CELL CYCLE ARREST
DNA REPAIR
APOPTOSIS

GOALS:

- Provide an overall description of how these three processes work to inhibit transformation.
- Describe how they are mechanistically connected.
- Show how they interact with radiation damage.
- Discuss molecular epidemiology implications for gene-environment interaction studies.
- Review epidemiological biases and confounding issues.

DNA damage is thought to be the primary mechanism by which radiation transforms cells.

Yet, only a small number of cells are actually transformed.

How are most cells protecting themselves from DNA damage-mediated transformation?

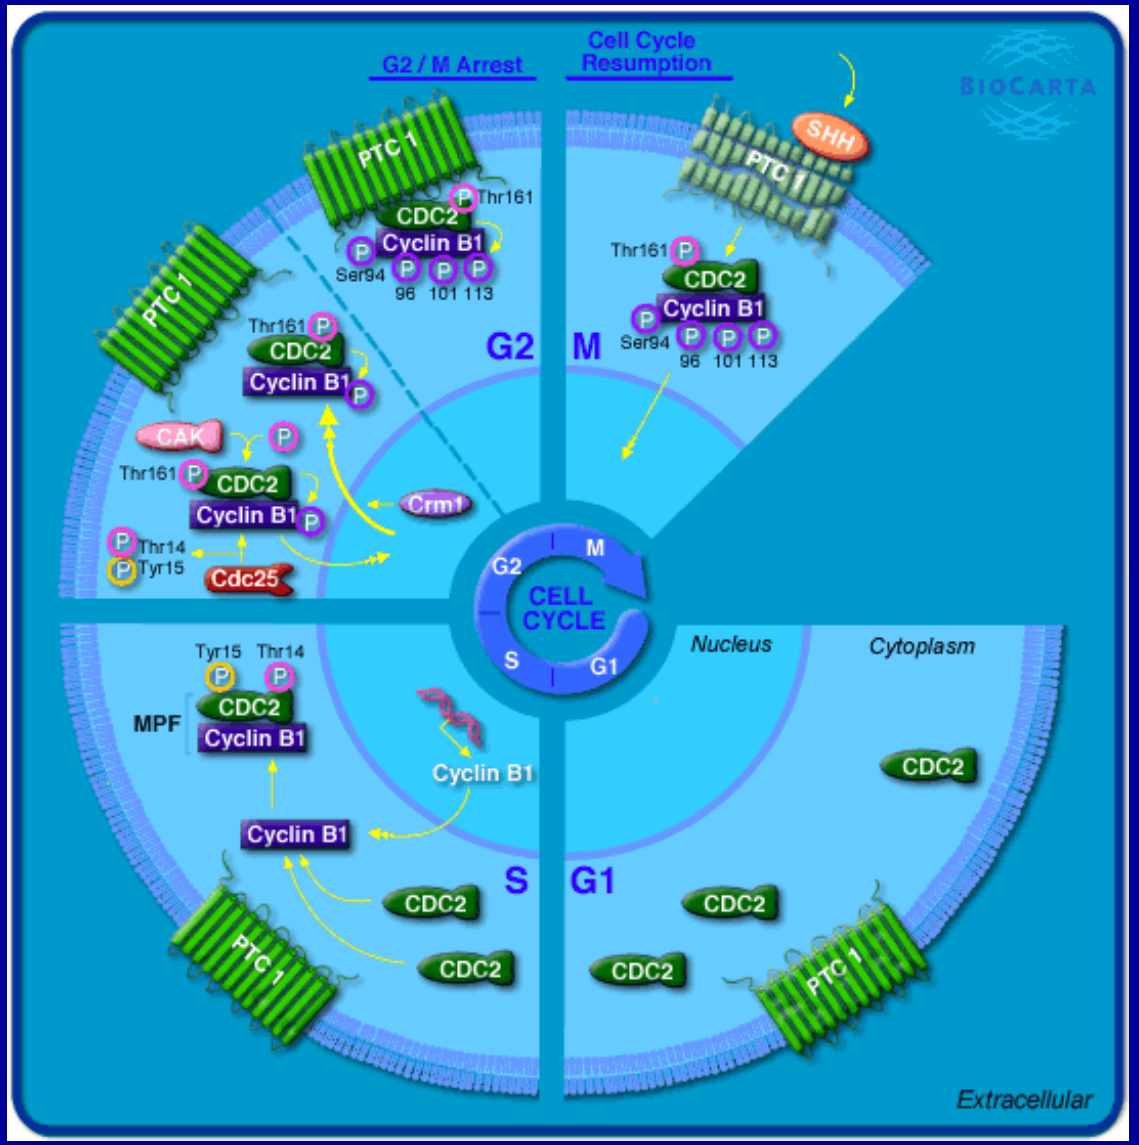
CELL CYCLE ARREST



Cancer cells “evolve” into a highly unstable phenotype:

Loss of contact inhibition

Loss of anchorage dependence

Tumorogenesis

Metastasis

- The ability to undergo successive genetic change suggests that a loss of genetic stability is an early event in carcinogenesis.

- Cell cycle control via cell cycle checkpoints, is thought to be a major mechanism by which cells maintain genetic stability.

WHY CHECKPOINTS?

Fidelity of cell division is dependent upon faithful copying and segregation of genetic material, both spatially and temporally. That is, the ordered sequence of specific events is essential to proper execution of the task.

For this reason, cells have developed checkpoints that insure that the previous replication step is complete before the next step begins.

HOW DO CHECKPOINTS WORK?

- Checkpoints are governed by phosphorylation activity of a group of proteins called CDK (cyclin dependent kinases).
- The CDKs are active only in complexes that contain at least one other protein, called a “cyclin”.
- Changes in the cyclin and kinase components of the complexes are the “switches” that control and regulate progression through the cell cycle.
- In this model, a cohort of proteins required for progression of a particular phase are activated (or inactivated) by phosphorylation of the cyclin/CDK complexes.

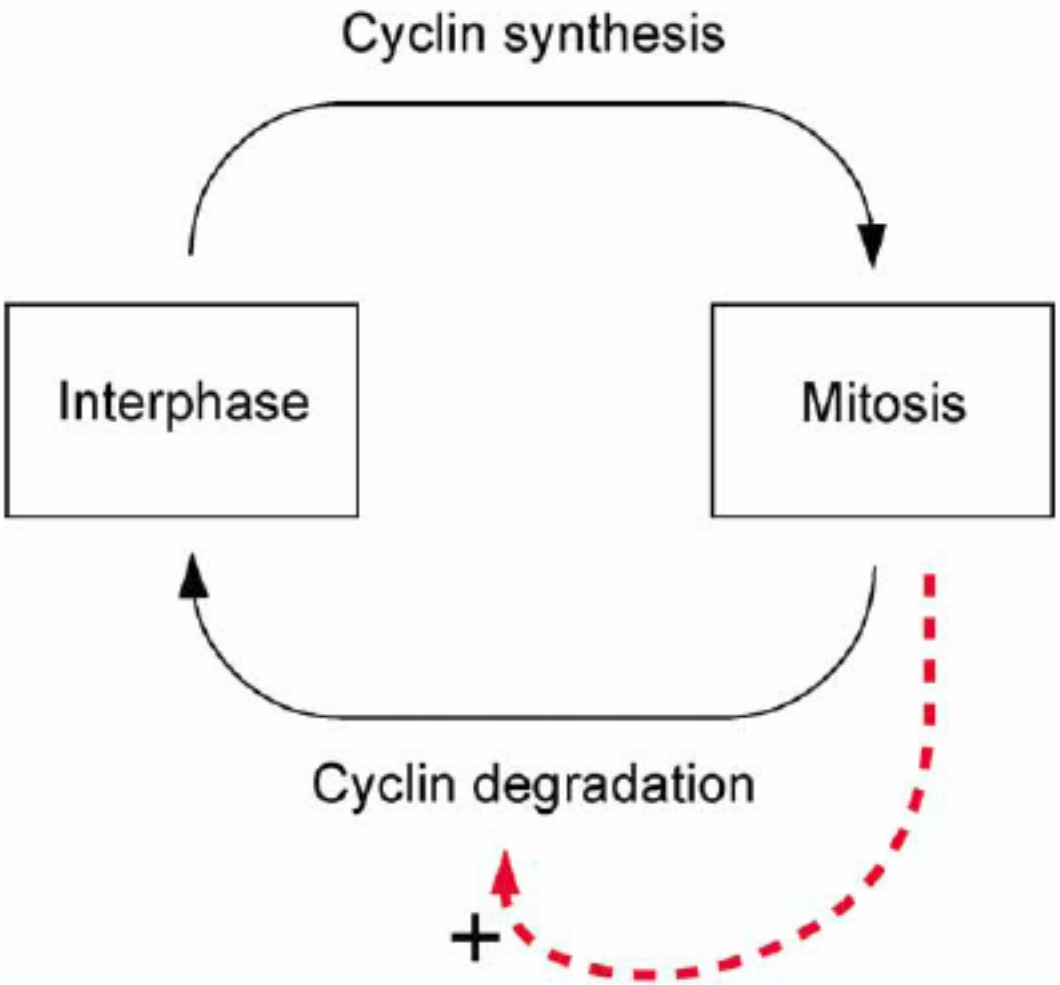


Figure 1. The Original Cyclin-Based Model for the Cell Cycle
The simplest possible model for the cell cycle based on the discovery of cyclin. See text for details.

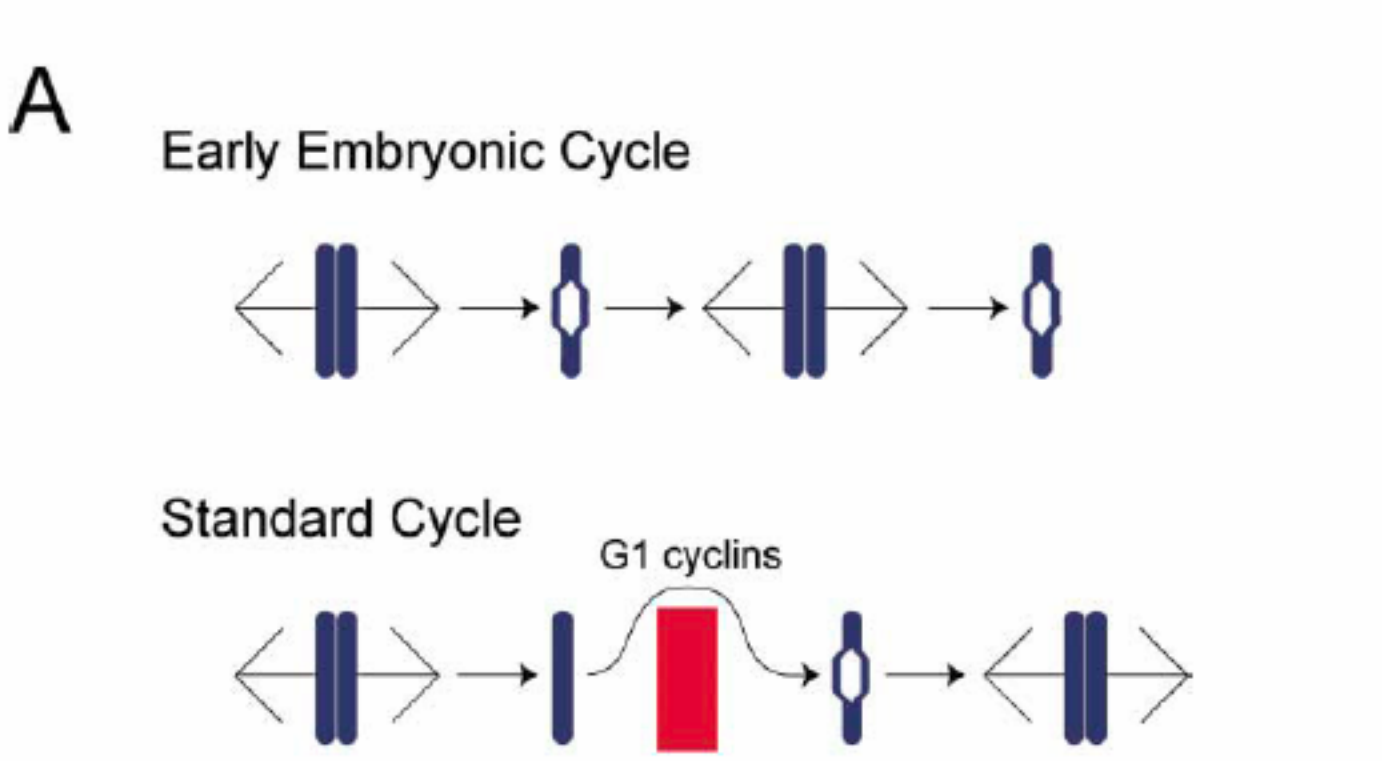

Figure 3. G1 Cyclins Overcome Inhibitors of Cell Cycle Progression

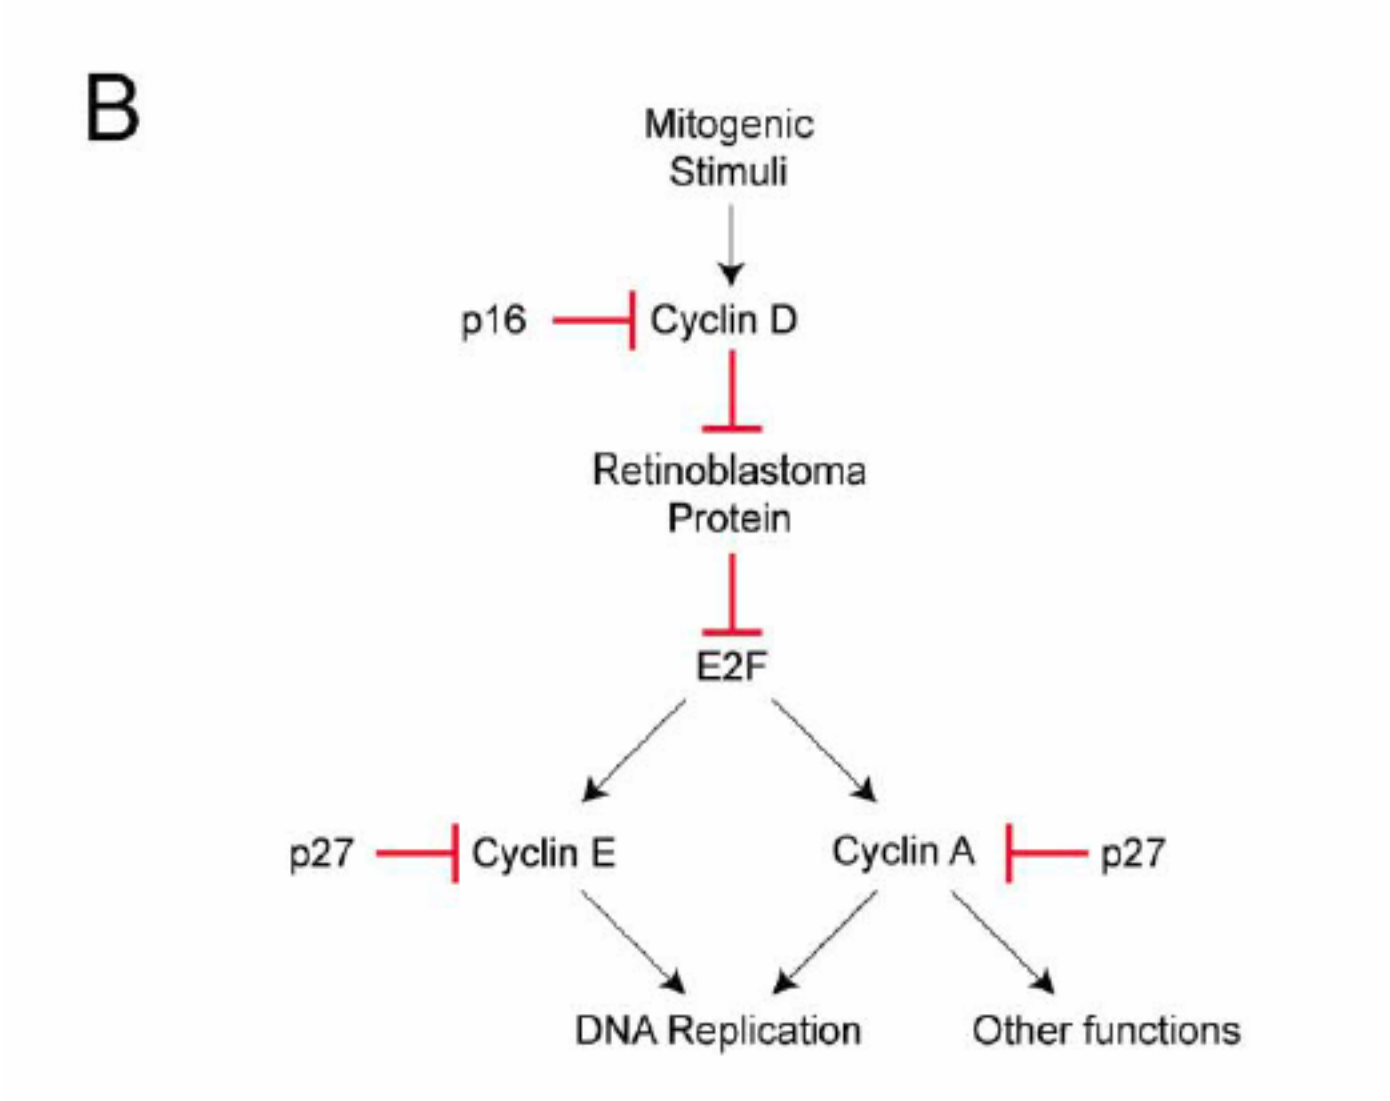
(A) In early embryonic cell cycles, DNA replication begins as soon as cells leave mitosis. In most cell cycles, however, the combination of anaphase promoting factor activity and Cdk inhibitors ensures that cells spend appreciable time in G1 and require the synthesis of G1 cyclins that overcome these inhibitory factors.



(B) The relationship between G1 (cyclin D) and S phase cyclins (A and E), growth factors, and Cdk inhibitors in animal cells. See text for details.

In yeast, only a single CDK is used by a sequence of different cyclins that are briefly transcribed and then quickly degraded at specific points in the cell cycle. The cyclin is, therefore, the important regulatory component determining the specificity of the CDK.

In mammalian cells, multiple CDKs appear to be involved:

	Cyclin
CDK4 functions early (in response to growth factors)	D
CDK2 is required to start DNA replication	E and/or A
CDC2 is essential for mitosis	A and B

Cyclin/CDK complexes seem to be regulated by a variety of feedback mechanism, both positive and negative, that include:

- Transcription of cyclin
- Degradation of cyclin
- Phosphorylation of CDKs

Negative feedback occurs during development, differentiation, and senescence. It probably acts to stop cell cycle progression when the integrity of the genome has been compromised for some reason.

WHAT EFFECT DOES DNA DAMAGE HAVE?

- A major challenge to genetic integrity is physical damage to DNA, and it appears that cells have developed strong negative feedbacks in response to DNA damage.

- Suppression of cell cycle works in concert with DNA repair to:
    1. Allow time for DNA repair
    2. To stimulate DNA repair activity

- Feedback mechanisms are mediated via intermediate proteins that detect or respond to either the damaging agent or the damage itself and act on the cyclin/CDK complexes to suppress their ability to promote progression to the next stage of the cell cycle. There are probably many checkpoints throughout the cell and only the major ones are known.

- At least two checkpoints are responsive to DNA damage:
    1. G1-S transition
    2. G2-M transition

- In mammalian cells the G1-S checkpoint is best understood.

G1-S checkpoint:

An early response to DNA damage is induction of p53 by a post-translational mechanism.

P53 then transcriptionally activates a set of p53 dependent genes:

- Gadd45 is a growth arrest DNA damage dependent gene
- p21 inhibits the kinase activity of multiple cyclin/CDK complexes.

The major consequence of p53 induction is either arrest in G1 or apoptosis.

DO DEFECTIVE CHECKPOINTS CAUSE CANCER?

Evidence suggests that the loss of the G1-S checkpoint can result in cancer:

1. p53 is commonly mutated in a wide variety of cancers.
2. p53 mutant cells are typically highly aneuploid and have gene amplifications.
3. Some cancer viruses express proteins that bind to p53.
4. Cells from A-T patients (cancer prone) have abnormal induction of p53.

Evidence for the role of the G2-M checkpoint in cancer is weaker:

1. Cells from A-T patients undergo reduced G2-M arrest in response to DNA damage.
2. Cancer cell lines often have reduced G2-M arrest.
3. Some cancer cells have altered expression of cyclins A, B, and CDC2.

Radiation-Induced G2 delay in lymphoblasts may be a good biomarker for lung cancer

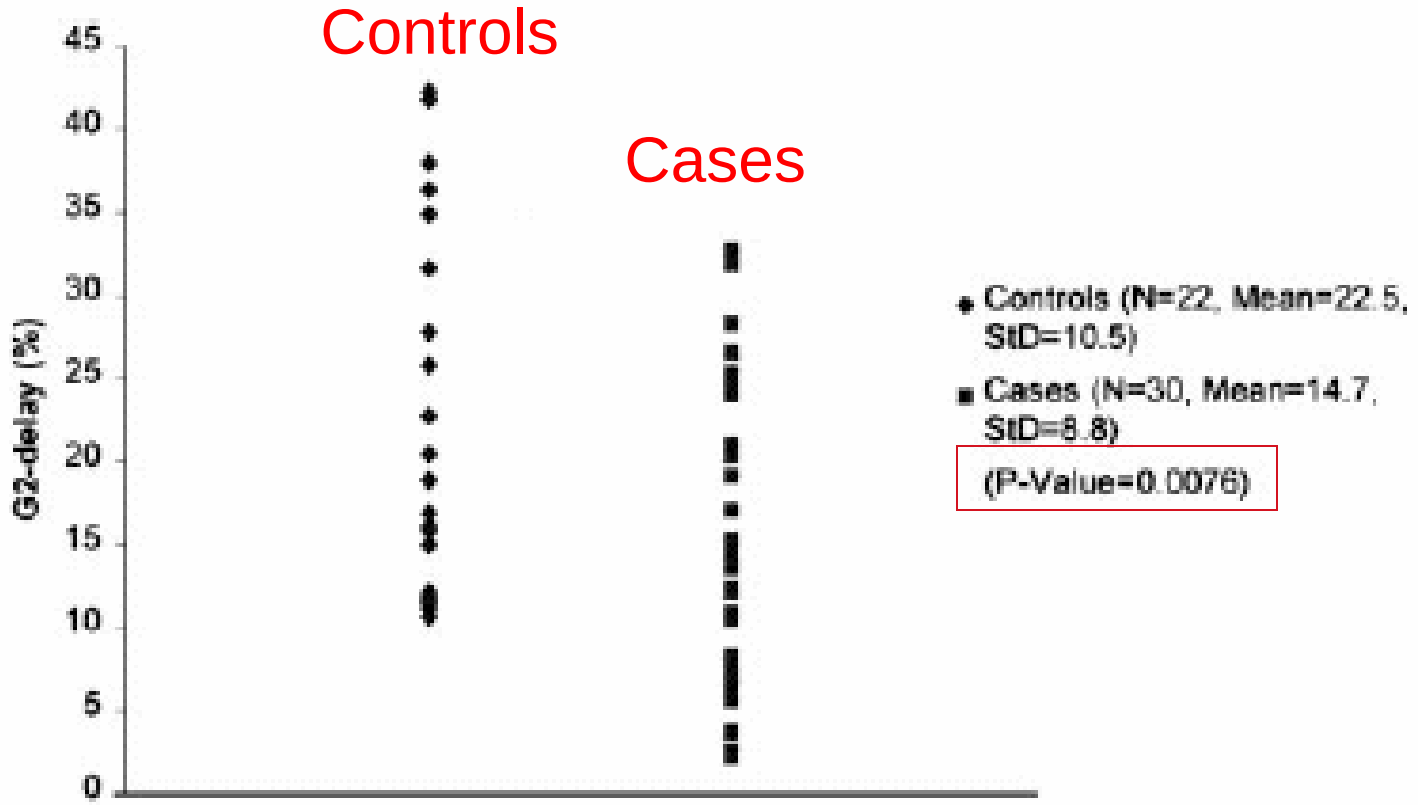


Fig. 3. Distribution of G_2 delay in lymphoblastoid cells of lung cancer cases and controls. Cell lines from 22 normal healthy donors and 30 lung cancer patients were exposed to 2.5 Gy of γ-radiation for 10 h. The values shown are the mean values from three separate experiments.

Fas Ligand: A Sensor for DNA Damage Critical in Skin Cancer Etiology

Laurie L. Hill, Allal Ouhtit, Susan M. Loughlin, Margaret L. Kripke, Honnavara N. Ananthaswamy, Laurie B. Owen-Schaub*

DNA-damaged cells can either repair the DNA or be eliminated through a homeostatic control mechanism termed "cellular proofreading." Elimination of DNA-damaged cells after ultraviolet radiation (UVR) through sunburn cell (apoptotic keratinocyte) formation is thought to be pivotal for the removal of precancerous skin cells. Sunburn cell formation was found to be dependent on Fas ligand (FasL), a pro-apoptotic protein induced by DNA damage. Chronic exposure to UVR caused 14 of 20 (70 percent) FasL-deficient mice and 1 of 20 (5 percent) wild-type mice to accumulate p53 mutations in the epidermis. Thus, FasL-mediated apoptosis is important for skin homeostasis, suggesting that the dysregulation of Fas-FasL interactions may be central to the development of skin cancer.

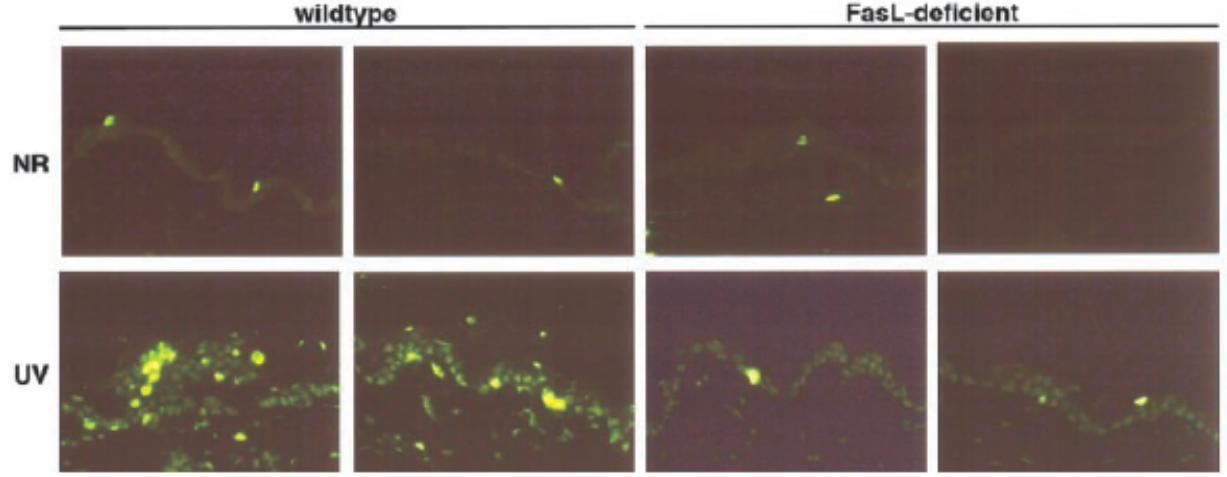

Fig. 2. Sunburn cell induction in wild-type and FasL-deficient (*gld/gld*) mice after UVR. Mice were acutely exposed to UV-B light (5 kJ/m^2), and skin sections were harvested for TUNEL analysis at 0 (NR) and 24 (UV) hours (*15*). A minimum of four mice (nonirradiated and irradiated) were examined; sections from two individual mice are shown. NR, nonirradiated. Magnification, ×10.

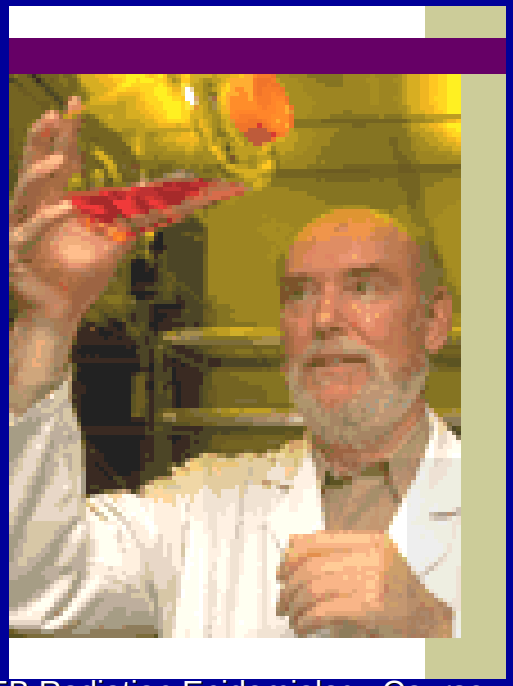
Defective Repair Replication of DNA in Xeroderma Pigmentosum

by

J. E. CLEAVER

Laboratory of Radiobiology,
University of California Medical Center,
San Francisco, California

Normal skin fibroblasts can repair ultraviolet radiation damage to DNA by inserting new bases into DNA in the form of small patches. Cells from patients with the hereditary disease xeroderma pigmentosum carry a mutation such that repair replication of DNA is either absent or much reduced in comparison to normal fibroblasts. Patients with xeroderma pigmentosum develop fatal skin cancers when exposed to sunlight, and so the failure of DNA repair in the skin must be related to carcinogenesis.



"… the failure of DNA repair in the skin *must* be related to carcinogenesis."
-- James E. Cleaver

Nucleotide Excision Repair (NER)

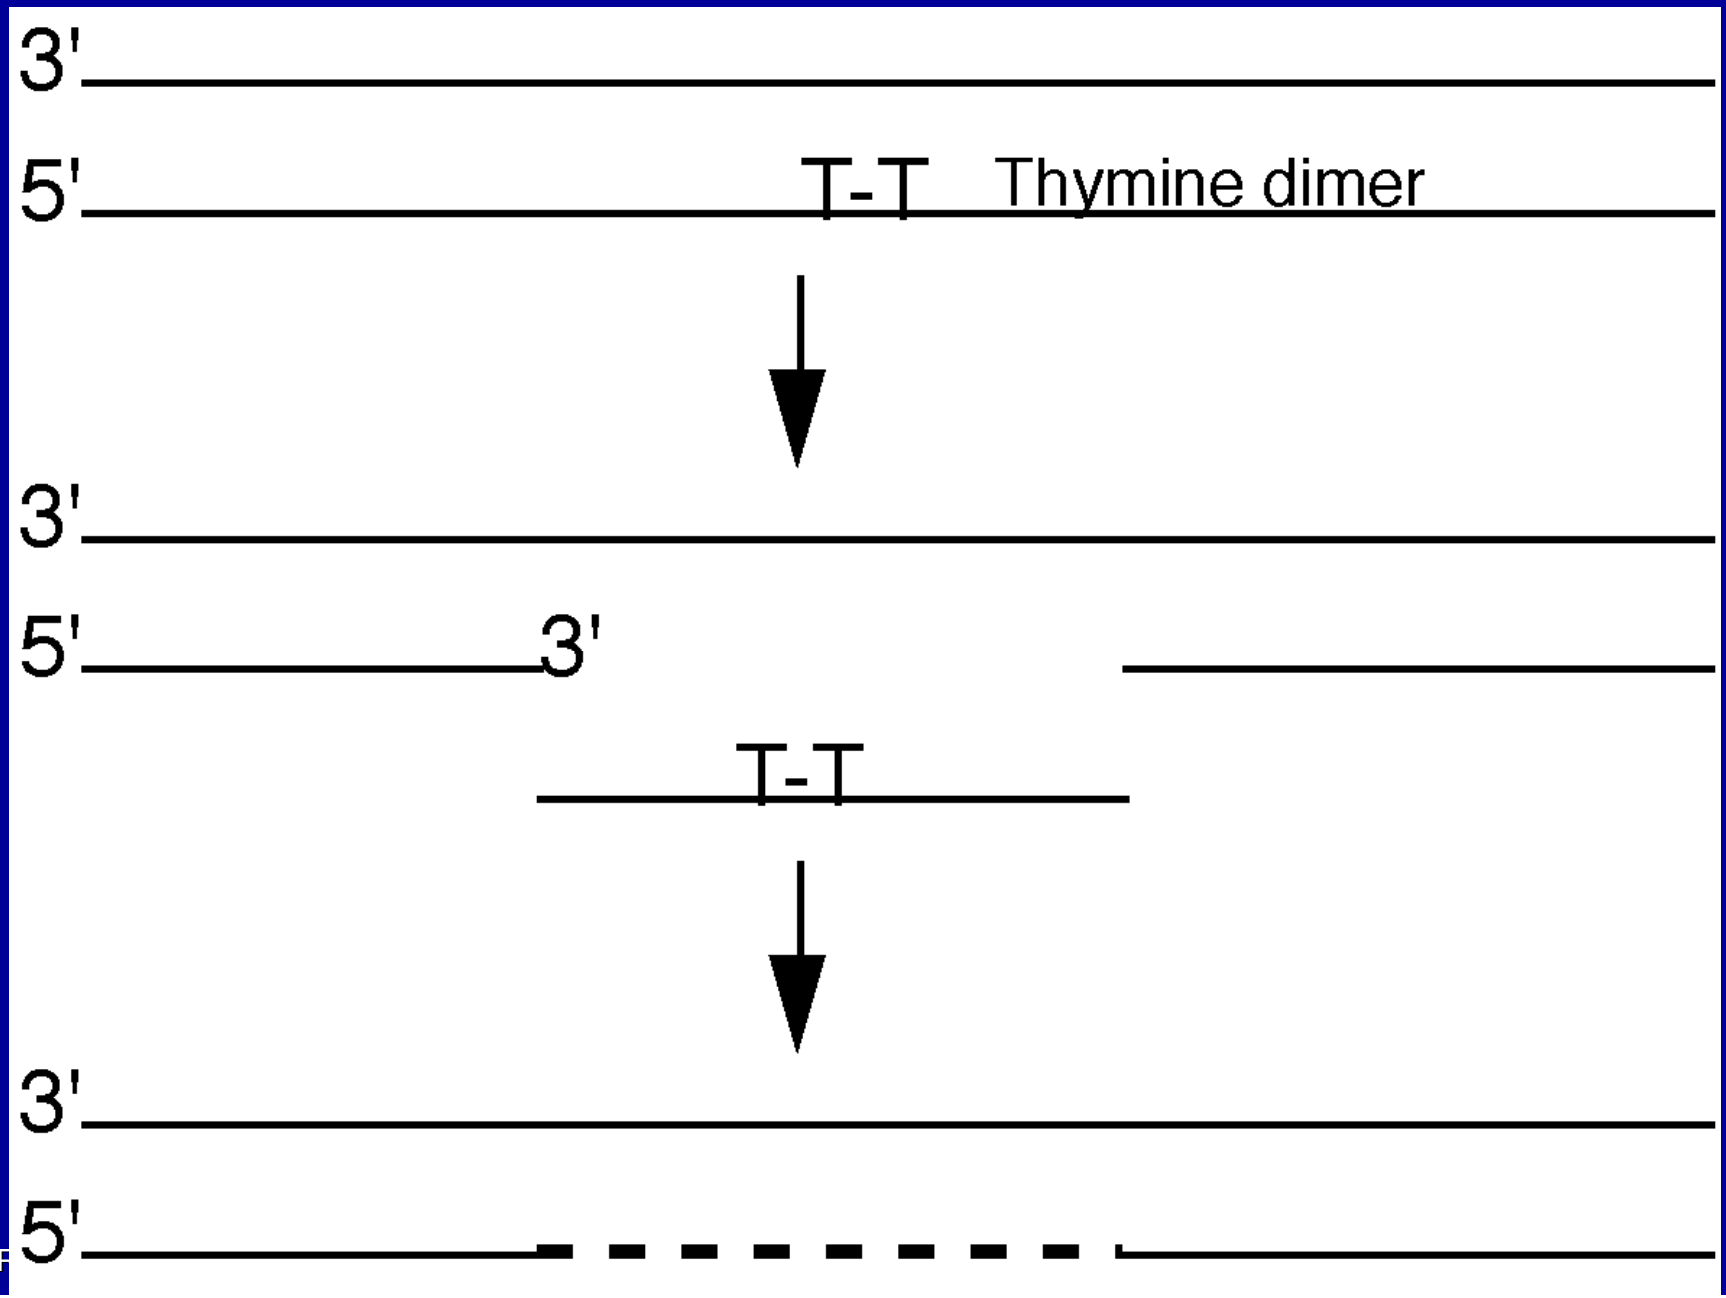


Fig. 3. Nucleotide excision repair in nontranscribed regions (the bulk of DNA). Initially, a distortion is recognized, probably by the XPC-hHR23B protein (**A**). An open bubble structure is then formed around a lesion in a reaction that uses the ATP-dependent helicase activities of XPB and XPD (two of the subunits of TFIIH) and also involves XPA and RPA (**B**). Formation of this open complex creates specific sites for cutting on the 3′ side by the XPG nuclease and then on the 5′ side by the ERCC1-XPF nuclease (**C**). After a 24- to 32-residue oligonucleotide is released, the gap is filled in by PCNA-dependent POL ε or δ and sealed by a DNA ligase, presumably LIG1 (**D**).

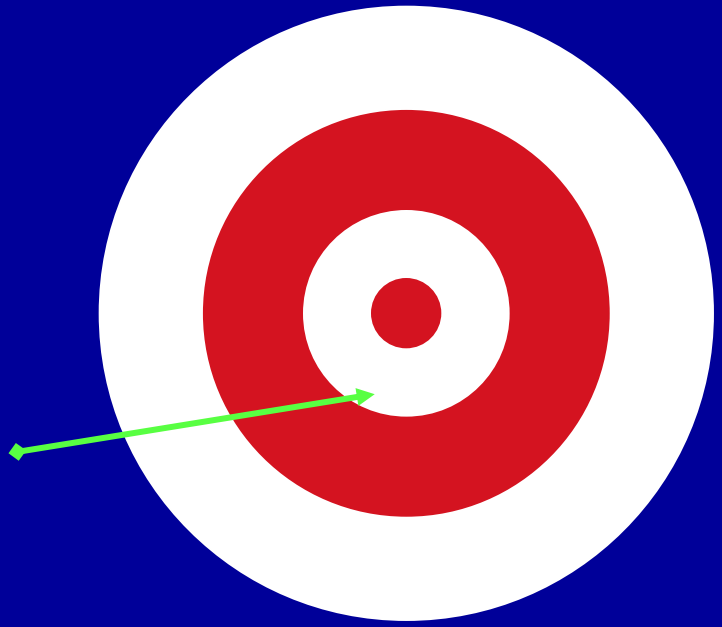
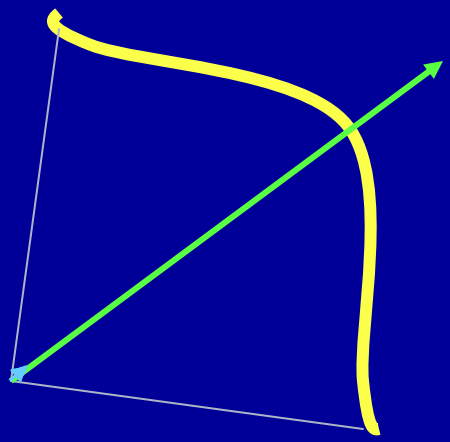
TARGET THEORY

NORMAL CELL

CANCER

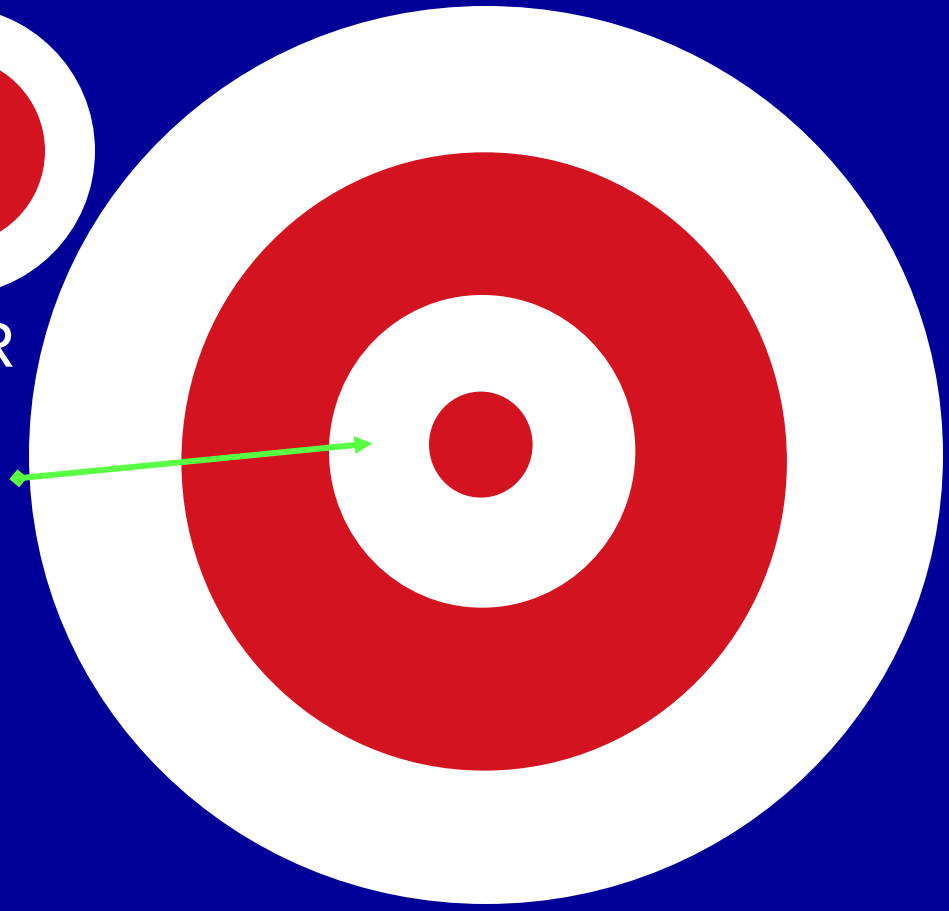


CELL DEATH

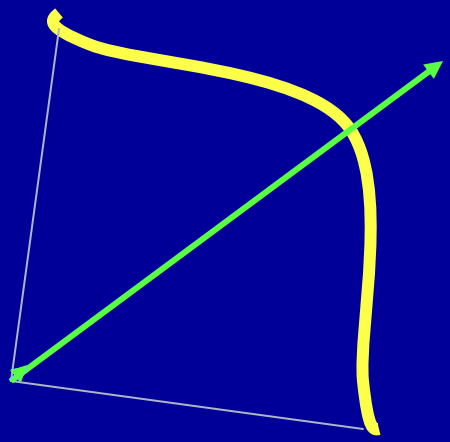


A-T CELL

CANCER

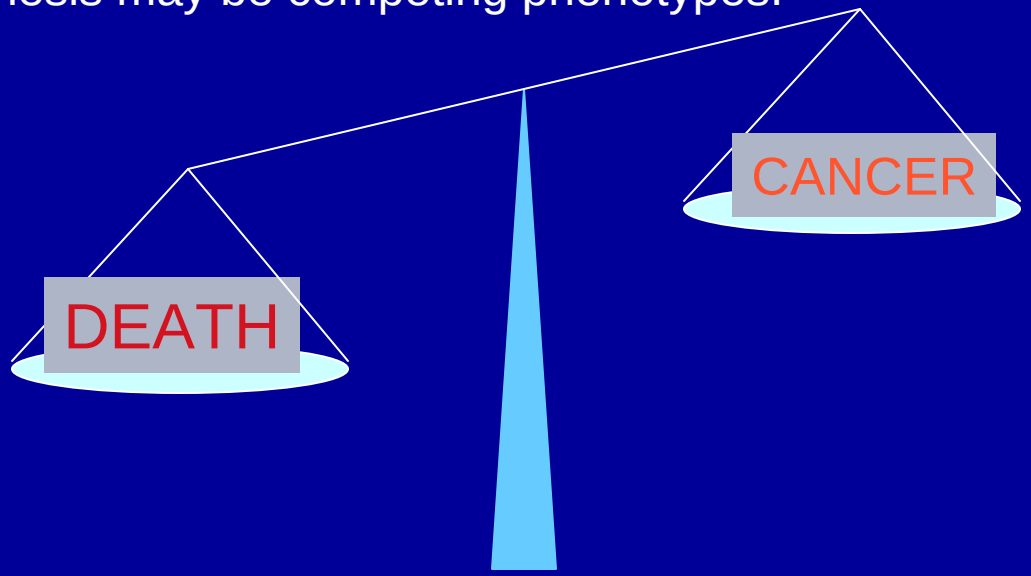


CELL DEATH



Are radiation sensitivity genes and radiation carcinogenesis genes the same?

- Several radiation sensitivity genes are known (e.g. ATM), but generally these genes confer sensitivity specifically to radiation-induced *killing*.
- Cellular radiosensitivity genes are potential radiation carcinogenesis genes, but association with increased cancer risk has not been established.
- The problem may be that sensitivity to radiation lethality and radiation carcinogenesis may be competing phenotypes.



OTHER TARGET QUESTIONS:

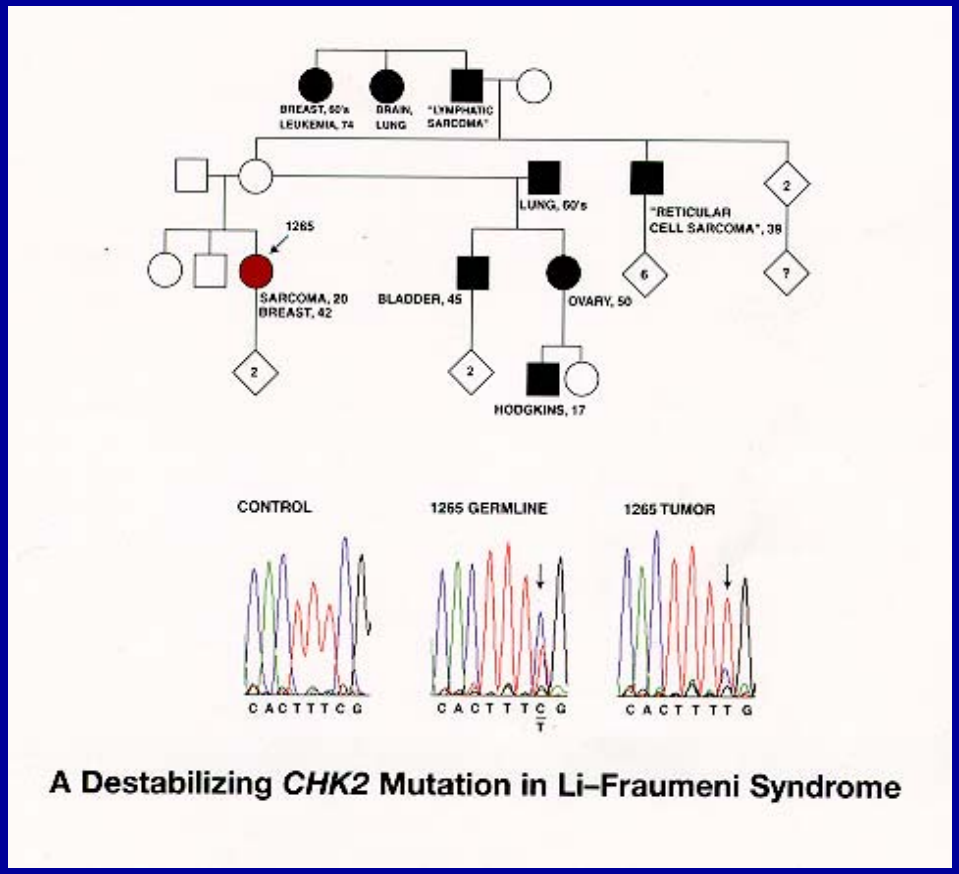
- If DNA repair deficiency predisposes to radiation induced cancer, then what are the mutated target genes that cause cellular transformation?

- What is the mechanism of transformation?

Li-Fraumeni Syndrome

- Caused by a germline mutation in p53 gene (TP53)
- Characterized by the occurrence of early onset:
  - sarcomas
  - breast cancer
  - brain tumours
  - leukemia
  - adrenocortical tumors

Mutations in Chk2 produce the Li-Fraumeni phenotype



Family pedigree with proband (1265, *arrow*) diagnosed with both breast cancer and sarcoma. A heterozygous germline mutation in *CHK2* is accompanied by loss of the wild type *CHK2* allele in breast cancer of the proband. The mutant R145W allele encodes and unstable protein. (S.B. Lee et al. Cancer Res. 61: 8062, 2001)

With all of these well-defined pathways and well-characterized genes that are known to be involved in resisting radiation damage to cells, it is tempting to speculate that different forms of the genes from these pathways might alter individual risk of radiation-induced cancer.

We know this to be true in the special case of individuals with genetic diseases that have functional mutations in both alleles. But is it true for heterozygotes of mutated genes, or normal individuals with polymorphic forms of these genes?

How do we go about answering this fundamental question?

CASE STUDY:

Finding Molecular Targets for Radiation-Induced Basal Cell Carcinoma

Gene-Environmental Interactions in Cancer

Which environmental carcinogens?

Which cancers?

Which genes?

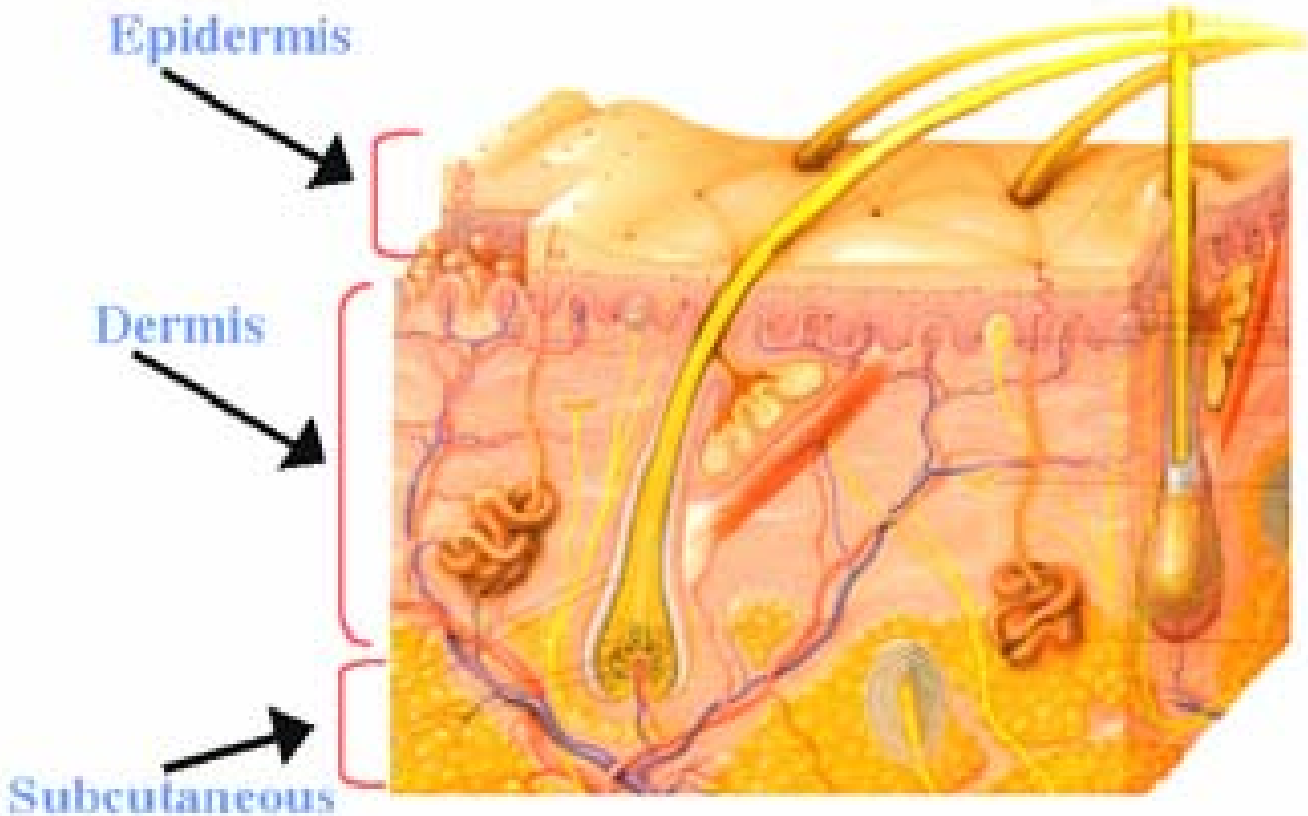
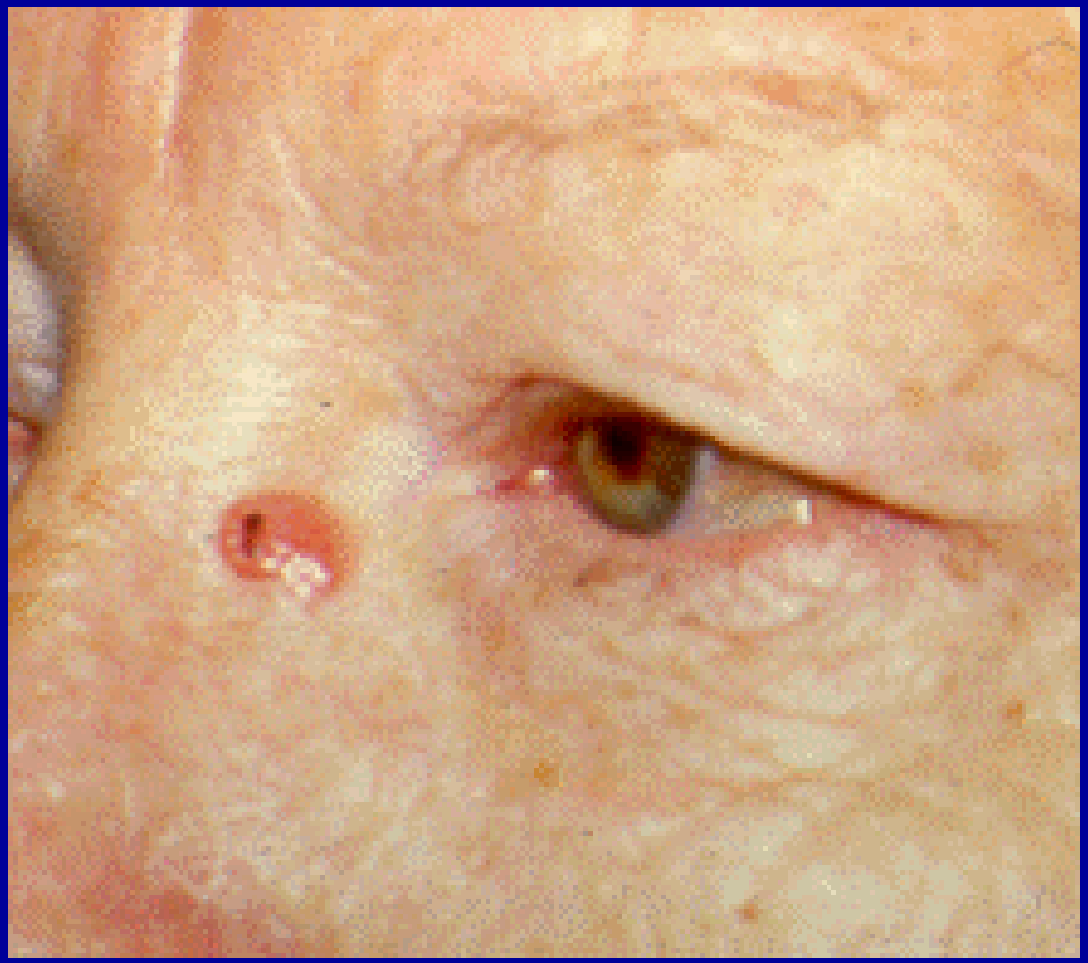
Skin Anatomy





Problems for Epidemiology of BCC

BCC and SCC are not in most cancer registries because:

- Large numbers to follow
- Multiple lesions per individual
- Multiple lesions diagnosed simultaneously
- High cure rate

Nevertheless, it is estimated that the combined incidence of BCC and SCC is nearly equal to the incidence of all other cancers combined.

Environmental Causes of BCC

- UV radiation
- Ionizing radiation
- Arsenic

Bazex-Dupre-Christol Syndrome

- Skin disorder with high incidence of BCC on face and hands
- BCC onset from 15-25 years of age
- X-linked transmission
- Gene unknown

Rombo Syndrome

- Similar to Bazex, but with male to male transmission
- Gene unknown

Xeroderma Pigmentosum

- High incidence in BCC, SCC, and melanoma
- Mean age of cancer onset is 8 years
- Defect in one of 7 nucleotide excision repair genes

Gorlin Syndrome

- Nevoid basal cell carcinoma syndrome (NBCC)
- 90% of patients have at least one BCC by age 40
- Germline mutation in the PTCH gene

QUESTIONS:

- If NER repair deficiency predisposes to radiation induced BCC, then what are the mutated target genes that cause cellular transformation?

- What is the mechanism of transformation?

Skin cancers have unique p53 mutations:

Table 1. Mutations in the p53 gene in invasive squamous cell carcinoma of the skin

Tumor	Age, yr	Sex	Site	Codon	Sequence	Base change	Amino acid change
NI 6	86	♀	Preauricular	7	tCt	C → G	Asp → His
NI 9	77	♀	Chest	56	tcttCa	C → A	Glu → stop
SI 2	82	♂	Preauricular	104/105	gcct	ΔC	Gly → Ala . . . stop
SI 20	82	♂	Temple	104/105	gcct	ΔC	Gly → Ala . . . stop
SI 16	69	♀	Scalp	151	cCccc	C → A	Pro → His
SI 15	69	♀	Hand	152	cccCc	C → T	Pro → Ser
NI 4	76	♂	Front scalp	179	acCa	C → A	His → Asn
NI 3	68	♂	Cheek	245	gcCg	C → A	Gly → Cys
NI 9	77	♀	Chest	245	gCCg	CC → TT	Gly → Asn
SI 13	80	♀	Nose	247–248	aCC*g	CC → TT	Asn-Arg → Asn-Trp
SCC 13	56	♀	Side of face	258	ttCc	C → T	Glu → Lys
NI 11	76	♂	Cheek	278	tCct	C → T	Pro → Ser
SI 1	85	♂	Face	285–286	tCCt	CC → TT	Glu-Glu → Glu-Lys
NI 5	89	♂	Forehead	286	tCct	C → T	Glu → Lys
NI 8	75	♂	Postauricular	317	cccCa	C → T	Gln → stop

The sequence is written 5′ → 3′ for the strand containing the pyrimidine. A wild-type allele was observed in all cases except SI 1, SI 15, and SCC 13. Sample NI 9 contained two point mutations. For SI 2, 13, 15, 16, and 20 and NI 4 and 11, an inherited mutation at the site could be excluded based on the presence of a normal sequence in a section of normal tissue or in a second tumor. For SI 13 and 16 and NI 3, 6, and 9, the mutant band was present at less than a 1:1 ratio to the wild-type band; these samples were also those that contained <70% neoplastic cells. SI, Sweden; NI, New York; uppercase letter of sequence, base mutated; ΔC, deletion of a C; C*, cytosine known to be methylated at this site.

DE Brash et al. *PNAS* 88:10124, 1991

Mutation spectrum matched UV mutagenesis and differs from mutations in internal tumors:

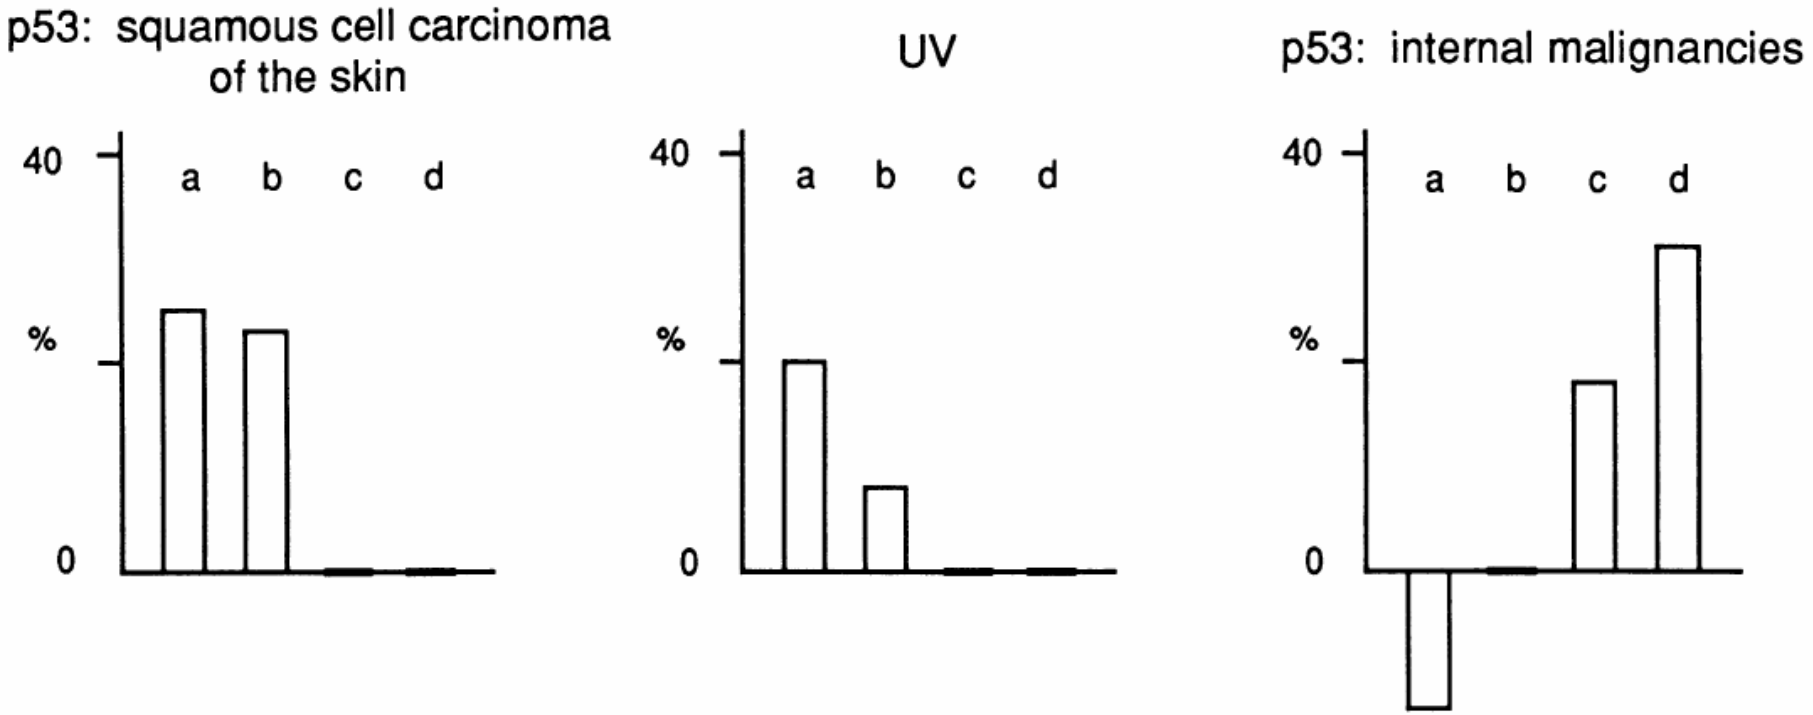

FIG. 2. Diagnostic types of base substitutions in p53 in 13 squamous cell carcinomas of the skin compared with p53 mutations reported in 97 internal malignancies (refs. 25, 27–31, and references therein) and compared with 66 UV mutations studied in endogenous genes in mammalian cells (10, 12). The comparisons are limited to endogenous genes because CG frequencies are underrepresented in mammalian DNA. The vertical axis indicates percentage of total skin squamous cell carcinoma p53 mutations, UV mutations, or internal malignancy p53 mutations that are of mutation type a, b, c, or d. Histograms: a, mutation located at a dipyrimidine site (in excess of the 75% expected randomly); b, CC → TT double-base substitution; c, C → T substitution not at a dipyrimidine site; d, C → T substitution at a CG dinucleotide.

DE Brash et al. *PNAS* 88:10124, 1991

For BCC, PTCH may be even a bigger target than p53

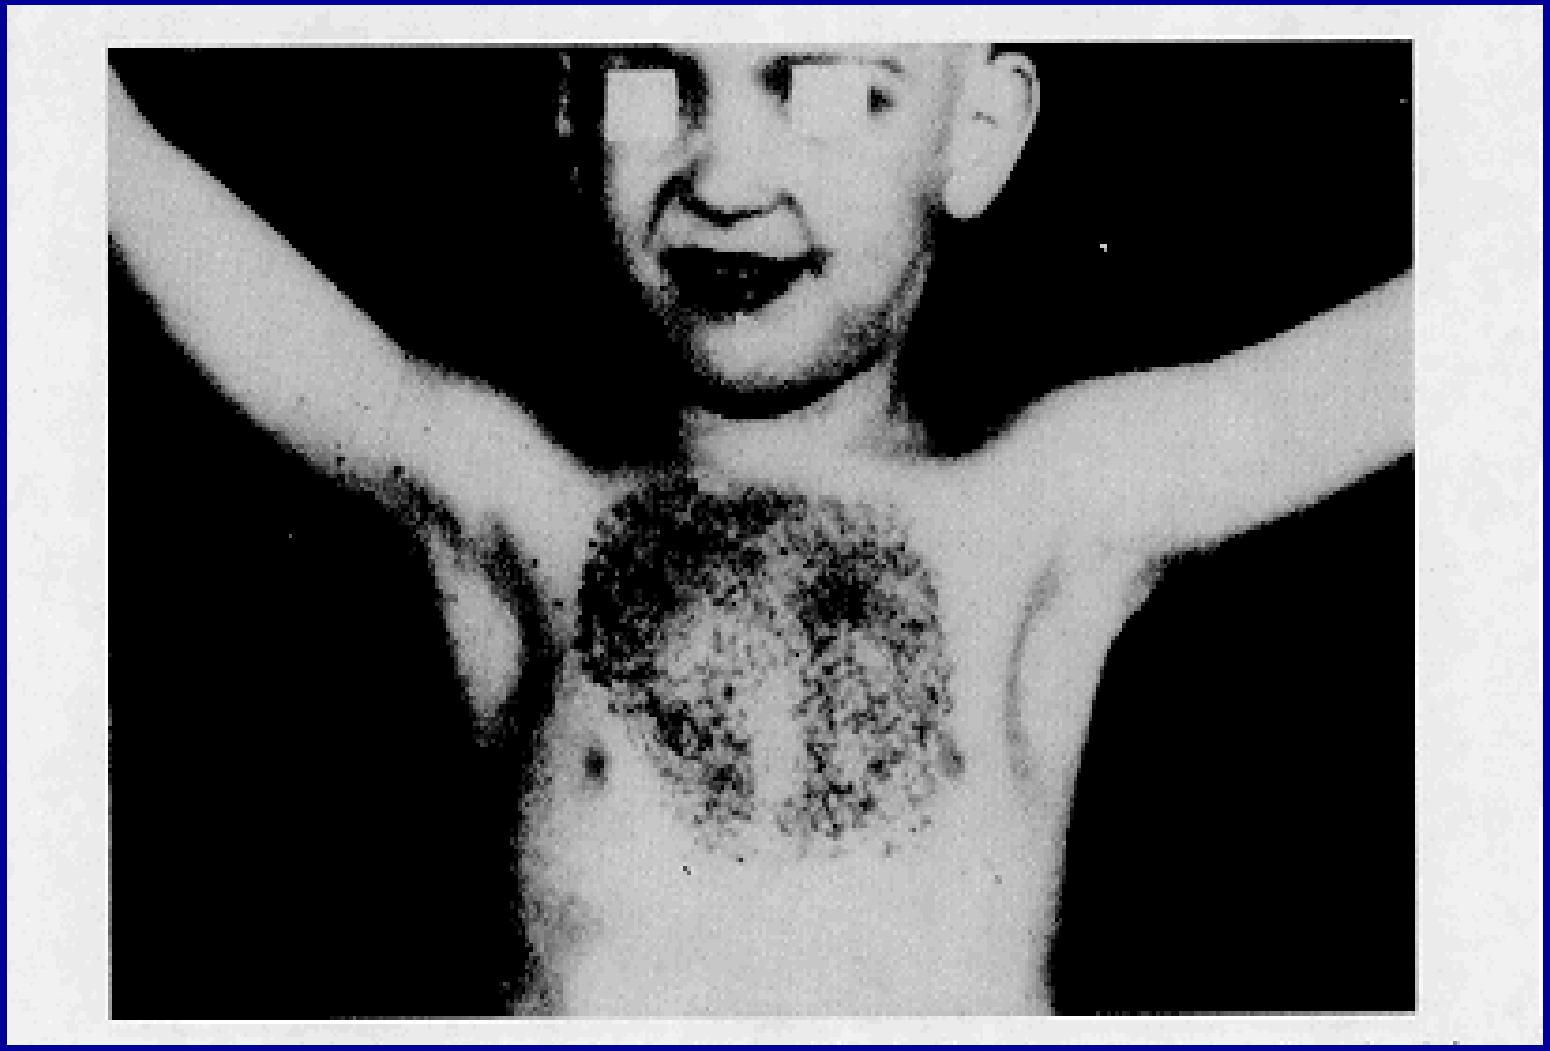
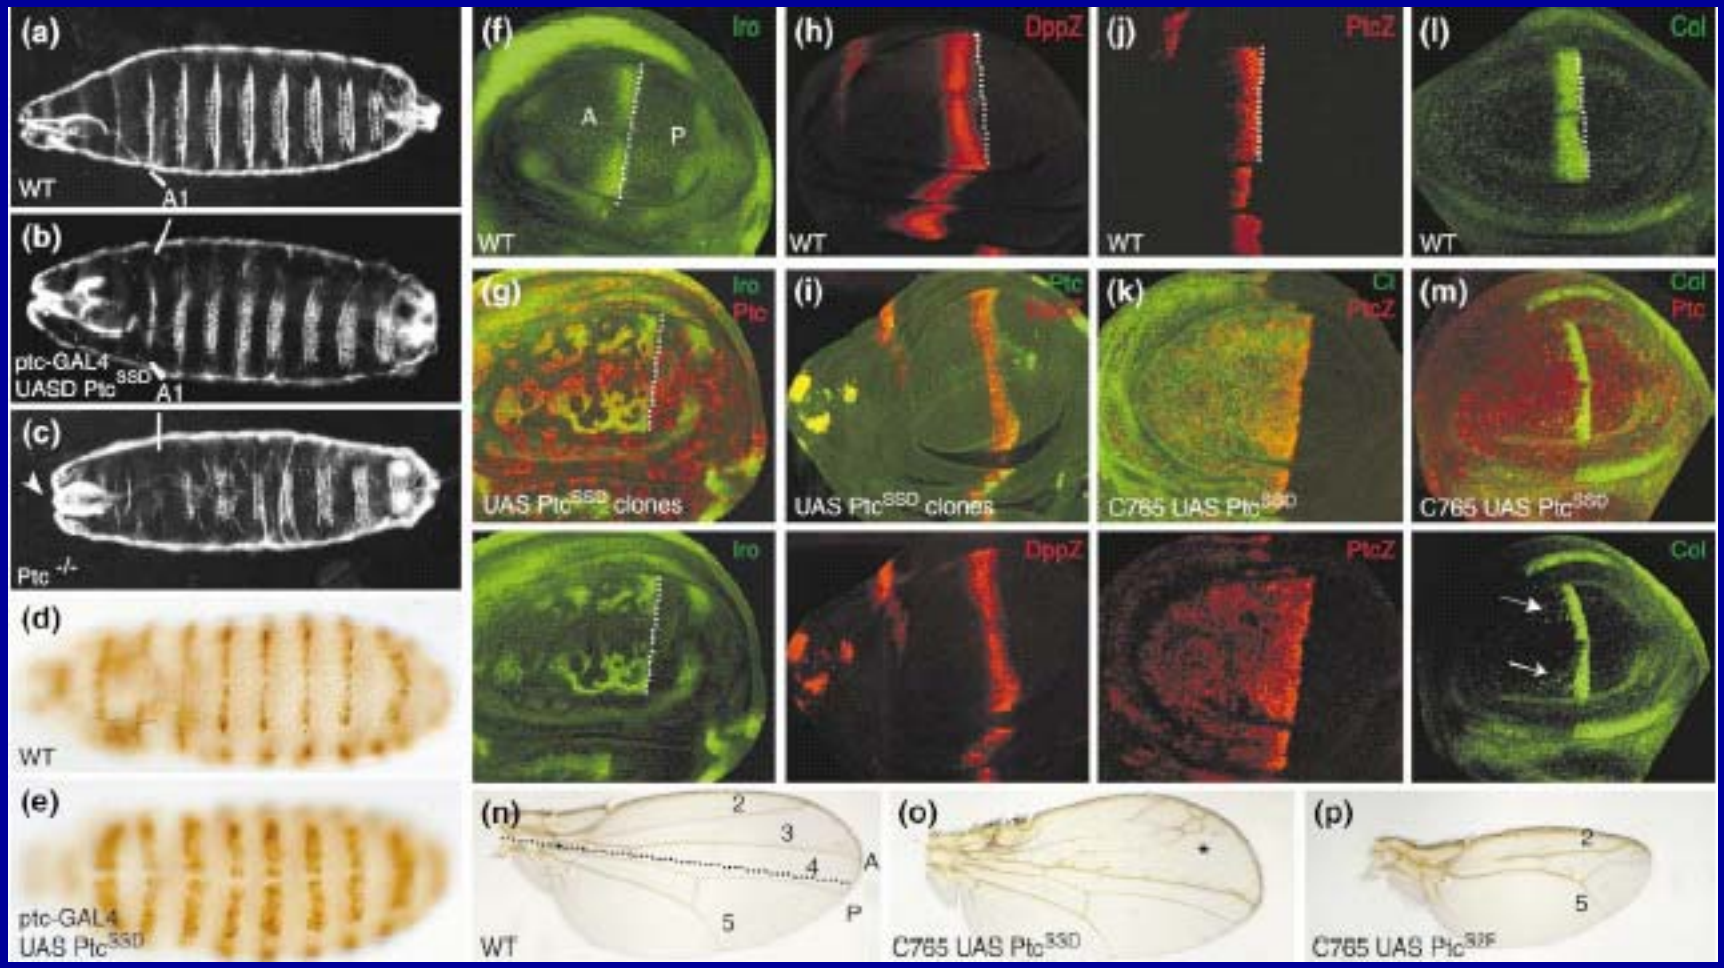
Gorlin Syndrome

- Nevoid basal cell carcinoma syndrome (NBCCS)
- Autosomal dominant disease with high penetrance
- Accounts for ~0.5% of all BCC cases (probably much higher percentage of early onset BCC)
- 20% of the patients also develop medulloblastoma and other cancers.
- Patients treated with radiotherapy develop large numbers of basal cell carcinomas in the radiation field.
- Gene responsible is the human homolog of the “Patched” gene (PTCH) in Drosophila, and may be a tumor suppressor in mammalian cells.
- Patched is a transmembrane signal transduction protein upstream of sonic hedgehog, Smoothened, and the proto-oncogene Gli1.
- PTCH heterozygote mice have enhanced sensitivity to radiation-induced teratogenesis.

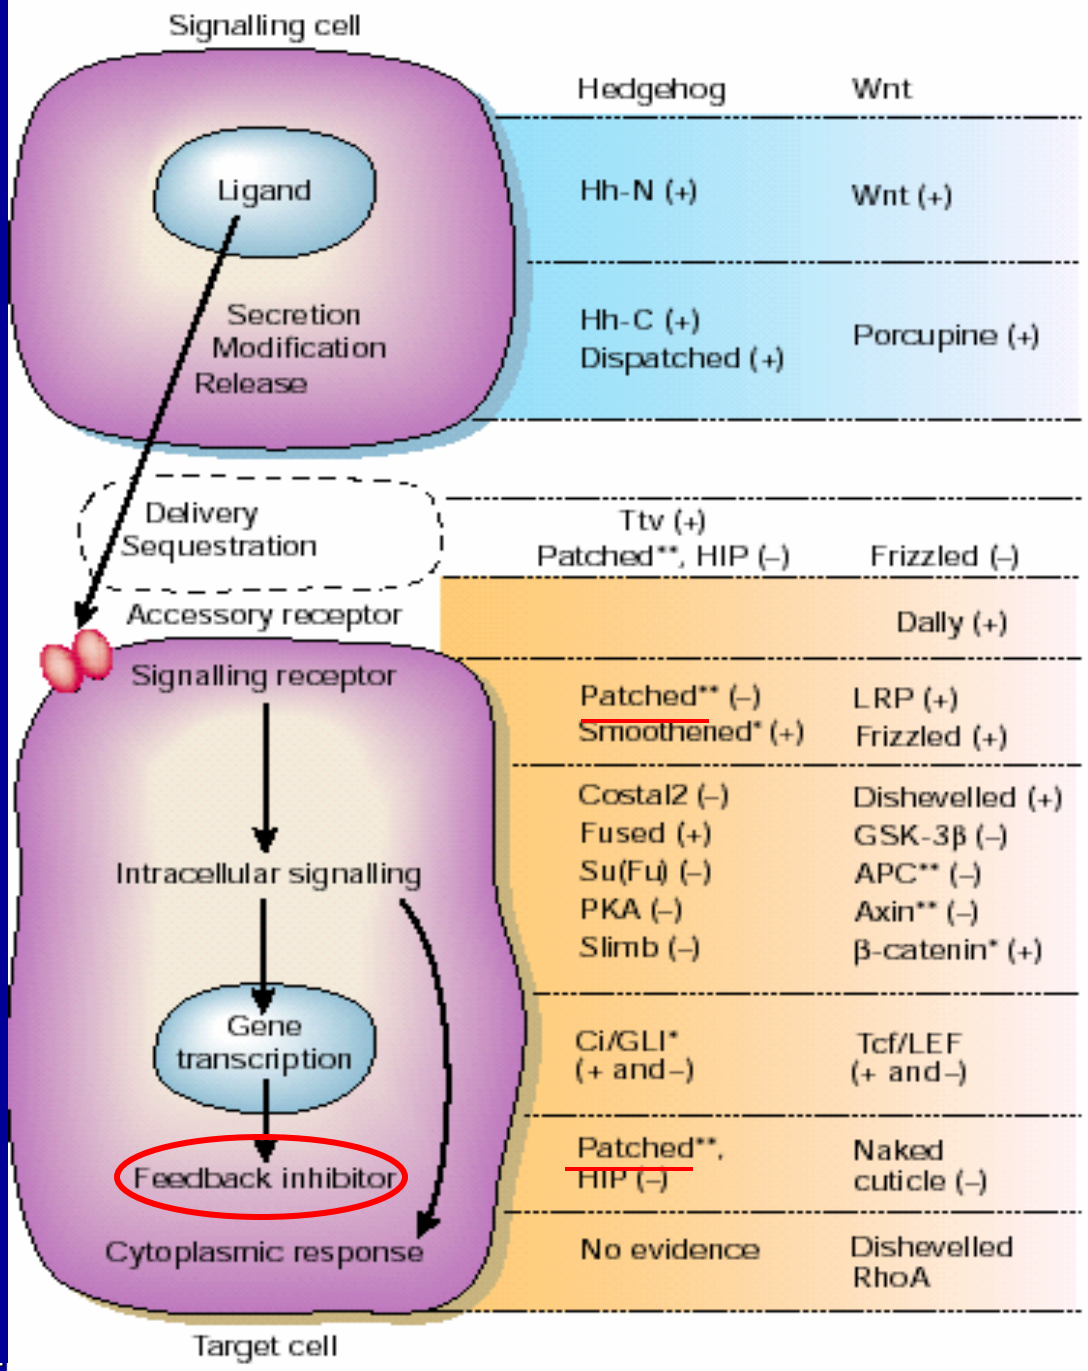


- Very early onset
- Many primary tumors

ICRP Publication 79, 1998



Verónica Martín, Graciela Carrillo, Carlos Torroja and Isabel Guerrero. The sterol-sensing domain of Patched protein seems to control Smoothened activity through Patched vesicular trafficking, *Curr. Biol*. 11: 601-607 (2001).



Hh and Wnt Pathways

Taipale J and Beachy PA

Nature 411:349-54 (2001)

Table 1 Wnt and Hedgehog pathways in cancer

Pathway	Tumour type	Occurrence of mutations in sporadic cases	Familial syndrome, tumour incidence
Hedgehog	Basal cell carcinoma	~50%	BCNS, ~100%
	Medulloblastoma	~25%	BCNS, 1–3%
	Fibrosarcoma	ND	BCNS, low
	Rhabdomyosarcoma	ND	BCNS, very low
Wnt	Colorectal cancer	85%	FAP, very high in untreated cases
	Desmoid tumour	74%	FAP, 10%
	Hepatoblastoma	67%	FAP, <1%

The list presented is not comprehensive and underestimates the prevalence of mutations, as neither all components of a given pathway nor transcriptional targets indicative of pathway activation have generally been examined. Included are cases where clear genetic evidence links increased cancer risk in humans or mice to a germline loss of function of a single copy of a tumour suppressor (*PTCH* in Hh, *APC* in Wnt). ND, no data; BCNS, basal cell nevus syndrome; FAP, familial adenomatous polyposis. (Source: OMIM (http://www.ncbi.nlm.nih.gov/omim/) and refs 2, 32, 33, 35, 47, 68–70.)

The case number, type of tumour (BCC or SCC *in situ*) and location of the tumour is given on the left. The presence (+) or absence (–) of gene expression is indicated, with strong expression indicated by ++. A section of each excision was also stained with haematoxylin and eosin (H&E) for histological examination and confirmation of the presence of tumour. Case no. 10 was ambiguous and was counted as negative for *Gli1* expression. Abbreviations: as, antisense RNA probe; s, sense RNA probe; Ab, antibody; lat., lateral.

Shh, PTCH, and SUFU mutations produce developmental defects, suggesting gene dosage effects.

Table 1. Diseases associated with mutations in the Sonic hedgehog (Shh) pathway

Gene	Condition	Clinical characteristics	References
Sonic hedgehog	Holoprosencephaly	Incomplete separation of cerebral hemispheres, craniofacial anomalies (e.g. cyclopia)	24,25
	Tumors	Basal cell carcinoma	41
		Medulloblastoma	41
		Breast carcinoma	41
Patched	Nevoid basal cell carcinoma syndrome (Gorlin syndrome)	Basal cell carcinomas, dyskeratotic palmar/plantar pits, jaw cysts, skeletal anomalies	8,33,34
	Tumors	Sporadic basal cell carcinoma	35
		Medulloblastoma	36
		Trichoepithelioma	39
		Breast carcinoma	37
		Meningioma	37

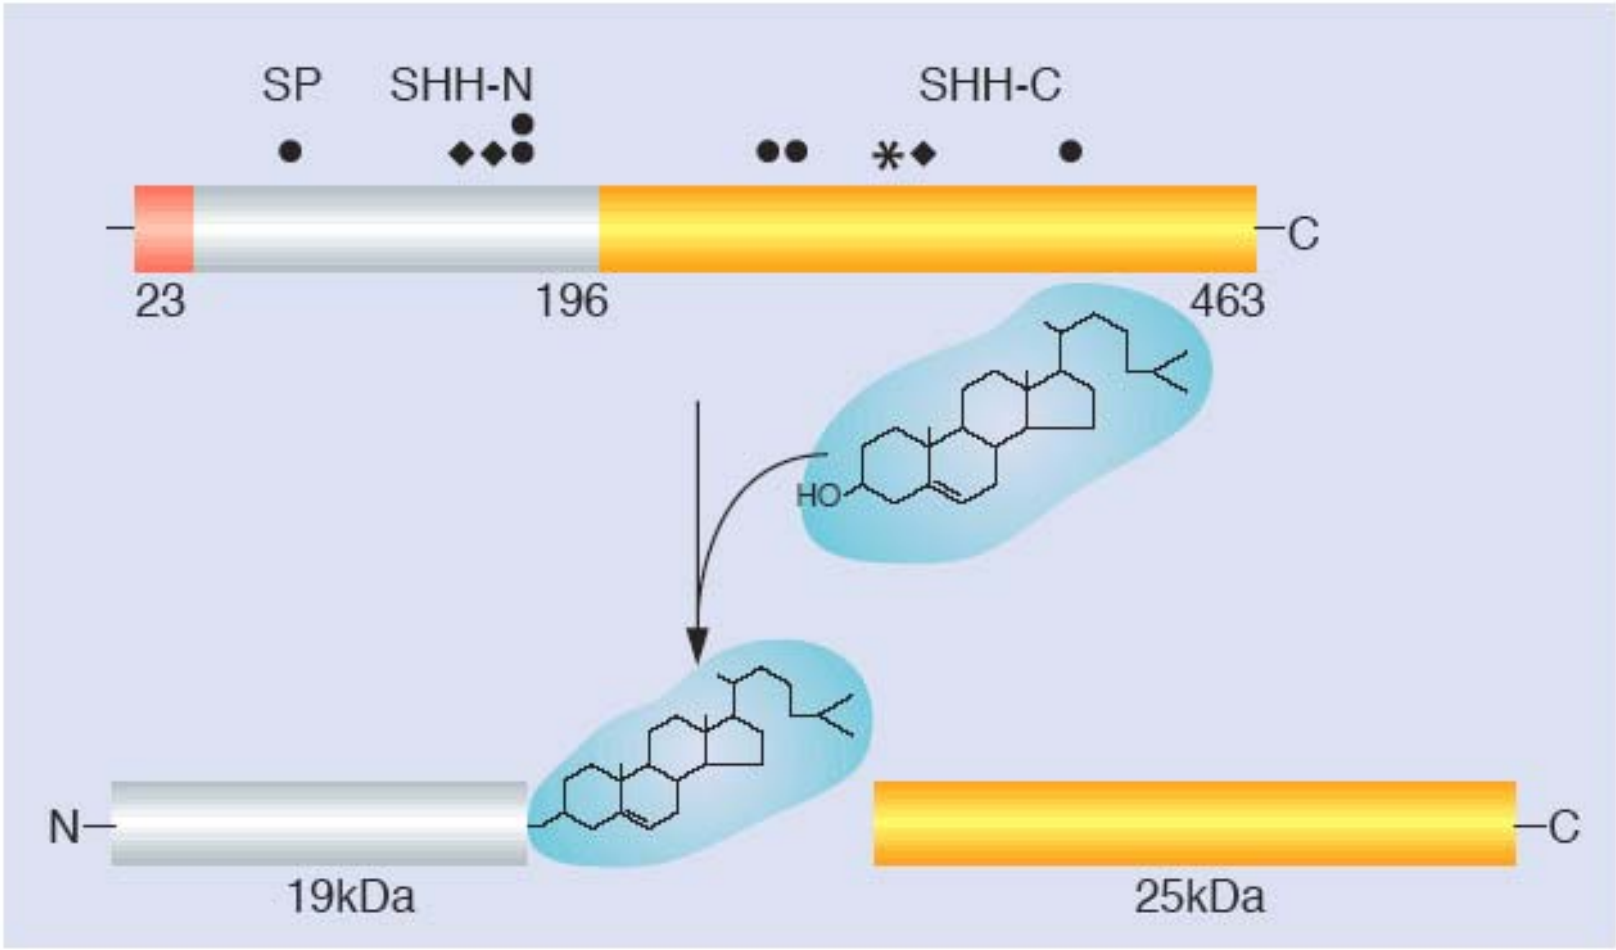

Figure 1. The Sonic hedgehog protein (SHH). Following translation, the signal peptide [SP, amino acids (aa) 1–23] is removed. Autocatalytic cleavage yields an N-terminal portion (SHH-N, aa 24–196) and a C-terminal portion (SHH-C, aa 197–463). A cholesterol transferase domain, located in SHH-C, directs the addition of cholesterol to the C-terminus of SHH-N. *SHH* mutations associated with holoprosencephaly (HPE) are distributed throughout the gene (filled diamond, nonsense mutation; filled circle, missense mutation; asterisk, 21 bp deletion).

AGE

SKIN COLOR

DOSE

AGE

The Bare Facts of Aging
Photograph by Sarah Leen

National Geographic Magazine, November 2002

WERNER SYNDROME

- A disease of accelerated aging.
- Gene (WRN) encodes a helicase (RecQ) involved in DNA repair and DNA replication.
- Normal aging may involve decrease in DNA repair.
- Scleroderma-like skin changes.
- Increased incidence of malignancy: GI tract, lung, kidney, ovary, breast.

Age and DNA Repair Capacity (DRC) in BCC

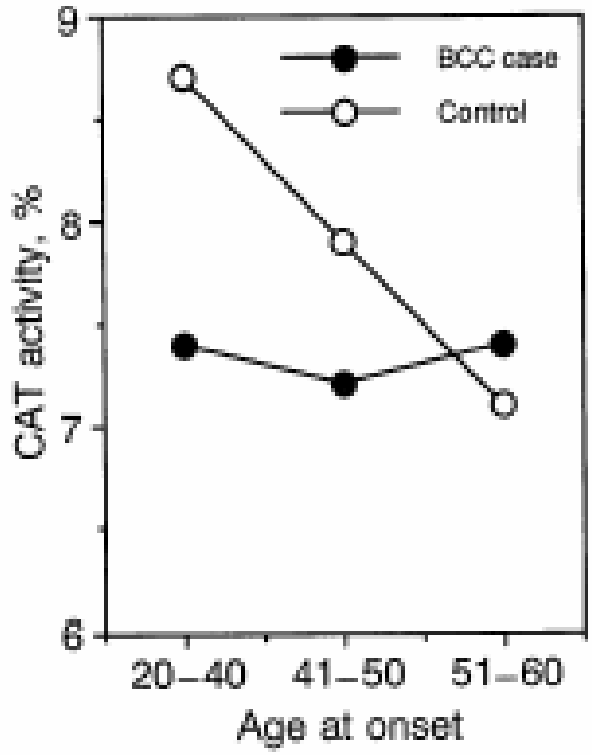

FIG. 1. Relationship between age at first BCC and DRC. The age-related decline in DRC among controls in comparison with that of age-matched cases is displayed. The linear-regression modeling and statistical tests of these data are presented in Table 5.

Wei et al. *PNAS* 90:1614, 1993

Age-Dependent Reactive Oxygen Species (ROS)

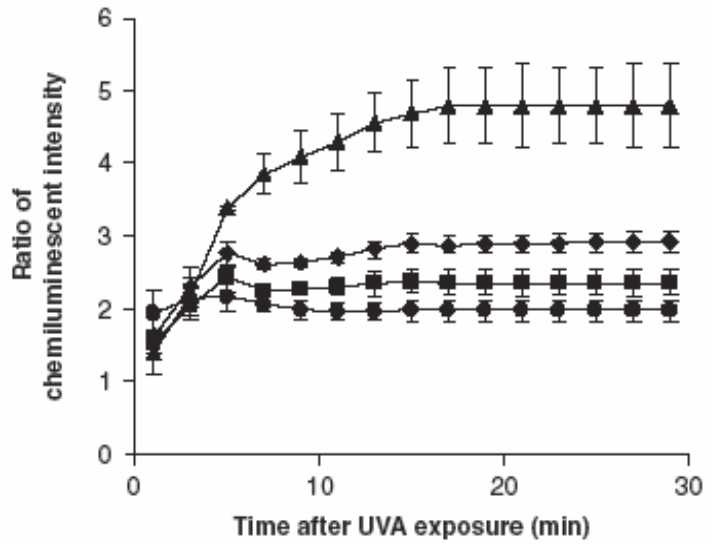

Figure 3. Age-dependent enhancement of the ratio of chemiluminescent intensities due to the ROS generation in UVA-exposed skin to those in the untreated skin of hairless rats aged 8 (●), 24 (■), 48 (◆), and 80 (▲) weeks. Data are expressed as the means ± standard deviations of six rats in each experiment.

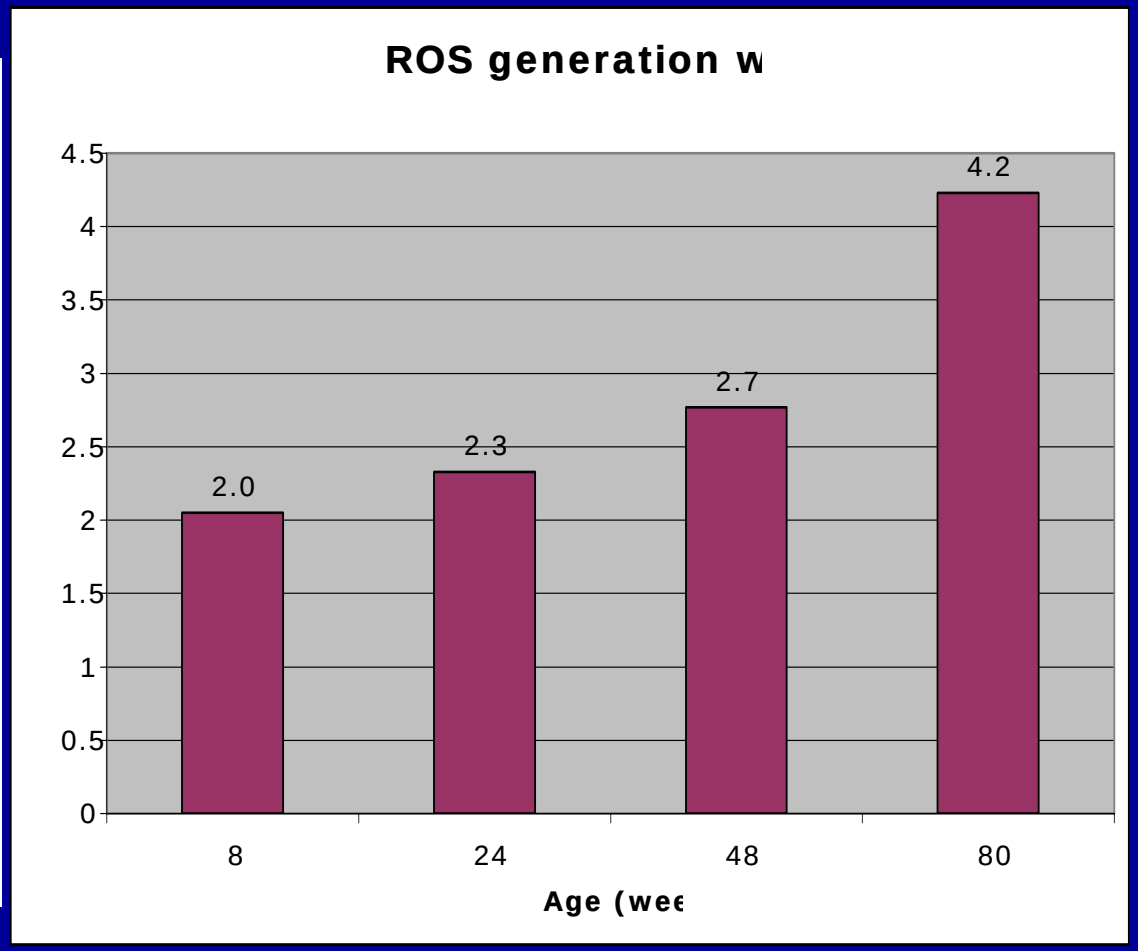
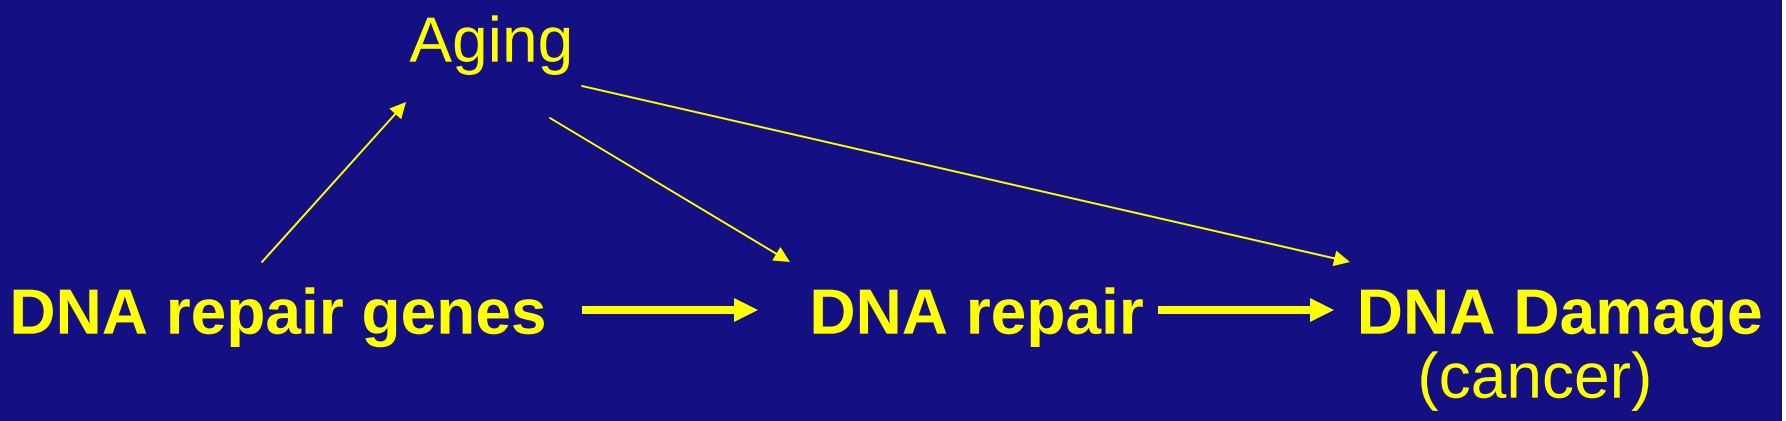
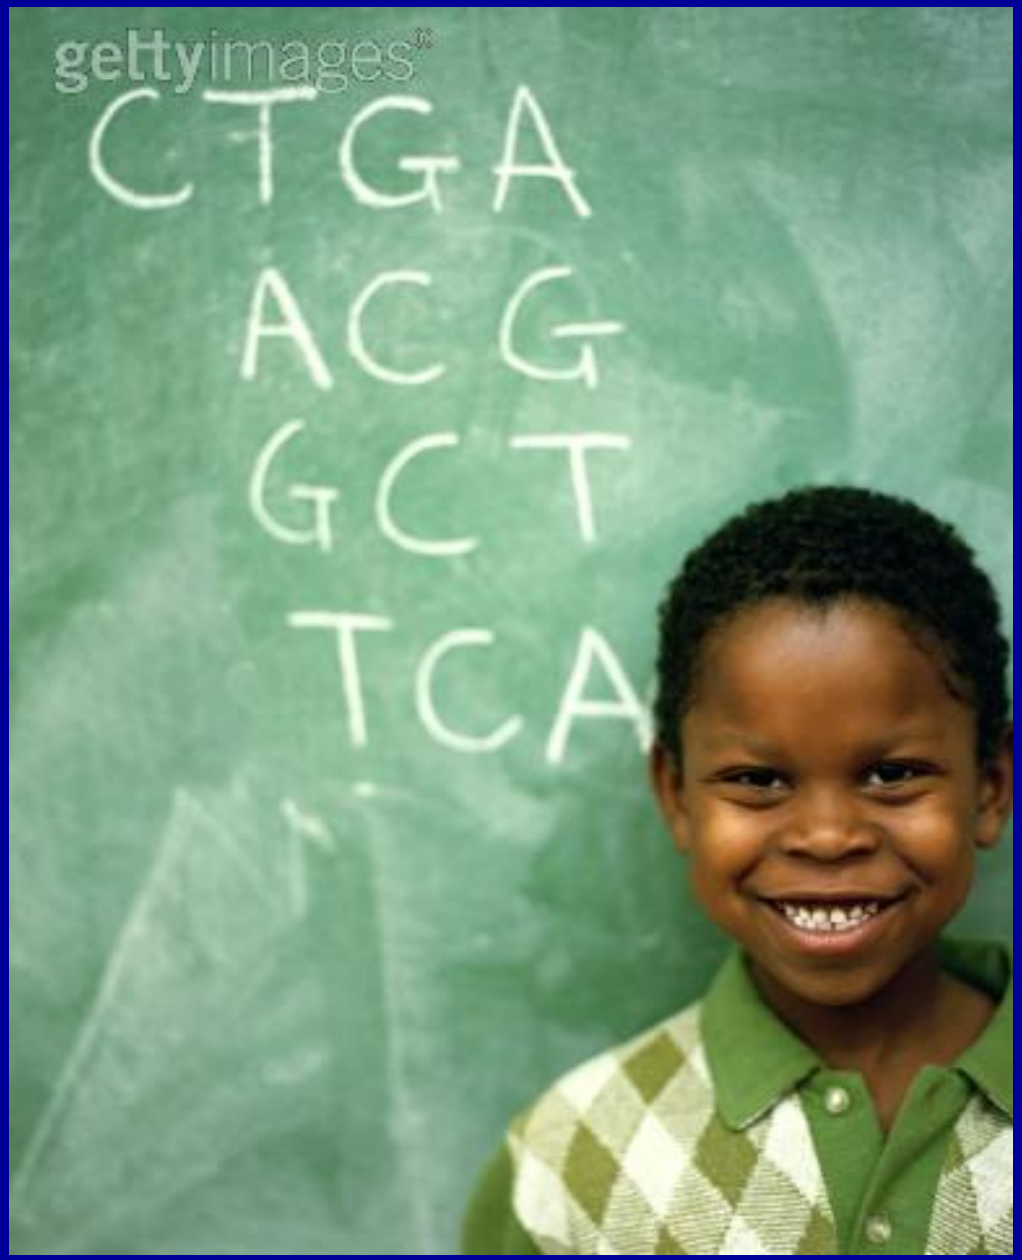


Exp Dematology 12:655, 2003



The multiple pathways through which aging can interact in the gene to cancer pathway, makes aging an important confounder that needs to be carefully adjusted for.

Epidemiological limitation is that we can only adjust for chronological age and not biological age.



SKIN COLOR GENETICS

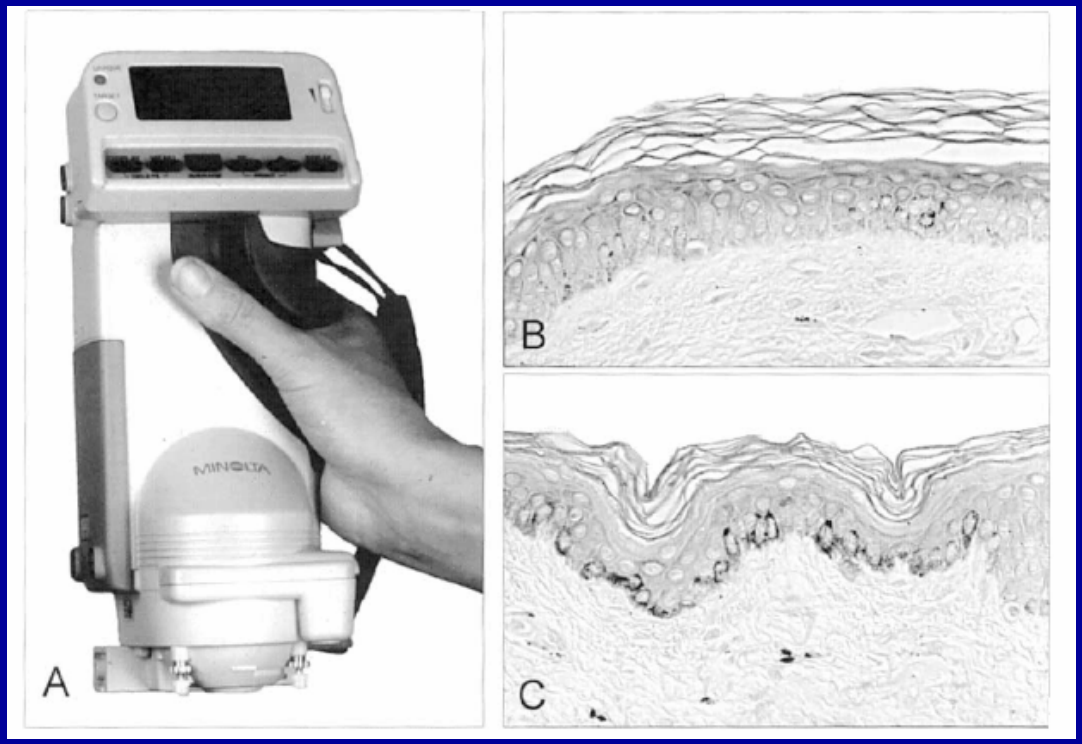
Skin color is a powerful risk modifier:

Whites have ~100-fold higher BCC incidence than blacks.

Whites have ~10-fold higher SCC incidence than blacks.

Am J Epidemiol 155: 614, 2002

Melanin density is inversely related to skin cancer risk.



Arm melanin (%)	No. of controls	CMM*			BCC*			SCC*		
		No. of subjects	OR*	95% CI*	No. of subjects	OR	95% CI	No. of subjects	OR	95% CI

HEALTH

UNPATTERNED FINGERPRINTS

NORMAL FINGERPRINTS

Case of the Missing Prints Cheryl Maynard (below) was born with a trait that old-time gangsters would have killed for—fingers that leave no prints. Along with an impaired ability to sweat and a lacy brown pigmentation over her body, the lack of a unique patterning on her fingers and palms comes from an exceedingly rare condition called dermatopathia pigmentosa reticularis—passed on for at least five generations in her mother's family. Like her relatives, Maynard has learned to live with it. Turning slick magazine pages requires her to lick her fingers for traction on the paper. Her hands slide right off the sides when she tries to carry a cardboard box.

Scientists recently found the root of Maynard's disorder: a genetic defect in a protein that also keeps cells from dying prematurely. Learning how that protein works may improve understanding of why skin cancer cells are hard to kill. Though there is no cure, Maynard still finds humor in situations such as security checks. Puzzled by her lack of prints, an official once asked, "Can't they just give you some?" No, she shot back, "but if I could have anybody's, I'd want Al Capone's." —*A. R. Williams*

NMSC: nonmelanoma skin cancer; OR: odds ratio.

[a] Percentages were based on women with a nonmissing response for the cancer in question who reported no history of nonmelanoma skin cancer (NMSC) and reported a history of NMSC, respectively.

Radiation as a Model Carcinogen:

- Known to be a human carcinogen for almost 100 years.
- Strong epidemiological evidence shows clear dose response.
- High dose risks known with reasonable precision/accuracy.
- Low dose risks are highly uncertain and model dependent.
- All tissues believed to be at risk.
- Some risk incurred at all dose levels (i.e. no threshold).
- Dosimetry is very good. (What is a “pack-year” anyway?!)
- All individuals in a population are exposed to some degree.
- Range of exposures within a population can be quite broad.
- Direct interaction with the target of carcinogenesis, and confines the problem to downstream of DNA damage.
- Major cellular protective molecular mechanisms known in some degree of detail (e.g. DNA repair and cell cycle arrest).
- Radiation is a relatively weak carcinogen (room for genetic enhancement).

TAKE-HOME MESSAGE

- Radiation has many advantages as a model carcinogen for studying gene-environment (G-E) interactions in cancer.
- BCC has many advantages as a cancer model for G-E interactions.
- DNA repair genes in the NER pathway are prime candidates for G-E interaction in BCC.
- Genes in Hedgehog pathway may also be very important to BCC etiology.
- Cell cycle, apoptosis, and other pathways may play a role in BCC, but the evidence is weaker.
- Care must be taken to avoid confounding genes, such aging and skin color related genes.
- Dose should be viewed as a powerful affect modifier and potential confounder.
- There is probably a strong multiplicative interaction between age of onset and BCC RR, that needs to be adjusted for.
- Genes involved in BCC are probably important for other cancers as well.
