory scores (i.e., a combination of several symptoms), have been observed at 0.16
14 ppm to 0.18 ppm O₃, 1-hr average, with heavy and very heavy exertion. Respiratory symptoms
15 also have been observed following exposure to 0.08, 0.10 and 0.12 ppm O₃ for 6.6 hr with
16 moderate exertion levels. Also, increases in nonspecific airway responsiveness in healthy adults
17 at rest have been observed after 1 to 3 hr of exposures to 0.40 ppm but not to 0.20 ppm O₃;
18 during very heavy exertion, these increases were observed at concentrations as low as 0.18 ppm
19 but not at 0.12 ppm O₃. Increases in nonspecific airway responsiveness during the 6.6 hr
20 exposures with moderate levels of exertion have been observed at 0.08, 0.10 and 0.12 ppm O₃.

21 The majority of asthma panel studies evaluated the associations of ambient O₃ with lung
22 function and respiratory symptoms in asthmatic children. Results obtained from these studies
23 show some inconsistencies, with some indicating significant positive associations and other
24 smaller studies not finding such effects. Overall, however, the multicity study by Mortimer et al.
25 (2002) and several credible single-city studies (e.g., Gent et al., 2003) indicate a fairly robust
26 association between ambient O₃ concentrations and increased respiratory symptoms in moderate
27 to severe asthmatic children (2006 CD, p. 8-35).

28 The 2006 CD (p. 8-75) concludes that lung inflammatory responses have been observed
29 in healthy human adults following 6.6 hr O₃ exposures as low as 0.08 ppm. These responses
30 have been found even in the absence of O₃-induced lung function decrements for some
31 individuals. Attenuation of most inflammatory markers occurs with repeated exposures over
32 several days, but none of the several markers of lung injury and permeability show attenuation,
33 which is indicative of continued lung tissue damage during repeated exposure. Laboratory
34 animal studies have reported that 1 to 3 hr O₃ exposures as low as 0.1 to 0.5 ppm can cause (1)
35 lung inflammatory responses (e.g., increased ROS and inflammatory cytokines, influx of PMNs,
36 and activation of AMs); (2) damage to epithelial airway tissues, (3) increases in permeability of

1 both lung endothelium and epithelium, and (4) increases in susceptibility to infectious diseases
 2 due to modulation of lung host defenses. Consistent with the above results of human and animal
 3 experimental studies, there is limited epidemiologic evidence of an association between acute
 4 ambient O₃ exposure (1-hr max of about 0.1 ppm) and airway inflammation in children, all of
 5 which taken together is indicative of a causal role for O₃ in inflammatory responses in the
 6 airways (2006 CD, p. 8-76). See Table 3.4 for a summary of short-term health effects of O₃
 7 based on clinical studies assessed in both the 1996 CD and 2006 CD.

8 The 1996 CD concluded that increased O₃ levels are associated with increased hospital
 9 admissions and ED visits for respiratory causes. Analyses from data in the northeastern U.S.
 10 suggested that O₃ air pollution is associated with a substantial portion of all summertime
 11 respiratory hospital visits and admissions. The 2006 CD concludes (CD, p. 8-36) that a large
 12 multi-city and several single-city studies have indicated a positive association between increased
 13 O₃ levels (especially during the warm season) and increased risk for hospital admissions.

14 **Table 3-4. Summary of Ozone-Induced Respiratory Health Effects from Clinical Studies²**

15

Health Effect	Exercise Level	Prolonged Exposure	Short-term Exposure	Lowest Ozone Effect Level
Pulmonary Function Decrements	Moderate	6.6 hr		0.08 ppm
	Moderate	4.6 hr		0.10 ppm
	Moderate	3.0 hr		0.12 ppm
	Competitive		1 hr	0.12-0.14 ppm
	Very Heavy		1-3 hr	0.16 ppm
	Heavy		1-3 hr	0.18 ppm
	Moderate		1-3 hr	0.30 ppm
	Light		1-3 hr	0.37 ppm
Increased Respiratory Symptoms	At rest		1-3 hr	0.50 ppm
	Moderate	6.6 hr		0.08 ppm
Airway Responsiveness	Very Heavy		1-3 hr	0.12 ppm
	At rest		1-3 hr	0.18 ppm
Respiratory Inflammation	Moderate	6.6 hr		0.40 ppm
	Very Heavy		1-3 hr	0.08 ppm
Changes in Host Defenses				0.20 ppm
Decreased Exercise Performance	Moderate	6.6 hr		0.08 ppm
	Competitive		1 hr	0.18 ppm

16

² Information contained in this table is based on scientific data assessed in Chapters 6 and 8 of the 2006 CD.

3.7.2 Cardiovascular Morbidity Effects of Short-term Exposures to Ozone

One health endpoint that was unrecognized in the 1996 CD, but is addressed in the 2006 CD, is O₃-induced cardiovascular effects. Newly available evidence has emerged since 1996 which provides considerable plausibility for how O₃ could exert cardiovascular effects (2006 CD, p. 8-77). Examples of such O₃-induced cardiovascular effects include: (1) O₃-induced release from lung epithelial cells of PAF that may contribute to blood clot formation that would increase the risk of serious cardiovascular outcomes (e.g., heart attack, stroke, mortality); (2) interactions of O₃ with surfactant components in ELF of the lung resulting in production of oxysterols and ROS that may exhibit PAF-like activity contributing to clotting and/or exerting cytotoxic effects on lung and heart cells; (3) possible mechanisms that may involve O₃-induced secretions of vasoconstrictive substances and/or effects on neuronal reflexes that may result in increased arterial blood pressure and/or altered electrophysiologic of heart rate or rhythm; (4) associations between O₃ and various cardiac physiologic endpoints suggesting a potential relationship between O₃ exposure and altered HRV, ventricular arrhythmias, and incidence of MI; and (5) positive associations during the warm season only between ambient O₃ concentrations and cardiovascular hospitalizations. While the only controlled human exposure study that evaluated effects of O₃ exposure on the cardiovascular system found no O₃-induced differences in ECG, heart rate, or blood pressure in healthy or hypertensive subjects, the study did report an overall increase in myocardial work and impairment in pulmonary gas exchange.

Also, animal toxicological studies have reported O₃-induced decreases in heart rate, mean arterial pressure and core temperature. Overall, the 2006 CD (p. 8-77) concludes that this generally limited body of evidence is highly suggestive that O₃ directly and/or indirectly contributes to cardiovascular-related morbidity, but much remains to be done to more fully substantiate links between short-term ambient O₃ exposures and adverse cardiovascular effects.

3.7.3 Mortality-Related Effects of Short-term Exposures to Ozone

The 1996 CD concluded that an association between daily mortality and O₃ concentration for areas with high O₃ levels (e.g., Los Angeles) was suggested. However, due to a very limited number of studies available at that time, there was insufficient evidence to conclude that the observed association was likely causal. Since 1996, new data are available from large multicity studies conducted in the U.S. and several single-city studies conducted all over the world, as well as from several meta-analyses that have combined information from multiple studies. The majority of these studies suggest an elevated risk of total nonaccidental mortality associated with acute exposure to O₃, especially in the summer or warm season when O₃ levels are typically high, with somewhat larger effect estimate sizes for associations with cardiovascular mortality (2006 CD, p. 7-175). The 2006 CD finds that the results from U.S. multicity time-series studies

1 provide the strongest evidence to-date for associations between short-term O₃ exposure and
2 mortality. These studies, along with recent meta-analyses, showed consistent effect estimates
3 that are unlikely to be confounded by PM, though the 2006 CD observes that future work is
4 needed to better understand the influence of model specifications on the effect estimates (2006
5 CD, p. 7-175). For cardiovascular mortality, the 2006 CD reports that effect estimates are
6 consistently positive, falling in the range of 1 to 8% increases per 40 ppb in 1-hr O₃ (2006 CD, p.
7 7-107). Overall, the 2006 CD concludes that these findings appear to be consistent with a causal
8 association between short-term O₃ exposure and mortality particularly in the warm season when
9 O₃ levels are typically high (2006 CD, p. 7-175).

10 **3.7.4 Health Effects of Repeated Short-term Exposures to Ozone**

11 The 1996 CD drew several conclusions regarding repeated short-term O₃ exposures (2006
12 CD, p. 8-15). Partial or complete attenuation is observed for some of the O₃-induced responses
13 after more than 2 days of exposure. After 5 days of exposure, lung function changes return to
14 control levels with the greatest changes usually occurring on the second day, but the attenuation
15 was reversed after 7 to 10 days without O₃ exposure. Most inflammatory markers (e.g., PMN
16 influx) attenuate after 5 days of exposure, but markers of cell damage (e.g., LDH enzyme
17 activity) do not attenuate and continue to increase. Recovery of some inflammatory markers
18 occurred a week to 10 days after exposure ceased, but some responses were not normal after 20
19 days. Animal studies suggest underlying cell damage continues throughout the attenuation
20 process. Also, attenuation may alter normal distribution of O₃ within the lungs, allowing more
21 O₃ to reach sensitive regions, possibly affecting lung defenses. Newer studies assessed in the
22 2006 CD (p. 8-74 and 8-75) supported all of these conclusions in addition to which it was
23 concluded that repeated daily, multi-hour exposure to lower concentrations of O₃ (0.125 ppm for
24 4 days) causes an increased response to bronchial allergen challenge in subjects with preexisting
25 allergic airway disease, with or without asthma. In these subjects, changes in airway
26 responsiveness after O₃ exposure appear to be resolved more slowly than changes in FEV₁ or
27 respiratory symptoms.

28 **3.7.5 Confidence in Various Health Outcomes Associated with Short-term** 29 **Exposures to Ozone**

30 In characterizing the extent to which relationships between the various health outcomes
31 discussed above and short-term exposures to ambient O₃ are likely causal, we note that several
32 different factors have informed the judgments made in the CD and here. These factors include
33 the nature of the evidence (i.e., controlled human exposure, epidemiological, and/or toxicological
34 studies) and the weight of evidence, including such considerations as biological plausibility,
35 coherence of evidence, strength of association, and consistency of evidence.

1 In assessing the health effects data base for O₃, it is clear that human studies provide the
2 most directly applicable information because they are not limited by the uncertainties of
3 dosimetry differences and species sensitivity differences, which would need to be addressed in
4 extrapolating animal toxicology data to human health effects. Controlled human exposure
5 studies provide data with the highest level of confidence since they provide human effects data
6 under closely monitored conditions and can provide clear exposure-response relationships.
7 Epidemiological data provide evidence of associations between ambient O₃ levels and more
8 serious acute and chronic health effects (e.g., hospital admissions and mortality) that cannot be
9 assessed in controlled human exposure studies. For these studies the degree of uncertainty
10 regarding potential confounding variables (e.g., other pollutants, temperature) and other factors
11 affects the level of confidence that the health effects being investigated are attributable to O₃
12 exposures, alone and in combination with other copollutants.

13 In using a weight of evidence approach to inform judgments about the degree of
14 confidence that various health outcomes are likely caused by exposure to O₃, our increases as the
15 number of studies and other factors, such as strength, consistency, and coherence of evidence,
16 consistently reporting a particular health endpoint grows. For example, there is a very high level
17 of confidence that O₃ induces lung function decrements in healthy adults and children due in part
18 to the dozens of studies consistently showing that these effects were observed. As noted above,
19 the 2006 CD (p. 8-74) states that studies provide clear evidence of causality for associations
20 between short-term O₃ exposures and statistically significant declines in lung function in
21 children, asthmatics and adults who exercise outdoors. An increase in respiratory symptoms
22 (e.g., cough, shortness of breath) has been observed in controlled human exposure studies of
23 short-term O₃ exposures, and significant associations between ambient O₃ exposures and a wide
24 variety of symptoms have been reported in epidemiology studies (2006 CD, p. 8-75). Aggregate
25 population time-series studies showing robust associations with respiratory hospital admissions
26 and ED visits are strongly supported by human clinical, animal toxicologic, and epidemiologic
27 evidence for lung function decrements, respiratory symptoms, airway inflammation, and airway
28 hyperreactivity. Taken together, the 2006 CD (p. 8-77) concludes that the overall evidence
29 supports the inference of a causal relationship between acute ambient O₃ exposures and
30 increased respiratory morbidity outcomes resulting in increased ED visits and hospitalizations
31 during the warm season. Recent epidemiologic evidence has been characterized in the CD (p. 8-
32 78) as highly suggestive that O₃ directly or indirectly contributes to non-accidental and
33 cardiopulmonary-related mortality.

34 As discussed above in section 3.5 and in section 8.6 of the 2006 CD, conclusions
35 regarding biological plausibility, consistency, and coherence of evidence of O₃-related health
36 effects are drawn from the integration of epidemiological studies with mechanistic information

1 from controlled human exposure studies and animal toxicological studies. This type of
2 mechanistic linkage has been firmly established for several respiratory endpoints (e.g., lung
3 function decrements, lung inflammation) but remains far more equivocal for cardiovascular
4 endpoints (e.g., cardiovascular-related hospital admissions). Finally, for epidemiological studies,
5 strength of association refers to the magnitude of the association and its statistical strength,
6 which includes assessment of both effects estimate size and precision (section 3.4.1). In general,
7 when associations yield large relative risk estimates, it is less likely that the association could be
8 completely accounted for by a potential confounder or some other bias. Consistency refers to the
9 persistent finding of an association between exposure and outcome in multiple studies of
10 adequate power in different persons, places, circumstances and times (section 3.4.3). For
11 example, the magnitude of effect estimates is relatively consistent across recent studies showing
12 association between short-term, but not long-term, O₃ exposure and mortality.

13 Figure 3-5 summarizes our judgments for the various health outcomes discussed above
14 concerning the extent to which relationships between various health outcomes and ambient O₃
15 exposures are likely causal. These judgments are informed by the conclusions and discussion in
16 the CD and in earlier sections of this chapter, reflecting the nature of the evidence and overall
17 weight of the evidence, and are taken into consideration in our quantitative risk assessment,
18 presented below in Chapter 5.

19 **3.7.6 Health Effects of Long-term Exposures to Ozone**

20 In the 1996 CD, available data, primarily from animal toxicology studies, indicated that
21 exposure to O₃ for periods of months to years causes structural changes in several regions of the
22 respiratory tract (2006 CD, p. 8-79). Effects may be of greatest importance in the CAR, where
23 the alveoli and conducting airways meet. This region of the lungs is typically affected in most
24 human airway diseases. However, data from epidemiological and clinical studies is lacking, and
25 most information on chronic O₃ effects in the distal lungs continues to come from animal
26 toxicology studies.

27 What had been previously been viewed as an apparent lack of reversibility of
28 effects during clean air exposures has been investigated since 1996 with animal toxicology
29 studies using exposure regimens simulating a seasonal exposure pattern. One long-term study
30 exposed rhesus monkeys to a simulated seasonal O₃ pattern (0.5 ppm O₃ 8hr/day for 5 days,
31 every 14 days for 11 episodes) and reported: (1) remodeling in the distal airways; (2)
32 abnormalities in tracheal basement membrane; (3) eosinophil accumulation in conducting
33 airways; and (4) decrements in airway innervation. These findings support and advance the
34 earlier information suggestive of injury and repair processes which are caused by seasonal O₃
35 exposures (2006 CD, p.8-79). Although adverse physiological changes associated with long-

Figure 3-5. Qualitative Characterization of Ozone-Related Health Effect Outcomes

Characterization	Overall Confidence in Causal Relationship With Ambient Ozone
<p style="text-align: center;">Causal</p>  <p style="text-align: center;">Suggestive</p>	<ul style="list-style-type: none"> -Lung function decrements in healthy children -Lung function decrements in asthmatic children -Lung function decrements in healthy adults -Respiratory symptoms in asthmatic children -Respiratory symptoms in healthy adults -Increased lung inflammation -Aggravation of asthma (i.e., increased medication usage, increased asthma attacks) -Respiratory-related hospital admissions -Respiratory related emergency department visits -Respiratory-related doctors visits -Increased school absences -Respiratory-related mortality during the O₃ season -Cardiorespiratory-related mortality during the O₃ season -Total nonaccidental mortality during the O₃ season -Cardiovascular-related hospital admissions

1 term O₃ exposures reported in animal studies suggest similar changes in humans, interspecies
2 differences in sensitivity to chronic effects of O₃ continue to be a limiting factor in extrapolation
3 of effect responses in animals to levels at which these responses would be expected to occur in
4 human health effects.

5 Epidemiological studies investigating chronic effects in humans following long-term
6 exposures to O₃ previously provided only limited suggestive evidence. However, recent studies
7 of lung function changes observed in children living in cities with high O₃ levels support the
8 conclusion that long-term O₃ exposure may play a role in causing irreversible lung damage.
9 Further investigation, however, is necessary before we are able to draw firmer conclusions about
10 chronic health effects of O₃ in human populations.

11 **3.7.7 Health Effects of Pollutant Mixtures Containing Ozone**

12 In the 1996 CD, it was recognized that coexposure of humans and animals to O₃ and
13 other pollutants, such as NO₂, SO₂, H₂SO₄, HNO₃, or CO, showed additive response for lung
14 spirometry or respiratory symptoms (2006 CD, p. 8-82). Since 1996, most animal toxicology
15 studies investigating O₃ in a mixture with NO₂ and H₂SO₄ have shown that effects can be
16 additive, synergistic, or even antagonistic, depending on the exposure regimen and the endpoint
17 studied. Ozone has served for a long time as a surrogate or indicator for the overall
18 photochemical oxidant mix. It is well recognized that the observed effects may be due to
19 components of that mix alone or in combination with O₃ and other gases and PM in the ambient
20 air. Although the issue of exposure to copollutants was previously described as poorly
21 understood, especially with regard to chronic effects, newer information from human and animal
22 studies of binary mixtures containing O₃ suggest potential interactions depending on the
23 exposure regimen and pollutant mix (CD, p. 8-82). Examples of this newer information include:
24 (1) continuous exposure to SO₂ and NO₂ increased inhaled O₃ bolus absorption, while continuous
25 exposure to O₃ decreased O₃ bolus absorption; (2) asthmatics exhibited enhanced airway
26 reactivity to house dust mite allergen following exposures to O₃, NO₂ and the combination of the
27 two gases; however, spirometric response was impaired only by O₃ and O₃+ NO₂ at higher
28 concentrations; and (3) animal toxicology studies with O₃ in mixture with NO₂, formaldehyde,
29 and PM demonstrated additive, synergistic, or antagonistic effects depending on the exposure
30 regimen and the endpoints evaluated.

31 One controlled-exposure study of children, designed to approximate conditions of an
32 epidemiological study by matching population and exposure atmosphere (0.1 ppm O₃, 0.1 ppm
33 SO₂, and 101 ug/m² H₂SO₄), failed to support the findings of the epidemiological study. This
34 demonstrates the difficulty of trying to link outcomes of epidemiological studies and controlled-
35 exposure studies with pollutant mixtures.

1 **3.7.8 Populations at Risk/Susceptibility Factors Associated with Ozone Exposure**

2 The 1996 CD (2006 CD, p. 8-80) identified several factors that may increase sensitivity
3 to O₃ of population groups, including: (1) biological variation in responsiveness to O₃; (2)
4 preexisting lung disease (e.g., asthma); (3) activity patterns (e.g., exertion levels); (4) personal
5 exposure history (e.g., time spent indoors v. outdoors); and (5) personal factors (e.g., age,
6 nutritional status, gender, smoking history, ethnicity). Based on the information assessed in the
7 1996 CD (2006 CD, p. 8-80), population groups that demonstrated increased responsiveness to
8 ambient concentrations of O₃ consisted of exercising, healthy and asthmatic individuals,
9 including children, adolescents, and adults. Since 1996, evidence from controlled-exposure
10 human and animal studies, as well as from epidemiological studies, has provided further support
11 for these and other susceptibility factors and populations at risk. For example, controlled-
12 exposure human studies continue to show differential biological response to O₃ based on
13 physical activity (exertion) and age. These studies demonstrate a large variation in sensitivity
14 and responsiveness to O₃, although specific factors that contribute to this intersubject variability
15 are yet to be identified. Associations of increased summertime hospital admissions for asthma
16 and COPD with ambient O₃ levels suggest that individuals with these respiratory diseases are
17 populations at risk to O₃ exposure effects. Also, based on O₃-induced differential response in
18 lung inflammation and airway responsiveness, asthmatic adults and children appear to have
19 potentially increased susceptibility to O₃. There is no evidence from controlled-exposure human
20 studies which suggests that individuals with COPD are more sensitive to health effects of O₃.

21 There is some animal toxicology evidence which has demonstrated the importance of
22 genetic background in O₃ susceptibility. Genetic and molecular characterization studies of
23 experimental animals have identified genetic loci responsible for both sensitivity and resistance.

24 Taking all of this information into account, the CD (p. 8-80 to 8-81) concludes that all
25 exercising (moderate to high physical exertion) healthy and asthmatic adults, adolescents, and
26 children appear to exhibit increased responsiveness to ambient O₃ levels and continue to be
27 considered at increased risk of O₃-induced health effects. Also, any individual with respiratory
28 or cardiovascular disease or any healthy individual who is engaged in vigorous physical activity
29 outdoors during periods when O₃ levels are high (e.g., active outdoor children) is potentially at
30 increased risk to O₃-induced health effects. In addition, healthy individuals and those with
31 cardiorespiratory impairment (e.g., those with COPD or cardiovascular disease) who are
32 “hyperresponsive” to O₃ exposure (i.e., exhibit much higher than normal lung function
33 decrements and/or respiratory symptoms) would be considered at greater risk to O₃ exposure.
34 Finally, individuals who are more likely to be exposed to air pollution while engaged in physical

- 1 activity (e.g., outdoor workers) and those with genetic polymorphisms for antioxidant enzymes
- 2 and inflammatory genes may be at heightened risk of effects of O₃ (2006 CD, p. 8-81).

4. CHARACTERIZATION OF HUMAN EXPOSURE TO OZONE

4.1 INTRODUCTION

As part of the last O₃ NAAQS review, EPA conducted exposure analyses for the general population, children who spent more time outdoors, and outdoor workers. Exposure estimates were generated for nine urban areas for “as is” (i.e., a recent year) air quality and for just meeting the existing 1-hr standard and several alternative 8-hr standards. EPA also conducted a health risk assessment that produced risk estimates for the number of children and percent of children experiencing lung function and respiratory symptoms associated with the exposures estimated for these same nine urban areas.

The exposure analysis conducted for the current review builds upon the methodology and lessons learned from the exposure analyses conducted for the last review (US EPA, 1996a). The methodology used to conduct the exposure analysis as well as summary results from the exposure analysis are described in this chapter. The exposure analysis technical support document, *Ozone Population Exposure Analysis for Selected Urban Areas* (US EPA, 2006a) (hereafter cited as “draft Exposure Analysis TSD”) presents a detailed description of the exposure analysis methodology.

Population exposures to ambient O₃ levels are modeled for 12 urban areas located across the U.S. using the Air Pollutants Exposure (APEX) model, also referred to as the Total Risk Integrated Methodology Inhalation Exposure (TRIM.Expo) model (US EPA, 2006c,d). Exposure estimates are developed for O₃ levels in recent years, based on 2002 and 2004 ambient air quality measurements. Exposures are also estimated for O₃ levels associated with just meeting the current 8-hr O₃ NAAQS and several potential alternative standards, based on adjusting data derived from the ambient monitoring network as described in section 4.5.8. Exposures to background levels of O₃ are also estimated, based on O₃ concentrations predicted by the GEOS-CHEM atmospheric photochemical model.

Exposures are modeled for 1) the general population, 2) all school-age children (ages 5-18), 3) active school-age children (defined below), and 4) asthmatic school-age children. The strong emphasis on children reflects the finding of the last O₃ NAAQS review that children, especially those who are active outdoors, are an important at-risk group.

This chapter provides a brief overview of the types of studies that provide data on which this analysis is based, followed by a description of the exposure model used for this analysis, the model input data, and the results of the analysis. The final sections of this chapter compare the exposure estimates with those from the prior review and summarize the sensitivity analyses and

1 model evaluation that have been conducted for the O₃ exposure model described in this chapter.
2 The uncertainty assessment and a technical description of the modeling effort are provided in
3 separate documents (Langstaff, 2006; US EPA, 2006a).

4 **4.2 OZONE EXPOSURE STUDIES**

5 Many studies have produced information and data supporting the development of
6 methods for estimating human exposure to ambient O₃ over the past several decades. These
7 studies have been reviewed in the current and previous EPA Ozone Air Quality Criteria
8 Documents (US EPA, 1986, 1996b, 2006b).

9 The types of studies which provide the basis for modeling human exposure to O₃ include
10 studies of people's activities, work and exercise patterns, physiology, physics and O₃-related
11 chemistry in microenvironments, atmospheric modeling of O₃, chamber studies of atmospheric
12 chemistry, and modeling of meteorology. Measurements that have proven to be useful for
13 understanding and estimating exposure obtained from personal exposure assessment studies
14 include fixed-site ambient concentrations, concentrations in specific indoor and outdoor
15 microenvironments, personal exposure levels, personal activity patterns, air exchange rates,
16 infiltration rates, deposition and decay rates, and meteorology.

17 **4.2.1 Exposure Concepts and Definitions**

18 *Human exposure* to a contaminant is defined as “contact at a boundary between a human
19 and the environment at a specific contaminant concentration for a specific interval of time,” and
20 has units of concentration times time (National Research Council, 1991). For airborne pollutants
21 the contact boundary is nasal and oral openings in the body, and *personal exposure* of an
22 individual to a chemical in the air for a discrete time period is quantified as (Lioy, 1990; National
23 Research Council, 1991):

$$24 \quad E_{[t_1, t_2]} = \int_{t_1}^{t_2} C(t) dt \quad (4-1)$$

25 where $E_{[t_1, t_2]}$ is the personal exposure during the time period from t_1 to t_2 , and $C(t)$ is the
26 concentration at time t in the breathing zone. We refer to the *exposure concentration* to mean the
27 concentration to which one is exposed. The breathing rate (ventilation rate) at the time of
28 exposure is an important determinant of the dose received by the individual. Although we do not
29 estimate dose, we refer to *intake* as the total amount of O₃ inhaled (product of exposure
30 concentration, duration, and minute ventilation rate).

31 Personal exposure to O₃ can be estimated directly by monitoring the concentration of O₃
32 in the person's breathing zone (close to the nose/mouth) using a personal exposure monitor.
33 Exposure can also be estimated indirectly, by estimating or monitoring the concentrations over

1 time in locations in which the individual spends time and estimating the time and duration the
2 individual spends in each location. In both of these methods, Equation 4-1 is used to calculate an
3 estimate of personal exposure. A key concept in modeling exposure is the *microenvironment*, a
4 term that refers to the immediate surroundings of an individual. A microenvironment is a
5 location in which pollutant concentrations are relatively homogeneous for short periods of time.
6 Microenvironments can be outdoors or indoors; some examples are outdoors near the home,
7 outdoors near the place of work, bedrooms, kitchens, vehicles, stores, restaurants, street-corner
8 bus stops, schools, and places of work. A bedroom may be treated as a different
9 microenvironment than a kitchen if the concentrations are significantly different in the two
10 rooms. The concentrations in a microenvironment typically change over time; for example, O₃
11 concentrations in a kitchen while cooking with a gas stove may be lower than when these
12 activities are not being performed, due to scavenging of O₃ by NO_x emissions from the gas
13 burned.

14 An important factor affecting the concentrations of O₃ indoors is the degree to which the
15 ambient outdoor air is transported indoors. This can be modeled using physical factors such as
16 air exchange rates (AERs), deposition and decay rates, and penetration factors. The *volumetric*
17 *exchange rate* (m³/hour) is the rate of air exchange between the indoor and outdoor air. The *AER*
18 between indoors and outdoors is the number of complete air exchanges per hour and is equal to
19 the volumetric exchange rate divided by the volume of the well-mixed indoor air. Indoor
20 concentrations of O₃ can be decreased by uptake of O₃ by surfaces and by chemical reactions.
21 The *deposition* and *chemical decay rates* are the rates (per hour) at which O₃ is removed from
22 the air by surface uptake and chemical reactions. Some exposure models employ an infiltration
23 factor, which is conceptually useful if distinguishing between the air exchange processes of air
24 blowing through open doors and windows and the infiltration of air through smaller openings.
25 Since measurements of AERs account for both of these processes (including infiltration), this
26 distinction is not useful in applied modeling of O₃ exposures and will not be discussed further
27 here. Simpler exposure models use a “factor model” approach to estimate indoor O₃
28 concentrations by multiplying the ambient outdoor concentrations by an indoor/outdoor
29 concentration ratio, referred to as a *penetration factor*.

30 **4.2.2 Monitoring Equipment Considerations**

31 Exposure assessment studies involve monitoring airborne O₃ and/or other pollutants, and
32 monitor design and placement play a critical role in interpreting the results of these studies. For
33 exposure assessment purposes there are two general classes of monitors, personal exposure
34 monitors (PEMs) and fixed site monitors.

1 PEMs are designed to be worn or carried easily by individuals and to measure the
2 concentrations experienced by individuals over a period of hours, days, or weeks. The
3 placement of PEMs is important; the desired placement is usually in the breathing zone near the
4 mouth and nose, but where the monitor will not be excessively impacted by exhaled air. This
5 placement is intended to represent the concentrations the individual breathes in. PEMs typically
6 report continuously measured O₃ concentrations with averaging times ranging from 1 to 24
7 hours.

8 The CD reviews O₃ PEMS (CD, Appendix AX3, p. 163-5) and notes that humidity, wind
9 velocity, badge placement, and interference with other pollutants may result in measurement
10 error. The CD reports PEM detection limits ranging from 5 to 23 ppb for averaging times from
11 24-hr to 1- hr.

12 Fixed-site monitors measure concentrations over time at a given location. There are
13 numerous fixed-site O₃ monitors which are part of national, state, and local air monitoring
14 networks. In addition to their role of being used to determine which areas are in compliance with
15 existing O₃ NAAQS, these are also useful for alerting the public to high O₃ days, providing air
16 quality data in support of photochemical modeling and exposure assessments for a study area, for
17 tracking O₃ levels and trends, and for studying the representativeness of measurements at these
18 monitors for the study area. Existing fixed-site monitors usually report hourly averaged
19 concentrations, and are in operation over a period of years. Federal reference and equivalent O₃
20 monitoring methods are required to have a lower detectable limit of 0.01 ppm and precision of
21 0.01 ppm for 1-hr average concentrations (40 CFR Ch. 1, §53.21). A discussion of monitoring
22 equipment and networks can be found in Chapter 2 of this draft Staff Paper and in section 2.6 in
23 the CD.

24 There are also stationary monitors expressly set up for particular exposure field studies.
25 These are used to measure concentrations over time in microenvironments, such as rooms in a
26 home, just outside a home, roadsides, and so forth. The stationary monitors which are outdoors
27 can provide information about community-scale representativeness of routinely operated fixed-
28 site monitors in or near the community.

29 **4.2.3 Personal Ozone Exposure Assessment Studies**

30 The most useful PEM studies have data collected repeatedly from each individual in the
31 study over a period of time, yielding a longitudinal time series of concentrations each individual
32 is exposed to. These studies permit analysis of both the temporal and spatial variability of each
33 person's personal exposure to O₃.

34 Some studies are designed so that the data are sampled randomly from the population,
35 which reduces bias and allows one to make inferences about exposure in the broader population.

1 Most studies addressing O₃ exposure have not been random. They might have specific goals for
2 which randomness is not required, or be subject to constraints which do not allow for random
3 sampling. Some studies draw upon data from existing measurement systems or historical data
4 collection efforts. These non-random studies can be very helpful in the development of models
5 of exposure; however, we recognize that they may not be representative of the broader
6 population.

7 **4.2.4 Microenvironmental Studies**

8 The focus of microenvironmental studies is on measuring concentrations in different
9 locations that people spend time in, as well as on measuring the movement of pollutants from
10 one microenvironment to another and on measuring other parameters that contribute to
11 variability in exposure. Typically, microenvironmental measurements include indoor and
12 outdoor concentrations of O₃ and other pollutants, AERs, infiltration factors, deposition rates,
13 decay rates, emissions of O₃, NO_x, VOCs, and other pollutants, operating characteristics of air
14 conditioning systems, and meteorological data such as wind velocity, temperature, and humidity.
15 The CD discusses several studies of microenvironments that contribute to our understanding of
16 the factors and processes that affect exposure to O₃ (CD Appendix AX3, p. 191-216).

17 There is a great deal of variability among individuals in the amount of time spent indoors,
18 but the majority of people spend most of their time indoors (Graham & McCurdy, 2004), and
19 therefore the concentrations of O₃ indoors can be an important determinant of people's exposure
20 to O₃. There are several factors affecting O₃ concentrations indoors. The ambient outdoor
21 concentration of O₃ and the AER are the primary determinants of the indoor concentrations.
22 Removal processes are also significant, the most important of which is deposition onto indoor
23 surfaces such as carpets, furnishings, and ventilation ductwork. Chemical reactions of O₃ with
24 other compounds, such as solvents from consumer products or NO_x emissions from gas stoves,
25 also deplete O₃ indoors. (Weschler, 2000; Monn, 2001.)

26 The primary sources of O₃ indoors are O₃-generating air cleaners and some photocopiers
27 and laser printers. Ozone generators can increase indoor concentrations by more than 50 ppb.
28 Some older photocopiers, if run continuously in an enclosed area, can increase O₃ concentrations
29 by as much as 150 ppb. Older laser printers can produce concentrations of up to 180 ppb. (US
30 EPA, 1995; CARB, 2005.)

1 **4.3 EXPOSURE MODELING**

2 Models of human exposure to airborne pollutants are typically driven by estimates of
3 ambient outdoor concentrations of the pollutants, which vary by time of day as well as by
4 location. These concentration estimates may be provided by measurements, by air quality
5 models, or by a combination of these. It is only possible to address hypothetical future scenarios
6 using modeling. The main purpose of this exposure analysis is to allow comparisons of
7 population exposures to O₃ within each urban area, associated with current air quality levels and
8 with several potential alternative air quality standards or scenarios. Human exposure, regardless
9 of the pollutant, depends on where an individual is located and what they are doing. Exposure
10 models are useful in realistically estimating personal exposures and intake based on activity-
11 specific ventilation rates, particularly when recognizing that these measurements cannot be
12 performed for a given population. This section provides a brief overview of the model used by
13 EPA to estimate O₃ population exposure. Details about the application of the model to estimate
14 O₃ population exposure are provided in the following sections and in the draft Exposure Analysis
15 TSD (EPA, 2006a).

16 **4.3.1 The APEX Model**

17 The EPA has developed the APEX model for estimating human population exposure to
18 criteria and air toxic pollutants. APEX also serves as the human inhalation exposure model
19 within the Total Risk Integrated Methodology (TRIM) framework (Richmond et al., 2002; EPA
20 2005c). APEX is conceptually based on the probabilistic NAAQS Exposure Model (pNEM) that
21 was used in the last O₃ NAAQS review (Johnson et al., 1996a; 1996b; 1996c). Since that time
22 the model has been restructured, improved, and expanded to reflect conceptual advances in the
23 science of exposure modeling and newer input data needed for the model. Key improvements to
24 algorithms include replacement of the cohort approach with a probabilistic sampling approach
25 focused on individuals, accounting for fatigue and oxygen debt after exercise in the calculation
26 of ventilation rates, and a new approach for construction of longitudinal activity patterns for
27 simulated persons. Major improvements to data input to the model include updated AERs,
28 census and commuting data, and the daily time-activities database. These improvements are
29 described later in this chapter.

30 APEX is a probabilistic model designed to account for the numerous sources of
31 variability that affect people's exposures. APEX simulates the movement of individuals through
32 time and space and their exposure to a given pollutant in indoor, outdoor, and in-vehicle
33 microenvironments. Figure 4-1 provides a schematic overview of the APEX model. The model
34 stochastically generates simulated individuals using census-derived probability distributions for

1 demographic characteristics (Figure 4-1, steps 1-3). The population demographics are drawn
2 from the year 2000 Census at the tract level, and a national commuting database based on 2000
3 census data provides home-to-work commuting flows between tracts.¹ Any number of simulated
4 individuals can be modeled, and collectively they approximate a random sampling of people
5 residing in a particular study area.

6 Daily activity patterns for individuals in a study area, an input to APEX, are obtained
7 from detailed diaries that are compiled in the Consolidated Human Activity Database (CHAD)
8 (McCurdy et al., 2000; EPA, 2002). The diaries are used to construct a sequence of activity
9 events for simulated individuals consistent with their demographic characteristics, day type, and
10 season of the year, as defined by ambient temperature regimes (Graham & McCurdy, 2004)
11 (Figure 4-1, step 4). APEX calculates the concentration in the microenvironment associated with
12 each event in an individual's activity pattern and sums the event-specific exposures within each
13 hour to obtain a continuous series of hourly exposures spanning the time period of interest
14 (Figure 4-1, steps 5, 6).

15 APEX has a flexible approach for modeling microenvironmental concentrations, where
16 the user can define the microenvironments to be modeled and their characteristics. Typical
17 indoor microenvironments include residences, schools, and offices. Outdoor microenvironments
18 include near roadways, at bus stops, and playgrounds. Inside cars, trucks, and mass transit
19 vehicles are microenvironments which are classified separately from indoors and outdoors.

20 Activity-specific simulated breathing rates of individuals are used in APEX to
21 characterize intake received from an exposure. These breathing, or ventilation, rates are derived
22 from energy expenditure estimates for each activity included in CHAD and are adjusted for age-
23 and gender-specific physiological parameters associated with each simulated individual. Energy
24 expenditure estimates themselves are derived from METS (metabolic equivalents of work)
25 distributions associated with every activity in CHAD (McCurdy et al., 2000), largely based upon
26 the Ainsworth et al. (1993) "Compendium of Physical Activities." METS are a dimensionless
27 ratio of the activity-specific energy expenditure rate to the basal or resting energy expenditure
28 rate, and the metric is used by exercise physiologists and clinical nutritionists to estimate work
29 undertaken by individuals as they go through their daily life (Montoye et al., 1996). This
30 approach is discussed more thoroughly in McCurdy (2000).

¹ There are approximately 65,400 census tracts in the ~3,200 counties in the U.S.

4.3.2 Key Algorithms

Ozone concentrations in each microenvironment are estimated using either a mass-balance or transfer factors approach, and the user specifies probability distributions for the parameters that are used in the microenvironment model that reflect the observed variabilities in the parameters. These distributions can depend on the values of other variables calculated in the model or input to APEX. For example, the distribution of AERs in a home, office, or car can depend on the type of heating and air conditioning present, which are also stochastic inputs to the model, as well as the ambient temperature. The user can choose to keep the value of a stochastic parameter constant for the entire simulation (which would be appropriate for the volume of a house), or can specify that a new value shall be drawn hourly, daily, or seasonally from specified distributions. APEX also allows the user to specify diurnal, weekly, or seasonal patterns for various microenvironmental parameters. The distributions of parameters input to APEX characterize the variability of parameter values, and are not intended to reflect uncertainties in the parameter estimates.

The mass balance method used within APEX assumes that the air in an enclosed microenvironment is well-mixed and that the air concentration is fairly spatially uniform at a given time within the microenvironment. The following four processes are modeled to predict the concentration of an air pollutant in such a microenvironment:

- Inflow of air into the microenvironment;
- Outflow of air from the microenvironment;
- Removal of a pollutant from the microenvironment due to deposition, filtration, and chemical degradation; and
- Emissions from sources of a pollutant inside the microenvironment.

The transfer factors model is simpler than the mass balance model, however, still most parameters are derived from distributions rather than single values, to account for observed variability. It does not calculate concentration in a microenvironment from the concentration in the previous hour and it has only two parameters, a proximity factor, used to account for proximity of the microenvironment to sources or sinks of pollution, or other systematic differences between concentrations just outside the microenvironment and the ambient concentrations (at the measurements site), and a penetration factor, which quantifies the degree to which the outdoor air penetrates into the microenvironment and is essentially the ratio of the concentration in the microenvironment to the outdoor concentration.

Regardless of the method used to estimate the microenvironmental concentrations, APEX calculates a time series of exposure concentrations that a simulated individual experiences during the modeled time period. APEX estimates the exposure using the concentrations calculated for each microenvironment and the time spent in each of a sequence of microenvironments visited

1 according to the “activity diary” of each individual. The hourly average exposures of each
 2 simulated individual are time-weighted averages of the within-hour exposures. From hourly
 3 exposures, APEX calculates the time series of 8-hr and daily average exposures that simulated
 4 individuals experience during the simulation period. APEX then statistically summarizes and
 5 tabulates the hourly, 8-hr, and daily exposures.

6 **4.3.3 Model Output**

7 There are several useful indicators of exposure and intake of people to O₃ air pollution.
 8 Factors that are important include the magnitude and duration of exposure, frequency of repeated
 9 high exposures, and the breathing rate of individuals at the time of exposure. In this analysis,
 10 exposure indicators include daily maximum 1-hr and 8-hr average O₃ exposures, stratified by a
 11 measure of the level of exertion at the time of exposure. The level of exertion of individuals
 12 engaged in particular activities is measured by an equivalent ventilation rate (EVR), ventilation
 13 normalized by body surface area (BSA), which is calculated as V_e/BSA , where V_e is the
 14 ventilation rate. Table 4-1 lists the ranges of EVR corresponding to “moderate” and “heavy”
 15 levels of exertion.

16
 17 **Table 4-1. Exertion levels in terms of equivalent ventilation rates (liters/min-m²)**

Averaging time	Moderate exertion	Heavy exertion
1 hour	16-30 EVR	≥ 30 EVR
8-hr	13-27 EVR	≥ 27 EVR

18 from Whitfield et al., 1996, page 15.

19
 20 APEX calculates two general types of exposure estimates: counts of the estimated
 21 number of people exposed to a specified O₃ concentration level and the number of times per O₃
 22 season that they are so exposed; the latter metric is in terms of “person-occurrences.” The
 23 former highlights the number of individuals exposed *one or more* times per O₃ season to the
 24 exposure indicator of interest. In the case where the exposure indicator is a benchmark
 25 concentration level, the model estimates the number of people who are expected to experience
 26 exposures to that level of air pollution, or higher, at least once during the modeled period. APEX
 27 also reports counts of individuals with multiple exposures. The person-occurrences measure
 28 estimates the number of times per season that individuals are exposed to the exposure indicator
 29 of interest and then accumulates these estimates for the entire population residing in an area.
 30 This metric conflates people and occurrences: one occurrence for each of 10 people is counted
 31 the same as 10 occurrences for one person.

1 APEX tabulates and displays the two measures for exposures above levels ranging from 0
2 to 0.16 ppm by 0.01 ppm increments, where the exposures are:

- 3 • Daily maximum 1-hr average exposures
- 4 • Daily maximum 8-hr average exposures
- 5 • Daily average exposures.

6 These results are tabulated for the following population groups:

- 7 • All ages and activity levels
- 8 • Children at all activity levels
- 9 • Active people of all ages
- 10 • Active children
- 11 • Asthmatic children.

12 Separate output tables are produced for different levels of exertion concomitant with the
13 exposures:

- 14 • All exertion levels
- 15 • Moderate exertion levels
- 16 • Heavy exertion levels.

17 APEX also produces tables of the time spent in different microenvironments, stratified by
18 exposure levels.

19 **4.3.4 Limitations of the Model**

20 APEX has a strong scientific foundation and incorporates several significant algorithmic
21 improvements and updates to input data since it's predecessor, pNEM, was used in the last
22 review. However, significant uncertainties in the predictions of APEX remain.

23 In the future, we expect to have better tools and data for characterizing personal exposure
24 to O₃ and other pollutants and integrating these with controlled human exposure health studies
25 and with epidemiological analyses. Important research needs to reduce uncertainties associated
26 with the current O₃ exposure analysis include conducting studies to provide better information
27 for refining methods for assessing exposure to O₃ as well as other pollutants. E.g., activity
28 diaries for sensitive groups; distributions of short-term O₃ concentrations near roadways and
29 inside homes (as a function of influential covariates). There is also a need for personal exposure
30 monitors with shorter averaging times and lower detection limits. The most pressing need at this
31 time is for evaluation of existing exposure models and specific algorithms which make up these
32 models. This would greatly improve our understanding of how well current models perform and
33 aid in prioritizing future data collection and model development efforts.

34 In this section we discuss qualitatively some of the limitations of this application of
35 APEX to model population exposures to O₃ pollution. We divide our discussion of the
36 limitations of APEX into four areas: estimation of ambient air quality, estimation of

1 concentrations in microenvironments, characterization of population demographics and activity
2 patterns, and modeling physiological processes. In general, limitations and uncertainties result
3 from variability not modeled or modeled incorrectly, erroneous or uncertain inputs, errors in
4 coding, simplifications of physical, chemical, and biological processes to form the conceptual
5 model, and flaws in the conceptual model. We restrict the discussion here to limitations of the
6 modeling of variability and the quality of input data. The implications of these limitations for
7 the uncertainty of the APEX results is discussed in Langstaff (2006).

8 **4.3.4.1 Estimation of Ambient Air Quality**

9 For estimating ambient O₃ concentrations to use in the exposure model, the urban areas
10 modeled have several monitors measuring hourly O₃ concentrations. The primary uncertainties
11 in the air quality data input to the model result from errors in estimating concentrations at
12 locations which are not close to monitoring sites (spatial interpolation) and from the estimation
13 of missing data. Concentrations of O₃ near roadways are particularly difficult to estimate due to
14 the rapid reaction of O₃ with NO_x emitted from motor vehicles.

15 If a single O₃ season is modeled, another source of uncertainty results from the year-to-
16 year variability of O₃ concentrations. We have modeled the year 2004, the most recent year with
17 air quality and meteorological data. For most of the 12 areas modeled, O₃ concentrations were
18 lower than previous years, due to a combination of reduced emissions of precursors and weather
19 patterns less conducive to the formation of O₃. Therefore, we also modeled the year 2002, to
20 account for year-to-year variability of air quality and meteorology.

21 Modeling exposures for an unspecified future year simulated to just meet alternative air
22 quality standards has, in addition to the uncertainties involved with modeling historical
23 scenarios, the uncertainties of the complex process of projecting to future years air quality,
24 population demographics, activity patterns, and other changing parameters. For the purpose of
25 estimating population exposure as an input to decisions about the appropriate level of a NAAQS,
26 EPA has historically not incorporated any projections in population demographics, activity
27 patterns, or other factors (e.g., air conditioning use, changes in housing types, etc). This allows
28 policy makers to focus on the impact of changing the allowed air quality distribution on
29 population exposure and public health while avoiding the additional uncertainties that inclusion
30 of these other factors would introduce.

31 **4.3.4.2 Estimation of Concentrations in Indoor Microenvironments**

32 The importance of estimation of concentrations in indoor microenvironments (homes,
33 offices, schools, restaurants, vehicles, etc.) is underscored by the finding that personal exposure

1 measurements of O₃ are often not well-correlated with ambient measurements (CD, pages 3-59
2 to 3-61).

3 The microenvironmental characteristics used to model the concentrations in
4 microenvironments tend to be highly variable, both between microenvironments (e.g., different
5 houses have varying characteristics) and within microenvironments (e.g., the characteristics of a
6 given house can vary over time). Since APEX is a probabilistic model, if data accurately
7 characterizing this variability could be provided to the model, such variabilities would not result
8 in uncertainties. However, input data are always a limiting factor. In addition to accurately
9 characterizing the distributions of each individual microenvironmental parameter, we also need
10 to account for the relationships between the different parameters, as well as the relationships
11 between the microenvironmental parameters, human activities, physiology, and other
12 components of the exposure model.

13 **4.3.4.3 Air Exchange Processes**

14 The AER is the single most important factor in determining the ratio of outdoor to indoor
15 concentrations of O₃. AERs are highly variable, both within a microenvironment over time and
16 between microenvironments of the same type. AERs depend on the physical characteristics of a
17 microenvironment and also on the behavior of the occupants of the microenvironment. There is
18 also some dependence on the atmospheric conditions. APEX uses probabilistic distributions of
19 AERs which were derived from several measurement studies in a number of locations, thought to
20 be sufficient to adequately characterize AERs for this analysis (see Appendix A of the draft
21 Exposure Analysis TSD).

22 **4.3.4.4 Deposition Processes**

23 The rate of deposition of O₃ to a surface depends on the material the surface is made of,
24 the humidity, and the concentration of O₃. The rate of removal of O₃ from a microenvironment
25 depends on the dimensions, the ratio of surface area to volume, surface coverings, and
26 furnishings in the microenvironment. Deposition is modeled in APEX by a distribution of decay
27 rates based on a study which measured decay rates in 26 homes in Southern California (Lee et
28 al., 1999). Although we do not expect inter-city differences in decay rates to be more important
29 than differences between homes within cities, there is some uncertainty associated with the small
30 sample size of this study. We do not expect this to be a major contributor to the uncertainty of
31 the modeling results. There can be additional O₃ loss, which is not currently modeled, due to the
32 use of HVAC systems, which significantly increase the effective surface area as air recirculates
33 through ductwork and filters.

1 **4.3.4.5 Chemical Reaction Processes**

2 Ozone reacts with a number of indoor pollutants, such as NO_x from gas stoves and VOCs
3 from consumer products. However, O₃ reacts slowly with most indoor pollutants, and this is
4 typically a less influential removal process than air exchange and surface removal (Weschler,
5 2000). The lack of a better treatment of indoor air chemistry is not considered to be a significant
6 limitation of APEX for modeling O₃, until we have sufficient information characterizing
7 intermittent personal activities such as using terpene-containing cleaners or cooking with a gas
8 stove (which have the potential to significantly modify short-term O₃ exposures) to allow them to
9 be modeled.

10 **4.3.4.6 Characterization of Population Demographics and Activity Patterns**

11 In addition to the uncertainty inherent in the human activity data input to APEX, there are
12 a number of population characteristics or attributes that contribute to the variability of exposures
13 which are modeled in APEX, but for which the assignment to simulated individuals is not
14 entirely reflective of the modeled population:

- 15 • Occupational category
- 16 • Longitudinal stability in occupation, exercise levels, and leisure activities
- 17 • Geographical locations of activities away from the home
- 18 • The specific microenvironments visited away from home
- 19 • Representativeness of CHAD diaries (numbers of diaries used (20,000 used to represent
20 several million people over long periods of time), age of diaries (some are more than 20
21 years old), diary structure differences, etc.)

22 In addition, the extent to which the human activity database provides a balanced
23 representation of the population being modeled is likely to vary across areas. Although the
24 algorithm that constructs activity sequences accounts to some extent for the effects of population
25 demographics and local climate on activity, this adjustment procedure is unlikely to fully account
26 for all intercity differences in people's activities. Our choice of parameters for the new
27 procedure for constructing multi-day activity patterns is based on very limited longitudinal
28 activity data on children only (discussed in Section 4.5.3). Thus, there remains considerable
29 uncertainty due to the uncertainty about within-person variance and between-person variance in
30 key variables (e.g., time spent outdoors). Activity patterns are likely to be affected by many
31 local factors, including topography, land use, traffic patterns, mass transit systems, and
32 recreational opportunities.

1 **4.3.4.7 Modeling Physiological Processes**

2 The modeling of physiological processes that are relevant to the exposure and intake of O₃ is
3 a complicated endeavor. APEX currently uses a built-in physiological model to simulate activity-
4 specific ventilation rate (V_E) which primarily drives O₃ intake dose rates. See Section 2.5 of the
5 draft Exposure Assessment TSD for a discussion of this model. These V_E estimates, when
6 normalized by BSA, are used to characterize exertion in compiling the summary exposure tables. In
7 addition, the physiological model is used to develop a daily-averaged indicator of each child's
8 Physical Activity Index (PAI), which itself is used to characterize the simulated children as
9 sedentary, moderately active, and active (McCurdy 2000).

10 There is uncertainty in using PAI values derived from the CHAD database of human
11 activities for this classification purpose. Using the CHAD database to classify children as being
12 sedentary, moderately active, and active is problematic due mostly to the manner in which the daily
13 activity diaries were constructed. A child, or her or his caregiver if younger than eight years old,
14 would code an activity being undertaken with a start and end time, with no relationship to the
15 exertion level involved with the activity. Exertion level, as MET (metabolic equivalent), was
16 inferred by developers of the CHAD database using standard values and distributions of those
17 values reported in the "Compendium of physical activities" developed by a expert panel of exercise
18 physiologists (Ainsworth et al., 1993). The process used by the CHAD developers to assign MET
19 distributions to activities in the database is described in McCurdy et al. (2000). While care was
20 used to apply the proper exertion levels to the coded activities, for children their activity levels
21 fluctuate widely within a single activity category; their pattern is often characterized as having
22 "bursts" of high energy expenditure movement within a longer time frame of less energy
23 expenditure (Freedson, 1989). This behavior is not well captured by the MET assignment
24 procedure since the diary data cannot distinguish between different activity levels within a single
25 event (i.e., the same activity occurring within one location).

26 When activity-specific MET values are averaged over a day, the resultant is the child's PAI
27 value for the simulated day. This is equivalent to total daily energy expenditure in a day divided by
28 the child's basal, or resting, metabolic rate. PAI is the metric used by exercise physiologists and
29 clinical nutritionists to define inactive/active children, where a PAI>1.75 is considered to be an
30 active child (see McCurdy 2000 for a discussion of this metric). Children having a PAI value lower
31 than that are considered to be sedentary or "low active." Children >2.00 are considered to be (very)
32 active. We use the 1.75 criterion as an indicator of an active child.

33 The uncertainty of the MET values carries over to the uncertainty of the modeled ventilation
34 rates. The ventilation rates are important, since they are used to characterize exertion levels in the
35 clinical studies of responses of exposure to ozone, and consequently we use them to classify
36 exposures of potentially greater risk. The classification of children as active is used to evaluate

1 whether a larger percentage of this subgroup of children is likely to experience more occurrences of
2 exposures of concern at moderate or greater exertion. However, there is no evidence that an active
3 child is at higher risk than an inactive child for any given exposure to O₃ at the same high level of
4 exertion.
5

6 **4.4 SCOPE OF EXPOSURE ASSESSMENT**

7 **4.4.1 Selection of Urban Areas to be Modeled**

8 The selection of urban areas to include in the exposure analysis takes into consideration the
9 location of O₃ epidemiological studies, the availability of ambient O₃ data, and the desire to
10 represent a range of geographic areas, population demographics, and O₃ climatology. These
11 selection criteria are discussed further in Chapter 5. Based on these criteria, we chose the 12 urban
12 areas listed in Table 4-2 to develop population exposure estimates.² The geographic extent of each
13 modeled area consists of the census tracts in the combined statistical area (CSA) as defined by
14 OMB (OMB, 2005).

15 **4.4.2 Time Periods Modeled**

16 The exposure periods modeled are the O₃ seasons for which routine hourly O₃ monitoring
17 data are available. The time periods modeled for both 2002 and 2004 for each area are listed in
18 Table 4-2.

19 **Table 4-2. Urban areas and time periods modeled**

Urban Area (CSA)	Period modeled
Atlanta -Sandy Springs-Gainesville, GA-AL	March 1 to Oct. 31
Boston -Worcester-Manchester, MA-NH	April 1 to Sept. 30
Chicago -Naperville-Michigan City, IL-IN-WI	April 1 to Sept. 30
Cleveland -Akron-Elyria, OH	April 1 to Oct. 31
Detroit -Warren-Flint, MI	April 1 to Sept. 30
Houston -Baytown-Huntsville, TX	Jan. 1 to Dec. 30
Los Angeles -Long Beach-Riverside, CA	Jan. 1 to Dec. 30
New York -Newark-Bridgeport, NY-NJ-CT-PA	April 1 to Sept. 30
Philadelphia -Camden-Vineland, PA-NJ-DE-MD	April 1 to Oct. 31
Sacramento --Arden-Arcade--Truckee, CA-NV	Jan. 1 to Dec. 30
St. Louis -St. Charles-Farmington, MO-IL	April 1 to Oct. 31
Washington -Baltimore-N. Virginia, DC -MD-VA-WV	April 1 to Oct. 31

² In the remainder of this chapter the city name in bold in Table 4-2 is used to represent the entire CSA.

4.4.3 Populations Modeled

Exposure modeling is conducted for the general population residing in each area modeled, as well as for school-age children (ages 5 to 18), active school-age children, and asthmatic school-age children. Due to the increased amount of time spent outdoors engaged in relatively high levels of physical activity (which increases intake), school-age children as a group are particularly at risk for experiencing O₃-related health effects. We report results for school-age children down to age five, but there is a trend for younger children to attend school. Some states allow 4-year-olds to attend kindergarten, and more than 40 states have preschool programs for children younger than five (Blank and Mitchell, 2001). In 2000, six percent of U.S. children ages 3 to 19 who attend school were younger than five years old (2000 Census Summary File 3, Table QT-P19: School Enrollment).

Levels of physical activity are categorized by a daily physical activity index (PAI), a time integrated measure of METS (discussed in section 4.3.1 above). Children are characterized as active if their median daily PAI over the period modeled is greater than 1.75, a level characterized by exercise physiologists as being “moderately active” (McCurdy, 2000). With this particular definition of “active,” about 45 percent of the children are classified as active.

The populations of asthmatic children are calculated using asthma prevalence data from the National Health Interview Survey (NHIS) for 2003 (Dey and Bloom, 2005). Asthma prevalence rates for children aged 0 to 17 years were calculated for each age, gender, and region. The regions defined by NHIS are “Midwest,” “Northeast,” “South,” and “West.” For this analysis, asthma prevalence was defined as the probability of a “Yes” response to the question: “Ever been told that ... had asthma?” among those that responded “Yes” or “No” to this question. The responses were weighted to take into account the complex survey design of the NHIS survey. Standard errors and confidence intervals for the prevalence were calculated using a logistic model, taking into account the survey design. A scatter plot smoothing technique using the LOESS smoother was applied to smooth the prevalence curves and compute the standard errors and confidence intervals for the smoothed prevalence estimates. Logistic analysis of the prevalence curves shows statistically significant differences in prevalence by gender and by region. Therefore we did not combine the prevalence rates for different genders or regions. A detailed description of this analysis is presented in the draft Exposure Analysis TSD.

Table 4-3 lists the year 2000 populations of the modeled areas. The 12 modeled areas combined represent 40 percent of the total U.S. urban population (approximately 222 million in 2000).

1 **Table 4-3. Population coverage of modeled areas (2002 analysis)**

Urban Area (CSA)	Modeled population (thousands)	Modeled children¹ (thousands)	Active children² (thousands)	Asthmatic children (thousands)
Atlanta	4,548	943	446	117
Boston	5,714	1,096	475	182
Chicago	9,311	1,951	850	279
Cleveland	2,945	594	244	279
Detroit	5,357	1,110	479	162
Houston	4,815	1,089	476	136

2 ¹ ages 5-18. ² PAI > 1.75

3

4 **4.5 INPUTS TO THE EXPOSURE MODEL**

5 The data inputs to the APEX model are briefly described in this section. A more detailed
6 description of the development of these data and the derivation of input distributions can be found
7 in the draft Exposure Analysis TSD.

8 **4.5.1 Population Demographics**

9 APEX takes population characteristics into account to develop accurate representations of
10 study area demographics. Population counts and employment probabilities by age and gender are
11 used to develop representative profiles of hypothetical individuals for the simulation. Tract-level
12 population counts by age in one-year increments, from birth to 99 years, come from the 2000
13 Census of Population and Housing Summary File 1. The Summary File 1 contains the 100-percent
14 data, which is the information compiled from the questions asked of all people and about every
15 housing unit.

16 Employment data from the 2000 Census provide employment probabilities for each gender
17 and specific age groups for every Census tract. The employment age groupings are: 16-19, 20-21,

1 22-24, 25-29, 30-34, 35-44, 45-54, 55-59, 60-61, 62-64, 65-69, 70-74, and >75 years of age.
2 Children under the age of 16 are assigned employment probabilities of zero.

3 **4.5.2 Population Commuting Patterns**

4 To ensure that individual's daily activities are accurately represented within APEX, it is
5 important to integrate working patterns into the assessment. The APEX commuting data are
6 derived from the 2000 Census and collected as part of the Census Transportation Planning Package
7 (CTPP). CTPP contains tabulations by place of residence, place of work, and the flows between the
8 residence and work. These data are available from the U.S. Department of Transportation, Bureau
9 of Transportation Statistics (U.S. Department of Transportation and U.S. Census Bureau, 2000).

10 For school age children we have not included commuting to and from school. We are
11 assuming that children attend a school in the same census tract as their residence. To the extent that
12 the highest ozone levels are generally in the period June through August when most students are not
13 in school, the absence of school commuting is less likely to have a significant impact on the
14 exposure estimates.

15 It was assumed that all persons with home-to-work distances up to 120 km are daily
16 commuters, and that persons who travel further than 120 km do not commute daily. Therefore the
17 list of commuting destinations for each home tract is restricted to only those work tracts that are
18 within 120 km of the home tract.

19 APEX allows the user to specify how to handle individuals who commute to destinations
20 outside the study area. One option is to drop them from the simulation. If they are included, the
21 user specifies values for two additional parameters, called L_M and L_A (Multiplicative and Additive
22 factors for commuters who Leave the area). While a commuter is at work, if the workplace is
23 outside the study area, then the ambient concentration cannot be determined from any air district
24 (since districts are inside the study area). Instead, it is assumed to be related to the average
25 concentration $C_{AVE}(t)$ over all air districts at the time in question. The ambient concentration
26 outside the study area at time t , $C_{OUT}(t)$, is estimated as:

$$27 \quad C_{OUT}(t) = L_M * C_{AVE}(t) + L_A \quad (4-2)$$

28 The microenvironmental concentration (for example, in an office outside the study area) is
29 determined from this ambient concentration by the same model (mass balance or factor) as applies
30 inside the study area. The parameters L_M and L_A were both set to zero for this modeling analysis;
31 thus, exposures to individuals are set to zero when they are outside of the study area. This was done
32 since we have not estimated ambient concentrations of O₃ in counties outside of the modeled areas.

33 **4.5.3 Human Activity Data**

34 The human activity data are drawn from the most recent version (December 2000) of the
35 Consolidated Human Activity Database (CHAD) (McCurdy et al., 2000; EPA, 2002), developed

1 and maintained by the Office of Research and Development's (ORD) National Exposure Research
2 Laboratory (NERL). The CHAD includes data from several surveys covering specific time periods
3 at city, state, and national levels, with varying degrees of representativeness. Table 4-4 summarizes
4 the studies in CHAD used in this modeling analysis, providing almost 16,000 diary-days of activity
5 data (3,075 diary-days for ages 5-18) collected between 1982 and 1998.

6 A key issue in this assessment is the development of an approach for creating O₃-season or
7 year-long activity sequences for individuals based on a cross-sectional activity data base of 24-hour
8 records. The average subject in the time/activity studies in CHAD provided less than two days of
9 diary data. For this reason, the construction of a season-long activity sequence for each individual
10 requires some combination of repeating the same data from one subject and using data from
11 multiple subjects. An appropriate approach should adequately account for the day-to-day and
12 week-to-week repetition of activities common to individuals while maintaining realistic variability
13 between individuals. The method in APEX for creating longitudinal diaries captures the tendency
14 of individuals to repeat activities, based on reproducing realistic variation in a key diary variable,
15 which is a user-selected function of diary variables. For this analysis the key variable is set to the
16 amount of time an individual spends outdoors each day, which is one of the more important
17 determinants of exposure to O₃.

18 The actual diary construction method targets two statistics, a population diversity statistic
19 (**D**) and a within-person autocorrelation statistic (**A**). The **D** statistic reflects the relative importance
20 of within-person variance and between-person variance in the key variable. The **A** statistic
21 quantifies the lag-one (day-to-day) key variable autocorrelation. Desired **D** and **A** values for the
22 key variable are selected by the user and set in the APEX parameters file, and the method algorithm
23 constructs longitudinal diaries that preserve these parameters. Longitudinal diary data from a field
24 study of school-age children (Geyh et al., 2000) and subsequent analyses (Xue et al., 2004) suggest
25 that **D** and **A** are stable over time (and perhaps over cohorts as well). Based on these studies,
26 appropriate target values for the two statistics for outdoor time for children are determined to be 0.2
27 for **D** and 0.2 for **A**. In the absence of data for estimating these statistics for younger children and
28 for adults, these values are also used for adults. This new method for constructing longitudinal
29 diaries from the CHAD data is described in detail in the draft Exposure Analysis TSD.

1 **Table 4-4. Studies in CHAD Used in This Analysis**

Study name	Geographic coverage	Study time period	Subject ages	Diary-days	Diary-days (ages 5-18)	Diary type and study design	Reference

1 **4.5.4 Physiological Data**

2 APEX requires values for various physiological parameters for subjects in order to
3 accurately model their metabolic processes that affect pollutant intake. This is because
4 physiological differences may cause people with the same exposure and activity scenarios to have
5 different pollutant intake levels. The physiological parameters file distributed with APEX
6 contains physiological data or distributions by age and gender for maximum ventilatory capacity
7 (in terms of age- and gender-specific maximum oxygen consumption potential), body mass,
8 resting metabolic rate, and oxygen consumption-to-ventilation rate relationships.

9 **4.5.5 Microenvironments Modeled**

10 In APEX, microenvironments provide the exposure locations for modeled individuals. For
11 exposures to be measured accurately, it is important to have realistic microenvironments that are
12 matched closely to where people are physically located on a daily basis. As discussed in Section
13 4.3.2 above, the two methods available in APEX for calculating pollutant concentrations within
14 microenvironments are a mass balance model and a transfer factor approach. Table 4-5 lists the
15 12 microenvironments selected for this analysis and the exposure calculation method for each.
16 The parameters used in this analysis for modeling these microenvironments are described in this
17 section.

18 **Table 4-5. Microenvironments Modeled**

Microenvironment	Calculation Method	Parameters¹
Indoors – Residence	Mass balance	AER and DE
Indoors – Bars and restaurants	Mass balance	AER and DE
Indoors – Schools	Mass balance	AER and DE
Indoors – Day-care centers	Mass balance	AER and DE
Indoors – Office	Mass balance	AER and DE
Indoors – Shopping	Mass balance	AER and DE
Indoors – Other	Mass balance	AER and DE
Outdoors – Near road	Factors	PR
Outdoors – Public garage/parking lot	Factors	PR
Outdoors – Other	Factors	None
In-vehicle – Cars and Trucks	Factors	PE and PR

19 ¹ AER=air exchange rate, DE=decay-deposition rate, PR=proximity factor, PE=penetration factor

1 **4.5.5.1 Air Exchange Rates for Indoor Residential Environments**

2 Distributions of AERs for the indoor microenvironments were developed using data from
3 several studies. The analysis of these data and the development of the distributions used in the
4 modeling is described in detail in the draft Exposure Analysis TSD. This analysis showed that
5 the AER distributions for the residential microenvironments depend on the type of air
6 conditioning (A/C) and on the outdoor temperature, as well as other variables for which we do
7 not have sufficient data to estimate. This analysis clearly demonstrates that the AER
8 distributions vary greatly across cities and A/C types and temperatures, so that the selected AER
9 distributions for the modeled cities should also depend upon the city, A/C type, and temperature.
10 For example, the mean AER for residences with A/C ranges from 0.39 for Los Angeles between
11 30 and 40 °C to 1.73 for New York between 20 and 25 °C. The mean AER for residences
12 without A/C ranges from 0.46 for San Francisco on days with temperature between 10 and 20 °C
13 to 2.29 for New York on days with temperature between 20 and 25 °C. The need to account for
14 the city as well as the A/C type and temperature is illustrated by the result that for residences
15 with A/C on days with temperature between 20 and 25 °C, the mean AER ranges from 0.52 for
16 Research Triangle Park to 1.73 for New York. For each combination of A/C type, city, and
17 temperature with a minimum of 11 AER values, exponential, lognormal, normal, and Weibull
18 distributions were fit to the AER values and compared. Generally, the lognormal distribution
19 was the best-fitting of the four distributions, and so, for consistency, the fitted lognormal
20 distributions are used for all the cases.

21 One limitation of this analysis was that distributions were available only for selected
22 cities, and yet the summary statistics and comparisons demonstrate that the AER distributions
23 depend upon the city as well as the temperature range and A/C type. Another important
24 limitation of the analysis was that distributions were not able to be fitted to all of the temperature
25 ranges due to inadequate data. A description of how these limitations were addressed can be
26 found in the draft Exposure Analysis TSD.

27 City-specific AER distributions were used where possible; otherwise data for a similar
28 city were used. We obtained estimates of A/C prevalence from the American Housing Survey
29 (AHS, 2003) for each metropolitan area. The final AER distributions used for the exposure
30 modeling are given the draft Exposure Analysis TSD.

31 Some residences, particularly in the Southwest, use evaporative coolers, also known as
32 “swamp coolers,” for cooling. We performed an analysis of AER distributions of residences
33 without A/C, with and without evaporative coolers, using data from three AER measurement
34 studies. This comparison is described in Appendix F in the draft Exposure Analysis TSD. This
35 analysis showed no improvement in the statistical air exchange model when the data were also

1 stratified by evaporative cooler presence or absence, given that they are already stratified by
2 CSA, air conditioner presence or absence, and outdoor temperature range.

3 **4.5.5.2 AER Distributions for Other Indoor Environments**

4 To estimate AER distributions for non-residential, indoor environments (e.g., offices and
5 schools), we obtained and analyzed two AER data sets: “Turk” (Turk et al., 1989); and “Persily”
6 (Persily and Gorfain, 2004; Persily et al., 2005). The earlier “Turk” data set (Turk et al., 1989)
7 includes 40 AER measurements from offices (25 values), schools (7 values), libraries (3 values),
8 and multi-purpose buildings (5 values), each measured using an SF₆ tracer over two or four hours
9 in different seasons of the year. The more recent “Persily” data (Persily and Gorfain, 2004;
10 Persily et al., 2005) were derived from the U.S. EPA Building Assessment Survey and
11 Evaluation (BASE) study, which was conducted to assess indoor air quality, including
12 ventilation, in a large number of randomly selected office buildings throughout the U.S. This
13 data base consists of a total of 390 AER measurements in 96 large, mechanically ventilated
14 offices; each office was measured up to four times over two days, Wednesday and Thursday,
15 AM and PM. The office spaces were relatively large, with at least 25 occupants, and preferably
16 50 to 60 occupants. AERs were measured both by a volumetric method and by a CO₂ ratio
17 method, and included their uncertainty estimates. For these analyses, we used the recommended
18 “Best Estimates” defined by the values with the lower estimated uncertainty; in the vast majority
19 of cases the best estimate was from the volumetric method.

20 Due to the small sample size of the Turk data, the data were analyzed without
21 stratification by building type and/or season. For the Persily data, the AER values for each office
22 space were averaged, rather using the individual measurements, to account for the strong
23 dependence of the AER measurements for the same office space over a relatively short period.
24 The mean values are similar for the two studies, but the standard deviations are about twice as
25 high for the Persily data. The proposed AER distributions were derived from the more recent
26 Persily data only.

27 We fitted exponential, lognormal, normal, and Weibull distributions to the 96 office
28 space average AER values, and the best fitting of these was the lognormal. The fitted parameters
29 for this distribution, used for AER distributions for the indoor, non-residential
30 microenvironments, can be found in the draft Exposure Analysis TSD.

31 **4.5.5.3 Proximity and Penetration Factors For Outdoors and In-vehicle**

32 For the outdoors near-road, public garage/parking lot, and in-vehicle proximity factors,
33 and for the in-vehicle penetration factors, we use distributions developed from the Cincinnati
34 Ozone Study (American Petroleum Institute, 1997, Appendix B; Johnson et al., 1995). This field

1 study was conducted in the greater Cincinnati metropolitan area in August and September, 1994.
2 Vehicle tests were conducted according to an experimental design specifying the vehicle type,
3 road type, vehicle speed, and ventilation mode. Vehicle types were defined by the three study
4 vehicles: a minivan, a full-size car, and a compact car. Road types were interstate highways
5 (interstate), principal urban arterial roads (urban), and local roads (local). Nominal vehicle
6 speeds (typically met over one minute intervals within 5 mph) were at 35 mph, 45 mph, or 55
7 mph. Ventilation modes were as follows:

- 8 • Vent Open: Air conditioner off. Ventilation fan at medium. Driver's window half open.
9 Other windows closed.
- 10 • Normal A/C: Air conditioner at normal. All windows closed.
- 11 • Max A/C: Air conditioner at maximum. All windows closed.

12 Ozone concentrations were measured inside the vehicle, outside the vehicle, and at six fixed-site
13 monitors in the Cincinnati area.

14 The draft Exposure Analysis TSD documents the distributions and the rationale for the
15 selection of distributions of penetration and proximity factors for outdoors and in-vehicle
16 microenvironments used in this modeling analysis.

17 **4.5.5.4 Ozone Decay and Deposition Rates**

18 A distribution for combined O₃ decay and deposition rates was obtained from the analysis
19 of measurements from a study by Lee et al. (1999). This study measured decay rates in the
20 living rooms of 43 residences in Southern California. Measurements of decay rates in a second
21 room were made in 24 of these residences. The 67 decay rates range from 0.95 to 8.05 hour⁻¹. A
22 lognormal distribution was fit to the measurements from this study, yielding a geometric mean of
23 2.5 and a geometric standard deviation of 1.5. This distribution is used for all indoor
24 microenvironments.

25 **4.5.6 Meteorological Data**

26 Daily average and maximum 1-hr temperatures are computed from hourly surface
27 temperature measurements obtained from the National Weather Service. APEX uses the data
28 from the closest weather station to each Census tract. Temperatures are used in APEX both in
29 selecting human activity data and in estimating AERs for indoor microenvironments.

30 **4.5.7 Ambient Ozone Concentrations**

31 APEX requires hourly ambient O₃ concentrations at a set of locations in the study area.
32 Data from EPA's AIRS Air Quality Subsystem were used to prepare the ambient air quality
33 input files for 2002 and 2004. The hourly O₃ concentrations at the AIRS sites in each CSA were
34 used as input to APEX to represent the ambient concentrations within each urban area. For near

1 road and parking garage microenvironments the ambient concentrations are adjusted by
2 proximity factors.

3 **4.5.8 Modeling Alternative Standards**

4 In addition to modeling exposures based on historical air quality, an analysis was
5 conducted using air quality representative of just meeting the current 8-hr O₃ NAAQS of 0.08
6 ppm. Seven alternative standards, reflecting different combinations of standard levels and form
7 are also being considered. Two of the alternatives examined are intended to reflect a different
8 rounding convention, where the rounding convention would use three instead of two decimal
9 places (in ppm) (e.g., 0.080 ppm for the current standard level instead of the current rounding
10 convention which uses 0.084 ppm as the highest level that is considered as meeting the current
11 0.08 ppm standard). Similarly, the alternatives analyzed also include a 0.070 ppm, average 4th
12 daily maximum 8-hr average scenario to reflect this alternative rounding convention. A 3rd high
13 form is considered for 0.08 and 0.07 ppm levels, and a 5th high for the 0.07 level. These
14 alternative scenarios are modeled using a quadratic rollback approach to adjust the hourly O₃
15 concentrations observed in 2002-2004 to yield a design value corresponding to the standard
16 being modeled. Table 4-6 shows the alternative standards, their corresponding attainment
17 thresholds (which the design values are rolled back to), the form of the standard used for each
18 scenario, and the notation used in the remainder of the Staff Paper. Design values for the current
19 8-hr O₃ NAAQS are calculated as the 3-year averages of the annual 4th daily maximum 8-hr
20 average concentration based on the maximum monitor within an urban area. These are given in
21 Table 4-7 for the 2002-2004 period.

22 The quadratic rollback technique combines both linear and quadratic elements to reduce
23 higher concentrations more than lower concentrations near ambient background levels. The
24 quadratic rollback adjustment procedure was considered in a sensitivity analysis during the last
25 review of the O₃ NAAQS and has been shown to be more realistic than the linear proportional
26 rollback method, where all of the ambient measurements are reduced by a constant multiplicative
27 factor regardless of their individual magnitudes. The quadratic rollback approach and evaluation
28 of this approach are described by Johnson (1997), Duff, Horst, and Johnson (1998), and Rizzo
29 (2005, 2006).

30 **Table 4-6. Alternative 8-hr ozone standard scenarios**

Alternative Standard	Attain. Threshold	Form of Standard	Notation
0.08 ppm (rounding ¹ to 0.01 ppm)	0.084 ppm	3 rd daily maximum 4 th daily maximum	84/3 84/4
0.08 ppm (rounding to 0.001 ppm)	0.080 ppm	4 th daily maximum	80/4
0.07 ppm (rounding to	0.074 ppm	3 rd daily maximum	74/3

0.01 ppm)		4 th daily maximum 5 th daily maximum	74/4 74/5
0.07 ppm (rounding to 0.001 ppm)	0.070 ppm	4 th daily maximum	70/4
0.06 ppm (rounding to 0.01 ppm)	0.064 ppm	4 th daily maximum	64/4

1 ¹ The rounding convention applied here involves truncating the design value to the nearest 0.001
2 ppm and then rounding according to the first column of this table.

3

4 **Table 4-7. 2002-2004 8-hr ozone design values for the modeled areas**

Urban Area (CSA)	2002-2004 design value (ppm)	Ratio of 0.084 to the design value
Atlanta	0.093	0.90
Boston	0.091	0.92
Chicago	0.094	0.89
Cleveland	0.095	0.88

7

8 **4.6 EXPOSURE ASSESSMENT RESULTS**

9

10 In this section we present results for children exposed to O₃ while engaged in moderate or
11 greater exertion. The results of the exposure analysis are presented as graphs of the numbers of
12 persons who experience daily maximum 8-hr average exposures above 0.06, 0.07, and 0.08 ppm-
13 8hr (expressed as percentages of the population), while experiencing moderate or greater levels
14 of exertion during the same 8-hr period that the exposure occurred. Exertion is characterized by
15 breathing rates, as described in Section 4.3.3. The exposure levels of 0.06, 0.07, and 0.08 ppm-
16 8hr are levels at which there is clear evidence of health effects in controlled human exposure

1 studies for some healthy individuals engaged in moderate exertion over a 6.6 hour period. The
2 Adams (2006) study demonstrated that exposure to 0.06 ppm O₃ over a 6.6 hour period caused
3 >10% FEV₁ lung function decline in seven percent of the healthy adult subjects, and effects on
4 lung function were seen at concentrations as low as 0.04 ppm (CD, p. 8-18).

5 The patterns of exposures in each city are similar for the different population groups, so
6 in this chapter we present results only for the group of all children exposed while engaged in
7 moderate or greater exertion. The similarity of patterns for different groups is illustrated in
8 Figures 4-1 and 4-2, which present the same exposure measures for three groups: all children,
9 active children, and asthmatic children.

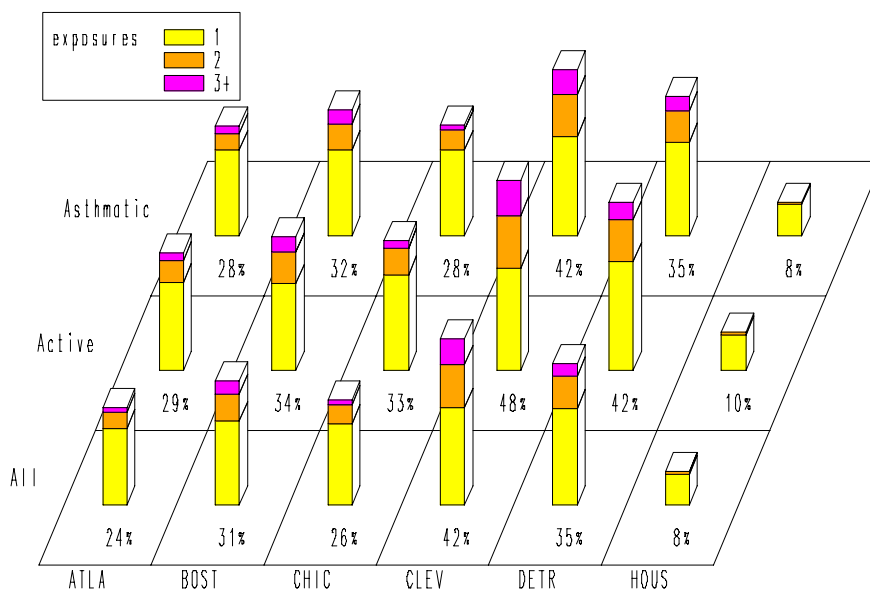

10 Table 4-8 presents counts of children (ages 5-18) with one or more 8-hr O₃ exposures
11 above 0.07 ppm-8hr, concomitant with moderate or greater exertion, for 2002 air quality
12 scenarios reflecting the current standard and four of the alternative standards considered (the
13 standards with the 4th high forms). As discussed in section 3.6.3, multiple exposures pose a
14 greater health concern than single exposures. Table 4-9 gives counts analogous to Table 4-8, but
15 for children with three or more exposures during the O₃ season.

16 Figures 4-3 through 4-20 illustrate the effect of the current and several potential
17 alternative standards on the percentages of children experiencing 1, 2, and 3 or more repeated
18 exposures above 0.08, 0.07, and 0.06 ppm-8hr concomitant with moderate or greater exertion,
19 for each of the cities modeled, based on rollback of 2002 and 2004 O₃ concentrations. The
20 notation in these figures for the alternative standards is defined in Table 4-6. These figures are in
21 terms of percents of the children ages 5-18 who have at least one instance of 8-hr moderate or
22 greater exertion at any exposure during the modeled period (total counts are listed in Table 4-8).

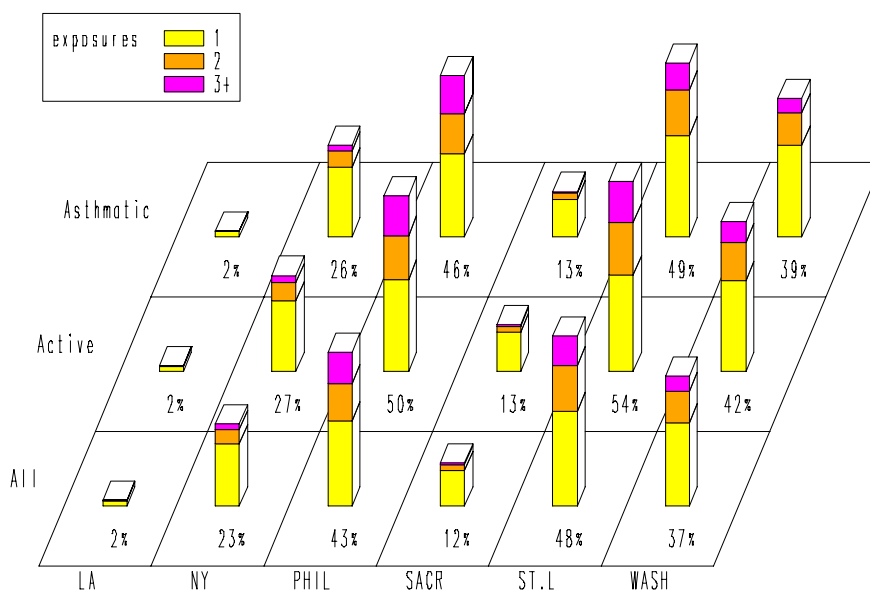

23 Inspection of these figures and Table 4-8 show marked differences between cities in the
24 levels of exposures under alternative standards. For example, under the same 0.074 ppm, 4th
25 daily maximum 8-hr average alternative standard, almost 5 percent of the Boston children but
26 less than 0.05 percent of the Los Angeles children experience 8-hr O₃ exposures above 0.07
27 ppm-8hr while engaged in moderate or greater exertion. This is primarily due to the larger range
28 of 2002-2004 4th highest concentrations for Boston compared to Los Angeles, which allows for
29 higher concentrations (and therefore exposures) in Boston.

30 The draft Exposure Analysis TSD presents additional exposure results, and describes an
31 evaluation of APEX and an analysis of model sensitivity to selected model inputs.

4.6.1 Comparison With Exposure Estimates From the Prior Review

The exposure models and the model inputs used in the current and previous (1997) reviews are very different. Table 4-10 lists the major differences between the current and previous reviews that are pertinent to this comparison. Table 4-11 compares exposure modeling results for Houston, and Table 4-12 compares exposure modeling results for six cities combined (Houston, Los Angeles, New York, Philadelphia, St. Louis, and Washington). The results from the previous (1997) review are taken from the memorandum “*Sensitivity of Exposure Estimates to Air Quality Adjustment Procedure*” (Johnson, 1997). Due to the several differences in what is being reported, the only relevant comparison is of the percent of modeled population. Table 4-10 gives the probable reasons for these differences, but we do not know which of these are most important.

Table 4-10. Comparison of exposure modeling between the current and the 1997 reviews

	Current	1997	Comments
The exposure model	APEX	pNEM	These models and their inputs are very different.
Population modeled	Outdoor children ages 5-18. 2000 Census data.	Active children ages 5-18. 1990 Census data.	Outdoor children and active children are defined differently, but are expected to have some overlap.
Exertion levels reported	Moderate and greater (EVR \geq 13 liters/min- m^2)	Moderate (EVR in range 13-27 liters/min- m^2)	The current range is larger than the 1997 range.
Period modeled	2002, 2004	1990 for 4 cities, 1991 for 1 city, 1992 for 1 city	For most cities 2002 was a high-ozone year and 2004 a low-ozone year. The years for the 1997 modeling were selected to be the middle years with respect to ozone levels.
Cities modeled	12 cities	6 cities	We can compare results for Houston and for the group of 6 cities combined that were included in both the prior and current review.
Extent of urban areas modeled	CSAs	Smaller areas	
Extent of Houston area modeled	Houston-Baytown-Huntsville, TX CSA (Brazoria, Chambers, Fort Bend, Galveston, Harris, Liberty, Montgomery, Waller Counties)	All census units with centers within 15 km of 11 selected monitors (these lie within 5 counties)	A “census unit” is described as a “census tract or block numbering area” in Section 4.1 of the April 1996 outdoor children exposure modeling report. The 1997 area is much smaller than the current area modeled.
Rollback method	Quadratic	Quadratic	The same method was used.
Modeled standard	84/3	84/3	This is the only standard for which we have results for both sets of analyses.

14

1 **Table 4-11. Comparison of exposure modeling results for the 84/3 standard between the**
 2 **current and the 1997 reviews (Houston)¹**

	Current (2002 air quality)	Current (2004 air quality)	1997
Modeled population (active children for current, outdoor children for 1997)	475,929	486,681	200,600 ²
Number of persons exceeding 0.08 ppm, 8-hr exposures	2,809	2,568	8,567
Percent of modeled population	0.6	0.5	4.27
Number of person-days (occurrences)	2,809	2,568	8,932

3 ¹ Current counts are for active children at moderate or greater exertion levels, 1997 counts are
 4 for outdoor children at moderate exertion levels.

5 ² A smaller geographic area was modeled in 1997.
 6

7 **Table 4-12. Comparison of exposure modeling results for the 84/3 standard between the**
 8 **current and the 1997 reviews (Houston, Los Angeles, New York, Philadelphia, St. Louis,**
 9 **and Washington combined)¹**

	Current (2002 air quality)	Current (2004 air quality)	1997
Modeled population (active children for current, outdoor children for 1997)	5.32 million	5.35 million	2.4 million ²
Number of persons exceeding 0.08 ppm, 8-hr exposures	108,000	2,800	55,496
Percent of modeled population	2.0	0.05	2.31
Number of person-days (occurrences)	116,400	2,800	62,720

10 ¹ Current counts are for active children at moderate or greater exertion levels, 1997 counts are
 11 for outdoor children at moderate exertion levels.

12 ² A smaller geographic area was modeled in 1997.

1 **4.6.2 Summary of Sensitivity, Uncertainty, and Evaluation Analyses**

2 **4.6.2.1 Sensitivity Analyses**

3 We conducted analyses of the sensitivity of APEX model results to four of the model
4 inputs: the activity data (CHAD), ozone decay rates, proximity factors, and air exchange rate.
5 These were done for the Boston and Houston 2002 base cases. In this section we give some of
6 the results of these analysis; additional sensitivity results can be found in the draft Exposure
7 Analysis TSD.

8
9 **Activity Patterns**

10 Because many of the studies included in the CHAD database are not national in scope,
11 nor do they necessarily correspond to the CSAs targeted here, it would be useful to know how
12 similar the component studies are. Strong similarity would suggest that extrapolation of activity
13 data gathered from one sample population to another population is appropriate. The most
14 comprehensive individual study currently in CHAD is the National Human Activity Pattern
15 Study (NHAPS) and we compared the exposure modeling results with corresponding results
16 using only the NHAPS data. The California database in CHAD is relatively large and represents
17 a very large population, and so we also compared the modeling results with corresponding
18 results using California activity patterns only. Table 4-13 summarizes these results for children
19 with 8-hr exposures above 0.07 ppm-8hr concomitant with moderate or greater exertion. The
20 model results are sensitive to the activity data used, with biases ranging from -21 to +66 percent
21 in this table.

22
23 **Table 4-13. Sensitivity to activity database: counts of children (ages 5-18) with any or**
24 **three or more 8-hr ozone exposures above 0.07 ppm-8hr concomitant with moderate or**
25 **greater exertion**

Urban Area (CSA)	One or more exposures			Three or more exposures		
	Base case	NHAPS only	CA only	Base case	NHAPS only	CA only
Boston (2002 base case)	4,672	4,693 (+0%)	4,400 (-6%)	775	849 (+10)	807 (+5%)
Houston (2002 base case)	3,542	3,794 (+7%)	3,130 (-12%)	169	281 (+66%)	133 (-21%)

26
27 The version of APEX used for this analysis includes a new approach to construct long-
28 term individual activity patterns, as described in section 2.3.3 and Appendix C in the draft
29 Exposure Analysis TSD. To test the sensitivity of the APEX results to this approach we
30 compared the base case exposure results with corresponding results where (a) the new approach
31 was not implemented, and (b) the diversity statistic was set to 0.75 instead of 0.2 (this increases
32 the repetitiveness of activities for each simulated individual). The results presented in Table

1 4-14 indicate that APEX is moderately sensitive to the method for longitudinal arrangement of
 2 activities.

3
 4 **Table 4-14. Sensitivity to longitudinal activity pattern algorithm: counts of Boston (2002**
 5 **base case) population groups with any or three or more 8-hr ozone exposures above 0.07**
 6 **ppm-8hr concomitant with moderate or greater exertion**

Population group	One or more exposures			Three or more exposures		
	Base case	Simple re-sampling	Diversity = 0.75	Base case	Simple re-sampling	Diversity = 0.75
General population	12,429	12,730 (+2%)	11,568 (-6%)	1,623	1,478 (-9%)	1,782 (+10%)
Children (ages 5-18)	4,672	4,817 (+3%)	4,294 (-8%)	775	740 (-5%)	841 (+9%)

7
 8 ***Ozone Decay Rates***

9 To test the sensitivity of the APEX predictions to the ozone decay rate distribution, we
 10 compared the base case results with corresponding results with the decay rate set uniformly to its
 11 10th percentile value and its 90th percentile value (a very large range). The results are presented
 12 in Table 4-15 for the number of children exposed to 8-hr average concentrations exceeding 0.07
 13 ppm-8hr concomitant with moderate or greater exertion. Considering the range of decay rates
 14 used, the model results are only moderately sensitive to the decay rate distributions.

15
 16 **Table 4-15. Sensitivity to ozone decay rate: counts of children (ages 5-18) with any or**
 17 **three or more 8-hr ozone exposures above 0.07 ppm-8hr concomitant with moderate or**
 18 **greater exertion**

Urban Area (CSA)	One or more exposures			Three or more exposures		
	rate=90 th percentile	Base case	Rate=10 th percentile	rate=90 th percentile	Base case	Rate=10 th percentile
Boston (2002 base case)	3,714 (-21%)	4,672	5,102 (+9%)	333 (-57%)	775	1,051 (+36%)
Houston (2002 base case)	3,154 (-11%)	3,542	3,734 (+5%)	105 (-38%)	169	182 (+8%)

19
 20 ***Proximity Factors***

21 As done for the decay rates, we set the proximity factors uniformly to the 10th percentile
 22 and 90th percentile values (a wide range) to test the sensitivity of the APEX predictions to the
 23 proximity factor distribution. These sensitivity results are given in Table 4-16, and are similar to
 24 the results for decay rates.

25

1 **Table 4-16. Sensitivity to proximity factor: counts of children (ages 5-18) with any or**
 2 **three or more 8-hr ozone exposures above 0.07 ppm-8hr concomitant with moderate or**
 3 **greater exertion**

Urban Area (CSA)	One or more exposures			Three or more exposures		
	Factor = 90 th percentile	Base case	Factor = 10 th percentile	Factor = 90 th percentile	Base case	Factor = 10 th percentile
Boston (2002 base case)	4,428 (-5%)	4,672	5,216 (+12%)	646 (-17%)	775	1,058 (+37%)
Houston (2002 base case)	3,384 (-4%)	3,542	4,034 (+14%)	135 (-20%)	169	244 (+44%)

4

5 ***Air Exchange Rates***

6 We set the AER distributions uniformly to the 10th percentile and 90th percentile values
 7 (again a wide range). Table 4-17 presents the results of these sensitivity simulations. It appears
 8 that the model is very sensitive to the input distributions of AERs.

9

10 **Table 4-17. Sensitivity to air exchange rate: counts of children (ages 5-18) with any or**
 11 **three or more 8-hr ozone exposures above 0.07 ppm concomitant with moderate or greater**
 12 **exertion**

Urban Area (CSA)	One or more exposures			Three or more exposures		
	Rate = 10 th percentile	Base case	Rate = 90 th percentile	Rate = 10 th percentile	Base case	Rate = 90 th percentile
Boston (2002 base case)	3,363 (-28%)	4,672	7,947 (+70%)	252 (-67%)	775	4,413 (+469%)
Houston (2002 base case)	3,029 (-14%)	3,542	8,130 (+130%)	89 (-47%)	169	3,274 (+1837%)

13

14 **4.6.2.2 Uncertainty Analyses**

15 We are conducting an analysis of the uncertainties of the exposure modeling using a
 16 Monte Carlo method for propagating the uncertainties of model inputs through to uncertainties of
 17 the model results, as well as selected sensitivity analyses. See Langstaff (2006) for interim
 18 results and the plan for completing this assessment of uncertainties.

19 **4.6.2.3 Model Evaluation**

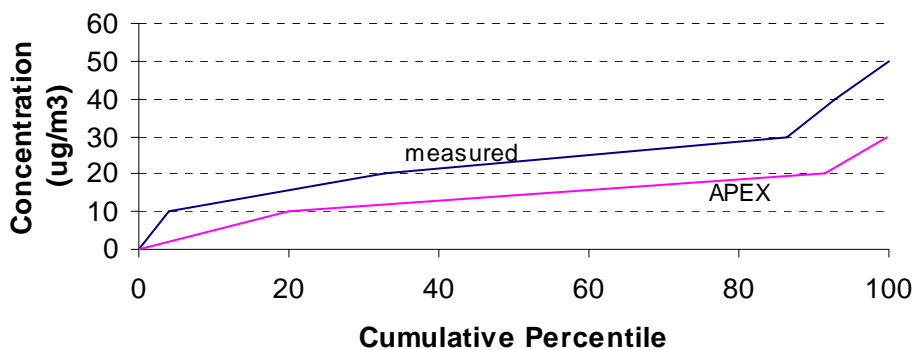

20 In order to evaluate the performance of APEX we compared APEX simulation results to
 21 personal O₃ concentration measurements taken from the Harvard Southern California Chronic
 22 Ozone Exposure Study (Xue et al. 2005, Geyh et al. 2000). Although this study of limited scope,
 23 and the measurements of ozone are averaged over 6 days, it is the only study we could find that
 24 measured enough personal exposures to O₃ to be useful for this evaluation and for which the data
 25 are available. In this study, children 7 to 12 years old were followed from June 1995 to May

1 1996. There are 160 subjects on which longitudinal O₃ concentrations have been made in at least
2 6 of the 12 months of the study period. Passive O₃ samplers were used to measure 6-day average
3 personal O₃ concentrations, as well as indoor and outdoor concentrations at participants homes,
4 for six days each month. The subjects resided in two separate areas of San Bernardino County:
5 urban Upland CA, and the small mountain towns of Lake Arrowhead, Crestline, and Running
6 Springs, CA.

7 For the APEX simulations we used hourly outdoor concentrations from fixed site
8 monitors located in Upland and Crestline as inputs. The AERs used were those developed for
9 Sacramento from measurements taken in the inland portions of the Los Angeles area:
10 Sacramento, Riverside, and San Bernardino Counties. For each 6-day period for which personal
11 measurements were available we simulated 10,000 subjects in the 7 – 12 age range in each of the
12 two study areas. For each case the distribution of simulated 6-day average exposure
13 concentrations was compared to the corresponding distribution of measured values.
14 Comparisons were also made between the continuous measurements made inside the subjects'
15 homes and the APEX indoor residential concentration estimates during the times of exposure,
16 and between the O₃ concentrations measured outside the homes of the study subjects and those
17 measured at the nearby fixed site monitors.

18 In general, APEX systematically underpredicts the measured values by 0.001 to 0.02 ppm
19 (zero to 50 percent). Figure 4-22, comparing the population distributions of modeled and
20 observed exposures for a 6-day period in Upland, is fairly typical of the comparisons performed.
21 Additional results and analyses of the reasons for the underpredictions are presented in the draft
22 Exposure Assessment TSD. Since this evaluation is based on 6-day average exposures, it is only
23 of limited relevance for assessing the uncertainty of daily maximum 8-hr average exposures.
24 However, it does indicate that APEX is not significantly overpredicting exposures and may be
25 underpredicting exposures.

Weekly Average Personal Ozone Concentration

5. CHARACTERIZATION OF HEALTH RISKS

5.1 INTRODUCTION

This chapter presents information regarding the results from an updated ozone (O₃) health risk assessment that builds upon the methodology used in the assessment conducted as part of the last O₃ NAAQS review. This updated assessment includes estimates of (1) risks of lung function decrements in school age children, respiratory symptoms in asthmatic children, respiratory – related hospital admissions, and respiratory, non-accidental, and cardiorespiratory mortality associated with recent ambient O₃ levels; and (2) risk reductions associated with just meeting the current and several alternative 8-hr O₃ NAAQS. The current risk assessment is more fully described and presented in a draft technical support document, *Ozone Health Risk Assessment for Selected Urban Areas* (Abt Associates, 2006a; henceforth referred to as the draft Risk Assessment Technical Support Document and cited as draft Risk Assessment TSD).

The goals of this O₃ risk assessment are: (1) to provide estimates of the potential magnitude of mortality and morbidity effects associated with current O₃ levels, and with meeting the current O₃ 8-hr NAAQS and alternative O₃ 8-hr standards, in specific urban areas; (2) to develop a better understanding of the influence of various inputs and assumptions on the risk estimates; and (3) to gain insights into the distribution of risks and patterns of risk reductions associated with meeting alternative O₃ standards. We recognize that while there are many sources of uncertainty and variability inherent in the inputs to this assessment which make the specific estimates uncertain, there is sufficient confidence in the direction and general magnitude of the estimates provided by the assessment, particularly with respect to relative differences between alternative potential standards, for the assessment to serve as a useful input to decisions on the adequacy of the O₃ standard. While some of these uncertainties have been addressed quantitatively in the form of estimated confidence ranges around central risk estimates, other uncertainties and the variability in key inputs are not reflected in these confidence ranges, but rather are addressed through separate sensitivity analyses or characterized qualitatively.

Following this introductory section, this chapter discusses the scope of the risk assessment, including selection of urban areas and health endpoints and the degree of confidence associated with the various health outcomes that have been associated with ambient O₃ exposures; components of the risk model; characterization of uncertainty and variability associated with the risk estimates; and key results from the assessment. The draft Risk Assessment TSD provides a more detailed discussion of the risk assessment methodology and includes additional risk estimates beyond those summarized herein.

1 **5.1.1 Overview of Risk Assessment From Last Review**

2 EPA conducted a health risk assessment that produced risk estimates for the number and
3 percent of children and outdoor workers experiencing lung function and respiratory symptoms
4 associated with the exposures estimated for 9 urban areas. This portion of the risk assessment
5 was based on exposure-response relationships developed from analysis of data from several
6 controlled human exposure studies which was combined with exposure estimates developed for
7 children who spent more time outdoors and for outdoor workers. The risk assessment for the last
8 review also included risk estimates for excess respiratory-related hospital admissions related to
9 O₃ concentrations for New York City based on a concentration-response relationship reported in
10 an epidemiological study (Thurston et al., 1992). Risk estimates for lung function decrements,
11 respiratory symptoms, and hospital admissions were developed associated with recent air quality
12 levels (referred to as “as is” air quality) and for just meeting the existing 1-hr standard and
13 several alternative 8-hr standards. The methodological approach followed in conducting the last
14 risk assessment and risk estimates resulting from that assessment are described in Chapter 6 of
15 the 1996 Staff Paper (EPA, 1996b) and in several technical reports and publications (Whitfield et
16 al., 1996; Whitfield, 1997; Whitfield et al., 1998).

17 In the 1997 review of the O₃ NAAQS, the risk estimates played a significant role in both
18 the staff recommendations and in the proposed and final decisions to revise the O₃ standards.
19 CASAC stated (Wolff, 1995) in its advice and recommendations to the Administrator on the O₃
20 Staff Paper that “EPA’s risk assessments must play a central role in identifying an appropriate
21 level,” while also noting that “because of the myriad of assumptions that are made to estimate
22 population exposure and risk, large uncertainties exist in these estimates.” In the 1997 notice (62
23 FR 38856) announcing the decision to revise the O₃ standards EPA indicated that the
24 Administrator considered the results of the exposure and risk analyses and key observations and
25 conclusions from these analyses in putting effects considered to be adverse to individuals into a
26 broader public health perspective and in making judgments about the level of a standard that
27 would be requisite to protect public health with an adequate margin of safety.

28 **5.1.2 Development of Approach for Current Risk Assessment**

29 The health risk assessment described in this Chapter and in the draft Risk Assessment
30 TSD builds upon the methodology and lessons learned from the risk assessment work conducted
31 for the last review. The current risk assessment also is based on the information evaluated in the
32 final CD. The general approach used in the current risk assessment was described in the draft
33 Health Assessment Plan (EPA, 2005a), that was released to the CASAC and general public in
34 April 2005 for review and comment and which was the subject of a consultation with the
35 CASAC O₃ Panel on May 5, 2005. The approach used in the current risk assessment reflects

1 consideration of the comments offered by CASAC members and the public on the draft Health
2 Assessment Plan, comments offered on the first draft Staff Paper and draft Risk Assessment TSD
3 at and subsequent to a consultation with CASAC on December 8, 2005, and CASAC comments
4 provided to the Agency in a June 5, 2006 letter (Henderson, 2006b).

5 The basic structure of the current risk assessment reflects the two different types of
6 human studies on which the O₃ health risk assessment is based: controlled human exposure
7 studies and epidemiological studies. Controlled human exposure studies involve volunteer
8 subjects who are exposed while engaged in different exercise regimens to specified levels of O₃
9 under controlled conditions for specified amounts of time. For the current health risk
10 assessment, we are using probabilistic exposure-response relationships based on analysis of
11 individual data that describe the relationship between a measure of personal exposure to O₃ and
12 measures of lung function recorded in the studies. The measure of personal exposure to ambient
13 O₃ is typically some function of hourly exposures – e.g., 1-hr maximum or 8-hr maximum.
14 Therefore, a risk assessment based on exposure-response relationships derived from controlled
15 human exposure study data requires estimates of personal exposure to ambient O₃, typically on a
16 1-hr or multi-hour basis. Because data on personal hourly O₃ exposures are not available,
17 estimates of personal exposures to varying ambient concentrations are derived through exposure
18 modeling, as described in Chapter 4.

19 In contrast to the **exposure-response** relationships derived from controlled human
20 exposure studies, epidemiological studies provide estimated **concentration-response**
21 relationships based on data collected in real world settings. Ambient O₃ concentrations,
22 measured as the average of monitor-specific measurements, using population-oriented monitors,
23 are used as a surrogate measure of population exposure. Population health responses for O₃
24 include respiratory symptoms in asthmatic children, hospital admissions for respiratory illness,
25 and premature mortality. As described more fully below, a risk assessment based on
26 epidemiological studies typically requires baseline incidence rates and population data for the
27 risk assessment locations.

28 The characteristics that are relevant to carrying out a risk assessment based on controlled
29 human exposure studies versus one based on epidemiology studies evaluated in the CD can be
30 summarized as follows:

- 31 • The relevant controlled human exposure studies in the CD provide data that can be
32 used to estimate exposure-response functions, and therefore a risk assessment based
33 on these studies requires as input (modeled) personal exposures to ambient O₃. The
34 relevant epidemiological studies in the CD provide concentration-response functions,
35 and therefore a risk assessment based on these studies requires as input (actual
36 monitored or adjusted based on monitored) ambient O₃ concentrations, and personal
37 exposures are not required as inputs to the assessment.

- 1 • Epidemiological studies are carried out in specific real world locations (e.g., specific
2 urban areas). To minimize uncertainty, a risk assessment based on epidemiological
3 studies has been performed for the locations in which the studies were carried out.
4 Controlled human exposure studies, carried out in laboratory settings, are generally not
5 specific to any particular real world location. A risk assessment based on controlled
6 human exposure studies can therefore appropriately be carried out for any location for
7 which there are adequate air quality and other data on which to base the modeling of
8 personal exposures. There are, therefore, some locations for which a risk assessment
9 based on controlled human exposure studies could appropriately be carried out but a
10 risk assessment based on epidemiological studies would involve considerably greater
11 uncertainty.
- 12 • The adequate modeling of hourly personal exposures associated with ambient
13 concentrations for use with exposure-response relationships requires more complete
14 ambient monitoring data than are necessary to estimate average ambient concentrations
15 used to calculate risks based on concentration-response relationships. Therefore, there
16 may be some locations in which an epidemiological studies-based risk assessment
17 could appropriately be carried out, but a controlled human exposure studies-based risk
18 assessment would involve considerably greater uncertainty.
- 19 • To derive estimates of risk from concentration-response relationships estimated in
20 epidemiological studies, it is usually necessary to have estimates of the baseline
21 incidences of the health effects involved. Such baseline incidence estimates are not
22 needed in a controlled human exposure studies-based risk assessment.

23

24 The scope of the current O₃ risk assessment is described in the next section along with air
25 quality considerations that are relevant to both parts of the risk assessment. Then, the methods
26 for the two parts of the risk assessment – the part based on controlled human exposure studies
27 and the part based on epidemiological and field studies – are discussed in sections 5.3.1 and 5.3.2
28 below, followed by presentation and discussion of the O₃ risk estimates in section 5.4. Both
29 parts of the risk assessment were implemented within a new probabilistic version of TRIM.Risk,
30 the component of EPA’s Total Risk Integrated Methodology (TRIM) model that estimates
31 human health risks.

32 **5.2 SCOPE OF OZONE HEALTH RISK ASSESSMENT**

33 The current O₃ health risk assessment estimates risks of various health effects associated
34 with exposure to ambient O₃ in a number of urban areas selected to illustrate the public health
35 impacts of this pollutant. The short-term exposure related health endpoints selected for the O₃
36 risk assessment, discussed in section 5.2.1, include those for which the CD concludes that the

1 evidence as a whole supports the general conclusion that O₃, acting alone and/or in combination
2 with other components in the ambient air pollution mix is likely causal¹.

3 As discussed in section 3.7, we recognize that there are varying levels of confidence that
4 various health effect endpoints are associated with O₃ at ambient levels. As discussed in section
5 3.7.5 there is clear evidence of a causal relationship between lung function decrements and O₃
6 exposures for school age children engaged in moderate exertion for 8-hours based on the
7 numerous controlled human exposure studies and summer camp field studies conducted by
8 various investigators over the last 30 years. We also judge that there is clear evidence of a causal
9 relationship between increased respiratory symptoms in moderate to severe asthmatic children
10 and O₃ exposures. There also is strong evidence of a causal relationship between increased
11 respiratory-related hospital admissions and O₃ exposure during the warm O₃ season based on
12 extensive and fairly consistent epidemiological studies as well as evidence from controlled
13 human exposure studies reporting increased lung inflammation and airway responsiveness.

14 The CD concludes that there is strong evidence which is highly suggestive of a causal
15 relationship between respiratory-related, non-accidental, and cardiorespiratory-related mortality
16 and O₃ exposures during the warm O₃ season. Our judgment with respect to these health
17 outcomes is based on the fairly consistent positive associations found between elevated warm O₃
18 season levels and these mortality outcomes even when the effect of PM is controlled for, and
19 supporting evidence about potential mechanisms of effects on the cardiovascular system from
20 animal toxicology, human clinical and epidemiological studies. There is certainly greater
21 uncertainty about these outcomes than the other effects discussed above. We also recognize, as
22 discussed in section 3.7.5, that for some of the effects observed in epidemiological studies, such
23 as increased respiratory-related hospital admissions and non-accidental and cardiorespiratory
24 mortality, O₃ may be serving as an indicator for reactive oxidant species in the overall
25 photochemical oxidant mix and that these other constituents may be responsible in whole or part
26 for the observed effects.

27 The current risk assessment includes risk estimates for 12 urban areas. The basis for
28 selection of these areas is discussed below (section 5.2.2).

29 Another important aspect of the current risk assessment is that the risks estimated are
30 only those associated with ambient O₃ concentrations exceeding estimated policy-relevant
31 background levels (hereafter, referred to as “background” in this Chapter).² Risks associated

¹ As discussed in 5.2.1, certain endpoints met this criteria of likely causality, but were not included in the risk assessment for other reasons, such as insufficient exposure-response data or lack of baseline incidence data.

² Policy relevant background is defined in section 2.7 of this Staff Paper and development of estimates for policy relevant background for use in the risk assessment are discussed in section 5.2.3.

1 with concentrations above this background are judged to be more relevant to policy decisions
2 about the NAAQS than estimates that include risks potentially attributable to uncontrollable
3 background concentrations.

4 **5.2.1 Selection of Health Endpoint Categories**

5 As noted above, in the last review a significant portion of the health risk assessment
6 involved developing risk estimates for both lung function decrements (≥ 10 , ≥ 15 , and $\geq 20\%$
7 changes in FEV₁) and respiratory symptoms in children (age 6 to 18 years old) who spend more
8 time outdoors and outdoor workers with 1-hr exposures at moderate and heavy exertion and 8-hr
9 exposures at moderate exertion. As discussed in section 3.3.1.2 and Chapter 6 of the CD, there is
10 a significant body of controlled human exposure studies reporting lung function decrements and
11 respiratory symptoms in adults associated with 1- and 6 to 8-hr exposures to O₃.

12 Consistent with the approach used in the last review, we judge that it is reasonable to
13 estimate exposure-response relationships for lung function decrements associated with O₃
14 exposures in children 5-18 years old based on data from adult subjects (18-35 years old). As
15 discussed in the 1996 Staff Paper and 1996 CD, findings from other chamber studies
16 (McDonnell et al., 1985) for children 8-11 years old at a single exposure level and summer camp
17 field studies in at least six different locations in the U.S. and Canada found lung function
18 decrements in healthy children similar to those observed in healthy adults exposed to O₃ under
19 controlled chamber conditions. The same approach is being used in the current assessment.
20 In the prior risk assessment, staff focused on the risk estimates for lung function decrements
21 associated with 1-hr heavy exertion, 1-hr moderate exertion, and 8-hr moderate exertion
22 exposures in children age 5-18 years of age. Since the 8-hr moderate exertion exposure scenario
23 in children who spend more time outdoors clearly resulted in the greatest health risks in terms of
24 both the magnitude of the lung function decrements and the percent of the population estimated
25 to experience these effects, and since no new information published since the last review
26 suggests any changes that would impact this conclusion, we have included only the lung function
27 decrements (≥ 10 , 15, and 20% FEV₁) associated with 8-hr moderate exertion exposures in
28 children and “active” children (age 5 to 18 years old) in the current risk assessment. As
29 discussed in Chapter 4 of the draft Staff Paper, levels of physical activity were categorized by a
30 daily Physical Activity Index (PAI). Children were characterized as active if their median daily
31 PAI over the period modeled was 1.75 or higher, a level characterized by exercise physiologists
32 as being “moderately active” or “active.”

33 Although respiratory symptoms in healthy children were estimated in the last review, we
34 have not included this endpoint in the current quantitative risk assessment. This is because
35 several field studies conducted since the last review failed to find respiratory symptoms in field

1 studies examining responses in healthy children. The CD concludes that “collectively, these
2 studies indicate that there is no consistent evidence of an association between O₃ and respiratory
3 symptoms among healthy children” (CD, p. 7-55). Thus, we decided to limit this portion of the
4 risk assessment to lung function decrements in children and to again base the exposure-response
5 relationships on data obtained for 18-35 year old subjects

6 While a number of controlled human exposure studies have reported additional health
7 endpoints associated with short-term exposures to O₃, including airway hyperresponsiveness,
8 inflammation, and immune system effects, there is insufficient exposure-response data at
9 different concentrations to develop quantitative risk estimates for these effects. These additional
10 effects are discussed in Chapter 3, and it is important to recognize that the current quantitative
11 risk assessment only presents a partial picture of the risks to public health associated with short-
12 term O₃ exposures.

13 As discussed in the CD and Chapter 3, a significant number of epidemiological studies
14 examining a variety of health effects associated with ambient O₃ concentrations in various
15 locations throughout the U.S., Canada, Europe, and other regions of the world have been
16 published since the last O₃ NAAQS review. Chapter 3 reviews the epidemiological evidence
17 evaluated in Chapter 7 of the CD. In selecting health endpoints to be included in the current
18 quantitative risk assessment, we have focused on health endpoints that are better understood in
19 terms of health consequences (i.e., where there is greater consensus about the degree of response
20 that should be considered as representing an adverse health effect in the population) and endpoint
21 categories for which the weight of the evidence supports the inference of a likely causal
22 relationship between O₃ and the effect category. Certain health endpoints met the criteria of
23 likely causality, but were not included in the risk assessment for other reasons, such as
24 insufficient exposure-response data or lack of baseline incidence data. Based on these
25 considerations, the following endpoints associated with short-term exposures to O₃ during the
26 “warm O₃ season” (April 1 to September 30) have been included:

- 27 • Respiratory symptoms in moderate/severe asthmatic children (ages 0 to 12);
- 28 • Hospital admissions for respiratory illness and asthma;
- 29 • Premature total non-accidental and cardiorespiratory mortality.

30 As discussed in section 3.3.1.2.1 of this Staff Paper, the CD also concludes that collectively,
31 the results of epidemiological studies suggest that respiratory symptoms and increased
32 medication use in asthmatic children are associated with acute exposure to O₃. These recent
33 studies provide strong evidence that some asthmatic children are likely to experience O₃-related
34 effects.

1 Large multi-city studies, as well as many studies from individual cities, have reported an
2 association of O₃ concentrations with respiratory-related hospital admissions. Studies with data
3 restricted to the summer or warm season, in general, indicated positive and robust associations
4 between ambient O₃ concentrations and respiratory-related hospital admissions. With respect to
5 acute O₃ effects on mortality, the CD concludes (p.7-175) that, “The majority of the studies
6 suggest an elevated risk of all cause mortality associated with acute exposure to O₃, especially in
7 the summer or warm season when O₃ levels are typically high.”

8 As discussed in Chapter 7 of the CD and sections 3.3.1.1 and 3.3.1.2.1 of this Staff Paper,
9 several additional health endpoints including ED visits for respiratory illness and increased
10 school absences have been reported to be associated with short-term O₃ exposures. The current
11 quantitative risk assessment does not include these additional health endpoints. Emergency
12 department visits were excluded from the quantitative risk assessment because of the limited and
13 less consistent database as well as the lack of baseline incidence data for ED visits. We also
14 judge that the data reporting an association between short-term O₃ exposures and school
15 absences is too limited to include in the current risk assessment.

16 **5.2.2 Selection of Study Areas**

17 The criteria and considerations that went into selection of urban areas for the O₃ risk
18 assessment included the following:

- 19 • The overall set of urban locations should represent a range of geographic areas, urban
20 population demographics, and climatology and be focused on areas that do not meet
21 the current 8-hr O₃ NAAQS.
- 22 • The largest areas with major O₃ nonattainment problems should be included.
- 23 • There must be sufficient air quality data for a recent three year period.
- 24 • An area should be the same or close to the location where at least one concentration-
25 response function for the health endpoints included in the assessment has been
26 estimated by a study that satisfies the study selection criteria (see below). If the study
27 was a hospital admissions study, then relatively recent location-specific baseline
28 incidence data had to be available.
- 29 • Locations in which more health endpoints have been assessed were preferred to those
30 with fewer.

31 Since the exposure-response functions for lung function decrements based on the controlled
32 human exposure studies were based on controlled laboratory conditions, the location of these
33 studies played no role in selecting urban locations for the risk assessment.

34 Based on the selection criteria and considerations listed above, the following urban areas
35 were included in the risk assessment:

- 36 • Atlanta

- 1 • Boston
- 2 • Chicago
- 3 • Cleveland
- 4 • Detroit
- 5 • Houston
- 6 • Los Angeles
- 7 • New York City
- 8 • Philadelphia
- 9 • Sacramento
- 10 • St. Louis
- 11 • Washington, D.C.

12 As discussed in Chapter 4, for the purposes of estimating population exposure and the risk of
13 lung function decrements associated with these population exposure estimates, the 12 urban
14 areas have been defined based on consolidated statistical areas (CSAs). The population
15 estimates for these 12 urban area CSAs are given in Table 4-9. About 40% of the total U.S.
16 urban population resides in these 12 urban areas including 18.3 million school age children (ages
17 5 to 18). As discussed in Chapter 4, we estimate that roughly 8 million of these 18.3 million
18 school age children would be considered “active children.”

19 In contrast to the risk assessment for lung function decrements, for the risk estimates for
20 premature mortality and excess hospital admissions, the urban areas have been defined to be
21 generally consistent with the geographic boundaries used in the epidemiological studies which
22 were the source of the concentration-response functions used in this risk assessment. In most
23 cases the epidemiological studies only included the core urban county or a limited number of
24 counties in one or more of the 12 urban areas. In addition, estimates of respiratory symptoms in
25 asthmatic children were developed for one urban area (the Boston CSA).

26 **5.2.3 Air Quality Considerations**

27 Both the portion of the risk assessment based on controlled human exposure and the
28 portion based on epidemiological studies include risk estimates for a recent year of air quality
29 (labeled “as is” air quality in the draft Risk Assessment TSD) and for air quality adjusted so that
30 it simulates just meeting the current 8-hr O₃ NAAQS based on a recent three-year period (2002-
31 2004). This period was selected to represent the most recent air quality data for which complete
32 data were available when the risk assessment was conducted.

33 In order to estimate health risks associated with just meeting the current and alternative 8-
34 hr O₃ NAAQS, it is necessary to estimate the distribution of hourly O₃ concentrations that would
35 occur under any given standard. Since compliance with the current O₃ standard is based on a 3-

1 year average, air quality data from 2002 to 2004 have been used to determine the amount of
2 reduction in O₃ concentrations required to meet the current standard. Estimated design values³
3 are used to determine the adjustment necessary to just meet the current 8-hr daily maximum
4 standard. The amount of control has then been applied to each of two single years of data (2002
5 and 2004) to estimate risks for a single O₃ season or single warm O₃ season, depending on the
6 health effect, in each of these individual years.

7 As described in section 4.5.6 and in more detail in Rizzo (2006), after considering several
8 approaches, including proportional rollback and Weibull adjustment procedures, we concluded
9 that the Quadratic air quality adjustment procedure generally best represented the pattern of
10 reductions across the O₃ air quality distribution observed over the last decade. The Quadratic air
11 quality adjustment procedure was applied in each of the 12 urban areas to the filled in 2002 and
12 2004 O₃ monitoring data, based on the 3-year period (2002-2004) O₃ design values, to generate
13 new time series of hourly O₃ concentrations for 2002 and 2004 that reflect air quality levels that
14 just meet the current 8-hr O₃ standard over this three year period.

15 We note that since compliance with the current standard is based on the 3-year average of
16 the 4th daily maximum 8-hr values, the air quality distribution in each of the 3 years can and
17 generally does vary. As a consequence, the risk estimates associated with air quality just
18 meeting the current standard also will vary depending on the year chosen for the analysis. We
19 include assessments involving adjustment of both 2002 and 2004 air quality data to illustrate the
20 magnitude of this year-to-year variability in the risk estimates. The year 2002 generally had
21 meteorology that was very conducive to producing O₃ over the eastern half of the U.S. and this
22 resulted in the highest O₃ levels over the 2002-2004 time period in the vast majority of the 12
23 urban study areas. In contrast, 2004 was a year associated with an unusually cool and rainy
24 summer in the eastern half of the U.S. and this contributed to the fact that the lowest O₃ levels
25 over this same three-year period were observed in this year in most of the urban areas included in
26 the assessment. The lower O₃ levels observed in 2004 also were lower, in part, as a result of
27 reductions in NO_x emissions associated with implementation of additional regional controls on
28 large power plants in the eastern half of the U.S. Differences in meteorology were less evident
29 in Texas and California and these latter areas also were not impacted by the recent additional

³ A design value is a statistic that describes the air quality status of a given area relative to the level of the NAAQS. Design values are often based on multiple years of data, consistent with the specification of the NAAQS in Part 50 of the CFR. For example, for the current O₃ NAAQS, the 3-year averages of the annual 4th daily maximum 8-hr average concentration based on the maximum monitor within an urban area are the design values.

1 regional controls imposed on large power plants. Thus, its not surprising that the daily maximum
2 8-hr levels observed in Houston in 2004 were somewhat higher than those observed in 2002 and
3 that 8-hr levels were similar in Los Angeles between these two years. The risk results for 2002
4 and 2004, thus, provide generally lower-end and upper-end estimates of the annual risks that can
5 occur over a three-year period when alternative standards are just met.

6 As noted earlier, the risk estimates developed for both the recent air quality scenario and
7 just meeting the current 8-hr standard represent risks associated with O₃ levels in excess of
8 estimated background concentrations. The results of the global tropospheric O₃ model GEOS-
9 CHEM have been used to estimate average background O₃ levels for different geographic
10 regions across the U.S. These GEOS-CHEM simulations include a background simulation in
11 which North American anthropogenic emissions of nitrogen oxides, non-methane volatile
12 organic compounds, and carbon monoxide are set to zero, as described in Fiore et al. (2003). We
13 estimated monthly background concentrations for each of the 12 urban areas based on the
14 GEOS-CHEM simulations, including daily diurnal profiles which were fixed for each day of
15 each month during the O₃ season (See Appendix 2-A of this Staff Paper for plots of these
16 estimated background values).

17 **5.3 COMPONENTS OF THE RISK MODEL**

18 As noted above in section 5.1.2, there are two parts to the health risk assessment: one
19 based on combining information from controlled human exposure studies with modeled
20 population exposure and the other based on combining information from community
21 epidemiological studies with either monitored or adjusted ambient concentrations levels. Section
22 5.3.1 below discusses the portion of the current risk assessment related to effects reported in
23 controlled human exposure studies and section 5.3.2 below discusses the portion of the current
24 risk assessment related to health effects reported in community epidemiological studies.

25 **5.3.1 Assessment of Risk Based on Controlled Human Exposure Studies**

26 **5.3.1.1 General Approach**

27 The major components of the portion of the health risk assessment based on data from
28 controlled human exposure studies are illustrated in Figure 5-1. As shown in Figure 5-1, under
29 this portion of the risk assessment, exposure estimates for a number of different air quality
30 scenarios (i.e, recent year of air quality, just meeting the current 8-hr standard, just meeting
31 alternative standards, and background) are combined with probabilistic exposure-response
32 relationships derived from the controlled human exposure studies to develop risk estimates

1 for recent air quality and just meeting the current and alternative standards in excess of
 2 background. As discussed above, the health effect included in this portion of the risk assessment
 3 is lung function decrement, as measured by FEV_{1i} .in school aged children engaged in moderate
 4 exertion for 8 hours. The air quality and exposure analysis components that are integral to this
 5 portion of the risk assessment are discussed in greater detail in Chapter 4 and in the draft
 6 Exposure Assessment TSD.

7 Several risk measures were generated for this portion of the risk assessment. In addition
 8 to the estimates of the number of school age children and “active” children experiencing one
 9 or more occurrences of a lung function decrement ≥10, ≥15, and ≥20% in an O₃ season, risk
 10 estimates have been developed for the total number of occurrences of these lung function
 11 decrements in school age children and “active” school age children. The population sizes for
 12 children and “active” children for each of the 12 urban areas used in this part of the risk
 13 assessment are given in Table 4-3 of this Staff Paper.

14 A population risk estimate for a given lung function decrement (e.g., ≥20% change in
 15 FEV₁) is an estimate of the expected number of people who will experience that lung function
 16 decrement. Since we are interested in risk estimates associated with O₃ concentrations in excess
 17 of background concentrations, the following steps were taken to estimate the risk associated with
 18 recent conditions in excess of background: (1) expected risk given the personal exposures
 19 associated with recent ambient O₃ concentrations was estimated, (2) expected risk given the
 20 personal exposures associated with estimated background ambient O₃ concentrations was
 21 estimated, and (3) the latter was subtracted from the former. As shown in Equation 5-1 below,
 22 the population risk is then calculated by multiplying the resulting expected risk by the number of
 23 people in the relevant population. Because response rates are calculated for 21 fractiles,
 24 estimated population risks are similarly fractile-specific.

25
 26 The risk (i.e., expected fractional response rate) for the kth fractile, R_k is:

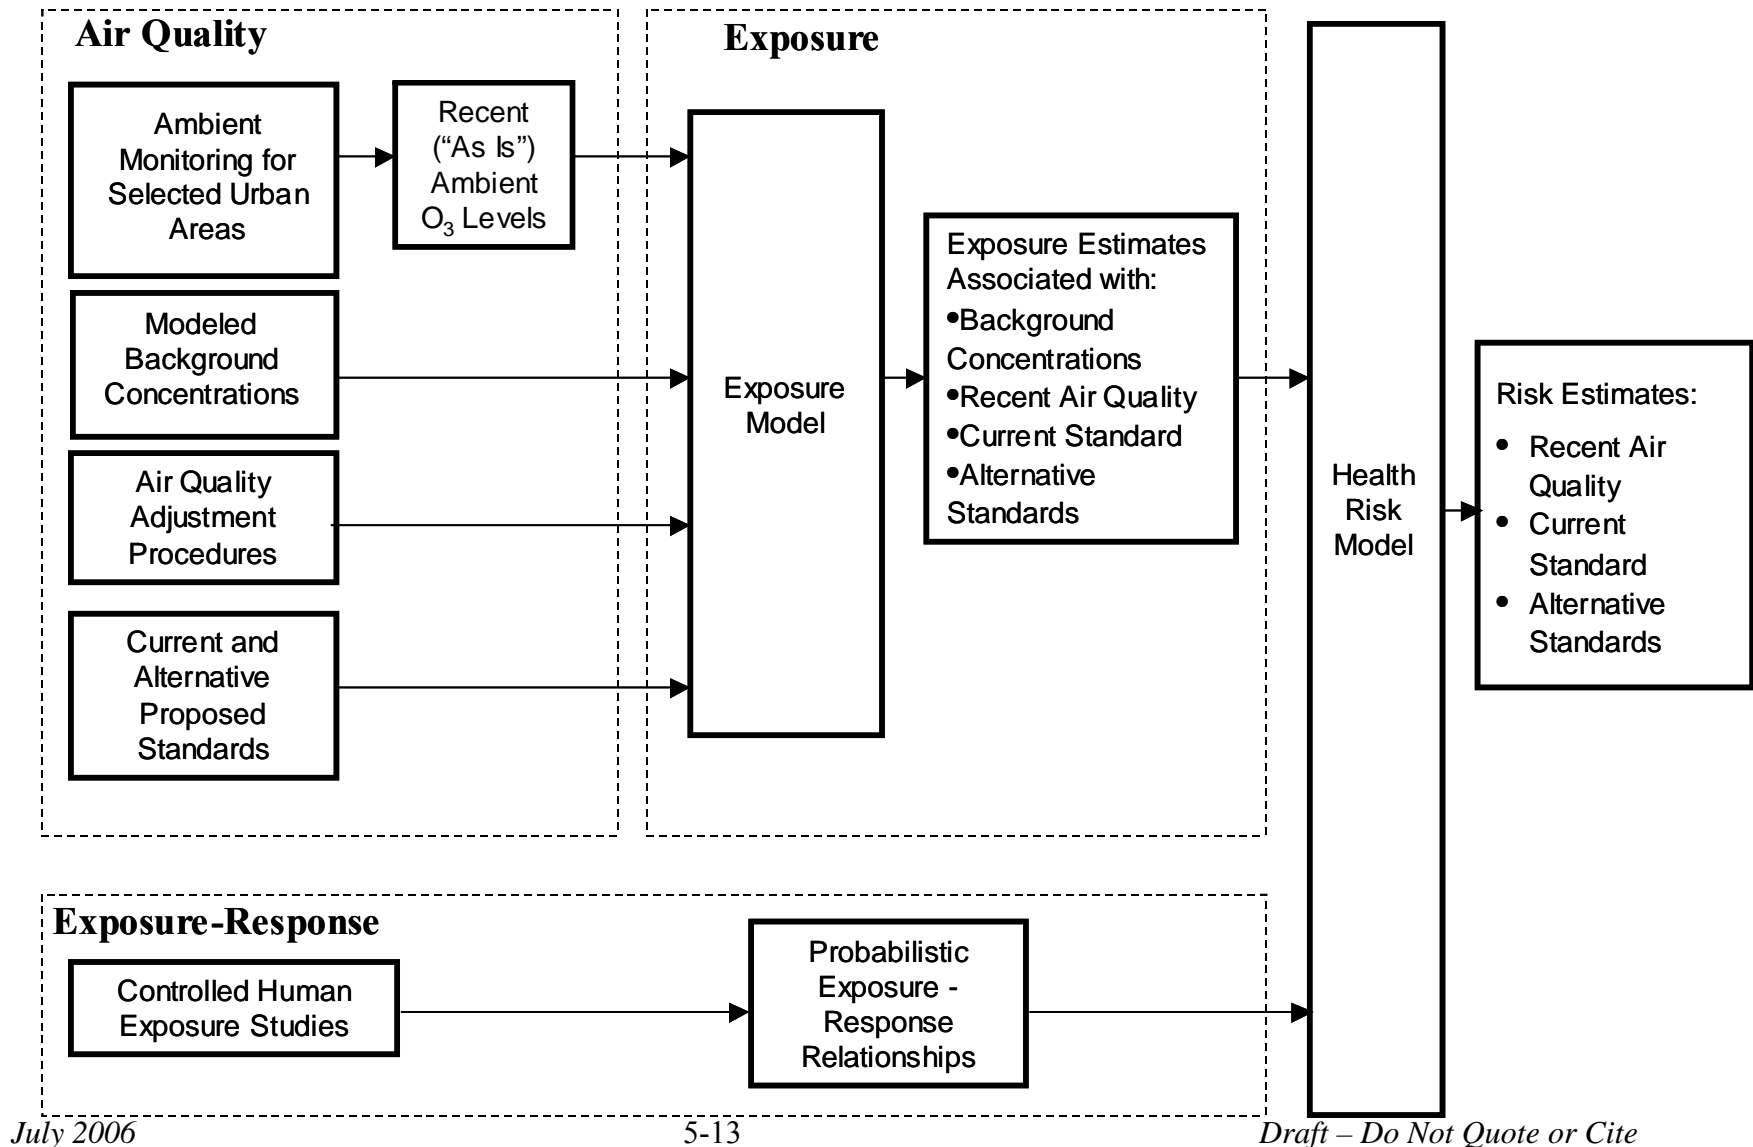

$$R_k = \sum_{j=1}^N P_j x (RR_k | e_j) - \sum_{i=1}^{N_b} P_i^b x (RR_k | e_i^b) \quad (\text{Equation 5-1})$$

27
 28 where:

29
 30
 31 e_j = (the midpoint of) the jth category of personal exposure to O₃, given recent ambient
 32 O₃ concentrations;
 33
 34

1 **Figure 5-1. Major Components of Ozone Health Risk Assessment Based on Controlled Human Exposure Studies**

2

1 e_i^b = (the midpoint of) the i th category of personal exposure to O_3 , given background
2 ambient O_3 concentrations;

3
4 P_j = the fraction of the population having personal exposures to O_3 concentration of e_j
5 ppm, given recent ambient O_3 concentrations;

6
7 P_i^b = the fraction of the population having personal exposures to O_3 concentration of
8 e_i^b ppm, given background ambient O_3 concentrations;

9
10 $RR_k | e_j$ = k -fractile response rate at O_3 concentration e_j ;

11
12 $RR_k | e_i^b$ = k -fractile response rate at O_3 concentration e_i^b ; and

13
14 N = number of intervals (categories) of O_3 personal exposure concentration, given recent
15 ambient O_3 concentrations; and

16
17 N_b = number of intervals of O_3 personal exposure concentration, given background
18 ambient O_3 concentrations.

19
20 For example, if the median expected response rate for recent ambient concentrations is
21 0.065 (i.e., the median expected fraction of the population responding is 6.5%) and the median
22 expected response rate for background ambient concentrations is 0.001 (i.e., the median expected
23 fraction of the population responding is 0.1%), then the median expected response rate
24 associated with recent ambient concentrations above background concentrations is $0.065 - 0.001$
25 $= 0.064$. If there are 300,000 people in the relevant population, then the population risk is 0.064
26 $\times 300,000 = 19,200$.

27 **5.3.1.2 Exposure Estimates**

28 Exposure estimates used in this portion of the risk assessment were obtained from
29 running TRIM.Expo for each of the 12 urban areas for the various air quality scenarios (i.e., for
30 2004 and 2002 air quality representing recent years, for 2004 and 2002 air quality adjusted to
31 just meet the current and several potential alternative 8-hr standards, and for air quality levels
32 representing background based on estimates from the GEOS-CHEM model). Chapter 4 and the
33 draft Exposure Assessment TSD (EPA, 2006d) provide additional details about the inputs and
34 methodology used to estimate population exposure in the 12 urban areas. Exposure estimates for

1 all and “active” school age children (ages 5 to 18) were separately combined with probabilistic
2 exposure-response relationships for lung function decrements associated with 8-hr exposure
3 while engaged in moderate exertion. Children were characterized as active if their median daily
4 physical activity index (see section 4.4.3) over the period modeled was 1.75 or higher, a level
5 characterized by exercise physiologists as being “moderately active” or “active.” Individuals
6 engaged in activities that resulted in an average equivalent ventilation rate (EVR) for the 8-hr
7 period at or above 13 l/min-m² were included in the exposure estimates for 8-hr moderate or
8 greater exertion. This range was selected to match the EVR for the group of subjects in the
9 controlled human exposure studies that were the basis for the exposure-response relationships
10 used in this portion of the risk assessment.

11 **5.3.1.3 Exposure-Response Functions**

12 A similar methodology to that developed in the prior risk assessment has been used to
13 estimate probabilistic exposure-response relationships for lung function decrements in school age
14 children and “active” school age children associated with 8-hr moderate exertion exposures.
15 Building on the prior assessment, a combined data set including the data from the Folinsbee et al.
16 (1988), Horstman et al. (1990), and McDonnell et al. (1991) studies used previously and the
17 more recent data from Adams (2002, 2003, 2006) have been used to estimate exposure-response
18 relationships for 8-hr exposures under moderate exertion. The previously used studies were all
19 conducted in EPA’s facility in Chapel Hill, while the Adams studies were conducted at the
20 University of California at Davis. Data from these controlled human exposure studies were
21 corrected for the effect of exercise in clean air to remove any systematic bias that might be
22 present in the data attributable to an exercise effect. Generally, this correction for exercise in
23 clean air was small relative to the total effects measures in the O₃-exposed cases. After we made
24 corrections for the effect of exercise in clean air, we averaged individual responses to the same
25 O₃ concentration under different exposure protocols within the same study. For example, in
26 Adams (2006) subjects were exposed to O₃ concentrations of 0.08 ppm in a square-wave pattern
27 in Protocol 2 and in a triangular pattern in Protocol 3, and we used the average of the responses
28 for each subject in estimating the exposure-response relationship used in the risk assessment.
29 The rationale for averaging the responses is that there are a multitude of patterns of exposure in
30 the real world, thus it seems sensible to include all of the data rather than rely on data for any
31 single pattern. However, averaging an individual’s responses across the various protocols may
32 lead to an underestimation of the fraction of the population experiencing a specified response in
33 lung function decrement. EPA is exploring alternative approaches to better reflect all of the
34 individual subject data that do not involve averaging the responses across the various protocols.

1 For the risk assessment conducted during the last O₃ NAAQS review, there were data for
2 only 3 exposure levels (0.08, 0.10, and 0.12 ppm) and a linear exposure-response relationship
3 was estimated for use in the risk assessment. With the addition of data from three more recent
4 Adams' studies that included 0.04, 0.06, and/or 0.08 ppm, 6.6 hour exposures, the combined data
5 set appears to be more S-shaped and, therefore, we used nonlinear regression techniques to fit a
6 3-parameter logistic function to the data for each of the three measures of lung function
7 decrement.^{4,5} Figures 5-2a,b,c shows both the linear exposure-response functions used
8 previously and the new 3-parameter logistic exposure-response functions used in the current risk
9 assessment for changes in FEV₁ ≥ 10%, ≥ 15% and ≥ 20%. of the draft Risk Assessment TSD.
10 These figures also show the currently available combined data points for which the 3-parameter
11 logistic functions were fit. We note that the fraction of the population experiencing FEV₁ ≥ 15%
12 and ≥ 20% associated with 0.08 ppm O₃ exposures is lower in the three Adams' studies compared
13 to the combined data set based on the studies by Folinsbee et al. (1991), Horstmann et al. (1990),
14 and McDonnell et al. (1991). For example, the fraction of the population experiencing FEV₁
15 decrements ≥ 15% associated with 0.08 ppm O₃ exposures was 3.3, 6.7, and 16.7% in the three
16 Adams studies compared to 18.3% in the combined data set from the Chapel Hill studies. The
17 0.08 ppm level is the only common level tested in both sets of studies. This observed difference
18 may be due to differences in sensitivity of the subjects tested, random variability due to the
19 relatively small number of subjects tested, and/or possibly greater attenuation of response for
20 subjects living in or near Davis, California (where the Adams studies were conducted) compared
21 to subjects living in or near Chapel Hill, NC (where the other studies were conducted). Adams
22 notes in his studies that they were conducted over a 6-month period when the 0.09 ppm, 1-hr
23 California standard was not exceeded in the area where his subjects resided. The difference in
24 observed responses between these two sets of studies is an additional uncertainty that should be
25 considered.

26 **5.3.1.4 Characterizing Uncertainty and Variability**

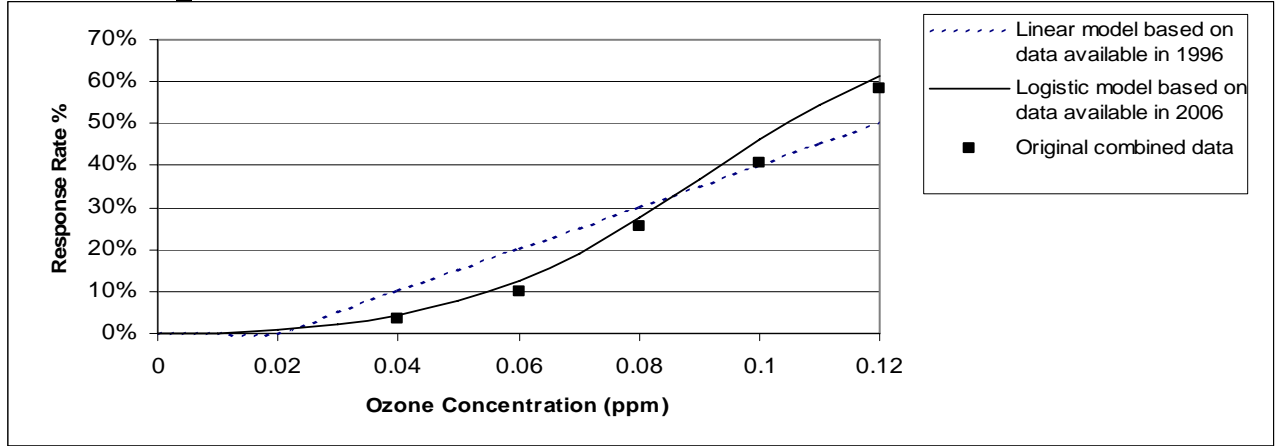

27 An important issue associated with any population health risk assessment is the
28 characterization of uncertainty and variability. *Uncertainty* refers to the lack of knowledge
29 regarding both the actual values of model input variables (parameter uncertainty) and the

⁴ As noted in Whitfield et al., 1996, the response data point associated with 0.12 ppm for the response measure FEV₁ ≥ 15% appeared to be inconsistent with the other data points (see Whitfield et al., 1996, Table 10, footnote c). Because of this, we estimated the probability of a response of FEV₁ ≥ 15% at an O₃ concentration of 0.12 ppm by interpolating between the FEV₁ ≥ 10% and FEV₁ ≥ 20% response rates at that O₃ concentration.

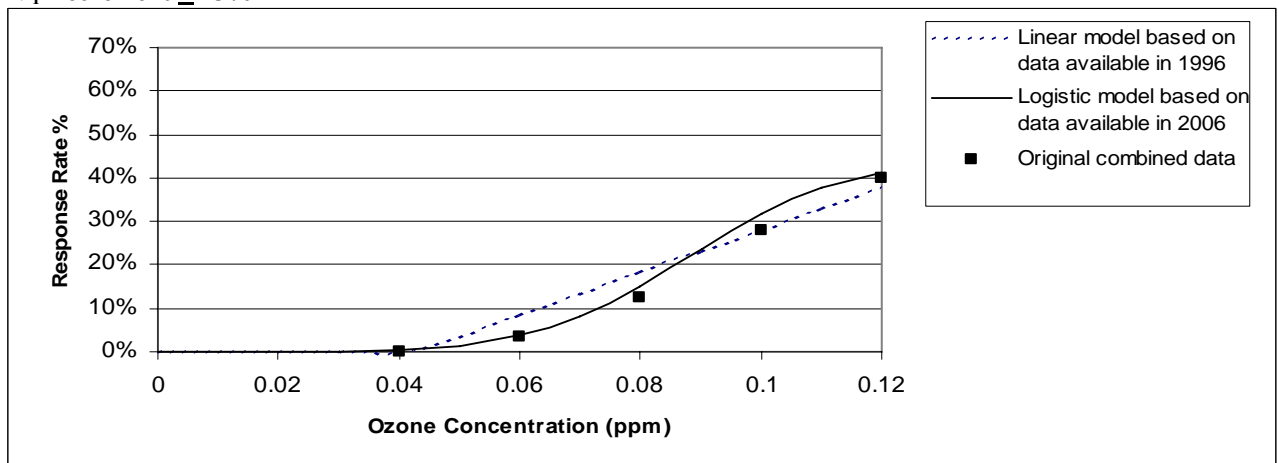

⁵ The 3-parameter logistic function is a special case of the 4-parameter logistic, in which the function is forced to go through the origin, so that the probability of response to 0.00 ppm is 0.

1 **Figure 5-2a, b, c. Probabilistic Exposure-Response Relationships for FEV₁ Decrement \geq**
 2 **10%, \geq 15%, and \geq 20% for 8-Hour Exposures Under Moderate Exertion**

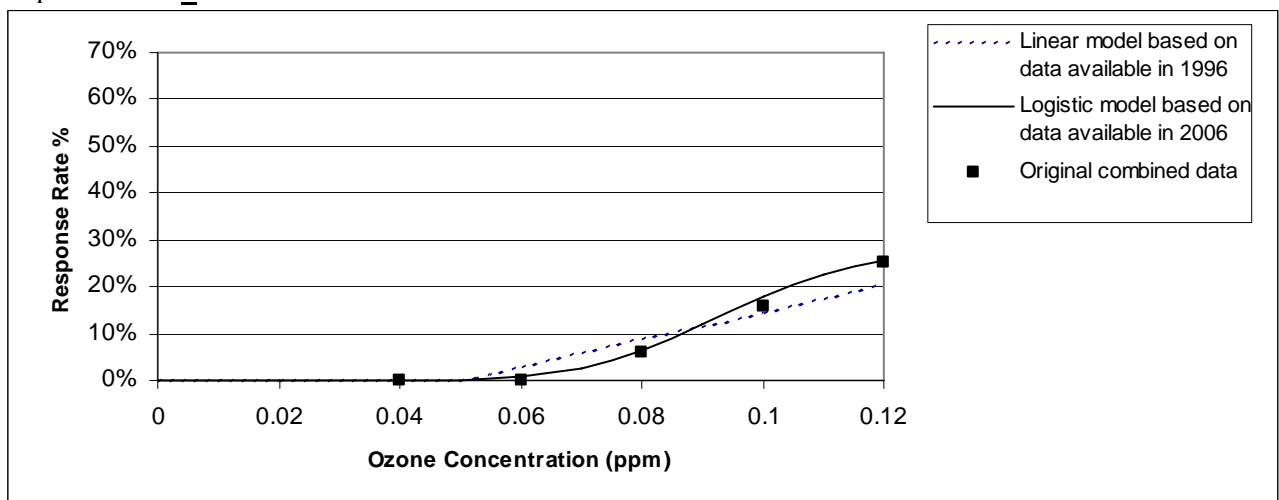

3 **a) FEV₁ Decrement \geq 10%**

25 **c) FEV₁ Decrement \geq 20%**

1 physical systems or relationships (model uncertainty – e.g., the shapes of concentration-response
2 functions). In any risk assessment, uncertainty is, ideally, reduced to the maximum extent
3 possible, but significant uncertainty often remains. It can be reduced by improved measurement
4 and improved model formulation. In addition, the degree of uncertainty can be characterized,
5 sometimes quantitatively. For example, the statistical uncertainty surrounding the estimated O₃
6 coefficients in the exposure-response functions is reflected in the credible intervals provided for
7 the risk estimates in this chapter and in the draft Risk Assessment TSD.

8 A Bayesian approach was used to characterize uncertainty attributable to sampling error
9 based on sample size considerations. In this approach, for any given O₃ concentration, we
10 specify a prior probability distribution describing our prior beliefs about the probability that the
11 rate of response to exposure to that O₃ concentration will fall in any specified range. Given this
12 prior distribution and the actual data – a sample size, N (the number of subjects exposed to the
13 specified O₃ concentration), and a number of responders, X – the Bayesian approach calculates a
14 posterior distribution, which provides a description of the uncertainty about the response rate
15 corresponding to the specified O₃ concentration. If the prior distribution is a Beta distribution
16 with parameters α and β , the posterior distribution is also a Beta distribution, but with parameters
17 $(\alpha+X)$ and $(\beta+N-X)$. For prior distributions we used diffuse Beta distributions, in which $\alpha = \beta =$
18 $0.$ ⁶ The resulting posterior distributions are therefore Beta distributions with parameters X and
19 $(N-X)$.

20 We have actual samples (and therefore actual sample sizes and numbers of responders),
21 however, for only five O₃ concentrations – 0.04, 0.06, 0.08, 0.10, and 0.12 ppm. Therefore a true
22 Bayesian approach can be carried out for only these five O₃ concentrations. As an alternative,
23 we approximated this approach by setting N=30 (the smallest of the five sample sizes) for all O₃
24 concentrations and calculating X for any given O₃ concentration as the number of responders
25 (out of 30 subjects) predicted by the estimated logistic exposure-response function. For
26 example, the estimated logistic exposure-response function for response defined as $\Delta FEV_1 \geq$
27 10% predicts a probability of response to 0.05 ppm O₃ to be 0.067475. The predicted number of
28 responders to 0.05 ppm O₃ is thus $0.067475 \times 30 = 2.024$. Applying the inverse Beta function
29 with parameters $X = 2.024$ and $(N-X) = (30 - 2.024)$, the predicted response rate associated with
30 any percentile of the posterior distribution for an O₃ concentration of 0.05 ppm can be calculated.
31 The 1st percentile response rate is 0.005, the 2.5th percentile response rate is 0.034, the 50th
32 percentile response rate is 0.058, and so forth.

⁶ The use of a diffuse prior distribution allows the data to determine the shape of the posterior distribution.

1 Because we don't actually have samples for every possible O₃ concentration, there is no
2 perfect method to characterize the uncertainty associated with sampling error for the entire
3 logistic exposure-response function. By using the smallest of the actual five sample sizes, we
4 maximize the estimated uncertainty associated with sample size considerations. Because other
5 sources of uncertainty about the exposure-response function cannot easily be quantified, we
6 believe this conservative approach to be reasonable. Figures 5-3a, b, and c show the resulting
7 2.5th percentile, 50th percentile (median), and 97.5th percentile curves for the three lung function
8 response definitions.

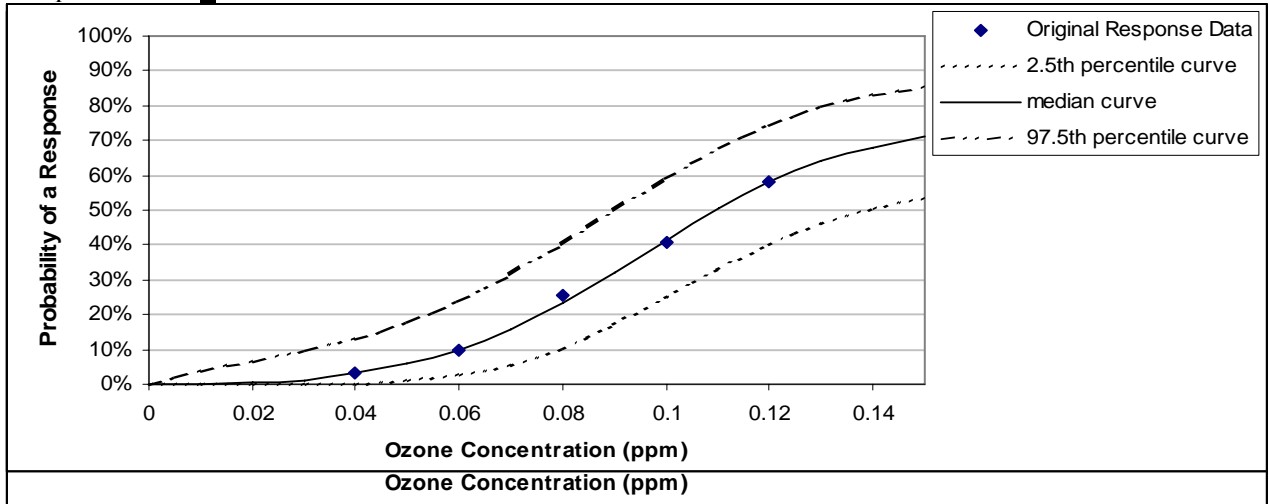

9 In addition to uncertainties arising from sample size considerations, there are other
10 uncertainties associated with the use of the exposure-response relationships for lung function
11 responses. For example, while we have used the combined data set for the current risk
12 assessment, as it represents the best available data, we believe that the observed differences in
13 response between the Adams studies and the Chapel Hill studies contribute to additional
14 uncertainty about the exact shape of the exposure-response relationship, especially for levels at
15 or below 0.08 ppm. Additional uncertainties with respect to the estimated exposure-response
16 relationships are briefly summarized below.⁷ These additional uncertainties include:

- 17 • Length of exposure. The 8-hr moderate exertion risk estimates are based on a
18 combined data set from three controlled human exposure studies conducted using 6.6-
19 hr exposures. The use of these data to estimate responses associated with an 8-hr
20 exposure are reasonable, in our judgment, because lung function response appears to
21 level off after exposure for 4 to 6 hours. It is unlikely that the exposure-response
22 relationships would have been appreciably different had the studies been conducted
23 over an 8-hr period.
- 24 • Extrapolation of exposure-response relationships. It was necessary to estimate
25 responses at O₃ levels below the lowest exposure levels used in the controlled human
26 studies (i.e., 0.04 ppm) down to background levels.
- 27 • Reproducibility of O₃-induced responses. The risk assessment assumed that the O₃-
28 induced responses for individuals are reproducible. This assumption is supported by
29 the evaluation in the CD (see section AX6.4) which cites studies by McDonnell et al.
30 (1985b) and Hazucha et al. (2003) as showing significant reproducibility of response.
31 The CD also notes that Hazucha et al. (2003) similarly observed generally reproducible
32 O₃-induced lung function responses in a controlled human exposure study
- 33 • Age and lung function response. As in the prior review, exposure-response
34 relationships based on controlled human exposure studies involving 18-35 year old
35 subjects were used in the risk assessment to estimate responses for school age children

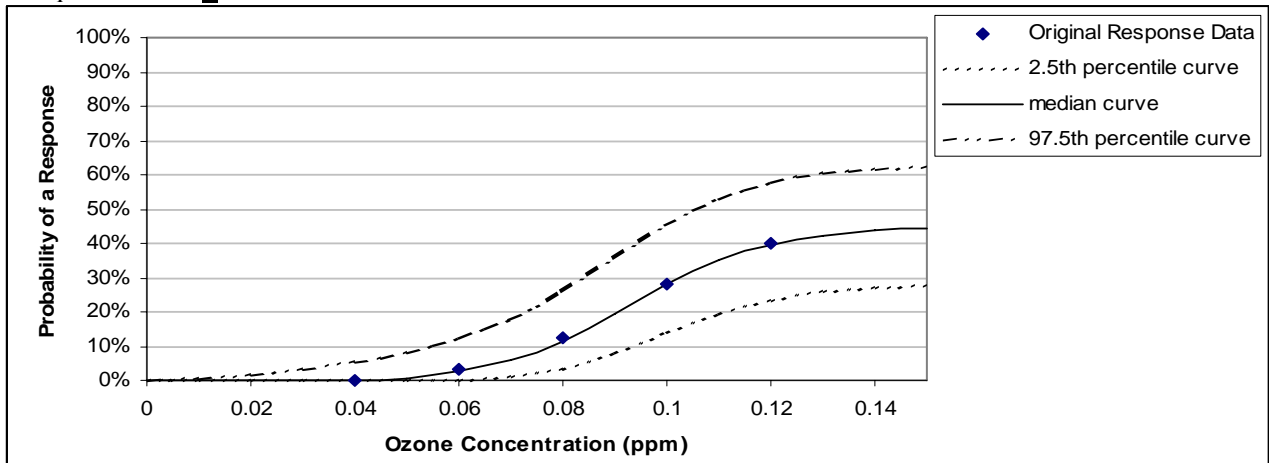

⁷ Additional uncertainties with respect to the exposure inputs to the risk assessment are described in Chapter 4 of this draft Staff Paper, in the draft Exposure Assessment TSD, and in Langstaff (2006).

1 **Figure 5-3a, b, c. Probabilistic Exposure-Response Relationships for FEV₁ Decrement \geq**
 2 **10%, \geq 15%, and \geq 20% for 8-Hour Exposures Under Moderate Exertion**

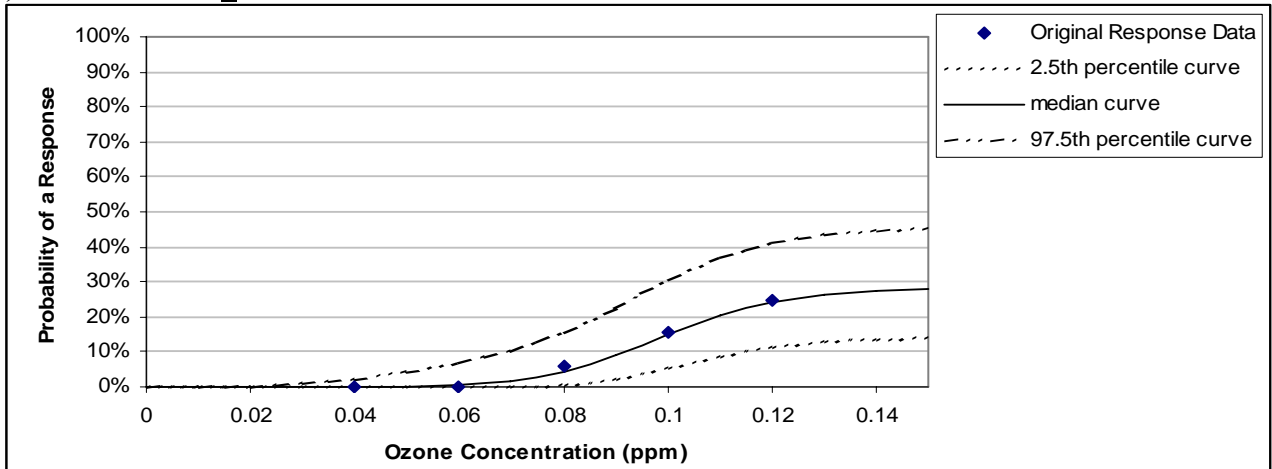

3 **a) FEV₁ Decrement \geq 10%**

15 **b) FEV₁ Decrement \geq 15%**

26 **c) FEV₁ Decrement \geq 20%**

1 (ages 5-18). This approach is supported by evaluation in the CD (see section AX6.4)
2 which cites the findings of McDonnell et al. (1985a) who reported that children 8-11
3 years old experienced FEV₁ responses similar to those observed in adults 18-35 years
4 old when both groups were exposed to concentrations of 0.12 ppm at an EVR of 35
5 L/min/m². . In addition, a number of summer camp studies of school age children
6 exposed in outdoor environments in the Northeast also showed O₃-induced lung
7 function changes similar to those observed in controlled human exposure studies.

- 8 • Exposure history. The risk assessment assumed that the O₃-induced response on any
9 given day is independent of previous O₃ exposures. As discussed in Chapter 3 and in
10 the CD, O₃-induced responses can be enhanced on the second day of exposure or
11 attenuated after more than 2 consecutive days of exposure. The possible impact of
12 recent exposure history on the risk estimates is an additional source of uncertainty that
13 is not quantified in this assessment. We note that the three Adams' studies which were
14 conducted in Davis, California reported a smaller fraction of the subjects experiencing
15 FEV₁ decrements ≥ 15 and 20% associated with O₃ exposures to 0.08 ppm for 6.6 hours
16 than the Folinsbee/Horstman/McDonnell studies conducted in Chapel Hill, NC at this
17 same level and exposure period. While Adams indicates in each of these studies that
18 O₃ levels did not exceed the 0.09 ppm, 1-hr California standard, we do not know
19 whether the exposures outside the chamber played any role in the differences observed
20 between these two sets of studies or whether the differences might reflect differential
21 sensitivity among the pools of subjects tested.
- 22 • Interaction between O₃ and other pollutants. Because the controlled human exposure
23 studies used in the risk assessment involved only O₃ exposures, it was assumed that
24 estimates of O₃-induced health responses would not be affected by the presence of
25 other pollutants (e.g., SO₂, PM_{2.5}, etc). Some evidence exists that other pollutants may
26 enhance the respiratory effects associated with exposure to O₃, but the evidence is not
27 consistent across studies.

28 *Variability* refers to the heterogeneity in a population or variable of interest that is
29 inherent and cannot be reduced through further research. The current controlled human exposure
30 studies portion of the risk assessment incorporates some of the variability in key inputs to the
31 analysis by using location-specific inputs for the exposure analysis (e.g., location-specific
32 population data, air exchange rates, air quality and temperature data). Although spatial
33 variability in these key inputs across all U.S. locations has not been fully characterized,
34 variability across the selected locations is embedded in the analysis by using, to the extent
35 possible, inputs specific to each urban area. Temporal variability is more difficult to address,
36 because the risk assessment focuses on some unspecified time in the future. To minimize the
37 degree to which values of inputs to the analysis may be different from the values of those inputs
38 at that unspecified time, we have used the most current inputs available – for example, year 2004
39 and 2002 air quality data for all of the urban locations, and the most recent available population
40 data (from the 2000 Census). However, future changes in inputs have not been predicted (e.g.,
41 future population levels).

5.3.2 Assessment of Risk Based on Epidemiological Studies

As discussed above, the current quantitative risk assessment based on epidemiological studies includes risk estimates for respiratory symptoms in moderate to severe asthmatic children, respiratory-related hospital admissions, and total non-accidental and cardiorespiratory mortality associated with short-term O₃ exposures in selected urban locations in the U.S. The methods used in this portion of the risk assessment are described below.

5.3.2.1 General Approach

In order to estimate the incidence of a particular health effect associated with recent conditions in a specific county or set of counties attributable to ambient O₃ exposures in excess of background, as well as the change in incidence of the health effect in that county or set of counties corresponding to a given change in O₃ levels resulting from just meeting the current or alternative 8-hr O₃ standards, the following three elements are required:

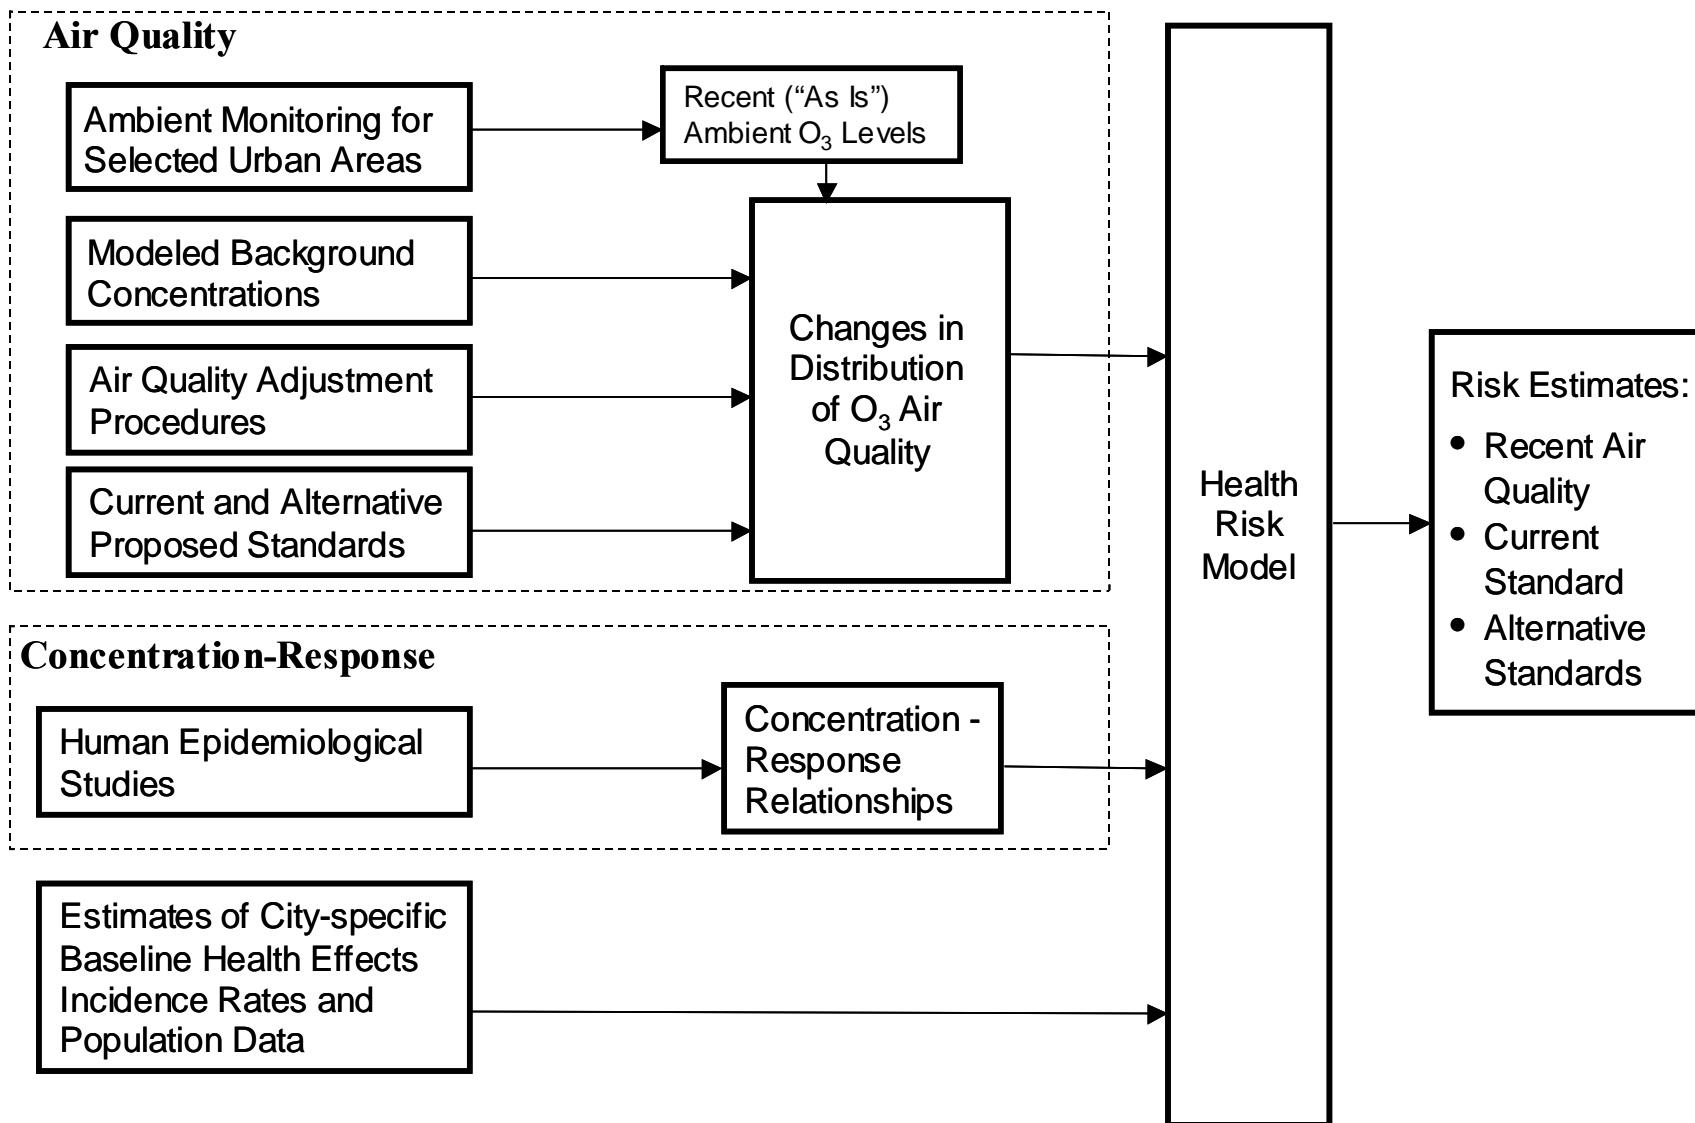

- **Air quality information** including: (1) recent air quality data for O₃ from population-oriented monitors in the assessment location, (2) estimates of background O₃ concentrations appropriate to this location, and (3) recent concentrations adjusted to reflect patterns of air quality estimated to occur when the area just meets the specified standards. (These air quality inputs are discussed in more detail in section 4.5.6)
- **Concentration-response function(s)** which provide an estimate of the relationship between the health endpoint of interest and ambient O₃ concentrations, preferably derived in the assessment location, as use of functions estimated in other increases uncertainty.
- **Seasonal baseline health effects incidence rate and population.** The baseline incidence rate provides an estimate of the incidence rate in the assessment location corresponding to recent O₃ levels in that location

Figure 5-3 provides a broad schematic depicting the role of these components in this part of the risk assessment. Each of the key components (i.e., air quality information, estimated concentration-response functions, and baseline incidence and population data) is discussed below, highlighting those points at which judgments have been made.

These inputs are combined to estimate health effect incidence changes associated with specified changes in O₃ levels. Although some epidemiological studies have estimated linear or logistic concentration-response functions, by far the most common form is the exponential (or log-linear) form:

$$y = Be^{fx}, \quad \text{(Equation 5-2)}$$

1 Figure 5-3. Major Components of Ozone Health Risk Assessment Based on Epidemiological Studies

1 where x is the ambient O_3 level, y is the incidence of the health endpoint of interest at O_3 level x ,
2 β is the coefficient of ambient O_3 concentration, and B is the incidence at $x=0$, i.e., when there is
3 no ambient O_3 . The relationship between a specified ambient O_3 level, x_0 , for example, and the
4 incidence of a given health endpoint associated with that level (denoted as y_0) is then

$$y_0 = Be^{\beta x_0} . \quad \text{(Equation 5-3)}$$

7
8 Because the log-linear form of concentration-response function (equation (5-2)) is by far the
9 most common form, we use this form to illustrate the derivation of the “health impact function”
10 used in this portion of the risk assessment.

11 The difference in health effects incidence, $\Delta y = y_0 - y$, from y_0 to the baseline incidence
12 rate, y , corresponding to a given difference in ambient O_3 levels, $\Delta x = x_0 - x$, can be derived by
13 dividing equation (5-3) by equation (5-2), which yields:

$$\Delta y = y[e^{\beta \Delta x} - 1] . \quad \text{(Equation 5-4)}$$

14
15
16
17 Alternatively, the difference in health effects incidence can be calculated indirectly using relative
18 risk. Relative risk (RR) is a measure commonly used by epidemiologists to characterize the
19 comparative health effects associated with a particular air quality comparison. The risk of
20 mortality at ambient O_3 level x_0 relative to the risk of mortality at ambient O_3 level x , for
21 example, may be characterized by the ratio of the two mortality rates: the mortality rate among
22 individuals when the ambient O_3 level is x_0 and the mortality rate among (otherwise identical)
23 individuals when the ambient O_3 level is x . This is the RR for mortality associated with the
24 difference between the two ambient O_3 levels, x_0 and x . Given a concentration-response function
25 of the form shown in equation (5-1) and a particular difference in ambient O_3 levels, Δx , the RR
26 associated with that difference in ambient O_3 , denoted as $RR_{\Delta x}$, is equal to $e^{\beta \Delta x}$. The difference
27 in health effects incidence, Δy , corresponding to a given difference in ambient O_3 levels, Δx , can
28 then be calculated based on this $RR_{\Delta x}$:

$$\Delta y = y[RR_{\Delta x} - 1] . \quad \text{(Equation 5-5)}$$

29
30
31
32 Equations (5-4) and (5-5) are simply alternative ways of expressing the relationship between a
33 given difference in ambient O_3 levels, Δx , and the corresponding difference in health effects
34 incidence, Δy . These health impact equations are the key equations that combine air quality

1 information, concentration-response function information, and baseline health effects incidence
2 information to estimate ambient O₃ health risk.

3 **5.3.2.2 Air Quality Considerations**

4 As illustrated in Figure 5-3, and noted earlier, air quality information required to conduct
5 the O₃ risk assessment includes: (1) recent air quality data for O₃ from suitable monitors for each
6 selected location, (2) estimates of background concentrations for each selected location, and (3)
7 air quality adjustment procedures to modify the recent data to reflect changes in the distribution
8 of hourly O₃ air quality estimated to occur when an area just meets a given O₃ standard. We
9 retrieved O₃ ambient air quality data for the years 2002 through 2004 from EPA's Air Quality
10 System (AQS).

11 To estimate the change in incidence of a health effect associated with a change in O₃
12 concentrations from recent levels to background levels in an assessment location, two time series
13 of O₃ concentrations are needed for that location: (1) hourly O₃ concentrations from a recent
14 year for the period April 1 through September 30, and (2) hourly background O₃ concentrations
15 for the same time period. In order to be consistent with the approach generally used in the
16 epidemiological studies that estimated O₃ concentration-response functions, the (spatial) average
17 ambient O₃ concentration on each hour for which measured data are available is deemed most
18 appropriate for the risk assessment. A composite monitor data set was created for each
19 assessment location based on averaging each hourly value from all monitors eligible for
20 comparison with the current standard for each hour of the day. Table 4-6 provides a summary of
21 the design values for the 12 urban study areas. Appendix 5A.1 to this Chapter provides more
22 detailed information on ambient O₃ concentrations for these locations.

23 Different exposure metrics have been used in epidemiological O₃ studies, including the
24 24-hr average and the daily 1-hr and 8-hr maximum. Therefore, daily changes at the composite
25 monitor in the O₃ exposure metric appropriate to a given concentration-response function were
26 calculated for use in the risk assessment (see Tables 5A-13 and 5A-14, Appendix 5A.1 for
27 summary statistics for the composite monitor O₃ concentrations in the 12 urban locations for
28 2002 and 2004). For example, if a concentration-response function related daily mortality to
29 daily 1-hr maximum O₃ concentrations, the daily changes in 1-hr maximum O₃ concentrations at
30 the composite monitor were calculated. In the first part of the epidemiology-based risk
31 assessment, in which risks associated with the recent levels of O₃ above background levels were
32 estimated, this required the following steps:

- 33 • Using the monitor-specific input streams of hourly O₃ concentrations from a recent
34 year, calculate a stream of hourly O₃ concentrations at the composite monitor. The
35 recent O₃ concentration at the composite monitor for a given hour on a given day is the
36 average of the monitor-specific O₃ concentrations for that hour on that day.

- 1 • Using this stream of hourly O₃ concentrations from a recent year at the composite
2 monitor, calculate the 1-hr maximum O₃ concentration for each day at the composite
3 monitor.
- 4 • Using the monitor-specific input streams of hourly background O₃ concentrations,
5 calculate a stream of hourly background O₃ concentrations at the composite monitor.
- 6 • Using this stream of background hourly O₃ concentrations at the composite monitor,
7 calculate the 1-hr maximum background O₃ concentration for each day at the
8 composite monitor.
- 9 • For each day, calculate $\Delta x =$ (the 1-hr maximum O₃ concentration for that day at the
10 composite monitor) - (the 1-hr maximum background O₃ concentration for that day at
11 the composite monitor).

12 The calculations for the second part of the epidemiology-based risk assessment, in which
13 risks associated with estimated O₃ levels that just meet the current and potential alternative 8-hr
14 standards above background levels were estimated, were done analogously. For this case the
15 series of monitor-specific adjusted hourly concentrations were used rather than the series of
16 monitor-specific recent monitored hourly concentrations. Similarly, calculations for
17 concentration-response functions that used a different exposure metric (e.g., the 8-hr daily
18 maximum or 24-hr average) were done analogously, using the exposure metric appropriate to the
19 concentration-response function.

20 **5.3.2.3 Concentration-Response Functions**

21 As indicated in Figure 5-3, another key component in the risk model based on
22 epidemiological studies is the set of concentration-response functions which provide estimates of
23 the relationships between each health endpoint of interest and ambient concentrations. As
24 discussed above, the health endpoints that have been included in the O₃ risk assessment include
25 respiratory symptoms in moderate-to-severe asthmatic children, respiratory-related hospital
26 admissions, and premature mortality associated with short-term exposures. For those health
27 endpoints, the assessment includes all estimates of response magnitude from studies judged
28 suitable for inclusion in this assessment, including those which are not statistically significant.
29 Effect estimates that are not statistically significant are used from studies judged suitable for
30 inclusion in this assessment to avoid introducing bias into the estimate of the magnitude of the
31 effect. Table 5-1 summarizes the studies included in this part of the risk assessment for each of
32 the urban locations.

33 Studies often report more than one estimated concentration-response function for the
34 same location and health endpoint. Sometimes models including different sets of co-pollutants
35 are estimated in a study; sometimes different lags are estimated. In some cases, two or more
36 studies estimated a concentration-response function for O₃ and the same health endpoint in the

1 same location (this is the case, for example, with O₃ and mortality associated with short-term
2 exposures). For some health endpoints, there are studies that estimated multi-city O₃
3 concentration-response functions, while other studies estimated single-city functions.

4 All else being equal, a concentration-response function estimated in the assessment
5 location is preferable to a function estimated elsewhere, since it avoids uncertainties related to
6 potential differences due to geographic location. That is why the urban areas selected this part of
7 the O₃ risk assessment are, generally, those locations in which concentration-response functions
8 have been estimated. There are several advantages, however, to using estimates from multi-city
9 studies versus studies carried out in single cities. These advantages include, but are not limited
10 to: (1) more precise effect estimates due to larger data sets, (2) greater consistency in data
11 handling and model specification that can eliminate city- to-city variation due to study design,
12 and (3) less likelihood of publication bias or exclusion of reporting of negative or nonsignificant
13 findings. Multi-city studies are applicable to a variety of settings, since they estimate a central
14 tendency across multiple locations. When they are estimating a single concentration-response
15 function based on several cities, multi-city studies also tend to have more statistical power and
16 provide effect estimates with relatively greater precision than single city studies due to larger
17 sample sizes, reducing the uncertainty around the estimated coefficient. Because single-city and
18 multi-city studies have different advantages, where both are available for a given location, risk
19 estimates have been developed for both functions.

20 As discussed in the CD and section 3.3.2.1 of this draft Staff Paper, O₃ epidemiological
21 studies have reported relationships based on single pollutant models and/or multi-pollutant
22 models (i.e., where PM, nitrogen dioxide, sulfur dioxide, or carbon monoxide were entered into
23 the health effects model along with O₃. To the extent that any of the co-pollutants present in the
24 ambient air may have contributed to the health effects attributed to O₃ in single pollutant models,
25 risks attributed to O₃ might be overestimated where concentration-response functions are based
26 on single pollutant models. However, if co-pollutants are highly correlated with O₃, their
27 inclusion in an O₃ health effects model can lead to misleading conclusions in identifying a
28 specific causal pollutant. When collinearity exists, inclusion of multiple pollutants in models
29 often produces unstable and statistically insignificant effect estimates for both O₃ and the co-
30 pollutants. Given that single and multi-pollutant models each have both potential advantages and
31 disadvantages, with neither type clearly preferable over the other in all cases, we report risk
32 estimates based on both single- and multi-pollutant models where both are available.

33 Epidemiological studies have reported effect estimates associated with varying lag
34 periods, but for the reasons discussed in the CD and summarized in section 3.4.5 above the CD
35 focuses on effect estimates from models using 0- or 1-day lag periods, with some consideration
36 of multi-day lag effects (CD, p. 7-11). For quantitative assessments, we conclude that it is

3 *This study estimated concentration-response functions for cardiorespiratory mortality.
 4
 5

1 appropriate to use results from lag period analyses consistent with those reported in the CD,
2 focusing on single day lag periods of 0-1 days for associations with mortality or respiratory
3 hospitalization, depending on availability of results (CD, p. 8-59). If the effect of O₃ on health
4 outcomes persists over several days, distributed lag model results can provide more accurate
5 effect estimates for quantitative assessment than an effect estimate for a single lag period (CD, p.
6 7-10). Therefore, we have used distributed lag models when they are available. Where only
7 single day lags are available we have focused on single day lag periods of 0-1 days for
8 associations with mortality or respiratory hospitalization, depending on availability of effect
9 estimates (CD, p. 8-59).

10 In summary:

- 11 • if a single-city concentration-response function was estimated in a risk assessment
12 location and a multi-city function which includes that location was also available for
13 the same health endpoint, both functions were included for that location in the risk
14 assessment;
- 15 • risk estimates based on both single- and multi-pollutant models were used when both
16 were available;
- 17 • distributed lag models were used, when available; when a study reported several single
18 lag models for a health effect, the initial selection of the appropriate lag structure for
19 the health effect was based on the overall assessment in the CD, considering all studies
20 reporting concentration-response functions for that health effect.

21 The locations, health endpoints, studies, and concentration-response functions included in
22 that portion of the risk assessment based on epidemiological studies are summarized in Tables
23 5B-1 through 5B-12 in Appendix 5B.1.

24 **5.3.2.4 Baseline Health Effects Incidence and Population Estimates**

25 As illustrated in Equation 5-4, the most common health risk model based on
26 epidemiological studies expresses the reduction in health risk (Δy) associated with a given
27 reduction in O₃ concentrations (Δx) as a percentage of the baseline incidence (y). To accurately
28 assess the impact of changes in O₃ air quality on health risk in the selected urban areas,
29 information on the baseline incidence of health effects in each location is therefore needed. For
30 this assessment, baseline incidence is the incidence under recent air quality conditions.

31 Population sizes, for both total population and various age ranges used in the risk assessment
32 were obtained for the year 2000 (U.S. Census) and are summarized in Table 5-2. Where
33 possible, county-specific incidence or incidence rates have been used in the assessment. County
34 specific mortality incidences were available for the year 2002 from CDC Wonder (CDC, 2005),
35 an interface for public health data dissemination provided by the Centers for Disease Control
36 (CDC). The baseline mortality rates for each risk assessment location are provided

1 in Table 5-3 and are expressed as a rate per 100,000 population.

2

3 County-specific rates for respiratory hospital discharges, and various subcategories (e.g.,
4 asthma, pneumonia) have been obtained, where possible, from state, local, and regional health
5 departments and hospital planning commissions for each of the risk assessment locations.⁸
6 Baseline hospitalization rates used in each risk assessment location are summarized in Table 5-4
7 and are expressed as a rate per 100,000 relevant population.

8 Baseline rates of symptoms among asthmatic children who used maintenance
9 medications in the Boston area were estimated by using the median rates of the respiratory
10 symptoms reported in Table 3 of Gent et al. (2003). Each symptom rate, the percentage of days
11 on which the symptom occurred, was calculated for each subject by dividing the number of days
12 of the symptom by the number of days of participation in the study and then multiplying by 100.
13 Median symptom rates among maintenance medication users for wheeze, chest tightness, and
14 shortness of breath were 2.8%, 1.2%, and 1.5% of days, respectively.

15 **5.3.2.5 Characterizing Uncertainty and Variability**

16 Section 5.3.1.4 previously defined what is meant by *uncertainty* and *variability* in the
17 context of this risk assessment. For the portion of the risk assessment based on epidemiological
18 studies, the statistical uncertainty surrounding the estimated O₃ coefficients in the reported
19 concentration-response functions is reflected in the confidence or credible intervals provided for
20 the risk estimates in this chapter and in the draft Risk Assessment TSD. Additional uncertainties
21 have been addressed quantitatively through sensitivity analyses and/or have been discussed
22 throughout section 5.3.

23 With respect to variability within this portion of the risk assessment, there may be
24 variability among concentration-response functions describing the relation between O₃ and
25 mortality across urban areas. This variability may be due to differences in population (e.g., age
26 distribution), population activities that affect exposure to O₃ (e.g., use of air conditioning), levels
27 and composition of co-pollutants, and/or other factors that vary across urban areas.

28

⁸ The data were annual hospital discharge data, which were used as a proxy for hospital admissions. Hospital discharges are issued to all people who are admitted to the hospital, including those who die in the hospital. Use of the annual or seasonal discharge rate is based on the assumption that the admissions at the end of the year (or season) that carry over to the beginning of the next year (or season), and are therefore not included in the discharge data, are offset by the admissions in the previous year (or season) that carry over to the beginning of the current year (or season).

1 **Table 5-2. Relevant Population Sizes for O₃ Risk Assessment Locations***

City	Counties	Population (in millions)*			
		Total	Ages ≥30	Ages ≥ 65	Children, Ages ≤ 12, with asthma**
Atlanta	Fulton, DeKalb	1.5	---	---	---
Boston	Suffolk	0.7	---	---	---

Washington, D.C.	Washington, D.C.	0.6	---	---	---

2 * Total population and age-specific population estimates taken from the 2000 U.S. Census. Populations are rounded to the nearest 0.1 million. The urban areas
3 given in this table are those considered in the studies used in the O₃ risk assessment, with the exception of the larger Boston area, which is the CSA for Boston
4 (since the study that estimated a concentration-response function for asthma among children was conducted in Springfield, MA and CT).

5 ** Population derived as follows: The populations of children <5 and 5 - 12 in the counties listed were multiplied by corresponding percents of children [in each
6 age group] in New England with “current asthma” -- 5.1% and 10.7% for the two age groups, respectively (see "The Burden of Asthma in New England."
7 Asthma Regional Council. March 2006. Table S-2. www.asthmaregionalcouncil.org). These estimated numbers of asthmatic children were then multiplied by
8 the estimated percent of asthmatic children using maintenance medications (40%) (obtained via email 4-05-06 from Jeanne Moorman) and the results were
9 summed.

2 ¹ Rates of unscheduled hospital admissions were calculated from patient discharge data for 1999, obtained from
3 California’s Office of Statewide Health Planning and Development, which also provided records of hospital
4 admissions for the study by Linn et al. (2000).

5 ² Rates of unscheduled hospital admissions were calculated from patient discharge data for 2001, obtained from the
6 New York Statewide Planning and Research Cooperative.

7 ³ Rates were calculated from hospitalization data for Wayne County for the year 2000, obtained from the Michigan
8 Health and Hospital Association in April 2002.

9 ⁴ Based on mean daily hospital admissions for ages 65+ for ICD-9 codes 460-519 -- Table 1 in Schwartz et al.
10 (1996).
11

1 The current risk assessment incorporates some of the variability in key inputs to the
2 analysis by using location-specific inputs (e.g., location-specific concentration-response
3 functions, baseline incidence rates, and air quality data). Although spatial variability in these
4 key inputs across all U.S. locations has not been fully characterized, variability across the
5 selected locations is imbedded in the analysis by using, to the extent possible, inputs specific to
6 each urban area. Temporal variability is more difficult to address, because the risk assessment
7 focuses on some unspecified time in the future. To minimize the degree to which values of
8 inputs to the analysis may be different from the values of those inputs at that unspecified time,
9 we have used recent input data – for example, years 2002 and 2004 air quality data for all of the
10 urban locations, and recent mortality baseline incidence rates (from 2002). However, future
11 changes in inputs have not been predicted (e.g., future population levels or possible changes in
12 baseline incidence rates).

13 A number of important sources of uncertainty were addressed where possible. Section
14 4.1.9 in the draft Risk Assessment TSD discusses in greater detail the uncertainties and
15 variability present in the health risk assessment. The following is a brief discussion of the major
16 sources of uncertainty and variability in the epidemiological portion of the risk assessment and
17 how they are dealt with or considered in the risk assessment:

- 18 • Causality. There is uncertainty about whether each of the estimated associations
19 between O₃ indicators and the various health endpoints included in this risk assessment
20 actually reflect a causal relationship. Our judgment, as discussed in more detail in
21 Chapter 3 (section 3.7.5), is that for the health effects included in the risk assessment
22 (i.e, increased respiratory symptoms in moderate to severe asthmatic children,
23 increased respiratory-related hospital admissions, total non-accidental mortality, and
24 cardiorespiratory mortality) we judge that there is, at a minimum, a likely causal
25 relationship with either short-term O₃ exposure itself or with O₃ serving as an indicator
26 for itself and other components of the photochemical oxidant mix, especially during the
27 warm O₃ season.
- 28 • Empirically estimated concentration-response relationships. In estimating the
29 concentration-response relationships, there are uncertainties: (1) surrounding estimates
30 of O₃ coefficients in concentration-response functions used in the assessment, (2)
31 concerning the specification of the concentration-response model (including the shape
32 of the relationship) and whether or not a population threshold or non-linear relationship
33 exists within the range of concentrations examined in the studies, (3) related to the
34 extent to which concentration-response relationships derived from studies in a given
35 location and time when O₃ levels were higher or behavior and/or housing conditions
36 were different provide accurate representations of the relationships for the same
37 locations with lower air quality distributions and different behavior and/or housing
38 conditions, and (4) concerning the possible role of co-pollutants which also may have
39 varied between the time of the studies and the current assessment period. The
40 approach taken to characterize uncertainties in the concentration-response functions

1 arising from sample size considerations is discussed below. With respect to the shape
2 of the function and whether or not a population threshold may exist, as discussed in
3 Chapter 3, the CD concludes (section 8.5, p.8-44) that “the limited evidence suggests
4 that if there is a threshold level in O₃ health effects, it is likely near the lower limit of
5 ambient O₃ concentrations in the United States.” As discussed in Chapter 3 and in the
6 CD (CD, p.7-175), results from recent large U.S. multi-city time-series studies and
7 meta-analyses also show effect estimates that are consistent across studies and robust
8 to control for potential confounders.

- 9 • Adequacy of ambient O₃ monitors as surrogate for population exposure. The extent to
10 which there are differences in the relationship between spatial variation in ambient O₃
11 concentrations and ambient exposures in the original epidemiology studies compared
12 to more recent ambient O₃ data introduces additional uncertainty in the risk estimates.
13 As discussed in the CD, Section 3.9, using ambient concentrations to determine
14 exposure generally overestimates true personal O₃ exposures by approximately 2- to 4-
15 fold in available studies, resulting in biased descriptions of underlying concentration-
16 response relationships and attenuated risk estimates. The implication is that the effects
17 being estimated occur at fairly low exposures and the potency of O₃ is greater than
18 these effects estimates indicate. Thus, the risk estimates presented here may
19 underestimate the overall impact of O₃ exposures on mortality and hospital admissions.
- 20 • Adjustment of air quality distributions to simulate just meeting the current standard.
21 The shape of the distribution of hourly O₃ concentrations that would result upon just
22 meeting the current or alternative 8-hr standards is unknown. Based on an analysis of
23 historical data, we believe that the Quadratic air quality adjustment procedure provides
24 reasonable estimates of the shape of the distribution; however, there is greater
25 uncertainty for those urban areas that have air quality well above the current standard
26 (e.g., Los Angeles, Houston). As noted previously, there is considerable year to year
27 variability in O₃ concentrations over a three-year period in many of the urban areas
28 examined. This leads to substantial year-to-year variability in risk estimates associated
29 with O₃ concentrations when air quality is simulated to just meet the current and
30 potential alternative standards.
- 31 • Estimated background concentrations for each location. The calculation of risk
32 associated with recent air quality in excess of background requires as an input
33 estimates of background concentrations for each location throughout the period of the
34 assessment. The estimated background concentrations have been obtained from runs
35 of the GEOS-CHEM global model (see section 2.7) and introduce some uncertainty
36 into the risk estimates for both the recent air quality scenario and the just meeting the
37 current 8-hr standard, both of which are calculated as risk in excess of background.
- 38 • Baseline incidence rates and population data. There are uncertainties related to: (1) the
39 extent to which baseline incidence rates, age distributions, and other relevant
40 demographic variables that impact the risk estimates vary for the year(s) when the
41 actual epidemiological studies were conducted, the recent year of air quality used in
42 this assessment, and some unspecified future year when air quality is adjusted to
43 simulate just meeting the current or alternative standards and (2) the use of annual or
44 seasonal incidence rate data to develop daily health effects incidence data. Spatial

1 variability in baseline incidence and population data is taken into account by use of
2 city-specific data in most cases.

3 One of the most critical elements in the risk assessment is the concentration-response
4 relationships used in the assessment. The uncertainty resulting from the statistical uncertainty
5 associated with the estimate of the O₃ coefficient in the concentration-response function was
6 characterized either by confidence intervals or by Bayesian credible intervals around the
7 corresponding point estimates of risk. Confidence and credible intervals express the range
8 within which the true risk is likely to fall if the only uncertainty surrounding the O₃ coefficient
9 involved sample size considerations. Other uncertainties, such as differences in study location,
10 time period, and model uncertainties are not represented by the confidence or credible intervals
11 presented.

12 Two large scale multi-city mortality studies, Bell et al. (2004) and Huang et al. (2004),
13 reported both multi-location and single-location concentration-response functions, using a
14 Bayesian two-stage hierarchical model. In these cases, the single-location estimates can be
15 adjusted to make more efficient use of the data from all locations. The resulting “shrinkage”
16 estimates are so called because they “shrink” the location-specific estimates towards the overall
17 mean estimate (the mean of the posterior distribution of the multi-location concentration-
18 response function coefficient). The greater the uncertainty about the estimate of the location-
19 specific coefficient relative to the estimate of between-study heterogeneity, the more the
20 location-specific estimate is “pulled in” towards the overall mean estimate. Bell et al. (2004)
21 calculated these shrinkage estimates, which were presented in Figure 2 of that paper. These
22 location-specific shrinkage estimates, and their adjusted standard errors were provided by the
23 study authors and were used in the risk assessment.

24 The location-specific estimates reported in Table 1 of Huang et al. (2004) are not
25 “shrinkage” estimates. However, the study authors provided the posterior distribution for the
26 heterogeneity parameter, τ , for their distributed lag model, shown in Figure 4(b) of their paper.
27 Given this posterior distribution, and the original location-specific estimates presented in Table 1
28 of their paper, we calculated location-specific “shrinkage” estimates using a Bayesian method
29 described in DuMouchel (1994) (see section 5B.3 in Appendix 5B of this Staff Paper). As with
30 the shrinkage estimates presented in Bell et al. (2004), the resulting Bayesian shrinkage estimates
31 use the data from all of the locations considered in the study more efficiently than do the original
32 location-specific estimates. The calculation of these shrinkage estimates is thus one way to
33 address the relatively large uncertainty surrounding estimates of coefficients in location-specific
34 concentration-response functions.

35 With respect to model form, most of the epidemiological studies estimated O₃ coefficients
36 using log-linear models. However, there still is substantial uncertainty about the correct

1 functional form of the relationship between O₃ and various health endpoints, especially at the low
2 end of the range of observed concentrations. While there are likely biological thresholds in
3 individuals for specific health responses, as discussed in section 3.4.6 available studies have
4 found little evidence for population thresholds. For example, in a recent study, Bell et al. (2006),
5 applied several statistical models to data on air pollution, weather, and mortality for the 98
6 NMMAPS communities to evaluate whether a threshold level exists for premature mortality.
7 The results suggested that even low levels of tropospheric O₃, well below 0.08 ppm, are
8 associated with premature mortality. However, as discussed in section 3.4.6 and in the CD, the
9 use of ambient O₃ concentrations may obscure the presence of thresholds in epidemiological
10 studies (CD p. 7-158). In those studies that provide suggestive evidence of thresholds, the
11 potential thresholds are at low concentrations (CD, p. 7-159).

12 The CD finds that no definitive conclusion can be reached with regard to the existence of
13 thresholds in epidemiological studies (CD, p. 8-44). We recognize, however, the possibility that
14 thresholds for individuals may exist for reported associations at fairly low levels within the range
15 of air quality observed in the studies, but not be detectable as population thresholds in
16 epidemiological analyses. Based on the CD's conclusions, we judge that there is insufficient
17 evidence to support use of potential threshold levels in the quantitative risk assessment, but we
18 do recognize there is increasing uncertainty about the concentration-response relationship at
19 lower concentrations that is not captured by the characterization of the statistical uncertainty due
20 to sampling error. Therefore, as discussed later in this Chapter, the risk estimates for premature
21 mortality, respiratory symptoms in moderate to severe asthmatic children, and respiratory-related
22 hospital admissions associated with exposure to O₃ must be considered in the light of
23 uncertainties about whether or not these O₃-related effects occur in the population at very low
24 concentrations.

25 Several recent meta-analyses (Bell et al. 2005; Levy et al., 2005; and Ito et al., 2005)
26 have addressed the impact of various factors on estimates of mortality associated with short-term
27 exposures to O₃. We reviewed these meta-analyses for additional information that might be used
28 to assist in characterizing the uncertainties associated with concentration-response functions for
29 this health outcome. As discussed in Chapter 3, the CD observes common findings across all
30 three analyses, in that all reported that effect estimates were larger in warm season analyses,
31 reanalysis of results using default GAM criteria did not change the effect estimates, and there
32 was no strong evidence of confounding by PM (CD, p. 7-97). Bell et al. (2005) and Ito et al.
33 (2005) both provided suggestive evidence of publication bias, but O₃-mortality associations
34 remained after accounting for that potential bias. The results from these meta-analyses, as well
35 as several single- and multiple-city studies, also indicate that copollutants generally do not
36 appear to substantially confound the association between O₃ and mortality.

1 As discussed in Chapter 3, while concluding that O₃-health associations are found to be
2 generally consistent, the recent O₃-mortality meta-analyses indicate that some heterogeneity
3 exists across studies (CD, pp. 7-96 – 7-97). The CD discusses a number of factors that could
4 result in heterogeneity in associations between different geographic areas, focusing particularly
5 on variables that can affect exposure to ambient O₃. For example, the use of air conditioning can
6 reduce ambient exposures during the warm season, while increased outdoor activity can increase
7 exposure.

8 **5.4 OZONE RISK ESTIMATES**

9 We present risk estimates associated with several air quality scenarios, including two
10 recent years of air quality as represented by 2002 and 2004 monitoring data in section 5.4.1. In
11 Section 5.4.2 we summarize risk estimates associated with air quality adjusted to simulate just
12 meeting the current and several potential alternative 8-hr standards. In Section 5.4.3 we discuss
13 and compare the risk estimates developed for the current review with the risk estimates
14 developed for the prior O₃ NAAQS review completed in July 1997. Finally, in section 5.4.4 we
15 present key observations from the health risk assessment.

16 **5.4.1 Recent Air Quality**

17 In the prior risk assessment, risks for lung function decrements associated with 1-hr
18 heavy exertion, 1-hr moderate exertion, and 8-hr moderate exertion exposures were estimated.
19 Since the 8-hr moderate exertion exposure scenario for children clearly resulted in the greatest
20 health risks in terms of lung function decrements, we have chosen to include only the 8-hr
21 moderate exertion exposures in the current risk assessment for this health endpoint. Thus, the
22 risk estimates presented here are most useful for making relative comparisons across alternative
23 air quality scenarios and do not represent the total risks for lung function decrements in children
24 or other groups within the general population associated with any of the air quality scenarios.
25 Thus, some outdoor workers and adults engaged in moderate exertion over multi-hour periods
26 (e.g., 6-8 hr exposures) also would be expected to experience similar lung function decrements.
27 However, the percentage of each of these other subpopulations expected to experience these
28 effects is expected to be smaller than children or “active” children who tend to spend more hours
29 outdoors while active based on the exposure analyses conducted during the prior review.

30 Tables 5-5 and 5-6 display the risk estimates for “active” school age children (ages 5-18)
31 associated with 2004 and 2002 O₃ concentrations for three different levels (≥ 10 , 15 and $\geq 20\%$)
32 of lung function decrement responses for the 12 urban areas. Similar estimates for ≥ 10 , 15, and
33 20% decrement in lung function for all school age children can be found in the draft Risk
34 Assessment TSD. These two tables also include risk estimates associated with air quality

1 adjusted to simulate just meeting the current 0.08 ppm, 8-hr standard, which will be discussed
2 further in section 5.4.2. All estimates in both tables reflect responses associated with exposure to
3 O₃ in excess of exposures associated with background O₃ concentrations. Table 5-5
4 shows the number and percent of “active” children estimated to have at least 1 lung function
5 response during the O₃ season. Table 5-6 displays the total number of occurrences for the
6 specified lung function responses during the O₃ season. As illustrated by the estimates shown in
7 these two tables, a child may experience multiple occurrences of a lung function response during
8 the O₃ season. For example, in Atlanta the median estimate is that 15,000 “active” school age
9 children experienced an FEV₁ decrement $\geq 15\%$ during the O₃ season with a median estimate of
10 48,000 occurrences of this same response in this population for 2004 air quality data. Thus, for
11 this example on average each child is estimated to have over 3 occurrences of this lung function
12 response during the O₃ season.

13 As shown in Table 5-5, across the 12 urban areas, the ranges in median estimates of the
14 percent of “active” school age children estimated to experience at least one FEV₁ decrement \geq
15 15% during the O₃ season are 1.2-6.5% for 2004 and 5.3-10.4% for 2002. The ranges in median
16 estimates of the percent of “active” school age children estimated to experience at least one
17 FEV₁ decrement $\geq 20\%$ during the O₃ season across these same 12 urban areas is 0.2-2.3% for
18 2004 and 1.8-4.4% for 2002.

19 In terms of total occurrences of FEV₁ decrement $\geq 15\%$ during the O₃ season, Table 5-6
20 shows a range of median estimates from 14,000 to over 500,000 responses in 2004 and from
21 37,000 to over 500,000 responses in 2002 for “active” school age children across the 12 urban
22 areas associated with O₃ concentrations. For FEV₁ decrement $\geq 20\%$ during the O₃ season, Table
23 5-6 shows a range of median estimates from 1,000 to 95,000 in 2004 and from 7,000 to over
24 130,000 across the 12 urban areas for total occurrences in “active” school age children.

25 Both Tables 5-5 and 5-6 also include 95% confidence intervals for the lung function
26 decrement risk estimates based on sample size considerations. These confidence intervals only
27 represent part of the uncertainty associated with these risk estimates. Additional uncertainties
28 are summarized in section 5.3.2.5 and should be kept in mind as one considers the risk estimates
29 in these tables.

30 The risk estimates associated with 2004 and 2002 O₃ concentrations for morbidity health
31 endpoints based on epidemiological studies are shown in Tables 5-7 and 5-8 for respiratory
32 symptoms in moderate to severe asthmatic children for the Boston urban area and in Tables 5-9
33 and 5-10 for excess hospital admissions for total respiratory illness and asthma (which is a subset
34 of total respiratory illness admissions) for the New York City urban area. Additional hospital
35 admission estimates for three other locations are provided in the draft Risk Assessment TSD. All

*Risks are estimated for exposures in excess of policy relevant background.

**Numbers are median (0.5 fractile) numbers of occurrences. Numbers in parentheses below the median are 95% confidence intervals based on statistical uncertainty surrounding the O3 coefficient. Numbers are rounded to the nearest 1000. Percents are rounded to the nearest tenth.

1
2
3

1 results are for health risks associated with short-term exposures to O₃ concentrations in excess of
2 background levels from April through September for 2004 and 2002, respectively.

3 As discussed previously, risk estimates were developed for several respiratory symptoms
4 in asthmatic children ages 0 to 12 who use maintenance medications based on the concentration-
5 response functions provided in Gent et al. (2003). These estimates were only developed for the
6 Boston urban area which was near the location of the original epidemiological study. Tables 5-7
7 and 5-8 show risk estimates for three different respiratory symptoms (i.e., chest tightness,
8 shortness of breath, and wheeze) for the Boston area associated with O₃ levels above background
9 for April through September of 2004 and 2002, respectively. The risk estimates are expressed in
10 terms of cases, cases per 100,000 relevant population, and percent of total incidence

11 Tables 5-9 and 5-10 show risk estimates of unscheduled hospital admissions for
12 respiratory illness in the New York City area associated with O₃ levels above background for
13 April through September of 2004 and 2002, respectively. The risk estimates are expressed in
14 terms of cases, cases per 100,000 relevant population, and percent of total incidence.

15 Tables 5-11 and 5-12 show risk estimates for non-accidental mortality associated with O₃
16 levels above background for April through September of 2004 and 2002, respectively. Similar
17 tables for cardiorespiratory mortality are included in the draft Risk Assessment TSD. The risk
18 estimates are presented in terms of estimated incidence, incidence per 100,000 relevant
19 population, and percent of total incidence.

20 Bell et al. (2004) reported both multi-location and single-location concentration-response
21 functions in a variety of locations, using a Bayesian two-stage hierarchical model. In these
22 cases, the single-location estimates can be adjusted to make more efficient use of the data from
23 all locations. The resulting “shrinkage” estimates are so called because they “shrink” the
24 location-specific estimates towards the overall mean estimate (the mean of the posterior
25 distribution of the multi-location concentration-response function coefficient). The greater the
26 uncertainty about the estimate of the location-specific coefficient relative to the estimate of
27 between-study heterogeneity, the more the location-specific estimate is “pulled in” towards the
28 overall mean estimate. Bell et al. (2004) calculated these shrinkage estimates, which were
29 presented in Figure 2 of that paper. These location-specific shrinkage estimates, and their
30 adjusted standard errors were provided to us by the study authors and were used in the risk
31 assessment. Thus, where available, risk estimates are included in Tables 5-11 and 5-12 based on
32 both single-city and multi-city functions. The ranges shown in these tables are based either on
33 the 95 percent confidence intervals around those estimates (if the coefficients were estimated
34 using classical statistical techniques) or on the 95 percent credible intervals (if the coefficients
35 were estimated using Bayesian statistical techniques).

4

1 We observe from Tables 5-11 and 5-12 that estimates of O₃-related non-accidental
2 mortality reported by Schwartz (2004) for Chicago, Detroit, and Houston, based on both single
3 city and multi-city concentration-response functions, tend to be higher than other estimates for
4 these locations. This is mainly due to the use of the 1-hr maximum O₃ concentration in Schwartz
5 (2004), rather than the 24-hr average, as the exposure metric. The changes from recent (2004 or
6 2002)) 1-hr maximum to background 1-hr maximum O₃ concentrations were generally larger in
7 the assessment locations than the corresponding changes from recent 24-hr average to
8 background 24-hr average O₃ concentrations. For example, for 2004 air quality the estimated
9 O₃-related (non-accidental) mortality in Detroit based on Bell et al. (2004), which used a 24-hr
10 average indicator, ranged from 0.2% (based on 95 city model) to 0.4% of total incidence (based
11 on single-city model). In contrast, the estimated O₃-related (non-accidental) mortality in Detroit
12 based on Schwartz (2004), which used a 1-hr maximum O₃ concentration as the indicator, ranged
13 from 0.7% (based on 14 city model) to 1.4% (based on single-city model).

14 Figures 5-4a and b show the estimated annual percent of non-accidental mortality
15 associated with short-term exposure to O₃ concentrations within specified ranges for the warm
16 O₃ season (April 1 to September 30) in two recent years. While the current O₃ standard is
17 expressed in terms of an 8-hr daily maximum indicator, the large multicity non-accidental (Bell
18 et al. (2004) and cardiorespiratory (Huang et al. (2004) mortality studies reported concentration-
19 response relationships for 24-hr average O₃ levels. Thus, the intervals shown in this figure are
20 for 24-hr average concentrations. To provide some perspective on the 24-hr intervals shown,
21 scatter plots comparing 8-hr daily maximum concentrations at the highest monitor with the
22 average of the 24-hr average over all monitors within an urban area were developed and are
23 included in Appendix 5A.2. These scatter plots show that 8-hr daily maximum concentrations on
24 average are roughly twice the observed 24-hr average levels, although there is considerable
25 variability in this relationship from day-to-day within an urban area. There also is some
26 variability in this relationship between 8-hr daily maximum and 24-hr average levels across the
27 12 urban areas.

28 As shown in Figure 5-4a, in 2004, all O₃-related non-accidental mortality was associated
29 with O₃ concentrations less than 0.06 ppm, 24 hr average, and most of that was associated with
30 O₃ concentrations less than 0.04 ppm, 24-hr average. As shown in Figure 5-4b, in 2002, all O₃-
31 related non-accidental mortality was associated with O₃ concentrations less than 0.08 ppm, 24-hr
32 average and the great majority was associated with O₃ concentrations less than 0.06 ppm, 24-hr
33 average. The results for cardiorespiratory mortality follow a similar pattern and are included in
34 the draft Risk Assessment TSD.

35

5.4.2 Just Meeting Current and Alternative O₃ Standards

As described in Chapter 4 and briefly in section 5.3.2.2, the risk estimates described in this section represent the risks for two separate O₃ seasons based on adjusting the O₃ levels observed in 2004 or 2002 to simulate O₃ levels associated with just meeting the current 0.08 ppm standard and several potential alternative 8-hr standards, using the 3-year design value from the 2002-2004 time period. To facilitate comparison of risk estimates across the 12 urban areas, figures used in this section present summaries of the risk estimates for the current and potential alternative 8-hr daily maximum standards using the current average 4th daily maximum 8-hr average form of the standard. Risk estimates for three additional alternative 8-hr standards (0.084 ppm, using an average 3rd daily maximum 8-hr average and 0.074 ppm using an average 3rd daily maximum 8-hr average form) are included in the tables in the draft Risk Assessment TSD. Because we had to simulate the profiles of O₃ concentrations that just meet the current and alternative 8-hour daily maximum O₃ standards in each location, there is additional uncertainty surrounding estimates of the reduced incidence associated with O₃ concentrations that just meet these O₃ standards.

This section first discusses the risk estimates for lung function responses, which are based on exposure-response relationships derived from controlled human exposure studies, and then risk estimates are explored for respiratory symptoms in asthmatic children, respiratory-related hospital admissions, and premature mortality which are based on concentration-response relationships obtained from epidemiological studies.

The risk estimates for lung function responses are for the O₃ season, which is all year in 3 of the study areas (Houston, Los Angeles, and Sacramento) and which is generally 6-7 months long in the other 9 urban study areas (e.g., April to September or October). The risk estimates for lung function responses in “active” school age children (ages 5 to 18) for just meeting the current 8-hr standard for 12 urban areas are summarized in Tables 5-5 and 5-6 presented in the previous section. Additional risk estimates for all school age children are presented in the draft Risk Assessment TSD.

In terms of total occurrences of FEV₁ decrement \geq 15% during the O₃ season, Table 5-6 shows a range of median estimates from 5,000 to nearly 60,000 responses during the O₃ season for “active” school age children based on adjusting 2004 air quality data to just meeting the current 8-hour standard and from 14,000 to nearly 200,000 responses across the 12 urban areas associated with adjusting 2002 O₃ concentrations to just meeting the current 8-hour standard. For FEV₁ decrement \geq 20% during the O₃ season, Table 5-6 shows a range of median estimates for “active” school age children across the 12 urban areas from 0 to 3,000 responses and from

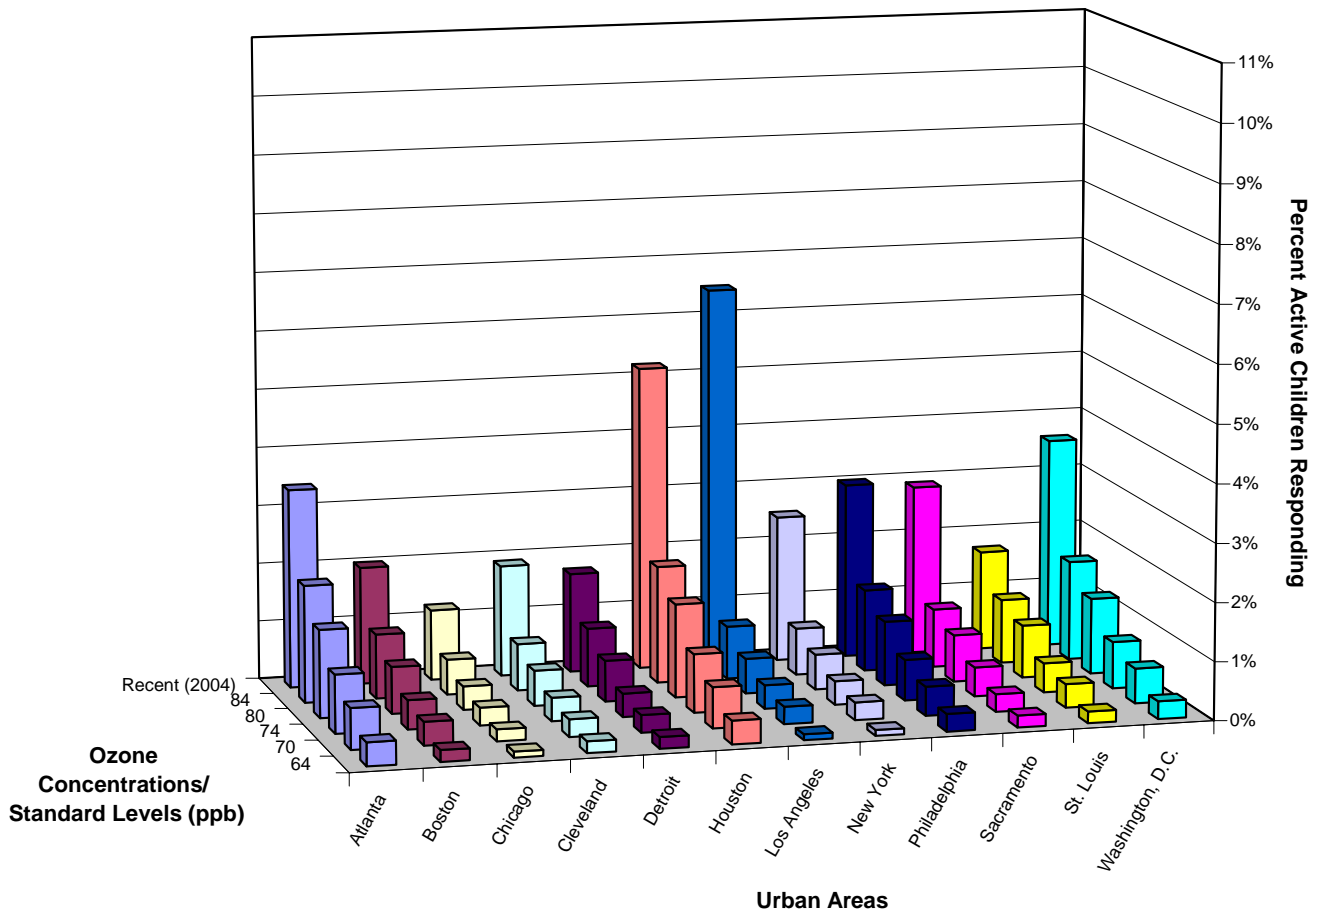

1 1,000 to 29,000 responses based on adjusting 2004 and 2002 air quality data, respectively, to just
2 meeting the current 8-hour standard.

3 Figures 5-5 shows the median estimates of the percent of “active” school age children
4 estimated to experience at least one FEV₁ decrement $\geq 15\%$ during the O₃ season across the 12
5 urban areas for recent air quality (2004) and upon just meeting the current and several alternative
6 8-hr standards. Figure 5C-1 in Appendix 5C of this Staff Paper shows a similar figure based on
7 2002 air quality data. For just meeting the current 8-hr standard the ranges of median estimates
8 across the 12 urban areas are 0.6-2% based on adjusting 2004 air quality data and 0.9-5.8%
9 based on adjusting 2002 air quality data. The ranges in median estimates of the percent of
10 “active” school age children estimated to experience at least one FEV₁ decrement $\geq 20\%$ during
11 the O₃ season across these same 12 urban areas are 0-0.4% and 0.1-1.9%, based on adjusting
12 2004 and 2002 air quality data, respectively.

13 As an illustration, the median estimate for the number of “active” school age children
14 estimated to experience FEV₁ decrements $\geq 15\%$ under the current standard ranges from 2,000 to
15 15,000 children per urban area across the 12 urban areas and this would be reduced to a range of
16 0 to 3,000 children under the most stringent alternative standard examined (i.e., 0.06 ppm,⁴
17 daily 8-hr maximum) Somewhat higher estimates are observed based on adjusting 2002 air
18 quality to just meet the current and alternative 8-hr standards (see Table 5C-3 in the Appendix).
19 By comparing the estimated number of occurrences shown in Tables 5C-1 and 5C-3 with the
20 number of “active” children estimated to experience 1 or more responses shown in Tables 5C-5
21 and 5C-6, one can get an estimate of the average number of occurrences of a given response in
22 an O₃ season. For example, for Atlanta it is estimated that 9,000 “active” children would have an
23 FEV₁ decrement $\geq 15\%$ and that there would be 27,000 occurrences of this response in this same
24 population when 2004 air quality is adjusted to just meet the current 8-hr standard. Thus, on
25 average it is estimated that there would be 3 occurrences per O₃ season per responding child for
26 air quality just meeting the current 8-hr standard in this urban area. We recognize that some
27 children in the population might have only 1 or 2 occurrences and some might have more than 3
28 per O₃ season.

29 Figure 5-6a and b shows the 95% confidence intervals for the lung function risk estimates
30 for each of the 12 urban areas using the FEV₁ decrement $\geq 15\%$ health response for recent O₃
31 levels (2004) and for 2004 air quality adjusted to just meet the current and alternative 8-hr
32 average 4th daily maximum standards. A comparable figure (Figure 5C-2a,b) using 2002 air
33 quality and adjusting 2002 air quality to just meet the current and alternative 8-hr standards is
34 included in Appendix 5C.

 5 **Location-Specific O₃ Seasons (Based on Adjusting 2004 Air Quality)**
 6

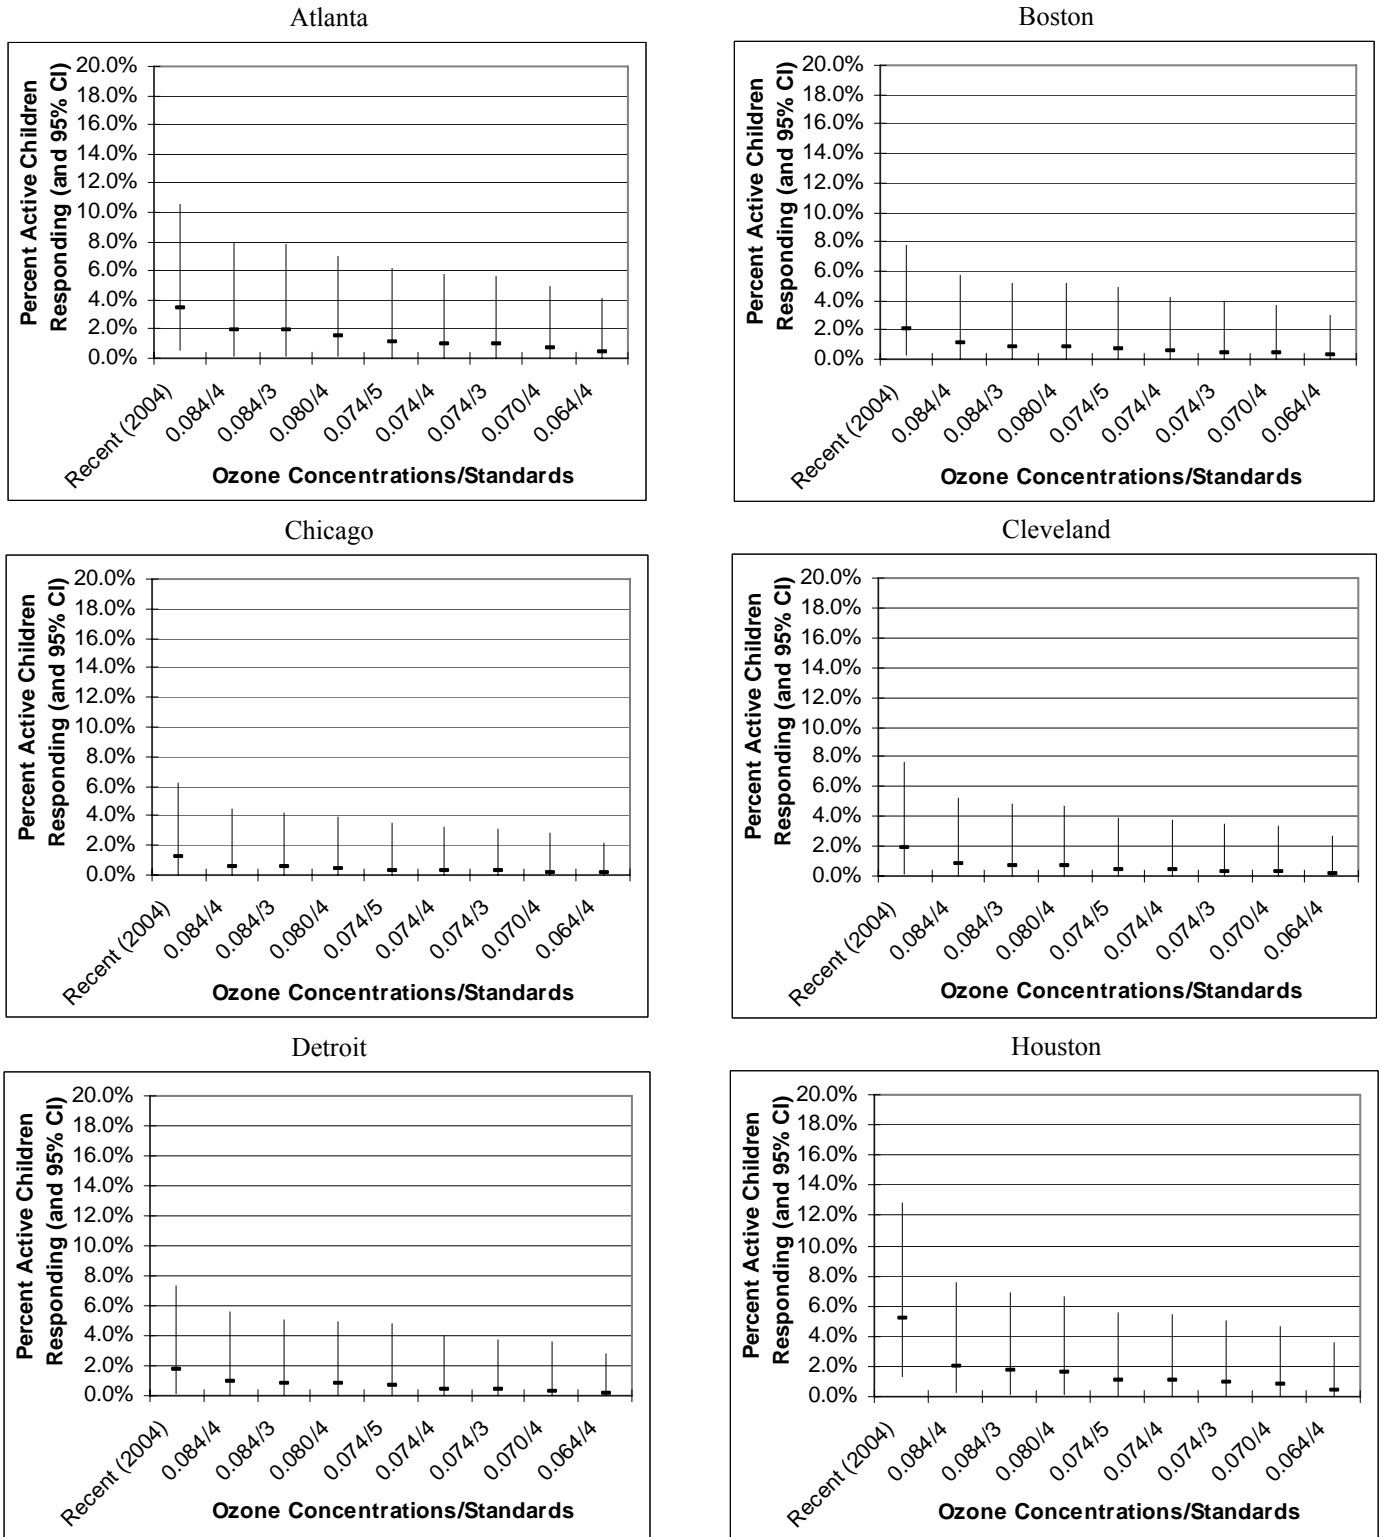

1 Figure 5-7 summarizes respiratory symptom response risk estimates associated with O₃
2 exposures during the April to September period for moderate/severe asthmatic children ages 0 to
3 12 in the Boston urban area based on the concentration-response relationships reported in Gent et
4 al. (2003) for 2004 air quality and the current and alternative 8-hr standards based on adjusting
5 2004 air quality data. Figure 5C-3 (Appendix 5C) presents comparable estimates associated with
6 2002 air quality and just meeting the current and alternative 8-hr standards based on adjusting
7 2002 air quality data. These figures includes risk estimates for chest tightness based on single
8 pollutant models and models that included PM_{2.5}. Two additional symptom endpoints, shortness
9 of breath and wheeze are included in the tables in the draft Risk Assessment TSD and show
10 similar patterns as the risk estimates for chest tightness.

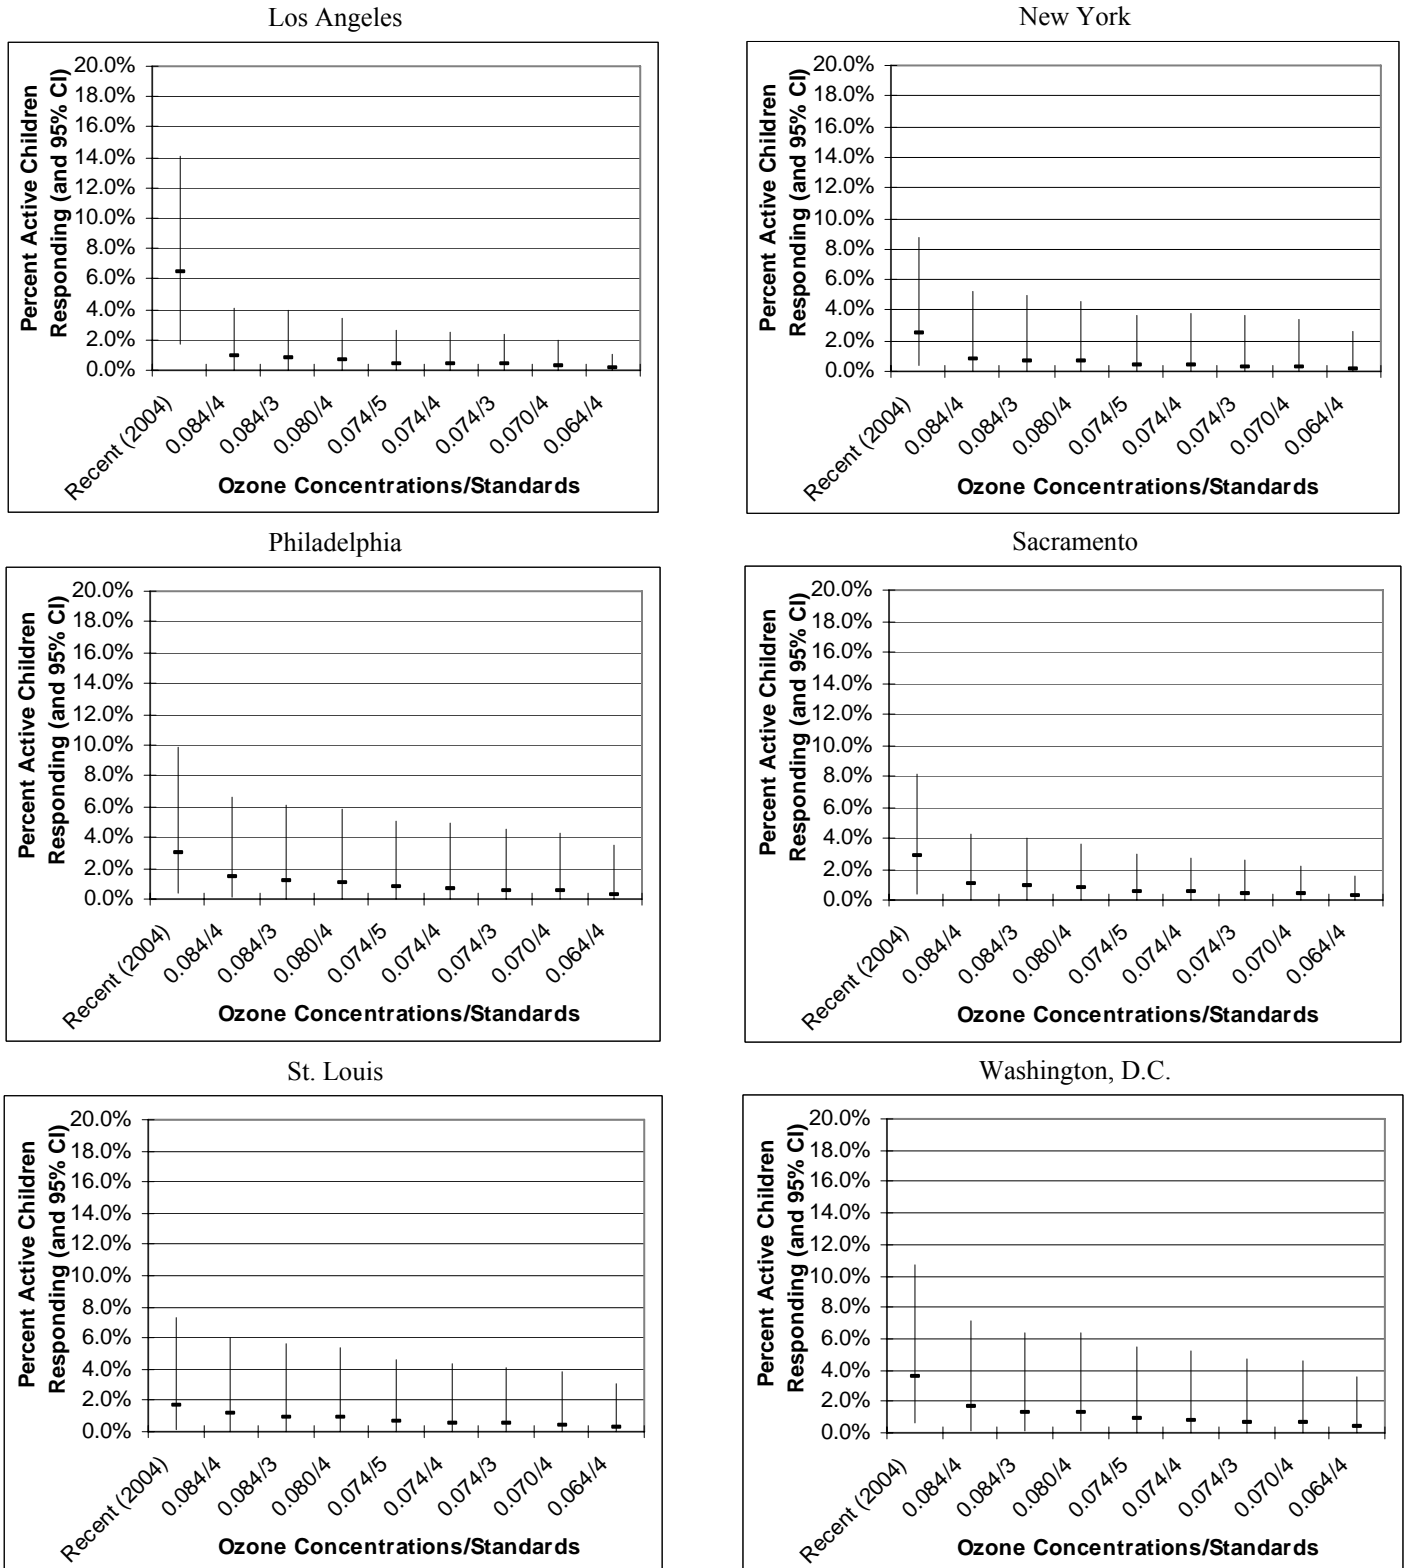

11 The median estimated number of days involving chest tightness (using the concentration-
12 response relationship with only O₃ in the model) ranges from 4,500 (based on adjusting 2004 air
13 quality) to 6,100 (based on adjusting 2002 air quality) upon meeting the current 8-hr standard
14 and these are reduced to 3,100 (based on adjusting 2004 air quality) to 4,600 days upon meeting
15 the most stringent alternative examined (0.064 ppm, 4th daily maximum 8-hr average). These
16 same ranges correspond to 8 to 11% of total incidence of chest tightness upon meeting the
17 current 8-hr standard and to about 5.5 to 8% of total incidence of chest tightness upon meeting a
18 0.064 ppm, 4th daily maximum 8-hr average standard. As shown in Tables 5C-7 and 5C-9
19 (Appendix 5C), the symptom with the greatest incidence is wheeze and is based on an O₃
20 concentration-response relationship that included PM_{2.5} in the model. These median estimates
21 range from about 13,000 days with wheeze (based on adjusting 2004 air quality) to nearly 18,000
22 days (based on adjusting 2002 air quality) upon meeting the current 8-hr standard and these
23 estimates are reduced to 9,000 (based on adjusting 2004 air quality) to about 13,000 (based on
24 adjusting 2002 air quality) upon meeting a 0.064 ppm, 4th daily maximum 8-hr average standard.
25 Confidence intervals, based on statistical uncertainty reflecting sample size considerations for
26 incidence and percent of total incidence are shown in Tables 5C-7 through 5C-10 (Appendix 5C)
27 based on adjusting 2004 and 2002 air quality.

28 Figure 5-8 summarizes unscheduled hospital admission risk estimates for respiratory
29 illness and asthma in New York City associated with short-term exposures to O₃ concentrations
30 in excess of background levels from April through September under recent air quality and when
31 the current and alternative 8-hr standards are just met based on adjusting 2004 and 2002 air
32 quality data, respectively. For total respiratory illness, Figure 5-8 shows about 4.6 cases per
33 100,000 relevant population, which represents 1% of total incidence or 366 cases when 2004 O₃
34 levels are adjusted to just meet the current 8-hr standard. For asthma-related hospital
35 admissions, which are a subset of total respiratory illness admissions, the estimates are about 3.9
36 cases per 100,000 relevant population, which represents about 2.4% of total incidence or 313

5 (Based on Gent et al., 2003)

38 *95% confidence intervals associated with these risk estimates are provided in Table 5C-5 of the Appendix.

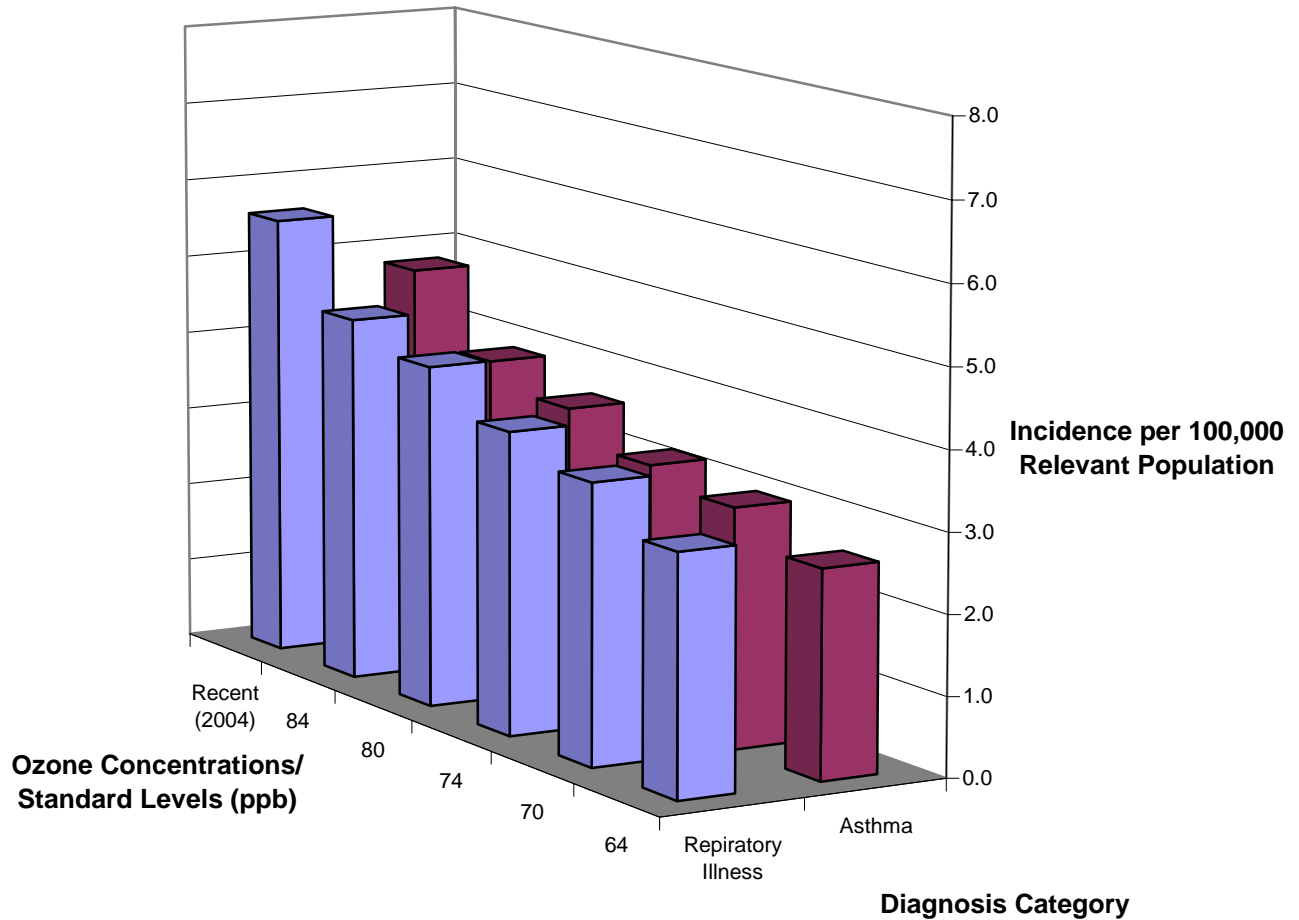

1 cases for this same air quality scenario. For increasingly more stringent alternative 8-hr
2 standards, Figure 5-8 shows a gradual reduction in the cases per 100,000 relevant population
3 from 4.6 cases per 100,000 upon just meeting the current 8-hr standard to about 3.0 cases per
4 100,000 under the most stringent 8-hr standard (i.e., 0.064 ppm, average 4th daily maximum)
5 analyzed. The comparable estimates based on adjusting 2002 air quality are shown in Figure 5C-
6 4 (Appendix 5C) and are somewhat higher, but show a similar pattern of gradual reduction.
7 Confidence intervals, based on statistical uncertainty reflecting sample size considerations for
8 incidence, incidence per 100,000 relevant population, and percent of total incidence are shown in
9 Tables 5C-11 and 5C-12 (Appendix 5C) based on adjusting 2004 and 2002 air quality data to just
10 meet the current and potential alternative standards.

11 Additional respiratory-related hospital admission estimates for three other locations are
12 provided in the draft Risk Assessment TSD. We note that the concentration-response functions
13 for each of these locations examined different outcomes in different age groups (e.g., > age 30 in
14 Los Angeles, >age 64 in Cleveland and Detroit, vs. all ages in New York City), making
15 comparison of the risk estimates across the areas very difficult. For hospital admissions in
16 Detroit, none of the estimates were statistically significant and the median estimates were
17 negative for 0- and 1-day lags and small but positive for 2- and 3-day lags for COPD-related and
18 pneumonia hospital admissions.

19 Figure 5-9 summarizes the results of the assessment of the reduced non-accidental
20 mortality risks associated with O₃ concentrations above background that just meet the current
21 and several potential alternative 8-hr daily maximum standards across the 12 urban areas for air
22 quality adjusted based on 2004 air quality data. The risk estimates in this figure are based on the
23 95-city function reported in Bell et al. (2004) for non-accidental mortality. Additional risk
24 estimates for cardiorespiratory mortality are included in the draft Risk Assessment TSD for 8 of
25 the 12 urban areas. Also, Figure 5C-5 (Appendix 5C) shows comparable risk estimates based on
26 adjusting 2002 air quality data. Figure 5-9 shows the annual median risk estimates for recent air
27 quality and for just meeting alternative 8-hr standards based on the O₃ coefficients estimated in
28 the studies. Ranges reflecting the statistical uncertainty, taking into account sample size
29 considerations, based either on the 95 percent confidence intervals around those estimates (if the
30 coefficients were estimated using classical statistical techniques) or on the 95 percent credible
31 intervals (if the coefficients were estimated using Bayesian statistical techniques) are presented
32 in Tables 5C-13 through 5C-16 (Appendix 5C) and in the draft Risk Assessment TSD.

 4 **al., 2004 – 95 U.S. Cities Function), Based on 2004 Ozone Concentrations**

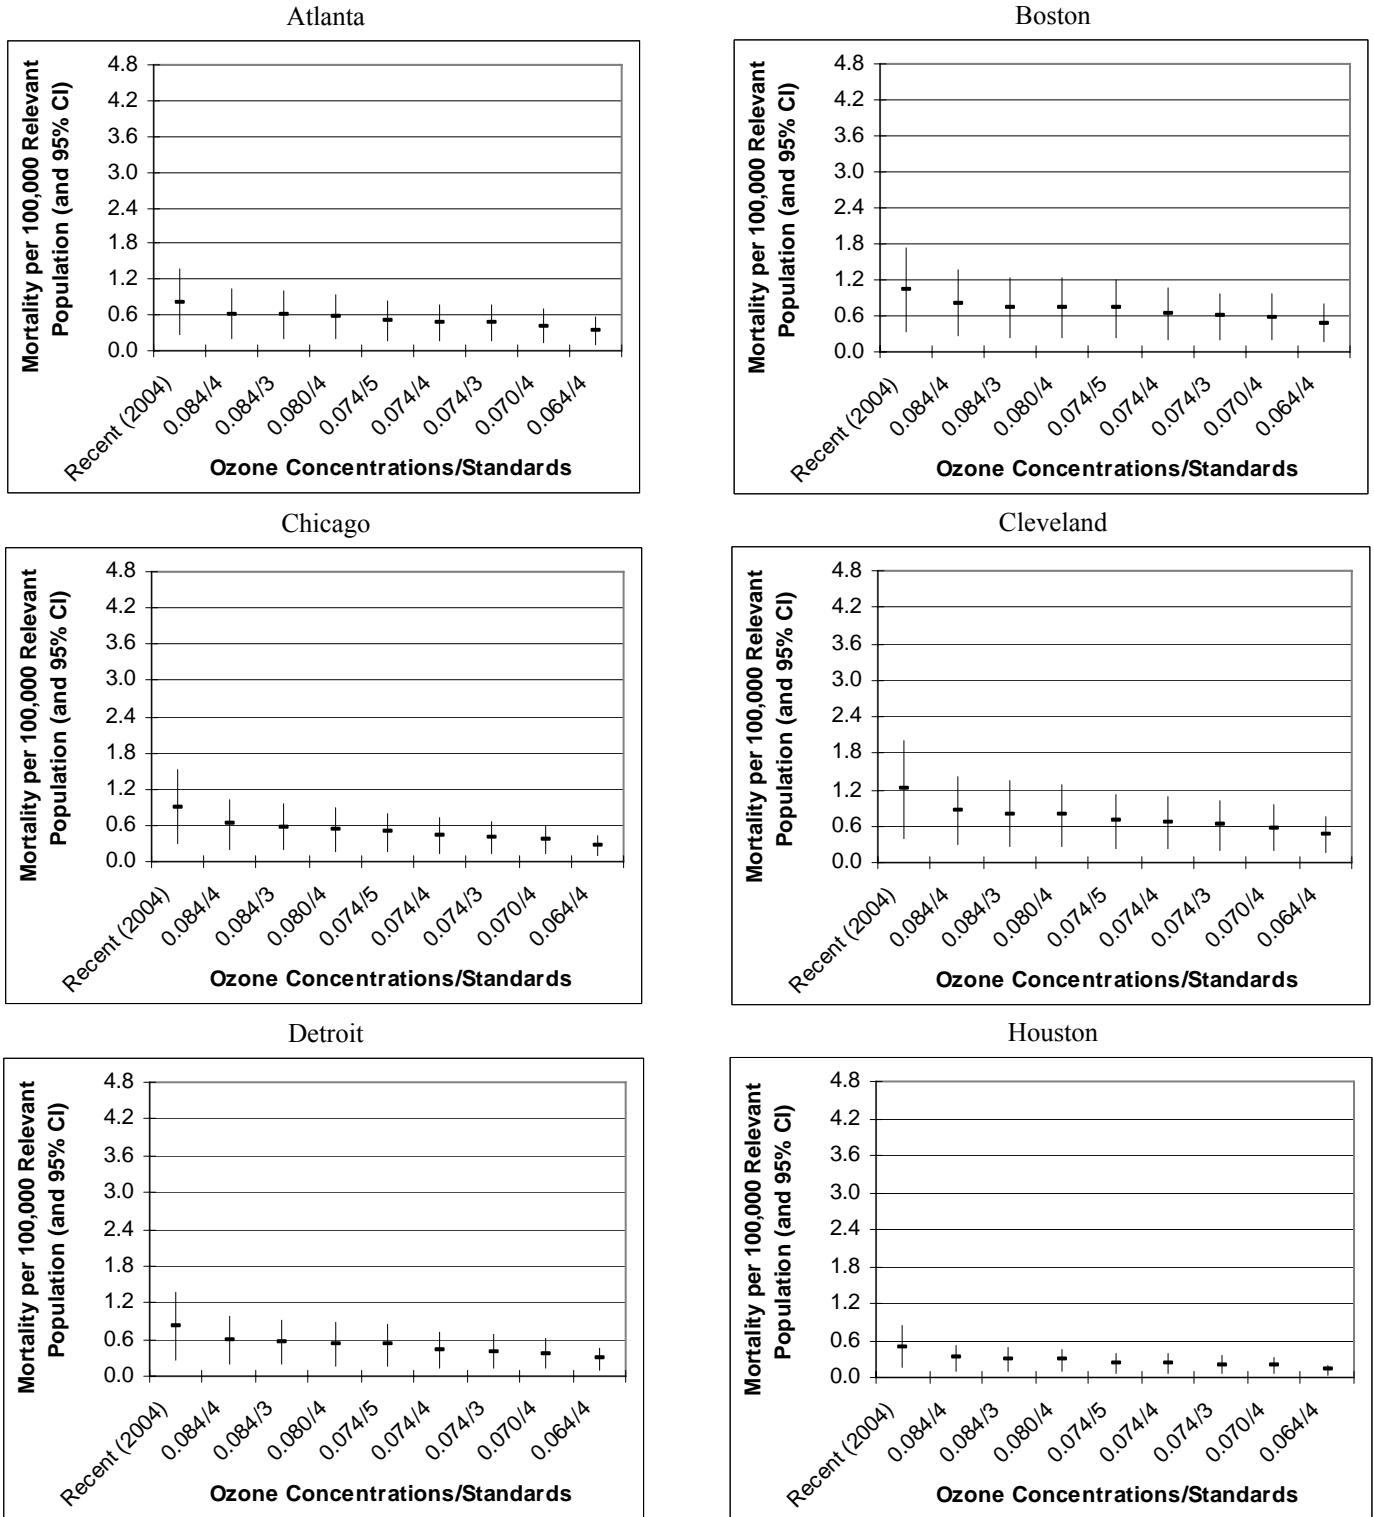

31
 32 *95% confidence intervals associated with these risk estimates are provided in Table 5C-13 of Appendix 5C and
 33 Figure 5-10a,b
 34 .

1 Figures 5-10a and b show the median estimates and 95% credible intervals for each of the
2 12 urban areas for non-accidental mortality based on the 95-cities concentration-response
3 function in Bell et al. (2004). Figure 5C-6a,b (Appendix 5C) present the comparable figure for
4 2002 air quality and just meeting alternative standards based on adjusting 2002 air quality data.
5 For example, Figure 5-10a shows a median risk estimate associated with just meeting the current
6 8-hr standard for non-accidental mortality in Atlanta is around 0.2% of total incidence and the
7 95% credible interval is < 0.1% to about 0.3% of total incidence. While the 95% credible
8 intervals get progressively smaller as one considers more stringent standards, as
9 discussed previously these credible intervals do not consider overall model uncertainty (e.g.,
10 whether or not the shape of the concentration-response relationship is best represented by a log
11 linear relationship versus a more sigmoidal shape, particularly at lower O₃ concentration levels).

12 The results in this portion of the risk assessment across the 12 urban areas follow the
13 same patterns as the results discussed in section 5.4.1 for risks associated with recent year O₃
14 concentrations, because they are largely driven by the same concentration-response function
15 coefficient estimates and confidence or credible intervals. While there is a noticeable reduction
16 in the median risk estimates in some of the urban areas between that associated with a recent
17 year of air quality and just meeting the current 8-hr standard, the reductions associated with
18 progressively more stringent alternative 8-hr standards are more modest. The range of median
19 estimates associated with O₃ upon just meeting the current standard is 0.3 to 1.2 cases per
20 hundred thousand relevant population across the 12 urban areas and this range is reduced to 0.2
21 to 0.7 cases per 100,000 relevant population upon just meeting the most stringent alternative
22 standard analyzed (0.064 ppm, average 4th daily maximum 8-hr average) We also note that the
23 risk estimates expressed in terms of incidence per 100,000 population are noticeably smaller for
24 Houston based on both 2002 and 2004 air quality data and for Los Angeles based on 2002 air
25 quality, especially upon just meeting the current or alternative 8-hr standards than the other
26 urban areas. The risk estimates are notably higher in most of the urban areas for 2002 air quality
27 data and air quality data simulated to just meet the current and alternative standards based on
28 adjusting 2002 data.

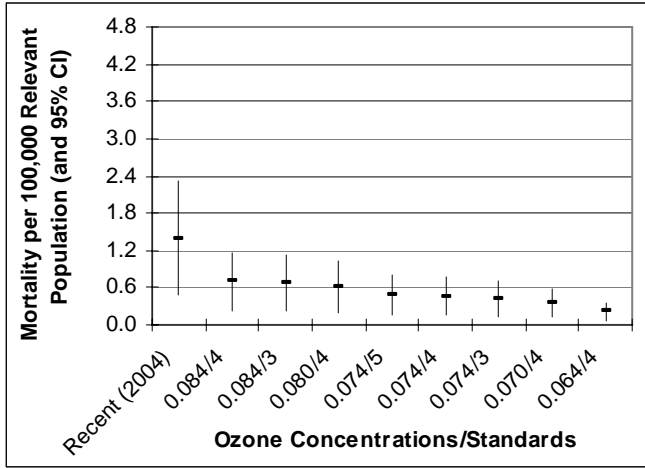

29 As shown in Table 5C-9 and 5C-10 in the Appendix to this Chapter, estimated O₃-related
30 (non-accidental) mortality reported by Schwartz (2004) for Chicago, Detroit, and Houston, based
31 on both the single-city and the multi-city concentration-response functions, tend to be higher
32 than the Bell et al. (2004) estimates in those locations in large part because Schwartz used the 1-
33 hr maximum O₃ concentration, rather than the 24-hr average, as the exposure metric. The
34 changes from 1-hr maximum O₃ concentrations that just meet the current 8-hr O₃ standard to

Los Angeles

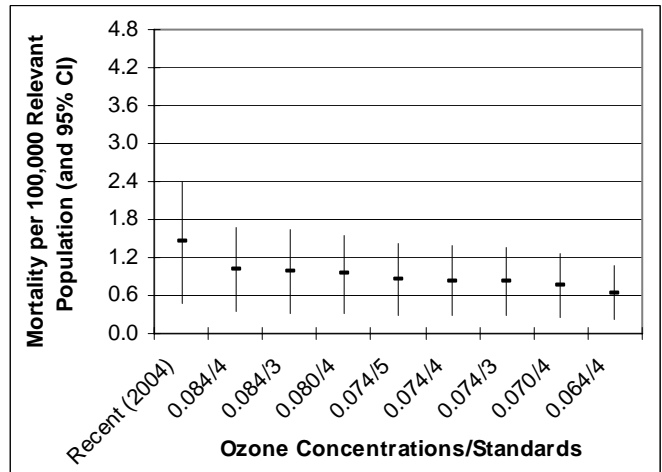

New York

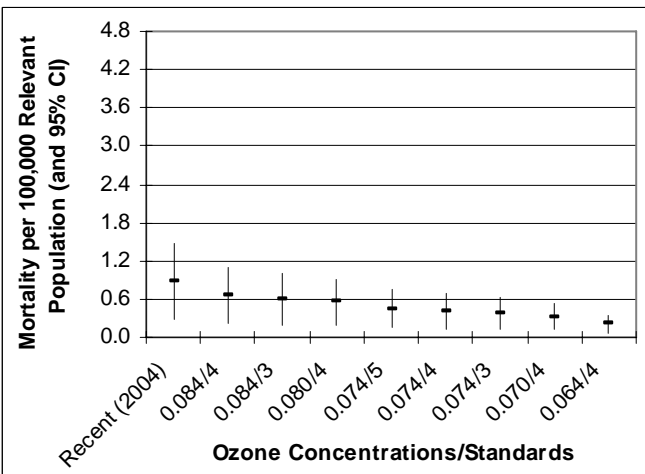

Philadelphia

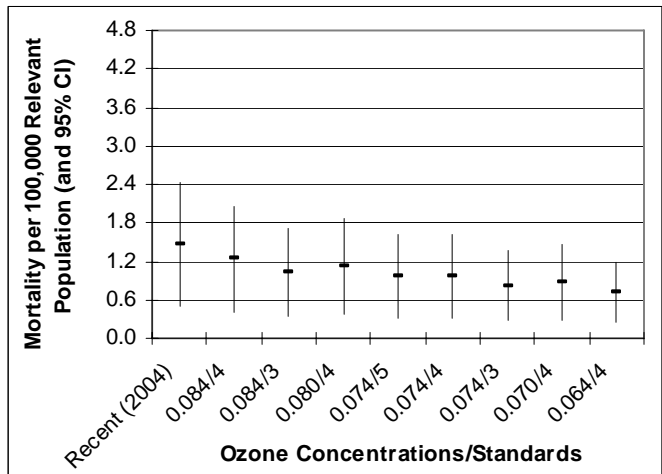

Sacramento

St. Louis

Washington, D.C.

1 background 1-hr maximum O₃ concentrations were generally larger in these assessment locations
2 than the corresponding changes using the 24-hr average metric.

3 Figure 5-11a and b shows the estimated annual percent of non-accidental mortality
4 mortality associated with short-term exposure to O₃ concentrations that just meet the current 8-
5 hour daily maximum standard that fall within specified ranges. The pattern of results is similar
6 to the pattern seen for recent year O₃ concentrations discussed in section 5.4.1. Using simulated
7 O₃ concentrations that just meet the current 8-hour standard based on 2004 air quality data, all
8 O₃-related non-accidental mortality was associated with O₃ concentrations less than 0.06 ppm,
9 24-hr average and most of that was associated with O₃ concentrations less than 0.04 ppm, 24-hr
10 average. Using simulated O₃ concentrations that just meet the current 8-hour standard based on
11 2002 air quality data, all O₃-related non-accidental mortality was associated with O₃
12 concentrations less than 0.08 ppm, 24-hr average and the great majority was associated with O₃
13 concentrations less than 0.06 ppm, 24-hr average. The results for cardiorespiratory mortality
14 follow a similar pattern. As discussed in section 5.4.1, scatter plots comparing 8-hr daily
15 maximum concentrations at the highest monitor with the average of the 24-hr average over all
16 monitors within an urban area were developed and are included in Appendix 5A.2 to provide
17 some perspective on the 24-hr intervals shown. These scatter plots show that 8-hr daily
18 maximum concentrations on average are roughly twice the observed 24-hr average levels,
19 although there is considerable variability in this relationship from day-to-day within an urban
20 area. There also is some variability in this relationship between 8-hr daily maximum and 24-hr
21 average levels across the 12 urban areas.

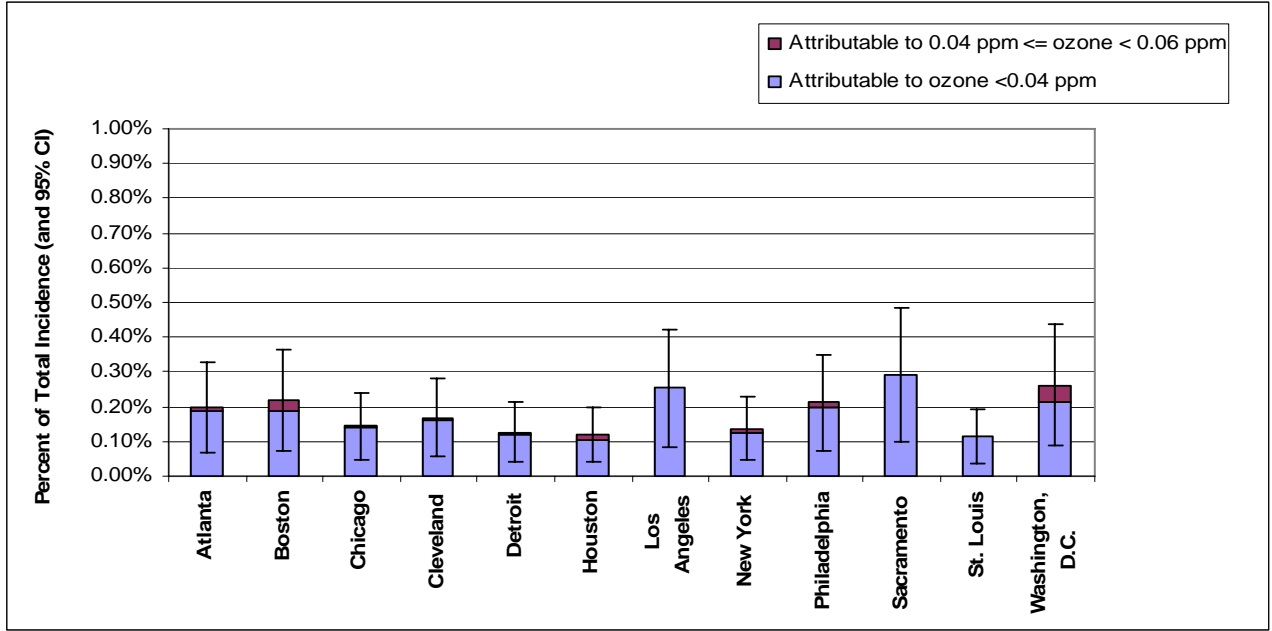

22 **5.4.3 Comparison with Risk Estimates from Prior Review**

23 As noted in section 5.1.1, EPA conducted a health risk assessment during the prior O₃
24 NAAQS review. For two of the health endpoints, lung function (FEV₁) decrements and
25 respiratory-related and asthma hospital admissions it is possible to do some limited comparison
26 between the estimates generated for the current review and previous estimates. The other two
27 health endpoints included in the current risk assessment, respiratory symptoms in
28 moderate/severe asthmatic children and non-accidental and cardiorespiratory mortality are based
29 on more recent scientific studies and, were not included in the prior review.

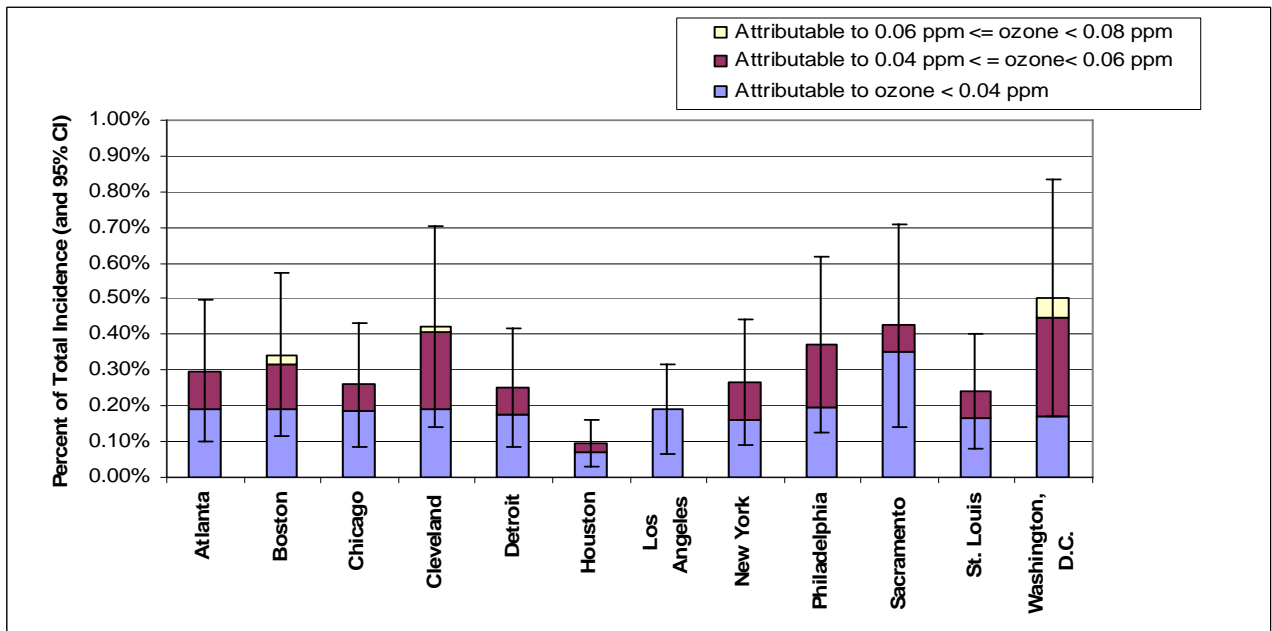

30 The lung function risk estimates developed for the current and prior review are based on
31 exposure distributions generated by running O₃ exposure models and exposure-response
32 relationships developed using the available controlled human exposure studies data. There have
33 been significant changes in the exposure model between the prior and current review. As

 4 **Total and Contribution of 24-Hour O₃ Ranges**
 5

6 **Figure 5-11a. Based on Adjusting 2004 Air Quality Data**

23 **Figure 5-11b. Based on Adjusting 2002 Air Quality Data**

1 discussed in Chapter 4, the estimated 8-hr exposures for children engaged in moderate exertion
2 associated with just meeting the current 8-hr standard from the new analysis range from being
3 roughly similar (using the estimates based on adjusting 2002 air quality data) to significantly
4 lower than (using the estimates based on adjusting 2004 air quality data) the most comparable
5 exposure estimates developed during the prior review.

6 For the 6 urban areas included in both the current and prior assessments, the median risk
7 estimates for lung function response, using FEV₁ decrements $\geq 15\%$ as an example, are
8 considerably lower in the current risk assessment associated with just meeting the current 8-hr
9 standard than in the assessment conducted for the prior review. The main reason for the lower
10 risk estimates is the change in the shape of the exposure-response relationship from a linear
11 relationship to one that is sigmoidal or s-shaped. During the prior review we only had data
12 available for 3 exposure levels (0.08, 0.10, and 0.12 ppm) for 6.6 hour exposures under moderate
13 exertion. With the addition of more recent data including observations at 0.04 and 0.06 ppm, as
14 well as providing additional data at 0.08 ppm, a 3-parameter logistic function provides a very
15 good fit to the available data. As one can see from Figure 5-12, there is a considerable difference
16 in the estimated fraction of the population that is expected to have FEV₁ decrements $\geq 15\%$
17 between the two exposure-response relationships and this difference has the effect of
18 significantly lowering the risk estimates relative to the estimates provided during the prior
19 review. For example, comparing the aggregate estimates for 6 urban areas (Houston, Los
20 Angeles, New York, Philadelphia, St. Louis, and Washington, DC.) using the quadratic air
21 quality adjustment procedure for “outdoor” children resulted in a median estimate of about 5.6%
22 experiencing 1 or more FEV₁ decrements $\geq 15\%$ associated with meeting the current 8-hr,
23 average 4th daily max standard. This contrasts with about 3% of “active” children estimated to
24 have this same response associated with meeting the current 8-hr standard in the current risk
25 assessment. We note that the definitions of “outdoor” and “active” children are not the same;
26 “outdoor” children represented about 47% of 6 to 13 year olds and 31% of 14 to 18 year olds in
27 the prior assessment compared to “active” children representing about 50% of 5 to 18 year olds
28 in the current assessment. The fact that a lower range of background values is used based on the
29 predictions from the GEOS-CHEM model (see discussion in section 2.7) in the current review
30 (i.e., background ranges from 0.015 to 0.035 ppm) compared to a fixed 0.04 ppm value used in
31 the prior review would tend to increase the estimated risk in excess of background. The
32 influence of changing the shape of the exposure-response relationship has a greater overall
33 impact than the change in estimated background levels, and thus, we observe lower risk
34 estimates for this health endpoint in the current assessment.

35 We note that the current estimates for O₃-related hospital admissions for respiratory
36 illness and asthma for New York City are higher than the estimates in the risk assessment

1 conducted during the prior O₃ NAAQS review. Both the prior and current assessments used the
2 same concentration-response functions for these health outcomes. The main reason for higher
3 estimates in the current assessment is the use of a single value of 0.04 ppm for background in the
4 prior review which is higher than the current modeled values for background in the current
5 assessment which are in the range of about 0.015 to 0.035 ppm. Thus, under the current risk
6 assessment O₃ levels above background but below 0.04 ppm are contributing additional
7 estimated cases that were not included in the assessment for the prior O₃ NAAQS review.

8 **5.4.4 Key Observations**

9 In considering the quantitative estimates from the risk assessment the limitations and
10 uncertainties associated with the risk estimates discussed in section 5.3.1.4 for lung function
11 decrements and section 5.3.2.5 for respiratory symptoms, hospital admissions, and pre-mature
12 mortality should be kept in mind. It is also important to consider the degree of confidence about
13 the extent to which O₃ is causally related to each of the effects for which risk estimates were
14 produced (see section 3.7.5). For example, there is clear and convincing evidence of causality
15 for lung function decrements in healthy children under moderate exertion for 8-hr average O₃
16 exposures. We also judge that there is strong evidence for a causal relationship between
17 respiratory symptoms in asthmatic children and O₃ exposures and between hospital admissions
18 for respiratory causes and ambient O₃ exposures. In contrast, there is greater uncertainty and
19 somewhat less confidence about the relationship between O₃ and non-accidental and
20 cardiorespiratory mortality, although the CD's overall evaluation is that it is highly suggestive
21 that this relationship exists.

22 ***Recent O₃ Air Quality Levels***

23 Section 5.4.1 has presented risk estimates associated with two recent years of air quality
24 as represented by 2002 and 2004 monitoring data. Presented below are key observations
25 resulting from this part of the risk assessment.

- 26 • The ranges in median estimates of the number of “active” school age children (ages 5-18)
27 estimated to experience at least one FEV₁ decrement \geq 15% due to 8-hr O₃ exposures
28 during the O₃ season across the 12 urban areas are 4,000 to 105,000 (based on 2004 air
29 quality) and 9,000 to 155,000 (based on 2002 air quality). In terms of percent of this
30 population the ranges in median estimates are 1.2 to 6.5% (based on 2004 air quality) and
31 5.3 to 10.4% (based on 2002 air quality). In terms of estimated occurrences of this same
32 response the ranges in median estimates are 15,000 to about 500,000 (based on 2004 air
33 quality) and 37,000 to about 470,00 (based on 2002 air quality). The average number of
34 occurrences per “active” child in an O₃ season ranged from about 2.5 to 5 (based on 2004
35 air quality) and from about 2 to 4 (based on 2002 air quality).
36
- 37 • Estimates for increased respiratory symptoms (i.e., chest tightness, shortness of breath,
38 and wheeze) in asthmatic children (ages 0-12) who used maintenance medications were

1 only developed for the Boston urban area. The ranges in median estimates of symptom
2 days for these three health outcomes are about 5,000 to 15,000 (based on 2004 air
3 quality) and about 7,000 to 20,000 (based on 2002 air quality). In terms of percent of
4 total incidence for these three health outcomes the ranges in median estimates are about 8
5 to 14% (based on 2004 air quality) and about 11 to 20% (based on 2002 air quality).
6

- 7 • Estimates for respiratory-related hospital admissions (e.g., asthma-related) were
8 developed for three urban areas (New York, Los Angeles, and Detroit). The median
9 estimates for New York are about 380 (based on 2004 air quality) and about 520 (based
10 on 2002 air quality) O₃-related excess hospital admissions for asthma. For 2004 and
11 2002 air quality, these estimates represent about 3 and 4%, respectively, of total
12 incidence.
13
- 14 • The risk assessment included a variety of estimates based on single- and multi-city
15 studies for non-accidental and cardiorespiratory mortality. Since the median estimates
16 from single-city and multi-city studies and models were generally of similar magnitude,
17 with a few notable exceptions, we have focused on the estimates based on the multi-city
18 studies to compare risk estimates across the 12 urban areas. The median estimates for
19 incidence for non-accidental mortality (based on Bell et al., 2004 – 95 cities
20 concentration-response function) range from about 3 to 130 (based on 2004 air quality)
21 which is about 0.2 to 0.4% of total incidence. These same estimates based on 2002 air
22 quality range from about 10 to 110 which is about 0.2 to 0.6% of total. Estimates of O₃-
23 related non-accidental mortality reported by Schwartz (2004) for Chicago, Detroit, and
24 Houston, based on both single city and multi-city concentration-response functions, are
25 somewhat higher than other estimates for these locations. This is mainly due to the use
26 of the 1-hr maximum O₃ concentration in Schwartz (2004), rather than the 24-hr average,
27 as the exposure metric.
28
- 29 • Examining the contribution of various O₃ ranges to these non-accidental mortality
30 estimates, we found all of the mortality was associated with 24-hr average concentrations
31 less than 0.06 ppm and most of it was associated with concentrations less than 0.04 ppm
32 for 2004 air quality. For 2002, all of the O₃-related non-accidental mortality was
33 associated with 24-hr average concentrations less than 0.08 ppm and the great majority
34 was associated with concentrations less than 0.06 ppm. Based on an examination of O₃
35 air quality relationships between 24-hr average concentrations average over the urban
36 monitors in an urban area on a given day and the daily maximum 8-hr average on the
37 corresponding day, we note that the 8-hr daily maximum concentrations are on average
38 about twice the 24-hr average level. So, for example, a range of 0.04 to 0.06 ppm, 24-hr
39 average corresponds with roughly daily maximum 8-hr levels in the range 0.08 to 0.12
40 ppm measured at the highest fixed-site monitor within an urban area.
41

42 ***Meeting the Current and Alternative 8-hr Standards***

43
44 Section 5.4.2 has presented risk estimates associated with just meeting the current and
45 several potential alternative 8-hr standards based on adjusting 2004 and 2002 monitoring data

1 using design values for the 2002-2004 time period. Presented below are key observations
2 resulting from this part of the risk assessment.

- 3
- 4 • In comparing risk estimates for alternative standards, uncertainties in quantifying the
5 health risks associated ambient O₃ concentrations would be expected to remain relatively
6 constant in different models. Thus, we have greater confidence in relative comparisons
7 in risk estimates between alternative standards than in the absolute magnitude of risk
8 estimates associated with any particular standard.
- 9
- 10 • Significant year-to-year variability in O₃ concentrations combined with the use of a 3-
11 year design value to determine the amount of air quality adjustment to be applied to each
12 year analyzed, results in significant year-to-year variability in the annual health risk
13 estimates associated with just meeting the current and potential alternative 8-hr standards.
14
- 15 • The ranges in median estimates of the number of “active” school age children (ages 5-18)
16 estimated to experience at least one FEV₁ decrement \geq 15% due to 8-hr O₃ exposures
17 during the O₃ season across the 12 urban areas are 1,000 to 15,000 (based on adjusting
18 2004 air quality to just meet the current 8-hr standard) and 4,000 to 62,000 (based on
19 adjusting 2002 air quality). In terms of percent of this population the ranges in median
20 estimates are 0.6 to 2% (based on adjusting 2004 air quality to just meet the current 8-hr
21 standard) and 2.1 to 5.8% (based on 2002 air quality). In terms of estimated occurrences
22 of this same response the ranges in median estimates are 5,000 to about 58,000 (based on
23 adjusting 2004 air quality to just meet the current 8-hr standard) and 14,000 to nearly
24 200,000 (based on 2002 air quality). The average number of occurrences per “active”
25 child in an O₃ season ranged from about 2.5 to 5 (based on adjusting 2004 air quality to
26 just meet the current 8-hr standard) and from about 2.5 to 4 (based on 2002 air quality).
27
- 28 • Estimates for increased respiratory symptoms (i.e., chest tightness, shortness of breath,
29 and wheeze) in moderate/severe asthmatic children (ages 0-12) were only developed for
30 the Boston urban area. The median estimated number of days involving chest tightness
31 (using the concentration-response relationship with only O₃ in the model) ranges from
32 4,500 (based on adjusting 2004 air quality) to 6,100 (based on adjusting 2002 air quality)
33 upon meeting the current 8-hr standard and these are reduced to 3,100 (based on
34 adjusting 2004 air quality) to 4,600 days upon meeting the most stringent alternative
35 examined (0.064 ppm, 4th daily maximum 8-hr average). These same ranges correspond
36 to 8 to 11% of total incidence of chest tightness upon meeting the current 8-hr standard
37 and to about 5.5 to 8% of total incidence of chest tightness upon meeting a 0.064 ppm, 4th
38 daily maximum 8-hr average standard. Similar patterns of reduction were observed for
39 each of the reported respiratory symptoms.
- 40
- 41 • Estimates for respiratory-related hospital admissions (e.g., respiratory illness, asthma-
42 related) were developed for three urban locations (New York City, Los Angeles, and
43 Detroit). For asthma-related admissions in New York City the estimates are about 3.9

1 cases per 100,000 relevant population, which represents about 2.4% of total incidence or
2 313 cases upon just meeting the current standard based on adjusting 2004 air quality data.
3 For increasingly more stringent alternative 8-hr standards, a gradual reduction in the
4 cases per 100,000 relevant population is observed from 3.9 cases per 100,000 upon just
5 meeting the current 8-hr standard to about 2.6 cases per 100,000 under the most stringent
6 8-hr standard (i.e., 0.064 ppm, average 4th daily maximum) analyzed. Based on adjusting
7 2002 air quality data, asthma-related admissions in New York City are about 5.5 cases
8 per 100,000 relevant population, which represents about 3.3% of total incidence or 438
9 cases upon just meeting the current standard. For increasingly more stringent alternative
10 8-hr standards, a gradual reduction is observed from 5.5 cases per 100,000 (3.3% of total
11 incidence) upon just meeting the current 8-hr standard to about 3.9 cases per 100,000
12 (2.4% of total incidence).
13

- 14 • Based on the median estimates for incidence for non-accidental mortality (based on Bell
15 et al., 2004 – 95 cities concentration-response function), meeting the most stringent
16 standard shown (0.064 ppm, 4th daily maximum) is estimated to reduce mortality by 55
17 percent of what it would be associated with just meeting the current standard (based on
18 adjusting 2004 air quality data). Adjusting 2002 air quality data to just meet the 0.064
19 ppm, standard results in a 40 percent reduction in non-accidental mortality relative to just
20 meeting the current 8-hr standard. The patterns for cardiorespiratory mortality are
21 similar. The aggregate O₃-related cardiorespiratory mortality at the most stringent
22 standard shown is estimated to be about 57 percent of what it would be at the current
23 standard, using simulated O₃ concentrations that just meet the current and alternative 8-
24 hour standards based on 2004 air quality data. Using 2002 air quality data, the
25 corresponding result is about 42 percent.
26
- 27 • Much of the contribution to the risk estimates for non-accidental and cardiorespiratory
28 mortality upon just meeting the current 8-hr standard is associated with 24-hr O₃
29 concentrations between background and 0.04 ppm. Based on examining relationships
30 between 24-hr concentrations and 8-hr daily maximum concentrations, 8-hr daily
31 maximum levels associated with these 24-hr levels are generally about twice as high.
32

33 *Uncertainty and Variability*

- 34
- 35 • There is noticeable variability in estimated O₃-related incidence of morbidity and
36 mortality across the 12 urban areas analyzed for both recent years of air quality and for
37 air quality adjusted to simulate just meeting the current and several potential alternative
38 8-hr standards. This variability is likely due to differences in air quality distributions,
39 differences in exposure related to many factors including varying activity patterns and air
40 exchange rates, differences in baseline incidence rates, and differences in susceptible
41 populations and the age distribution across the 12 urban areas. For the lung function part
42 of the risk assessment, spatial variability in air quality and population exposure inputs has
43 been included in the assessment by use of a location specific exposure analysis and
44 location specific input data to that analysis. For the epidemiology-based health
45 endpoints, spatial variability in key inputs has been embedded in the analysis by use of

1 location specific inputs (e.g., air quality, population data, baseline incidence data,
2 concentration-response relationships).
3

- 4 • The most important uncertainty is the extent to which the associations between O₃ and
5 the health endpoints included in the assessment actually reflect causal relationships. For
6 lung function decrements, respiratory symptoms in moderate to severe asthmatic
7 children, and respiratory-related hospital admissions there is clear and very strong
8 evidence supporting the judgment that the relationships are causal. With respect to non-
9 accidental and cardiorespiratory mortality, there is greater uncertainty, with the CD
10 concluding that the overall body of evidence is highly suggestive that O₃ directly or
11 indirectly contributes to nonaccidental and cardiopulmonary-related mortality (CD, p. 8-
12 78).
13
- 14 • Statistical uncertainty in the exposure-response relationships associated with sampling
15 error has been characterized in the lung function part of the risk assessment. Other
16 important uncertainties in the exposure-response relationship for the lung function health
17 outcomes include:
18
 - 19 - uncertainty associated with extrapolation of the exposure-response relationship to
20 levels below 0.04 ppm, the lowest tested level in controlled human exposure
21 studies;
 - 22 - uncertainty due to use of 6.6-hr data for subjects engaged in moderate exertion to
23 estimate response associated with 8-hr exposures under moderate or greater
24 exertion;
 - 25 - uncertainty about whether O₃-induced responses are reproducible, although this
26 is generally supported by other controlled human exposure studies showing
27 significant reproducibility of response;
 - 28 - uncertainty introduced by use of exposure-response relationships based on 18 to
29 35 year old subjects to represent the relationship for school age children age 5 to
30 18, although the use of adult data is supported by a study testing 8 to 11 year olds
31 and observations from a number of summer camp field studies of school age
32 children which found comparable responses to those observed in adults;
 - 33 - uncertainty in the estimated exposure-response relationship due to assumption
34 that response on any given day is independent of previous O₃ exposure; and
35 - uncertainty in the estimated exposure-response due to assumption that the
36 response would not be affected by the presence of other co-pollutants.
37
- 38 • Uncertainties related to estimating the concentration-response relationships for the
39 epidemiological-based part of the risk assessment include:
40
 - 41 - statistical uncertainty due to sampling error which is characterized in the
42 assessment;
 - 43 - model uncertainty (i.e., uncertainty about the shape and magnitude of the
44 concentration-response relationship taking into account lags, other pollutants,
45 etc.); and

1 - uncertainty about whether a concentration-response function provides an accurate
2 representation of the relationship in the location of interest because of a) the
3 possible role of associated co-pollutants, b) variations in the relationship of total
4 ambient exposure to ambient monitoring in different location, and c) differences
5 in population characteristics and population behavior patterns across locations or
6 over time in the same location.

- 7
- 8 • Uncertainties related to the air quality data affect both the controlled human exposure
9 studies-based and epidemiological studies-based parts of the risk assessment and
10 include:
 - 11 - uncertainties associated with the air quality adjustment procedure that was used to
12 simulate just meeting the current and alternative 8-hr standards; and
 - 13 - uncertainties about estimated background concentrations for each location.
- 14

15 Our judgment based on sensitivity analyses conducted during the prior review of
16 alternative air quality adjustment approaches, is that the choice of adjustment procedure has only
17 a modest impact on the risk estimates. With respect to the uncertainties about estimated
18 background concentrations, as discussed in section 2.7, based on EPA's assessment of the
19 validity of the GEOS-Chem model, the CD states "in conclusion, we estimate that the PRB
20 ozone values reported by Fiore et al. (2003) for afternoon surface air over the United States are
21 likely 10 ppbv too high in the southeast in summer, and accurate within 5 ppbv in other regions
22 and seasons." Thus, uncertainty about background concentrations also is likely to have only a
23 modest impact on the risk estimates developed during the current review.

**7. POLICY-RELEVANT ASSESSMENT OF WELFARE EFFECTS
EVIDENCE**

7.1 INTRODUCTION

This chapter presents information critical to the review of the secondary NAAQS for O₃. Welfare effects addressed by a secondary NAAQS include, but are not limited to, effects on soils, water, crops, vegetation, man-made materials, animals, wildlife, weather, visibility and climate, damage to and deterioration of property, and hazards to transportation, as well as effects on economic values and on personal comfort and well-being. Of these welfare effects categories, the effects of O₃ on vegetation, including agricultural crops, trees in managed and unmanaged forests, and herbaceous and woody species growing in natural settings are of most concern at concentrations typically occurring in the U.S. As stated in earlier reviews, "of the phytotoxic compounds commonly found in the ambient air, O₃ is the most prevalent, impairing crop production and injuring native vegetation and ecosystems more than any other air pollutant" (U.S. EPA, 1989, 1996b).

Ozone can also affect other ecosystem components such as soils, water, wildlife, and habitat, either directly, or indirectly, through its effects on vegetation. These individual ecosystem components are associated with one or more of six essential ecological attributes (EEAs) recently described in *A Framework for Assessing and Reporting on Ecological Condition: an SAB report* (Young and Sanzone, 2002) as part of a conceptual framework useful for assessing and reporting on ecological condition (see Figure 7-19 and discussion in section 7.7). This framework can be used to link O₃ effects at the species level to potential impacts at higher levels in the hierarchy (e.g., EEAs). Some of these species level impacts have direct, quantifiable economic value, while others are currently not quantifiable, but still have societal value. In the absence of sufficient research to allow quantification of O₃ impacts at the ecosystem level, including impacts on ecosystem goods and services, only a qualitative discussion is included. However, the staff infers, based on the linkages described in the SAB framework, that increasing protection for vegetation from O₃ related effects would also improve the protection afforded to ecosystems and their related public welfare categories.

Other O₃ related welfare effects categories include damage to certain manmade materials (e.g., elastomers, textile fibers, dyes, paints, and pigments) and climate interactions. The amount of damage to actual in-use materials and the economic consequences of that damage are poorly characterized, however, and the scientific literature contains very little new information to adequately quantify estimates of materials damage from photochemical oxidants (EPA, 1996a, b,

1 2006). Therefore, staff judges that there is insufficient information in the materials damage
2 literature to inform secondary standard setting and so it will not be discussed further. Interested
3 readers are referred to Chapter 11 in the CD (EPA, 2006). In contrast, the welfare impact of O₃
4 on local, regional and global climates has received more attention in recent years. Ozone
5 enhances the heat capacity of the atmosphere. The overall body of scientific evidence suggests
6 that high concentrations of O₃ on a regional scale could have a discernable influence on climate,
7 leading to surface temperature and hydrological cycle changes. However, the CD states that
8 confirming this effect will require further advances in monitoring and improvement in chemical
9 transport and regional-scale modeling. Thus, staff concludes that insufficient information is
10 available at this time to quantitatively inform the secondary NAAQS process with regard to this
11 aspect of the O₃-climate interaction and will not address it further. Another aspect, e.g., potential
12 modification of plant response to O₃ under conditions of changing climate, will be included in
13 the discussion of factors that can modify the predicted vegetation responses (See Section 7.4.2).

14 To summarize, this chapter includes an integrated discussion of the key policy relevant
15 science regarding O₃-related effects on vegetation (sections 7.2 through 7.4) and ecosystems
16 (section 7.7), as described in the previous CD (EPA, 1996a) and reiterated in the current CD
17 (EPA, 2006). The remaining sections (7.5 and 7.6) of this chapter are focused on a discussion of
18 the analyses that have been conducted in support of this current NAAQS review that update and
19 expand upon the exposure, risk and benefits assessments conducted in the last review (EPA,
20 1996b). These updated assessments incorporate newer data, models, and approaches, and take
21 into account alternative O₃ air quality scenarios under consideration. The environmental
22 assessment technical support document, *Technical Report on Ozone Exposure, Risk, and Impacts*
23 *Assessments for Vegetation* (Abt, 2006) (hereafter cited as “draft Environmental Assessment
24 TSD”) presents a detailed description of the exposure, risk and impacts analysis methodology.
25 Results from these assessments, along with key uncertainties and limitations, are also described
26 in sections 7.5 and 7.6. This information forms the basis for a discussion in Chapter 8 of
27 preliminary conclusions and a range of options identified for the Administrator to consider with
28 respect to the secondary O₃ NAAQS.

29

30 **7.2 MECHANISMS GOVERNING PLANT RESPONSE TO OZONE**

31 The interpretation of predictions of risk associated with vegetation response at ambient
32 O₃ exposure levels can be informed by scientific understanding regarding O₃ impacts at the
33 genetic, physiological, and mechanistic levels. In most cases, the mechanisms of response are
34 similar regardless of the degree of sensitivity of the species. The information assessed in the
35 1996 CD (EPA 1996a) regarding the fundamental hypotheses concerning O₃-induced changes in

1 physiology continues to be valid. However, during the last decade, our understanding of the
2 cellular processes within plants has been further clarified and enhanced. Therefore, this section
3 reviews the key scientific conclusions identified in 1996 O₃ CD (EPA, 1996a), and incorporates
4 new information from the current CD (EPA, 2006). This section describes: (1) O₃ uptake, (2)
5 cellular to systemic O₃ response, (3) plant compensation and defense mechanisms, (4) O₃-
6 induced changes to plant metabolism, and (5) plant response to chronic exposures.

8 **7.2.1 Ozone Uptake: Canopy, Plant and Leaf**

9 To cause injury, O₃ must first enter the plant through the stomata of the leaves. Leaves
10 exist in a three dimensional environment called the plant canopy, where each leaf has a unique
11 orientation and receives a different exposure to ambient air, microclimatological conditions, and
12 sunlight. In addition, a plant may be located within a stand of other plants which further
13 modifies ambient air exchange with individual leaves. Not all O₃ entering a plant canopy is
14 absorbed into the leaves, but may be adsorbed to other surfaces e.g., leaf cuticles, stems, and soil
15 (termed non-stomatal deposition) or scavenged by reactions with intra-canopy biogenic VOCs
16 and naturally occurring NO_x emissions from soils. Because O₃ does not penetrate the leaf's
17 cuticle, it must reach the stomatal openings in the leaf for absorption to occur. The movement of
18 O₃ and other gases such as CO₂ into and out of leaves is controlled primarily through the
19 stomata. The aperture of the stomata are controlled by guard cells, which respond to a variety of
20 internal species-specific factors as well as external site specific environmental factors such as
21 light, humidity, CO₂ concentration, soil fertility and water status, and in some cases the presence
22 of other air pollutants, including O₃ (See Section 7.4.2). These modifying factors produce
23 stomatal conductance that vary across the diurnal cycle, days and seasons. Once O₃ is inside the
24 leaf, a phytotoxic effect will only occur if sufficient amounts of O₃ reach sensitive cellular sites
25 that are subject to the various physiological and biochemical controls within the leaf cells (see
26 the discussion in section 7.2.3 below – Compensation and Detoxification).

27 A measure of O₃ flux is attractive because it incorporates both relevant environmental
28 factors and physiological processes, and is considered the measure that most closely links
29 exposure to plant response. Unfortunately, measurement of flux is very complex, making it
30 difficult to extrapolate uptake from an individual leaf to that of a whole plant or canopy. Since
31 the last review, interest has been increasing, particularly in Europe, in using mathematically
32 tractable flux models for O₃ assessments at the regional and national scale (Emberson et al.,
33 2000a, b). Though significant new research has been done with respect to flux model
34 development, it has still not advanced to a point of being generally applicable across a range of

1 species and environments at a national scale. These topics are discussed in more detail in
2 Appendix A of this document and in the 2006 CD (EPA, 2006).

3 **7.2.2 Cellular to Systemic Response**

4 Once O₃ diffuses into the leaf air spaces it can react with varied biochemical compounds
5 that are exposed to the air (path 1) or is solubilized into the water lining the cell wall of the air
6 spaces (path 2). Having entered the aqueous phase, it can be rapidly altered to form oxidative
7 products that can diffuse more readily into and through the cell and react with many
8 biochemicals. The initial sites of membrane reactions seem to involve transport properties and,
9 possibly, the external signal transducer molecules (EPA, 2006). The alteration in plasma
10 membrane function is clearly an early step in a series of O₃ -induced events that lead to leaf
11 injury.

12 Under certain circumstances, O₃ reacts with organic molecules to generate peroxides,
13 including hydrogen peroxide (H₂O₂). The role of hydrogen peroxide as a signaling molecule in
14 plants is now better understood. The primary set of metabolic reactions that O₃ triggers clearly
15 includes those typical of “wounding” responses generated by cutting of the leaf or by
16 pathogen/insect attack. One aspect of this total response is the production of O₂ and H₂O₂ by the
17 cell (Lamb and Dixon, 1997). The presence of higher-than-normal levels of H₂O₂ within the
18 apoplastic space is a potential trigger for the normal, well-studied pathogen defense pathway.

19 Ethylene is another compound produced when plants are subjected to biotic or abiotic
20 stressors. Increased ethylene production by plants exposed to O₃ stress was identified as a
21 consistent marker for O₃ exposure decades ago (Tingey et al., 1976). These studies suggested
22 that increased production of stress- ethylene correlated well with the degree of foliar injury that
23 developed within hours or days after O₃ exposure. Thus, one could postulate that O₃ generates a
24 wounding response with a production of ethylene, which would, in turn, generate a change in
25 stomatal conductance and photosynthesis.

26 **7.2.3 Compensation and Detoxification**

27 Ozone injury will not occur if (1) the rate and amount of O₃ uptake is small enough for
28 the plant to detoxify or metabolize O₃ or its metabolites or (2) the plant is able to repair or
29 compensate for the O₃ impacts (Tingey and Taylor, 1982; EPA, 1996a). Leaves may physically
30 exclude O₃ from sensitive tissues. A few studies have documented a direct stomatal closure or
31 restriction in response to the presence of O₃ ranging from within minutes to hours or days of
32 exposure (Moldau et al., 1990; Dann and Pell, 1989; Weber et al., 1993). However, exclusion of
33 O₃ also restricts the uptake of CO₂, thus limiting photosynthesis and growth.

1 Additionally, plants can also effectively protect tissue against damage by dissipating
2 excess oxidizing power using antioxidants. Since 1996, the role of detoxification in providing a
3 level of resistance to O₃ has been further investigated. A number of antioxidants, including
4 ascorbate, glutathione peroxidase, and sulfuroxide dimutase which are highly reactive, can
5 detoxify the chemicals generated by O₃. The pattern of changes in these antioxidant proteins
6 varies greatly among different species and conditions. Most recent reports indicate that
7 ascorbate within the cell wall provides the first significant opportunity for detoxification to
8 occur. The balance between the total O₃ flux and the detoxification process has been defined as
9 the “effective flux” (Dämmgen et al., 1993; Grünhage and Haenel, 1997; Musselman and
10 Massman, 1999).

11 In spite of the new research, however, it is still not clear as to what extent detoxification
12 protects against O₃ injury. Specifically, data are needed especially on the potential rates of
13 antioxidant production and on the subcellular location of the antioxidants. Potential rates of
14 antioxidant production are needed to assess whether they are sufficient to detoxify the O₃ as it
15 enters the cell. The subcellular location(s) is needed to assess whether the antioxidants are in
16 cell wall or plasmalemma locations that permit contact with the O₃ before it has a chance to
17 damage subcellular systems. In addition, generation of these antioxidants in response to O₃-
18 induced stress potentially diverts resources away from other sinks and expends energy. Thus,
19 scientific understanding of the detoxification mechanisms is not yet complete and requires
20 further investigation (EPA, 2006).

21 Once O₃ injury has occurred in leaf tissue, some plants are able to repair or compensate
22 for the impacts (Tingey and Taylor, 1982). In general, plants have a variety of compensatory
23 mechanisms for low levels of stress including reallocation of resources, changes in root/shoot
24 ratio, production of new tissue, and/or biochemical shifts, such as increased photosynthetic
25 capacity in new foliage and changes in respiration rates, indicating possible repair or replacement
26 of damaged membranes or enzymes. Since these mechanisms are genetically determined, not all
27 plants have the same complement or degree of tolerance, nor are all stages of a plant’s
28 development equally sensitive to O₃. It is not yet known to what degree or how the use of plant
29 resources for repair processes affects the overall carbohydrate budget or subsequent plant
30 response to O₃ or other stresses (EPA, 1996a, EPA, 2006).

31 **7.2.4 Changes to Plant Metabolism**

32 Ozone inhibits photosynthesis, the process by which plants produce energy rich
33 compounds (e.g., carbohydrates) in the leaves. This impairment can result from direct impact to
34 chloroplast function and/or O₃-induced stomatal closure resulting in reduced uptake of CO₂. A
35 large body of literature published since 1996 has further elucidated the mechanism of effect of

1 O₃ within the chloroplast. Pell et al. (1997) showed that O₃ exposure results in a loss of Rubisco,
2 the central carboxylating enzyme that plays an important role in the production of carbohydrates.
3 Due to its central importance, any decrease in Rubisco may have severe consequences for the
4 plant's productivity. Several studies have found that O₃ had a greater effect as leaves aged, with
5 greatest impact of O₃ on the oldest leaves (Fiscus et al., 1997; Reid and Fiscus, 1998; Noormets
6 et al., 2001; Morgan et al., 2004). The loss of Rubisco and its messenger RNA as a function of
7 increasing O₃ exposure is also linked to an early senescence or a speeding up of normal
8 development leading to senescence. If total plant photosynthesis is sufficiently reduced, the
9 plant will respond by reallocating the remaining carbohydrate at the level of the whole organism
10 (see section 7.3 below) (EPA, 1996a, 2006).

11 **7.2.5 Plant Response to Chronic/Long-term Exposures**

12 Many changes that occur with O₃ exposure can be observed within hours, or perhaps
13 days, of the exposure, including those connected with wounding and elicitor-induced changes in
14 gene expression. Other effects due to O₃, however, take longer to occur and tend to become
15 most obvious under long periods of low-O₃ concentrations. These have been linked to
16 senescence or some other physiological response very closely linked to senescence. The
17 understanding of how O₃ affects long-term growth and resistance to other biotic and abiotic
18 insults in long-lived trees is unclear. Often, the conditions to which a tree is subjected to in one
19 year will affect or "carry over" the response of that tree into the next year (EPA, 2006). In other
20 words, a condition in an earlier year sets the stage for a reaction in the next year; thereby giving a
21 "cause-effect" scenario (EPA 2006). In perennial plant species, growth affected by a reduction
22 in carbohydrate storage may result in the limitation of growth the following year (Andersen et
23 al., 1997). Carry-over effects have been documented in the growth of tree seedlings (Hogsett et
24 al., 1989; Sasek et al., 1991; Temple et al., 1993; EPA, 1996a) and in roots (Andersen et al.,
25 1991; EPA, 1996a). Accumulation of carry-over effects over time will affect survival and
26 reproduction. Understanding of how O₃ interacts with the plant at a cellular level has
27 dramatically improved in recent years. However, additional work remains to more fully
28 elucidate the translation of those cellular mechanisms into altered cell metabolism, whole plant
29 productivity, and other physiological effects.

30 **7.3 NATURE OF EFFECTS ON VEGETATION**

31 Science published since the conclusion of the 1996 review continues to support and
32 strengthen key conclusions regarding O₃ effects on vegetation and ecosystems found in the
33 previous CD (EPA 1996a) and reiterated in the current CD (EPA, 2006). For additional detail
34 the reader is referred to Chapter 9 and AX9 in the current CD (EPA, 2006)

7.3.1 Vegetation Effects Endpoints

Ozone injury at the cellular level, when it has accumulated sufficiently, will be propagated to the level of the whole leaf or plant. These larger scale effects can include: visible foliar injury and premature senescence; reduced carbohydrate production and reallocation; reduced growth or reproduction; and reduced plant vigor. Much of what is now known about O₃ exposure-plant response relationships, as summarized below, is based on research that was available in the last review. Thus, the present discussion is largely based on the conclusions of the 1978, 1986, and 1996 CDs (EPA, 1978; 1986; 1996a). Further, research results published since 1996 have not invalidated the earlier EPA conclusions (EPA, 1978, 1986, 1996a) and in some cases have expanded and strengthened those conclusions. The paragraphs below describe our current understanding of the physiological effects of O₃ on vegetation

Visible Foliar Injury and Premature Senescence. Cellular injury can and often does become visible. Acute injury usually appears within 24 hours after exposure to O₃ and, depending on species, can occur under a range of exposures and durations from 0.04 ppm for a period of 4 hours to 0.41 ppm for 0.5 hours for crops, and 0.06 ppm for 4 hours to 0.51 ppm for 1 hour for trees and shrubs (Jacobson, 1977). Chronic injury may be mild to severe. In some cases, cell death or premature leaf senescence may occur. The significance of O₃ injury at the leaf level depends on how much of the total leaf area of the plant has been affected, as well as the plant's age, size, developmental stage, and degree of functional redundancy among the existing leaf area. As a result, it is not presently possible to determine with consistency across species and environments what degree of injury at the leaf level has significance to the vigor of the whole plant. However, even the presence of visible symptoms due to O₃ exposures can reduce the market value of certain crops and ornamentals where leaves are the product (such as spinach, lettuce, petunia, geranium, and poinsettia) and affect the aesthetics of scenic vistas in protected natural areas such as national parks and wilderness areas.

Foliar injury symptoms on mature trees have also been documented and studied. In recent years, field surveys have become more common, with greater attention to the standardization of methods and the use of reliable indicator species (Campbell et al., 2000; Smith et al., 2003). Specifically, the United States Forest Service (USFS) through the Forest Health Monitoring Program (FHM) (1990 - 2001) and currently the Forest Inventory and Analysis (FIA) Program collects data regarding the incidence and severity of visible foliar injury on a variety of O₃ sensitive plant species throughout the U.S. (Coulston et al. 2003, 2004; Smith et al. 2003). Section 7.6.3.2 contains additional information on the use of foliar injury incidence on bioindicator species as a measure of the occurrence of phytotoxic levels of O₃ in the ambient air. Previous CDs have noted the difficulty in relating foliar injury symptoms to other vegetation

1 effects such as individual tree growth, stand growth, or ecosystem characteristics (EPA, 1996a).
2 This difficulty remains to the present day.

3
4 **Carbohydrate Production and Allocation** When total plant photosynthesis is sufficiently
5 reduced, the plant will respond by reallocating the remaining carbohydrate at the level of the
6 whole organism. Many studies have demonstrated that root growth is more sensitive to O₃
7 exposure than is stem or leaf growth (EPA, 2006). When less carbohydrate is present in the
8 roots, less energy will be available for root-related functions such as acquisition of water and
9 nutrients. Mycorrhizal fungi in the soil form a symbiotic relationship with many terrestrial
10 plants. For host plants, these fungi improve the uptake of nutrients, protect the roots against
11 pathogens, produce plant growth hormones, and may transport carbohydrates from one plant to
12 another (CD, 1996a). Ozone can disrupt the association between mycorrhizal fungi and host
13 plants by inhibiting photosynthesis and the amount of carbohydrates available for transfer to the
14 roots. This effect has recently been documented in the field. Data from a long-studied pollution
15 gradient in the San Bernardino Mountains of southern California suggest that O₃ substantially
16 reduces root growth in natural stands of ponderosa pine. Root growth in mature trees was
17 decreased at least 87% in a high-pollution site as compared to a low-pollution site (Grulke et al.,
18 1998), and a similar pattern was found in a separate study with whole-tree harvest along this
19 gradient (Grulke and Balduman, 1999). Though effects on other ecosystem components were
20 not examined, a reduction of root growth of this magnitude could have significant implications
21 for the below ground communities at those sites. In contrast, a study in Great Smoky Mountains
22 National Park in Tennessee (Neufeld et al., 2000) found no statistically significant effects of O₃
23 exposure on stem or root biomass for several tree species. The difference in the results from
24 these two studies may reflect the species specific nature of the symbiont-host relationship.

25 Unlike root systems, effects on leaf and needle carbohydrate content under O₃ stress
26 range from a reduction (Barnes et al., 1990; Miller et al., 1989), to no effect (Alscher et al.,
27 1989), to an increase (Luethy-Krause and Landolt, 1990). Therefore, studies that only examine
28 above-ground vegetative components may miss important O₃-induced changes below ground.
29 These below-ground changes could signal a shift in nutrient cycling with significance at the
30 ecosystem level (Young and Sanzone, 2002).

31 32 **Growth and Reproduction.**

33 Studies of the growth response of trees to O₃ have established that, individual deciduous
34 trees are generally less sensitive to O₃ than are most annual plants, with the exception of a few
35 genera such as *Populus*, which are highly sensitive and in some cases (for instance, poplars and
36 black cherry), are as sensitive to O₃ as annual plants. The O₃ sensitivity of seedlings and mature

1 trees within species and between species varies widely. In general, mature deciduous trees are
2 likely to be more sensitive to O₃ compared to seedlings, while mature evergreen trees are likely
3 to be less sensitive than seedlings. Based on these results, stomatal conductance, O₃ uptake, and
4 O₃ effects cannot be assumed to be equivalent in seedlings and mature trees.

5 Depending on exposure duration, concentrations of O₃ currently in the United States are
6 sufficient to affect the growth of a number of tree species during the annual growing season.
7 However, these conclusions do not take into account the possibility of “carry over” effects on
8 growth in subsequent years, an important consideration in the case of long-lived species. Given
9 that multiple-year exposures may cause a cumulative effect on the growth of some trees (Hogsett
10 et al. 1989; Simini et al., 1992; Temple et al., 1993), it is likely that a number of species
11 currently are being impacted.

12 Other research in the U.S. in the last 10 years has focused on perennial forage crops
13 (EPA, 2006). Recent results confirm that yields and quality of multiple-year forage crops are
14 reduced at sufficient magnitude to have nutritional and possibly economic implications to their
15 use as ruminant animal feed at O₃ exposures that occur in some years over large areas of the
16 U.S... Ozone may also reduce the quality or nutritive value of annual species.

17 Recent studies have also further demonstrated O₃ effects on different stages of
18 reproduction. Effects of O₃ have been observed on pollen germination, pollen tube growth,
19 fertilization, and abortion of reproductive structures, as reviewed by Black et al. (2000). For
20 seed-bearing plants, reproductive effects will culminate in seed production. The recent scientific
21 literature supports the conclusions of the 1996 CD that ambient O₃ concentrations are reducing
22 the yield of major crops in the U.S. For example, the yield reductions for soybean are generally
23 similar to those reported previously (EPA, 2006).

24
25 **Reduced Plant Vigor.** Though O₃ levels over most of the U.S. are not high enough to kill
26 vegetation directly, current levels have been shown to reduce the ability of many sensitive
27 species and genotypes within species to adapt to or withstand other environmental stresses.
28 These may include increased susceptibility to freezing temperatures, pest infestations and/or root
29 disease, compromised ability to compete for available resources. For example, when species are
30 grown in mixtures, O₃ exposure can increase the growth of O₃ -tolerant species while
31 exacerbating the growth decrease of O₃ -sensitive species. In the long run, the result of this loss
32 in vigor may be plant death.

34 **7.4 IMPACTS ON PUBLIC WELFARE**

1 **7.4.1 What Constitutes an Adverse Vegetation Impact from Ozone Exposure?**

2 Ozone can cause a variety of effects, beginning at the level of the individual cell and
3 accumulating up to the level of whole leaves, plants, plant populations, communities and whole
4 ecosystems. Not all O₃-related effects, however, have been classified as “adverse” to public
5 welfare. Previous reviews have classified O₃ vegetation effects as either “injury” or “damage” to
6 help in determining adversity. Specifically, injury is defined as encompassing all plant reactions,
7 such as reversible changes in plant metabolism (e.g., altered photosynthetic rate), altered plant
8 quality, or reduced growth, that does not impair the intended use or value of the plant (Guderian,
9 1977). In contrast, damage includes those injury effects that also reduce or impair the intended
10 use or value of the plant. Damage includes reductions in aesthetic values (e.g., foliar injury in
11 ornamental species) as well as losses in terms of weight, number, or size of the plant part that is
12 harvested (yield loss). Yield loss also may include changes in crop quality, i.e., physical
13 appearance, chemical composition, or the ability to withstand storage. While this construct has
14 proved useful in the past, it appears most useful in the context of evaluating effects on single
15 plants or species grown in monocultures such as agricultural crops or managed forests. It is less
16 clear how it might apply to potential effects on natural forests or entire ecosystems such as shifts
17 in species composition or nutrient cycling where the intended use or value of the system is not
18 specifically quantified.

19 A more recent construct for assessing risks to forests described in Hogsett et al. (1997)
20 suggests that “adverse effects could be classified into one or more of the following categories:
21 (1) economic production, (2) ecological structure, (3) genetic resources, and (4) cultural values.”
22 This expands the context for evaluating the adversity of O₃ related effects beyond the species
23 level. In another recent publication, *A Framework for Assessing and Reporting on Ecological*
24 *Condition: an SAB report* (Young and Sanzone, 2002), additional support is provided for
25 expanding the consideration of adversity by making explicit the linkages between stress (e.g. O₃)
26 related effects at the species level and higher levels within an ecosystem hierarchy. Staff
27 suggests that consideration of adverse effects undertaken within the context of such a broader
28 paradigm would be appropriate in the context of this secondary NAAQS review.

30 **7.4.2 Factors That Modify Functional and Growth Response**

31 The caveat that must be placed on results from any experimental study on the response of
32 living organisms to a stressor in a specific setting is that uncertainty is introduced when
33 attempting to extrapolate or apply those results outside that specific setting (e.g., to a different set
34 of organisms, scales, or exposure/growing conditions). The description of plant response to O₃
35 is no different. Because staff must necessarily rely on experimental data produced under very

1 specific sets of conditions in conducting this assessment, it is important to understand the range
2 of factors that can influence plant response to O₃ and the magnitude and direction of that
3 response, in order to better assess the likelihood of observing the experimentally predicted
4 response in the ambient environment.

5 Plant response to O₃ exposure is a function of the plant's ongoing integration of genetic,
6 biological, physical and chemical factors both within and external to the plant. The corollary is
7 also true that O₃ exposure can modify the plant's subsequent integrated response to other
8 environmental factors, both by influencing the plant response directly, and by contributing to
9 altered climatic factors that influence plant response through its greenhouse gas forcing
10 properties.

11 The 1996 O₃ CD (EPA, 1996a) concluded with a statement that our understanding
12 regarding modifying factors was too fragmented to permit drawing many general conclusions.
13 Unfortunately, in the interval since the 1996 criteria document little additional information has
14 become available and this earlier conclusion remains unchanged. Therefore, only a brief
15 overview of the current understanding from this research is provided. The reader is referred to
16 the 1996 CD (EPA 1996a) and the current 2006 CD (EPA 2006) for further information.
17

18 **7.4.2.1 Genetics**

19 Plant response to O₃ is determined by genes that are directly related to oxidant stress and
20 to an unknown number of genes that are not specifically related to oxidants but instead that
21 control leaf and cell wall thickness, stomatal conductance, and the internal architecture of the air
22 spaces. It is unlikely that single genes are responsible for O₃ tolerance, except in rare cases
23 (Engle and Gabelman, 1966). Recent studies using molecular biological tools and with
24 transgenic plants have begun to positively verify the role of various genes and gene products in
25 O₃ tolerance and are beginning to increase the understanding of O₃ toxicity and differences in O₃
26 sensitivity. Specifically, O₃ has been shown to trigger the production of a number of compounds
27 (e.g. ethylene) and the signaling of these molecules determines in some cases the O₃
28 susceptibility of plants (EPA, 2006). Because the genetic code is species specific, species vary
29 greatly in their responsiveness to O₃. Even within a given species, individual genotypes or
30 populations can also vary significantly with respect to O₃ sensitivity. Thus, caution should be
31 taken when ranking species categorically as having an absolute degree of sensitivity to O₃.
32

33 **7.4.2.2 Biological Factors**

34 The biological factors within the plant's environment that may directly or indirectly
35 influence its response to O₃ in a positive or negative manner encompass insects, other animal

1 pests, diseases, weeds, and other competing plant species. Ozone and other photochemical
2 oxidants may influence the severity of a disease or infestation by either direct effects on the
3 causal species, or indirectly by affecting the host, or both. Likewise, mutually beneficial
4 relationships or symbioses involving higher plants and bacteria or fungi may also be affected by
5 O₃. Ozone can also have indirect effects on herbivorous animals due to O₃-induced changes in
6 feed quality.

7 New evidence with regard to insect pests and diseases has done little to remove the
8 uncertainties noted in the 1996 CD (EPA 1996a). Most of the large numbers of such
9 interactions that may affect crops, forest trees, and other natural vegetation have yet to be
10 studied. With respect to any particular O₃-plant-insect interaction, we are still far from being able
11 to predict its likelihood, or its severity. The situation is only a little clearer with respect to
12 interactions involving facultative necrotrophic plant pathogens, with O₃ generally leading to
13 increased disease. In contrast, with obligate biotrophic fungal, bacterial, and nematode diseases
14 there are twice as many reports indicating O₃-induced inhibitions than enhancements. At this
15 time, therefore, although some diseases may become more widespread or severe as a result of
16 exposure to O₃, it is still not possible to predict which diseases are likely to present the greatest
17 risks to crops and forests.

18 The latest studies on O₃ interactions with root symbionts present a more complex picture
19 than was described in the last review. In addition to adverse effects of O₃ on the functioning of
20 tree root symbioses with mycorrhizae (discussed in section 7.3.1), there is also evidence that the
21 presence of mycorrhizae may help plants overcome root diseases stimulated by O₃ and/or
22 encourage the spread of mycorrhizae to the roots of uninfected trees.

23 The few recent studies of the impact of O₃ on intraspecific plant competition have again
24 confirmed that grasses frequently show greater resilience than other types of plants. In grass-
25 legume pastures, the leguminous species suffer greater growth inhibition. Separately, the
26 suppression of ponderosa pine (*Pinus ponderosa*) seedling growth by blue wild-rye grass was
27 markedly increased by O₃ (Andersen et al. 2001). Due to the limited number of species studied
28 under competitive situations to date, however, we are far from being able to predict the outcome
29 of O₃ exposure on other specific competitive situations, such as successional plant communities
30 or crop-weed interactions. Clearly, however, O₃ stress creates a selective pressure in some
31 vegetative communities that can lead to a shift in community composition. This community
32 change may be undesirable in some settings.

1 **7.4.2.3 Physical Factors**

2 A plant's interaction with its physical environment (e.g., light, temperature, relative
3 humidity, soil moisture and wind speed/turbulence) influences the degree and or nature of the
4 plant response to O₃ exposure. Light is an essential "resource" whose energy content drives
5 photosynthesis and CO₂ assimilation. It has been suggested that increased light intensity may
6 increase the sensitivity of light-tolerant species to O₃ while decreasing the O₃ sensitivity of
7 shade-tolerant species, but this appears to be an oversimplification with many exceptions.

8 Temperature affects the rates of all physiological processes based on enzyme-catalysis
9 and diffusion, and each process and overall growth (the integral of all processes) has a distinct
10 optimal temperature range. Although some recent field studies have indicated that O₃ impact
11 significantly increases with increased ambient temperature, other studies have revealed little
12 effect of temperature. But temperature is unquestionably an important variable affecting plant
13 response to O₃ in the presence of the elevated CO₂ levels contributing to global climate change
14 (see below). In contrast, evidence continues to accumulate to indicate that exposure to O₃
15 sensitizes plants to low temperature stress by reducing below-ground carbohydrate reserves,
16 possibly leading to responses in perennial species ranging from rapid demise to impaired growth
17 in subsequent seasons.

18 High relative humidity of the ambient air has generally been found to increase the
19 adverse effects of O₃ by increasing stomatal conductance and thereby increasing O₃ flux.
20 Similarly, abundant evidence indicates that the ready availability of soil moisture results in
21 greater sensitivity to O₃. The opposite condition, drought, has been observed in field
22 experiments and modeled in computer simulations to provide partial "protection" against the
23 adverse effects of O₃ as would be expected. However, there is also compelling evidence that O₃
24 can predispose plants to drought stress. Hence, the response will depend to some extent upon the
25 sequence in which the stresses occur, and the species-specific nature of the response. Regardless
26 of the interaction, however, the net result of drought on growth in the short-term is negative,
27 although in the case of tree species, other responses such as increased water use efficiency could
28 be a benefit to long-term survival.

29 Wind speed and air turbulence affect the thickness of the boundary layers over leaves and
30 canopies and, hence, affects gas exchange rates. These factors can have a significant impact on
31 the relationship between ambient air exposures and actual exposure concentrations at the leaf or
32 canopy surface.

33 **7.4.2.4 Chemical Factors**

34 Mineral nutrients in the soil, other gaseous air pollutants, and agricultural chemicals
35 constitute chemical factors in the environment. The evidence regarding interactions with

1 specific nutrients is still too contradictory to permit any sweeping conclusions. Somewhat
2 analogously with temperature, it appears that any shift away from the nutritional optimum may
3 lead to greater sensitivity, but the shift would have to be substantial before a significant effect on
4 response to O₃ was observed.

5 Interactions of O₃ with other air pollutants have received relatively little recent attention.
6 The situation with SO₂ remains inconsistent, but seems unlikely to pose any additional risk to
7 those related to the individual pollutants. With NO and NO₂, the situation is complicated by
8 their nutritional value as N sources. In leguminous species, it appears that NO₂ may reduce the
9 impact of O₃ on growth, with the reverse in other species, but the nature of the exposure pattern,
10 i.e., sequential or concurrent, also determines the outcome. Much more investigation is needed
11 before we will be able to predict the outcomes of different O₃-NO-NO₂ scenarios. The latest
12 research into O₃ × acid rain interactions has confirmed that, at realistic acidities, significant
13 interactions are unlikely. A continuing lack of information precludes offering any
14 generalizations about interactive effects of O₃ with NH₃, HF, or heavy metals. More evidence
15 has been reported that the application of fungicides affords some protective effects against O₃.

16 Over the last decade, considerable emphasis has been placed on research into O₃
17 interactions with two components of global climate change: increased atmospheric CO₂ and
18 increased mean global temperature. Most of these studies, however, have tended to regard
19 increased CO₂ levels and increased mean temperatures as unrelated phenomena, in spite of the
20 crucial role of temperature as a climatic determinant (Monteith and Elston, 1993). Thus,
21 experiments that examine the effects of doubled CO₂ levels at today's mean ambient
22 temperatures are not particularly helpful in trying to assess the impact of climate change on
23 responses to O₃, since most of the biotic and chemical interactions with oxidants may be
24 modified by these climatic changes. Though it is now known from limited experimental
25 evidence and evidence obtained by computer simulation that an atmosphere sufficiently enriched
26 with CO₂ (e.g., 600 + ppm) would more than offset the impact of O₃ on responses as varied as
27 wheat yield or the growth of young Ponderosa pine trees, the concurrent increase in temperature
28 would reduce, but probably not eliminate, the net gain.

29 Little if any experimental evidence exists related to three-way interactions, such as O₃ ×
30 CO₂ × disease or O₃ × CO₂ × nutrient availability. Increased use of computer simulations may
31 be important in suggesting outcomes of the many complex interactions of O₃ and various
32 combinations of environmental factors. However, the results obtained will only be as reliable as
33 the input data used for their parameterization. Thus, additional data from organized, systematic
34 study is needed.

35 It is important to recognize that wide variations in net impacts of climate change in
36 different geographic areas are expected. Many regions are predicted to experience severe,

1 possibly irreversible, adverse effects due to climate change. The EPA is currently leading a
2 research effort that uses regional-scale climate models with the goal of identifying changes to O₃
3 and PM concentrations that may occur in a warming climate. An assessment of the results of this
4 effort is expected to be available for consideration in the next review of the O₃ NAAQS.

5 **7.5 CHARACTERIZATION OF VEGETATION EXPOSURES TO OZONE**

6 **7.5.1 Key Considerations in Vegetation Exposure Characterization**

7 In the last review, the Administrator chose to make the secondary NAAQS equal to the
8 primary standard set as the 4th highest daily maximum 8-hr average at the level of 0.08 ppm.
9 While recognizing this as a reasonable policy choice, she also recognized that “a SUM06
10 seasonal standard is more biologically relevant and, therefore, ... also appropriate to consider.”
11 (62 FR 38877). This conclusion by the Administrator in 1997 is again supported by the recent
12 body of science reviewed in the 2006 O₃ CD (EPA, 2006). Staff, therefore, continue to express
13 hourly O₃ monitoring data in terms of both average and seasonal cumulative index forms for
14 comparison. Staff considers the cumulative, concentration weighted SUM06 and W126 index
15 forms discussed in the 1996 Staff Paper (EPA, 1996b). The rationale for including the W126
16 will emerge from the discussions of current patterns of air quality and of policy-relevant
17 background (PRB) in the remainder of this section. Below are the definitions of the three index
18 forms considered in this review and how they will be referred to in the rest of this document:
19

20 Current 8-hr form: 4th highest daily maximum 8-hr average over the O₃ season.

21
22 12-hr SUM06: 3-month sum of all 1-hr average O₃ concentrations greater than or equal
23 to 0.06 ppm observed during the daily 12-hr period between 8 am and 8 pm.

24
25 12-hr W126: Sigmoidally weighted 3-month sum of all 1-hr average O₃ concentrations
26 observed from 8 am to 8 pm.

27
28 More specifically, W126 is defined in Lefohn et al., 1988 as:

29
30
$$W126 = \sum_{i=8AM}^{i<8PM} w_{C_i} C_i, \text{ where } C_i = \text{hourly O}_3 \text{ at hour } i, \text{ and } w_{C_i} = \frac{1}{1 + 4403e^{-0.126C_i}}$$

31 Staff selected two levels of air quality to evaluate for each of these alternative standard
32 forms. Specifically, we looked at the 0.084 and 0.070 ppm, the 25 and 15 ppm-hr, and the 21
33 and 13 ppm-hr levels for the 8-hr average, the SUM06 and the W126 forms, respectively.

1 Since the conclusion of the last review, significant improvements in monitored O₃ air
2 quality have occurred in some areas of the U.S.. In the eastern U.S., these improvements may be
3 attributable in part to the reductions in NO_x emissions resulting from the initiation of Phase II of
4 Title IV in 1997 (The Ozone Report: Measuring Progress through 2003, EPA, 2004) and the
5 NO_x SIP call in 2002 (Chapter 2 of this SP). In addition, efforts to attain the current NAAQS
6 have no doubt contributed to some air quality improvements, including lower hourly maximum
7 values and fewer occurrences of those maximum values at some sites. One example of this is at
8 the Crestline site in California, where the number of days with concentrations \geq 95 ppb have
9 been declining steadily over the last decade, matched by a decline in peak 1-hr concentrations
10 and 12-hr SUM06 values. These declines match a similar trend in NO_x and reactive organic
11 gases (2006 CD section AX9-207, Figure AX9-17) (EPA 2006; Lee et al 2003). However, not
12 all areas in the U.S. show this trend. Staff urge that caution be used, however, in making
13 assumptions about trends in future years (see discussion of national parks below), as 2005 air
14 quality does not always appear to follow this trend.

15 The 1997 final rule recognized that “it remained uncertain as to the extent to which air
16 quality improvements designed to reduce 8-hr O₃ concentrations would reduce O₃ exposures
17 measured by a seasonal SUM06 index” (62 FR 38876). At that time, staff undertook an analysis
18 to explore that question. Results of that analysis suggested that improvements in national air
19 quality from attaining an 8-hr average standard within the recommended range of levels would
20 also reduce levels below those of concern for vegetation in those same areas. However,
21 considerable uncertainty remained as to the exact strength of the relationship, especially between
22 urban O₃ air quality and distributions that occur in non-monitored rural or remote areas. Using
23 recent (2001-2004) county-level air quality data, staff has performed a similar analysis to
24 compare the degree to which the 8-hr form appears to control air quality of concern for
25 vegetation expressed in terms of the SUM06. Figures 7-1 and 7-2 depict plots county air quality
26 in terms of both the current secondary standard 8-hr average form (Y axis) and the 1996
27 proposed SUM06 form (X axis) for the years 2002 (a relatively high O₃ year) and 2004 (a
28 relatively low O₃ year). Both the 25 and 15 ppm-hr cutpoints for SUM06 were considered. For
29 2002, only a few (5) counties would have both a SUM06 higher than the 1996 proposed standard
30 level of 25 ppm-hrs while meeting the 0.08 level of the current 8-hr form. When a lower SUM06
31 cutpoint of 15 ppm-hr is used, an additional 35 counties would fit that category. By contrast, the
32 relatively low year (2004) shows that 16 counties were above the SUM06 of 25 ppm-hr while
33 meeting the 8-hr standard level. When the lower SUM06 level of 15 ppm-hr is compared, a
34 much larger number of counties (128) fall in that category. Based on this comparison, air quality
35 levels associated with adverse vegetation response can be occurring in many areas that meet the
36 current 8-hr secondary NAAQS.

1 Thus, staff suggests caution should be used in evaluating the likely vegetation impacts
2 associated with a given level of air quality expressed in terms of the 8-hr form in the absence of
3 parallel SUM06 or W126 information. Unfortunately, much of the data published both in this
4 review and in other Agency reports only depicts trend information in terms of the 8 hr average
5 index. Additionally, staff plans to further assess the strength of the relationship between the 8-hr
6 average and cumulative forms at a subset of more rural and remote sites, including high elevation
7 national parks, prior to finalizing this draft Staff Paper.

8 National Parks represent nationally recognized areas of ecological significance afforded a
9 higher level of protection. Therefore, staff has also focused on air quality in the subset of
10 National Park sites and important natural areas. Two recent reports present some discussion of
11 O₃ trends in a subset of National Parks (See discussion in The Ozone Report: Measuring
12 Progress through 2003 (EPA, 2004) and 2005 Annual Performance and Progress Report: Air
13 Quality in National Parks (NPS, 2005). Unfortunately, much of this information is presented
14 only in terms of the current 8 hr average standard form. Therefore, staff has selected a subset of
15 National Parks and other significant natural areas representing 4 general regions of the U.S. to
16 analyze air quality changes in terms of the 12-hr W126 levels over the 4 year period (2001 –
17 2004, Figures 7-3 and 7-4). A subset of parks had air quality data available for 2005 and it is
18 also included on the Figures. From these graphs it can be seen that many national parks and
19 natural areas have O₃ levels above those being considered in this review and which have been
20 shown to decrease plant growth. For example, a 12-hr W126 of 24 ppm-hr has been estimated to
21 cause a 10% biomass loss in 50% of 51 tree seedling cases studies (Lee and Hogsett, 1996) and
22 sensitive tree species such as black cherry and aspen have been reported to have 10% yield losses
23 at levels as low as 4 and 11 ppm-hr (Lee and Hogsett, 1996).

24 Another key aspect to be considered when evaluating exposure levels of concern to
25 vegetation is distinguishing between pollution levels that can be controlled by U.S. regulations
26 (or through international agreements with neighboring countries) from levels that are generally
27 considered uncontrollable by the U.S., e.g., policy-relevant-background (PRB). As described in
28 Chapter 2 of this SP, the global photochemical transport model GEOS-CHEM (Fiore et al.,
29 2003) was used to estimate PRB levels. This model shows that PRB O₃ concentrations, which
30 vary as a function of season, altitude and total surface O₃ concentration, are generally predicted
31 to be in the range of 0.015 to 0.035 ppm at the surface in the afternoon, and they decline under
32 conditions conducive to O₃ episodes. They are highest during spring and decline into summer.
33 Higher values tend to occur at higher elevations during spring due to contributions from
34 hemispheric pollution and stratospheric intrusions. The stratospheric contribution to surface O₃

1 is typically well below 0.020 ppm and only rarely elevates O₃ concentrations at low-altitude sites
2 and only slightly more often elevate them at high-altitude sites (EPA, 2006, AX3-148).

3 The modeled range of 0.015 to 0.035 ppm in the 2006 CD is lower than the 0.03 to 0.05
4 ppm range used as background O₃ in the 1996 O₃ NAAQS Review (EPA, 2006). This is
5 significant for the secondary standard review because the higher end of the range (0.05 ppm)
6 provided an important policy consideration for staff in 1996 for selecting the cumulative SUM06
7 exposure index that did not weight concentrations below 0.06 ppm. Thus, SUM06 was not
8 influenced by concentrations thought to be at background levels in the 1996 O₃ NAAQS review.

9 Partially on the basis of these lower estimates of PRB, as well as declining peak O₃ levels
10 at some sites, staff has re-evaluated the usefulness of using the sigmoidally weighted W126
11 index to capture more of the vegetation relevant exposures below 0.06 ppm. Though the W126
12 index weights all concentrations, the concentrations below 0.04 ppm receive substantially
13 smaller weights (3 percent or less) so as not to contribute significantly to the value of the index
14 (Lefohn et al. 1988). In addition, because the W126 form does not contain an absolute threshold
15 like the SUM06 form, it is more in keeping with scientific consensus that there is no threshold
16 for exposures that cause effects on vegetation (Heck and Cowling 1997, EPA 2006). Therefore,
17 staff have incorporated 12-hr W126 in the vegetation risk analyses where feasible to do so.
18 Figure 7-5 shows the relationship between W126 and SUM06 as measured at O₃ monitors in
19 2001. The metrics are highly correlated, though it appears that in some cases SUM06
20 underestimates exposures compared to W126. This difference between the metrics is most likely
21 because of the inclusion of weighting hourly concentrations between 0.04 and 0.06ppm in W126.
22 Because the inflection point of W126 is approximately 0.06ppm, SUM06 metric is essentially a
23 simple approximation of the sigmoidally weighted W126 form and it is not surprising that the
24 two metrics measure O₃ exposures in a very similar way at most monitoring stations (Lee et al.
25 1988).

7.5.2 Monitor Networks: National Coverage

Hourly O₃ monitor data is available from two national networks: (1) Air Quality System (AQS; <http://www.epa.gov/ttn/airs/airsaqs>) and (2) Clean Air Status and Trends Network (CASTNET; <http://www.epa.gov/castnet/>). The locations of these monitors are presented in Figure 7-6 and are described in section 2.3.1 and 2.3.2 of Chapter 2. The AQS monitoring network currently has over 1100 active O₃ monitors which are generally sited near population centers. However, this network also includes approximately 36 monitors located in National Parks. CASTNET is the nation's primary source for data on dry acidic deposition and rural, ground-level ozone. It consists of over 80 sites across the eastern and western U.S. and is cooperatively operated and funded with the National Park Service. Due to the overall stability in these monitoring networks and standardized, rigorous QA/QC and data handling protocols, they provide useful information regarding long term trends in air quality across regions and at specific sites. For more on the AQS protocols, see section 2.3.1 of this Staff Paper or Code of Federal Regulations, Title 40, Part 58 (40 CFR Part 58). CASTNET, in terms of data quality, achieved 98% to 99% of all precision and accuracy audits being within the ±10% criteria for both precision and accuracy. Overall, CASTNET O₃ monitors are stable and show only very small variation (U.S. EPA 2003, p.22). Both networks take O₃ measurements on an hourly time step which allows for quick comparisons between different air quality index forms and different averaging times.

In spite of the size and quality of these monitoring networks, however, vast rural areas of the U.S., where important crops and natural vegetation occur, still do not have O₃ monitor coverage (Figure 7-6). As was the case in the 1996 review, staff found it necessary to select a method that could be used to characterize O₃ air quality over broad geographical areas of concern (see sections 7.5.3 and 7.5.4 below) to support a national scale risk assessment of the effects of ambient O₃ exposures on vegetation and ecosystems. Staff's review of the monitor data showed that within the five most recent years available (2000 to 2004), 2001 was a fairly moderate O₃ year. Based on this information, and because it coincided with the most recently available air quality model data (see section 7.5.3. below), 2001 was selected as the initial (base) air quality year for most of the quantitative vegetation risk analyses conducted in this review. In a few cases (e.g. foliar injury and tree growth modeling), monitor data from other air quality years were used.

7.5.3 Community Multi-scale Air Quality Model (CMAQ)

Staff investigated the appropriateness of using the O₃ outputs from the EPA/NOAA Community Multi-scale Air Quality model system (<http://www.epa.gov/asmdnerl/CMAQ>, Byun and Ching, 1999; Arnold et al. 2003, Eder and Yu, 2005) to improve spatial interpolations based on the regionally limited and unevenly distributed O₃ monitoring network in the western U.S. (see section 7.5.2). The CMAQ model is a multi-pollutant, multiscale air quality model that contains state-of-science techniques for simulating all atmospheric and land processes that affect the transport, transformation, and deposition of atmospheric pollutants and/or their precursors on both regional and urban scales. It is designed as a science-based modeling tool for handling many major pollutants (including photochemical oxidants/O₃, particulate matter, and nutrient deposition) holistically. The CMAQ model can generate estimates of hourly O₃ concentrations for the contiguous U.S., making it possible to express model outputs in terms of a variety of exposure indices (e.g., SUM06, 8-hr average). Due to the significant resources required to run CMAQ, however, model outputs are only available for a limited number of years. For this review, 2001 outputs from CMAQ version 4.5 were the most recent data available. This version of CMAQ utilizes the more refined 12 km x 12 km grid for the eastern U.S., while using the 36 km x 36 km grid for the western U.S. The 12 km x 12 km domain covers an area from roughly central Texas, north to North Dakota, east to Maine, and south to central Florida. More detailed information on CMAQ can be found in Appendix 7B. Section 7.5.4 below describes the very limited capacity in which staff used the CMAQ results. As explained below, in the final analysis, staff opted not to use O₃ values calculated from the CMAQ model, but instead only used model results to scale interpolations in the western U.S.

7.5.4 Generation of Potential Ozone Exposure Surfaces (POES)

Staff evaluated ten approaches for interpolating O₃ air quality across the U.S. which included (1) use of the CMAQ model alone; (2) use of the monitor data only Voronoi Neighbor Averaging (VNA) technique; and (3) use of a combination of monitor and CMAQ information called enhanced Voronoi Neighbor Averaging (eVNA). The evaluations were based on how well the CMAQ model or interpolation techniques were able to predict the 12-h SUM06, 12-h W126 and the 4th highest 8hr max average at each monitor. For VNA and eVNA evaluations each monitor was dropped out sequentially and a value for the monitor was interpolated with the remaining monitors. At each monitor site Normalized Mean Bias (NMB), Normalized Mean Error (NME), Absolute Mean Bias (AMB) and Absolute Mean Error (NME) were calculated

1 (Table 7-1, for more details see discussion under Uncertainties below and in the draft
2 Environmental Assessment TSD). From the results of these evaluations, the eVNA and VNA
3 performed equally in many cases and CMAQ model alone performed the poorest. The staff
4 chose to use separate interpolation techniques in the east and the west. The simpler VNA
5 approach was chosen for the eastern U.S. since it was determined that enhancing the
6 interpolation with CMAQ did not add much information to the eastern U.S. interpolation where
7 the monitoring network has greater coverage than in the west (Figure 7-4). Using the simpler
8 VNA approach in the east also allowed staff to maintain the option of producing eastern U.S.
9 interpolations for other years without the need for CMAQ results. In the west, eVNA was
10 chosen because of the sparse monitoring network in those states. Although the VNA and eVNA
11 interpolation approaches are not as complex or sophisticated as some techniques (e.g. Bayesian
12 methods), they have the advantages of relying on readily available data, being relatively
13 inexpensive to run, and being able to quickly produce estimates of any exposure index, for
14 multiple months or years, and for different air quality scenarios.

15 To generate the POES, a set of geographical locations for which O₃ data would be
16 interpolated was needed. Ideally these locations would be regularly spaced, cover the
17 continental US, and be close enough to each other to provide a good spatial resolution. Staff
18 chose to use the regularly spaced grid structure of the CMAQ model as a basis for these
19 locations. Specifically, the center of each grid cell was identified both for cells in the 12km x
20 12km grid (which covers only the Eastern U.S.), and the 36km x 36km grid (the Western US).
21 This approach produced the densest possible non-redundant “composite” grid of 44432 regularly
22 spaced grid cell center locations throughout the U.S. Using VNA in the eastern U.S. and eVNA
23 in the West, O₃ values were interpolated for each grid cell center in the composite grid (see draft
24 Environmental Assessment TSD for more details).

25 To support the vegetation exposure and risk assessments, ambient O₃ exposures were
26 projected using seasonal O₃ air quality for the 2001 base year in terms of the 3-month 12-hr
27 SUM06 (Figure 7-7) and W126 exposure indices (Figure 7C-1 in appendix 7C). The
28 uncertainties of this interpolation are discussed below. Taking the uncertainties into account, in
29 the absence of more complete monitoring data, staff find the POES serves as a useful tool for
30 identifying areas across the country where exposure levels would be expected to exceed those
31 known to produce yield or biomass loss at given levels for crops and trees, respectively. Figure
32 7-7, suggests that under the base year (2001) air quality, a large portion of California has
33 seasonal SUM06 above 38 ppm-hr, while broader multistate regions in the east and west are
34 predicted to have SUM06 above 25 ppm-hr which is greater than the secondary standard
35 proposed in 1996. Much of the east and Arizona and California have seasonal SUM06 values
36 above 15 ppm-h. Thus, the staff concludes that current air quality levels could result in

1 significant impacts to vegetation. However, these exposures may be overestimated with respect
2 to vegetation with canopy heights below monitor inlet heights, e.g., crops and tree seedlings. In
3 the crop risk/benefit assessments, staff tested an adjustment of monitored O₃ to take into account
4 the vertical O₃ gradient that exists from the height of the monitoring probe (~4 meters) to the
5 approximate height of crops and seedlings (See Section 7.6.2.3 for details).

6 To evaluate changing vegetation exposures and risks under changing air quality, maps
7 were also generated for selected "just meet" scenarios (Figures 7-8, 7-9, 7-10, 7-11) by
8 analytically adjusting air quality distributions with the quadratic method to reflect "just meeting"
9 the level of various alternative primary and secondary standard options (see Horst and Duff,
10 1995; Rizzo, 2006; Lee, 2006). This technique combines both linear and quadratic elements to
11 reduce larger O₃ concentrations more than smaller ones. In this regard, the quadratic method
12 attempts to account for reductions in emissions without greatly affecting lower concentrations
13 near ambient background levels. The following "just meet" air quality scenarios were generated:

- 14 • 4th highest daily maximum 8-hr average of 0.084 ppm (current EPA standard)
- 15 • 4th highest daily maximum 8-hr average of 0.070 ppm (alternate standard)
- 16 • 3-month, 12-hr. SUM06 of 25 ppm-hr (alternate standard proposed in the 1996 review)
- 17 • 3-month, 12-hr. SUM06 of 15 ppm-hr (alternate standard)

18
19 These maps of "just meet" scenarios, used in estimating benefits of improved air quality, can
20 also depict areas which might experience residual risk after attainment of the standard. When
21 2001 air quality is rolled back to attaining the current 0.08 ppm, 8-hour 4th highest max average
22 primary and secondary NAAQS, the overall seasonal 12-hr SUM06 exposures do not improve
23 very much (Figure 7-8). Under this attainment scenario, there are still many areas of the country
24 that have seasonal O₃ levels above the level of the secondary standard proposed in 1996 (12-hr
25 SUM06 of 25 ppm-hr). Thus, staff concludes that attaining the current (primary and secondary)
26 NAAQS may not provide adequate protection of vegetation.

27 In contrast, the exposure maps generated for the 0.07 ppm, 8-hour 4th highest max.
28 average and SUM06 of 25 and 15 ppm-hr alternatives (Figures 7-9, 7-10, 7-11) show a markedly
29 improved picture of O₃ air quality compared to Figures 7-8. In the 0.07 ppm, 8-hour 4th highest
30 max average scenario (Figure 7-9) only California, Nevada, and Arizona have areas predicted to
31 exceed the 1996 proposed secondary standard (SUM06 of 25 ppm-hr). Obviously, rollback
32 scenarios to SUM06 of 25 and 15 ppm-hr improve the air quality the most for vegetation. Thus,
33 the staff concludes that the 0.07 ppm, 8-hour 4th highest max average and SUM06 of 25 and 15

1 ppm-hr alternative standards, when attained at all locations, would be expected to provide
2 significantly improved protection of vegetation from seasonal O₃ exposures of concern.

4 ***Uncertainties***

5 Staff recognizes there are inherent uncertainties in the interpolation that must rely on
6 sparse data representative of urban and near-urban areas with little representation of rural areas.
7 This network could bias the picture of the O₃ exposure estimate especially in the western U.S.
8 where monitoring sites can be very far apart. Intuitively, it is expected that the eVNA approach
9 with spatial scaling from CMAQ approach would be an improvement over a simple interpolation
10 in the West. However, it is difficult to test for this because the lack of monitoring in the western
11 U.S. To quantify the uncertainty of the exposure surface, each monitor was sequentially dropped
12 out of the interpolation and recalculated with the remaining monitors. At each monitor site
13 Normalized Mean Bias (NMB), Normalized Mean Error (NME), Absolute Mean Bias (AMB)
14 and Absolute Mean Error (NME) was calculated. These statistics are defined below:

$$17 \quad NMB = average_{i \in dropouts} \left(100 * \frac{predictedMETRIC_i - actualMETRIC_i}{actualMETRIC_i} \right)$$

$$19 \quad NME = average_{i \in dropouts} \left(100 * \frac{|predictedMETRIC_i - actualMETRIC_i|}{actualMETRIC_i} \right)$$

$$21 \quad AMB = average_{i \in dropouts} (predictedMETRIC_i - actualMETRIC_i)$$

$$23 \quad AME = average_{i \in dropouts} (|predictedMETRIC_i - actualMETRIC_i|)$$

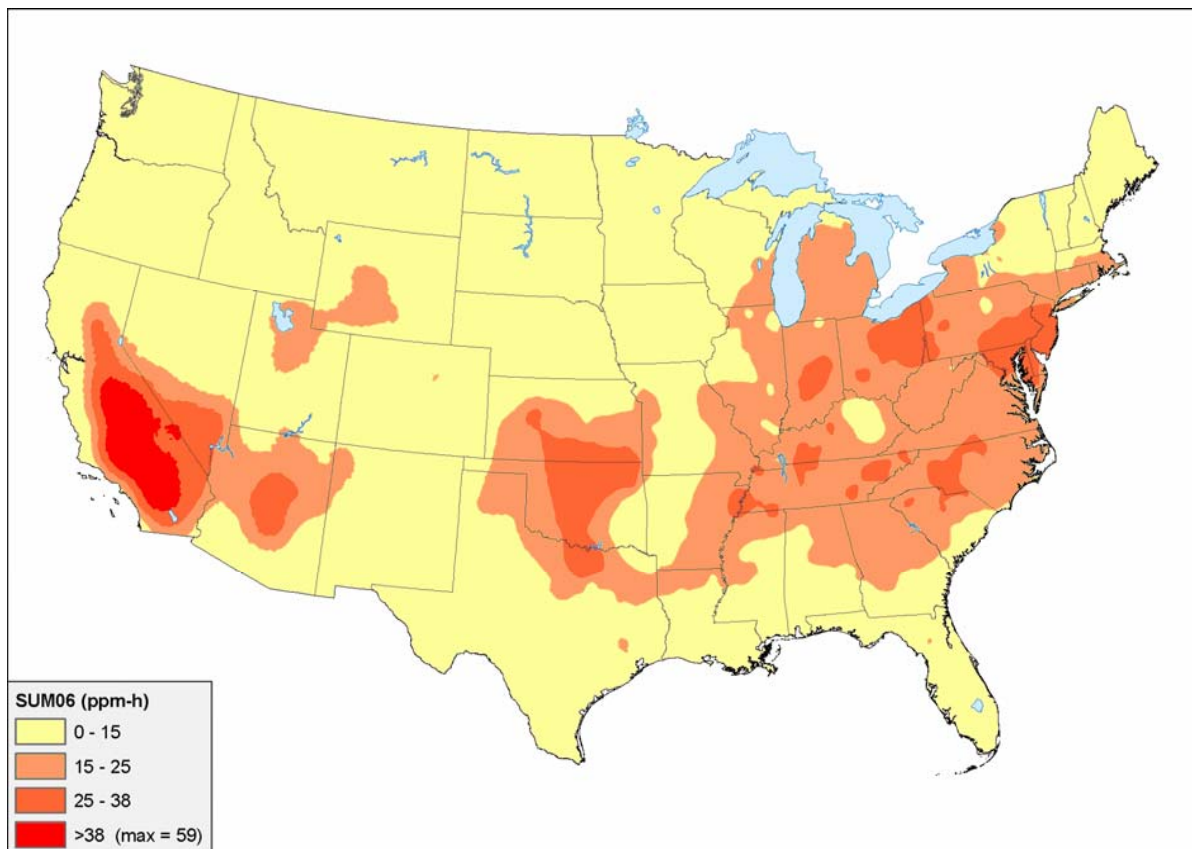

25 This method of evaluation will be a slight overestimation of error for the exposure surface since
26 dropping out monitors loses information that interpolation uses in that local area. Summary error
27 and bias metrics are presented in Table 7-1a and b. More detailed information from this analysis
28 is presented in the draft Environmental Assessment TSD. As expected the interpolation
29 performed better in the East than in the West. Using all the monitors, the Eastern U.S.
30 interpolation had an NME of about 26% for the 12-h SUM06 metric. Western interpolation had
31 a much higher NME of approximately 57%. However, since SUM06 and W126 values are often
32 low numbers, NME can be calculated to be large while the absolute difference is small. For
33 example, if a monitor with a SUM06 of 4 ppm-hr is measured and the interpolation predicts a
34 SUM06 of 6 ppm-hr then the NME would be 50%. Therefore, staff thought it was useful to also

1 report the absolute mean bias and error. In absolute terms the average bias for SUM06 was
2 slightly low (-1.83 ppm-h in the East and -2.41 ppm-h in the West). CASTNET monitors are
3 also presented to illustrate how well the interpolation techniques predicted air quality in that rural
4 monitoring network. In general, the interpolations in the East and West under-predicted the 12-
5 hr SUM06 values. This under-prediction is likely a result of the averaging inherent in the
6 interpolation. Similar results are seen for the 12-h W126 and SUM06 (Table 7-1b). However in
7 almost all cases the interpolation was able to predict monitored W126 slightly better than
8 SUM06. The calculation of error and bias metrics for the interpolation represents a notable
9 improvement over the 1996 assessment which did not have an evaluation of the exposure
10 surface.

7.6 CHARACTERIZATION OF VEGETATION RISKS

7.6.1 Scope of Vegetation Risk Assessment

The vegetation impact assessment conducted for the current review (see Figure 7-12a-c), consists of exposure, risk and benefits analyses and is meant to improve and build upon the similar analyses performed in support of the 1996 secondary NAAQS review. The vegetation exposure assessment was discussed above in section 7.5. The organization of this section reflects the remaining risk and benefit components of the assessment. The vegetation risk discussion which follows is divided between the crop and tree analyses. The crop analysis discussed in section 7.6.2 includes estimates of the risks to crop yields from current and alternative O₃ exposure conditions and the associated change in economic benefits expected to accrue in the agriculture sector upon meeting the levels of various standards. The tree risk analysis described in section 7.6.3 includes three distinct lines of evidence: (1) estimates of seedling growth loss under current and alternative O₃ exposure conditions; (2) observations of foliar injury in the field linked to monitored O₃ air quality for the years 2001 - 2004; and (3) simulated mature tree growth reduction using the TREGRO model to simulate the effect of meeting alternative air quality standards on a single western species (ponderosa pine) and two eastern species (red maple and tulip poplar). These analyses reflect earlier input received during a consultation with the CASAC O₃ Panel in October 2005. This second draft Staff Paper also includes both quantitative and qualitative discussions of known sources and ranges of uncertainties associated with the components of this assessment.

7.6.2 Characterization of Crop Risks and Associated Economic Benefits

7.6.2.1 Exposure Methodologies Used in Vegetation Research

In the 1996 review, O₃ exposure studies were dominated by the use of various versions of the open-top chamber (OTC), first described by Heagle et al. (1973) and Mandl et al. (1973). Hogsett et al. (1985, 1987) described in detail many of the various modifications to the original OTC designs that appeared subsequently. The OTC method continues as a widely used technique in the U.S. and Europe for exposing plants to varying levels of O₃ (EPA, 2005b).

Chambered systems, including open-top chambers, have several advantages. For instance, they can provide a range of treatment levels including charcoal-filtered (CF), clean-air control, and above ambient for O₃ experiments. Depending on experimental intent, a replicated, clean-air control treatment is an essential component in many experimental designs. The OTC can provide a consistent, definable exposure because of the constant wind speed and delivery systems. From a policy prospective, the statistically robust concentration-response (C-R) functions developed using such systems are necessary for evaluating the implications of various alternative air quality scenarios on crop response.

Nonetheless, there are several characteristics of the OTC design and operation that can lead to exposures that might differ from those experienced by plants in the field. First, the OTC plants are subjected to constant turbulence, which, by lowering the boundary layer resistance to diffusion, results in increased uptake. This may lead to an overestimation of effects in areas with less turbulence (Krupa et al., 1995; Legge et al., 1995). As with all methods that expose vegetation to modified O₃ concentrations in the field, OTCs create internal environments that differ from ambient air. This so-called “chamber effect” refers to the modification of microclimatic variables, including reduced and uneven light intensity, uneven rainfall, constant wind speed, reduced dew formation, and increased air temperatures (Fuhrer, 1994; Manning and Krupa, 1992). However, staff notes that the uncertainties associated with the influence of other modifying factors occurring in the field such as water and nutrient availability (see discussion above in section 7.4.2) are likely to be greater than the uncertainties in the data due to the influence of OTCs. Because of the standardized methodology and protocols used in NCLAN, the database can be assumed to be internally consistent.

While it is clear that OTCs can alter some aspects of the microenvironment and plant growth, the question to be answered is whether or not these differences affect the plant’s response to O₃. As noted in the 1996 O₃ CD (EPA, 1996a), evidence from a number of comparative studies of OTCs and other exposure systems suggested that responses were

1 essentially the same regardless of exposure system used and chamber effects did not significantly
2 affect response. For example, a study of chamber effects examined the responses of tolerant and
3 sensitive white clover clones (*Trifolium repens*) to ambient O₃ in greenhouse, open-top, and
4 ambient plots (Heagle et al., 1996). The response found in OTCs was the same as in ambient
5 plots. The California Air Resources Board (CARB), during its recent O₃ standard review, came
6 to a similar conclusion about the usefulness of OTC data. Its review states “there is little
7 scientific justification for the categorical discounting of ozone yield-response relationships
8 obtained using the OTC technology” (CEPA, 2005).

9 In recent years, a few studies have employed a modified Free Air CO₂ Enrichment
10 (FACE) method to expose vegetation to elevated O₃ without using chambers. This exposure
11 methodology was originally developed to expose vegetation to elevated levels of CO₂, but has
12 been modified to include O₃ exposure in Illinois and Wisconsin for soybean and deciduous trees,
13 respectively (Dickson et al., 2000; Morgan et al., 2004). The FACE method releases gas (e.g.,
14 CO₂, O₃) from a series of orifices placed along the length of the vertical pipes surrounding a
15 circular field plot and uses the prevailing wind to distribute it. This exposure method may more
16 closely replicate conditions in the field and, more importantly for forest research, has the benefit
17 of being able to expand vertically with the growth of the trees, allowing for exposure
18 experiments to span numerous years.

19 The FACE methodology has a different set of limitations than those of the OTC. Most
20 importantly, it is not possible with FACE to produce a number of replicated treatment levels,
21 including O₃ concentrations below ambient that are needed to build the statistically robust C-R
22 functions possible with OTCs. Despite the differences in these two exposure methods, recent
23 evidence obtained using FACE and OTC systems appear to support the results observed in OTC
24 studies used in the 1996 review. For example, a series of studies undertaken using free-air O₃
25 enrichment in Rhineland, WI (Isebrands et al., 2000, 2001) showed that O₃-symptom
26 expression was generally similar in OTCs, FACE, and ambient-O₃ gradient sites, and supported
27 the previously observed variation among trembling aspen clones (*Populus tremuloides* L.) using
28 OTCs (Karnosky et al., 1999). As more FACE data become available, a more quantitative
29 comparison of findings from these two systems would be useful. An example of this type of
30 comparison is presented in section 7.6.2.2 below.

31 Other exposure methods described both in the 1996 and 2006 O₃ CDs (EPA, 1996a; EPA
32 2006) also provide useful information on plant responses to O₃ exposure. For example, Gregg et
33 al. 2002, found significant effects of O₃ on the growth of poplars along an ambient O₃ gradient in
34 the New York City area, similar to those reported in OTCs. Other exposure methods include but
35 are not limited to chemical protectants (e.g. EDU), exclusion, and passive monitors.
36 Nonetheless, given a continued policy need for robust C-R functions, provided by OTC studies,

1 to evaluate vegetation response under alternative air quality scenarios and that other approaches
2 confirm OTC results, staff conclude that the robust C-R functions derived using the OTC
3 methodology are currently the most useful in a policy context and we continue to rely on them in
4 the following analyses.

6 **7.6.2.2 Basis for C-R Functions**

7 The 1996 crop assessment was built upon the NCLAN (National Crop Loss Assessment
8 Network) O₃ C-R functions. Since very few new studies have published C-R functions that
9 would be useful in an updated assessment, C-R functions from NCLAN remain the best data
10 available for a national assessment of crop loss under various O₃ air quality scenarios. The
11 NCLAN protocol was designed to produce crop C-R data representative of the areas in which the
12 crops were typically grown. The U.S. was divided into 5 regions over which a network of field
13 sites was established. In total, 15 crop species (corn, soybean, winter wheat, tobacco, sorghum,
14 cotton, barley, peanuts, dry beans, potato, lettuce, turnip, and hay [alfalfa, clover, and fescue]),
15 were studied. The first 12 of these 15 listed species were analyzed for the 1996 review and
16 included 38 different cultivars studied under a variety of unique combinations of sites, water
17 regimes, and exposure conditions, producing a total of 54 separate cases. Figure 7-13 uses the
18 regression equations for each of the 54 cases to graph predicted relative yield loss at various
19 exposure levels in terms of a 12-hr SUM06 (Figure 7D-1 presents a similar figure with the 4th
20 highest 8-hr max. average). Figure 7-14a-c shows composite graphs for some individual crops
21 from NCLAN and the variations in sensitivity between important crops. According to the most
22 recent USDA National Agricultural Statistical Survey (NASS) data, the 12 species analyzed in
23 the the last review account for greater than 70% of principal crops acreage planted in the U.S. in
24 2004.¹ Corn, soybean, and winter wheat alone accounted for 62% of principal crop acreage
25 planted. For the economic analysis described in section 7.6.2.4, a reduced list of 9 species (69%
26 of principal crop) were included (e.g., cotton, field corn, grain sorghum, peanut, soybean, winter
27 wheat, lettuce, kidney bean, potato), with tobacco, turnip and barley not evaluated.

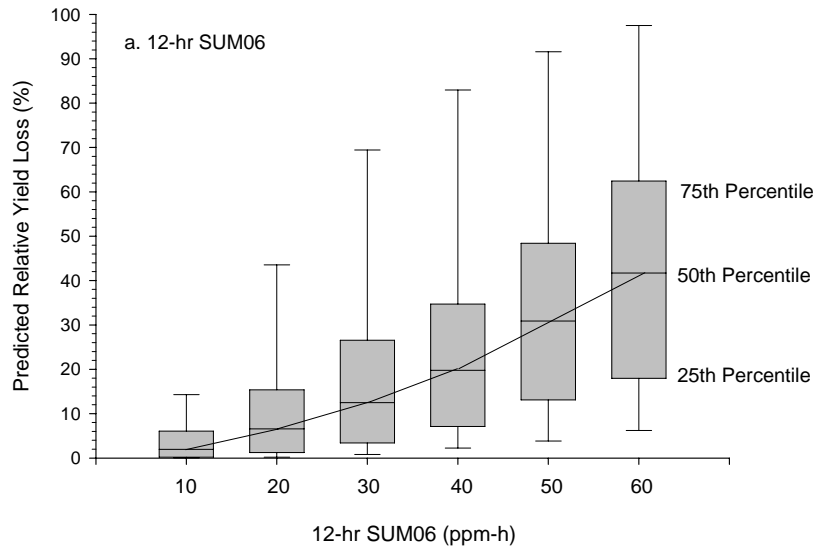

28 Since the NCLAN studies were performed during the years 1980 to 1988, there is some
29 uncertainty whether the crop cultivars tested in NCLAN are representative of crops grown today.
30 In general, new crop varieties are not specifically bred for O₃ tolerance. The fact that O₃ levels
31 are not consistent from year to year does not allow crop breeders to select for O₃ tolerance under
32 natural conditions. Additionally, the cultivars used today were bred from the same very narrow

¹ Principal crops as defined by the USDA include corn, sorghum, oats, barley, winter wheat, rye, Durum wheat, other spring wheat, rice, soybeans, peanuts, sunflower, cotton, dry edible beans, potatoes, sugar beets, canola, proso millet, hay, tobacco, and sugarcane. Acreage data for the principal crops was taken from the USDA NASS 2005 Acreage Report (<http://usda.mannlib.cornell.edu/reports/nassr/field/pcp-bba/acrg0605.pdf>)

1 genetic stock available in the 1980's and it is not expected that there would be much difference
2 in O₃ tolerance between cultivars used today and when the NCLAN studies were done. Since the
3 last review there has been little evidence that crops are becoming more tolerant of O₃ (EPA,
4 2006). For cotton, some newer varieties have been found to have higher yield loss due to O₃
5 compared to older varieties (Olszyk et al. 1993, Grantz and McCool 1992). In a meta-analysis of
6 53 studies, Morgan et al. (2003) found consistent deleterious effects of O₃ exposures on soybean
7 from studies published between 1973 and 2001. Further, early results from the SoyFACE
8 experiment in Illinois indicate a lack of any apparent difference in the O₃ tolerance of old and
9 recent cultivars of soybean in a study of 22 soybean varieties (Long et al. 2003).

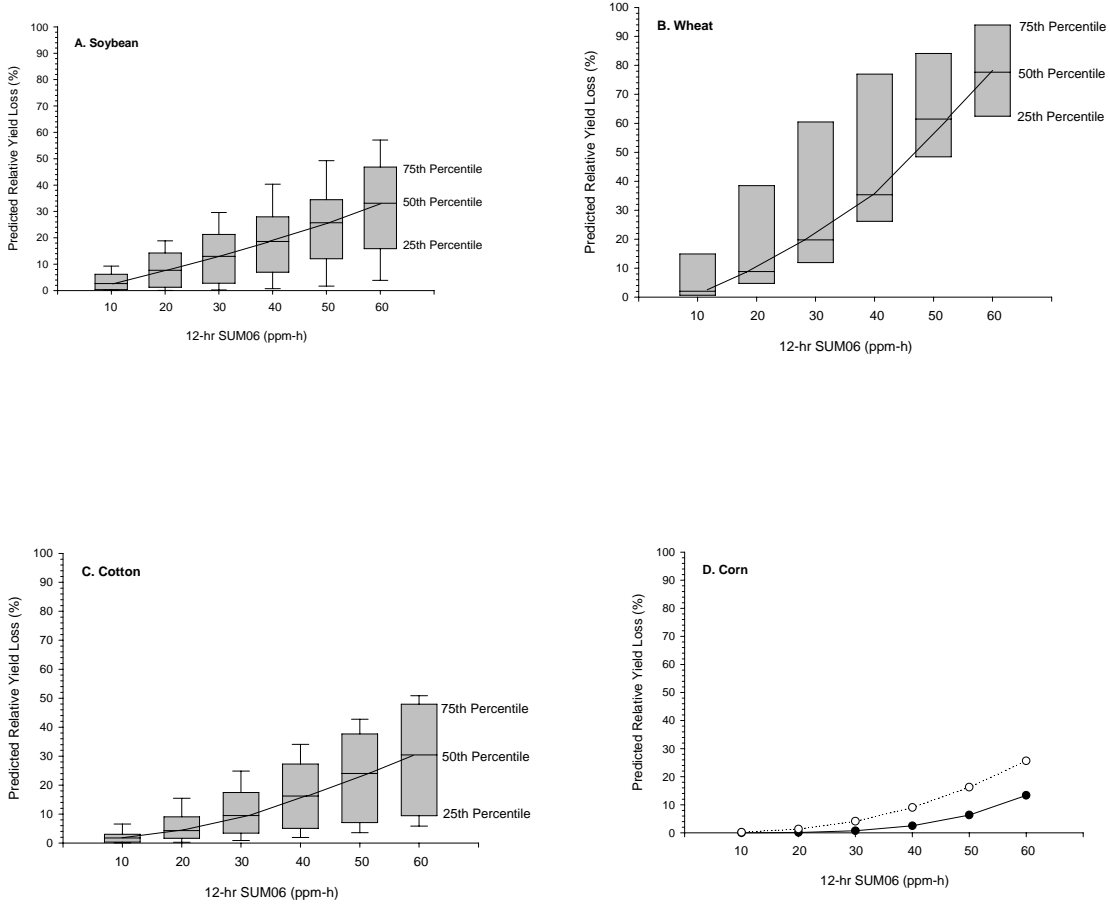

10 Soybean (Pioneer cultivar) yield loss data from a two year study at the SoyFACE (free air
11 exposure) experimental site in Illinois was recently published (Morgan et al. 2006). This
12 provided staff with an opportunity to test how well the soybean C-R function derived from
13 NCLAN studies predicted observed yield losses at a field FACE site. This type of analysis is
14 useful, given staff's necessary reliance on these functions for the foreseeable future to conduct
15 national exposure assessments. Using the NCLAN median soybean C-R function, staff predicted
16 soybean yield losses that would be expected to occur at the same exposure levels used in the
17 Illinois SoyFACE experiment and compared them to the yield losses actually observed in the
18 study. The 3-month, 12hr SUM06 and W126 values measured at the SoyFACE site before
19 harvest in the ambient and elevated treatments are given in Table 7-2. When ambient hourly O₃
20 concentrations were increased by approximately 20%, measured yields decreased by 15% and
21 25% in 2002 and 2003, respectively (Morgan et al. 2006). The median NCLAN C-R function
22 for soybean in SUM06 and W126 slightly over-predicted (2-5%) the yield loss of soybean in
23 2002 (Table 7-2), while it under-predicted (9-13%) the yield losses in 2003. However,
24 researchers reported that in 2003 a spring hail storm significantly damaged the soybean crop and
25 may have contributed to exacerbating the O₃ effect on soybean yield. Thus, it might be expected
26 that NCLAN derived C-R functions would underestimate losses with the additional hail storm
27 stress in 2003. Staff believes this limited analysis gives further evidence that the NCLAN C-R
28 functions are able to estimate the relative magnitude of yield loss due to O₃ in sensitive crops in
29 the field.

Figure 7-13. Median crop yield loss from NCLAN crops characterized with the 12-hr SUM06

Distribution of yield loss predictions from Weibull exposure-response models that relate yield to O₃ exposure characterized with the 12-hr SUM06 statistic using data from 31 crop studies from National Crop Loss Assessment Network (NCLAN). Separate regressions were calculated for studies with multiple harvests or cultivars, resulting in a total of 54 individual equations from the 31 NCLAN studies. Each equation was used to calculate the predicted relative yield or biomass loss at 10, 20, 30, 40, 50, and 60 ppm-h, and the distributions of the resulting loss were plotted. The solid line represents the Weibull fit at the 50th percentile. Source: EPA, 1996a; Lee and Hogsett 1995.

Figure 7-14 (A-D). Median soybean (A), wheat (B), cotton (C) and corn (D) yield loss from NCLAN crops characterized with the 12hr SUM06

Distribution of yield loss predictions from Weibull exposure-response models that relate yield to O_3 exposure characterized with the 12-hr SUM06 statistic using data from 22 soybean, 7 wheat, 9 cotton and 2 corn studies from National Crop Loss Assessment Network (NCLAN). Separate regressions were calculated for studies with multiple harvests or cultivars. Each equation was used to calculate the predicted relative yield loss at a 12-h SUM06 of 10, 20, 30, 40, 50, and 60 ppm-h, and the distributions of the resulting loss were plotted. Source: EPA, 1996a; Lee and Hogsett 1995.

2 **Table 7-2. Air quality and soybean yield loss data from the SOYFACE experiment in Illinois.**

3

4

Year	Metric	Ambient O₃	Elevated O₃	Pred. PRYL (%)	Meas. PRYL (%)
2002	12-h SUM06	26.37	56.87	20	15
2003*	12-h SUM06	14.04	41.37	16	25
2002	12-h W126	25.07	51.52	17	15
2003*	12-h W126	10.59	34.32	12	25

5

6 NOTE: Reported are the ambient and elevated 3-month 12-hr SUM06 and W126 exposures measured in the ambient and elevated
7 ozone treatment plots. Predicted Percent Relative Yield Loss (PRYL) was calculated from the median soybean C-R function NCLAN
8 and measured PRYL was the measured yield loss reported by Morgan et al. (2006).

9 *In 2003 there was hail-storm that severely damaged the soybean plants.

10

11

1

2 **7.6.2.3 Considerations for Exposures at Crop Canopy Height**

3 An additional consideration when predicting crop yield and/or tree seedling biomass loss
4 using monitored O₃ exposure levels is the potential positive exposure bias associated with the
5 height at which the measurement is taken. Inlets to ambient monitors are typically at heights of 3
6 to 5 meters, and thus are located in the inner part of the planetary boundary layer (EPA, 2005b).
7 It is well known that within this layer O₃ reacts with vegetation and volatile compounds and can
8 create a vertical gradient of decreasing O₃ concentration from the inlet height of the monitors to
9 the surface of vegetation. The magnitude of the gradient is determined in large part by the
10 intensity of turbulent mixing in the surface layer. During daytime hours, the vertical O₃ gradient
11 is relatively small because turbulent mixing maintains the downward flux of O₃. For example,
12 Horvath et al. (1995) calculated a 7% decrease in O₃ going from a height of 4 meters down to 0.5
13 meters above the surface during unstable (or turbulent) conditions in a study over low vegetation
14 in Hungary [See Section AX3.3.2. of the 2006 CD (EPA, 2006)]. This is compared to a 20%
15 decrease during stable conditions which usually occur during the night. The average decrease
16 for all times measured was 10%. The daytime versus nighttime bias is an important distinction
17 considering the assessments outlined below rely heavily on daytime metrics such as the 12-hr
18 SUM06 and W126. Thus, staff selected 10% as a daytime downward adjustment factor to apply
19 to hourly monitor-derived exposures (including interpolated values) prior to estimating crop
20 yield and tree seedling biomass loss values. We consider this 10% adjustment at the upper-end
21 of the differences between the monitor height and top of the canopy of low vegetation in the
22 daytime.

23 Staff recognizes that a 10% adjustment to hourly monitor data across the country is a
24 very simple method to deal with a complicated issue. The exchange of O₃ between the
25 atmosphere and vegetation is controlled by complex interactions of meteorological and
26 biological processes. Ideally one should account for the exact height of each monitor, canopy
27 roughness for each crop and the seasonal and diurnal nature of turbulence. This was not possible
28 in our analyses and therefore, there is uncertainty with applying a 10% adjustment to all
29 monitors and crop canopies. To quantify the effect of the 10% adjustment, staff plans to perform
30 a sensitivity analysis by also calculating crop benefits without an adjustment and/or alternative
31 adjustment levels taking into account future CASAC advice. However, at this time only results
32 with the 10% are available.

33 The 10% hourly adjustment had a dramatic effect on the predicted 12hr SUM06 and
34 W126 exposures. Reducing each hourly value by 10% over the entire interpolated surface
35 resulted in an average reduction of the 3 month 12-hr SUM06 by 53% and an average reduction

1 of 42% in the 3month 12hr W126. These dramatic reductions in the SUM06 and W126
2 exposures are most likely a result of many hourly concentrations measured at the monitor inlets
3 near the cut-off point for SUM06 and the inflection point for W126 (approximately 0.06 ppm).
4 When these “mid-level” hourly O₃ values are reduced by 10%, many fall below 0.06 ppm,
5 dramatically decreasing the amount of hourly values counted (SUM06) or contributing to
6 (W126) these metrics.

7 Given the somewhat lesser impact of the 10% adjustment on exposures using the W126
8 and the lack of evidence for a biological threshold for effects at 0.06 ppm, staff concluded that
9 the W126 index form would be the more appropriate for conducting the crop yield and tree
10 seedling biomass loss risk assessment. Other information that supports this decision includes: 1)
11 studies that document effects on crops and other sensitive vegetation at concentrations below
12 0.06 ppm [e.g., exposures as low as a 0.04 ppm 7-hr seasonal average (EPA 2006)]; 2) the high
13 degree of correlation between both forms when describing ambient exposures (see Figure 7-5)
14 and their similar predictive power of NCLAN crop data results in retrospective analyses (Lee et
15 al., 1988; EPA, 1996, 2006); and 3) the use of the 12-hr W126 metric in the crop assessment
16 performed for the 1996 Staff Paper. It should be noted that in some cases, W126 is calculated to
17 be higher than SUM06. Though this is due to the inclusion of concentrations below 0.06 ppm,
18 exposures below 0.04 ppm are not significantly weighted (Lefohn et al. 1988) and so is not
19 significantly influenced by policy relevant background levels (0.02 to 0.035 ppm).

21 **7.6.2.4 Quantifiable Risk of Yield Loss In Select Commodity, Fruit and** 22 **Vegetable Crops**

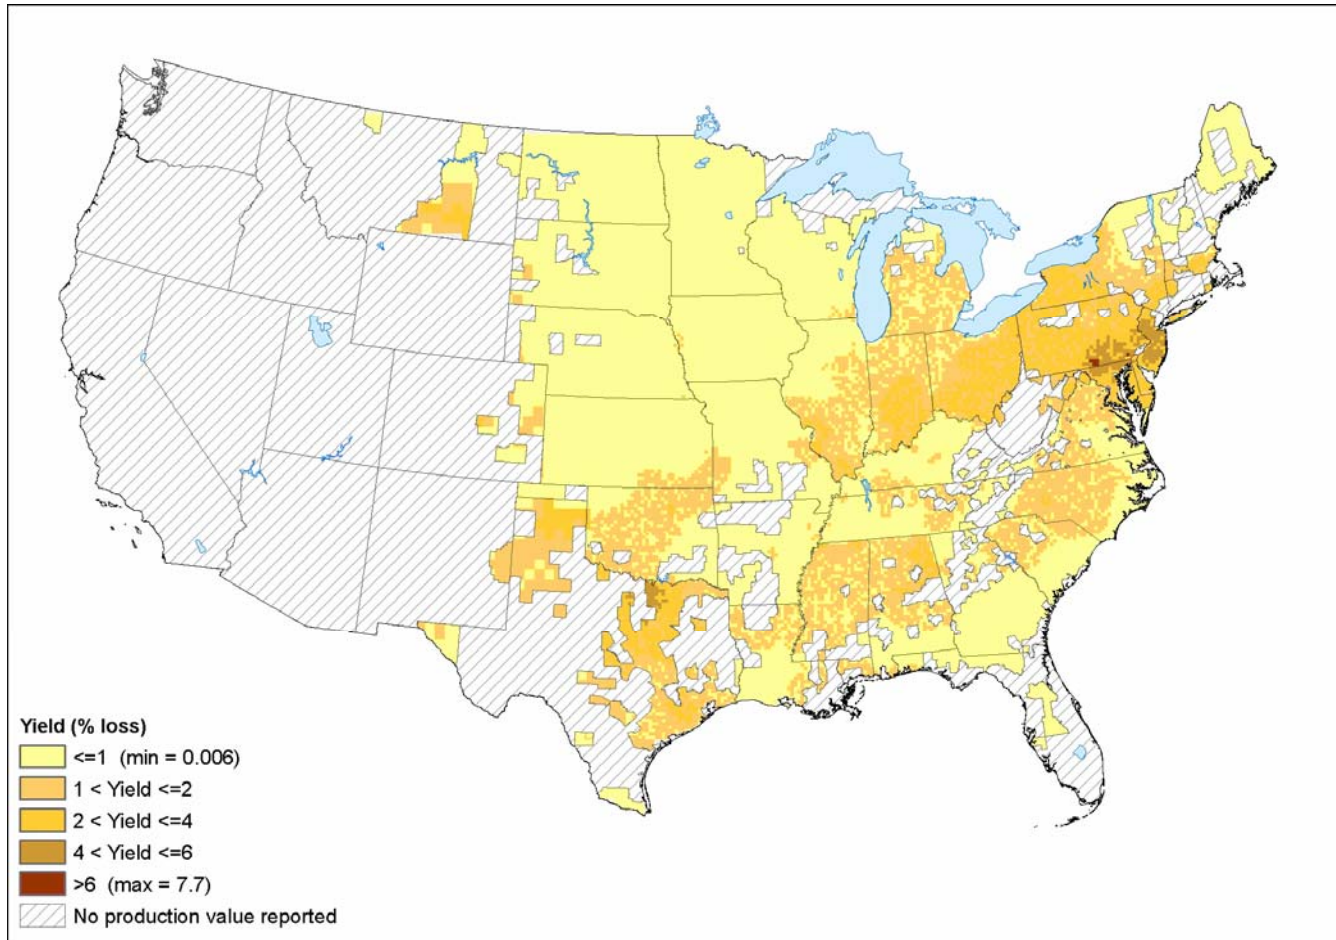

23 The 2001 county-level crop planting data were obtained for the 9 commodity crops (corn,
24 soybean, winter wheat, sorghum, cotton, peanuts, kidney bean, potato & lettuce) from USDA-
25 NASS (National Agricultural Statistics Service; <http://www.usda.gov/nass>). The appropriate
26 NCLAN C-R functions (available in the 12-hr W126 format) were identified for each of the nine
27 commodity crops from the analysis done for the 1996 staff paper (Table 7E-1). The appropriate
28 C-R functions (available in the 7-hr or 12-hr average format) for six fruit and vegetable species
29 (Tomatoes-processing, grapes, onions, rice, cantaloupes, Valencia oranges) were identified from
30 the 1996 California fruit and vegetable analysis (Table 7E-2). Staff combined these C-R
31 functions with the crop planting information and with projections of 2001 O₃ exposure based on
32 a 12-hr W126 calculated for the 3 months prior to the harvest date for each commodity crop and
33 the appropriate 7-hr or 12-hr average used for the fruits and vegetables. Calendar periods used
34 for computing W126, 7-hr and 12-hr exposure statistics are based on the harvest date and are
35 done on a state-specific basis. This allows for geographic variation and better reflects actual O₃

1 exposure during the true growing period of the crop so that calculated expected yield change for
2 each crop, fruit and vegetable is specific to where they were planted.

3 The results of this risk assessment are presented in Appendix 7E in Table 7E-4. This
4 table depicts the relative change in crop yield loss under air quality scenarios of just meeting
5 various alternative standard options under consideration. Maps of predicted yield loss for
6 selected major crops are presented in Appendix 7F. Figure 7-15 shows a map of predicted yield
7 loss for soybean from 2001 using the 10% adjusted “as is” estimated O₃ exposure scenario.
8 Soybean is predicted to have the largest yield loss in southwestern Pennsylvania, southern New
9 Jersey and east Texas. However, these areas are not places of high soybean production. In a
10 high soybean producing state, such as Illinois, yield loss was predicted to reach a maximum
11 range of 2-4%. Corn, another major commodity crop, was not predicted to have any loss in
12 2001. This is because the two corn cultivars studied in NCLAN were not sensitive to O₃. In
13 contrast, cotton, a more sensitive crop, had predicted yield loss above 10% in southern California
14 (see Appendix 7F).

7.6.2.5 Economic Benefits Assessment – AGSIM

This section presents results of the quantitative economic benefits analysis associated with attaining alternate standards. Adequate data are currently available to assess economic benefits for 9 of the commodity crops studied in the NCLAN project and 6 fruit and vegetable species. Fruits and vegetables were evaluated in the 1996 review using a separate regional benefits model due to the fact that only regional data was available at the time for those fruits and vegetables. In the current benefits assessment, both commodity crops and fruits and vegetables are evaluated together in the same national scale model. However, because fruit and vegetables are a large part of the U.S. agricultural sector and are especially susceptible to O₃ pollution because much of the production is located in the San Joaquin Valley region of California, which has very high levels of O₃ exposure (CEPA, 2005), information on fruits and vegetables is also sometimes presented separately. For example, in 2004, cash income from California fruit and nut production was worth more than 9.6 billion dollars and over 7.2 billion dollars for vegetable crops (California Agricultural Resource Directory, 2005, <http://www.cdfa.ca.gov/>).

The Agriculture Simulation Model (AGSIM) (Taylor, 1994; Taylor et al., 1993) has been utilized recently in many major policy evaluations.² AGSIM is an econometric-simulation model used to calculate agricultural benefits of changes in O₃ exposure and is based on a large set of statistically estimated demand and supply equations for agricultural commodities produced in the U.S. A number of updates to AGSIM were performed before running this analysis: (1) an update of the commodity data for 2001, (2) incorporation of the most recent version of the official USDA baseline model, (3) an econometric component added to AGSIM to compute total farm program payments for different levels of farm program parameters, and (4) farm payment program component added to the economic surplus module. The AGSIM model was run to provide benefit estimates for nine major commodity crops (soybeans, corn, winter wheat, cotton, peanuts, sorghum, potato, lettuce, kidney bean) and six fruits and vegetables mainly grown in California (tomatoes-processing, grapes, onions, rice, cantaloupes, Valencia oranges). As described earlier, hourly O₃ exposures were adjusted downward by 10% before calculating the W126, 7-h or 12-h exposure metrics.

Percent relative yield losses (PYRL) calculated as the change in yield occurring between just meeting ‘as is’ air quality and various alternative standard scenarios were the relevant input

² For example, AGSIM© has been used in EPA’s prospective study of the benefits derived from the Clean Air Act Amendments of 1990 required by section 812-B of the Clean Air Act, non-road land-based diesel engine rule, and proposed Clear Skies legislation.

1 parameters to the AGSIM model. The AGSIM model predicted acreage, production, supply and
2 price parameters for each crop for each year, as well as yield per harvested acre, based on
3 calculated new yield-per-planted acre values, as well as on lagged price data, ending stocks from
4 the previous year and other variables. From these results and demand relationships embedded in
5 the model, AGSIM calculated the utilization of each crop (i.e., exports, feed use, other domestic
6 use, etc), as well as change in consumer surplus, net crop income, deficiency payments and other
7 government support payments. Total undiscounted economic surplus was calculated as the crop
8 income plus consumer surplus. The AGSIM model was run for 14 years for each scenario in
9 order for the model parameters to adjust to the initial change in yield. Annual changes in total
10 undiscounted economic surplus were calculated for each of the 14 years. The annual averages
11 for the 14 years are reported in Table 7-3.

12 Table 7-3 presents the results from applying the AGSIM model to determine commodity
13 crop benefits based on meeting the level of the current 8-h standard and three alternative
14 standards. The 0.070 4th highest maximum average O₃ scenario was chosen as a possible
15 alternative primary standard level. Alternative secondary standards are expressed in maximum 3
16 month 12-h SUM06. For the SUM06 index, the level 25 ppm-hr is the level proposed in the
17 1996 review and is associated with a yield loss prevention of about 10% in 50% of crops studied
18 in the NCLAN experiments. The other 12-h SUM06 of 15 ppm-hr is associated with a yield loss
19 prevention of about 10% in 75% of crops studied in the NCLAN experiments. Staff plans to also
20 add two equivalent levels of a 12-h W126 (21 and 13 ppm-hrs) for the final O₃ Staff Paper.

21 In summary, this analysis estimates a range of benefits using both the available minimum
22 and maximum yield loss equations for each crop. Results are presented in annual 2001 dollars
23 for the commodity crops, fruits and vegetables and total agricultural sector. Overall, benefits
24 from the fruit and vegetable species in this analysis accounted for a relatively large portion of the
25 total agricultural benefits compared with the commodity crops. This is likely because many of
26 the fruits and vegetables are grown in parts of California with high O₃ exposures and any rolling
27 back of air quality produced greater changes in O₃ levels, resulting in higher changes in yield.
28 All of the alternative standards analyzed showed positive incremental benefits greater than those
29 associated with just meeting the level of the current 8-hr standard. Meeting the SUM06 of 25
30 proposed in the last review produced an additional incremental benefit of \$102-\$134 million for
31 the total agricultural sector. Of all the scenarios, SUM06 of 15 ppm-hrs and 0.07 4th highest
32 maximum 8 hour average had the largest economic benefit. Meeting the alternative SUM06 of
33 15 produced incremental benefits of \$275-\$436 million for the total agricultural sector. It is
34 important to note that these results represent a macro-analysis of the U.S. agricultural economy.
35 Farmers in areas that have higher O₃ levels are more adversely affected than farmers that are in
36 areas with low O₃ levels. These important effects are difficult to quantify in a macro-analysis.

1 The current CD reports very few studies have been conducted on the economic effect of
2 O₃ on U.S. agriculture. A study by Murphy et al. (1999) confirmed the general magnitude of
3 economic effects reported by the two key studies performed a decade earlier (Adams, 1986;
4 Adams et al., 1985). Specifically, Murphy et al. (1999) evaluated benefits to eight major crops
5 associated with several scenarios concerning the reduction or elimination of O₃ precursor
6 emissions from motor vehicles in the United States. Their analysis reported a \$2.8 to 5.8 billion
7 (1990 dollars) benefit from complete elimination of O₃ exposures from all sources, i.e., ambient
8 O₃ reduced to a background level assumed to be 0.025 to 0.027 ppm. In comparison, AGSIM
9 calculates up to \$800 million (2001 dollars) in economic benefit when O₃ levels are reduced to
10 near background. These analyses are quite difficult to compare for many reasons: different
11 economic models, different air quality years, how farm payment programs are counted, dollar
12 value unadjusted for inflation, etc. However, it is apparent that the benefits for this assessment
13 are substantially lower than in past analyses. Staff suspects a major factor is the 10% adjustment
14 of the hourly O₃ data measured at monitoring height and the use of different economic models.
15 For the final draft staff paper, we will present economic benefits without the 10% adjustment
16 factor. Also, 2001 was a moderate O₃ year and it would be expected that benefits would be
17 notably greater if this analysis was run for a higher O₃ year like 2002. Staff are considering
18 expanding the analysis to include another year if air-quality for comparison.

19 It is important to restate and summarize the uncertainties associated with the results of the
20 AGSIM analysis presented above. Uncertainties are introduced by: (1) the extrapolation of
21 limited air quality monitoring data to national air quality distributions; (2) the application of
22 exposure-response functions from open-top chamber studies extrapolated to 2001 ambient air
23 exposure patterns and crop production; (3) the use of a quadratic rollback methodology to project
24 the "just attain" air quality distributions without a direct link to an emissions control strategy;
25 and (4) the inherent uncertainties associated with use of an economic model such as AGSIM. It
26 is also important to note that the range of results from this analysis represents impacts associated
27 only with available NCLAN experimental data and a limited number of fruits and vegetable
28 studies. Not all crops have been subjected to exposure-response experiments and effects on
29 those crops would be missed. Despite the amount of uncertainty, this analysis provides useful
30 insights for comparing the relative benefits obtained as a result of attaining alternative regulatory
31 scenarios.

7.6.3 Tree Risk Assessments

In the last review (EPA 1996b), analyses of the effects of O₃ on trees were limited to 11 tree species for which C-R functions for the seedling growth stage had been developed from OTC studies conducted by NHEERL-WED. Since the last review, only a few studies have developed C-R functions for additional tree seedling species (EPA, 2006). Section 7.6.3.1 describes how staff updated the tree seedling risk analysis performed in the last review. Section 7.6.3.2. discusses the approach for assessing O₃ effects on vegetation in natural settings using visible foliar injury data. Section 7.6.3.3 discusses the analysis and results for modeling O₃ impacts on mature trees in the Eastern and Western U.S. The tree and/or forest analyses outlined below will enable staff to begin to assess important long-term effects of various secondary standard levels on forest ecosystem health and services.

7.6.3.1 Quantifiable Risk of Biomass Loss In Select Tree Seedling Species

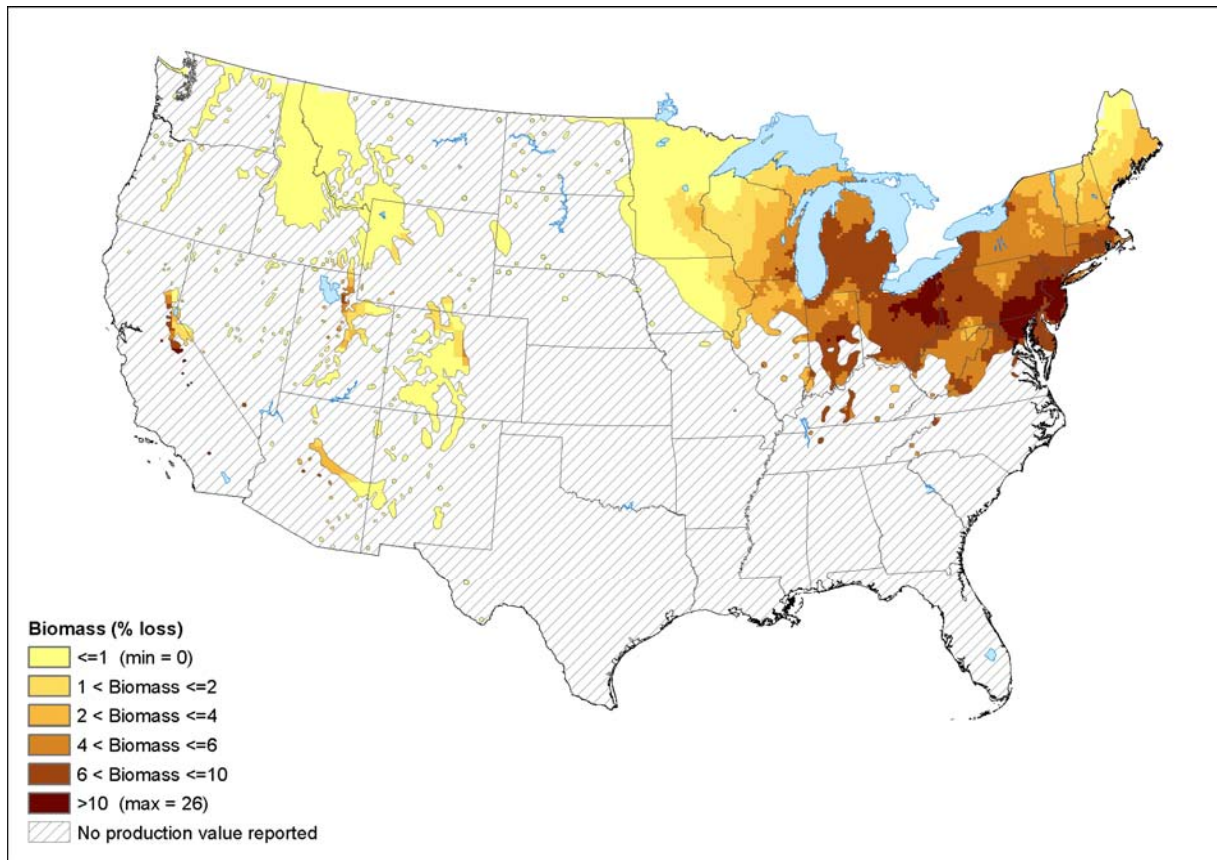

In a process similar to that used for crops above (7.6.2.4), C-R functions for biomass loss for a subset of seedling tree species taken from the CD (Table 7E-3) and information on tree growing regions derived from the U.S. Department of Agriculture's Atlas of United States Trees (Little, 1971) were combined with projections of air quality based on 2001 POES, to produce estimated biomass loss for each of the seedling tree species individually. The results of this risk assessment are presented in Table 7E-5 in Appendix 7E. In addition, maps depicting these results for selected tree seedling species are found in Appendix 7G

Figure 7-16 shows an example of the aspen tree species. The aspen map shows significant variability in projected seedling biomass loss across its range for 2001. Aspen seedling biomass loss is projected to be greater than 6% over much of its geographic range, though it can reach as high as 26% in some areas. In Appendix 7G there are additional maps of Ponderosa pine and black cherry along with maps of seedling biomass gain when various standards levels are met. These biomass gain maps indicate that substantial improvements in seedling biomass growth may be achieved when the alternative standards are met, especially the 0.07ppm 4th highest max. and SUM06 of 15ppm-hr. It should be noted that the species mapped are generally sensitive and they are also important tree species in ecosystems across vast areas of the U.S. Though each map shows the geographical range for a species, it does not indicate that an individual of that species will be found at every point within its range. It should also be recognized that the production of these maps incorporates several separate sources of uncertainty, beginning with the C-R functions produced for seedlings in OTCs to the uncertainties associated with the inputs used to generate the POES. Furthermore, percent

1 biomass loss in tree seedlings is not intended to provide any information on expected biomass
2 loss in mature trees of the same species (see section 7.6.3.3 for modeling of mature tree growth).
3 Studies indicate that mature trees can be more or less sensitive than seedlings depending on the
4 species. Further, seedling biomass loss cannot be considered comparable to percent yield loss in
5 agricultural crops. This is because a small biomass loss per year in a perennial tree species, if
6 compounded over multiple years of exposure could have a large effect on the growth of that tree,
7 while yield loss in annual crops is only affected by the O₃ exposure for that year. In summary,
8 this analysis indicates that current air quality can produce significant seedling biomass loss in the
9 areas which those trees grow. Meeting the level of alternative standards is expected to improve
10 biomass growth in the seedlings analyzed.

11

Figure 7-16. Estimated aspen seedling annual biomass loss based on interpolated 2001 maximum 3-month 12-hr W126. This map indicates the geographic range for aspen, but it does not necessarily indicate that aspen will be found at every point within its range.

7.6.3.2 Foliar Injury Incidence

The use of sensitive plants as biological indicators to detect phytotoxic levels of O₃ is a longstanding and effective methodology (Chappelka and Samuelson, 1998; Manning and Krupa, 1992). Some well defined bioindicators for ambient O₃ include blackberry, black cherry, green ash, milkweed, quaking aspen, sassafras, yellow poplar, and white ash. Each of these bioindicators exhibits typical O₃ injury symptoms when exposed under appropriate conditions. These symptoms are considered diagnostic as they have been verified in exposure-response studies under experimental conditions. Typical visible injury symptoms on broad leaved plants include: 1) acute exposure (pigmented lesions (stippling), flecking, surface bleaching, and/or bifacial necrosis); 2) chronic exposure (pigmentation (bronzing), chlorosis or premature senescence). Typical visible injury symptoms for conifers include: 1) chlorotic banding or tipburn (acute exposure); 2) flecking or chlorotic mottling, premature senescence of needles (chronic exposure). Though common patterns of injury develop within a species, these foliar lesions can vary considerably between and within taxonomic groups. Furthermore, the degree and extent of visible foliar injury development varies from year to year and site to site, even among co-members of a population exposed to similar O₃ levels, due to the influence of co-occurring environmental and genetic factors. It is important to note that the foliar injury occurs only when sensitive plants are exposed to elevated O₃ concentrations in a predisposing environment. Thus great care must be taken when assessing the response of bioindicators to ambient O₃ (Flagler, 1998).

The United States Forest Service (USFS) through the Forest Health Monitoring Program (FHM) (1990 - 2001) and currently the Forest Inventory and Analysis (FIA) Program has been collecting data regarding the incidence and severity of visible foliar injury on a variety of O₃ sensitive plant species throughout the U.S. (Coulston et al. 2003, 2004; Smith et al. 2003). FIA biomonitoring sites are located throughout the country and analysis of foliar injury within these sites follows a set of established protocols (for more details see <http://fiaozone.net/>). Since the conclusion of the 1996 NAAQS review, the FIA monitoring program network and database has continued to expand. The visible foliar injury indicator has been identified as a means to track stress trends in the nation's natural plant communities as a result of changes in O₃ air quality in EPA's most recent Report on the Environment (EPA, 2003; <http://www.epa.gov/indicators/roe>). EPA staff also considers it important to assess the degree to which O₃-induced visible foliar injury observed *in situ*, corresponds with monitored O₃ air quality in recent years. In a collaborative effort with FIA staff, EPA staff conducted an analysis to compare the incidence of foliar injury at different levels of air quality (e.g., the current

1 standard and alternative levels under consideration) by county throughout the US. This analysis
2 potentially provides a measure of the effectiveness and degree of protection provided by the
3 current form/level of the secondary standard for this welfare effect.

4 The major confounding effect for O₃ induced foliar injury is the amount of soil moisture
5 (local rainfall) available to a plant during the year that the foliar injury is being assessed. This is
6 because lack of soil moisture decreases stomatal conductance of plants and therefore, limits the
7 amount of O₃ entering the leaf that can cause injury. Many researchers have shown that dry
8 periods in local areas tend to decrease the incidence and severity of foliar injury caused by O₃ in
9 plants measured by the USFS (Smith et al. 2002). Therefore, the incidence of foliar injury is not
10 always higher in years with higher O₃, especially when there is drought in areas where foliar
11 injury is assessed.

12 Due to a congressional requirement that the US Forest Service protect landowner privacy,
13 FIA cannot publicize the exact locations of their biosites. As a result, all data in our analysis are
14 reported on a county-level. County-level foliar injury data were available for the years 2001 to
15 2004 for all areas of the U.S. except the Mountain West region. However, according to the FIA
16 staff, no O₃ injury was reported at any site in that region. Figure 7-17, shows that the incidence
17 of foliar injury in 2001 was widespread across the eastern and western U.S. The 2001 data are
18 indicative of the incidence of foliar injury in the years 2001 to 2004. (see appendix 7H for
19 2002). This indicates that O₃ levels are above phytotoxic levels sufficient to cause adverse
20 effects in natural plant populations in many areas. It is important to note that direct links
21 between O₃ induced visible foliar injury symptoms and other adverse effects (e.g., biomass loss),
22 are not always found. However, in a few cases, visible foliar symptoms have been correlated
23 with decreased vegetative growth (Karnosky et al., 1996; Peterson et al., 1987; Somers et al.,
24 1998) and with impaired reproductive function (Black et al., 2000; Chappelka, 2002). Though
25 visible injury is a valuable indicator of the presence of phytotoxic concentrations of O₃ in
26 ambient air it is not always reliable indicator of damage or other injury endpoints. The lack of
27 visible injury does not indicate a lack of phytotoxic concentrations of O₃ nor a lack of non-
28 visible O₃ effects.

29 In an attempt to assess how meeting various O₃ standard levels affected the incidence of
30 foliar injury, staff matched up county-level O₃ monitoring data with counties that had US Forest
31 Service biosites. In counties containing multiple O₃ monitors, staff used the monitor measuring
32 the highest O₃ to characterize county air quality. Because visible foliar injury symptoms reflect
33 the O₃ stress of the year in which they are observed, staff looked at yearly snapshots of county-
34 level air quality data. Between 235 and 286 FIA biomonitoring sites have been surveyed in
35 counties containing an O₃ monitor for the years 2001 – 2004, respectively (see Table 7-4).
36 However, because the specific locations of the USFS biosite are not publicly available, staff was

1 unable to determine how close the biosites within each county are to the O₃ monitor selected to
2 represent that county. Air quality was evaluated in terms of both the current 8 hr. average and
3 12-h SUM06 forms, using a number of different cutpoints. Table 7-4 shows the percentage and
4 number of counties with and without visible foliar injury at or below various standard levels for
5 the 2001-2004 period. Because the FIA program reorganized the locations of biosites in 2002
6 and expanded the number of biosites in 2003 and 2004, the total number of counties containing
7 both an O₃ monitor and an FIA biosite changed each year and it is difficult to interpret changes
8 in the number of counties in different categories between years. Therefore, staff found it more
9 informative to present results in terms of percent of total counties with or without injury under
10 different levels of air quality. Firstly, this table illustrates that foliar injury is occurring in areas
11 that are attaining the current 8-h standard. The table also illustrates that the secondary standard
12 option of a SUM06 of 25 ppm-hrs proposed in 1996 did not appear to offer more protection from
13 foliar injury than the current 8 hr. standard form. By comparison, the SUM06 of 15 ppm-hrs and
14 the 8 hour average of 0.074 provided more protection across all years than either the 0.084 8-h or
15 SUM06 of 25 standards. At the 0.084, 8 hr. average, the percent of counties showing injury
16 ranged from 21% to 39%. Under a SUM06 of 25 ppm-hrs., percent of counties with injury
17 increased slightly, ranging from 26% to 49%. For the two lower air quality alternatives (0.074
18 ppm 8 hr avg. and SUM06 of 15 ppm-hrs), values ranged from 12% injured to 30% and 35%,
19 respectively.

20 In summary, this analysis indicates that incidence of O₃ induced foliar injury is
21 widespread across the eastern and western U.S. Foliar injury was observed in counties that are
22 attaining the current level of the 8-h standard and secondary standard option of a SUM06 of 25
23 ppm-hrs proposed in 1996. Lower standards in the 8-hr and SUM06 forms would be expected to
24 have lower incidences of foliar injury. However, the level of protection would depend heavily
25 on local environmental variable such as soil moisture. Finally, in the consensus workshop on
26 held on the secondary O₃ standard, researchers were in agreement that a 3 month 12-h SUM06
27 value of 8 to 12 ppm-h should be considered for protection from foliar injury to natural
28 ecosystems (Heck and Cowling, 1997). The analysis above supports this recommendation that
29 these levels would reduce the incidence of foliar injury to natural ecosystems.

30
31

Figure 7-17. 2001 County-level incidence of visible foliar injury in the eastern and western U.S. as measured by the US Forest Service FIA program.

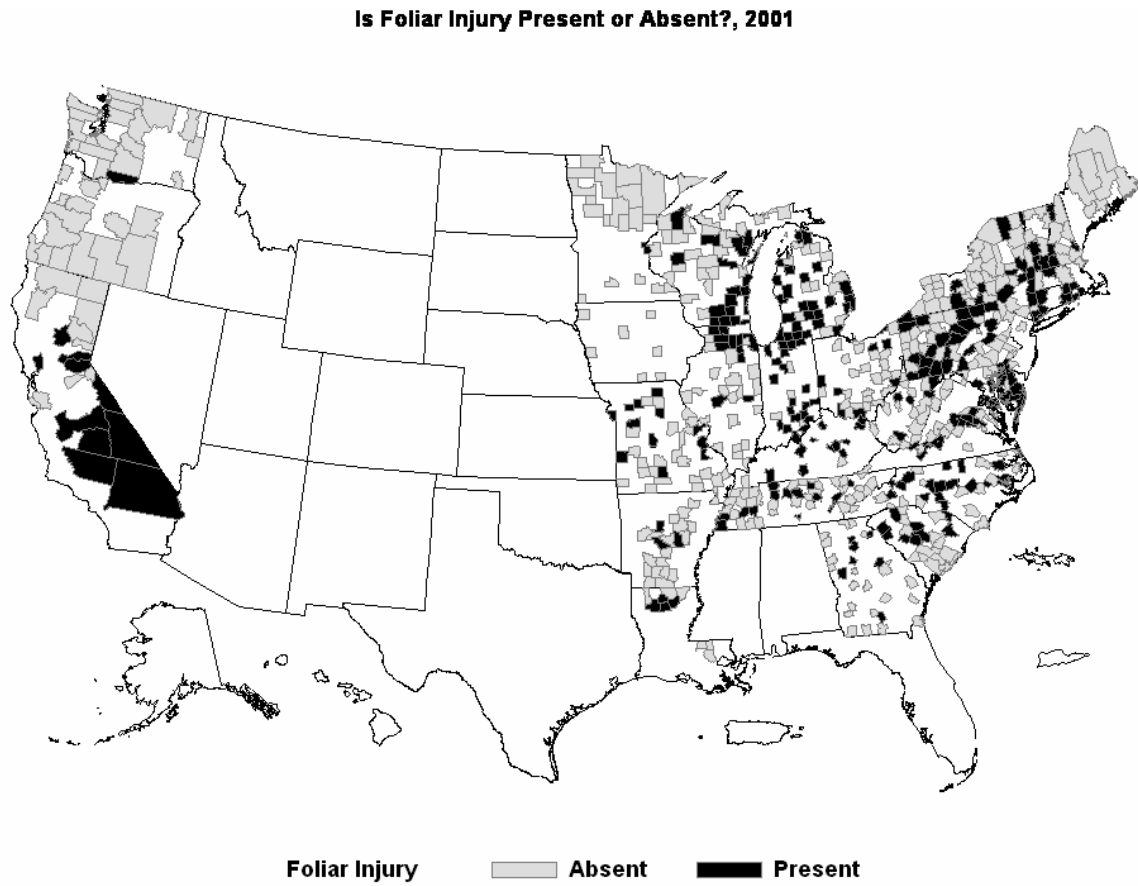

Table 7-4. Percentage and number of counties with visible foliar injury and without injury (none) below various standard levels for the years 2001-2004. Each county had an O₃ monitor and a USDA forest service FIA plot tracking visible foliar injury due to O₃ exposure.

Year		≤0.084*	≤0.074*	≤SUM06 25	≤SUM06 15	Total Counties with O ₃ monitoring & FIA site
2001	Tot. counties	99	36	134	48	235
	% injured	39% (39)	25% (9)	49% (65)	23% (11)	
	% not injured	61% (60)	75% (27)	51% (69)	77% (37)	
2002	Tot. counties	89	43	129	59	270
	% injured	21% (19)	12% (5)	26% (33)	12% (7)	
	% not injured	79% (70)	88% (38)	74% (96)	88% (52)	
2003	Tot. counties	185	61	236	135	285
	% injured	28% (52)	11% (7)	34% (81)	25% (34)	
	% not injured	72% (133)	89% (54)	66% (155)	75% (101)

	% injured	35% (91)	30% (47)	37% (91)	35% (76)	
	% not injured	65% (169)	70% (112)	63% (158)	65% (144)	

*These standard levels represent the annual 4th highest 8hr max average

7.6.3.3 Modeled Mature Tree Growth Response: Eastern and Western Species Case Studies

In the 1996 O₃ Staff Paper, evaluations of O₃ impacts on tree growth were limited to the seedling growth stage. At that time, robust C-R functions were available only for 11 tree seedlings developed from OTC data. Few studies had been done comparing seedling sensitivity to that of a mature tree of the same species. Recent experiments using the FACE methodology have been able to expose 3 tree species to O₃ beyond the seedling growth stage. However, this methodology has not yielded C-R functions at this time, due to the limited number of exposure regimes used. Findings from FACE publications, however, do show decreased biomass growth under elevated O₃ in trees beyond the seedling stage (King et al., 2005). In order to better characterize the potential O₃ effects on mature tree growth, staff used a tree growth model (TREGRO) as a tool to evaluate the effect of changing O₃ air quality scenarios from just meeting alternative O₃ standards on the growth of mature trees.

TREGRO is a process-based, individual tree growth simulation model (Weinstein et al, 1990) and has been used to evaluate the effects of a variety of O₃ scenarios and linked with concurrent climate data to account for ozone and climate/meteorology interactions on several species of trees in different regions of the U.S. (Tingey et al., 2001; Weinstein et al., 1991; Retzlaff et al., 2000; Laurence et al., 1993; Laurence et al., 2001; Weinstein et al., 2005). The model provides an analytical framework that accounts for the nonlinear relationship between O₃ exposure and response. The interactions between ozone exposure, precipitation and temperature are integrated as they affect vegetation thus providing an internal consistency for comparing effects in trees under different exposure scenarios and climatic conditions (see the draft Environmental Assessment TSD for more details on TREGRO). An earlier assessment of the effectiveness of national air quality standards, in place since the early 1970s, took advantage of 40 years of air quality and climate data for the Crestline site in the San Bernardino Mountains of California to simulate Ponderosa pine growth over time with the improving air quality using TREGRO (Tingey et al., 2004).

Staff collaborated with the EPA NHEERL-WED lab to use the TREGRO model to assess growth of ponderosa pine (*Pinus ponderosa*) in the San Bernardino Mountains of California (Crestline) and the growth of yellow poplar (*Liriodendron tulipifera*) and red maple (*Acer rubrum*) in the Appalachian mountains of Virginia and North Carolina, Shenandoah National Park (Big Meadows) and Linville Gorge Wilderness Area (Cranberry), respectively. Total tree growth associated with ‘as is’ air quality, and air quality adjusted to just meet alternative O₃ standards was assessed (Table 7-5).

1 Ponderosa pine is one of the most widely distributed pines in western North America, a
2 major source of timber, important as wildlife habitat, and valued for aesthetics (Burns
3 and Honkala, 1990). Red maple is one of the most abundant species in the eastern U.S.
4 and is important for its brilliant fall foliage and highly desirable wildlife browse food
5 (Burns and Honkala, 1990). Yellow poplar is an abundant species in the southern
6 Appalachian forest. It is 10% of the cove hardwood stands in southern Appalachians
7 which are widely viewed as some of the country's most treasured forests because the
8 protected, rich, moist set of conditions permit trees to grow the largest in the eastern U.S.
9 The wood has high commercial value because of its versatility and as a substitute for
10 increasingly scarce softwoods in furniture and framing construction. Yellow poplar is
11 also valued as a honey tree, a source of wildlife food, and a shade tree for large areas
12 (Burns and Honkala, 1990).

13 At the western site, staff and NHEERL-WED scientists used Crestline, CA air
14 quality and climate data from the years 1995 to 2000 to run TREGRO, while at the
15 eastern sites, staff used Big Meadows, VA and Cranberry, NC air quality and climate
16 data from the years 1993 to 1995. These three years were the only years in the east with
17 readily available O₃ and climate data that could be used in TREGRO. The years chosen
18 to run the TREGRO at each site appear to have annual O₃ exposures typical of the last 15
19 years (Figure 7-18). Air quality from each site and year was adjusted using the quadratic
20 roll-back method to 'just meet' the current 8-hr secondary standard (4th highest maximum
21 average = 0.08 ppm), a 12hr SUM06 of 25 ppm-hr, and 1st highest max average of 0.07
22 ppm. Staff also tested the 4th highest 0.07 ppm level on the Cranberry and Big Meadows
23 sites. For the ponderosa pine at Crestline, TREGRO was run for "as is" and "just meet"
24 in four 3 year increments to increase the accountability of climate variability and the
25 annual average biomass determined from these 4 simulations to yield an annual average
26 biomass change over the 6 years of ozone exposure. For the yellow poplar and red
27 maple, two sites (Big Meadows, VA and Cranberry, NC) were chosen to run TREGRO to
28 increase the variability in climate since there were only 3 years of data available at each
29 site. The differences between growth under "just meet" air quality and "as is" air quality
30 were compared to evaluate the effectiveness of the current secondary standard and
31 alternative standards in protecting these three tree species.

32 Results of the TREGRO simulations are presented in Table 7-5. Clearly, the
33 greatest simulated growth benefits in the scenarios are seen in ponderosa pine at the
34 Crestline site in California. As shown in Figure 7-18, O₃ levels are much higher at
35 Crestline than the sites in the eastern US. Meeting the level of the current standard was
36 simulated to result in an 8.63% increase annual growth and a SUM06 of 25 is expected

1 increase growth 10.33% in ponderosa pine. In the eastern sites (Cranberry and Big
2 Meadows) O₃ levels are much lower (Figure 7-18) and had less of an affect on the
3 simulated growth of red maple and yellow poplar. In fact, the Cranberry, NC site was
4 below level of the current 8 hr standard and the SUM06 of 25 scenarios and therefore, no
5 benefits were calculated for those levels. At Big Meadows, VA, the current 8hr standard
6 and SUM06 scenarios resulted in relatively small growth increases for yellow poplar
7 (0.03-0.07%) and red maple (0.34-0.41%). This was mostly because the Big Meadows
8 site was close to meeting those levels in 1993-1995 (Figure 7-18). Red maple was
9 simulated to have a similar response (~2%) to the 0.07 ppm 1st and 4th highest 8hr max. in
10 Big Meadows and Cranberry. For the same scenarios, yellow poplar had a very different
11 response to O₃ reduction at Big Meadows (0.34-0.38%) compared to Cranberry (3.91-
12 6.54%). The climate at Cranberry is much more ideal for yellow poplar than under the
13 cool temperatures of Big Meadows, making it much more likely that its growth would be
14 suppressed by ozone and that, conversely, it would respond much more to ozone
15 reductions at Cranberry. Red maple has a much larger geographical distribution, so that
16 the temperature differences between Big Meadows and Cranberry are less likely to affect
17 the growth response. This phenomenon was reflected in the simulations.

18 The effect of O₃ on an individual tree may be quite different than the predicted
19 effect on a forest stand after many years. Some researchers have used the ZELIG model,
20 a forest stand simulator, to predict stand growth using growth rates of individual species
21 from TREGRO scenarios (Laurence et al., 2001; Weinstein et al., 2005). Small changes
22 in growth of an individual over a short period of time have sometimes been simulated to
23 have large changes in basal area as it develops over a long time period. For example,
24 Weinstein et al. (2005) found a simulated O₃ effect on an individual ponderosa pine at
25 Crestline to reduce growth by 6.7% in three years under normal precipitation, yet stand
26 basal area was calculated to be reduced by 29% after 100 years. Similarly, Laurence et
27 al. (2001) found individual yellow poplar in NC with an O₃ induced growth loss of 1.7%
28 which was then calculated to reduce basal area by 14% after 100 years. This suggests
29 that small effects on individual tree growth may result in substantial effects on forest
30 stand growth after many years.

31

1

2 **Table 7-5. Relative increase in total annual tree biomass growth, simulated with the TREGRO model, if the level current and**
3 **alternative standards are met.**

4

Species	red maple	red maple	yellow poplar	yellow poplar	ponderosa pine
Site	Big Meadows, VA (1993-1995)	Cranberry, NC (1993-1995)	Big Meadows, VA (1993-1995)	Cranberry, NC (1993-1995)	Crestline, CA (1995-2000)
0.08 4 th highest	0.41%	<i>no rollback</i> ¹	0.03%	<i>no rollback</i> ¹	8.63%
0.07 1 st highest	2.71%	2.31%	0.38%	6.54%	10.81%
0.07 4 th highest	2.24%	1.38%	0.34%	3.91%	<i>n.a.</i> ²
SUM06 = 25	0.34%	<i>no rollback</i> ¹	0.07%	<i>no rollback</i> ¹	10.33%
SUM06 = 15	4.49%	2.99%	0.60%	8.26%	<i>n.a.</i> ²

5

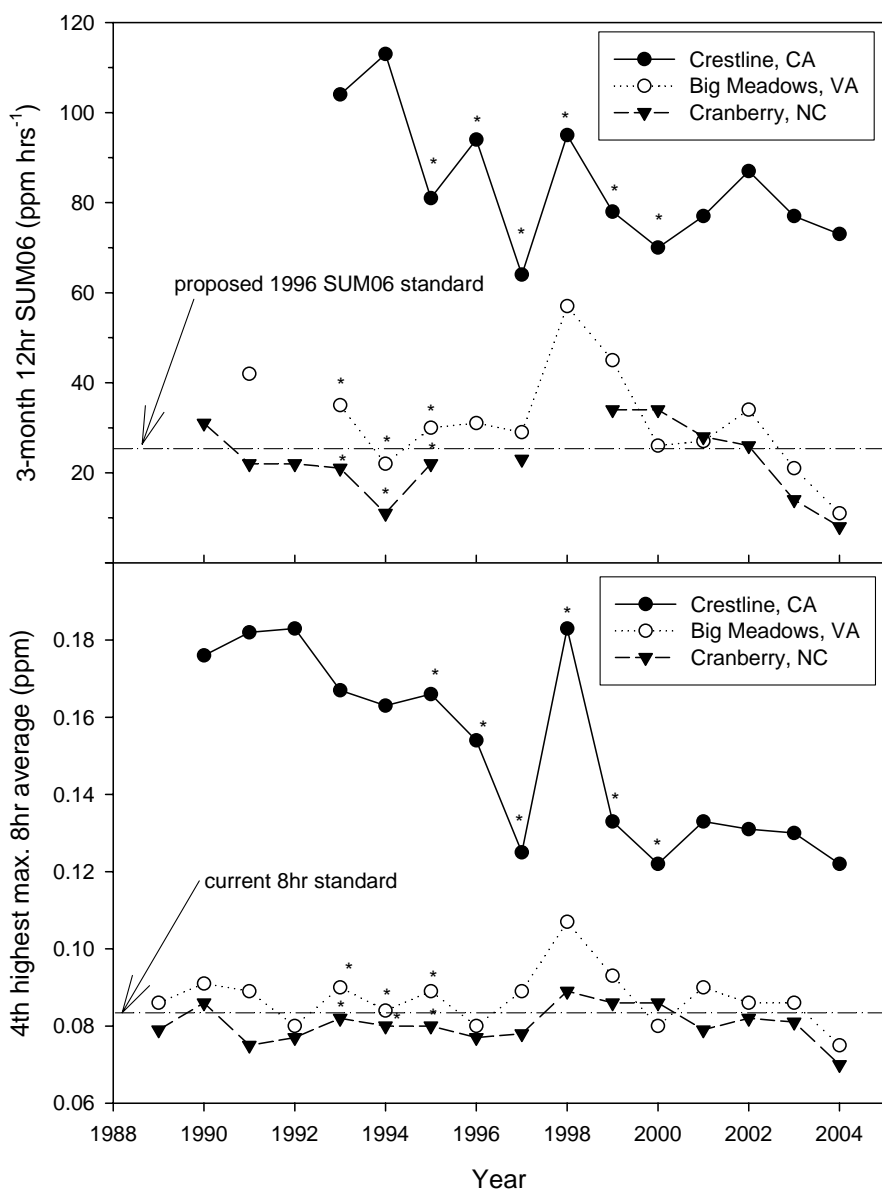

6 ¹A rollback was not necessary for the Cranberry site for the 0.08 4th highest and SUM06 = 25 scenarios since air quality was at or
7 below the levels of those scenarios.

8 ² TREGRO was not run for ponderosa pine for the 0.07 4th highest scenario.

9

10

Figure 7-18. Historical O₃ data as measured in the 3-month 12-hr SUM06 and 4th highest 8hr metrics for the 3 sites used to run the TREGRO model. For Big Meadows, VA and Cranberry, NC, climate and O₃ data from 1993 to 1995 was used to run TREGRO and for Crestline, CA, 1995 to 2000 was used. Missing data points in the top panel indicate incomplete data to calculate a SUM06. * indicates which years of data were used in the TREGRO model at each site.

1

2 **7.7 QUALITATIVE RISK: ECOSYSTEM CONDITION, FUNCTION AND**
3 **SERVICES**

4 Ecosystems are comprised of complex assemblages of organisms that provide distinct
5 ecological attributes, many of which may be adversely affected by ozone (EPA, 2006). A new
6 effort has been initiated within the Agency to identify indicators of ecological condition whose
7 responses can be clearly linked to changes in air quality and be used to track improvements in
8 environmental protection attributable to environmental program actions/implementation.
9 Moreover, a recent critique of the secondary NAAQS review process published in the report by
10 the National Academy of Sciences on Air Quality Management in the United States (NRC, 2004)
11 stated that “EPA’s current practice for setting secondary standards for most criteria pollutants
12 does not appear to be sufficiently protective of sensitive crops and ecosystems” This report
13 made several specific recommendations for improving the secondary NAAQS process and
14 concluded that “There is growing evidence that tighter standards to protect sensitive ecosystems
15 in the United States are needed” However, the vast majority of information regarding the
16 effects of ozone involves the sensitivity of individual species. Therefore, this section lays out
17 some examples of our current understanding of how O₃ may be affecting ecosystems and
18 identifies areas of research needed to address this issue.

19 An ecosystem is defined as comprising all of the organisms in a given area interacting
20 with the physical environment, so that a flow of energy leads to a clearly defined trophic
21 structure, biotic diversity, and cycling of materials between living and nonliving parts (Odum,
22 1963). Individuals within a species and populations of species are the building blocks from
23 which communities and ecosystems are constructed. Classes of natural ecosystems, e.g., tundra,
24 wetland, deciduous forest, and conifer forest, are distinguished by their dominant vegetation
25 forms. Ecosystem boundaries are delineated when an integral unit is formed by their physical
26 and biological parts. Defined pathways for material transport and cycling and for the flow of
27 energy are contained within a given integrated unit.

28 Each level of organization within an ecosystem has functional and structural
29 characteristics. At the ecosystem level, functional characteristics include, but are not limited to,
30 energy flow; nutrient, hydrologic, and biogeochemical cycling; and maintenance of food chains.
31 The sum of the functions carried out by ecosystem components provides many benefits to
32 humankind, as in the case of forest ecosystems (Smith, 1992). Some of these benefits include
33 food, fiber production, aesthetics, genetic diversity, and energy exchange.

34 A conceptual framework for discussing the effects of O₃ on ecosystems was developed
35 by the EPA Science Advisory Board (Young and Sanzone, 2002). Their six essential ecological

1 attributes (EEAs) include landscape condition, biotic condition, organism condition, ecological
2 processes, hydrological and geomorphological processes, and natural disturbance regimes.
3 Figure 7-19 outlines the how common anthropogenic stressors, including tropospheric O₃, might
4 affect the essential ecological attributes outlined by the SAB.

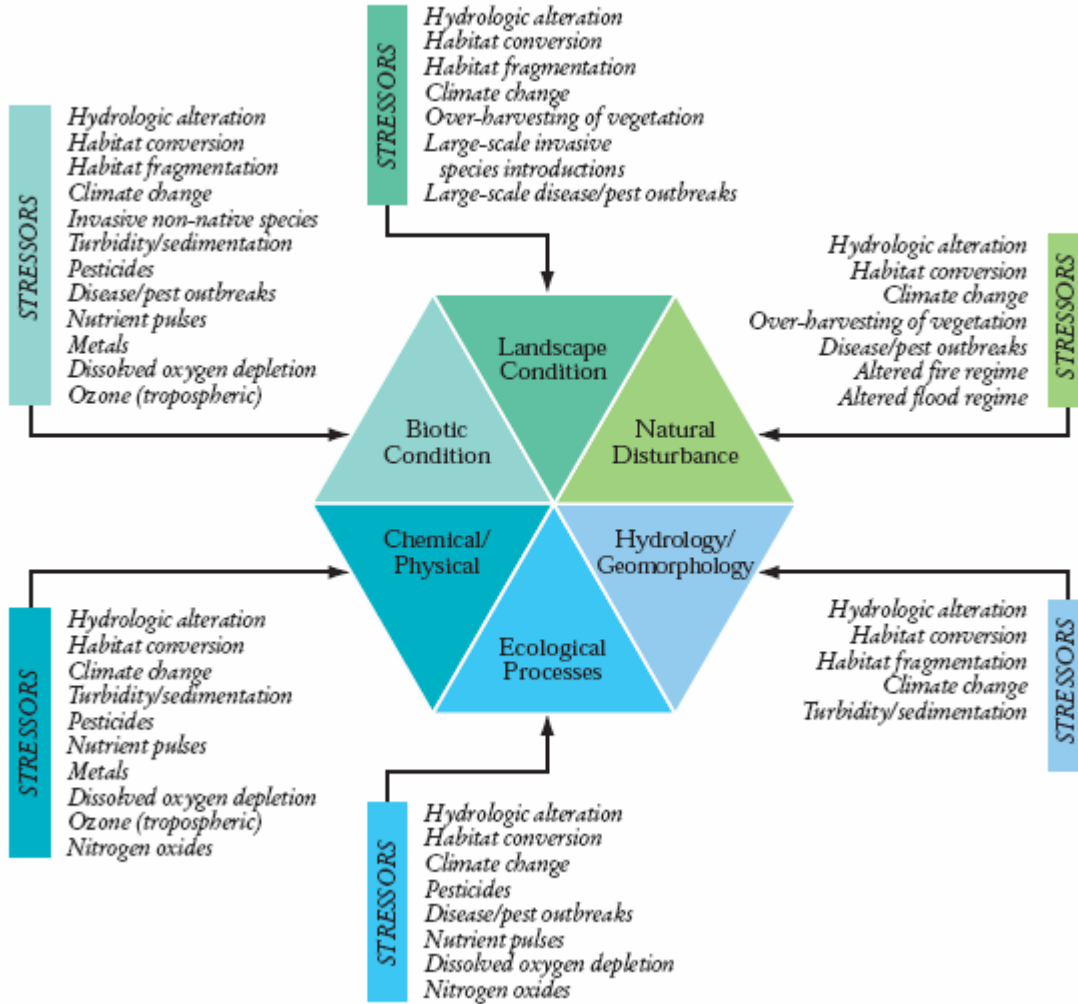

5 There is evidence that tropospheric O₃ is an important stressor of ecosystems, with
6 documented impacts on the biotic condition, ecological processes, and chemical/physical nature
7 of natural ecosystems (EPA, 2006). Most of the effects on ecosystems must be inferred from O₃
8 exposure to individual plants and processes that are scaled up through the ecosystem affecting
9 processes such as energy and material flow, inter- and intraspecies competition, and net primary
10 productivity (NPP). Thus, effects on individual keystone species and their associated microflora
11 and fauna, which have been shown experimentally, may cascade through the ecosystem to the
12 landscape level. By affecting water balance, cold hardiness, tolerance to wind and by
13 predisposing plants to insect and disease pests, O₃ may even impact the occurrence and impact of
14 natural disturbance (e.g., fire, erosion).

15 Another approach to assessing O₃ effects on ecosystems is the identification and use of
16 indicators. For example, the main indicators of phytotoxic O₃ exposures used for forest
17 ecosystems are visible foliar injury (as described in section 7.6.3.2 above) and radial growth of
18 trees. Systematic injury surveys demonstrate that foliar injury occurs on O₃-sensitive species in
19 many regions of the United States. However, there is not always a direct relationship between
20 the severity of the visible foliar symptoms and growth. This essentially means it is difficult to
21 quantify or characterize the degree which EEAs may be impacted when foliar injury is found in
22 the field. Investigations of the relationship between changes in radial growth of mature trees and
23 ambient O₃, in combination with data from many controlled studies with seedlings, suggest that
24 ambient O₃ is reducing the growth of mature trees in some locations. However, definitively
25 attributing growth losses in the field to O₃ in a wide array of ecosystems is often difficult
26 because of confounding factors with other pollutants, climate, insect damage and disease.

27 The draft CD (EPA, 2006) outlines seven case studies where O₃ effects on ecosystems
28 have either been documented or are suspected. However, in most cases, only a few components
29 in each of these ecosystems have been examined and characterized for ozone effects, and
30 therefore the full extent of ecosystem changes in these example ecosystems is not fully
31 understood. Clearly, there is a need for highly integrated ecosystem studies that specifically
32 investigate the effect of O₃ on ecosystem structure and function in order to fully determine the
33 extent to which ozone is altering ecosystem services.

7.7.1 Evidence of Potential Ozone Alteration of Ecosystem Structure and Function

The seven case studies listed in the 2006 CD demonstrate the potential for O₃ to alter ecosystem structure and function. The oldest and clearest example involves the San Bernardino Mountain forest ecosystem. In this example, O₃ appeared to be a predisposing factor leading to increased drought stress, windthrow, root diseases, and insect infestation (Takemoto et al., 2001). Increased mortality of susceptible tree species including ponderosa and Jeffrey pine resulting from these combined stresses has shifted community composition towards white fir and incense cedar and has altered forest stand structure (Miller et al., 1989). A shift of community composition towards white fir may make this ecosystem more susceptible to fire. Although the role of O₃ was extremely difficult to separate from other confounding factors, such as high N deposition, there is evidence that this shift in species composition has altered trophic structure and food web dynamics (Pronos et al., 1999) and C and N cycling (Arbaugh et al., 2003). Ongoing research in this important ecosystem will reveal the extent to which ecosystem services have been affected.

One of the best-documented studies of population and community response to O₃ effects are the long-term studies of common plantain (*Plantago major*) in native plant communities in the United Kingdom (Davison and Reiling, 1995; Lyons et al., 1997; Reiling and Davison, 1992c). Elevated O₃ significantly decreased the growth of sensitive populations of common plantain (Pearson et al., 1996; Reiling and Davison, 1992a, b; Whitfield et al., 1997) and reduced fitness as determined by decreased reproductive success (Pearson et al., 1996; Reiling and Davison, 1992a). While spatial comparisons of population responses to O₃ are complicated by other environmental factors, rapid changes in O₃ resistance were imposed by ambient levels and variations in O₃ exposure (Davison and Reiling, 1995). At the site of plantain seed collection the highest correlations occurred between O₃ resistance and ambient O₃ concentrations (Lyons et al., 1997). In this case study, it appears that O₃-sensitive individuals are being removed by O₃ stress and the genetic variation represented in the population could be declining. If genetic diversity and variation is lost in ecosystems, there may be increased vulnerability of the system to other biotic and abiotic stressors, and ultimately a change in the services provided by those ecosystems.

Reconstructed ecosystems in artificial exposure experiments have also provided new insight into how ozone may be altering ecosystem structure and function (Karnosky et al., 2005). For example, the Aspen Free-Air CO₂ Enrichment facility was designed to examine the effects of both elevated CO₂ and O₃ on aspen (*Populus tremuloides*), birch (*Betula papyrifera*), and sugar

1 maple (*Acer saccharum*) in a simple reconstructed plantation characteristic of Great Lakes
2 aspen-dominated forests (Karnosky et al., 2003b; Karnosky et al., 1999). They found evidence
3 that the effects on above- and below-ground growth and physiological processes have cascaded
4 through the ecosystem, even affecting microbial communities (Larson et al., 2002; Phillips et al.,
5 2002). This study also confirmed earlier observations of O₃-induced changes in trophic
6 interactions involving keystone tree species, as well as important insect pests and their natural
7 enemies (Awmack et al., 2003; Holton et al., 2003; Percy et al., 2002).

8 Collectively these examples suggest that O₃ is an important stressor in natural
9 ecosystems, but it is difficult to quantify the contribution of O₃ due to the combination of stresses
10 present in ecosystems. Continued research, employing new approaches, will be necessary to
11 fully understand the extent to which O₃ is affecting ecosystem services.
12

13 **7.7.2 Effects on Ecosystem Products and Services**

14 Since it has been established that O₃ affects photosynthesis and growth of plants, O₃ is
15 most likely affecting the productivity of crop and forest ecosystems. Therefore, it is desirable to
16 link effects on growth and productivity to essential ecosystem services. However, it is very
17 difficult to quantify ecosystem-level productivity losses because of the amount of complexity in
18 scaling from the leaf-level or individual plant to the ecosystem level, and because not all
19 organisms in an ecosystem are equally affected by ozone. Below is a discussion of potential
20 effects of O₃ on an important ecological service.
21

22 **7.7.2.1 Carbon Sequestration**

23 Terrestrial ecosystems are important in the Earth's carbon (C) balance and could help
24 offset emissions of CO₂ by humans if anthropogenic C is sequestered in vegetation and soils.
25 The annual increase in atmospheric CO₂ is less than the total inputs from fossil fuel burning and
26 land use changes (Prentice et al., 2001) and much of this discrepancy is thought to be attributable
27 to CO₂ uptake by plant photosynthesis (Tans & White, 1998). Temperate forests of the northern
28 hemisphere have been estimated to be a net sink of 0.6 to 0.7 Pg of C per year (Goodale et al.
29 2002). Ozone interferes with photosynthesis, causes some plants to senesce leaves prematurely
30 and in some cases, reduces allocation to stem and root tissue. Thus, O₃ decreases the potential
31 for C sequestration. For the purposes of this discussion, we define C sequestration as the net
32 exchange of carbon by terrestrial the biosphere. However, long-term storage in the soil organic
33 matter is considered to be the most stable form of C storage in ecosystems.

1 In a study including all ecosystem types, Felzer et al. (2004), estimated that US Net
2 Primary Production (net flux of C into an ecosystem) was decreased by 2.6-6.8% due to O₃
3 pollution in the late 1980's to early 1990's. Ozone not only reduces C sequestration in existing
4 forests, it can also affect reforestation projects (Beedlow et al. 2005). This effect, in turn, has
5 been found to ultimately inhibit C sequestration in forest soils which act as long-term C storage
6 (Loya et al., 2003; Beedlow et al. 2005). The interaction of rising O₃ pollution and rising CO₂
7 concentrations in the coming decades complicates predictions of future sequestration potential.
8 Models generally predict that in the future C sequestration will increase with increasing CO₂, but
9 often do not account for the decrease in productivity due to the local effects of tropospheric O₃.
10 In the presence of high O₃ levels, the stimulatory effect of rising CO₂ concentrations on forest
11 productivity has been estimated to be reduced by more than 20% (Tingey et al 2001; Ollinger et
12 al. 2002; Karnosky et al. 2003).

13 In summary, it would be anticipated that attaining lower O₃ standards would increase the
14 amount of CO₂ uptake many ecosystems in the US. However, the amount of this improvement
15 would be heavily dependent on the species composition of those ecosystems. Many ecosystems
16 in the U.S. do have O₃ sensitive plants. For, example forests ecosystems with dominant species
17 such as aspen or ponderosa pine would be expected to increase CO₂ uptake more with lower O₃
18 than forests with more O₃ tolerant species.

1 **8. STAFF CONCLUSIONS ON SECONDARY OZONE NAAQS**

2 **8.1 INTRODUCTION**

3 This chapter provides staff conclusions for consideration by the Administrator about
4 whether the existing secondary O₃ standard should be revised and, if so, what options should be
5 considered. Our conclusions on this standard and on options for consideration are based on the
6 scientific and technical information contained in the CD and on staff analyses and evaluations
7 presented in Chapters 2 and 7 of this Staff Paper.

8 The provisions of the Clean Air Act require the Administrator to establish secondary
9 standards that, in the Administrator’s judgment, are requisite to protect the public welfare from
10 any known or anticipated adverse effects. In so doing, the Administrator seeks to establish
11 standards that are neither more nor less stringent than necessary for this purpose. As noted in
12 Chapter 7, welfare effects, as defined in section 302(h) (42 U.S.C. 7602(h)) include, but are not
13 limited to, “effects on soils, water, crops, vegetation, manmade materials, animals, wildlife,
14 weather, visibility, and climate, damage to and deterioration of property, and hazards to
15 transportation, as well as effects on economic values and on personal comfort and well-
16 being”(62 FR 38857). As in the last review, this review has focused on crops and other
17 vegetation since these public welfare effects are of most concern at O₃ concentrations typically
18 occurring in the U.S. In addition, by affecting commercial crops and natural vegetation, O₃ may
19 also indirectly affect natural ecosystem components such as soils, water, animals, and wildlife.
20 As discussed above in Chapter 7, insufficient new information is available on other welfare
21 effects categories to provide a basis for selecting an averaging time and level for a distinct
22 secondary standard to address such effects and therefore they are not discussed further.

23 In identifying a range of secondary standard options for the Administrator to consider,
24 staff notes that the final decision is largely a public policy decision. A final decision regarding
25 the adequacy of the current standard and the range of options presented will draw upon: (1) the
26 most policy-relevant scientific information on vegetation effects associated with exposure to
27 ambient levels of O₃; (2) staff analyses of air quality, vegetation exposure, risk, and associated
28 economic values; and (3) judgments about how to deal with the range of uncertainties that are
29 inherent in the relevant scientific evidence and analyses. The range of options identified by the
30 staff for the Administrator to consider, include options regarding an appropriate pollutant
31 indicator, averaging time, form, and level of the secondary O₃ NAAQS.

32

1 8.2 APPROACH

2 In evaluating whether the current secondary standard is adequate or whether
3 consideration of revisions is appropriate, our approach in this review builds upon the general
4 approach used in the last review by expanding and modifying the exposure, risk, and benefits
5 assessments to reflect the availability of new tools, assessment methods, and a larger and more
6 diverse body of evidence. In developing conclusions on the O₃ standard, we have taken a weight
7 of evidence approach that evaluates information across a variety of vegetation-related research
8 areas described in the CD, combined with assessments of air quality, exposures, risks, and both
9 quantitative and qualitative assessments of the benefits associated with protection of commercial
10 crops, forest tree species and ecosystems.

11 With respect to vegetation effects information, we have taken into account past as well as
12 more recent evidence from chamber, free air, gradient, and field observation studies for a variety
13 of vegetation effects endpoints. We place greater weight on U.S. studies due to the often
14 species-, site-, and climate-specific nature of O₃-related vegetation response. With respect to
15 quantitative exposure-, risk, and benefits-based considerations, we have relied on interpolated O₃
16 exposures as described in section 7.5.4 of Chapter 7. A range of alternative air quality scenarios
17 were generated to reflect the alternative standard options under consideration. These scenarios
18 include current “as is” air quality (2001), as well as four “just meet” scenarios for which air
19 quality is adjusted using the rollback method to just meet the level of the alternative standard
20 options. We have quantified the uncertainties associated with the interpolated O₃ exposure
21 surface by comparing actual monitor data to the interpolated surface value at each monitor site.
22 In the benefits assessment, staff acknowledges the presence of unknown and unquantifiable
23 sources of uncertainty associated with use of the agronomic benefits model, AGSIM, as is typical
24 with all such models.

25 Our review of the adequacy of the current secondary standard begins by considering
26 whether the currently available body of evidence assessed in the 2006 CD suggests that revision
27 of any of the basic elements of the standards would be appropriate. More specifically, this
28 evaluation of the adequacy of the current standard involves addressing questions such as the
29 following:

- 30 • To what extent does newly available information reinforce or call into question evidence
31 of associations with effects identified in the last review?
- 32 • To what extent does newly available information reinforce or call into question any of the
33 basic elements of the current standards?
- 34 • To what extent have important uncertainties identified in the last review been reduced
35 and have new uncertainties emerged?

1 To the extent that the evidence suggests that revision of the current standards would be
2 appropriate, we then consider whether the currently available body of evidence supports
3 consideration of standards that are either more or less protective by addressing the following
4 questions:

5 • Is there evidence that vegetation effects occur at air quality levels that are as low as or
6 lower than had previously been observed, and what are the important uncertainties
7 associated with that evidence?

8 • Are exposures of concern and vegetation risks estimated to occur in areas that meet the
9 current standard; are they important from a public welfare perspective; and what are
10 the important uncertainties associated with the estimated risks?

11 To the extent that there is support for consideration of revised standards, we then identify ranges
12 of standards (in terms of indicators, averaging times, levels, and forms) that would reflect a range
13 of alternative public welfare policy judgments, based on the currently available evidence, as to
14 the degree of protection that is requisite to protect public welfare from any known or anticipated
15 adverse effects. In so doing, staff addresses the following questions:

16 • Does the evidence provide support for considering a different O₃ indicator?

17 • Does the evidence provide support for considering different averaging times?

18 • What ranges of levels and forms of alternative standards are supported by the evidence,
19 and what are the uncertainties and limitations in that evidence?

20 • To what extent do specific levels and forms of alternative standards reduce the estimated
21 exposures of concern and risks attributable to O₃, and what are the uncertainties in the
22 estimated exposure and risk reductions?

23 Staff's review of the secondary standard for O₃ is addressed in section 8.3 below, including our
24 consideration of the adequacy of the current secondary O₃ standard based on key policy-relevant
25 information on vegetation and ecosystem effects, exposures, risks, and benefits, and
26 considerations of each of the major elements that define the O₃ standard: pollutant indicator,
27 averaging time, form, and level. Section 8.4 summarizes the range of alternative secondary
28 standard options identified by staff for the Administrator's consideration. This chapter
29 concludes with a summary of key uncertainties and research needs related to setting a secondary
30 O₃ NAAQS in section 8.5.

1 **8.3 SECONDARY O₃ STANDARD**

2 **8.3.1 Background**

3 In the final rule for the O₃ NAAQS published in July 1997 (62 FR 38877), the
4 Administrator decided to replace the then existing 1-hr, 0.12-ppm secondary NAAQS with a
5 standard that was identical in every way to the new revised primary standard of an 8-hr, 0.08
6 ppm annual fourth highest maximum 8-hr average standard averaged over 3 years. Her decision
7 was based on her judgment that: (1) the then existing secondary standard did not provide
8 adequate protection for vegetation against the adverse welfare effects of O₃; (2) CASAC advice
9 “that a secondary NAAQS, more stringent than the present primary standard, was necessary to
10 protect vegetation from O₃” (Wolff, 1996); (3) the new 8-hr average standard would provide
11 substantially improved protection for vegetation from O₃-related adverse effects as compared to
12 the level of protection provided by the then current 1-hr, 0.12-ppm secondary standard; 4)
13 significant uncertainties remained with respect to exposure dynamics, air quality relationships,
14 and the exposure, risk, and monetized valuation analyses presented in the proposal, resulting in
15 only rough estimates of the increased public welfare likely to be afforded by each of the
16 proposed alternative standards, which are important factors in selecting an appropriate secondary
17 standard; 5) there was value in allowing more time to obtain additional information to better
18 characterize O₃-related effects on vegetation under field conditions from additional research and
19 to develop a more complete rural monitoring network and air quality database from which to
20 evaluate the elements of an appropriate seasonal secondary standard; and 6) there was value in
21 allowing more time to evaluate more specifically the improvement in rural air quality and in O₃-
22 related vegetation effects resulting from measures designed to attain the new primary standard
23 (62 FR 38877-78).

24 As discussed in Chapter 7, additional information has become available since the last
25 review. On the basis of staff assessments that incorporate the most policy-relevant aspects of
26 this new information, we have evaluated the adequacy of the current secondary standard in
27 protecting public welfare.
28

29 **8.3.2 Adequacy of Current O₃ Standard**

30 More recent research has further confirmed and strengthened our earlier understanding
31 and conclusions regarding the effects of O₃ on vegetation at current ambient exposures. Results
32 from the exposure, risk and benefits assessments conducted by staff and described in Chapter 7
33 characterize to what degree impacts would be expected to occur upon meeting the current 8-hr
34 secondary standard. As documented below, we have evaluated the adequacy of the current

1 standard both on the evidence and significance of vegetation effects at or below the level of the
2 standard in conjunction with the additional considerations presented in discussions on indicator,
3 averaging time, form, and level.

4 **8.3.2.1 Considerations Based on Vegetation Effects Evidence**

5 Based on a weight of evidence approach that integrates information from across the
6 various vegetation-related research areas described in the O₃ CD, including chamber and free air
7 exposure crop yield and tree seedling biomass experimental studies, visible foliar injury data
8 from biomonitoring plots, and modeled mature tree growth, we conclude that vegetation effects
9 continue to occur at levels that impact public welfare at air quality levels that just meet or are
10 below the current standard.

11 Staff exposure and risk assessments estimate that just meeting the current 8-hr standard
12 would still allow significant levels of yield loss to occur in several fruit and vegetable species
13 and major commodity crop species currently grown in the U.S. (see Table 7.3 in section 7.6.2.4
14 of Chapter 7). For example, grapes, cantaloupes and Valencia oranges had estimated median
15 yield losses of 20.5, 19, and 15%, respectively, when air quality just met the level of the current
16 standard. Fruits and vegetables are a large part of the U.S. agricultural sector and are especially
17 susceptible to O₃ pollution because much of the production occurs in the San Joaquin Valley
18 region of California. Median yield losses for the commodity crops were not as large. Cotton, for
19 example, had estimated median yield losses of 4.8% at air quality levels that just meet the current
20 standard. Soybean had an even smaller estimated median yield loss of 1.7% under just meet air
21 quality for the current standard. However, soybean is grown in 40 of the lower 48 states,
22 suggesting that even small changes in individual plant yield, when applied across large acreages,
23 can be significant.

24 Another group of crops, multiple year forage crops, have also received additional study
25 since the last review. Based on these new studies, the yields and quality of multiple-year forage
26 crops have also been shown to be sufficiently reduced as to have nutritional and possibly
27 economic implications for their use as ruminant animal feed at O₃ exposures that occur in some
28 years over large areas of the U.S. However, it is not clear at this time to what degree they are
29 impacted at lower levels of air quality.

30 Biomass loss in sensitive tree seedlings is still predicted to occur under O₃ exposures that
31 just meet the level of the current secondary standard (see Table 7.5 in section 7.6.3.1 of Chapter
32 7). For instance, black cherry, ponderosa pine, eastern white pine and aspen had estimated
33 median seedling biomass losses of 24, 10, 5.8, and 5.6%, respectively. Percent biomass loss in
34 tree seedlings is not intended to provide any information on expected biomass loss in mature
35 trees of the same species, and cannot be considered comparable to percent yield in annual crops.

1 However, due to the potential for compounding effects over multiple years, there is scientific
2 consensus that biomass loss greater than 1-2% annually can be significant. Decreased seedling
3 root growth and survivability could affect overall stand health and composition in the long term.

4 Visible foliar injury, not quantitatively explored in the last review, has been more fully
5 assessed in Chapter 7 (see Table 7.6 in section 7.6.3.2). Visible injury symptoms diagnostic of
6 phytotoxic O₃ exposures continue to be documented on sensitive bioindicator plants at many U.S.
7 Forest Service Forest Inventory and Analysis biomonitoring sites throughout the U.S. at current
8 levels of O₃ air quality. Staff assessments of recent data show that of the counties with air
9 quality levels at or below that of the current 8-hr standard, 0.084 ppm that also contained FIA
10 biomonitoring sites, incidence of foliar injury ranged from 21 to 39% during the four year period
11 (2001-2004). These percentages suggest that phytotoxic exposures would still occur after full
12 attainment of the current secondary standard. Additionally, the data show that foliar injury
13 occurrence is geographically widespread and is occurring on a variety of plant species in forested
14 systems. Though linking foliar injury to other plant effects is still problematic, its presence
15 indicates that other O₃-related vegetation effects could also be present.

16 Our analysis using modeled mature tree growth response under different air quality
17 scenarios for the western species (ponderosa pine) and two eastern species (red maple and tulip
18 poplar) projected that just meeting the current standard could be reducing annual net biomass
19 gain in simulated species (see Table 7.7 in section 7.6.3.3 in Chapter 7). This judgment is based
20 in part on model outputs that estimate that as O₃ levels are reduced below those of the current
21 standard, significant improvements in growth would occur. For instance, estimated growth in
22 red maple increased by 4.08% and 2.99% at Big Meadows and Cranberry sites, respectively,
23 when air quality was rolled back to just met a SUM06 of 15 ppm-hr. Yellow poplar was
24 projected to have a growth increase between 0.6 and 8.26% under the same scenario at the two
25 sites.

26 Though there is significant uncertainty associated with this analysis, we judge that this
27 information should be given careful consideration in light of several other pieces of evidence.
28 Specifically, limited evidence from experimental studies that go beyond the seedling stage show
29 continued decreased growth under elevated O₃ in trees. Some mature trees such as red oak, have
30 shown greater sensitivity to O₃ than seedlings of the same species. As indicated above, smaller
31 growth loss increments may be significant for perennial species. The potential for cumulative
32 “carry over” effects as well as compounding must be considered. The accumulation of such
33 “carry-over” effects over time may affect long term survival and reproduction of individuals and
34 ultimately the abundance of sensitive tree species in forest stands.

35 In summary, O₃ levels that would be expected to remain after meeting the level of the
36 current secondary standard, are sufficient to cause reduced crop yields, reduced above and below

1 ground seedling and mature tree growth, and visible foliar injury. Other O₃ induced effects
2 described in the literature include an impaired ability of many sensitive species and genotypes
3 within species to adapt to or withstand other environmental stresses such as freezing
4 temperatures, pest infestations and/or root disease, and reduced ability to compete for available
5 resources. In the long run, the result of these impairments (e.g., loss in vigor) may be plant
6 death. Though effects on other ecosystem components have not been examined, except in
7 isolated cases, effects such as those described above, could have significant implications for
8 plant community and associated species biodiversity and the structure and function of whole
9 ecosystems (Young and Sanzone, 2002).

10 **8.3.2.2 Pollutant Indicator**

11 The staff concludes that O₃ remains the appropriate pollutant indicator for use in a
12 secondary NAAQS that provides protection for public welfare from exposure to all
13 photochemical oxidants. This conclusion is based on the same rationale presented in the
14 previous Staff Paper (U.S. EPA, 1996), which recognizes that among the other photochemical
15 oxidants, the database for vegetation effects only raises concern at levels found in the ambient air
16 for O₃ and, therefore, control of ambient O₃ levels provides the best means of controlling other
17 photochemical oxidants of potential welfare concern. There is nothing in the recent literature to
18 warrant reconsideration of this conclusion.

19 **8.3.2.3 Averaging Times**

20 Plants, unlike people, are exposed to ambient air 24 hr a day, every day for their entire
21 life. For annual species, this is for only a period within one year, for perennials, for multiple
22 years, decades or centuries. Regardless of plant type, it has been well established in the literature
23 that O₃ effects are cumulative, and that longer exposure durations have a greater impact than
24 shorter durations, all else being equal. Air quality indices that account for the exposure duration
25 overall do a better job predicting plant response than long term averages. However, O₃ levels are
26 not continuously elevated and plants are not equally sensitive to O₃ over the course of a day,
27 season or lifetime. Thus, it becomes necessary to identify periods of exposure that have the most
28 relevance for plant response.

29 *Seasonal Window.* Many recent studies described in the 2006 CD have specifically
30 selected exposure indices that take into account the cumulative, concentration-weighted impact
31 of O₃-induced effects throughout the growing season when measuring growth and yield impacts
32 and have substantiated the 1996 CD and 1996 Staff Paper conclusions on the importance of
33 cumulative, seasonal exposures. In general, the period of maximum potential growth for annual
34 crops, herbaceous species and deciduous trees and shrubs occurs within the annual period
35 defined as the O₃ season, which varies on a state-by-state basis. Annual crops are typically

1 grown for periods of two to three months before being harvested. In contrast, perennial species
2 may be photosynthetically active up to 12 months each year, depending on the species and where
3 it is grown. In the 1996 Staff Paper and proposal notice, we noted that the selection of any single
4 averaging time for a national standard would represent a compromise, given the significant
5 variability in growth patterns and lengths of growing seasons among the wide range of
6 vegetation species that may experience adverse effects associated with O₃ exposure, but
7 concluded, based on the information available at that time, that selection of the maximum
8 consecutive 3-month period within the O₃ season was reasonable, and in most cases, would most
9 likely coincide with the periods of greatest plant sensitivity on an annual basis. Based on the
10 information assessed in the current CD (EPA, 2006) and Chapter 7 of this document, we again
11 conclude the maximum consecutive 3-month period within the O₃ season is a reasonable
12 averaging time for vegetation.

13 *Diurnal Window.* Stomata are the entry points for O₃ into plant leaves. Over the course of
14 a day, plant stomatal conductance varies along with light level, soil moisture and other factors.
15 In general, stomata are most open during daylight hours in order to allow sufficient CO₂ uptake
16 for use in carbohydrate production through photosynthesis. At most locations, O₃ concentrations
17 are also highest during the daytime, potentially coinciding with maximum stomatal uptake.
18 Ozone uptake impairs photosynthesis, which can then lead to impacts on plant growth,
19 reproduction (yield) and root function. In the last review, studies had shown that by increasing
20 the diurnal window from 7 to 12 or 24 hrs, the index captured more of the peak O₃ concentrations
21 that occur in some environments. However, the associated reductions in growth or yield (which
22 are a result of impaired photosynthesis) and increases in foliar injury had not been seen to
23 increase proportionally with increasing diurnal period. Though limited work has been done
24 recently to more fully characterize O₃ uptake at night and its potential contribution to total plant
25 uptake and response, we conclude that such information remains preliminary and not
26 generalizable at this time (see also Appendix A of Chapter 7).

27 Based on these considerations, as well as information assessed in the current CD (EPA,
28 2006) and Chapter 7 of this document, we again conclude that a 12-hr (8:00 am to 8:00 pm)
29 diurnal window remains appropriate for a secondary NAAQS designed to protect a wide range of
30 vegetation growing in environmental conditions found across the U.S.

31 **8.3.2.4 Form of the Standard**

32 In the last review, based on a substantial body of vegetation effects literature that
33 demonstrated the importance of taking into account exposure duration and the differential impact
34 of higher concentrations when predicting vegetation response, the Administrator judged that a 3-
35 month, 12-hr SUM06 seasonal secondary standard (set at a level of 25 ppm-hr) would also be

1 appropriate to protect public welfare from known or anticipated adverse effects given the
2 available scientific knowledge and that such a seasonal standard "...is more biologically
3 relevant..." (62 FR 38876 -77). On the basis of that history, Chapters 2 and 7 of this Staff Paper
4 characterize information in terms of both the current 8-hr, 0.08 ppm secondary standard form and
5 the alternative 3-month, 12-hr SUM06 form proposed in the last review. Due to a number of
6 additional technical and policy-relevant considerations discussed in section 7.5.1 of Chapter 7, we
7 also included the W126 as an alternative cumulative, concentration weighted form.

8 *Comparison of 8-Hour Average and Cumulative Seasonal Forms.* The 1997 final rule
9 recognized that "it remained uncertain as to the extent to which air quality improvements
10 designed to reduce 8-hr O₃ concentrations would reduce O₃ exposures measured by a seasonal
11 SUM06 index." (62 FR 38876)

12 An analysis undertaken by EPA at the time to explore that question showed that there
13 was considerable overlap between areas that would be expected not to meet the range of
14 alternative 8-hr standards being considered for the primary NAAQS and those expected not to
15 meet the range of values (expressed in terms of the SUM06 index) of concern for vegetation.
16 Though this result suggested that improvements in national air quality from attaining an 8-hr
17 primary standard within the recommended range of levels would also reduce levels below those
18 of concern for vegetation in those same areas, there was considerable uncertainty as to the exact
19 strength of the relationship between urban O₃ air quality and distributions that occur in non-
20 monitored rural or remote areas.

21 Using recent county-level air quality data (2001 – 2004), we again performed an analysis
22 to compare the degree to which the 8-hr form controlled air quality of concern for vegetation
23 expressed in terms of the SUM06. Based on data from AQS sites and the subset of CASTNET
24 sites that had the highest O₃ levels for the county in which they are located, this analysis again
25 shows that only a few counties have SUM06 values above 25 ppm-hr after attaining the current
26 0.08-ppm, 8-hr average standard (see Figures 7-1 and 7-2 in Chapter 7). However, these patterns
27 varied considerably between years with differing levels of O₃, with the higher O₃ year (2002)
28 showing a stronger association between SUM06 and the 8-hr standard, and the lower O₃ year
29 (2004) showing less of one. Further, at SUM06 levels at or below 25 ppm-hr (see discussion on
30 Level below), the relationship between the 8-hr standard and SUM06 levels potentially of
31 concern to vegetation did not hold. Prior to finalizing this draft Staff Paper, we plan to further
32 assess the strength of the relationship between the 8-hr and SUM06 standard forms at a subset of
33 more rural and remote sites, including high elevation national parks.

34 In conclusion, meeting the current 8-hr 4th highest maximum average standard would
35 result in air quality improvements that could potentially benefit vegetation in some areas.
36 However, based on the above analysis, as well as scientific consensus supporting the use of a

1 cumulative concentration-weighted form to describe exposures of concern for vegetation as
2 described in Chapter 7, we conclude that the use of the 8-hr index as a tool to track and predict
3 vegetation risk remains problematic.

4 *Comparison of SUM06 and W126 Cumulative, Concentration-Weighted Forms.* In
5 addition to evaluating the 8-hr average form, we evaluated the appropriateness of the SUM06
6 alternative proposed in the last review by comparing it to another cumulative, concentration-
7 weighted form discussed in the 1996 Staff Paper, the W126. In the 1996 Staff Paper, our
8 preference for the SUM06 over other cumulative forms was based on the following science and
9 policy considerations:

10 1) All cumulative, peak-weighted exposure indices considered, including W126 and
11 SUM06, were about equally good as exposure measures to predict exposure-response
12 relationships reported in the NCLAN crop studies.

13 2) the SUM06 form would not be influenced by background O₃ concentrations (defined
14 at the time as 0.03 to 0.05 ppm) under many typical air quality distributions.

15 In the current review, we have reconsidered whether the SUM06 form is the most
16 appropriate cumulative form based on the following:

- 17 • Model predictions of policy-relevant background (PRB) in the range of 0.02 to 0.035
18 ppm for the current review are below the range of 0.03 to 0.05 ppm described as
19 background in the previous review. Thus, background concentrations become much
20 less of a factor influencing the choice of an appropriate cumulative index.
- 21 • There is no evidence of a biological exposure threshold for eliciting plant response in
22 the extensive vegetation effects literature. An index with a threshold set at 0.06 ppm
23 artificially truncates exposures that have been shown to produce vegetation effects of
24 concern given sufficient duration. Without the policy consideration of not including
25 PRB O₃ concentrations up to a level of 0.05 ppm, it may be appropriate to consider a
26 more biologically-based form that includes concentrations below 0.06 ppm, such as the
27 W126.

28 While recognizing that no one concentration-weighted exposure index can fully account
29 for the complex relationships between O₃ concentrations and plant responses across a wide range
30 of species and environments, we conclude, on the basis of the information highlighted above,
31 that the W126 form is a more appropriate biologically-based and policy- relevant cumulative,
32 concentration-weighted form.

1 **8.3.2.5 Level of the Standard**

2 The level at which a secondary standard should be set depends on a blending of science
3 and policy judgments by the Administrator as to the level of air quality which is requisite to
4 protect the public welfare from any known or anticipated adverse effects associated with the
5 pollutant in the ambient air. The exposure, risk and benefits assessments conducted in Chapter 7
6 and summarized briefly above, provide information regarding the effects associated with a
7 number of different welfare endpoints at different levels of air quality, often expressed in terms
8 of both the current 8-hr average form and the SUM06 (or W126) seasonal form(s).

9 At the end of the last review, we identified a range for a 3-month, 12-hr SUM06 standard
10 form of 25 to 38 ppm-hr, for the Administrator's consideration. These levels were estimated to
11 allow 10% to 20% yield loss, respectively, to occur in no more than 50% of the studied NCLAN
12 agricultural crops. These levels were also estimated to provide an increased level of protection
13 for other categories of vegetation such as tree seedlings and mature trees in commercial, Class I,
14 and other forested areas in urban, rural, and remote environments. It was recognized, however,
15 that a standard set within this range would not protect the most sensitive species or individuals
16 within a species from all potential effects related to O₃ exposures. The Administrator proposed
17 the lower end of the range (e.g., 25 ppm-hr) as necessary to provide a requisite level of
18 protection for vegetation against the adverse effects of O₃.

19 As discussed more fully in Appendix 7A, in the interim between the 1996 proposal notice
20 and the 1997 final rule, the results of a consensus-building workshop on the need for a long-term
21 cumulative secondary O₃ standard were published. At this workshop, expert scientists expressed
22 their judgments on what standard form(s) and level(s) would provide vegetation with adequate
23 protection from O₃-related adverse effects. Consensus was reached with respect to selecting
24 appropriate ranges of levels in terms of a 3-month, 12-hr SUM06 standard for a number of
25 vegetation effects endpoints. We have included estimated equivalent levels in terms of the 3-
26 month, 12-hr W126, shown in parentheses, for reference. For yield reductions in agricultural
27 crops – a range of 15 to 20 (13 to 18) ppm-hr; for growth effects to tree seedlings in natural
28 forest stands – a range of 10 to 15 (9 to 13) ppm-hr; for growth effects to tree seedlings and
29 saplings in plantations – a range of 12 to 16 (11 to 14) ppm-hr; and for foliar injury to natural
30 ecosystems – a SUM06 range of 8 to 12 (7 to 11) ppm-hr (Heck and Cowling, 1997).

31 In the final rule, the Administrator pointed to the results of this workshop as providing
32 important support to her view that the then current secondary standard was not adequately
33 protective of vegetation, contributing to her rationale that revision of the secondary standard was
34 needed. Additionally, she felt that this consensus report foreshadowed the direction of future
35 scientific research in this area, the results of which could be important in future reviews of the O₃
36 secondary standard (62 FR 38877).

1 The expert recommendations identified above informed our assessment of a range of
2 levels appropriate for the Administrator to consider in this review. We judge that the upper
3 bound of this range, the SUM06 level of 25 ppm-hr, as proposed in the last review, is an
4 appropriate upper level for consideration, and that a SUM06 level of 15 ppm-hr is an appropriate
5 lower level. We conclude that approximately equivalent levels of a W126 (13 to 21 ppm-hr)
6 would also be appropriate to consider. The level of protection to vegetation at the upper end of
7 this range is expected to be roughly equivalent to that provided by the current 8-hr secondary
8 standard in most areas. Levels below the upper end but within this range would provide
9 increased protection for vegetation over the current level of the 8-hr standard. Further, the
10 degree of protection varies depending on the vegetation effects endpoint(s) considered. The
11 lower end of this range, 15 ppm-hr, was selected for the following reasons: 1) it represents an
12 increase in protection for agricultural crops studied in NCLAN to no more than 10% yield loss in
13 75% of studied crop species and/or cultivars; 2) it falls at or near the upper end of the range
14 suggested as protective of tree seedling growth in natural forest stands and plantations,
15 respectively; 3) it would provide some additional protection for visible foliar injury in natural
16 systems.

17 In arriving at this conclusion, we placed greater weight on those welfare effects endpoints
18 that could be quantified or directly assessed. For example, the crop economic benefits analysis
19 estimates that when the current 8-hr standard is just met across the entire U.S., an average annual
20 benefit of \$70-\$96 million would be realized for the total agricultural sector. Meeting a SUM06
21 of 25 ppm-hr produced an estimated average annual benefit of \$172-\$230 million for the total
22 agricultural sector. However, at the SUM06 of 15 ppm-hr, estimated benefits increased to
23 approximately \$345-\$532 million. These numbers clearly suggest a significant annual impact
24 from O₃ that could reasonably be judged to be important from a public welfare perspective. We
25 note that that these impacts would not be distributed equally across the country, but would
26 impact certain regions disproportionately.

27 In addition to crops, the lower level would improve protection against decreased growth
28 in tree seedlings and mature trees. Tree growth is an important endpoint to consider because it
29 can be related to other aspects of societal welfare such as sustainable production of timber and
30 related goods, recreation, and carbon (CO₂) sequestration. Equally important, impacts on tree
31 growth can also affect ecosystems through shifts in community species composition and the loss
32 of genetic diversity due to the loss of O₃ sensitive individuals or species. Though it is not
33 possible to quantify all the ecological and societal benefits associated with varying levels of
34 alternative secondary standards, based on our analyses of seedling and mature tree growth and
35 the scientific literature we would anticipate that the lower end of the range identified for the

1 Administrator's consideration would improve tree growth and decrease the adverse effects of O₃
2 on forested ecosystems.

3 Additionally, it is anticipated that the lower end of this range would provide increased
4 protection from the more subtle impacts of O₃ acting in synergy with other natural and man-made
5 stressors to adversely affect individual plants, populations and whole systems. By disrupting the
6 photosynthetic process, decreasing carbon storage in the roots, increasing early senescence of
7 leaves and affecting water use efficiency in trees, O₃ exposure can disrupt or change the nutrient
8 and water flow of an entire system. Weakened trees can become more susceptible to other
9 environmental stresses such as pest and pathogen outbreaks or harsh weather conditions.
10 Though insufficient information exists to estimate the severity of these impacts as a function of
11 the level of alternative secondary standards, we conclude that this information should be weighed
12 in considering the extent to which a secondary standard should be precautionary in nature in
13 protecting against effects that have not yet been adequately studied and evaluated.

14 **8.4 ALTERNATIVE SECONDARY STANDARD OPTIONS FOR CONSIDERATION**

15 We have identified a range of options for the Administrator to consider in determining
16 whether revisions to the secondary standard are appropriate. These options reflect the results
17 from the environmental assessment described in Chapter 7 above, as well as a number of policy-
18 relevant considerations identified both in the last and current reviews.

19 In the last review, the Administrator took into account the following in reaching her final
20 decision: 1) the varying degrees of protection afforded by the alternative primary standards
21 recommended in Section VI; 2) the incremental protection associated with alternative
22 cumulative, seasonal secondary standards under consideration; and 3) the value of establishing a
23 seasonal form for the secondary standard that is more representative of biologically relevant
24 exposures; and 4) the extent to which a secondary standard should be precautionary in nature
25 given the possibility of ozone impacts acting in synergy with other natural and manmade
26 stressors to impact climate and other environmental endpoints, particularly given the potential
27 significance at a regional scale and in Class I areas.

28 In the current review, several additional policy-relevant issues may warrant
29 consideration. First, the Agency has undertaken a number of activities geared toward improving
30 ecosystem-related program tracking and accountability and is currently engaged in efforts to
31 identify relevant indicators for that purpose. Having a biologically-relevant air quality index
32 would assist with that process. Secondly, the National Research Council recently published a
33 comprehensive report titled *Air Quality Management in the United States* (NRC, 2004). In that
34 report, the Agency was encouraged to evaluate its historic practice of setting the secondary
35 NAAQS equal to the primary. "Whatever the reason that led EPA to use identical primary and

1 secondary NAAQS in the past, it is becoming increasingly evident that a new approach will be
2 needed in the future. There is growing evidence that the current forms of the NAAQS are not
3 providing adequate protection to sensitive ecosystems and crops.”(NRC, 2004)

4 Based on these new policy-relevant considerations, combined with the weight of the
5 scientific evidence, we conclude that consideration should be given to a distinct secondary
6 standard with a more biologically relevant form, in addition to considering retaining the current
7 standard.

8 The following secondary standard options encompass the breadth of policy-relevant
9 considerations described above:

10 1) ***Set a biologically relevant secondary standard.*** Selecting a cumulative, seasonal,
11 concentration-weighted form (e.g., SUM06 or W126) has the benefit of making it easier
12 to track the expected impact to vegetation of different levels of air quality and to better
13 link environmental improvements with Agency programs, as well as improve protection
14 to vegetation in some areas. In Chapter 7 of this Staff Paper, we described several
15 policy-relevant issues, including lower estimated levels of PRB and the lack of a
16 scientific basis for a biological threshold that led to the inclusion of a W126 form for
17 consideration as a more appropriate alternate to the previously proposed SUM06 form.
18 Under this option, we have identified a range of levels appropriate for the Administrator
19 to consider based on the discussions above: for SUM06, a range of 15 to 25 ppm-hr and
20 the comparable range of 13 to 21 ppm-hr for a W126.

21 2) ***Continue to set secondary standard identical to primary.*** Meeting the current 0.08-
22 ppm secondary standard would provide additional protection to vegetation and
23 ecosystems. However, at the 0.08-ppm level, some areas of the country will still
24 experience exposures sufficient to produce a significant level of crop yield and tree
25 seedling biomass loss, mature tree impacts, foliar injury, economic impacts and
26 unquantifiable ecosystem effects, taking into account expected year-to-year variability.
27 In addition, tracking the success of the secondary NAAQS program would be more
28 difficult without a biologically based form.

29 **8.5 SUMMARY OF KEY UNCERTAINTIES AND RESEARCH RECOMMENDATIONS** 30 **RELATED TO SETTING SECONDARY O₃ STANDARDS**

31 Staff has identified the following key uncertainties and research questions that have been
32 highlighted in Chapter 9 of the CD and Chapter 7 herein, associated with this review of the
33 welfare-based secondary standards. The first set of key uncertainties and research
34 recommendations discussed below is that associated with the extrapolation to species or growing
35 conditions outside of specific experimental or field study conditions. The second set of key

1 uncertainties and research recommendations pertain to our ability to assess the impact of O₃ on
2 ecosystem structure and function. Thirdly, we identify research recommendations related to the
3 development of approaches, tools, or methodologies useful in characterizing the relationship
4 between O₃ and plant response in a policy context. These three areas are described below.

5 (1) Species-Level Extrapolations:

- 6 • To reduce uncertainties associated with extrapolating plant response for a given level
7 of O₃ using composite response functions across differing regions and climates, studies
8 using large numbers of plant species across regions where those species are indigenous
9 are recommended. In addition, to better understand the full range of response of plant
10 species to O₃, research on more species is recommended.
- 11 • To reduce uncertainty associated with estimating the risk to vegetation of differing
12 amounts of O₃-induced visible foliar injury over the plant's leaf area, research to
13 explore the relationship between visible foliar injury and other O₃-related effects is
14 recommended.
- 15 • To reduce uncertainty associated with estimated or modeled flux into plants, research is
16 recommended to evaluate the factors that affect O₃ flux into plants, including the
17 species specific roles of nocturnal flux and detoxification. Research that explores the
18 relative importance of flux rate versus total cumulative flux or dose, and that leads to a
19 database of O₃ flux-response relationships for vegetation, similar to the extensive
20 concentration-response database that currently exists is recommended to further reduce
21 existing uncertainties.
- 22 • To reduce uncertainties in extrapolating from O₃ effects on juvenile to mature trees and
23 from trees grown in the open versus those in a closed forest canopy in a competitive
24 environment, additional research is recommended.
- 25 • To reduce uncertainties in extrapolating individual plant response spatially or to higher
26 levels of biological organization, including ecosystems, research that explores and
27 better quantifies the nature of the relationship between O₃, plant response and multiple
28 biotic and abiotic stressors, including those associated with climate change, is
29 recommended.

30 (2) Ecosystem Level Impacts:

- 31 • To reduce uncertainties associated with projections of the effects of O₃ on the
32 ecosystem processes of water, carbon, and nutrient cycling, particularly at the stand
33 and community levels, research is needed on the effects on belowground ecosystem

1 processes in response to O₃ exposure alone and in combination with other stressors.
2 These below ground processes include interactions of roots with the soil or
3 microorganisms, effects of O₃ on structural or functional components of soil food webs
4 and potential impacts on plant species diversity, changes in the water use of sensitive
5 trees, and if the sensitive tree species is dominant, potential changes to the hydrologic
6 cycle at the watershed and landscape level.

- 7 • To conclusively show whether O₃ affects biodiversity or genetic diversity, research on
8 competitive interactions under elevated O₃ levels are recommended. This research
9 could be strengthened by modern molecular methods to quantify impacts on diversity.
- 10 • To fill the data gaps regarding interactions and potential feedback mechanisms between
11 O₃ and O₃ precursor (e.g., volatile organic carbons) production, atmospheric processes,
12 and climate change variables, research is recommended to evaluate whether O₃ will
13 negate the positive effects of an elevated CO₂ environment on plant carbon and water
14 balance, whether the likelihood of various biotic stressors such as pest epidemics and
15 insect outbreaks would be expected to increase in the future
- 16 • To reduce uncertainties associated with scaling O₃ effects up from the responses of
17 single or a few plants to effects on communities and ecosystems, additional research is
18 recommended. Because these uncertainties are multiple and significant due to the
19 complex interactions involved, new research will likely require a combination of
20 manipulative experiments with model ecosystems, community and ecosystem studies
21 along natural O₃ gradients, and extensive modeling efforts to project landscape-level,
22 regional, national and international impacts of O₃.

23 (3) Approaches, Tools, Methodologies:

- 24 • To reduce uncertainties associated with valuing improved vegetation and ecosystem
25 function from improved O₃ air quality, research is needed on methodologies to
26 determine the values associated with important services and benefits derived from
27 natural ecosystems such that these could be used in comprehensive risk assessment for
28 O₃ effects on natural ecosystems
- 29 • To reduce uncertainties associated with evaluating the performance of different
30 exposure indices given different patterns of O₃ exposures, experiments would need to
31 be designed to specifically test the performance of different indices in predicting plant
32 response under different exposure regimes.
