## NOAA TECHNICAL REPORT NMFS

The major responsibilities of the National Marine Fisheries Service (NMFS) are to monitor and assess the abundance and geographic distribution of fishery resources, to understand and predict fluctuations in the quantity and distribution of these resources, and to establish levels for their optimum use. NMFS is also charged with the development and implementation of policies for managing national fishing grounds, development and enforcement of domestic fisheries regulations, surveillance of foreign fishing off United States coastal waters, and the development and enforcement of international fishery agreements and policies. NMFS also assists the fishing industry through marketing service and economic analysis programs, and mortgage insurance and vessel construction subsidies. It collects, analyzes, and publishes statistics on various phases of the industry.

The NOAA Technical Report NMFS series was established in 1983 to replace two subcategories of the Technical Reports series: "Special Scientific Report-Fisheries" and "Circular." The series contains the following types of reports: Scientific investigations that document long-term continuing programs of NMFS; intensive scientific reports on studies of restricted scope; papers on applied fishery problems; technical reports of general interest intended to aid conservation and management; reports that review in considerable detail and at a high technical level certain broad areas of research; and technical papers originating in economics studies and from management investigations. Since this is a formal series, all submitted papers receive peer review and those accepted receive professional editing before publication.

Copies of NOAA Technical Reports NMFS are available free in limited numbers to governmental agencies, both Federal and State. They are also available in exchange for other scientific and technical publications in the marine sciences. Individual copies may be obtained from: U.S. Department of Commerce, National Technical Information Service, 5285 Port Royal Road, Springfield, VA 22161. Although the contents have not been copyrighted and may be reprinted entirely, reference to source is appreciated.

#### Abstract

This report presents meristic data for nearly all of the known species of Sebastes. Rudimentary caudal ray counts tend to be higher in more active species. The number of caudal rays supported by the hypurals is consistently 14 , whereas the number of branched caudal rays varies between 11 and 13. Vertebral counts and most fin-ray counts tend to be lower in species or populations in warmer latitudes, except for pectoral ray counts which tend to have an opposite geographic pattern. On the basis of the small magnitude of meristic and morphometric differences and the lack of other differences between northern and southern samples of "Sebastes caurinus," Sebastichthys vexillaris Jordan and Gilbert is regarded as a junior synonym of Sebastes caurinus Richardson. The patterns of bilateral variation in paired meristics are analyzed and their mechanism discussed. The frequency distribution of pectoral ray counts in their right-left combination is shown to be useful in species separation. No association was found between any combination of two meristic features in any species. The author proposes that intrasample associations between meristic features are evidence of sampling heterogeneity.

## INTRODUCTION

Meristic characters, in a strict sense, are countable structures, the numbers of which are associated with body segmentation. In practice, however, any enumerable feature can be referred to as a meristic character. Features of this kind are easy to examine, require no subjective numerical conversion in analysis, and are important in fish identification and species separation. This is especially true in fishes of the genus Sebastes in which there are very few other characters available, particularly when dealing with larval or juvenile specimens.

This paper provides baseline meristic data of species of the genus Sebastes, discusses the mechanics and patterns of interspecific, individual, geographic, and bilateral variation, and the use of these patterns in species separation.

## MATERIALS AND METHODS

More than 4,000 specimens of 100 species of Sebastes have been examined in this study. Additional data (see footnotes in Table 1) were gathered from the literature. Robert Lea (California Department of Fish and Game) provided data on two specimens of $S$. gillii and two specimens of S. brevispinis, and Jergen Westrheim (Pacific Biological Station, Nanaimo, B.C., Canada) provided pectoral ray counts of 52 specimens of S. polyspinis.

In counting rays of dorsal and anal fins, the two last rays are counted as one when they are in contact at their bases, without interspace, as is usually the case. When a space gap is obvious between the bases of the two last rays, however, they are counted separately. In counting lateral-line pores, the total number of pores is given without reference to placement of the structural base of the caudal fin. Gill-raker counts are the total number of rakers on the outer row of the first gill arch, including all the rudimentary ones. In vertebral counts, the ural centrum, with the upturned urostyle, is counted as the last vertebra. Principal caudal ray count is the number of branched caudal rays plus 2 and may not be the same as the number of caudal rays supported by the hypurals. Rudimentary caudal rays are small fin-rays preceeding the principal caudal rays at the upper and lower edge of the caudal fin.
In tabulating data of pectoral, dorsal, and anal soft-ray counts, instead of using the conventional frequency distribution format, the frequency distribution of the extent of deviation from the modal number is given. This modified format conserves space and provides a clearer picture of the overall pattern emphasized in this report.

## RESULTS AND DISCUSSION

Data on the vertebral numbers and principal caudal ray counts, dorsal spine and dorsal soft-ray counts, anal soft-ray and pectoral ray counts, gill-raker counts, and lateral line pore counts are presented in Tables 1, 2, 3, 4, and 5, respectively.

Data on anal spine counts are not tabulated. All of the 2,765 specimens of the 91 species examined for this feature have three anal spines.

## Caudal ray counts

Counts of rudimentary caudal rays are presented in Table 6. Rybachuk (1976) examined the rudimentary caudal ray counts in S. jordani and $S$. nebulosus and reported higher counts in the more active swimming S. jordani. The data in Table 6 are arranged in descending order by caudal ray counts. The resulting pattern does
support Rybachuk's contention. In general, species with higher counts (upper table) tend to have slender bodies, small dorsal and anal fins, and their dorsal, anal, and caudal fins have straight distal profiles and sharp corners, typical for active swimming fish. Species with lower counts (lower table), however, tend to have robust bodies, large dorsal and anal fins, and the distal profiles of their dorsal, anal, and caudal fins are rounded, typical of slow swimming but highly maneuverable fish. Although closely related species (such as the entomelas-rufus-ovalis-hopkinsi group and the exsul-ensifer-lentiginosus-capensis-helvomaculatus group) tend to appear near one another in the table, the same is true of remotely related species, suggesting evolutionary convergence.
The principal caudal ray counts show inter- and intra-specific variation (Table 1). In the majority of species the modal ccunt is 14. In the three species of the subgenus Sebastiscus (albofasciatus, marmoratus, and tertius) the count tends to be 13 , and in species of the subgenera Mebarus (inermis, joyneri, thompsoni, and atrovirens) and Takenokius (vulpes, zonatus, ijimae, trivittatus, nivosus, and oblongus) the count is often 15.
Principal caudal ray counts were made by adding two to the number of branched caudal rays. This definition is different from that of some other workers who define principal rays as those rays supported by the hypurals. From radiographs, I find that in all specimens of Sebastes examined there are 14 caudal rays supported by the hypurals and one supported by the parhypural. When there are 11 branched caudal rays (thus a principal caudal ray count of 13 by my definition), the two uppermost and the two lowermost rays supported by the hypurals and parhypural are unbranched. When there are 12 branched caudal rays, the two uppermost rays supported by the hypurals and the ray supported by the parhypural are unbranched. When there are 13 branched caudal rays, the uppermost ray supported by the hypurals and the ray supported by the parhypural are unbranched.
In higher teleosts the reduction of principal caudal rays from the dominant count of 17 (Greenwood et. al. 1966) seems often to be associated with abandonment of an active swimming mode of life, as seen in Cottids, Gobiids, Callionymids, and Blenniids. Many of the species of Sebastes do swim quite actively and should not be expected to have low principal caudal ray counts. That counts of 13,14 , or 15 in Sebastes are lower than the usual 17 in activeswimming higher teleosts, but higher than observed in other Scorpaenids (Chen 1981) which are basically inactive bottom-dwellers, suggests that in terms of evolution the active swimming life in Sebastes is a secondary event and that Sebastes probably was evolved from a benthic scorpaenid. This is contrary to a once-popular opinion that Sebastes is an offshoot at the base of the scorpaenid phylogenetic tree (Matsubara 1943).

## Vertebral numbers

Counts for a given species were made mostly from samples within a limited geographic area. This may have attributed to the intraspecific constancy in the data. However, the 49 counts of $S$. diploproa were combined from two widely separated samples, one from off British Columbia and the other from off Southern California, and no variation is observed. Samples of $S$. entomelas and $S$. phillipsi demonstrate some intraspecific variation, although the small sample size precludes any judgment as to the significance of such variation. It is clear, however, that such variation is not related to geography as all of the counts of these two species are from specimens taken between San Francisco and Los Angeles, California.

Although little intraspecific variation is observed, interspecifically a geographic trend is obvious. In the subgenus Allosebastes, the northern species group proriger-variegatus-zacentrus-emphaeuswilsoni has 27 vertebrae, while the southern species group semicinctus-saxicola-sinensis-diploproa-cortezi-peduncularisvarispinis has 26. Sebastes aleutianus and S. borealis, the two northern counterparts of the 26 -count southern $S$. melanostomus, both have 27 vertebrae. Sebastes ciliatus, the northern counterpart of the 26 -count melanops-mystinus-serranoides-flavidus group, has 28 vertebrae. The two northern trans-Pacific species $S$. alutus and $S$. polyspinis have high counts of 27 and 28 , respectively. The only exception is the predominantly southern subgenus Acutomentum, represented by $S$. ovalis, S. rufus, S. entomelas, and S. hopkinsi, which has a count of mainly 27 rather than 26 . That all four species of Acutomentum are southern but have 27 vertebrae, and the condition in the two species groups of Allosebastes discussed above, suggest that in addition to the latitudinal trend, vertebral number probably has phylogenetic implication.

## Geographic trends in fin-ray counts

The geographic trend in vertebral counts, with lower numbers in southern species, seems true in some of the fin ray counts as well. In examining the number of dorsal fin rays (Table 2) and anal softrays (Table 3), I find that species endemic to the Gulf of California (cortezi, exsul, peduncularis, sinensis, spinorbis, and varispinis) tend to have reduced meristic elements, sometimes with only 11 dorsal soft-rays and 5 anal soft-rays. More peculiar, however, is the possession of only 12 dorsal spines in over $20 \%$ ( 10 out of 48 ) of the specimens of $S$. varispinis. Dorsal spine number in Sebastes is a very conservative character. Table 2 presents the dorsal spine counts of Sebastes, including those documented by Chen (1971 and 1975) and Matsubara (1943). Of the 2,571 specimens used in Table 2 . only 24 have counts below and 27 above the modal number ( $2 \%$ deviation). It must be noted that 17 of the 51 (33\%) deviations are from a sample of 227 specimens ( $9 \%$ of the 2,571 total) of seven species from the Gulf of California, and 10 of the 17 are of $S$. varispinis.

An analysis of the data of $S$. varispinis indicates that the numbers of dorsal spines and dorsal soft-rays are negatively correlated (Table 7, $\chi^{2}=5.109, \alpha=0.025$ ), suggesting either that the reduction in dorsal fin elements in the warm environment of the Gulf of California does not discriminate between spiny-rays and soft-rays, or that evolution is in the process of transforming spiny-rays into soft-rays. In $S$. sinensis, although the number of dorsal soft-rays has been reduced from 12 to 11 , as judged from the fact that this is the only species of Sebastes with less than 12 dorsal soft-rays (Table 2), the low dorsal spine count of 12 occurs only rarely ( 3 out of 68). In the three species of Sebastiscus (albofasciatus, marmoratus, and tertius), the only subgenus of Sebastes occurring in the tropics, the number of dorsal spines has been reduced to 12 , whereas the number of dorsal soft-rays remains at 12. (Although I believe that Sebastes came from a tropical low meristic ancestor, I regard the condition of low meristic numbers in Sebastiscus as a secondary event.) That low dorsal soft-ray count has resulted in one line of evolution, whereas low dorsal spiny-ray count has resulted in another line of evolution, suggests that in the process of reducing dorsal fin elements, natural selection does distinguish between spiny-rays and soft-rays, ruling out the first hypothesis proposed above to explain the negative correlation between spiny ray number and soft-ray number in the dorsal fin of $S$. varispinis.

Chen (1971) explained the low anal soft-ray count in S. sinensis as a feature favored in warm waters, either directly by natural selection or indirectly, because of the selective advantage of the other pleiotropic expressions of the controlling genes. This is substantiated by the meristic reduction in the Gulf of California endemics herein reported and the high number of vertebrae, dorsal spines, dorsal soft-rays, and anal soft-rays in the cold temperate $S$. polyspinis (28, XIV, 13-16, 7-9), S. glaucus (29, XIV, 15, 8), S. owstoni (30, XIV, 14, 9), S. marinus (31, XV, 14-15, 8-9), S. mentella (30, XV, 14, 8-9) and $S$. fasciatus (30, XV, 13-14, 7-8) (Westrheim and Tsuyuki 1971; Matsubara 1943; Kelly et al. 1961).
In contrast to the trend of lower meristic counts in southern forms discussed above, the number of pectoral rays in Sebastes seems to vary in the opposite direction, being higher in southern forms. This is exemplified by the pattern seen in the subgenus Sebastomus which has a predominant pectoral ray count of 17 . In this subgenus the only northern species, S. helvomaculatus, has 16 pectoral rays whereas species with greater tropical affinity (including the $S$. capensis complex which has successfully crossed the tropics, S. spinorbis which is endemic to the Gulf of California, and S. notius which is known only from off Baja California) tend to have 18 pectoral rays. It must be pointed out that all Sebastomus species in the Gulf of California are deep-living, and the crossing of tropics by the capensis complex could have involved submergence. Thus there is the possibility that the geographic pattern described above is caused by a bathymetric effect, as demonstrated by the chlorostictus-rosenblatti-eos group in which the deep water S. eos is the only other species of Sebastomus possessing 18 pectoral rays. The saxicola-sinensis-cortezi-diploproa complex of the subgenus Allosebastes serves as another example, with 16 pectoral rays in S. saxicola off the coast of California and Washington, but with 18 pectoral rays in $S$. cortezi and $S$. sinensis of the Gulf of California and in S. diploproa which is believed to have reinvaded the outer coast from the Gulf of California (Chen 1975). This trend seems also to be true intraspecifically when one compares conspecific samples from waters of different temperature. For example, $S$. diploproa tends to have more pectoral rays in individuals from southern populations (Table 8), and S. macdonaldi tends to have more pectoral rays in individuals from the Gulf of California than those from the outer coast (Chen 1975).
Functionally it is not clear if a higher pectoral ray count in warmer water in rockfishes has any adaptive meaning. In the largely sympatric chlorostictus-rosenblatti-eos species complex of the subgenus Sebastomus, the deep- (thus cold)water S. eos has 18 pectoral rays whereas the shallow- (thus warm)water S. chlorostictus and $S$. rosenblatti have 17 pectoral rays. Taning (1952) found that in Salmo trutta the pectoral rays and vertebral elements responded to different temperature in opposing manners, with the former being described by a ' $V$ '-shape curve and the latter by an 'inverse $V$ 'shape curve.

## The caurinus-vexillaris problem

One of the species problems in Sebastes taxonomy concerns the specific distinction between Sebastes caurinus Richardson, 1845 (type locality: Sitka, Alaska) and Sebastichthys vexillaris Jordan and Gilbert, 1880 (type localities: Santa Barbara Channel and San Francisco). The type of $S$. caurinus no longer exists, and the diagnostic features given in the original description of the species do not distinguish it from the types of $S$. vexillaris (USNM 26997 and 27087). To date, no morphological distinctions are known that can serve to separate the two nominal species. Phillips (1957) used
the width of orbit to separate the two species (northern and southern samples of ''S. caurinus''), but later (Phillips 1968) admitted such separation to be unsatisfactory.

Through analysis of covariance, I have compared 28 different body measurements [see Chen (1971) for list of measurements] between two samples, 23 specimens of $S$. caurinus from Puget Sound and 29 specimens from off Southern California, and find that the two samples are statistically different in preanal length, head length, pectoral fin length, pelvic fin length, upper peduncle length, and length of first anal spine. The differences, however, are well within the magnitude of intraspecific geographic variation observed in other species of Sebastes (Chen 1971 and unpubl. data). Meristically, samples of what I regard as $S$. caurinus from different geographic regions are different in gill-raker counts and lateral line pore numbers (Tables $8,9,10$ ); but considering the allopatric relationship among the samples, the differences are not of a magnitude to warrant species separation. Although to a lesser extent, similar differences between northern and southern samples can be seen in S. paucispinis, S. diploproa, and S. elongatus (Tables 8, 9, 10). Although conspicuous geographic variation in meristics in Sebastes probably is not a common event (Chen 1971), clinal variation in diagonal scale row counts has been documented (Westrheim 1965) for $S$. zacentrus. All of the above seems to support my earlier contention (Chen 1975) that $S$. vexillaris should be regarded as a junior synonym of $S$. caurinus.

## Lack of sexual dimorphism

Sexes in Sebastes can be determined through morphology of the genital papillae. There is no other documented sexual dimorphism in fishes of this genus. Tables 8,9 , and 10 also compare various meristic features between sexes in $S$. semicinctus. This species is different from other species of Sebastes in being sexually dimorphic in size, with females growing significantly larger than males (personal unpubl. data). Meristically, however, no sexual difference is detected, as evidenced in the tables.

## Bilateral pattern and its significance in species separation

The biological species concept, advocated by Mayr (1963), defines a species as a group of populations separated from other population groups by irreversible genotypic gaps, and that such irreversible gaps are maintained by reproductive isolation. In practice, however, the irreversibility of such a gap is often not determinable and can be inferred only by consistent phenotypic discontinuity. Such inferences are subjective and are based on the assumption that hybrids are phenotypically intermediate, and the absence of intermediate forms indicates lack of interbreeding.

In separating species of Sebastes, meristic characters play a very important role; however, meristic features, by their nature, have discontinuous distributions. The numerical gap between succeeding counts may or may not indicate the presence of a genotypic gap. The utilization of a numerical gap between succeeding counts as inference of the existence of a biological gap between species is thus a difficult task.
The conventional means of presenting pectoral ray numbers of a species of fish is either to give the modal number and then the range of variation, or to give the frequency distribution of unilateral counts. In this kind of presentation, it is difficult to distinguish between a high degree of intraspecific variation, such as that in $S$. eos, S. jordani, S. serranoides or S. maliger (Table 3), or a case
of sampling heterogeneity, such as in Tables 11 and 12 in which the data of two different species are purposely lumped.
When the pectoral ray counts are presented in their right and left combination, however, the picture is different. In the combined data of S. serranoides and S. flavidus and of S. proriger and S. aleutianus, bimodality is clearly demonstrated, with two modes at 17,17 and 18,18 , but with very few intermediates of 17,18 rays (Tables 11,12 ). Valentine et al (1973) used the degree of bilateral meristic asymmetry in fishes as a measure of environmental stress, with the assumption that in these animals asymmetry is a result of developmental perturbation. The view that vertebrates are genetically and bilaterally symmetrical and that the right and left halves of the body are under the same genetic control is probably held by a large number of zoologists. If this is true in Sebastes, then the low frequency of occurrence of the intermediate 17,18 combination, in comparison with those of 17,17 and 18,18 demonstrated in Tables 11 and 12, is to be expected, regardless of the degree of homogeneity or heterogeneity of the sample.
In examining the bilateral pattern of pectoral ray numbers in presumably homogeneous samples of different species of Sebastes (Table 13), however, the picture becomes different. Of 2,551 specimens of 68 species of Sebastes included in Table 13, most ( $87 \%$ ) are bilaterally symmetrical. This high degree of bilateral symmetry, however, seems to have to do with the low degree of deviation of pectoral ray counts from their modal number. It seems that the tendency for the left and right pectoral fins to have the same number of rays is because the two are highly channelized toward the same modal number and tend not to deviate from this modal number. The probability of deviating from the modal number is low, and the probability of having deviation on both sides of the same body is even lower. Thus when there is deviation from the modal number, bilateral symmetry tends to break down. In Table 13 , about $20 \%$ of the specimens show deviation from the modal number; of these, bilaterally asymmetrical specimens outnumber bilaterally symmetrical specimens almost 2 to 1 . The above evidence seems to suggest that in Sebastes the right and left pectoral ray numbers are of independent genetic control. Although both the left and right pectoral ray numbers are subjected to the same selective forces and tend to be channelized toward the same optimum number, they are not mandatorily identical.
Most species of Sebastes are probably stabilized at a condition in which the genotypic mode of the pectoral ray number is the one favored by natural selection. In species at stages of evolutionary transition, however, when the genotypic mode of the pectoral ray number does not coincide with the mode favored by natural selection, or when the natural selective force on the modal number is relaxed (resulting in an increase in the relative strength of the selective force for bilateral symmetry), the distribution pattern of pectoral ray combinations in the population can be modified. This probably explains the few exceptions to the usual pattern observed in Table 13 (S. aurora, S. miniatus, and S. serriceps). One can postulate that these could represent cases of ongoing sympatric divergence, a speciational mode probably used more often in this speciose genus than in most of the other fish groups.
Because of the wide range of variation, the data of gill-raker counts and those of lateral-line pore counts cannot be presented in the form of frequency distribution tables in their right-left combinations, as in the case of the pectoral rays, but must be in the form of contingency tables (Tables 14, 15). Sampling heterogeneity cannot be detected as easily in these two paired meristics as in the pectoral rays. Analysis has been made on data of all of the species with reasonable sample size, and they all show a pattern similar
to that demonstrated in Tables 14 and 15. In these two paired features the tendency for bilateral symmetry is conspicuous even in cases of deviation from the modal number. Superficially this seems to suggest mandatory symmetry, i.e., the right and left counts have to be equal because they are pleiotropically associated. The numbers of gill-rakers and lateral-line pores on one side of the body tend to be the same as those on the other side of the body. However, in specimens in which the number on one side of the body deviates from the mode, the corresponding frequency distribution of counts on the other side of the body tend to be skewed, with bunching toward the modal number (Tables 14, 15). Although bilateral symmetry and optimum meristic number are both favored by natural selection, the functional reasons may be different. When the right and the left elements are under independent genetic controls, the attainment of symmetry and of the optimum number do not have to be concurrent.

## Character association and its significance in species separation

Tables 2 and 3 show that the dorsal and anal soft-ray counts in Sebastes, like the pectoral ray counts, have little variability, with a conspicuous mode in their distribution, and a deviation from the mode rarely greater than one. Since these features are not paired, the data cannot be presented in the form of right-left combinations to distinguish sampling heterogeneity from high variability. In this case, sampling heterogeneity can be detected through the occurrence of character association.

Contingency tables have been constructed for any combination of two different meristics for all species examined. With the exceptions of the association between dorsal spine and soft-ray numbers in $S$. varispinis (Table 7) and the association between right and left counts discussed above, there is no indication of association between any two meristics. Tables 7 and 16 are examples of such analysis. Data in these tables demonstrate that there is no pleiotropic association between different meristics, that is, different meristic features have separate unlinked genetic determinants. Intraspecifically, genetically based variation in a meristic feature would not mandate the other features to vary in a predetermined direction. Any intrasample association between different meristics thus would suggest sampling heterogeneity. Table 12 represents the combined data of $S$. aleutianus and S. proriger, and Table 11 represents the combined data of S. serranoides and S. flavidus. In Table 12 there is definite association between dorsal soft-ray number and pectoral ray count, and in Table 11 the numbers of dorsal soft-rays and pectoral rays, the numbers of anal soft-rays and dorsal soft-rays, are clearly correlated, as well as the numbers of anal soft-rays and pectoral rays. This kind of association is probably functionally significant, and the existence of such an association suggests the presence of more than one adaptive peak, each represented by a meristic combination.

From the above discussion, it seems reasonable to conclude that when dealing with sympatric samples of Sebastes, bimodality in the distribution of pectoral ray counts in their right-left combination and association between different meristic features can be used as a basis for species separation.
