### New Results and Findings

This Report is concerned with temperature changes in the atmosphere, differences in these changes at various levels in the atmosphere, and our understanding of the causes of these changes and differences. Considerable progress has been made since the production of reports by the National Research Council (NRC) and the Intergovernmental Panel on Climate Change (IPCC) in 2000 and 2001. Data sets for the surface and from satellites and radiosondes (temperature sensors on weather balloons) have been extended and improved, and new satellite and radiosonde data sets have been developed<sup>1</sup>. Many new model simulations of the climate of the 20<sup>th</sup> century have been carried out using improved climate models<sup>1</sup> and better estimates of past forcing changes, and numerous new and updated model/observed data comparisons have been performed. The present Report reviews this progress. A summary of the main results is presented first. Then, to address the issues in more detail, six questions that provide the basis for the six main chapters in this Synthesis/Assessment Report are posed and answered.

The important new results presented in this Report include:

## Global Average Temperatures

• Since the late 1950s, the start of the study period for this Report, the surface and troposphere have warmed<sup>2</sup> substantially, while the stratosphere has cooled<sup>2</sup>. These changes are in accord with our understanding of the effects of radiative forcing agents and with model predictions.

• Since the late 1950s, the low and mid troposphere have warmed at a rate slightly faster than the rate of warming at the surface.

During the satellite era (1979 onwards), both the low and mid troposphere have warmed. The majority of data sets show warming at the surface that is greater than in the troposphere.
 Some data sets, however, show the opposite – tropospheric warming that is greater than that at the surface.

• For global-mean temperature changes in the new climate model simulations, some show more warming in the troposphere than at the surface, while a slightly smaller number of simulations show the opposite behavior. Given the range of observed results and the range of model results, there is no inconsistency between models and observations at the global scale.

• Studies to detect climate change and attribute its causes using patterns of observed temperature change in space and time (rather than global averages) show clear evidence of human influences on the climate system (due to changes in greenhouse gases, aerosols, and stratospheric ozone).

• The observed patterns of change cannot be explained by natural processes alone, nor by the effects of short-live species (such as aerosols and tropospheric ozone) alone.

- Tropical Temperatures (20°S to 20°N)
- The majority of observed data sets show more warming at the surface than in the troposphere, while some newer observed data sets show the opposite behavior. Almost all model simulations show more warming in the troposphere than at the surface.

These results characterize important changes in our understanding of the details of temperature changes at the surface and higher in the troposphere. In 2000 and 2001, the NRC and the IPCC both concluded that global-mean surface temperature increases were larger and differed significantly from temperature increases in the troposphere. The new and improved observed data sets and new model simulations that have been developed require modifications of these conclusions.

The crucial issue here is whether changes in the troposphere are greater or less than those at the surface. Greater changes in the troposphere would mean that changes there are "amplified" relative those at the surface. We use the short-hand notation "amplification" to refer to this possibility. Studies of amplification in the tropics have considered changes on month-to-month, year-to-year and decade-to-decade time scales.

At the global-mean level, observed changes from 1958 through 2004 exhibit amplification: i.e., they show greater warming trends in the troposphere compared with the surface. Since 1979, however, the situation is different: most data sets show slightly greater warming at the surface.

Whether or not these results are in accord with expectations based on climate models is a complex issue, one that we have been able to address more comprehensively now using new model results. Over the period since 1979, the range of recent model simulations is almost evenly divided among those that show greater global-mean warming at the surface and others

that show greater warming aloft. Given this range of results, there is no conflict between			
observed changes and the results from climate models.			
In the transies, the component between models and charged into demands on the time scale			
In the tropics, the agreement between models and observations depends on the time scale			
considered. For month-to-month and year-to-year variations, models and observations both show			
amplification (i.e., the month-to-month and year-to-year variations are larger aloft than at the			
surface). The magnitude of this amplification is essentially the same in models and observations.			
On decadal and longer time scales, however, while almost all model simulations show greater			
warming aloft, most observations show greater warming at the surface.			
These results have at least two possible explanations, which are not mutually exclusive. Either			
amplification effects on short and long time scales are controlled by different physical			
mechanisms, and models fail to capture such behavior; and/or remaining errors in some of the			
observed tropospheric data sets adversely affect their long-term temperature trends. The second			
explanation is judged more likely.			
1. How do we expect vertical temperature profiles to change?			
This Section considers the first question:			
Why do temperatures vary vertically (from the surface to the stratosphere) and what do we understand about why they might vary and change over time?			
This is addressed in both Chapter 1 and Chapter 5 of this Report.			
In response to this question, Chapter 1 notes the following			

118 (1) Temperatures vary vertically.

The effects of solar heating of the surface of the planet combined with the physical properties of the overlying air, lead to the highest temperatures, on average, occurring at the surface. Surface heat is mixed vertically and horizontally, and this mixing, combined with the effects of various physical processes, produces a decrease of temperature with height up to the tropopause (marking the top of the troposphere, i.e., the lower 8 to 16 km of the atmosphere, depending on latitude). Above this, the radiative properties of the air produce a warming with height through the stratosphere (up to about 50 km).

- (2) Temperature trends at the surface can be expected to be different from temperature trends higher in the atmosphere because:
  - The physical properties of the surface vary substantially according to location and this produces strong horizontal variations in near-surface temperature. Above the surface, these contrasts are quickly smoothed out so the patterns of change in the troposphere must differ from those at the surface. Temperature trend variations with height must, therefore, vary according to location.
  - Changes in atmospheric circulation or modes of atmospheric variability (e.g., the El Niño-Southern Oscillation [ENSO]) can produce different temperature trends at the surface and aloft.
  - Under some circumstances, temperatures may increase with height near the surface or higher in the troposphere, producing a "temperature inversion." Such inversions are more common at night, in winter over continents, and in the trade wind regions. Since

the air in inversion layers is resistant to vertical mixing, temperature trends can differ
 between inversion layers and adjacent layers.
 Forcing factors, either natural or human-induced<sup>3</sup>, can result in differing temperature

trends at different levels in the atmosphere, and these vertical variations may change

over time.

145

146

147

148

149

150

151

152

144

As noted above, temperatures in the atmosphere vary naturally as a result of internal factors and natural and human-induced perturbations ("forcings"<sup>3</sup>). These factors are expected to have different effects on temperatures near the surface, in the troposphere, and in the stratosphere, as summarized in Table 1. When all forcings are considered, we expect the troposphere to have warmed and the stratosphere to have cooled since the late 1950s (and over the whole 20<sup>th</sup> century). The relative changes in the troposphere and stratosphere provide information about the causes of observed changes.

Table 1: Summary of the most important global-scale climate forcing factors and their likely individual effects on global, annual-mean temperatures; based on Figure 1.3 (which gives temperature information) and Table 1.1 (which gives information on radiative forcing) in Chapter 1, and literature cited in Chapter 1. The stated effects are those that would be expected if the change specified in column 1 were to occur. The top two rows are the primary natural forcing factors, while the other rows summarize the main human-induced forcing factors. The relative importance of these different factors varies spatially and over time.

Forcing Factor	Surface	Low to Mid Troposphere	Stratosphere
Increased solar output	Warming	Warming	Warming
Volcanic eruptions	Cooling	Cooling	Short-term warming
Increased concentrations of well-mixed greenhouse gases (CO <sub>2</sub> , CH <sub>4</sub> , N <sub>2</sub> O, halocarbons)	Warming	Warming	Cooling
Increased tropospheric ozone (O <sub>3</sub> )	Warming	Warming	Slight cooling
Decreased stratospheric ozone	Negligible except at high latitudes	Slight cooling	Cooling
Increased loading of sulfate (SO <sub>4</sub> ) aerosol – sum of direct plus indirect effects	Cooling	Cooling	Negligible
Increased loading of carbonaceous aerosol (black carbon (BC) and organic matter (OM)) – sum of direct plus indirect effects	Regional cooling – possible global-mean cooling	Warming	Uncertain
Land use and land cover changes	Regional cooling or warming – probably slight global-mean cooling	Uncertain	Negligible

Within the troposphere, the relative changes in temperature at different levels are controlled by different processes according to latitude. In the tropics, the primary control is the thermodynamics of moist air (i.e., the effects of evaporation at the surface and the release of latent heat through condensation that occurs in clouds as moist air rises due to convection), and the way these effects are distributed and modified by the atmospheric circulation.

Thermodynamic principles require that temperature changes in the tropics will be larger in the troposphere than near the surface ("amplification"), largely independent of the type of forcing. In mid to high latitudes, the processes controlling how temperature changes in the vertical are more complex, and it is possible for the surface to warm more than the troposphere. These issues are addressed in Chapter 1 and Chapter 5.

173

# 2. Strengths and limitations of the observational data

- 176 The second question is:
- What kinds of atmospheric temperature variations can the current observing systems detect and what are their strengths and limitations, both spatially and temporally?

179

180 This is addressed in Chapter 2 of this Report. Chapter 2 draws the following main conclusions ...

181

- 182 (1) The observing systems available for this Report are able to detect small surface and upper air 183 temperature variations from year to year as well as trends<sup>4</sup> in climate since the late 1950s (and 184 over the last century for surface observations), once the raw data are successfully adjusted for 185 changes over time in observing systems and practices, and micro-climate exposure.
- Measurements from all systems require such adjustments. This Report relies solely on adjusteddata sets.

standards.

(2) Independently-performed adjustments to the land surface temperature record have been sufficiently successful that trends given by different data sets are very similar on large (e.g., continental) scales. This conclusion holds to a lesser extent for the ocean surface record.

(3) Adjustments for changing instrumentation are most challenging for upper-air datasets. While these show promise for trend analysis, it is not clear that current upper-air climate records have achieved sufficient accuracy to resolve trend-related scientific questions.

• Upper-air datasets have been subjected to less scrutiny than surface datasets.

Adjustments are complicated, large compared to the linear trend signal, involve
 expert judgments, and cannot be stringently evaluated because of lack of traceable

 Unlike surface trends, reported upper-air trends vary considerably between research teams beginning with the same raw data owing to their different decisions on how to remove non-climatic factors.

Many different methods are used to measure temperature changes at the Earth's surface and at various levels in the atmosphere. Near-surface temperatures have been measured for the longest period, over a century, and are measured directly by thermometers. Over land, these data come from fixed meteorological stations. Over the ocean, measurements are of both air temperature and sea-surface (top 10 meters) temperature taken by ships or from buoys.

The next-longest records are upper-air data measured by radiosondes (temperature sensors carried aloft by weather balloons). These have been collected routinely since 1958. There are still substantial gaps in radiosonde coverage.

Satellite data have been collected for the upper air since 1979 with almost complete global coverage. The most important satellite records come from Microwave Sounding Units (MSU) on polar orbiting satellites. The microwave data from MSU instruments require calculations and adjustments in order to be interpreted as temperatures. Furthermore, these satellite data do not represent the temperature at a particular level, but, rather, the average temperature over thick atmospheric layers (see Figure 2.2 in Chapter 2). Channel 2 data (mid to upper troposphere, T<sub>2</sub>) have a latitudinally-dependent contribution from the stratosphere, while Channel 4 data (lower stratosphere, T<sub>4</sub>) have a latitudinally-dependent contribution from the troposphere, factors that complicate their interpretation.

All measurement systems have inherent uncertainties associated with: the instruments employed; changes in instrumentation; and the way local measurements are combined to produce area averages. All data sets require careful examination for instrument biases and reliability, and adjustments to remove changes that might have arisen for non-climatic reasons. The term "homogenization" is used to describe this adjustment procedure. Recent improvements in and corrections to some of these adjustments have resulted in better agreement between data sets.

#### 3. What temperature changes have been observed?

233	This Section combines information related to questions 3 and 4:				
234 235 236	What do observations indicate about the changes of temperature in the atmosphere and at the surface since the advent of measuring temperatures vertically?				
237 238 239	What is our understanding of the contribution made by observational or methodological uncertainties to the previously reported vertical differences in temperature trends?				
240	These questions are addressed in Chapters 3 and 4 of this Report. The following conclusions are				
241	drawn in these chapters. Supporting information is given in Figure 1 and Figure 2.				
242					
243	(1) Surface temperatures: For global-mean changes, as well as in the tropics (20°S to 20°N), all				
244	data sets show warming at the surface since 1958, with a greater rate of increase since 1979.				
245	Differences between the data sets are small.				
246					
247	• Global-mean temperature increased at about 0.12°C per decade since 1958, and about				
248	0.16°C per decade since 1979. In the tropics, temperature increased at about 0.11°C per				
249	decade since 1958, and about 0.13°C per decade since 1979.				
250					
251	• Local biases in surface temperatures may exist due to changes in station exposure and				
252	instrumentation over land <sup>5</sup> , or changes in measurement techniques by ships and buoys in				
253	the ocean. It is likely that these biases are largely random and therefore cancel out over				
254	large regions such as the globe or tropics, the regions that are of primary interest to this				
255	Report.				
256					
257	• Errors in observed surface/troposphere trend differences are more likely to come from				
258	errors in tropospheric data than from errors in surface data.				

(2) Tropospheric temperatures: All data sets show that the global-mean and tropical troposphere has warmed from 1958 to the present, with the warming in the troposphere being slightly more than at the surface. Since 1979, due to the considerable disagreements between tropospheric data sets, it is not clear whether the troposphere has warmed more than or less than the surface.

• Global-mean tropospheric temperature increased at about 0.14°C per decade since 1958, and between 0.10°C and 0.20°C per decade since 1979. In the tropics, temperature increased at about 0.13°C per decade since 1958, and between 0.02°C and 0.19°C per decade since 1979.

• It is very likely that trends in troposphere temperatures are affected by errors that remain in the homogenized radiosonde data sets. Such errors arise because the methods used to produce these data sets are only able to detect and remove the more obvious cases, and involve many subjective decisions. The full consequences of these errors for large-area averages, however, have not yet been fully resolved. Nevertheless, it is likely that a net spurious cooling corrupts the area-averaged homogenized radiosonde data in the tropical troposphere, causing these data to indicate less warming than has actually occurred there.

 For tropospheric satellite data, a primary cause of trend differences between different versions is differences in how the data from different satellites are merged together.
 Corrections required to account for drifting measurement times, and diurnal cycle adjustments are also important.

$\boldsymbol{\circ}$	O	$\mathbf{a}$
_	О	2
	_	

284

285

• Comparisons between satellite and radiosonde temperatures for the mid to upper tropospheric layer (MSU channel 2; T<sub>2</sub>) are very likely to be corrupted by excessive stratospheric cooling in the radiosonde data

286

287

288

289

(3) Lower stratospheric temperatures: All data sets show that the stratosphere has cooled considerably from 1958 and from 1979 to the present, although there are large differences in the linear trend values from different data sets.

290

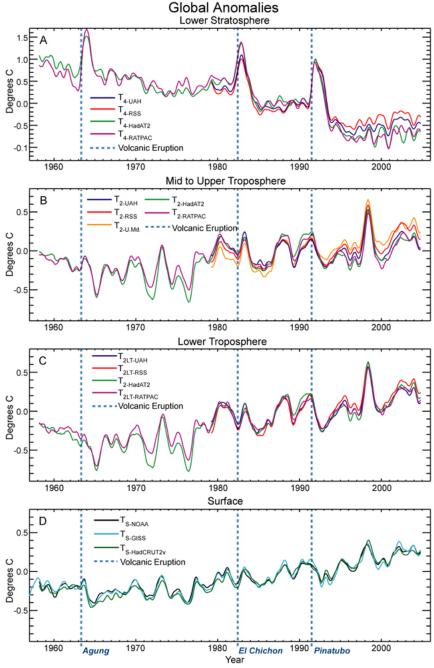

291

292

293

The largest differences between data sets are in the stratosphere, particularly between the
radiosonde and satellite-based data sets. It is very likely that the satellite/radiosonde
discrepancy arises primarily from uncorrected errors in the radiosonde data.

Figure 1 shows the various temperature time series examined in this Report.

**Figure 1:** Observed surface and upper air global-mean temperature records. From top to bottom: A, lower stratosphere (denoted  $T_4$ ) records from two satellite analyses (UAH and RSS) together with equivalently-weighted radiosonde records based on HadAT2 and RATPAC data; B, mid- to upper-troposphere ( $T_2$ ) records from three satellite analyses (UAH, RSS and U.Md.) together with equivalently-weighted radiosonde records based on HadAT2 and RATPAC; C, lower troposphere ( $T_{2LT}$ ) records from UAH and RSS (satellite), and from HadAT2 and RATPAC (equivalently-weighted radiosonde); D, surface ( $T_3$ ). All time series are based on monthly-mean data smoothed with a 7-month running average, expressed as departures from the Jan. 1979 to Dec. 1997 average. Note that the  $T_2$  data (panel B) contain a small contribution (about 10%) from the lower stratosphere. Information here is from Figures 3.1, 3.2 and 3.3 in Chapter 3.

For the lower stratosphere, the cooling trend since the late 1950s (which is as expected due to the effects of greenhouse-gas concentration increases and stratospheric ozone depletion) is punctuated by short-term warming events associated with the explosive volcanic eruptions of Mt. Agung (1963), El Chichón (1982) and Mt. Pinatubo (1991).

Both the troposphere and the surface show warming since the late 1950s. For the surface, most, if not all of the temperature increase since 1958 occurs starting around the mid-1970s, a time coincident with a previously identified climate regime shift. However, there does not appear to be a strong jump up in temperature at this time; rather, the major part of the rise seems to occur in a more gradual fashion. For the balloon-based tropospheric data, the major part of the temperature increase since 1958 appears in the form of a rapid rise in the mid-1970s, apparently in association with the climate regime shift that occurred at this time.

The dominant shorter time scale fluctuations are those associated with the El Niño-Southern Oscillation phenomenon (ENSO). The major ENSO warming event in 1998 is obvious in all records. Cooling following the eruptions of Mt. Agung and Mt. Pinatubo is also evident, but the cooling effect of El Chichón is masked by an ENSO warming that occurred at the same time. The changes following volcanic eruptions (i.e., surface and tropospheric cooling and stratospheric warming) are consistent with our physical understanding and with model simulations.

Global-mean temperature changes over the periods 1958 through 2004 and 1979 through 2004 are shown in Figure 2 in degrees Celsius and degrees Fahrenheit.

Figure 2: Total global-mean temperature changes for the surface and different atmospheric layers, from different data sets and over two periods, 1958 to 2004 and 1979 to 2004. The values shown are the total change over the stated period in both degrees Celsius (degC; lower scales) and degrees Fahrenheit (degF; upper scales). All changes are statistically significant at the 5% level except RSS  $T_4$  and RATPAC, HadAT2 and UAH  $T_2$ . Total change in degC is the linear trend in degC per decade (see Tables 3.2 and 3.3 in Chapter 3) times the number of decades in the time period considered. Total change in degF is this number times 1.8 to convert to degF. For example, the Table 3.2 trend for NOAA surface temperatures over January 1958 through December 2004 is  $0.11^{\circ}$ C/decade. The total change is therefore 0.11 times 4.7 decades to give a total change of  $0.53^{\circ}$ C, Multiplying this by 1.8 gives a total change in degrees Fahrenheit of  $0.93^{\circ}$ F. Warming is shown in red, and cooling in blue.

342	

## 4. Are model simulations consistent with the observed temperature changes?

Computer-based climate models encapsulate our understanding of the climate system and the driving forces that lead to changes in climate. Such models are the only tools we have for estimating the likely patterns of response of the climate system to different forcing mechanisms.

The crucial test of our understanding is to compare model simulations with observed changes.

348 The fifth question therefore is:

How well can the observed vertical temperature changes be reconciled with our understanding of the causes of these changes?

This question is addressed in Chapter 5 of this Report. Chapter 5 draws the following conclusions ...

### PATTERN STUDIES

(1) Results from many different pattern-based "fingerprint" studies (see Box 5.5 in Chapter 5) provide consistent evidence for human influences on the three-dimensional structure of atmospheric temperature changes over the second half of the 20<sup>th</sup> century.

• Fingerprint studies have identified greenhouse gas and sulfate aerosol signals in observed surface temperature records, a stratospheric ozone depletion signal in stratospheric temperatures, and the combined effects of these forcing agents in the vertical structure of atmospheric temperature changes.

(2) Natural factors have influenced surface and atmospheric temperatures, but cannot fully explain their changes over the past 50 years.

## LINEAR TREND COMPARISONS<sup>4,6</sup>

(3) When models are run with natural and human-induced forcings, simulated global-mean temperature trends for individual atmospheric layers are consistent with observations.

(4) Comparing trend differences between the surface and the troposphere exposes potential model/observed data discrepancies in the tropics.

• In the tropics, the majority of observational data sets show more warming at the surface than in the troposphere, while almost all model simulations have larger warming aloft than at the surface.

#### AMPLIFICATION OF SURFACE WARMING IN THE TROPOSPHERE

(5) Amplification means that temperatures show larger changes aloft than at the surface. In the tropics, on monthly and inter-annual time scales, both models and observations show amplification of temperature variability in the troposphere relative to the surface. This amplification is of similar magnitude in models and observations. For multi-decadal trends, models show the same amplification that is seen on shorter time scales. A number of observed data sets, however, do not show this amplification.

• These results have several possible explanations, which are not mutually exclusive. One
explanation is that "real world" amplification effects on short and long time scales are
controlled by different physical mechanisms, and models fail to capture such behavior. A
second explanation is that remaining errors in some of the observed tropospheric data sets
adversely affect their long-term temperature trends. The second explanation is more
likely in view of the model-to-model consistency of amplification results, the large
uncertainties in observed tropospheric temperature trends, and independent physical

evidence supporting substantial tropospheric warming.

398

399

397

### OTHER FINDINGS

400

401

402

(6) Because of differences between different observed data sets, it is important to account for observational uncertainty in comparisons between modeled and observed temperature changes.

403

Large "construction" uncertainties in observed estimates of global-scale atmospheric
 temperature change can critically influence the outcome of consistency tests between
 models and observations.

407

408

409

410

(7) Inclusion of previously-ignored spatially-heterogeneous forcings in the most recent climate models does not fundamentally alter conclusions about the amplification of warming in the troposphere relative to the surface.

• Changes in sulfate aerosols and tropospheric ozone, which have spatially-heterogeneous forcings, have been incorporated routinely in climate model experiments for a number of years. It has been suggested that the spatially-heterogeneous forcing effects of black carbon aerosols and land use/land cover may have had significant effects on regional temperatures that might modify previous conclusions regarding vertical temperature changes. These forcings have been included for the first time in about half of the global model simulations considered here. Within statistical uncertainties, model simulations that include these forcings show the same amplification of warming in the troposphere relative to the surface at very large spatial scales (global and tropical averages) as simulations in which these forcings are neglected.

Chapter 5 analyses state-of-the-art model simulations from 19 institutions globally, run using combinations of the most important natural and human-induced forcings. The Chapter compares the results of these simulations with a number of different observational data sets for the surface and different atmospheric layers, resulting in a large number of possible model/observed data comparisons.

Figures 3 and 4 summarize the new model results used in this Report, together with the corresponding observations. Figure 3 gives global-mean results, while Figure 4 gives results for the tropics (20°S to 20°N). Model and observed results are compared in these Figures using linear trends over the period January 1979 through December 1999<sup>7</sup> for the surface, for individual layers, and (right-hand panels) for surface changes relative to the troposphere.

Rectangles are used to illustrate the ranges of both model trends (red rectangles) and observed trends (blue rectangles). Individual observed-data trends are also shown.

Since statistical uncertainties (see Appendix) are not shown in these Figures, the rectangles do not represent the full ranges of uncertainty. However, they allow a meaningful first-order assessment of model/observed similarities and differences. Fully overlapping rectangles indicate consistency, partially overlapping rectangles point to possible discrepancies, while rectangles that either do not overlap or show minimal overlap indicate important model/observed data inconsistencies. At the global-mean level, models and observations generally show fully overlapping rectangles. The only potentially serious inconsistency is in the tropics (Figure 4) where the troposphere warms more rapidly than the surface in all except two of the 49 individual model simulations examined here, while, in the majority of observational data sets, the surface has warmed more rapidly than the troposphere.

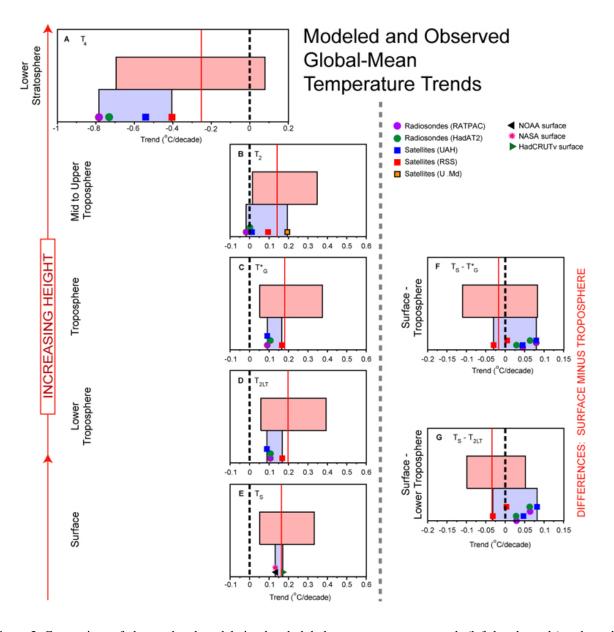

Figure 3: Comparison of observed and model-simulated global-mean temperature trends (left-hand panels) and trend differences (right-hand panels) over January 1979 through December 1999, based on Table 5.4A and Figure 5.3 in Chapter 5. The upper red rectangles in each box show the range of model trends from 49 model simulations. The lower blue rectangles show the range of observed trends, with the individual trends from different data sets indicated by the symbols. From bottom to top, the left-hand panels show trends for the surface  $(T_S)$ , the lower troposphere  $(T_{2LT})$ , the troposphere  $(T^*)$ , the mid troposphere to lower stratosphere  $(T_2)$ , and the lower stratosphere  $(T_4)$ . The right-hand panels show differences in trends between the surface and either the troposphere or the lower troposphere, with a positive value indicating a stronger warming at the surface. The red vertical lines show the average of all model results. The vertical black dashed lines show the zero value. For the observed trend differences, there are eight values corresponding to combinations of the four upper-air data sets (as indicated by the symbols) and either the HadCRUT2v surface data or the NASA/NOAA surface data (which have almost identical trends).

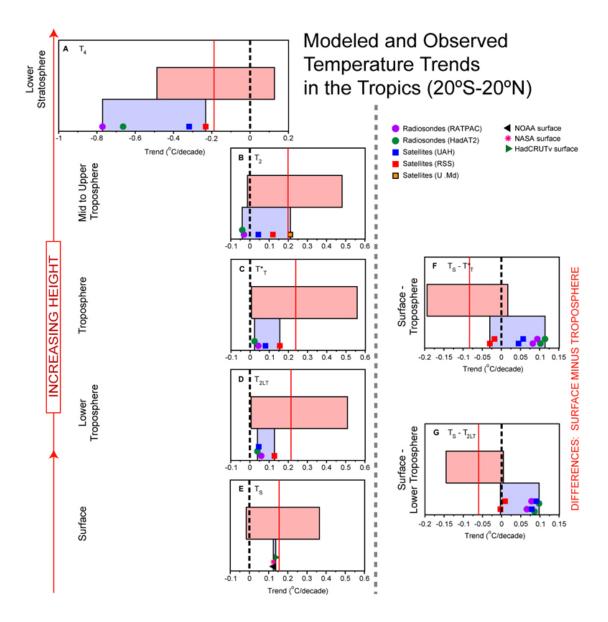

Figure 4: As Figure 3, but for the tropics (20°S to 20°N), based on Table 5.4B and Figure 5.4 in Chapter 5.

## 5. Recommendations

This Section addresses question 6:

What measures can be taken to improve the understanding of observed changes?

In answer to this question, drawing on the material presented in the first five chapters of this Report, a set of primary recommendations has been developed and is described in detail in Chapter 6. It should be noted that, rather than invent new proposals or recommendations, the items described in Chapter 6 expand and build upon existing ideas, emphasizing those that are

considered to be of highest utility. The seven recommendations are:

(1) In order to encourage further independent scrutiny, data sets and their full metadata (i.e., information about instrumentation used, observing practices, the environmental context of observations, and data-processing procedures) should be made openly available. Comprehensive analyses should be carried out to ascertain the causes of remaining differences between data sets and to refine uncertainty estimates.

(2) Efforts should be made to archive and make openly available surface, balloon-based, and satellite data and metadata that have not previously been exploited. Emphasis should be placed on the tropics.

(3) Efforts should be made to create climate quality data sets<sup>8</sup> for a range of variables other than temperature. These data sets should subsequently be compared with each other and with temperature data to determine whether they are consistent with our physical understanding.

(4) Efforts should be made to create several homogeneous atmospheric reanalyses<sup>9</sup>. Particular care needs to be taken to identify and homogenize critical input data. Identification of critical data requires, in turn, observing system experiments where the impacts and relative importance of different observation types from land, radiosonde, and space-based observations are assessed.

(5) Models that appear to include the same forcings often differ in both the way the forcings are quantified and how these forcings are applied to the model. Hence, efforts are required to separate more formally uncertainties arising from model structure from the effects of forcing uncertainties. This requires running multiple models with standardized forcings, and running the same models individually under a range of plausible scenarios for each forcing.

(6) The GCOS (Global Climate Observing System) climate monitoring principles should be fully adopted. In particular, when any particular type of instrument is changed or re-sited, there should be a period of overlap between old and new instruments or configurations that is sufficient to allow analysts to adjust for the change with small uncertainties that do not prejudice the analysis of climate trends. The minimum period is a full annual cycle of the climate.

(7) A small subset (about 5%) of the operational radiosonde network should be developed and implemented as reference sites for all kinds of climate data from the surface to the stratosphere.

#### **Footnotes**

<sup>1</sup> For details of new observed data see Table 3.1 in Chapter 3. For details of new models and model simulations see Chapter 5 and http://www-pcmdi.llnl.gov/ipcc/model.documentation.

<sup>2</sup> We use the words "warming" and "cooling" here to refer to temperature increases or decreases, as is common usage. Technically, these words refer to changes in heat content, which may occur through changes in either the moisture content and/or the temperature of the atmosphere. When we say that the atmosphere has warmed (or cooled) over a given period, this means that there has been an overall positive (or negative) temperature change based on a linear trend analysis.

 $^3$  The main natural perturbations are changes in solar output and the effects of explosive volcanic eruptions. The main human-induced ("anthropogenic") factors are: the emissions of greenhouse gases (e.g., carbon dioxide [CO<sub>2</sub>], methane [CH<sub>4</sub>], nitrous oxide [N<sub>2</sub>O]); aerosols (tiny droplets or particles such as smoke) and the gases that lead to aerosol formation (most importantly, sulfur dioxide); and changes in land cover and land use. Since these perturbations act to drive or "force" changes in climate, they are referred to as "forcings". Tropospheric ozone [O<sub>3</sub>], which is not emitted directly, is also an important greenhouse gas. Tropospheric ozone changes occur through the emissions of gases like carbon monoxide, nitrogen oxides and volatile organic compounds, which are not important directly as greenhouse gases.

 <sup>4</sup> Many of the results in this Report (and here in the Executive Summary) are quantified in terms of linear trends, i.e., by the value of the slope of a straight line that is fitted to the data. A simple straight line is not always the best way to describe temperature data, so a linear trend value may be deceptive if the trend number is given in isolation, removed from the original data. Nevertheless, used appropriately, linear trends provide the simplest and most convenient way to describe the overall change over time in a data set, and are widely used. For a more detailed discussion, see the Appendix.

<sup>5</sup> Some have expressed concern that land temperature data might be biased due to urbanization effects. Recent studies specifically designed to identify systematic problems using a range of approaches have found no detectable urban influence in large-area averages in the data sets that have been "homogenized" (i.e., adjusted to remove non-climatic influences).

<sup>6</sup> Fingerprint studies use rigorous statistical methods to compare the patterns of observed temperature changes with model expectations and determine whether or not similarities could have occurred by chance. Linear trend comparisons are less powerful than fingerprint analyses for studying cause-effect relationships, but can highlight important differences and similarities between models and observations.

<sup>7</sup> This is the longest period common to all model simulations.

<sup>8</sup> Climate quality data sets are those where the best possible efforts have been made to identify and remove non-climatic effects that might produce spurious changes over time.

565

<sup>9</sup> Reanalyses are mathematically blended products based upon as many observing systems as practical. Observations are assimilated into a global weather forecasting model to produce globally-comprehensive data sets that are most consistent with both the available data and the assimilation model.
