### **FOREWORD**

The National Toxicology Program (NTP) is made up of four charter agencies of the U.S. Department of Health and Human Services (DHHS): the National Cancer Institute (NCI), National Institutes of Health; the National Institute of Environmental Health Sciences (NIEHS), National Institutes of Health; the National Center for Toxicological Research (NCTR), Food and Drug Administration; and the National Institute for Occupational Safety and Health (NIOSH), Centers for Disease Control. In July 1981, the Carcinogenesis Bioassay Testing Program, NCI, was transferred to the NIEHS. The NTP coordinates the relevant programs, staff, and resources from these Public Health Service agencies relating to basic and applied research and to biological assay development and validation.

The NTP develops, evaluates, and disseminates scientific information about potentially toxic and hazardous chemicals. This knowledge is used for protecting the health of the American people and for the primary prevention of disease.

The studies described in this Technical Report were performed under the direction of the NIEHS and were conducted in compliance with NTP laboratory health and safety requirements and must meet or exceed all applicable federal, state, and local health and safety regulations. Animal care and use were in accordance with the Public Health Service Policy on Humane Care and Use of Animals. The prechronic and chronic studies were conducted in compliance with Food and Drug Administration (FDA) Good Laboratory Practice Regulations, and all aspects of the chronic studies were subjected to retrospective quality assurance audits before being presented for public review.

These studies are designed and conducted to characterize and evaluate the toxicologic potential, including carcinogenic activity, of selected chemicals in laboratory animals (usually two species, rats and mice). Chemicals selected for NTP toxicology and carcinogenesis studies are chosen primarily on the bases of human exposure, level of production, and chemical structure. The interpretive conclusions presented in this Technical Report are based only on the results of these NTP studies. Extrapolation of these results to other species and quantitative risk anlayses for humans require wider analyses beyond the purview of these studies. Selection per se is not an indicator of a chemical's carcinogenic potential.

These NTP Technical Reports are available for sale from the National Technical Information Service, U.S. Department of Commerce, 5285 Port Royal Road, Springfield, VA 22161 (703-487-4650). Single copies of this Technical Report are available without charge while supplies last from NTP Central Data Management, NIEHS, P.O. Box 12233, MD E1-02, Research Triangle Park, NC 27709 (919-541-3419). Listings of all published NTP reports and ongoing studies are also available from NTP Central Data Management. The Abstracts and other study information for 2-year studies are also available at the NTP's World Wide Web site: http://ntp-server.niehs.nih.gov.

### **ABSTRACT**

### 1-TRANS-DELTA'-TETRAHYDROCANNABINOL

CAS No. 1972-08-3

Chemical Formula:  $C_{21}H_{30}O_2$ 

Molecular Weight: 314.5

Synonyms:

3-Pentyl-6,6,9-trimethyl-6a,7,8,10a-tetrahydro-6h-dibenzo(b,d)pyran-1-ol; delta<sup>1</sup>-tetrahydrocannabinol;

(-)-delta<sup>1</sup>-3,4-trans-tetrahydrocannabinol; delta<sup>9</sup>-tetrahydrocannabinon; THC; delta<sup>1</sup>-THC; delta<sup>9</sup>-THC

Trade names: Dronabinol; Marinol

1-Trans-delta<sup>9</sup>-tetrahydrocannabinol (THC) was nominated by the National Cancer Institute to the NTP for study because it is the major psychoactive component of marijuana and a widely used Schedule I substance. Male and female F344/N rats and B6C3F<sub>1</sub> mice received THC (97% pure) in corn oil by gavage for 13 weeks, 13 weeks with a 9-week recovery period, or 2 years. Genetic toxicology studies were conducted in *Salmonella typhimurium*, cultured Chinese hamster ovary cells, and mouse peripheral blood cells.

### 13-WEEK STUDY IN RATS

Groups of 10 male and 10 female rats received 0, 5, 15, 50, 150, or 500 mg THC/kg body weight in corn oil by gavage, 5 days per week for 13 weeks. Six male and six female rats receiving 500 mg/kg died before the end of the study. The final mean body weights and weight gains of all dosed groups of males and females, except 5 mg/kg females, were significantly lower than those of the controls. Feed consumption by dosed groups was similar to that by controls. Clinical findings observed during the study included lethargy, sensitivity to touch, convulsions, tremors, and aggressiveness. There were no clinical pathology differences considered to be directly related to the

administration of THC. The absolute and relative uterus weights of 50, 150, and 500 mg/kg females were significantly lower than those of the controls. Treatment-related multifocal atrophy was observed in the testes of 150 and 500 mg/kg males; uterine and ovarian hypoplasia observed in 150 and 500 mg/kg females was also considered to be related to THC administration. Based on final mean body weights and mortality observed in the 13-week study, doses selected for the 2-year rat study were 12.5, 25, and 50 mg/kg.

### 13-WEEK STUDY IN MICE

Groups of 10 male and 10 female mice received 0, 5, 15, 50, 150, or 500 mg THC/kg body weight in corn oil by gavage, 5 days per week for 13 weeks. There were no treatment-related deaths. The final mean body weight and weight gain of 500 mg/kg males were significantly lower than those of the controls. Clinical findings included lethargy and aggressiveness, and both male and female mice in all dosed groups were easily startled. There were no absolute or relative organ weight differences, clinical pathology differences, or microscopic changes observed that were considered to be related to the administration of THC. Due to the minimal THC-related effects

observed in the 13-week study, doses selected for the 2-year mouse study were 125, 250, and 500 mg/kg.

## 13-WEEK WITH 9-WEEK RECOVERY STUDY IN RATS

Groups of 10 male and 10 female rats received 0. 5. 15, 50, 150, or 500 mg THC/kg body weight in corn oil by gavage, 5 days per week for 13 weeks, and then were allowed to recover during a 9-week treatmentfree period. Five male and eight female 500 mg/kg rats, five male and two female 150 mg/kg rats, and three male and two female 50 mg/kg rats died before the end of the study. During the 13-week dosing period, mean body weight gains of all dosed groups of rats were lower than those of the controls but returned to normal during the recovery period. Final mean body weights of all dosed groups were similar to those of the controls. Clinical findings observed during the recovery period included sensitivity to touch, convulsions, and aggressiveness. The absolute right testis weight of 500 mg/kg males was significantly lower than that of the controls. Treatmentrelated multifocal atrophy of the testis was observed in 150 and 500 mg/kg males. There were no treatment-related lesions observed in females administered THC.

## 13-WEEK WITH 9-WEEK RECOVERY STUDY IN MICE

Groups of 10 male and 10 female mice received 0, 5, 15, 50, 150, or 500 mg THC/kg body weight in corn oil by gavage, 5 days per week for 13 weeks, and then were allowed to recover during a 9-week treatment-free period. The final mean body weights of all dosed groups were similar to those of the controls. Clinical findings observed during the study included lethargy and aggressiveness, and both male and female mice in all dosed groups were easily startled. The absolute and relative uterus weights of 150 and 500 mg/kg female mice were significantly lower than those of the controls, as was the absolute uterus weight of 50 mg/kg females.

### 2-YEAR STUDY IN RATS

Groups of 62 vehicle control male rats, 60 low-dose male rats, 70 mid- and high-dose male rats, and 60 female rats were administered 0, 12.5, 25, or 50 mg THC/kg body weight in corn oil by gavage for

104 to 105 weeks. Nine or ten animals from each group were evaluated at 15 months.

Survival, Body Weights, and Clinical Findings Survival of all dosed groups was generally significantly greater than that of the controls. Mean body weights of dosed groups of males and females were lower than those of the controls throughout the study. Convulsions and seizures were observed in all dosed groups of male and female rats, usually following dosing or handling.

### Hematology and Clinical Chemistry

At the 15-month interim evaluation, total leukocyte and lymphocyte counts in all dosed groups of females were greater than those of the controls, and platelet counts in these groups were lower than that of the controls. Levels of follicle stimulating and luteinizing hormones in all dosed groups of males were significantly greater than those of the controls, as was the serum corticosterone level of 25 mg/kg females.

### Pathology Findings

No increased incidences of neoplasms were considered related to administration of THC. The incidences of mammary gland fibroadenoma and uterine stromal polyps were decreased in dosed groups of females, as were the incidences of pituitary gland adenomas, interstitial cell adenomas of the testis, and pancreatic adenomas in dosed males.

### 2-YEAR STUDY IN MICE

Groups of 62 vehicle control male mice, 60 low-dose male mice, 61 mid-dose male mice, and 60 high-dose male mice and 60 female mice were administered 0, 125, 250, or 500 mg THC/kg body weight in corn oil by gavage for 104 to 105 weeks (males) or 105 to 106 weeks (females).

Survival, Body Weights, and Clinical Findings Survival of 500 mg/kg males was significantly less than that of the controls; survival of all other groups

than that of the controls; survival of all other groups of males and of all dosed groups of females was similar to that of the controls. Mean body weights of all dosed groups were markedly lower than those of the controls throughout the study. Clinical findings in dosed groups included hyperactivity, convulsions, and seizures which occurred following dosing or handling.

### Hematology

At the 15-month interim evaluation, total leukocyte and lymphocyte counts in all dosed groups of males were significantly lower than those of the controls.

### Pathology Findings

Increased incidences of thyroid gland follicular cell adenoma occurred in 125 mg/kg males and females, but the increase was not dose-related. Increased incidences of thyroid gland follicular cell hyperplasia occurred in all dosed groups of males and females. Increased incidences of forestomach hyperplasia and ulcers occurred in all groups of males administered THC. Incidences of hepatocellular adenoma and of hepatocellular adenoma or carcinoma (combined) occurred with a significant negative trend in male and female mice, as did incidences of eosinophilic foci and fatty change in the liver.

### **GENETIC TOXICOLOGY**

THC was not mutagenic in Salmonella typhimurium strains TA97, TA98, TA100, or TA1535 with or without rat and hamster liver S9 fractions. In cultured Chinese hamster ovary cells, THC induced sister chromatid exchanges at the highest dose tested in the presence of S9; at this dose level, cell cycle delay indicative of toxicity was observed. THC did not induce chromosomal aberrations in cultured

Chinese hamster ovary cells with or without S9 metabolic activation enzymes. *In vivo*, no increase in the frequency of micronucleated erythrocytes was observed in the peripheral blood of male or female mice administered THC by gavage for 13 weeks.

### **CONCLUSIONS**

Under the conditions of these 2-year gavage studies, there was no evidence of carcinogenic activity\* of 1-trans-delta9-tetrahydrocannabinol in male or female F344/N rats administered 12.5, 25, or 50 mg/kg. There was equivocal evidence of carcinogenic activity of THC in male and female B6C3F<sub>1</sub> mice based on the increased incidences of thyroid gland follicular cell adenomas in the 125 mg/kg groups.

Increased incidences of thyroid gland follicular cell hyperplasia occurred in male and female mice, and increased incidences of hyperplasia and ulcers of the forestomach were observed in male mice.

The incidences of mammary gland fibroadenomas and uterine stromal polyps were decreased in dosed groups of female rats, as were the incidences of pancreatic adenomas, pituitary gland adenomas, and interstitial cell adenomas of the testis in dosed male rats and liver neoplasms in dosed mice. These decreases were likely related to lower body weights in dosed animals.

<sup>\*</sup> Explanation of Levels of Evidence of Carcinogenic Activity is on page 9. A summary of the Technical Reports Review Subcommittee comments and the public discussion on this Technical Report appears on page 11.

# Summary of the 2-Year Carcinogenesis and Genetic Toxicology Studies of 1-Trans-Delta<sup>9</sup>-Tetrahydrocannabinol

Variable	Male F344/N Rats	Female F344/N Rats	Male B6C3F <sub>1</sub> Mice	Female B6C3F <sub>1</sub> Mice	
Doses	0, 12.5, 25, or 50 mg/kg in corn oil by gavage	0, 12.5, 25, or 50 mg/kg in corn oil by gavage	0, 125, 250, or 500 mg/kg in corn oil by gavage	0, 125, 250, or 500 mg/kg in corn oil by gavage	
Body weights	Dosed groups lower than controls	Dosed groups lower than controls	Dosed groups lower than controls	Dosed groups lower than controls	
2-Year survival rates	22/52, 35/51, 33/52, 31/52	23/51, 40/51, 33/51, 32/50	50/62, 53/60, 45/61, 34/60	47/60, 50/60, 44/60, 41/60	
Nonneoplastic effects	None	None  Forestomach: hyperplasia (7/62, 33/58, 38/58, 18/56); ulcer (5/62, 17/58, 14/58, 8/56) Thyroid gland (follicular cell): hyperplasia (16/62, 48/60, 45/61, 27/57)		Thyroid gland (follicular cell): hyperplasia (28/60, 46/60, 40/60, 33/60)	
Neoplastic effects	None	None	None	None	
Uncertain findings	None	None	Thyroid gland (follicular cell): adenoma (0/62, 6/60, 3/61, 1/57)	Thyroid gland (follicular cell): adenoma (4/60, 9/60, 3/60, 1/60)	
Decreased incidences	Pancreas: adenoma (8/52, 0/51, 2/52, 0/52); Pituitary gland: adenoma (21/52, 19/51, 14/51, 9/52); Testis: interstitial cell adenoma (46/52, 40/51, 36/52, 43/52)	Mammary gland: fibroadenoma (15/51, 11/51, 11/51, 8/50); Uterus: stromal polyp (8/51, 5/51, 2/51, 2/50)	Liver: hepatocellular adenoma (25/62, 11/60, 6/61, 2/57); hepatocellular adenoma or carcinoma (31/62, 13/60, 9/61, 3/57); eosinophilic foci (18/62, 1/60, 0/61, 0/57); fatty change (20/62, 11/60, 1/61, 1/57)	Liver: hepatocellular adenoma (17/60, 9/60, 7/59, 3/60); hepatocellular adenoma or carcinoma (22/60, 14/60, 11/59, 4/60); eosinophilic foci (9/60, 0/60, 1/59, 1/60); fatty change (13/60, 3/60, 0/59, 2/60)	
Level of evidence of carcinogenic activity	No evidence	No evidence	Equivocal evidence	Equivocal evidence	
Genetic toxicology  Salmonella typhimurium gene mutations: Sister chromatid exchanges  Cultured Chinese hamster ovary cells in vitro: Chromosomal aberrations  Cultured Chinese hamster ovary cells in vitro: Micronucleated erythrocytes		Negative in strains TA97, TA98, TA100, and TA1535 with and without S9 Positive with S9; negative without S9 Negative with and without S9			
Mouse periphera		No increase in frequency observed			

### EXPLANATION OF LEVELS OF EVIDENCE OF CARCINOGENIC ACTIVITY

The National Toxicology Program describes the results of individual experiments on a chemical agent and notes the strength of the evidence for conclusions regarding each study. Negative results, in which the study animals do not have a greater incidence of neoplasia than control animals, do not necessarily mean that a chemical is not a carcinogen, inasmuch as the experiments are conducted under a limited set of conditions. Positive results demonstrate that a chemical is carcinogenic for laboratory animals under the conditions of the study and indicate that exposure to the chemical has the potential for hazard to humans. Other organizations, such as the International Agency for Research on Cancer, assign a strength of evidence for conclusions based on an examination of all available evidence, including animal studies such as those conducted by the NTP, epidemiologic studies, and estimates of exposure. Thus, the actual determination of risk to humans from chemicals found to be carcinogenic in laboratory animals requires a wider analysis that extends beyond the purview of these studies.

Five categories of evidence of carcinogenic activity are used in the Technical Report series to summarize the strength of the evidence observed in each experiment: two categories for positive results (clear evidence and some evidence); one category for uncertain findings (equivocal evidence); one category for no observable effects (no evidence); and one category for experiments that cannot be evaluated because of major flaws (inadequate study). These categories of interpretative conclusions were first adopted in June 1983 and then revised in March 1986 for use in the Technical Report series to incorporate more specifically the concept of actual weight of evidence of carcinogenic activity. For each separate experiment (male rats, female rats, male mice, female mice), one of the following five categories is selected to describe the findings. These categories refer to the strength of the experimental evidence and not to potency or mechanism.

- Clear evidence of carcinogenic activity is demonstrated by studies that are interpreted as showing a dose-related
  (i) increase of malignant neoplasms, (ii) increase of a combination of malignant and benign neoplasms, or (iii) marked increase of benign neoplasms if there is an indication from this or other studies of the ability of such tumors to progress to malignancy.
- Some evidence of carcinogenic activity is demonstrated by studies that are interpreted as showing a chemical-related increased incidence of neoplasms (malignant, benign, or combined) in which the strength of the response is less than that required for clear evidence.
- Equivocal evidence of carcinogenic activity is demonstrated by studies that are interpreted as showing a marginal
  increase of neoplasms that may be chemical related.
- No evidence of carcinogenic activity is demonstrated by studies that are interpreted as showing no chemical-related increases in malignant or benign neoplasms.
- Inadequate study of carcinogenic activity is demonstrated by studies that, because of major qualitative or quantitative limitations, cannot be interpreted as valid for showing either the presence or absence of carcinogenic activity.

When a conclusion statement for a particular experiment is selected, consideration must be given to key factors that would extend the actual boundary of an individual category of evidence. Such consideration should allow for incorporation of scientific experience and current understanding of long-term carcinogenesis studies in laboratory animals, especially for those evaluations that may be on the borderline between two adjacent levels. These considerations should include:

- adequacy of the experimental design and conduct:
- · occurrence of common versus uncommon neoplasia;
- · progression (or lack thereof) from benign to malignant neoplasia as well as from preneoplastic to neoplastic lesions;
- some benign neoplasms have the capacity to regress but others (of the same morphologic type) progress. At present, it is impossible to identify the difference. Therefore, where progression is known to be a possibility, the most prudent course is to assume that benign neoplasms of those types have the potential to become malignant;
- combining benign and malignant tumor incidence known or thought to represent stages of progression in the same organ or tissue;
- latency in tumor induction;
- multiplicity in site-specific neoplasia;
- · metastases;
- supporting information from proliferative lesions (hyperplasia) in the same site of neoplasia or in other experiments (same lesion in another sex or species);
- · presence or absence of dose relationships;
- · statistical significance of the observed tumor increase;
- concurrent control tumor incidence as well as the historical control rate and variability for a specific neoplasm;
- · survival-adjusted analyses and false positive or false negative concerns;
- structure-activity correlations; and
- · in some cases, genetic toxicology.

### NATIONAL TOXICOLOGY PROGRAM BOARD OF SCIENTIFIC COUNSELORS TECHNICAL REPORTS REVIEW SUBCOMMITTEE

The members of the Technical Reports Review Subcommittee who evaluated the draft NTP Technical Report on 1-trans-delta9-tetrahydrocannabinol on June 21, 1994, are listed below. Subcommittee members serve as independent scientists, not as representatives of any institution, company, or governmental agency. In this capacity, subcommittee members have five major responsibilities in reviewing NTP studies:

- · to ascertain that all relevant literature data have been adequately cited and interpreted,
- to determine if the design and conditions of the NTP studies were appropriate,
- · to ensure that the Technical Report presents the experimental results and conclusions fully and clearly,
- · to judge the significance of the experimental results by scientific criteria, and
- · to assess the evaluation of the evidence of carcinogenic activity and other observed toxic responses.

### SUMMARY OF TECHNICAL REPORTS REVIEW SUBCOMMITTEE COMMENTS

On June 21, 1994, the draft Technical Report on the toxicology and carcinogenesis studies of 1-transdelta9-tetrahydrocannabinol (THC) received public review by the National Toxicology Program Board of Scientific Counselors Technical Reports Review Subcommittee. The review meeting was held at the National Institute of Environmental Health Sciences, Research Triangle Park, NC.

Dr. P.C. Chan, NIEHS, introduced the toxicology and carcinogenesis studies of THC by discussing the uses of the chemical and rationale for study, describing the experimental design, reporting on survival and body weight effects, and commenting on chemical-related neoplasm and nonneoplastic lesion incidences. He also presented toxicokinetic data for male rats. The proposed conclusions were no evidence of carcinogenic activity in male and female F344/N rats and equivocal evidence of carcinogenic activity in male and female B6C3F<sub>1</sub> mice.

Dr. Klaassen, a principal reviewer, agreed with the proposed conclusions. He asked for a table in the discussion outlining decreases in neoplasm incidences and the correlation of these decreases with body weights. Dr. Chan said a table would be added. Dr. Klaassen asked why a 9-week recovery period was included in the present studies. Dr. Chan said that the effects of THC linger, so a recovery period was included to study the effects of the chemical, particularly on the reproductive system, and to aid in possible extrapolation of the effects in humans.

Dr. Taylor, the second principal reviewer, agreed with the proposed conclusions. Dr. Taylor asked for an expansion of the discussion of arachidonic acid metabolism modification by THC, noting it would be helpful to indicate the extent and direction and the possible therapeutic or physiologic implications. Dr. Chan agreed (page 17). Dr. Taylor said a comment explaining the selection of gavage as the route of administration should be added to the report, noting that this route differs from the typical routes of human exposure. Dr. Chan said that insufficient compound was available to perform an inhalation study, intraperitoneal injection was less akin to human routes of exposure, and only a small historical database exists for the intraperitoneal injection route.

Dr. van Zwieten, the third principal reviewer, agreed with the proposed conclusions. He asked for comments on the apparent inverse dose-response relationship for the thyroid gland neoplasm incidences in mice (page 76).

Dr. Ward asked if step sectioning of mouse thyroid glands had been considered in view of the equivocal findings. Dr. M.R. Elwell, NIEHS, said that because of the small size of the gland, one cross-section is fairly representative of the entire organ. Dr. Ward asked if lower body weights of dosed groups could have been caused by exceeding maximum tolerated doses. Dr. J.R. Bucher, NIEHS, said that because THC can affect weight gain, the possibility of exceeding the maximum tolerated dose would be difficult to interpret. Dr. Chan added that because THC is taken up and stored in adipose tissue, THC buildup during chronic administration could cause the maximum tolerated dose to be exceeded. Dr. Russo asked for comments on the lower serum levels of follicle stimulating hormone and luteinizing hormone in female rats and mice when compared to male rats and mice. Dr. Bucher said although the reproductive effects of THC were well studied, there was no explanation for the difference in the hormone levels in males and females in the present studies. Dr. van Zwieten noted that many decreased neoplasm incidences observed in dosed groups were within historical control ranges from 2-year NTP gavage studies. Dr. Miller suggested including data contrasting human and animal THC plasma levels and including levels typically achieved in humans to discourage the concept of THC as a cancer inhibitor. Dr. Bucher noted that the results of these studies could be misinterpreted to demonstrate that exposure to THC could provide beneficial therapeutic effects and added that the NTP has attempted to stress that most of the observed changes were due to decreased weight gain.

Dr. Klaassen cited a report in the text that the amount of THC taken in by habitual marijuana smokers was estimated to range from 0.3 to 12.0 mg/kg, which would be comparable to doses administered to rats in the present studies. Dr. Taylor pointed out that plasma levels resulting from a dose administered via inhalation would be much higher than those resulting from the same dose administered orally.

3

Dr. Klaassen moved that the Technical Report on 1-trans-delta<sup>9</sup>-tetrahydrocannabinol be accepted with the revisions discussed and the conclusions as written for male and female rats, no evidence of carcinogenic

activity, and for male and female mice, equivocal evidence of carcinogenic activity. Dr. Bailey seconded the motion, which was accepted unanimously with eleven votes.

### INTRODUCTION

#### 1-TRANS-DELTA'-TETRAHYDROCANNABINOL

CAS No. 1972-08-3

Chemical Formula: C<sub>21</sub>H<sub>30</sub>O<sub>2</sub>

Molecular Weight: 314.5

Synonyms:

3-Pentyl-6,6,9-trimethyl-6a,7,8,10a-tetrahydro-6h-dibenzo(b,d)pyran-1-ol; delta<sup>1</sup>-tetrahydrocannabinol; (-)-delta<sup>1</sup>-3,4-trans-tetrahydrocannabinol; delta<sup>9</sup>-tetrahydrocannabinon; THC; delta<sup>1</sup>-THC; delta<sup>9</sup>-THC

Trade names: Dronabinol; Marinol

### **CHEMICAL AND PHYSICAL PROPERTIES**

1-Trans-delta9-tetrahydrocannabinol (THC) is an oil with a boiling point of 200° C. When stored, THC decomposes and becomes reddish in color. It is insoluble in water and soluble in organic solvents such as ethanol, hexane, and chloroform. unstable in air, light, and acidic media and at high temperatures. THC is more stable in ethanol than in carbon tetrachloride or hexane. Thin films of THC are less stable than THC in solutions. Stability is not improved by adding antioxidants. The major product of THC decomposition is cannabinol and the minor product is delta<sup>8</sup>-THC. Due to its high lipid/aqueous partition coefficient, THC has a higher affinity for biomembranes than for aqueous media (Martin, 1986). Octanol/water and benzene/water partition coefficients of THC are about 6,000 (Pertwee, 1988).

# PRODUCTION, USE, AND HUMAN EXPOSURE

More than  $60 \, C_{21}$  compounds grouped together under the general designation of cannabinoids are found in the *Cannabis sativa* plant. Among the naturally occurring cannabinoids, THC is the main psycho-

active component of marijuana and hashish. Marijuana is the chopped flowering tops of the female hemp plant, Cannabis sativa, and hashish is the resinous material derived from the flowering tops. The other pharmacologically active isomer, D<sup>8</sup>-THC, is found only in a few strains of the plant. Maximal biological activity depends on the double bond at the D<sup>8</sup> or D<sup>9</sup> position. In most pharmacological assays, D<sup>8</sup>-THC is approximately one-third as potent as THC. The other cannabinoids are relatively pharmacologically inactive but may interact in or influence the metabolism of THC (Bornheim, 1989).

The concentration of THC in fresh samples of cannabis is low; of the cannabinoids present, about 95% is ordinarily found in the form of D<sup>9</sup>-tetrahydro-cannabinolic acid, a pharmacologically inactive compound. On aging and development of the plant, storage of the cut plant material, or heating, D<sup>9</sup>-tetrahydrocannabinolic acid is decarboxylated to form the pharmacologically active compound THC. The THC content of marijuana from American wild strains of C. sativa is about 0.1%. Tropical strains yield as much as 4%. Careful cultivation and genetic manipulation have raised the THC content of marijuana to much higher levels.

About one-half to three-fourths of the THC contained in a typical 500 mg marijuana cigarette (approximately 5 mg) is lost during smoking. Habitual smokers receive 0.3 to 12 mg THC/kg per day (ARF/WHO, 1981). THC is not commercially available in the U.S., but drug companies have been developing analogues of THC to exploit the medical potential of the compound without subjecting the patient to its disruptive central nervous system effects. Current production volumes of the analogues are not available.

Marijuana and hashish are among the most widely used drugs known to man. Uses of the drugs include: treatment of pain and inflammation; lowering of intraocular pressure in glaucoma; relief from nausea associated with cancer chemotherapy; appetite stimulation; decreasing intestinal motility (diarrhea); and relief from muscle spasms, epilepsy, and asthma. The drugs are also used as antirheumatics and antipyretics (Hollister, 1984). In the United States, marijuana is widely used. The social and medicinal uses of marijuana date back at least 4,000 years (Zias et al., 1993).

Marijuana and cannabinoids have been classified in the U.S. as Schedule I substances under the Drug Abuse Prevention and Control Act. This classification is for compounds that currently have no accepted medical uses in the United States but have high abuse potential and/or safety risks associated with their use.

# ABSORPTION, DISTRIBUTION, METABOLISM, AND EXCRETION

### Experimental Animals

In cats, peak plasma concentration (1.10  $\mu$ g/mL) of THC was reached 1 hour after receiving a single oral dose of 2 mg/kg (McCarthy et al., 1984). Peak plasma concentration of THC was reached in 4 hours in rats after an oral dose of 50 mg/kg (Abel and Subramanian, 1990). The peak plasma level of THC in rats was maintained for at least 24 hours (Bronson et al., 1984). The plasma half-life of THC in dogs is 8 days, in rabbits 2 to 4 days, and in rats 5 days (Agurell et al., 1986).

In plasma, approximately 97% to 99% of THC and its metabolites are bound to lipoproteins and albumin

(Dewey, 1986). Two hours after rabbits were administered an intraperitoneal dose of <sup>3</sup>H-THC, the greatest amount of radiolabel was found in the kidney, urine, and bile, with lesser amounts detected in the lung and liver, and still smaller amounts in the adrenal glands, spleen, and ileum. The least amount of radiolabeled compound was detected in the brain and spinal cord. Compared to the levels in other tissues, the quantity of radiolabel had increased in adipose tissue 72 hours following administration of the dose to rabbits (Agurell et al., 1970). THC is lipophilic and is accumulated in higher concentrations in the adipose tissues than in other tissues (Lemberger and Rubin, 1976; Bronson et al., 1984). Preferential accumulation of THC has been observed in the gonadal fat tissues of male and female mice (Rawitch et al., 1979). THC has been shown to cross the placenta and enter the fetuses of experimental animals (Kennedy and Waddell, 1972), and to transfer to suckling young via the milk of rats and monkeys (Jakubovič et al., 1973; Chao et al., 1976).

THC is metabolized primarily by the microsomal enzymes which are inducible (Burstein and Kupfer, 1971; Okamoto *et al.*, 1972). The isozyme involved in metabolizing THC has been identified and purified from male mice and has been designated as  $P_{450}$  MUT-2 which belongs to the  $P_{450}$  2C subfamily (Watanabe *et al.*, 1993).

There are qualitative differences in the metabolism of THC between different organs in an animal. For example, in the rat liver the predominant metabolite is the 11-hydroxylated THC, whereas in the lung it is the  $6\alpha$ -hydroxy-THC (Agurell et al., 1986). There are also species differences in the biotransformation patterns of THC. In mice (strain unspecified)  $6\alpha$ -hydroxylation is dominant over B-hydroxylation, whereas in man the reverse is true (Agurell et al., 1986). A general outline of the major metabolic and excretory pathway is shown in Figure 1.

#### Humans

Inhaled or orally administered THC is readily absorbed. Serum levels measured following inhalation of [14C]-THC were higher than those measured after oral administration, and levels of serum radiolabel persisted for a shorter duration following inhalation (Lemberger *et al.*, 1971). In the study by Lemberger, 5 mg of THC inhaled resulted in a

FIGURE 1
Major Metabolic and Excretory Pathway of 1-Trans-Delta<sup>9</sup>-Tetrahydrocannabinol (Garrett, 1979)

maximum plasma concentration of 100 ng/mL after 5 minutes, and the level declined rapidly; however, 20 mg of THC orally administered resulted in a maximum plasma concentration of 10 ng/mL after 1 hour. The resulting differences in the two routes of administration are due to slow and incomplete absorption, liver extraction and enzymatic metabolism, and transformation of the compound into inactive cannabinoids by stomach acid (Ohlsson et al., 1980). The oral route of administration produced less intense intoxication and a longer latency of onset compared with the inhalation route.

The pharmacokinetics of THC are not dose dependent, but are characterized by rapid disappearance of the compound from plasma and a much longer period during which THC can be detected in various body tissues. The compound remains discernable due to continuous penetration into and return from numerous body compartments. The half-life of THC in the tissues is 7 days. Complete elimination of a single dose of THC may take more than a month. THC administered daily is continuously accumulated in the body (Nahas, 1979).

In a study by Lemberger and Rubin (1976), the plasma half-life of THC in a person not previously exposed to the compound was 56 hours, whereas the half-life in a chronic marijuana smoker was only 27 hours. The shorter half-life of THC in a chronic marijuana user is probably due to higher metabolic enzyme activities. However, Hunt and Jones (1980) and Ohlsson et al. (1982) found no significant differences in plasma profiles for chronic, moderate, and infrequent users; the half-life in all subjects studied was about 20 hours. There is no evidence that chronic THC administration alters disposition or metabolism of THC in the brain and peripheral tissues.

In humans, as in most mammalian species, the biotransformation pathway for cannabinoids is hydroxylation occurring at several positions. The most prominent pathway is hydroxylation at the allylic positions (C-8 and/or C-11).

The biological activity of THC may be largely attributable to the 11-hydroxy metabolite (Watanabe *et al.*, 1990). Hydroxylation at C-8 diminishes the biological activity. The dihydroxylated metabolites are also less potent than the parent compound (Dewey *et al.*, 1984). A trace amount of  $9\alpha$ ,  $10\alpha$ -epoxyhexahydro-

cannabinol has been reportedly formed in human liver (Halldin et al., 1982), but the biological significance of the epoxide is not known.

The secondary metabolism of THC involves glucuronidation of the carboxylic and phenolic groups. Following a single oral dose of THC in a human, the metabolites, in the form of free acid and glucuronide conjugates, are detected in the blood for up to 5 days (Law et al., 1984). The glucuronides are stored in body fat for a long period of time and can be detected in urine several weeks after exposure (Mechoulam et al., 1992). Generally, the polyhydroxylated compounds, the 11-oic acids (11-nor-acids) and their conjugates, are excreted in the bile and urine. However, the biliary-excreted metabolites (the acids and the hydroxylated compounds and conjugates) were enterohepatically recirculated, which contributed to their persistence in the body (Lemberger, 1972).

Biliary excretion via the feces is the major route of THC excretion. About 40% to 50% of administered THC is excreted in the feces within 5 days. Fecal metabolites are nonconjugated and contain both acidic and neutral metabolites.

Urinary excretion is a minor route of elimination of THC. In humans, about 13% to 16% of administered THC is found as metabolites in the urine within 72 hours (Well et al., 1984). However, the metabolites of orally administered THC can be detected in the urine for up to 12 days (Law et al., 1984). The urinary metabolites are excreted as glucuronide conjugates. The major urinary metabolite is 11-nor-THC-9-carboxylic acid (THC-COOH). Only trace quantities of neutral cannabinoids are found in the urine.

### MECHANISM OF ACTION

Many of the characteristic motor and cognitive effects of THC have been shown to be mediated via a G-protein-coupled receptor (Pertwee, 1993). However, since the effects of THC are diverse, many of the effects may be mediated via other mechanisms. There is evidence for the existence of THC receptors. The double bond in the 9/10 position of the A ring in the THC molecule is essential for activity, suggesting a structure-activity relationship. Interactions with binding sites and second messenger systems and the

Introduction 17

behavioral effects of cannabinoids are determined by the structural and geometric features of the cannabinoid molecules, indicating chemical selectivity and stereoselectivity. Additionally, the potency of THC is similar to those of other types of drugs known to act through receptors, and large amount of specific, high-affinity cannabinoid binding sites in the brain have been detected through the use of antagonists (Pertwee, 1993). THC inhibits adenyl cyclase activity in a dose-dependent, reversible, stereoselective and pertussis toxin-sensitive manner, suggesting a signal transduction mechanism (interaction with second messenger systems, cAMP and calcium). Finally, a functional cannabinoid receptor (SKR6) has been cloned, and the specific binding sites in rat and human brain tissues have been identified. identification of an endogenous cannabinoid named anandamide has strengthened the concept of the existence of cannabinoid receptors (Devane et al., 1992). As a result, the idea that cannabinoids react nonspecifically with membrane lipids has been rejected (Pertwee, 1993).

Binding of THC to the receptor activates G protein to stimulate phospholipase A2 or C to hydrolyze phospholipids and release arachidonate. The release of free arachidonic acid is followed by the synthesis of eicosanoids, including prostaglandins, leukotrienes, and 5-hydroxyeicosatetraenoic acid. Many of the biological effects of THC (i.e., sedation, catalepsy, antiinflammation, analgesia, hypothermia) have been shown to be mediated via eicosanoids. For example, it has been demonstrated in rodents that sedation or catalepsy induced by THC was mediated via an increase in prostaglandin E2 in brain tissue and in plasma (Burstein, 1992).

### **TOLERANCE**

Tolerance to THC can be divided into 2 types: pharmacokinetic and pharmacodynamic. Pharmacokinetic tolerance refers to changes in absorption, distribution, metabolism, or excretion; the changes lead to a reduction of the active form of the chemical at the site of action. Pharmacodynamic tolerance is the result of adaptational changes in the brain. Tolerance to THC is believed to be pharmacodynamic in nature (Pertwee, 1988). After repeated THC exposure, tolerance to THC in humans and animals develops (Dewey, 1986; Pertwee, 1991). The rate of onset and degree of tolerance is governed by

dose and exposure frequency. Tolerance does not develop when doses are small or infrequent and the exposure duration is short. Tolerance to some chemical effects (cataleptic, ataxic, convulsive and anticonvulsive, hypothermic, hypotensive, antinociceptive, immunosuppressive, alterated response rates and accuracy of schedule-controlled behaviors) appears to develop more readily, or the effect may be reversed (e.g., hypothermia becomes hyperthermia [Pertwee, 1991; Abood and Martin, 1992]).

Lemberger et al. (1971) showed that labeled THC administered intravenously had a half-life of 28 hours in the plasma of chronic marijuana users and 57 hours in the plasma of non-users. However, these results have not been confirmed by other investigators (Agurell et al., 1986). Daily intramuscular administration of THC to rhesus monkeys disrupted menstrual cycles, ovulation, and cyclic serum sex hormone levels during the first few months of administration. After that, normal menstrual cycles and serum estradiol, progesterone, and prolactin levels resumed (Smith et al., 1983). Because there are no differences in the metabolism or disposition of cannabinoids in THC-tolerant animals, tolerance could develop as a result of functional changes (loss of sensitivity to the effects of THC) (Agurell et al., 1984; Dewey, 1986; Pertwee, 1991).

Neurochemicals such as acetylcholine, dopamine, 5-hydroxytryptamine, opioids, and prostaglandins may play a role in the development of tolerance (Pertwee, 1991). Smith *et al.* (1983) have suggested that tolerance is due to adaptation of neural mechanisms in the hypothalamus.

One cellular mechanism for tolerance is the downregulation of receptors. Eldridge et al. (1991) demonstrated that rats repeatedly exposed to THC had decreased numbers of receptors in the brain, resulting in reduced sensitivity to THC. The amounts of THC bound in all structures measured in selected striatal levels of rat brain were reduced following daily intraperitoneal administration of THC at 10 mg/kg for 14 days; the levels in the medial septum/ diagonal band were reduced 32%, and those in the lateral caudate-putamen were reduced 52% (Oviedo et al., 1993). The change in the amount of THC bound was a result of a loss of binding capacity (B<sub>max</sub>) rather than a change in affinity (KD) (Oviedo et al., Westlake et al. (1991) demonstrated that there were no irreversible changes in brain cannabinoid receptor populations in rats following their exposure to THC for 6 months and in monkeys after exposure to marijuana smoke for one year.

In a study by Dill and Howlett (1988), tolerance developed through the uncoupling of receptors from their second messenger systems. When N18TG2 neuroblastoma cells were exposed to THC, a loss of cannabinoid-mediated inhibition of adenylate cyclase activity occurred. The attenuation process is time-and dose-dependent and reversible (Dill and Howlett, 1988).

### BIOLOGICAL EFFECTS

### Experimental Animals

Neurobehavioral effects of THC in experimental animals include central nervous system stimulation and depression, aggressiveness (rats), "popcorn effects" (mice), static ataxia (dogs), corneal areflexia (rabbits), and overt behavior (monkeys).

In squirrel monkeys injected intravenously with THC (2 to 30 mg/kg), an euphoric, quiet effect with disruption of perception was observed at low doses, stimulation and lack of coordination at medium doses, and severe psychomotor incapacitation at higher doses (McIsaac et al., 1971). Rhesus monkeys fed THC displayed increased irritability and aggressiveness (Nahas and Paton, 1979). In cats, a single intravenous, oral, or intramuscular 800  $\mu$ g/kg dose of THC produced marked ataxia, vocalization, excitement, and pronounced startle behavior (McCarthy et al., 1984).

In rats fed up to 50 mg THC/kg body weight for 6 months, behavioral alterations varied with the time interval of treatment. Central nervous system depression, which included symptoms of ataxia, incoordination, decreased exploratory activity, and general depression, was observed initially. Prolonged treatment led to tolerance development and central nervous system stimulation symptoms which included irritability, hypersensitivity, hyperactivity, aggression, tremors, and convulsions (Luthra et al., 1975). The animals also exhibited impaired specific motor and learning skills and unusual aggressive behavior toward smaller rodents (Nahas and Paton, 1979). Mice treated with a single dose of THC showed increased aggression (Leuschner et al., 1984).

In monkeys exposed to marijuana via a smoking machine for 3 to 6 months, permanent brain wave changes were observed in the limbic structures that control emotion, pleasure, endocrine function, and memory storage. The brain wave changes consisted of irritative tracings with high amplitude waves or Ultrastructural examination showed that histopathologic alterations occurred in the hippocampus of the brain in monkeys exposed to 0.69 mg THC/kg body weight intravenously daily for 6 months. The histopathologic changes included presence of electron-opaque material and clumping of synaptic vesicles in the synapse, fragmentation and disorganization of the rough endoplasmic reticulum. and inclusion bodies in the nuclei. The changes persisted during an 8-month postexposure period (Heath et al., 1980). Oral treatment with THC (50 mg/kg for 180 days) depressed brain acetylcholinesterase activity in females rats, but the enzyme activity was elevated in male rats (Luthra et al., 1975).

THC appears to affect all major neurotransmitter systems (release and/or uptake) including the cholinergic, dopaminergic, adrenergic, serotonergic, and GABAergic systems (Martin, 1986; Pertwee, 1988). THC appears to act presynaptically to alter neurotransmitter synthesis, storage, release, and fate, and postsynaptically to alter neurotransmitter receptormediated events both at the level of the recognition site and at the level of second messenger systems. Evidence has been presented to demonstrate that THC affects memory via the hippocampal acetylcholine-releasing neurons, locomotor activity via dopamine-releasing neurons of the nucleus accumbens, catalepsy via the dopamine-releasing neurons of the striatum, and convulsions via y-aminobutyric acid turnover in the septum and substantia nigra (Pertwee, 1988). However, the causal relationships between the THC-induced changes in neurouptake/release and psychological, behavioral, physiological, and neuropharmacological changes in an animal remain to be established.

THC is a potent hypothermic agent. Dose-related hypothermia effects in mice were reported at doses of 5 to 100 mg/kg (Dewey, 1986). The hypothermic effect may be mediated in part by depressing thermogenesis at centers in the caudal brain stem, as well as by an action at the thermosensory neurons in the anterior hypothalamus and preoptic area (Schmeling

and Hosko, 1980; Fitton and Pertwee, 1982; Howlett et al., 1990). The effect may also be mediated by interference of neurotransmitter uptake and release, possibly by inhibition of the membrane-bound adenosine triphosphatase (ATPase) associated with synaptosomes or synaptic vesicles. Certain prostaglandins are known to produce hyperthermia. THC has been shown to reduce prostaglandin production in the hypothalamus (Martin, 1986). Holtzman et al. (1969) reported that change in brain levels of 5-hydroxytryptamine following THC administration correlated with the duration of hypothermia in mice. Others have reported that the hypothermic effect of THC did not correlate with the change in brain 5-hydroxytryptamine levels (Watanabe et al., 1984) and suggested that the effect is mediated by catecholamines (Yagiela et al., 1974; Singh and Das, 1976). Serotonergic mechanisms have also been suggested (Dewey, 1986). Thus, further work is required to understand the mechanism involved in hypothermia.

THC interacts with the nuclear membrane of cells and causes changes of membrane configuration leading to conformational changes of membrane bound transport and enzyme systems. This interaction causes interference with the synthesis of nucleic acids and proteins. Inhibition of the synthesis of DNA, RNA, and protein has been reported in cultured lymphocytes from THC-treated monkeys, rats, guinea pigs, and mice. Various unicellular organisms, cultured malignant cells, and human lymphocytes exposed to THC in vitro have also showed suppressed macromolecular synthesis (ARF/WHO 1981, Desoize et al., 1991). example, growth of transplantable Lewis lung adenocarcinoma in vivo was retarded by oral administration of THC (25, 50, or 100 mg/kg daily for 10 days) in a dose-dependent fashion (Munson et al., 1975). The mechanism may involve dissolution of cell membrane by THC, which would prevent the transport of precursors for DNA, RNA, and protein synthesis and inhibition of acetylation and phosphorylation of chromosomal proteins. Finally, the mechanism would prevent the transcription of DNA (Nahas and Paton, The inhibitory effect of macromolecular synthesis has important implications because of the possible impact on the rapidly proliferating cells of the immune system, the intestinal mucosa, and the cells involved in spermatogenesis and fetal development.

THC also inhibits ATPases, adenylate cyclase, monoamine oxidase, and a number of enzyme systems in vivo (Martin, 1986). The general inhibitory effect of THC on enzymes implies perturbation of cell membranes; however, the precise biochemical process involved is not clear (Martin, 1986). The inhibitory effect on adenylate cyclase is similar to that produced by hormone-receptor interactions.

#### Humans

Neurobehavioral effects of THC in humans include: euphoria, tranquility, difficulty in thinking or remembering, rapid flow of thoughts, dreamy states, impairment of short-term memory consolidation, altered perception of visual or auditory stimuli, and distortions in duration of time. An acute dose of marijuana induces changes in mood, perception, judgment, memory, and psychomotor coordination. These changes can include anxiety, panic, paranoia, disorientation, catatonia-like immobility, mixed anxiety and sedation, euphoria, and impaired short-term memory. The effect peaks immediately after smoking and lasts for 2 to 3 hours after a single cigarette. With oral doses, the onset of behavioral effects is delayed, and the effects last longer. Chronic effects of marijuana on behavior have also been described, but quantitative data are lacking (Comm. Inst. Med., 1982).

Discussion of Biological Effects Across Species Herkenham et al. (1990) first identified the stereospecific THC receptors on brain slices sampled from rat, rhesus monkey, and man. The pattern of binding is conserved across these species. The greatest density of receptors is observed in the globus pallidus, the substantia nigra pars reticulata, the molecular layer of the dentate gyrus of the hippocampus, and the cerebellar molecular layer. Binding at these sites appears to correlate well with behavioral alterations. There is evidence suggesting that the frontal cortex is the site where incoming information is processed and where voluntary somatosensory stimuli required for equilibrium and motor coordination are initiated. The hippocampus is the site for memory transfer and consolidation (Rawlins, 1985). Its also codes temporal and spatial relations between stimuli and responses (Eichenbaum and Cohen, 1988). The limbic area is involved in short memory recall, and the basal ganglia in cataleptic response.

THC appears to affect all major neurotransmitter systems (release and/or uptake) including the cholinergic, dopaminergic, adrenergic, serotonergic, and GABAergic systems *in vitro* (Martin, 1986; Pertwee, 1988).

In humans, THC use is associated with moderately strong cardiovascular effects. Oral doses of THC of 70 to 210  $\mu$ g per day in humans initially produced tachycardia (increased heart rate, decreased standing blood pressure, and increased supine blood pressure). THC appears to act on the alpha-adrenoceptors that are located in the neighborhood of the cerebral ventricle and cause increased sympathetic outflow in the accelerans nerves (Graham, 1986a,b). But tolerance developed after repeated doses of THC and tachycardia became bradycardia (Jones and Benowitz 1976; Perez-Reyes et al., 1991). In contrast, in most other mammalian species the response to acute exposure to marijuana or THC is bradycardia (Vollmer et al., 1974; ARF/WHO, 1981); tolerance to this effect also developed after prolonged exposure (Adams et al., 1976).

Because THC and steroids have similar chemical structures and physical properties and the brain appears to have receptors for all five classes of steroids (estrogens, progestins, androgens, gluco-corticoids, and mineralocorticoids), many THC effects may be exerted at steroid hormone target sites (Martin, 1986).

THC exerts an inhibitory effect on the hypothalamopituitary-gonad axis. The effect disturbs the synthesis and secretion of follicle stimulating hormone, luteinizing hormone, prolactin, thyroxin, testosterone, estrogen, and progesterone, which in turn affects the maturation of germ cells and ovarian function. Conversely, THC elevates serum adrenal cortical steroids levels.

Chronic exposure to THC significantly suppresses plasma levels of prolactin in male and female rats and rhesus monkeys (Chakravarty et al., 1975; Kramer and Ben-David, 1978; Asch et al., 1979). Smoking of marijuana cigarettes also significantly lowers plasma prolactin levels during the luteal phase of menstrual cycles in women (Mendelson et al., 1985). The inhibitory effect of THC on prolactin release was observed only during the morning of estrus in female rats (Bonnin et al., 1993). The effect was mediated

through increases in the activity of tuberoinfundibular dopaminergic (TIDA) neurons and the sensitivity of the anterior pituitary gland to dopamine (Bonnin et al., 1993). THC may also act directly on the anterior pituitary by antagonizing the effects of estradiol on anterior pituitary prolactin release in immature female rats (Murphy et al., 1991, in Bonnin et al., 1993).

THC inhibits the midcycle luteinizing hormone surge and resultant ovulation in female rats (Ayalon et al., 1977), rabbits (Asch et al., 1979), and rhesus monkeys (Asch et al., 1981). Smith et al. (1980a) reported that plasma luteinizing hormone and follicle stimulating hormone in castrated rhesus monkeys fell significantly following acute administration of THC. However, luteinizing hormone release was stimulated by luteinizing hormone-releasing factor and prolactin release was stimulated by thyrotropin-releasing hormone in the castrated monkeys. The experiment demonstrated that THC acts at the hypothalamus.

THC alters the output of gonadotropin in the pituitary resulting in decreased estrogen activity. Direct interaction of THC with estrogen receptors to produce an estrogenic or antiestrogenic effect has been suggested, but evidence shows that THC was unable to compete with estradiol in binding to cytosol from monkey and human uteri (Martin, 1986). Direct inhibitory effects on progesterone and estradiol production in rat granulosa cells (Adashi et al., 1983) and isolated graafian follicles (Reich et al., 1982) and on progesterone production in rat luteal cells (Lewysohn et al., 1984) have been demonstrated. Treinen et al. (1993) showed that the inhibitory effect of THC on steroidogenesis by granulosa cells was due to inhibition of follicle stimulating hormone-activated cAMP accumulation.

A single oral dose (10 mg/kg) of THC significantly decreased serum testosterone levels in male rats (Rosenkrantz and Esber, 1980) and in men (Martin, 1986). The effect may be due primarily to the inhibition of gonadotropin secretion from the pituitary. However, chronic treatment with THC did not reduce serum testosterone in monkeys (Smith et al., 1980b) or in men (Martin, 1986). THC may also have a direct action at the gonadal level. Lactate and transferrin secretions in rat Sertoli cells are stimulated when testicular tissue is exposed to THC in vitro (Newton et al., 1993). THC also modulates

Sertoli cell response to follicle stimulating hormone. Reduction in steroidogenesis, protein and nucleic acid synthesis, glucose utilization, lactate and transferrin secretion,  $\gamma$ -glutamyl transpeptidase activity, and cyclic AMP levels have also been demonstrated.

Acute treatment with THC (2 to 20 mg) in rats and mice produced a prompt rise in serum corticosteroid levels, presumably caused by the action of THC on the hypothalamus and pituitary gland to increase adrenocorticotropic hormone. The response was muted after repeated treatment for 7 or 14 days (Eldridge et al., 1991). However, chronic treatment of rats and mice with THC led to increased adrenal weight. The adrenal cortical response to cannabinoids could not be demonstrated in other species, including humans. THC-mediated simulation of pituitary adrenocortical hormone secretion has been suggested to account for many of the behavioral, electroencephalographic, and pharmacologic actions of THC in animals (Drew and Slagel, 1973).

An oral dose (10 mg/kg) of THC for 14 days significantly decreased serum thyroxine and triiodothyronine levels in male rats (Rosenkrantz and Esber, 1980). The effect was not thought to be on the pituitary or the thyroid glands since the same dose of THC did not alter thyrotropin-releasing hormone in these animals. Prolonged administration of THC may promote thyroid hyperplasia.

### THERAPEUTIC EFFECTS

THC has been shown to have antiemetic properties. The antiemetic effect may result from actions affecting the vomiting center in the brain stem or affecting connected structures such as the amygdala and neocortex that modulate the activity of the vomiting center (Howlett et al., 1990).

Because the mechanism of action by which THC exerts its effect is not understood, the use of THC as an antiemetic is problematic. There are questions about its efficacy against a broad range of therapeutic regimens, and there are reservations about its neurobehavioral side effects. Recently, interests on the antiemetic properties of THC are waning as use of antagonists to the 5-hydroxytryptamine receptor, 5-HT<sub>3</sub> has become more widespread (Iversen, 1993).

THC has been used to reduce intraocular pressure in the treatment of glaucoma. However, no definitive evidence is available to explain the alteration of intraocular pressure by THC (Martin, 1986). THC may act as a vasodilator and cause a decrease in capillary pressure within the ciliary body, or the effects may be related to reduction of prostaglandins in the eye (Martin, 1986). The use of THC to treat glaucoma is impractical because it cannot be applied topically due to its insolubility in water and because of its psychoactive properties when given systemically. The use of  $\beta$ -adrenoceptor blockers or pilocarpine to treat glaucoma has diminished the interest in THC as a therapeutic agent for reducing intraocular pressure (Iversen, 1993).

THC has been shown to have bronchodilating action, but very little is known about its mechanism of action. Inhibition of prostaglandin synthesis has been suggested (Martin, 1986).

THC has been shown to be antinociceptive in experimental animals in the tail flick, hot plate, Nilsen, acetic acid or phenylquinone writhing tests, and pinch tests (Segal, 1986), but the effect is less potent than that of morphine (Dewey, 1986). The interest in the antinociceptive effect of THC is because the chemical does not induce physical dependence. Reports on the anti-inflammatory, analgesic, and antipyretic activity of THC are confusing (Dewey, 1986). THC appears to interact with a prostaglandin receptor coupled to adenylate cyclase to inhibit cAMP formation while producing the antinociceptive effect. The antiinflammatory and antinociceptive effects of THC may be mediated via a prostaglandin pathway. However, further studies are needed to determine its action.

THC depresses feed consumption in rats in a dose-related manner (Dewey, 1986), but tolerance develops after repeated exposure. Conversely, THC has been recommended for stimulating appetite in cancer and acquired immune deficiency syndrome patients (Plasse *et al.*, 1991). The mechanism of appetite stimulation by THC is not clear.

THC induces convulsions in rabbits and mice (Martin and Consroe, 1976; Karler et al., 1986; Turkanis and Karler, 1984). However, THC has also been shown to be an anticonvulsant (Fried and McIntyre, 1973; Karler et al., 1974, 1986; Corcoran et al., 1978). Pertwee (1988) has postulated that the anticonvulsant property of THC is due to its inhibition of depolarization-dependent Ca<sup>++</sup> uptake into brainstem synaptosomes.

### **TOXICITY**

### **Experimental Animals**

Signs of acute toxicity in rats include hypothermia, bradypnea, rapid weight loss, inactivity, wide stance, ataxia, muscle tremors, diarrhea, lacrimation, hyperexcitability, depression, loss of righting reflex, prostration, and dyspnea progressing to respiratory arrest. Deaths in animals after acute doses of THC are usually due to cardiac arrest or respiratory failure, and cardiac dysfunction is considered to be the major cause of death. The toxic signs disappear in 24 hours in the surviving animals. Table 1 presents LD<sub>50</sub> and LC<sub>50</sub> values for rat, mouse, and monkey studies.

Animals receiving chronic doses of cannabinoids exhibited behavioral changes characterized by hyperactivity, vertical jumping, fighting, and seizures (Rosenkrantz and Esber, 1980). Delayed lethality has been reported in animals receiving repeated high doses of THC, likely related to the cumulative effects of THC and/or its metabolites accumulated in the tissues (ARF/WHO, 1981).

### Humans

In humans, acute toxic effects include depression of the brain reticular system and the primary sensory pathways, disorientation, dissociation of personality, euphoria, emotional excitement, uncontrolled laughter, hallucinations, illusions, distortion of the sense of time and space, increased sensitivity to sound, loss of motor control and paresthesia. Acute and subacute doses of cannabis may produce vomiting, diarrhea, and abdominal distress (ARF/WHO, 1981).

# REPRODUCTIVE AND DEVELOPMENTAL TOXICITY

### **Experimental Animals**

Chronic oral doses of cannabinoids induced testicular atrophy in rats (Thompson et al., 1973). The weights of the ventral prostate, seminal vesicle, and epididymis were reduced in adult rats given marijuana extracts. Rats administered marijuana via inhalation through a smoking machine had significantly lower sperm counts and an increased number of abnormal sperm compared to controls; specifically, the abnormalities included dissociation of sperm heads and tails (Huang et al., 1979). Treatment of mice with THC produced reversible cytolytic changes in the testes (Dixit et al., 1974) and induced increased number of ring and chain translocations in primary spermatocytes (Zimmerman et al., 1979).

In vitro studies of cannabinoids on rat testicular cells and testicular slices support that THC acts directly on the testes. Protein synthesis of rat testicular tissues and testosterone production of Leydig cells in culture were depressed by THC (Jakubovič and McGreer, 1977; Jakubovič et al., 1979). In addition, THC has been shown to be antiandrogenic by competing with androgens for receptors (Purohit et al., 1980). Cannabinoid treatment also reduced the circulating levels of testosterone in rats (Fujimoto et al., 1978).

Introduction 23

Inhibition of ovulation, prolongation of estrous cycles, decrease of uterine and ovarian weights, and reduction in size of primordial ova by cannabinoids have also been observed in experimental animals (Dixit et al., 1975; Fujimoto et al., 1979; Smith et al., 1979). Female mice treated with THC had a higher incidence of abnormal fertilized ova (Henrich et al., 1983). THC given intraperitoneally to 27-day-old female rats twice daily at 10 mg/kg body weight retarded sexual maturation; the appearance of estrus and ovulation was delayed (Field and Tyrey, 1984). The effects of cannabinoids on the female reproductive system are probably due to their inhibitory actions on the hypothalamus and the subsequent effects on follicle stimulating hormone, luteinizing hormone, and prolactin releases by the pituitary. Specifically, THC has been shown to inhibit the midcycle luteinizing hormone surge and the resultant ovulation, progesterone, and estradiol production in rat granulosa cells. THC has also been shown to compete with estrogen for estrogen receptors, but the data have not been confirmed (Purohit et al., 1980).

The changes observed in sperm number and motility, endocrine profiles, and menstrual/estrous cycle after exposure to THC are expected to influence fertility. Dalterio et al. (1982) reported reduced fertility, increased pre- and post-natal fetal death, and reduced litter size among offspring of male mice treated with high doses of cannabis, but Wright et al. (1976) reported that subchronic or chronic treatment of rodents with THC had no effect on fertility, results that may have been related to the dosage used in the studies.

Cannabinoids are embryotoxic. Treatment with cannabinoid during the first two-thirds of gestation is associated with increased frequency of fetal resorption and decreased birth weights in mice, rats, rabbits, and hamsters (ARF/WHO, 1981). Body weight at birth and fetal resorption rates were dose related. Abel et al. (1981) demonstrated by pair feeding that neonatal mortality and intrauterine growth retardation were not due to maternal undernutrition resulting from marijuana or THC treatment. Pregnant rabbits given marijuana extracts had small placentas. In pregnant rodents treated with THC, the greatest concentration of the chemical was observed in the mother, a smaller concentration in the placenta, and still less was observed in the fetus. THC retention in the placenta appears to serve as a barrier against THC transfer to the fetus, but the absorbed THC in the placenta disrupts placental development or function (Sassenrath et al., 1979) and may contribute to abnormal fetal development and absorption. Hutchings and Dow-Edwards (1991) observed that dams treated with THC gave birth to more male offspring than female and postulated that THC may be selectively lethal to female embryos. Female rhesus monkeys treated chronically with THC and mated with untreated males had incidences of abortion and neonatal mortality four times greater than those in the control group (Sassenrath et al., 1979). Rosenkrantz and Esber (1980) demonstrated that THC altered serum follicle stimulating hormone and estrogen levels in pregnant rats. It is possible that the embryotoxicity evoked by THC is due in part to hormonal imbalance in the dams. The hormonal changes may also interfere with sexual differentiation of the fetuses (Dalterio and Bartke, 1981).

Animal studies have shown that marijuana extracts and THC are teratogenic. Pregnant hamsters and rabbits given marijuana extracts had embryos with malformations in the brain, spinal cord, forelimb, and liver (Gerber and Schramm, 1969). The offspring of pregnant mice administered THC (240 mg/kg) at critical stage of development (days 12 and 13) had significantly high incidences of cleft palate (Bloch et al., 1986) and exencephaly (Joneja, 1976), but abnormalities were not found in the fetuses when the pregnant mice were administered THC at 150 mg/kg during the 6th to 15th days of pregnancy (Fleischman Morishima (1982) observed that et al., 1975). 48-hour-old embryos from THC-treated mice contained abnormalities resulting from segregation errors and concluded that THC acts by disrupting the mitotic apparatus of the embryonic cells.

No behavioral teratogenicity was observed in rats exposed to THC *in utero* (Abel, 1984). However, offspring of treated female rhesus monkeys reportedly present anomalies of behavior and neuroendocrine function (Nahas, 1979).

Animal studies have repeatedly shown that cannabinoids cause a reversible reduction in body weight gain. This is likely due to decreased feed consumption and altered endocrine function (ARF/WHO, 1981). The body weights return to normal levels after THC treatment is stopped. Postnatal growth of rats exposed to THC in utero (dams administered

50 mg/kg throughout gestation) was normal when the rats were nursed by surrogate mothers, despite lower body weights at birth (Abel et al., 1981). However, Luthra (1979) reported that the offspring of rats treated during gestation and lactation with 5 or 10 mg/kg THC showed decreases in brain protein, RNA, and DNA.

#### Humans

Marijuana or THC appear to affect all phases of reproduction in males and females, including serum sex hormone levels, weight and functions of reproductive organs, and fetal development. These effects on reproduction may be due to the action of cannabinoids directly on the reproductive organs, indirectly by altering serum sex hormone levels, or a combination of both.

Chronic marijuana smokers had a significant decline in sperm concentration and total sperm count; sperm motility also decreased (Hembree et al., 1991). The sperm nuclei of hashish users showed abnormal staining characteristics (Stefanis and Issidorides, 1976). An oligospermia associated with abnormal forms and a decrease in spermatozoa motility were observed in 16 young marijuana smokers inhaling THC in 8 to 20 cigarettes per day for 5 to 6 weeks. Because hormonal suppression of spermatogenesis normally takes longer than 4 weeks to achieve and is usually not accompanied by an increase in abnormal sperm or a decrease in sperm motility, the authors concluded that the impairment was not due to hormonal changes but due to a direct effect of the cannabinoids on the seminiferous germinal epithelium (Hembree et al., 1991).

In females, THC or marijuana has been shown to block ovulation and disrupt the menstrual/estrous cycles. A group of young women smoking marijuana at least three times weekly had an increased incidence of abnormal menstrual cycle (Nahas, 1979).

In humans, in utero exposure to marijuana has been reported to be associated with voice anomalies, short stature, low body weight, decreased head circumferences, and decreased verbal and memory scores in infants and children (Nahas, 1993). There is no information on long-term effects of marijuana or THC on growth and body weight in humans.

### **IMMUNOTOXICITY**

### **Experimental Animals**

THC induces immunological defects, including: elongation of allogenic skin graft survival; reduction of primary antibody production against sheep red cells and number of plaque-forming cells (Schatz et al., 1993); suppression of mouse blood lymphocyte blastogenesis and splenocytes in response to plant mitogens or bacterial antigens (Friedman, 1991, Pross et al., 1993); alteration of delayed hypersensitivity response; involution of the thymus; depression of bone marrow myelopoiesis; perturbations of macrophage structure, function, and mobilization (Levy et al., 1974; Levy and Heppner, 1978; Johnson and Wierseman, 1974; Lefkowitz et al., 1978; Desoize et al., 1981); suppression of phagocytosis and spreading of mouse macrophages in vitro (Friedman, 1991); inhibition of natural killer cell activity, interferon production, interleukin 2 (IL-2) production, and ability to respond to Candida albicans and Legionella pneumophila infection of mouse lymphoid cells in vitro (Friedman, 1991); and suppression of macrophage extrinsic antiviral activity to herpes simplex virus type 2 (Cabral and Vasquez, 1992). Compared to controls, mice treated with THC were more prone to infection by Listeria monocytogenes or herpes simplex virus (Morahan et al., 1979; Cabral et al., 1986). The immunotoxic effects of THC are considered related to inhibition of macromolecular synthesis in response to external stimuli (Cabral and Vasquez, 1991).

However, the immunosuppressive effects of THC have been observed only at very high dose levels (Levy and Heppner, 1980). In rats, THC induced a dose-dependent increase in serum corticosterone levels (Zuardi et al., 1984). It is possible that certain aspects of immune suppression observed in vivo after THC administration are mediated by increased corticosteroid release.

#### Humans

Reports on the effects of marijuana on human immune systems are inconsistent. Decreases in T-cell counts, responsiveness to phytohemagglutinin stimulation of lymphocytes, phagocytic activity of polymorphonuclear leukocytes, and macrophage antiviral and antitumor activities have been observed. In addition, impairment of orderly T-cell replication and

cytolytic function, suppression of natural killer cell function, and suppression of interleukin-1, interleukin-2, cytokine, and interferon productions have also been reported (Donald, 1991). Conversely, other studies have reported that marijuana smoking has no effect on the human immune system and that hashish was a slight stimulant to the system. The inconsistency probably is due to the variation in doses, history of use, age, and assay systems (Comm. Inst. Med., 1982; Pross et al., 1993).

Recently, a cannabinoid receptor, termed CX5, has been found in the human spleen, tonsils, thymus, and peripheral blood mononuclear and polynuclear leukocytes, suggesting a possible role in inflammatory and immune responses (Boulaboula et al., 1993). The finding implies that THC may be able to modulate immunoresponses via the receptors. It also raises the possibility that the brain and peripheral cannabinoid receptors are different and that the differences can be exploited for medical use (Iversen, 1993).

### **NEUROTOXICITY**

Rats receiving THC initially exhibit signs of central nervous system depression, but central nervous system stimulation is observed as tolerance to the depression develops. The typical signs of neurotoxicity include popcorn response (involuntary vertical jumping reaction), tremors, convulsions, and aggressive behavior (fighting). Cessation of the drug results in symptoms of withdrawal or dependence, with restlessness, irritability, and insomnia.

Alterations in the hippocampus of animals exposed to THC have been reported. Monkeys administered 5 mg/kg body weight per day for 2 months developed altered synaptic width, endoplasmic reticulum alterations, and nuclear inclusions (Heath et al., 1979). Rats receiving THC orally at doses of 40 to 60 mg/kg body weight per day for 60 days had decreased density of neuronal cells, reduction in synapse number, decrease in dendritic length, and increased extracellular space (Scallet et al., 1987). Rats administered 8 mg THC/kg body weight per day subcutaneously five times weekly for 8 months also showed decreased neuronal density and increased cytoplasmic inclusion (Landfield et al., 1988).

Young Fischer rats treated subcutaneously with 10 mg/kg THC for 8 months had significantly reduced

neuronal density and content of type II glucocorticoid receptors in the hippocampus. The type I glucocorticoid receptors were not affected. The degenerative changes were similar to those seen in older, untreated rats, or in rats treated with high levels of glucocorticoids (Eldridge et al., 1991).

### **CARCINOGENICITY**

### Experimental Animals

THC is not structurally related to any known carcinogen. Because the metabolites of THC include allylic alcohols and an epoxide, there may exist some potential for carcinogenicity through the ability of these metabolites to function as alkylating agents.

Rodents exposed to marijuana smoke showed changes in bronchial epithelium (ARF/WHO, 1981) and bronchiolitis and alveolitis with occasional granuloma formations (Fleishman *et al.*, 1979).

Montour et al. (1981) reported that radiation carcinogenesis was significantly enhanced by injecting marijuana extracts three times weekly following gamma irradiation. In this study, whether enhanced carcinogenesis was due to immunosuppression or tumor promotion by marijuana extract is not clear. The effects of THC alone could not be identified.

THC at 0.01  $\mu$ g/mL transformed Fischer rat embryo cells infected with Raucher leukemia virus after 13 passages. Injection of these cells to newborn Fischer rats produced sarcomas at the injection site (Price et al., 1972). Subcutaneous injection of THC into mice resulted in fibrosarcomas and mammary carcinomas at the site of injection; details of the studies are not available (Szepsenwol et al., 1978; 1980).

Rats treated with THC orally at doses of 2, 10, or 50 mg/kg for 6 months showed no histopathological changes despite reduced growth rate and increased organ/body weight ratio (Rosenkrantz *et al.*, 1975).

### Humans

No human epidemiological or case reports associating THC with human cancer have been found in the literature. However, regular use of marijuana reportedly has been associated with cancer of the respiratory tract (Taylor, 1988), upper digestive tract (Donald, 1991), lung (Ferguson *et al.*, 1989), and tongue

(Caplan and Brigham, 1990) in patients under the age of 40. Robison *et al.* (1989) reported increased incidences of leukemia in offspring of mothers who smoked marijuana before or during pregnancy.

Marijuana/hashish smoking has been implicated in chronic degenerative cellular changes in the lung (Abramson, 1974) and in the appearance of foci of bronchiolar ulceration, squamous metaplasia, and pigmented macrophages through much of the lung parenchyma (Morris, 1985).

Cultured human lung tissues exposed to marijuana smoke developed cellular aberrations which included abnormalities in mitosis, DNA complement and chromosomal number, and cellular proliferation (Leuchtenberger and Leuchtenberger, 1984). Dermal application of marijuana smoke condensate resulted in alterations of cell development in the sebaceous glands and in neoplasm formation.

### GENETIC TOXICITY

THC has been tested for mutagenic effects in a limited number of assays, but no adverse genetic effects of THC exposure have been convincingly demonstrated. THC was not mutagenic in Salmonella (Stoeckel et al., 1975; Blevins and Shelton, 1983; Zeiger et al., 1988), and no induction of chromosomal aberrations was observed in cultured human lymphocytes (Stenchever and Allen, 1972).

In vivo mammalian studies with THC appear to show conflicting results, but the positive responses reported in the literature are questionable. For example, Zimmerman et al. (1979) reported increased frequencies of abnormal sperm in mice treated by injection with 10 mg THC/kg body weight, once daily for five consecutive days. No similar studies using intraperitoneal injection as the route of administration have been reported.

Dalterio et al. (1982) observed increased frequencies of ring and chain quadrivalents in diakinesis-metaphase I spermatocytes of male mice treated with a single oral dose of 100 mg THC/kg body weight. In addition, they observed a marked reduction in fertility of male mice exposed to 50 mg THC/kg body weight three times per week for 5 weeks. This reduction was presumably the result of induced chromosomal abnormalities in the germ cells of the treated males.

However, only eight offspring, which demonstrated gross phenotypic abnormalities, were examined cytologically and only two of the eight were confirmed translocation carriers. In contrast, Stoeckel et al. (1975) reported no induction of dominant lethal mutations in an unspecified strain of male mice treated with up to 200 mg THC/kg body weight for 4 weeks. Generoso et al. (1985), concerned by the implications from the Dalterio et al. (1982) study of possible widespread germ cell damage among human populations exposed to marijuana, conducted a similar study. However, they increased the frequency of treatments from 3 per week to 5 per week; the dose level of 50 mg THC/kg body weight used by Dalterio et al. (1982) was retained. Generoso et al. (1985) found no induction of either dominant lethal mutations or heritable translocations in THC-treated male (C3H  $\times$  101)F<sub>1</sub> mice.

Results of in vivo micronucleus tests were mixed. Positive results were reported by Zimmerman and Raj (1980) in male B6C3F<sub>1</sub> mice administered an intraperitoneal injection of 10 mg THC/kg body weight once a day for 5 days or 5 to 20 mg/kg once. They also reported significant increases in chromosomal aberrations in bone marrow cells of mice treated five times with 10 mg THC/kg body weight. However, the lack of clarity in the protocol and data presentations in this report makes evaluation of the results difficult. No increases in the frequencies of micronucleated erythrocytes were observed in male or female Swiss mice injected intraperitoneally with 5, 10, or 20 mg THC/kg body weight twice at 24-hour intervals; bone marrow samples were taken 24 hours after the second dosing (Van Went, 1978). Additional negative micronucleus test results with THC administered by gavage were reported by Legator et al. (1974) and Stoeckel et al. (1975). THC, administered as a single subcutaneous injection (10 or 1,000 mg/kg) to Syrian hamsters, did not induce an increase in chromosomal aberrations in bone marrow cells harvested 1.5 to 96 hours after treatment (Joneja and Kaiserman, 1978).

There have been some reports of increased frequencies of chromosomal aberrations in peripheral lymphocytes of marijuana smokers (Stenchever et al., 1974), but because the subjects in these human studies were not screened for conventional cigarette use, and because subjects in the Gilmour et al. (1971) study were users of multiple drugs in addition to

marijuana, the data are unreliable. Nichols et al. (1974) reported no increase in the frequency of chromosomal aberrations in peripheral blood lymphocytes from healthy male volunteers administered 20 mg THC per day orally for a period of 12 days. All of these volunteers had histories of prior marijuana use. Thus, these human studies indicate that purified THC is probably not mutagenic, but that some other components of marijuana might be capable of inducing chromosomal damage.

### STUDY RATIONALE

The use of marijuana in the United States is wide-spread, and its major psychoactive component is THC. THC has been used to reduce intraocular pressure in glaucoma treatment and as an antiemetic drug during cancer chemotherapy, an analgesic, a muscle relaxant, an anticonvulsant, and to treat bronchial asthma, insomnia, hypertension, and depression. In spite of the widespread abuse of marijuana and its potential medical uses, no carcinogenicity study of THC has been reported. The

National Institute of Drug Abuse requested that carcinogenicity studies of marijuana be conducted. The Food and Drug Administration needed toxicity and carcinogenicity data in view of the medical uses of THC. In conjunction with these other agencies, the Chemical Selection Working Group of the National Cancer Institute nominated THC for study by the NTP.

This document reports the results of 13-week studies, 13-week with 9-week recovery studies, and 2-year studies in which THC was administered in corn oil by gavage to male and female F344/N rats and B6C3F<sub>1</sub> mice. The 13-week with 9-week recovery studies were conducted to investigate the persistence of the toxic effects of THC. In addition, genetic toxicology studies were conducted in Salmonella typhimurium, cultured Chinese hamster ovary cells, and mouse peripheral blood cells.

The gavage route of administration was selected because the amount of THC available for the studies was limited and because the quantity of THC administered could be accurately controlled.

### MATERIALS AND METHODS

# PROCUREMENT AND CHARACTERIZATION OF 1-TRANS-DELTA9TETRAHYDROCANNABINOL

1-Trans-delta9-tetrahydrocannabinol (THC) obtained from A. D. Little (Cambridge, MA) in one lot (16792-123), which was used during the 13-week and 13-week with 9-week recovery studies (recovery studies). For the 2-year studies, four lots (AJ-86.8, AJ-86.9, AJ-86.10, and AJ-86.11) were obtained from Aerojet Strategic Development Co. (Sacramento, CA) by the analytical chemistry laboratory, Midwest Research Institute (Kansas City, MO) and assigned lot number A042487. Identity, purity, and stability analyses were conducted by the analytical chemistry laboratory. Reports on analyses performed in support of the THC studies are on file at the National Institute of Environmental Health Sciences. The methods and results of these studies are detailed in Appendix I.

Both lots of the chemical, a honey-colored viscous liquid, were identified as THC by infrared, ultraviolet/ visible, and nuclear magnetic resonance spectroscopy. The purity of lots 16792-123 and A042487 was determined by elemental analyses, Karl Fischer water analysis, thin-layer chromatography, high-performance liquid chromatography, and gas chromatography. Elemental analysis for hydrogen was in good agreement with the theoretical values for THC: elemental analysis for carbon was higher than the theoretical value for THC. Karl Fischer water analysis indicated less than 1.4% water. Thin-layer chromatography showed one minor impurity spot. High-performance liquid chromatography with ultraviolet detection at 220 nm revealed a major peak and two impurities with areas of 0.5% and 1.1% of the major peak area for lot 16792-123, and a major peak and three impurities with areas of 0.2%, 0.8%, and 1.5% of the major peak area for lot A042487. Gas chromatography indicated one major peak and seven impurities with a combined peak area of 3.8% relative to the major peak for lot 16792-123 and one major peak and five impurities with a combined peak area of 2.6% relative to the major peak for lot A042487. The overall purity was determined to be

approximately 96% for lot 16792-123 and approximately 97% for lot A042487.

An impurity observed in lot 16792-123 by gas chromatography was identified by capillary gas chromatography/mass spectrometry as cannabinol. Cannabinol was quantitated to be 1.0% in this sample by high-performance liquid chromatography. For lot A042487, the 0.2% and 0.8% impurity peaks were identified as cannabinol and trans-delta8-tetrahydrocannabinol by retention time matching and by spiking with known standards.

Stability studies were performed by the analytical chemistry laboratory using high-performance liquid chromatography. These studies indicated that THC was stable as a bulk chemical for at least 2 weeks when stored in evacuated containers protected from light at temperatures up to 25° C. To ensure stability, the bulk chemical was stored at 5° C, protected from light, in evacuated glass septum vials with Teflon-lined septa. The stability of the bulk chemical was monitored by the study laboratory during the 13-week, recovery, and 2-year studies using high-performance liquid chromatography. No degradation of the bulk chemical was detected.

# PREPARATION AND ANALYSIS OF DOSE FORMULATIONS

The dose formulations were prepared by mixing THC with corn oil to give the required concentrations (Table I1). Dose formulation stability studies performed by the analytical chemistry laboratory using gas chromatography confirmed that the formulations were stable for 3 weeks at room temperature when stored under a nitrogen headspace protected from light. The dose formulations were stored for up to 3 weeks at approximately 5° C under a nitrogen or argon headspace.

Periodic analyses of the dose formulations of THC were conducted at the study laboratory and analytical chemistry laboratory using gas chromatography. During the 13-week and recovery studies, the dose formulations were analyzed 5 times; all were within

10% of the target concentrations (Table I2). During the 2-year studies, the dose formulations were analyzed approximately every 8 weeks, and were within 10% of the target concentrations 99% (68/69) of the time for both rats and mice (Table I3). Periodic analyses of the corn oil vehicle by the study laboratory demonstrated peroxide levels within the acceptable limit of 10 mEq/kg. Results of periodic referee analyses performed by the analytical chemistry laboratory agreed with the results obtained by the study laboratory (Table I4).

# 13-WEEK AND 13-WEEK WITH 9-WEEK RECOVERY STUDIES

The 13-week studies were conducted to evaluate the cumulative toxic effects of repeated exposure to THC and to determine the appropriate doses to be used in the 2-year studies. The 13-week with 9-week recovery studies (recovery studies) were conducted to evaluate the effect of a 9-week recovery period on the chemical-related changes observed following 13-week dosing.

Male and female F344/N rats and B6C3F<sub>1</sub> mice were obtained from Simonsen Laboratories, Inc. (Gilroy, CA). On receipt, the rats were 3 weeks old and the mice were 4 weeks old. Animals were quarantined for 13 or 14 days and were 5 or 6 weeks old on the first day of the studies. Before initiation of the studies, five male and five female rats and mice were randomly selected for parasite evaluation and gross observation for evidence of disease. At the end of the studies, serologic analyses were performed on 10 male and 10 female control rats and mice using the protocols of the NTP Sentinel Animal Program (Appendix K).

Groups of 10 male and 10 female rats and mice received THC in corn oil by gavage for 13 weeks at doses of 0, 5, 15, 50, 150, or 500 mg/kg. Additional groups of 10 male and 10 female rats received THC in corn oil by gavage for 13 weeks at the same dose levels, and were then allowed to recover during a 9-week treatment-free period. Feed and water were available ad libitum. Rats and mice were housed five per cage. Animals were observed twice daily, and clinical findings were recorded weekly. The animals were weighed initially, weekly, and at the end of the studies. Details of the study design and animal maintenance are summarized in Table 2.

At the end of the 13-week and recovery studies, samples were collected from all rats and mice for sperm morphology and vaginal cytology evaluations. The parameters evaluated are listed in Table 2. Methods used were those described in the NTP General Statement of Work (April, 1987). 7 consecutive days prior to scheduled terminal sacrifice, the vaginal vaults of the females were moistened with saline, if necessary, and samples of vaginal fluid and cells were stained. Relative numbers of leukocytes, nucleated epithelial cells, and large squamous epithelial cells were determined and used to ascertain estrous cycle stage (i.e., diestrus, proestrus, estrus, and metestrus). All male animals used in this special study were evaluated for sperm morphology, count, and motility. The right testis and right epididymis were isolated and weighed. The tail of the epididymis (cauda epididymis) was then removed from the epididymal body (corpus epididymis) and weighed. Test yolk (rats) or modified Tyrode's buffer (mice) was applied to slides and a small incision was made at the distal border of the cauda epididymis. The sperm effluxing from the incision were dispersed in the buffer on the slides, and the numbers of motile and nonmotile spermatozoa were counted for five fields per slide by two observers. Following completion of sperm motility estimates, each right cauda epididymis was placed in buffered saline solution. Cauda were finely minced, and the tissue was incubated in saline solution and then heat fixed at 65° C. Sperm density was then determined microscopically with the aid of a hemacytometer. To quantify spermatogenesis, testicular spermatid head count was determined by removing the tunica albuginea and homogenizing the left testis in phosphate-buffered saline containing 10% dimethyl sulfoxide. Homogenization-resistant spermatid nuclei were counted with a hemacytometer.

At the end of the 13-week and recovery studies, blood was collected for hematology from all surviving animals by cardiac puncture. Hematology analyses were performed automatically by a Coulter S560 whole blood analyzer, and leukocyte differentials were performed by microscopic identification of 200 leukocytes per animal. The hematology parameters measured are listed in Table 2. A necropsy was performed on all animals and organ weights were taken from all animals that survived to the end of the studies; organs weighed were brain, heart, right kidney, liver, lungs, right testis, thymus, and uterus. Tissues for microscopic examination were fixed and

preserved in 10% neutral buffered formalin, processed and trimmed, embedded in paraffin, sectioned to a thickness of 5 to 6  $\mu$ m, and stained with hematoxylin and eosin. A complete histopathologic examination was performed on all vehicle control and 500 mg/kg rats and mice, 150 mg/kg rats, and all rats and mice that died during the study. The organs and tissues routinely examined are listed in Table 2.

### 2-YEAR STUDIES

### Study Design

Groups of 60 to 80 male rats and 60 female rats were administered 0, 12.5, 25, or 50 mg THC/kg body weight in corn oil by gavage for 104 to 105 weeks. Groups of 60 to 80 male mice and 60 female mice were administered 0, 125, 250, or 500 mg THC/kg body weight in corn oil by gavage for 104 to 105 weeks (males) or 105 to 106 weeks (females). Up to 18 male rats and 18 male mice were removed for special studies at 15 months; results of these special studies are not presented in this Technical Report. As many as 10 male and 10 female rats and mice from each group were evaluated at 15 months for alterations in clinical chemistry and hematology parameters.

### Source and Specification of Animals

Male and female F344/N rats and B6C3F<sub>1</sub> mice were obtained from Taconic Farms (Germantown, NY) for use in the 2-year studies. Male rats were quarantined for 13 days and female rats were quarantined for 14 days before the beginning of the study. Male and female mice were quarantined for 15 days before the beginning of the studies. Rats and mice were approximately 7 weeks old at the beginning of the studies. Prior to study start, five male and five female rats and mice were selected for parasite evaluation and gross observation of disease. Serology samples were collected for viral screening. The health of the animals was monitored during the studies according to the protocols of the NTP Sentinel Animal Program (Appendix K).

#### **Animal Maintenance**

Rats and mice were housed individually. Feed and water were available *ad libitum*. Cages and racks were rotated once every 2 weeks. Further details of animal maintenance are given in Table 2. Information on feed composition and contaminants is provided in Appendix J.

### **Clinical Examinations and Pathology**

All animals were observed twice daily. findings were recorded at 4-week intervals. animals were weighed initially, weekly for the first 13 weeks, and at 4-week intervals thereafter. A complete necropsy and microscopic examination were performed on all rats and mice. At the 15-month interim evaluation, the adrenal glands, brain, right kidney, liver, ovary, prostate gland, right testis, seminal vesicle, spleen, thymus, and uterus were weighed. At necropsy, all organs and tissues were examined for grossly visible lesions, and all major tissues were fixed and preserved in 10% neutral buffered formalin, processed and trimmed, embedded in paraffin, sectioned to a thickness of 5 to 6  $\mu$ m, and stained with hematoxylin and eosin for microscopic examination. For all paired organs (i.e., adrenal gland, kidney, ovary), samples from each organ were examined. Tissues examined microscopically are listed in Table 2.

At the 15-month interim evaluation, samples were collected from all female rats for vaginal cytology evaluations. The parameters evaluated are listed in Table 2. Methods used were those described for the 13-week and 13-week with 9-week recovery studies.

At the 15-month interim evaluation, blood was collected for clinical chemistry (rats only) and hematology from the retroorbital sinus of as many as 10 males and 10 females from each dose group. Serum hormone levels were measured using radio-immunoassay kits and reagents from various manufacturers. Hematology analyses were performed by a Sysmex TOA E-2500, computer-controlled, 18-parameter fully automated hematology analyzer. It is used for the "in-vitro" diagnostic testing of whole blood specimens. The clinical chemistry and hematology parameters measured are listed in Table 2.

At the end of the 2-year study, serum was collected at various intervals from three male rats from each dose group for plasma THC levels. Sampling times and methodologies are listed in Table 2.

Microscopic evaluations were completed by the study laboratory pathologist, and the pathology data were entered into the Toxicology Data Management System. The microscopic slides, paraffin blocks, and residual wet tissues were sent to the NTP Archives for inventory, slide/block match, and wet tissue audit. The slides, individual animal data records, and

pathology tables were evaluated by an independent quality assessment laboratory. The individual animal records and tables were compared for accuracy, the slide and tissue counts were verified, and the histotechnique was evaluated. The quality assessment pathologist microscopically reviewed selected neoplasms and nonneoplastic lesions.

The quality assessment report and the reviewed slides were submitted to the NTP Pathology Working Group (PWG) chairperson, who reviewed the selected tissues and addressed any inconsistencies in the diagnoses made by the laboratory and quality assessment pathologists. Representative histopathology slides containing examples of lesions related to chemical administration, examples of disagreements in diagnoses between the laboratory and quality assessment pathologist, or lesions of general interest were presented by the chairperson to the PWG for review. The PWG consisted of the quality assessment pathologist and other pathologists experienced in rodent toxicologic pathology. This group examined the tissues without any knowledge of dose groups or previously rendered diagnoses. For the 2-year studies, tissues examined in male and female rats included the forestomach (males), lung, pituitary gland, liver, pancreas (males), spleen, and testis. Tissues examined in male and female mice included the adrenal gland (females), brain, forestomach, kidney, liver, and thyroid gland. When the PWG consensus differed from the opinion of the laboratory pathologist, the diagnosis was changed. Thus, the final diagnoses represent a consensus of quality assessment pathologists, the PWG chairperson, and the PWG. Details of these review procedures have been described, in part, by Maronpot and Boorman (1982) and Boorman et al. (1985). For subsequent analyses of the pathology data, the diagnosed lesions for each tissue type were evaluated separately or combined according to the guidelines of McConnell et al. (1986).

### STATISTICAL METHODS Survival Analyses

The probability of survival was estimated by the product-limit procedure of Kaplan and Meier (1958) and is presented in the form of graphs. Animals found dead of other than natural causes were censored from the survival analyses; animals dying from natural causes were not censored. Statistical analyses for possible dose-related effects on survival used

Cox's (1972) method for testing two groups for equality and Tarone's (1975) life table test to identify dose-related trends. All reported P values for the survival analyses are two sided.

### Calculation of Incidence

The incidences of neoplasms or nonneoplastic lesions as presented in Tables A1, A5, B1, B5, C1, C5, D1, and D5 are given as the number of animals bearing such lesions at a specific anatomic site and the number of animals with that site examined microscopically. For calculation of statistical significance, the incidences of most neoplasms (Tables A3, B3, C3, and D3) and all nonneoplastic lesions are given as the numbers of animals affected at each site examined microscopically. However, when macroscopic examination was required to detect neoplasms in certain tissues (e.g., skin, intestine, harderian gland, and mammary gland) before microscopic evaluation, or when neoplasms had multiple potential sites of occurrence (e.g., leukemia or lymphoma), the denominators consist of the number of animals on which a necropsy was performed. Tables A3, B3, C3, and D3 also give the survival-adjusted neoplasm rate for each group and each site-specific neoplasm, i.e., the Kaplan-Meier estimate of the neoplasm incidence that would have been observed at the end of the study in the absence of mortality from all other competing risks (Kaplan and Meier, 1958).

### **Analysis of Neoplasm Incidences**

The majority of neoplasms in these studies were considered to be incidental to the cause of death or not rapidly lethal. Thus, the primary statistical method used was logistic regression analysis, which assumed that the diagnosed neoplasms were discovered as the result of death from an unrelated cause and thus did not affect the risk of death. In this approach, neoplasm prevalence was modeled as a logistic function of chemical exposure and time. Both linear and quadratic terms in time were incorporated initially, and the quadratic term was eliminated if the fit of the model was not significantly enhanced. The neoplasm incidences of exposed and control groups were compared on the basis of the likelihood score test for the regression coefficient of This method of adjusting for intercurrent mortality is the prevalence analysis of Dinse and Lagakos (1983), further described and illustrated by Dinse and Haseman (1986). When neoplasms are incidental, this comparison of the time-specific neoplasm prevalences also provides a comparison of the time-specific neoplasm incidences (McKnight and Crowley, 1984).

In addition to logistic regression, other methods of statistical analysis were used, and the results of these tests are summarized in the appendixes. These methods include the life table test (Cox, 1972; Tarone, 1975), appropriate for rapidly lethal neoplasms, and the Fisher exact test and the Cochran-Armitage trend test (Armitage, 1971; Gart et al., 1979), procedures based on the overall proportion of neoplasm-bearing animals.

Tests of significance included pairwise comparisons of each exposed group with controls and a test for an overall dose-related trend. Continuity-corrected tests were used in the analysis of neoplasm incidence, and reported P values are one sided. The procedures described in the preceding paragraphs were also used to evaluate selected nonneoplastic lesions. For further discussion of these statistical methods, refer to Haseman (1984).

### **Analysis of Nonneoplastic Lesion Incidences**

Because all nonneoplastic lesions in this study were considered to be incidental to the cause of death or not rapidly lethal, the primary statistical analysis used was a logistic regression analysis in which nonneoplastic lesion prevalence was modeled as a logistic function of chemical exposure and time. For lesions detected at the interim evaluation, the Fisher exact test was used, a procedure based on the overall proportion of affected animals.

### **Analysis of Continuous Variables**

Two approaches were employed to assess the significance of pairwise comparisons between exposed and control groups in the analysis of continuous variables. Organ and body weight data, which have approximately normal distributions, were analyzed using the parametric multiple comparison procedures of Dunnett (1955) and Williams (1971, 1972). Clinical chemistry, hematology, spermatid, and epididymal spermatozoal data which have typically skewed distributions, were analyzed using the nonparametric multiple comparison methods of Shirley (1977) and Dunn (1964). Jonckheere's test (Jonckheere, 1954) was used to assess the significance of the dose-related trends and to determine whether a trend-sensitive test (Williams' or Shirley's test) was more appropriate for pairwise comparisons than a test that does not assume a monotonic dose-related trend (Dunnett's or Dunn's test). Prior to statistical analysis, extreme values identified by the outlier test of Dixon and Massey (1951) were examined by NTP personnel, and implausible values were eliminated from the analysis. Average severity values were analyzed for significance using the Mann-Whitney U test (Hollander and Wolfe, 1973). Because vaginal cytology data are proportions (the proportion of the observation period that an animal was in a given estrous state), an arcsine transformation was used to bring the data into closer conformance with a normality assumption. Treatment effects were investigated by applying a multivariate analysis of variance (Morrison, 1976) to the transformed data to test for simultaneous equality of measurements across dose levels.

#### **Historical Control Data**

Although the concurrent control group is always the first and most appropriate control group used for evaluation, historical control data can be helpful in the overall assessment of neoplasm incidence in certain instances. Consequently, neoplasm incidences from the NTP historical control database (Haseman et al., 1984, 1985) are included in the NTP reports for neoplasms appearing to show compound-related effects.

### **QUALITY ASSURANCE METHODS**

The 13-week, 13-week with 9-week recovery, and 2-year studies were conducted in compliance with Food and Drug Administration Good Laboratory Practice Regulations (21 CFR, Part 58). In addition, as records from the 2-year studies were submitted to the NTP Archives, these studies were audited retrospectively by an independent quality assurance contractor. Separate audits covering completeness and accuracy of the pathology data, pathology specimens, final pathology tables, and a draft of this NTP Technical Report were conducted. Audit procedures and findings are presented in the reports and are on file at NIEHS. The audit findings were reviewed and assessed by NTP staff, so all comments had been resolved or were otherwise addressed during the preparation of this Technical Report.

### **GENETIC TOXICOLOGY**

The genetic toxicity of THC was assessed by testing the ability of the chemical to induce mutations in various strains of Salmonella typhimurium, sister chromatid exchanges and chromosomal aberrations in cultured Chinese hamster ovary cells, and by assessing the frequency of micronucleated erythrocytes in peripheral blood. The protocols for these studies and the results are given in Appendix E.

The genetic toxicity studies of THC are part of a larger effort by the NTP to develop a database that would permit the evaluation of carcinogenicity in experimental animals from the structure and responses of the chemical in short-term in vitro and in vivo genetic toxicity tests. These genetic toxicity tests were originally developed to study mechanisms of chemically induced DNA damage and to predict carcinogenicity in animals, based on the electrophilic theory of chemical carcinogenesis and the somatic mutation theory (Miller and Miller, 1977; Straus, 1981; Crawford, 1985).

There is a strong correlation between a chemical's potential electrophilicity (structural alert to DNA reactivity), mutagenicity in Salmonella, and carcino-

genicity in rodents. The combination of electrophilicity and Salmonella mutagenicity is highly correlated with the induction of carcinogenicity in rats and mice and/or at multiple tissue sites (Ashby and Tennant, 1991). Other in vitro genetic toxicity tests do not correlate well with rodent carcinogenicity (Tennant et al., 1987; Zeiger et al., 1990), although these other tests can provide information on the types of DNA and chromosome effects that can be induced by the chemical being investigated. Data from NTP studies show that a positive response in Salmonella is currently the most predictive in vitro test for rodent carcinogenicity (89% of the Salmonella mutagens were rodent carcinogens), and that there is no complementarity among the in vitro genetic toxicity tests. That is, no battery of tests that included the Salmonella test improved the predictivity of the Salmonella test alone. The predictivity for carcinogenicity of a positive response in bone marrow chromosome aberration or micronucleus tests is not yet defined.

#### 13-Week Studies

#### **Recovery Studies**

#### 2-Year Studies

#### Histopathology

Complete histopathology was performed on all animals that died before the end of the study, and on 0 and 500 mg/kg rats and mice, and 150 mg/kg rats. In addition to gross lesions and tissue masses, the tissues examined were: adrenal gland, bone and marrow, brain, epididymis, esophagus, gallbladder (mouse). heart, kidney, large intestine (cecum, colon, and rectum), liver, lymph node (mandibular and mesenteric), mammary gland, nose, ovary, pancreas, parathyroid gland, prostate gland, salivary gland, seminal vesicle. skin, small intestine (duodenum, jejunum, and ileum), spinal cord, spleen, stomach (forestomach and glandular stomach), testis, thymus, thyroid gland, trachea, urinary bladder, and uterus. The following organs were examined in surviving rats administered 5, 15, and 50 mg/kg: epididymis, stomach, and testis in males and adrenal gland, ovary, stomach, liver, and uterus in females. Additional organs examined in surviving mice at 5, 15, 50, and 150 mg/kg were: adrenal gland, epididymis, liver, testis, and thyroid gland in males and liver, ovaries. spleen, stomach, and uterus in females.

Complete histopathology was performed on all animals that died before the end of the study, and on 0 and 500 mg/kg rats and mice, and 150 mg/kg rats. In addition to gross lesions and tissue masses, the tissues examined were: adrenal gland, bone and marrow, brain, epididymis, esophagus, gallbladder (mouse), heart, kidney, large intestine (cecum, colon, and rectum), liver, lymph node (mandibular and mesenteric), mammary gland, nose, ovary, pancreas, parathyroid gland, prostate gland, salivary gland, seminal vesicle, skin, small intestine (duodenum, jejunum, and ileum), spinal cord, spleen, stomach (forestomach and glandular stomach), testis, thymus, thyroid gland, trachea, urinary bladder, and uterus. The following organs were examined in surviving rats administered 5, 15, and 50 mg/kg: epididymis, stomach, and testis in males and liver and uterus in females. Additional organs examined in surviving male mice a 5, 15, 50, and 150 mg/kg were: adrenal gland, epididymis, liver, testis, and thyroid gland. The uterus of surviving 15 and 50 mg/kg females was also examined.

Complete histopathology was performed on all animals that died before the end of the study, and on 0, 12.5, 25, and 50 mg/kg rats and on 0, 125, 250, and 500 mg/kg mice. In addition to gross lesions and tissue masses, the tissues examined were: adrenal gland, bone and marrow, brain, clitoral gland, epididymis, esophagus, eyes, gallbladder (mouse), heart, kidney, large intestine (cecum, colon, and rectum), liver, lungs, lymph node (mandibular and mesenteric), mammary gland, mainstem bronchi, nose, ovary, pancreas, parathyroid gland, pharynx, pituitary gland, preputial gland, prostate gland, salivary gland, seminal vesicle, skin, small intestine (duodenum, jejunum, and ileum), spinal cord, spleen, stomach (forestomach and glandular stomach), testis, thymus, thyroid gland, trachea, urinary bladder, uterus, and vagina.

#### Sperm Morphology and Vaginal Cytology Evaluations

At terminal sacrifice sperm samples were collected from all male animals for sperm morphology evaluations. The parameters evaluated included: sperm density, morphology, and motility. The right epididymis, and right testis were weighed. Vaginal samples were collected for up to 7 consecutive days prior to the end of studies from all female animals for vaginal cytology evaluations. The parameters evaluated included: relative frequency of estrous stages and estrous cycle length.

Same as 13-week studies

At the 15-month interim sacrifice, vaginal samples were collected for up to 7 consecutive days prior to the end of the study from all female rats for vaginal cytology evaluations. The parameters evaluated included: relative frequency of estrous stages and estrous cycle length.

# RESULTS

# RATS 13-WEEK AND 13-WEEK WITH 9-WEEK RECOVERY STUDIES

In the 13-week study, six male and six female rats receiving 500 mg/kg, two 50 mg/kg male rats, and one female administered 15 mg 1-trans-delta<sup>9</sup>-tetrahydrocannabinol (THC)/kg body weight died before the end of the study (Table 3a). With the exception of 5 mg/kg rats, the final mean body weights and weight gains of all dosed groups of males

and females were significantly lower than those of the controls.

In the 13-week with 9-week recovery study (recovery study), four male and seven female 500 mg/kg rats, three male 150 mg/kg rats, and one male 50 mg/kg rat died before the end of the study (Table 3b). Rats administered THC during the first 13 weeks of the recovery study gained weight quickly during the 9-week recovery period. Final mean body weights of all dosed groups were similar to those of the controls.

<sup>&</sup>lt;sup>a</sup> Number of animals surviving/number initially in group

Feed consumption by dosed groups of male and female rats was less than that by controls during the first part of the 13-week study, but was similar to that by controls at the end of 13 weeks (Table 3a). In the recovery study, feed consumption by 500 mg/kg females was less than that by controls during week 1, but was similar at weeks 13 and 22. Feed consumption by all other dosed groups of females and all dosed groups of males was similar to that by controls at weeks 1, 13, and 22 of the study (Table 3b).

Aggressive behavior became evident in both male and female rats during the 13-week and recovery studies; most of the rats had bite wounds on the tail and head. Other clinical findings observed during the studies included lethargy, sensitivity to touch,

diarrhea, convulsions, and tremors. Beginning at week 5 of the 13-week study, convulsions were observed in 150 and 500 mg/kg males and females. Convulsions were observed following the dosing procedure and at feeding or cleaning of cages (when the animals were handled) and were more frequent near the end of the week. The entire sequence of events that took place during a single convulsion occurred in a time span of approximately 10 to 30 seconds, and rats were hyperexcitable to routine handling for more than 5 minutes following the initial reaction. Convulsions may have occurred at times other than the daily treatment/observation periods. Convulsions were often followed by piloerection or prostration, and in some cases by rapid Beginning at week 8 of the recovery breathing.

b Weights and weight changes are given as mean ± standard error. Differences from the control group were not significant by Williams' or Dunnett's test.

<sup>&</sup>lt;sup>c</sup> Feed consumption is expressed as grams per animal per day.

<sup>&</sup>lt;sup>d</sup> Week of death: 13

e Week of death: 8, 13, 13

f Week of death: 1, 1, 12, 13

g Week of death: 1, 1, 1, 1, 2, 8, 10

study, convulsions were observed in 150 and 500 mg/kg males and females. Convulsions were often followed by hypersensitivity to touch.

At 13 weeks, the erythrocyte count and the hematocrit and hemoglobin values of 500 mg/kg female rats were significantly greater than those of the controls (Table G1), consistent with dehydration. At the end of the recovery study, erythrocyte count and hematocrit and hemoglobin values of 500 mg/kg females were similar to those of the controls (Table G2).

At 13 weeks, increases in the relative brain, heart, right kidney, and right testis weights of 15, 50, 150, and 500 mg/kg males were attributed to lower final mean body weights, as were the increases in relative liver weights of 150 and 500 mg/kg males (Table F1). Also at the end of the 13-week study, the right epididymal weight of 500 mg/kg males was significantly decreased, and there was an increase in the percentage of abnormal sperm in this group (Table H1). Treatment-related multifocal atrophy was observed in the testes of 150 and 500 mg/kg males in both the 13-week studies (Table 4). Atrophic seminiferous tubules were few to moderate in number, decreased in diameter, scattered across the histological section, and contained only a few spermatogonia-type cells and/or Sertoli cells surrounding empty lumens.

At the end of the recovery study, the relative liver weights of 150 and 500 mg/kg males were significantly greater than that of the controls (Table F2). The absolute right testis weight of 500 mg/kg males was significantly lower than that of the controls.

In females at the end of the 13-week study, the absolute and relative heart, right kidney, and liver weights of 500 mg/kg females were significantly greater than those of the controls, but the absolute and relative uterus weight of 50, 150, and 500 mg/kg females were significantly lower than those of the

controls (Table F1). Estrous cycle lengths of 15, 50, 150, and 500 mg/kg females were significantly longer than that of the controls (Table H1). Uterine and ovarian hypoplasia observed in 150 and 500 mg/kg females were considered to be related to THC administration (Table 4). The small uteri had decreased cellularity and thickness of the epithelial lining and a decreased number of endometrial glands. Ovarian hypoplasia was characterized by a decrease in the size of maturing follicles.

In females at the end of the recovery study, there were no significant differences in absolute or relative organ weights (Table F2), hematology parameters (Table G2), vaginal cytology, or estrous cycle lengths (Table H2). There were no treatment-related lesions observed in females.

Histopathology was performed on the brains of rats from the 13-week and recovery studies to detect any brain lesions that might be associated with convulsions. Hematoxylin- and eosin-stained sections of brain from all male and female vehicle control and 500 mg/kg rats from both studies were examined. Three sections of brain (frontal cortex and basal ganglia, parietal cortex and thalamus, and cerebellum and pons) were contained on each slide. Sections of brain from 500 mg/kg rats that convulsed during the studies did not differ from the sections of brain from rats that did not convulse or from vehicle control rats. Review of the sections revealed no evidence of lesions associated with convulsions or other treatment-related lesions in male or female rats from both studies.

Dose Selection Rationale: Based on reduced mean body weight gains, convulsions, and mortality observed in the 13-week study, dose levels selected for the 2-year gavage study in rats were 12.5, 25, and 50 mg/kg. The anticipation of tolerance development and dose levels reported in other investigators' studies were also taken into consideration.

#### 2-YEAR STUDY

#### Survival

Estimates of 2-year survival probabilities for male and female rats are shown in Table 5 and in the Kaplan-Meier survival curves (Figure 2). Survival of dosed male and female groups was generally significantly greater than that of the controls.

#### **Body Weights**

Mean body weights of dosed groups of males and females were lower than those of the controls throughout the study, but the final mean body weights of all dosed groups were only marginally lower than those of the controls (Figure 3 and Tables 6 and 7).

<sup>&</sup>lt;sup>a</sup> Interim evaluation occurred during weeks 65 and 66.

# Feed Consumption, Clinical Findings, and Organ Weights

Feed consumption was measured at 4-week intervals from week 65 to the end of the study. Feed consumption by dosed groups was similar to that by controls (Table 8). A slight but consistent trend of lower feed consumption was observed in vehicle control females. Convulsions and seizures were observed in all dosed groups of male and female rats. Convulsions were observed beginning at week 35 in 50 mg/kg males and week 22 in 50 mg/kg females, at week 41 for 25 mg/kg males, at week 31 for 25 mg/kg females, at week 66 for 12.5 mg/kg males, and at week 49 for 12.5 mg/kg females. The number of animals convulsing peaked at approximately weeks 62 through 65, when 47 males and 43 females adminis-

tered 50 mg/kg were observed with convulsions. Convulsions/seizures were more frequent in females than in males, and frequency appeared to be dose related (Figure 4); however, the intensity and duration of convulsions were similar in males and females. At the 15-month interim evaluation, relative brain and liver weights were generally significantly increased in dosed groups of males (Table F3). Relative brain, liver, and adrenal gland weights of dosed groups of females were also increased. Relative thymus weights of dosed groups of females were decreased. In females at the 15-month interim evaluation, there were no significant differences in vaginal cytology or estrous cycle lengths (Table H3). There were no treatment-related lesions observed in females.

TABLE 8

Daily Convulsion Incidence for Rats Administered THC in Corn Oil
by Gavage for 2 Years

## Hematology and Clinical Chemistry

Total leukocyte and lymphocyte counts in 25 and 50 mg/kg females were significantly greater than those of the controls at the 15-month interim evaluation (Table G3). The lymphocyte count of 12.5 mg/kg females was also significantly greater than that of the control. Concentrations of follicle stimulating and luteinizing hormones were increased in all male dosed groups.

#### Pathology and Statistical Analyses

This section describes the statistically significant or biologically noteworthy changes in the incidences of neoplasms and/or nonneoplastic lesions of the pancreas, pituitary gland, testis, mammary gland, uterus, lung, and brain and in the incidences of mononuclear cell leukemia in females. Summaries of the incidences of neoplasms and nonneoplastic lesions, individual animal tumor diagnoses, statistical analyses

of primary neoplasms that occurred with an incidence of at least 5% in at least one animal group, and historical incidences for the neoplasms mentioned in this section are presented in Appendix A for male rats and Appendix B for female rats. The incidences of benign and malignant neoplasms in male (Table A3) and female (Table B3) rats were decreased in a dose-related manner.

Mononuclear Cell Leukemia: At the end of the 2-year study, the incidence of mononuclear cell leukemia was marginally increased in 25 mg/kg females (Tables 9 and B3); however, the increase was not significant by life table analysis (the most appropriate test for these generally fatal neoplasms), and there was no significant trend. The increased incidence was due in part to the longer survival of dosed groups of animals, and the increase was not considered to be related to the administration of THC.

TABLE 9
Incidences of Mononuclear Cell Leukemia in Female Rats in the 2-Year Gavage Study of 1-Trans-Delta<sup>9</sup>-Tetrahydrocannabinol

Dose	Vehicle Control	12.5 mg/kg	25 mg/kg	50 mg/kg

Overall rate <sup>b</sup>	9/51 (18%)	17/51 (33%)	20/51 (39%)	13/50 (26%)
Adjusted rate <sup>c</sup>	32.3%	38.1%	47.6%	32.3%
Terminal rated	6/23 (26%)	13/40 (33%)	12/33 (36%)	6/32 (19%)
First incidence (days)	524	534	509	454
Life table test <sup>e</sup>	P = 0.460	P = 0.407	P = 0.130	P = 0.481
Logistic regression test	P=0.292	P = 0.102	P = 0.027	P = 0.246

Historical incidence of lymphocytic, monocytic, mononuclear cell, or undifferentiated cell type leukemia for 2-year NTP gavage studies with corn oil vehicle control groups (mean ± standard deviation): 277/1,070 (25.9% ± 7.2%); range, 12%-38%

Number of neoplasm-bearing animals/number of animals necropsied.

c Kaplan-Meier estimated neoplasm incidence at the end of the study after adjustment for intercurrent mortality

d Observed incidence at terminal kill

e Beneath the control incidence is the P value associated with the trend test. Beneath the dosed group incidence are the P values corresponding to pairwise comparisons between the controls and that dosed group. The logistic regression test regards lesions in animals dying prior to terminal kill as nonfatal. The life table test regards neoplasms in animals dying prior to terminal kill as being (directly or indirectly) the cause of death.

Results 53

Lung: Increased incidences of foreign bodies in the lung occurred in all dosed groups of males (vehicle control, 8/52; 12.5 mg/kg, 26/51; 25 mg/kg, 26/52; 50 mg/kg, 15/52; Table A5). All dosed groups of females had increased incidences of chronic inflammation at the 15-month interim evaluation (3/9, 3/9, 5/9, 4/10) and at the end of the 2-year study (25/51, 48/51, 43/51, 42/50; Table B5). Foreign body in the lung was characterized by droplets of yellow oil in alveolar spaces. In general, the presence of the droplets was not associated with the inflammatory process. Chronic inflammation was minimal to mild in severity. The incidence of chronic inflammation was approximately equal across the dose groups. Although the incidence was increased in dosed female rats, approximately one-half of the vehicle control females had a similar lesion. In addition, the incidence of chronic inflammation in males was approximately equal across all groups (37/52, 40/51, 40/52, 36/52). Therefore, this lesion was probably not due to a systemic effect of the chemical.

Brain: As in the 13-week and recovery studies, brain tissues from animals evaluated at 15 months and at the end of the 2-year study were subjected to a special review. Tissues from rats with a history of convulsions or seizures were examined; additional or special procedures were performed to facilitate detection of neuropathologic changes. Brain tissues from two vehicle control females and six 50 mg/kg females were step-sectioned in their entirety and examined. In addition, step sections were performed on the brain tissues of three 50 mg/kg males and one 50 mg/kg female killed moribund during the study and fixed by perfusion with Trump's fixative, vehicle control and 50 mg/kg males and females from the 15-month interim evaluation, and 50 mg/kg males and females that survived to the end of the 2-year study. No microscopic lesions were observed in any tissues evaluated by step section; no treatment- or convulsion-related lesions were observed. Neuronal necrosis was present in the cerebral cortex (25 mg/kg, 1/52), hippocampus (vehicle control, 4/52; 12.5 mg/kg 1/50), or cerebellar cortex (25 mg/kg, 1/52) in male rats and in the hippocampus (12.5 mg/kg, 1/51) and cerebellar cortex (12.5 mg/kg, 1/51) in female rats. Some of these animals also developed mononuclear cell leukemia, which may have resulted in localized ischemia (neuronal necrosis) due to neoplastic cells within vessels.

Decreased Neoplasm Incidences: Incidences of neoplasms were decreased in various organs in male and female rats (Tables 10, A3, and B3). These included pancreatic acinar cell adenomas in males (significantly decreased in all dose groups), pituitary gland adenomas in males (significantly decreased in 50 mg/kg males), uterine stromal polyps (significantly decreased in 25 and 50 mg/kg females), and mammary gland fibroadenomas (decreased in all dosed groups of females). Many of the decreased incidences may have been associated with decreased mean body weights in dosed groups of rats.

Incidences of interstitial cell adenomas of the testis were also significantly decreased in 12.5 and 25 mg/kg male rats. The decreased incidence was more prominent for bilateral interstitial cell adenomas (Tables 10 and A1). A similar response was observed at 15 months where nine vehicle control males and one 12.5 mg/kg male had interstitial cell adenomas. As in the 2-year study, this response was more striking for bilateral interstitial cell adenomas, where adenomas were observed in six vehicle controls, but none were observed in dosed groups. Although there was a decrease in the incidence of interstitial cell adenomas, the incidence of hyperplasia at 15 months and at 2 years was slightly increased. Proliferative lesions involving the interstitial cells of the testis in F344/N rats are common age-related changes. The decreased incidence of interstitial cell adenomas was considered to be related to THC administration.

#### THC Plasma Concentration Analyses

The concentration of THC in plasma from dosed male rats was measured at various time points following the end of the 2-year study (Figures 5 and 6). THC was detectable in samples 120 hours after the final dose was administered, and the levels were proportional to the amount of THC administered. Throughout the 2-year study, serum THC levels likely fluctuated near the ranges reflected in Figure 6 at 24 hours following the final dose.

#### **MICE**

# 13-WEEK AND 13-WEEK WITH 9-WEEK RECOVERY STUDIES

One 500 mg/kg male, three 150 mg/kg females, one male and one female administered 50 mg/kg, one 15 mg/kg female, one male and two females administered 5 mg/kg, and one vehicle control male died prior to the end of the 13-week study (Table 11a). The deaths were considered related to gavage error. The final mean body weight and weight gain of 500 mg/kg males were significantly lower than those of the controls.

In the 13-week with 9-week recovery study, one 50 mg/kg male and five 15 mg/kg males died before the end of the study, as did one 500 mg/kg female, two 150 mg/kg females, four 50 mg/kg females, two 15 mg/kg females, one 5 mg/kg female, and one vehicle control female (Table 11b). The final mean body weights of all dosed groups were similar to those of the controls.

Feed consumption by all dosed groups of males and females in the 13-week study was similar to that by

controls (Table 11a). During the recovery study, average feed consumption by dosed groups of males and females was slightly greater than that by controls (Table 11b), but the difference was not significant.

During both the 13-week studies, mice were aggressive, lethargic, and easily startled. In both studies, fighting among mice became more frequent after a few weeks of treatment. A number of mice were observed with wounds and/or hair loss on the head and/or abdomen, labored breathing, piloerection, and brief convulsions.

At the end of the 13-week study, the hematocrit, hemoglobin, and mean erythrocyte hemoglobin levels of 500 mg/kg males were significantly lower than those of the controls, as were the hemoglobin and mean erythrocyte hemoglobin levels of 500 mg/kg females (Table G4). At the end of the recovery study, there were no statistically significant differences in erythrocyte variables of male and female mice (Table G5).

<sup>\*</sup> Significantly different (P≤0.05) from the control group by Williams' or Dunnett's test.

At the end of the 13-week study, the relative liver weights of 500 mg/kg males and females were significantly greater than those of the controls (Table F4). Estrous cycle lengths of 5, 15, and 500 mg/kg females were significantly longer than for the controls (Table H4).

At the end of the recovery study, the absolute and relative uterus weights of 150 and 500 mg/kg females and the absolute uterus weight of 50 mg/kg females were significantly lower than those of the controls

(Table F5). Sperm concentration in 500 mg/kg males was significantly lower than that in controls (Table H5); there were no other significant differences in sperm morphology, vaginal cytology, or estrous cycle length parameters.

Dose Selection Rationale: Due to the absence of significant histopathologic lesions and marked effects on mean body weight gains in the 13-week study, doses selected for the 2-year mouse study were 125, 250, and 500 mg/kg.

## 2-YEAR STUDY

## Survival

Estimates of 2-year survival probabilities for male and female mice are shown in Table 12 and in the Kaplan-Meier survival curves (Figure 7). Survival of 500 mg/kg males was significantly less than that of the controls; survival of all other dosed groups of

males and of all dosed groups of females was similar to those of the controls.

#### **Body Weights**

Mean body weights of all dosed groups were markedly lower than those of the controls throughout the 2-year study (Figure 8 and Tables 13 and 14).

#### Feed Consumption and Clinical Findings

Feed consumption by male and female mice, measured at 4-week intervals beginning at week 94 of the study, was similar to that by controls (Table 15). Clinical findings in dosed groups included hyperactivity, convulsions, and seizures. Convulsions occurred following handling of the mice and were observed initially in 250 and 500 mg/kg males and females during the fourth month of the study, in male mice during the eleventh month of the study, and in 125 mg/kg female mice during the ninth month of the study. No convulsions were observed in vehicle control groups, and if any convulsions occurred at times other than daily treatment or handling inter-

vals, they were not recorded. Convulsions were not induced by auditory stimuli (i.e., hand clapping). Animals displayed periods of hyperactivity following convulsions. The frequency of convulsions is presented in Figure 9.

#### Hematology

Total leukocyte and lymphocyte counts in all dosed groups of males were significantly lower than those in the controls (Table G6). No other biologically significant differences in hematology parameters were observed in the remaining dosed groups of male mice or in dosed groups of females.

## Pathology and Statistical Analyses

This section describes the statistically significant or biologically noteworthy changes in the incidences of neoplasms and/or nonneoplastic lesions of the thyroid gland, liver, forestomach, and urinary tract. Summaries of the incidences of neoplasms and nonneoplastic lesions, individual animal tumor diagnoses, statistical analyses of primary neoplasms that occurred with an incidence of at least 5% in at least one animal group, and historical incidences for the neoplasms mentioned in this section are presented in Appendix C for male mice and Appendix D for female mice. The total number of neoplasm-bearing mice and the incidences of benign and malignant neoplasms in male (Table C3) and female (Table D3) mice were decreased in a dose-related manner.

Thyroid Gland: Marginally increased incidences of follicular cell adenoma occurred in 125 mg/kg males and females (Tables 16, C3, and D3), but the incidences did not increase with increasing dose. Additionally, one carcinoma was observed in a vehicle control male and one in a 125 mg/kg female, and the incidence of thyroid gland follicular cell hyperplasia was increased in all dosed groups of mice. This would suggest an increase in proliferative follicular cell lesions, but no clear developmental progression from hyperplasia to adenoma to carcinoma by the end of the study.

Proliferation of follicular cells is generally considered to follow a developmental progression from hyperplasia to adenomas and carcinomas. As with other endocrine glands, clear distinction between these categories is sometimes difficult because morphologic criteria are not always predictive of biologic behavior.

Follicular cell hyperplasia was focal or diffuse. Generally, the follicular architecture was maintained. Follicles were of variable size and the follicular epithelium was cuboidal to tall columnar and nuclei were sometimes hyperchromatic. Hyperplasia consisted of an enlarged follicular space containing multiple smaller follicles. The follicular epithelium was multilayered in small areas, but was not a prominent feature of the lesion.

Follicular cell adenomas were usually well-circumscribed, expansile lesions that often caused compression of the adjacent parenchyma. Nuclei of neoplastic cells were often more hyperchromatic than the surrounding thyroid follicular cells and neoplastic cells formed variably sized follicular structures or large cystic spaces. In larger cysts, the neoplastic cells often formed papillary structures that protruded into the lumen. The neoplastic cells were often multilayered with both follicular and papillary patterns. Follicular cells in the adenoma varied from cuboidal to columnar, often with a high nucleus-to-cytoplasm ratio. Nuclear crowding was a common feature and the mitotic rate was variable.

Follicular cell carcinomas had solid to papillary follicular cell patterns. Occasionally, the follicular cells were highly pleomorphic. Cellular pleomorphism often helped distinguish follicular cell carcinoma from follicular cell adenoma. The mitotic rate was usually variable and moderately high.

<sup>\*\*</sup> Significantly different (P≤0.01) from the control by the logistic regression test

<sup>(</sup>T)Terminal sacrifice

a Number of animals with organ examined microscopically

b Number of animals with lesion

c Average severity grade of lesions in affected animals (1=minimal; 2=mild; 3=moderate; 4=marked)

d Number of animals with neoplasm per number of animals with examined microscopically

<sup>&</sup>lt;sup>e</sup> Kaplan-Meier estimated neoplasm incidence at the end of the study after adjustment for intercurrent mortality

Observed incidence at terminal kill

Beneath the control incidence is the P value associated with the trend test. Beneath the dosed group incidence are the P values corresponding to pairwise comparisons between the controls and that dosed group. The logistic regression test regards lesions in animals dying prior to terminal kill as nonfatal. A negative trend or lower incidence in a dosed group is indicated by N.

h Not applicable; no neoplasms in animal group

Historical incidence for 2-year NTP gavage studies with corn oil vehicle control groups (mean ± standard deviation): 15/929 (1.6% ± 1.4%); range, 0%-4%

Historical incidence: 19/934 (2.0%  $\pm$  2.6%); range, 0%-8%

Liver: Significantly decreased incidences of hepatocellular adenomas and carcinomas occurred in dosed groups of males and females, as did decreased incidences of eosinophilic foci and fatty change (Tables 17, C1, C5, D1, and D5). The incidence of hepatocellular adenoma or carcinoma (combined) in 500 mg/kg males was below that observed in recent NTP 2-year gavage studies (range, 14%-72%). The decrease was probably related to decreased body weight (Haseman et al., 1994; Seilkop, 1995).

Forestomach: Increased incidences of forestomach hyperplasia (vehicle control, 7/62; 125 mg/kg, 33/58; 250 mg/kg, 38/58; 500 mg/kg, 18/56) and ulcers (5/62, 17/58, 14/58, 8/56) occurred in all groups of males administered THC (Table C5). No increased incidences of forestomach hyperplasia or ulcers were observed in females. The increased incidence of ulcerations and hyperplasia in males may have been secondary to the gavage process.

<sup>(</sup>T) Terminal sacrifice

Number of neoplasm-bearing animals/number of animals examined microscopically.

Beneath the control incidence is the P value associated with the trend test. Beneath the dosed group incidence are the P values corresponding to pairwise comparisons between the controls and that dosed group. The logistic regression test regards lesions in animals dying prior to terminal kill as nonfatal. A negative trend or lower incidence in a dose group is indicated by N.

<sup>&</sup>lt;sup>c</sup> Kaplan-Meier estimated neoplasm incidence at the end of the study after adjustment for intercurrent mortality

d Observed incidence at terminal kill

Historical incidence for 2-year NTP gavage studies with corn oil vehicle control groups (mean ± standard deviation): 388/951 (40.8% ± 15.1%); range, 14%-72%

Historical incidence: 133/948 (14.0% ± 8.0%); range, 2%-34%

Urinary Tract: Slightly increased incidences of focal to multifocal chronic inflammation in the renal pelvis occurred in 500 mg/kg males (1/62, 2/60, 5/61, 12/60; Table C5). Similarly, focal to multifocal chronic inflammation of the urinary bladder occurred in 500 mg/kg males (0/62, 0/60, 4/61, 9/58). Urinary bladder transitional epithelium hyperplasia also occurred in 500 mg/kg males (0/62, 0/60, 2/61, 8/58). The epithelial hyperplasia in the urinary bladder was not considered to be directly related to the administration of THC, but was considered to be secondary to the inflammatory lesions.

### **GENETIC TOXICOLOGY**

There is little evidence for mutagenic activity attributable to THC in vitro or in vivo. THC (100 to  $10,000~\mu g/\text{plate}$ ) was not mutagenic in Salmonella typhimurium strains TA97, TA98, TA100, or TA1535, with or without Aroclor 1254-induced male Sprague-Dawley rat or Syrian hamster liver S9 (Zeiger et al., 1988; Table E1). In cytogenetic tests with cultured

Chinese hamster ovary cells, THC induced doserelated increases in sister chromatid exchanges in the presence of S9; however, only at the highest scorable dose (12.5  $\mu$ g/mL) was the response significantly different from the control level (Table E2). Significant slowing of the cell cycle was observed at doses of 10 µg/mL and above, necessitating a delayed harvest to allow sufficient cells to accumulate for evaluation. No induction of chromosomal aberrations was observed in cultured Chinese hamster ovary cells treated with THC, with or without S9 (Table E3). Severe toxicity was noted at the highest dose scored in the absence of S9 (15  $\mu$ g/mL) and only 28 cells were evaluated for chromosomal aberrations at this dose level.

The single *in vivo* assay that was performed with THC provided no evidence of induced chromosomal damage. No increase in the frequency of micronucleated normochromatic erythrocytes was observed in peripheral blood samples obtained from male and female mice at the end of the 13-week study (Table E4).

# DISCUSSION AND CONCLUSIONS

The use of marijuana in the United States remains widespread. The major psychoactive component of marijuana and hashish is 1-trans-delta9-tetrahydro-cannabinol (THC). THC has antiemetic, analgesic, muscle relaxant, and anticonvulsant properties. The chemical has been used to reduce intraocular pressure in glaucoma patients and to treat bronchial asthma, insomnia, hypertension, and depression. Because of the widespread use of marijuana and its potential medical applications, the National Cancer Institute nominated THC for study.

In the 13-week studies, THC was administered by gavage to groups of male and female rats and mice at doses of 0, 5, 15, 50, 150, or 500 mg THC/kg body weight. In the recovery studies, male and female rats and mice were administered the same doses of THC for 13 weeks and allowed to recover for 9 weeks without further THC administration. Six male and six female 500 mg/kg rats died before the end of the 13-week study; these deaths were considered related to the administration of THC. With the exception of 5 mg/kg rats, the final mean body weights and weight gains of all dosed groups of male and female rats were significantly lower than those of the controls. Feed consumption data showed that weight gain was not due to lower feed consumption. In the recovery study, male and female rats gained weight quickly following cessation of dosing; at the end of the 9-week recovery period, their body weights were similar to those of the controls. In accord with the reported effects of THC on reproductive organs, testicular atrophy was observed in 150 and 500 mg/kg rats at the end of the 13-week study and in 500 mg/kg rats at the end of the recovery study. However, at doses of 50 mg/kg or less, testicular atrophy was not observed in either the 13-week or recovery studies. Absolute and relative uterine weights of all dosed groups of female rats were lower than those of the controls, estrous cycles were lengthened, and uterine and ovarian hypoplasia were observed in 150 and 500 mg/kg rats at the end of the 13-week study.

Survival of male and female mice in both the 13-week and recovery studies was unaffected by the administration of THC. The final mean body weight and weight gain of 500 mg/kg male mice in the 13-week study were significantly lower than those of the controls. Final mean body weights and weight gains of all other dosed groups of male mice and of all dosed groups of female mice in the 13-week study were similar to those of the controls, as were those of all dosed groups of male and female mice in the recovery study. Feed consumption by dosed groups of male and female mice in both the 13-week and recovery studies was similar to that by controls; no histopathologic changes related to the administration of THC were observed in mice from either study.

During the course of the 13-week study, dosed groups of rats and mice initially showed clinical signs of lethargy, becoming aggressive and hyperactive later in the study. During handling of the animals, convulsions occurred in THC-dosed rats and mice in both the 13-week and recovery studies.

In the 9-week period following dosing, the rats recovered from the effects of THC on body weight depression and the ovarian effects largely resolved. However, hypersensitivity to stimulation and convulsions were observed during the recovery period in rats and mice, as were testicular atrophy and reduced leukocyte and lymphocyte counts in 500 mg/kg male rats. These effects may have persisted after cessation of treatment due to the long half-life of THC.

Dose levels selected for the 2-year studies were based on lower mean body weight gains observed in dosed rats and mice in the 13-week studies and on mortality observed in rats in the 13-week study. Fighting among dosed animals, convulsions observed in dosed groups from the present 13-week and recovery studies, reported tolerance development to THC in long-term exposure studies, and dose levels reportedly used by other investigators were also considered in the dose selection. According to calculations based on body surface area, an oral dose of 2.1 mg/kg to rats is equivalent to a human smoking one marijuana cigarette; 10 mg/kg is equivalent to the content of THC in a hashish cigarette (Luthra et al., 1975; Rosenkrantz et al., 1975). The amount of THC taken in by habitual smokers was estimated to range from

0.3 to 12 mg/kg per day (ARF/WHO, 1981). THC at doses of up to 10 mg/kg administered orally to Fischer rats daily during a 21 to 22 day gestation period was considered nonteratogenic and did not cause adverse effects on the dams as determined by reproductive data, endocrine organ weights, and body weights (Luthra, 1979). THC at 50 mg/kg per day orally for 21 days during gestation did not affect litter size or pup weight at birth, although maternal weight was reduced (Abel, 1984). A 10 mg/kg dose intraperitoneally is commonly used to show clear inhibitory effects of cannabinoids on spontaneous activity in an open field test (Little et al., 1988; Oviedo et al., 1993). Landfield et al. (1988) reported that rats subcutaneously administered THC at doses of 4 and 8 mg/kg five times weekly for 8 months were irritable; their open field activity and active avoidance training were not different from those of the controls. These authors concluded that the dose was not high enough to exert behavioral effects. Thus, the dose levels of 12.5 to 50 mg/kg selected for the 2-year rat studies were considered reasonable.

In the 2-year studies, growth rates of dosed male and female rats were less than those of the controls. Feed consumption by rats was measured during the final 9 months of the 2-year study; there was little difference in feed consumption by dosed and control groups. The lower body weights of THC-dosed rats were probably not due to reduced feed consumption earlier in the study. Thus, it seems that growth retardation of the dosed rats was a pharmacologic effect of THC that was marked even in rats administered 12.5 mg/kg (the low dose). Increased metabolic rates may be required for the hyperactive, adaptive, and detoxification effects induced by THC treatment. Significant elevations in plasma adrenocorticotropic hormone (ACTH) and corticosterone (Zuardi et al., 1984; Landfield et al., 1988; Eldridge et al., 1991) and increases in relative thyroid and adrenal weights (Borgen et al., 1971) following THC administration have been reported. Serum corticosterone levels measured at 15 months were elevated in both male and female rats, but thyroxine levels were similar to those of the controls. The corticosterone may have played a role in the lower mean body weight gains. Data from the present studies coincided with data from the Thompson et al. (1973) study in which growth rates of dosed male and female Fischer rats (administered 50, 250, 400, or 500 mg THC per kg body weight by gavage for 119 days) were lower than those of the controls, but there was little difference in body weights among the dosed groups. Rosenkrantz et al. (1975) also reported that Fischer rats treated orally with 10 or 50 mg THC/kg body weight daily for 180 days showed weight reduction despite an elevation in feed consumption. According to Thompson et al. (1973), the reduced weight gain was due to depletion in body fat stores; female rats were more severely affected than males. Urinary output was also higher in the THC-dosed rats than in controls.

Survival of the dosed male and female rats was greater than that of the controls in the 2-year study; the difference was significant in each dose group except the 50 mg/kg males. The increased survival rates of the dosed male and female rats may be due to the lower mean body weights throughout the experimental period. Higher survival rates have been associated with lower body weight in diet restriction studies (Kari and Abdo, 1996).

Oviedo et al. (1993) administered 10 mg THC/kg body weight intraperitoneally daily for 2 weeks to male Sprague-Dawley rats. Within 10 minutes after the first dose, the rats became inactive. When placed in the center of a circular open field in the behavioral study, the rats crouched on one side. After some time, the animals started to walk in a circular fashion. They exhibited normal activity after 2 weeks. Thompson et al. (1973) reported that Fischer rats treated orally with up to 500 mg/kg daily for 119 days initially exhibited depression, followed by hyperactivity, aggressiveness, and convulsions. The frequency and onset of convulsions were dose-related. Luthra et al. (1975) reported that rats fed THC at 50 mg/kg for 6 months exhibited generalized depression and ataxia followed by irritability, hyperactivity, aggression, tremors, and convulsions. Tolerance developed after prolonged treatment. Luthra and Rosenkrantz (1974) and Luthra et al. (1975) demonstrated that oral treatment of male and female Fischer rats with up to 50 mg THC per/kg body weight daily for 180 days lowered the ribonucleic acid (RNA) content in the frontal cortex, parietal cortex, and subcortex of the brain. Acetylcholinesterase activity increased in the frontal cortex, parietal cortex, and subcortex of male rats, but decreased in the female rats. The degree of neurochemical alteration diminished as treatment was prolonged. Peak convulsive activity occurred near day 130; the activity fell Discussion and Conclusions 75

progressively and was not observed by 180 days. The authors believed the brain RNA and acetyl-cholinesterase activity and neurobehavioral changes were related.

In the present 2-year rat study, initial depression was followed by hyperactivity. Aggressive behavior was averted by housing the animals individually. The rats receiving THC had grand mal seizures usually induced by sensory stimulation and the time of onset and frequency appeared to correlate with dose levels. Female rats displayed seizure earlier and more frequently than male rats. The convulsive activity was still recorded during the last 6 months of the 2-year study. Apparently, tolerance did not develop. Brain lesions were not identified in the hematoxylin- and eosin-stained sections or in tissues from rats perfused with Trump's fixative. The issue of tolerance could have been more directly addressed, but evaluations of the excitatory (glutamate and aspartate) and inhibitory (γ-aminobutyric acid, glycine, and taurine) neurotransmitter amino acids and their binding sites and affinities of monoaminergic (noradrenergic/ dopaminergic and serotinergic) transmitter systems and of the cholinergic system were not attempted. There was no histopathologic evidence of brain lesions in rats. However, structural and functional alterations of the hippocampal pyramidal neurons as indicated by reduced cytoplasmic and nuclear volumes and decreased synaptic density in rodents treated orally with THC (10 to 60 mg/kg) daily for 90 days have been reported (Slikker et al., 1991). Landfield et al. (1988) also reported that rats administered THC (8 mg/kg) subcutaneously daily for 8 months had reduced numbers of neurons in striatum pyramidale of field CA1 of the hippocampus and increased cytoplasmic inclusions in hippocampal astrocytes.

Several investigators have studied the effects of THC on the endocrine system, particularly the pituitary gland, and reported altered ACTH, corticosterone, follicle stimulating hormone (FSH), and thyroid hormone levels. Landfield et al. (1988) reported that rats receiving THC subcutaneously at 8 mg/kg daily had significant elevations in plasma ACTH and corticosterone levels. Borgen et al. (1971) reported increased relative thyroid and adrenal gland weights in pregnant female Long-Evans rats administered 100 or 200 mg/kg THC daily by gavage during the 20-day gestation period; serum thyroid hormone levels were not determined. These authors interpreted the organ weight changes to be a result of general stress

response to THC administration. In the present study, there was a significant dose-related decrease in the incidence of pituitary adenoma in male rats, and serum corticosteroid levels at 15 months in male and female rats were elevated, but thyroxine levels were normal. The corticosteroid levels, body weights, and pituitary adenoma incidences in the 2-year study are probably related.

At the 15-month interim evaluation, serum FSH levels of THC-dosed males were higher than that of the controls. At the end of the 2-year study, the incidences of mammary gland neoplasms and uterine stromal polyps were lower in the 25 and 50 mg/kg females than in the controls. Kari and Abdo (1996) reported low body weights brought about by diet restriction decreased the incidence of mammary gland neoplasms and uterine stromal polyps in female rats. The lower body weights observed in THC-dosed rats from the 2-year study may have played a role in reducing the incidences of interstitial cell adenoma of the testis in males and mammary gland neoplasms and uterine stromal polyps in females. However, THC has been reported to affect the hypothalamopituitary-gonad axis and alter luteinizing hormone and FSH secretion (Rosenkrantz and Esber, 1980; Martin, 1986) and may also act directly at the gonadal level on steroidogenesis by the testes (Newton et al., 1993) and the ovary (Treinen et al., 1993). Thus, the lower incidences of interstitial cell adenoma of the testis, mammary gland neoplasms, and uterine stromal polyps observed in the 2-year study may be related to the effects of THC on the hypothalamo-pituitary-gonad axis and the gonads.

The decreased incidence of acinar cell adenomas of the pancreas in dosed male rats may have been related to decreased body weights. The incidence of acinar adenoma in the vehicle control group is greater than that in nontreated (dosed feed) control male rats and has been attributed to effects of chronic administration of corn oil (Haseman and Rao, 1992).

Survival rates of dosed mice in the 2-year study, except that of 500 mg/kg males, were similar to those of the controls; survival in the 500 mg/kg males was significantly lower than that in the controls. No specific reason for this was determined. In the 2-year mouse study, mean body weight gains of dosed male and female mice were significantly lower than those of the controls, even during the first 13 weeks. In the

13-week study, mice housed five per cage exhibited aggressive fighting behavior; therefore, mice in the 2-year study were housed individually. Mean body weight gains were not different among the dosed groups and the controls in the 13-week study. It appears that individual housing affected the growth rates of control and THC-dosed mice differently, even though feed consumption was similar. Judging from the growth rate data in the 13-week study and those during the first 13 weeks of the 2-year study, control male and female mice grew faster when housed individually. This phenomenon may account partially for the larger reduction in body weights recorded in the THC-dosed mice in the 2-year study.

Convulsions were also observed in the THC-dosed mice and the onset and frequency were dose related. Histopathologic changes in the hippocampus were not identified in mice. Abood et al. (1993) reported the cannabinoid receptor mRNA levels and the receptor binding capacity and affinity were not altered in whole brain homogenates of male ICR mice administered 10 mg/kg intraperitoneal injections of THC twice daily for 6.5 days. Receptor changes were not determined in the 2-year study.

Incidences of eosinophilic foci, fatty change, and hepatocellular adenoma and carcinoma (combined) of dosed male and female mice were significantly lower than those of the controls in the 2-year study. The decrease was dose related. Incidences of hepatocellular neoplasms correlate well with body weights in male and female B6C3F<sub>1</sub> mice (Rao et al., 1990; Turturro et al., 1993). However, the lower body weights of the THC-dosed mice were not due to lower feed consumption. The dose-related decrease in the incidence of hepatocellular neoplasms in the present study was probably related to decreases in body weights resulting from physiological and hormonal changes brought about by THC administration as discussed above.

Incidences of thyroid gland follicular cell hyperplasia were significantly increased in all dosed male groups and in 125 and 250 mg/kg female mice in the 2-year study. The severity of hyperplasia did not increase with increasing dose. Hyperplasia of the thyroid gland follicular epithelium was not observed in the 13-week study; marginally increased incidences of thyroid gland follicular cell adenoma occurred in the 125 mg/kg males and females, but the incidences did not increase with increasing dose. Additionally, single carcinomas were observed in a vehicle control male and a 125 mg/kg female. There was no clear developmental progression from hyperplasia to adenoma to carcinoma by the end of the study. Serum thyroid hormone levels in dosed mice were not determined. Thyroid gland follicular cell neoplasms are relatively uncommon in historical control corn oil gavage mice. The NTP historical incidence for mouse thyroid gland follicular cell neoplasms from 2-year gavage studies is 1.6% for males and 2.0% for females. Thus, the incidences of 10% and 17% observed in the 125 mg/kg males and females were higher than the historical control ranges. The incidences of thyroid gland follicular cell neoplasms in the 250 and 500 mg/kg groups were lower than that observed in the 125 mg/kg groups. There were no marked differences in survival or body weights among dosed groups that could account for this lack of dose response. Thus, the evidence of carcinogenic activity of THC in male and female mice is considered to be "equivocal."

The primary effect of the 2-year administration of THC in the present studies was to lower body weight gains in male and female Fischer rats and B6C3F<sub>1</sub> mice. THC also induced lethargy, followed by aggressive behavior, convulsions, and hyperactivity. The total number of benign and malignant neoplasms in male and female rats and mice decreased in a dose-related manner (Tables 18, A3, B3, C3, and D3), as did mortality rates of dosed male and female rats; both effects may be related to reduced body weights.

Logistic regression test	P<0.001N	P=0.001N	P<0.001N	P<0.001N
Female				
Final Mean Body Weights	49.7	37.0	33.3	33.7
Liver: Hepatocellular Adenoma				
Overall rate	17/60 (28%)	9/60 (15%)	7/59 (12%)	3/60 (5%)
Adjusted rate	34.4%	18.0%	15.5%	7.3%
Terminal rate	15/47 (32%)	8/49 (16%)	6/44 (14%)	3/41 (7%)
First incidence (days)	659	714	694	737 (T)
Logistic regression test	P = 0.001N	P=0.053N	P = 0.032N	P = 0.002N
Liver: Hepatocellular Adenoma or Carcinoma				
Overall rate	22/60 (37%)	14/60 (23%)	11/59 (19%)	4/60 (7%)
Adjusted rate	43.0%	27.3%	23.8%	9.4%
Terminal rate	18/47 (38%)	12/49 (24%)	9/44 (20%)	3/41 (7%)
First incidence (days)	659	661	674	701
Logistic regression test	P<0.001N	P = 0.071N	P = 0.035N	P<0.001N

(T)Terminal sacrifice

Weights are presented in grams.

b Number of neoplasm-bearing animals/number of animals examined. Denominator is number of animals examined microscopically for liver, pancreas, pituitary gland, testes, and uterus; for other tissues, denominator is number of animals necropsied.

c Kaplan-Meier estimated neoplasm incidence at the end of the study after adjustment for intercurrent mortality

d Observed incidence at terminal kill

Beneath the control incidence are the P values associated with the trend test. Beneath the dosed group incidence are the P values corresponding to pairwise comparisons between the controls and that dosed group. The life table test regards neoplasms in animals dying prior to terminal kill as being (directly or indirectly) the cause of death. The logistic regression test regards these lesions as nonfatal. The Cochran-Armitage and Fisher exact tests compare directly the overall incidence rates. For all tests, a negative trend or a lower incidence in a dose group is indicated by N.

Not applicable; no neoplasms in animal group

#### CONCLUSIONS

Under the conditions of these 2-year gavage studies, there was no evidence of carcinogenic activity\* of 1-trans-delta9-tetrahydrocannabinol in male or female F344/N rats administered 12.5, 25, or 50 mg/kg. There was equivocal evidence of carcinogenic activity of THC in male and female B6C3F<sub>1</sub> mice based on the increased incidences of thyroid gland follicular cell adenomas in the 125 mg/kg groups.

Increased incidences of thyroid gland follicular cell hyperplasia occurred in male and female mice, and increased incidences of hyperplasia and ulcers of the forestomach were observed in male mice.

The incidences of mammary gland fibroadenomas and uterine stromal polyps were decreased in dosed groups of female rats, as were the incidences of pancreatic adenomas, pituitary gland adenomas, and interstitial cell adenomas of the testis in dosed male rats, and liver neoplasms in male and female mice. These decreases were likely related to lower body weights in dosed animals.

<sup>\*</sup> Explanation of Levels of Evidence of Carcinogenic Activity is on page 9. A summary of the Technical Reports Review Subcommittee comments and the public discussion on this Technical Report appears on page 11.

All Organs: Benign or Malignant Neoplasms				
Overall rate	51/52 (98%)	50/51 (98%)	48/52 (92%)	47/52 (90%)
Adjusted rate	100.0%	100.0%	100.0%	100.0%
Terminal rate	22/22 (100%)	35/35 (100%)	33/33 (100%)	31/31 (100%)
First incidence (days)	438	282	211	531
Life table test	P = 0.026N	P = 0.005N	P = 0.008N	P = 0.013N
Logistic regression test	P = 0.018N	P = 0.823N	P = 0.612N	P = 0.096N
Cochran-Armitage test	P = 0.034N			
Fisher exact test		P = 0.748N	P = 0.181N	P = 0.102N

(T)Terminal sacrifice

Number of neoplasm-bearing animals/number of animals examined. Denominator is number of animals examined microscopically for adrenal gland, liver, pancreas, pancreatic islets, pituitary gland, testes, and thyroid gland; for other tissues, denominator is number of animals necropsied.

b Kaplan-Meier estimated neoplasm incidence at the end of the study after adjustment for intercurrent mortality

C Observed incidence at terminal kill

Beneath the control incidence are the P values associated with the trend test. Beneath the dosed group incidence are the P values corresponding to pairwise comparisons between the controls and that dosed group. The life table test regards neoplasms in animals dying prior to terminal kill as being (directly or indirectly) the cause of death. The logistic regression test regards these lesions as nonfatal. The Cochran-Armitage and Fisher exact tests compare directly the overall incidence rates. For all tests, a negative trend or a lower incidence in a dose group is indicated by N.

e Not applicable; no neoplasms in animal group

TABLE A4a Historical Incidence of Pancreatic Adenomas in Male F344/N Rats Receiving Corn Oil by Gavage<sup>a</sup>

Study	Incidence in Controls				
Historical Incidence at TSI Mason Research Institut	re

Fisher exact test		P = 0.289N	P = 0.500N	P = 0.021N

(T)Terminal sacrifice

Number of neoplasm-bearing animals/number of animals examined. Denominator is number of animals examined microscopically for adrenal gland, clitoral gland, liver, pituitary gland, and thyroid gland; for other tissues, denominator is number of animals necropsied.

b Kaplan-Meier estimated neoplasm incidence at the end of the study after adjustment for intercurrent mortality

Observed incidence at terminal kill

Beneath the control incidence are the P values associated with the trend test. Beneath the dosed group incidence are the P values corresponding to pairwise comparisons between the controls and that dosed group. The life table test regards neoplasms in animals dying prior to terminal kill as being (directly or indirectly) the cause of death. The logistic regression test regards these lesions as nonfatal. The Cochran-Armitage and Fisher exact tests compare directly the overall incidence rates. For all tests, a negative trend or a lower incidence in a dose group is indicated by N.

e Not applicable; no neoplasms in animal group

TABLE B4a Historical Incidence of Mammary Gland Fibroadenomas in Female F344/N Rats Receiving Corn Oil by Gavage<sup>a</sup>

(T)Terminal sacrifice

Observed incidence at terminal kill

e Not applicable; no neoplasms in animal group

<sup>&</sup>lt;sup>a</sup> Number of neoplasm-bearing animals/number of animals examined. Denominator is number of animals examined microscopically for liver, lung, and thyroid gland; for other tissues, denominator is number of animals necropsied.

b Kaplan-Meier estimated neoplasm incidence at the end of the study after adjustment for intercurrent mortality

d Beneath the control incidence are the P values associated with the trend test. Beneath the dosed group incidence are the P values corresponding to pairwise comparisons between the controls and that dosed group. The life table test regards neoplasms in animals dying prior to terminal kill as being (directly or indirectly) the cause of death. The logistic regression test regards these lesions as nonfatal. The Cochran-Armitage and Fisher exact tests compare directly the overall incidence rates. For all tests, a negative trend or a lower incidence in a dose group is indicated by N.

(T)Terminal sacrifice

<sup>&</sup>lt;sup>a</sup> Number of neoplasm-bearing animals/number of animals examined. Denominator is number of animals examined microscopically for liver, lung, pituitary gland, and thyroid gland; for other tissues, denominator is number of animals necropsied.

b Kaplan-Meier estimated neoplasm incidence at the end of the study after adjustment for intercurrent mortality

Observed incidence at terminal kill

d Beneath the control incidence are the P values associated with the trend test. Beneath the dosed group incidence are the P values corresponding to pairwise comparisons between the controls and that dosed group. The life table test regards neoplasms in animals dying prior to terminal kill as being (directly or indirectly) the cause of death. The logistic regression test regards these lesions as nonfatal. The Cochran-Armitage and Fisher exact tests compare directly the overall incidence rates. For all tests, a negative trend or a lower incidence in a dose group is indicated by N.

e Not applicable; no neoplasms in animal group

TABLE D5
Summary of the Incidence of Nonneoplastic Lesions in Female Mice in the 2-Year Gavage Study of 1-Trans-Delta<sup>9</sup>-Tetrahydrocannabinol<sup>a</sup>

	Vehicle Control	125 mg/kg	250 mg/kg	500 mg/kg
Disposition Summary				- <u>-</u>
Animals initially in study	60	60	60	60
Early deaths				
Accidental deaths				2
Moribund	3	5	3	3
Natural deaths	10	5	13	14
Survivors				
Terminal sacrifice	47	50	44	41
Animals examined microscopically	60	60	60	60
Alimentary System .				
Esophagus	(60)	(60)	(60)	(59)
Perforation				1 (2%)
Periesophageal tissue, inflammation, s		450	7# AS	1 (2%)
Gallbladder	(53)	(59)	(54)	(54)
Infiltration cellular, lymphocyte		1 (2%)		
Epithelium, ulcer, chronic active	(55)	1 (2%)	(50)	(57)
ntestine large, colon	(57)	(60)	(58)	(57)
Serosa, inflammation, chronic	(57)	1 (2%)	(50)	(57)
Intestine large, cecum	(57)	(60)	(58)	(57)
Atrophy	1 (2%)	(60)	(57)	(54)
Intestine small, duodenum  Dysplasia	(57)	(60) 1 (2%)	(57)	(54)
Intestine small, jejunum	(57)	(60)	(57)	(55)
Serosa, inflammation, chronic	(3.)	1 (2%)	(5.)	(55)
Liver	(60)	(60)	(59)	(60)
Angiectasis	1 (2%)	()	()	` '
Atrophy	- (=,,		1 (2%)	
Basophilic focus		2 (3%)	1 (2%)	1 (2%)
Clear cell focus	1 (2%)	3 (5%)	` ,	• ,
Congestion	` ,	. ,		1 (2%)
Eosinophilic focus	9 (15%)		1 (2%)	1 (2%)
Fatty change	13 (22%)	3 (5%)	• •	2 (3%)
Hematopoietic cell proliferation	6 (10%)	2 (3%)	2 (3%)	3 (5%)
Infarct			1 (2%)	
Infiltration cellular, lymphocyte	1 (2%)	2 (3%)		
Inflammation, acute	1 (2%)			1 (2%)
Inflammation, chronic	1 (2%)		<u></u>	
Mixed cell focus	2 (3%)	1 (2%)	2 (3%)	4 (00)
Necrosis	2 (3%)			1 (2%)
Bile duct, hyperplasia			1 (00)	1 (2%)
Central vein, dilatation			1 (2%)	1 (20%)
Centrilobular, fibrosis	(11)	(1)	(1)	1 (2%)
Mesentery	(11)	(1)	(1)	(3)
Inflammation, chronic		1 (100%)		2 (67%)
Inflammation, chronic active	0 (00%)	1 (100%)	1 /100%\	
Fat, necrosis	9 (82%)		1 (100%)	

a Number of animals examined microscopically at the site and the number of animals with lesion

#### GENETIC TOXICOLOGY

#### SALMONELLA MUTAGENICITY TEST PROTOCOL

Testing was performed as reported by Zeiger et al. (1988). 1-Trans-delta<sup>9</sup>-tetrahydrocannabinol (THC) was sent to the laboratory as a coded aliquot from Radian Corporation (Austin, TX). It was incubated with the Salmonella typhimurium tester strains TA97, TA98, TA100, and TA1535 either in buffer or S9 mix (metabolic activation enzymes and cofactors from Aroclor 1254-induced male Sprague-Dawley rat or Syrian hamster liver) for 20 minutes at 37° C. Top agar supplemented with *l*-histidine and *d*-biotin was added, and the contents of the tubes were mixed and poured onto the surfaces of minimal glucose agar plates. Histidine-independent mutant colonies arising on these plates were counted following incubation for 2 days at 37° C.

Each trial consisted of triplicate plates of concurrent positive and negative controls and at least five doses of THC. In the absence of toxicity,  $10,000~\mu g/p$ late was selected as the high dose. All positive trials were repeated under the conditions that elicited the positive response. If no positive responses were seen, all negative trials were repeated.

In this assay, a positive response is defined as a reproducible, dose-related increase in histidine-independent (revertant) colonies in any one strain/activation combination. An equivocal response is defined as an increase in revertants that is not dose related, not reproducible, or is of insufficient magnitude to support a determination of mutagenicity. A negative response is obtained when no increase in revertant colonies is observed following chemical treatment. There was no minimum percentage or fold increase required for a chemical to be judged positive or weakly positive.

#### CHINESE HAMSTER OVARY CELL CYTOGENETICS PROTOCOLS

Testing was performed as reported by Galloway et al. (1987). THC was sent to the laboratory as a coded aliquot by Radian Corporation. It was tested in cultured Chinese hamster ovary (CHO) cells for induction of sister chromatid exchanges (SCEs) and chromosomal aberrations (Abs), both in the presence and absence of Aroclor 1254-induced male Sprague-Dawley rat liver S9 and cofactor mix. Cultures were handled under gold lights to prevent photolysis of bromodeoxyuridine-substituted DNA. Each test consisted of concurrent solvent and positive controls and of at least three doses of THC; the high dose was limited by toxicity. A single flask per dose was used, and tests yielding equivocal or positive results were repeated.

Sister Chromatid Exchange Test: In the SCE test without S9, CHO cells were incubated for 25.5 to 33.0 hours with THC in McCoy's 5A medium. Bromodeoxyuridine (BrdU) was added 2 hours after culture initiation. After 25.5 to 33.0 hours, the medium containing THC was removed and replaced with fresh medium plus BrdU and Colcemid, and incubation was continued for 2 hours. Cells were then harvested by mitotic shake-off, fixed, and stained with Hoechst 33258 and Giemsa. In the SCE test with S9, cells were incubated with THC, serum-free medium, and S9 for 2 hours. The medium was then removed and replaced with medium containing serum and BrdU and no THC and incubation proceeded for an additional 25.5 to 29.3 hours, with Colcemid present for the final 2 hours. Harvesting and staining were the same as for cells treated without S9. All slides were scored blind and those from a single test were read by the same person. Fifty second-division metaphase cells were scored for frequency of SCEs/cell from each dose level. Because significant chemical-induced cell cycle delay was seen, incubation time was lengthened as indicated in Table E2, to ensure a sufficient number of scorable (second-division metaphase) cells.

Genetic Toxicology 257

Statistical analyses were conducted on the slopes of the dose-response curves and the individual dose points (Galloway et al., 1987). An SCE frequency 20% above the concurrent solvent control value was chosen as a statistically conservative positive response. The probability of this level of difference occurring by chance at one dose point is less than 0.01; the probability for such a chance occurrence at two dose points is less than 0.001. An increase of 20% or greater at any single dose was considered weak evidence of activity; increases at two or more doses resulted in a determination that the trial was positive. A statistically significant trend (P<0.005) in the absence of any responses reaching 20% above background led to a call of equivocal.

Chromosomal Aberrations Test: In the Abs test without S9, cells were incubated in McCoy's 5A medium with THC for 20 hours; Colcemid was added and incubation continued for 2 hours. The cells were then harvested by mitotic shake-off, fixed, and stained with Giemsa. For the Abs test with S9, cells were treated with THC and S9 for 2 hours, after which the treatment medium was removed and the cells were incubated for 8.5 hours in fresh medium, with Colcemid present for the final 2 hours. Cells were harvested in the same manner as for the treatment without S9. The harvest time for the Abs test was based on the cell cycle information obtained in the SCE test; because cell cycle delay was anticipated in the absence of S9, the incubation period was extended.

Cells were selected for scoring on the basis of good morphology and completeness of karyotype  $(21 \pm 2 \text{ chromosomes})$ . All slides were scored blind and those from a single test were read by the same person. One hundred first-division metaphase cells were scored at each dose level unless cytotoxicity limited the number of cells obtained at harvest. Classes of aberrations included simple (breaks and terminal deletions), complex (rearrangements and translocations), and other (pulverized cells, despiralized chromosomes, and cells containing 10 or more aberrations).

Chromosomal aberration data are presented as percentage of cells with aberrations. To arrive at a statistical call for a trial, analyses were conducted on both the dose response curve and individual dose points. For a single trial, a statistically significant ( $P \le 0.05$ ) difference for one dose point and a significant trend ( $P \le 0.015$ ) were considered weak evidence for a positive response; significant differences for two or more doses indicated the trial was positive. A positive trend test in the absence of a statistically significant increase at any one dose resulted in an equivocal call (Galloway et al., 1987). Ultimately, the trial calls were based on a consideration of the statistical analyses as well as the biological information available to the reviewers.

#### MOUSE PERIPHERAL BLOOD MICRONUCLEUS TEST PROTOCOL

A detailed discussion of this assay can be found in MacGregor et al. (1990). Peripheral blood samples were obtained from male and female  $B6C3F_1$  mice at the end of the 13-week toxicity study. Smears were immediately prepared and fixed in absolute methanol, stained with a chromatin-specific fluorescent dye mixture of Hoechst 33258/pyronin Y (MacGregor et al., 1983), and coded. Slides were scanned to determine the frequency of micronuclei in 10,000 normochromatic erythrocytes (NCEs) in each of nine animals per dose group. The criteria of Schmid (1976) were used to define micronuclei, with the additional requirement that the micronuclei exhibit the characteristic fluorescent emissions of DNA (blue with 360 nm and orange with 540 nm UV illumination); the minimum size limit was approximately one-twentieth the diameter of the NCE cell. In addition, the percentage of PCEs among the total erythrocyte population was determined.

The frequency of micronucleated cells among NCEs was analyzed by a statistical software package (ILS, 1990) which employed a one-tailed trend test across dose groups and a t-test for pairwise comparisons of each dose group to the concurrent control.

#### RESULTS

There is little evidence for mutagenic activity attributable to THC, in vitro or in vivo. THC (100 to  $10,000~\mu g/\text{plate}$ ) was not mutagenic in Salmonella typhimurium strains TA97, TA98, TA100, or TA1535, with or without Aroclor 1254-induced male Sprague Dawley rat or Syrian hamster liver S9 (Zeiger et al., 1988; Table E1). In cytogenetic tests with CHO cells, THC induced dose-related increases in SCEs in the presence of S9; however, only at the highest scorable dose (12.5  $\mu$ g/mL) was the response significantly different from the control level (Table E2). Significant slowing of the cell cycle was observed at doses of  $10~\mu$ g/mL and above, necessitating a delayed harvest to allow sufficient cells to accumulate for evaluation. No induction of chromosomal aberrations was observed in CHO cells treated with THC, with or without S9 (Table E3). Severe toxicity was noted at the highest dose scored in the absence of S9 (15  $\mu$ g/mL) and only 28 cells were evaluated for chromosomal aberrations at this dose level.

The single in vivo assay that was performed with THC provided no evidence of induced chromosomal damage. No increase in the frequency of micronucleated NCEs was observed in peripheral blood samples obtained from male and female mice at the termination of the 13-week toxicity study where THC was administered by gavage (Table E4).

Study performed at SRI International. The detailed protocol and these data are presented in Zeiger et al. (1988).

Revertants are presented as mean ± standard error from three plates.

The positive controls in the absence of metabolic activation were sodium azide (TA1535 and TA100), 9-aminoacridine (TA97), and 4-nitro-o-phenylenediamine (TA98). The positive control for metabolic activation with all strains was 2-aminoanthracene. Precipitate on plate

Positive response (P<0.01)</li>

Study performed at Litton Bionetics, Inc. A detailed description of the protocol and these data are presented in Galloway et al. (1987). SCE=sister chromatid exchange; BrdU=bromodeoxyuridine.

SCEs/chromosome in treated cells versus SCEs/chromosome in solvent control cells

<sup>&</sup>lt;sup>c</sup> Because THC induced a delay in the cell division cycle, harvest time was extended to maximize the proportion of second division cells available for analysis.

d Significance of relative SCEs/chromosome tested by the linear regression trend test vs. log of the dose

<sup>&</sup>lt;sup>a</sup> Study performed at Litton Bionetics, Inc. The detailed protocol and these data are presented in Galloway et al. (1987).

Because of significant chemical-induced cell cycle delay, incubation time prior to addition of Colcemid was lengthened to provide sufficient metaphase cells at harvest.

<sup>&</sup>lt;sup>c</sup> Fewer cells counted due to toxicity

d Significance of percent cells with aberrations tested by the linear regression trend test vs. log of the dose

TABLE E4 Frequency of Micronuclei in Mouse Peripheral Blood Erythrocytes Following Treatment with 1-Trans-Delta9-Tetrahydrocannabinol by Gavage for 13 Weeksa

## CHEMICAL CHARACTERIZATION AND DOSE FORMULATION STUDIES

## PROCUREMENT AND CHARACTERIZATION OF 1-TRANS-DELTA<sup>9</sup>-TETRAHYDROCANNABINOL

1-Trans-delta-9-tetrahydrocannabinol (THC) was obtained from A. D. Little, Inc. (Cambridge, MA) in one lot (16792-123), which was used during the 13-week and 13-week with 9-week recovery studies. For the 2-year studies four lots (AJ-86.8, AJ-86.9, AJ-86.10, and AJ-86.11) were obtained from Aerojet Strategic Development Co. (Sacramento, CA) and then blended by the analytical chemistry laboratory, Midwest Research Institute (Kansas City, MO) and assigned lot number A042487. Identity, purity, and stability analyses were conducted by the analytical chemistry laboratory and confirmed by the study laboratory. Reports on analyses performed in support of the THC studies are on file at the National Institute of Environmental Health Sciences.

Both lots of the chemical, a honey-colored viscous liquid, were identified as THC by infrared, ultraviolet/visible, and nuclear magnetic resonance spectroscopy. All spectra were consistent with the literature spectra (*Mechoulam*) of THC (Figures I1 and I2). The specific optical activity was determined for lot 16792-123 as  $[\alpha]_D^{25} = -182 \pm 3^\circ$ .

The purities of lots 16792-123 and A042487 were determined by elemental analyses, Karl Fischer water analysis, thin-layer chromatography (TLC), high-performance liquid chromatography (HPLC), and gas chromatography. TLC for lot number 16792-123 was performed on Silica Gel 60 F-254 plates with two solvent systems: 1) Acetone:chloroform (20:80), and 2) Cyclohexane:ethyl acetate (83:17). Azoxybenzene was used as a reference standard. The plates were sprayed with Fast Blue B followed by 0.1 N sodium hydroxide and examined with ultraviolet light (254 and 366 nm). TLC for lot A042487 was performed on Silica Gel 25 F-254 plates with the same solvent systems, reference standard, and methods of visualization described for lot 16792-123. HPLC for lot 16792-123 was performed with an Altex Ultrasphere-ODS column using ultraviolet detection (220 and 280 nm) and an isocratic solvent system of 35% water and 65% acetonitrile at a flow rate of 1.0 mL/minute. HPLC for lot A042487 was performed with a Fisher Resolvex C18 column using ultraviolet detection (220 and 280 nm) and a solvent system of 60% acetonitrile for 60 minutes, then raised to 100% acetonitrile over 10 minutes, and then held at 100% acetonitrile for 10 minutes at a flow rate of 1.0 mL/minute. Gas chromatography was performed using a flame ionization detector with a helium carrier gas at a flow rate of 35 mL/minute for lot 16792-123, and 8 mL/minute for lot A042487. The system used for lot 16792-123 consisted of an SE-52 fused silica column (24 m × 0.3 mm ID), with an oven temperature programmed from 175 to 275° C at increments of 2° C/minute. The system used for lot A042487 was a large-bore, fused silica DB capillary column (30 m × 0.53 mm ID), with an initial oven temperature of 200° C, a program rate of 1° C/minute increments, and a final temperature of 300° C.

Elemental analyses for carbon were slightly higher than the theoretical values for THC in lot 16792-123. Elemental analysis for hydrogen was in good agreement with the theoretical values for THC; elemental analysis for carbon was higher than the theoretical value for THC. Karl Fischer water analysis indicated  $1.3\% \pm 0.4\%$  water in lot 16792-123, and  $0.59\% \pm 0.03\%$  water in lot A042487. TLC for lot 16792-123 showed one minor impurity spot by system 2. TLC for lot A042487 indicated one major impurity spot with system 1 and one major and one minor impurity with system 2. HPLC revealed a major peak and two impurities with areas greater than 0.1% relative to the major peak area for lot 16792-123, and a major peak and three impurities with areas greater than or equal to 0.1% of the major peak area for lot A042487. Concomitant HPLC analysis with another batch of lot 16793-123 revealed seven impurities at 280 nm and three at 220 nm with areas greater than or equal to the major peak. Six of these impurities eluted before the major peak. Gas chromatography for lot 16792-123 indicated one major peak and seven impurities with areas greater than 0.1% relative to the major peak. Gas chromatography for lot A042487

indicated one major peak and five impurities with areas greater than or equal to 0.1% relative to the major peak. The overall purity was determined to be approximately 96% for lot 16792-123 and approximately 97% for lot A042487.

Stability studies of the bulk chemical for lot 16792-123 were performed by the analytical chemistry laboratory. HPLC was performed for the purity analysis with an Altex Ultrasphere ODS, 250 × 4.6 mm I.D. column using a solvent system of water:acetonitrile (30:70), and a flow rate of 1.0 mL/min. These studies indicated that THC was stable as a bulk chemical for 2 weeks when stored in evacuated containers protected from light at temperatures up to 25° C. To ensure stability, the bulk chemical was stored at 5° C, protected from light, in evacuated glass septum vials with Teflon-lined septa. Stability was monitored during the 13-week, recovery, and 2-year studies by the study laboratory using HPLC. No degradation of the bulk chemical was detected.

#### PREPARATION AND ANALYSIS OF DOSE FORMULATIONS

The dose formulations were prepared by mixing THC with corn oil to give the required concentrations (Table I1). The dose formulations prepared with lot 16792-123 were stored for up to 2 weeks at  $5^{\circ}$  C under a nitrogen headspace. The dose formulations prepared with lot A042487 were stored for up to 3 weeks at  $3^{\circ} \pm 5^{\circ}$  C under an argon headspace.

Dose formulation stability studies were performed by the analytical chemistry laboratory. For the 13-week and recovery studies aliquots of the 0.5 mg/mL formulation of THC were extracted with 10 mL of methanol. After clarification by centrifugation, 5 mL aliquots of the extracts were mixed with 2 mL of internal standard solution (N-phenyl-carbazole, 0.1 mg/mL in methanol). Gas chromatography was performed using a flame ionization detector with a nitrogen carrier gas at a flow rate of 30 mL/minute. The system used a 3% OV-17 on 100/120 mesh Supelcoport column with an oven temperature program of 238° C for 10 minutes then an increase at 10° C per minute to 280° C. The stability of the 0.5 mg/mL dose formulation was confirmed for 3 weeks at room temperature when stored under a nitrogen headspace protected from light.

Periodic analyses of the dose formulations of THC were conducted at the study laboratory and analytical chemistry laboratory using gas chromatography. During the 13-week and recovery studies, the dose formulations were analyzed 5 times; all were within 10% of the target concentrations (Table I2). During the 2-year studies, the dose formulations were analyzed approximately every 8 weeks, and were within 10% of the target concentrations 95% of the time for rats (58/61) and 97% of the time for mice (57/59) (Table I3). Samples from each dose level retained in the animal rooms were analyzed approximately every 24 weeks during the 2-year studies and were within 10% of the target concentrations. Periodic analyses of the corn oil vehicle by the study laboratory demonstrated peroxide levels within the acceptable limit of 10 mEq/kg. Results of periodic referee analyses performed by the analytical chemistry laboratory agreed with the results obtained by the study laboratory (Table I4).

Dosing volume for rats = 5 mL/kg; 2.5 mg/mL = 12.5 mg/kg; 5 mg/mL = 25 mg/kg; 10 mg/mL = 50 mg/kg. Dosing volume for

mice = 10mL/kg; 12.5 mg/mL = 125 mg/kg; 25 mg/mL = 250 mg/kg; 50 mg/mL = 500 mg/kg.

Doses were prepared on a weight/weight basis; concentrations reported were converted to mg/mL by multiplying by a fixed value for density of the dose formulations (0.91).

Ground #2 yellow shelled corn	24.50	
Ground hard winter wheat	23.00	
Soybean meal (49% protein)	12.00	
Fish meal (60% protein)	10.00	
Wheat middlings	10.00	
Dried skim milk	5.00	
Alfalfa meal (dehydrated, 17% protein)	4.00	
Corn gluten meal (60% protein)	3.00	•
Soy oil	2.50	
Dried brewer's yeast	2.00	
Dry molasses	1.50	
Dicalcium phosphate	1.25	
Ground limestone	0.50	
Salt	0.50	
Premixes (vitamin and mineral)	0.25	

TABLE J2 Vitamins and Minerals in NIH-07 Rat and Mouse Ration<sup>a</sup>

	Amount	Source
Vitamins	<u> </u>	
A	5,500,000 IU	Stabilized vitamin A palmitate or acetate
$D_3$	4,600,000 IU	D-activated animal sterol
K <sub>3</sub>	2.8 g	Menadione
d-α-Tocopheryl acetate	20,000 IU	
Choline	560.0 g	Choline chloride
Folic acid	2.2 g	
Niacin	30.0 g	
d-Pantothenic acid	18.0 g	d-Calcium pantothenate
Riboflavin	3.4 g	•
Thiamine	10.0 g	Thiamine mononitrate
B <sub>12</sub>	4,000 μg	
Pyridoxine	1.7 g	Pyridoxine hydrochloride
Biotin	140.0 mg	d-Biotin
Minerals		
Iron	120.0 g	Iron sulfate
Manganese	60.0 g	Manganous oxide
Zinc	16.0 g	Zinc oxide
Copper	4.0 g	Copper sulfate
Iodine	1.4 g	Calcium iodate
Cobalt	0.4 g	Cobalt carbonate

<sup>&</sup>lt;sup>a</sup> Per ton (2,000 lb) of finished product

a NCI, 1976; NIH, 1978
 b Ingredients were ground to pass through a U.S. Standard Screen No. 16 before being mixed.

TABLE J3
Nutrient Composition of NIH-07 Rat and Mouse Ration

	Mean ± Standard		
Nutrient	Deviation	Range	Number of Samples
Protein (% by weight)	23.13 ± 0.69	21.8 – 24.2	25
Crude fat (% by weight)	$5.24 \pm 0.21$	4.6 - 5.6	25
Crude fiber (% by weight)	$3.61 \pm 0.39$	2.8 - 4.3	25
Ash (% by weight)	$6.44 \pm 0.21$	6.1 - 6.9	25
mino Acids (% of total diet)			
Arginine	$1.287 \pm 0.084$	1.100 - 1.390	10
Cystine	$0.306 \pm 0.075$	0.181 - 0.400	10
Glycine	$1.160 \pm 0.050$	1.060 - 1.220	10
Histidine	$0.580 \pm 0.024$	0.531 - 0.608	10
Isoleucine	$0.917 \pm 0.034$	0.867 - 0.965	10
Leucine	$1.972 \pm 0.052$	1.850 - 2.040	10
Lysine	$1.273 \pm 0.051$	1.200 - 1.370	10
Methionine	$0.437 \pm 0.115$	0.306 - 0.699	10
Phenylalanine	$0.994 \pm 0.125$	0.665 - 1.110	10
Threonine	$0.896 \pm 0.055$	0.824 - 0.985	10
Tryptophan	$0.223 \pm 0.160$	0.107 - 0.671	10
Tyrosine	0.677 ± 0.105	0.564 - 0.794	10
Valine	$1.089 \pm 0.057$	0.962 - 1.170	10
Essential Fatty Acids (% of total diet)			
Linoleic	$2.389 \pm 0.233$	1.830 - 2.570	9
Linolenic	$0.277 \pm 0.036$	0.210 - 0.320	9
Vitamins			
Vitamin A (IU/kg)	$6,728 \pm 1,943$	4,180 - 12,140	25
Vitamin D (IU/kg)	$4,450 \pm 1,382$	3,000 - 6,300	4
a-Tocopherol (ppm)	$36.92 \pm 9.32$	22.5 – 48.9	9
Thiamine (ppm)	$19.08 \pm 2.31$	16.0 - 28.0	25
Riboflavin (ppm)	$7.92 \pm 0.93$	6.10 - 9.00	10
Niacin (ppm)	$100.95 \pm 25.92$	65.0 - 150.0	9
Pantothenic acid (ppm)	$30.30 \pm 3.60$	23.0 - 34.6	10
Pyridoxine (ppm)	$9.25 \pm 2.62$	5.60 - 14.0	10
Folic acid (ppm)	$2.51 \pm 0.64$	1.80 - 3.70	10
Biotin (ppm)	$0.267 \pm 0.049$	0.19 - 0.35	10
Vitamin B <sub>12</sub> (ppb)	$40.14 \pm 20.04$	10.6 - 65.0	10
Choline (ppm)	$3,068 \pm 314$	2,400 - 3,430	9
Minerals			
Calcium (%)	$1.21 \pm 0.11$	1.00 - 1.54	25
Phosphorus (%)	$0.94 \pm 0.03$	0.85 - 1.00	25
Potassium (%)	$0.887 \pm 0.067$	0.772 - 0.971	8
Chloride (%)	$0.526 \pm 0.092$	0.380 - 0.635	8
Sodium (%)	$0.325 \pm 0.092$ $0.315 \pm 0.344$	0.258 - 0.370	10
Magnesium (%)	$0.313 \pm 0.044$ $0.168 \pm 0.008$	0.151 - 0.180	10
Sulfur (%)	$0.274 \pm 0.063$	0.208 - 0.420	10
Iron (ppm)	$356.2 \pm 90.0$	255.0 - 523.0	10
Manganese (ppm)	92.24 ± 5.35	81.70 - 99.40	10
Zinc (ppm)	58.14 ± 9.91	46.10 - 81.60	10
Copper (ppm)	11.50 ± 2.40	8.090 - 15.39	10
		1.52 - 5.83	10
Iodine (ppm)	$3.70 \pm 1.14$		9
Chromium (ppm)	$1.71 \pm 0.45$	0.85 - 2.09	6
Cobalt (ppm)	$0.797 \pm 0.23$	0.490 - 1.150	U

TABLE J4
Contaminant Levels in NIH-07 Rat and Mouse Ration (continued)

- <sup>a</sup> CFU = colony forming units, MPN = most probable number, BHC is hexachlorocyclohexane or benzene hexachloride.
- b For values less than the limit of detection, the detection limit is given for the mean.
- <sup>c</sup> The lots milled 2 March 1989 and 2 June 1989 contained more than 0.6 ppm. All other lots were less than or equal to the detection limit.
- No Aflatoxin measurement was recorded for the lot milled 2 October 1989
- Sources of contamination: alfalfa, grains, and fish meal
- f Sources of contamination: soy oil and fish meal
- g All values were corrected for percent recovery
- h The lot milled 1 September 1989 contained more than 0.51 ppm.

## APPENDIX K SENTINEL ANIMAL PROGRAM

<b>METHODS</b>		312
TABLE K1	Murine Virus Antibody Determinations for Rats and Mice in the 13-Week, Recovery,	
	and 2-Year Studies of 1-Trans-Delta9-Tetrahydrocannabinol	314

#### SENTINEL ANIMAL PROGRAM

#### **METHODS**

Rodents used in the Carcinogenesis Program of the National Toxicology Program are produced in optimally clean facilities to eliminate potential pathogens that may affect study results. The Sentinel Animal Program is part of the periodic monitoring of animal health that occurs during the toxicologic evaluation of chemical compounds. Under this program, the disease state of the rodents is monitored via serology on sera from extra (sentinel) animals in the study rooms. These animals and the study animals are subject to identical environmental conditions. The sentinel animals come from the same production source and weanling groups as the animals used for the studies of chemical compounds.

Serum samples were collected from randomly selected rats and mice during the 13-week, 13-week with 9-week recovery (recovery), and 2-year studies. Blood from each animal was collected and allowed to clot, and the serum was separated. The samples were processed appropriately and sent to Microbiological Associates, Inc. (Bethesda, MD), for determination of antibody titers. The laboratory serology methods and viral agents for which testing was performed are tabulated below; the times at which blood was collected during the studies are also listed.

#### Method and Test
