Preface

The Agency for Healthcare Research and Quality (AHRQ), through its Evidence-Based Practice Centers (EPCs), sponsors the development of evidence reports and technology assessments to assist public- and private-sector organizations in their efforts to improve the quality of health care in the United States. This report was requested by the NIH Office of Medical Applications of Research as a background paper for the State-of-the-Science Conference on Prevention of Fecal and Urinary Incontinence in Adults. The reports and assessments provide organizations with comprehensive, science-based information on common, costly medical conditions, and new health care technologies. The EPCs systematically review the relevant scientific literature on topics assigned to them by AHRQ and conduct additional analyses when appropriate prior to developing their reports and assessments.

To bring the broadest range of experts into the development of evidence reports and health technology assessments, AHRQ encourages the EPCs to form partnerships and enter into collaborations with other medical and research organizations. The EPCs work with these partner organizations to ensure that the evidence reports and technology assessments they produce will become building blocks for health care quality improvement projects throughout the Nation. The reports undergo peer review prior to their release.

AHRQ expects that the EPC evidence reports and technology assessments will inform individual health plans, providers, and purchasers as well as the health care system as a whole by providing important information to help improve health care quality.

We welcome written comments on this evidence report. They may be sent to the Task Order Officer named below at: Agency for Healthcare Research and Quality, 540 Gaither Road, Rockville, MD 20850, or by email to **epc@ahrq.gov.**

Acknowledgments

We would like to thank the librarians, Jim Beattie, M.L.I.S., Judy Stanke, M.A., and Delbert Reed, Ph.D., for their contributions to the literature search; Jing Du, Ryan Ping, Joseph Kaiya M.D., Susan Penque, and Mary Dierich for their assistance with the literature search and data abstraction; Marilyn Eells for editing and formatting the report; and Charmaine Bird and Kristina Mucha for assistance with data entry and formatting tables.

We also want to thank Linda Brubaker, M.D., Tomas Griebling, M.D., Robert Madoff, M.D., Richard Nelson, M.D., Joseph Ouslander, M.D., Neil Resnick, M.D., Carolyn Sampselle, Ph.D., David Thom, M.D., Ph.D., and Joanne Townsend, R.N., for serving on our Technical Expert Panel, Chadwick Huckabay, M.D., for advice and counsel on urinary incontinence management, and Ingrid Nygaard, M.D., Mary H. Palmer, Ph.D., and Debra Saliba, M.D., for reviewing the draft of this report and providing us with helpful recommendations for revisions and clarifications.

Structured Abstract

Objectives: To assess the prevalence of and risk factors for urinary (UI) and fecal (FI) incontinence in adults in long-term care (LTC) settings and in the community, the effectiveness of diagnostic methods to identify adults at risk and patients with incontinence, and to review the effectiveness of clinical interventions to reduce the risk of incontinence.

Data Sources: MEDLINE® (PubMed), CINAHL, and Cochrane Databases.

Review Methods: Observational studies were reviewed to examine the prevalence and incidence of UI and FI and the association with risk factors. The effects of treatments on patient outcomes were analyzed from randomized controlled and multicenter clinical trials. The diagnostic values of the tests were compared from the original epidemiologic studies of different designs. Of the 6,097 articles identified, 1,077 articles were eligible for analysis.

Results: The prevalence of UI, FI, and combined incontinence increased with age and functional dependency. Cognitive impairment, limitations in daily activities, and prolonged institutionalization in nursing homes were associated with a higher risk of incontinence. Stroke, diabetes, obesity, poor general health, and comorbidities were associated with UI and FI in community dwelling adults. Parity, anal trauma, and vaginal prolapse in women and urological surgery and radiation for prostate cancer in men are risk factors for UI and FI. Intensive individualized management and rehabilitation programs improved continence status in nursing home residents and adults after stroke. Self-administered behavioral interventions including pelvic floor muscle training with biofeedback and bladder training resolved UI in incontinent women. Electrical stimulation and sacral neuromodulation improved urge UI, but improvement for FI was inconsistent. Tension-free vaginal tape procedures and modified surgical techniques for prolapse to support the bladder neck resolved stress UI in the majority of treated women. Behavioral treatments of FI resulted in small improvements in severity and quality of life related to incontinence. The effects on FI of surgical techniques for hemorrhoids, rectal prolapse, rectal cancer, and anal fissures are not consistent across studies. Surgical interventions in patients with ulcerative colitis resulted in the same rates of fecal continence when compared to each other. The few clinical interventions to treat FI that were tested in well-designed trials had no clear evidence of better effects of the compared treatments. Instrumental outcomes to evaluate the effectiveness of treatments did not correlate with patient outcomes. Epidemiologic surveys to detect persons at risk and patients with undiagnosed UI have the same diagnostic value and less cost compared to professional examinations and diagnostic tests. Self-reported questionnaires and scales have unsatisfactory validity to diagnose FI.

Conclusions: Epidemiologic surveys are cost-effective ways to estimate the prevalence of UI in large nationally representative population groups. Routine clinical evaluation should include an assessment of the risk factors, symptoms, and signs of incontinence. Pregnant or menopausal women, women with vaginal prolapse, males treated for prostate disease, patients with rectal prolapse, and frail elderly and nursing home residents are high risk groups. Individualized management programs can improve continence in LTC facilities but are hard to sustain. Regular monitoring and documentation of the continence status in relation to implemented continence

services should be quality of care indicators for nursing homes. Pelvic floor muscle trainings with biofeedback can resolve incontinence and improve quality of life. Surgery is effective in curing stress UI in females. Clinical interventions for UI in males and for FI in adults need future investigation. A list of research recommendations is offered.

Executive Summary

Introduction

The high prevalence of urinary (UI),[1,2] fecal (FI),[3] and combined[4,5] incontinence in long-term care (LTC) settings and in community dwelling adults[6-9] and the substantial impact of incontinence on quality of life[10-12 13,14] underscores the need for more and better research on effective strategies to identify patients at risk[15-17] and clinical interventions to reduce the risk of incontinence.[13,18-21] Prevalence and risk factors depend on baseline physiological mechanisms, including weakness of pelvic floor muscles important for both UI and FI, hyperactive bladder that may result in urge UI, poor urethral sphincter function associated with stress UI,[22,23] and impaired structural and functional integrity of pudendal nerve activity, rectal compliance and rectal sensation, and anal sphincter associated with FI.[17,20,23,24]

Updated evidence-based recommendations to detect high-risk subgroups and to diagnose and treat symptoms and baseline causes of incontinence could improve effective patient-centered health care.[25-27]

This systematic review was commissioned as background material for an NIH/OMAR State-of-the-Science Conference on the *Prevention of Fecal and Urinary Incontinence in Adults*. The aims of this review are to synthesize the published evidence of effective methods to identify individuals at risk and patients with undiagnosed UI and FI in the community and in LTC settings and to compare the effectiveness of different clinical interventions to prevent the occurrence and progression of UI and FI in adults.

The following questions were developed for this review:

1. What are the prevalence and incidence of urinary and fecal incontinence in the community and long-term care settings? How does prevalence differ in race, ethnicity, and gender groups?
2. What are the independent contributions of risk factors for urinary and fecal incontinence, including age, functional impairment, institutionalization, parity, childbirth, and postpartum state, menopause, dietary factors, smoking, obesity, genetic factors, prostate disorders, dementia, psychiatric disorders, specifically depression, diabetes, urinary tract infection, chronic gastrointestinal conditions, cardiovascular and pulmonary diseases, gastrointestinal, gynecologic, and urological procedures, neurological disorders, such as stroke and spinal cord problems?
3. What is the evidence to support specific clinical interventions to reduce the risk of urinary and fecal incontinence?
4. What are the strategies to improve the identification of persons at risk and patients who have urinary and fecal incontinence?
5. What are the research priorities for identifying effective strategies to reduce the burden of illness in these conditions?

For Question 1 we reviewed population-based surveys of prevalence and incidence of incontinence in LTC settings and in the community. We compared the diagnostic accuracy of different questionnaires, scales, and instrumental methods to the methods that are believed to be the "gold standard" to detect incontinence in adults. For Question 2 we evaluated the absolute risk of incontinence in subpopulations with risk factors, including surgical procedures and specific diseases, and adjusted relative risk or odds ratios of incontinence in adults with different levels of risk factors. For Question 3 we synthesized the results of the randomized controlled

clinical trials (RCTs) and large multicenter trials to determine which treatments resulted in better rates of cure and improvement in symptoms and quality of life. Severity (frequency and amount of involuntary leakage of urine and feces) and impact on quality of life of incontinence were analyzed from the published articles.

Methods

Original epidemiologic studies from 1990 to 2007 that examined the risk of incontinence in adults were identified from the National Library of Medicine, CINAHL, and Cochrane Databases. Randomized controlled clinical trials and nonrandomized large multicenter trials (for FI) were reviewed to compare the effects of different treatments.

We use the terminology of the International Continence Society (ICS) of urinary (stress, urge, mixed) (Chapter 3), anal (flatus and fecal: solid, and liquid feces), and combined incontinence (Chapter 5).[20,21,23] To facilitate the discussion of fecal incontinence, we use the term fecal incontinence in the text to encompass both fecal and anal incontinence and in the evidence tables we use the exact definitions from the original reports. These two terms are frequently used interchangeably in the literature and create a great deal of confusion.

Results

Of 6,097 potentially relevant articles, we found 1,077 articles eligible for analysis.

Prevalence of Incontinence in LTC Settings

The prevalence of UI in nursing homes varied from 30 to 77 percent.[2,28-31] More than half of the residents were incontinent at admission,[32] while the estimated annual incidence rate was 20 percent for occasional urge and 14.5 percent for occasional stress UI.[33] The majority of women in LTC (60-78 percent) reported UI.[28-30,32] The prevalence of UI in men ranged from 23 to 72 percent.[28-30,32] Prevalence rates increased with advancing age in both men and women of all races.[2,29,30,32] One of the largest cross-sectional studies of 10,215 older nursing home residents found that 40 percent of the residents suffer from combined UI and FI.[5] Involuntary loss of solid or liquid feces was experienced by 46 percent of nursing home residents[3] with an annual incidence of 14 percent.[4] Eighty-three percent of nursing home residents with severe cognitive impairment had FI.[34]

Prevalence of Incontinence in Community Dwelling Adults

Large population-based studies reported that 9-22 percent of adults had UI,[8,9,30,35-38] with even higher rates (37 percent) in a recent study of 145,765 men and women 65 years and over.[39] Pooled analysis of 117 epidemiological studies of UI prevalence in community dwelling women[7,8,30,35-148]suggested that the prevalence of ever having UI increased from 21 percent in 19-44 year old (17 studies) to 34 percent in 45-64 year old (45 studies), and to 39 percent among elderly women (11 studies). Younger females reported UI in the past year less frequently (two studies), the prevalence increased to 35-41 percent among women 45-64 years (11 studies) and older than 65 years (13 studies). Elderly women reported UI in the past month (four studies)

more often. Overall prevalence of monthly UI was the highest in elderly females (two studies)[111,133] and in women 45-64 years old (nine studies).[43,45,46,62,116,124,132,133,148] Weekly incontinence was experienced more often by women older than 65 years[42,94,97,148] and elderly women over 80.[42] Few studies reported daily UI, 5 percent of younger women (19-44 years old)[96] and 17 percent of women older than 65 years[79] reported having daily leakage. The prevalence of total UI increase in age categories from 19 percent in women 19-44 years (18 studies)[57,64,68,69,75,80,85,86,92,96,98-100,119,130,133,145,148] to 29 percent in those older than 45 years. Stress incontinence was the most prevalent type in women 19-44 years old (15 studies) [37,57,64,80,85,91,95,98,104,108,109,130,133,145,124] and in those 45-64 years of age (36 studies). [37,38,44,51,57,61,70,73-75,77,78,80,84,85,87,89,95,104,108,116,117,122,124,127,129,131,135-137,139,141,145,148,149] However, mixed UI was the most prevalent type of incontinence in older women; 16.8 percent of women older than 65 (19 studies)[30,35,59,66,71,72,74,80,85,90,104,106,108,110,121,128,142,143,145] and 16 percent of elderly women reported mixed UI (seven studies).[71,74,80,84,106,124,133] The prevalence of urge incontinence gradually increased from 5 percent in younger women[37,57,64,80,85,91,95,98,101,104, 108,130,133,145] to 10 percent in women 45-64 (32 studies),[37,44,51,57,61,70,73-75,77,78,80,84,85,87,89,95,102,104, 108,116,117,124,126,127,129,131,137,139,145,148,149] and to 12 percent in women older than 65 years (28 studies).[30,35,37,56,59,61,63,66,71,72,74,80,84,85,90,104,106,108,110,118,121,123,125,128,133,142,143,145]

Pooled annual incidence of UI (18 studies)[38,45,47,56,59,62,103,134,139,149-157] was 6.25 percent for all ages, with the highest in elderly women; 7 percent in those older than 65 years and 8.52 percent in women over 80. Overall, middle aged and elderly women developed stress UI more often (four studies). Annual incidence of mixed UI was close to stress UI (two studies). Less than 7 percent of women 45-79 years old developed urge UI (three studies).

Pooled analysis detected a clear pattern of increased prevalence of total UI in aging men from 5 percent in those 19-44 years old (11 studies) to 11 percent in those 45-64 years old (27 studies), to 21 percent in males over 65 years of age (41 studies). The highest prevalence of UI was reported in elderly males of 32 percent (17 studies). Urge UI was the most prevalent type of UI in males among all age categories, increasing from 3 percent in those 19-44 years old (7 studies) to 12 percent in those older than 65 years of age (20 studies) The prevalence estimations varied substantially depending on the definitions, with the higher prevalence of UI during the last year in American males 19-44 years old (18 percent) and 45-64 years old (25 percent) compared to UI during the last month. Older American males reported UI during the last month more frequently, from 29 percent among those older than 65 years of age to 42 percent in elderly males. Stress UI ever was experienced by 2 percent of American men 45-64 years old, 1 percent reported stress UI during the last month, and 1 percent during the last year. Urge UI was the more prevalent during the last year (7 percent of men 45-64 years old). Men over 65 years of age reported having urge UI during the last month (11 percent). Pooled analysis estimated that daily UI was experienced by 5 percent of males 45-64 years, 8 percent of men over 65 years old, and 9 percent of elderly men. Severe UI that required change of underwear was reported by 2 percent of those 45-64 years old and 4 percent of elderly men.

Combined UI and FI is experienced by 3 percent[111] to 6 percent[158] of older adults in the community. The prevalence of FI increased with age,[111,159] 3 percent of adults had daily leakage of feces;[159] weekly FI was reported by 4-5 percent[159,160] and monthly FI by 7 percent.[159] Pooled prevalence of FI in community dwelling men (22 studies) varied across the studies depending on definitions of incontinence and population characteristics. The lowest prevalence of anal incontinence (AI) of 2 percent was reported in two studies with median age of participants between 45 and 64 years. The prevalence of FI was less than 10 percent in all age groups and

increased from 6 percent in those 45-64 years old to 10 percent in elderly men. The prevalence of solid feces incontinence was reported by 1 percent of men 45-64 years of age and by 2 percent of elderly males. The most prevalent was combined incontinence in elderly, 16 percent of men over 80 years experienced UI and FI. Prevalence of AI was the highest in women compared to other definitions and increased from 22 to 45 percent with aging (38 studies). An inclusion of flatus incontinence in the definition may contribute to an increased prevalence estimates in females. Prevalence of FI was higher than in males and increased from 7 percent in those 45-64 to 10 percent among elderly women. UI and FI were experienced by 10-12 percent of women. Severity of FI in females increased with age.[161] The prevalence of monthly FI varied from 6 percent[162] to 25 percent;[125] 1 percent[162] to 5 percent[163] of women had more than one FI episode per month. The prevalence of weekly FI was less than 7 percent in the majority of the studies.[125,160,161,163] Less than 2 percent of community dwelling women reported daily FI.[125,161]

Risk Factors for Incontinence in LTC

The residents of LTC with cognitive impairment,[1,34] physical dependency,[4,29,34,164,165] prolonged institutionalization,[28] diabetes,[29,34] and FI[29] had higher prevalence of UI. The odds of UI increased by 24 percent with each 5 years of age among LTC residents,[4,165] by 20-40 percent after stroke,[4,165] by 300-400 percent in adults with impaired activities of daily living (ADL),[4,164] and by 700 percent among wheelchair users and bedridden residents.[29] Women in LTC experienced UI more often than males.[29,165] FI was associated with 10[29] to 20[165] times larger odds of UI. Dependence in daily activities was associated with 6-7 times higher odds of FI, and dependency in eating with four times higher odds of FI.[3] Increased length of stay in nursing homes from 2 weeks to 1 year was associated with a seven times higher prevalence of FI.[166] Limited evidence suggested that the prevalence of combined UI and FI was twice as high in non-White as White residents of nursing homes.[4,5]

Risk Factors for Incontinence in Community Dwelling Adults

The prevalence of UI in men with prostate cancer was less than 10 percent in the majority of the studies.[167-174] UI rates after radical prostatectomy in 12,079 Medicare beneficiaries decreased from 20 percent in 1991 to 4 percent in 1995, being the highest in older patients.[175] Age was an independent risk factor for male UI in two studies.[58,97] Non White men had the same rates of UI compared to Whites.[175] Two studies showed that sedentary life was associated with UI in males.[83,92] Alcohol intake[72,83,84,92] and smoking[72,83,92] did not show a significant association with male UI. Males with diabetes had significantly higher adjusted rates of UI[58,72,86,97,176] with a pooled odds ratio of 1.4. Co morbidities and poor general health were associated with UI in several studies.[81,84,92,97] Males with arthritis had higher adjusted odds of total[86] or urge UI.[176] Memory problems, epilepsy, and neurological diseases were associated with higher rates of UI.[4,58,72,86,97,114,176-178] Stroke was shown as a strong and independent risk factor for UI in nursing home residents[4] and in community dwelling males[58,86,97,176,177] with pooled odds ratio of 2. Restrictions in activities of daily living were associated with higher crude and adjusted odds of UI in males in all studies that examined the relationship.[4,81,92,97,106,114] Males with urologic symptoms[72,170,174,179] or urinary tract infections had higher adjusted rates of UI with a pooled odds ratio of 3.5.[72,74,92,97,106] Men with prostate diseases had higher rates of UI after adjustment for confounding factors in the majority of the studies.[72,83,92,170,176,180-183]

Age tends to be linearly associated with female UI prevalence and incidence rates.[7,41,53,55,56,62,65,80,81,83,85,99,105,133,138,143,184] Prevalent UI significantly increased with age in 20 [7,55,66,67,73,74,81,84,92,96,97,105,118,124,133,138,149,185-187] of 28 studies that reported the association.[7,55,62,66,67,73,74,81,84,92,93,95-97,105,118,124,132,133,138,140,144,149,185-189]

The evidence of the association between race and incident UI is limited to two studies[123,149] being higher in Whites. African American women had higher odds of incident urge but lower odds of incident stress UI. Hispanic women developed weekly UI more often compared to Caucasians. Prevalence of mild, moderate, and severe UI was lower among African American women than White women in all six studies that examined the association.[93,105,137,138,149,189] Prevalence of moderate UI was lower among Hispanic women compared to Caucasian women in four of five studies.[93,105,138,149,189]

Obesity was associated with higher incidence of UI in women in two studies.[103,149] Prevalent urge UI showed a positive dose response association in individual studies.[51,133] The strength of the association varied depending on definitions of UI. Adjusted odds of UI in the past month were higher in overweight and obese females.[83,92,133,143] Weekly UI was more prevalent in obese but not overweight women with a dose response increase per one unit of BMI.[66,90,92,96,138,189] With the definition of UI in the past year, the majority of the studies showed a significant increase in UI [7,51,59,68,72,144] and daily UI corresponding to an increase in BMI per one unit.[55,67,70,149,189] Obese women had greater odds of at least monthly UI compared to women with normal weight.[67,104,121,124,138,149,190] Daily and weekly stress UI were significantly associated with an increase in BMI in all studies that examined this association.[51,66,70,118,132,133,135,149,187]

One large prospective cohort, the Nurses' Health Study, reported that intensive physical activity in women 50-79 years of age was associated with a significant reduction in incident total UI and stress UI.[156] Higher education was associated with increased odds of prevalent UI in several studies.[67,70,72,83,93,149,189,191] Six studies[92,93,138,186,189,192] of 12[67,72,83,92,93,138,143,186,189,191,192] found a significant positive association between smoking and UI but the effect was not consistent in dose response models.

The studies of impaired cognitive function reported conflicting results about the association with incident[147,186] or prevalent UI.[97,114,132,186] Prevalence of UI was significantly higher in depressed women in five studies[90,124,149,189,191] of eight[90,97,106,118,124,149,189,191] that examined the association in multivariate analysis. Decreased physical function measured by self report and physical performance was significantly associated with UI in six studies[67,81,92,97,144,189] of eight[67,81,92,97,106,132,144,189] that examined this association.

The association between parity and UI in females was examined in 24 observational studies.[55,59,64,68,70,72,83,92,93,95,96,105,119,124,133,135,138,149,185,191,193-196] Incident UI was not associated with parity.[149,193] A positive significant association between prevalent UI and parity was reported in 13 studies,[68,72,83,93,96,105,119,124,138,185,191,193,195] while six studies did not find a significant increase in prevalent UI in relation to parity.[59,64,92,133,149,194] The number of births did not show a dose response association with prevalent UI but did with moderate severe UI and severe UI. All six studies that measured prevalent stress UI reported a significant positive association with parity.[72,95,133,149,195,196] Prevalent stress UI and severe stress UI did not show a significant dose response association with the number of births. Only one study[195] of four[72,133,195,196] found an increase in urge UI corresponding to parity. The role of parity is complex and decreases as a woman ages.[68,118,128,195] Evidence suggests that UI developing during pregnancy is a risk factor for UI in the immediate postpartum period[197] and in subsequent years[64,96] raising the odds of UI by two to 11 times.[96,198]

The association between UI and modes of delivery was conflicting. Cesarean section was associated with lower odds of UI in seven studies,[119,197,199-203] by 80 percent[201] to 41 percent[200] and did not show a significant association in five studies.[135,141,196,204,205] Two studies reported higher odds of UI when women after Cesarean section were compared with nulliparous females.[7,206] Few prospective studies reported protective effects of Cesarean section on UI compared to vaginal delivery.[119,197,202,205]

Individual studies suggested that menopausal status can be associated with UI, increasing the odds by 127 percent[93] to 144 percent.[191] Five[55,83,108,124,138] studies of eight[55,62,72,83,108,124,138,144,191] that examined the association between UI and hysterectomy reported significantly higher adjusted rates of total UI among women after hysterectomy. The increase was 160 percent for UI in the past month,[108] 130 percent for at least monthly UI,[124] 140 percent for daily UI (OR 1.4, 95 percent CI 1.1, 1.6),[55] and 160 percent for severe UI.[138] Several epidemiological studies have examined estrogen therapy as a risk factor for UI.[55,59,96,105,118,138,144,191]

Women with urinary tract infections had higher rates of UI in 11 studies[66,72,74,90,92,97,108,116,121,127,144] of 15[66,70,72,74,90,92,96,97,106,108,116,121,127,144,187] that examined the association.

Evidence from three studies,[7,86,118] suggested that women with arthritis had higher rates of UI by 80-88 percent.[7,86] Two studies[134,149] of three[134,149,186] reported that women with diabetes develop UI more often. Incidence of weekly UI was higher by 147 percent in women with duration of diabetes more than 10 years.[134] The same Nurses' Health Study cohort showed that incidence of severe UI was increased by 175 percent and very severe by 262 percent.[134] The Study of Women's Health Across the Nation found a 302 percent increase in developing monthly UI in women with diabetes independent of other risk factors.[149] Prevalence of stress UI was greater in women with diabetes in three studies[95,133,149] of six[66,95,108,133,135,149] that examined the association with pooled odds ratios that were not significant. However, the majority of the studies reported a significant increase in adjusted odds of total UI among women with diabetes[55,66,72,86,93,97,108,116,124,127,128,133,134,138,149,186] (16 studies). Four of five studies found a significant increase in adjusted odds of urge UI among women with diabetes[66,108,118,133,149] (five studies).

One prospective cohort, the Canadian Study of Health and Aging, found that elderly community dwelling women had a higher risk of developing UI after stroke.[207] Prevalence of UI was significantly higher among women after stroke in five[55,86,97,133,186] of six[55,67,86,97,133,186] studies that examined this association (pooled OR 1.7). Women with two or more comorbid diseases had higher adjusted rates of UI.[55,84,92,121,124,149,189] Three studies[68,121,144] reported a significant increase in adjusted odds of UI in women with constipation among six studies that examined this association.[68,74,97,121,144]

Consistent evidence showed that FI increased with age in women.[208-213] AI increased by 87 percent for every additional 10 years of age in Asians and by 36 percent in White females.[187] Maternal age older than 25 years was associated with greater odds of FI[214] and persistent FI.[215] The odds of FI increased by 271 percent after age 75.[58] Diabetes,[58,216,217] obesity,[218] and sedentary lifestyle were among risk factors for FI in community dwelling adults.[125] Adults with poor general health and comorbidities,[163,219] including kidney diseases,[186] transient ischemic attack,[219] and arterial hypertension[213] had higher odds of FI. Post stroke patients suffered from combined UI and FI five times more often[58] and from FI three[216] to five[58] times more often compared to adults without a stroke, with an increased risk in older adults,[220] diabetics,[220] and survivors with functional dependency after severe stroke.[220,221] Adults with functional limitations,[222,223] women with major depression,[163] older men with depression,[219] and adults with

impaired cognitive status[186,223,224] had higher prevalence of FI. Constipation,[187,212] irritable bowel syndrome,[187,211,212] and hemorrhoid surgery in women were associated with increased odds of FI.[211] The adjusted rates of FI were higher by 240 percent[225] to 450 percent[219] in women with diarrhea, by 190 percent in irritable bowel syndrome patients, by 250 percent in females with anal fistula, by 140 percent after cholecystectomy,[225] and by 400 percent in adults with incomplete bowel evacuation.[217 224] Women after previous gynecological surgery complained about AI 1.8 times more often.[213] Adjusted odds of FI increase by 4.6 times in females after perianal surgery.[217] The adjusted odds of FI in women with UI were two to six times higher compared to continent females.[162,163,219,226]

Delivery of heavy babies,[202] FI during pregnancy,[209] increased number of births,[215,226] and high degree of perineal injury[187,209,218,227-231] were significant risk factors for FI. A dose response association was found between FI and number of births[209,213,215,226] and with degree of birth related perineal damage.[228-230] The adjusted odds of persistent FI were 3.2 times greater among women after four or more deliveries.[215] Women with birth related sphincter tears after perianal trauma had 230 percent[209] to 280 percent[231,232] higher rates of FI.

Effects of Clinical Interventions on UI

Clinical interventions to reduce the progression of UI in adults in LTC settings. Conservative management programs improved UI in nursing home residents.[233-237] Individualized prompted voiding and intensive endurance and strength training exercises significantly improved the continence status of the residents.[234] A computerized quality management pathway would avoid progression of UI in 140 per 1,000 treated residents of nursing homes.[238] Limited evidence suggested that the number of patients continent at discharge after stroke was four times larger after active compared to conventional rehabilitation programs, which would result in 722 additional cases of continence per 1,000 treated adults with stroke.[239]

Community-based conservative management programs. Urinary continence service in the community that included lifestyle advice, bladder, and pelvic floor muscle training for 6 months[240] increased the proportion of continent patients by 50 percent and patients with improved UI by 20 percent. With this community-based continence service, UI was improved in an additional 100 subjects per 1,000 subjects treated; quality of life improved in 90 subjects and satisfaction with present urinary symptoms in 110.[240] Complex community-based intervention implemened by registered nurses, occupational therapist, and public health educators[241] and a continence management program implemented by nurse continence advisers with physician expertise[242] were effective to reduce the severity of UI in females.

Behavioral intervention for primary prevention of UI in women. Continence rates after behavioral modification programs, including pelvic floor muscle training, bladder training, and individualized test of knowledge and adherence implemented in 359 postmenopausal, continent women 55 years and older to prevent UI, were the same compared to usual care at 12 months of followup (continence rate 37 percent vs. 28 percent) but resulted in an improvement rate 136 percent higher than standard care in one RCT.[243,244] Intensive lifestyle therapy to lose and maintain at least 7 percent of initial body weight and to engage in moderate-intensity physical activity reduced stress UI by 15 percent after 2.9 years of followup in the Diabetes Prevention Program RCT among 2,191 overweight pre-diabetic women with BMI ±24 kg/m^2 (RR 0.85).[245]

Clinical interventions for primary prevention of UI in pregnant women were examined in eight large RCTs with more than 100 women[246-253] and one smaller trial;[254] three RCTs

reported continence rates with 3-10 months of followup.[249,250,253] Conservative advice about self-administered pelvic floor muscle training at 5, 7, and 9 months after delivery supplemented with bladder training did not change the risk of stress UI and tended to decrease the risk of severe UI at 12 months postpartum.[251,252] Continence rates after intensive exercise care[253] and self-administered perineal massage[250] were comparable to usual care. Pelvic floor muscle training with biofeedback and electrostimulation started at 9 weeks after vaginal delivery resulted in continence ten times more often compared to usual care at 10 months of followup.[249]

Clinical interventions for primary prevention of UI in males with urological diseases. The behavioral interventions on UI in males with prostate diseases were examined in 12 RCTs[255-266] but only two[257 ,261] of eight trials with continence outcomes[255,256,257 ,259,261,262,264,265] reported significant benefit after pelvic floor muscle training with biofeedback compared to usual care. The highest continence rate (99percent) was reported in a large, well designed RCT of early pelvic floor muscle training and biofeedback in participants who had radical retropubic prostatectomy for localized prostate cancer at 1 year of followup with a small significant relative benefit compared to usual care (RR 1.1).[257] The relative effect in the same RCT was larger when continence status was measured with the International Continence Society male questionnaire specific for UI (RR 1.3).[257] Continence rates in the control groups were more than 60 percent across other RCTs with no statistically significant differences compared to active treatments. The comparative effectiveness of pelvic floor muscle training compared to usual care in males after different treatment options for prostate cancer requires future confirmation in well-designed RCTs.

Pelvic floor muscle training for secondary prevention of UI. A large body of evidence suggested beneficial effects of behavioral interventions on UI in females.[267-287] Pelvic floor muscle training resulted in continence in females more often than usual care in four[275,280,288,289] of ten trials that compared usual care with active treatments.[275,280,281,288-292] Pooled results of relative benefits of pelvic floor muscle training (RR 7.1)[275,280,288,289] and pelvic floor muscle training combined with biofeedback (RR 11.2)[288,289] were sensitive to one small RCT[288] with a 2 month followup. Pelvic floor muscle training combined with bladder training increased continence rates by 175 percent compared to usual care (pooled RR 1.8).[243,280,290,291]

Electrical stimulation for secondary prevention of UI. Urinary continence 1-6 months after electrical stimulation in females was reported in seven RCTs.[293-298] Two RCTs that assessed continence at 6 months or more of followup failed to show significant benefit from electrical stimulation compared to continent services or medications.[293,299] Other RCTs also did not demonstrate significant relative benefit of electrical simulation compared biofeedback assisted training[297] or placebo.[295,296,300,301] Electrical stimulation would result in improvement in UI in 180 women per 1,000 treated.[302] Electrical stimulation would improve UI in more than 400 women per 1,000 treated compared to placebo.[303] Home-managed electrical stimulation with vaginal or anal stimulators would avoid 50 cases of UI per 1,000 treated women.[304] The rates of continence from urge UI were more than 70 percent in one RCT after functional magnetic stimulation[298] with significant relative benefit compared to sham stimulation in only one trial at 2 months of followup (RR 3.5).[298]

Neuromodulation for secondary prevention of UI. In community dwelling adults the implantation of a multiprogrammable neurostimulator cured 47 percent of participants with urge UI[305] with significant relative benefit compared to standard medical therapy.[305] Sacral root neuromodulation resulted in urge continence more than nine times more often than conservative

management with medications or pelvic floor muscle training (RR 9.86).[306] Sacral nerve stimulation would avoid 385[306] to 430[305] cases of urge UI per 1,000 treated adults.

Injectable bulking agents for secondary prevention of UI. The effects of different bulking agents for secondary prevention of female UI were examined in four RCTs with one study of more than 100 females[307] and several smaller trials[308-310] with 6[309] to 12 months[307,308,310] of followup. However, only one RCT reported significant relative benefit in 63 women with stress UI at 12 months of followup after transurethral ultrasonography-guided injections of autologous myoblasts and fibroblasts compared to conventional endoscopic injections of collagen (RR 9.5).[308]

Medical devices for secondary prevention of UI included Hodge pessary,[311] disposable intravaginal devices,[312,313] urethral plug,[314] and vaginal cones[299,315,316] in females and UroLume sphincteric stent[317]or penile compression devices in males.[318] Blocking urinary leakage using a urethral insert device with disposable applicator resulted in continence in 67 percent of women with mixed or stress UI but showed no relative benefit compared to a urethral insert with a sterile balloon device.[313] One RCT of 122 women with stress UI did not show differences in continence rates after vaginal cones compared to continence guard services at 6 months of followup.[299] Limited evidence suggested that medical devices resulted in modest improvement in UI, not better than other interventions in females[299,311-313,315] and in males.[317,318]

Surgical interventions for primary prevention of UI in women. Among examined gynecological surgeries, intrafascial total abdominal hysterectomy significantly reduced the risk of urge UI compared to the extrafascial approach.[319] Total or subtotal abdominal hysterectomy resulted in comparable continence rates 1 year after the surgery.[320] Prolapse surgeries in continent women (negative stress test at baseline) were examined in two RCTs.[321,322] Cystopexy alone compared to cystopexy with posterior pubourethral ligaments plication resulted in the same rates of UI at 1 year of follow up.[322] Incidence of stress UI was several times higher after Burch colposuspension. Compared to colposacropexy without prophylactic colposuspension at 3 years of followup.[321]

Surgical interventions for secondary prevention of UI in women. Tension-free vaginal tape and sling procedures resolved stress UI in more than 75 percent of treated women[323-342] with some evidence of greater relative benefit compared to Burch colposuspension.[343] Surgery with Burch colposuspension for stress UI resulted in continence in more than 75 percent of women in the majority of the studies[344-361] with inconsistent relative benefit when compared to other treatments. Few RCTs reported significant relative increase in objective cure at 1 year of followup after tension-free vaginal tape procedure compared to active treatment.[330,331] Burch retropubic urethropexy resulted in continence in more than 90 percent of women and provided the largest relative benefit compared to modified anterior colporrhaphy (RR 5.1)[353] and anterior colporrhaphy with Kelly plication (RR 1.4).[345] Burch colposuspension with abdominal hysterectomy compared to anterior colporrhaphy with vaginal hysterectomy resulted in higher continence rates (RR 1.6) in women undergoing surgery for primary stress incontinence and a concurrent grade 2 or 3 cystocele.[362]

The largest relative benefits with more than 300 excessive cases of stress UI per 1,000 treated females were reported after pelvic floor muscle training compared to regular care, and Burch colposuspensions, and tension-free vaginal tape compared to other surgical procedures. Hormone replacement therapy increased the risk and progression of UI in postmenopausal females. A few studies demonstrated relative benefits of local estrogen administration on stress UI by 64 percent[363] and urge by 55 percent.[364]

Hormone therapy for primary prevention of UI increased incident mixed UI by 50 percent (RR1.5) and incident stress UI in postmenopausal women by 80 percent (RR 1.8).[365] Incident urge UI increased by 30 percent and total UI by 40 percent (RR 1.4) after estrogen combined with progestin (RR 1.3).[366] Oral estrogen alone without progestin increased incident stress UI by 210 percent (RR 2.1)[365] and worsened UI by 530 percent (RR 5.3).[367]

Hormone therapy for secondary prevention of UI. Urinary continence was reported in four RCTs that examined the curative effects of local hormone therapy on secondary prevention among incontinent women.[364,368-370] The highest rates of continence were reported after transdermal administration of an estrogen patch (100 percent) and estrogen gel (90 percent) among postmenopausal women with self-reported urinary symptoms.[368] Topical estrogen in suppositories or creams combined with physiotherapy and electrostimulation cured 22 percent of women 50-74 years of age with regular mild incontinence (>2 leakage episodes per month) compared to 0 percent after no hormone treatment.[364]

Pharmacological agents for secondary prevention of UI. Clenbuterol was more effective to achieve continence in females with stress UI compared to placebo but not to pelvic floor muscle training. Extended release tolteradine for 2-12 weeks resulted in greater rates of cure or improvement compared to placebo in adults with overactive bladder syndrome. Duloxetin administered for 3-12 weeks in patients with predominantly stress UI improved UI, but the rates of continence did not differ from placebo. Long-term effects of medications combined with pelvic floor training on continence are unknown. Comparative effectiveness of combined treatments, including medication, requires future research.

Clinical Interventions to Reduce the Risk of FI

Conservative management programs for secondary prevention of FI in LTC settings. Consistent benefits of conservative management programs,[233-235] integrated FI care,[235] and functional individualized endurance and strength-training exercises[234] on FI in nursing homes were reported in several studies.

Pelvic floor muscle training for primary prevention of FI was examined in one RCT of 747 women with postnatal UI.[251,252] Assessment by nurses of incontinence with conservative advice on pelvic floor muscle training at five, seven, and nine months after delivery reduced the risk of any FI by 51 percent at 1 but not 6 years after index delivery.

Dietary intervention for secondary prevention of FI was reported in one RCT of 42 adult volunteers with incontinent loose or liquid stools at least weekly.[371] Usual diet supplemented with 25g of Metamucil did not reduce the proportion of incontinent stools at 1 month of followup.

Pelvic floor muscle training with biofeedback for secondary prevention of FI. Sensory biofeedback training with pelvic floor muscle training resulted in control of feces (fecal continence) twice as frequently in women with FI after obstetric and sphincter trauma as pelvic floor muscle training alone,[372] which would prevent 382 cases of FI per 1,000 treated. Studies of behavioral treatments of FI reported less than 40 percent improvement in severity and quality of life related to FI.[372-375] Limited evidence suggested a significant reduction in FI after complex behavioral interventions, including lifestyle changes and exercises augmented with biofeedback.[376]

Neuromodulation for secondary prevention of FI. Individualized sacral nerve continuous stimulation improved FI in 89 percent of patients with severe baseline FI compared to 17 percent

after sham stimulation in one study,[377] resulting in an improvement in symptoms in 720 additional patients among 1,000 treated.

Pharmacological agents for FI. Few pharmacological interventions[378-380] resulted in fecal continence in more than 50 percent of patients but were not statistically better than placebo[378,379] or surgery.[380]

Surgical interventions to repair external anal sphincter after acute obstetric trauma (primary prevention). Four RCTs compared end-to-end technique to overlapping repair of obstetric anal sphincter lacerations;[381-384] six reported patient outcomes with inconsistent benefit from end-to-end technique.

Early detection of anal sphincter tears immediately after vaginal delivery followed by surgical repair significantly reduced the risk of FI 3 months and 1 year postpartum in RCTs of 752 pregnant women.[385]

Delivery interventions for primary prevention of FI. The effects of episiotomy were examined in two RCTs;[386,387] the effects of Cesarean or vaginal delivery were compared in two RCTs;[388,389] the effects of delayed or immediate pushing in the second stage of labor with epidural analgesia in one RCT;[390] and the effects of delivery by forceps or vacuum extractor in three RCTs[391-393] without significant relative benefit of instrumental compared to vaginal delivery.

Surgical interventions for primary prevention of FI. Of nine RCTs that compared different surgical techniques for hemorrhoidectomy, none reported significant relative FI benefits.[394-402] The effects of "chemical sphincterotomy" in patients with chronic anal fissure were analyzed in three RCTs,[403-405] with no significant result on FI.

The effects of surgical procedures on FI in adults with full-thickness rectal prolapse were evaluated in nine RCTs,[406-414] with no significant difference between treatments.

Different surgical techniques resulted in similar rates of FI in patients with anorectal abscesses,[415] fistula-in-ano,[416-418] and anal fissure.[419-423] Adjuvant radiotherapy for adenocarcinoma of the rectum[424-426] consistently increased the risk of FI in three RCTs, by 60 percent during the day (RR 1.6), by 90 percent during the night (RR 1.9), by 70 percent in utilization of pads (RR 1.7) compared to mesorectal excision,[424] and by 220 percent (RR 2.2) compared to the low anterior resection.[424]

Surgical interventions for secondary prevention of FI. The implantation of artificial bowel sphincter reduced FI severity[427] in a multicenter, prospective, nonrandomized clinical trial of 115 patients. However, 25 percent experienced post surgical infection that required surgical revision and 37 percent needed reimplantations.

Gluteus maximus transposition did not show significant benefit compared to total pelvic floor postanal repair with anterior levatoroplasty on women with post obstetric FI.[428]

One multicenter noncontrolled nonrandomized clinical trial (Dynamic Graciloplasty Therapy Study Group) reported significant improvements in quality of life (Medical Outcomes Study Short Form 36 physical function and social functioning) after dynamic gracioplasty. The proportion of continent stools among total number of stools of more than 50 percent was 62-56 percent in nonstoma patients at 12-24 months and 37.5-43 percent in stoma patients at 24 months of followup.[429,430]

Surgical interventions used to treat ulcerative colitis[431-434] resulted in comparable fecal continence during the first 10 years after surgery, with an increased risk of FI during the longer period of followup. Clinical interventions resulted in comparable incidence and progression of FI in the majority of the RCTs with no clear evidence of better prevention of FI.

Strategies to Improve Identification of Persons at Risk and Patients who have UI and FI

Few well-designed studies examined the strategies to detect incontinence in adults. Positive clinical history of UI was associated with a small likelihood of urodynamic UI in females.[435-455] Inconsistent evidence implied that diagnostic values of x-ray,[456-461] single channel urodynamic,[462-465] and Q-tip test measuring straining angle[466-469] are similar to multichannel urodynamics. Translabial Doppler ultrasound[470,471] and transrectal ultrasound for the evaluation of the bladder neck anatomy and urethrovesical junction[472-477] (stress UI was defined as rethrovesical junction drop during stress of ≥1cm) were comparable to fluoroscopy for the detection of urinary leakage during urodynamic investigation in community adults and residents of nursing homes. Despite differences in positive predictive likelihood ratios compared to "gold standard" of urodynamic testing, the number needed to screen to detect one case of UI was similar and consistent among the studies. Effectiveness of self-reported scales, professional assessment of clinical history, and ultrasound to detect UI in women was comparable to urodynamic and consistent across race, age, and socioeconomic groups. However, clinical history and diaries were used by less than half the incontinent patients who actively sought health care for UI.[112,155,478] Population-based surveys using validated scales[447,479,480] yielded predictive likelihood ratios and the number needed to screen to detect one case of UI comparable to clinical history[435,436] but also had lower cost ($36-$67 vs. $175-$255 respectively).

The diagnostic value of tests among different age, race, and socioeconomic status subgroups has not been well established; however, the prevalence of undiagnosed UI differed by 10-20 percent in such groups.[146] Therefore, screening programs should target patients at high risk of UI. Limited evidence suggests that the Resident Assessment Protocol included in the Minimum Data Set (MDS) had a definitive predictive likelihood ratio to diagnose UI in nursing home residents.[481] Self-reported questionnaires and scales have unsatisfactory validity to diagnose FI in adults. Anal ultrasonography has the largest diagnostic value to detect anal trauma in patients with FI.[482]

Discussion

Public awareness of incontinence, its risk factors, and possible treatment options may reduce the burden of incontinence. Consistent definitions of incontinence and measures of success are important to compare the results from different studies. Despite extensive efforts to standardize the definitions of incontinence,[483] the original studies produced a plethora of measures. They measured self-reported symptoms and signs of incontinence, severity, and quality of life related to incontinence, and objective instrumental evidence of leakage inconsistently within and across the studies. Ratings of success by doctors and patients about quality of life in FI were also different.[484] Objective measures of UI showed random changes in most RCTs and could not be recommended as a measure of success for primary and secondary prevention of UI. The objective improvements in selected physiological measures were not consistent after the same interventions and did not correlate with self-reported continence and reduction in severity of UI.[322,330,485-491] The effects of treatments on quantitative measures of incontinence, including frequency and amount of leakage, were less compared to qualitative improvements in symptoms.

Other systematic reviews analyzed predominantly self-reported cure and improvement in UI, practically omitting objective measures of incontinence still commonly used in individual studies.[492-494] One review of two clinical trials with urodynamic tests concluded that the data is not sufficient to propose this invasive and costly testing as a measure of success.[495] The association between physiological testing and patient perception of severity of incontinence and quality of life is weak. The relationships between objective physiological measures of incontinence that are related to quality of life and primary diseases resulting in incontinence need future investigation. Long-term continence should be the primary outcome for future RCTs to consider the most effective clinical interventions.

Previous reviews did not find anal manometry a good measure of success in reducing FI.[496-500] Anal manometry was not a good measure of success in clinical trials of FI showing random changes between active and control interventions.[372,375,376,403,501-503] Improvement in self-reported FI was inconsistent with changes in anal manometry.[373,376,378,503] Few trials demonstrated the same direction and effect of treatment on improvement in FI and objective measures of FI.[372] Composite outcomes, including both self-reported changes in severity of incontinence and physiologic parameters in a common scale may offer a better choice to measure success of clinical interventions.[504,505]

The strength of evidence varied for the research questions in the present review. Studies of diagnostic methods had the lowest quality with few RCTs conducted.[437,462,506,507] Large population-based surveys reported prevalence of incontinence in age, gender, and race subgroups.[8,9,50,67,508] The independent contribution of risk factors on UI and FI were analyzed with adjusted odds ratios in cross-sectional and retrospective cohort studies. However, multivariate models included different sets of risk factors. Since causality between risk factors and incontinence could not be determined from such studies and the majority of risk factors are not modifiable, we hesitated to estimate events attributable to risk factors. Efficacy and comparative effectiveness of clinical interventions to reduce the risk and progression of incontinence were analyzed from RCTs. The majority of the RCTs had good quality, did not exclude subjects from the analysis of the outcomes, and provided adequate randomization. However, allocation concealment was not adequate in a large proportion of RCTs.[258,261,266,277,286,372,375,376,502,509-512] The RCTs of interventions that are regulated by the FDA, including hormone replacement therapy, had the best quality.[240,245,253,304,365,366,389,513,514] Large RCTs, including weight reduction and increased physical activity,[245] complex conservative management of UI,[240] delivery management,[388,389] and early prevention of UI in postnatal care[253] also had high quality. Variations in populations, interventions, and measures of outcomes, rather than quality of RCT resulted in heterogeneity between studies.

Conclusions

Epidemiologic surveys with behavioral risk factor surveillance systems are cost-effective to estimate the prevalence of urinary incontinence in large nationally representative population groups. Routinely collected clinical history should include an evaluation of the risk factors, symptoms, and signs of incontinence. Pregnant, obese, and aging women, women with vaginal prolapse, males treated for prostate disease, patients with rectal prolapse, and frail elderly and nursing home residents are high risk groups. Individualized management programs can improve continence in LTC facilities but are hard to sustain. Regular monitoring and documentation of the continence status in relation to implemented continence services should be quality of care

indicators for nursing homes. Pelvic floor muscle and bladder training are effective to reduce the risk of incontinence. Preventive strategies might include assessment and reduction of modifiable risk factors in early stages of incontinence. Surgery is effective in curing stress UI in females. Clinical interventions for UI in males and for FI in adults need future investigation.

Future Research

An important unresolved problem is clear definitions of the type of incontinence and patho-physiology of baseline conditions to have better estimations of prevalence and risk factors of incontinence. Inconsistencies between patient reports and physiological measures continue to pose a serious problem.[484,515] For efficacy studies, some combined measure might be applied, but for prevalence assessments, such an approach would pose serious logistical problems. Long-term effects of drugs, stimulators, and medical devices need future investigation in well-designed randomized trials. Given the social problems caused by incontinence, enthusiasm for surgical treatment remains high for treating both stress UI and FI, although future research is needed to examine the balance between benefits and harms related to surgery and the cost-effectiveness of surgical treatments compared to conservative interventions.

Managing both types of incontinence in LTC settings remains problematic. Programs that work under experimental conditions have not been sustained because they are labor intensive and essentially unreimbursed. Indeed, case mix based payments for nursing homes create a disincentive to manage incontinence.

Several other specific areas have been identified as needing more research. They include:

- Interaction between age, race, and other risk factors for UI and FI in women and men
- Effective strategies to prevent UI and FI in women and men in community and LTC settings
- Association between race and severity of UI and FI and quality of life related to UI and FI in men and women from the community and in LTC settings
- Strategies to reduce the risk of UI and FI related to pregnancy and childbirth
- Effectiveness of clinical interventions for incontinence by cognitive and physical functioning, gender, and ethnicity
- Long-term effectiveness of individual conservative therapies, conservative management programs, including community-based nonmedical interventions, and mechanical devices for UI and FI
- Comparative long-term effectiveness of conservative interventions, pharmacological interventions, combined conservative and pharmacological interventions, mechanical devices, and surgery for UI
- Individual patient factors that may modify the effects of different procedures
- Effects on FI of surgeries for hemorrhoids, rectal prolapse, rectal cancer, and anal fissures
- Effective strategies to identify patients at risk of UI and FI, including residents of LTC settings

Evidence Report

Chapter 1. Introduction

Overview

Urinary (UI) and fecal (FI) incontinence affect substantial proportions of adults in different population groups.[20] Baseline mechanisms of UI include hyperactive bladder that may result in urge UI and poor urethral sphincter function that can result in primary urethral incompetence and stress UI.[22,23] Loss of structural and functional integrity of pudendal nerve activity, pelvic floor muscles, rectal compliance and rectal sensation, and the anal sphincter may result in FI.[17,20,23,24] The differences in baseline mechanisms of incontinence lead to variable definitions of UI and FI, some specific for each type of incontinence risk factors, and effective interventions to prevent and treat UI and FI.[17,23,24] The estimated prevalence of UI in adults was 9 to 22 percent[8,9,30,35-38] but varies widely as a result of differences in definitions and sampled populations subgroups.[18] For example, recent studies reported that 25 percent of young women,[516] 44 percent[148] to 57 percent of middle-age and post-menopausal women,[93] and 75 percent of elderly females in nursing homes[32] experienced some degree of involuntary urine loss. UI is prevalent among women of all races, though the magnitude, severity, and bother may vary; 41 percent of White women, 20 percent of African-American women, and 36 percent of Hispanic women reported difficulties controlling their bladders.[18] The severity of incontinence influences quality of life and treatment decisions. In the 1999-2000 National Health and Nutrition Examination Survey, 32 to 51 percent of women experienced daily episodes of UI and 20 to 32 percent experienced weekly episodes.[9] The prevalence of UI in men varied from 11 percent among those 60-64 years old to 31 percent in older males, and from 16 percent among White men to 21 percent among African American men.[8] Daily incontinence was reported by 30 to 47 percent and weekly incontinence by 15 to 37 percent of community dwelling men[8] and by 72 percent of male nursing home residents.[32] The fraction of nursing home admissions attributable to UI in the elderly population was 10 percent for men and 6 percent for women.[517]

The prevalence of FI ranges from 0.8 to 5 percent in men and 2 to 6 percent in women living in the community[518] and to more than 50 percent in nursing home residents. Indeed, FI is among the most common reasons for nursing home admission.[21] The prevalence of combined UI and FI in adults in LTC facilities varied from 4 percent[519] to 44 percent.[34]

Population-based studies underestimate the incidence of incontinence due to sampling and self selection of the survey participants.[20] Clinic-based studies included patients actively seeking treatment for incontinence, who represent only a small proportion of incontinent adults.[13,19,146,520] Only 45 percent of women and 22 percent of men with weekly incontinence episodes ever sought medical care for UI. Primary care providers diagnosed UI in 21 percent of older incontinent women and in 10 percent of older incontinent men.[521] Despite the tremendous impact on quality of life, less than 50 percent of older adults with FI ever asked for professional help.[17,522-524]

Strategies to detect persons at risk and individuals with incontinence have been systematically reviewed for UI[15,16] but not for FI, with no special attention to high-risk populations in either group. Comparative predictive likelihood ratios of diagnostic tests for community dwelling adults and residents in long-term care (LTC) facilities are not well established.[20,21] No systematic reviews addressed the positive likelihood of diagnostic procedures for FI.[13]

Clinical interventions to reduce UI have been extensively reviewed during the last years by the Cochrane Group,[492-495,525-548] and FI[497-500,549-557] the International Continence Society,[20,21] the American College of Gastroenterology Practice Parameters Committee,[17] and the Agency for Healthcare Research and Quality.[25,26] The basis for measuring successful treatment varied across the studies that examined different interventions; the criteria for deeming a treatment successful are not well established. Pooled analyses of the selected outcomes included small samples of the studies and showed substantial heterogeneity across interventions. Patients and clinicians need synthesized analysis of clinical efficacy and comparative effectiveness of diagnostic and treatment options to make informed decisions of effective care. Policymakers require evidence-based estimations attributable to effective treatment events in different clinical settings and for subgroups of patients.

The cost of incontinence care in the United States increased over the past decades;[558] in 2004 it averaged $19.5 billion annually.[559] One estimate places the 2000 annualized cost of nursing home admissions due to incontinence at $6.0 billion ($3.0 billion each for elderly men and women).[517] Evidence-based recommendations to reduce the risk of incontinence in LTC facilities and in the community could improve health care and the quality of life for incontinent patients.

This review was commissioned as background material for an NIH/OMAR State of the Science Conference on Incontinence. The aims of the present project are: 1) to systematically review published evidence to identify individuals at risk and patients with undiagnosed UI and FI in the community and in LTC settings and 2) to synthesize evidence of the effectiveness of different clinical interventions to prevent the occurrence and progression of UI and FI in adults.

The following questions were developed for this review:

1. What are the prevalence and incidence of urinary and fecal incontinence in the community and long-term care settings?
   - Race
   - Ethnicity
   - Gender
2. What are the independent contributions of risk factors for urinary and fecal incontinence, including:
   - Age
   - Functional impairment
   - Institutionalization
   - Parity, childbirth, and postpartum state
   - Menopause
   - Dietary factors
   - Smoking
   - Obesity
   - Genetic factors
   - Prostate disorders
   - Dementia
   - Psychiatric disorders, specifically depression
   - Diabetes
   - Urinary tract infection
   - Chronic gastrointestinal (GI) conditions such as irritable bowel syndrome (IBS), diarrhea, constipation, and inflammatory bowel diseases (IBD)
   - Cardiovascular and pulmonary conditions

- Gastrointestinal, gynecologic, and urological procedures
- Neurological disorders, such as stroke and spinal cord problems

3. What is the evidence to support specific clinical interventions to reduce the risk of urinary and fecal incontinence?
4. What are the strategies to improve the identification of persons at risk and patients who have urinary and fecal incontinence?
5. What are the research priorities for identifying effective strategies to reduce the burden of illness in these conditions?

The analytical framework for Question 2 focuses on risk factors of incontinence in adults (definitions are included in Appendix A). These risk factors can be combined in one person. Independent contributions of isolated risk can be addressed in studies with adequate multivariate analysis. Such population-based studies are available for some risk factors, including age and age-related conditions and behavioral risk factors, but not for surgical procedures and rare diseases. Given this reality, the present systematic review addressed the adjusted relative risk of incontinence in adults with different levels of risk factors when possible and the absolute risk of incontinence in populations after surgical procedures and with specific diseases.

The analytical framework for the strategies to identify patients who have UI and FI included examination of diagnostic values of different tests compared to multichannel urodynamics as a "gold standard" for UI and physician diagnosis for FI. Sensitivity, specificity, positive predictive values, predictive likelihood ratio, and cost effectiveness of the index tests were compared to standard tests. The validity and reliability of incontinence-specific scales were analyzed from published literature. Conceptual and operational definitions of incontinence and risk factors of incontinence are presented in the analytical framework.

To facilitate the discussion of fecal incontinence, we have adopted the practice of using that term to encompass both fecal and anal incontinence. These two terms are frequently used interchangeably in the literature and create a great deal of confusion.

Chapter 2. Methods

Literature Search Strategy and Eligibility Criteria

Search Strategy

Studies were sought from a wide variety of sources, including MEDLINE® via PubMed®, CINAHL, Cochrane databases, and manual searches of reference lists from systematic reviews and the proceeding of the International Continence Society (ICS). The search strategies for the four research questions are described in Appendix B. Excluded references are shown in Appendix C. All work was conducted under the guidance of a Technical Expert Panel (TEP), whose members are identified in Appendix D.

Eligibility

Three investigators independently decided on the eligibility of the studies according to recommendations from the Cochrane manual for systematic reviews.[560] The algorithm to define eligibility of the studies was developed for each research question (Appendix A). We reviewed abstracts to exclude secondary data analysis, reviews, letters, comments, and case reports. Then we confirmed eligible target populations of adults in community and LTC settings. The full texts of the original epidemiologic studies published in English after 1989 were examined to include studies with eligible outcomes defined as prevalence and incidence of incontinence, absolute and adjusted relative risk of incidence, and progression of urinary, fecal, and combined incontinence (operational definitions in Appendix A). We also developed a list of risk factors for UI and FI for Question 2 (operational definitions of known risk factors of UI and FI in Appendix A). For Question 3, we included studies that examined the effects of clinical interventions (operational definitions of clinical interventions for the primary and secondary prevention of incontinence in Appendix A). For Question 4, we included studies that evaluated different strategies to detect patients with incontinence and persons at risk. Then we excluded studies that did not test the associative hypotheses and did not provide adequate information on tested hypotheses (e.g., least square means, relative risk).

Finally, we confirmed eligible levels of evidence for each research question. The following inclusion criteria were applied to select articles for full review: For questions of prevalence and risk factors of incontinence in large population-based cross-sectional analyses and cohort studies, large cross-sectional analyses and cohorts in LTC settings, case-control studies with randomly selected controls and case series with more than 100 subjects were selected. For the question on clinical interventions to reduce the risk of UI and FI, we selected randomized controlled clinical trials and multicenter nonrandomized clinical trials (fecal and combined incontinence). For the question on strategies to detect incontinence, we selected randomized controlled clinical trials, multicenter controlled clinical trials, large (>100 subjects) observational studies, and case-control studies with >10 cases that reported sensitivity, specificity, and reliability of different diagnostic methods.

Appendixes cited in this report are available at http://www.ahrq.gov/clinic/tp/fuiadtp.htm

The exclusion criteria included the following:

- Studies with target population as children and adolescents
- Studies with no information relevant to incidence and progression of incontinence
- Studies that examined the distribution of different types of incontinence among incontinent patients (all incontinent in denominator)
- Studies that evaluated the association between incontinence as independent variables in association with other patient outcomes
- Case series with small numbers of cases and no control comparison
- Studies that reported absolute values of the diagnostic tests in incontinent patients
- Studies that did not report true and false positive and negative cases of diagnostic tests
- Observational studies and nonrandomized clinical trials that examined treatments in incontinent patients and short term (less than 1 year of followup) drug trials that did not report continence rates

Quality Assessment and Rating the Body of Evidence

Study quality was analyzed using the following criteria: subject selection, length and loss of followup, adjustment for confounding factors in observational studies and intention to treat principle in clinical trials, masking the treatment status, randomization scheme and adequacy, allocation concealment, and justification of sample sizes in RCTs.[561]

The level of evidence for all studies was estimated using a subset of the U.S. Preventive Services Task Force criteria noted below.[562]

I: Properly designed randomized controlled trial

II-2A: Well-designed cohort (prospective) study with concurrent controls and multivariate analysis of the associations

II-2B: Well-designed cohort (prospective) study with historical controls and multivariate analysis of the associations

II-2C: Well-designed cohort (retrospective) study with concurrent controls and multivariate analysis of the associations

II-3: Well-designed case controlled (retrospective) study and multivariate analysis of the associations

III: Large differences from comparisons between times and/or places with or without interventions (cross-sectional comparisons).

For all questions, evidence tables were developed identifying the purpose of the study, sample, design, independent and dependent variables, and findings. For Questions 1, 2, and 3, incidence and prevalence cases of incontinence, relative risk of incontinence in categories of risk factors and clinical interventions, and outcomes level to assess severity and progression of incontinence for treatment differences were abstracted.[563,564] Baseline data were compared in different studies to test differences in the target population and unusual patterns in the data.[565,566] Standard deviations, regression coefficients, and 95 percent CI were calculated from reported means, standard errors, and sample size.[563,564] The protocol for the meta-analyses was created according to recommendations for meta-analysis of randomized controlled trials: the QUOROM statement.[567]

Applicability

Applicability of the population was estimated by evaluating the selection of the subjects in observational studies and clinical trials.[568] Large observational cohorts based on national registries, population-based surveys, and nationally representative administrative and clinical databases had high applicability. We compared the differences in prevalence of incontinence in studies that selected subjects from administrative and clinical databases and that reported random and convenience sampling of participants.[569] Applicability of the intervention duration was high for studies with followup 1 year or more and acceptable for studies with followup of 6-12 months.

We assumed the presence of publication bias and did not use statistical tests for bias defined as the tendency to publish positive results and to predict association when all conducted (published and unpublished) studies are analyzed.[560,570-572] We used several strategies to reduce bias, including comprehensive literature search of published and unpublished evidence in several databases the reference lists of systematic reviews and proceedings of the ICS, contacts with experts for additional references they might provide, and agreement on the eligibility status by several investigators.

Data Extraction

Evaluations of the studies and data extraction were performed manually and independently by three researchers. The data abstraction forms are shown in Appendix E. Errors in data extractions were assessed by a comparison with the established ranges for each variable and the data charts with the original articles. Any discrepancies were detected and discussed. Patient populations were classified as community and LTC settings. Adjustments for patient age, race, gender, comorbidities, socioeconomic status, provider characteristics, and clustering of patients and providers were extracted from the studies. The details on extracted variables are presented in the analytic framework in Appendix A.

Data Synthesis

For Questions 1 and 2, results of individual studies (expressed as crude and adjusted for confounding factors) were summarized in evidence tables to analyze differences in incontinence in categories by subject age, race, ethnicity, residency, and risk factors.

Definitions of incontinence. We analyzed separately urinary, fecal, and combined incontinence. We used the definitions of signs and symptoms of UI promoted by the ICS (Appendix A) including mixed, stress, and urge incontinence. We defined anal incontinence (AI) as involuntary loss of flatus, liquid, or solid stool. In the text we used the term FI and in the tables clarified the operational definitions of anal (flatus and fecal), FI, solid, or liquid incontinence, or its combinations. Continence was defined as self-reported absence of involuntary urine or feces loss. We defined combined incontinence as a combination of urine and fecal incontinence. When the authors reported prevalence of UI or FI but not combined incontinence in the same populations, we define the outcomes as UI only or FI only without additional assumption about possible misclassification. We also analyzed urinary continence defined as negative stress and pad tests. We used the term "urodynamic UI" to replace the older

term "genuine stress incontinence." Frequency of UI or FI was abstracted as daily, weekly, or monthly episodes of urine leakage or feces loss. Severity of UI was defined using the objectively measured urine loss in pad weight tests or self-reported pad use. Severity of FI was defined as self-reported amount of feces loss and pad use. Wet status in nursing home residents was analyzed to define severity of incontinence and effects of the treatments. We classified residents who needed indwelling urinary catheters and an external urinary drainage device as having severe or always UI. Restriction of daily activities, and perceived quality of life with UI or FI were defined using scales and composite scores.

Definitions of outcomes. We defined prevalence of incontinence as the probability of experiencing incontinence within a defined population and at a defined time point.[20,21] We defined true population incidence as newly diagnosed cases of incontinence that developed annually in the target population. True population incidence estimates were derived from large population-based surveys. However, for Question 3 we defined incidence as the probability of developing incontinence under study after active and control interventions during time of followup.[20,21] We defined reported incontinence as the prevalence of total incontinence or episodes of different types of incontinence when the authors did not access continence status as baseline or did not exclude prevalence cases from overall estimation

The absolute risk of incontinence among patients with rare risk factors was compared to the general population when no other evidence was available to estimate the adjusted relative risk.

For Question 3, relative risk (RR) and 95 percent confidence intervals (CIs) and differences in outcomes were calculated.

Patient outcomes (clinical events). We report both incidence and progression of incontinence as they were used by the authors of the original studies and with calculated rates of cure, improvement, and progression for purposes of comparison:

1. the number of patients that developed newly diagnosed incontinence (incidence cases) or the number of incontinent patients after active and control interventions (prevalence cases)
2. the number of patients cured by the clinical interventions
3. the number of patients with improved continence
4. the number of patients with progression defined as failure to cure or improve and increase in frequency and severity of incontinence.

Relative risk/odds ratio of developing incontinence was analyzed in the studies that reported incident cases. Relative risk/odds ratio of incontinence was analyzed in the studies that reported prevalence cases. Relative benefit of continence was defined as the likelihood of continence in patients after active treatment relative to those after control interventions. We defined relative benefit of improvement as a likelihood of improved incontinence in patients after active treatment relative to those after control interventions. We defined relative risk of progression of incontinence as the likelihood of increasing frequency and severity of incontinence and failure to cure/improve incontinence in patients after active treatment relative to those after control interventions

We analyzed continence separately from improvement in incontinence because continence is the most clinically desirable patient outcome and is well defined, whereas improvement can include substantial differences in definitions and changing perceptions of qualitative and quantitative parameters of improvement. We used such conservative approaches to generate precise estimates of the effectiveness. Clinicians and patients can make informed decisions based

on the treatments that resulted in greater rates of long-term continence in well designed randomized controlled trials (RCTs).

We compared the effectiveness of different clinical interventions in relation to baseline rates of incontinence, assuming undiagnosed incontinence when the authors did not report objective assessment of continence status at baseline. We defined the clinical intervention to reduce the risk of incontinence (primary prevention) when the investigators selected the subjects in clinical trials by underlying condition, not by continence status. We defined clinical intervention to reduce the progression of incontinence when incontinent patients were invited to participate in clinical trials (secondary prevention).

For surgical interventions that aimed to treat the baseline conditions, including prolapse, cancer, ulcerative colitis, hemorrhoids, and anal fissures, incontinence was analyzed as the secondary outcome. The goal of the present review was to compare rates of incontinence after such procedures rather than review other therapeutic effects on baseline diseases or all complications of surgery.

Continuous outcomes (surrogates). We defined *subjective continuous outcomes* as the number of incontinent episodes, use of supplies, and scores from validated scales to analyze the quality of life with incontinence. We defined *objective continuous outcomes* as the results of objective tests to measure the severity of incontinence.

Pooling criteria included the same operational definitions of incontinence outcomes and the same risk factors or clinical interventions.[573] Homogeneity in clinical interventions was analyzed comparing published information on behavioral, instrumental (devices), pharmacological, and surgical treatments. Meta-analysis was used to assess the consistency of the association between treatments and incontinence outcomes with random effects models.[574] The analyses were conducted separately for symptoms and signs of incontinence. Assumptions underlying meta-analysis included valid measurements of continence status and similarity in study and target populations.

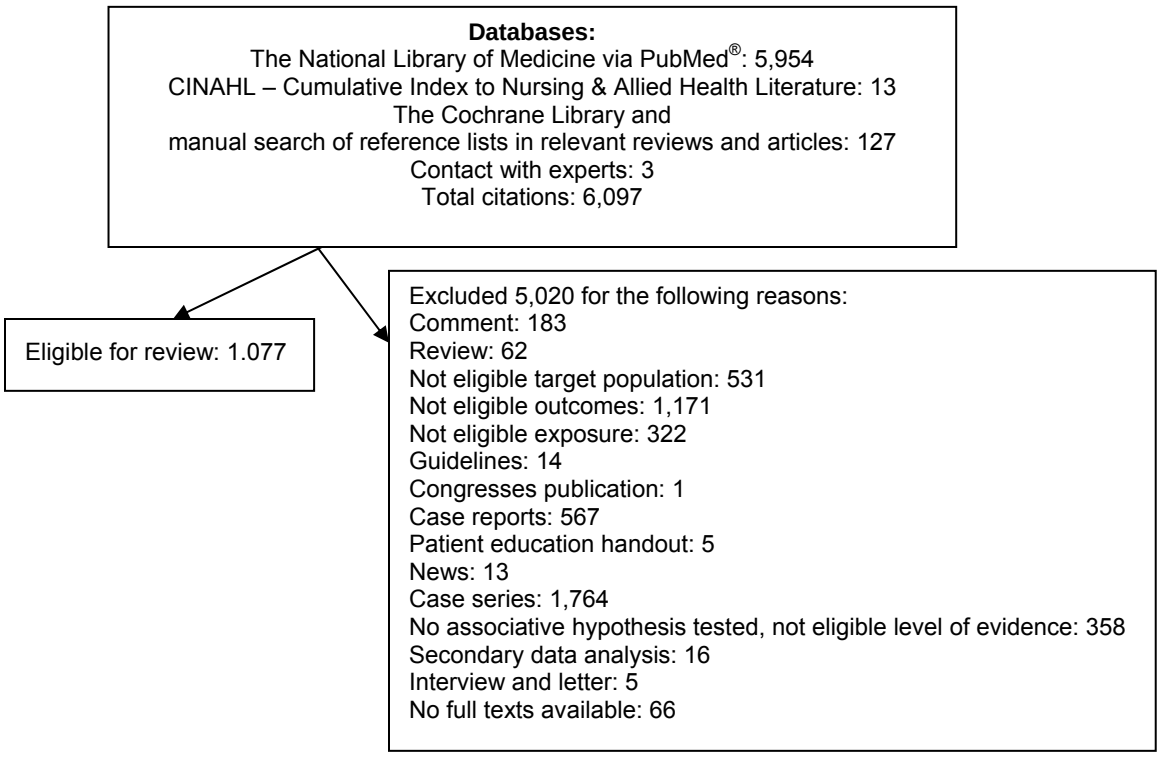
Consistency in the results was tested comparing the direction and strength of the association. Chi squared tests were used to assess heterogeneity in study results.[575,576] Significant heterogeneity means the effects of interventions on UI were not consistent in the studies (not replicable results). We explored heterogeneity with meta-regression and sensitivity analysis and reported the results from random effects models only. The analytic framework and algorithms for the meta-analysis are shown in Appendix A. Calculations were performed using STATA software at the 95 percent confidence level.[577]

For Question 4 we calculated positive predictive value, predictive likelihood ratio, number needed to screen to diagnose one case of incontinence, and number of diagnostic tests needed to detect one case of incontinence (Appendix A). Cost-effectiveness of diagnostic methods was estimated by comparing the cost and number needed to screen and the number of diagnostic tests using different tests.

Chapter 3. Results

Figure 1 traces the flow of our literature search for Questions 1-4. We retrieved 6,038 potentially relevant references (5,938 from MEDLINE®, 16 from CINAHL, 22 from the Cochrane database and a manual search of the Cochrane reviews, and 63 from a manual search of other published reviews and articles). We excluded 71 percent of the retrieved studies; 40 percent were case series; 13 percent case reports; 5 percent studies with ineligible independent variables, 19 percent with no eligible outcomes, and 12 percent with ineligible target populations.

Figure 1. Flow of study selection



Question 1. What are the Prevalence and Incidence of UI in the Community and LTC Settings?

UI in the Adult Population (Appendix Table F1)

Overview. Fourteen epidemiological studies of UI prevalence in community settings have reported prevalence rates in a combined sample of adult women and men (Table 1). Five studies were conducted in the United States,[8,30,39,54,120] two studies in Sweden,[37,114] three studies in the United Kingdom,[36,38,43] and one study each in China,[33] the Netherlands,[111] Spain,[35] Japan,[58] and Australia.[33] The majority of these population-based surveys sampled middle-aged and older adult populations. Three studies included younger adults ages 18 years and over.[36,37,54] There are

Appendixes cited in this report are available at http://www.ahrq.gov/clinic/tp/fuiadtp.htm

methodological and reporting differences among the studies. Some studies used mailed questionnaires, whereas others involved in-home interviews. Most studies reported on the actual prevalence of UI in the sample; however, one study extrapolated the prevalence estimate using census statistics for the entire United States population.[8,9] There is limited information available on the incidence, progression, and remission of UI in the adult population combining men and women.

Prevalence, severity, and impact of UI. Prevalence estimates for the adult population are fairly consistent, with most estimating between 16 to 22 percent.[8,9,30,35,37,38,120] However, estimates varied according to age and gender. Adults ages 60 years and over have the highest rates of UI. Prevalence rates differ substantially by gender, with women having higher rates across all age groups. One large study of adults ages 40 and over reported a female to male ratio at 2:6.[38]

Incidence of UI. The incident rate for the adult population varies by age, gender, and race. In a sample of 17,421 men and women ages 40 years and over, the 1-year incidence was 6 percent,[38] whereas in a study of 2,087 adults over age 70, the 2-year incidence was 20 percent, with 21 percent for urge UI and 20 percent for stress UI.[33] The largest survey involving 58,658 American men and women 65 years and over estimated a 2-year incidence rate of UI at 37 percent,[39] with rates being significantly higher in women than men, 44 and 28 percent, respectively. In this study, the incidence of UI measured as any urine loss experienced in the past 6 months increased with age beginning at 32 percent in adults 65-69 years and increasing to 54 percent in those over age 95. The impact of UI was greatest in the oldest age groups, with those rating a big impact varying from 14 percent of those 65-69 years to 27 percent for those 90-94, and 38 percent in those over 95 years. This study also found that non-Hispanics (38 percent) are more likely to be incontinent than Hispanics (31 percent), and American Indians and Whites had higher rates of UI than Blacks and Asians.[39] In contrast, Hispanics rated a slightly greater UI impact, e.g., a big problem (25 percent) compared to non-Hispanics (17 percent). A higher proportion of American Indians (30 percent) rated UI as having a big impact compared to Blacks (20 percent), Whites (17 percent), and Asians (15 percent).[39]

Progression and Remission of UI in Community Dwelling Adults

There is limited data on UI progression and remission rates comparing men and women. Evidence in adults ages 60 and over suggests that changes in severity over a 2-year period progress from continence to mild UI, and from mild to moderate UI.[47] Few people advanced to severe incontinence (e.g., 300 or more days of urine leakage and/or greater than a quarter cup of urine loss per day on 50 or more days during past 12 months)[47] One study found change patterns varied between women and men ages 60 years and over.[47] Women first developed stress UI and mixed UI as a primary condition, with urge UI as a secondary condition, whereas men developed urge UI, with stress UI as a potential secondary condition. Significantly more men than women developed urge UI over the 2-year followup period. Conflicting findings were noted in examining progression rates over a longer followup period. In a study of adults ages 70 and over involving a 10-year followup, women developed urge UI more frequently than men (23 versus 11 percent).[578]

UI remission rates vary by gender, with women having more stable incontinence (e.g., lower remission rates).[47] At 1 year, the remission rates for women and men were 11 and 27 percent, respectively, and at 2 years, they were 13 and 32 percent, respectively.[47]

Prevalence of UI in Community Dwelling Women

Overview. We identified 117 epidemiological studies of UI prevalence in community dwelling women[7,8,30,35-148] that have been published over the past 17 years, with both broad and narrow age spans of women within specific countries or regions of countries. The majority of the studies have been conducted in the United States (40 studies),[8,30,39,44,45,47,50,54-56,59,66,67,88-90,93,102,105,110,113,118,120,123,124,126,128,130,134,136-141,144,146-149] UK (10 studies),[36,38,43,52,70,77,82,103,112,132] or Northern Europe, including 13 studies from Sweden,[37,48,53,57,61,69,71,99,114,115,119,129,131] four studies from Norway,[49,62,80,98] six studies from Denmark,[51,64,73,78,96,133] and one study from Finland.[106]

Prevalence rates regarding these variations can be attributed to differences in study populations, survey methodology (including sampling, definition, and measurement of UI), and reporting methods (Table 1)**.** Although most studies of women are concentrated in middle-age and older women, other studies incorporate a broader age span with samples beginning at ages 15, 18, to 20 years and over. Study designs vary from probability-based methods of sampling of either large populations or random samples drawn from general practices, insurance plan enrollees; cross-sectional analyses of prospective cohorts of women who are participants in longitudinal studies or clinical trials in which UI is not a primary aim, cross-sectional studies of clinical populations or national panels, to case-control studies examining the effect of surgical interventions such as hysterectomy. Survey methodology involves mailed questionnaires, in-home interviews by trained interviewers, computer-assisted telephone interviews, or clinical evaluations. The definition and measurement of UI vary widely; over 20 definitions have been used (Table 1). Pooled prevalence of ever having UI was increased from 21 percent in 19-44 years old (17 studies) to 34 percent in 45-64 years old (45 studies), and to 39 percent among elderly women (11 studies) (Table 2). The differences across studies can create artifacts, as seen in Table 2, where the mean pooled prevalence for "ever" is less than the monthly rate. Younger females reported UI in the past year less frequently (9.61 percent, two studies), the prevalence increased to 35 percent among women 45-64 (11 studies) and to 41 percent among those older than 65 years old (13 studies). Elderly women reported UI in the past month (four studies) more often (56.7 percent).

Prevalence, severity, and impact of UI were reported using standardized scales or instruments. Following the method used by the 3rd International Consultation on Incontinence in summarizing prevalence estimates in women,[579] the authors used the most inclusive definition of UI ("monthly UI," "weekly UI," and "daily UI"). Severity was measured by volume of urine lost, by categorical rating scale of the individual's perception, or by seeking professional help. The amount of urine lost was typically categorized as "drops" to "wets outer clothing" or "runs down the legs/floor." In some studies, a higher percentage of women tended to lose drops[45,121,122] in comparison to larger volumes, whereas in other studies, women were more likely to have damp underwear and/or wet underwear or clothing than losing drops.[128] The severity of the leakage has been shown to vary by the frequency of leakage, with infrequent leakage more likely to be associated with drops, whereas daily leakage with a greater number having to change undergarments or outergarments.[45] There are conflicting findings about whether younger or older populations rate their UI as more severe.[38,130] In one study, older women tended to rate their UI as more severe than much younger women.[38] In a few studies, severity was measured by the perception of how severe a problem UI is to how much daily life is restricted.[37,55,190,580]

Differences in reporting prevalence rates in UI types make comparisons challenging across studies, as some studies report frequencies within the incontinent group and others report the rates within the overall population (Table 3). Overall prevalence of monthly UI was the highest in elderly females (25.3 percent, 95 percent CI 14.1; 36.5) (two studies)[111,133] and in women 45-64 years old (20.5 percent, 95 percent CI 18.3; 22.8) (9 studies).[43,45,46,62,116,124,132,133,148] Weekly incontinence was experienced more often by women older than 65 years (16.9 percent, 95 percent CI 15.1; 18.8)[42,94,97,148] and elderly women over 80 (29.9 percent, 95 percent CI 25.4; 34.4).[42] Few studies reported daily UI, 5 percent of younger women (19-44 years old)[96] and 17 percent of women older than 65 years[79] reported having daily leakage. Severe UI, defined as wet clothes or severe enough to seek treatment, was experienced by 9 percent of women over 65 (8.96 percent, 95 percent CI 7.51; 6),[59,76,77,86,128,144] and 10 percent of middle-aged women (95 percent CI 9.37;11) (seven studies).[40,51,60,77,86,89,131] Less than 2 percent of women younger than 45 years old experienced severe UI.[86]

Racial/ethnic differences. The majority of epidemiological studies have been conducted in White women in North America, Europe, Australia, and New Zealand. Although several studies have been conducted in Asian countries, including Turkey,[58,60,79,95,116,121] because of methodological differences, it is difficult to directly compare those to studies in which varying racial/ethnic groups have been sampled. There have been a limited number of studies from Middle Eastern countries, with only one study from an African country.

Eight population-based studies in the United States have reported on racial/ethnic differences in the prevalence of UI in women (Table 1). The majority of these studies document a higher prevalence of UI (including all types) in White women as compared to Black, Hispanic, and Asian women.

Type of UI. In general, stress and mixed UI were the most common types in studies that have compared stress, urge, and mixed UI (16 out of 28 studies) (Table 4). Although surveys have found differences in the frequencies of the different types of UI by age and race, these differences are inconsistent across studies. Some surveys found higher rates of stress UI in young and middle-aged women,[57,74,80,104,108] whereas others have found higher rates in older women.[37,85,133,145,581] Similar inconsistencies are noted with urge UI, with some studies reporting higher rates in older women[37,106,145] and others reporting it is more prevalent in middle-aged women[108,133] (Table 5). The prevalence of total UI increase in age categories from 19 percent in women 19-44 years (18 studies)[57,64,68,69,75,80,85,86,92,96,98-100,119,130,133,145,148] to 29 percent in those older than 45 years. Stress incontinence was the most prevalent type in women 19-44 years old (12.8 percent, 95 percent CI 8.3; 17.4) (15 studies),[37,57,64,80,85,91,95,98,104,108,109,130,133,145,124] and in those 45-64 years of age (21.5 percent, 95 percent CI 18.9; 24.1) (36 studies).[37,38,44,51,57,61,70, 73-75,77,78,80,84,85,87,89,95,104,108,116,117,122,124,127,129,131,135-137,139,141,145,148,149] However, mixed UI was the most prevalent type of incontinence in older women, 16.8 percent of women older than 65 (95 percent CI 13.7; 19.9) (19 studies)[30,35,59,66,71,72,74,80,85,90,104,106,108,110,121,128,142,143,145] and 16 percent of elderly women (95percent CI 7.3; 24.4) reported mixed UI (seven studies).[71,74,80,84,106,124,133] Prevalence of urge incontinence gradually increased from 5 percent in younger women (4.9 percent, 95 percent CI 3.7; 6.1)[37,57,64,80,85,91,95,98,101,104,108,130,133,145] to 10 percent in women 45-64 (10.2 percent, 95 percent CI 8.9; 11.5) (32 studies),[37,44,51,57,61,70,73-75,77,78,80,84,85,87,89,95,102,104,108,116,117,124,126,127,129,131,137,139,145,148,149] and to 12 percent in women older than 65 years (12.2 percent, 95 percent CI 9.9; 14.5) (28 studies).[30,35,37,56,59,61,63,66,71,72,74,80,84,85,90,104,106,108,110,118,121,123,125,128,133,142,143,145]

A small number of population-based surveys conducted in the United States have compared racial/ethnic differences in UI types.[89,118,137,149] In general, White women have higher rates of stress UI than Black, Hispanic, or Asian women,[89,149] although one study did find Hispanic women had a higher rate of stress UI than White, Black, and Asian women.[137] Black women are more likely to have higher rates of urge UI and mixed UI as compared to Whites and Hispanics.[137,149]

Incidence of UI in Community Dwelling Women

There are limited data from 18 studies on the incidence of UI in community dwelling women (Table 6).[38,45,47,56,59,62,103,134,139,149-157] Variations in incidence rates can be attributed to differences in study populations, UI definition, followup periods, and reporting methods. One-year incidence rates varied from <1 percent in Norwegian women ages 50-74 years[62] to 26 percent in American women ages 20-84 years.[139] Annual cumulative incidence rates averaged between 1-4 percent,[139,153,155] with rates increasing with advancing age.[33,38,139] In one study that examined incidence rates with respect to age, the incidence increased from 8 percent in women ages 40-49 years to 15 percent in those 80 years and over,[38] whereas in another study, rates increased from 15 percent in women ages 20-36 years to 47 percent in women 70 years and over.[139] There is a paucity of studies examining racial/ethnic differences in UI incidence rates. In one study, Whites had a slightly higher annual cumulative incidence (13 percent) than Black women (12 percent).[149]

Pooled annual incidence (Table 7) was 6.25 percent (95 percent CI 5.57; 6.93) for all ages with the highest in elderly women, 7 percent (95 percent CI 6.12; 9.37) in those older than 65 years, and 8.52 percent in women over 80 (95 percent CI 3.07; 13.98). Few surveys on the incidence of UI in women have included questions on incontinence types (Figure 2). One study involving 2,283 women ages 40-60 reported a 1-year incident rate for stress UI of 4 percent.[73] In a survey of 2,025 women ≥65 years, the 3-year incidence rate for stress and urge UI was 29 percent each.[56] In a recent survey in the United States involving 3,302 women ages 40-55 years, the 5-year cumulative incidence rates were highest for stress UI (25 percent), followed by urge UI (16 percent) and mixed UI (12 percent); other or unclassified UI had the lowest incidence rate (3 percent).[149] In this same survey, Whites and Japanese-American women had the highest incidence of stress UI compared to Chinese, Hispanic, and Black women. White women also had the highest incidence of urge UI; however, Black women had a higher incidence than Chinese, Japanese, and Hispanic women, respectively. Black women had the highest incidence of mixed UI, followed by White, Chinese, Hispanic, and Japanese women.

Overall, middle aged and elderly women developed stress UI more often (pooled annual incidence from 4 studies 9.7 percent, 95 percent CI 5.4; 13.9). Annual incidence of mixed UI was close to stress UI (pooled annual incidence from two studies 7.6 percent, 95 percent CI 4.1; 11.0). Less than 7 percent of women 45-79 years old developed urge UI (pooled annual incidence from three studies 6.44 percent, 95 percent CI 2.3; 10.6).

Summary. Evidence from large observational studies from different countries (level of evidence IIB) suggested that UI is a prevalent condition among women of all ages with overall prevalence close to the estimations of the National Health and Nutrition Examination Survey (38 percent).[9] Prevalence increased in women older than 45 years of age with further small increases in elderly women. Stress UI is the most prevalent type if UI in women 45-64 years old, while elderly women experienced mixed UI more frequently. Incidence of UI (level of evidence IIA-B)

gradually increases with age. Differences in definitions of UI contributed substantially to variability in the results from individual studies.

Progression and Remission of UI in Community Dwelling Women

There is limited data on the natural history of UI in women. Of the several studies of UI during and following childbirth, most report prevalence rates making it difficult to determine the progression and remission rates of UI in this subpopulation of women. Available data suggest that UI is a dynamic process in women, although the rates for full remission tend to be low. In nonchildbearing populations, annual remission rates range from 3 to 11 percent.[33,47,139,150,151,155] Remission rates tend to decrease with advancing age,[150,155] with one study reporting women ages 22-30 had remission rates more than twice that of women ages 41-50, 33 and 13 percent, respectively.[155] Duration of incontinence did not affect the chance of remission in a study involving women ages 20-59 years; 20 percent in the remission group and 24 percent in the incontinent group had been incontinent for at least 10 years.[151] Evidence indicates that the severity of UI tends to worsen over time.[33,47]

Data on the progression and remission of the different types of UI is scarce, with variable followup periods making it challenging to summarize remission rates. Data in women ages 60 years and over suggest that when women become incontinent they tend to first develop stress UI, either alone or in combination with urge UI. Those with stress UI alone either continue with stress UI alone or develop mixed UI over a 2-year followup period.[47] Some evidence indicates that the type of UI is relatively stable over 3 to 6.5 years,[56,139,155] particularly for stress UI. One study involving women ages 20-84 years found that the majority of women (52 percent) had the same form of UI after 6.5 years.[139] In this study, urge UI had the highest remission rate (38 percent) followed by stress and mixed UI (21 and 15 percent, respectively). In another study of women ages 40-60 years, the 1-year remission rates were 41 percent for stress UI, 42 percent for urge UI, and 38 percent for mixed UI.[150] In a study of women ages 65 years and over, the 3-year remission rates were 25 percent for stress UI and 22 percent for urge UI.[56] A study examining 10-year incidence and progression rates reported that women ages 70 and over with or without urgency had incontinence rates for urge UI of 11 percent and 15 percent respectively.[582] There was also a higher percent of women with urge UI at followup (6 percent at baseline and 26 percent at 10-years).

Prevalence of UI in Community Dwelling Men

In comparison to women, there have been fewer epidemiological studies in men (Appendix Table F2) with highly variable samples, including age categories and definitions of UI. Although there is a broad age range in the prevalence studies, the majority concentrate on middle age and older male populations (e.g., beginning at age 40, 60, or 65 years and over)[8,30,35,37,39,47,61,72,74,81,88,97,107,111,113-115,181,583-586] with fewer studies of men younger than 40 years,[37,52,54,86,145,181,587-589] including a recent national survey of men ages 18 years and over in the United States.[589] The majority of these studies have been conducted in North America or European countries using predominantly White populations. Two studies have incorporated Asian populations.[107,585] Pooled analysis (Table 8) detected a clear pattern of increased prevalence of total UI in aging men from 4.8 percent (95 percent CI 3.7; 5.9) in 19-44 years old (11 studies) to 11.2 percent (95 percent CI 10.1; 12.3) in those 45-64 years old (27 studies), to 21.1 percent (95 percent CI 19.9;

22.4) in males over 65 years of age (41 studies). The highest prevalence of UI was reported in elderly males of 32.2 percent (95 percent CI 29.6; 32.7) (17 studies). Urge UI was the most prevalent type of UI in males among all age categories increasing from 3.1 percent (95 percent CI 2.0; 4.2) in 19-44 years old (7 studies) to 11.7 percent (95 percent CI 9.3; 14.1) in those older than 65 years of age (20 studies).

Type of UI. The prevalence of UI, defined in various ways (ever, current, any, greater than two times/week, or leakage within past 4 weeks, 2, 6, or 12 months), is estimated between 3 percent in men 30 years and over in a study conducted in the United Kingdom[52] to 37 percent in men 39-91 years in a Norwegian study.[586] In a large population-based study conducted in five countries (Canada, Germany, Italy, Sweden, and the United Kingdom), the prevalence rate for men ages 18 and over was 5 percent.[145]

Studies in American men reported UI as involuntary leakage of urine during the last year, last month, or ever (Appendix Table F3). The prevalence estimations varied substantially depending on the definitions, with the higher prevalence of UI during the last year in males 19-44 years old (18.4 percent , 95 percent CI 4.5; 32.2) and 45-64 years old (24.6 percent 95 percent CI 19.92; 29.35) compared to UI during the last month (Table 9). Older males reported UI during the last month more frequently, from 29.2 percent (95 percent CI 24.4; 34.0) among those older than 65 years of age to 42.4 percent (95 percent CI 32.8; 52.0) in elderly males. Two percent of American men 45-64 years old ever experienced stress UI (95 percent CI 2.0; 2.0) and one percent reported stress UI during the last month. Urge UI was the more prevalent during the last year (6.7 percent, 95 percent CI 6.7; 6.7) of men 45-64 years old. Men over 65 years of age reported having urge UI during the last month (10.6 percent, 95 percent CI 10.6; 10.6).

Severity of UI. Fewer studies provided estimates for severity of UI in American men **(**Appendix Table F4).[54,164,181,590,591] A survey of 922 males older than 20 years who were recruited in the primary care clinic[54] reported that wet underwear less than once per month was experienced by 9 percent, monthly by 5 percent, weekly by 7 percent, and daily by 14 percent of the responders. A community-based cross-sectional survey of 778 men older than 40 years[590] reported that 10.8 percent of the responders had wet underclothing during the last year. Among males 41-60 years old from primary care clinics in a Veterans Affairs facility, 4.4 to 4.8 percent experienced daily UI. [181] The prevalence of daily UI increased to 8.4 to 8.9 percent among those older than 60 years of age. Pooled analysis (Table 10) estimated that daily UI was experienced by 4.8 percent of males 45-64 years (95 percent CI 4.8; 4.8), 8.3 percent men over 65 years old (95 percent CI 7.0; 9.6), and 9.3 percent elderly men (95 percent CI 4.5; 14.1). Severe UI that required a change of underwear was reported by 2 percent of those 45-64 years old and 4 percent of elderly men (95 percent CI 3.9; 4.1).

Racial/ethnic differences. The majority of studies have been conducted in White male populations (Table 1). Three studies from the United States provided data on prevalence rates in racial/ethnic groups using different survey methodology, including methods for estimating prevalence.[8,39,181] In one large population-based survey using a weighted prevalence estimate, non-Hispanic Black men were found to have a higher rate of UI (21 percent) compared to non-Hispanic White men (16 percent) and Mexican-American men (14 percent).[8] In the other study, non-Hispanics (38 percent) were more likely than Hispanics (31 percent) to have UI.[39] This latter study also found that American Indians and Whites had higher rates of UI than Asians and Blacks, respectively. A sample of male veterans receiving care in primary care clinics found similar rates of incontinence between Whites (32 percent) and Blacks (33 percent).[181] In a cross-national comparison of UI prevalence rates, South Korean men had the lowest rates (4 percent)

followed by men in France (7 percent), the United Kingdom (14 percent), and the Netherlands (16 percent).[585]

Incidence of UI in Community Dwelling Men

There is scarce data on the incidence of UI in community dwelling men, excluding studies of men following prostatectomy (Table 6). One-year incidence rates vary depending on the age of the study population. In one study of men 40 years and over residing in the United Kingdom, the 1-year incident rate was 4 percent, with incidence of involuntary leakage increasing from 2 percent in those 40-49 years to 11 percent in those 80 years and over.[38] In a study of American men 60 years and over, the 1-year incidence rate of involuntary leakage was 20 percent (weighted for nonresponders).[47] There are no data available on the incidence of the different types of UI or comparisons by racial/ethnic groups.

Progression and remission of UI in community dwelling men. There is limited evidence on the progression and remission of UI in men. Evidence indicates that when men became incontinent, they developed urge or other types of UI; those with urge UI alone either stayed as urge UI or developed mixed UI.[47] In one study over a 10-year period, 3 percent of men without either urgency or urgency with incontinence at baseline developed urge UI. There was a slight nonsignificant decline in men with urge UI at baseline to have it at the 10-year followup (5 percent vs. 4 percent, respectively).[582]

Epidemiology of UI in Long-Term Care Settings

Overview. In contrast to community settings, there have been fewer epidemiological studies on the prevalence, incidence, progression, and remission of UI in LTC settings. Differences in study populations, survey methodology, and definitions and measurement of UI affect the variability in prevalence estimates. Also, the timing of the survey, e.g., at admission or at a later date, also adds to the variability in estimates. More recent studies have relied on the bladder continence item on the Minimum Data Set (MDS) to operationalize UI. Two studies report data from the same cohort but derive slightly different estimates.[28,166] There are scarce data on the severity and impact of UI.

Prevalence of UI in the LTC population. The majority of studies sample both men and women ages 65 years and over residing in LTC facilities (Table 11). Although most studies provide prevalence estimates by gender, some provided only a prevalence estimate that included both men and women. For the combined group, prevalence estimates using varying definitions (e.g., any daytime urinary incontinence, at least two episodes of urine loss in the past 2 weeks, urine loss at least twice a month, or medical record or staff report of UI) ranges from 30-77 percent.[2,28-31] Measuring UI with the MDS, prevalence estimates varied from 30 percent in a large sample of 29,645 adults ages 20-109 years[31] to 77 percent in a smaller sample of 380 adults 65 years and over.[30] In a recent population-based study involving 95,911 older nursing home residents from eight southeastern states, the prevalence rate at admission was 65 percent.[32]

The prevalence of UI in female residents in LTC settings is estimated at between 60 and 78 percent.[28-30,32,164] In one study using data from the National Nursing Home Survey, the prevalence in women was estimated to be 74-85 percent.[2] However, in this same study when UI was identified from the medical record, the prevalence rate was <1 percent (1,366 per 100,000). The prevalence of UI in men ranges from 23-72 percent.[28-30,32,164]

Prevalence rates increase with advancing age in both men and women.[2,29,30] There is limited data available on racial/ethnic differences in UI prevalence. Those studies available indicate conflicting findings. In one large study involving nursing home residents from eight states, there was a higher prevalence in Blacks (71 percent) compared to Whites (64 percent) at admission, but after admission the prevalence rate was more similar (78 percent vs. 74 percent, respectively.[32]

Incidence of UI in LTC settings. Minimal data are available on the incidence of UI in LTC settings An early study involving 430 nursing home residents reported an incidence of 27 percent 2 months after admission and 19 percent at 1 year.[166] This is consistent with a later study that reported an incidence rate of 20 percent at 1 year.[33] The incidence of daytime UI between 2 months and 1 year after admission was higher in males (46 percent) than in females (16 percent).[166]

Progression and remission of UI in LTC settings. Few studies have examined the progression and remission of UI in LTC settings in a way that can be easily interpreted. Although there are no large changes documented, the evidence available suggests that UI is a dynamic condition that does change over time, including improvement. One large study involving nursing home residents from eight states that examined UI at admission and within a 4-year post-admission period reported a 0 percent progression rate.[32] In another study, the remission rate at 1 year was reported to be 10 percent.[33]

Table 1. Prevalence of UI in community dwelling adults by age and race

Author Sample	Country	Ages (years)	Design	UI Definition	Response Rate (%)	Number	UI Prevalence (%)
Prevalence of UI in Adults (Women and Men Combined)							
Miles, 2001[592]	USA	65 years & over	Population-based mailed survey	Difficulty holding urine	--	2,660	14.1%

Question 1. What are the Prevalence and Incidence of FI in the Community and LTC Settings?

The absence of a standard and accepted definition of FI has hampered drawing conclusions about the epidemiology of both fecal and dual incontinence. Definitions vary by the inclusion of flatus, severity characteristics of FI, and subjective significance (e.g., requiring FI to be a social or hygienic problem). There is often a lack of data to determine whether dual incontinence is actually present. The ICS recommended analyzing the prevalence of AI, including involuntary loss of flatus, in all age groups because this extended definition gives a more precise estimation of impact of incontinence on quality of life in young adults.[21] In this review, prevalence and incidence are reported for any FI (i.e., with or without UI), any AI (i.e., FI and flatus incontinence), dual incontinence, and FI only (without UI) when data are available The authors also reported the prevalence of different types of incontinence (including loss of solid or liquid feces) and severity of incontinence.

Prevalence of Combined UI and FI in Adults in LTC Settings

Prevalence of combined UI and FI in adults in LTC settings varied from 4 percent[519] to 44 percent[34] across the studies (Table 12). One of the largest cross-sectional studies of 10,215 older nursing home residents in the United States, identified from the MDS, reported 40 percent prevalence of combined incontinence.[5] By contrast, another study found a prevalence of 18 percent, analyzing data from the regional census of older residents.[519] Almost half the residents in Canadian LTC hospitals had combined incontinence.[34] The prevalence was lower in nursing homes in the United Kingdom (4 percent), and in short-term nursing homes (9 percent).[519] Residents in geriatric (27 percent), private nursing (33 percent), and psycho-geriatric nursing homes had higher rates of combined incontinence.[519]

Prevalence of FI with or without UI in Adults in LTC Settings

Prevalence of FI with or without UI in adults in LTC settings varied from less than 5 percent across nursing homes in the United Kingdom[519] to 12 percent in the largest national American study.[5] One study at the state level reported a prevalence of 46 percent[3] and an annual incidence of FI in nursing homes of 14 percent.[4] The prevalence varied depending on baseline disease, from 27 percent in residents who needed supervision to 83 percent in patients with severe mental impairment.[34] More than half of the residents in geriatric and psycho-geriatric LTC facilities wear pads for FI.[519] The prevalence depended on the definitions of incontinence and whether having only FI (versus combined UI and FI) was reported (Appendix Table F5). Moderate FI was reported in 8 percent of women in nursing homes.[161] Thirteen percent of residents experienced incontinent episodes 1-3 days per week, 16 percent 4-7 days per week, and 23 percent less than once a week.[602] Frail residents (16 percent) and patients with stroke (25 percent) and dementia (45 percent) had the highest prevalence of frequent FI.[602]

In conclusion, fecal and combined incontinence is prevalent in LTC facilities. Combined incontinence is more prevalent than FI alone. Rates depend on the data set, definitions and severity of incontinence, and baseline diseases status. The prevalence among race, age, and ethnic groups needs future research.

Prevalence of FI in Community Dwelling Elderly Adults

Three percent[111] to 6 percent[158] of older adults living at home suffer from combined UI and FI (Table 13). The prevalence in elderly men varied substantially from 2 to 6 percent in Europe[111] to 39 percent in the United States.[6] The same prevalence of 4 to 6 percent of combined incontinence was found in European elderly women[111] with a rate several times higher in American females (27 percent).[6]

The prevalence of FI varied from 6 to 10 percent in Europe[111,603] to 15 percent in Japan[58] to 26 percent in the United States.[158] The prevalence of solid FI was around 2 percent in two studies,[111,158] while liquid FI was more than ten times higher in the American study (17 percent)[158] than in Europe (1 percent).[111] The prevalence did not show consistency in elderly males with ranges in FI from 3 percent[6] to 16 percent.[219] The prevalence of FI in elderly women averaged 6 to 8 percent in Europe[111] and 12 percent in the United States.[219]

Prevalence of FI in Community Dwelling Men

Prevalence of FI in community dwelling men varied across the studies depending on definitions of incontinence and population characteristics, including the proportion of subjects with FI only in the samples when anal or combined incontinence were analyzed.(Table 14).

Combined UI and FI were reported in 6 to 15 percent of younger men, while 7 to11 percent experienced FI in a cross-sectional, community-based study.[6] Less than 2 percent of younger men were incontinent with solid or liquid feces;[604-606] 6 percent[605] to 21 percent[604] reported stains in underwear. Older European men had combined incontinence less often (1-4 percent)[111] than American men (15 to 25 percent).[6]

The prevalence of FI was consistently <10 percent in several studies of men older than 60 years[6,50,111,508,604,606-609] and in studies with combined age groups.[7,217,610-612] One Portuguese study reported the highest rate (16 percent) of FI in patients of a geriatric ambulatory service.[613]

Pooled prevalence of FI in community dwelling men varied across the studies with a less expected fact that the addition of flatus incontinence did not increase the prevalence of AI compared to reported prevalence of FI only (Table 15).p The lowest prevalence of AI (1.6 percent) was reported in two studies with the median age of participants between 45 and 64 years. The prevalence of FI was less than 10 percent in all age groups and increased from 6.4 percent in those 45-64 years old to 9.6 percent in elderly men. The prevalence of solid feces incontinence was reported by 1.4 percent of men 45-64 years of age and by 2 percent of elderly males. The most prevalent was combined incontinence in elderly persons; 16 percent of men over 80 years experienced UI and FI.

Prevalence of FI in Community Dwelling Women

Although no study investigated FI vs. AI in the same sample, there was a consistent pattern of a higher prevalence (two to four-fold) of AI than that of FI in women across age categories; this suggests that combining incontinence of flatus and feces in the same definition may contribute to increased prevalence estimates.

Less than 10 percent of females in the community experienced combined incontinence (Table 16).[6,111,162,212,614] Older women had higher rates of combined incontinence, but only in one

study.[6] The prevalence of AI increased with age from 11 percent in females under 40 to 36 to 45 percent in older women.[615]

The prevalence of FI also increased with age from 6 percent in women younger than 40 years,[161] to 9 percent in those 50-59 years and 13 to 18 percent in older women.[6,42] Association with age was found in two studies,[6,111] but the rates were not consistent across studies. The prevalence of FI varied by the type of incontinence (Appendix Table F6). The prevalence of flatus was less than 10 percent in the majority of the studies.[162,205,232,604,612,613,616-618] Only four studies reported flatus incontinence in more than 20 percent of women.[99,125,212,619] The prevalence of incontinence of liquid feces was less than 10 percent in 50 percent of the studies.[163,205,604,612,616,617,619] Few studies reported a prevalence of more than 10 percent[125] or 20 percent.[99] The prevalence of incontinence of solid and liquid feces was <10 percent in four of 12 studies that reported this outcome.[163,508,604,606] Most of the studies found that 5-10 percent of women were incontinent of solid and liquid feces.[42,50,99,607-609,613] The prevalence of solid feces was <5 percent in 10 of 15 studies that assessed this outcome.[125,163,205,217,604,612,616,617,619,620] Four studies found that 5-10 percent experience incontinence of solid feces.[99,161,615,621] Severity of FI in females increased with age (Appendix Table F7).[161] The prevalence of monthly FI varied from 6 percent[162] to 25 percent;[125] One percent[162] to 5 percent[163] of women had more than one FI episode per month. The prevalence of weekly FI was less than 7 percent in the majority of the studies.[125,160,161,163] Less than 2 percent of community dwelling women reported daily FI.[125,161]

Pooled prevalence of AI was the highest in women compared to other definitions and increased from 22 percent to 45 percent with aging (Table 17) An inclusion of flatus incontinence in the definition contributes to increased prevalence estimates in females. Prevalence of FI was higher than in males and increased from 7 percent in those 45-60 years of age to 10 percent among elderly women. Combined UI and FI were experienced by 10 to 12 percent of women. The prevalence of monthly FI varied from 6 percent to 25 percent; 1 percent to 5 percent of women had more than one FI episode per month. The prevalence of weekly FI was less than 7 percent in four studies. Less than 2 percent of community dwelling women reported daily FI in three studies.

Prevalence of FI in Community Dwelling Adults

Several studies did not differentiate prevalence of FI by gender (Appendix Table F8). Combined UI and FI increased with age[111] and varied from 1 percent to 6 percent in older adults.[222] The prevalence of FI was 2 percent in an American study[622] and 5 percent in a French study.[623] The prevalence of FI also increased with age and sample;[111,159] it varied from approximately 5 to 8 percent in a community based study[111] to 12-19 percent among adults visiting primary care physicians or gastroenterologists.[159] The prevalence of FI of liquid feces was 7 percent,[624] higher than FI of solid or liquid feces (3 percent[625] to 4 percent[626]). Daily FI was reported by 3 percent of adults,[159] weekly FI by 4 percent[160] to 5 percent,[159] and monthly FI by 7 percent[159] (Appendix Table F9). Daily incontinence of solid feces was found in 0.4 percent of adults;[627] weekly incontinence was experienced by 0.1 percent[623] to 3 percent[627] of adults.

Prevalence of FI in Community Dwelling Adults by Race

African American and White men had the same prevalence of FI (14 percent vs. 11 percent, respectively) (Appendix Table F10).[219] Prevalence of FI varied in African American women

from 9 percent[219] to 19 percent[628] and in White women from 7 percent[187] to 21 percent,[628] being lowest in Asian American women (4 percent).[187] The prevalence of combined UI and FI was 11 percent in Asian women and 20 percent in White women.[187]

Limitations

Variations in definitions of FI and its severity, few population level studies with multivariate analyses, differences in samples, and inconsistency in factors adjusted in statistical modeling prevent firm conclusions; pooled estimates and meta-analysis procedures could not be conducted in many instances. Data were inconsistently reported for FI severity characteristics (frequency, amount, consistency of leakage, and duration) and analyses of associated factors were few, so knowledge is limited. Use of a standard definition of FI that excludes flatus and determination of a minimum set of variables to be collected and used in multivariate analyses are recommended.

Summary

In conclusion, the published evidence, level IIB-III, suggests that the prevalence of FI increases with age and varies, depending on the country where studies were conducted; population-based, clinic-based, or administrative sampling of the adults; and definitions of FI with increased prevalence of AI in women but not in men.. Data were inconsistently reported for FI severity characteristics (frequency, amount, consistency of leakage, and duration), and analyses of associated factors were few, so knowledge is limited. Use of a standard definition of FI that excludes flatus and determination of a minimum set of variables to be collected and used in multivariate analyses are recommended.

Less than 10 percent of females in the community experienced combined incontinence. The prevalence of combined incontinence in men was not consistent and varied by age and residency categories. The prevalence of FI was consistently <10 percent in men of different age groups. Most of the studies found that 5 to 10 percent of women were incontinent of solid and liquid feces and <5 percent of solid feces. The prevalence of FI was the same among race categories. Heterogeneity in prevalence across studies does not allow valid pooled estimates. The primary cause for FI; risk factors, age, and gender may contribute to differences in results. Adjusted prevalence and incidence of FI should be investigated in prospective studies. Studies with older adults identified through medical records and administrative databases reported higher prevalence of FI. Differences between quantitative definitions of FI account for variation in the results. Studies of FI incidence and risk factors are greatly needed.

Question 2. What are the Independent Contributions of Risk Factors for Urinary, Fecal, and Combined Urinary and Fecal Incontinence?

Overview of Risk Factors for UI

Early epidemiological studies identified a number of potential risk factors of UI in a variety of adult populations (childbearing women, nonchildbearing women, men, men following prostate surgery) using univariate or bivariate analyses. In the past decade, there have been an increasing number of large population-based studies that incorporate multivariate analyses enabling the determination of the independent effect of a particular risk factor. However, the majority of studies have been cross-sectional in design which provides data only on risk factors for prevalent incontinence (Appendix F Table 1). Many of these studies are national population-based surveys on the general health of a particular population and are limited by the variables included in the study. Longitudinal studies incorporating multivariate analyses that provide data on the risk factors for incident incontinence are scarce.

In women, the major modifiable risk factors included obesity, vaginal trauma, and vaginal prolapse. Studies on risk factors such as lifestyle factors, selected chronic diseases, and medication use are limited. Inconsistencies in findings related to particular risk factors might be explained, in part, by the differences in the age of the study populations, the definition and measurement of UI, and the risk factors available for analysis. Longitudinal studies have found that risk factors for prevalent vs. incident UI vary.[149] In general, the risk factors for the various types of UI (stress, urge, and mixed) also vary. Aging tends to be associated with changing risk profiles associated with UI and UI type. The evidence presented next includes only those studies that incorporated multivariate analyses.

Risk Factors for UI in Community Dwelling Women

Age. Age tends to be linearly associated with UI, with prevalence and incidence rates increasing steadily with advancing age.[7,41,53,55,56,62,65,80,81,83,85,99,105,133,138,143,184] However, in older women an increase in incidence of weekly[123] UI was not significant when women 75-79 years were compared to those 70-74 years of age (Appendix Table F11). The large Canadian Study of Health and Aging cohort reported no significant increase in annual incidence of UI in women 75-84 or older than 85 years compared to women younger than 75 years of age.[186]

Prevalent UI significantly increased with age in 20[7,55,66,67,73,74,81,84,92,96,97,105,118,124,133,138,149,185-187] of 28 studies that reported the association.[7,55,62,66,67,73,74,81,84,92,93,95-97,105,118,124,132,133,138,140,144,149,185-189] Only one population-based cross-sectional study of 5,701 female participants in the Health and Retirement Study showed a decrease of 3 percent per 1 additional year in prevalence of moderate UI with 15 or fewer days with incontinence episodes in the last month.[189] Adjusted odds of prevalent stress UI increased by 110 percent per 5 year incremental increase in age in participants of the Heart & Estrogen/Progestin Replacement Study[66] with nonsignificant dose response association in the British cohort of 12,570 female respondents older than 40 years.[132] The largest increase in odds of stress UI (239 percent) was reported among women over 80 years compared to those younger than 60 years[133] in the European population-based study of 5,795 elderly community dwelling females.[133]

Prevalence of total weekly UI significantly increased by 106 percent per additional 1 year[96,149] and daily UI by 103 per additional 5 years of age.[140] Adjusted odds of occasional monthly UI was 1.2 and odds of severe UI 1.3 times in women 40-44 years compared to those younger than 40 years old.[138] Women 45-54 years old experienced UI 2.1 times more often and those older than 55 years of age 3.1 time more often than those 15-34 years old.[7] Odds of reporting any UI was 3.7 times greater in women 50-59 than those 41-49 years old.[84] Women older than 70 years experienced UI 1.49[81] to 2.9 times[84] more often than women under 50. The dose response association with severity of UI was shown in the Nurses' Health Study with odds ratio 1.45 for occasional, 1.56 for occasional severe, 1.67 for frequent and severe, and 1.81 for weekly severe UI in women older than 70 compared to those under 50.[84] Women 75-84 years old had 1.47[186] to 6.7[92] times higher odds of UI compared to women under 75 years and those 15-24 years old, respectively.

Adjusted prevalence rates of weekly urge UI increased by 1.2[66] per 5 additional years of age and by 1.8 times [187] per 10 additional years of age in a dose response model. Monthly urge UI was 1.8 time more frequent[133] among women 60-80 years old than for those under 60. Elderly women older than 80 years reported monthly UI four times more often than women younger than 60.[133] One community base Japanese survey of 968 women older than 40 years reported lower odds of urge UI among those older than 60.[74]

Maternal age at the time of either the first or last delivery has been examined as a risk factor for subsequent UI; however, the effect age has on the development of UI appears to lessen by age 50.[630] Several studies have found that age 35 years or older at first delivery increased the risk of UI or frequent UI when compared to younger women.[105,197] Similarly, one study found a lower risk in women who were 25 years or younger at their first delivery than their older counterparts (23 percent vs. 28 percent, respectively).[630] Another study found that being age 30 or more at the second delivery doubled the odds of becoming incontinent.[197] Two studies reported that the strongest associations with UI were for women who were under the age of 22 years at their first delivery.[105,135] In one study examining maternal age at subsequent deliveries, women older than 30 and 40 years at a second vaginal delivery had lower rates of UI and urge UI.[64] Other studies have not been able to demonstrate an independent effect of age on UI in the immediate postpartum period.[198] Age at last delivery appears to be less of a risk factor.[630]

Gender. Female gender has been consistently documented as a strong predictor of UI in bivariate analyses,[30,36,39,47,61,74,92,97,107,114] with an age-adjusted odds of UI of 3.1.[92] One in six women after age 30 have UI, compared to 1 in 20 men.[587] Women have higher rates of UI than men in all age groups.[81,86] In early adult years, women have a two to four times higher rate of UI than men; however, in advanced years (e.g., ages 75 or 85 and over), even though women continue to have higher rates, the prevalence rates are more similar.[81] In a study of 54,920 adults ≥30 years, the UI rate in women was 2.5 per 100 versus 1.4 per 100 in men.[86] Other studies find that UI prevalence is 6.8 times higher in women.[75]

Race/Ethnicity. There is growing evidence that race/ethnicity is a predictor of UI, UI severity, and UI type in nonchildbearing and childbearing women (Appendix Table F12). In earlier studies, White women tended to have higher rates of UI than other ethnic/racial groups (Blacks, Asian Americans, including Japanese and Chinese, and Hispanics).[30,59,89,93,105,120,138] In more recent studies, being non-White was associated with lower odds of having UI and severe UI,[144] with the exception of being Hispanic.[138] A higher UI incident rate in Whites was reported in two studies (OR 3.1, 95 percent CI 2; 4.8) (Figure 3).[123,149] African American women had

higher odds of incident urge but lower odds of incident stress UI. Hispanic women developed weekly UI more often compared to Caucasian (OR 2.96, 95 percent CI 1.06; 8.18).

Prevalence of mild, moderate, and severe UI was lower among African American women than White women in all six studies that examined the association (Figure 4).[93,105,137,138,149,189] Prevalence of moderate UI was lower among Hispanic women compared to Caucasian women in four of five studies (Figure 5).[93,105,138,149,189] However, evidence was not consistent. Prevalence of mild or severe UI was either less or the same in Hispanic women than in White women. Asian women had lower odds of moderate or severe UI (Appendix Figure F1) in two studies.[105,138]

Race/ethnicity was associated with different types of UI, including stress, urge, or mixed UI (Appendix Table F12). After multiple adjustments, the risk of stress UI was higher in White women than in Black and Asian American women.[118,137] In one study White women had a 2.8 times higher risk of stress UI than Black women.[66] In contrast, the risk of urge UI was similar in Black and Asian American women compared to White women.[59] In other studies, White women had three times the risk of Black women with respect to urge UI.[118]

Obesity. Obesity has been consistently established as a strong predictor of UI, especially severe UI (Appendix Table F13). Incident monthly UI was 110 percent higher and daily 112 percent higher per one unit increase in BMI.[149] Obese females developed monthly UI 1.7 times more often (95 percent CI 1.2; 2.5) than women with normal weight.[103]

Prevalent urge UI showed a positive dose response association 1.1 times per one unit increase in BMI,[51] (OR 1.08, 95 percent CI 1.1; 1.1), 1.4 times in women with BMI 25-30 than <25 kg/m^2,[133] and 1.8 times (OR 1.8 95 percent CI 1.4; 2.4) in those with BMI >30 kg/m2.[133] Asian overweight women experienced urge UI three times more often than those with normal weight (OR 3.4, 95 percent CI 1.2; 9.2).[187]

The largest increase in stress UI was shown in obese women with uterovaginal prolapse compared to normal weight females without prolapse (OR 33.0, 95 percent CI 12.5; 87.1).[95] In contrast, underweight women after surgery for UI reported stress UI more often than females with greater BMI.[631] Severe UI was more prevalent in overweight women (BMI 25-29kg/m^2 OR 1.5, 95 percent CI 1.4; 1.6) and obese women (BMI >30 OR 3.1, 95 percent CI 2.9; 3.3).[138]

The effect of BMI differed depending on definitions of UI (Figure 6). Odds of ever having UI were higher in underweight and overweight women.[116,191] Adjusted odds of UI in the past month were higher in overweight and obese females.[83,92,133,143] Weekly UI was more prevalent in obese but not overweight women with a dose response increase per one unit of BMI.[66,90,92,96,138,189] With the definition of UI in the past year (Figure 7), the majority of the studies showed a significant increase in UI corresponding to greater BMI.[7,51,59,68,72,144]

The association between BMI and UI varied depending on frequency of leakage episodes (Figure 8) The majority of the studies reported a significant raise in daily UI corresponding to an increase in BMI per one unit (OR 1.44, 95 percent CI 1.3; 1.6), per five units (OR 1.6, 95 percent CI 1.4; 1.7), or in overweight women (OR 1.65, 95 percent CI 1.3; 2.1).[55,67,70,149,189] Incremental increase per one unit in BMI was not associated with higher adjusted rates of at least monthly UI; however, obese women had greater odds of UI compared to women with normal weight.[67,104,121,124,138,149,190] Underweight and obese women had increased odds of having at least weekly UI.[67,92,138,185] Daily and weekly stress UI were significantly associated with an increase in BMI in all studies (Figure 9).[51,66,70,118,132,133,135,149,187] The association with UI at least monthly or in the past year was less consistent.

Studies in older women have found that a higher BMI (OR 1.3 per 5kg/m^2, CI 1.1; 1.6) was associated with stress UI but not urge UI.[118] Other studies found that increasing BMI was

associated with urge UI in women ages 40-60 years, whereas one study did not find an association.[66]

Some studies have incorporated alternative anthropomorphic measures such as waist circumference, visceral fat area measured by computed tomography scan of the abdomen, and sagittal diameter[66,118,149] with mixed outcomes (Appendix Table F14). One study found that waist to hip ratio was predictive of stress UI.[66] Other studies found increasing waist circumference is weakly associated with prevalent mixed UI (OR 1.0, 95 percent CI 1.0; 1.1 per 1cm increase in waist circumference), stress UI (OR 1.0, 95 percent CI 1.0; 1.1), and total monthly UI (OR 1.1, 95 percent CI 1.0; 1.1).[149]

Evidence on maternal weight and maternal weight gain during pregnancy is conflicting. In one study, women with higher BMIs (>25kg/m^2) and higher maternal BMIs (during pregnancy) increased their odds by 168 percent in developing UI at 3 months postpartum as compared to women with lower BMIs.[197] In another study, higher predelivery BMI (per 5kg/$m^{2)}$ increased the odds of UI at 6 months postpartum by 20 percent.[203] In other studies, maternal weight gain was not associated with UI[199] or the development of stress UI 10 years after the index delivery.[196]

Genetic influence. Evidence from four studies suggests a genetic influence on UI.[632-635] In one study, daughters of mothers with stress UI had a higher prevalence of stress UI than age-matched controls, 71.4 percent versus 40.3 percent, respectively.[632] Furthermore, UI symptoms appeared 7 years earlier in "incontinent families" than in those without a history of incontinence.[632] In a case-control study examining relatives of women with urodynamically diagnosed UI, first-degree relatives had a UI prevalence of 20.3 percent versus 7.8 percent in relatives of the control group.[635] Both mothers and sisters had significantly higher prevalence rates of stress UI than controls. Although daughters had a UI prevalence rate twice as high as controls, the difference was not significant. [635] In a population-based study, daughters of mothers with any type of UI had a 1.3 times higher risk of being incontinent, (95 percent CI 1.2; 1.4), a 1.5 times higher risk (95 percent CI 1.3; 1.8) of stress UI and 1.8 times higher risk (95 percent CI 0.8; 3.9) of urge UI.[633] Daughters were also at higher risk of having severe incontinence if the mother had severe incontinence (1.9; 95 percent CI 1.3; 3.0). [633] Younger sisters of female siblings with UI, stress UI, or mixed UI had increased relative risks, respectively of 1.6 (95 percent CI 1.3; 1.9), 1.8 (95 percent CI 1.3; 2.3), and 1.7 (95 percent CI 1.1; 2.8).[633] In another population-based study involving 548 monozygotic and 620 dizygotic twin pairs, the heritability for urge UI was 42 percent (95 percent CI 16; 63) among women ages 48-64 years and 49 (95 percent CI 29; 65) in those ages70-94 years.[634] Mixed UI also had a substantial genetic component; however, the role of genetic factors was less clear.[634]

Lifestyle Factors

Physical activity. There is limited data on the role of physical activity as a risk factor for UI (Appendix Table F14). Intensive physical activity in women 50-79 years of age in the Nurses' Health Study was associated with a significant reduction in incident UI (OR 0.9, 95 percent CI 0.8; 1.0).[156] Physically active women developed stress UI less frequently (OR 0.71, 95 percent CI 0.56; 0.91).[156] The same study reported a significant negative association between walking and incident urge UI (OR 0.7, 95 percent CI 0.5; 0.9).[156]

In a large study of women ≥20 years, after adjusting for age, number of children, coughing, and wheezing/dyspnea, increasing levels of low physical activity had weak and negative associations with UI.[192] No significant effects were noted for high intensity physical activity with

respect to stress, urge, and mixed UI. Similarly, a large study of women ≥40 years did not find an effect for those with different levels of physical activity or participating in vigorous activities.[103] In a study examining the impact of physical activity on urine leakage in 665 primiparous women, high impact exercise before pregnancy was significantly associated with UI 1 year after childbirth, increasing the odds of UI by 40 percent.[636] In two surveys, physical exercise in the past year was not associated with UI.[55,83]

Education and occupational status. Studies on occupational factors and UI risk are rare. In a study involving 1,581 Taiwanese women ≥20 years, having an occupation that involved weight lifting or other labor was not significantly associated with stress UI.[95] Women without private health insurance had higher adjusted odds of urinary symptoms (OR 2.6, 95 percent CI 1.4; 5).[84]

Surprisingly, higher education was associated with increased odds of prevalent UI in the majority of the studies.[67,70,72,83,93,149,189,191] College graduates 42-52 years old experienced UI 1.31 times more often compared to women without degrees;[93] university graduates 50-64 years old reported UI 2 times more often (OR 2.0; 95 percent CI 1.8; 2.3)[191] than females with lower education. One study found that higher education was an independent risk factor for UI for all ethnic groups except Chinese Americans but that educational level was not associated with moderate/severe UI.[93] However, in contrast to these studies, one study of postpartum incontinence reported that having less than a college education doubled the risk of UI.[203]

Marital status and social support. Married women had the same prevalence of UI as women who were widowed, divorced, or never married.[84] A large Study of Women's Health Across the Nation[149] suggested no association between level of social support and incident monthly UI. However, the same cohort reported higher prevalence rates of UI among women within the lower quartile of social support.[149] Psychological stress was associated with greater urinary symptoms including UI (OR 2.7, 95 percent CI 1.1; 7)[84] but not with UI in the past month.[83] Low social activity was not associated with risk of stress, urge, or mixed UI in women ≥70 years.[106] The interpretation of whether decreased social activity and poor social support precipitates UI or is a result of UI is unclear.

Dietary factors.

Caffeine. Evidence of caffeine consumption as a risk factor for UI is limited and conflicting. In a Norwegian study of 34,755 women ≥20 years of age, coffee consumption (number of cups/day) was not associated with UI in a multivariate analysis, whereas tea drinkers were at a slightly higher risk for all types of UI. (Appendix Table F15).[192] In other studies, coffee consumption has either not been associated with UI risk[55,103] or was shown to reduce the odds by 50 to 60 percent, depending on the amount consumed.[72] One large study in the United Kingdom did not find an association between tea consumption and UI risk.[103]

Carbonated beverages. Data on the type and amount of beverages consumed is scarce. In one study involving 6,424 women, daily consumption of carbonated beverages increased the odds of stress UI in women ≥40 years by 62 percent.[103] Although this study also examined the effect of carbonated beverages in women with overactive bladder, it was not possible to determine the effect in those who had urge UI alone.

Food consumption. Only one study has examined the role of different food groups on the risk of stress UI.[103] Consumption of various amounts of vegetables and chicken were not associated with stress UI, whereas eating bread daily or more was associated with decreasing the odds of stress UI by 24 percent.[103]

Alcohol use. Few studies have examined the effect of alcohol consumption on UI.[55,67,72,83,84,92,190] Some studies that did examine alcohol use, including the type of alcohol

consumed, did not include it in a multivariate analysis.[103,118] Alcohol consumption, as measured by number of glasses of alcoholic beverages consumed over a two-week period and the number consumed each week, has not been found to be a risk factor for UI.[55,72,83,192] Only one study reported a greater odds of weekly UI among women with daily alcohol use compared to never drinkers.[83] Women with low and moderate alcohol consumption had lower adjusted rates of occasional UI.[190]

Smoking. Smoking as a risk factor for UI has been assessed in several studies.[55,72,83,93,103,118,138,192] (Appendix Table F16). Six studies[92,93,138,186,189,192] of 12[67,72,83,92,93,138,143,186,189,191,192] found a significant positive association between smoking and UI. One study suggests that smoking status per se is not associated with UI, but rather examining the dose-response relationship between numbers of cigarettes smoked, either as a former or current smoker, may be more relevant.[192] In this study both former and current smoking was associated with UI, but only for those who smoked more than 20 cigarettes per day, raising the odds of UI by 2.7 and 3.0, respectively.[192] However, severe incontinence was weakly associated with smoking, regardless of number of cigarettes. Interestingly, adjusted odds of current smokers in the same study[192] had higher odds of mixed and total but significantly lower odds of stress UI. Neither smoking status nor a dose response between numbers of cigarettes smoked per day was found to be a risk factor in a survey involving 2,767 Italian women.[72] Although a survey of 1,262 women in the United Kingdom found that the number of cigarettes was not associated with UI, being a former smoker did increase the odds by 30 percent.[83] In a large study of 83,355 American women ages 37-54 years, former smoking was not associated with UI, whereas current smoking was significantly associated with frequent and severe UI.[138] Current smoking increases the odds of moderate/severe UI by 20-55 percent.[93,138] Smoking during pregnancy independently increased the odds of UI by 290 percent (odds ratio 2.9, 95 percent CI 1.4; 3).[198]

Functional status.

Cognitive function. Studies on the role of cognitive function as a predictor of UI in community dwelling women are scarce (Appendix Table F17). The prospective Canadian Study of Health and Aging did not find a significant association between impaired cognitive function and incident UI in elderly community dwelling women.[186] However, another prospective study, Study of Osteoporotic Fractures, reported an increase in odds of developing UI by 1.3 times (OR 1.3, 95 percent CI 1.1; 1.6) among older women with decline in walking speed, by 1.4 times (OR 1.4, 5 percent CI 1.2; 1.6) among those with decline in chair stand speed, and by 1.6 times in females with reduced Mini-Mental State Examination scores (OR 1.6, 95 percent CI 1.1; 2.1).[147]

Prevalence of UI was higher by 166 percent in frail community dwelling elderly with impaired cognitive status (OR 1.7, 95 percent CI 1.3; 2.1), who were participants in the Italian Silver Network Home Care project.[97] However, the Canadian Study of Health and Aging did not find a significant association between cognitive decline and prevalent UI.[186] In a survey of adults ≥75 years, memory problems significantly increased the odds of UI by 70 percent.[114] One study found that memory difficulties significantly increased the odds of having stress UI in a cross-sectional analysis but not in a longitudinal analysis at 1 year.[132]

Depression. An increasing number of studies are examining depression as a risk factor for UI (Appendix Table F17).[59,90,106,118,191] Postmenopausal women with depressive symptoms developed UI 2.7 time more often (OR 2.7, 95 percent CI 1.4; 5.3) during 2 years of followup in a prospective cohort study.[123] The association was random in another large cohort of the Study of Women's Health Across the Nation with 6 years of followup.[149]

Prevalence of UI was significantly higher in depressed women in five studies[90,124,149,189,191] of eight[90,97,106,118,124,149,189,191] that examined the association in multivariate analysis. The largest increase in adjusted odds of UI was observed in women with current depression (OR 2.0, 95 percent CI 1.2; 7.6)[90] or current major depression (OR 2.5, 95 percent CI 1.7; 3.7).[124] Some studies indicated that depressive symptoms are a risk factor for a particular type of UI rather than UI in general. Depressive symptoms have been strongly associated with urge UI in some studies, raising the risk by 2.7 times in women ages 70-79 years.[118]

Physical function. Decreased physical function measured by self report and physical performance tests has been consistently documented as a strong predictor for UI in six studies[67,81,92,97,144,189] of eight[67,81,92,97,106,132,144,189] that examined this association (Appendix Table F17). Poor mobility increased the odds of UI by 4.7 times in women over the age of 60[42] and in other studies mobility limitations, including difficulty walking, increased the odds of UI ranging from 23 to 81 percent in older women.[81,114]

ADL impairments strongly increase the risk of UI and UI types, although findings vary. Physical impairment was associated with increased odds of stress UI by 40 to 70 percent, except in the worst level of functioning, where it was not significantly associated.[132] However, in another study, it was not associated with stress UI but strongly associated with urge UI.[98] In a study of women ages 55-75 years, lower scores on the SF-36 physical function scale were significantly associated with any and severe UI.[144] In another study involving women ≥65 years, ADL disability increased the odds of UI by 175 percent.[81] The strongest association was reported in the national health survey in Belgium with increased prevalence of UI by 415 percent (OR 4.2, 95 percent CI 1.9; 6.0) in women with moderate physical limitations and by 521 percent (OR 5.2; 95 percent CI 1.2; 8.6) among those with severe physical limitations.[92]

Decreased physical performance measured with an objective Health ABC Performance Scale (performance on repeated chair stands, gait speed, standing balance, and a narrow walk test of balance), was associated with urge UI (OR 1.6 per point on 0-4 scale, 95 percent CI 1.1; 2.3), whereas it was not associated with stress UI.[118] Muscle strength as measured by grip and quadriceps strength was not associated with daily UI; however, faster gait speed (OR 0.8 per 2 units, 95 percent CI 0.6; 1.0) was associated with decreased incontinence.[55]

The variability in populations, definitions, and measurement of UI and functional status contributed to the differences in the results from individual studies.

Gynecological Factors

Parity. We identified 24 observational studies that reported odds ratios of UI in association with parity (Table 18).[55,59,64,68,70,72,83,92,93,95,96,105,119,124,133,135,138,149,185,191,193-196] Incident UI was not associated with parity.[149,193] A positive significant association between prevalent UI and parity was reported in 13 studies,[68,72,83,93,96,105,119,124,138,185,191,193,195] while six studies did not find a significant increase in prevalent UI in relation to parity (Figure 10).[59,64,92,133,149,194] The number of births did not show a dose response association with prevalent UI (odds ratio per one additional birth 1.0, 95 percent CI 1.0; 1.1) but did with moderate severe UI (odds ratio per one additional birth 1.1, 95 percent CI 1.0; 1.1) and severe UI (odds ratio per one additional birth 1.1, 95 percent CI 1.0; 1.1). All six studies that measured prevalent stress UI reported a significant positive association with parity (Figure 11).[72,95,133,149,195,196] Prevalent stress UI and severe stress UI did not show a significant dose response association with the number of births. Only one study[195] of four [72,133,195,196] found an increase in urge UI corresponding to parity.

The role of parity is complex and changes as a woman ages. One study reported that age modified the association between parity and UI with a significant association in young and middle aged women and attenuation of the association in older females.[195] Particularly in studies of perimenopausal and postmenopausal an association has not been found between parity and UI or with UI type,[118,128] suggesting that aging tends to diminish this effect. In a study involving separate multivariate analyses in three age cohorts (ages 18-23, 45-50, and 70-75 years), the effect of increasing parity declined with age.[68] In other studies involving both cross-sectional and longitudinal analyses, the role of parity changes after 1 year. Odds ratios associated with parity are higher in women <60 years than in women ≥60 years.[105] Certain risk factors, such as vaginal delivery, are strong predictors of UI in younger women, but with changes associated with aging and menopause, this effect seems to disappear. In premenopausal women, the number of vaginal childbirths was strongly associated with UI.[96] In other studies, the relative risk of having stress UI 10 years after childbirth was not associated with the number of vaginal deliveries.[196]

Obstetric and fetal factors.

UI during and following pregnancy. Evidence suggests that UI developing during pregnancy is a risk factor for UI in the immediate postpartum period[197] and in subsequent years[64,96] raising the odds of UI by two to 11 times[96,198] (Appendix Table F18). One study found that the odds of developing UI, stress, urge, and mixed UI were 2.2, 3.4, and 3.2 times higher, respectively, for women who had UI during pregnancy than women who did not.[64]

Women who experienced postpartum UI had four to five times higher odds of developing UI,[64,119] with four times higher odds for developing stress UI, and 2.6 and 3.2 odds for developing urge and mixed incontinence, respectively.[64]

Mode of Delivery. The majority of the studies report that spontaneous vaginal deliveries are more likely to be associated with UI,[7,197,199] stress UI and severe stress UI,[135] and subsequent stress UI surgery[631] compared to Cesarean delivery (labored and unlabored). Cesarean section was associated with lower odds of UI in seven studies,[119,197,199-203] by 80 percent[201] to 41 percent[200] and did not show a significant association in five studies[135,141,196,204,205] (Table 19). Two studies reported higher odds of UI when women after Cesarean section were compared with nulliparous females (Figure 12).[7,206] Vaginal delivery compared to Cesarean increased the risk of total UI with little evidence of association with stress and urge UI. Adjusted odds of UI was higher after forceps delivery by 150 percent[199] to 187 percent[198] compared to vaginal delivery (Figure 13), by 310 percent to 430 percent[199] compared to Cesarean section, and by 430 percent compared to nulliparous women.[206] Vacuum delivery was associated with random changes in UI in the majority of the studies (Table 19). One study found that previous pregnancy was a risk factor for severe stress UI in women who reached the age of 50, although the mode of delivery had less effect.[135] Breech delivery was not associated with an increased risk of UI or any UI type.[98]

Few prospective studies reported protective effects of Cesarean section on UI compared to vaginal delivery.[119,197,202,205]

*Oxytocin***.** The prior use of oxytocin significantly increased the odds of UI by 1.9 times in women ≥60 years.[59]

Epidural analgesia. Evidence does not support that epidural analgesia increases the risk of incontinence.[98]

Duration of labor. Several studies have examined labor time and the duration of specific stages of labor. One study found that labor time, duration of second, passive, and active stages, as well as the duration that the fetal head was deeply engaged was not associated with UI.[199]

Another study found that labor beyond 24 hours was not associated with UI.[59] In contrast, a study found that functional delivery disorders increased the odds of having moderate/severe UI.[98]

Episiotomy, lacerations, and perineal suturing. Episiotomy has not been associated with UI, either having had one or several episiotomies.[59,64,196] Perineal rupture and perineal suturing were not significantly associated with UI.[59,64,196]

Gestational age. Relatively few studies have examined gestational age as a risk factor for UI. Studies available do not support an independent association with UI.[59,98,197]

Fetal weight and head circumference. There is inconsistent data on the effect of fetal weight on UI. Two studies found that heavier babies increased the risk of UI.[98,197] In one study, heavier babies (birth weight in the top quartile or ≥4,000 grams increased the odds of becoming incontinent by 10-56 percent,[98] and in another a heavier fetal weight increased the odds of developing stress UI but not urge or mixed UI.[98] However, most studies do not report a significant association between fetal weight and UI.[196,199] Relatively few studies have examined fetal head circumference as a risk factor. Data from three studies indicate that it is not an independent risk factor for UI,[98,199] although one study found it to significantly increase the odds of urge UI by 80 percent.[98]

*Lactation***.** Breast feeding as a risk factor for subsequent UI has been examined in a few studies with conflicting findings.[96,198] Although lactation was associated in bivariate analysis with UI, in multivariate analyses, it was not independently associated with UI.[96] In another study, length of breast-feeding slightly increased the odds of UI by 17 percent.[198]

Menstrual cycle and menopause. Because of the presence of estrogen and progesterone receptors in the lower urinary tract, female UI is assumed to be associated with a woman's hormonal status and the fluctuations in it (Appendix Table. F19).One study 2,158 premenopausal women in Denmark examining the role of hormonal variation found that self-reported UI the day before completing a survey questionnaire was strongly associated with a recent decrease in bleeding duration (OR 2.2, 95 percent CI 1.3; 3.6).[96]

Because of the increased prevalence of UI in the perimenopausal years, menopause has been assumed to be a key risk factor in UI. One study found that perimenopausal status was independently associated with UI, increasing the odds by 127 percent (OR 1.3, 95 percent CI 1.1; 1.5).[93] The large Women's Health in the Lund Area study found an increase in adjusted odds of UI by 144 percent among premenopausal women (OR 1.4, 95 percent CI 1.1; 1.8) and by 1.5 percent in depressed premenopausal women (OR 1.5, 95 percent CI 1.1; 2.0).[191] Studies examining menopause assessed by self report have not found it to be an independent risk factor for stress UI.[70,95] Although menopause was not found to be significantly associated with UI, the number of years past menopause did increase the odds of UI by 15 percent, suggesting the aging process may have a greater role in the development of UI than hormonal status.[90]

Gynecological or abdominal surgery. There is mixed evidence related to prior gynecological surgery as a risk factor (Appendix Table F20). Five[55,83,108,124,138] studies of eight[55,62,72,83,108,124,138,144,191] that examined this association reported significantly higher adjusted rates of total UI among women after hysterectomy. The increase was 160 percent (OR 1.6, 95 percent CI 1.1; 2.1) for UI in the past month,[108] 130 percent for at least monthly UI (OR 1.3, 95 percent CI 1.1; 1.6),[124] 140 percent for daily UI (OR 1.4, 95 percent CI 1.1, 1.6),[55] and 160 percent for severe UI (OR 1.6; 95 percent 1.5; 1.7).[138] In contrast, rates of stress UI were either the same after hysterectomy in four studies[87,108,118,135] or were less in the Women's Health Australia study (OR 0.8, 95percent CI 0.7; 0.9).[68] Women after hysterectomy also had the same prevalence of urge UI in three studies.[70,74,108] Only one European cross-sectional study reported

higher adjusted odds of bothersome urge UI among women after hysterectomy (OR 2.6, 95 percent CI 1.4; 4.4).[87] Depressed women after hysterectomy had UI 1.3 times more often (OR 1.3, 95 percent CI 1.0;1.7).[191] Diabetics after hysterectomy also had increased adjusted rates of weekly UI (OR 2.3, 95 percent CI 1.0; 5.2).[140]

Evidence on the relationship between UI and other gynecological conditions and procedures is conflicting (Appendix Table F21). Women with previous gynecological surgery had stress UI twice as often (OR 2, 95 percent CI 1.1; 3.7).[95] Women with prolapse (OR 4.11, 95 percent CI 2.15; 7.86)[92] and after prolapse surgery had increased odds of UI.[62,68] In another study, pelvic organ prolapse surgery was not significantly associated with UI.[135] Women who had both a hysterectomy and prolapse repair were 1.8 to 2.3 times more likely to have UI compared to women without these surgeries.[68]

Other surgeries on the uterus, excluding hysterectomies, led to conflicting findings, depending on the measurement of UI, when UI was confirmed by objective measures, they did raise the odds of having UI by 2.2 times, but when self report was used as the UI measure, there was no association.[62] In another study of premenopausal women, having had abdominal or gynecological surgery was associated with a 170 percent higher risk when compared to women without this surgery;[96] and in another study involving both premenopausal and postmenopausal women, prior gynecological surgery doubled the odds of having UI.[95]

Pelvic floor muscle contraction strength. Two studies examined the role of pelvic floor muscle contraction or exercises on either the prevalence or incidence of UI. In one cross-sectional study involving 507 women who completed a clinical evaluation, poor ability to contract pelvic floor muscles was strongly associated with UI (adjusted odds ratio of 3.5 for objectively confirmed according to the ICS definition UI and 4.5 for self-reported UI) depending on the definition of UI.[62] In a study of primiparous women, inability to interrupt urine flow doubled the odds of being incontinent.[636]

Other factors. One clinical study found that abnormal findings on a gynecological examination were significantly associated with having UI in women ages 50-74.[62] Vaginal symptoms (dryness, discharge, itching, dyspareunia) in postmenopausal women are significantly associated with any UI and severe UI.[144] In this same study, atrophic vaginitis was significantly associated with any UI but not severe UI. Vaginal colonization with E. coli was not independently associated with any or severe UI.[144]

In a study of 665 primiparous women, perceived discomfort in the lower abdomen increased the odds of UI by 3.6 times.[636] One large survey of middle-aged American women found that fibroids were associated with prevalent UI but not incident UI.[149]

Urological Factors

Childhood voiding dysfunction. There is limited evidence available on the role of childhood voiding dysfunctions as a risk factor for UI in adulthood. Evidence available suggests that childhood nocturnal enuresis is associated with the development of UI in adulthood, particularly urge UI. In one study, the odds of having UI were increased by 2.4 times among premenopausal women.[96] In two other studies, childhood nocturnal enuresis increased the odds of urge UI by 2.7 times.[70,637] but was not associated with stress UI.[70] It was also associated with increasing the risk of severe UI almost 3-fold.(Kuh, 1999, #1578). Childhood daytime incontinence has also shown to be associated with adult urge UI (OR 2.6, 95 percent CI 1.1; 5.9).[637]

Lower urinary tract symptoms. Few epidemiological studies have examined the association of lower urinary tract symptoms (urgency, frequency, nocturia, dysuria, difficulty with bladder emptying) as independent risk factors for either prevalent or incident UI. Findings are inconsistent across studies (Appendix Table F22). Urinary frequency was independently associated with UI in women ≥60 years,[42] whereas it was not associated with UI risk in women ages 20-84 years.[139] Urgency increased the odds of UI by 9.3 times in women ages 60-84 years, but was not found to be associated in those ≥85 years.[42] However, in another study with women ages 20-84 years, urgency did not predict UI risk.[139] Nocturia increased the odds of UI in women ≥85 years but not in those ages 60-84.[42] Stinging or burning urine was significantly associated with UI in three age cohorts (ages 18-23, 45-50, and 70-75 years).[68]

In a study of postpartum women, frequency of urination increased the odds of having UI one year after delivery.[198]

Urinary tract infections. There is inconsistent data on the role of urinary tract infections as a risk factor for UI (Appendix Table 23). Women with urinary tract infections had higher rates of UI in 11 studies[66,72,74,90,92,97,108,116,121,127,144] of 15[66,70,72,74,90,92,96,97,106,108,116,121,127,144,187] that examined the association. Women with recurrent urinary tract infection had the highest increase in UI by 230 percent for weekly UI (OR 2.3, 95 percent CI 1.3; 3.9)[127] and for monthly UI (OR 2.3, 95 percent CI 1.6; 3.1),[108] 220 percent for UI in the past year (OR 2.2, 95 percent CI 1.4; 3.4),[72] and by 470 percent for ever having UI (OR 4.7, 95 percent CI 4.7; 8.9).[116]

Several studies reported that menopausal status can influence the association between urinary tract infections and UI. One study in premenopausal women,[96] one study in postmenopausal women,[106] and one study that included both premenopausal and postmenopausal women did not find a significant increase in odds of UI among women with urinary tract infection.[139] In contrast, one survey in postmenopausal women found that the lifetime number of urinary tract infections (six or more) increased the risk of UI by 1.9 times for any UI and 2.0 times for severe UI.[144] Two studies found urinary tract infection increased the odds of UI by 4.8 times in women who were perimenopausal and by 3.4 in women who were menopausal.[90,152]

Urinary tract infections have been associated with UI type; in one survey two or more urinary tract infections in the past year doubled the odds of having urge UI.[66] In another study, cystitis was significantly associated with stress UI at baseline and 1 year later, increasing the odds of stress UI by 50 to 90 percent.[132]

Postvoid residual bladder volume. One study found that postvoid residual bladder volume was not associated with UI in postmenopausal women.[128]

Bladder or urinary surgery. Several studies have examined whether prior bladder or urinary surgery is a risk factor for UI. Some studies have not found significant associations,[144] whereas another study found that UI surgery doubled the odds of having UI in perimenopausal women.[135]

Medical Conditions

Arthritis and musculoskeletal disorders. Evidence from three studies,[7,86,118] suggested that women with arthritis had higher rates of UI (Figure 14). Two studies found that arthritis was associated with increased odds of UI by 80-88 percent.[7,86] Arthritis was also an independent risk factor for UI type. In a study involving women ages 70-79 years, arthritis was significantly associated with both urge and stress UI.[118]

Joint pain was significantly associated with stress UI in a 1-year followup study, increasing the odds of UI by 40 percent.[132] A history of hip fracture increased the odds of UI by 38 percent.[81] Osteoporosis was associated with UI in one study,[7] but the association can be confound by age.

Diabetes. There is growing evidence to suggest that diabetes mellitus increases the odds of having UI (Appendix Table F24).Two studies[134,149] of three[134,149,186] reported that women with diabetes develop UI more often. Incidence of weekly UI was higher by 147 percent (OR 1.5; 95 percent CI 1.2; 1.9) in women with duration of diabetes more than 10 years.[134] The same Nurses' Health Study cohort showed that incidence of severe UI was increased by 175 percent (OR 1.8, 95 percent CI 1.3, 2.3) and very severe by 126 percent (OR 2.6; 95 percent CI 1.4; 5.0).[134] The Study of Women's Health Across the Nation found 302 percent increase in developing monthly UI in women with diabetes independent on other risk factors (OR 3.0, 95 percent CI 1.1; 8.1).[149]

Prevalence of stress UI was greater in women with diabetes in three studies[95,133,149] of six[66,95,108,133,135,149] that examined the association (Figure 15). Pooled odds ratio of prevalent stress UI was not significant (OR 1.4, 95 percent 0.9; 2.1). The result of meta-analysis was sensitive to one study, The Heart & Estrogen/Progestin Replacement Study Research Group, randomized trial of 2,763 women taking combination hormone therapy to prevent coronary heart disease, that did not find a significant association between diabetes and stress UI.[66] However, the majority of the studies reported a significant increase in adjusted odds of total UI among women with diabetes (Figure 16)[55,66,72,86,93,97,108,116,124,127,128,133,134,138,149,186] Pooled analysis of 16 studies resulted in an odds ratio of 1.4 (95 percent CI 1.2; 1.5) of having prevalent UI in women with diabetes. Four of five studies found a significant increase in adjusted odds of urge UI among women with diabetes (Figure 17).[66,108,118,133,149] Pooled analysis of five studies estimated that diabetic women had urge UI 1.7 times more frequently than nondiabetics (95 percent CI 1.2; 2.2).

Diabetic complications such as macroalbuminuria, retinopathy, and/or peripheral neuropathy significantly increased the odds of having UI in two studies.[128,140] Diabetic neuropathy was associated with an adjusted odds ratio of 2.4 and macroalbuminuria increasing the odds by 3.8.[140] However, in another study, a BMI adjustment decreased the strength of these associations.[128] This same study also found that neither diabetes treatment (diet, pill, or insulin) nor duration of treatment was associated with UI after adjustment for BMI. Blood glucose control as measured by HbA_{1c} was also not associated with UI.[128]Women who have insulin-dependent diabetes were found to have a 3.5 times higher risk of urge UI when compared to women without diabetes.[128]

Stroke. One prospective cohort , the Canadian Study of Health and Aging, found that elderly community dwelling women had higher risk of developing UI after stroke (OR 1.6, 95 percent CI 1.1; 2.2).[207] Prevalence of UI was significantly higher among women after stroke in five[55,86,97,133,186]of six[55,67,86,97,133,186] studies that examined this association (Figure 18) Pooled analysis of six studies estimated an increase by 167 percent of UI in women with history of stroke (OR 1.7 95 percent CI 1.4; 2.1). Severe UI was more prevalent in women with history of stroke in one study (OR 1.9, 95 percent CI 1.4; 2.8).[67] Paraplegia was also associated with UI (OR 1.6, 95 percent CI 1.1; 2.6).[133]

Neurological disorders. There is conflicting evidence on neurological diseases and prevalent UI (Appendix Table F25). Women with any neurological diseases had greater rates of ever having UI (OR 3.8, 95 percent CI 1.7; 8.6).[116] Parkinson's disease was associated with increased odds of having UI in one study (OR 2.3, 95 percent CI 1.1; 4.5)[81] while two other studies[97,133] did not find a significant association.

Pulmonary disorders. Asthma and chronic obstructive pulmonary disease (COPD) have been studied as potential risk factors for UI in several studies with conflicting findings (Appendix Table F26). Although most studies find COPD to predict UI risk,[81,124,133] in a large study involving 29,520 women,[86] COPD was not associated with UI. In a smaller survey involving 1,531 women ≥65 years, COPD increased the odds of UI by 53 percent.[81] In other studies, COPD was associated with the type of UI. In women ages 55-75 years, the odds of having stress UI were increased five-fold, although it was not associated with urge UI risk.[118] Asthma was not associated with UI risk in one study,[86] whereas in another study it increased the odds of stress UI by 50 percent at baseline but was not significantly associated 1 year later.[132] Several studies indicated that frequent or prolonged coughing increases the odds of UI by 33 to 60 percent[114,638]

Comorbidity and poor health. Some studies have examined the role of comorbidity in relation to UI (Appendix Table F26). Elderly community dwelling women with kidney problems (OR 1.7, 95 percent CI 1.2; 2.3) and foot diseases (OR1.4, 95 percent CI 1.0; 1.8) were at risk of developing UI.[186] Women with two or more comorbid diseases had higher adjusted rates of UI (OR 5.9, 95 percent CI 3.7; 9.6).[92] Increased comorbidity index was associated with higher adjusted odds of UI in three studies.[121,124,189]

In studies involving community dwelling females, poor self-rated health increased the odds of having daily UI by 60 percent[55] and was weakly associated with stress UI.[118] In another study, poor health was not associated with stress or urge UI in post-menopausal women; however, it did increase the odds of having mixed UI by 143 percent (OR 1.4, 95 percent CI 1.1; 1.8).[66] In a large survey of women ages 40-55 years, poor health was associated with increased odds of urge UI but not mixed or stress UI.[149] Women with poor or fair health experienced UI 2.6[187] to 2.9[84] times more often.

Cardiovascular disorders. There is limited evidence on the role of cardiovascular disorders such as heart problems and hypertension on UI (Appendix Table F26). Hypertension was strongly associated with UI in two studies,[83,127] whereas two studies did not find a significant association with any UI[639] or with stress UI.[95] In large surveys, heart problems,[639] including congestive heart failure,[55,97] were not associated with UI.

Gastrointestinal diseases and procedures.

Constipation. A limited number of studies have explored the role of constipation as a UI risk factor (Appendix Table F27).[68,144,152] Three studies[68,121,144] reported a significant increase in adjusted odds of UI in women with constipation among six studies that examined this association.[68,74,97,121,144] One study found that constipation increased the odds of having severe UI by 50 percent, whereas it was weakly associated with having any UI.[144] In another study involving different multivariate analyses in three age cohorts (ages 18-23, 45-50, and 70-75 years), constipation nearly tripled the odds of having UI.[68] However, two studies did not find a significant association between constipation and UI; one study in homecare patients[97] and the other with women ages 45 years and over.[143] Bowel straining significantly increased the odds of stress UI at baseline by 150 percent; however, the effect was not present 1 year later.[132] Constipation was not associated with urge UI.[74] Constipation 4-6 weeks after childbirth was independently associated with UI at 1-year postpartum in all women (primiparae and multiparae women combined), and in primiparae alone but not in multiparae women.[119] Women with bowel symptoms had higher adjusted rates of UI in one study[68]with random findings in another.[185] One study[96] of seven reported a significant increase in prevalence of UI after abdominal surgery.[72,96,108,135,144,185]

Other surgical procedures. One study found that varicose veins and hemorrhoids were independently associated with UI at 1-year post-partum in primiparous women by 50 percent.[640] Previous surgery for UI was associated with increased odds of weekly UI (OR 1.4, 95 percent CI 1.2; 1.8)[83] and stress UI (OR 1.3, 95 percent CI 1.3; 4).[135] In one study, urological surgeries were not associated with prevalent UI in women.[72]

Medications

Relatively few studies have investigated the independent effect of medications on prevalent or incident UI (Appendix Table F28).

Incident UI. Only one study reported incident UI in women with diabetes treated with pharmacological agents and found that insulin administration but not oral medications were association with a 350 percent increase in developing of UI (OR 3.5, 95 percent CI 1.6; 7.9).[123]

Diuretics. The evidence on the role of diuretics on UI risk is conflicting. Earlier studies that examined bivariate associations indicated that diuretics were associated with UI in older adults.[641] However, large studies involving multivariate analyses did not find that diuretics including nonthiazide diuretics increased the odds of having UI.[55,86] Diuretics is a strong predictor of UI type, particularly urge UI.[133] One study found that diuretics significantly increased the odds for stress and urge UI in women ages 40-60 years by two to four times.[78]

Estrogen. Several epidemiological studies have examined estrogen therapy as a risk factor for UI (Appendix Table F29).[55,59,105,118,144,191] The risk of UI is elevated among women taking postmenopausal hormones (oral and transdermal estrogen with and without progestin) as compared to those who have never taken them.[153] Women taking transdermal estrogen with and without progestin (RR 1.7, 95 percent CI 1.4; 2.06 and RR 1.5, 95 percent CI 1.2; 1.8, respectively) had a slightly higher risk of UI than those who took the oral forms (RR 1.5, 95 percent CI 1.4; 1.6 and RR 1.3, 95 percent CI 1.2; 1.4). This same study also found there was little risk after cessation of hormones and a decreasing risk of incontinence with increasing time since last hormone use.[105] Ten years after stopping hormone use, the risk was identical in women who had and had not taken hormone therapy. Two studies found that oral hormone replacement therapy increased the odds of having UI by 1.9 times.[55,59] Vaginal estrogen cream use was significantly associated with any UI in women ages 55-75 years, although this same association was not found with severe UI.[144] Systemic hormone replacement therapy is strongly associated with urge and stress UI. In a study of 1,584 women ages 70-79 years, current oral estrogen use increased the odds of urge UI by 70 percent and stress UI by 98 percent, respectively.[118] Hormone use for menstrual disorders was also an independent risk factor for UI.[96] Former use of oral contraceptives increases the odds of UI by 18-20 percent, although current use was not associated.[138]

Psychotropic medications. A few studies have examined whether antidepressants in general or specific types of antidepressants are a risk factor for UI. In a large survey, antidepressant use was associated with increased odds of having UI by 75 percent.[86] In a study involving 6,642 women, the use of selective serotonin reuptake inhibitors (SSRIs) or serotonin norephinephrine reuptake inhibitors (SNRIs) was not associated with UI in multivariate models that included all women, depressed women only, and nondepressed women who reported depressive symptoms.[191] However, in a subanalysis of depressed women on SSRI/SNRIs, there was a significant association between drug use and UI.[191] Tranquilizers have been shown to increase the risk of UI by 65 percent.[86] The contribution of psychotropic medications, independent from

baseline disease on UI, has not been examined in prospective observational studies. The results from RCTs showed that serotonin-noradrenaline reuptake inhibitor, duloxetine improved stress UI,[642] suggesting that depression rather than the antidepressant could be considered as a risk factor for UI.

Other medications. In a large survey of 29,520 women, pain, narcotics, asthma, hypertensive, and heart medications were not associated with an increased risk of UI.[86] In this same survey, antibiotics were significantly associated with UI, increasing the odds by 64 percent, laxatives by 67 percent, and hypnotics by 52 percent. However, another study did not find an association between sleeping medications and UI risk.[106] Polypharmacy (e.g., three drugs or more) was not associated with UI risk in women ages 70 years and over.[106]

Summary. Limited evidence, Level IIA from prospective cohort studies suggested that increased BMI, diabetes, comorbidities, cognitive decline, and hormone therapy were associated with developing UI in community dwelling females. Prevalence of UI was higher in aging and depressed women, after stroke, vaginal trauma, and in women with physical dependency. The strength of the association depends on definitions of UI by time, type, and severity. Differences in assessment of associated factors may also contribute to the effects on UI. Hormone status of women modified the effects of other associated factors. Comparisons across the studies were difficult to make due to methodological heterogeneity in adjustment and statistical models.

Risk Factors for UI in Community Dwelling Men

The prevalence of UI in elderly males with different risk factors was examined in one population based survey (Appendix Table F30).[607] Men with arthritis had the highest prevalence of mixed (51 percent), urge (43 percent), and stress UI (46 percent) compared to other internal diseases. Mixed UI was reported in 29-39 percent of males with hearing and vision problems; 35 percent reported urge UI. Diabetics experienced stress UI more often than men with other diseases (36 percent). Urge UI was prevalent in men with pulmonary diseases (27 percent). The prevalence of UI was 36 percent in men who used diuretics, 38 percent in men treated for prostate problems, and 60 percent in those taking antispasmodic agents [181] After prostate surgery (47 percent) and bladder surgery (58 percent of men) had a higher prevalence of UI.[181] However, one European survey of 840 men reported lower compared to other studies prevalence of UI after transvesical prostatectomy for benign prostatic hyperplasia.[643]

The prevalence of UI in men with prostate cancer varied from less than 1 percent[173] to 30 percent[180] and 44 percent[181] being lower than 10 percent in the majority of the studies[167-174] (Appendix Table F31). The rates of UI in men treated for prostate cancer varied substantially depending on the treatment use, time of followup, population characteristics, and definitions of UI (Appendix Table F32). The largest case series reported that 8 percent of men experienced UI after radical prostatectomy (Appendix Table F33).[644] A retrospective analysis of a national random sample of 12,079 Medicare beneficiaries showed that the incontinence rate after radical prostatectomy decreased from 20 percent in 1991 to 4 percent in 1995, being the highest in older patients.[175] One prospective population-based cohort, the Prostate Cancer Outcomes Study, found differences in the rates of occasional and frequent UI after radical prostatectomy.[172] The rates of UI after radiation therapy differed across the published case series. The largest (1,192 males followed for 52 months after external beam radiotherapy) reported 5 percent with Grade 1 UI using the modified Radiation Therapy Oncology Group/Subjective, Objective, Management,

and Analytic scale (Grade I - Occasional [less frequent than weekly] use of incontinence pads).[170]

Associations between UI and risk factors were reported in several studies (Table 20).[72,74,81,83,84,86,92,97,170,174,175,180-182,644] Age was an independent risk factor for UI in two studies.[58,97] One study reported crude significant association,[81] not confirmed in the largest retrospective cohort study of Medicare beneficiaries.[175] Limited evidence suggested that age was significantly associated with urge UI (OR 5.34, 95 percent CI 2.26; 12.62) among those older than 70 years compared to younger men,[74] with random association with stress UI.[645] Non-White men had the same rates of UI compared to Whites.[175] Marital status[84] and education in men[72,83,92] were not associated with lower odds of UI. Two studies showed that a sedentary lifestyle was associated with UI in males.[83,92]

Alcohol intake (Figure 19)[72,83,84,92] did not show an association with male UI. Only one study of 748 men 61-70 years old showed that 15-21 alcoholic drinks weekly were associated with lower adjusted odds of urine loss during the last year).[72] Three studies examined crude and adjusted odds of UI among smokers and none found a significant association (Figure 20).[72,83,92]

BMI in relation to UI was examined in two studies with univariate[79,92] and three studies with multivariate[72,83,84] analysis (Figure 21). Only one study of 232 males reported an increase in adjusted odds of total UI by 320 percent among obese males.[84] Males with diabetes had significantly higher adjusted rates of UI in two[97,176] studies of five[58,72,86,97,176] with pooled odds ratio of 1.4 (95 percent CI 1.1;1.6) (Figure 22).

Comorbidities and poor general health were associated with UI in several studies (Table 21).[81,84,92,97] The presence of FI was associated with an increased odds of urge UI in one study of 2,198 males (OR 17, 95 percent CI 7.5; 40)[176] but with random changes in another.[106] Males with arthritis had higher adjusted odds of total[86] (OR1.6, 95 percent CI 1.1; 2.4) or urge UI (OR 1.8, 95 percent CI 1.4; 2.4).[176]

Dementia was associated with an increase adjusted odds of UI in nursing home male residents[4] but not in community dwelling older men in Japan.[58] The National Population Health Survey in Canada reported that use of narcotics, laxatives, and diuretics were associated with greater odds of UI independent of other risk factors.[86] Memory problems, epilepsy, and neurological diseases were associated with higher rates of UI (Figure 23).[4,58,72,86,97,176-178] Stroke was shown as a strong and independent risk factor for UI (Figure 24) in nursing home residents[4] and in community dwelling males[58,86,97,176,177] with a pooled odds ratio of 2.12 (95 percent CI 1.36; 3.29). Restrictions in activities of daily living were associated with higher crude and adjusted odds of UI in males in all studies that examined the relationship (Figure 25).[4,81,92,97,106,114]

Males with urinary tract infections had higher adjusted rates of UI (Figure 26) with a pooled odds ratio of 3.5 (95 percent CI 2.3; 5.2).[72,74,92,97,106] Acute genitourinary toxicity, enuresis, incomplete urination, and other urological conditions were associated with higher adjusted odds of UI in all studies that examined the relationship (Figure 27).[72,170,174,179]

Men with prostate diseases had higher rates of UI after adjustment for confounding factors in the majority of the studies (Figure 28).[72,83,92,170,176,180-183] Prostate cancer (RR 2 95 percent, CI 1.5; 2.8), radical prostatectomy (RR 4.3, 95 percent CI 2.6; 7.3), and radiotherapy for prostate cancer (RR 2.3, 95 percent CI 1.3; 4.1) were associated with increased adjusted relative risk of UI.[180]

Summary. Consistent published evidence, Level IIb-III suggested that poor general health, limitation in daily activities, stroke, diabetes, and treatments for prostate cancer were associated with higher risk of UI in men.

Association between Stroke and UI in Community Dwelling Adults

Acute stroke was associated with a 280-520 percent higher prevalence of UI compared to age-matched adults without stroke.[177] The prevalence of UI among patients with acute stroke varied from 7 percent[646] to more than 30 percent[220,647-649] (Table 22).The prevalence varied depending on definitions of UI from 11 percent for partial to 36 percent for complete UI.[220] One study reported the incidence of UI in patients with stroke as 2 percent for women and 4 percent for men.[650] The prevalence decreased with the time of followup after an acute stroke (11 to 36 percent) to 8 to 11 percent at 6 months.[220] Elderly patients experienced UI more often, from 35 percent in younger patients to 57 percent among those older than 80 years (Table 23).[647] The adjusted odds of UI remained higher 4 years after stroke.[177] Age was associated with increased risk of UI among patients with stroke by 72 percent per 10 years.[220] The results, however, were not consistent across the studies, with 16 times greater odds of UI after 75 years of age in one study[651] but an association in the opposite direction in another.[652] Functional impairment after stroke including dysphasia, dysphagia, visual field defect, motor weakness, and cognitive impairment was associated with significant increase in UI.[177,651-653]

Risk Factors for UI in LTC Settings

Association between risk factors and UI in LTC settings. The prevalence of UI increased with the length of stay in nursing homes from 39 percent at 2 weeks to 44 percent at 1 year after admission.[28] It is not clear if this is an effect of prolonged exposure or a difference in case mix (Table 24). The majority of residents with cognitive impairment experienced UI (72 to 84 percent).[1] The proportion of incontinent patients increased responding to severity of impairment, from 60 percent in mild to 93 percent in severely demented.[34] Physical dependency was associated with a higher prevalence of UI, from 26 percent in independent residents to 81 percent immobile.[34] The prevalence of UI among dependent residents was more than 70 percent in seven countries and varied from 87 percent in Iceland to 72 percent in the United States.[1] The prevalence of UI among residents with diabetes ranged from 55 percent[29] to 65 percent.[34] Almost all (93 percent) residents with FI also experienced UI.[29] One study of 9,013 patients with multiple sclerosis reported 21 percent UI and 9 percent of frequent UI.[654] The estimations were not consistent; however, the prevalence of UI among patients with urinary tract infection in Italy was 63 percent in one study[1] and 81 percent in another.[29] Few studies examined adjusted odds ratios of UI among residents in LTC independent of other confounding factors. Aging was associated with increased odds of UI by 3 percent per year to 24 percent per 5 years of age (Table 25).[4,165] In contrast with higher incidence of UI in males,[166] prevalence of UI was lower in males than females in two studies[29,165] of three [29 ,165,655] that examined this association. Race, BMI, diabetes, arthritis, and cardiovascular diseases did not show significant association with UI, but the evidence was limited to one state survey of nursing homes.[4,165]

Stroke increased the adjusted odds of UI by 20 to 40 percent.[4,165] Physical dependency was a strong and independent risk factor for UI in several studies (Table 26).[4,29,164,165] Impairment of ADLs was associated with three to four times larger odds of UI.[4,164] Residents with dependency

in toilet use experienced UI six times more often.[165] The odds of UI were seven times higher among wheelchair users and bedridden residents.[29] Mental impairment was associated with 192 to 361 percent higher prevalence of UI.[29]

FI was associated with ten[29] to 20[165] times larger odds of UI. The conditions that assume intensive bowel control and frequent checking of wet condition of residents, including tube feeding and diarrhea, were associated with lower UI. In conclusion, consistent evidence suggests that restrictions in ADL, physical dependency, and cognitive impairment are risk factors for UI in LTC. Factors that induce UI also seem to affect FI.

Overview of Risk Factors for FI

Age. In the past decade, a large body of evidence has suggested an association between FI and patient age . Age was a strong predictor of FI and combined UI and FI in the majority of the studies (79 percent or 22/28) (Table 27). The association between age and FI was examined among women only.[187,208-213] Adjusted odds of AI increased by 87 percent for every additional 10 years of age in Asian women and by 36 percent in White women.[187] The frequent comorbidity of FI and UI may be attributable to the common cause of both disorders, such as pelvic floor sphincter injuries.[4,58,162,186] Women over age 42 reported combined UI and FI 16 times more often than younger females after adjustment for other risk factors.[186] Japanese adults over age 75 had 319 percent higher odds of combined UI and FI compared to those 65-74 years old.[58] The association between age and FI was not linear.[657] However, one study reported a 30 percent increase in the adjusted odds of FI corresponding to a 10 year increment in age in women.[225] The threshold age for women was related to menopausal age; no significant increase in FI was shown when women older than 30 or 35 years were compared to women younger than 29 years of age.[230] The results became significant when 30-49 year old women were compared to those 50-69 years old (211 percent increase in FI) or those 70-90 years old (222 percent increase in FI).[163] No studies reported adjusted odds ratios of FI in men, with an inconsistent increase in the crude odds of FI after 35,[658] 44,[659] or 65 years of age.[221] Studies with women and men analyzed together reported a 2 percent increase in FI in adults older than 40 years[222] and a 271 percent increase in FI after age 75[58] after adjustment for other risk factors.

Age not only increases the risk of FI, it likely modifies the effects of other risk factors, including birth related anal trauma. Maternal age older than 25 years was associated with greater odds of FI[214] and persistent FI.[215] Women 20-24 years old at the time of delivery did not experience a larger risk of FI compared to younger pregnant women.[218] Less expected was the fact that pregnant women below age 20 experienced FI more often than women over 30.[218]

The interaction between age and other risk factors requires future research. Pooled analysis indicated that studies with older adults reported higher crude rates of FI, but the estimation had low validity due to significant statistical heterogeneity between studies.[518]Age, but not study quality, contributed to differences in rates of FI.[518] The authors used different age categories which made pooling more questionable. Pooled analysis of patients' individual data should give better information of the curve-linear association and meaningful cut-points for men and women independent of other risk factors.

Gender. This line of research shows mixed results (Table 28). Traditionally, FI is believed to be more prevalent in women.[6,622] Two recent studies confirmed this finding by reporting a greater prevalence of FI in women.[7,508] One study reported greater prevalence of combined incontinence (FI + UI) in community-living elderly women than men.[660] However, three different groups of researchers found no differences in the prevalence of FI in women and men.[4,216,217] Four other studies showed that male gender is an independent risk factor for FI[3,58,222,224] and combined incontinence.[58] One study indicated that men ages 75-79 or 85-89 are more likely to have FI, combined incontinence, and less severe FI than women in the same group.[114] The majority of these studies involved a large sample (more than 4,000) elderly people (>65 years) and adjusted for at least one risk factor. However, a definite association between gender and FI cannot be drawn given varying study designs, sampling and statistical methods, FI definitions, and varying control for potential risk factors. Valid synthesis of different studies

would be possible when relative risk of incident incontinence, adjusted for age and gender-specific confounding factors, was examined in prospective cohorts.

Race. Limited evidence from one study suggested that Asian women had a higher prevalence of birth related FI compared to other ethnic groups after adjustment for mode of delivery, maternal age, perineal trauma, BMI, and total number of births (Appendix Table F34).[215] The prevalence of combined UI and FI was two times higher in non-White than White residents of nursing homes in Wisconsin, independent of other risk factors identified in the Health Care Financing Administration Minimum Data Set.[4] Younger Taiwanese women living in the community (mean age of 43 years) had a prevalence of FI of 2.5 percent,[213] a rate similar or less than that reported in non-Asian women of a similar age group.[218,232] The association between race and severity of FI and quality of life related to FI in men and women from the community and in LTC facilities requires future investigation.

Diet, BMI, and diabetes. The highest prevalence of FI (44 percent) was reported among women with morbid obesity undergoing laparoscopic weight loss surgery (Appendix Table F35). The prevalence of FI among patients with diabetes mellitus varied from 1 percent in women[163,211] to 13 percent in a study of both genders;[626] 3 percent of men and women with diabetes experienced incontinence of solid feces and 13 percent solid or liquid feces.[626]

Adults with decreased serum levels of vitamin B12 (300pg/ml or less) had a significantly higher prevalence of combined UI and FI (Table 29).[661] No other dietary intakes have been shown to increase the risk of FI. Increased BMI and the presence of diabetes in residents of nursing homes were not associated with higher rates of combined UI and FI.[3,4] Higher BMI in women did not increase the risk of FI[208,210-213] but was associated with higher prevalence of flatus[662] and liquid feces incontinence.[185] One study of 8,774 women reported a 70 percent increase in risk of persistent postnatal FI in obese women (Appendix Table F36).[218]

Inconsistent evidence suggested that men and women with diabetes had FI more frequently than nondiabetics with rates higher by 70 percent[216] to 300 percent[58] in older adults and by 207 percent in younger adults[217] after adjustment for other risk factors.

Physical activity. Physically active adults had a 70 percent lower risk of fecal urgency after adjustment for other risk factors (Appendix Table F37).[125] Distance runners had a FI prevalence of 12 percent in one study with no formal control comparison.[663] The association between physical activity and incidence of FI and quality of life related to FI in adults in community and LTC requires future investigation.

Smoking and pulmonary diseases. The association between smoking and FI is inconsistent in direction and effect size (Table 30).[125,185,186,208,218,226,227] White women with obstructive pulmonary diseases had a 208 percent higher rate of FI after adjustment for possible confounding factors.[187] Women with chronic bronchitis had liquid incontinence 3.5 times more often in a bivariate analysis.[185] Older men and women with protracted coughing experienced increased risk of combined UI and FI by 65 percent.[114]

Muscle-skeletal disorders. The crude prevalence of FI was 71 percent higher among older men with arthritis with attenuation of the association in multivariate analysis (Table 31).[186] Foot and ankle problems in elderly adults were associated with a two-fold increase in prevalence but not incidence of FI.[186] Arthritis in older men and women increased the risk of liquid FI by 80 percent in bivariate analysis of 1,352 adults over 75 years old.[158]

Neoplasm. Older patients with rectal cancer had the highest prevalence of FI (55 percent),[664] but other studies showed lower prevalence of FI among patients with rectal cancer[665,666]

(Appendix Table F38). Patients after proctocolectomy with J-pouch anastomosis reported 25 percent prevalence of FI with lower rates after W-pouch anastomosis.[667]

Comorbidities. High rates of medical comorbidities in women were associated with a 2.6 times higher adjusted risk of FI (Table 32).[163] Incremental increases in the Charlson Comorbidity Scale scores in women were associated with 76 percent higher adjusted odds of FI.[219] The presence of kidney diseases in older adults was associated with a significant risk of incident FI by 48 percent in women and 94 percent in men.[186] Men suffering from transient ischemic attack had a three times higher prevalence of FI.[219] Women with arterial hypertension reported FI 2.4 times more often compared to normotensive females after adjustment for other risk factors.[213] Heart disease in nursing home residents did not increase the risk of FI.[3,4]

Stroke and other neurological disorders. The prevalence of FI was 30 percent[221] to 34 percent[220] after acute stroke (Appendix Table F39). The absolute risk of FI was less than 10 percent several months after stroke in most studies.[220-222,668] Stroke was associated with a significant increase in adjusted odds of FI in the majority of the studies (Table 33). Combined UI and FI was five times more frequent in community dwelling adults after stoke[58] but not in residents of nursing homes.[4] Incident FI occurred twice as frequently in women but not in men after a stroke.[186] Adjusted prevalence of FI was three[216] to five[58] times higher in stroke survivors compared to adults without a stroke. Incremental 10-year increase in age at the time of a stroke was associated with a 45 percent higher probability of FI 6 months after the stroke.[220] Diabetics experienced FI 2.2 times more often after stroke compared to non diabetics after adjustment for confounding factors.[220] Severity of stroke was positively associated with FI.[220,221] Functional dependency and need for assistance with toilet access 3 months after stroke in men and women was associated with a 349 percent increase in FI. Residents of nursing homes after stroke suffered from FI 1.2-1.3 times more often.[4] Adjustment for other risk factors of FI attenuated the strength of association, but a higher odds ratio was still highly significant (4.9, 95 percent CI 14; 16).[58]

Several studies examined the prevalence of FI in patients with neurological diseases (Appendix Table F40). The prevalence of FI was 10 percent in men and 5 percent in women with Parkinson's Disease.[669] Two studies of patients with multiple sclerosis reported that 21 percent[524] to 51 percent[670] experienced FI. Among patients with spinal cord injury, subjects with tetraplegia had the highest prevalence of FI (14 percent)[671] compared to 4 percent in cases with paraplegia, and 2 percent in patients with incomplete injury.[671]

Functional impairments and dependency status in association to FI in residents of nursing homes were examined in one study using Wisconsin annual nursing home surveys (Table 34).[3,4] Tube feeding was associated with an 8-9 percent increase in the odds of FI,[3] dependence in daily activities with 6-7.3 higher odds of FI, and dependency in eating with four times higher odds of FI after adjustment for all risk factors in the model.[3] Nursing home institutionalization was examined in one study of 430 residents.[166] Increased length of stay from 2 weeks to 1 year was associated with a seven times higher prevalence of FI.[166] Residents with pressure ulcers experienced FI 2.3 to 2.6 times more often; this increase was independent of other FI risk factors. (Appendix Table F41)[3]

Functional status and mental health in association with FI in community dwelling adults. Poor general health and dementia increased the risk of combined UI and FI in adults after adjustment for confounding factors (Table 35).[58] Crude rates of combined incontinence were significantly higher in older adults with memory problems, edema in legs, and slow healing wounds.[114] The odds ratios of FI were significantly higher by 188 percent in women and by 218

percent in men with poor general health,[219] by 400 percent in adults with functional limitations,[222] and by 80 percent in adults with decreased mobility and severe/mild physical activity impairment.[223] Major depression in women was associated with 273 percent higher rates of FI independent of other risk factors.[163] Geriatric depression in men was associated with a 283 percent higher risk of FI.[219] Adults with dementia had FI twice as often in two studies after adjustment for other risk factors of FI.[223,224] Impaired cognitive status in men was associated with a five-fold increase in the adjusted odds ratio of FI.[186] Older men and women with Mini-Mental State Examination (MMSE) score <15 had a 250 percent increase in the adjusted rates of FI.[223]

Chronic gastrointestinal conditions. Constipation, chronic diarrhea, and fecal impaction increased the adjusted relative odds of FI, but not combined incontinence, in residents of nursing homes (Appendix Table F42).[3,4] Constipation increased the risk of FI by 209-211 percent in women (Table 36).[187,212] Women with irritable bowel syndrome experienced FI 2.7 to 6.3 times more often after adjustment for other risk factors.[187,211,212] Crude rates of combined incontinence were significantly higher in men and women with chronic gastrointestinal disorders.[114] The adjusted rates of FI were 240 percent[225] to 450 percent[219] higher in women with diarrhea, 190 percent higher in irritable bowel syndrome patients, 250 percent higher in females with anal fistula, and 140 percent higher after cholecystectomy.[225] Adults with incomplete bowel evacuation had four times higher odds of FI.[217] Frequent diarrhea and water stools were associated with higher rates of liquid FI (Appendix Table F43).[224] One study reported increased crude rates of severe FI in association with chronic gastrointestinal problems in adults.[158]

Surgical procedures. The majority of women (97 percent) after surgery for rectal prolapse experienced FI (Appendix Table F44).[672] Hemorrhoid surgery in women was associated with a 270 percent increase in the odds of FI.[211] Patients with inflammatory bowel disease after ileal pouch-anal anastomosis and pouchitis had a 43 percent prevalence of occasional and 11 percent of frequent FI.[673] Perianal surgery of the skin outside of the anal canal was associated with a five times higher adjusted odds ratio of FI.[217] The odds of FI were not significantly different among women after anorectal surgery after adjustment for parity and delivery.[225] Isolated flatus incontinence at least once a week occurred 1.5 times more often after previous lower abdominal or urological surgery.[227] The association was not consistent across different surgeries and studies. Gynecological surgery increased the adjusted odds ratio of AI by 180 percent (Appendix Table F45).[213]

Drug administration. Crude rates of combined UI and FI were higher after diuretic and laxative use (Appendix Table F46).[661] One large study of 6,099 adults over 65 years old reported a significant increase in the adjusted odds of FI after anticonvulsants, antidepressants, anti Parkinson medications, antipsychotic, narcotics, and hypnotics.[216] Hormone replacement therapy in morbidly obese women before laparoscopic weight loss surgery[208] and contraceptive use[225] did not show a significant association with FI.

Prostate diseases. The prevalence of FI was less than 10 percent in all studies among men with prostate diseases (Appendix Table F47).[180,674,675] Prostate diseases, including prostate cancer, were associated with an increased adjusted odds ratio of FI (Table 37).[180,219] Both baseline prostate diseases and treatments have been associated with an increased risk of FI. Baseline FI before perineal prostatectomy for localized prostate cancer was associated with 600 percent higher adjusted rates of FI and 400 percent higher rates of severe FI after surgery.[676] Patients with positive surgical margins experienced severe FI seven times more often after surgery.[676] Radical prostatectomy was associated with a significant increase in the adjusted odds

ratio of FI by 530 percent compared to healthy controls.[180] External beam radiation was associated with higher rates of bowel symptoms than radical prostatectomy independent of other confounding factors.[677,678]

Anal trauma. Consistent evidence suggests that anal trauma was associated with significant risk of FI independent of other risk factors (Table 38). The adjusted odds of FI were 4.4 times higher in women with anal sphincter tear.[232] Women with anal injury not related to childbirth had 240 percent increases in FI.[225] The adjusted odds ratio of bothersome FI was 16 times higher in women with anal sphincter defect.[679] A combination of anal injury and pelvic organ prolapse increased the odds of bothersome FI by seven times. Women with anal injury, pelvic organ prolapse, and UI had an adjusted odds ratio of 55 to experience bothersome FI.[679] Perianal injury increased risk of FI by 262 percent in men and women in one study.[217] The independent contribution of anal injuries in males and females by age and race categories requires future investigation. Abortions were not associated with FI in one study (Appendix Table F48).[227] Menopause did not increase the adjusted odds of FI[210,213] but was associated with a higher prevalence of FI in another study[226] (Appendix Table F49).

FI in association with UI. The prevalence of FI was 25 percent[210] to 28 percent[680] in women with stress UI and 41 percent in women with overactive bladder.[210] UI was associated with 11-12 times higher odds of FI in residents of nursing homes in one study (Appendix Table F50).[3] Several studies reported an increase in the crude odds of FI in patients with UI[187,208,210-213,681] but only one study[211] found a significant (1.9 times) increase in the adjusted odds ratio of FI in 881 women with UI (Table 39). Urinary symptoms other than UI in men and women were associated with a significant increase in crude odds of combined UI and FI in one study.[114] UI in men and women was associated with 2.9[223] to eight times greater odds of FI.[222] The adjusted odds of FI in women with UI were two to six times higher compared to continent females.[162,163,219,226] The presence of stage II pelvic organ prolapse and/or urinary incontinence compared to stage 0 or I pelvic organ prolapse and no UI increased the adjusted odds of bothersome FI by 4.9 times.[679]

Prolapse. Most studies reported a prevalence of FI of more than 10 percent in women with genital prolapse (Appendix Table F51). The adjusted odds of FI were 1.9 times in patients with rectal prolapse[211] and 3.2[213] to five times in women with utero-vaginal prolapse (Appendix Table F52). One study reported a significant increase in the crude odds of flatus, liquid, and solid FI in women with genital prolapse.[185] More than a third of men and women with rectal prolapse reported FI.[682] Burch colposuspension was associated with greater adjusted odds of flatus and liquid FI compared to healthy controls 14 years after surgery.[683] Women after Burch colposuspension also experienced more severe flatus and liquid incontinence with greater impact on their quality of life (Appendix Table F53).[683]

FI related to pregnancy and birth. Consistent evidence suggested a significant dose response increase in the absolute risk of FI after vaginal trauma. The prevalence of FI was 7 percent at 3 months and 5 percent at 12 months postpartum (Appendix Table F54).[684] Women with sphincter tears experienced higher rates of FI, from 15 percent among nullipara to 30 percent after more than two deliveries.[685] The highest prevalence (40 percent) was reported in nullipara with fourth degree sphincter tear after index delivery.[686] Less than 1 percent of women experienced FI after vacuum delivery.[211] The prevalence was 2 percent[211] to 5 percent[687] after forceps delivery and 13 percent[211] after episiotomy or vaginal delivery.[210] The prevalence of combined UI and FI was 6 percent at 10 months[688] and 2 percent at 24 months postpartum.[684] Pregnant women[657] and women after episiotomy[628] reported 13 percent FI. The prevalence of FI was lower by 1 percent in nulliparous and 3 percent after spontaneous vaginal delivery.[163] The

prevalence of FI was lowest (0.3 percent) after Cesarean sections.[163] The prevalence of flatus was 4 percent in pregnant women with one previous delivery,[227] 6 percent at 3 months after delivery,[684] 8 percent after instrumental delivery,[689] and 25 percent after previous multiple pregnancies[689] and among multiparous women.[658] One small study reported the highest prevalence of flatus 30 years postpartum in women with anal disruption (59 to 76 percent) and episiotomy (70 percent).[690] The prevalence of liquid incontinence was less than 6 percent[227,658] and solid incontinence less than 5 percent[227,658,684,688] in pregnant women and after different modes of delivery. Women with obstetric sphincter tears experienced higher rates of incident FI and severe FI (Appendix Table F55). More than 5 percent of women with complete third-degree tears after the first pregnancy and more than two deliveries after that experienced severe FI.[685] Almost 7 percent of women 12 months after instrumental delivery and/or a high birth weight infant reported solid and liquid FI.[658] Complete FI with liquid and solid incontinence was reported by 12 percent of women 13 years after an obstetrical anal sphincter tear.[691] More than 2 percent of young women 3 months postpartum complained about weekly solid or liquid incontinence.[228]

The relative effects of different risk factors were less consistent across the studies and depended on the definitions of FI and adjustment for confounding factors (Table 40). The adjusted odds of FI were significantly increased after delivery of heavy babies,[202] among women with narrow subpubic arch angle,[692] and with FI during pregnancy,[209] after increased number of births,[215,226] and a high degree of perineal injury.[187,209,228-231] No independent significant risk factors were reported for solid FI.[185,693,694] Caesarean section was associated with a reduced risk of frequent FI[214] in contrast with forceps delivery followed by frequent and persistent FI[214,215,218] (Table 41). The number of births[215] and anal injury[218,227] were associated with higher adjusted odds of severe FI.

Fetal characteristics were examined in association to FI in 11 studies (Appendix Table F56).[202,205,218,226-228,232,662,689,692,695] Fetal weight was associated with random changes in AI[205,228,232,692] and FI,[662,689] but with a significant increase in the adjusted odds of FI by 240 percent in one study of 3,887 women.[202] Head circumference of the baby did not show a significant relationship with FI[205,692] or fecal urgency.[205]

Women with FI during pregnancy experienced higher rates of FI after delivery (Table 42).[209,662] Women with narrow subpubic arch angle experienced FI almost nine times more often independent of other risk factors.[692] The number of births associated with FI was examined in 18 studies,[163,185,186,208,212,218,227,229,230,657,658,695,696] but only five found a significant increase in odds of FI independent on other risk factors.[209,213,215,226,232] Women giving birth had FI three times more often compared to childless females.[232] Four studies reported dose response associations between FI and the number of births.[209,213,215,226] Adjusted odds of persistent FI were 3.2 times greater among women after four or more deliveries.[215]

The association between FI and delivery management was examined in several studies (Appendix Table F57). Mediolateral episiotomy after the first pregnancy was associated with lower odds by 83 percent of FI in one study[229] of seven.[202,227-229,695,697] Prolonged pushing time was associated with 22 percent higher odds of solid FI.[218] Cesarean surgery was shown to reduce the risk of FI by 42 percent and frequent FI by 64 percent in one study[214] of 14.[163,185,202,205,208,214,215,218,225,226,228,692,695,698] Forceps delivery was associated with increased adjusted odds of FI in one multicenter study[215] with random results in others.[202,214,215,218,226-228,692,699-701] An inconsistent increase in FI was shown after instrumental delivery in one study.[230] The operative delivery in women with stage II pelvic organ prolapse and/or UI was associated with a 4.5 times greater

adjusted odds of bothersome FI.[679] Vacuum extraction did not show a significant association with postpartum FI.[214,215,218,227,694,701] Vaginal delivery was not shown as a significant risk factor for FI.[7,163,185,210,212,213,225,229,231,695]

Birth related perianal trauma was associated with a large increase in adjusted rates of FI in eight of 24 studies (Table 43)[187,209,218,228-232] Women with sphincter tears had 230 percent[209] to 280 percent[231,232] higher rates of FI. The degree of perineal damage showed dose response association with FI.[229,230] Women with stage IV perineal damage experienced FI more often compared to damage of grades I-II.[228,229] Full thickness of the internal anal sphincter defect was associated with 510 percent higher rates of FI after adjustment for other risk factors.[230]

Summary. In conclusion, aging and dependency in daily activities were strongly associated with the development of FI in LTC facilities. Neurological disorders, perineal trauma, and rectal diseases, including neoplasm, are among the independent risk factors of FI in community dwelling adults. Women are at risk of FI related to pregnancy and birth. The strength of the association varied depending on the definitions of FI. Primary prevention of diseases associated with increased risk of FI could reduce the incidence and severity of incontinence in adults. Strategies to reduce the risk of FI related to pregnancy and birth are not well documented and require future research.

Question 3. What is the Evidence to Support Specific Clinical Interventions to Reduce the Risk of UI and FI?

Baseline mechanisms of incontinence include abnormal detrusor and sphincter functions. Detrusor muscle contraction is regulated by a complex pathway of cholinergic innervations by the pelvic nerves, prostaglandins, and calcium ions.[22,23] A hyperactive bladder would lead to urge UI. Urethral sphincter function is regulated by alpha-adrenergic activity and an anatomically correct position of the urethra in the abdominal cavity to transfer increased abdominal pressure to urethra. Poor urethral sphincter function can result in primary urethral incompetence and stress UI. Effective clinical interventions aim to improve control over bladder contractions, increase strengths of pelvic floor muscles supporting bladder, correct anatomic disposition of dispositional uterus in women, decrease atrophy of tissues and muscles related to estrogen deficiency, and treat injuries due to childbirth.

Effects of Clinical Interventions on UI in Adults in LTC Settings

Implementation of evidence-based guidelines. The implementation of guidance-driven continence care in nursing homes[238,708] did not improve the incontinence status of the residents (Appendix Table F58). The protocol included staff education and direct patient care implemented by advanced practice gerontological nurses in a consecutive cohort of newly admitted residents in three licensed proprietary nursing homes. A quasi-experimental study[708] evaluated UI using the Incontinence Monitoring Schedule with frequent observations for 3 days before and after the continence protocol was implemented (Appendix Table F58). The implementation resulted in a nonsignificant tendency to reduce the proportion of incontinence episodes and total prevalence of UI from 71 percent in patients after regular care to 64 percent in the intervention group (Appendix Table F59).[708] A multicenter uncontrolled intervention of a computerized quality management model in nursing homes, based on guidelines for medical assessment and individualized prompted voiding protocols of UI, was associated with a nonsignificant reduction in wet episodes among total checks by nurses from 31 to 17 percent.[238]

Conservative management programs. Conservative management programs in nursing homes[709,710] resulted in inconsistent improvement in UI in female residents (Appendix Table F60). Behavioral therapy included hourly wet checks, prompted and assisted toileting, positive reinforcement, and bladder training implemented by trained nursing research assistants. Nursing research assistants reported an improvement in UI in females after active intervention three times more often compared to usual care (26 percent vs. 8 percent, RR 3.1, 95 percent CI 1.3; 7.4) (Appendix Table F61)[710] However, the changes in urinary wet episodes were not statistically significant (Appendix Table F62).[709] Conservative management programs reduced the progression of UI in the majority of RCTs that included male and female residents of nursing homes (Appendix Table F63).[233-237] The effect size was small and differed depending on the definition of the outcomes. Integrated incontinence care that included fluid prompting, prompted toileting, and regular wet checks in combination with exercises reduced the frequency of UI by 1.6 percent (95 percent CI -2.5;-0.8) compared to regular care (Appendix Table F64).[235] Prompted voiding treatment increased the proportion of appropriate toileting to 60 percent compared to 17 percent after regular care (mean difference 1.7 percent, 95 percent CI 1.3; 2.2.[233] Individualized habit training for UI with verbal encouragement administered by nursing staff[237] significantly decreased the frequency of incontinence episodes by 19 percent in elderly residents

without neurological diseases but not in memory-impaired residents.[236] Individualized prompted voiding and intensive endurance and pelvic floor muscle training significantly reduced the proportion of wet checks by nurses among total checks to 25 percent compared to 50 percent after usual care.[234] One RCT[239] examined the effects of rehabilitation based on the Functional Independence Measure scale on risk of UI in 34 patients with acute hemispheric stroke (Appendix Table F65). The number cured at discharge was four times larger after active rehabilitation compared to a conventional rehabilitation program (RR 4.1, 95 percent CI 1.5; 11.2) (Appendix Table F66).

One RCT of 32 women examined the effects of oral estrogen (0.63 mg) combined with progesterone (2.5 mg) and regular toileting assistance (prompted voiding) by trained research and did not report significance on rates of positive cough test or appropriate toileting rate.[711]

Level of evidence. The evidence from nine RCTs[233-237,708-711] and one nonrandomized trial[238] was analyzed in relation to a variety of clinical outcomes in residents of nursing homes. One trial reported preplanned intention to treat analysis; four justified sample size;[234,237,709,710] allocation concealment was unclear in all open label trials. Baseline characteristics of the participants did not differ and confirmed adequacy of randomization in five trials.[234-236,708,711] Adherence of nursing staff to the protocol was not consistently analyzed, thus preventing valid comparisons of the treatment effects between the studies.

Summary. In conclusion, in contrast to numerous studies of the management of UI, only a few RCTs aimed at slowing progression in LTC settings. Individualized management programs that included prompted voiding, exercise, and positive feedback modestly improved the severity of symptoms. Active rehabilitation with self management of urinary symptoms resulted in continence in the majority of the patients after stroke. Fully powered RCTs would better estimate the effectiveness of individualized evidence-based conservative management programs. Cluster trials with randomization of nursing units, adequate allocation concealment, and preplanned intention to treat analysis are needed to provide valid results. The effectiveness of clinical interventions should be examined in subgroups of residents by cognitive and physical functioning, gender, and ethnicity. The effects of conservative management programs on the quality of life in these populations have not been investigated in RCTs. Staff participation in developing combined management protocols and adherence to protocols should be continuously measured as quality of care indicators in LTC facilities.

Effects of Clinical Interventions on UI in Community Dwelling Adults

Implementation of evidence-based guidelines (Appendix Table F67). National evidence-based guidelines were implemented in gynecology units in four district general hospitals across Scotland. Women were advised to follow the recommended appropriate protocol for 1 year. This intervention did not improve self-reported severity of UI and quality of life in women at 1 year of followup (Appendix Table F68).[712]

Conservative management programs. Urinary continence service delivered by specially trained nurses included advice on diet and fluids, bladder training, and pelvic floor muscle awareness[240] in a large, well designed RCT of 3,746 incontinent men and women living in private households (Appendix Table F69). The proportion of cured patients was 1.5 times higher after the continence service (RR 1.5, 95 percent CI 1.3; 1.7) (Appendix Table F70). More patients reported improvement in UI 6 months after active treatment (RR 1.2, 95 percent CI 1.1; 1.3). The continence service also reduced progression of urgency to very strong or overwhelming

by 30 percent (RR 0.7, 95 percent CI 0.7; 0.8). The complex rehabilitation program by nurse continence advisors and consulting urogynecologists including bladder training, gradual increase in fluid intake, pelvic floor muscle training, and transvaginal electrical stimulation resulted in urinary continence in 50 percent of women but with no statistically significant differences compared to usual care (Appendix Table F71).[510] Small significant improvement compared to usual care was detected in two quality of life measures, the Life Urogenital Distress Inventory (2.9 percent) and in the Short Form Urogenital Distress Inventory (16 percent) (Appendix Table F72). Community-based interventions, including education, bladder training, managing the urge to urinate, and pelvic floor muscle training, resulted in continence in 35 percent of women vs. 30 percent after usual care (RR 1.7, 95 percent CI 1; 2.9).[241] The majority of women reported more than 50 percent improvement in incontinence (RR 1.6, 95 percent CI 1.1; 2.2).[241] A continence management program implemented by nurse continence advisers with physician expertise included lifestyle modification sessions for 446 incontinent subjects.[242] Daily incontinence events were significantly reduced after active treatment with no changes in pad use (Appendix Table F73).[242] Educational programs about bladder health and recorded incontinence episodes in a voiding diary, in addition to listening to an audiotape daily, were examined in one RCT.[713] The combination of education and cognitive interventions significantly reduced the number of incontinent episodes (RR 1.7, 95 percent CI 1.1; 2.7) but did not improve perceived incontinence measured using the Urinary Incontinence and Frequency Comfort Questionnaire (Appendix Table F74).

Dietary and other lifestyle interventions in females (Appendix Table F75). A standard low calorie liquid diet, increased physical activity to 60 minutes per day, training by a nutritionist, and exercise supervised by a physiologist or behavioral therapist improved stress UI in 92 percent, urge UI in 70 percent, and overall UI in 60 percent of participating women (RR of improvement in overall UI 3.5, 95 percent CI 1.3; 9.1) (Appendix Table F76).[714] Self-selected diet with low fat and low cholesterol foods and 25g of soy protein (Appendix Table F75) did not reduce the risk of stress and urge UI in women compared to a diet without soy (Appendix Table F77).[715] Increasing fluid intake by 500cc did not change the frequency of UI.[716] Restriction in caffeine intake in combination with increasing decaffeinated fluids significantly reduced the number of UI episodes by 87 percent but did not change urine loss in the pad weight test (Appendix Table F77).[717] A significant decrease in daytime episodes of involuntary urine loss after caffeine restriction was reported in another RCT.[718] A positive insignificant tendency to reduce the risk of stress UI was observed after the lifestyle interventions associated with the Diabetes Prevention Program RCT (RR 0.9, 95 percent CI 0.7; 1) (Appendix Table F78).[245]

In adults, bladder training, fluid intake modification, and restricted caffeine intake to <100mg/day significantly decreased the number of voids by 6 percent, and daily urgency episodes by 21 percent, with random differences in daily leakage episodes compared to bladder training alone (Appendix Table F79).[719]

Attributable to conservative management program events. We analyzed the number of avoided/excessive events per 1,000 treated from RCTs that reported significant effects of conservative combined interventions on UI (Table 44). Compared to usual care, continence service resulted in 90 additional cases of resolved UI (continent) 1,000 treated community dwelling adults (95 percent CI 49; 136).[240] A specially designed rehabilitation program resulted in 722 additional cases of resolved UI (continent) per 1,000 treated adults with stroke (95 percent CI 121; 235).[239] With continence service, UI was improved in an additional 100 subjects per 1,000 subjects treated (95 percent CI 56; 146), quality of life improved in 90 subjects (95 percent

CI 52; 129), and satisfaction with present urinary symptoms in 110 (95 percent CI 66; 157).[240] A computerized quality management model for medical assessment and individualized prompted voiding would avoid progression of UI in 140 per 1,000 treated residents of nursing homes (95 percent CI 13; 216).[238]

Primary prevention of female UI related to pregnancy and birth was examined in eight large RCTs with more than 100 women[246-253] (two studies were published twice with different duration of followup[246,251]) and one smaller trial[254] (Appendix Table F80). Conservative advice about self-administered pelvic floor muscle training at 5, 7, and 9 months after delivery supplemented with bladder training did not change the risk of stress UI and tended to decrease the risk of severe UI at 12 months postpartum (Appendix Table F81).[251,252] No improvement was seen in women with severe (>1 week) UI at baseline.[252] Self-rated severity was significantly reduced by 87 percent (95 percent CI -93.0; -81.1) compared to usual postpartum care (Appendix Table F82). Pelvic floor muscle training that occurred within 48 hours of delivery reduced the risk of self-reported UI 3 months postpartum (RR 0.8, 95 percent CI 0.7; 1.0),[246] but the effect was attenuated at 12 months[248] (Appendix Table F83). Pelvic floor muscle training that started 1 month before delivery reduced the risk of postpartum stress incontinence (RR 0.6, 95 percent CI 0.4; 0.9).[247] Standardized instruction in pelvic floor muscle training started before delivery did not decrease the risk of stress UI compared to regular care in a small RCT without justified sample size.[254] In addition to visits and phone calls by community midwives, reminders, feedback to self measure squeeze pressure, and voiding diary, pelvic floor muscle training did not reduce the risk of incontinence 3 months postpartum in an RCT of 1,800 participants.[253] The combination of pelvic floor muscle training with biofeedback and intravaginal electrostimulation resulted in a continence rate of 19 percent vs. 2 percent after usual care (RR of continence 11.0, 95 percent CI 1.5; 82.8) with no significant improvement in urodynamic outcomes (Appendix Table F84).[249] Self-administered perineal massage daily from the 34th or 35th week of pregnancy until delivery did not improve the continence rate in a large sample of pregnant women with (n = 493) and without (n = 1,034) a previous vaginal birth.[250]

We estimated that assessment of UI by nurses with conservative advice on pelvic floor muscle training supplemented with bladder training could avoid 121 cases of UI (95 percent CI 7; 152) and 59 cases of severe incontinence (95 percent CI 5; 99) among 1,000 treated (Table 45).[251]

Pelvic floor muscle training for secondary prevention of UI in community dwelling females. Complex behavioral modification programs, including pelvic floor muscle training, bladder training, and individualized testing of knowledge, adherence, and skills, were implemented in 359 postmenopausal, continent women 55 years and older (Appendix Table F85).[243,244] Behavioral modification did not cure UI at 1 year of followup, although the improvement rate in urinary symptoms was 36 percent higher after intervention vs. standard care (RR 1.4, 95 percent CI 1.1; 1.7).[243]

The effects of behavioral interventions on UI in females were examined in 21 RCTs.[267-287] The effects of pelvic floor muscle training on stress UI in women were examined in 18 RCTs (Appendix Table F86).[288-290,292,299,316,720-731] The rates of cure of UI, improvement or progression of UI, continuous severity measures, and urodynamic outcomes after active treatments were compared to usual care or active controls.

Outcome - continence. Several RCTs reported subjective cure of UI[275,290,299] or objective continence during a stress test or urodynamic exam[268,299,721,731] (Appendix Table F87). Curative behavioral interventions included pelvic floor muscle training, bladder training, and

electromyography biofeedback. The rate of continence after treatment varied from less than 10 percent[253,299,730] to more than 75 percent.[288] Smaller trials tended to report greater continence rates.[275,288,731] The largest relative benefit on continence was observed after electromyography (EMG)-assisted biofeedback with pelvic floor muscle training compared to usual care in postmenopausal women with stress UI taking hormone replacement therapy (RR 17.3, 95 percent CI 1.1; 261.7).[288] Pelvic floor muscle training in groups with skilled physical therapists increased subjective cure from stress UI (RR 15.4, 95 percent CI 2.2; 110.3).[299] Women with stress UI experienced objective cure after this treatment six times more often compared to untreated controls (RR 6.1, 95 percent CI 1.5; 25.1).[299] Older women with sphincteric incompetence reported cure from stress UI eight times more often compared to regular care (RR 8.8, 95 percent CI 1.2; 66).[289] Individualized behavioral intervention with pelvic floor muscle training for stress UI or bladder training for urge UI resulted in continence in 19 percent of women with substantial relative benefit compared to regular care (RR 10.4, 95 percent CI 14; 78.3).[280] The trials with active controls reported comparable rates of continence without significant relative benefit on urinary continence.[268,269,271,274-276,721,727,730,731]

Outcome - Improvement in UI in community dwelling females. The majority of RCTs that examined behavioral interventions reported improvement in self-reported severity of UI and quality of life (Appendix Table F88).[243,268,269,278-281,283,286,288,289,292,299,724,725,727,730] The rates of improvement varied from 20 percent in improved pad test after pelvic floor muscle training with intravaginal EMG biofeedback[288] to 94 percent in improved stress test after pelvic floor muscle training.[725]

Individual pelvic floor muscle training and bladder training with delayed voiding resulted in self-reported improvement in 94 percent of women.[286] Behavioral training that included biofeedback-assisted pelvic floor muscle training, home exercises, bladder control strategies, and self monitoring with bladder diaries reduced weekly incontinence episodes by more than 50 percent in 86 percent of women ages 40-78 years with all types of UI.[268] The same consistent effect was observed after bladder training with positive reinforcement in older women with clinical and urodynamic UI >1 leakage/week.[281] Significant improvement in restriction of daily activities attributable to UI was reported after pelvic floor muscle training (RR 12.5, 95 percent CI 3.2; 48.6).[292] Two small RCTs of pelvic floor muscle training[292] and exercises with biofeedback[724] reported substantial relative benefits when no women reported improvement in UI after usual care. Other RCTs showed more than 25 percent relative benefit after biofeedback-assisted behavioral training (RR 1.6, 95 percent CI 1.1; 2.3[279] or after bladder training (RR 3.1, 95 percent CI 2.0; 4.9;[281] RR 3.4, 95 percent CI 1.9; 6.1[278]) compared to usual care. Women reported more than 50 percent reduction in UI episodes after bladder training (RR 3.1, 95 percent CI 2.0; 4.9) compared to usual care.[281] Two RCTs reported significantly larger benefits of behavioral training compared to self-administered behavioral changes using a booklet.[268,283]

Outcome - Progression of UI in community dwelling females. Severity of UI was estimated with self-reported frequency of leakage episodes, pad utilization, and bothersomeness of UI. Community-based intervention that included bladder training and performing pelvic floor muscle training among elderly women resulted in 30 percent reduction in pad use for UI (RR 0.7, 95 percent CI 0.6; 0.9). (Appendix Table F89)[291] Intensive pelvic floor muscle training with 8-12 maximum contractions in 3 series/day and 45 minutes/week group sessions among women with clinically and urodynamically proven stress UI reduced the prevalence of UI with sexual intercourse by 80 percent (10.5 percent vs. 41.7 percent RR 0.2, 95 percent CI 0.2; 0.8).[720] The adverse impact on quality of life was reduced by 30 percent (RR 0.7, 95 percent CI 0.6; 0.9)[291] to

40 percent (RR 0.6, 95 percent CI 0.4; 0.9)[720] The relative benefit of behavioral interventions was demonstrated when compared to usual care but not to active controls.

Clinical interventions for primary prevention of UI in community dwelling males.

Outcome - Continence. The behavioral interventions on UI in males with prostate diseases were examined in 12 RCTs (Appendix Table F90).[255-266] Pelvic floor rehabilitation programs resulted in continence rates from 77 percent[255] to 99 percent[257] (Appendix Table F91). The highest continence rate was reported in a large well designed RCT of early pelvic floor rehabilitation in patients who had radical retropubic prostatectomy for clinical stage T1 or T2 prostate cancer.[257] The majority of patients (99 percent) reported continence after the intervention that included verbal explanations, palpation, and Kegel exercises with a small significant relative benefit compared to usual care (RR 1.1, 95 percent CI 1.1; 1.2).[257] The relative effect in the same RCT was larger when continence status was measured with a scale specific for UI (RR 1.3, 95 percent CI 1.2; 1.5).[257] Continence rates in the control groups were more than 60 percent across all RCTs with no statistically significant differences compared to active treatments (Figure 29).

Outcome - UI in community dwelling males. The effects of behavioral interventions on severity of UI were inconsistent in direction and size compared to usual care (Appendix Table F92). Few RCTs reported significant benefits of behavioral treatments to reduce the risk of UI. The rate of self-reported UI was 70 percent less after verbal instruction and feedback on contractions of pelvic floor muscles in 63 patients with bladder outflow obstruction and diagnosis of symptomatic benign prostatic hyperplasia who undergo transurethral prostatectomy (RR 0.3, 95 percent CI 0.1; 0.9).[263] Pelvic floor muscle training, including a strong post-void "squeeze out" pelvic floor muscle contraction, biofeedback, and suggestions to change lifestyle, significantly reduced post micturition dribble and urine loss in men with erectile dysfunction.[266] One large trial showed a substantial benefit of a complex floor rehabilitation program including patient education, assessment of pelvic floor muscles strength, and visualization of Kegel pelvic floor muscle training compared to regular care with reduction in severity and pad utilization (RR of using two pads/day 0.1, 95 percent CI 0; 0.7).[257]

Behavioral clinical interventions for secondary prevention of urinary continence in adults. The effects of behavioral interventions in males and females were examined in four RCTs (Appendix Table F93).[43,732-734] One large RCT of pelvic floor muscle training and bladder retraining supervised by non-specialist nurses in 561 adults 35 years and older with regular UI reported a significant increase in cure (RR 15.5, 95 percent CI 2.1; 112.5) and improvement of UI (RR 12.6, 95 percent CI 6; 26.2) (Appendix Table F94).[43]

Effects of Behavioral Interventions on Severity of UI and Quality of Life

Surrogate outcomes.

Subjective measures of severity of UI and quality of life in females (continuous surrogate variables). The authors measured severity of UI using self-reported numbers of episodes of UI per time period. The effects of behavioral interventions on quality of life were estimated from questionnaires and scales expressing the effects as mean differences between active and control treatments (Appendix Table F95). We calculated the effect size as the percent change in outcome variables compared to the control group. Overall, behavioral interventions resulted in small random changes in outcomes compared to control groups. No consistent benefit was seen across

RCTs on severity or quality of life. The largest differences were reported in one RCT that showed a reduction in the number of daily leakages after pelvic floor muscle training in groups supervised with skilled physical therapists (mean difference -0.7, 95 percent CI -1.2;-0.2).[299] The same RCT reported a significant increase in the Social Activity Index (mean differences 0.6, 95 percent CI 0.1; 1.1).[299] The results were inconsistent within trials. Pelvic floor muscle training improved self-reported UI measured with the Visual Analog Scale of UI but also increased the number of stress incontinence episodes.[288] Behavioral interventions reduced the number of incontinence episodes by 0.5-1 per day.[282,292] The effect on quality of life was also small with less than 1 percent differences in scores on the Incontinence Impact Questionnaire (mean difference -0.5, 95 percent CI -0.9;-0.2).[284]

Objective measures of severity of UI in females (pad test, urodynamic cystometry, and perineometry). Few behavioral interventions improved objective severity compared to either regular care or other treatments (Appendix Table F96). Behavioral management for continence reduced urine loss per 24 hours in the pad weight test compared to regular care (mean difference -0.5, 95 percent CI -0.8; -0.2).[282] The same benefit (approximately 1 percent difference compared to the control group) was reported after bladder training.[281] The largest significant differences (44 percent compared to usual care) in the 1 hour pad test was shown after pelvic floor muscle training with digital biofeedback (mean difference -12.3, 95 percent CI -15.6; -9).[288] Several RCTs of behavioral interventions reported small significant reductions in vaginal pressure[274] and significant increase in peak pressure[285,729] and pelvic floor muscle training.[288,725]

One RCT examined the effects of contracting the pelvic floor muscles before and during a cough (Knack Maneuver) in 27 women with self-reported stress UI and did not show significant improvement in urine leakage during the cough paper towel test.[722]

Subjective measures of severity of UI in males. Self-reported urinary symptoms and pad use did not change after active treatments compared to regular care (Appendix Table F97). One RCT reported increased urine loss in the pad weight test after intensive pelvic floor muscle training conducted by a physiotherapist (Appendix Table F98).

Subjective measures of severity of UI in adults. The frequency of UI in adults after behavioral interventions was reported in two RCTs (Appendix Table F99).[732,733] The larger RCT showed reduced UI episodes/day (mean difference -0.6, 95 percent CI -1.0; -0.2) after biofeedback-assisted pelvic floor muscle training.[732]

Pooled estimates of behavioral interventions on urinary continence in adults. The differences in populations and treatments, including difference in training regimes and frequency, made a pooled analysis questionable. We compared the relative benefit of urinary continence after behavioral interventions to usual care (Table 46). Pelvic floor muscle training, biofeedback assisted pelvic floor muscle training, and a combination of pelvic floor muscle training with bladder training showed an inconsistent relative benefit across studies. Pooled relative benefits of pelvic floor muscle training in females (RR 7.1, 95 percent CI 2.8; 18)[280,288,289,299] and pelvic floor muscle training combined with biofeedback (RR 11.2, 95 percent CI 2.2; 56.4)[288,289] were sensitive to one small RCT[288] with 2 month followup (Figure 30). Pelvic floor muscle training combined with bladder training increased continence by 175 percent compared to usual care (pooled RR 1.8, 95 percent CI 1.1; 2.9).[241,243,280,290]

The majority of RCTs demonstrated significant improvement in UI after pelvic floor muscle training compared to regular care. An improvement was shown eight times more often after pelvic floor muscle training (RR 8.1, 95 percent CI 2.3; 28.4), twice as frequently after biofeedback assisted pelvic floor muscle training (RR 1.9, 95 percent CI 1.0; 3.5), and 2.5 times

more often after pelvic floor muscle training and bladder training (RR 2.5, 95 percent CI 1.4; 4.6) (Figure 31).

Attributable benefits of behavioral interventions. Few RCTs showed significant relative benefit of behavioral interventions on urinary continence (Table 47). The number of avoided stress UI cases per 1,000 varied from 170[249] to 749[288] when treated with behavioral interventions. The relative benefits on total UI was smaller.[43,257] Ignoring different definitions of improvements and possible attenuation of the improvement over time, weight reduction would result in improved stress UI in 990 adults per 1,000 treated (Table 48).[714]

Intensive lifestyle changes would avoid 54 cases of stress UI per 1,000 treated (Table 49).[245] Pelvic floor muscle training and strategies to improve adherence among pregnant women would avoid 390 cases of UI per 1,000 treated (Table 50).[246]

Level of evidence. The evidence from RCTs (level I) was analyzed to compare the effects of behavioral interventions on UI.

Summary. In conclusion, behavioral interventions resulted in improvement in UI across RCTs, but the estimation of the overall effect was difficult due to heterogeneity between studies. The long-term continence outcomes among subjects that experienced improvement while participating in RCTs are restricted to 1 year of followup. Several large well-designed RCTs reported a significant benefit of behavioral interventions on cure of incontinence with greater effects on stress UI in females and very limited evidence on urge incontinence and male incontinence. Weight reduction in combination with physical activity showed promising protection against incident UI. Preventive complex pelvic floor rehabilitation programs in specific populations, including males undergoing prostate surgery and pregnant women, demonstrated relative benefit on several measures of urinary continence. The effects on quality of life and objective instrumental outcomes are inconsistent and small. Active interventions provided better outcomes compared to usual care with no relative benefit compared to each other.

Effects of Physiotherapeutic Interventions on UI in Community Dwelling Adults

Electrical or magnetic stimulation of pelvic floor muscles were examined in 17 RCTs[293-295,297,298,300-302,512,735-742] and one large prospective cohort study,[304] and neuromodulation of sacral nerve roots in nine RCTs[296,303,305,306,743-747] (Appendix Table F100). One RCT examined the effects of massage and stretching of perineum during the second stage of labor with a water soluble lubricant[514] and one study examined the effects of acupuncture to improve UI.[748] The majority of RCTs included less than 100 subjects; only three RCTs included more than 100 patients.[302,736,746]

Patient outcomes.

Continence in community dwelling females. Urinary continence after electrical stimulation in females was reported in five RCTs (Appendix Table F101)[293-295,297,298] and the effects of neuromodulation in one RCT.[296] The rates of cure from urge UI were more than 70 percent in one RCT after functional magnetic stimulation.[298] Electrical stimulation resulted in continence in about 20 percent of women.[293,294] The significant relative benefit of active magnetic to sham stimulation was shown in only one trial (RR 3.5, 95 percent CI 1.6; 7.8).[298] Other RCTs did not demonstrate significant relative benefit of cure compared to Kegel exercises,[293] biofeedback

assisted training,[297] or placebo stimulation.[295] Magnetic stimulation of sacral roots did not provide better continence rates compared to sham neuromodulation.[296]

In community dwelling adults, implantation of a multiprogrammable neurostimulator cured 47 percent of adults with urge UI[305] with significant relative benefit compared to standard medical therapy (RR 43.5, 95 percent CI 2.7; 695).[305] Sacral root neuromodulation resulted in urge continence more than nine times more often than conservative management with medications or pelvic floor muscle training (RR 9.9, 95 percent CI 1.4; 71.4).[306]

Studies that examine the effects of electrical stimulation of pelvic floor failed to provide relative cure more often than control treatments.[300,301]

Improvement in UI in community dwelling females. Several RCTs reported improvement in UI after stimulation in females;[293-297,302,303,735,737,740,745] with an improvement rate from 8 percent after percutaneous neuromodulation[303] to 85 percent after intravaginal stimulation[737] (Appendix Table F102). The improvement after magnetic stimulation varied from 23 percent in urge UI after electrical[298] to 74 percent in stress UI after neuromodulation therapy.[296] The greatest improvement in urge UI (85 percent) was observed after intravaginal electrical stimulation in women with predominantly urge UI.[737] The greatest improvement in stress UI (74 percent) was reported in women with mild stress incontinence after magnetic stimulation of sacral roots.[296] The rates of quantitative improvement were less than qualitative from 38 percent after neuromodulation[303] to 46 percent after electrical stimulation[294] in rates of negative pad test and only 15 percent in daily pad usage.[303] Transvaginal electric stimulation for 40 minutes/day was more effective than sham stimulation in women with either UI due to detrusor instability or stress UI, or both (mixed incontinence) (RR 2.1, 95 percent CI 1.1; 4.1).[302] However, the superiority of electrical stimulation compared to placebo treatment or regular care was not confirmed in other RCTs.[294,737,740]

Magnetic neuromodulation of sacral roots compared to placebo improved UI twice as often in women with stress UI (RR 2.3, 95 percent CI 1.3; 4.0).[296] Magnetic stimulation of pelvic floor, in contrast, did not improve predominant urge UI.[740] However, abdominal pain related to urge UI was reported less often after magnetic stimulation compared to placebo (RR 8.1, 95 percent CI 1.1; 57.9).[740]

Electrical stimulation was not more effective than Kegel exercises.[293,735] Home-managed electrical stimulation with vaginal/anal stimulators for at least 3 months reduced the frequency of urine loss in a large prospective cohort of Norwegian women (RR 0.7, 95 percent CI 0.7; 0.8).[304]

Neuromodulation with surgical first stage lead placement compared to percutaneous needle electrode significantly improved refractory urge UI in women who failed medical, behavioral, and pelvic floor reeducation management.[303]

UI in community dwelling females. Electrical[302,739] and magnetic[740]stimulation of pelvic floor and neuromodulation[745] did not reduce the prevalence of urge UI and detrusor over-activity compared to sham treatment (Appendix Table F103). Intravaginal electrical stimulation did not decrease the progression of mixed UI compared to Kegel exercises.[735] One prospective cohort study showed a significant reduction in frequency of urine loss and self perceived severity of UI.[304]

One RCT of acupuncture in 85 women older than 18 years with symptoms of overactive bladder with urge UI did not significantly reduce self-reported severity of urge UI and did not improve the Urinary Distress Inventory scores or urodynamic outcomes compared to placebo acupuncture treatment designed to promote relaxation.[748] However, a small reduction in the number of total UI episodes (mean difference -0.6, 95 percent CI -1; -0.1) was detected compared to placebo treatment.

Continence in community dwelling adults. Electrical stimulation of pelvic floor[301] or neuromodulation [305,306,744] resulted in urinary continence in males and females in several RCTs (Appendix Table F104). The rates of continence varied from 8 percent after electrical[300] to 47 percent after neuromodulation.[305] The highest continence rate (>40 percent) was achieved with a sacral neurostimulator in patients with refractory urinary urge incontinence.[305,306] Electrical stimulation with intravaginal electrodes in women and anal in men resulted in continence in a small proportion of subjects with no relative benefit compared to sham treatment.[300] Larger cure rates were substantially higher after subcutaneous implantation of a multiprogrammable neurostimulator in the lower quadrant of the abdomen with the lead positioned to target sacral nerve compared to standard medical care (RR 43.5, 95 percent CI 2.7; 695.0).[305] Sacral root stimulation compared to prior conservative management, including medications and pelvic floor muscle training, cured urge UI (RR 9.9, 95 percent CI 1.4; 71.4).[306] Both trials showed a wide 95 percent CI because of zero[305] or only one case of improvement[306] after control interventions.

Improvement in UI in community dwelling adults. Stimulation improved UI with rates varying from 0.5 percent after electrical stimulation of pelvic floor[512] to 77 percent after neuromodulation of sacral nerve roots[305] (Appendix Table F105). Functional magnetic stimulation improved UI in 30 percent of 32 patients with UI due to detrusor overactivity.[512] The highest rate of improvement in urge UI (89.7 percent) was observed after combined therapy of Stoller afferent neuromodulation and 5mg of oral oxybutynin hydrochloride with no significant relative benefit compared to stimulation alone.[744] Implantation of a multiprogrammable sacral neurostimulator improved severe urge incontinence (RR 8.8, 95 percent CI 3.4; 22.8) and increased the proportion of patients who did not need to use absorbent pads (RR 23.0, 95 percent CI 3.2; 162.9) compared to standard care.[305] A significant reduction was also seen in daily urge incontinent episodes (>50 percent) (RR 6.6, 95 percent CI 1.6; 27.5).[305] Electrical stimulation did not show relative benefit compared to sham treatment in an underpowered RCT of 68 patients with UI due to detrusor overactivity.[301]

Surrogate outcomes.

Subjective measures of severity and quality of life of UI in community dwelling females. The effects of electrical stimulation on frequency and amount of urine loss were compared to sham treatment or behavioral interventions (Appendix Table F106). Only two RCTs reported significant relative differences in urinary leakage episodes after active compared to sham stimulation. Women with urodynamically proven stress incontinence reported a 12 percent reduction in incontinence episodes (mean difference -0.7, 95 percent CI -1.3; -0.1) and a 6 percent reduction in pad use compared to placebo treatment (mean difference -0.7, 95 percent CI -1.3; -0.1).[294] Women with stress, urge, or mixed UI experienced a 59 percent reduction in urinary leakage after transvaginal electrical stimulation with adjustable current intensity compared to inactive stimulation (mean difference -1.8, 95 percent CI -2.6; -0.9).[742]

The impact on quality of life of UI was measured using the Urogenital Distress Inventory scores, the Incontinence Impact Questionnaire, and the Visual Analog Scale of UI. Only one RCT showed a significant improvement in quality of life from the complex pelvic floor rehabilitation program that included electrical stimulation of the pelvic floor muscle combined with an assisted pelvic floor muscle training program in premenopausal women with persistent postnatal stress UI.[267]

Objective measures of severity of UI in community dwelling females. Severity of UI after electrical stimulation was estimated with the pad test and urodynamic cystometry (Appendix Table F107). Random changes or small improvements compared to control interventions were

reported in the majority of the RCTs. The largest improvement was seen in pelvic floor muscle maximum strength (mean difference 0.9, 95 percent CI 0.3; 1.6, 194 percent compared to control) and changes from baseline in maximum rate of force development (mean difference 0.9, 95 percent CI 0.3; 1.6, 201 percent compared to control) after a complex pelvic floor rehabilitation program in women with persistent postnatal stress UI compared to relaxation massage for the back and extremities.[267]

Subjective measure of severity of UI in community dwelling adults. The effects of electrical stimulation or neuromodulation on the frequency and amount of urine loss were compared to sham treatment or behavioral interventions (Appendix Table F108).

Sacral root neuromodulation with an implantable impulse generator reduced pad use for urge UI by 28 percent and leakage episodes of urge UI by 18 percent compared to the control group in patients with refractory urge incontinence.[306] The same effect was observed in another RCT after implantation of a multiprogrammable neurostimulator; severity rank of urge UI was decreased by 78 percent; pad use was decreased by 29 percent, and urge incontinence episodes by 14 percent compared to sham treatment.[305]

Objective measure of severity of UI in community dwelling adults. The effects of electrical stimulation or neuromodulation on the frequency and amount of urine loss were reported compared to sham treatments or active controls (Appendix Table F109).[300,301,746] Functional magnetic stimulation compared to electrical stimulation did not show differences in urodynamic outcomes in patients with UI due to detrusor overactivity.[512]

Events attributable to stimulation therapy. We estimated that functional magnetic stimulation would avoid 390 cases of urge UI per 1,000 treated women (Table 51). Transvaginal electric stimulation with individually adjusted intensity would result in improvement in UI in 180 women per 1,000 treated.[302] Home-managed electrical stimulation with vaginal/anal stimulators would avoid 50 cases of UI per 1,000 treated women (Table 52).[304]

Sacral nerve stimulation would avoid 385[306] to 460[305] cases of urge UI per 1,000 treated adults. Electrical stimulation with surgical first stage lead placement would improve UI in more than 400 women per 1,000 treated compared to placebo.[303]

Summary. In conclusion, evidence from several small RCTs (<100 subjects), three large RCTs, and one prospective cohort suggested that electrical and magnetic stimulation of pelvic floor and sacral nerve roots neuromodulation can improve predominantly urge UI in adults but the curative effects are not consistent.

Effects of Medical Devices on UI in Community Dwelling Females

Eight RCTs examined different devices to treat UI in females, including Hodge pessary,[311] disposable intravaginal devices,[312,313] urethral plug,[314] and vaginal cones[299,315,316] (Appendix Table F110).

Patient outcomes.

Continence and improvement of UI in community dwelling females. A new blocking leakage urethral sterile device with disposable applicator resulted in the highest continence rate (67 percent) in women with mixed or stress UI with no relative benefit compared to a sterile balloon device (Appendix Table F111).[313] Continence during physical activity was achieved in 36 percent of exercisers ages 33-73 with stress UI after using a Hodge pessary but there was no relative benefit compared to a super tampon.[311] A Conveen continence disposable intravaginal

device cured stress UI in 36 percent compared to 48 percent with a Contrelle continence tampon with no statistically significant difference between treatments.

The use of vaginal cones of 20, 40, and 70g for 20 minutes/day resulted in nonsignificant improvement in subjective and objective cure in women with clinically and urodynamically proven stress UI.[299] Use of vaginal cones showed no improvement in UI compared to pelvic floor muscle training and functional electrical stimulation biofeedback.[315]

Severity of UI and quality of life with UI in community dwelling females. A continence disposable intravaginal device and tampon reduced urine loss during the 24-hour pad weight test compared to no treatment.[312]

Vaginal cones did not improve the results of the stress pad test and the 24-hour pad weight test compared to no treatment but improved the leakage index.[299] Vaginal cones were not more effective in reducing self-reported severity of UI than biofeedback assisted pelvic floor muscle training[315] or regular care[299] (Appendix Table F112). The effects of vaginal cones on restricting exercise and avoiding places due to incontinence were less than those of biofeedback-assisted pelvic floor muscle training.[315]

UI in community dwelling males. Two RCTs examined medical devices on UI in males (Appendix Table F113).[317,318] One small RCT did not show a relative benefit of a UroLume sphincteric stent inserted cystoscopically to conventional external sphincterotomy in 57 men with spinal cord injury and electromyographic and manometric evidence of external detrusor-sphincter dyssynergia (Appendix Table F114).[317] A second small crossover RCT compared penile compression devices in men 6 months after radical prostatectomy[318] and did not show differences in resistance index and urine loss during the 4-hour pad test compared to no device (Appendix Table F115).

In conclusion, limited evidence suggests that medical devices result in modest improvement in UI in women with a tendency to provide relative benefit compared to no treatments but not to other interventions.

Effects of Bulking Agents on UI in Community Dwelling Females

The effects of different bulking agents on female UI were examined in two RCTs with more than 100 females[307,749] and three smaller RCTs[309,310,750] with 6-24 months of followup (Appendix Table F116).

Outcomes.

Continence. Curative effects at 12 months of followup were shown after intraurethral collagen injection in women with stress UI (51.5 percent were dry during 24-hour pad test) (Appendix Table F117).[307] Transurethral porcine dermal implant injection resulted in negative pad test (cure) in 60 percent of women with urodynamically proven stress UI at 6 months of followup.[309] Peri-urethral injections of autologous fat from the anterior abdominal wall or buttock with up to three injections depending on individual response cured or improved UI at 24 months of followup in 17 percent of women with stress UI.[750] Transurethral injection of the bulking agent, dextran copolymer, resulted in objective cure at 12 months of followup in 15 percent of women with stress or mixed incontinence with minor and controlled urge component, who failed prior conservative treatments.[310]

Improvement in UI. Four RCTs reported improvement in UI after bulking agents. The highest rates of improvement (60 percent of women had an improved pad test) were reported after periurethral porcine dermal implant injection.[309] The same treatment improved the UI scores in

50 percent of women and the results of the Kings College Hospital Quality of Health Questionnaire in 56 percent.[309] Injection of the bulking agent Durasphere improved UI in 43 percent of women with refractory stress UI due to intrinsic sphincter deficiency.[749]

UI. The risk of complete urinary retention was lower after intraurethral collagen submucosal injection compared to surgical procedures, including needle bladder neck suspensions, Burch colposuspensions, and intravaginal slings (RR 0.1, 95 percent CI 0.0; 0.9). However, no RCTs showed a significant relative benefit of bulking agents compared to placebo[750] or other treatments.[307,309,310,749] The incidence of urgency was higher after the synthetic bulking agent compared to bovine collagen (RR 2.1, 95 percent CI 1.3; 3.3).[749] Bulking agents did not result in consistent improvement in urodynamic outcomes, pad weight test results, or quality of life measures (Appendix Table F118). We estimated that 119 patients would avoid complete urinary retention after collagen injection compared to surgical interventions (Table 53). In conclusion, no evidence suggests that bulking agents improve efficacy compared to placebo or effectiveness compared to other treatments in females.

Transurethral radiofrequency energy collagen micro-remodeling was examined in one RCT of 110 women with stress UI and showed no significant improvement in a quality of life questionnaire in women with stress UI and bladder outlet hypermobility compared to placebo injections.[751]

Clinical Effects of Obstetric Interventions on UI

Patient outcome - UI. The effects of different obstetric strategies to reduce the risk of UI were examined in seven large RCTs[386-389,391,752,753] and one smaller RCT[382] with justified sample size that evaluated surgical techniques for the primary repair of obstetric anal sphincter lacerations on UI (Appendix Table F119). Planned Cesarean delivery compared to vaginal birth reduced the risk of stress UI by 40 percent (RR 0.6, 95 percent CI 0.4; 0.9) at 3 months but not 2 years postpartum (Appendix Table F120).[389] Caesarean section was more protective against UI compared to vaginal delivery 3 months postpartum in the large RCT with no intention to treat and a 4.3 percent rate of cross treatments decided by the attending physician.[752] Caesarean section reduced the risk of any UI by 70 percent (RR 0.3, 95 percent CI 0.1; 0.7) in primiparous women and in the subgroup of primiparous women with a history of UI (RR 0.3, 95 percent CI 0.1; 0.9).[752] The risk of stress UI was reduced by 70 percent in primiparous women (RR 0.3, 95 percent CI 0.2; 0.5), with the same reduction in females with and without previous UI. The protective effect was not seen in multiparous women.

Restrictive vs. liberal policies for episiotomy[386,753] did not reduce the risk of UI 1.5-3 years postpartum. Mediolateral episiotomy compared to no episiotomy[387] did not decrease the risk of stress or urge UI 3 months after delivery. The same proportion of women requiring assisted vaginal delivery reported stress and urge UI after delivery with vacuum extractor or forceps delivery 5 years postpartum.[391] End-to-end repair compared to overlapping technique did not result in a lower risk of UI in 51 women with complete third or fourth degree anal sphincter laceration who underwent primary repair at the time of vaginal delivery.[382] Episiotomy did not affect urodynamic outcomes (Appendix Table F121).[386,387]

Effects of Hysterectomy on UI

Patient outcome - *UI*. Three powered RCTs[320,754,755] and two smaller RCTs with no justification for sample size[319,756] examined the effects of hysterectomy on the incidence and progression of UI (Appendix Table F122). Total abdominal hysterectomy was compared to subtotal supracervical hysterectomy in women with benign diseases of the uterus (Appendix Table 123). No differences in total, urge, or stress UI were detected between the two treatments. Intrafascial total abdominal hysterectomy significantly reduced the risk of urge UI compared to the extrafascial approach.[319]

Surrogate outcome - *Objective measures of severity of UI*. Two RCTs evaluated urodynamic outcomes and self-reported severity of UI and did not show differences between subtotal and total hysterectomy (Appendix Table F124).[754,756]

Effects of Vaginal Tapes and Sling Procedures on UI

The effects of vaginal tapes and sling procedures to reduce the progression of UI in women with predominantly stress UI were examined in 25 RCTs (Appendix Table F125).[325,327,331,338,749,757,758 323,324,326,329,332-337,339-342,485,488,491,759,760]

Patient outcomes.

Continence (curative effects). The majority of the RCTs (20/25) reported continence after vaginal tapes and sling procedures (Appendix Table F126).[323-342] The sample size included more than 100 women in nine RCTs.[325-327,331,332,334,340,341] The rate of continence was above 75 percent in the majority of RCTs; only two RCTs reported cure rates <75 percent,[334,337] All RCTs compared the effectiveness of vaginal tapes and sling procedures to active controls; no efficacy trials were identified. Cure rates were comparable after all tested procedures with no significant relative benefits. Only two RCTs reported significant relative increase in objective cure.[330,331] Tension-free vaginal tape procedures increased the rate of negative postoperative cough provocation tests by 60 percent compared to plication of the endopelvic fascia (RR 1.6, 95 percent CI 1.1; 1.4) in a small trial that examined women with severe genital prolapse treated with vaginal hysterectomy, culdoplasty, and cystocele repair for pelvic floor defects.[330] Tension-free vaginal tape under local anesthesia with polypropylene mesh tape placed under the midurethra resulted in a negative stress test 50 percent more often than laparoscopic mesh colposuspension under general anesthesia (RR 1.5, 95 percent CI 1.1; 2.4).[331]

Improvement of UI in females. The majority of RCTs reported improvement in UI after vaginal tape and sling procedures (Appendix Table F127).[323,325-327,329,332,334,336,339,342,485,760] The rates of improvement differed from 2.2 percent after transobturator suburethral sling procedure[339] to 100 percent after transvaginal antimicrobial mesh synthetic mesh,[323] depending on definitions of improvement. The rates were higher for stress UI after transvaginal antimicrobial synthetic mesh,[323] vesicourethral suspension by allogenic sling,[485] and suprapubic arc sling.[760] The rates were lower (19.4 percent) after the same procedure on quantitative improvement in stress UI defined as a decrease of >50 percent in urine loss.[336] The largest rate of improvement in urge UI (71.1 percent) was reported after intra-vaginal sling procedures.[760] A significant relative benefit was shown in one RCT that compared suburethral slingplasty with the suprapubic arc to intravaginal sling in 195 patients with urodynamic UI refractory to conservative management. Improvement in urge UI occurred 2.7 times more often after suprapubic arc compared to intravaginal sling (RR 2.7, 95 percent CI 1.3; 5.5).[334]

UI in females. The effects of vaginal tape and sling procedures were evaluated on self-reported incontinence and quality of life and objective measures of severity of UI including the pad weight test (Appendix Table F128). Few trials reported significant reduction in the progression of stress UI. Persistent subjective symptoms of stress UI were reported less often after tension-free vaginal tape than suprapubic urethral support sling in one trial (RR 0.5, 95 percent CI 0.3; 0.9).[341] Tension-free vaginal tape reduced stress UI by 90 percent compared to plication of the endopelvic fascia in one trial (RR 0.1, 95 percent CI 0; 0.8.[330] Women after tension-free vaginal tape reported subjective treatment failure less often (RR 0.6, 95 percent CI 0.3; 0.9) compared to suprapubic urethral support sling in one trial.[341]

Surrogate outcomes.

Subjective measure of severity of UI. RCTs compared self-reported frequency and severity of UI and quality of life of UI after tape and sling procedures compared to other active treatments (Appendix Table F129). Inconsistent progression in UI was reported in one RCT after tension-free vaginal tape under local anesthesia compared to laparoscopic mesh colposuspension under general anesthesia (mean difference in UI Severity Score 1.6, 95 percent CI 0.27; 2.94, mean difference in Visual Analog Scale of UI 1.3, 95 percent CI 0.7; 2.1).[331] One RCT reported improvement in global discomfort related to UI after suburethral sling procedure with retropubic routes compared to transobturator routes (mean difference 0.5, 95 percent CI 0.1; 0.9).[342]

Objective measure of severity of UI. Inconsistencies in direction and effect size in urodynamic cystometry after tested treatments were found in the majority of RCTs (Appendix Table F130).

Effects of Surgical Interventions on UI in Community Dwelling Women

(Appendix Table F131)

Six RCTs examined the effects of surgical treatments of prolapse to prevent UI.[322,330,486,487,761,762] One well designed RCT tested the effects of preoperative physiotherapy on UI.[763] The majority of RCTs included women with stress UI and compared different surgical techniques to treat UI.[321,343-350,353-362,764-778]

Patient outcomes.

Continence. Forty RCTs reported continence rates after different surgical procedures (Table 54).[319,345-351,353,355-362,486,487,764,767-770,772-774,777,778 321,343,344,491,757,766,771,775,776] The definitions varied from subjective cure with no symptoms or complaints, and need for pad use to objective cure during urodynamic evaluation and stress test. The continence rates demonstrated a substantial variability after the same procedures from 3.1 percent[770] to 85.1 percent[346] after laparoscopic colposuspension and from 8.7 percent[777] to 93.3 percent[490] after laparoscopic Burch procedures. Burch retropubic urethropexy resulted in continence in more than 90 percent of women and provided the largest relative benefit compared to modified anterior colporrhaphy (RR 5.1, 95 percent CI 1.8; 14.1)[353] and anterior colporrhaphy with Kelly plication (RR 1.4, 95 percent CI 1.1; 1.8).[345] The relative benefit of continence after Burch urethropexy was larger in another RCT that examined the same procedures (RR 2.3, 95 percent CI 1.3; 3.8).[774] Burch colposuspension with abdominal hysterectomy compared to anterior colporrhaphy with vaginal hysterectomy resulted in higher continence rates (RR 1.6, 95 percent CI 1.1; 2.3) in women undergoing surgery for primary stress incontinence and a concurrent grade 2 or 3 cystocele.[362] The relative benefit of the same procedure differed depending on the definition of cure. For example, the same trial that showed a 60 percent relative benefit for urinary continence with the

Burch procedure compared to anterior colporrhaphy reported a 300 percent relative benefit on cure defined as a negative cotton swab test (RR 3.2, 95 percent CI 1.6; 6.4).[362] The largest relative benefit of Burch retropubic suspension or pubovaginal sling was shown when compared with Oxybutynin 5mg three times/day (RR 41.3, 95percent CI 2.6; 645).[769]

Improvement in UI. Improvement in self-reported UI and the pad weight test was reported in 12 RCTs (Appendix Table F132).[346,347,354-356,766-768,771,775,776,778] One RCT reported improvement in more than 80 percent of women after laparoscopic colposuspension and Burch open colposuspension.[346] No significant relative benefit was detected when different treatments were compared.

Incidence of UI. The incidence of UI was 3.8 times higher after sacropexy combined with a Burch colposuspension compared to sacropexy alone (RR 3.8, 95 percent CI 1.2; 12.1) in continent women with advanced prolapse and a negative stress test before and after prolapse reduction (Appendix Table F133).[321] Another RCT demonstrated the opposite association with a lower incidence of stress UI after sacrocolpopexy with Burch colposuspension vs. sacrocolpopexy alone (RR 0.5, 95 percent CI 0.3; 0.7).[761] A large well-designed RCT also reported a significant reduction in severe stress UI after prophylactic surgery (RR 0.3, 95 percent CI 0.1; 0.5).[761] The sling procedure resulted in a significant reduction in stress UI 2 years after surgery compared to the Burch procedure in 665 women with predominant stress UI.[343]

Surrogate outcomes.

Subjective measures of UI. Burch retropubic urethropexy decreased the frequency of incontinent episodes and pad use compared to modified anterior colporrhaphy (Appendix Table F134).[353] Three RCTs reported improvement in quality of life after Burch colposuspension compared to other treatments.[353,761,765] The comparative effectiveness of different surgical procedures was not consistent in direction and effect size.

Objective measures of UI. Inconsistent differences in urodynamic outcomes with less than 10 percent of control levels were reported in all RCTs (Appendix Table F135).

Possible predictors of better effect. The trials used stratified randomization by a surgeon[761] and by participating centers[343,771,779] to estimate valid treatment effects independent of provider differences. Patient age, previous bladder neck surgery,[771] and concomitant rectocele repair for symptomatic rectocele[779] were balanced between treatment groups with stratified randomization to avoid effect measure modification. One trial reported the incidence of UI after sarcopexy combined with a Burch colposuspension compared to colposacropexy without prophylactic colposuspension in subgroups with baseline maximum urethral closure pressure above and below 35cmH_20.[321] No evidence suggested a significant effect modification by patient baseline conditions.

We analyzed the comparative effectiveness of different surgical procedures on urinary continenc***e*** in females (Table 55). The laparoscopic Burch procedure with sutures did not provide significant benefit compared to staples.[361,777] The laparoscopic Burch procedure compared to open Burch surgery resulted in higher continence rates in one RCT, lower in another, and random differences in three RCTs. Sling procedures were compared to Burch colposuspension with significant relative benefit of continence in one RCT and random differences in four RCTs. The Burch procedure compared to the tension-free tape procedure did not result in higher cure rates in four RCTs. An increase in continence was observed after the Burch procedure compared to colporrhaphy in two RCTs. One RCT reported higher continence rates after Burch operation vs. retropubic urethropexy with random differences in two other RCTs. No significant differences in cure were observed in two RCTs that compared retropubic urethrocystopexy and

pelvic floor repair. Tension-free tape procedures resulted in a very small relative benefit in continence compared to the sling procedure in five RCTs, while six RCTs reported random differences.

We estimated that different surgical procedures may result in a large number of avoided stress and total UI in women with no consistent benefit of one procedure over others (Tables 56-58).

Summary. In conclusion, a large body of evidence suggests that surgical procedures of stress UI in women result in continence and improvement in UI in more than 75 percent of treated women. Different surgical procedures have comparable effectiveness with no differences in incident urge incontinence. The absolute risk of de novo urgency and urge incontinence after surgery for stress UI requires an RCT, powered to estimate the balance between benefits and harms in continent women with prolapse and patients with stress incontinence. The comparative effectiveness of behavioral interventions and surgery are not known. Individual patient factors that may modify the effects of different procedures also require future research.

Reducing the Adverse Effects of Clinical Interventions Done for Other Purposes

Effects of clinical interventions on UI in adults with adenocarcinoma of the rectum. One large RCT of 1,861 patients with histologically confirmed adenocarcinoma of the rectum compared the effects of surgery and adjuvant radiotherapy on UI (Appendix Table F136). The incidence of UI and incontinence that required pad use was the same among patients after total mesorectal excision and adjuvant radiotherapy before surgery (Appendix Table F137).

Effects of clinical interventions on UI in males with urological diseases. Eleven RCTs examined clinical interventions to prevent UI in patients with prostate cancer[780-790] and three RCTs included patients with benign prostate diseases[489,791-793] (Appendix Table F138).

Patient outcome - Continence. Urinary continence was reported in four RCTs.[782,783,785] The highest rate of urinary continence (>92 percent) was reported after radical retropubic prostatectomy with bladder neck preservation (Appendix Table F139).[783]

Artificial urethral sphincter implantation and macroplastique injection in the sphincter region of the urethra resulted in continence in 80 percent and 91 percent of patients with minimal baseline incontinence, respectively.[785] The rates of "social continence" were lower and differed substantially depending on baseline incontinence.[785] Only one RCT reported continence (77 percent) after combined therapy of prostate cancer.[782] No evidence showed a significant relative benefit of continence between compared interventions.

Patient outcome - Incidence of UI. The highest rates of UI were reported in one RCT that examined the effects of bladder neck mucosal eversion during retropubic radical prostatectomy (Appendix Table F140).

Almost all patients with benign prostate diseases were continent after transurethral resection of the prostate with the thick vapor resection loop[792] and transurethral resection of the prostate.[793] In contrast, Holmium laser enucleation resulted in 50 percent of UI in the same population of men with bladder outflow obstruction secondary to benign prostatic hyperplasia.[489]

Patients with prostate cancer reported different rates of UI depending on the type and definition. Retropubic radical prostatectomy and vesico-urethral anastomosis with and without bladder neck eversion resulted in UI in more than 90 percent of patients.[781] The highest rate of urge UI (44 percent) was shown after radiation therapy with a four-field box technique to a dose of 70Gy.[780] The same treatment resulted in only 7 percent of self-reported stress UI in this

trial.[780] The lowest incidence of UI among patients with prostate cancer was reported after supplemental beam radiation with I-125 (144Gy) (1 percent).[784]

Indirect comparisons showed inconsistent relative risks of UI after surgical treatments and radiotherapy. The largest relative differences were observed in the risk of transient stress incontinence after transurethral resection of the prostate compared electro vaporization in patients with benign hypertrophy of prostate (0.1 percent vs. 18.6 percent respectively.[793] The rates of UI were substantially higher after adjuvant hormone therapy and surgery (300mg of diethylstilbestrol diphosphate/day) compared to adjuvant hormone therapy and external beam radiation (RR 35.5, 95 percent CI 2.2; 569.3). Patients with total baseline incontinence for >6 months after radical retropubic prostatectomy, transvesical prostatectomy, or transurethral prostatectomy reported cure more often after macroplastique injection to the sphincter region of the urethra compared to artificial urethral sphincter implantation (RR 0.3, 95 percent CI 0.1; 0.9.[785] Pad utilization was higher after radiotherapy compared to active surveillance (RR 8.3, 95 percent CI 1.1; 62.6).[790]

Surrogate outcome - Subjective measures of quality of life. Few RCTs examined the effects of clinical interventions on quality of life specific for UI (Appendix Table F141).[489,784,790,791] Two regimens of radiotherapy resulted in different urinary scores of the American Urologic Association and Radiation Therapy Oncology Group criteria (mean difference 11.0, 95 percent CI 9.5; 12.5).[784] Bother from urinary difficulties was greater after transurethral resection of prostate compared to watchful waiting (mean difference 0.7 on a scale of 100 for least impairment, 95 percent CI 0.5; 0.9) in patients with benign prostate hypertrophy.[791] No differences in quality of life were seen in patients with prostate cancer after radiotherapy compared to active surveillance.[790]

Surrogate outcome - Objective measures of UI. No differences in urodynamic outcomes were reported after different treatments of benign prostate diseases (Appendix Table F142).[489,791,793]

Summary. In conclusion, some limited evidence suggests that UI as a secondary outcome related to both baseline diseases and treatments is more severe after surgery and radiotherapy compared to active surveillance. The baseline level of incontinence may modify the effects of the treatments. Bladder preservation surgical techniques did not provide consistent and significant benefit on UI. No consistent evidence across RCTs suggests that different treatments for prostate cancer and benign hyperplasia can provide better long-term outcomes. The reproducibility of large relative differences in outcomes in several RCTs requires future confirmation.

Effects of hormone therapy on UI in community dwelling women. The effects of systemic oral hormone therapy on continence status in postmenopausal women were examined in 19 RCTs (Appendix Table F143).[352,365-367,369,513,794-806] The effects of transdermal and intravaginal estrogen therapy to improve continence status in postmenopausal women were administered in 10 RCTs (Appendix Table F144).[363,364,368,370,490,807-811]

Patient outcome - Continence. The preventive effects of systemic hormone replacement therapy in postmenopausal women were examined in several large RCTs (Appendix Table F145).[797,801,806] Only two RCTs reported positive significant effects of oral hormone therapy compared to baseline levels or placebo.[364,797] The administration of 2mg 17β-oestradiol combined with either 2.5, 5, 10, or 15mg dydrogesterone, orally once a day for 6 months cured incontinence in 23 percent of healthy postmenopausal nonhysterectomized women (RR 47.0, 95 percent CI 2.9; 763.5).[797] Oral hormone administration was less effective in achieving continence compared to local estrogen therapy (RR 0.4, 95 percent CI 0.3; 0.6).[368]

Urinary continence was reported in RCTs that examined the curative effects of local therapy among incontinent women.[364,368-370] The highest rates of continence were reported after transdermal administration of an estrogen patch (100 percent) and gel 1.25g/day (90 percent) among postmenopausal women with self-reported urinary symptoms (Appendix Table F145).[368] Local estrogen in vagitories or jelly combined with physiotherapy and electrostimulation cured 22 percent of women 50-74 years of age with regular mild incontinence (>2 leakage episodes per month) compared to 0 percent after no hormone treatment (RR 20.7, 95 percent CI 1.2; 346.5).[364]

Patient outcome - Improvement of UI. Several RCTs reported improvement in UI after local and oral hormone use[363,364,794,797,798,802,806,808] with the rates varying from 7 percent[794] to 68 percent,[363] depending on the route of the administration and the definition of the improvement (Appendix Table F146). The highest rate of improvement (68 percent) was reported after 6 months of intravaginal estrogen administration in incontinent postmenopausal women.[363] Combined estrogen and progesterone therapy cured nocturia, one of the risk factors of UI, in 65 percent of women.[797] Self-reported improvement in incontinence symptoms occurred in 45 percent of women after combined therapy of estrogen with alpha-adrenoreceptor agonist and in 40 percent after estrogen alone.[802]

The combination of local estrogen administration with physiotherapy and electrostimulation reduced the frequency of wet episodes in 39 percent of incontinent women.[364]

Hormone therapy improved UI compared to placebo treatments, but the effects were not consistent across RCTs. Intravaginal estrogen administration resulted in cure or improvement four times more often compared to placebo suppositories (RR 4.3, 95 percent CI 2.1; 8.7).[363] The same relative effect was reported after the combination of intravaginal estrogen with electrical stimulation (RR 4.3, 95 percent CI 1.5; 11.9).[364] In contrast, only one RCT showed a greater reduction in the number of incontinent episodes after placebo vs. ultra low dose of transdermal estrogen (RR 0.7, 95 percent CI .5; 0.9).[808]

Patient outcome - UI. The investigations that were designed to evaluate protective effects of hormone therapy on postmenopausal UI reported either random differences or relative increase in UI after estrogen therapy compared to placebo controls (Appendix Table F147).[363,365-367,513,794-796,798,801,806,808,809]Only one RCT showed a reduction in subjective complaints of stress UI after intravaginal estrogen administration (RR 0.4, 95 percent CI 0.2; 0.6).[363] The majority of RCTs demonstrated a consistent significant relative increase in UI across different routes of administration and definitions of UI. Incident mixed UI was increased by 50 percent (RR1.5, 95 percent CI 1.1; 2.2) and incident stress UI by 80 percent (RR 1.8, 95 percent CI 1.6; 2.2) after estrogen therapy.[365] Incident urge UI increased by 30 percent and total UI by 40 percent (RR 1.4, 95 percent CI 1.3; 1.6) after estrogen combined with progestin (RR 1.3, 95 percent CI 1.2; 1.5).[366] Oral estrogen alone without progestin increased incident stress UI by 210 percent (RR 2.1, 95 percent CI 1.7; 2.5)[365] and worsened UI by 530 percent (RR 5.3, 95 percent CI 1.2; 23.5).[367]

Patient outcome - Subjective progression of UI. Several RCTs obtained self-reported changes in severity after hormone therapy[364,367,794,796,801,808] and did not demonstrate differences compared to placebo (Appendix Table F148). One RCT reported a reduction in worsening of UI after transdermal estrogen (RR 0.2, 95 percent CI 0.1; 0.6).[808]

Surrogate outcome - Subjective measures of severity of UI. No differences were found after hormone therapy compared to placebo treatments (Appendix Table F149).[369,794,800,801,803,805,807] One RCT reported an increase in daily incontinence episodes after estrogen (mean difference 0.9, 95 percent CI 0.3; 1.4).[801]

Surrogate outcome - Objective measures of severity. There were no differences compared to controls or demonstrated small inconsistent changes (Appendix Table F150).

Summary. In conclusion, consistent evidence suggests that system hormone therapy increased the risk and progression of UI in postmenopausal females (Table 59). The relative harm varied from 42 to 106 percent for stress UI, 129 to 906 percent for any, and differed substantially for trials that measured urge UI.

Few RCTs demonstrated relative benefits of local estrogen administration for treatment of stress UI by 64 percent[363] and urge by 55 percent.[364]

The effective clinical interventions that resulted in long-term stress urinary continence in more than 75 percent of participating females (Table 60) included Burch colposuspension techniques and sling and tension-free tape procedures. Total urinary continence in more than 75 percent of women was observed in several RCTs after tension-free tape and sling procedures (Table 60). The effective clinical interventions that resulted in long-term urinary continence in males with prostatic diseases included pelvic floor muscle training, electrical stimulation with biofeedback, radical retropubic prostatectomy with bladder neck preservation, and implantation of an artificial urethral sphincter (Table 61). Overall, consistent evidence from RCTs suggests that pelvic floor muscle training augmented with biofeedback, Burch colposuspension, and tension-free tape and sling procedures are effective to reduce the absolute risk of stress UI in women (Tables 62 and 63).

Tension-free tape and sling procedures decreased the absolute risk of total UI. No clinical interventions demonstrated consistent reduction in absolute risk of urge UI.

The largest relative benefits with more than 300 excessive cases of resolved stress incontinence were reported in RCTs per 1,000 females treated with pelvic floor muscle training, Burch colposuspensions, and tension-free vaginal tape compared to usual care or other treatments (Table 64). Few RCTs reported large relative benefits on total urinary continence in females with local estrogen, Burch colposuspension with abdominal hysterectomy, and pubovaginal sling. Few small RCTs reported more than 300 cases of resolved urge incontinence in males and females after electrical or magnetic stimulation.

Effects of pharmacological agents on UI. Three systematic Cochrane reviews reported UI after drug administration. The reviews analyzed randomized trials of anticholinergic drugs on overactive bladder,[812] of adrenergic drugs for urinary incontinence,[813] and of serotonin and noradrenaline reuptake inhibitors for stress UI in adults.[642] We estimated attributable events of cure, improvement, or progression from the RCTs published after 1990. Adrenergic drugs were better than placebo in two of five RCTs (Table 65). Continence rates after pelvic floor muscle exercise were comparable with rate after adrenergic drugs. A combination of phenylpropanolamine that was withdrawn from the market when it was linked to intracerebral hemorrhage with estrogen resulted in continence in 0-40 percent of women. No trials included males. Clenbuterol resulted in continence 2 to 4.6 times more often than placebo in two trials but was not more effective compared to pelvic floor muscle training.

The Cochrane review of 61 trials of adults with overactive bladder syndrome that compared anticholinergic drugs with placebo treatment or no treatment reported the combined outcome of cure or improvement in UI from eight RCTs (Table 66). The other 53 RCTs did not report patient outcomes. No trials were conducted in men. Administration of propiverine (two RCTs) or extended release tolteradine (two RCTs) for 2-12 weeks resulted in greater rates of cure or improvement compared to placebo. Pooled analysis of six RCTs of different drugs resulted in 139 percent higher rates of cure of improvement (RR 1.4, 95 percent CI 1.3; 1.5).[812] The authors

also reported significant reduction in daily leakage episodes (mean difference -0.5, 95 percent CI -0.7; -0.4) after drug administration.

The review of eight RCTs of duloxetine administered for 3-12 weeks in patients with predominantly stress UI concluded that the drug failed to show better curative effects than placebo (Table 67). However, improvement rates and quality of life scores were better after active duloxetine compared to placebo. The long-term effects of pharmacological agents on UI are not clear. The effects on surrogates reported in many trials may not reflect patient outcomes. The comparative effectiveness of drugs compared to other conservative interventions remains unclear.

One multicenter RCT of 695 males 40 years or older with overactive bladder examined the effects of alpha 1 adrenoreceptor blocker tamsulosin for treatment of benign prostatic hyperplasia.[814] Men were treated with 0.4mg of tamsulosin, 4mg of tolterodine ER, both tolterodine ER plus tamsulosin, or placebo for 12 weeks. Urge incontinence rates were the same after tamsulosin (RR 1.1, 95 percent 0.8; 1.6), tolterodine (RR 1.1, 95 percent CI 0.8; 1.7), or the combinations of both drugs (RR 1.1, 95 percent CI 0.8; 1.6) compared to placebo.

Summary. Clenbuterol was more effective than a placebo in achieving continence in females with stress UI but not compared to pelvic floor muscle training. Extended release tolteradine for 2-12 weeks resulted in greater rates of cure or improvement compared to placebo in adults with overactive bladder syndrome. Duloxetin administered for 3-12 weeks in patients with predominantly stress UI improved UI, but the rates of continence did not differ from placebo. Long-term effects of medications combined with pelvic floor training on continence are unknown. Comparative effectiveness of combined treatments, including medication, requires future research.

O'Brien, 1991[43] N = 561 76% female 3 month followup	Four sessions of PFMT+BT supervised by non-specialist nurse	Usual care	182/378	7/183	48.15	3.83	**12.59 (6.04; 26.22)**	2 (1; 5)	443 (193; 965)E
Subak, 2002[278] N = 152 100% female 1.5 month followup	6 weekly 20-minute group instructional sessions on BT by nurse educators and followed individualized voiding schedules	Usual care	39/77	11/75	50.00	15.00	**3.41 (1.89; 6.15)**	3 (1; 7)	350 (134; 772)E
Lagro-Janssen, 1992[280] N = 106 100% female 3 month followup	PFMT alone (stress) or BT (urge) or its combination (mixed)	Usual care	40/54	2/56	74.00	3.00	**20.74 (5.27; 81.63)**	1 (0; 8)	710 (128; 2,419)E
McFall, 2000[241] N = 145 100% female 3 month followup	Community-based intervention: BT, managing the urge to urinate, and PFMT	Usual care	44/72	28/73	61.00	38.00	**1.59 (1.13; 2.25)**	4 (2; 20)	230 (49; 474)E
Fantl, 1991[281] N = 131 100% female 1.5 month followup	BT using 6 weekly visits included patient education; voiding schedule to have micturition from every 30-60 minutes to every 2.5-3 hours; and positive reinforcement.	Usual care	49/65	16/66	75.00	24.00	**3.11 (1.99; 4.87)**	2 (1; 4)	510 (237; 929)E
Burgio, 2002[283] N = 222 100% female 2 month followup	BFB+PFMT+ behavioral training implemented by nurse practitioners	Self-administered behavioral treatment using a self-help booklet to advice PFMT	33/73	20/75	45.21	26.67	**1.70 (1.08; 2.66)**	5 (2; 48)	185 (21; 444)E
	4 visits of		36/74	20/75	48.65	26.67	**1.82**	5	220

Table 48. Comparative effectiveness of behavioral interventions to improve UI in adults (continued)

Author Sample Followup	Active Treatment	Control Treatment	Number of Cases After Active Treatment/ Number Randomized	Number of Cases After Control Treatment/ Number Randomized	Rate (%) After Active Treatment	Rate (%) After Control Treatment	Relative Risk (95% CI)	Number Needed to Treat (95% CI)	Number of Attributable Events per 1,000 Treated (95% CI)
	behavioral training without BFB (verbal feedback based on vaginal palpation). PFMT with 10 second contractions and 10 second relation for 45 minutes/day	and bladder control					**(1.17; 2.84)**	(2; 22)	(46; 490)E
Hu, 1990[710] N = 143 100% female 3 month followup	Behavioral therapy program in nursing homes implemented by the project-trained NRAs.	Usual care	19/72	6/71	26.00	8.00	**3.12** **(1.32; 7.36)**	6 (2; 38)	180 (26; 509)E
Dorey, 2004[266] N = 55 0% female 3 month followup	PFMT including a strong post-void "squeeze out" pelvic floor muscle contraction, BFB, and suggestions for lifestyle changes.	Advice on lifestyle changes	14/28	1/27	50.00	3.70	**13.50** **(1.90; 95.71)**	2 (0; 30)	463 (33; 3,508)E
Burns, 1990[724] N = 128 100% female 6 month followup	Kegel PFMT 4 times/day	Usual care	21/38	0/40	54.00	0	**45.21** **(2.83; 720.96)**	2	539 E
Goode, 2003[268] N = 200 100% female 2 month followup	Behavioral training (BFB+PFMT, home exercises, bladder control strategies, and self-monitoring with bladder diaries)	Self-administered behavioral training administered with a self-help booklet	53/66	38/67	80.00	57.00	**1.42** **(1.11; 1.80)**	4 (2; 16)	230 (64; 457)E

Table 48. Comparative effectiveness of behavioral interventions to improve UI in adults (continued)

Author Sample Followup	Active Treatment	Control Treatment	Number of Cases After Active Treatment/ Number Randomized	Number of Cases After Control Treatment/ Number Randomized	Rate (%) After Active Treatment	Rate (%) After Control Treatment	Relative Risk (95% CI)	Number Needed to Treat (95% CI)	Number of Attributable Events per 1,000 Treated (95% CI)
Improvement in Urge UI									
Subak, 2005[714] N = 48 100% female 3 month followup	Weight reduction intervention	Delayed weight reduction intervention	17/24	3/24	70.00	11.00	**5.67** **(1.91; 16.84)**	2 (1; 10)	590 (100; 1,742)E
Goode, 2002[279] N = 70 100% female 2 month followup	Four sessions (over 8 weeks) of biofeedback-assisted behavioral training by nurse practitioners	Usual care	27/35	19/37	82.30	51.50	**1.59** **(1.12; 2.27)**	3 (2; 16)	308 (62; 652)E

* Sampling of continent adults at baseline, interventions to reduce the risk of incontinence
Bold - significant differences in outcomes at 95% confidence level; PFMT - pelvic floor muscle training, BFB - biofeedback; BT - bladder training; number needed to treat to benefit one patient for positive patient outcomes (continence and improvement) or to harm one patient for negative patient outcomes (incontinence); E - number of excessive events per 1,000 treated; A - number of avoided events per 1,000 treated.

Table 49. Comparative effectiveness of behavioral interventions on UI in adults

Author Sample Followup	Active Treatment	Control Treatment	Number of Cases After Active Treatment/ Number Randomized	Number of Cases After Control Treatment/ Number Randomized	Rate (%) After Active Treatment	Rate (%) After Control Treatment	Relative Risk (95% CI)	Number Needed to Treat (95% CI)	Number of Attributable Events/1,000 Treated (95% CI)
Outcome - Stress UI									
Brown, 2006[245]* N = 1,957 100% female 34.8 month followup Primary prevention	Intensive lifestyle therapy to lose and maintain at least 7% of initial body weight through a low-fat diet and to engage in moderate-intensity physical activity for at least 150 minutes each week	Placebo twice daily	206/659	242/660	31.30	36.70	**0.85 (0.73; 0.99)**	19 (10; 329)	54 (3; 98)A
Reilly, 2002[247]* N = 268 100% female 5 month followup Primary prevention	Supervised by physiotherapist PFMT 1/month before delivery	Verbal advice on PFMT	23/120	36/110	19.20	32.70	**0.59 (0.37; 0.92)**	7 (5; 40)	135 (25; 205 25)A
Bo, 2000[720] N = 59 100% female 6 month followup	PFMT with 8-12 maximum contractions in 3 series/day and 45 minute/week group sessions	Untreated control group	3/29	13/30	10.50	41.70	**0.24 (0.08; 0.75)**	3 (3; 10)	312 (385; 104)A
Outcome - Any UI									
Chiarelli, 2002[246]* N = 720 100% female 3 month followup Primary prevention	Training in PFMT and incorporated strategies to improve adherence	Usual postpartum care	115/370	134/350	31.00	38.40	**0.81 (0.66; 0.99)**	14 (8; 390)	74 (3; 129)A

Table 49. Comparative effectiveness of behavioral interventions on UI in adults (continued)

Author Sample Followup	Active Treatment	Control Treatment	Number of Cases After Active Treatment/ Number Randomized	Number of Cases After Control Treatment/ Number Randomized	Rate (%) After Active Treatment	Rate (%) After Control Treatment	Relative Risk (95% CI)	Number Needed to Treat (95% CI)	Number of Attributable Events/1,000 Treated (95% CI)
Filocamo, 2005[257]* N = 300 0% female 12 month followup Primary prevention	Early pelvic floor rehabilitation program with verbal explanations, Kegel PFMT: 3 sets of 10 contractions for 5 seconds and 10 seconds of muscular relaxation under digital BFB	No formal training Outcome: occasional leakage in International Continence Society (ICS) - male questionnaire	14/150	29/150	9.33	19.33	**0.48 (0.27; 0.88)**	10 (7; 42)	100 (142; 24)A
		Outcome ICS - male questionnaire: 2 pads/day	1/150	11/150	0.67	7.33	**0.09 (0.01; 0.70)**	15 (14; 45)	67 (22; 72)A
		Outcome: self-reported urinary incontinence	2/150	18/150	1.33	12.00	**0.11 (0.03; 0.47)**	9 (9; 16)	107 (64; 117)A
Porru, 2001[263]* N = 58 0% female 1 month followup Primary prevention	Verbal instruction, BFB+PFMT, and verbal reinforcement to teach selective contractions of anal sphincter muscles and relaxation of abdominal muscles 45 times/day	Standard care without instruction on PFMT	4/30	12/28	13.33	42.86	**0.31 (0.11; 0.85)**	3 (3; 16)	295 (63; 380)A

* Sampling of continent adults at baseline; Bold - significant differences in outcomes at 95% confidence level; PFMT - pelvic floor muscle training, BFB - biofeedback; BT - bladder training; A - number of avoided events per 1,000 treated; number needed to treat to benefit one patient for positive patient outcomes (continence and improvement) or to harm one patient for negative patient outcomes (incontinence)

Table 50. Comparative effectiveness of behavioral interventions on severity of UI in adults

Author Sample Followup	Active Treatment	Control Treatment	Number of Cases After Active Treatment/ Number Randomized	Number of Cases After Control Treatment Number Randomized	Rate (%) After Active Treatment	Rate (%) After Control Treatment	Relative Risk (95% CI)	Number Needed to Treat (95% CI)	Number of Attributable Events/1,000 Treated (95% CI)
Outcomes - Severity of Stress UI									
Bo, 2000[720] N = 59 100% female 6 month followup	PFMT with 8-12 maximum contractions in 3 series/day and 45 minutes/week group sessions	Untreated control group. Outcome: problems with interference with social life	1/29	12/30	3.70	40.70	**0.09 (0.01; 0.62)**	3 (2; 6)	370 (154;402)A
		Outcome: problem with interference with physical activity	13/29	24/30	43.50	79.30	**0.56 (0.36; 0.87)**	3 (2; 10)	358 (507; 102)A
Outcomes -Severity of Any UI									
Lagro-Janssen, 1992[280] N = 106 100% female 3 month followup	PFMT alone (stress) or BT (urge) or its combination (mixed)	Usual care Outcome-severe UI	4/54	23/56	7.41	41.07	**0.18 (0.07; 0.49)**	3 (3; 5)	337 (211; 383)A
McFall, 2000[291] N = 145 100% female 3 month followup	Community-based intervention: BT, managing the urge to urinate, and PFMT	Usual care. Outcome: self-reported bothersomeness of UI	42/72	62/73	58.90	85.20	**0.69 (0.55; 0.85)**	4 (3; 8)	263 (124; 381)A
		Outcome: use absorbent pads for UI	39/72	56/73	54.00	77.00	**0.71 (0.55; 0.90)**	4 (3; 14)	230 (74; 345)A
Fantl, 1991[281] N = 131 100% female 1.5 month followup	BT (6 weekly visits) included patient education; voiding schedule and positive reinforcement	Usual care Outcome: increase in episodes of UI	5/65	28/66	8.00	43.00	**0.18 (0.07; 0.44)**	3 (3; 4)	350 (241; 398)A

Table 50. Comparative effectiveness of behavioral interventions on severity of UI in adults (continued)

Author Sample Followup	Active Treatment	Control Treatment	Number of Cases After Active Treatment/ Number Randomized	Number of Cases After Control Treatment Number Randomized	Rate (%) After Active Treatment	Rate (%) After Control Treatment	Relative Risk (95% CI)	Number Needed to Treat (95% CI)	Number of Attributable Events/1,000 Treated (95% CI)
Chiarelli, 2002[246]* N = 720 100% female 3 month followup	Training in PFMT and incorporated strategies to improve adherence	Usual postpartum care outcome: severe mixed UI	37/370	59/350	10.10	16.80	**0.59 (0.40; 0.87)**	15 (10; 46)	67 (22; 100)A

* Sampling of continent adults at baseline; Bold - significant differences in outcomes at 95% confidence level; PFMT - pelvic floor muscle training, BFB - biofeedback; BT - bladder training; A - number of avoided events per 1,000 treated; number needed to treat to benefit one patient for positive patient outcomes (continence and improvement) or to harm one patient for negative patient outcomes (incontinence)

Table 51. Comparative effectiveness of electrical stimulation or neuromodulation on UI in adults

Author Sample Followup	Active Treatment	Control Treatment	Number of Cases After Active Treatment/ Number Randomized	Number of Cases After Control Treatment/ Number Randomized	Rate (%) After Active Treatment	Rate (%) After Control Treatment	Relative Risk (95% CI)	Number Needed to Treat (95% CI)	Number of Attributable Events/1,000 Treated (95% CI)
Urge specific Continence									
But, 2003[298] N = 52 100% female 2 month followup	Functional magnetic stimulation with Pulsegen device, which produced a pulsating magnetic field of B = 10 microT intensity and a frequency of 10Hz	Placebo treatment with sham not active device. Outcome: success of treatment	24/30	5/22	79.00	22.00	**3.52** **(1.60; 7.76)**	2 (1; 8)	570 (131; 1,488)E
		Outcome: Cured from urge UI	12/30	0/22	40.00	0	**18.55** **(1.16; 297.42)**	3	390 E
Schmidt, 1999[305] N = 98 81% female 5 month followup	Neuromodulation Therapy: Implantation of multiprogrammable neurostimulator subcutaneously in lower quadrant of the abdomen with lead positioned to target sacral nerve and anchored in place.	Standard medical therapy Outcome: cured from urge UI	24/52	0/46	47.00	0	**43.45** **(2.72; 695.03)**	2	460E
Weil, 2000[306] N = 44 91% female 36 month followup	Neuromodulation Therapy: Sacral root neuromodulation with an implantable impulse generator	Prior conservative management: medications or PFMT Outcome: cured from urge UI	9/21	1/23	42.86	4.35	**9.86** **(1.36; 71.36)**	3 (0; 64)	385 (16; 3,059)E

Table 51. Comparative effectiveness of electrical stimulation on UI in adults (continued)

Author Sample Followup	Active Treatment	Control Treatment	Number of Cases After Active Treatment/ Number Randomized	Number of Cases After Control Treatment/ Number Randomized	Rate (%) After Active Treatment	Rate (%) After Control Treatment	Relative Risk (95% CI)	Number Needed to Treat (95% CI)	Number of Attributable Events/1,000 Treated (95% CI)
Improvement in Stress UI									
Fujishiro, 2000[296] N = 62 100% female 1 week followup	Neuromodulation Therapy: Magnetic stimulation of sacral roots with 15Hz frequency, 50% intensity output for 5 seconds per minute for 30 minutes	Sham stimulation with inactive device Outcome: improved stress UI	23/31	10/31	74.00	32.00	**2.30 (1.33; 3.99)**	2 (1; 10)	420 (57;104)E
Improvement in UI									
Brubaker, 1997[302] N = 148 100% female 2 month followup	Transvaginal electric stimulation for 20 minutes 2 times/day using frequency of 20Hz, a 2-second - 4-second work-rest cycle with a range of stimulation intensities, from 0 to 100mA	Sham inactive device Outcome: improved UI	21/61	10/60	35.00	17.00	**2.14 (1.10; 4.14)**	6 (2; 59)	180 (17; 535)E
Borawski, 2007[303] N = 30 100% female 2 week followup	Neuromodulation Therapy: Electrical stimulation with percutaneous needle electrode (22-G spinal needle) placement	Electrical stimulation with surgical first stage lead placement: >50% improvement in 24 hour pad weight	4/13	13/17	30.77	76.47	**0.40 (0.17; 0.95)**	2 (2; 25)	457 (40; 634)A
		>50% Improvement in 24 hour pad usage	2/13	11/17	15.38	64.71	**0.24 (0.06; 0.89)**	2 (2; 14)	493 (70; 606)A
		>50% Improvement in daily incontinence episodes	1/13	14/17	7.69	82.35	**0.09 (0.01; 0.62)**	1 (1; 3)	747 (311; 812)A

Table 51. Comparative effectiveness of electrical stimulation on UI in adults (continued)

Author Sample Followup	Active Treatment	Control Treatment	Number of Cases After Active Treatment/ Number Randomized	Number of Cases After Control Treatment/ Number Randomized	Rate (%) After Active Treatment	Rate (%) After Control Treatment	Relative Risk (95% CI)	Number Needed to Treat (95% CI)	Number of Attributable Events/1,000 Treated (95% CI)
Improvement in Urge UI									
But, 2003[298] N = 52 100% female 2 month followup	Functional magnetic stimulation with Pulsegen device, which produced a pulsating magnetic field of B = 10 microT intensity and a frequency of 10Hz	Placebo treatment with sham not active device. Outcome- Less abdominal pain related to urge UI	11/30	1/22	36.70	5.00	**8.07 (1.12; 57.95)**	3 (0; 163)	317 (6; 2,847)E
Schmidt, 1999[305] N = 98 81% female 5 month followup	Neuromodulation Therapy: Implantation of multiprogrammable neurostimulator subcutaneously in lower quadrant of the abdomen with lead positioned to target sacral nerve and anchored in place	Standard medical therapy. Improvement in severity: heavy urge incontinence at baseline and none at 5 months	40/52	4/46	77.00	8.00	**8.85 (3.43; 22.83)**	1 (1; 5)	690 (194; 1,747)E
		Significant reduction in daily urge UI episodes (>50%)	15/52	2/46	29.00	5.00	**6.63 (1.60; 27.48)**	4 (1; 33)	240 (30; 1,324)E
		No need of absorbent pads or diapers for urge UI	26/52	1/46	50.00	2.00	**23.00 (3.25; 162.88)**	2 (0; 22)	480 (45; 3,238)E

Bold - significant differences in outcomes at 95% confidence level; number needed to treat to benefit one patient for positive patient outcomes (continence and improvement) or to harm one patient for negative patient outcomes (incontinence); A - number of avoided and E - number of excessive events per 1,000 treated.

Table 52. Comparative effectiveness of electrical stimulation on any UI in adults

Author Sample Followup	Active Treatment	Control Treatment	Number of Cases After Active Treatment/ Number Analyzed	Number of Cases After Control Treatment/ Number Analyzed	Rate (%) After Active Treatment	Rate (%) After Control Treatment	Relative Risk (95% CI)	Number Needed to Treat (95% CI)	Number of Attributable Events/1,000 Treated (95% CI)
Outcome - UI									
Spruijt, 2003[735] N = 51 100% female 2 month followup	Intravaginal electrical stimulation of the pelvic floor using stimulator generated biphasic current pulses with a duration of 1ms and a frequency of 50Hz (stress) or 20Hz (urge)	Kegel PFMT with verbal instructions on how to exercise at home	6/25	7/12	25.00	54.50	**0.41 (0.18; 0.96)**	3 (2; 44)	295 (23; 449)A
Progression of UI									
Indrekvam, 2001 N = 3,008 100% female 3 month followup	Home-managed electrical stimulation with vaginal/anal stimulators (20-50Hz)	Baseline data. Outcome: substantial amounts of usual leakage	331/3008	451/3008	11.00	15.00	**0.73 (0.64; 0.84)**	25 (19; 41)	40 (24; 54)A
		Pad use >5 during 24 hours	391	632	13.00	21.00	**0.62 (0.55; 0.69)**	13 (11; 16)	80 (64; 94)A

Bold - significant differences in outcomes at 95% confidence level; PFMT - pelvic floor muscle training; A - number of avoided events per 1,000 treated

Table 53. Comparative effectiveness of bulking agents on UI in females

Author Sample Followup	Active Treatment	Control Treatment	Number of Cases After Active Treatment/ Number Randomized	Number of Cases After Control Treatment/ Number Randomized	Rate (%) After Active Treatment	Rate (%) After Control Treatment	Relative Risk (95% CI)	Number Needed to Treat (95% CI)	Number of Attributable Events/1,000 treated (95% CI)
Outcome - Urgency									
Lightner2001[749] N = 355 100% female 12 month followup	Injection of bulking agent 1.0ml durasphere maximum 5 times with a minimum 7 day interval	Injection of bulking agent bovine collagen maximum 5 times with a minimum 7 day interval	43/176	22/188	24.70	11.90	**2.09 (1.30; 3.34)**	8 (4; 28)	128 (36; 279)E
Outcome - Complete Retention									
Corcos, 2005[307] N = 133 100% female 12 month followup	Intraurethral collagen sub mucosal injection	Surgery (needle bladder neck suspensions, Burch, and slings)	1/66	9/67	1.52	13.43	**0.11 (0.01; 0.87)**	8 (8; 55)	119 (18; 132)A

Bold - significant differences in outcomes at 95% confidence level; number needed to treat to benefit one patient for positive patient outcomes (continence and improvement) or to harm one patient for negative patient outcomes (incontinence); E - number of excessive events per 1,000 treated; A - number of avoided events per 1,000 treated

.

Table 54. Effects of surgical interventions on urinary continence in females (secondary prevention) (sorted by rate of urinary continence after active treatment, from highest to lowest)

Author Sample Followup	Active	Control	Definition of Continence	Number of Cases After Active Treatment/ Number Randomized	Number of Cases After Control Treatment/ Number Randomized	Rate (%) After Active Treatment	Rate (%) After Control Treatment	Relative Risk (95% CI)	Number Needed to Treat (95% CI)	Number of Attributable Events/1,000 Treated (95% CI)
Colombo, 1996[348] N = 36 6 month followup	Burch colposuspension with placement of two couples of permanent polybutylate-coated polyester sutures	Abdominal paravaginal defect repair with 5-7 pairs of permanent braided silicone-coated polyester suture.	Cure as no incontinence episodes and no urine loss at stress test	18/18	13/18	100.0	72.2	1.4 (1.0; 1.8)		
Laurikainen, 2007[491] N = 273 2 month followup	Retropubic tension-free vaginal polypropylene tape procedure by Ulmsten	Transobturator tension-free vaginal polypropylene tape procedure by de Leval	Objective cure as negative stress test	134/136	125/132	98.5	94.7	1.0 (1.0; 1.1)		
Kammerer-Doak, 1999[353] N = 35 12 month followup	Burch retropubic urethropexy	Modified anterior colporrhaphy	Subjective cure as no self-reported urinary incontinence	18/19	3/16	94.7	18.8	**5.1 (1.8; 14.1)**	1 (0; 7)	760 (152; 2,454)E
Sand, 2000[358] N = 36 3 month followup	Burch procedures with four 2-0 polytetrafluoroethylene sutures and tension placed on the periurethral sutures (modified Tanagho method)	Suburethral sling with continuous polytetraflouroethylene strip from rectus fascia into retropubic space and beneath urethra at urethrovesical junction level	Subjective cure	18/19	17/17	94.7	100.0	1.0 (0.8; 1.1)	.	

Table 54. Effects of surgical interventions on urinary continence in females (secondary prevention) (table is sorted by rate of urinary continence after active treatment, from highest to lowest) (continued)

Author Sample Followup	Active	Control	Definition of Continence	Number of Cases After Active Treatment/ Number Randomized	Number of Cases After Control Treatment/ Number Randomized	Rate (%) After Active Treatment	Rate (%) After Control Treatment	Relative Risk (95% CI)	Number Needed to Treat (95% CI)	Number of Attributable Events/1,000 Treated (95% CI)
Zullo, 2001[361] N = 60 12 month followup	Transperitoneal laparoscopic Burch procedure using nonabsorbable sutures	Transperitoneal laparoscopic Burch procedure using Prolene mesh fixed with tacks or staples	Subjective cure (visual analog scale)	28/30	26/30	93.3	86.7	1.1 (0.9; 1.3)		
Schraffordt Koops, 2006[757] N = 809 2-36 month followup	Previous surgery for prolapse/ incontinence +TVT performed with Ulmsten's method	No prior surgery + TVT performed with Ulmsten's method.	Cured - no leakage during physical activity, coughing or sneezing	122/131	628/378	92.9	92.6	1.0 (1.0; 1.1)

Effects of Clinical Interventions on FI

Baseline mechanisms of FI comprise loss of structural and functional integrity of pudendal nerve activity, of pelvic floor muscles, of rectal compliance and of the anal sphincter and loss of rectal sensation.[17,20,23,24] Disposition of the rectum into the anus (rectal prolapse) or protrusion of the rectum through the vagina (rectocele) also can result in FI. Clinical types of FI include urge incontinence (discharge of feces despite active attempts to retain bowel contents), passive incontinence (involuntary discharge of stool or flatus without awareness), and fecal seepage (leakage of small amount of stool without awareness or staining of undergarments following an otherwise normal evacuation). The aim of effective clinical intervention is to restore the structure and function of these mechanisms, improve the strength and coordination between the pelvic floor and the anal sphincter muscles during voluntary squeeze and following rectal perception, enhance anorectal sensory perception and control, regulate pudendal nerve activity, and provide normal anatomical positioning of the rectum.

Clinical Interventions to Reduce Progression of FI in Adults in Nursing Homes and LTC Settings

Conservative management of FI in nursing homes. Consistent benefits of combined nurse led interventions on the severity of incontinence were reported in three RCTs that examined the effects of conservative management of FI in nursing homes (Appendix Table F151).[233-235] The largest improvement (10 percent increase in appropriate toileting) was achieved after prompted voiding treatment, including checks for incontinence, offering toileting assistance, prompted voiding, and social reinforcement of appropriate toileting (Appendix Table F152).[233] The percentage of incontinent wet checks among total checks by nurses was reduced by 3 percent.[233] Integrated incontinence care and frequent exercises showed a significant reduction of 6 percent in the proportion of wet episodes.[235] Functional incidental training that included prompted voiding combined with individualized endurance and strength-training exercises reduced the number of wet stool checks among total checks by 1.2 percent.[234]

Pharmacological interventions on FI in LTC settings. One RCT examined the effects of laxative agents in elderly patients with FI associated with chronic fecal impaction (Appendix Table F151).[817] The number of FI episodes per patient day did not differ when an osmotic agent with a rectal stimulant and weekly tap-water enemas were compared to single osmotic laxative (Appendix Table F153).[817]

Evidence-based conservative management of FI included the assessment of patient history and rectal examination, patient education on regular toilet habits, pelvic floor and sphincter-strengthening exercises, and individualized doses of laxatives.[509] Implementation of this program did not reduce the frequency of self-reported fecal episodes (Appendix Table F154) and did not improve quality of life (Appendix Table 155) in stroke patients with constipation and FI (Appendix Tables F156 and F157).

Summary. In conclusion, very few well-designed RCTs examined the clinical interventions on FI in nursing homes and LTC settings. A small improvement in severity of FI was reported after integrated care in nursing homes that included prompted toileting and exercise. The effects of conservative management of FI in subgroups by gender, race, and ethnicity remain unknown. Clinical interventions that can reduce the risk of incidence and progression of FI in LTC settings have not beet tested in RCTs.

Dietary Interventions on FI in Community Dwelling Adults

One small placebo-controlled RCT examined the effects of fiber supplements on FI. A usual diet supplemented with 7.1g of soluble fiber psyllium reduced the rate of incontinent stools to 17 percent compared to 50 percent after placebo treatments, but the relative risk was not significant (RR 0.3, 95 percent CI 0.1; 1.2) (Appendix Table F158).[371]

Supplementation with 25g of gum Arabic increased stool weight by 3 percent compared to placebo with no difference in water content and holding capacity (Appendix Table F159). The effects of dietary fiber on FI need future investigation in a large clinical trial.

Effects of Conservative Management of Postnatal FI in Females

In an RCT of 747 women with postnatal UI (Appendix Table F151)[251,252] intensive pelvic floor muscle training reinforced by visiting nurses within 9 months after delivery significantly reduced the rate of any FI to 4.4 percent compared to 10.5 percent after standard care (RR 0.5, 95 percent CI 0.3; 1.0) at 1 year but not 6 years of followup (Appendix Table F159 and F160). However, severe FI did not differ between groups either at 1 or at 6 years.

Summary. The effects of behavioral changes supervised by health care providers that would provide long-term protection from postnatal FI require further investigation.

Behavioral Interventions on FI in Females

Self-administered behavioral interventions in females were examined in three RCTs.[250,372,511]

Patient outcomes.

Continence. Sensory biofeedback training with a vaginal perineometer and standard Kegel pelvic floor muscle training produced continence twice as often in women with FI after obstetric and sphincter trauma as augmented biofeedback pelvic floor muscle training with audiovisual feedback and electric stimulation (RR 2.0, 95 percent CI 1.1; 3.9) (Appendix Table F161).[372] We estimated that 382 cases of FI would be prevented per 1,000 women with FI after obstetric and sphincter trauma treated with augmented biofeedback and electrostimulation (95 percent CI 27; 1,055). Pelvic floor muscle training with visual and verbal biofeedback therapy using a radial catheter with a latex balloon cured no more women with frequent idiopathic FI than pelvic floor muscle training (Appendix Table F162).[511]

FI. In an RCT of 493 pregnant women with and 1,034 women without previous vaginal birth, self-administered perineal massage during pregnancy until delivery did not improve postnatal FI at 3 months postpartum (Appendix Table F163).[250]

Surrogate outcome - O*bjectively measured mean maximum resting pressure* was increased by 5 percent and squeeze pressure by 3 percent compared to the control intervention (Appendix Table F164).[372]

Effects of Behavioral Interventions on FI in Community Dwelling Adults

The effects of behavioral interventions on FI in Community dwelling adults (secondary prevention) were examined in six RCTs[373-376,502,818] and one nonrandomized controlled trial[501] (Appendix Table F151).

Patient outcomes.

Continence. Continence was reported in one large RCT of 171 patients with FI of different causes.[376] Bowel training with instructions on sphincter exercises with and without biofeedback was no better than standard care (Appendix Table F165).

Improvement of FI. A nonrandomized controlled clinical trial examined the effects of telephone-assisted biofeedback treatment for patients with refractory FI living in rural areas.[501] Improvement in self-reported Pascatori and St Mark scores and in anal manometry outcomes was not greater compared to the standard face-to-face protocol (Appendix Table F166).Rates of improvement in FI (45 to 55 percent) were the same after hospital-based computer-assisted sphincter pressure biofeedback with and without electrostimulation, as well as after receiving advice on diet, fluid intake, and bowel training (Appendix Table F167).[376] Education and biofeedback therapy using a radial catheter resulted in nonsignificant improvement in FI in 50 percent of patients with idiopathic FI.[511] Standard care combined with pelvic floor muscle training improved symptoms of FI in 45 percent of the patients.[511] Pelvic floor muscle training with manometry and ultrasound improved FI in 43 percent of the patients.[501]

In conclusion, a few tested behavioral interventions cured 5 to 10 percent and improved FI in more than 40 percent of the patients but with no statistically significant differences compared to standard care.

FI. The effects of behavioral clinical interventions were examined on self-reported frequency of incontinent episodes and severity scores as well as on objective instrumental outcomes (Appendix Table F168). Progression of FI was three times more frequent after telephone-assisted biofeedback compared to individualized biofeedback.[501]

Surrogate outcome - S*ubjectively measure severity of FI and quality of life with FI.*

Hospital-based training and biofeedback services combined with sphincter exercises and electromyelogram biofeedback devices significantly reduced the number of fecal accidents per week by 47 percent.[376] The same intervention without the device reduced fecal episodes by 52 percent.[376] In a small crossover RCT of 23 patients with idiopathic FI associated with abnormal perineal descent and frequent irritable bowel syndrome, pelvic floor muscle training with active sensory retraining reduced FI episodes by 37 percent compared to exercises with no instructions.[373] One RCT reported a significant reduction in weekly pad use for FI by 78 percent after hospital biofeedback in combination with an electromyelogram device, by 61 percent after hospital-based computer-assisted sphincter pressure biofeedback, and by 89 percent after lifestyle changes and sphincter exercises.[376]

Behavioral interventions did not improve total FI scores in the majority of the trials.[375,376,502,818] Only one RCT reported a small significant improvement in St Mark FI scores by 9 percent.[375] One RCT showed significant improvement in quality of life after pelvic floor muscle training and biofeedback compared to baseline levels by 4 percent in Pescatori scores of family and relationship and by 16 percent in Pescatori scores of travel restriction.[374]

Summary. In conclusion, four RCTs of behavioral treatments of FI reported small (<40 percent) improvement in severity and quality of life (Appendix Table F169).[372-375] Limited

evidence suggested a significant reduction in FI after complex behavioral interventions, including lifestyle changes and exercises augmented with biofeedback (Appendix Table F170).[376]

Effects of Electrical Stimulation and Neuromodulation on FI

Several RCTs examined the effects of electrical stimulation or neuromodulation on FI (Appendix Table F151).[377,819-821]

Patient outcomes.

Continence. Active anal stimulation did not produce better cure (Appendix Table F171), significant, or small improvement in FI compared to sham stimulation (Appendix Table F172).[819]

Improvement. Individualized sacral nerve continuous stimulation improved FI in 89 percent of patients with severe baseline FI compared to 17 percent after sham stimulation.[377] We estimated that 720 additional patients among 1,000 treated would experience an improvement in symptoms of FI after individualized sacral nerve stimulation.

Surrogate outcomes.

Subjective measures of quality of life. However, the treatments did not improve quality of life with random differences after active and sham stimulation (Appendix Table F173). Electrical stimulation of the anal sphincter in addition to intra-anal EMG biofeedback did not change FI compared to standard training of the pelvic floor.[821] Active stimulation therapy using an anal plug with a pulse generator did not improve patient satisfaction with bowel habits of the incomplete evacuation score.[820]

Objective measures of severity of FI. All RCTs reported small inconsistent differences in anal manometry outcomes after active stimulation compared to the control (Appendix Table F174).

Summary. In conclusion, electrical stimulation did not improve FI in the majority of the RCTs. The significant relative improvement after sacral nerve stimulation in patients with severe baseline FI requires future confirmation in a large well designed RCT with long-term followup.

Effects of Massage on FI

One RCT did not show significant differences in risk of FI 3 months postpartum from massage and stretching of the perineum during the second stage of labor with a water soluble lubricant.[514]

Effects of Pharmacological Agents on FI in Community Dwelling Adults

Pharmacological agents on FI in community dwelling adults were examined in 12 RCTs (Appendix Table F151).[378-380,403-405,822-827]

Botulinum toxin.

Outcome - FI. Four RCTs examined the effects of botulinum toxin in patients with constipation and symptoms of outlet obstruction.[380,822,826,827] The incidence of FI was not significantly higher after Botox compared to lateral internal anal sphincterotomy.[380] All patients were continent after local injection of Botox to the each side of the puborectalis or to the posterior aspect of this muscle (Appendix Table F175).[822]

Surrogate outcome - Subjective measures of severity of FI. Self-reported modified Wexner Fecal Continence scores[826] were not improved after Botox administration (Appendix Table F176).

Surrogate outcome - Objective measure of severity of FI. Anal manometry outcomes[827] were not improved after Botox administration (Appendix Table F176).

Loperamide.

Two RCTs examined the effects of loperamide in patients after restorative proctocolectomy for ulcerative colitis[378] and in patients with chronic diarrhea and FI.[823]

Surrogate outcome - Subjective measure of severity of UI. Neither treatment resulted in better outcomes. Frequency of FI episodes and use of pads at night were the same after loperamide or placebo (Appendix Table F177).[378] Loperamide reduced fecal urgency in patients with chronic diarrhea and FI (mean difference -1.0, 95 percent CI -1.9; -0.1)[823]

Surrogate outcome - Objective measures of severity of FI. Loperamide in patients after restorative proctocolectomy for ulcerative colitis[378] and in patients with chronic diarrhea and FI[823] did not improve anal manometry outcomes[378,823] (Appendix Table F176).

Synthesizing the evidence from all available clinical trials, few interventions[378-380] resulted in fecal continence in more than 50 percent of patients but were not statistically better than placebo[378,379]or surgery[380] (Appendix Tables F178-F180). Chemical sphincterotomy with isosorbide-5-mononitrate,[404] glycerine trinitrate, and Botox resulted in 100 percent continence rate.[405] Chemical sphincterotomy with phenylephrine demonstrated significant efficacy compared to placebo.[824] Reproducibility of the significant effects of chemical sphincterotomy using different agents should be confirmed in the large RCTs.

Effects of Chemical Sphincterotomy

Three RCTs analyzed the effects of chemical sphincterotomy (primary prevention) in patients with chronic anal fissure.[403-405]

Patient outcomes - C*ontinence*. All patients were continent after rectal administration of isosorbide-5-mononitrate[404] and after glycerine trinitrate ointment[405] (Appendix Table F177). Healing of anal fissures was observed four times more often after isosorbide-5-mononitrate compared to placebo (RR 4, 95 percent CI 1; 13).[404] We estimated that rectal administration of isosorbide-5-mononitrate would result in 580 healed patients among 1,000 treated.

Surrogate outcome - S*ubjective and objective measures of severity of FI*. Chemical sphincterotomy with oral nifedipine[403] or rectal administration of isosorbide-5-mononitrate[404] did not result in consistent improvement in the Wexner scores and anal manometry outcomes (Appendix Table F176).

Effects of Alpha-Adrenergic Agonist on FI

Patient outcome - *Improvement in FI.* Topical 10 percent phenylephrine, alpha-adrenergic agonist increasing anal sphincter pressure, applied to the anus improved FI symptoms three times more often than placebo in patients with dysfunctional anal sphincter (RR 3, 95 percent CI 1; 13).[824]

Surrogate outcome - *Subjective measures of severity of FI.* Anal administration of phenylephrine significantly improved FI scores and FI symptom scores[503] but not the Wexner scale scores[824] (Appendix Table F176).

Effects of Nonabsorbable Basic Aluminum Salt on Late Rectal Injury Related to Radiotherapy

Patient outcome - *FI.* Oral sucralfate did not prevent FI in prostate cancer patients treated with radiotherapy at a 3 month followup.[379]

Effects of Medical Bowel Confinement on FI

Patient outcome - *Improvement in FI.* Medical bowel confinement and regular diet did not improve FI after anorectal reconstructive surgery at 13 months of followup.[825]

Summary. Synthesizing the evidence from all available clinical trials, a few interventions[378-380] resulted in fecal continence in more than 50 percent of patients but were not statistically better than placebo[378,379] or surgery[380] (Appendix Tables F158 and F159s). Chemical sphincterotomy with isosorbide-5-mononitrate,[404] glycerine trinitrate, and Botox resulted in 100 percent continence rate.[405] Administration of phenylephrine to improve sphincter function in patients with FI after ileoanal pouch construction demonstrated significant efficacy compared to placebo.[824] Reproducibility of the significant effects of chemical sphincterotomy using different agents should be confirmed in the large RCTs.

Effects of Different Techniques to Repair External Anal Sphincter after Acute Obstetric Trauma

Four RCTs compared end-to-end technique to overlapping repair of obstetric anal sphincter lacerations (Appendix Table F151).[381-384]

Patient outcome - *FI.* Defects of internal or external sphincter did not differ after two techniques (Appendix Table F181).[383] The rates of self-reported fecal and flatus incontinence were the same after both interventions.[382] Only one RCT reported a significant reduction in fecal urgency at 6 and 12 months postpartum after end-to-end technique compared to overlapping repair.[381] We estimated that 250 per 1,000 treated women would not experience fecal urgency at 6 months and 283 at 12 months postpartum.

Surrogate outcome - *Subjective and objective measures of FI.* Self-reported symptoms of FI and anal manometry were comparable after overlap or end-to-end anal sphincter repair (Appendix Tables F182 and F183).[828] FI scores and instrumental outcomes did not differ after two interventions (Appendix Table F184).[383,384]

Effects of Clinical Interventions to Prevent FI after Delivery

The effects of episiotomy were examined in two RCTs,[386,387] the effects of Cesarean or vaginal delivery were compared in two RCTs,[388,389] the effects of delayed or immediate pushing in the second stage of labor with epidural analgesia in one RCT,[390] and the effects of delivery by forceps or vacuum extractor in three RCTs[391-393] (Appendix Table F151).

Patient outcome - *FI.* Self-reported FI 18 months postpartum was the same after restrictive or liberal episiotomy.[386] The same proportion of women after mediolateral episiotomy or vaginal birth experienced FI (Appendix Table F185).[387]

Cesarean vs. vaginal delivery resulted in the same rates of fecal and flatus incontinence at 3 months and 2 years postpartum.[388,389] However, only 43 percent of women randomized to vaginal delivery underwent Cesarean section.

Delayed or immediate pushing in the second stage of labor with epidural analgesia demonstrated the same rates of FI and sphincter defects in ultrasound at 3 months postpartum.[390]

Delivery with a vacuum extractor tended to increase the risk of anal (RR 3.5, 95 percent CI 1.0; 12.2) [393] or FI (RR 1.8) [391] compared to forceps delivery with borderline significance of the differences (Appendix Table F185).

Surrogate outcome - *Subjective and objective measures of FI*. Self-reported FI scores and instrumental outcomes did not differ after all tested treatments.(Appendix Table F186)

Summary. No evidence suggested that Cesarean section or instrumental delivery can prevent FI postpartum compared to vaginal delivery.

Effects of Early Ultrasound Diagnosis of Anal Obstetric Trauma

Clinical and ultrasound examination of the anal sphincter to diagnose tears followed by immediate surgical repair were examined in one well-designed RCT of 752 nulliparous women with second-degree perineal tear (Appendix Table F187).[385]

Patient outcomes - *FI.* Self-reported FI and fecal urgency at 3 months and 1 year of followup did not differ among women who underwent ultrasound examinations compared to clinical examinations alone. Severe FI was reduced by 60 percent after ultrasound examination at 3 months (RR 0.4, 95 percent CI 0.2; 0.7) with no differences at 1 year of followup.

In conclusion, effective clinical interventions to reduce the risk of FI related to obstetric trauma are not well known and require future investigation.

Effects of Surgical Interventions on FI in Females with Rectal Prolapse

The effects of surgical procedures on FI in women with full-thickness rectal prolapse were evaluated in two small and underpowered RCTs.[413,414] Abdominal resection rectopexy was compared to perineal rectosigmoidectomy and pelvic floor repair in 20 elderly female patients with FI who were followed up for 17 months.[413]

Patient outcome - *Continence*. Both treatments resulted in continence rate of 40 percent (Appendix Table F188). Marlex mesh posterior rectopexy alone cured 56 percent and sigmoidectomy combined with a sutured posterior rectopexy cured 46 percent of 29 women with full-thickness rectal prolapse with no significant differences between treatments.[414]

Effects of Surgical Interventions on Females with FI

The effects of surgical interventions on neuropathic FI in community dwelling women were examined in several RCTs.[428,829-831]

Patient outcome - *Continence*. Gluteus maximus transposition failed to cure 33 percent and total pelvic floor postanal repair with anterior levatoroplasty failed to cure 42 percent of women with post obstetric FI (Appendix Table F189).[428] Total pelvic floor repair cured 75 percent, postanal repair cured 33 percent, and anterior levatoroplasty and sphincter plication cured 33 percent of 36 women 28-75 years with neuropathic FI with no statistically significant differences

between groups.[829] Adjuvant biofeedback following anal sphincter repair and anterior overlapping sphincter repair cured <6 percent of 38 females with persistent FI and external anal sphincter defect with no statistically significant differences between groups.[830]

Surrogate outcome - *Subjective and objective measures of severity of FI.* Self-reported FI scores, patient satisfaction, and quality of life were comparable after the tested interventions (Appendix Table F190).[385,428] Surgeries resulted in random differences in instrumental outcomes inconsistent in the direction and effect size (Appendix Table F191). Small changes in maximum resting pressure were observed after adjuvant internal anal sphincter plication in pelvic floor repair compared to pelvic floor repair alone in 33 women with severe neuropathic FI related to vaginal delivery.[831]

Patient outcome - *FI.* FI did not differ at 12 months after total abdominal or subtotal abdominal hysterectomy in a well-designed RCT of 279 women with benign uterine diseases.[754]

Summary. Overall, limited evidence from small RCTs suggested that surgical procedures result in comparable risk of FI and quality of life. The effect size varied depending on the definition of FI and baseline cause and severity of FI. The effectiveness of the interventions in the subgroups of different age and severity categories require future investigation.

Effects of Clinical Interventions in Men with Prostate Diseases on the Risk of FI

Patient outcomes.

Continence. The effects of radiotherapy on FI in men with prostate diseases were examined in three RCTs (Appendix Table F151).[780,788,790] Both regimes of radiation resulted in more than an 80 percent continence rate.[780]

FI. Three-dimensional conformal radiotherapy with a dose of 68Gy reduced rates of FI with frequent pad use in 7 percent compared to 12 percent after a dose of radiation of 78Gy at 4 years (RR 0.5, 95 percent CI 0.3; 0.9) but not at 5 years of followup (Appendix Table F192).[788] Patients with prostate cancer reported the same use of sanitary shields for stool leakage after radiotherapy or active surveillance.[790]

Surrogate outcome - *Subjective measure of severity of FI*. Self-reported stool leakage tended to be greater after radiotherapy compared to active surveillance (Appendix Table F193).[790]

Effects of Bowel Management on FI in Patients with Spinal Cord Injury

Surrogate outcomes - *Subjective measures of severity of FI.* Transanal irrigation showed a small positive effect compared to conservative bowel management in 87 patients after spinal cord injury and symptoms of neurogenic bowel dysfunction (Appendix Table F194).[832] Neurogenic bowel dysfunction scores were reduced by 3 percent, St Mark's FI scores by 7 percent, and Cleveland Clinic constipation scores by 6 percent. The other incontinence outcomes, including the American Society of Colon and Rectal Surgeons FI scores, influence of FI on daily activities, and the number of episodes of clothes change, however, showed no differences (Appendix Table F194).

Effects of Different Techniques of Hemorrhoidectomy on FI

The effects of hemorrhoidectomy on FI in adults were examined in nine RCTs (Appendix Table F151).[394-402]

Patient outcomes.

Continence. Several interventions resulted in fecal continence in all patients, including stapled and excision hemorrhoidectomy,[394] ligature and open diathermy hemorrhoidectomy,[396] submucosal hemorrhoidectomy with radiofrequency bistouries and Conventional Parks' hemorrhoidectomy,[399] excisional hemorrhoidectomy with ultrasonically activated scalpel, and closed excisional hemorrhoidectomy assisted by electrocautery[401] (Appendix Table F195). The rates of continence were not consistent across RCTs; for example, all patients were continent after ligature haemorrhoidectomy in one,[396] but only 67 percent in another trial.[398] The rates of FI after open haemorrhoidectomy varied from 0.1 percent in a small RCT (N=42)[397] to 7 percent in an RCT with 250 patients.[400]

Improvement in FI. Improvement in FI did not differ after open or closed hemorrhoidectomy.[400] However, no statistical differences in outcomes after the tested procedures were shown. Self-reported increase in FI was observed in 15 percent of patients after ligature and in 25 percent of patients after open diathermy haemorrhoidectomy (RR not significant) (Appendix Table F196).[396]

Surrogate outcome - *Objective measure of severity of FI.* Anorectal outcomes demonstrated inconsistent changes across four RCTs,[397,400-402] with significant differences in one.[397] (Appendix Table F197).

Effects of Clinical Interventions in Patients with Colorectal Diseases on FI (FI-Secondary Outcome)

The effects of surgical interventions on FI were compared in patients with anorectal abscesses,[415] fistula-in-ano,[416-418] anal fissure,[419-423] and adenocarcinoma of the rectum[424-426] (Appendix Table F151).

Patient outcome - *FI.* Incision, drainage, and fistulectomy with primary partial internal sphincterectomy compared to incision and drainage alone did not reduce the risk of flatus incontinence and soiling in patients with anorectal abscesses (Appendix Table F198).[415] Special fibrin sealant combined with intra-adhesive cefoxitin, surgical closure of primary opening, or both modifications resulted in fecal continence in all patients with chronic anal fistula.[416] Adjuvant radiotherapy before total excision in patients with rectal cancer consistently increased the risk of FI in three RCTs, by 60 percent during the day (RR 1.6, 95 percent CI 1.4; 1.9), by 90 percent during the night (RR 1.9, 95 percent CI 1.4; 2.6), by 70 percent in utilization of pads (RR 1.7, 95 percent CI 1.4; 2.1) compared to mesorectal excision,[424] and by 220 percent (RR 2.2, 95 percent CI 1.2; 4.2) compared to the low anterior resection.[424] The harm of adjuvant radiotherapy reported in an RCT of 171 patients who survived for a minimum of 5 years after treatment with an increased relative risk of incontinence of liquid stool (RR 2.1, 95 percent CI 1.3; 3.2), incontinence of solid stool (RR 4.1, 95 percent CI 1.2; 14.2), and utilization of pads (RR 2.2, 95 percent CI 1.4; 3.5) [425] was larger. We estimated that surgery without adjuvant radiation would avoid 240 cases of daytime FI per 1,000 treated,[424] 310 cases of self-reported FI,[424] 260 cases of

loose stool, and 110 cases of loose solids.[425] Adjuvant radiation also restricted social activities almost three time more often compared to surgery (RR 2.9, 95 percent CI 1.4; 5.8).[425]

Surrogate outcome - *Subjective measures of severity of FI*. Postoperative radiotherapy, in addition to intensive daily pelvic floor muscle training with intra-anal biofeedback, improved the modified Cleveland Incontinence Scores at 1 year by 5.6 percent (mean difference -0.6, 95 percent CI -1.0; -0.2) compared to behavioral treatments without radiation (Appendix Table F199).[426]

The clinical effects of glyceril trinitrate application were compared to lateral sphincterotomy with no significant difference in FI among patients with chronic anal fissure.[419-423] Quality of life was the same after both treatments.[422]

The trial that compared dermal island flap anoplasty with cutaneous advancement flap into the rectum to conventional open fistulotomy or seton insertion in 20 patients with fistula-in-ano reported comparable FI scores (Appendix Table F199).[418] Another RCT did not show difference in FI Wexner scores after internal sphincterotomy compared to the application of 0.25 percent nitroglycerin tid to perianal area in 90 patients with symptomatic chronic anal fissures (Appendix Table F199).[422]

A trial that compared dermal island flap anoplasty with cutaneous advancement flap into the rectum with conventional open fistulotomy or section in 20 patients with fistula-in-ano reported comparable FI scores.[418] Another RCT did not show differences in FI. Wexner scores after internal sphincterotomy compared the application of 0.25 percent nitroglycerin tid to the perineal area in 90 patients with symptomatic chronic anal fissures[422] (Appendix Table F199).

Effects of Clinical Interventions in Patients with Rectal Prolapse on FI

The effects of clinical interventions in patients with rectal prolapse on FI were examined in seven RCTs (Appendix Table F151).[406-412]

Patient outcome - *FI*. The risk of complete FI was reduced by 60 percent (RR 0.4, 95 percent CI 0.2; 0.7) after posterior sutured abdominal rectopexy combined with sigmoidectomy and end-to-end stapled anastomosis compared to polyglycolic acid mesh rectopexy without sigmoidectomy (Appendix Table F200).[406]

Surrogate outcome - *Subjective and objective measures of severity of FI*. Surgical procedures did not reduce the risk of FI, self-reported severity scores, or instrumental outcomes (Appendix Table F201).

Effects of Surgical Treatments of Anal Sphincter on FI

The effects of surgical treatments of anal sphincter on FI related to chronic anal fissure, fistulas, or neurogenic causes were examined in several RCTs (Appendix Table F151).[427,833-839]

Patient outcomes.

Continence. Open lateral internal sphincterotomy, as well as the anal administration of isosorbide dinitrate, resulted in fecal continence in all 63 patients with chronic anal fissure (Appendix Table F202).[834]

FI. Implantation of artificial bowel sphincter reduced urge FI by 80 percent (RR 0.2, 95 percent CI 0.2; 0.3), pad utilization by 40 percent (RR 0.6, 95 percent CI 0.5; 0.7), and restrictions in physical activities by 60 percent (RR 0.4, 95 percent CI 0.3; 0.5) compared to baseline levels (Table 68 and Appendix Table F202).[427]

Progression of FI was reduced by 80 percent (RR 0.2, 95 percent CI 0.1; 0.9) after closed compared to open lateral sphincterotomy.[833] Improvement in FI was increased by 40-50 percent after anterior levatorplasty with mobilization of external sphincter compared to anal (and vaginal in women) plug electrostimulation of the pelvic floor[837] in patients with idiopathic severe refractory FI. Physical restrictions were reduced by 50 percent (RR 0.5, 95 percent CI 0.2;0.9).

Surrogate outcome - *Subjective and objective measures of severity of FI.* Artificial bowel sphincter reduced FI scores (0-120 for complete FI) from 106 to 48 (mean difference -1.7, 95 percent CI -1.4;-2.0) or by 2 percent compared to the baseline condition.[427] Artificial bowel sphincters reduced the Cleveland Clinic Scoring and the American Medical Systems quality of life questionnaire specific to FI compared to usual supportive care.[839](Appendix Table F203).

Guidance by endoanal ultrasound of injections of silicon biomaterial into inter-sphincteric space and internal anal sphincter improved the Wexner and visual analog scores and FI Quality of Life Index compared to injections without a guide (Appendix Table F204).[838]

All procedures resulted in small inconsistent changes in anal manometry outcomes (Appendix Table F204).

Surrogate outcome - *Dynamic graciloplasty.* One multicenter noncontrolled nonramdomized clinical trial (Dynamic Graciloplasty Therapy Study Group) reported significant improvements quality of life (Medical Outcomes Study Short Form 36 physical function and social functioning). The majority of nonstoma patients (56 to 62 percent) at 12-24 months had continent stools/total number of stools ≥50 percent. In the stoma patients 37.5 percent at 12 months to 43 percent at 24 months reported having continent stools.[429,430]

Summary. In conclusion, implanting an artificial bowel sphincter demonstrated some consistent effects to reduce the risk of FI. Adjuvant radiation in patients with prostate cancer resulted in a consistent significant increase in FI compared to surgery alone. The protective effects on FI of surgeries for hemorrhoids, rectal prolapse, rectal cancer, and anal fissures are not replicable across RCTs and require future confirmation in well-designed long-term RCTs.

Surgical Interventions (Restorative Proctocolectomy) on FI in Adults (FI as Secondary Outcome)

Surgical interventions (restorative proctocolectomy) on FI in adults (FI as secondary outcome) were examined in patients with cancer in 13 RCTs,[840-852] in patients with ulcerative colitis in four RCTs,[431-434]and one retrospective cohort,[853] in patients with rectal prolapse in one RCT,[854] and in patients with sphincter damage in one RCT[855] (Appendix Table F151).

Patient outcome - *Continence*. The majority of patients with cancer were continent after standardized resection with J pouch anastomosis or straight coloanal anastomosis across RCTs (Table 69). Rates of FI did not differ between treatment groups. Abdominal colectomy with hand sewing or double stapling the pouch to the anal canal provided the highest rates of continence in patients with ulcerative colitis with no differences between the two surgeries.[431] All patients were continent after duplicated or quadruplicated ileal reservoirs in restorative proctocolectomy with no differences between them.[432,433] Abdominal rectopexy with or without sigmoidectomy resulted in the same continence rates in patients with rectal prolapse.[854]

Fecal continence was reported in 75 percent of 1,885 patients operated for chronic ulcerative colitis at 1 year and gradually decreased to 59 percent after 20 years of followup (Appendix Table F205).[853] The proportion of patients continent after surgery increased during the last decades from 57 percent in 1981-1985 to 70 percent from 1996-2000 (Appendix Table F206).[853]

Surrogate outcome - *Subjective and objective measures of severity of FI.* Severity of FI differed between types of surgical anastomosis in patients with cancer (Appendix Table F207). Low anterior resection with straight anastomosis increased FI scores by 61 percent compared to J pouch anastomosis (mean difference in a scale from 0 to18 for complete FI, 1.2, 95 percent CI 0.8; 1.7).[844] In contrast, another RCT showed a significant increase in the Wexner FI scores after J anastomosis (mean difference 1.3, 95 percent CI 0.5; 2.0),[841] The Fecal Incontinence Severity Index decreased after J anastomosis (mean difference -4.6, 95 percent CI -5.6; -3.5) and the FI quality of life scale improved (mean difference 0.7, 95 percent CI 0.1; 1.3).[856] Severity of FI did not differ after the tested interventions in patients with ulcerative colitis or rectal prolapse.

Anal manometry outcomes demonstrated random changes after surgical interventions with inconsistent direction and effect size. Smaller RCTs reported greater differences (Appendix Table F208).

Summary. In conclusion, different types of anastomosis (J-pouch-anal or straight) combined with resection of cancer resulted in comparable fecal continence rates across the RCTs. Surgical interventions in patients with ulcerative colitis were comparable between active treatments for fecal continence in the majority of the patients during the first 10 years after surgery with an increased risk of FI during longer period of followup. The effects of treatments on quality of life were inconsistent in direction and effect size.

Clinical interventions resulted in comparable incidence and progression of FI in the majority of the RCTs. Significant relative benefits on fecal continence were reported in small trials of <100 subjects (Table 70). Definite harm of adjuvant radiotherapy compared to surgery alone was shown in RCTs of 597 patients[424] and 171 patients[425] with rectal cancer. Short-term benefits of pelvic floor muscle training supplemented with bladder training and supervised by nurses was reported in RCTs of 747 pregnant women.[251] Early detection of anal sphincter tears after vaginal delivery, followed by immediate surgical repair, significantly reduced the risk of FI 3 months and 1 year postpartum in RCTs of 752 pregnant women.[385] The significant results of small RCTs need future confirmation in well-designed long-term trials.

Table 68. Comparative effectiveness of surgical interventions in anal sphincter on FI in adults (events)

Author Sample Followup	Active Treatment	Control Treatment	Outcome	Number of Cases After Active Treatment/ Number Treated	Number of Cases After Control Treatment/ Number Treated	Rate (%) After Active Treatment	Rate (%) After Control Treatment	Relative Risk (95% CI)	Number Needed to Treat (95% CI)	Number of Attributable Events/1,000 Treated (95% CI)
Wiley, 2004[833] N = 79 54% female 12 month followup	Closed lateral internal sphincterotomy (Hoffman and Goligher) using a short stab incision and blind division of internal sphincter guided by the surgeon finger	Open lateral sphincterotomy (Parks) via a 1cm radial incision with division of internal sphincter under direct vision	Self-reported deterioration in FI	2/38	10/41	5.3	24.4	**0.2 (0.1; 0.9)**	5 (4; 53)	191 (19; 232)A

Table 70. Comparative effectiveness of clinical interventions on FI in community dwelling adults (significant differences only shown) (continued)

Author Sample Followup	Active Treatment	Control Treatment	Outcome	Number of Cases After Active Treatment/ Number Treated	Number of Cases After Control Treatment/ Number Treated	Relative Risk (95% CI)	Number Needed to Treat (95% CI)	Number of Attributable Events/1,000 Treated (95% CI)
Peeters, 2005[424] N = 597 38% female 60 month followup	Radiotherapy with total dose of 25Gy administered in 5 fractions over 5 to 7 days before total mesorectal excision	Total mesorectal excision	Use of pads for fecal incontinence	171/306	96/291	**1.69 (1.40; 2.05)**	4 (3; 8)	230 (132; 347)E
Wiley, 2004[833] N = 79 54% female 12 month followup	Closed lateral internal sphincterotomy (Hoffman and Goligher) using a short stab incision and blind division of the internal sphincter guided by surgeon's finger	Open lateral sphincterotomy (Parks) via a 1cm radial incision with division of the internal sphincter under direct vision	Self-reported deterioration in FI	2/38	10/41	**0.22 (0.05; 0.92)**	5 (4; 53)	191 (232; 19)A
Wong, 2002[427] N = 112 75% female 12 month followup	Implantation of Acticon trade mark artificial bowel sphincter - solid silicone elastomer device	Baseline condition	Self reported using pad for FI	60/112	99/112	**0.61 (0.50; 0.73)**	3 (2; 4)	340 (238; 437)A
			Self reported using diapers for FI	19/112	57/112	**0.33 (0.21; 0.52)**	3 (2; 4)	340 (244; 401)A
			Avoiding physician activities due to FI	32/112	91/112	**0.35 (0.26; 0.48)**	2 (2; 2)	520 (423; 600)A
Peeters, 2006[788] N = 669 0% female 12 month followup	Three-dimensional conformal radiotherapy 68Gy	Three-dimensional conformal radiotherapy 78Gy	FI as use of incontinence pads for rectal loss of blood, mucus, or stools (requiring use of pads more than twice a week)	21/326	40/330	**0.53 (0.32; 0.88)**	18 (12; 69)	57 (15; 83)A

Bold - significant differences at 95% confidence level; number needed to treat to benefit one patient for positive patient outcomes (continence and improvement) or to harm one patient for negative patient outcomes (incontinence); A - number of avoided events per 1,000 treated; E - number of excessive events per 1,000 treated

Question 4. What are the Strategies to Improve the Identification of Persons at Risk and Patients who have UI and FI?

Strategies to Improve the Identification of Persons at Risk and Patients who have UI

Evidence from large observational studies suggests that a substantial proportion of community dwelling adults have undiagnosed UI. Prevalence varied across gender and age groups. The majority (66.2 percent) of women with UI after pregnancy did not report the symptoms to their nurses or doctors.[858] Healthcare professionals did not assess bladder control in 77 percent and did not examine pelvic floor muscles during routine vaginal examination in 94 percent of pregnant women.[859] The majority of young women 18-23 years old (77 percent) with symptoms of UI never sought medical help, and only 11.5 percent received care they were satisfied with.[860] The prevalence of undiagnosed UI was consistent across Western countries: 55 percent for mid-age and older women from a large Australian Longitudinal Study on Women's Health,[860] 56 percent in an Austrian cohort,[139] 62 percent in the Netherlands,[122] and higher in Turkey (85 percent)[861] and in the United Arab Emirates (69.1 percent).[862] The prevalence of undiagnosed UI is higher in recent studies. For example, 75 percent of Swedish women with UI had not sought professional help,[155] 75 percent in Spain, 67 percent in France, 60 percent in Germany,[112] and 75 percent[112] to 86 percent[478] in the United Kingdom.

The prevalence of undiagnosed UI is also high in men; only one third of American men[863] and 46 percent of Swedish men[583] with UI received professional care for UI, and only 33 percent obtained information about UI from the health service.[61] Only 55 percent of men 45-75 years old with bothersome urinary symptoms contacted general practitioners, and only 40 percent of those were referred to a urologist for a specialized exam and advice.[598] Specialized care was given to 11 percent of adults with UI in Belgium.[587] Among males with overactive bladder symptoms living in 11 Asian countries, only 6 percent discussed this condition with a physician.[864]

The proportion of older community dwelling adults with undiagnosed UI varied from 25 percent of men and 40 percent of women in Spain,[35] to 91 percent in Thailand,[865] and 82 percent in Japan.[63] Primary care providers in the United States assessed UI in 21 percent of older incontinent women and 10 percent of older incontinent men.[521] The prevalence of undiagnosed UI was highest in Black women and in Hispanic men.[146]

The diagnostic pathway to detect persons at risk and patients with UI includes population-based epidemiologic surveys with validated questionnaires and scales,[866] clinical history, and simple self-administered diagnostic tests. Treatment decisions are made based on instrumental methods, including ultrasound and multi-channel urodynamics, considered as a "gold standard," essential to decide the most effective intervention.[867]

Valid questionnaires to assess UI (Appendix Table F209). The Symptom and Quality of Life Committee of the International Consultation on Incontinence (ICI) systematically reviewed available questionnaires and scales to diagnose UI and evaluate quality of life in patients with UI.[866] The committee highly recommended the questionnaires with rigorous validity, reliability, and responsiveness in several clinical studies graded with the highest level of evidence (level A) (Appendix Table F210).[866] The ICI Questionnaire combined symptoms of UI and impact on life for both genders.[868] The Bristol Female Lower Urinary Tract Symptoms Questionnaire[869] and the

Stress and Urge Incontinence and Quality of Life Questionnaire (SUIQQ)[870] are recommended to estimate the severity and impact on life of stress and urge UI in women (Appendix Table F211).[866] The ICS male questionnaire measures voiding patterns, stress, urge UI, and impact on quality of life related to UI.[871] The overactive bladder questionnaire demonstrated validity and reliability to measure symptoms of overactive bladder in males and females.[872] Most of the questionnaires are gender specific and include UI and other symptoms of lower urinary tract problems in females (Urogenital Distress Inventory;[873] Urogenital Distress Inventory-6;[874] Incontinence Severity Index;[875] Bristol Female Lower Urinary Tract Symptoms Questionnaire[876] and in males ICS Male, Lower Urinary Tract Symptoms[877] and Danish Prostatic Symptom Score, Lower Urinary Tract Symptoms[878]). The questionnaires on Quality of Life in Persons with UI[879] and the Incontinence Classification System[880] estimate perceived UI, social interactions, personal strain, impact on sexual life, and overall health in both genders. Several scales are recognized as valid tools to measure quality of life in incontinent women: King's Health Questionnaire;[881] Incontinence Impact Questionnaire;[882] Incontinence Impact Questionnaire-7; UI Severity Score (UISS);[883,884] and CONTILIFE-Urinary Incontinence-Specific Measure of Quality of Life.[885] The committee did not find good evidence to recommend scales of quality of life in males. Standard recommendations developed by the Symptom and Quality of Life Committee of the ICI did not include sensitivity, specificity, and positive predictive likelihood of different questionnaires compared to objective physician diagnosis or instrumental methods. The assessment of validity based on significant correlation coefficients can be biased by the sample size of the studies and the distribution of the responses.

Diagnostic value of questionnaires and scales for UI. Several studies examined the diagnostic value of questionnaires and validated scales compared to multichannel video urodynamic testing,[452,480,506,886-889] physician diagnosis based on medical history, urine analysis, and micturition charts and diaries and urodynamics,[447,890-892] detailed interviews with nurses,[893] or other objective tests including the pad test,[894] provocative cough stress test, and computerized urethra-cystometrogram (Table 71).[895] One study tested a simple screening tool to detect common geriatric problems in community dwelling adults including UI.[479] The scales included questions on the presence and severity of symptoms of UI and quality of life. The majority of studies examined females only; three studies included both males and females.[479,480,892] An epidemiologic survey could identify only 56 percent of women who had urge UI and 66 percent of women who had stress UI.[447] Survey questions for geriatric UI could identify only 60 percent of incontinent adults.[480] The highest sensitivity of 98 percent was reported in a nonrandomized multicenter study of 531 patients with overactive bladder and urge UI detected with a simple, five-item questionnaire.[892]

The sample size of the studies was not associated with the sensitivity of the scales to detect UI (Appendix Table F212). The specificity of the scales varied from 21 percent[480] to 100 percent.[895] The lowest specificity was demonstrated for a survey in elderly patients to detect urge UI.[480] The Medical, Epidemiologic, and Social Aspects of Aging Urinary Incontinence Questionnaire did not provide any false positive results of stress UI.[895] Such large variability in specificity of the scales could not be explained by differences in sample size (Appendix Table F212). The scales had comparable specificity for different types of UI; 95 percent for mixed UI,[479] 96 percent for stress UI,[480] and 96 percent for urge UI.[447]

Three scales suggested a greater likelihood of UI compared to urodynamic evaluations[480,895] and physician diagnosis[447,479] (Appendix Table F213). The same scale resulted in larger positive likelihood ratios for urge (positive LR 14) and lower for stress UI (positive LR 5.5).[447] The

majority of scales resulted in only a small (positive LR <4) probability of UI diagnosed with multichannel urodynamics,[452,480,506,887-889] pad test,[894] or physician diagnosis.[890,891] The moderate diagnostic value of the Urogenital Distress Inventory was reported in a systematic review with a pooled likelihood ratio of 2.2, 95 percent CI 1.5; 2.9.[452,888] Larger studies tended to report lower likelihood ratios, but the sample size could explain only small proportions of differences in ratios (Appendix Table F212). Across the studies, the consistent number needed to screen to detect one case of UI was two to three patients (Table 71).

Several studies estimated the validity of the questionnaires with correlation coefficients. One study of 384 older women reported a significant correlation (correlation coefficient ratio 0.2-0.7) between the Incontinence Impact Questionnaire and the Urogenital Distress Inventory with the clinical diagnosis of UI.[896] The Incontinence Severity Index was correlated with the 48-hour "pad weighing" test (correlation coefficient 0.6-0.6).[875,897]

A large RCT reported a significant correlation between the Incontinence Quality of Life Questionnaire, Patient Global Impression of Improvement and Severity Questionnaire, and stress pad test results.[507] Secondary analyses of three clinical drug trials reported a significant correlation between the Urgency Perception Scale and patient voiding diary variables and other patient assessments, including perception of bladder condition, perception of treatment benefit, the Medical Outcomes Study Short-Form 36 health survey, the King's Health Questionnaire, the OAB Questionnaire, and the Overall Treatment Effect scale.[898] The significance of correlation coefficients depends on the sample size of the studies. For example, a large RCT reported a correlation coefficient ratio of 0.2-0.4 as significant.[507]

In conclusion, two questionnaires demonstrated good diagnostic value compared to multichannel urodynamics to detect UI in epidemiologic surveys.[447,895] Two screening questionnaires may accurately detect UI in older adults.[479,480] Several questionnaires of severity and quality of life of UI that demonstrated rigorous validity and reliability were recommended for clinical practice and research. The clinical and economical value of self-reported perceived UI needs future research.

Diagnostic value of clinical history compared to multichannel urodynamic for stress UI in community dwelling adults. The diagnostic value of clinical history to detect stress UI compared to a "gold standard" multichannel urodynamics was examined in 24 studies with inconsistent results.[435-455,899] Most of the studies included females; one evaluated stress UI in men after radical prostatectomy[899] (Table 72). The authors used ICS criteria to define urodynamic UI, noted during filling cystometry as the involuntary leakage of urine during increased abdominal pressure, in the absence of a detrusor contraction.[483] Clinical history assessments varied but were poorly reported. The common assessment included duration and severity of involuntary urine leakage, exacerbating factors, baseline diseases, self management, and impact on quality of life.

The sensitivity of the clinical history compared to multichannel urodynamics varied from 44 percent in the largest study[437] to 100 percent in several studies in females[435,443,446] and males.[899] The larger study tended to report lower sensitivity; 20 percent of the variation in sensitivity was attributable to sample size (Appendix Figure F2).

Specificity also varied substantially from 13 percent in a study with elderly women[455] to 95 percent in the smallest study of 46 patients with complaints of UI or voiding disorders.[435] The largest study of 1,455 women reported specificity of 87 percent.[437] Clinical history resulted in 50 percent false positive results in males.[899] The variability in specificity could not be explained by the sample size of the studies; only 3 percent was attributable to the number of subjects

(Appendix Table F212). Positive predictive values as the proportion of true positives among all positives also varied from 66 percent in a study of 66 females[445] to 92 percent in a study of 566 patients.[453] Larger studies tended to report greater positive predictive values of clinical history (Appendix Figure F3); 22 percent of the differences in positive predictive values were attributable to the sample size of the study. Only one study of 46 women showed that clinical history was associated with a definite increase in the likelihood of disease (positive likelihood ratio of 20).[435] One study of 198 Japanese women reported a moderate increase in the likelihood of stress UI identified with clinical history compared to multichannel urodynamics (positive likelihood ratio of 7.7).[436] The majority of the studies found only small increases (positive likelihood ratios >2) in the likelihood of stress UI identified with clinical history[440-447,899] or minimal (positive likelihood ratios >1).[442,448-455] The differences in sample size could not explain the variability in positive likelihood ratios (Appendix Table F212). One systematic review reported a small positive likelihood ratio (2.09, 95 percent CI 1.83; 2.35) associated with the pooled sensitivity and specificity in females using studies published before 2003.[867] The review reported highly significant heterogeneity between studies ($p<0.0001$) in sensitivity and specificity with no clear explanations for substantial variability in diagnostic values of clinical history to detect stress UI.

Diagnostic value of clinical history compared to multichannel urodynamics for urge UI in community dwelling adults. The diagnostic value of clinical history to detect urge UI and detrusor overactivity compared to a "gold standard" multichannel urodynamic, was examined in 18 studies.[436,437,440-443,447,450,452,454,455,899-905] The majority of studies included females; two studies evaluated urge UI in men after radical prostatectomy[899] and in older males with persistent lower urinary tract symptoms.[904] The authors used the ICS criteria to define urodynamic urge UI during filling cystometry.[483] The sensitivity of clinical history to detect urge UI varied: it was 14 percent in one study of older women,[455] less than 50 percent in seven studies[437,443,450,452,454,905] to 50 to 80 percent in eight studies,[440-442,447,899,901,903,904] and more than 80 percent in two studies.[436,902] Large trials reported sensitivity of 28 percent[905] to 41 percent.[437] The sample size of the studies could explain only 7 percent of the differences in sensitivity (Appendix Table F212).

The specificity of clinical history varied from 13 percent in one comparative study of 1,000 females with lower urinary tract symptoms[442] to 45-80 percent in six studies, including two studies in men,[440,899-902,904] while the majority of the studies reported specificities greater than 85 percent.[436,437,441,443,447,450,452,454,455,903,905] Inconsistency in diagnostic values varied by study design to reduce bias in estimations. RCTs reported a specificity of 96 percent,[437] while a nonrandomized clinical trial of 4,500 women showed a lower specificity of 86 percent.[905] Substantial variability in specificity was not attributable to differences in sample size. Full cross-tabulations of the results were available in eight studies to calculate positive predictive values as the proportion of true positives among all positives that were detected with clinical history. One study in males reported the lowest positive predictive value (PPV) of 33 percent;[452] six studies showed PPV as 62 to 77 percent.[440,441,443,447,450,902] The highest PPV of 81 percent was reported in a comparative study of 198 Japanese women.[436] The sample size of the studies was not associated with differences in PPV. Several studies found that clinical history could increase the likelihood of urge UI with positive likelihood ratios between 10 and 22.[436,437,441,443,447,450] Two studies reported moderate probability of urge UI detected with clinical history with positive likelihood ratios between 5 and 9.[455,903] The majority of the studies showed only a small increase in likelihood of urge UI detected with clinical history.[440,452,454,899-902,904,905] One study of 1,000 women with symptoms of lower urinary tract dysfunction demonstrated a very low positive

likelihood ratio of clinical history (<1) to diagnose urge UI.[442] Larger studies tended to report lower positive predictive likelihood, but only 2 percent of the variability was attributable to the sample size of the studies. A systematic review of eight studies reported a small positive likelihood ratio of 4.69, 95 percent CI 4.05 to 5.33 associated with the pooled sensitivity and specificity to detect detrusor overactivity and urge UI in females.[867] Heterogeneity between studies was significant (p<0.0001) with no well defined reasons for such variability in diagnostic value of clinical history.

Two studies examined the diagnostic value of clinical history to detect mixed UI and reported sensitivity from 68 percent[437] to 91 percent,[442] specificity from 47 percent to 24 percent respectively, and a small positive predictive likelihood of 1.3 or 1.2 respectively.

Diagnostic values of different tests to detect persons at risk and patients with UI were examined in 23 studies with sample sizes varying from 20[906] to 981 adults[907] (Appendix Table F214). The diagnostic value of the tests varied substantially, depending on index methods, populations, and type of UI. Sensitivity differed from a low of 25 percent to detect outlet obstruction in males with ambulatory compared to conventional urodynamic testing[908] to 100 percent to detect female urge UI with cystometry by fetal cardiotocographic monitor for pressure recording[909] or stress UI by the fluid bridge test.[910] Specificity was the lowest (7 percent) for ambulatory urodynamic monitoring compared to multichannel urodynamics to detect stress UI in female soldiers.[911] The majority of studies demonstrated specificity of the index tests less than 90 percent. The fluid bridge test had a 76 percent probability (specificity of 24 percent) of false positive results. Urethral pressure profile examination had a specificity of more than 90 percent in two studies.[912,913] Cough stress test and single-channel medium-fill cystometry[914] and cystometry using a fetal monitor[909] also had a low probability of false positive results for urge UI compared to multichannel urodynamics (specificity 96 percent). The Resident Assessment Protocol included in the MDS demonstrated a specificity of 97 percent to detect stress UI in 123 randomly selected residents of 13 nursing homes in five states compared to multichannel urodynamics with definitions adjusted for impaired contractility in elderly patients.[481] The positive likelihood ratio was defined as the ratio of the probability of a patient with UI having a positive test to the probability of an individual without UI having a positive test was 25.3 to diagnose significant stress leakage in residents of these nursing homes.[481] Several studies examined diagnostic values of the urethral pressure profile; one nonrandomized clinical trial of 108 women reported a large predictive likelihood of 24.5 to detect stress UI.[913] Results were inconsistent across the same comparisons in other studies with small[915-917] or moderate positive likelihood[907,912] to diagnose UI. The majority of studies showed that tested diagnostic methods provided only a small likelihood of UI in adults (Appendix Table F214).

The majority of the studies that examined the diagnostic value of x-ray compared to multichannel urodynamics reported a small positive likelihood ratio to detect UI (Appendix Table F215).[456-459,461] One large study of 1,584 males and females showed a likelihood ratio of 10.11 for micturating cystourethrography to detect UI.[460] The full bladder clinical stress test had a conclusive diagnostic value with a likelihood ratio of 33.5 in one study[464] and moderate likelihood ratios between 5 and 10 in three studies.[465,918,919] Single channel urodynamics demonstrated inconsistent diagnostic value for stress and urge UI with likelihood ratios varying from 1.9 in the geriatric population[463] to 24.5 in younger women.[462]

Diagnostic value of ultrasound compared to UI in community dwelling adults. The diagnostic values of ultrasound exams to detect UI compared to multichannel urodynamics were examined in ten studies in community dwelling females to detect mixed[470,473] or stress

UI[471,472,474-477,920,921] with no studies conducted in males (Table 73). One study of 201 incontinent nursing home residents, which examined a portable ultrasound device to diagnose post-void residual volume confirmed with catheterization, showed the lowest sensitivity of 59 percent to detect post-void residual volume >150ml.[922] The same study reported a high sensitivity of 95 percent to detect low post-void residual volume (<100ml).[922]

The studies used different ultrasound techniques and definitions of UI including transrectal ultrasound[475,921] to detect a drop in urethrovesical junction pressure during stress as a criterion for stress UI; translabial[470,923] or vaginal[471] ultrasound to observe urine leakage during the stress test; or perineal ultrasound to examine the opening of bladder neck and rotational angle.[474,476,477]

Bladder neck funneling on ultrasonography had 60 percent sensitivity to detect low leak point pressure in a study of 320 women.[477] The highest sensitivity (>90 percent) was reported in two studies to observe urine leakage using translabial[470] or vaginal ultrasound.[471] Specificity ranged from 69 to 99 percent, depending on definitions of UI[922] and ultrasound techniques.[470,471,474,475,921,923] The PPV was lowest (19.8 percent) in a study to detect low leak point pressure in women with stress UI.[477] Three studies reported PPV >93 percent to detect urine leakage[470,471] or a drop in urethrovesical junction pressure.[475] An ultrasound exam with a portable device provided a definite diagnosis of post-void residual urine volume >200ml in nursing home residents with a positive likelihood ratio of 69.[922] Transrectal ultrasound conclusively detected a drop in urethrovesical junction pressure during stress tests in women with stress UI with a positive likelihood ratio of 21.5[475] and in women undergoing surgery for stress urinary incontinence of 9.4.[921] Ultrasound findings of urine leakage were associated with a moderate probability of UI in two studies with positive likelihood ratios >5.[470,471] The differences in sample size could explain only 2 percent of the variability in likelihood ratios.

In conclusion, clinical history of UI results in a small likelihood of urodynamic UI and in a moderate likelihood of urodynamic urge UI in females. Very limited evidence in males suggests that clinical history of UI is not accurate to predict urodynamic UI. Inconsistent evidence implied that diagnostic values of x-ray, single channel urodynamic, full bladder clinical test, and Q-tip test are similar to multichannel urodynamics. Ultrasound diagnosis of urinary leakage and bladder neck anatomy was comparable to urodynamic UI and urinary retention in community dwelling adults and residents of nursing homes. MDS algorithms accurately diagnosed UI in LTC settings.

To assess the effectiveness of diagnostic methods to detect UI in adults, we estimated the number needed to screen to detect one case of UI and the number of diagnostic tests needed to detect one case of UI using the recently published prevalence of undiagnosed UI in age, gender, race, and socioeconomic status categories.[146] The cost of different procedures was obtained from the systematic review and cost-effectiveness analysis of diagnostic tests of UI.[867] Despite substantial differences in positive predictive likelihood ratios, the number needed to screen and the number of needed tests was similar and consistent among the studies (Table 74). Epidemiologic surveys with self-completed scales and questionnaires would cost less than $70 to detect one case of UI. The professional assessment of clinical history would cost from $175 in males after radical prostatectomy[899] to nearly $400 in women with stress UI.[437] Health care providers would need to collect clinical history in five to 15 patients to detect one case of urodynamic UI; the cost would not be more than $250. Clinical history had the lowest cost to diagnose urge UI in males with persistent lower urinary tract symptoms[904] and the highest cost to detect detrusor overactivity in elderly women.[455] The detection of urge UI with professional assessment of clinical history would cost more than $300 in the majority of the studies. The cost

of ultrasound exams to detect one case of urodynamic UI varied from $600 to $900. The effectiveness of self-reported scales, professional assessment of clinical history, and ultrasound to detect UI in women was comparable and consistent across race, age, and socioeconomic groups; one to four women should be examined to detect one case of UI (Table 75). The number needed to screen males to detect one case of UI was also consistent in population groups (Appendix Table F216). The cost of different treatment options was beyond present analysis but may affect the cost of diagnostic pathways. One of the most expensive diagnostic methods, multichannel urodynamic evaluation, is an important step to diagnose intrinsic sphincter deficiency (urodynamic urinary incontinence and a maximum urethral closure pressure ≤20cm H_2O) in combination with hypermobility in women planning surgery for stress UI.[924] However, this costly invasive examination may not be necessary for women who prefer behavioral treatments including lifestyle changes, bladder training, and pelvic floor muscle training. The effects of population-based screening and educational programs on clinical outcomes, quality of life, and cost of available treatments need future investigations in well designed RCTs.

Table 71. Diagnostic value of validated questionnaires and scales to detect persons at risk and patients with UI

Author Sample	Level of Evidence	UI Type	Index Test (Scale)	Gold Standard	Sensitivity (%)	Specificity (%)	Predictive Likelihood Ratio	NNS: Women
Moore, 1996[479] N = 109; 66% female	II-2	Mixed	"Screen"	Blinded geriatricians' assessments	89	95	17.80	5
Kirschner-Hermanns, 1998[480] N = 132; 80% female	II-2	Stress	Questionnaire	Multichannel video urodynamic testing	60	96	15.00	8
Sandvik, 1995[447] N = 250; 100% female	II-2	Urge	Questionnaire	Physicians' diagnosis based on medical history, urine analysis, and micturition chart	56	96	14.00	9
		Stress	Questionnaire	Physicians' diagnosis based on medical history, urine analysis, and micturition chart	66	88	5.50	9

Strategies to Improve the Identification of Persons at Risk and Patients who have FI

The diagnostic pathway to detect persons at risk and patients with FI includes self-reported symptoms using questionnaires and scales,[866] clinical history of patients seeking help, anal manometry, sensory testing, anal endosonography, magnetic resonance imaging, and colonoscopy to detect baseline causes for FI.[17] Treatment decisions are made based on instrumental methods including ultrasound and anal manometry, but no consensus exists about which test is a "gold standard," essential to estimate the diagnostic values of other tests.[926] Treatment decisions are made based on clinical assessments and functional and anatomical evaluations of the anorectum.[17]

The Symptom and Quality of Life Committee of the International Consultation on Incontinence could not find sufficient evidence of psychometric properties to attain grade A status for the questionnaires and scales for FI and related quality of life (Appendix Table F217).[866] However, three questionnaires were recommended for evaluation of patients with FI, including the Fecal Incontinence Quality of Life Scale;[484] the Manchester Health Questionnaire,[927] and the Birmingham Bowel and Urinary Symptoms Questionnaire[928] (Appendix Table F218) The questionnaires assess the presence and severity of FI and the perceived quality of life including role and physical limitations, emotional impact of FI, personal relationships, and sexual restrictions related to FI. The American College of Gastroenterology Practice Parameters Committee advised using the Cleveland Clinic Grading system to evaluate the degree of incontinence and the efficacy of therapy,[17] but this was not recommended by the ICI committee. These guidelines do not provide sensitivity, specificity, or likelihood of FI as criteria to grade scales or to recommended questionnaires for research.

Very few studies examined the diagnostic values of scales to detect FI compared to physician diagnosis. The Epidemiology of Prolapse and Incontinence Questionnaire demonstrated 87 percent sensitivity, 70 percent specificity, 61 percent positive predictive value, and a small predictive likelihood ratio (2.9) to diagnose FI in 294 enrolled women with pelvic floor prolapse compared to examiner diagnosis.[929] The Bowel Symptom Questionnaire had a 48.5 percent sensitivity, a 79.2 percent specificity, a 43.2 percent positive predictive value, and a small likelihood ratio (2.3) to identify anal sphincter trauma related to vaginal delivery in 156 women.[930] The Bowel Symptom Questionnaire detected 57.1 percent of the cases of external anal sphincter disruption with specificity of 75.8 percent, positive predictive value of 21.6 percent, and positive likelihood ratio of 2.4.[930]

The American College of Gastroenterology Practice Parameters Committee described a detailed algorithm to evaluate patients with FI or risk factors of FI. However, diagnostic values of the recommended tests were not well documented. For example, when health care professionals did not actively ask questions about continence status, routine clinical history and physical examination identified only 8 percent of patients with constipation and 11 percent with FI, compared to complex diagnostic methods including anal manometry, cinedefecography, electromyography of the anal sphincter, and assessment of terminal motor latency of the pudendal nerve.[931] Self reported and professional evaluations of severity and quality of life related to FI showed agreement in a study of 118 patients with FI.[515] However, surgeons defined solid incontinence as more severe, while patients assigned more severity scores to liquid FI. Clinical values and the economical cost of self-reported questionnaires to detect patients with undiagnosed incontinence require future research.

Anal manometry with an asymmetry index >25 percent had an 81 percent sensitivity, 71 percent specificity, and only a 2.8 positive likelihood ratio to predict combined anal sphincter defect detected with ultrasonography in 61 women with previous vaginal delivery and no past anoperineal surgery.[932] Anal manometry compared to endoanal ultrasonography in patients with idiopathic FI with intact sphincters had different diagnostic value for manometry outcomes. Abnormal resting pressure gradient (<1.78) had 89 percent sensitivity, 96.3 percent specificity, and a large predictive likelihood ratio of 24 to identify FI; maximal mean resting pressure (<40mmHg) had 55 percent sensitivity, 98 percent specificity, and a predictive likelihood ratio of 22, while vector volume (<11.8) had 53 percent sensitivity, 88 percent specificity, and a small predictive ratio of 4.3.[933] A combination of anal manometry and the strength-duration curve had better diagnostic values than tests alone with sensitivity of 95 percent and specificity of 100 percent to predict female FI due to sphincter weakness.[934] Abnormal anal pressure identified only 70 percent of incontinent patients with 68 percent specificity and a 2.5 predictive ratio. Strength duration data demonstrated 77 percent sensitivity and 84 percent specificity with a predictive value of 4.8.[934] Anal manometry with low squeeze sphincter pressure had 52 percent sensitivity to detect FI, impaired rectal sensation could identify only 36 percent incontinent patients; pudendal neuropathy was present in 50 percent of patients with FI diagnosed by colonoscopy or sigmoidoscopy.[935] Anal manometry, rectal capacity measurement, and saline-infusion tests did not demonstrate significant association with FI and could not differentiate 350 incontinent and 80 continent patients.[936]

Endoanal ultrasound had 100 percent specificity and sensitivity to detect external sphincter defects and 100 percent sensitivity, 95 percent specificity, and a 20 predictive likelihood ratio to identify internal sphincter defects compared to morphological surgical findings in 40 women 26-80 years old with FI undergoing pelvic floor repair.[482]

Endoanal magnetic resonance had 56 percent sensitivity, 69 percent specificity, 71 percent predictive positive value, and a 1.8 predictive likelihood ratio to detect defects of anal sphincter compared to endoanal ultrasonography in 237 patients with FI undergoing anal sphincter repair.[937] Endoanal ultrasonography identified 90 percent of external anal sphincter defects with an 85 percent positive predictive value compared to surgical findings. Endoanal magnetic resonance detected 81 percent of external anal sphincter defects with 40 percent specificity, 89 percent positive predictive value, and a small 1.3 positive likelihood ratio.[937]

In conclusion, self-reported questionnaires and scales have unsatisfactory diagnostic clinical validity to diagnose anatomical or physiological causes of FI in adults. For tools using summary scores or scales, different ones are needed for FI and AI since these problems are defined differently. Anal ultrasonography has the highest diagnostic value to detect anal trauma in patients with FI. Patient complaints about FI assessed with a clinical history should be followed by the diagnostic procedures to diagnose primary conditions that may result in FI. Future research is needed to determine effective strategies to identify patients at risk of FI, including residents of LTC facilities.

Chapter 4. Discussion

The present report synthesizes the evidence following the clinical pathway of detection, clinical diagnosis, treatment, and prevention of incontinence in community dwelling adults in and in LTC settings.

Detection of UI

The first big challenge is to define what we call UI. Physiological and clinical self reports yield different results. A person with substantial symptoms despite no urodynamic signs of UI still has a substantial problem. The diagnostic detection rates from scales and clinical history for UI do not correlate closely to multichannel urodynamics.[16] The question is which should take precedence. Most of the evidence comes from women, with few studies for men.[899,904] The yield from screening is high, on average: two to four subjects should be screened to detect one case of UI.[146] A previous systematic review showed that in primary care settings clinical history and diaries are the most cost-effective methods to detect UI in women.[16] However, less than half the incontinent patients who actively sought health care for UI could provide clinical histories or use diaries.[112,155,478] Population-based surveys using validated scales[447,479,480] yielded predictive likelihood ratios and the number needed to screen to detect one case of UI comparable to clinical history[435,436] but at a lower cost ($36-$67 vs. $175-$255 respectively). Such population-based surveys can yield nationally representative valid estimations of prevalent and "bothersome" UI. Routine clinical examinations in high risk groups, including pregnant women and frail adults, should include assessment of UI.

The diagnostic value of the tests among different age, race, and socioeconomic status subgroups has not been well established; however, the prevalence of undiagnosed UI differed by 10-20 percent in such groups.[146] Therefore, screening programs should target patients at high risk of UI including aging and frail adults with functional dependency and cognitive impairment, patients with stroke, diabetes, obesity, poor general health, and comorbidities, pregnant females and women after vaginal birth or with vaginal prolapse, and males after urological surgery and radiation for prostate cancer. Limited evidence suggests that the Resident Assessment Protocol included in the MDS had a definitive predictive likelihood ratio to diagnose UI in nursing home residents.[481] Systematic evaluations of functional status of residents, including noninvasive examinations of incontinence without multichannel urodynamics, would be the preferable screening method in LTC settings.

Detection of FI

Few validated questionnaires[866] and instrumental methods were examined to detect the presence and baseline of causes for FI[17] with no consensus on which test is the "gold standard," essential to estimate the diagnostic values of other tests,[926] despite the tremendous impact of FI on quality of life and health care cost. [17 523] Patient reports do not correlate well with anatomical and physiological measures. Anal manometry does not correlate well with ultrasonography[932] or sigmoidoscopy.[935] Endoanal ultrasound demonstrated the highest predictive likelihood ratio,[482,937] but the use of this method is restricted to adults seeking medical treatment.[522,524] The severity and impact of incontinence on quality of life can be estimated from self-reported

frequency, amount of leakage, and restrictions on daily activities[8,9,32] but not from instrumental methods.[483] However, treatment decisions are made based on objective measures of incontinence.[17,21] Instrumental physiological measurements that are associated with patient outcomes and may reflect better effects of different interventions should be analyzed in well designed experiments.

Treatment

The present report confirmed the significant diversity of interventions used, sampling strategies and definitions, and measurement of outcomes.[17,21,25]

Sampling

Studies of UI and FI in LTC facilities were limited to those that agreed to participate in clinical trials.[233,234,238,708] Recruitment of residents was restricted by cognitive function or comorbidities.[709,710] The loss of followup was substantial in most studies in LTC.[233-235] Studies of behavioral interventions among community dwelling adults relied largely on patients in clinics,[250,372,501,510,712,714,716] with few studies that reported population based recruitment.[240,242,245] Clinic-based sampling was used for most RCTs of surgical treatments of UI and FI among patients who decided to undergo surgery. Selection criteria varied for the same interventions. For example, only women with intact uteri were included in some,[366,794,796,797] but not all, RCTs[367] of hormone therapy. Studies that included continent subjects reported baseline leakage[243,244] and previous surgery for incontinence;[761] few excluded patients with a positive stress test.[321,322] Baseline characteristics of the patients were balanced with stratified randomization in several RCTs.[379,400,712,771,788,800,803,808,837,938] However, some clinical trials reported significant differences at baseline among treatment groups despite randomization.[274,276,303,710,787,789] Pooling analysis was questionable due to sampling differences in the present report and previous systematic reviews.[529,536,539,546] Applicability of clinical interventions that demonstrated significant improvement in incontinence was restricted to the sampled population groups. Whether these effective interventions would result in the same clinical benefit in other populations requires future research.

Definitions of Incontinence and Measures of Success

Despite extensive efforts to standardize the definitions of incontinence,[483] the original studies measured self-reported symptoms and signs of incontinence, severity, and quality of life related to incontinence, and objective instrumental evidence of leakage inconsistently within and across the studies.The prevalence of stress (68.9 percent) was higher than the prevalence of any UI (45.5 percent) in the one report.[122] The Women's Health In the Lund Area study reported an increase in self-reported UI from 32 percent to an estimated 66 percent when the authors removed the restriction that the UI had to represent hygienic bother.[131] Another study estimated 20 cases of stress UI but 89 women answered positively to the question of urine leakges during coughing or sneezing.[61] Ratings of success including improvement in incontinence and in quality of life by doctors and patients were also different.[484] Objective measures of UI showed random changes in most RCTs. The objective improvements in selected physiological measures were not consistent after the same interventions and did not correlate with self-reported

continence and reduction in severity of UI.[322,330,485-491] A small proportion of RCTs reported significant improvements in quality of life[284] and social adaptation[288,299] after behavioral interventions. Severity of UI and discomfort due to UI were reduced after pelvic floor muscle training with biofeedback in one RCT.[729] One RCT of a complex behavioral program supervised by nurse advisors and a consulting urogynecologist demonstrated improvement in quality of life using several scales.[510] Sacrocolpopexy with Burch colposuspension compared to other active treatments resulted in a small improvement in medical, epidemiological, and social aspects of aging scores for stress incontinence[761] and overall quality of life.[353] The effects of treatments on quantitative measures of incontinence, including frequency and amount of leakage, were less compared to qualitative improvements in symptoms.

Other systematic reviews analyzed predominantly self-reported cure and improvement in UI, omitting objective measures of incontinence.[492-494] One review of two clinical trials with urodynamic tests concluded that the data is not sufficient to propose this invasive and costly testing as a measure of success.[495]

Previous reviews did not find anal manometry a good measure of success in reducing FI.[496-500] Anal manometry showed random changes between active and control interventions.[372,375,376,403,501-503] Improvement in self-reported FI was inconsistent with changes in anal manometry.[373,376,378,503] Few trials demonstrated the same direction and effect of treatment on improvement in FI and objective measures of FI.[372] Composite outcomes, including both self-reported changes in severity of incontinence and physiologic parameters in a common scale may offer a better choice to measure success of clinical interventions.[504,505]

Clinical Effectiveness to Reduce the Risk of Incontinence

Primary Prevention

Few studies that reported inclusion of continent women at baseline also reported baseline urinary leakage[243,244] or previous surgery for UI in some participants;[761] only two RCTs excluded patients with a positive stress test.[321,322] The RCTs with primary prevention of incontinence did not always assess the continence status of the subjects at baseline and therefore, they cannot provide valid estimations of the preventive effects of the treatments. In many cases baseline conditions (prostate diseases in males and pregnancy in females), as well as examined interventions including delivery modes or prostate surgery, were associated with higher risks of incontinence. Without objective assessment of baseline incontinence we assumed that some of the participants may have had incontinence at baseline. To avoid bias at baseline status, we reviewed RCTs that equally distributed patients with diagnosed or undiagnosed (not reported in the articles) incontinence between active and control groups and thus provide valid estimates of the treatment effects. We also emphasized the effects of the treatments on continence, where continence was a well defined outcome and there was a clear goal to reduce the risk of incontinence in patients with either diagnosed or undetected (and hence not reported) incontinence.

Many surgical interventions reviewed here aimed to treat baseline conditions, including rectal cancer, anal fissures, ulcerative colitis, and hemorrhoids, reported incontinence as a secondary outcome to complications of surgery. We focused on the continence status only, rather than the primary therapeutic outcomes and surgical complications previously analyzed.[557,939,940] Therefore, we had to estimate the relative benefits attributable to these surgical procedures on

reducing the risk of incontinence and improving quality of life. All clinically relevant outcomes should be taken into account when comparing the effectiveness of surgical procedures to treat cancer and other baseline diseases.

Secondary Prevention

Clinical effectiveness to reduce the risk of incontinence included self-managed behavioral changes (especially pelvic floor muscle exercises), physiotherapy, pharmacological administration, use of medical devices, and surgery for UI and FI. Considerable variations in dose and length of interventions and followup periods and modifications of surgical techniques made overall comparisons across trials difficult and imprecise. The present report found a significant increase in continence after pelvic floor muscle training by 250 percent (RR 2.5, 95 percent CI 1.2; 5.3). Substantial heterogeneity between RCTs of biofeedback assisted pelvic floor muscle training and pelvic floor muscle training combined with bladder training was demonstrated in both the present and previous reviews.[539,552] Implemented behavioral changes did not show significant improvement in UI among residents in LTC settings in the analyzed trials and in previous assessments.[528,529]

Despite substantial heterogeneity among studies, attributable benefit for public health can be estimated from individual RCTs. Compared to regular care, behavioral interventions could avoid 170-749 cases of stress UI per 1,000 treated.[249,288] Weight reduction would result in improved stress UI in 990 adults per 1,000 treated.[714] Intensive lifestyle changes would avoid 54 cases of stress UI per 1,000 treated.[245] Intensive supervised pelvic floor muscle training among pregnant women would prevent 390 cases of UI per 1,000 treated.[246]

The largest attributable benefit on stress UI was demonstrated from small RCTs of 40-127 participants (Table 64). The effect size of pelvic floor muscle training on continence was smaller but still significantly better compared to usual care in the pooled analysis. The Cochrane systematic review reported better effects from pelvic floor muscle training on cure from single studies with no overall estimation.[539]

This report confirms previous reviews of consistent significant benefits on female stress UI of laparoscopic and open colposuspension,[492,494,535] but inconsistent effects from containment products or mechanical devices to prevent urine leakage [493,941] and suburethral slings.[343,546] Future research may demonstrate more valid estimation of long-term benefits and harms after invasive treatments compared to early behavioral interventions when incontinence is minimal and does not affect the quality of life. We also attempted to review clinical interventions that could achieve total urinary continence (free from stress and urge UI) (Table 61). Limited evidence suggested that tension free vaginal tapes,[328,340,770] sling procedures,[334,342] and local estrogen therapy[368] can result in comparable benefits to colposuspension continence rates.[486,775] Not surprisingly, behavioral interventions provided the largest number of avoided cases of UI per 1,000 treated (Table 64). The role of early behavioral interventions to reduce the risk of incontinence in community dwelling adults has been intensively discussed in the medical literature.[483,942]

The role of self-motivation to manage UI was beyond the scope of this review; however, some evidence suggests that individualized focus group interviews,[943] self-confidence in treatment benefits[944] and personal efficacy[945] may be associated with better outcomes.

We uncovered few well-designed RCTs among case series of clinical interventions for FI that demonstrated significant improvements, with conclusions similar to previous systematic

analyses of evidence.[496-500,549-557] Conservative management of FI was effective in LTC.[233-235] Limited evidence suggests possible benefits from anal sphincter exercises and biofeedback therapy for women with obstetrically related FI.[497] Very few pharmacological interventions[378-380] resulted in fecal continence in more than 50 percent of patients and were not statistically better than placebo[378,379]or surgery.[380] Chemical sphincterotomy in patients with chronic anal fissure[404,405] resulted in a 100 percent continence rate. Different delivery modes and surgical techniques to repair obstetric anal sphincter lacerations demonstrated low clinical efficacy and comparable effectiveness. Surgeries for rectal prolapse achieved fecal continence in 40-56 percent with no significant differences between treatments.[413,414] The effect size of surgical procedures to treat FI varied depending on the definition of FI and baseline cause and severity of FI with no good evidence of the superior effectiveness of alternative surgical procedures.[945] Future well-designed research is necessary to examine surgical treatments of FI in different population groups.[496]

Strength of the Evidence

Studies of diagnostic methods had the lowest quality with few RCTs conducted.[437,462,506,507] Large-population-based surveys reported prevalence of incontinence in age, gender, and race subgroups.[8,9,50,67,508] The independent contribution of risk factors on UI and FI were analyzed with adjusted odds ratios in cross-sectional and retrospective cohort studies. Care must be taken to distinguish associations from actual risks. Moreover, many of the risks are immutable (e.g., age and gender) The temporality between these diseases and UI can be estimated from prospective cohort studies measuring the incidence of UI. Such studies have not yet been conducted. Observational studies cannot establish causality between comorbidities and UI. Adjusted odds ratio estimated probability of having incontinence among people with particular diseases compared to those without such diseases. The estimations are still valuable because they identify subgroups at higher probability of UI. However, multivariate models included different sets of risk factors. Since causality between risk factors and incontinence could not be determined from such studies, and the majority of risk factors are not modifiable, we hesitated to estimate events attributable to risk factors.

Efficacy and comparative effectiveness of clinical interventions to reduce the risk and progression of incontinence were analyzed from 365 RCTs. The quality of the RCTs was evaluated in terms of the preplanned intention to treat principle, masking of the treatment status, adequate allocation concealment, randomization scheme and adequacy, and justification for sample size. The majority of the RCTs showed good quality; did not exclude subjects from the analysis of the outcomes, and provided adequate randomization. However, allocation concealment was not adequate in a large proportion of RCTs.[258,261,266,277,286,372,375,376,502,509-512] The RCTs of interventions that are regulated by the FDA, including hormone replacement therapy, had the best quality.[240,245,253,304,365,366,389,513,514] Large RCTs, including the Diabetes Prevention Program,[245] complex conservative management of UI,[240] delivery management,[388,389] and early prevention of UI in postnatal care[253] had high quality.

RCTs remain a “gold standard” to establish causality of the treatments on the outcomes. Inadequate randomization and allocation concealment, exclusion of subjects from the analysis, and inadequate power to detect differences all threaten the validity of the results and waste time and resources. Central randomization, randomization of the clinics rather than patients, adequate allocation concealment, and preplanned intention to treat analysis are possible for all tested

treatments. Variations in populations, interventions, and measures of outcomes, rather than quality of RCTs, resulted in heterogeneity between studies.

We did not include case series that described the experience of individual institutions to treat UI and FI (Chapter 25).[21] Such publications may be useful to generate hypotheses for well-designed trials but have poor internal and external validity and do not provide good evidence about comparative effectiveness of different treatments.

Policy Implications

Public awareness of incontinence, its risk factors, and possible treatment options may reduce the burden on incontinence. The behavioral risk factor surveillance system may assess prevalence and annual incidence of incontinence in large nationally representative population groups. Routinely collected clinical history should include evaluation of the risk factors, symptoms, and signs of incontinence. Pregnant, obese, and aging women, males with prostate diseases, patients with vaginal and rectal prolapse, and frail elderly should be actively screened for incontinence. Quality indicators for nursing homes, including access to toilets and wet status of the residents, should be continuously monitored and analyzed. Instrumental methods, including multichannel urodynamics and anal manometry, cannot be recommended as outcomes to examine effectiveness of clinical interventions on incontinence. Early behavioral changes in weight, physical activity, and pelvic floor muscle training may reduce the incidence of incontinence in adults. Preventive strategies might include assessment and reduction of modifiable risk factors in early stages of incontinence when incontinence is minimal and does not affect the quality of life.

Question 5. What are the Research Priorities for Identifying Effective Strategies to Reduce the Burden of Illness in these Conditions?

Future research should examine the reproducibility of effective clinical interventions, including local estrogen therapy, weight reduction combined with increased physical activity, individualized electrical and magnetic stimulation, sphincteric stents, penile compression devices, and artificial bowel sphincter. Several of these interventions are being tested in ongoing clinical trials registered in www.clinicaltrials.gov (Table 76). Consistency in long-term results would provide a better basis for clinical and policy decisions.

Further investigation is needed on the long-term curative effects of self-reported continence of combined behavioral and drug therapies on clinical outcomes at 6 months or more followup rather than surrogate tests. The balance between the curative effects of surgical procedures for incontinence and adverse effects and costs should be further examined in well-designed RCTs. Administrative databases can provide useful information on comparative treatment effectiveness, but the results can be biased if provider characteristics are ignored.

The effectiveness of clinical interventions should be tested in subgroups of patients by race, comorbidities and concomitant treatments, and baseline functional conditions of the pelvic floor, including trauma and pelvic floor muscle strength. Better preplanned randomization schemes could yield sufficient numbers of patients among treatment groups to support subgroup analysis that would give valid estimations of treatment effects in different patient populations. The choice

of outcomes should reflect patient perception of cure and quality of life rather than solely provider evaluation and instrumental testing.

The effects of early behavioral interventions in high risk populations on incidence of incontinence should be examined in well-designed RCTs. Pregnant and pre-menopausal continent women should be the target population for future preventive RCTs of complex lifestyle modification. The large proportion of incontinent adults who do not seek care requires changes in the public perception of incontinence as an embarrassing condition with no cure.[946-949] Clinical examination of pregnant women should include assessment of continence status. Pregnancy and postpartum care should include a quality indicator for continence evaluation. Continence service should be a quality indicator for health care during pregnancy and postpartum. Early detection of incontinence in annual population-based surveys (the Behavioral Risk Factor Surveillance System) may improve public awareness of incontinence. Several ongoing studies will test different diagnostic strategies to detect incontinence (Table 77).

The pathophysiology of incontinence needs further investigation to develop effective preventive and curative treatments. Muscle-derived stem cells showed promising results in animal and in vivo studies.[950,951] Injections of myoblasts to bladder walls resulted in regeneration of myofibers and improved contractility.[952] Recombinant human insulin-like growth factor-I delivered with plasmid to denervated sphincter muscle improved recovery of sphincter function in animal models.[953] Gene transfer therapy with hMaxi-K was successfully tested in one Phase I clinical trial.[954] Another ongoing trial in patients with overactive bladder will examine the effects of gene therapy of the alpha subunit of the human smooth muscle Maxi-K channel (NCT00495053). Continence devices that work on demand, similar to cardiac pacemakers, may be developed in the future to prevent involuntary leakage of urine and feces.

An important continuing and unresolved problem is defining what is meant by either type of incontinence. The failure to resolve this issue impedes both prevalence and diagnostic and efficacy research. The inconsistencies between patient reports and physiological measures continue to pose a serious problem. For efficacy studies, some combined measure might be applied, but for prevalence assessments, such an approach would pose serious logistical problems. The differences are even more severe when one considers the implications of differences in utility weights applied to measures of incontinence between patients and clinicians.[484,515]

The pressures for finding effective treatments have increased as a result of advertising of medications to treat UI that is directed to patients. Expectations have been raised. The need for more and better studies of treatments for both types of incontinence (UI and FI) remains. Given the social problems caused by incontinence, enthusiasm for surgical treatment remains high for treating both UI and FI,[955-957] although future research is needed to examine the balance between benefits and harms related to surgery and the cost-effectiveness of surgical treatments compared to conservative preventive interventions.

Managing both types of incontinence in LTC settings remains problematic. Programs that work under experimental conditions have not been sustained because they are labor intensive and essentially unreimbursed. Indeed, case mix based payments for nursing homes create a disincentive to manage incontinence.

Several other specific areas have been identified as needing more research. They include:

- Interaction between age, race, and other risk factors for UI and FI in women and men
- Effective strategies to prevent UI in women and men in community and LTC settings
- Effective interventions to reduce risk of institutionalization due to UI or FI.

- Association between race and severity of FI and quality of life related to FI in men and women from the community and in LTC settings
- Strategies to reduce the risk of FI related to pregnancy and childbirth
- Effectiveness of clinical interventions for incontinence across subgroups by cognitive and physical functioning, gender, and ethnicity
- Long-term effectiveness of individual conservative therapies, conservative management programs including community-based nonmedical interventions, and mechanical devices for UI and FI
- Comparative long-term effectiveness of conservative interventions, pharmacological interventions, combined conservative and pharmacological interventions, mechanical devices, and surgery for UI
- Individual patient factors that may modify the effects of different procedures
- Effects on FI of surgeries for hemorrhoids, rectal prolapse, rectal cancer, and anal fissures
- Cost-effective strategies to identify patients at risk of FI, including residents of LTC settings
- Long-term effects of conservative management programs for FI in community dwelling adults and residents of LTC settings

List of Acronyms/Abbreviations

ADL	Activities of daily living
AI	Anal incontinence
BMI	Body mass index
CI	Confidence interval
COPD	Chronic obstructive pulmonary disease
EMG	Electromyography
FI	Fecal incontinence
FIQL	Fecal incontinence quality of life
GI	Gastrointestinal
IBD	Inflammatory bowel disease
IBS	Irritable bowel syndrome
ICI	International consultation on incontinence
ICS	International Continence Society
LTC	Long-term care
MDS	Minimum data set
MMSE	Mini mental state examination
PPV	Positive predictive value
RCT	Randomized controlled trial
RR	Relative risk
SNRI	Serotonin norephinephine reuptake inhibitors
SSRI	Selective serotonin reuptake inhibitors
SUIQQ	Stress and urge incontinence and quality of life questionnaire
TEP	Technical expert panel
UI	Urinary incontinence
UISS	Urinary incontinence severity score

Appendix A. Analytic Framework

Appendix D contains details on analytical framework of the report: algorithm to define eligibility of the studies, definitions, hypotheses, and statistical models.

Conceptual and operational definitions of incontinence and risk factors of incontinence are presented below.

Conceptual Definitions

Fecal Incontinence—failure of voluntary control of the anal sphincters, with involuntary passage of feces and flatus (solid and liquid) and flatus[1]

Urinary Incontinence—complaint of any involuntary leakage of urine[2]
Urge urinary incontinence—involuntary urine leakage accompanied by or immediate preceded by urgency, usually related to the involuntary contractions of the detrusor muscle of the bladder (detrusor overactivity)[2]

Stress Urinary Incontinence—involuntary urine leakage as a result of physical effort or exertion that increases abdominal pressure on the urinary bladder in the absence of detrusor contraction [2]

Table 1. Operational definitions of incontinence

Variable	Definition
Symptoms of Urinary incontinence[2]	The complaint of any involuntary leakage of urine.
Signs of urinary Incontinence.	Urine leakage seen during examination: this may be urethral or extraurethral.
Extra-urethral incontinence	The observation of urine leakage through channels other than the urethra.
Uncategorized incontinence	The observation of involuntary leakage that cannot be classified into one of the above categories on the basis of signs and symptoms
Transient urinary incontinence[3,4]	A potentially reversible incontinence due to conditions that may resolve if the underlying cause is managed. These conditions include: delirium/confusional state; infection—urinary (symptomatic); atrophic urethritis/vaginitis; pharmaceuticals use; psychological conditions, especially depression; excessive urine output (e.g., CHF, hyperglycemia); restricted mobility; stool impaction
Established urinary incontinence[3,4]	Urinary incontinence that is attributed to bladder or urethral dysfunction such as: detrusor overactivity; detrusor underactivity; urethral obstruction; urethral incompetence
Stress urinary incontinence	Complaint of involuntary urine leakage on effort or exertion, or in sneezing or coughing
Urge urinary incontinence	Complaint of involuntary leakage accompanied by or immediately preceded by urgency
Overflow incontinence [5]	Urinary incontinence associated with: bladder overdistention; a contractile detrusor; hypotonic or underactive detrusor secondary to drugs, fecal impaction, diabetes, lower spinal cord injury, or disruption of the motor innervation of the detrusor muscle
Mixed urinary incontinence[2,6]	The complaint of involuntary leakage associated with urgency and also with exertion, effort, sneezing, or coughing
Situational urinary incontinence	The report of incontinence during sexual intercourse, or giggle incontinence.

Variable	Definition
Continuous urinary leakage	Complaint of continuous urinary leakage
Acute incontinence[7]	Sudden onset of symptoms related to an illness, treatment, or medication
Chronic incontinence	Persistent urinary incontinence includes disorders of storage (stress and urge), disorder of emptying (overflow), and functional and mixed incontinence.
Severity of incontinence	Incontinent episodes/unit time; pad changes/unit time; pad weight/unit time; number of micturitions/unit time; urinary pad test—measured loss; urodynamic-diagnosed detrusor overactivity; urodynamic stress incontinence
Sandvik's severity index[8]	Multiplied reported frequency (4 levels) by the amount of leakage (2 levels).
Slight incontinence	Leakage of drops a few times a month (~6g/24 hours, 95%CI 2-9)
Moderate incontinence	Daily leakage or drops (~17g/24 hours, 95%CI 13-22)
Severe incontinence	Leakage of large amount of urine at least once a week (~56g/24 hours, 95%CI 44-67)
Impact of incontinence	Actions patients have taken to ameliorate the incontinence including wearing pads, reducing activities, seeking medical treatment (visits to clinicians, prescriptions of medications, surgical procedures).
Impact of incontinence on quality of life	Measurement using a validated generic or condition-specific measure of quality of life developed to address issues related specifically to fecal incontinence or urinary incontinence
Remission of incontinence	Diminution of symptoms and signs of incontinence.
Contained Incontinence	Urine contained with pads or appliances
Dependent Continence	Dry with toileting assistance, behavioral treatment, and/pr medications
Independent Continence	Dry, not dependent on ongoing treatment
Symptoms of Incontinence[2,6]	The subjective indicator of incontinence or change in its severity as perceived by the patient, caregiver, or partner and may lead him/her to seek help from health care professionals.
Signs of Incontinence	Observed by the physician including simple means, to verify symptoms and quantify them.
Urodynamic observations	Observations made during urodynamic studies which have a number of possible underlying causes and do not represent a definitive diagnosis of a disease.
Measures of the frequency, severity and impact of urinary incontinence[2]	
Micturition time chart	Records of times of micturitions, day and night, for at least 24 hours.
Frequency volume chart (FVC)	Records of volumes voided as well as the time of each micturition, day and night, for at least 24 hours.
Bladder diary	Records of times of micturitions and voided volumes, incontinence episodes, pad usage, and other information such as fluid intake, the degree of urgency, and the degree of incontinence.
Daytime frequency	The number of voids recorded during waking hours and includes the last void before sleep and the first void after waking and rising in the morning.
24-hour frequency	The total number of daytime voids and episodes of nocturia during a specified 24-hour period
24-hour production	All urine produced during 24 hours
Maximum voided volume	The largest volume of urine voided during a single micturition and is determined either from the frequency/volume chart or bladder diary.
Pelvic floor muscle function	Measured during rectal examination by the tone at rest and the strength of a voluntary contraction, as strong, weak or absent. A pelvic muscle contraction may be assessed by visual inspection, by palpation, electromyography, or perineometry. Factors to be assessed include strength, duration, displacement, and repeatability
Pad testing	The amount of urine lost during incontinence episodes (a short provocative test to a 24-hour pad test)
Improvement in incontinence	Reduction frequency and severity of incontinence episodes. Reduction in restrictions of daily activities due to incontinence.
Progression of incontinence	Increase in frequency and severity of incontinence episodes. Increase in restrictions of daily activities due to incontinence. Failure of achieve continence. Failure to reduce frequency and severity of incontinent episodes.

Variable	Definition
Urodynamic Techniques[2,9-11]	
Conventional urodynamic studies	Urodynamic laboratory measurement of artificial bladder filling—filling the bladder, via a catheter, with a specified liquid at a specified rate.
Ambulatory urodynamic studies	A functional test of the lower urinary tract, utilizing natural filling (the bladder is filled by the production of urine rather than by an artificial medium), and reproducing the subject's every day activities
Intravesical pressure	The pressure within the bladder
Abdominal pressure	The pressure surrounding the bladder. In current practice it is estimated from rectal, vaginal or, less commonly, from extraperitoneal pressure or a bowel stoma. The simultaneous measurement of abdominal pressure is essential for the interpretation of the intravesical pressure trace.
Detrusor pressure	The component of intravesical pressure that is created by forces in the bladder wall (passive and active). It is estimated by subtracting abdominal pressure from intravesical pressure.
Filling cystometry	Urodynamic investigation of the filling phase of the micturition cycle. The method by which the pressure/volume relationship of the bladder is measured during bladder filling
Bladder function during filling.	The rate at which the bladder is filled.
Physiological filling rate	A filling rate less than the predicted maximum – predicted maximum body weight in kg divided by 4 expressed as ml/min
Nonphysiological filling rate	A filling rate greater than the predicted maximum filling rate –predicted maximum body weight in kg divided by 4 expressed as ml/min.
Bladder storage function	Bladder sensation, detrusor activity, bladder compliance, and bladder capacity.
Normal bladder sensation	Sensation judged by three defined points noted during filling cystometry and evaluated in relation to the bladder volume at that moment and in relation to the patient's symptomatic complaints.
First sensation of bladder filling	The feeling the patient has, during filling cystometry, when he/she first becomes aware of the bladder filling.
First desire to void	The feeling, during filling cystometry that would lead the patient to pass urine at the next convenient moment, but voiding can be delayed if necessary.
Strong desire to void	Persistent desire to void without the fear of leakage.
Increased bladder sensation	An early first sensation of bladder filling (or an early desire to void) and/or an early strong desire to void, which occurs at low bladder volume and which persists.
Reduced bladder sensation	Diminished sensation throughout bladder filling.
Absent bladder sensation	The absence of bladder sensation during filling cystometry.
Bladder pain	A self explanatory term and is an abnormal finding.
Urgency	A sudden compelling desire to void.
The vesical/urethral sensory threshold	The least current which consistently produces a sensation perceived by the subject during stimulation at the site under investigation.
Normal detrusor function	Bladder filling with little or no change in pressure. No involuntary phasic contractions occur despite provocation.
Detrusor overactivity	An urodynamic observation characterized by involuntary detrusor contractions during the filling phase which may be spontaneous or provoked.
Phasic detrusor overactivity	Defined by a characteristic wave form and may or may not lead to urinary incontinence
Terminal detrusor overactivity	A single, involuntary detrusor contraction, occurring at cystometric capacity, which cannot be suppressed and results in incontinence usually resulting in bladder emptying (voiding).
Detrusor overactivity incontinence	Incontinence due to an involuntary detrusor contraction.
Neurogenic detrusor overactivity	Detrusor overactivity caused by a relevant neurological condition.
Idiopathic detrusor overactivity	Detrusor overactivity with unknown cause.
Provocative maneuvers	Techniques used during urodynamics in an effort to provoke detrusor overactivity; for example, rapid filling, use of cooled or acid medium, postural changes and hand washing.

Variable	Definition
Bladder compliance during filling	
Cystometry	Description of the relationship between change in bladder volume and change in detrusor pressure; calculated by dividing the volume change (ΔV) by the change in detrusor pressure (Δpdet) during that change in bladder volume (C=V. Δpdet). It is expressed in ml/cm H2O. Two standard points: 1. The detrusor pressure at the start of bladder filling and the corresponding bladder volume (usually zero) 2. The detrusor pressure (and corresponding bladder volume) at cystometric capacity or immediately before the start of any detrusor contraction that causes significant leakage (and therefore causes the bladder volume to decrease, affecting compliance calculation). Both points are measured excluding any detrusor contraction.
Bladder capacity during filling cystometry	
Cystometric capacity	The bladder volume at the end of the filling cystometrogram, when "permission to void" is usually given. The end point should be specified, for example, if filling is stopped when the patient has a normal desire to void. The cystometric capacity is the volume voided together with any residual urine.
Maximum cystometric capacity	The volume at which the patient feels he/she can no longer delay micturition (has a strong desire to void).
Maximum anaesthetic bladder capacity	The volume to which the bladder can be filled under deep general or spinal anesthetic and should be qualified according to the type of anesthesia used and the speed, the length of time, and the pressure at which the bladder is filled.
Urethral function during filling cystometry	The urethral closure mechanism during storage
Normal urethral closure mechanism	A positive urethral closure pressure during bladder filling even in the presence of increased abdominal pressure, although it may be overcome by detrusor overactivity.
Incompetent urethral closure mechanism	Patho-physiologic condition which allows leakage of urine in the absence of a detrusor contraction.
Urethral relaxation incontinence	A leakage due to urethral relaxation in the absence of raised abdominal pressure or detrusor overactivity.
Urodynamic stress incontinence (genuine stress incontinence)	The involuntary leakage of urine during increased abdominal pressure, in the absence of a detrusor contraction
Assessment of urethral function during filling cystometry	
Urethral pressure measurement	The fluid pressure needed to just open a closed urethra.
The urethral pressure profile	A graph indicating the intraluminal pressure along the length of the urethra
The urethral closure pressure profile	Given by the subtraction of intravesical pressure from urethral pressure
Maximum urethral pressure	The maximum pressure of the measured profile.
Maximum urethral closure pressure (MUCP)	The maximum difference between the urethral pressure and the intravesical pressure.
Functional profile length	The length of the urethra along which the urethral pressure exceeds intravesical pressure in women.
Pressure "transmission" ratio	The increment in urethral pressure on stress as a percentage of the simultaneously recorded increment in intravesical pressure
Abdominal leak point pressure	The intravesical pressure at which urine leakage occurs due to increased abdominal pressure in the absence of a detrusor contraction.
Detrusor leak point pressure	The lowest detrusor pressure at which urine leakage occurs in the absence of either a detrusor contraction or increased abdominal pressure.

Variable	Definition
Pressure Flow Studies	The method by which the relationship between pressure in the bladder and urine flow rate is measured during bladder emptying.
Urine flow	Continuous, that is without interruption, or as intermittent urine flow, when an individual states that the flow stops and starts during a single visit to the bathroom in order to void. The continuous flow curve is defined as a smooth arc-shaped curve or fluctuating when there are multiple peaks during a period of continuous urine flow
Flow rate	The volume of fluid expelled via the urethra per unit time expressed in ml/s
Voided volume	The total volume expelled via the urethra
Maximum flow rate	The maximum measured value of the flow rate after correction for artifacts
Voiding time	Total duration of micturition, i.e., includes interruptions. When voiding is completed without interruption, voiding time is equal to flow time
Flow time	The time over which measurable flow actually occurs.
Average flow rate	Voided volume divided by flow time. The average does not reflect flow interruptions or terminal dribble.
Time to maximum flow	The elapsed time from onset of flow to maximum flow.
Pressure measurements during pressure flow studies (PFS)	
Premicturition pressure	The pressure recorded immediately before the initial isovolumetric contraction.
Opening pressure	The pressure recorded at the onset of urine flow.
Opening time	The elapsed time from initial rise in detrusor pressure to onset of flow.
Maximum pressure	The maximum value of the measured pressure
Pressure at maximum flow	The lowest pressure recorded at maximum measured flow rate.
Closing pressure	The pressure measured at the end of measured flow.
Minimum voiding pressure	The minimum pressure during measurable flow but is not necessarily equal to either the opening or closing pressures.
Flow delay	The time delay between a change in bladder pressure and the corresponding change in measured flow rate.
Detrusor function during voiding	
Normal detrusor function	Allows bladder filling with little or no change in pressure. No involuntary phasic contractions occur despite provocation
Detrusor underactivity	A contraction of reduced strength and/or duration, resulting in prolonged bladder emptying and/or a failure to achieve complete bladder emptying within a normal time span.
Acontractile detrusor	No contractility can be detected during urodynamic studies.
Post void residual (PVR)	The volume of urine left in the bladder at the end of micturition
Urethral function during voiding	
Normal urethra function	Urethra that opens and is continuously relaxed to allow the bladder to be emptied at a normal pressure.
Abnormal urethra function	Obstruction to urethral overactivity or the urethra cannot open due to anatomic abnormality, such as an enlarged prostate or a urethral stricture
Bladder outlet obstruction	Obstruction during voiding and is characterized by increased detrusor pressure and reduced urine flow rate diagnosed by studying the synchronous values of flow rate and detrusor pressure.
Dysfunctional voiding	An intermittent and/or fluctuating flow rate due to involuntary intermittent contractions of the periurethral striated muscle during voiding in neurologically normal individuals.
Detrusor sphincter dyssynergia	A detrusor contraction concurrent with an involuntary contraction of the urethral and/or periurethral striated muscle.
Non-relaxing urethral sphincter obstruction	Non-relaxing, obstructing urethra resulting in reduced urine flow in individuals with a neurological lesion

Long-term care—care over an extended period, usually for a chronic condition or disability, requiring periodic, intermittent, or continuous care

Conceptual definition of race—continental population groups of individuals whose putative ancestry is from native continental populations based on similarities in physical appearance

Conceptual definition of ethnicity—ethnic groups of people with a common cultural heritage that sets them apart from others in a variety of social relationships

Table 2. Operational definitions of patient race and ethnicity[12]

Variable	Definition
Race	
African Continental Ancestry Group	Individuals whose ancestral origins are in the continent of Africa.
Asian Continental Ancestry Group	Individuals whose ancestral origins are in the continent of Asia.
European Continental Ancestry Group	Individuals whose ancestral origins are in the continent of Europe
Ethnic Groups	
African Americans	Persons living in the United States having origins in any of the black groups of Africa
Arabs	Members of a Semitic people inhabiting the Arabian peninsula or other countries of the Middle East and North Africa. The term may be used with reference to ancient, medieval, or modern ethnic or cultural groups
Asian Americans	Persons living in the United States having origins in any of the original peoples of the Far East, Southeast Asia, or the Indian subcontinent.
Hispanic Americans	Persons living in the United States of Mexican (Mexican Americans), Puerto Rican, Cuban, Central or South American, or other Spanish culture or origin. The concept does not include Brazilian Americans or Portuguese Americans.

Conceptual definitions of risk factors[12]—aspects of personal behavior or lifestyle, environmental exposure, or inborn or inherited characteristic, which, on the basis of epidemiologic evidence, is known to be associated with urinary and fecal incontinence considered important to prevent incontinence.

Prevalence of incontinence—probability of experiencing a symptom or having a disease within a defined population and at a defined time point.[1,6]

Incidence—probability of developing incontinence under study during a defined time period, usually reported for one, two-, or five-year interval.[1,6]

Relative risk estimation of the magnitude of an association between exposure and a condition, indicates the likelihood of having the condition in the exposed group relative to those who are not exposed.[1,6]

Odds ratio is the odds for having a risk factor in persons with a condition divided by the odds among those without the condition[1,6].

Table 3. Operational definitions of known risk factors of urinary and fecal incontinence

Variable	Definition
Age	Persons classified by age from birth to octogenarians and older Age categories: 19-44 years; 45-64 years, 65+ years; 80 and over
Elderly	Aged- person 65 through 79 years of age; 80 and over
Functional impairment (Frailty) [13]	Combination of three or more of five factors: unintentional weight loss (10 pounds or more in a year); general feeling of exhaustion; weakness (as measured by grip strength); slow walking speed; low levels of physical activity.
Prostate disorders[3,4]	Prostatic enlargement, urethral stricture, bladder neck contracture, or prostate cancer that may cause urethral obstruction
Pregnancy[12]	The status during which female mammals carry their developing young embryos, or fetuses in uteri before birth, beginning from fertilization to birth
Postpartum period	In females, 4 weeks after giving birth

Variable	Definition
Menopause	The last menstrual period. Permanent cessation of menses usually defined after 6 to 12 months of amenorrhea in a woman over 45 years of age.
Institutionalization	Caring for individuals in institutions and their adaptation to routines characteristic of the institutional environment, and/or their loss of adaptation to life outside the institution.
Dementia	An acquired organic mental disorder with loss of intellectual abilities of sufficient severity to interfere with social or occupational functioning. The dysfunction is multifaceted and involves memory, behavior, personality, judgment, attention, spatial relations, language, abstract thought, and other executive functions. The intellectual decline is usually progressive, and initially spares the level of consciousness.
Depression	Depressive states usually of moderate intensity in contrast with major depression present in neurotic and psychotic disorders
Depressive disorder	An affective disorder manifested by either a dysphoric mood or loss of interest or pleasure in usual activities. The mood disturbance is prominent and relatively persistent.
Depression, postpartum	Depression in postpartum women, usually within four weeks after giving birth. The degree of depression ranges from mild transient depression to neurotic or psychotic depressive disorders
Depressive disorder, major	Marked depression appearing in the involution period and characterized by hallucinations, delusions, paranoia, and agitation
Psychiatric disorders	Psychiatric illness or diseases manifested by breakdowns in the adaptational process expressed primarily as abnormalities of thought, feeling, and behavior producing either distress or impairment of function
Diabetes	A heterogeneous group of disorders characterized by hyperglycemia and glucose intolerance
Diabetes mellitus, Type 2	A subclass of diabetes that is not Insulin-responsive or dependent (NIDDM). It is characterized initially by insulin resistance and hyperinsulinemia; and eventually by glucose intolerance; hyperglycemia and overt diabetes. Patients often exhibit obesity
Diabetes mellitus, Type 1	A subtype of diabetes mellitus that is characterized by Insulin deficiency. It is manifested by the sudden onset of severe hyperglycemia, rapid progression to diabetic ketoacidosis, and death unless treated with insulin.
Obesity	A status with body weight that is grossly above the acceptable or desirable weight, usually due to accumulation of excess fats in the body. The standards may vary with age, sex, genetic or cultural background. In the body mass index, a BMI greater than 30.0 kg/m2 is considered obese, and a BMI greater than 40.0 kg/m2 is considered morbidly obese
Diet	Regular course of eating and drinking adopted by a person measured by a nutrient intake over a specific period of time
Irritable bowel syndrome	A disorder with chronic or recurrent colonic symptoms. This condition is characterized by chronic or recurrent abdominal pain, bloating, mucus in feces, and an erratic disturbance of defecation
Diarrhea	An increased liquidity or decreased consistency of feces, such as running stool. Fecal consistency is partially related to the ratio of water-holding capacity of insoluble solids to total water, rather than only the amount of water present. Diarrhea is not hyperdefecation or increased fecal weight
Constipation[14]	Presence of at least two symptoms, which must be present at least 25% of the time. Symptoms include: fewer than 3 bowel movements per week, hard or lumpy stools, straining with defecation, a sensation of incomplete evacuation, a sensation of anorectal obstruction, and the use of manual maneuvers to assist defecation. Chronicity: 12 weeks in the previous year, which do not need to be consecutive. 3 subtypes:[14] colonic inertia (delayed motility), outlet obstruction, and functional constipation.

Variable	Definition
Inflammatory Bowel Diseases	Chronic, nonspecific inflammation of the gastrointestinal tract including Crohn disease and ulcerative colitis
Irritable Bowel Syndrome	A disorder with chronic or recurrent colonic symptoms without a clear-cut etiology characterized by chronic or recurrent abdominal pain, bloating, mucus in feces, and an erratic disturbance of defecation
Fecal impaction	Formation of a firm impassable mass of stool in the rectum or distal colon
Cardiovascular diseases	Pathological conditions involving the cardiovascular system including the heart; blood vessels; or pericardium: arrhythmia; congestive heart failure; coronary disease; myocardial infarction; hypertension
Smoking	Inhaling and exhaling the smoke of tobacco or something similar to tobacco
Smoking related respiratory tract diseases	Lung neoplasm Chronic obstructive pulmonary disease—a disease of chronic diffuse irreversible airflow obstruction Pneumonia—Inflammation of the lungs Asthma—A form of bronchial disorder associated with airway obstruction, marked by recurrent attacks of paroxysmal dyspnea, with wheezing due to spasmodic contraction of the bronchi.
Gastrointestinal procedures	Proctocolectomy, Restorative—A surgical procedure involving the excision of the colon and rectum and the formation of an illeoanal reservoir
Major abdominal/pelvic surgery	Anterior resection; abdominal aortic aneurism surgery
Gynecologic procedures	Surgery performed on the female genitalia. Colposcopy—The examination, therapy or surgery of the cervix and vagina by means of a specially designed endoscope introduced vaginally Culdoscopy—Endoscopic examination, therapy, or surgery of the female pelvic viscera by means of an endoscope introduced into the pelvic cavity through the posterior vaginal fornix. Hysteroscopy—Endoscopic examination, therapy, or surgery of the interior of the uterus Gynecological surgery for pelvic organ prolapse repair, pelvic organ prolapse
Urologic surgical procedures	Surgery performed on the urinary tract or its parts in the male or female Cystectomy—Used for excision of the urinary bladder Cystoscopy—Endoscopic examination, therapy, or surgery of the urinary bladder Ureteroscopy—Endoscopic examination, therapy, or surgery of the ureter. Urinary diversion—Temporary or permanent diversion of the flow of urine through the ureter away from the urinary bladder in the presence of a bladder disease or after cystectomy Prostatectomy—Complete or partial surgical removal of the prostate. Three primary approaches are commonly employed: suprapubic—removal through an incision above the pubis and through the urinary bladder; retropubic—as for suprapubic but without entering the urinary bladder; and transurethral Ultrasound, high-intensity focused, transrectal—Tissue ablation of the prostate performed by ultrasound from a transducer placed in the rectum
Stroke	A sudden, nonconvulsive loss of neurologic function due to an ischemic or hemorrhagic intracranial vascular event classified by anatomic location in the brain, vascular distribution, etiology, age of the affected individual, and hemorrhagic vs. nonhemorrhagic nature
Spinal cord diseases	Pathologic conditions which feature spinal cord damage or dysfunction, including disorders involving the meninges and perimeningeal spaces surrounding the spinal cord. Traumatic injuries, vascular diseases, infections, and inflammatory/autoimmune processes may affect the spinal cord.
Hip fractures	Fractures of the femur head; the femur neck; the trochanters; or the inter- or subtrochanteric region

Variable	Definition
Degenerative joint diseases	Diseases of the bones and cartilage viewed collectively.
Osteoarthritis	A progressive, degenerative joint disease, the most common form of arthritis, especially in older persons
Parkinson's disease	A progressive, degenerative neurologic disease characterized by a tremor that is maximal at rest, retropulsion, rigidity, stooped posture, slowness of voluntary movements, and a mask like facial expression.
Multiple sclerosis	An autoimmune disorder mainly affecting young adults and characterized by destruction of myelin in the central nervous system. Pathologic findings include multiple sharply demarcated areas of demyelination throughout the white matter of the central nervous system. Clinical manifestations include visual loss, extra-ocular movement disorders, paresthesias, loss of sensation, weakness, dysarthria, spasticity, ataxia, and bladder dysfunction
Rectal diseases and surgeries	Hemorroidectomy -surgical removal of hemorrhoids; bowel resection; anal and recto-vaginal fistula; rectal prolapse; acute sphincter trauma and sphincter repair
Obstetrical and other injuries to the pelvic floor	Parity—the number of offspring a female has borne Delivery, Obstetric—delivery of the fetus and placenta under the care of an obstetrician or a health worker including vaginal, forceps delivery; vacuum extraction; episiotomy; and cesarean. Fetal characteristics: increased fetal weight and head circumference
Family History	History of incontinence in parents and first degree siblings
History of childhood nocturnal enuresis	History of childhood involuntary discharge of urine during sleep at night after expected age of completed development of urinary control
Demographics:	
Education	Educational attainment or level of education of individuals
Socioeconomic factors	Social and economic factors that characterize the individual or group within the social structure
Marital status	Person's status with respect to marriage, divorce, widowhood, singleness.
Physical activity	The physical activity as a behavioral phenomenon characterized by frequency and intensity of motor activity per unit of time (day, week).
Sexual abuse	Violation of established legal or moral codes in respect to sexual behavior. A condition in which there is a derivation of pleasure from inflicting pain, discomfort, or humiliation on another person or persons.
Torture	The intentional infliction of physical or mental suffering upon an individual.
Sodomy	Anal sexual intercourse
Alcohol use	Behaviors associated with the ingesting of alcoholic beverages, including social drinking
Nutritional deficits, malnutrition, fiber-free tube-feeding formulas	An imbalanced nutritional status resulting from insufficient intake of nutrients to meet normal physiological requirement. Nutritional support given via the alimentary canal or any route connected to the gastrointestinal system (i.e., the enteral route). This includes oral feeding, sip feeding, and tube feeding using nasogastric, gastrostomy, and jejunostomy tubes
Mobility status	Bedbound, wheelchair bound, assistive device; physical restraints
Sleep disturbances	Conditions characterized by disturbances of usual sleep patterns or behaviors: dyssomnias (i.e., disorders characterized by insomnia or hypersomnia), parasomnias (abnormal sleep behaviors), and sleep disorders secondary to medical or psychiatric disorders

Conceptual definition of clinical interventions to reduce the risk of fecal and urinary incontinence—epidemiologic investigations designed to test a hypothesized cause-effect relation between intervention and incidence (progression) of fecal and urinary incontinence in the study population

Primary prevention—specific practices for the prevention of incontinence in susceptible individuals or populations; aims to remove the causes of the disease

Secondary prevention[1,6]— intervention for existing symptoms of incontinence to prevent disease progression

Table 4. Operational definitions of clinical interventions for the primary and secondary prevention of incontinence

Variable	Definition
Health education	Education that increases the awareness and favorably influences the attitudes and knowledge relating to the early detection and prevention of fecal and urinary incontinence
Behavioral therapy	The application of behavioral changes to detect and manage incontinence including: education about urinary and fecal tract structure and function; development of individualized diaries of daily dietary, physical activities, urinary and fecal habits; pelvic floor muscle exercises; voiding schedules: prompted, timed, habit retraining, patterned urge response toileting
Biofeedback	Process by which a person uses biofeedback information to gain voluntary control over pelvic floor muscle function, urination and defecation processes
Pelvic floor muscle training for urinary incontinence	A systematic program of pelvic floor muscle exercises (Kegel exercises) designed to improve the strength and coordination of the pelvic floor muscles in order to improve urinary sphincter function and to control urgency
Pelvic floor muscle training for fecal incontinence	Training technique to become aware of the presence of fecal material in the rectum and relearning skills necessary for coordinating contractions of external anal sphincter and improving the force of muscle contraction.
Vaginal cones	Insertion of vaginal cone (weighted device) into the vagina and contraction of the pelvic floor muscles in an effort to hold the device in place.
Electrical stimulation	Application of electric current in treatment without the generation of perceptible heat. Using low-voltage electric current to stimulate the correct group of muscles delivered using an anal or vaginal probe
Sacral neuromodulation	Placement of a "bladder pacemaker" for continuous stimulation to the sacral nerve that controls the urinary sphincter Placement of a "pacemaker" for continuous stimulation of the sacral nerves to control fecal incontinence Percutaneous tibial neuromodulation—Placement of a fine needle into the skin above the ankles for intermittent stimulation of the post tibial nerve
Urethral "plugs" and patches	Insertion of plastic shapes into the urethra to stop the flow of urine or placed externally at the urinary meatus to prevent urine leakage; Used for female stress urinary incontinence
Pessaries	A plastic or silicone device which is inserted into the vagina to provide support to the uterus, vagina, bladder, or rectum when there is pelvic organ prolapse. Special pessaries with knobs are available for use in treatment of urinary incontinence.
Sanitary shield	Sanitary products for a single use in incontinent patients

Variable	Definition
Penile compression devices	A special clamp that is placed around the penis to prevent urinary leakage.
Intermittent catheterization	Drainage or aspiration of the bladder or a urinary reservoir with subsequent removal of the catheter. Intermittent self-catheterization is performed by the patient himself/herself Intermittent catheterization is performed by an attendant (e.g., doctor, nurse or relative) Clean intermittent catheterization: use of a clean technique. This implies ordinary washing techniques and use of disposable or cleansed reusable catheters. Aseptic intermittent catheterization: use of a sterile technique. This implies genital disinfection and the use of sterile catheters and instruments/gloves.
Indwelling catheterization	Indwelling catheter remains in the bladder, urinary reservoir, or urinary conduit for a period of time longer than one emptying. Clamps and compression rings in males are placed over the penis to squeeze the urethra shut
Bladder reflex triggering	Various maneuvers performed by the patient or the therapist in order to elicit reflex detrusor contraction by exteroceptive stimuli including suprapubic tapping, thigh scratching, and anal/rectal manipulation.
Weight loss	Intentional decrease in existing body weight as a results of reduced calorie intake and/or increased physical activity
Smoking cessation	Discontinuation of the habit of smoking, the inhaling and exhaling of tobacco smoke
Diet therapy	Adjusting the quantity and quality of food intake to improve health status of an individual (alcohol, fluid, and caffeine intake)
Magnetic stimulation	Stimulation with a brief magnetic field on the pelvic floor muscles and sacral roots without insertion of an annals or vaginal probe
Elective Caesarian delivery	Extraction of the fetus by means of abdominal hysterotomy
Direct neuromodulation of the sacral spinal cord	Placement of quadripolar electrode into S3 foramen for stimulation of S3 nerve in order to normalize vesico urethral function
Urethropexy	Surgical suspension of the urethra from the posterior surface of the pubic symphysis in order to correct urinary stress incontinence
Laparoscopic and open Burch retropubic urethropexies	Extra/transperitoneal laparoscopic/retropubic urethropexies using non absorbable sutures or prolene meshes fixed with tackers or staplers
Abdominal sacrocolpopexy	Support of the vaginal vault by affixing it to the periosteum of the sacrum following a hysterectomy Traditional Burch urethropexy included the basic principles of the Tanagho modification: (1) minimal dissection within 2cm of the urethrovesical junction and urethra, (2) placement of sutures through full thickness of shiny white paravaginal fascia, (3) use of two sutures on each side, one opposite to the urethrovesical junction and another at the level of the midurethra, (4) removal of adipose tissue lateral to the sutures to stimulate fibrosis, and (5) facilitating typing of sutures to the Cooper ligament with intravaginal fingers elevating the anterior vaginal wall. Modified Burch colposuspension includes the suspension of anterior vaginal wall at the level of the bladder neck with permanent sutures connected to the iliopectineal ligament
Urethral bulking procedures: Transurethral or periurethral injection techniques for females and transurethral or antegrade injection for males	Artificially inflating the submucosal tissues of the bladder neck Urethral bulking agents approved by the FDA include collagen (Contigen), autologous fat, and carbon bead technology (Durasphere). Autologous fat from the lower abdomen injected around the urethra. Glutaraldehyde, cross-linked collagen-extracted and purified bovine collagen. Durasphere - pyrolytic carbon-coated beads suspended in a water-based gel. Synthetic calcium

Variable	Definition
	hydroxylapatite, cross-linked hyaluronic acid (HA), and ethylene vinyl alcohol copolymer suspended in dimethyl sulfoxide are under investigation.
Anterior colporrhaphy (anterior repair)	An operation of placating and suturing the anterior wall of the vagina to provide support to the anterior wall of the vagina and the bladder.
Posterior colporrhaphy (posterior repair)	An operation of placating and suturing of the posterior wall of the vagina to provide support to the rectum.
Artificial bowel sphincter	A surgical procedure that inserts an inflatable artificial sphincter in cases of bowel (fecal) incontinence caused by a sphincter dysfunction or injury. Devices implanted under the skin to mimic the natural function of the anal sphincter include an inflatable cuff, placed in the anus, a balloon reservoir, placed in the pubic area, and a pump, placed in the pubic area, connecting the cuff and balloon
Overlapping sphincteroplasty	A surgical technique designed to restore integrity and function to anal sphincter: Incision and removal of episiotomy scar tissue from the sphincter muscles; mobilization of external anal sphincter muscle; the stitching of muscle to itself
Dynamic graciloplasty	Transposition of the gracilis muscle to the anus with the implantation of stimulating electrodes
Hormone replacement therapy	Therapeutic use of hormones to alleviate the effects of hormone deficiency in menopausal females
Topical estrogen therapy	Topical vaginal administration of estrogenes

Table 5. Clinical interventions by type of incontinence

Urinary Incontinence	Fecal Incontinence
Prolapse surgery	Prolapse surgery
Estrogens: Topical; oral	Dietary fiber supplements, diet high in fiber foods, or fiber supplemented tube feeding formula
Scheduled voiding regimens, e.g., timed voiding, prompted voiding, patterned urge response toileting, habit training, bladder training	Yogurt, other lactobacillus preparations, or and other probiotics, fructooligosaccharides
Pelvic floor muscle training	Diet modifications: avoiding caffeine, sorbitol containing artificial sweeteners
Vaginal cones	Overlapping sphincteroplasty
Biofeedback	Dynamic graciloplasty
Electrical stimulation	Biofeedback
Urethral "plugs," patches, and urethral pessaries	Electrical stimulation
Penile compression devices	Antimotility or antidiarrheal medications
Bladder reflex triggering	Artificial bowel sphincter
Detrol (tolterodine tartrate)	Anal plug
Ditropan, oxytrol (oxybutynin chloride)	Overlapping sphincteroplasty
Sanctura (trospium chloride)	Pelvic floor muscle or Kegel exercises
Enablex (darifenacin)	Urgency suppression, relaxation
Vesicare (solifenacin succinate)	Bowel training techniques: toileting, prompting, scheduled toileting upon awakening or after meals, digital stimulation, abdominal massage
Magnetic stimulation	Rectal evacuation or irrigation using small enema, suppository or laxative
Direct neuromodulation of the sacral spinal nerves	Direct neuromodulation of the sacral spinal nerves
Percutaneous nerve stimulation	
Urethropexy	
Laparoscopic and open Burch retropubic urethropexies	
Abdominal sacrocolpopexy	
Anterior colporrhaphy (anterior repair)	
Posterior colporrhaphy (posterior repair)	
Artificial sling	
Botulinum toxin injections for detrusor-sphincter dyssyndergia or detrusor hyperreflexia)	
Bulking injections	

Commonly used medications that may affect urinary and fecal continence

Type of Medication	Examples	Potential Effects on Continence
Sedatives/hypnotics	Long-acting benzodiazepines (e.g., diazepam, flurazepam)	Sedation, delirium, immobility
Alcohol		Polyuria, frequency, urgency, sedation, delirium, immobility
Anticholinergics	Dicyclomine, disopyramide, sedating antihistamines	Urinary retention, overflow incontinence, delirium, impaction
Antipsychotics	Thioridazine, haloperidol	Anticholinergic actions, sedation, rigidity, immobility
Tricyclic antidepressants Selective serotonin reuptake inhibitors Serotonin norepinephrine reuptake inhibitors	Amitriptyline, desipramine Duloxetine fluoxetine, citalopram, paroxetine, sertraline, fluvoxamine, and venlafaxine	Anticholinergic actions, sedation
Antiparkinsonians	Trihexyphenidyl, benztropine mesylate (not L-dopa/selegiline)	Anticholinergic actions, sedation
Narcotic analgesics	Opiates	Urinary retention, fecal impaction, sedation, delirium
α-Adrenergic antagonists	Prazosin, terazosin, doxazosin	Urethral relaxation may precipitate stress incontinence in women
α-Adrenergic agonists	Nasal decongestants	Urinary retention in men
Calcium channel blockers	All dihydropyridines	Urinary retention; nocturnal diuresis due to fluid retention
Potent diuretics	Furosemide, bumetanide	Polyuria, frequency, urgency
Angiotensin-converting enzyme inhibitors	Furosemide, bumetanide	Drug-induced cough can precipitate stress incontinence in women and in some men with prior prostatectomy
Thiazolidinediones	Rosiglitazone	Nocturnal diuresis due to fluid retention
Cyclooxygenase 2 selective NSAIDs	Rofecoxib, celecoxib	Nocturnal diuresis due to fluid retention
Vincristine		Urinary retention

Algorithm to Define Eligibility of Studies

RESEARCH QUESTION.

1. What are the prevalence and incidence of fecal and urinary incontinence in the community and long-term care settings? By:
   - Race
   - Ethnicity
   - Gender
   - Age

   What is the range of estimates?
   What factors account for the variance?
   - Nature of the sample
   - Definition of incontinence
   - Manner of ascertainment

VERIFICATION/SELECTION OF STUDY ELIGIBILITY

Criteria 1 - Confirm eligibility of target population
Eligible descriptors:
Adults in the community Yes No Combined
Adults in long-term care settings Yes No Combined
If NO – exclude

Criteria 2 - Confirm eligibility of the outcomes
Eligible descriptors:
Prevalence of urinary/fecal incontinence Yes No Combined
Incidence of urinary/fecal incontinence Yes No Combined
If No – exclude

Criteria 3. Confirm eligible level of evidence
Eligible descriptors:
Large population based cross sectional analyses Yes
Large population based cohort studies Yes
Large cross sectional analyses in long-term care settings Yes
Large cohort studies in long-term care settings Yes
Case-series with more than 100 subjects Yes
If NO for all descriptors – exclude

2. What are the independent contributions of risk factors for fecal and urinary incontinence, including:
   - Age
   - Frailty
   - Prostate disorders
   - Pregnancy and postpartum state
   - Menopause
   - Institutionalization
   - Neurological impairment
   - Dementia
   - Psychiatric disorders, specifically depression
   - Diabetes
   - Obesity
   - Chronic GI conditions such as IBS, diarrhea, constipation, and IBD
   - Cardiovascular and pulmonary conditions, specifically smokers
   - Gastrointestinal, gynecologic, and urological procedures
   - Neurological disorders, such as stroke and spinal cord problems

VERIFICATION/SELECTION OF STUDY ELIGIBILITY

Criteria 1 – Confirm eligibility of target population
Eligible descriptors:
Adults in the community
Adults in long-term care settings Yes No Combined
If NO – exclude

Criteria 2 – Confirm eligibility of the outcomes
Eligible descriptors:
Prevalence of urinary/fecal incontinence Yes No Combined
Incidence of urinary/fecal incontinence Yes No Combined
If No – exclude

Criteria 3 – Confirm eligibility of risk factors
Eligible descriptors are listed in the tables with definitions (Table 2)
If NO – exclude

Criteria 4 - Confirm eligible level of evidence
Eligible descriptors:
Large population based cross sectional analyses Yes
Large population based cohort studies Yes
Large cross sectional analyses in long-term care settings Yes
Large cohort studies in long-term care settings Yes
Case-series with more than 100 subjects Yes
Case-control studies with randomly selected controls Yes
If NO for all descriptors – exclude

3. What is the evidence to support specific clinical interventions to reduce the risk of fecal and urinary incontinence?

VERIFICATION/SELECTION OF STUDY ELIGIBILITY

Criteria 1 - Confirm eligibility of target population
Eligible descriptors:
Adults in the community
Adults in long-term care settings Yes No Combined
If NO – exclude

Criteria 2 – Confirm eligibility of the outcomes
Eligible descriptors:
Prevalence of urinary/fecal incontinence Yes No Combined
Incidence of urinary/fecal incontinence Yes No Combined
Progression of urinary/fecal incontinence Yes No Combined
If No – exclude

Criteria 3 – Confirm eligibility of interventions
Eligible descriptors are listed in tables with definitions (Table 4-5)
If NO – exclude

Criteria 4 – Confirm eligible level of evidence
Eligible descriptors:
For the studies that examined urinary incontinence
Randomized controlled clinical trials Yes No
If NO – exclude

For the studies that examined the effects of drug treatment on progression of incontinence:
Length of follow up 12 months or more Yes No
If NO – exclude
For the studies that examined fecal and combined incontinence
Randomized controlled clinical trials Yes No
Multi center not randomized clinical trials Yes No
If NO – exclude

4. What are the strategies to improve the identification of persons at risk and patients who have fecal and urinary incontinence?

VERIFICATION/SELECTION OF STUDY ELIGIBILITY

Criteria 1 – Confirm eligibility of target population
Eligible descriptors:
Adults in the community
Adults in long-term care settings Yes No Combined
If NO – exclude

Criteria 2 - Confirm eligibility of diagnostic strategies.
Eligible descriptors are listed in tables with definitions (Table 1) and in the Conceptual model 2.
If NO – exclude

Criteria 3 – Confirm eligibility of outcomes.
Eligible descriptors:
Diagnosis of urinary and fecal incontinence Yes No Combined
Cost-effectiveness of diagnostic strategies Yes No Combined
If No – exclude

Criteria 4 – Confirm eligibility of the outcomes assessment:
Eligible descriptors:
True positive Yes No
True negative Yes No
False positive Yes No
False negative Yes No
Sensitivity Yes No
Specificity Yes No
Positive predictive likelihood of the test Yes No
Validity of the scale Yes No
Validity of the questionnaire Yes No
Reliability of the scale Yes No
Reliability of the questionnaire Yes No
For the studies that examined urinary incontinence
Inter-observer variability Yes No
If No for all descriptors – exclude

Criteria 5 – Confirm the eligible level of evidence:
Eligible descriptors:

Randomized controlled clinical trials	Yes	No
Multicenter controlled clinical trials	Yes	No
Large (>100 subjects) observational studies	Yes	No
Case-control studies with >10 cases	Yes	No

If No for all descriptors – exclude

International classification of diseases, diagnostic codes of incontinence:[15]
625.6 Stress incontinence, female
787.6 Incontinence of feces
Encopresis NOS
Incontinence of sphincter ani
788.32 Stress incontinence, male
788.31 Urge incontinence
788.38 Overflow incontinence
788.39 Other urinary incontinence
788.34 Incontinence without sensory awareness
788.33 Mixed incontinence (female) (male)
596 Other disorders of bladder
788.30 Urinary incontinence, unspecified
788.63 Urgency of urination
788.3 Urinary incontinence
599.6 Urinary obstruction
Use additional code to identify urinary incontinence (625.6, 788.30-788.39)
598 Urethral stricture Includes: pinhole meatus; stricture of urinary meatus
Use additional code to identify urinary incontinence (625.6, 788.30-788.39)
596.51 Hypertonicity of bladder
Hyperactivity
Overactive bladder
344.61 With neurogenic bladder
Acontractile bladder
Autonomic hyperreflexia of bladder
Cord bladder
Detrusor hyperreflexia
788.43 Nocturia
788.41 Urinary frequency
Frequency of micturition

Definitions of the studies' design characteristics to estimate the level of evidence.
Level of evidence as defined by the U.S. Preventive Services Task Force[16]
Level I: Evidence obtained from at least one properly designed randomized controlled trial.
Level II-1: Evidence obtained from well-designed controlled trials without randomization.
Level II-2: Evidence obtained from well-designed cohort or case-control analytic studies, preferably from more than one center or research group.
Level II-3: Evidence obtained from multiple time series with or without the intervention. Dramatic results in uncontrolled trials.

Level III: Opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert committees.

Independent intervention variables for the question 3 extracted from the studies:
Type of intervention as a categorical variable: behavioral interventions, drug therapy, device therapy, surgery.
Type of intervention as a categorical variable using author's definitions.
Dose of the drug as a continuous variable.

Dependent incontinence variables for question 3 extracted from the studies:
Type of incontinence as a categorical variable: Urinary, Anal, Combined.
Urinary incontinence as stress, urge, mixed, total.
Anal incontinence as flatus, fecal, combined.
Incontinence outcomes as a categorical variable using author's definitions.
Number of cases with outcomes in the active and the control groups as a continuous variable.
Rates of outcomes (%) in the active and control groups as a continuous variable.
We applied intention-to treat principle and calculated the number of cases in the active and control groups among randomized when the authors reported the rates of outcomes among analyzed.
Outcomes level in the active and control groups as a continuous variable. We extracted means and standard deviations of outcomes from the articles. We calculated standard deviations when the authors reported standard errors:
Standard deviation = Standard Error * Square root of the sample size in the group.
We extracted medians when the authors did not reported means assuming normal distribution of the outcome.
Relative risk of the outcome in the active group compared to the control group.
Regression coefficient with standard error of association between intervention and outcome.

Tested sources of heterogeneity:[17]
Clinical settings as a categorical variable: Community, nursing homes.
Sample size as a continuous variable equals the number of randomized subjects.
Proportion of females in the sample as a continuous variable (%)
Length of followup months as a continuous variable
Loss o followup as a continuous variable (%)
Masking of the treatment status as a categorical variable: open label, single blind, double blind
Adequacy of randomization and allocation concealment as a categorical variable: not reported, adequate, not adequate.
Intention to treat principle as categorical variable: Yes, no, not stated when all randomized subjects were analyzed but the authors did not plan Intention to treat principle in the study design.
We tested the possible sources of heterogeneity as interaction variables which could modify the effect of clinical interventions on incontinence outcomes and conducted sensitivity analysis within each category of effect modifiers.
Analytical framework for pooled analysis of prevalence of incontinence in adults:
Prevalence was calculated as number of subjects with incontinence among total number of patients in the study, standard error and confidence interval for population prevalence were calculated with Wilson estimate as follows:[18]

SEρ=√ [ρ*(1-ρ)]/[n+4]

95% level C confidence interval ρ±1.96*SEρ
Where p – prevalence, n- sample size. We calculated logarithm of prevalence for pooling analysis.

Hypotheses tested in pooled analysis[19]

1. The urinary incontinence outcome is associated with an active treatment as a categorical variable compared to the control interventions. Random effects model was used to incorporate differences between studies.
2. The effect size of an active treatment can be modified by the proportion of males and females in the sample (when applicable).

We grouped pelvic floor muscle training programs into one category in the text and for a pooled analysis providing the details about different regimes of exercise in the tables.
We grouped different definitions of continence and improvement in incontinence to have an overall estimation of the interventions.
Algorithms of meta-analysis[19]
Pooled estimate as a weighted average:

$$\theta_{IV} = \frac{\sum_i w_i \theta_i}{\sum_i w_i}$$

Weights are inverse of variance (standard error):

$$w_i = \frac{1}{SE(\theta_i)^2}$$

Standard error of pooled estimate:

$$SE(\theta_{IV}) = \frac{1}{\sqrt{\sum_i w_i}}$$

Heterogeneity (between-study variability) measured by:

$$Q = \sum_i w_i (\theta_i - \theta_{IV})^2$$

Assumptions for random effects model: true effect sizes *qi* have a normal distribution with mean *q* and variance *t2*; *t2* is the between-study variance
Between study variance:

$$\tau^2 = \frac{Q - (k-1)}{\sum_i w_i - \left(\frac{\sum_i w_i^2}{\sum_i w_i} \right)}$$

Where:
wi are the weights from the fixed effect inverse-variance method

Q is the heterogeneity test statistic from before (either from inverse-variance method or Mantel-Haenszel method)
k is the number of studies, and
t2 is set to zero if *Q*<*k*-1
Random effect pooled estimate is weighted average:

$$\theta_{DL} = \frac{\sum_i w'_i \theta_i}{\sum_i w'_i}$$

Weights used for the pooled estimate are similar to the inverse-variance, but now incorporate a component for between-study variation:

$$w'_i = \frac{1}{SE(\theta_i)^2 + \tau^2}$$

Standard error of pooled estimate

$$SE(\theta_{DL}) = \frac{1}{\sqrt{\sum_i w'_i}}$$

Meta regression with random effects was obtained using aggregate level data.

Additive component of variance tau2 was estimated:

$$y[i] = a + B*x[i] + u[i] + e[i],$$

where u[i] is a normal error (standard deviations that may vary across units), e[i] is a normal error with variance tau2 to be estimated, assumed equal across units.
t-distribution was used calculating p-values and confidence intervals[17,20]
Attributable risk was calculated as the outcome events rate in patients exposed to different clinical interventions[21-23]
Attributable risk of the outcome = rate of events in patients in the control group x (relative risk -1)

Number needed to treat to prevent one event of incontinence was calculated as reciprocal to absolute risk differences in rates of outcomes events in the active and control groups:[22,24]
1/(control group event rate - treatment group event rate).

The number of avoided or excess events (respectively) per 1000 population is the difference between the two event rates multiplied by 1000:

(control group event rate - treatment group event rate)*1000

We calculated diagnostic values of different tests to diagnose incontinence:
Sensitivity=TP/(TP+FN)
Specificity=TN/(FP+TN)
Prevalence=(TP+FN)/(TP+FN+FP+TN)

Predictive value positive=TP/(TP+FP)
Positive predictive likelihood ratio:

$$LR+ = \frac{\text{probability of an individual with the condition having a positive test}}{\text{probability of an individual without the condition having a positive test}}$$

$$LR+ = \frac{\text{sensitivity}}{1\text{-specificity}}$$

Number needed to screen to identify one undiagnosed incontinence case = [(prevalence of undiagnosed incontinence)(sensitivity of the diagnostic method)]$^{-1}$
Number of diagnostic tests to identify one undiagnosed incontinence case = 2 + number needed to screen (1 - prevalence of undiagnosed incontinence)(1 – specificity of the diagnostic test).[25]

No studies reported fecal incontinence as an outcomes.

Analysis 01.34. Comparison 01 CISAPRIDE versus PLACEBO, Outcome 34 Number of bowel motions or successes bowel care routine per week
Review: Management of faecal incontinence and constipation in adults with central neurological diseases
Comparison: 01 CISAPRIDE versus PLACEBO
Outcome: 34 Number of bowel motions or successes bowel care routine per week

	Mean difference (95% CI)
Badiali 1991	-0.5 (-2.26; 1.26)
de Both 1992	-0.1 (-1; 0.8)
Total (95% CI)	-0.18 (-0.99; 0.62)

Analysis 01.35. Comparison 01 CISAPRIDE versus PLACEBO, Outcome 35 Ease of evacuation or straining effort (score)
Review: Management of faecal incontinence and constipation in adults with central neurological diseases
Comparison: 01 CISAPRIDE versus PLACEBO
Outcome: 35 Ease of evacuation or straining effort (score)

	Mean difference (95% CI)
Badiali 1991	0.6 (-0.18; 1.38)
de Both 1992	-0.1 (-0.51; 0.31)
Total (95% CI)	0.05 (-0.31; 0.42)

Analysis 01.36. Comparison 01 CISAPRIDE versus PLACEBO, Outcome 36 Oro-anal transit time (hours)
Review: Management of faecal incontinence and constipation in adults with central neurological diseases
Comparison: 01 CISAPRIDE versus PLACEBO
Outcome: 36 Oro-anal transit time (hours)

	Mean difference (95% CI)
Badiali 1991	10 (-19.01; 39.01)
de Both 1992	19.2 (-38.23; 76.63)
Total (95% CI)	11.87 (-14.02; 37.76)

Authors' conclusions: ”There is still remarkably little research on this common and, to patients, very significant condition. It is not possible to draw any recommendation for bowel care in people with neurological diseases from the trials included in this review. Bowel management for these people must remain empirical until well-designed controlled trials with adequate numbers and clinically relevant outcome measures become available”.

Topic: Operative procedures for fissure in ano.
Reference: Nelson R. Operative procedures for fissure in ano.
Cochrane Database Syst Rev. 2005 Apr 18;(2):CD002199. Review.
