p-CHLOROANILINE HYDROCHLORIDE

CAS No. 20265-96-7

 $C_6H_6NCl \cdot HCl$

Molecular weight 164.1

Synonyms: 1-amino-4-chlorobenzene hydrochloride; 4-chlorophenylamine hydrochloride; 4-chlorobenzenamine hydrochloride

ABSTRACT

p-Chloroaniline has a large production volume and is used as a dye intermediate. Toxicology and carcinogenesis studies of p-chloroaniline (greater than 99% pure) were conducted by administering pchloroaniline hydrochloride in water by gavage to groups of F344/N rats and $B6C3F_1$ mice of each sex for 16 days, 13 weeks, or 2 years. Vehicle controls were given deionized water by gavage. All doses were calculated as p-chloroaniline; the chemical was administered as the hydrochloride after dissolution in water containing molar equivalents of hydrochloric acid. Genetic toxicology studies were conducted in *Salmonella typhimurium*, mouse L5178Y lymphoma cells, and Chinese hamster ovary (CHO) cells. Hematologic parameters were measured at the end of the 13-week studies and at 6, 12, 18, and 24 months in the 2-year studies. Supplemental studies of the distribution and disposition of pchloroaniline were conducted in male F344 rats.

Sixteen-Day and Thirteen-Week Studies: In the 16-day studies, male and female rats and mice received 25, 50, 100, 200, or 400 mg/kg of body weight. The vehicle controls received deionized water. All rats and mice that received 200 or 400 mg/kg died during the first 6 days of the studies. Some deaths occurred in each of the lower dose groups of mice. Splenic enlargement was observed at necropsy in rats administered 25, 50, or 100 mg/kg. Congestion of the spleen and hemosiderin deposition in the renal cortical tubular epithelial cells were observed at 100 mg/kg in male and female rats. Compound-related lesions in mice included hemosiderosis of the liver Kupffer cells and congestion of the spleen.

In the 13-week studies, 10 rats of each sex were administered doses of 0, 5, 10, 20, 40, or 80 mg/kg. All male rats lived to the end of the 13-week studies. One of 10 female rats that received 80 mg/kg died from unknown causes. The final mean body weights of rats that received 80 mg/kg were 16% lower than that of vehicle controls for males and 4% lower for females. In the 13-week studies in mice, 10 animals of each sex were administered doses of 0, 7.5, 15, 30, 60, or 120 mg/kg. Deaths in mice were not related to p-chloroaniline hydrochloride administration. The final mean body weights of dosed and vehicle control mice were similar. In both rats and mice, no chemically related effects on organ weights were observed at necropsy, except for the spleen, which was enlarged as a function of increasing dose. Methemoglobin was increased in dosed groups and resulted in a secondary anemia, the severity of which was dose related. Compound-related lesions observed histologically, including pigmentation (hemosiderin) in the kidney, spleen, and liver and hematopoiesis in the liver and spleen, reflected the response to the hemolytic anemia and methemoglobinemia induced by p-chloroaniline hydrochloride.

Based on these results, groups of 50 rats of each sex were administered 2, 6, or 18 mg/kg *p*-chloroaniline hydrochloride in water by gavage, 5 days per week for 103 weeks. Groups of 50 mice of each sex were administered 3, 10, or 30 mg/kg on the same schedule.

Metabolism and Disposition Studies in Rats: The metabolism and disposition studies in F344/N rats showed that metabolic and excretory pathways were not saturated by *p*-chloroaniline administered orally at doses ranging from 0.3 to 30 mg/kg. *p*-Chloroaniline was rapidly metabolized and excreted primarily in urine with a half-life of approximately 2 hours.

Body Weight and Survival in the Two-Year Studies: Mean body weights of dosed rats were generally within 5% of those of vehicle controls throughout the studies. The survival of the low and mid dose groups of male rats and of the low and high dose groups of female rats was significantly greater than that of the vehicle controls (male: vehicle control, 18/49; low dose, 32/50; mid dose, 32/50; high dose, 21/50; female: 27/50; 39/50; 36/50; 37/50). The increased survival was attributed to the decreased incidences of mononuclear cell leukemia. Mean body weights of high dose male and female mice were generally within 5% of those of vehicle controls throughout the studies. The survival of the mid dose group of male mice was lower than that of the vehicle controls after week 99 (male: 43/50; 36/50; 29/50; 35/50; female: 39/50; 42/50; 41/50).

Nonneoplastic and Neoplastic Effects in the Two-Year Studies: Fibrosis of the spleen was increased in dosed male and high dose female rats (male: vehicle control, 3/49; low dose, 11/50; mid dose, 12/50; high dose, 41/50; female: 1/50; 2/50; 3/50; 42/50). Cellular infiltration of lipocytes (fatty metaplasia) was observed in the spleen at increased incidences in high dose rats (male: 0/49; 0/50; 0/50; 24/50; female: 0/50; 0/50; 0/50; 11/50). The incidence of uncommon sarcomas of the spleen in high dose male rats was significantly greater than that in the vehicle controls (fibrosarcomas, osteosarcomas, or hemangiosarcomas, combined: 0/49; 1/50; 3/50; 38/50). Many of these tumors metastasized to one or more sites. In female rats, one fibrosarcoma of the spleen was found in a mid dose animal, and one osteosarcoma of the spleen was found in a high dose animal. The historical incidence of splenic connective tissue sarcomas (all types) in water gavage vehicle controls is 1/298 (0.3%) for male rats and 0/297 for female rats. The historical incidence of hemangiosarcomas in water gavage controls is 0/300 for male rats and 1/297 (0.3%) for female rats.

Adrenal medullary hyperplasia was observed at an increased incidence in high dose female rats (4/50; 4/50; 7/50; 24/50). Marginally increased incidences of pheochromocytomas were seen in high dose male (13/49; 14/48; 15/48; 26/49) and female (2/50; 3/50; 1/50; 6/50) rats. The historical incidence of pheochromocytomas in water gavage vehicle control male F344/N rats is 121/299 (40% \pm 16%); the historical incidence in water gavage vehicle control female F344/N rats is 20/295 (7% \pm 2%).

The incidences of mononuclear cell leukemia in dosed male and female rats were lower than those in vehicle controls (male: 21/49; 3/50; 2/50; 3/50; female: 10/50; 2/50; 1/50; 1/50). The incidences of malignant lymphomas in dosed male and female mice were lower than those in vehicle controls (male: 10/50; 3/49; 9/50; 3/50; female: 19/50; 12/50; 5/50; 10/50).

Hematologic and methemoglobin measurements were made on blood samples collected from 15 randomly selected male and female rats per dose group at 6, 12, 18, and 24 months. In general, the high dose group at various intervals showed mild hemolytic anemia and dose-related increases in methemoglobin.

In rats, compound-related nonneoplastic lesions were seen histopathologically in the bone marrow, spleen, and liver. These lesions included bone marrow hyperplasia, hepatic hemosiderosis, and splenic fibrosis and suggest compound-related effects on the hematopoietic system in general, the erythropoietic system specifically, and mesenchymal cells in the spleen.

In male mice, the incidence of hemangiosarcomas of the liver or spleen in high dose male mice was greater than that in the vehicle controls (4/50; 4/49; 1/50; 10/50). The historical incidence of hemangiomas or hemangiosarcomas at all sites (combined) in water gavage vehicle control male $B6C3F_1$ mice is 11/350 ($3\% \pm 3\%$).

The incidences of hepatocellular adenomas or carcinomas (combined) were increased in dosed male mice (11/50; 21/49; 20/50; 21/50), primarily due to increased incidences of hepatocellular carcinomas (3/50; 7/49; 11/50; 17/50). Hepatocellular carcinomas metastasized to the lung in 1/50 vehicle control, 1/49 low dose, 2/50 mid dose, and 9/50 high dose male mice. The historical incidence of hepatocellular neoplasms in water gavage vehicle controls is 106/347 ($31\% \pm 6\%$).

Genetic Toxicology: p-Chloroaniline was mutagenic in S. typhimurium strains TA98 and TA100 in the presence of exogenous metabolic activation; no increase in revertant colonies was observed in strains TA97, TA1535, or TA1537. p-Chloroaniline induced trifluorothymidine (Tft) resistance in mouse L5178Y lymphoma cells with and without metabolic activation. In cultured CHO cells, treatment with p-chloroaniline produced significant increases in sister chromatid exchanges (SCEs) both with and without metabolic activation (S9); chromosomal aberrations were significantly increased only in the presence of S9.

Audit: The data, documents, and pathology materials from the 2-year studies of *p*-chloroaniline have been audited. The audit findings show that the conduct of the studies is documented adequately and support the data and results given in this Technical Report.

Conclusions: Under the conditions of these 2-year water gavage studies, there was *clear evidence of carcinogenic activity*^{*} of *p*-chloroaniline hydrochloride for male F344/N rats, as indicated by increased incidences of uncommon sarcomas of the spleen. Pheochromocytomas of the adrenal gland may also have been associated with chemical administration. There was *equivocal evidence of carcinogenic activity* of *p*-chloroaniline hydrochloride for female F344/N rats, as indicated by the presence of uncommon sarcomas of the spleen in one mid and one high dose animal and the increased incidence of pheochromocytomas of the adrenal gland. There was *some evidence of carcinogenic activity* of *p*-chloroaniline hydrochloride for male B6C3F₁ mice, as indicated by increased incidences of hepatocellular neoplasms and of hemangiosarcomas of the liver or spleen. There was *no evidence of carcinogenic activity* of *p*-chloroaniline hydrochloride for female B6C3F₁ mice administered 3, 10, or 30 mg/kg by gavage for 2 years.

The incidences of mononuclear cell leukemia in male and female rats and of malignant lymphomas in male and female mice were decreased by administration of *p*-chloroaniline hydrochloride. Compound-related splenic fibrosis was present in male and female rats.

^{*}Explanation of Levels of Evidence of Carcinogenic Activity is on page 7.

A summary of the Peer Review comments and the public discussion on this Technical Report appears on page 10.

EXPLANATION OF LEVELS OF EVIDENCE OF CARCINOGENIC ACTIVITY

The National Toxicology Program describes the results of individual experiments on a chemical agent and notes the strength of the evidence for conclusions regarding each study. Negative results, in which the study animals do not have a greater incidence of neoplasia than control animals, do not necessarily mean that a chemical is not a carcinogen, inasmuch as the experiments are conducted under a limited set of conditions. Positive results demonstrate that a chemical is carcinogenic for laboratory animals under the conditions of the study and indicate that exposure to the chemical has the potential for hazard to humans. Other organizations, such as the International Agency for Research on Cancer, assign a strength of evidence for conclusions based on an examination of all available evidence including: animal studies such as those conducted by the NTP, epidemiologic studies, and estimates of exposure. Thus, the actual determination of risk to humans from chemicals found to be carcinogenic in laboratory animals tory animals requires a wider analysis that extends beyond the purview of these studies.

Five categories of evidence of carcinogenic activity are used in the Technical Report series to summarize the strength of the evidence observed in each experiment: two categories for positive results ("Clear Evidence" and "Some Evidence"); one category for uncertain findings ("Equivocal Evidence"); one category for no observable effects ("No Evidence"); and one category for experiments that because of major flaws cannot be evaluated ("Inadequate Study"). These categories of interpretative conclusions were first adopted in June 1983 and then revised in March 1986 for use in the Technical Reports series to incorporate more specifically the concept of actual weight of evidence of carcinogenic activity. For each separate experiment (male rats, female rats, male mice, female mice), one of the following quintet is selected to describe the findings. These categories refer to the strength of the experimental evidence and not to either potency or mechanism.

- Clear Evidence of Carcinogenic Activity is demonstrated by studies that are interpreted as showing a dose-related (i) increase of malignant neoplasms, (ii) increase of a combination of malignant and benign neoplasms, or (iii) marked increase of benign neoplasms if there is an indication from this or other studies of the ability of such tumors to progress to malignancy.
- Some Evidence of Carcinogenic Activity is demonstrated by studies that are interpreted as showing a chemically related increased incidence of neoplasms (malignant, benign, or combined) in which the strength of the response is less than that required for clear evidence.
- Equivocal Evidence of Carcinogenic Activity is demonstrated by studies that are interpreted as showing a marginal increase of neoplasms that may be chemically related.
- No Evidence of Carcinogenic Activity is demonstrated by studies that are interpreted as showing no chemically related increases in malignant or benign neoplasms.
- Inadequate Study of Carcinogenic Activity is demonstrated by studies that because of major qualitative or quantitative limitations cannot be interpreted as valid for showing either the presence or absence of carcinogenic activity.

When a conclusion statement for a particular experiment is selected, consideration must be given to key factors that would extend the actual boundary of an individual category of evidence. This should allow for incorporation of scientific experience and current understanding of long-term carcinogenesis studies in laboratory animals, especially for those evaluations that may be on the borderline between two adjacent levels. These considerations should include:

- The adequacy of the experimental design and conduct;
- Occurrence of common versus uncommon neoplasia;
- Progression (or lack thereof) from benign to malignant neoplasia as well as from preneoplastic to neoplastic lesions;
- Some benign neoplasms have the capacity to regress but others (of the same morphologic type) progress. At present, it is impossible to identify the difference. Therefore, where progression is known to be a possibility, the most prudent course is to assume that benign neoplasms of those types have the potential to become malignant;
- Combining benign and malignant tumor incidences known or thought to represent stages of progression in the same organ or tissue;
- Latency in tumor induction;
- Multiplicity in site-specific neoplasia;
- Metastases;
- Supporting information from proliferative lesions (hyperplasia) in the same site of neoplasia or in other experiments (same lesion in another sex or species);
- The presence or absence of dose relationships;
- The statistical significance of the observed tumor increase;
- The concurrent control tumor incidence as well as the historical control rate and variability for a specific neoplasm;
- Survival-adjusted analyses and false positive or false negative concerns;
- Structure-activity correlations; and
- In some cases, genetic toxicology.

CONTRIBUTORS

The NTP Technical Report on the Toxicology and Carcinogenesis Studies of *p*-Chloroaniline Hydrochloride is based on 13-week studies that began in March 1981 and ended in June 1981 and on 2-year studies that began in January 1982 and ended in January 1984 at Battelle Columbus Laboratories (Columbus, Ohio).

PEER REVIEW PANEL

The members of the Peer Review Panel who evaluated the draft Technical Report on *p*-chloroaniline hydrochloride on April 18, 1988, are listed below. Panel members serve as independent scientists, not as representatives of any institution, company, or governmental agency. In this capacity, Panel members have five major responsibilities: (a) to ascertain that all relevant literature data have been adequately cited and interpreted, (b) to determine if the design and conditions of the NTP studies were appropriate, (c) to ensure that the Technical Report presents the experimental results and conclusions fully and clearly, (d) to judge the significance of the experimental results by scientific criteria, and (e) to assess the evaluation of the evidence of carcinogenicity and other observed toxic responses.

SUMMARY OF PEER REVIEW COMMENTS ON THE TOXICOLOGY AND CARCINOGENESIS STUDIES OF p-CHLOROANILINE HYDROCHLORIDE

On April 18, 1988, the draft Technical Report on the toxicology and carcinogenesis studies of *p*-chloroaniline hydrochloride received public review by the National Toxicology Program Board of Scientific Counselors' Technical Reports Review Subcommittee and associated Panel of Experts. The review meeting was held at the National Institute of Environmental Health Sciences (NIEHS), Research Triangle Park, North Carolina.

Dr. R.S. Chhabra, NIEHS, began the discussion by reviewing the experimental design, results, and proposed conclusions (clear evidence of carcinogenic activity for male rats, equivocal evidence of carcinogenic activity for female rats, some evidence of carcinogenic activity for male mice, no evidence of carcinogenic activity for female mice).

Dr. Sivak, a principal reviewer, agreed with the conclusions. However, he suggested that the unusually low hepatic tumor incidence in vehicle control male mice, coupled with a tumor yield in high dose male mice not much above the historical control range, might be mentioned. Dr. Chhabra agreed and pointed out that the effects were mainly due to carcinomas and, further, that there was considerable metastasis of these tumors to the lung (1/50, vehicle controls vs. 9/50, high dose). Dr. Sivak stated that inclusion of pharmacokinetic data indicating that saturation was not reached, even at the highest dose, was an important addition to the data base. He suggested deleting the speculation that increased sensitivity to aniline toxicity was based on differences in a single erythrocyte enzyme, and Dr. Chhabra agreed.

Dr. Hughes, the second principal reviewer, agreed with the conclusions. He requested an explanation for poor survival in male and female vehicle control rats compared with that in dosed groups. Dr. Chhabra noted that there appeared to be a correlation with a marked negative trend for mononuclear cell leukemia. Dr. Hughes thought that the addition of structure-activity data on genetic toxicity, carcinogenicity, and other effects for the aniline compounds was useful.

Dr. Gallo, the third principal reviewer, agreed with the conclusions, although he argued that if rarity of the tumors is the criterion for the level of evidence, then the level in female rats should be the same as that in male rats. Dr. J. Haseman, NIEHS, said that to his knowledge, the Program had never made a call above equivocal evidence based on a single tumor, regardless of rarity. Dr. Gallo commented that there were marked increases in methemoglobinemia for both rats and mice in the 13-week studies, even at the lowest doses, and suggested that chronic methemoglobinemia could be an appropriate criterion for dose selection for this type of compound.

In response to inquiries as to why the 1979 NCI studies (NCI Technical Report No. 189) were repeated, Dr. Chhabra said *p*-chloroaniline was considered to be a good candidate for restudy because the findings from the NCI studies were unclear as to carcinogenicity and because of the nature of the chemical and the degree of industrial exposure of humans. Dr. J. Huff, NIEHS, added that three of the four previous studies were equivocal, the duration of exposure was only 18 months, and the gavage route was used in the current studies.

Dr. Sivak moved that the Technical Report on *p*-chloroaniline hydrochloride be accepted with the revisions discussed and with the conclusions as written: for male rats, clear evidence of carcinogenic activity; for female rats, equivocal evidence of carcinogenic activity; for male mice, some evidence of carcinogenic activity; and for female mice, no evidence of carcinogenic activity. Dr. Hughes seconded the motion, which was approved by eight members, with one abstention (Dr. Ashby).

I. INTRODUCTION

Physical and Chemical Properties Use, Production, and Exposure Absorption, Distribution, Metabolism, and Excretion Genetic Toxicology Toxicity and Carcinogenicity Study Rationale

p-CHLOROANILINE HYDROCHLORIDE

CAS No. 20265-96-7

 $C_6H_6NCl \cdot HCl$

Molecular weight 164.1

Synonyms: 1-amino-4-chlorobenzene hydrochloride; 4-chlorophenylamine hydrochloride; 4-chlorobenzenamine hydrochloride

Physical and Chemical Properties

p-Chloroaniline forms colorless orthorhombic crystals and has a melting point of 72.5° C and a boiling point of 232° C. It is soluble in hot water and freely soluble in alcohol, ether, acetone, and carbon disulfide (Merck, 1983). *p*-Chloroaniline (99% pure) was used to prepare *p*-chloroaniline hydrochloride solutions for administration to animals.

Use, Production, and Exposure

p-Chloroaniline is an aromatic amine widely used in the dye, chemical, textile, rubber, and other industries (Beard and Noe, 1981). p-Chloroaniline is used as an intermediate in the manufacture of more than 10 dyes and pigments (Colour Index, 1956) and has been detected as a degradation product in some pharmaceutical preparations (Ciarlone et al., 1976). In rats, pchloroaniline is one of the metabolites of the urea herbicides monuron, buturon, and monolinuron (Ernst, 1969; Hargesheimer et al., 1981). Monuron is carcinogenic in male rats, causing increased incidences of tubular cell adenocarcinomas of the kidney, tubular cell adenomas of the kidney, and neoplastic lesions of the liver (NTP, 1988). p-Chloroaniline has also been identified as a degradation product of 4,4'dichloro-3-(trifluoromethyl)carbanilide, an active component of deodorant bars (Demers and Yates, 1977).

Specific production data for *p*-chloroaniline are not available; however, the Toxic Substance Control Act (TSCA) Inventory listed two companies that manufactured *p*-chloroaniline in 1977 (USEPA, 1978). One company reported that it produced between 100,000 pounds and 1,000,000 pounds; the other company did not report its production volume in the nonconfidential portion of the TSCA inventory. Four companies were reported to import *p*-chloroaniline in 1977. Of these four, two reported a combined import volume of between 10,000 and 101,000 pounds; the other two companies did not report import volumes.

No data are available on the number of workers exposed to this chemical, but the use pattern of *p*-chloroaniline suggests an exposure potential to workers in the dye, agricultural, and chemical industries. It is also a potential food contaminant because of its release as a metabolic degradation product from herbicides used in agriculture. Aromatic organochlorine compounds are known to be persistent in the aquatic environment. Schauerte et al. (1982) studied the longterm fate of hexachlorobenzene, pentachlorobenzene, and *p*-chloroaniline in small experimental ponds in southern Germany. The chemicals, with added ¹⁴C-labeled tracers, were applied to the ponds for 4-6 weeks in amounts sufficient to maintain an average concentration of 50 µg/ liter. Chemical residue concentrations were determined in water, sediment, flora, and fauna up

to 166 weeks after application. Residues of these compounds were initially present in the biota at relatively high concentrations; concentrations of residue slowly built up and then declined in the sediment. Suss et al. (1978) studied the degradation of aniline, p-chloroaniline, and 3,4-dichloroaniline in four different soil types in the laboratory and reported low degradation rates and strong adsorption for the chloroanilines, suggesting accumulation in the soil. However, according to Freitag et al. (1984), laboratory soil mobility studies, which normally have much higher leaching rates and shorter time spans than those conducted under environmental conditions, are not suitable for predicting the longterm behavior of *p*-chloroaniline.

Absorption, Distribution, Metabolism, and Excretion

p-Chloroaniline is readily absorbed through skin and from the gastrointestinal tract after oral administration. It causes more intense methemoglobinemia after dermal exposure than after oral exposure, suggesting greater or more rapid hepatic metabolism following absorption from the gastrointestinal tract (Gosselin et al., 1984). Distribution and excretion studies of $[^{14}C]p$ chloroaniline hydrochloride in rats showed that *p*-chloroaniline is excreted rapidly after oral administration at 0.3, 3.0, or 30 mg/kg (Perry et al., 1981a,b; Appendix H). Within 24 hours, 81% of the administered dose appeared in urine and 10% in feces. An average of 98% of the dose was recovered in excreta (87% in urine, 11% in feces) 7 days after administration. At day 7, essentially all of the remaining radioactivity was located in the erythrocytes. The preliminary results from a single intravenous dose (3 mg/kg) also revealed an accumulation of p-chloroaniline-derived radioactivity in erythrocytes. The ratio of concentration of p-chloroaniline in erythrocytes to that in plasma increased with time and was 2:1 at 2 hours, 20:1 at 12 hours, and 74:1 at 2 days. These studies also revealed that p-chloroaniline administered to F344 rats by intravenous injection was rapidly N-acetylated to *p*-chloroacetanilide as the first step in metabolism and excretion. The absence of any pchloroacetanilide in urine indicated further metabolism before excretion.

Concurrent disposition studies in mongrel dogs and in A/J and Swiss Webster mice also were performed by Perry et al. (1981a,b). Dogs administered 3 mg/kg [14C]p-chloroaniline by intravenous injection excreted 93% of the radioactivity in urine and 3% in feces within 2 days, whereas mice of both strains eliminated 75% in urine and 10% in feces in a similar time period; recovery of mouse urine was probably not complete. For all species, the disappearance of total radioactivity from whole blood displayed twophase decay kinetics, but the rates were substantially different. The initial decay constants in both strains of mice were 10 times greater than those in dogs and rats, and the terminal rates were greater by a factor of 2 to 4. The halflife of the radioactivity in plasma was similar in F344 rats and dogs. Dogs and rats rapidly eliminated the parent compound in a manner best described by biexponential decay kinetics, with a half-life of less than 10 minutes for the first phase and 1.5-4.6 hours for the second phase. The parent compound could not be detected after 4 hours in dogs and rats or after 1 hour in mice. p-Chloroaniline clearance by mice was too rapid to permit calculation of the kinetic parameters.

The biologic activity, including mutagenicity and carcinogenicity, of a number of aromatic amines may be due to their N-hydroxy metabolites (Poirier and Weisburger, 1972; Weisburger and Weisburger, 1973; Selkirk, 1980). A number of in vitro studies have shown N-oxidation of *p*-chloroaniline by the hepatic microsomal cytochrome P450 system (Smith and Gorrod, 1978; Liu and Franklin, 1984; Hlavica, 1984). N-oxidation of *p*-chloroaniline during lipid peroxidation promoted by various mechanisms in rabbit liver microsomal preparations was also reported (Golly et al., 1984). In addition, based on in vitro studies of the N-oxidation of p-chloroaniline by rabbit hemoglobin, Golly and Hlavica (1983) proposed that erythrocytes may be a site of bioactivation of aromatic amines. This proposal of a reactive intermediate produced by, and reacting with, erythrocytes would be consistent with the observed persistence of p-chloroanilinederived radioactivity in erythrocytes by Perry et al. (1981a,b). However, this conclusion has not been confirmed because it was not possible to extract the *p*-chloroaniline-derived radioactivity from erythrocytes. Microbial oxidation of p-chloroaniline was shown by Kaufman et al. (1973); Corbett et al. (1980) demonstrated the N-oxidizing action of the fungal enzyme chloride peroxidase in vitro.

Genetic Toxicology

p-Chloroaniline has been tested for mutagenicity by numerous laboratories in bacterial assays with Escherichia coli and Salmonella typhimurium. Test results reported in the literature were generally negative (Garner and Nutman, 1977; Pai et al., 1978; Rosenkranz and Poirier, 1979; Seuferer et al., 1979; Gilbert et al., 1980; Zimmer et al., 1980; Thompson et al., 1983) with two exceptions: a positive response for gene mutation in S. typhimurium strain TA98 in the presence of S9 metabolic activation (Dunkel et al., 1985) and the observation of growth inhibition due to DNA damage in E. coli polA⁺/polA⁻ (Rosenkranz and Poirier, 1979). p-Chloroaniline was tested for mutagenicity in S. typhimurium for the NTP by three independent laboratories. Mutagenic activity was observed by two laboratories in strain TA98 in the presence of Aroclor 1254-induced male Sprague Dawley rat or Syrian hamster S9, and one laboratory noted an increase in revertant colonies in strain TA100 in the presence of hamster S9 only. No mutagenic activity was reported in strains TA97, TA1535, or TA1537 (Mortelmans et al., 1986; Table 27). Several of the negative studies that were reported in the literature tested pchloroaniline within dose ranges similar to those used by the NTP laboratories (1,000-2,000 $\mu g/plate$).

In addition to the bacterial assays, gene mutation was also reported in Aspergillus nidulans after administration of 200 μ g/ml p-chloroaniline in the absence of exogenous metabolic activation (Prasad, 1970) and in cultured mouse L5178Y lymphoma cells both with and without Aroclor 1254-induced male F344 rat liver S9 (Myhr and Caspary, 1989; Table 28).

Treatment of primary hepatocyte cultures from adult male F344 rats with 20 μ g/ml *p*-chloroaniline was reported to induce unscheduled DNA synthesis (UDS) (Williams et al., 1982); another such investigation detected no induction of UDS at doses of 6.35 μ g/ml and lower and found toxicity at all doses greater than $10 \mu g/ml$ (Thompson et al., 1983). Therefore, it may be that only doses within a narrow range close to toxic levels elicit a positive response in this assay.

The NTP tested several structural analogs of pchloroaniline for mutagenic activity, including aniline, o- and m-chloroaniline, and p-bromoaniline. All these compounds produced a negative response in the Salmonella gene mutation assay (Haworth et al., 1983; Zeiger et al., 1987). Aniline and *m*-chloroaniline induced SCEs in cultured CHO cells with and without S9 from Aroclor 1254-induced male Sprague Dawley rat liver; both compounds also induced chromosomal aberrations in this test system, but aniline required the addition of S9 for a positive response (Galloway et al., 1987). Aniline induced trifluorothymidine (Tft) resistance in mouse L5178Y lymphoma cells with and without Aroclor 1254induced male F344 rat liver S9 (Myhr and Caspary, 1989; Mitchell et al., 1989). Published reports on the absence of mutagenic activity of aniline, *p*-bromoaniline, and *m*-chloroaniline in bacteria support the NTP results (Garner and Nutman, 1977; Simmon, 1979; Chung et al., 1981; De Flora, 1981; Probst et al., 1981; Ashby et al., 1983; Thompson et al., 1983). Although ochloroaniline was reported to be nonmutagenic in Salmonella, it was observed to produce growth inhibition due to DNA damage in E. coli strain polA⁺/polA⁻, with and without S9 activation (Rosenkranz and Poirier, 1979; Rosenkranz and Leifer, 1980). The only reported genetic effects of aniline exposure were the induction of SCEs in vitro (Wilmer et al., 1981; Tohda et al., 1983) and in vivo (Parodi et al., 1983) and DNA damage as determined by alkaline elution sedimentation in liver and kidney cells of Sprague Dawley rats administered 420 mg/kg aniline; no DNA damage was observed in the spleen cells of these rats (Parodi et al., 1982a.b). Swiss mice administered identical doses of aniline showed no liver, kidney, or bone marrow DNA damage (Parodi et al., 1982a). No induction of UDS was observed in primary hepatocyte cultures from F344 rats, DS-1 mice, or Syrian golden hamsters; the cultures contained 1 imes 10^{-3} or 1 × 10^{-5} M aniline (Williams, 1981; McQueen et al., 1981).

Mutagenicity information is available on paminophenol, one of the purported metabolites of p-chloroaniline (Ichikawa et al., 1969). Although *p*-aminophenol is not generally observed to be mutagenic in Salmonella (NTP unpublished results; Garner and Nutman, 1977; Degawa et al., 1979; Thompson et al., 1983), there is one report of a positive response in the absence of S9 in S. typhimurium strain TA1535 (Wild et al., 1980). In addition, induction of Tft resistance in mouse L5178Y lymphoma cells has been reported (Amacher and Turner, 1982; Oberly et al., 1984) as well as in vivo induction of chromosomal aberrations (Mitra and Manna, 1971), micronuclei (Wild et al., 1980), and sperm head abnormalities (Topham, 1980). Treatment of human EBV-transformed lymphoblastoid cells with *p*-aminophenol resulted in inhibition of DNA synthesis presumably through alterations of the DNA superstructure as noted by changes in the sedimentation rate of DNA extracts from treated cells (Hayward et al., 1982). SCE induction in human lymphocytes was reported after exposure to p-aminophenol (Takehisa and Kanaya, 1982).

Toxicity and Carcinogenicity

The dominant toxic effect of aromatic amines is methemoglobin formation (Beard and Noe, 1981). Specific information on p-chloroaniline toxicity in humans is limited. Short-term exposure to p-chloroaniline produces cyanosis, a manifestation of methemoglobin formation that could develop with or without loss of hemoglobin. Medical intervention is required when methemoglobin levels are at or above 10% in the blood of humans. Long-term exposure could produce reversible anemia (Linch, 1974). p-Chloroaniline administered dermally induces more intense methemoglobin formation than when administered orally (Gosselin et al., 1984). A threshold limit value for aniline and its homologs has been set at 2 ppm for dermal exposure (ACGIH, 1988-89). McLean et al. (1969) studied methemoglobin formation in cats by a number of substituted anilines including *p*-chloroaniline. These studies showed that chloro- and bromoanilines, especially the 3- and 4-halo compounds, tend to produce a long-lasting methemoglobin response. The oral LD_{50} value in rats for *p*-chloroaniline was reported to be 310 mg/kg, and the

dermal LD_{50} value in rabbits was reported to be 360 mg/kg (Smyth et al., 1962).

Aniline hydrochloride was carcinogenic for male F344/N rats (NCI, 1978a; Gralla et al., 1979). Azobenzene (NCI, 1979a), D & C Red No. 9 (NTP, 1982a), dapsone (NCI, 1977a), and o-toluidine hydrochloride (NCI, 1979b), all structurally related to aniline, are carcinogens in rats. Carcinogenesis studies on p-chloroaniline in feed were conducted by the National Cancer Institute in F344/N rats and B6C3F1 mice of each sex (NCI, 1979c). The dietary concentrations were 250 and 500 ppm for rats and 2,500 and 5,000 ppm for mice. The duration of compound administration was 78 weeks, followed by an observation period of 24 weeks for rats and 13 weeks for mice. Mesenchymal neoplasms (including six fibromas, one sarcoma, one fibrosarcoma, one osteosarcoma, and one hemangiosarcoma) in the spleen of male rats (vehicle control, 0/20; low dose. 0/49; high dose. 10/49) and hemangiomatous neoplasms in mice (male: 2/20; 10/50; 14/50; female: 0/18; 3/49; 8/42) may have been related to p-chloroaniline administration. However, the conclusions of the studies given in the Technical Report were that "sufficient evidence was not found to establish the carcinogenicity of p-chloroaniline for F344/N rats and $B6C3F_1$ mice."

p-Chloroaniline is 1 of 17 compounds with a chloroaniline moiety which have been evaluated or are under evaluation by the NCI/NTP (Table 1). Six of the nine compounds evaluated to date were found to be carcinogenic, whereas the results of the original p-chloroaniline carcinogenesis studies were considered equivocal. 2-Chloro-p-phenylenediamine sulfate (NCI, 1978b) and 3-chloro-p-toluidine (NCI, 1978c) were determined not to be carcinogenic in rats or mice.

No epidemiologic study of *p*-chloroaniline carcinogenicity was available in the literature. However, an epidemiologic study on an analog, 4-chloro-2-methylaniline, indicated the possibility of bladder cancer in exposed workers (USEPA, 1986). Other structurally related chemicals such as 4,4'-methylene bis(2methylaniline) and toluidine were reported to be

Structure	Chemical	CAS Number	NTP Testing Status Genetic Toxicity	Carcinogenicity and Other
NH ₂ Ci	o-Chloroaniline	95-51-2	Negative in Salmonella (Zeiger et al., 1987)	Not evaluated for carcinogenicity

associated with increased deaths from urinary bladder cancer in dyestuff factory workers in northern Italy (Rubino et al., 1982; Lamb et al., 1986).

Study Rationale

In a previous *p*-chloroaniline study, rare splenic neoplasms were found in dosed male rats; however, the number of neoplasms was considered to be insufficient to establish clearly the carcinogenicity of *p*-chloroaniline (NCI, 1979c). *p*-Chloroaniline is unstable in feed, and the animals may have received the chemical at less than the targeted dietary concentration. Thus, the study is considered to be inadequate for determining carcinogenicity.

The widespread exposure of workers to *p*-chloroaniline in the dye, chemical, and pharmaceutical manufacturing industries and the structural resemblance of *p*-chloroaniline to known carcinogens were the rationale for reevaluating this chemical for toxicity and carcinogenicity in laboratory animals. The studies described in this report were conducted in F344/N rats and B6C3F₁ mice of each sex at three doses. The gavage route with a water vehicle was selected because the chemical was found to be unstable in feed.

GENETIC TOXICOLOGY

PROCUREMENT AND CHARACTERIZATION OF p-CHLOROANILINE

p-Chloroaniline (S2 flaked, technical grade) was obtained in one lot (lot no. 127) from E.I. DuPont de Nemours and Company, Inc. (Wilmington, Delaware). Purity and identity analyses were conducted at Midwest Research Institute (MRI) (Kansas City, Missouri). MRI reports on the analyses performed in support of the *p*-chloroaniline studies are on file at the National Institute of Environmental Health Sciences. Lot no. 127 was identified as *p*-chloroaniline by infrared (Figure 1), ultraviolet/visible, and nuclear magnetic resonance spectra (Figure 2), which were consistent with those expected for the structure and the spectra in the literature (Sadtler Standard Spectra).

Purity was determined by elemental analysis, Karl Fischer water analysis, titration of the amine component with perchloric acid, thinlayer chromatography, and gas chromatography. Cumulative data indicated that lot no. 127 was 99.1% pure. Results of elemental analysis of lot no. 127 were in agreement with theoretical values for carbon, hydrogen, chlorine, and nitrogen. Water content was 0.020% by Karl Fischer titration. Titration of the amine group in glacial acetic acid with perchloric acid indicated a purity of 98.8%. Thin-layer chromatography with two different solvent systems (chloroform:methanol:acetic acid, 95:4:1, or diethylamine) showed a single spot. Gas chromatography performed with a 10% Carbowax 20M column indicated one impurity after the major peak with an area 0.14% that of the major peak and three other impurities, two before and one after the major peak, with individual peak areas less than 0.1% that of the major peak. A second gas chromatographic system with a 3% SP2100(DB) column indicated one impurity after the major peak with an area 0.13% that of the major peak and a group of unresolved impurities after the major peak, with a total area 0.15% that of the major peak.

PREPARATION AND CHARACTERIZATION OF p-CHLOROANILINE HYDROCHLORIDE DOSE MIXTURES

All dose mixtures administered to animals in these studies were prepared from weighed quantities of p-chloroaniline dissolved in water containing hydrochloric acid: all doses refer to the pchloroaniline content of the solution. p-Chloroaniline and molar equivalents of 1.0 N hydrochloric acid were mixed together in a calibrated container (Table 2). The resulting p-chloroaniline hydrochloride solutions were diluted to the appropriate concentration with deionized water and had a pH of approximately 2. The solutions were refrigerated for 1 day and filtered through filter paper to remove precipitate. The stability of p-chloroaniline hydrochloride in water gavage solutions (5 mg/ml as p-chloroaniline) was determined by gas chromatography with a 3% SP2401 on 100/200 mesh Supelcoport packed column after dilutions with methanol and additions of biphenyl as an internal reference. The chemical was found to be stable in water for at least 14 days at room temperature. For the 16day and 13-week studies, dose mixtures were prepared at weekly intervals, placed in foilwrapped containers, and refrigerated until the day of dosing. For the 2-year studies, the filtrates were stored in amber bottles at 5° C and were used as the stock solutions or as the dose mixtures for the highest dose groups of rats and mice.

Periodic analysis of formulated *p*-chloroaniline hydrochloride in water dose mixtures by ultraviolet spectroscopy at 216 nm was conducted at the study and analytical chemistry laboratories. The study laboratory analyzed dose mixtures by ultraviolet spectroscopy two times during the 13-week studies (Table 3). During the 2-year studies, the dose mixtures were analyzed at approximately 8-week intervals. The number of times that concentrations were not within specifications can be extrapolated to indicate the frequency with which mixtures were formulated

within the specified $\pm 10\%$ of the target concentrations. For the 2-year *p*-chloroaniline hydrochloride studies, 72/72 dose mixtures were formulated within $\pm 10\%$ of the target concentrations, and it is therefore estimated that 100%

of the dose mixtures were properly prepared (Table 4). Results of periodic referee analyses performed by the analytical chemistry laboratory indicated good agreement with the results from the study laboratory (Table 5).

SIXTEEN-DAY STUDIES

Male and female F344/N rats and $B6C3F_1$ mice were obtained from Charles River Breeding Laboratories and held for 14 days (rats) or 15 days (mice) before the studies began. The rats were approximately 7 weeks old when placed on study, and the mice were 8 weeks old.

Groups of five rats and mice of each sex were administered 25, 50, 100, 200, or 400 mg/kg *p*-chloroaniline by gavage in aqueous hydrochloric acid, 5 days per week for a total of 12 doses over 16 days. Vehicle controls received deionized water by gavage.

Animals were housed five per cage. Water and feed were available ad libitum. Rats and mice were observed twice per day. A necropsy was performed on all animals. Details of animal maintenance are presented in Table 6.

THIRTEEN-WEEK STUDIES

Thirteen-week studies were conducted to evaluate the cumulative toxic effects of repeated administration of p-chloroaniline hydrochloride and to determine the doses to be used in the 2-year studies.

Four-week-old male and female F344/N rats and 6-week-old male and female $B6C3F_1$ mice were obtained from Harlan Industries, observed for 19 days, distributed to weight classes, and assigned to dose groups according to a table of random numbers. Rats were approximately 7 weeks old when placed on study, and mice were 9 weeks old.

Groups of 10 rats of each sex were administered 5, 10, 20, 40, or 80 mg/kg *p*-chloroaniline by gavage in water acidified with hydrochloric acid, 5 days per week for 13 weeks for a total of 64 or 65 doses. Groups of 10 mice of each sex were administered 7.5, 15, 30, 60, or 120 mg/kg on the same schedule for a total of 66 or 67 doses. Vehicle controls received deionized water by gavage.

Rats and mice were housed five per cage. Feed and water were available ad libitum. Animals were observed two times per day; moribund animals were killed. Individual animal weights were recorded once per week. Further experimental details are summarized in Table 6.

At the end of the 13-week studies, survivors were killed. A necropsy was performed on all animals except those excessively autolyzed or cannibalized. Tissues and groups examined are listed in Table 6.

On the day of necropsy, blood was taken for hematologic and methemoglobin determinations from the vena cava of pentobarbital-anesthetized rats or from the retro-orbital sinus of unanesthetized mice. Blood was collected in Becton-Dickinson[®] microtainers containing sodium EDTA. Hematologic analyses were performed with an Ortho ELT-8 Hematology Analyzer. The methemoglobin concentration was determined by the method of Evelyn and Malloy (1938).

TWO-YEAR STUDIES

Study Design

Groups of 49 or 50 rats of each sex were administered 2, 6, or 18 mg/kg *p*-chloroaniline by gavage in aqueous hydrochloric acid, 5 days per week for 103 weeks. Groups of 50 mice of each sex were administered 3, 10, or 30 mg/kg on the same schedule. Vehicle controls received deionized water by gavage.

Source and Specifications of Animals

The male and female F344/N rats used in these studies were produced under strict barrier conditions at Charles River Breeding Laboratories, and the B6C3F₁ (C57BL/6N, female \times C3H/ HeN MTV⁻, male) mice used in these studies were produced at Frederick Cancer Research Center. Breeding stock for the foundation colonies at the production facilities originated at the National Institutes of Health Repository. Animals shipped for study were progeny of defined microflora-associated parents that were transferred from isolators to barrier-maintained rooms. Rodents were shipped to the study laboratory at 5-6 weeks of age. Rats were quarantined at the study laboratory for 20 days and

mice for 12 days. Thereafter, a complete necropsy was performed on five animals of each sex and species to assess their health status. The rodents were placed on study at 7-8 weeks of age. The health of the animals was monitored during the course of the studies according to the protocols of the NTP Sentinel Animal Program (Appendix E).

Animal Maintenance

Animals were housed five per cage. Feed and water were available ad libitum. Cages and racks were rotated. Further details of animal maintenance are given in Table 6.

Clinical Examinations and Pathology

Blood samples for hematologic and methemoglobin determinations were collected in Vacutainers[®] containing EDTA by retro-orbital puncture from 15 randomly selected rats from each group at 6, 12, 18, and 24 months. Rats were dosed for 2 consecutive days before blood collection except at 24 months when collection was performed 11-14 days after administration of the last dose. Hematologic analyses were performed with an Ortho ELT-8 Hematology Analyzer; methemoglobin concentration was determined by the method of Evelyn and Malloy (1938).

All animals were observed two times per day. Clinical signs were recorded once per week for 13 weeks and then at least once per month. Individual body weights were recorded once per week for the first 13 weeks of the studies and once per month thereafter. Mean body weights were calculated for each group. Animals found moribund and those surviving to the end of the studies were humanely killed. A necropsy was performed on all animals including those found dead, unless they were excessively autolyzed or cannibalized, missexed, or missing. Thus, the number of animals from which particular organs or tissues were examined microscopically varies and is not necessarily equal to the number of animals that were placed on study.

During necropsy, all organs and tissues were examined for grossly visible lesions. Tissues were preserved in 10% neutral buffered formalin, embedded in paraffin, sectioned, and stained with hematoxylin and eosin. Histopathologic examination of tissues was performed according to an "inverse pyramid" design (McConnell, 1983a,b). That is, complete histopathologic examinations (Table 6) were performed on all high dose and vehicle control animals and on lower dose animals dying before the end of the study. In addition, histopathologic examinations were performed on all grossly visible lesions in all dose groups. Potential target organs for chemically related neoplastic and nonneoplastic effects were identified from the short-term studies or the literature and were determined by examination of the pathology data; these target organs/tissues in the lower dose groups were examined histopathologically. If mortality in the highest dose group exceeded that in the vehicle control group by 15%, complete histopathologic examinations were performed on all animals in the second highest dose group in addition to those in the high dose group.

When the pathology evaluation was completed, the slides, paraffin blocks, and residual wet tissues were sent to the NTP Archives for inventory, slide/block match, and wet tissue audit. The slides, individual animal data records, and pathology tables were sent to an independent quality assessment laboratory. The individual animal records and tables were compared for accuracy, slides and tissue counts were verified, and histotechnique was evaluated. All tumor diagnoses, all target tissues, and all tissues from a randomly selected 10% of the animals were evaluated by a quality assessment pathologist. The quality assessment report and slides were submitted to the Pathology Working Group (PWG) Chairperson, who reviewed all target tissues and those about which there was a disagreement between the laboratory and quality assessment pathologists.

Representative slides selected by the Chairperson were reviewed by the PWG, which includes the laboratory pathologist, without knowledge of previously rendered diagnoses. When the consensus diagnosis of the PWG differed from that of the laboratory pathologist, the laboratory pathologist was asked to reconsider the original diagnosis. This procedure has been described, in part, by Maronpot and Boorman (1982) and Boorman et al. (1985). The final diagnoses represent a consensus of contractor pathologists and the NTP Pathology Working Group. For subsequent analysis of pathology data, the diagnosed lesions for each tissue type are combined according to the guidelines of McConnell et al. (1986).

Slides/tissues are generally not evaluated in a blind fashion (i.e., without knowledge of dose group) unless the lesions in question are subtle or unless there is an inconsistent diagnosis of lesions by the laboratory pathologist. Nonneoplastic lesions are not examined routinely by the quality assessment pathologist or PWG unless they are considered part of the toxic effect of the chemical.

Statistical Methods

Survival Analyses: The probability of survival was estimated by the product-limit procedure of Kaplan and Meier (1958) and is presented in the form of graphs. Animals were censored from the survival analyses at the time they were found to be missing or dead from other than natural causes; animals dying from natural causes were not censored. Statistical analyses for a possible dose-related effect on survival used the method of Cox (1972) for testing two groups for equality and Tarone's (1975) life table test for a doserelated trend. When significant survival differences were detected, additional analyses using these procedures were carried out to determine the time point at which significant differences in the survival curves were first detected. All reported P values for the survival analysis are two-sided.

Calculation of Incidence: The incidence of neoplastic or nonneoplastic lesions is given as the ratio of the number of animals bearing such lesions at a specific anatomic site to the number of animals in which that site was examined. In most instances, the denominators include only those animals for which the site was examined histologically. However, when macroscopic examination was required to detect lesions (e.g., skin or mammary tumors) prior to histologic sampling, or when lesions could have appeared at multiple sites (e.g., lymphomas), the denominators consist of the number of animals on which a necropsy was performed.

Analysis of Tumor Incidence: The majority of tumors in this study were considered to be incidental to the cause of death or not rapidly lethal. Thus, the primary statistical method used was a logistic regression analysis, which assumed that the diagnosed tumors were discovered as the result of death from an unrelated cause and thus did not affect the risk of death. In this approach, tumor prevalence was modeled as a logistic function of chemical exposure and time. Both linear and quadratic terms in time were incorporated initially, and the quadratic term was eliminated if it did not significantly enhance the fit of the model. The dosed and vehicle control groups were compared on the basis of the likelihood score test for the regression coefficient of dose. This method of adjusting for intercurrent mortality is the prevalence analysis of Dinse and Lagakos (1983), further described and illustrated by Dinse and Haseman (1986). When tumors are incidental, this comparison of the time-specific tumor prevalences also provides a comparison of the time-specific tumor incidences (McKnight and Crowley, 1984).

In addition to logistic regression, alternative methods of statistical analysis were used, and the results of these tests are summarized in the appendixes. These include the life table test (Cox, 1972; Tarone, 1975), appropriate for rapidly lethal tumors, and the Fisher exact test and the Cochran-Armitage trend test (Armitage, 1971; Gart et al., 1979), procedures based on the overall proportion of tumor-bearing animals.

Tests of significance include pairwise comparisons of each dosed group with vehicle controls and a test for an overall dose-response trend. Continuity-corrected tests were used in the analysis of tumor incidence, and reported P values are one-sided. The procedures described above also were used to evaluate selected nonneoplastic lesions. (For further discussion of these statistical methods, see Haseman, 1984.)

Historical Control Data: Although the concurrent control group is always the first and most appropriate control group used for evaluation, there are certain instances in which historical control data can be helpful in the overall assessment of tumor incidence. Consequently, control tumor incidences from the NTP historical control data base (Haseman et al., 1984, 1985) are included for those tumors appearing to show compound-related effects.

GENETIC TOXICOLOGY

Salmonella Protocol: Testing was performed as reported by Ames et al. (1975) with modifications listed below and described in greater detail by Haworth et al. (1983) and Mortelmans et al. (1986). Chemicals were sent to three different laboratories as coded aliquots from Radian Corporation (Austin, Texas). The study chemical was incubated with the Salmonella typhimurium tester strains (TA97, TA98, TA100, TA1535, and/or TA1537) either in buffer or S9 mix (metabolic activation enzymes and cofactors from Aroclor 1254-induced male Sprague Dawley rat or Syrian hamster liver) for 20 minutes at 37° C before the addition of soft agar supplemented with L-histidine and D-biotin and subsequent plating on minimal glucose agar plates. Incubation was continued for an additional 48 hours.

Chemicals were tested in a series (four strains used) or in a hierarchy (initial testing in TA98 and TA100; if results were negative, then the chemical was tested further in additional strains). If all results were negative, the chemical was retested in all strains with a different concentration of S9.

Each test consisted of triplicate plates of concurrent positive and negative controls and of at least five doses of the study chemical. The high dose was limited by toxicity or solubility but did not exceed 10 mg/plate. All negative assays were repeated, and all positive assays were repeated under the conditions that elicited the positive response.

A positive response was defined as a reproducible, dose-related increase in histidine-independent (revertant) colonies in any one strain/activation combination. An equivocal response was defined as an increase in revertants which was not dose related, not reproducible, or of insufficient magnitude to support a determination of mutagenicity. A response was considered negative when no increase in revertant colonies was observed after chemical treatment.

Mouse Lymphoma Protocol: The experimental protocol is presented in detail by Myhr et al. (1985) and follows the basic format of Clive et al. (1979). All study chemicals were supplied as coded aliquots from Radian Corporation (Austin, Texas). The highest dose of the study compound was determined by solubility or toxicity and did not exceed 1 mg/ml. Mouse lymphoma L5178Y cells were maintained at 37° C as suspension cultures in Fischer's medium supplemented with 2 mM L-glutamine, 110 µg/ml sodium pyruvate, 0.05% pluronic F68, antibiotics, and heat-inactivated horse serum; normal cycling time was about 10 hours. To reduce the number of spontaneously occurring trifluorothymidine (Tft)-resistant cells, subcultures were exposed once to medium containing thymidine, hypoxanthine, methotrexate, and glycine for 1 day, to thymidine, hypoxanthine, and glycine for 1 day, and to normal medium for 3-5 days. For cloning, horse serum content was increased and Noble agar was added. Freshly prepared S9 metabolic activation factors were obtained from the liver of either Aroclor 1254-induced or noninduced male F344 rats.

All doses within an experiment, including concurrent positive and solvent controls, were

replicated. Treated cultures contained 6×10^6 cells in 10 ml of medium. This volume included the S9 fraction in those experiments performed with metabolic activation. Incubation with the study chemical continued for 4 hours, after which time the medium plus chemical was removed and the cells were resuspended in 20 ml of fresh medium and incubated for an additional 2 days to express the mutant phenotype. Cell density was monitored so that log phase growth was maintained. After the 48-hour expression period, 3×10^6 cells were plated in medium and soft agar supplemented with Tft for selection of Tft-resistant cells $(TK^{+/+})$, and 600 cells were plated in nonselective medium and soft agar to determine cloning efficiency. Plates were incubated at 37° C under 5% carbon dioxide for 10-12 days. All data were evaluated statistically for both trend and peak response. Both responses had to be significant (P < 0.05) for a chemical to be considered capable of inducing Tft resistance; a single significant response led to an "equivocal" conclusion, and the absence of both a trend and a peak response resulted in a "negative" call.

Minimum criteria for accepting an experiment as valid and a detailed description of the statistical analysis and data evaluation are presented in Myhr et al. (1985). This assay was initially performed without S9; if a clearly positive response was not obtained, the experiment was repeated with induced S9.

Chinese Hamster Ovary Cytogenetics Assays: Testing was performed as reported by Galloway et al. (1985, 1987) and is described briefly below. Chemicals were sent to the laboratories as coded aliquots from Radian Corporation (Austin, Texas). Chemicals were tested in cultured Chinese hamster ovary (CHO) cells for induction of sister chromatid exchanges (SCEs) and chromosomal aberrations both in the presence and absence of Aroclor 1254-induced male Sprague Dawley rat liver S9 and cofactor mix. Cultures were handled under gold lights to prevent photolysis of bromodeoxyuridine (BrdU)-substituted DNA. Each test consisted of concurrent solvent and positive controls and of at least three doses of the study chemical; the high dose was limited by toxicity or solubility but did not exceed 5 mg/ml.

In the SCE test without S9, CHO cells were incubated for 26 hours with the study chemical in McCoy's 5A medium supplemented with 10% fetal bovine serum, L-glutamine (2 mM), and antibiotics. BrdU was added 2 hours after culture initiation. After 26 hours, the medium containing the study chemical was removed and replaced with fresh medium plus BrdU and colcemid, and incubation was continued for 2 more hours. Cells were then harvested by mitotic shake-off, fixed, and stained with Hoechst 33258 and Giemsa. In the SCE test with S9, cells were incubated with the chemical, serum-free medium, and S9 for 2 hours. The medium was then removed and replaced with medium containing BrdU and no study chemical; incubation proceeded for an additional 26 hours, with colcemid present for the final 2 hours. Harvesting and staining were the same as for cells treated without S9.

In the chromosomal aberration test without S9, cells were incubated in McCoy's 5A medium with the study chemical for 8 hours; colcemid was added, and incubation was continued for 2 hours. The cells were then harvested by mitotic shake-off, fixed, and stained with Giemsa. For the chromosomal aberration test with S9, cells were treated with the study chemical and S9 for 2 hours, after which the treatment medium was removed and the cells were incubated for 10 hours in fresh medium, with colcemid present for the final 2 hours. Cells were harvested in the same manner as for the treatment without S9.

For the SCE test, if significant chemical-induced cell cycle delay was seen, incubation time was lengthened to ensure a sufficient number of scorable cells. The harvest time for the chromosomal aberration test was based on the cell cycle information obtained in the SCE test; if cell cycle delay was anticipated, the incubation period was extended approximately 5 hours.

Cells were selected for scoring on the basis of good morphology and completeness of karyotype $(21 \pm 2 \text{ chromosomes})$. All slides were scored blind, and those from a single test were read by the same person. For the SCE test, 50 seconddivision metaphase cells were usually scored for frequency of SCEs per cell from each dose; 100 first-division metaphase cells were scored at each dose for the chromosomal aberration test. Classes of aberrations included simple (breaks and terminal deletions), complex (rearrangements and translocations), and other (pulverized cells, despiralized chromosomes, and cells containing 10 or more aberrations).

Statistical analyses were conducted on both the slopes of the dose-response curves and the individual dose points. An SCE frequency 20% above the concurrent solvent control value was chosen as a statistically conservative positive

response. The probability of this level of difference occurring by chance at one dose point is less than 0.01; the probability for such a chance occurrence at two dose points is less than 0.001. Chromosomal aberration data are presented as percentage of cells with aberrations. As with SCEs, both the dose-response curve and individual dose points were statistically analyzed. A statistically significant (P<0.003) trend test or a significantly increased dose point (P<0.05) was sufficient to indicate a chemical effect.

SIXTEEN-DAY STUDIES

All rats that received 200 or 400 mg/kg p-chloroaniline hydrochloride died within 5 days (Table 7). The final mean body weights of rats that received 100 mg/kg were 19% lower than that of vehicle controls for males and 5% lower for females. Compound-related clinical signs included blue extremities and eyes, indicative of cyanosis. Rats that received 200 or 400 mg/kg were lethargic, and rats that received 25 or 50 mg/kg had labored breathing. Splenic enlargement was observed at 25, 50, and 100 mg/kg. Sinusoidal congestion of the spleen and hemosiderin deposition in the renal cortical tubular epithelial cells were observed in 2/2 males and 2/2 females that received 100 mg/kg.

(a) All doses calculated as milligrams p-chloroaniline per kilogram body weight

(b) Number surviving/number initially in group

(c) Initial group mean body weight

(d) Mean body weight change of the group

(e) Day of death: 4,4,4,4,5

(f) No data are reported due to the 100% mortality in this group.

(g) Day of death: 2,2,2,3,3

(h) Day of death: 2,2,3,3,3

THIRTEEN-WEEK STUDIES

All male rats lived to the end of the studies (Table 8). One of 10 female rats that received 80 mg/kg died before the end of the studies. The final mean body weights of rats that received 80 mg/kg were 16% lower than that of vehicle controls for males and 4% lower for females. The weights of brain, liver, thymus, kidney, heart, lung, and testis for dosed groups were comparable to those of vehicle controls, except that the brain and lung weights of male rats at 80 mg/kg were significantly lower than those of vehicle controls and the heart and kidney weights of female rats were significantly greater than those of vehicle controls (Table F1). Spleen weights were increased in dosed groups, and a clear doseresponse relationship was observed (Figure 3; Table F1). Spleen weights were not recorded for male vehicle controls, but the spleens of untreated animals of comparable age weigh 0.678-0.848 g (NTP data base). The hematocrit value, the hemoglobin concentration, and the erythrocyte count for all dosed groups of rats were significantly lower than those for vehicle controls (Table 9; Figures 4 and 5). The methemoglobin concentrations for all dosed groups of rats were significantly greater than those for vehicle controls. Blood samples for hematologic analysis were taken 72 (male) or 24 (female) hours after administration of the final dose.

This time difference probably contributed to the lower methemoglobin concentrations observed for males compared with those for females. Compound-related increases were seen for the number of segmented neutrophils, the mean corpuscular hemoglobin, the mean corpuscular hemoglobin concentration, the mean corpuscular hemoglobin concentration, the mean corpuscular volume, and the numbers of nucleated and polychromatophilic erythrocytes. The leukocyte count and lymphocyte count were significantly increased for male rats at 40 mg/kg (but not at 80 mg/kg) and for all dosed groups of female rats.

41 *p*-Chloroaniline Hydrochloride, NTP TR 351

Compound-related lesions included bone marrow hyperplasia (severe at 80 mg/kg and minimal at 5 mg/kg), pigmentation (hemosiderin) of the kidney, spleen, and Kupffer cells of the liver, hematopoiesis of the liver and spleen, and splenic congestion, which are attributable to increased erythrocyte destruction secondary to methemoglobin formation (Table 10).

(a) Ten animals in each group examined; all doses calculated as milligrams p-chloroaniline per kilogram body weight.

Dose Selection Rationale: Major compoundrelated effects observed in rats were hemolytic anemia, methemoglobinemia, and splenomegaly. The hemolytic anemia and splenomegaly responses were dose related. Methemoglobin levels were approximately 1%-4% in the highest dose groups and slightly lower in the other dose groups. It was judged that doses higher than 20 mg/kg for the 2-year studies might produce severe anemia in animals because hematocrit and erythrocyte values were reduced substantially in the 13-week studies at doses of 40 and 80 mg/kg. Furthermore, the magnitude of splenomegaly was considered to be too great to permit selection of doses higher than 20 mg/kg. Therefore, 18 mg/kg was selected as the high dose and 2 and 6 mg/kg, as the low and mid doses, respectively. This dose regimen was expected to achieve a no-effect level at the low dose and to produce some effects on the hematopoietic system at the mid dose in the 2-year studies.

TWO-YEAR STUDIES

Body Weights and Clinical Signs

The mean body weights of high dose female rats were 4%-6% lower than those of vehicle controls after week 70 (Table 11 and Figure 6). Mean body weights of dosed male rats were generally within 5% of those of vehicle controls throughout the studies. Mid and high dose male rats and high dose female rats had blue extremities indicative of cyanosis.

TABLE 11. MEAN BODY WEIGHTS OF RATS IN THE TWO-YEAR GAVAGE STUDIES OF ρ -CHLOROANILINE HYDROCHLORIDE

(a) The number of animals weighed was lower than the number of animals surviving.

FIGURE 6. GROWTH CURVES FOR RATS ADMINISTERED p-CHLOROANILINE HYDROCHLORIDE BY GAVAGE FOR TWO YEARS

(all doses calculated as milligrams p-chloroaniline per kilogram body weight)

45 p-Chloroaniline Hydrochloride, NTP TR 351

Survival

Estimates of the probabilities of survival for male and female rats administered p-chloroaniline hydrochloride at the doses used in these studies and for vehicle controls are shown in Table 12 and in the Kaplan and Meier curves in Figure 7. The survival of the low and mid dose groups of male rats was significantly greater than that of the vehicle controls after week 94. The survival of the high dose group of female rats was significantly greater than that of the vehicle controls at the end of the study; the survival of the low dose female group was significantly greater than that of the vehicle controls after week 77.

Hematology at Six, Twelve, Eighteen, and Twenty-Four Months

Hematologic changes at 6 months for male and female rats included decreases in hemoglobin concentration, erythrocyte count, and hematocrit value and increases in mean corpuscular volume, nucleated erythrocytes, and mean corpuscular hemoglobin (Tables 13 and 14). These changes, which were mild in the mid dose groups and moderate in the high dose groups, are consistent with a regenerative response (increases in mean corpuscular hemoglobin, nucleated erythrocytes, and mean corpuscular volume) secondary to a decreased erythrocyte mass (decrease in erythrocyte count, hematocrit value, and hemoglobin concentration). The increases in methemoglobin concentrations in the dosed groups indicate a hemolytic mechanism through the oxidation and subsequent denaturation of hemoglobin as the cause of the regenerative anemia. The increase in methemoglobin was more pronounced in high dose male rats (approximately sevenfold that of vehicle controls) compared with that in the high dose female rats (approximately twofold that of vehicle controls); however, the regenerative response, as measured by nucleated erythrocyte count and mean corpuscular volume, was greater in female rats.

TABLE 12. SURVIVAL OF RATS IN THE TWO-YEAR GAVAGE STUDIES OF ρ -CHLOROANILINE HYDROCHLORIDE (a)

	Vehicle Control	2 mg/kg	6 mg/kg	18 mg/kg
MALE (b)		···· · · ·		
nimals initially in study	50	50	50	50
Nonaccidental deaths before termination (c)	31	18	16	28
Accidentally killed	0	0	2	1
nimals missexed	1	0	0	0
Cilled at termination	18	32	32	20
Died during termination period	0	0	0	1
urvival P values (d)	0.793	0.007	0.005	0.367
FEMALE (b)				
nimals initially in study	50	50	50	50
Jonaccidental deaths before termination (c)	23	11	14	13
Killed at termination	27	39	36	37
urvival P values (d)	0.244	0.011	0.075	0.043

(a) All doses calculated as milligrams p-chloroaniline per kilogram body weight

(b) First day of termination period: 730 (week 105)

(c) Includes animals killed in a moribund condition

(d) The result of the life table trend test is in the vehicle control column, and the results of the life table pairwise comparisons with the vehicle controls are in the dosed columns.

TABLE 14. HEMATOLOGY FOR FEMALE RATS IN THE TWO-YEAR GAVAGE STUDY OF p-CHLOROANILINE HYDROCHLORIDE (Continued)

(a) Mean ± standard error; P values vs. the vehicle controls by Williams' test (Williams, 1971, 1972); doses calculated as *p*-chloroaniline.

(b) P<0.01

(c) P < 0.05

(d) Blood taken for analysis 11-14 days after the last dose was administered

At 12 months, dose-related changes in the erythron were minimal to mild. Mild increases in mean corpuscular volume, nucleated erythrocytes, mean corpuscular hemoglobin, and methemoglobin were detected. At 18 months, however, changes in the erythrocyte mass and in methemoglobin concentrations were similar to those detected at 6 months. Approximately twofold to fourfold increases in methemoglobin concentrations in mid and high dose male and female rats were associated with hematologic evidence of regenerative anemia. At 24 months, results of methemoglobin and hematologic analyses were essentially unremarkable. Because these animals had not been dosed for 11-14 days before the collection of the samples, these data suggest that the direct hematologic effects of pchloroaniline hydrochloride are transient.

Pathology and Statistical Analyses of Results

This section describes the statistically significant or biologically noteworthy changes in the incidences of rats with neoplastic or nonneoplastic lesions of the spleen, adrenal gland, testis, bone marrow, liver, hematopoietic system, and anterior pituitary gland.

Summaries of the incidences of neoplasms and nonneoplastic lesions, individual animal tumor diagnoses, statistical analyses of primary tumors that occurred with an incidence of at least 5% in at least one animal group, and historical control incidences for the neoplasms mentioned in this section are presented in Appendixes A and B for male and female rats, respectively.

Spleen: The incidences of proliferative mesenchymal lesions, which varied from nonneoplastic fibrous connective tissue (fibrosis) to highly malignant sarcomas, were increased in the spleen of dosed rats. The incidences of splenic fibrosis were increased in dosed males and females, whereas the incidences of sarcomas (fibrosarcomas, osteosarcomas, and hemangiosarcomas) were increased in males (Table 15). Many of the splenic sarcomas metastasized to one or more sites. Cellular infiltration of lipocytes (fatty metaplasia) was observed in high dose rats (male: vehicle control, 0/49; low dose, 0/50; mid dose, 0/50; high dose, 24/50; female: 0/50; 0/50; 0/50; 11/50). A fibrosarcoma was observed in one mid dose female rat, and an osteosarcoma was observed in one high dose female rat.

Fibrosis consisted of focal or diffuse proliferation of bundles of dense collagen intermixed with mildly to moderately pleomorphic fibroblasts. Fibrosis usually affected the splenic red pulp, where it replaced the splenic parenchyma, but in some animals fibrosis occurred in the splenic capsule with the formation of cysts on the capsular surface. In two high dose males, the fibrous tissue formed well-demarcated expansile lesions that were diagnosed as fibromas. Sarcomas were poorly demarcated, expansile, and invasive

lesions; in some cases, fibrosis and sarcomas were present in the same spleen. Fibrosarcomas had a typical morphology consisting of irregular, interlacing bundles of collagen mixed with spindle cells having highly pleomorphic, anaplastic nuclei. Many of the neoplasms with features of fibrosarcomas also contained either areas of osteoid formation or cavernous or sinusoidal vascular spaces; these neoplasms were diagnosed as osteosarcomas or hemangiosarcomas, respectively. Cellular infiltration of lipocytes was seen concurrently with fibrosis or sarcomas and consisted of a few to several clumped and/or scattered, variably sized adipose cells within the areas of fibrosis or neoplasia. This change appeared to represent metaplasia of the proliferating fibrous tissue elements to adipose cells (fatty metaplasia).

Adrenal Gland: Medullary hyperplasia was observed at an increased incidence in high dose female rats; pheochromocytomas were also observed in vehicle control and dosed females (Table 16). Pheochromocytomas or malignant pheochromocytomas (combined) in male rats occurred with a significant positive trend; the incidence in the high dose group was significantly greater than that in the vehicle controls.

TABLE 15. SPLENIC FIBROSIS AND PRIMARY SARCOMAS IN RATS IN THE TWO-YEAR GAVAGESTUDIES OF p-CHLOROANILINE HYDROCHLORIDE (a)

(a) The statistical analyses used are discussed in Section II (Statistical Methods) and Table A3 (footnotes); all doses calculated as milligrams *p*-chloroaniline per kilogram body weight.

(b) Historical incidence of all sarcomas in water gavage vehicle controls (mean \pm SD): 1/298 (0.3% \pm 0.8%); historical incidence in untreated controls in NTP studies: 8/1,906 (0.4% \pm 0.8%); no benign tumors, fibrosarcomas, or osteosarcomas have been observed in untreated controls.

(c) No P value is reported because no tumors were observed in the vehicle control and dosed groups.

(d) Historical incidence of hemangiomas or hemangiosarcomas (combined, for all organs) in water gavage vehicle controls (mean \pm SD): 2/300 (0.7% \pm 2%); historical incidence in untreated controls in NTP studies: 12/1,936 (0.6% \pm 1%)

(e) Historical incidence of sarcomas in water gavage vehicle controls: 0/297; historical incidence of sarcomas in untreated controls in NTP studies: 1/1,961 (mean \pm SD) ($0.05\% \pm 0.4\%$); no fibrosarcomas or osteosarcomas have been observed.

TABLE 16. ADRENAL MEDULLARY LESIONS IN RATS IN THE TWO-YEAR GAVAGE STUDIES OFp-CHLOROANILINE HYDROCHLORIDE (a)

(a) All doses calculated as milligrams *p*-chloroaniline per kilogram body weight

(b) Historical incidence in water gavage vehicle controls (mean \pm SD): 121/299 (40% \pm 16%); historical incidence in untreated controls in NTP studies: 489/1,915 (26% \pm 14%)

(c) Historical incidence of pheochromocytomas or malignant pheochromocytomas (combined) in water gavage vehicle controls (mean \pm SD): 20/295 (7% \pm 2%); historical incidence in untreated controls in NTP studies: 99/1,968 (5% \pm 4%)

Testis: The incidences of interstitial cell adenomas in the dosed groups of male rats were greater than that in the vehicle controls (vehicle control, 36/49; low dose, 44/46; mid dose, 44/50; high dose, 46/50). These marginal increases were not considered to be related to chemical exposure.

Bone Marrow: Femoral hyperplasia was observed at increased incidences in high dose male and mid and high dose female rats (male: vehicle control, 26/49; low dose, 36/50; mid dose, 35/49; high dose, 46/50; female: 11/50; 12/48; 21/50; 37/47). Femoral reticular cell hyperplasia was observed at increased incidences in mid and high dose female rats (male: 0/49; 0/50; 3/49; 0/50; female: 1/50; 2/48; 7/50; 7/47).

Liver: Hemosiderin pigmentation was observed at an increased incidence in high dose male rats (male: vehicle control, 1/49; low dose, 0/50; mid dose, 0/49; high dose, 26/49; female: 0/50; 0/50; 0/50; 1/50).

Hematopoietic System: Mononuclear cell leukemia in male and female rats occurred with significant negative trends; the incidences in the dosed groups were significantly lower than those in the vehicle controls (Table 17).

Anterior Pituitary Gland: Cysts of the pars distalis were observed at increased incidences in female rats (male: vehicle control, 3/47; low dose, 0/18; mid dose, 0/19; high dose, 1/46; female: 2/50; 3/33; 7/35; 12/50). The incidence of adenomas in high dose male rats was significantly lower than that in vehicle controls (20/47; 13/18; 11/19; 11/46; P = 0.027).

SIXTEEN-DAY STUDIES

Deaths occurred in all dosed groups (Table 18). The final mean body weights of dosed and vehicle control mice were comparable. Cyanosis was indicated by the bluish extremities of dosed mice. Compound-related lesions at 100 mg/kg included diffuse hemosiderosis of the liver Kupf-fer cells and diffuse congestion of the spleen in 2/2 males and 2/2 females.

THIRTEEN-WEEK STUDIES

Two male mice that received 120 mg/kg, three female mice that received 60 mg/kg, one female mouse that received 30 mg/kg, and one female vehicle control mouse died before the end of the studies (Table 19). Deaths were attributed to pneumonia. The pneumonia was generally confined to the terminal bronchioles and surrounding alveoli and was characterized by necrosis of bronchiolar and alveolar epithelium, suppurative inflammation, fibrosis, and varying degrees of hyperplasia of the remaining epithelium, sometimes leading to bronchiolization of alveoli. Epithelial cells in one affected animal contained intracytoplasmic inclusions. The mice were positive for Sendai titer, and the appearance of the pneumonia was compatible with Sendai virus infection. The final mean body weights of dosed and vehicle control mice were similar. The heart weights of male mice at 30 mg/kg or more, the lung weights of male mice at 60 and 120 mg/kg, the spleen weights of all groups of dosed male mice, and the spleen weights of

female mice at 30 mg/kg or more were significantly greater than those of vehicle controls (Figure 8; Table F2). The hematocrit value and the erythrocyte count for almost all dosed groups of mice were significantly lower than those for vehicle controls (Table 20; Figures 9 and 10). The methemoglobin concentration for all groups of male mice and female mice dosed at 15 mg/kg or more was significantly greater than those for vehicle controls. Compound-related increases were seen for the hemoglobin concentration, the number of segmented neutrophils (females only), the mean corpuscular hemoglobin, the mean corpuscular hemoglobin concentration, the mean corpuscular volume, and the number of nucleated erythrocytes. Erythrocytes from male and female mice in the mid (30 mg/kg) and high (120 mg/kg) dose groups had moderate to marked numbers of Heinz bodies (inclusions of denatured hemoglobin). Related findings included moderate to marked polychromasia and poikilocytosis (presence of erythrocytes with abnormal shapes).

TABLE 20. HEMATOLOGY FOR MICE IN THE THIRTEEN-WEEK GAVAGE STUDIES OFp-CHLOROANILINE HYDROCHLORIDE (a)

(a) Mean ± standard error. MCH = mean corpuscular hemoglobin; MCHC = mean corpuscular hemoglobin concentration; MCV = mean corpuscular volume; P values are vs. the vehicle controls; Dunnett's test was used when a nonsignificant result was obtained by the Jonckheere trend test; otherwise Williams' test was used (Dunnett, 1980; Jonckheere, 1954; Williams, 1971, 1972); doses calculated as *p*-chloroaniline.

(b) P < 0.05 vs. vehicle controls

(c) P < 0.01 vs. vehicle controls

FIGURE 9. PERCENTAGE HEMATOCRIT AND ERYTHROCYTE COUNT (AND STANDARD DEVIATION) FOR MALE MICE IN THE THIRTEEN-WEEK GAVAGE STUDIES OF ρ -CHLOROANILINE HYDROCHLORIDE

(all doses calculated as milligrams *p*-chloroaniline per kilogram body weight)

FIGURE 10. PERCENTAGE HEMATOCRIT AND ERYTHROCYTE COUNT (AND STANDARD DEVIATION) FOR FEMALE MICE IN THE THIRTEEN-WEEK GAVAGE STUDIES OF p-CHLOROANILINE HYDROCHLORIDE

(all doses calculated as milligrams *p*-chloroaniline per kilogram body weight)

Compound-related effects in the 13-week studies included increased incidences of pigmentation (hemosiderin) of the kidney and Kupffer cells of the liver and hematopoiesis of the spleen (Table 21). The severity of the hematopoiesis increased as the dose increased.

Dose Selection Rationale: Major compound-related effects observed in mice were hemolytic anemia, methemoglobinemia, and splenomegaly. The hemolytic anemia and splenomegaly responses were dose related. Methemoglobin levels ranged from 0.3% to 3.8% in dosed groups compared with 0.3% to 0.6% in vehicle controls. It was judged that doses higher than 30 mg/kg for the 2-year studies might produce severe anemia in animals because hematocrit and erythrocyte values were reduced substantially in the 13-week studies at doses of 60 and 120 mg/kg. Furthermore, the magnitude of splenomegaly was thought to be too great for selection of doses higher than 30 mg/kg. Based on this information, 30 mg/kg was selected as the high dose and 3 and 10 mg/kg as the low and mid doses, respectively. This dose regimen was expected to achieve a no-effect level at the low dose and some effects on the hematopoietic system at the mid dose in the 2-year studies.

TWO-YEAR STUDIES

Body Weights and Clinical Signs

Mean body weights of high dose male and female mice were generally within 5% of those of vehicle controls throughout the studies (Table 22 and Figure 11). No compound-related clinical signs were observed.

TABLE 22. MEAN BODY WEIGHTS OF MICE IN THE TWO-YEAR GAVAGE STUDIES OF -CHLOROANILINE HYDROCHLORIDE

(a) The number of animals weighed was lower than the number of animals surviving.

FIGURE 11. GROWTH CURVES FOR MICE ADMINISTERED p-CHLOROANILINE HYDROCHLORIDE BY GAVAGE FOR TWO YEARS

(all doses calculated as milligrams p-chloroaniline per kilogram body weight)

Survival

Estimates of the probabilities of survival for male and female mice administered *p*-chloroaniline hydrochloride at the doses used in these studies and for vehicle controls are shown in Table 23 and in the Kaplan and Meier curves in Figure 12. The survival of the mid dose group of male mice was significantly lower than that of the vehicle controls after week 99. No other significant differences in survival were observed between any groups of males or females.

Pathology and Statistical Analyses of Results

This section describes the statistically significant or biologically noteworthy changes in the incidences of mice with neoplastic or nonneoplastic lesions of the liver, circulatory system, hematopoietic system, and kidney.

Summaries of the incidences of neoplasms and nonneoplastic lesions, individual animal tumor diagnoses, statistical analyses of primary tumors that occurred with an incidence of at least 5% in at least one animal group, and historical control incidences for the neoplasms mentioned in this section are presented in Appendixes C and D for male and female mice, respectively.

TABLE 23. SURVIVAL OF MICE IN THE TWO-YEAR GAVAGE STUDIES OF p-CHLOROANILINEHYDROCHLORIDE (a)

	Vehicle Control	3 mg/kg	10 mg/kg	30 mg/kg
MALE (b)	- Magnal - An I. - Canada - An I. - Canada - C	<u></u>		
Animals initially in study	50	50	50	50

Nonaccidental deaths before termination (c)	10	5	6	9
Accidentally killed	1	3	0	0
Killed at termination	39	42	44	41
Survival P values (d)	0.875	0.298	0.408	0.966

(a) All doses calculated as milligrams p-chloroaniline per kilogram body weight

(b) First day of termination period: 728 (week 104)

(c) Includes animals killed in a moribund condition

(d) The result of the life table trend test is in the vehicle control column, and the results of the life table pairwise comparisons with the vehicle controls are in the dosed columns.

FIGURE 12. KAPLAN-MEIER SURVIVAL CURVES FOR MICE ADMINISTERED p-CHLOROANILINE HYDROCHLORIDE BY GAVAGE FOR TWO YEARS (all doses calculated as milligrams p-chloroaniline per kilogram body weight)

p-Chloroaniline Hydrochloride, NTP TR 351 66

Liver: Pigmentation (hemosiderin) of the Kupffer cells was observed in high dose mice (male: vehicle control, 0/50; low dose, 0/49; mid dose, 0/50; high dose, 50/50; female: 0/50; 0/50; 1/50; 46/50). Hepatocellular adenomas in male mice occurred with a significant negative trend, and hepatocellular carcinomas in male mice occurred with a significant positive trend (Table 24). The incidences of hepatocellular carcinomas in mid and high dose males and of hepatocellular adenomas or carcinomas (combined) in low, mid, and high dose males were significantly greater than those in vehicle controls. Hepatocellular carcinomas metastasized to the lung in 1/50 vehicle control, 1/49 low dose, 2/50 mid dose, and 9/50 high dose male mice. Hepatocellular adenomas or carcinomas (combined) were observed in 6/50 vehicle control, 9/50 low dose, 8/50 mid dose, and 11/50 high dose female mice.

(a) The statistical analyses used are discussed in Section II (Statistical Methods) and Table C3 (footnotes); all doses calculated as milligrams *p*-chloroaniline per kilogram body weight.

(b) Historical incidence in water gavage vehicle controls (mean \pm SD): 54/347 (16% \pm 4%); historical incidence in untreated controls in NTP studies: 259/2,032 (13% \pm 7%)

(c) Historical incidence in water gavage vehicle controls (mean \pm SD): 56/347 (16% \pm 8%); historical incidence in untreated controls in NTP studies: 379/2,032 (19% \pm 7%)

(d) Historical incidence in water gavage vehicle controls (mean \pm SD): 106/347 (31% \pm 6%); historical incidence in untreated controls in NTP studies: 609/2,032 (30% \pm 8%)

Circulatory System: The incidence of hemangiosarcomas in high dose male mice was marginally increased relative to that in vehicle controls (Table 25). Nearly all of the hemangiosarcomas occurred in the liver or spleen (liver: vehicle control, 2/50; low dose, 2/49; mid dose, 1/50; high dose, 6/50; spleen: 3/50; 2/49; 0/50; 5/50). One vehicle control male mouse and three high dose male mice had liver neoplasms with characteristics of hepatocellular carcinomas but which also contained vascular elements similar to those of

hemangiosarcomas; both hepatocellular carcinomas and hepatic hemangiosarcomas were diagnosed in each of these animals. However, it is not uncommon for hepatocellular carcinomas to contain prominent, dilated, vascular spaces or areas of necrosis and hemorrhage with reactive endothelial cells and fibroblasts that resemble a vascular neoplasm. For these lesions, it is difficult to determine if two distinctly different primary neoplasms are present.

TABLE 25. HEMANGIOSARCOMAS IN MALE MICE IN THE TWO-YEAR GAVAGE STUDY OFp-CHLOROANILINE HYDROCHLORIDE (a)

	Vehicle Control	3 mg/kg	10 mg/kg	30 mg/kg
Liver Overall Rates	2/50 (4%)	2/50 (4%)	1/50 (2%)	6/50 (12%)
Spleen Overall Rates	3/50 (6%)	2/50 (4%)	0/50 (0%)	5/50 (10%)
All Sites (b)				
Overall Rates	4/50 (8%)	4/49 (8%)	1/50 (2%)	10/50 (20%
Adjusted Rates	9.3%	9.7%	3.4%	23.9%
Terminal Rates	4/43 (9%)	2/36 (6%)	1/29 (3%)	5/35 (14%)
Day of First Observation	728	479	728	399
Life Table Tests	P = 0.011	P = 0.560	P = 0.315N	P = 0.047
Logistic Regression Tests	P = 0.014	P = 0.639N	P = 0.313N	P = 0.083

(a) All doses calculated as milligrams p-chloroaniline per kilogram body weight

(b) Historical incidence of hemangiomas or hemangiosarcomas (combined) in water gavage vehicle controls (mean \pm SD):

11/350 (3% \pm 3%); historical incidence in untreated controls in NTP studies: 98/2,040 (5% \pm 4%)

Hematopoietic System: Proliferation of hematopoietic cells in the liver was observed at increased incidences in dosed female mice (male: vehicle control, 7/50; low dose, 4/49; mid dose, 7/50; high dose, 5/50; female: 15/50; 29/50; 24/50; 31/50). The incidences of malignant lymphomas in low and high dose males and in mid and high dose females were significantly lower than those in vehicle controls (Table 26).

Kidney: Multifocal renal tubular pigmentation (hemosiderin) was observed in high dose female mice (male: vehicle control, 0/50; low dose, 0/6; mid dose, 0/10; high dose, 4/49; female: 0/50; 0/7; 0/4; 38/49).

(b) Historical incidence of lymphomas or leukemia (combined) in water gavage vehicle controls (mean \pm SD): 42/350 (12% \pm 6%); historical incidence in untreated controls in NTP studies: 252/2,040 (12% \pm 7%)

(c) Historical incidence of lymphomas or leukemia (combined) in water gavage vehicle controls (mean \pm SD): 122/350 (35% \pm 10%); historical incidence in untreated controls in NTP studies: 636/2,040 (31% \pm 13%)

Mutagenic activity for *p*-chloroaniline was observed by two laboratories in strain TA98 in the presence of Aroclor 1254-induced male Sprague Dawley rat or Syrian hamster S9, and one laboratory noted an increase in revertant colonies in strain TA100 in the presence of hamster S9 only (Table 27). No mutagenic activity was reported in strains TA97, TA1535, or TA1537. Trifluorothymidine resistance was observed in cultured mouse L5178Y lymphoma cells both with and without Aroclor 1254-induced male F344 rat liver S9 (Table 28). *p*-Chloroaniline induced sister chromatid exchanges (SCEs) both in the presence and absence of Aroclor 1254-induced male Sprague Dawley rat liver S9; tests performed at Environmental Health Research and Testing (EHRT) found an increase in SCEs only in the absence of S9 (Table 29). Chromosomal aberration studies conducted at Litton Bionetics, Inc. (LBI), showed a significant increase in aberrations in the presence of S9 (Table 30). No significant increase in aberrations in either the presence or absence of S9 was observed in a study conducted by EHRT; however, the maximum doses of p-chloroaniline used in this study were lower than the doses that produced positive responses in the LBI study.

TABLE 27. MUTAGENICITY OF p-CHLOROANILINE IN SALMONELLA TYPHIMURIUM (Continued)

(a) The detailed protocol is presented by Mortelmans et al. (1986). Cells and study compound or solvent (dimethyl sulfoxide) were incubated in the absence of exogenous metabolic activation (-S9) or with Aroclor 1254-induced S9 from male Syrian hamster liver or male Sprague Dawley rat liver. High dose was limited by toxicity or solubility but did not exceed 10 mg/plate; 0 µg/plate dose is the solvent control.

(b) Revertants are presented as mean \pm standard error from three plates.

(c) Positive control; 2-aminoanthracene was used on all strains in the presence of S9. In the absence of metabolic activation, 4-nitro-o-phenylenediamine was used with TA98, sodium azide was used with TA100 and TA1535, and 9-aminoacridine was used with TA97 and TA1537.

TABLE 28. MUTAGENICITY OF p-CHLOROANILINE IN MOUSE L5178Y LYMPHOMA CELLS (Continued)

(a) The experimental protocol is presented in detail by Myhr et al. (1985) and follows the basic format of Clive et al. (1979). The highest dose of study compound is determined by solubility or toxicity and may not exceed 5 mg/ml. All doses are tested in triplicate; the average for the three tests is presented in the table. Cells $(6 \times 10^5/\text{ml})$ were treated for 4 hours at 37° C in medium, washed, resuspended in medium, and incubated for 48 hours at 37° C. After expression, 3×10^6 cells were plated in medium and soft agar supplemented with trifluorothymidine (Tft) for selection of Tft-resistant cells, and 600 cells were plated in nonselective medium and soft agar to determine the cloning efficiency. (b) Mean \pm standard error from replicate trials of approximately 1×10^6 cells each. All data are evaluated statistically for

(b) Mean \pm standard error from replicate trials of approximately 1×10^6 cells each. All data are evaluated statistically for both trend and peak response (P<0.05 for at least one of the three highest dose sets). Both responses must be significantly (P<0.05) positive for a chemical to be considered capable of inducing Tft resistance. If only one of these responses is significant, the call is "equivocal"; the absence of both trend and peak response results in a "negative" call.

(c) Mutant fraction (frequency) is a ratio of the Tft-resistant cells to the cloning efficiency, divided by 3 (to arrive at MF per 1×10^6 cells treated); MF = mutant fraction.

(d) Data presented are the average of four tests.

(e) Significant positive response; occurs when the relative mutant fraction (average MF of treated culture/average MF of solvent control) is greater than or equal to 1.6.

(f) Data presented are the average of two tests.

(g) Tests conducted with metabolic activation were performed as described in (a) except that S9, prepared from the liver of Aroclor 1254-induced F344 rats, was added at the same time as the study chemical and/or solvent.

(h) Data presented are for one test.

(i) Data presented are for one test. The dose in one test was lethal.

(j) Data presented are the average of two tests. The dose in one test was lethal.

(k) Data presented are for one test. The dose in two tests was lethal.

TABLE 29. INDUCTION OF SISTER CHROMATID EXCHANGES IN CHINESE HAMSTER OVARY CELLS BY ρ -CHLOROANILINE (Continued)

TABLE 29. INDUCTION OF SISTER CHROMATID EXCHANGES IN CHINESE HAMSTER OVARY CELLS BY p-CHLOROANILINE (Continued)

(a) SCE = sister chromatid exchange; BrdU = bromodeoxyuridine. A detailed description of the SCE protocol is presented by Galloway et al. (1985). Briefly, Chinese hamster ovary cells were incubated with study compound or solvent (dimethyl sulfoxide) as described in (c) or (e) below and cultured for sufficient time to reach second metaphase division. Cells were then collected by mitotic shake-off, fixed, air-dried, and stained.

(b) SCEs/cell in treated culture expressed as a percent of the SCEs/cell in the control culture

ì

(c) In the absence of S9, Chinese hamster ovary cells were incubated with study compound or solvent for 2 hours at 37° C. Then BrdU was added, and incubation was continued for 24 hours. Cells were washed, fresh medium containing BrdU and colcemid was added, and incubation was continued for 2-3 hours.

(d) Because some chemicals induce a delay in the cell division cycle, harvest times are occasionally extended to maximize the proportion of second division cells available for analysis.

(e) In the presence of S9, cells were incubated with study compound or solvent for 2 hours at 37° C. Then cells were washed, and medium containing BrdU was added. Cells were incubated for a further 26 hours, with colcemid present for the final 2-3 hours. S9 was from the liver of Aroclor 1254-induced male Sprague Dawley rats.

TABLE 30. INDUCTION OF CHROMOSOMAL ABERRATIONS IN CHINESE HAMSTER OVARY CELLS BY ρ -CHLOROANILINE (a)

TABLE 30. INDUCTION OF CHROMOSOMAL ABERRATIONS IN CHINESE HAMSTER OVARY CELLS BY p-CHLOROANILINE (Continued)

(a) Abs = aberrations. A detailed presentation of the technique for detecting chromosomal aberrations is presented by Galloway et al. (1985). Briefly, Chinese hamster ovary cells were incubated with study compound or solvent (dimethyl sulfoxide) as indicated in (b) or (c). Cells were arrested in first metaphase by addition of colcemid and harvested by mitotic shake-off, fixed, and stained in 6% Giemsa.

(b) In the absence of S9, Chinese hamster ovary cells were incubated with study compound or solvent (dimethyl sulfoxide) for 8-10 hours at 37° C. Cells were then washed, and fresh medium containing colcemid was added for an additional 2-3 hours followed by harvest.

(c) In the presence of S9, cells were incubated with study compound or solvent (dimethyl sulfoxide) for 2 hours at 37°C. Cells were then washed, medium was added, and incubation was continued for 8-10 hours. Colcemid was added for the last 2-3 hours of incubation before harvest. S9 was from the liver of Aroclor 1254-induced male Sprague Dawley rats.

(d) Harvest time, 23.0 hours; because of significant chemically induced cell cycle delay, incubation time before addition of colcemid was lengthened to provide sufficient metaphases at harvest.

(e) Harvest time, 12.0 hours

(f) Harvest time, 13.0 hours

IV. DISCUSSION AND CONCLUSIONS

Toxicity Carcinogenicity Possible Mechanisms of Splenic Toxicity and Carcinogenicity Audit Conclusions

Toxicity

The current p-chloroaniline hydrochloride 13week studies in rats and mice revealed that the hematopoietic system was the major target of pchloroaniline hydrochloride toxicity. Methemoglobin formation and the accompanying hemolytic anemia, extramedullary hematopoiesis, and splenomegaly were indicative of erythrocyte toxicity induced by p-chloroaniline hydrochloride. In the 2-year studies, results of hematologic analyses in rats and the occurrence of nonneoplastic lesions in the spleen and liver in both rats and mice and the kidney in mice showed that the hematopoietic system was also affected by long-term administration of p-chloroaniline hydrochloride. Erythrocyte toxicity as expressed by methemoglobin formation is the dominant toxic effect seen in laboratory animals and humans exposed to a number of amino and nitro aromatic compounds (Beard and Noe, 1981; Beutler, 1985). Methemoglobin formation in evthrocytes results from the change of heme iron from the ferrous to ferric state. The brown pigment formed is called methemoglobin, a derivative of hemoglobin that is physiologically inactive. Acute methemoglobinemia may be life threatening when the level of methemoglobin exceeds half of the total circulating hemoglobin (Beutler, 1972).

Short-term exposure of humans to p-chloroaniline produces cyanosis, a manifestation of methemoglobin formation. Long-term exposure may result in reversible anemia (Linch, 1974). The methemoglobin can be reduced to hemoglobin in mammalian species by a NADH-dependent methemoglobin reductase located in the erythrocytes. A tenfold difference exists in the activity of this enzyme among various species. Enzymic activity in rat and mouse erythrocytes is 5 and 10 times higher, respectively, than that in human erythrocytes (Smith, 1986), suggesting that humans are more susceptible to this particular toxic effect of aniline and its homologs. The formation of methemoglobin by aromatic nitro and amino compounds, mechanism(s) of formation, and toxicologic implications have been reviewed extensively (Kiese, 1966; Beard and Noe, 1981). There is convincing evidence that an N-hydroxy metabolite is the reactive species responsible for this toxic effect (Selkirk, 1980; Weisburger, 1983). The p-chloroaniline hydrochloride-induced erythrocyte toxicity seen in the current studies also could be due to an N-hydroxy derivative, since p-chloroaniline was shown to be metabolized to its Nhydroxy derivative by the hepatic microsomal mono-oxygenase system of guinea pigs, rabbits, hamsters, mice, and rats (Smith and Gorrod, 1978; Uehleke and Hellmer, 1971). According to Bus and Popp (1987), the N-oxidation pathway of aniline, an analog of p-chloroaniline, is inconsequential for rat liver, as liver rapidly reduces N-oxidized metabolites back to the parent compound. On the contrary, the small amount of N-phenylhydroxylamine taken up by the erythrocytes is rapidly oxidized by oxyhemoglobin to nitrosobenzene, with concurrent formation of methemoglobin. The metabolism and pattern of erythrocyte toxicity of p-chloroaniline hydrochloride suggest that the mechanisms of methemoglobin formation by aniline and its analog pchloroaniline have common characteristics.

In the 13-week studies, a dose-related increase in splenic weights was observed for both rats and mice. A similar enlargement in the spleen was seen in rats dosed with aniline (Gralla et al. 1979). Bus (1983) suggested that splenic weight increases in aniline-dosed rats were due to excessive deposition of damaged erythrocytes as a result of aniline toxicity and thus that splenomegaly is a secondary effect of erythrocyte toxicity. Results of the current studies support this contention, as rats and mice in the 13-week pchloroaniline hydrochloride studies did not show any degenerative changes in the spleen. The increases in spleen weight were probably a result of increased vascular engorgement in response to methemoglobinemia.

Carcinogenicity

Recent carbon-13 nuclear magnetic resonance studies on relationships between chemical structure and carcinogenicity of chlorinated monocyclic aromatic compounds predicted that p-chloroaniline would be carcinogenic (Sakamoto and Watanabe, 1986). The results of previous 2-year studies on p-chloroaniline were strongly suggestive of carcinogenicity because several rare fibromas and sarcomas of the spleen were found in exposed male rats (NCI, 1979c). The results

from those studies have been substantiated by results from the current studies, which show that p-chloroaniline hydrochloride is carcinogenic for male rats, based on the increased incidence of splenic sarcomas in high dose male rats (see Table 15). The possibility exists that in the first set of studies p-chloroaniline was administered to animals at less than target concentrations due to the instability of the chemical in feed. The target concentrations in feed for that study were approximately equivalent to 15 and 30 mg/kg body weight of rats, compared with 2, 6, and 18 mg/kg in the current gavage studies. The different modes of oral administration (single dose per day by gavage and continuous dosing by feed) could possibly have resulted in differences in pharmacokinetics and might have been responsible for quantitative differences seen between the results of these two studies. The dose response for splenic tumors in male rats in the current studies was nonlinear with increases in dose; although the high dose was 3 times the mid dose, the incidence of sarcomas in the high dose group was 12 times that in the mid dose group. The doses used in these studies apparently did not saturate the metabolic and excretory pathways, as evidenced by disposition studies on *p*-chloroaniline and *p*-chloroaniline hydrochloride conducted by the NTP (Appendix H).

Other structurally related aniline compounds seem to exhibit nonlinear responses for the occurrence of splenic tumors in male rats (Table 31). The carcinogenesis study conducted by the Chemical Industry Institute of Toxicology (CIIT) on aniline hydrochloride administered to male rats at 0, 10, 30, or 100 mg/kg body weight (0, 200, 600, or 2,000 ppm) in feed also showed a similar type of nonlinearity in tumor response (Bus and Popp, 1987). In that study, an apparent no-observable-effect level of 10 mg/kg aniline was found, whereas in the current studies with *p*-chloroaniline hydrochloride, no apparent no-observable-effect level for splenic tumors in male rats was reached. The female rats were less sensitive than the males to p-chloroaniline hydrochloride induction of splenic neoplasms, since neoplasms were seen in only one mid dose and one high dose female rat in the NTP studies. Table 31 shows that similar sex differences in the incidences of splenic tumors were seen with

other aniline compounds, except for azobenzene and o-toluidine hydrochloride studies in which female rats were equally sensitive. In the current studies, the incidences of splenic fibrosis in high dose male and female rats were 41/50 and 42/50, respectively. Fibrosis of the spleen is a potential preneoplastic lesion that may progress to fibrosarcomas (Goodman et al., 1984).

The incidence of adrenal gland pheochromocytomas in male rats occurred with a positive trend (see Table 16). Medullary hyperplasia was observed at an increased incidence in high dose female rats; pheochromocytomas were seen in 2/50vehicle control and 10/150 dosed females. Examination of Table 31 shows that aniline hydrochloride was the only structurally related chemical studied by the NCI/NTP that clearly caused an increase in the incidences of these neoplasms in dosed male rats and, to a lesser extent, in females. The incidences of adrenal gland tumors in the current studies may have been related to *p*-chloroaniline administration.

For mice, the body weights and survival in the current 2-year studies were in general not affected by the administration of *p*-chloroaniline hydrochloride. No splenic fibrosarcomas or osteosarcomas were observed in mice of either sex. The species differences between rats and mice in aromatic amine-induced neoplasms were reviewed by Weisburger (1983). None of the aromatic amines studied for carcinogenic potential by the NCI/NTP caused increased incidences of splenic tumors in mice. However, induction of liver tumors by those chemicals was frequently observed in mice. The tumor incidences in mice administered p-chloroaniline hydrochloride in the current studies followed the pattern reported by Weisburger (1983), with the incidences of hepatocellular carcinomas being increased in dosed male mice. Even though the incidence of hepatocellular carcinomas in vehicle controls is much lower than that in historical water gavage controls (6% versus 16%), the strong doseresponse relationship and the metastasis to the lung of the carcinomas are additional evidence for a chemically related effect. Also, there was a marginal increase in the incidence of hemangiosarcomas in the liver in high dose male mice. The significance of the increased incidences of neoplasms in dosed male mice was further

supported by the apparent reduction in the latency period for liver neoplasms. The first day of observation of these neoplasms in vehicle controls was 728; in dosed groups, it ranged from day 432 to day 490. Table 32 gives the incidence of hepatocellular neoplasms in mice dosed with those aniline compounds shown to also cause splenic neoplasms in male rats. Administration of all the aniline compounds listed seemed to result in some increase in the incidences of hepatocellular neoplasms in male or female mice.

In the current studies, p-chloroaniline hydrochloride was carcinogenic for rats and mice, but the sites of compound-related neoplasia were different. The species differences between rats and mice with regard to splenic and liver neoplasms could be due to differences in metabolism and disposition of p-chloroaniline. Perry et al. (1981a) studied the disposition of 14C-labeled pchloroaniline or *p*-chloroaniline hydrochloride in F344 rats, mongrel dogs, and A/J and Swiss Webster mice. They showed that the initial decay constants for *p*-chloroaniline clearance from whole blood in both strains of mice were 10 times greater than those in dogs and rats. The p-chloroaniline clearance in mice was too rapid to permit calculation of kinetic parameters.

The differences in the metabolism and disposition of aniline have also been suggested as the reason for differences in the carcinogenicity of aniline in rats and mice. The larger concentrations of the putative reactive metabolite N-phenylhydroxylamine in rats were considered to be responsible for the production of splenic tumors in rats (McCarthy et al., 1985). If excessive methemoglobin formation in dosed animals and the subsequent progression to splenic sarcomas constitute one of the mechanisms of action of aniline compounds, then methemoglobin reductase activity or diaphorase activity, which is two times greater in mice than in rats, may be another reason for a species difference.

Decreases were seen in the incidences of certain neoplasms in *p*-chloroaniline hydrochloridedosed animals and were considered related to chemical administration. The incidences of mononuclear cell leukemia in rats and malignant lymphomas in mice were decreased in dosed animals of each sex. Such decreases were not seen in animals exposed to other aniline compounds listed in Table 31.

Possible Mechanisms of Splenic Toxicity and Carcinogenicity

The unusual and rare tumors of the spleen induced in F344 rats by a number of structurally related aniline compounds led some workers to study the pathogenesis of splenic lesions and to perform disposition studies of ¹⁴C-labeled aniline to explain the possible mechanism(s) of action of these chemicals. Goodman et al. (1984) studied splenic lesions from male rats in the NCI/NTP studies listed in Table 31 and proposed that fibrosis of the splenic parenchyma was a potential preneoplastic lesion. They postulated that methemoglobin bound with aniline compounds or their reactive metabolites is broken down in the red pulp of the spleen and reactive metabolites are released which bind to splenic mesenchymal tissues, resulting in fibrosis that progresses to formation of splenic tumors. Weinberger et al. (1985) proposed a similar hypothesis with their detailed analysis of splenic tumors in NCI/NTP studies on D & C Red No. 9 (NTP, 1982a) and aniline hydrochloride (NCI, 1978a). Bus and Popp (1987) reviewed splenic tumors caused by administration of the chemicals listed in Table 31, CIIT-sponsored aniline carcinogenesis studies in rats, and their own disposition studies on ¹⁴C-labeled aniline in rats and mice. They proposed several possible mechanisms for splenic-directed toxicity of aniline compounds. The scheme proposed for these possible mechanisms is reproduced in Figure 13. According to this scheme, the occurrence of splenic tumors in rats may be the result of erythrocyte toxicity. The authors suggest that there is strong evidence for the nongenetic mechanism in the formation of splenic tumors. However, there is a possibility that a direct-acting genotoxic mechanism is involved in the induction of the neoplasms, as shown by McCarthy et al. (1985), who found that in rats and mice, [14C]aniline binds to a greater extent to the kidney, small intestine, large intestine, and spleen than to other tissues. Protein and RNA were major macromolecular targets for [14C]aniline binding; DNA binding occurred to a lesser extent. The possibility for

(c) Gavage studies in water

FIGURE 13. PROPOSED MECHANISTIC SCHEME FOR THE SPLEEN-DIRECTED TOXICITY OF ANILINE AND STRUCTURALLY RELATED COMPOUNDS

(Taken from Bus and Popp, 1987)

involvement of genotoxic mechanisms is further supported by Parodi et al. (1982a,b), who showed that aniline induces DNA damage in vivo in the liver and kidney of rats. Also, aniline was clearly positive in induction of sister chromatid exchanges (SCEs) in vivo in male Swiss mice. The damage to DNA seen in the liver, kidney, and bone marrow was absent in male Swiss mice.

The patterns of *p*-chloroaniline hydrochlorideinduced splenic toxicity and carcinogenicity and results of disposition studies suggest that the mechanism(s) of p-chloroaniline hydrochloride toxicity and carcinogenicity could likely follow the scheme proposed by Bus and Popp (1987). However, whether the mechanism of carcinogenesis is mediated through genotoxic or nongenotoxic events is unresolved. p-Chloroaniline is clearly genotoxic in vitro. In the Salmonella assay and the test for chromosomal aberrations in Chinese hamster ovary cells, p-chloroaniline was mutagenic only in the presence of S9 metabolizing enzymes. p-Chloroaniline also increased the fraction of cultured mouse lymphoma cells exhibiting trifluorothymidine resistance and the frequency of SCEs in Chinese hamster ovary cells, both in the presence and absence of S9. Thus, the in vitro genotoxic activity of p-chloroaniline appears to be dependent on metabolism for its full expression. Experimental evidence indicates that *p*-chloroaniline undergoes oxidative transformations as a reactive amine, with the probable formation of electrophilic intermediates that could be stablized by the chlorine. For example, p-chloro-N-hydroxyaniline (Von Jagow et al., 1966), which may be formed through a nitronium ion intermediate in the presence of oxidative enzymes, and *p*-aminophenol (Ichikawa et al., 1969), which may be formed via an arene oxide intermediate possibly in the absence of metabolizing enzymes, have been reported as metabolites of *p*-chloroaniline in the rabbit. Both of these intermediates are potential electrophiles and could covalently bind macromolecules.

Audit

The experimental and tabulated data for the NTP Technical Report on *p*-chloroaniline hydrochloride were examined for accuracy, consistency, completeness, and compliance with Good Laboratory Practice regulations. As summarized in Appendix I, the audit revealed no major problems with the conduct of the studies or with collection and documentation of the experimental data. No discrepancies were found that influenced the final interpretation of the results of these studies.

Conclusions

Under the conditions of these 2-year water gavage studies, there was clear evidence of carcinogenic activity* of p-chloroaniline hydrochloride for male F344/N rats, as indicated by increased incidences of uncommon sarcomas of the spleen. Pheochromocytomas of the adrenal gland may also have been associated with chemical administration. There was equivocal evidence of carcinogenic activity of p-chloroaniline hydrochloride for female F344/N rats, as indicated by the presence of uncommon sarcomas of the spleen in one mid and one high dose animal and the increased incidence of pheochromocytomas of the adrenal gland. There was some evidence of carcinogenic activity of p-chloroaniline hydrochloride for male B6C3F1 mice, as indicated by increased incidences of hepatocellular neoplasms and of hemangiosarcomas of the liver or spleen. There was no evidence of carcinogenic activity of p-chloroaniline hydrochloride for female B6C3F1 mice administered 3, 10, or 30 mg/kg by gavage for 2 vears.

The incidences of mononuclear cell leukemia in male and female rats and of malignant lymphomas in male and female mice were decreased by administration of *p*-chloroaniline hydrochloride. Compound-related splenic fibrosis was present in male and female rats.

^{*}Explanation of Levels of Evidence of Carcinogenic Activity is on page 7.

A summary of the Peer Review comments and the public discussion on this Technical Report appears on page 10.

(a) Number of tumor-bearing animals/number of animals examined at the site; doses calculated as p-chloroaniline.

(b) Kaplan-Meier estimated tumor incidences at the end of the study after adjusting for intercurrent mortality

(c) Observed tumor incidence at terminal kill

(e) Incomplete sampling of tissues

(f) No P value is reported because no tumors were observed in the dosed and vehicle control groups.

(g) A carcinoma was observed in a 12th animal.

⁽d) Beneath the vehicle control incidence are the P values associated with the trend test. Beneath the dosed group incidence are the P values corresponding to pairwise comparisons between that dosed group and the vehicle controls. The life table analysis regards tumors in animals dying prior to terminal kill as being (directly or indirectly) the cause of death. The logistic regression test regards these lesions as nonfatal. The Cochran-Armitage and Fisher exact tests compare directly the overall incidence rates. A negative trend or lower incidence in a dosed group is indicated by (N).

TABLE A4a. HISTORICAL INCIDENCE OF SPLENIC CONNECTIVE TISSUE TUMORS IN MALE F344/N RATS (a)

Study	Incidence in Controls	
Historical Incidence for All Water Gavage Vehicle	Controls (b)	
odinated glycerol	0/50

(a) Number of tumor-bearing animals/number of animals examined at the site; doses calculated as p-chloroaniline.

(b) Kaplan-Meier estimated tumor incidences at the end of the study after adjusting for intercurrent mortality

(c) Observed tumor incidence at terminal kill

(d) Beneath the vehicle control incidence are the P values associated with the trend test. Beneath the dosed group incidence are the P values corresponding to pairwise comparisons between that dosed group and the vehicle controls. The life table analysis regards tumors in animals dying prior to terminal kill as being (directly or indirectly) the cause of death. The logistic regression test regards these lesions as nonfatal. The Cochran-Armitage and Fisher exact tests compare directly the overall incidence rates. A negative trend or lower incidence in a dosed group is indicated by (N).

(e) Incomplete sampling of tissues

TABLE B4a. HISTORICAL INCIDENCE OF SPLENIC SARCOMAS IN FEMALE F344/N RATS (a)

Study	Incidence in Controls

Fisher Exact Test (d)		P = 0.039 N	P = 0.500 N	P = 0.036N

(a) Number of tumor-bearing animals/number of animals examined at the site; doses calculated as *p*-chloroaniline.

(b) Kaplan-Meier estimated tumor incidences at the end of the study after adjusting for intercurrent mortality

(c) Observed tumor incidence at terminal kill

(d) Beneath the vehicle control incidence are the P values associated with the trend test. Beneath the dosed group incidence are the P values corresponding to pairwise comparisons between that dosed group and the vehicle controls. The life table analysis regards tumors in animals dying prior to terminal kill as being (directly or indirectly) the cause of death. The logistic regression test regards these lesions as nonfatal. The Cochran-Armitage and Fisher exact tests compare directly the overall incidence rates. A negative trend or lower incidence in a dosed group is indicated by (N).

(e) Incomplete sampling of tissues

TABLE D1. SUMMARY OF THE INCIDENCE OF NEOPLASMS IN FEMALE MICE IN THE TWO-YEAR
GAVAGE STUDY OF p-CHLOROANILINE HYDROCHLORIDE (Continued)

	Vehicle Control	Low Dose	Mid Dose	High Dose
TUMOR SUMMARY				
Total animals with primary neoplasms **	36	26	21	31
Total primary neoplasms	54	32	24	44
Total animals with benign neoplasms	20	15	12	17
Total benign neoplasms	29	15	13	22
Total animals with malignant neoplasms	24	16	10	21
Total malignant neoplasms	25	17	11	22
Total animals with secondary neoplasms **	* 1	1	2	4
Total secondary neoplasms	3	1	3	5

* Number of animals receiving complete necropsy examination; all gross lesions including masses examined microscopically.

** Primary tumors: all tumors except secondary tumors
 *** Secondary tumors: metastatic tumors or tumors invasive into an adjacent organ

TABLE D3. ANALYSIS OF PRIMARY TUMORS IN FEMALE MICE IN THE TWO-YEAR GAVAGE STUDY OF p-CHLOROANILINE HYDROCHLORIDE (Continued)

(a) Number of tumor-bearing animals/number of animals examined at the site; doses calculated as p-chloroaniline.

(b) Kaplan-Meier estimated tumor incidences at the end of the study after adjusting for intercurrent mortality

(c) Observed tumor incidence at terminal kill

(d) Beneath the vehicle control incidence are the P values associated with the trend test. Beneath the dosed group incidence are the P values corresponding to pairwise comparisons between that dosed group and the vehicle controls. The life table analysis regards tumors in animals dying prior to terminal kill as being (directly or indirectly) the cause of death. The logistic regression test regards these lesions as nonfatal. The Cochran-Armitage and Fisher exact tests compare directly the overall incidence rates. A negative trend or lower incidence in a dosed group is indicated by (N).

(e) Incomplete sampling of tissues

APPENDIX E. SENTINEL ANIMAL PROGRAM

Methods

Rodents used in the Carcinogenesis Program of the National Toxicology Program are produced in optimally clean facilities to eliminate potential pathogens that may affect study results. The Sentinel Animal Program is part of the periodic monitoring of animal health that occurs during the toxicologic evaluation of chemical compounds. Under this program, the disease state of the rodents is monitored via viral serology on sera from extra (sentinel) animals in the study rooms. These animals are untreated, and these animals and the study animals are both subject to identical environmental conditions. The sentinel animals come from the same production source and weanling groups as the animals used for the studies of chemical compounds.

Fifteen $B6C3F_1$ mice and 15 F344/N rats of each sex were selected at the time of randomization and allocation of the animals to the various study groups. Five animals of each designated sentinel group were killed at 6 and 18 months on study. Data from animals surviving 24 months were collected from 5/50 randomly selected vehicle control animals of each sex and species. The blood from each animal was collected and clotted, and the serum was separated. The serum was cooled on ice and shipped to Microbiological Associates' Comprehensive Animal Diagnostic Service for determination of the viral antibody titers. The following tests were performed:

	Hemagglutination <u>Inhibition</u>	Complement <u>Fixation</u>	ELISA
Mice	PVM (pneumonia virus of mice) Reo 3 (reovirus type 3) GDVII (Theiler's encephalomyelitis virus) Poly (polyoma virus) MVM (minute virus of mice) Ectro (infectious ectromelia) Sendai (18, 24 mo)	M. Ad. (mouse adenovirus) LCM (lymphocytic choriomeningitis virus) Sendai (6 mo)	MHV (mouse hepatitis virus)
Rats	PVM KRV (Kilham rat virus) H-1 (Toolan's H-1 virus) Sendai (18, 24 mo)	RCV (rat coronavirus) (6 mo) Sendai (6 mo)	RCV/SDA (sialo- dacryoadenitis virus) (18, 24 mo)
Results			

Results are presented in Table E1.

	Interval (months)	Number of Animals	Positive Serologic Reaction for
RATS	<u></u>		
	6		None positive
	18		None positive
	24		None positive
ICE			
	6		None positive
	18	1/10	MHV
	24	1/10 2/10	PVM MHV

TABLE E1. MURINE VIRUS ANTIBODY DETERMINATIONS FOR RATS AND MICE IN THE TWO-YEAR GAVAGE STUDIES OF ρ -CHLOROANILINE HYDROCHLORIDE (a)

(a) Blood samples were taken from sentinel animals at 6 and 18 months after the start of dosing and from the vehicle control animals just before they were killed; samples were sent to Microbiological Associates (Bethesda, MD) for determination of antibody titers.

	THE CONCENTRATION OF p-CHLOROACETANILIDE IN TISSUES OF F344 RATS ADMINISTERED p-CHLOROANILINE BY INTRAVENOUS INJECTION	252

APPENDIX H. DISTRIBUTION AND DISPOSITION

A study of the distribution and disposition of *p*-chloroaniline and *p*-chloroaniline hydrochloride in F344 rats was conducted at the University of Arizona under the sponsorship of the National Toxicology Program (NIEHS contract no. NO1-ES-8-2130). The laboratory report is on file at the National Toxicology Program, National Institute of Environmental Health Sciences, Research Triangle Park, North Carolina.

OVERVIEW OF p-CHLOROANILINE PHARMACOKINETICS IN F344 RATS

In F344 rats, *p*-chloroaniline was rapidly eliminated after a single oral dose. The primary route of excretion was the urine, where approximately 75% of the administered carbon-14 appeared within 24 hours, and approximately 10% was found in the feces. Elimination was found to be independent of dose within a hundredfold dose range (0.3-30 mg/kg). Seven days after administration, the only tissue containing significant amounts of radioactivity was the erythrocyte fraction of whole blood.

The excretory profile after a single 0.3 mg/kg intravenous dose of $[^{14}C]p$ -chloroaniline was essentially identical to that following oral administration. Urinary excretion of carbon-14 was rapid, with approximately 60% of the dose appearing in urine within 4 hours. By 24 hours, only 4% of the urinary carbon-14 was present as p-chloroaniline, and less than 1% of the dose appeared in the feces. No p-chloroacetanilide, a major circulating metabolite of p-chloroaniline, was detected in either urine or feces over a 3-day period.

There were no apparent tissue depots of *p*-chloroaniline or metabolites after a single intravenous dose of 3 mg/kg except for erythrocytes. Tissue levels of carbon-14 peaked 30 minutes to 1 hour after intravenous administration, with the highest percentage of dose being found in liver, muscle, fat, and skin. Elimination from all tissues followed bi-exponential kinetics.

The pharmacokinetics of *p*-chloroacetanilide followed mono-exponential decay kinetics with an appearance phase. The appearance half-life $(t_{a\frac{1}{2}})$ of *p*-chloroacetanilide was about 10 minutes, and the elimination $(t_{\beta\frac{1}{2}})$ was on the order of 1.5-2 hours.

These results demonstrate that after intravenous administration to F344 rats, p-chloroaniline is rapidly N-acetylated to p-chloroacetanilide as the first step in metabolism and excretion of p-chloroaniline. The absence of any p-chloroacetanilide in the urine indicates further metabolism of p-chloroacetanilide prior to excretion via that route.

MATERIALS AND METHODS

Chemicals and Animals

Uniformly ring-labeled [14C]p-chloroaniline (specific activity 5.0 mCi/mmol) was purchased from KOR Inc. (Cambridge, Massachusetts). Unlabeled p-chloroaniline was purchased from Aldrich Chemical Co. (Milwaukee, Wisconsin) and was recrystallized twice from ethanol:water (1:1) before use. Spectrophotometric-grade p-nitrophenol was obtained from Sigma Chemical Co. (Milwaukee, Wisconsin). p-Chloroacetanilide was prepared by refluxing p-chloroaniline with acetic anhydride. Recrystallization from 50% acetic acid produced colorless needles with a melting point of 176°-178° C (compared with 177°-178° C, Merck, 1983). Mass spectra of the synthesized p-chloroacetanilide confirmed its structure. p-Chloroglycoanilide was prepared by the method of Shapiro et al. (1959). The identity of this material was confirmed by proton magnetic resonance spectroscopy and mass spectrometry. Heptane sulfonic acid sodium salt was obtained from Eastman Kodak Co. (Rochester, New York), and high-performance liquid chromatography-grade acetonitrile was purchased from Burdick and Jackson Laboratories (Muskegon, Michigan). Inactin® (methylpropyl-N'-ethylthiobarbiturate) was obtained from Andrew Lockwood Association (Madison, Wisconsin). All other chemicals were of reagent or scintillation quality as required.

Male F344 rats weighing 150-200 g, purchased from M.A. Bioproducts (Walkersville, Maryland), were housed individually in stainless steel metabolism cages designed to separate urine from feces and were provided with feed and water ad libitum.

Distribution/Disposition Studies

The effect of dose on the disposition of *p*-chloroaniline after oral administration of 0.3, 3, or 30 mg/kg *p*-chloroaniline in 0.01 N hydrochloric acid was determined in rats (three animals per dose). Rats at the two higher doses received 40 μ Ci/kg, and those at the lowest dose received 9 μ Ci/kg. Urine and feces were collected daily and analyzed for total carbon-14, and the percentage of excreted dose was calculated. Urine samples (0.5 ml) were added directly to Betaphase scintillation fluid (Westchem Products, San Diego, California) and analyzed directly by liquid scintillation counting (LS-100C Beckman Instruments, Fullerton, California). Feces were digested in 15 ml of 0.5 N sodium hydroxide, and 0.5 g aliquots were oxidized to carbon[¹⁴C] dioxide in a Packard Tri-Carb sample oxidizer (Packard Instruments, Downers Grove, Illinois), as previously described (Miller et al., 1982).

Tissue distribution and pharmacokinetic studies were conducted in rats after a single intravenous injection via the tail vein with 3 mg/kg p-chloroaniline (30 μ Ci/kg) dissolved in a mixture of ethanol:propylene glycol:water (1:1:8). Three animals were killed at times ranging from 15 minutes to 3 days. Tissues saved for analysis included brain, lung, liver, kidney, spleen, small intestine, testis, renal fat, muscle, and skin. Urinary bladder and intestinal contents were combined with that day's urine and feces, respectively. Blood was obtained by cardiac puncture, and a 1-ml aliquot was immediately mixed with two volumes of acetonitrile for later analysis for p-chloroaniline. The remainder of the sample was stored at 4°C in heparinized glass tubes. Tissue samples were kept frozen at -10° C prior to analysis.

Tissue aliquots (0.1-0.5 g) were analyzed in duplicate for total carbon-14 as previously described. The percentage of the total dose found in tissues was based on the wet tissue weight, with estimates of 9%, 50%, 7%, and 16% of the total body weight being used for blood, muscle, fat, and skin, respectively (Matthews and Anderson, 1975).

Biliary Excretion

Bile was collected from the common bile duct of anesthetized (100 mg/kg Inactin[®]) rats after cannulation with PE10 polyethylene tubing (Clay Adams, New York). After 30 minutes of bile collection, 3 mg/kg *p*-chloroaniline (30 μ Ci/kg) was administered via the tail vein. Bile samples were collected at 30-minute intervals for 6.0 hours. Duplicate 25-µl samples were assayed directly by liquid scintillation counting for quantification of total carbon-14. Pooled 6-hour samples were also analyzed for *p*-chloroaniline as described below for urine.

Separation of *p*-Chloroaniline from Metabolites

p-Chloroaniline was separated from its metabolites in those tissues that contained greater than 1% of the administered dose and was assayed by high-performance liquid chromatography. Blood samples for high-performance liquid chromatography analysis were added to two volumes of acetonitrile at the time of collection, and the protein precipitate was separated by centrifugation. The supernatant was then extracted with two additional volumes of acetonitrile. The extracts were pooled and washed with 1 ml of hexane to remove lipids. The hexane layer was discarded, since it contained less than 100 disintegrations per minute (dpm) of carbon-14. The pooled acetonitrile extracts were evaporated to near dryness under a stream of dry nitrogen before the addition of 200 μ l of a mixture of acetonitrile: water:acetic acid (25:24:1) which contained 40 μ g/ml unlabeled *p*-chloroaniline and *p*-nitrophenol. The protein pellets remaining after the acetonitrile extractions were oxidized to carbon[¹⁴C] dioxide to determine nonextractable radioactivity. Urine samples were diluted with an equal volume of acetonitrile containing 40 µg/ml p-chloroaniline and p-nitrophenol prior to high-performance liquid chromatographic analysis. All other tissues were solubilized in 0.5 N sodium hydroxide at 40° C for 24 hours and extracted twice with a diethyl ether: acetonitrile: hexane (8:1:1) mixture. The pooled extracts were concentrated under a stream of dry nitrogen. The residue was dissolved in 1 ml of acetonitrile and extracted with 1 ml of hexane. The hexane washes contained notable quantities of metabolites which were taken into account in the calculations. The washed acetonitrile extracts from tissue homogenates were then treated as those for blood. These extraction procedures recovered more than 90% of the [14C]p-chloroaniline added to control blood, liver homogenates, and urine samples; stability studies showed that p-chloroaniline and p-chloroacetanilide levels were unaffected by these procedures. However, recovery of total carbon-14 from tissues was between 30% and 80% regardless of the time point, and that from blood ranged from 80% at 15 minutes to less than 1% by 24 hours, suggesting that substantial binding may have occurred. This nonextractable radioactivity was assumed to be unidentified metabolites of p-chloroaniline.

For high-performance liquid chromatographic analysis, a 250×4.6 mm Spherisorb 5 μ C-6 reverse phase column (Chromanetics Inc., Baltimore, Maryland) was used. The mobile phase was acetonitrile:water:acetic acid (37:62:1), containing 5 mM heptane sulfonic acid as an ion-pairing agent at a 1.5 ml/minute flow rate. A Spectra Physics Model 3500 B high-performance liquid chromatography system was used with a Spectra Physics model 8200 ultraviolet detector set at 254 nm. With this system, *p*-chloroglycoanilide, *p*-nitrophenol, *p*-chloroacetanilide, and *p*-chloroaniline elute at 4, 5, 6, and 7 minutes, respectively. Quantification of tissue extracts was accomplished by collecting the column effluent at 1-minute intervals (*p*-chloroaniline and *p*-chloroacetanilide were collected as discrete peaks) and analyzing for carbon-14 by liquid scintillation counting. With this method, the limit of detection was determined to be 100 dpm above background.

Pharmacokinetic Analysis

Pharmacokinetic analyses were performed on the distribution data for total carbon-14, p-chloroacetanilide, and p-chloroaniline in blood, tissues, and excreta by the nonlinear regression program NONLIN (Metzler, 1969). The equations used to derive the kinetic curves representing the best statistical fit (P < 0.05) to the data were described by Gibaldi and Perrier (1975).

The concentration (C) of p-chloroaniline and of total carbon-14 was best described by the bi-exponential equation I:

I.
$$C = A_e - a_1 t + B_e - a_2 t$$

For total carbon-14 in urine and feces, the data were best described by equation II:

II.
$$C = A(1 - e^{\alpha t})$$

The presence of total carbon-14 showed an appearance phase in the intestinal contents which fit equation III:

III. $C = A(e - a_1 t - e - a_2 t)$

The previous equation (III) was also used to fit the *p*-chloroacetanilide data for all tissues except liver and blood. Data for liver and blood were described by equation IV:

IV. C = Ae - at

In the above equations, A and B are constants and a_1 and a_2 are first and second phase rate constants, respectively. Time (t) is in hours.

RESULTS

After oral administration of 0.3, 3, or 30 mg/kg p-chloroaniline, [14C]p-chloroaniline equivalents were rapidly excreted. At 24 hours, 77% of the dose appeared in the urine and 10% in the feces. After 7 days, 83.7% \pm 7.9% of the dose had been excreted in the urine and 10.8% \pm 1.9% in the feces (Figure H1). At this time, the only tissue containing greater than 1% of the administered dose was the cellular component of blood, which contained 1%-2% of the dose. Since excretion was found to be independent of dose, the mid dose of 3 mg/kg was used for subsequent intravenous studies.

Total Carbon-14 Kinetics

After an intravenous injection of [14C]p-chloroaniline, total radioactivity was rapidly distributed, with maximal levels being reached in most tissues within 15 minutes. At this time, muscle (34%), fat (14%), skin (12%), liver (8%), and blood (7%) contained the majority of radioactivity, and the small intestine and kidney each contained approximately 3% of the dose. The elimination of total carbon-14 from all tissues was best described by first order biphasic elimination kinetics (Figures H2 and H3). The initial elimination half-lives were similar for all tissues and ranged between 1.5 and 4 hours. By 8 hours, approximately 90% of the administered dose was eliminated from the blood and tissues into the urine and feces. Because of this rapid elimination, accurate terminal decay rate constants were difficult to determine but were calculated to be approximately 48 hours. The terminal elimination phase of carbon-14 equivalents represented only 6% of the dose, and 4% of the dose was found in whole blood (Figure H4).

p-Chloroaniline Kinetics

Accurate determination of the rate of p-chloroaniline elimination from tissues was difficult because of its rapid disappearance. Tissues analyzed displayed bi-exponential decay kinetics with initial half-lives of approximately 8 minutes and terminal half-lives of 3-4 hours, except for adipose tissue and small intestine which had terminal half-lives of 29 and 23 hours, respectively (Table H1). With blood, muscle, fat, and skin, the best fit for the kinetic curve was determined after deleting data at 1 hour. These tissues had concentrations of p-chloroaniline at 1 hour which were considerably higher than at the other time points. The results at 1 hour were confirmed in a repeated experiment; therefore, the data were not considered to be in error.

p-Chloroacetanilide Pharmacokinetics

The kinetics of p-chloroacetanilide in those tissues examined followed monophasic elimination kinetics preceded by a short appearance phase in all tissues except liver and whole blood (Table H2). The distribution of p-chloroacetanilide was similar to that of total carbon-14, with the highest levels being found in muscle, skin, fat, liver, and blood. The half-life of appearance of p-chloroacetanilide was approximately 10 minutes, and the elimination half-life was 3 hours.

(a) Dose = 3 mg/kg. Liver and blood data were fitted to equation IV described in the Materials and Methods section of Appendix H; all other data were fitted to equation I.

Biliary Excretion of [14C]p-Chloroaniline

The biliary excretion of total carbon-14 occurred rapidly after intravenous administration of $[^{14}C]_{p-chloroaniline}$ (Figure H5). Cumulative recovery accounted for $25\% \pm 2.7\%$ of the dose after 6.0 hours of collection. High-performance liquid chromatographic analysis of pooled bile extracts revealed only small amounts of *p*-chloroaniline (10%) and *p*-chloroacetanilide (7%), with the remainder being unidentified polar metabolites.

APPENDIX I

AUDIT SUMMARY

APPENDIX I. AUDIT SUMMARY

The pathology specimens, experimental data, study documents, and draft NTP Technical Report No. 351 for the 2-year studies of *p*-chloroaniline hydrochloride in rats and mice were audited for accuracy, consistency, completeness, and compliance with the Good Laboratory Practice (GLP) regulations of the Food and Drug Administration (fully implemented by the National Toxicology Program [NTP] beginning October 1, 1981). The studies were conducted by Battelle Columbus Laboratories (Columbus, Ohio). Dosing of animals by gavage began on January 25, 1982, for rats and on February 8, 1982, for mice. The retrospective audit was conducted for the National Institute of Environmental Health Sciences (NIEHS) at the NTP Archives during September, October, and November 1987 by Argus Research Laboratories, Inc. The complete audit report is on file at the NIEHS. The audit included a review of:

- (1) All records concerning animal receipt, quarantine, randomization, and disposition prior to study start.
- (2) All inlife records including protocol, correspondence, animal husbandry, environmental conditions, dosing, external masses, mortality, animal identification, and serology.
- (3) Body weight data and clinical observation data for a random 10% sample of animals in each study group.
- (4) All chemistry records.
- (5) All postmortem records for individual animals concerning disposition codes, condition codes, tissue accountability, correlation of masses or clinical signs recorded at the last inlife observation with gross observations and microscopic diagnoses, and correlations between gross observations and microscopic diagnoses.
- (6) All wet tissue bags for inventory and wet tissues from a random 20% sample of rats in all study groups, plus other relevant cases to verify animal identity and to examine for untrimmed potential lesions.
- (7) Blocks and slides of tissues from a random 20% sample of animals from each study group to examine for proper match and inventory.
- (8) All red-lined diagnoses on the intermediate pathology table to verify incorporation of changes in the final tables.
- (9) Correlation between the data, results, and procedures for the 2-year studies presented in the preliminary Technical Report and the records available at the NTP Archives.

The archival records documented adequately all inlife procedures and events except for the disposition of surplus animals. The records documented the preparation, analysis, and administration of doses. A random sample of group mean body weights was recalculated and found to be accurate. Of the external masses observed inlife, 139/149 in rats and 211/212 in mice were correlated with necropsy observations. The date of death recorded at necrospy for one mid dose male mouse did not agree with the date entered into the computer at the time of animal removal; survival for that group appeared to be 28 rather than 29 mice. Clinical signs were recorded in a generally consistent manner. Hematologic and clinical chemical data were not audited.

Review of the pathology specimens showed that individual animal identifiers (clipped toes and ears) were present and correct in the tissue bags for 99/100 rats and 87/95 mice examined. Followup on animals with less than complete and correct identifiers indicated that individual animal identity had been maintained. The audit found seven untrimmed potential lesions in rats (none in target organs) and none in mice. All gross observations made at necropsy were correlated with microscopic observations, except for one in one rat. Tissue slides and blocks were inspected, and sections matched each other properly. All diagnoses on intermediate tables had been incorporated into the final pathology tables.

Details of these and other audit findings are presented in the audit reports. In conclusion, the data and results presented in the Technical Report for the 2-year gavage studies of p-chloroaniline hydrochloride are supported by the records at the NTP Archives.
