Northeast Fisheries Science Center Reference Documents

This series is a secondary scientific series designed to assure the long-term documentation and to enable the timely transmission of research results by Center and/or non-Center researchers, where such results bear upon the research mission of the Center (see the outside back cover for the mission statement). These documents receive internal scientific review, and most receive copy editing. The National Marine Fisheries Service does not endorse any proprietary material, process, or product mentioned in these documents.

All documents issued in this series since April 2001, and several documents issued prior to that date, have been copublished in both paper and electronic versions. To access the electronic version of a document in this series, go to *http://www.nefsc.noaa.gov/nefsc/publications/*. The electronic version is available in PDF format to permit printing of a paper copy directly from the Internet. If you do not have Internet access, or if a desired document is one of the pre-April 2001 documents available only in the paper version, you can obtain a paper copy by contacting the senior Center author of the desired document. Refer to the title page of the document for the senior Center author's name and mailing address. If there is no Center author, or if there is corporate (*i.e.*, non-individualized) authorship, then contact the Center's Woods Hole Laboratory Library (166 Water St., Woods Hole, MA 02543-1026).

This document's publication history is as follows: manuscript submitted for review July 24, 2008; manuscript accepted through technical review July 28, 2008; manuscript accepted through policy review July 28, 2008; and final copy submitted for publication July 28, 2008. Pursuant to section 515 of Public Law 106-554 (the Information Quality Act), this information product has undergone a pre-dissemination review by the Northeast Fisheries Science Center, completed on July 28, 2008. The signed pre-dissemination review and documentation is on file at the NEFSC Editorial Office. This document may be cited as:

TABLE OF CONTENTS

FOREWORD

The Northeast Regional Stock Assessment Workshop (SAW) process has three parts: preparation of stock assessments by the SAW Working Groups and/or by ASMFC Technical Committees / Assessment Committees; peer review of the assessments by a panel of outside experts who judge the adequacy of the assessment as a basis for providing scientific advice to managers; and a presentation of the results and reports to the Region's fishery management bodies.

Starting with SAW-39 (June 2004), the process was revised in two fundamental ways. First, the Stock Assessment Review Committee (SARC) is now a smaller panel with panelists provided by the University of Miami's Independent System for Peer Review (Center of Independent Experts, CIE). Second, the SARC no longer provides management advice. Instead, Council and Commission teams (e.g., Plan Development Teams, Monitoring and Technical Committees) formulate management advice, after an assessment has been accepted by the SARC.

Reports that are produced following SAW/SARC meetings include: An *Assessment Summary Report* - a brief summary of the assessment results in a format useful to managers; this *Assessment Report* – a detailed account of the assessments for each stock; and the SARC panelist report – a summary of the reviewer's opinions and recommendations as well as individual reports from each panelist. SAW/SARC assessment reports are available online at http://www.nefsc.noaa.gov/nefsc/publications/series/crdlist.htm. The CIE review reports and assessment reports can be found at *http://www.nefsc.noaa.gov/nefsc/saw/*.

The 47th SARC was convened in Woods Hole at the Northeast Fisheries Science Center, June 16-20, 2008 to review one assessment (summer flounder *Paralichthys dentatus*). CIE reviews for SARC47 were based on detailed reports produced by the NEFSC Southern Dmersal Working Group. This Introduction contains a brief summary of the SARC comments, a list of SARC panelists, the meeting agenda, a list of working group meetings and a list of attendees (Tables 1 – 3). Maps of the Atlantic coast of the USA and Canada are also provided (Figures 1 - 4).

Outcome of Stock Assessment Review Meeting:

Based on the Review Panel reports (available at http://www.nefsc.noaa.gov/nefsc/saw/ under the heading "SARC 47 Panelist Reports"), the SARC review committee concluded that the assessment successfully met all of its terms of reference. The SARC felt that the extensive data for the assessment were correctly compiled, and the assessment was conducted in accord with good scientific practice. The review committee agreed that the 'ASAP' catch-age model best estimated stock status parameters, and that F35% and F40% were reasonable new proxies for the overfishing threshold and the target fishing mortality, respectively. The new assessment used a revised natural mortality rate value (changed from M = 0.20 to M = 0.25), which took account of differential longevity between the sexes. The SARC accepted this revision, but noted that model results are sensitive to M, and that estimation of M could be revisited in the future.

The SARC felt that: (1) combining separate surveys is a significant research question beyond the scope of this assessment; (2) treating zero catches from the survey as missing values was acceptable;

(3) alternative models were examined and adequately presented; (4) the final assessment model provides a credible basis for developing management advice; (5) the number of catch-at-age matrices and fleets that can be modeled separately is constrained by data availability; (6) spatial and temporal patterns in age compositions of both the commercial landings and trawl surveys were adequately explored; (7) sex ratios, and differences in growth and maturity between males and female summer flounder were explored, but only limited analyses could be undertaken as sex-specific data from the commercial and recreational fisheries (as well as from State surveys) are not available; and (8) the inclusion of certain environmental factors in the current model configurations did not improve model performance.

The SARC understood that a minimal number of projections were provided, and that additional projections would subsequently be prepared in consultation with fishery managers.

The SARC felt that comparison of the new assessment results with the "existing biological reference points" (developed in 2006) is not advisable - due to the changes this year in the assessment model and the yield per recruit inputs.

The SARC noted that the description of the commercial and recreational fisheries provided in the reports was incomplete. Furthermore, the Panel recommends that future reports contain a more synoptic and transparent description of the model specification and model building/selection procedures, including estimates of uncertainty in F/Fmsy and SSB/SSBmsy.

(EDITOR'S NOTE: The appendixes referred to in this Summer flounder Assessment Report are in Northeast Fisheries Science Center Reference Document (CRD) 08-12b.

A. ASSESSMENT OF SUMMER FLOUNDER FOR 2008

by

SAW Southern Demersal Working Group
National Marine Fisheries Service
Northeast Fisheries Science Center
166 Water Street

EXECUTIVE SUMMARY

This June 2008 assessment of the summer flounder (*Paralichthys dentatus*) stock along the Atlantic coast (Maine to North Carolina) is an update through 2007 of commercial and recreational fishery catch data, research survey indices of abundance, and the analyses of the data. For 2007, commercial and recreational fishery final quotas were 4,401 mt and 3,030 mt, respectively, for a total of 7,431 mt. The first term of reference (TOR 1) was addressed and indicates that the reported commercial landings used in this assessment for 2007 were 4,489 mt, while estimated recreational landings were 4,445 mt, for a 2007 landings total of 8,934 mt. The 2008 commercial and recreational final quotas are 4,291 mt and 2,862 mt, respectively, for a total of 7,153 mt.

While the GLM integrated indices explored under TOR 2a provide a useful summary of mean survey trends, it was concluded that the use of integrated indices as VPA calibration input does not guarantee substantially more accurate or precise results than calibration using the original survey indices. Extensive work examining the effects of filling zero survey values under TOR 2b suggests that it is more appropriate to treat "zero" observations as "missing" in the survey series. Under TOR 3a there was consideration given to the use of a single catch at age matrix as has been done in previous assessments, two matrices for retained and discarded components of the fishery, and as many as six matrices; two matrices for retained and discarded components were used for this assessment. Exploratory analyses were conducted under TOR 3b to examine if some of the patterns observed in the summer flounder assessment (i.e. some retrospective pattern, large positive residuals primarily at ages 3 and 4 in NEFSC winter, spring, and CT, RI, and NJ indices) could be explained by changes in the spatial distribution of the commercial fishery and or the summer flounder stock. This work suggested that the development of assessment models which include a regional (spatial) component may be worthwhile. The assessment examined a variety of biological parameters (by year and sex), including maximum age, length-at-age, weight-at-age, growth rates, and sex ratios (TOR 3c). Consideration of the evidence to support an estimate of M (TOR 3d) resulted in the development of an abundance weighted combined sex M-schedule at age that ranged from 0.26 at age 0 to 0.24 at age 7+, with a mean of 0.25. Analyses were conducted to explore measured environmental factors such as regional water temperature anomalies and larger scale climate indices in relation to metrics of summer flounder recruitment success (TOR 6). Predictive relationships were not developed from this work.

Three modeling approaches were explored in detail for this assessment (TOR 4). A virtual population analysis (VPA) of commercial and recreational total catch at age (landings

plus discards) was conducted. In addition two statistical catch-at-age models were explored (Age Strucured Assessment Program [ASAP] and Stock Synthesis 2 [SS2]). The same suites of fishery-independent indices of recruitment and stock abundance were used in all three modeling approaches; these were developed from the Northeast Fisheries Science Center (NEFSC) winter, spring, and autumn surveys; Massachusetts spring and autumn surveys; Rhode Island survey; Connecticut spring and autumn surveys; and New Jersey trawl survey. Recruitment indices from surveys conducted by the states of North Carolina, Virginia, and Maryland were also used.

The Age-structured Assessment Program (ASAP) was selected as the best analytical tool to assess the summer flounder population and revised the biological reference points (TOR 5 and 7). The summer flounder stock is not overfished and overfishing is not occurring relative to the proposed 2008 assessment biological reference points. Fishing mortality calculated from the average of the currently fully recruited ages (3-7+) ranged between 1.143 and 2.042 during 1982-1996. The fishing mortality rate has declined to below 1.000 since 1996 and was estimated to be 0.288 in 2007, below the proposed fishing mortality reference point = F35% = FMSY = 0.310. There is an 80% probability that the fishing mortality rate in 2007 was between 0.253 and 0.325. Spawning stock biomass (SSB) declined from 24,674 mt in 1982 to 7,017 in 1989, then increased to 43,932 mt by 2004. SSB was estimated to be 43,363 in 2007, about 72% of the proposed SSB35% = SSBMSY reference point = 60,074 mt. There is an 80% chance that SSB in 2007 was between 39,325 and 48,122 mt. The arithmetic average recruitment from 1982 to 2007 is 41.6 million fish at age 0. The 1982 and 1983 year classes are the largest in the assessment time series, at 73.5 and 81.6 million fish; the 1988 year class is the smallest at only 12.8 million fish. The 2007 year class is estimated to be about 40.0 million fish, which is very close to the longterm average. The assessment has exhibited a retrospective pattern of underestimation of F and overestimation of SSB. There is no consistent retrospective pattern in recruitment evident. Over the last 3 years, the annual retrospective change in fishing mortality has ranged from +30 [2004] to -5% [2006]; over the last 3 years, the annual retrospective change in SSB has ranged from -29 [2004] to +6% [2006].

Future TALs (TOR 8) that correspond to fishing at or near the fishing mortality rate threshold (F35% = FMSY = 0.310) may result in overfishing if the assessment has underestimated F or overestimated B. Adopting TALs lower than those indicated by forecast median values would decrease the chance of overfishing. If landings in 2008 are 7,153 mt (15.8 million lbs; the 2008 TAL) and discards are 885 mt (2.0 million lbs), the forecast estimates a median (50% probability) F in 2008 = 0.238 and a median SSB on November 1, 2008 of 46,992 mt, above the proposed biomass threshold of one-half SSBMSY = 30,037 mt Fishing at Frebuild = 0.274 in 2009 results in forecast median (50%ile) landings of 9,211 mt (20.3 million lbs); the corresponding 25%ile of landings would be 8,653 mt (19.1 million lbs). Continued fishing at Frebuild = 0.274 during 2010-2012 is forecast to rebuild the stock to SSBMSY = 60,074 in 2012.

Current research recommendations were reviewed and new research recommendations were identified under TOR 9.

INTRODUCTION TO THE ASSESSMENT AND BACKGROUND

WORKING GROUP PROCESS

The Southern Demersal Working Group (WG) began work in 2007 to produce this benchmark assessment of summer flounder through 2007/2008. The WG met via conference call on November 2007 and in person in February 2008, April 2008, and May 2008. The Stock Assessment Workshop (SAW) was held during June 16-20, 2008 to present the benchmark assessment of summer flounder through 2007/2008 to the Stock Assessment Review Committee (SARC). The following scientists and managers participated in the WG meetings and benchmark assessment update:

Ken Able	Rutgers University
Jeff Brust	New Jersey Division of Fish and Wildlife (NJDFW)
Paul Caruso	Massachusetts Division of Marine Fisheries (MADMF)
Jessica Coakley (chair)	Mid-Atlantic Fishery Management Council (MAFMC)
Victor Crecco	Connecticut Department of Environmental Protection (CTDEP)
Greg DiDomenico	Garden State Seafood Association (GSSA)
Bruce Freeman	Partnership for Mid-Atlantic Fisheries Science (PMAFS)
Emerson Hasbrouck	Cornell University
Toni Kerns	Atlantic States Marine Fisheries Commission (ASMFC)
Laura Lee	Virginia Marine Resources Commission (VMRC)
Chris Legault	NMFS NEFSC
Brian Murphy	Rhode Island Department of Environmental Management, Division of Fish and Wildlife (RIDFW)
Mark Maunder	Quantitative Resource Assessment (QRA)
Paul Nitschke	NMFS NEFSC
Bill Overholtz	NMFS NEFSC
Eric Powell	Rutgers University
Paul Rago	NMFS NEFSC
Michael Ruccio	NMFS Northeast Regional Office (NMFS NERO)
Kathy Sosebee	NMFS NEFSC
Mark Terceiro	NMFS NEFSC
Alice Weber	New York Department of Environmental Conservation (NYDEC)
Greg Wojcik	Connecticut Department of Environmental Protection (CTDEP)
Richard Wong	Delaware Department of Fish and Wildlife (DEDFW)

Although they were unable to attend the meeting, David Simpson of the CTDEP, Don Byrne of the NJDFW, Stew Michels of the DEDFW, Steve Doctor of the Maryland Department of Natural Resources (MDDNR), Chris Bonzak of the Virginia Institute of Marine Science (VIMS), Rob O'Reilly of the VMRC, and Chris Batsavage of the North Carolina Division of Marine Fisheries (NCDMF) provided research survey and/or fisheries catch data used in the assessment.

STOCK UNIT

For assessment purposes, the previous definition of Wilk et al. (1980) of a unit stock extending from Cape Hatteras north to New England has been accepted in this and previous assessments (e.g., NEFSC 2002). The Mid-Atlantic Fishery Management Council (MAFMC) and the Atlantic States Marine Fisheries Commission (ASMFC) Fishery Management Plan (FMP) define the management unit for summer flounder as extending from the southern border of North Carolina, northward to the U.S.-Canadian border. A recent summer flounder genetics study, which revealed no population subdivision at Cape Hatteras (Jones and Quattro, 1999), is consistent with the definition of the management unit. Recent consideration of summer flounder stock structure incorporating new tagging data concluded that evidence supported the existence of stocks north and south of Cape Hatteras, with the stock north of Cape Hatteras possibly composed of two distinct spawning aggregations, off New Jersey and Virginia-North Carolina (Kraus and Musick, 2003). The conclusions of Kraus and Musick (2003) are consistent with the current assessment stock unit.

HISTORY OF MANAGEMENT AND THE ASSESSMENT

An overview of the history of the summer flounder FMP and assessment is provided in this section and the box below. Management of the summer flounder fishery began through the implementation of the original Summer Flounder FMP, which was approved by National Marine Fisheries Service in 1988. This 1988-1989 time period coincides with the lowest levels of stock biomass for summer flounder since 1982.

There are two management entities that cooperatively develop fishery regulations for this resource; the ASMFC and the MAFMC in conjunction with the National Marine Fisheries Service (NMFS) as the federal implementation and enforcement entity. The cooperative management endeavor was developed because a significant portion of the catch is taken from both state (0-3 miles offshore) and federal waters (3-200 miles offshore).

Amendment 1 to the FMP in 1990 established the fishing definition for summer flounder; it is the fishing mortality rate equal to F_{MAX}, initially estimated as 0.23 (NEFSC 1990). Amendment 2 (1992) established target fishing mortality rates for summer flounder for 1993-1995 as F = 0.53, and F_{MAX} = 0.23 for 1996 and beyond. Regulations enacted under Amendment 2 to meet those fishing mortality rate targets included: 1) an annual fishery landings quota, with 60% allocated to the commercial fishery and 40% to the recreational fishery, based on the historical (1980-1989) division of landings; the commercial allocation is further distributed among the states based on their share of commercial landings during 1980-1989; 2) commercial minimum landed fish size limit at 13 in (33 cm), as established in the original FMP; 3) a minimum mesh size of 5.5 in (140 mm) diamond or 6.0 in (152 mm) square for commercial vessels using otter trawls that possess 100 lbs (45 kg) or more of summer flounder, with exemptions for the flynet fishery and vessels fishing in an exempted area off southern New England (the Northeast Exemption Area) during 1 November to 30 April; 4) permit requirements for the sale and purchase of summer flounder; and 5) annually adjustable regulations for the recreational fishery, including seasons, a 14 in (36 cm) minimum landed fish size, and possession limits.

The results of previous assessments indicated that summer flounder abundance was not increasing as rapidly as projected when Amendment 2 regulations were implemented. In anticipation of the need to drastically reduce fishery quotas in 1996 to meet the management

target of F_{MAX} , the MAFMC and ASMFC modified the fishing mortality rate reduction schedule in 1995 to allow for more stable landings from between years, while slowing the rate of stock rebuilding. Amendment 7 to the FMP set target fishing mortality rates of 0.41 for 1996 and 0.30 for 1997, with a target of F_{MAX} = 0.23 for 1998 and beyond. Total landings were to be capped at 8,400 mt (18.51 million lbs) in 1996-1997, unless a higher quota in those years provided a realized F = 0.23.

Amendment 12 (1999) defined overfishing for summer flounder as occurring when the fishing mortality rate exceeds the threshold fishing mortality rate of F_{MSY}. Because F_{MSY} could not be reliably estimated for summer flounder, F_{MAX} = 0.24 was used as a proxy for F_{MSY}. This was also defined as the target fishing mortality rate (F_{TARGET}= F_{MSY}= F_{MAX}). Under this amendment, the stock was defined to be overfished when total stock biomass falls below the minimum biomass threshold of one-half of the biomass target, B_{MSY}. Because B_{MSY} could not be reliably estimated, the biomass target was defined as the product of total biomass per recruit and contemporary (1982-1996) median recruitment, at that time estimated to be 153,350 mt (338 million lbs), with the minimum biomass threshold defined as 76,650 mt (169 million lbs). Through the 1999 stock assessment (Terceiro 1999), those reference points were updated using updates of median recruitment (1982-1998) and mean weights at age (1997-1998), which resulted in a biomass target of 106,444 mt (235 million lbs) and minimum biomass threshold of 53,222 mt (118 million lbs). The Terceiro (1999) reference points were retained in the 2000 and 2001 stock assessments (NEFSC 2000, MAFMC 2001a) because of the stability of the input data. Concurrent with the development of the 2001 assessment, the MAFMC and ASMFC convened the ASMFC Summer Flounder Overfishing Definition Review Committee to review these biological reference points. The work of this Committee was later reviewed by the MAFMC Scientific and Statistical Committee (SSC) in August 2001. The SSC recommended that using the F_{MSY} proxy for F_{MAX} = 0.26 was appropriate and be retained for 2002, and endorsed the recommendation of SARC 31 (NEFSC 2000) which stated that "...the use of F_{MAX} as a proxy for F_{MSY} should be reconsidered as more information on the dynamics of growth in relation to biomass and the shape of the stock recruitment function become available" (MAFMC 2001b).

The benchmark stock assessment in 2002 (SAW 35; NEFSC 2002) indicated the summer flounder stock was overfished and overfishing was occurring relative to the current biological reference points. The fishing mortality rate had declined from 1.32 in 1994 to 0.27 in 2001, marginally above the overfishing reference point ($F_{THRESHOLD}$ = F_{TARGET} = F_{MAX} = 0.26). Total stock biomass in 2001 was estimated as 42,900 mt (94.6 million lbs), or 19% below the biomass threshold (53,200 mt; 117.3 million lbs). The review of the 2002 stock assessment (SARC 35) concluded that updating the biological reference points was not warranted at that time (NEFSC 2002). Updates to the stock assessment were completed in 2003 (Terceiro 2003a), 2004 (SDWG 2004), and 2005 (SAW 41; NEFSC 2005). While the 2003 assessment found the summer flounder stock was not overfished and no overfishing was occurring, the 2004 and 2005 assessments found the stock again experiencing overfishing. The 2005 SAW 41 assessment recommended updating the values for the fishing mortality and stock biomass reference points.

The most recent assessment peer review on summer flounder was the NMFS Office of Science and Technology Division (S&T) Peer Review of the 2006 SDWG assessment (October 2006; Terceiro 2006a, 2006b). This review made several recommendations, including modification of the definition of the overfished stock from what was originally defined under Amendment 2 to the FMP. Instead of using total stock biomass (as estimated on January 1), the

stock was now considered overfished when November 1 spawning stock biomass fell below one-half SSBMSY = 44,706 mt (98.6 million lbs). The 2007 assessment update (SDWG 2007) found that relative to the biological reference points, the stock is overfished and overfishing is occurring. The fishing mortality rate estimated for 2006 was 0.35, a significant decline from the 1.32 estimated for 1994 but above the threshold F of 0.28. The assessment presented in this document builds off the recommendations of numerous peer reviews since the FMP was implemented that have facilitated methodological improvements in the assessment and reference point calculations.

Summary of the history of the Summer Flounder, Scup, and Black Sea Bass FMP.

Year	Document	Plan Species	Management Action
1988	Original FMP	summer flounder	- Established management plan for summer flounder
1991	Amendment 1	summer flounder	- Established an overfishing definition for summer flounder
1993	Amendment 2	summer flounder	- Established rebuilding schedule, commercial quotas, recreational harvest limits, size limits, gear restrictions, permits, and reporting requirements for summer flounder - Created the Summer Flounder Monitoring Committee
1993	Amendment 3	summer flounder	- Revised the exempted fishery line - Increased the large mesh net threshold - Established otter trawl retentions requirements for large mesh use
1993	Amendment 4	summer flounder	- Revised state-specific shares for summer flounder quota allocation
1993	Amendment 5	summer flounder	- Allowed states to combine or transfer commercial summer flounder quota
1994	Amendment 6	summer flounder	- Set criteria for allowance of multiple nets on board commercial vessels for summer flounder - Established deadline for publishing catch limits, commercial mgmt. measures for summer flounder
1995	Amendment 7	summer flounder	- Revised the F reduction schedule for summer flounder

Summary of the history of the Summer Flounder, Scup, and Black Sea Bass FMP.			
Year	**Document**	**Plan Species**	**Management Action**
1996	Amendment 8	summer flounder and scup	- Incorporated Scup FMP into Summer Flounder FMP and established scup measures including commercial quotas, recreational harvest limits, size limits, gear restrictions, permits, and reporting requirements
1996	Amendment 9	summer flounder and black sea bass	- Incorporated Black Sea Bass FMP into Summer Flounder FMP and established black sea bass measures including commercial quotas, recreational harvest limits, size limits, gear restrictions, permits, and reporting requirements
1997	Amendment 10	summer flounder, scup, and black sea bass	- Modified commercial minimum mesh requirements, continued commercial vessel moratorium, prohibited transfer of fish at sea, and established special permit for party/charter sector for summer flounder
1998	Amendment 11	summer flounder, scup, and black sea bass	- Modified certain provisions related to vessel replacement and upgrading, permit history transfer, splitting, and permit renewal regulations
1999	Amendment 12	summer flounder, scup, and black sea bass	- Revised FMP to comply with the SFA and established framework adjustment process
2001	Framework 1	summer flounder, scup, and black sea bass	-Established quota set-aside for research for all three species
2001	Framework 2	summer flounder	- Established state-specific conservation equivalency measures for summer flounder
2003	Amendment 13	summer flounder, scup, and black sea bass	- Addressed disapproved sections of Amendment 12 and included new EIS
2003	Framework 3	scup	- Allowed the rollover of winter scup quota - Revised start date for summer quota period for scup fishery
2003	Framework 4	scup	- Established system to transfer scup at sea
2004	Framework 5	summer flounder, scup, and black sea bass	- Established multi-year specification setting of quota for all three species
2006	Framework 6	summer flounder	- Established region-specific conservation equivalency measures for summer flounder
2007	Amendment 14	scup	- Established rebuilding schedule for scup
2007	Framework 7	summer flounder, scup, and black sea bass	- Built flexibility into process to define and update status determination criteria for each plan species - Scup GRAs made modifiable through framework adjustment process

TERMS OF REFERENCE

SARC 47 Summer flounder

1. Characterize the commercial and recreational catch, effort and CPUE, including descriptions of landings, discards and discard mortality.

2. Review methods for using fishery-independent surveys as abundance indices in assessment models.

    a. Evaluate whether to combine several of the surveys into a composite survey index. If appropriate, implement this approach.

    b. Develop and implement an appropriate statistical method to account for the probability of observing zeros in NEFSC survey tows.

3. Evaluate the feasibility of implementing alternative approaches to assess status of summer flounder stock and comment on any potential effects on estimates of F, SSB, and BRPs. Alternative approaches could consider:

    a. Separate Catch at age matrices for commercial and recreational fisheries, and resulting partial recruitment vectors for each fishery.

    b. Regional differences (north, south) in catch at age matrices.

    c. Potential gender differences in life span, growth rate, and natural mortality and implications of these factors for observed age- and length-specific sex ratios.

    d. Strength of evidence for natural mortality rate used in the assessment; Update the estimate if appropriate.

4. Compare results from alternative modeling approaches with those from the VPA model, to evaluate the robustness of VPA model results. Perform retrospective analyses of F, SSB, and recruitment for the models, and describe potential effects of retrospective patterns on assessment and rebuilding.

5. Based on the "best" model or models, estimate fishing mortality rate, recruitment, spawning stock biomass, and total stock biomass for the current year and characterize the uncertainty of those estimates. If possible, also include estimates for earlier years with uncertainty estimates.

6. Examine and evaluate the role of the environment on past and present summer flounder recruitment success.

7. Biological Reference Points

    a. Update or redefine biological reference points (BRPs; proxies for B_{MSY} and F_{MSY}), taking into account conclusions from earlier assessments and findings from TOR 6 (i.e.,

recruitment and the environment). Estimate uncertainty in BRPs. Comment on the scientific adequacy of existing and redefined BRPs.

b. Evaluate current stock status with respect to the existing BRPs, as well as with respect to updated or redefined BRPs (from TOR 7a).

8. Stock Projections

a. Recommend what modeling approaches and data should be used for conducting single and multi-year stock projections, computing TACs or TALs, and measures of uncertainty.

b. If possible,

i. Provide numerical examples of short term projections (2-3 years) of biomass and fishing mortality rate, and characterize their uncertainty, under various TAC/F strategies and

ii. Compare projected stock status to existing rebuilding or recovery schedules, as appropriate.

9. Review, evaluate and report on the status of the Research Recommendations offered in recent SARC reviewed assessments and in the 2006 "Methot" Review.

1.0 Characterize the commercial and recreational catch, effort and CPUE, including descriptions of landings, discards and discard mortality.

1.1 Commercial Fishery Landings

Total U.S. commercial landings of summer flounder from Maine to North Carolina peaked in 1979 at nearly 18,000 mt (39.7 million lbs, Table 1, Figure 1). The reported landings in 2007 of 4,489 mt (9.89 million lbs) were slightly over the final 2007 quota of 4,401 mt (9.79 million lbs). Since 1980, about 70% of the commercial landings of summer flounder have come from the Exclusive Economic Zone (EEZ; greater than 3 miles from shore). Large variability in summer flounder landings exist among the states, over time, and the percent of total summer flounder landings taken from the EEZ has varied widely among the states.

Northeast Region (Maine to Virginia)

Annual commercial landings data for summer flounder in years prior to 1994 were obtained from trip-level detailed landings records contained in master data files maintained by the NEFSC (the "weighout system"; 1963-1993) and from summary reports of the Bureau of Commercial Fisheries and its predecessor the U.S. Fish Commission (1940-1962). Beginning in 1994, landings estimates were derived from mandatory dealer reports under the current NMFS Northeast Region (NER) summer flounder quota monitoring system.

Prior to 1994, summer flounder commercial landings were allocated to NEFSC 3-digit statistical area according to interview data (Burns et al. 1983). During 1994-2007, dealer

landings were allocated to statistical area using fishing Dealer and fishing Vessel Trip Reports (VTR data) in a multi-tiered allocation procedure at the fishing-trip level (Wigley et al., 2007) A comparison of the distribution of landings by state and month as indicated by the dealer, VTR, and exact matched set data for trips with summer flounder landings during 1994-2007 is presented in Tables 2-15. Since the implementation of the annual commercial landings quota in 1993, the commercial landings have become concentrated during the first calender quarter of the year, with about 50% of the landings taken during the first quarter.

The distribution of Northeast Region (ME to VA) 1992-2007 landings by three-digit statistical area are presented in Table 16. Areas 537-539 (Southern New England), areas 611-616 (New York Bight), areas 621, 622, 625, and 626 (Delmarva region), and areas 631 and 632 (Norfolk Canyon area) have generally accounted for over 80% of the NER commercial landings. A summary of length and age sampling of summer flounder landings collected by the NEFSC commercial fishery port agent system in the NER is presented in Table 17. For comparability with the manner in which length frequency sampling in the recreational fishery has been evaluated, sampling intensity is expressed in terms of metric tons of landings (mt) per 100 fish lengths measured. The sampling is proportionally stratified by market category (jumbo, large, medium, small, and unclassified), with the sampling distribution generally reflecting the distribution of commercial landings by market category. Overall sampling intensity has improved markedly since 1995, from 165 mt per 100 lengths to 17 mt per 100 lengths (Table 17), and temporal and geographic coverage has generally improved as well (Tables 18-31).

The age composition of the NER commercial landings for 1994-2002 was generally estimated semiannually by market category and (usually) 1-digit statistical area (e.g., area 5 or area 6), using standard NEFSC procedures (market category length frequency samples converted to mean weights by length-weight relationships; mean weights in turn divided into landings to calculate numbers landed by market category; market category numbers at length apportioned to age by application of age-length keys, on semiannual area basis). For 2000-2002, sampling was generally sufficient to make quarterly estimates of the age composition in area 6 (in some cases, by division) for the large and medium market categories. For 2003-2007, sampling was generally sufficient to make quarterly estimates of the age composition in areas 5 and 6 for the jumbo, large, and medium market categories. The distribution of 1994-2007 length frequency samples by market category, 1- and 2-digit statistical area (division), and calendar quarter is presented in Tables 18-31.

NER landed numbers at age were raised to total NER (general canvas) commercial landings when necessary by assuming that landings not accounted for in the weighout/mandatory reporting system had the same age composition as that sampled. This was done as follows: calculate proportion at age by weight; apply proportions at age by weight to total NER commercial landings to derive total NER commercial catch at age by weight; divide by mean weights at age to derive total NER commercial landed numbers at age. The proportion of large and jumbo market category fish (generally of ages 3 and older) in the NER landings has increased since 1996, while the proportion of small market category landings (generally of ages 0 and 1) has become very low (Table 32, Figure 2). The mean size of fish landed in the NER commercial fishery has been increasing since 1993, and was 0.9-1.0 kg (2.0-2.2 lbs) during 2000-2007, typical of an age 3 summer flounder (Table 33).

North Carolina

The North Carolina winter trawl fishery accounts for about 99% of summer flounder commercial landings in North Carolina. A separate landings at age matrix for this component of the commercial fishery was developed from North Carolina Division of Marine Fisheries (NCDMF) length and age frequency sampling data. The NCDMF program samples about 10% of the winter trawl fishery landings annually, most recently (2005, 2006, and 2007) at a mean rate of 9 mt, 9 mt, and 5 mt of landings per 100 lengths measured, respectively (Table 34). All length frequency data used in construction of the North Carolina winter trawl fishery landings at age matrix were collected in the NCDMF program; age-length keys from NEFSC commercial data and NEFSC spring survey data (1982-1987) and NCDMF commercial fishery data (1988-2007) were combined by appropriate statistical area and semiannual period to resolve lengths to age. Fishery regulations in North Carolina also changed between 1987 and 1988, with increases in both the minimum mesh size of the codend and minimum landed fish size taking effect. It is not clear whether the change in regulations or the change in keys, or some combination, is responsible for the decreases in the numbers of age-0 and age-1 fish estimated in the North Carolina commercial fishery landings since 1987. Landed numbers at age (Figure 3) and mean weights at age from this fishery are shown in Tables 35-36.

1.2 Commercial Fishery Discards and Discard Mortality

In the 1993 SAW 16 assessment, analysis of variance of fishery observer data for summer flounder was used to identify stratification variables for an expansion procedure to estimate total landings and discards from the observer data kept and discard rates (weight per day fished) in the commercial fishery. Initial models included year, quarter, fisheries statistical division (2-digit area), area (divisions north and south of Delaware Bay), and tonnage class as main effects. Quarter and division consistently emerged as significant main effects without significant interaction with the year (NEFSC 1993). The estimation procedure expands transformation bias-corrected geometric mean catch (landings and discards) rates in year, quarter, and division strata by total days fished (days fished on trips landing any summer flounder by any mobile gear, including fish trawls and scallop dredges) to derive fishery landings and discards. The use of fishery effort as the multiplier (raising factor) allows estimation of landings from the fishery observer data for comparison with dealer reported landings, to help judge the potential accuracy of the procedure and/or sample data.

For strata with no fishery observer sampling, catch rates from adjacent or comparable strata were substituted as appropriate (except for Division 51, which generally has very low catch rates and negligible catch). Estimates of discard were stratified by 2 gear types (scallop dredges; trawls) for years when data were adequate (1992 and later years). Estimates at length and age were stratified by gear for 1994-2000 and 2002-2007, again due to sample size considerations. Only 11 fish were sampled from the sea scallop dredge fishery 2001, and so the scallop dredge discards were assumed to have the same length and age composition as the trawl fishery discards in 2001.

While estimates of catch rates from the NER fishery observer data were used in this assessment to estimate total discards, catch rate information is also reported in the VTR data. A comparison of discard to total catch ratios for the fishery observer and VTR data sets for trawl and scallop dredge gear indicates similar discard rates from the two data sources. Overall fishery observer and VTR discard to total catch ratios for 1994-2007 were generally within 10-15% of

each other; 2001 was an exception, with an overall discard to total catch ratio of 49% in the fishery observer data and 29% in the VTR data.

The most recent year (2007) was also an exception with an overall discard to total catch ratio of 59% in the fishery observer data and 36% in the VTR data. Discard rates of summer flounder in the scallop dredge fishery were much higher than in the trawl fishery (Tables 37-38).

The change in mid-1994 from the interview/weighout data reporting system to the VTR/mandatory dealer report system required a change in the estimation of effort (days fished) to estimate total discards. An initial examination of days fished and catch per unit effort (CPUE; landings per day fished) for cod conducted at SAW 24 (NEFSC 1997a) compared these quantities as reported in the full weighout and VTR data sets (DeLong et al., 1997). This comparison indicated a shift to a higher frequency of short trips (trips with one or two days fished reported), and to a mode at a lower rate of CPUE. It was not clear at SAW 24 if these changes were due to the change in reporting system (units reported not comparable), or real changes in the fishery, and so effort data reported by the VTR system were not used quantitatively in the SAW 24 assessments. In the SAW 25 assessment for summer flounder (NEFSC 1997b), a slightly different comparison was made. The port agent interview data for 1991-93 and merged dealer/VTR data for 1994-1996 (the matched set data), which under each system serve as the "sample" to characterize the total commercial landings, were compared in relative terms (percent frequency). For summer flounder, the percent frequency of short trips (lower number of days fished per trip) increased during 1991-1996, but not to the degree observed for cod, and the mode of CPUE rates for summer flounder increased in spite of lower effort per trip. For the summer flounder fishery, these may reflect actual changes in the fishery, due to increased restrictions on allowable landings per trip (trip landings limits might lead to shorter trips) and stock size increases (higher CPUE). As for cod, however, the influence of each of these changes (reporting system, management changes, stock size changes) has not been quantified. Total days fished in the summer flounder fishery were comparable between the period from 1989-1993 and 1994 (Tables 39-45; WO DF and WO/VTR DF). Since 1994, total days fished have ranged from 20,670 days in 1999 to 8,872 days in 2007, with a mean of about 12,000 days, a substantial decline relative to the 1989-1993 mean of 22,000 days (Tables 46-73). Questions will remain about the accuracy of the VTR data. However, because the effort measure is critical to the estimation of discards for summer flounder, the VTR data were used as the best data source to estimate summer flounder fishery days fished for 1994-2007.

Two adjustments were made to the dealer/VTR matched data subset days fished estimates to fully account for summer flounder fishery effort during 1994-2007. First, the landings to days fished relationship in the matched set was assumed to be the same for unmatched trips, and so the days fished total in each discard estimation stratum (2-digit area and quarter) was raised by the dealer to matched set landings ratio. This step in the estimation accounted for days fished associated with trips landing summer flounder, and provided an estimate of discard for trips landing summer flounder (Tables 46-73, variable OB EST DISC 1).

Given the restrictions on the fishery however, there is fishing activity which results in summer flounder discards, but no landings, especially in the scallop dredge fishery. The days fished associated with these trips was accounted for by raising strata discard estimates by the ratio of the total days fished on trips catching any summer flounder (trips with landings and discard, plus trips with discard only) to the days fished on trips landing summer flounder (trips with landings and discard) (Tables 46-73, variable NO KEPT RATIO), for VTR trips reporting discard of any species (DeLong et al. 1997). For this step , it is necessary to assume that the

discard rate (as indicated by the fishery observer data, which includes trips with discard but no landings, and which is used in previous estimation procedure steps) is the same for trips with only discards as for trips with both landings and discards.

Discard estimates for 1989-2007 are summarized in Tables 39-73 (variable OB EST DISC MT). Commercial fishery discard mortality in weight was highest in 1990-1991 and 1999, and lowest in 2004-2005 (Table 74). Estimates of landings from observer data ranged from +53% (1999) to -77% (2007) of the reported landings in the fisheries (Table 75), with discards ranging from 38% (1990) to 6% (1995) of the dealer reported landings. Total discards estimated for 2005, 2006, and 2007 were 10%, 10%, and 16% of the reported landings. Scallop dredge fishery discard to landed ratios are much higher than trawl fishery ratios, purportedly because of closures and trip limits. Although the scallop dredge landings of summer flounder are less than 5% of the total, the discards of summer flounder are of the same order of magnitude as in the trawl fishery.

The discard estimates described above were based only on the day fished data for ports in the NER during 1989-1996, and so it was necessary to raise the discard estimate to account for discarding occurring outside the NER reporting system (i.e., NER state reporting systems such as Connecticut and Virginia, and North Carolina). To determine the proper raising factor, landings accounted for by the NER reporting system (which result from the fishing effort on which the fishery observer discard estimate is based) were compared with total NER landings, plus that portion of North Carolina landings from the EEZ (it is assumed that only the North Carolina fishery in the EEZ would experience significant discard, as mesh regulations in state waters have resulted in very low discards in state waters since implementation of the regulation in 1989; R. Monaghan, NCDMF; personal communication, June 30, 1997). As a result of this exercise, the total discard estimates were raised by 11 to 38% for the 1989-1996 period. Since 1996, all states' landings and are included in the NER dealer reporting system, so no raising is necessary to account for missing landings. As recommended by SAW 16 (NEFSC 1993), a commercial fishery discard mortality rate of 80% was assumed to develop the final estimate of discard mortality (Table 66). The group did consider some preliminary information from a 2007 Cornell University Cooperative Extension study which conducted ten scientific trips that were made on inshore multispecies commercial trawling vessels to determine discard mortality rates relative to tow duration, fish size, and the amount of time fish were on the deck of the vessel (Working Paper 2; Appendix 1). The median mortality for all tows combined was 78.7%, very close to the estimated overall discard mortality of 80% currently used in the summer founder assessment. The mean of 64.6% however is considerably less. The SDWG recommended additional work be conducted to understand factors affecting discard mortality rates and the difference between the inshore (day-trip) and offshore (multi-day) components of the multispecies trawl fishery to facilitate future application of this information at a broader scale.

Existing fishery observer data were used to develop estimates of commercial fishery discard for 1989-2007. However, adequate data (e.g., interviewed trip data, survey data) are not available to develop summer flounder discard estimates for 1982-1988. Discard numbers were assumed to be very small relative to landings during 1982-1988 (because of the lack of a minimum size limit in the EEZ), but to have increased since 1989 with the implementation of fishery regulations under the FMP. It was recognized that not accounting directly for commercial fishery discards in 1982-1988 would result in an underestimation of fishing mortality and population sizes in these years.

NEFSC fishery observer length frequency samples were converted to sample numbers at age and sample weight at age frequencies by application of NEFSC survey length-weight relationships and fishery observer, commercial fishery, and survey age-length keys. Sample weight proportions at age were next applied to the raised fishery discard estimates to derive fishery total discard weight at age. Fishery discard weights at age were then divided by fishery observer mean weights at age to derive fishery discard numbers at age. Classification to age for 1989-1993 was done by semiannual (quarters 1 and 2 pooled, quarters 3 and 4 pooled) periods using NEFSC fishery observer age-length keys, except for 1989, when first period lengths were aged using combined commercial landings (quarters 1 and 2) and NEFSC spring survey age-length keys. For 1994-2007, only NEFSC winter, spring, and fall survey age-length keys were used, since fishery observer age-length keys were not yet available and commercial landings age-length keys contained an insufficient number of small summer flounder (<40 cm = 16 inches) that comprise most of the discards. Fishery observer sampling intensity and estimates are summarized in Table 74. Table 75 presents a comparison of commercial fishery dealer reported landings of summer flounder with estimates of summer flounder commercial landings from landings rates of NEFSC Domestic Observer sampling and commercial fishing effort (days fished) reported on commercial Vessel Trip Reports (VTR). Estimates of discarded numbers at age, mean length and mean weight at age are summarized in Tables 76-78.

The reason for discarding in the trawl and scallop dredge fisheries has been changing over time. During 1989 to 1995, the minimum size regulation was recorded as the reason for discarding summer flounder in over 90% of the observed trawl and scallop dredge tows. In 1999, the minimum size regulation was provided as the reason for discarding in 61% of the observed trawl tows, with quota or trip limits given as the discard reason in 26% of the observed tows, and high-grading in 11% of the observed tows. In the scallop fishery in 1999, quota or trip limits was given as the discard reason in over 90% of the observed tows. During 2000-2005, minimum size regulations were identified as the discard reason in 40-45% of the observed trawl tows, quota or trip limits in 25-30% of the tows, and high grading in 3-8%. In the scallop fishery during 2000-2005, quota or trip limits was given as the discard reason for over 99% of the observed tows. During 2006-2007, minimum size regulations were identified as the discard reason in 15-20% of the observed trawl tows, quota or trip limits in 60-70% of the tows, and high grading in 5-10%. In the scallop fishery during 2006-2007, quota or trip limits was given as the discard reason for about 40% of the observed tows, with about 50% reported as "unknown." As a result of the increasing impact of trip limits, fishery closures, and high grading as reasons for discarding, the age structure of the summer flounder discards has also changed, with a higher proportion of older fish being discarded (Table 76, Figures 4 and 5).

The WG considered other methods for the calculation of the discard estimates (Working Paper 1; Appendix 1); but ultimately determined the current methods are appropriate for the current assessment (i.e. make no changes to the discard estimation approach used in the 2008 benchmark assessment). It was recommended, however, in the working paper that future work focus on trawl and scallop dredge gear; other approaches should be examined such as using sums of ratio (NBRD2) estimators with alternative landings or effort raising factors, possibly for a "characteristic" group of landed species trips in the trawl fishery (e.g., fluke, scup, black sea bass, *Loligo* and *Illex* squids, yellowtail flounder, winter flounder, cod, haddock, silver hake, etc.)

1.3 Recreational Fishery Landings

Summary landings statistics for the summer flounder recreational fishery (catch type A+B1) as estimated by the National Marine Fisheries Service (NMFS) Marine Recreational Fishery Statistics Survey (MRFSS) are presented in Tables 79 and 80. Recreational fishery landings decreased 19% by number and 12% by weight from 2006 to 2007, as the fishery landed 47% over (4,445 mt; 9.80 million lbs) the harvest limit established for 2007 of 3,030 mt (6.68 million lbs).

The commercial fishery VTR system provides an alternative set of reported recreational landings by the party/charter boat sector. A comparison of VTR reports and MRFSS estimates indicates that MRFSS estimates are higher by an average factor of 2.68 for the 1995-2007 period, with an increasing trend in recent years and ranging from a factor of 1.02 in 1998 to 5.47 in 2005 (Table 81). It is unclear if this is due mainly to under-reporting of party/charter boat recreational landings in the VTR system, or a systematic positive bias of MRFSS landings estimates for the party/charter boat sector.

Length frequency sampling intensity for the recreational fishery for summer flounder was calculated by MRFSS subregions (North - Maine to Connecticut; Mid - New York to Virginia; South - North Carolina) based on a metric tons of landings per hundred lengths measured basis (Burns et al. In Doubleday and Rivard, 1983). For 2007, aggregate sampling intensity averaged 132 mt of landings per 100 fish measured (Table 82).

MRFSS sample length frequency data, NEFSC commercial age-length data, and NEFSC survey age-length data were examined in terms of number of fish measured/aged on various temporal and geographical bases. Correspondences were made between MRFSS intercept date (quarter), commercial quarter, and survey season (spring and summer/fall), and between MRFSS subregion, commercial statistical areas, and survey depth strata to integrate data from the different sources. Based on the number, size range, and distribution of lengths and ages, a semiannual (quarters 1 and 2; quarters 3 and 4), subregional basis of aggregation was adopted for matching of commercial and survey age-length keys with recreational length frequency distributions to convert lengths to ages.

Limited MRFSS length sampling for larger fish resulted in a high degree of variability in mean length for older fish, especially at ages 5 and older during the first decade of the time series. Attempts to estimate length-weight relationships from the MRFSS biological sampling data provided unsatisfactory results. As a result, quarterly length (mm) to weight (g) relationships from Lux and Porter (1966) were used to calculate annual mean weights at age from the estimated age-length frequency distribution of the landings.

The recreational landings historically were dominated by relatively young fish. Over the 1982-1996 period, age 1 fish accounted for over 50% of the landings by number; summer flounder of ages 0 to 4 accounted for over 99% of landings by number. No fish from the recreational landings were determined to be older than age 7. With increases in the minimum size since 1996 (to 14.5 in [37 cm] in 1997, 15 in [38 cm] in 1998-1999, generally 15.5 in [39 cm] in 2000, and various state minimum sizes from 14.0 [36 cm] to 19.5 in [50 cm] in 2001-2007) and a trend to lower fishing mortality rates, the age composition of the recreational landings now includes mainly fish at ages 3 and 4. The number of summer flounder of ages 4 and older landed by the recreational fishery in 2007 (34% of the landings by number) was the highest in the time series (Table 83, Figure 6).

1.4 Recreational Fishery Discards and Discard Mortality

MRFSS catch estimates were aggregated on a subregional basis for calculation of the proportion of live discard (catch type B2) to total catch (catch types A+B1+B2) in the recreational fishery for summer flounder. The live discard has varied from about 18% (1985) to about 86% (2007) of the total catch during 1982-2007 (Table 84).

To account for all removals from the summer flounder stock by the recreational fishery, some assumptions about the biological characteristics and hooking mortality rate of the recreational live discard need to be made, because biological samples are not routinely taken of MRFSS catch type B2 fish. In previous assessments, data available from New York Department of Environmental Conservation (NYDEC) surveys (1988-92) of New York party boats suggested the following: 1) nearly all (>95%) of the fish released alive from boats were below the minimum regulated size (during 1988-92, 14 in [36 cm] in New York state waters); 2) nearly all of these fish were age 0 and age 1 summer flounder; and 3) age 0 and 1 summer flounder occurred in approximately the same proportions in the live discard as in the landings. It was therefore assumed that all B2 catch would be of lengths below regulated size limits, and be either age 0 or age 1 in all three subregions during 1982-1996. Catch type B2 was allocated on a semi-annual, subregional basis in the same ratio as the annual age 0 to age 1 proportion observed in the landings during 1982-1996. Mean weights at age were assumed to be the same as in the landings during 1982-1996.

The minimum landed size in federal and most state waters increased to 14.5 in (37 cm) in 1997, to 15.0 in (38 cm) in 1998-1999, and to 15.5 in (39 cm) in 2000. Applying the same logic used to allocate the 1982-1996 recreational released catch to size and age categories during 1997-2000 implied that the recreational fishery released catch included fish of ages 2 and 3. Investigation of data from the CTDEP Volunteer Angler Survey (VAS) for 1997-1999 and from the American Littoral Society (ALS) for 1999, and comparing the length frequency of released fish in these programs with the MRFSS data on the length frequency of landed fish below the minimum size, indicated this assumption was valid for 1997-1999 (MAFMC 2001a). The CTDEP VAS and ALS data, along with data from the NYDEC Party Boat Survey (PBS) was used to validate this assumption for 2000. For 1997-2000 all B2 catch was assumed to be of lengths below regulated size limits, and therefore comprised of ages 0 to 3. Catch type B2 was allocated on a sub-regional basis in the same ratio as the annual age 0 to age 3 proportions observed in the landings at lengths less than 37 cm in 1997, 38 cm in 1998-1999, and 39 cm in 2000.

In 2001, many states adopted different combinations of minimum size and possession limits to meet management requirements. As a result, minimum sizes for summer flounder ranged from 15.5 in (39 cm) in Federal, VA, and NC waters, 16 in (41 cm) in NJ, 16.5 in (42 cm) in MA, 17 in (43 cm) in MD and NY, to 17.5 in (44 cm) in CT, RI, and DE. Examination of data provided by MD sport fishing clubs, the CTDEP VAS, the ALS, and the NYDEC PBS indicated that the assumption that fish released are those smaller than the minimum size remained valid for 2001, and so catch type B2 was characterized by the same proportion at length as the landed catch less than the minimum size in the respective states. The differential minimum size by state has continued since 2001. For 2002-2007, increased samples of the recreational fishery discards by the CT VAS, NYDEC PBS, and the MRFSS For Hire Survey (FHS) has allowed direct characterization the length frequencies of the discards from sample data (Table 85).

Studies conducted to estimate hooking mortality for striped bass and black sea bass suggest a hooking mortality rate of 8% for striped bass (Diodati and Richards 1996) and 5% for black sea bass (Bugley and Shepherd, 1991). Work by the states of Washington and Oregon with Pacific halibut (a potentially much larger flatfish species, but otherwise morphologically similar to summer flounder) found "average hooking mortality...between eight and 24 percent" (IPHC, 1988). An unpublished tagging study by the NYDEC (Weber MS 1984) on survival of released sublegal summer flounder caught by hook-and-line suggested a total, non-fishing mortality rate of 53%, which included hooking plus tagging mortality as well as deaths by natural causes (i.e., predation, disease, senescence). Assuming deaths by natural causes to be about 18%, (an instantaneous rate of 0.20), an annual hooking plus tagging mortality rate of about 35% can be derived from the NYDEC results. In the SARC 25 (NEFSC 1997b) and earlier assessments of summer flounder, a 25% hooking mortality rate was assumed for summer flounder released alive by anglers.

However, two more recent investigations of summer flounder recreational fishery release mortality suggest that a lower release mortality rate is more appropriate. Lucy and Holton (1998) used field trials and tank experiments to investigate the release mortality rate for summer flounder in Virginia, and found rates ranging from 6% (field trials) to 11% (tank experiments). Malchoff and Lucy (1998) used field cages to hold fish angled in New York and Virginia during 1997 and 1998, and found a mean short term mortality rate of 14% across all trials. Given the results of these release mortality studies conducted specifically for summer flounder, a 10% release mortality rate was adopted in the Terceiro (1999) stock assessment and has been retained in all subsequent assessments. Ten percent of the total B2 catch at age is therefore the basis of estimates of summer flounder recreational fishery discard at age. In 2007, the number of fish discarded and assumed dead in the recreational fishery was 60% by number and 25% by weight of the total landed (Tables 84-86, Figure 7).

1.5 Total Catch Composition

NER commercial fishery landings and discards at age, North Carolina winter trawl fishery landings and discards at age, and MRFSS recreational fishery landings and discards at age totals were summed to provide a total fishery catch at age matrix for 1982-2007 (Table 88; Figure 8). The percentage of age-3 and older fish in the total catch in numbers has increased during the last decade from only 4% in 1993 to 68% in 2007. Overall mean lengths and weights at age in the total catch were calculated as weighted means (by number in the catch at age) of the respective mean values at age from the NER commercial (Maine to Virginia), North Carolina commercial, and recreational (Maine to North Carolina) fisheries (Tables 87-90; Figure 9). The recreational fishery component of the total summer flounder catch has generally increased since 1995 (Table 91; Figure 10).

2.0 Review methods for using fishery-independent surveys as abundance indices in assessment models.

Descriptions of the fishery independent surveys and their associated indices of recruitment and stock abundance are given below. A total of 51 age-specific indices were initially considered as input for the calibration of the assessment modeling frameworks. However, the final base run

configurations for each of the modeling approaches under consideration (ADAPT VPA, ASAP, and SS2) included 39 survey indices at age (see section 4.2 for additional detail and discussion).

NEFSC spring

Long-term trends in summer flounder abundance were derived from a stratified random bottom trawl survey conducted in spring by NEFSC between Cape Hatteras and Nova Scotia since 1968 (Clark 1979). NEFSC spring survey indices suggest that total stock biomass last peaked during 1976-1977. The 2007 index (3.17 kg/tow) represents a time series high before falling by over half to 1.41 kg/tow in 2008 (Table 92, Figure 11). Age composition data from the NEFSC spring surveys indicate a substantial reduction in the number of ages in the stock between 1976-1990 (Table 93, Figure 12). For the period 1976-1981, fish of ages 5-8 were captured regularly in the survey, with the oldest individuals aged 8-10 years. From 1982-1986, fish aged 5 and older were only occasionally observed in the survey, and by 1986, the oldest fish observed in the survey were age 5. In 1990 and 1991, only three age groups were observed in the survey catch, and there was an indication that the 1988 year class was very weak. Since 1991, the survey age composition has expanded significantly. There is strong evidence in the 1998-2002 NEFSC spring surveys of increasing abundance of age-3 and older fish, due to increased survival of the 1994 and subsequent year classes. Mean lengths at age in the NEFSC spring survey are presented in Table 94.

NEFSC Autumn

Summer flounder are frequently caught in the NEFSC autumn survey at stations in inshore strata (< 27 meters = 15 fathoms = 90 feet) and at offshore stations in the 27-55 meter depth zone (15-30 fathoms, 90-180 feet) at about the same bathymetry as in the spring survey (Table 92). Furthermore, the autumn survey catches age-0 summer flounder in abundance, providing an index of summer flounder recruitment (Table 95, Figure 13). NEFSC autumn survey indices suggest improved recruitment since the late 1980s, and an increase in abundance of age-2 and older fish since 1995. The NEFSC autumn surveys indicate that the 1995 year class was the most abundant in recent years, and that subsequent, weaker year classes are experiencing increased survival (Table 95). Mean lengths at age in the NEFSC autumn survey are presented in Table 96.

NEFSC Winter

A new series of NEFSC winter trawl surveys was initiated in February 1992 to provide improved abundance indices for flatfish, including summer flounder. The surveys targeted flatfish when they are concentrated offshore during the winter. A modified 36 Yankee trawl was used that differed from the standard trawl employed during the spring and autumn surveys in that long trawl sweeps (wires) were added before the trawl doors to better herd fish to the mouth of the net, and the large rollers used on the standard gear were absent with only a chain "tickler" and small spacing "cookies" present on the footrope.

The design and conduct of the winter survey (timing, strata sampled, and the use of the modified 36 Yankee trawl gear) resulted in greater catchability of summer flounder compared to the other surveys. Most fish were captured in survey strata 61-76 (27-110 meters; 15-60 fathoms) off the Delmarva and North Carolina coasts. Other concentrations of fish were found in strata 1-12, south of the New York and Rhode Island coasts, in slightly deeper waters. Significant

numbers of large summer flounder were often taken along the southern flank of Georges Bank (strata 13-18).

Indices of summer flounder abundance from the winter survey indicate stable stock size during 1992-1995, with catch per tow values ranging from 10.9 in 1995 to 13.6 in 1993 (Tables 93 and 97). For 1996, the winter survey index increased by 290% over 1995, from 10.9 to 31.2 fish per tow. The largest increases in 1996 occurred in the Mid-Atlantic Bight region (offshore strata 61-76), where increases up to an order of magnitude occurred in several strata, with the largest increases in strata 61, 62, and 63 off the northern coast of North Carolina. Most of the increased catch in 1996 consisted of age-1 summer flounder from the 1995 year class. In 1997, the index dropped to 10.3 fish per tow, due to the lower numbers of age-1 (1996 year class) fish caught. From 1998-2003, the Winter trawl survey indices increased; with the 2003 Winter survey number and weight per tow indices being the highest in the time series at 27.58 kg/tow (Tables 93 and 97, Figure 11). The Winter survey index was lower from 2004-2007, and values ranged from 10.3 to 15.9 fish per tow. Similar to the other NEFSC surveys, there is strong evidence in recent winter surveys of increased abundance of age-3 and older fish relative to earlier years in the time series (Table 98). Mean length at age in the NEFSC winter survey are presented in Table 99. TheWinter survey series ended in 2007.

Massachusetts DMF

Spring and fall bottom trawl surveys conducted by the Massachusetts Division of Marine Fisheries (MADMF) show a decline in abundance in numbers of summer flounder from high levels in 1986 to record lows in 1990 and 1991 (MADMF fall and spring survey, respectively). In 1994, the MADMF survey indices increased to values last observed during 1982-1986, but then declined substantially in 1995, although the indices remain higher than the levels observed in the late 1980s. Since 1996, both the MADMF spring and fall indices have increased to record high levels (Tables 100 and 101, Figure 14). The MADMF also captures a small number of age-0 summer flounder in a seine survey of estuaries, and these data constitute an index of recruitment (Table 102, Figure 15).

Connecticut DEP

Spring and fall bottom trawl surveys are conducted by the Connecticut Department of Environmental Protection (CTDEP). The CTDEP surveys show a decline in abundance in numbers of summer flounder from high levels around 1986 to record lows in 1989. The CTDEP surveys indicate recovery since 1989, and evidence of increased abundance at ages 2 and older since 1995. The 2003 spring and 2002 autumn indices were the highest in the respective time series; although index values decreased in 2004-2007 (Tables 103 and 104, Figure 16). An index of recruitment from the autumn series is available (Table 104, Figure 13).

Rhode Island DFW

Standardized bottom trawl surveys have been conducted since 1979 during the spring and fall months in Narragansett Bay and state waters of Rhode Island Sound by the Rhode Island Department of Fish and Wildlife (RIDFW). Indices of abundance at age for summer flounder have been developed from the autumn survey data using NEFSC autumn survey age-length keys. Survey indices show that the 1984-1987, 1999, 2000, and 2002 year classes are all strong. The autumn survey reached a time series high in 2003 (Table 105, Figure 14). An abundance index has also been developed from a set of fixed stations sampled monthly during 1990-2007. Age-1

indices from this series indicate that strong year classes recruited to the stock in 1996, 1999, 2000, 2002, and 2003 with age 2+ abundance peaking in 2003 (Table 106). Recruitment indices are available from both the autumn (Figure 15) and monthly fixed station surveys.

New Jersey BMF

The New Jersey Bureau of Marine Fisheries (NJBMF) has conducted a standardized bottom trawl survey since 1988. Indices of abundance for summer flounder incorporate data collected from April through October (Table 107, Figure 17). The NJBMF survey mean number per tow indices and frequency distributions were converted to age using the corresponding annual NEFSC combined spring and fall survey age-length keys. Indices of the 1995 year class at age-0 and at older ages in subsequent years indicate that this cohort is the strongest in the time series. Since 1998, most year classes are at or below average; however, the 2005 year class is above average (Figure 18).

Delaware DFW

The Delaware Division of Fish and Wildlife (DEDFW) has conducted a standardized bottom trawl survey with a 16 foot headrope trawl since 1980, and with a 30 foot headrope trawl since 1991. Recruitment indices (age 0 fish; one index from the Delaware estuary proper for 1980 and later, one from the inland bays for 1986 and later) have been developed from the 16 foot trawl survey data. Indices for age-0 to age-4 and older summer flounder have been compiled from the 30 foot headrope survey. The indices use data collected from June through October (arithmetic mean number per tow), with age 0 summer flounder separated from older fish by visual inspection of the length frequency. The 16 foot headrope survey indices suggest poor recruitment in 1983, 1988, and 1993, improved recruitment in 1994-1995, and above average recruitment in 2000 (Tables 108 and 109, Figure 18). The 30 foot headrope survey indices suggest stable stock sizes over the 1991-2001 time series, with strong recruitment in 1991, 1994, 1995, and 2000. The 2004 index from the 30 foot survey was a time series low, along with lower index values from 2002 onwards, with an increase in 2007 (Table 110, Figure 17). These lower index values presumably reflect decreased availability to the survey, rather than a true decrease in abundance.

Maryland DNR

The Maryland Department of Natural Resources (MDDNR) has conducted a standardized trawl survey in the seaside bays and estuaries around Ocean City, MD since 1972. Samples collected during May to October with a 16 foot bottom trawl have been used to develop a recruitment index for summer flounder for the period 1972-2007. This index suggests that weakest year class in the time series recruited to the stock in 1988 and the strongest in 1972, 1983, 1986, 1994, and 1998. The 2001 and 2007 index values were above average, while the 2002 to 2005 values were the lowest values in the last 10 years (Table 111, Figure 18).

Virginia Institute of Marine Science

The Virginia Institute of Marine Science (VIMS) conducts a juvenile fish survey using trawl gear in Virginia rivers and the mainstem of Chesapeake Bay. The time series for the rivers began in 1979. With the Bay included, the series is available only since 1988, but many more stations are included. Trends in the two time series are very similar. An index of recruitment developed from the rivers only series suggests weak year classes recruited to the stock in 1987

and 2005, with strong year classes recruiting during 1980-1984, and 1990, 1991, and 1994. Recruitment indices since 1990 have been below average (Table 112, Figure 19).

North Carolina DMF

The North Carolina Divisions of Marine Fisheries (NCDMF) has conducted a stratified random trawl survey using two 30 foot headrope nets with 3/4" mesh codend in Pamlico Sound since 1987. An index of recruitment developed from these data suggests weak year classes recruited to the stock in 1988 and 2000, with strong year classes in 1987, 1992, and 1996-1998, 2001, and 2002, and 2005 (Table 113, Figure 19). The survey normally takes place in mid-June, but in 1999 was delayed until mid-July. The 1999 index is therefore inconsistent with the other indices in the time series, and the 1999 value was excluded from the VPA calibration in the SARC 31 assessment (NEFSC 2000).

2.1 Evaluate whether to combine several of the surveys into a composite survey index. If appropriate, implement this approach.

2.1.1 Integration of Survey Indices

For this assessment, a working paper was prepared that examined methods to better integrate trends in abundance provided by survey indices, prior to their use in population model calibration. Past peer reviews of the summer flounder assessment (NEFSC 2005), as well as other Northeast species assessments, have recommended investigation of methods to better integrate trends in abundance provided by survey indices (state and federal), prior to their use in population model calibration. These recommendations stem, in part, from the realization that the abundance indices from some state surveys do not index trends for the entire stock, but merely components or substocks of the whole. While some state survey indices may in fact capture stock-wide trends, the peer-review panel research recommendations suggested that a method to statistically summarize and/or appropriately weight indices which are considered *a priori* to adequately characterize stock-wide trends - to Aintegrate them@ - will provide more reliable and transparent results than if the indices were simply used in their original form in Virtual Population Analysis (VPA) calibration. The complete working group paper is provided in Appendix 2. A summary of the methods and conclusions from this paper is provided below.

A GLM approach was used with research survey data to calculate integrated indices of abundance at age for use in a VPA calibration. Data from a recent NER assessment (NEFSC 2005) for summer flounder were used as an empirical test case. The time series of years for the fishery catch and research survey indices was 1982-2003/2004; the VPA calibration used survey indices at age (0-7+) from three seasonal NEFSC trawl survey series and 12 seasonal state surveys. The analytical approach is analogous to a GLM standardization analysis of commercial fishing vessel catch per unit effort data: with the Ayear@ main effect classification variable serves as the index of abundance, while the Asurvey@ classification variable is analogous to a Avessel@ classification variable, each with its= own time series of catch per unit effort that has some relationship to the underlying true abundance of the stock. The mean index of abundance is modeled as a log-linear function of the classification variables, with a log-normal error distribution assumption. The analysis could be expanded by including additional classification variables, such as the sampling gear type or tow duration, temporal variables (e.g., spring/fall; day/night) or environmental variables (e.g., water temperature anomalies). However, such

details typically are not available for most assessments, and indices are most often presented as aggregate annual or seasonal indices at age. As configured here, the analysis provided average, or integrated, annual indices of abundance at age.

GLM models were constructed for ages 0, 1, 2, 3, 4, and 5-7+. Main effects were limited to the year of sampling (1982, 1983...2004) and the identity of the survey (NEFSC age 1, NEFSC age 2...NEFSC age 5-7+). The resulting year effect coefficients, corrected for lognormal-transformation bias and re-transformed to the original scale were used as a single index of abundance at age input to the VPA calibration in place of the original survey series. Results indicate that without the inclusion in the GLM model of significant main effects (beyond year of sampling and survey identity) that account for a large proportion of the variance of survey series at age from the simple overall means, use of a GLM to develop integrated indices at age provides no clear advantage over using the original indices as input to the VPA calibration. While the GLM integrated indices provide a useful summarization of mean survey trends, the use of integrated indices as VPA calibration input does not guarantee substantially more accurate or precise results than calibration using the original survey indices. The general linear modeling of integrated indices of abundance did provide a useful summarization of mean survey trends. However, the empirical example for summer flounder shows that the use of integrated indices as input to virtual population analysis calibration does not guarantee substantially more accurate or precise results than using the original survey indices.

2.2 Develop and implement an appropriate statistical method to account for the probability of observing zeros in NEFSC survey tows.

The problem of zeros in tuning indices is that a lognormal error distribution is assumed under many assessment frameworks. Since the logarithm of zero is undefined, these zero tuning indices must be either treated as missing data or else be replaced by a positive value. The issue of handling zero observations in the summer flounder assessment tuning indices is not new and has been addressed in a previous Southern Demersal Working Group (SDWG) working paper used in preparing the 2004 summer flounder assessment (SDWG 2003; beginning on page 8). That work responded to the 2002 SAW 35 (NEFSC 2002) summer flounder assessment Research Recommendation: *Explore the sensitivity of the VPA calibration to the addition of 1 and/or a small constant to values of survey series with "true zeros."* In the 2002 (NEFSC 2002) and 2003 (Terceiro 2003a) summer flounder assessments, the addition of the constant value of 1 was made for five age 0 recruitment indices: the MA DMF Seine, CT DEP fall trawl, RI DFW fall trawl, RI DFW monthly trawl, and DE DFW 16 foot bay trawl survey series (note that the latter series was not included in the final ADAPT VPA tuning configuration). No constant was added to survey series with "zero" observations for other age classes. The choice of the value of 1 as the additive constant was based on recommendations from statistical texts (e.g., Snedecor and Cochran 1967, Sokal and Rohlf 1981) for the ln-transformation of data.

Berry (1987) provides guidance on the objective selection of the appropriate value of the additive constant based on the statistical properties (skewness and kurtosis) of data series to be ln-transformed. Work using the procedures suggested by Berry (1987) with recreational fishery catch rates as indices of abundance indicated that the additive constant of 1 was an appropriate value for those data, typically with values between zero and 50 (Terceiro 2003b). The SDWG (2003) work applied the method suggested by Berry (1987) to summer flounder age 0 surveys with "zero" observations. Of the five age 0 series with "zero" observations, the MA DMF series

varies between 0 and 70, while the other four series contained small values that varied between 0 and 1. The 2003 work (SDWG 2003) found that for the MA DMF series, the additive constant of 1 minimized the value of *g*. For the other four series, *g* was minimized by small values of the additive constant ranging from 0.001 to 0.1, with an "average" best additive constant of 0.1. The SDWG (2003) therefore recommended use of the revised, varying (1 or 0.1) additive constants in future assessments, and this revision was made in the 2004-2006 assessment, for age 0 survey series only. No constant was added for survey series of other age classes, pending further research.

The 2006 assessment of summer flounder (Terceiro 2006b) was subject to a NMFS Office of Science and Technology (S&T) Peer Review (Methot 2006). Among the recommendations made by the S&T Peer Review panel was the following:

The Panel finds that one immediate modification of the VPA is justifiable and reduces the retrospective pattern in stock size during 2003-2005. The VPA model currently treats survey observations of zero as missing values. An observation of zero for a particular age of fish in a particular survey year does not mean that there are no fish of that age in the stock, only that the number of survey samples was not sufficient to detect any fish of that age. This VPA model, as with most assessment models, tunes to the logarithm of the survey observations so cannot explicitly deal with observations of zero. However, treating these zeroes as missing values can result in a bias because time periods of low abundance are underrepresented in the data input to the assessment model. In the case of summer flounder, the result may be an underestimate of the degree to which the stock has rebuilt since the low levels that occurred around 1990. The committee did not discuss this issue during the Sept 14-15 meeting, so is not prepared to present a definitive solution. An interim approach would use a small value in place of the zeroes. A value equal to one sixth of the smallest observed positive value would be reasonable until a more complete statistical solution can be developed.

As a result, the 2006 summer flounder assessment was revised (Terceiro 2006b). The previous treatment of "zero" observations for age 0 indices was retained (additive constant of 1 for MA DMF seine survey, 0.1 for the CT DEP fall trawl, RI DFW fall trawl, RI DFW monthly trawl, and DE DFW 16 foot bay trawl surveys) and age-1-7+ survey observations of zero were replaced with values equal to one sixth of the smallest observed positive value for those series. Typically, the minimum non-zero value in these series was 0.01, and so the additive constant was 0.001667 (Terceiro 2006b).

To more fully understand the implications of this recommendation three working group papers were prepared in support of the current assessment to explore methods to address observed zeros in survey indices and to determine how zeros in the tuning indices should be handles in the current assessment. The complete working group papers are provided in Appendix 2. A summary of the methods and conclusions from these papers are provided below. In addition, the WG examined the findings of the ICES working group ICES working group report on this issue entitled " Report of the Working Group on Methods of Fish Stock Assessment" ICES WGMG Report 2007 (ICES CM 2007/RMC:04).

The first working paper on this subject conducted two types of simulation analyses. The first was a simple spreadsheet example of how a single artificially generated time series is impacted by different levels of fish detection. This artificial population (which exhibited a decline and increase) included values that were rounded to two, one, and zero decimal places creating observations of zero for 2, 4, and 7 years, respectively. A series of constants was added to the time series ranging from 0.0001 to 10 so that the holes were filled and new catchability

coefficients were calculated that minimized the difference between the true population and the observed [modified] survey time series. The differences between observed and predicted values depend strongly on the constant added to the time series. However, the more disturbing result demonstrated is that the addition of a constant value to replace the zeros in a survey time series artificially imposed a pattern that may not match the actual pattern in the population. This is most clearly seen in the round 0 case where seven zeros are filled with the same value even though the true population declines then increases during the seven year period.

The second simulation conducted generated many random sets of data for VPA from a known case, created zeros for some of the indices in some years, and compared different methods for dealing with these zeros, and including treating them as missing values, replacing the zeros with a fixed small value, and the one sixth of the smallest observation rule. The simulated population was loosely based on the summer flounder assessment with the population; exhibiting a population decline and increase, spanned 24 years, consisting of 8 age classes (last age class as a plus group), M=0.2, and variable recruitment and F. One index was generated for each age and the suites of identical (age-specific) indices were given four different treatments: Case 1 - actual values used, Case 2 - replaced with 0.0 and treated as missing, Case 3 - replaced with the arbitrary constant 0.01, Case 4 - replaced with 0.0 then a constant of 1/6 times the smallest non-zero element in the index vector added to all index vector elements including zeros. The median values of F and N at age from the 100 realizations of the VPA model under the four cases were compared with the true values from the simulated population. Due to the convergence properties of VPA, the medians from the 4 cases are essentially identical for years 1982-1994. The most striking feature seen is the poor performance of Case 3 (arbitrary constant of 0.01), with values well below the true values while the estimated population abundances were well above the true values, demonstrating the potential for introducing bias by replacing zeros in tuning index time series with an arbitrary constant. While not as clear, generally the Case 4 (add 1/6 of smallest non-zero element) estimates were more biased than the Case 2 (treat zeros as missing) estimates. The exception to this generality is seen in age 1 results where the VPA formulation had to be modified slightly to estimate only ages 3-8 in the terminal year +1 due to the lack of information for age 2 in the terminal year +1 when the index was zero. For older ages, Case 2 actually outperformed Case 1 (all data used) relative to the truth. It is not clear why this happened and may be an artifact of the bias introduced by the mis-ageing matrix used to generate the catch data. However, even if Case 1 is used as the basis for comparison, instead of the true values, Case 2 performs at least as well as Case 4 for all ages except age 1.

An alternative method to determining the constant to use in place of zeros consists of finding the constant that minimizes a function of the skewness plus kurtosis of the raw data Berry (1987). This approach was not considered appropriate for use with tuning index data because the residuals are assumed to follow a lognormal distribution, not the raw observations.

While the 1/6 of the smallest non-zero approach appears to provide reasonable results in some cases, it is an arbitrary rule. In some situations, 1/5 or 1/7 of the smallest non-zero index value would perform better than 1/6. However, filling zeros with a constant value, no matter how that constant is selected, creates a pattern that may not match reality and has the potential to bias the results. The simulations in this working paper demonstrated show that this approach can produce results further from the truth than treating zeros as missing values. In reality, zeros do have information; but results should be checked to ensure that predicted values are not high when index is zero. These two simulation studies demonstrated problems that can arise when tuning indices with zero values are replaced with arbitrary constants. This practice assumes that

the correct magnitude can be chosen to fill the zeros and that it is better to provide the model with information that the index is low rather than treat the data as missing. Results demonstrate that this premise is not always correct. Thus, this working paper recommends the NEFSC treat zero values in tuning indices for VPA as missing values.

The second working paper on this subject included a simple regression example to further examine the consequences of adding 1/6 of the smallest non-zero value in tuning series to all values from that series. A 26 year population time series was simulated, with each value varying uniformly between zero and 50,000 fish. Four time series of values were created either with or without a constant of 1/6 of the smallest non-zero value (+c) in the observed time series: ln(obs), ln(obs+c), ln(pred), and ln(pred+c) where ln(obs) was missing when the observed value was zero. Two slopes were computed, one for ln(obs) vs ln(pred) denoted "missing" and the other for ln(obs+c) vs ln(pred+c) deonted "add c." Since in both cases the only source of error is the lognormal error assumed around the observed values, the expectation is that both lines will have slope equal to one. Random series of populations and observation errors were drawn 10,000 times and the two slopes computed for each realization.

When zero observations were treated as missing, the slope was slightly negatively biased (mean 0.983; 90% CI (0.864, 1.109)) and when a constant of 1/6 the smallest non-zero value was added to all observed and predicted values, the slope was highly positively biased (mean 1.261; 90% CI (1.018, 1.483)). Note that the 90% confidence interval for the "add c" case does not overlap one and has a range nearly twice as large as the "missing" case. Under this regression example, the constant was added to both observed and predicted data because to ensure an appropriate comparison. However, in a separate simulation the author did not replace values less than 0.5 with zero and found nearly identical distributions for the "missing" and "add c" slopes; which demonstrated that filling of zeros causes the problem, not the addition of a constant. In order for the "add c" approach to be unbiased, the constant would have to be selected for each realization such that the average of the ln(pred+c) was the same as ln(obs+c) for the values when obs=0. This cannot happen because the predicted values are positive while the observed values are by definition set to zero. Thus, adding a constant to all values when a zero is in the time series will always bias the results. Therefore, the regression example documented in this working paper suggest that filling observed zeros in tuning indices causes a bias relative to the true population that is much greater than the bias introduced by treating the zeros as missing in this simple regression example.

A third working paper on this subject applied the Berry (1987) approach to the summer flounder survey series for all ages with observed "zeros" to determine the best additive constant to use to remove these "zero" observations from the ADAPT VPA calibration data. There were 24 survey series examined and these are characterized by non-zero values between 0.001 and 70, CVs that generally exceed 100%, positive skewness (long right hand tail), and significant kurtosis (high degree of peak, or contagion, near the mean). The proportion of "zeros" in the time series ranged from 1 of 31 = 3% (NEFSC Spring Age 3 index) to 13 of 28 = 46% (MA Fall 4).

Briefly, the methodology of Berry (1987) consists of 1) addition of a range of constants from very large (e.g., 100) to very small (e.g., 0.0001) to the original values in the series, 2) ln-transformation of the modified series, 3) calculation of the skewness and kurtosis of the modified series, and 4) summation of the absolute value of the skewness and kurtosis (providing the statistic g) of the modified series. The additive constant that minimizes g for a given series of data is the one that best minimizes the effect of outliers and normalizes residuals from the

lognormal error distribution, hence best adhering to the assumption of the lognormal distribution. These methods applied to the 24 series produced values of *g* that were minimized for constants between 0.001 and 100, for the age 0, 1, 2, 3, 4, and 5-7+ (aggregate) survey indices (number per tow or haul). There was no statistically significant correlation between the value of the additive constant that minimizes g and the given statistical parameters. Examination of these results for the age-specific indices demonstrated that there is no consistent pattern in the identification of the additive constant that minimizes the absolute value of Berry's (1987) *g* statistic. There is no strong relationship between the absolute magnitude of the index values, the length of the time series, the number of zeros, the magnitude of the smallest observed value, or any of the usual statistical moments of the series (mean, maximum, non-zero minimum, CV, skewness, kurtosis), and the value of the additive constant that minimizes *g*. Further, while the "one-sixth" of the minimum observed value was identified as the "best" additive constant in 5 of the 24 (21%) cases examined, this level is not high enough to justify this approach as a reliable rule-of-thumb. In fact, the additive constant of 0.01 was identified as "best" for a higher percentage of series (6 of 24 = 25%). Given the inability to identify a constant that consistently minimizes *g*, the best rule is to maintain the current approach of making no adjustment and continue to treat "zero" observations as "missing."

The three working group papers developed for the current assessment all suggest that it is more appropriate to treat "zero" observations as "missing" in the survey series. The ICES "Report of the Working Group on Methods of Fish Stock Assessment" ICES WGMG Report 2007 (ICES CM 2007/RMC:04), suggests that it may be more appropriate to change the models to assume an error structure other than lognormal, as opposed to filling zero values in the survey series with small positive values.

3.0 Evaluate the feasibility of implementing alternative approaches to assess status of summer flounder stock and comment on any potential effects on estimates of F, SSB, and BRPs.

BIOLOGICAL DATA

Aging

Work performed for the SAW 22 assessment (NEFSC 1996b) indicated a major expansion in the size range of 1-year old summer flounder collected during the 1995 and 1996 NEFSC winter bottom trawl surveys. This also brought to light differences between ages determined by NEFSC and NCDMF fishery biology staffs; therefore, age structure (scale) exchanges were performed after the SAW 22 assessment to explore these differences. The results of the first two exchanges, reported at SAW 22 (NEFSC 1996b), indicated low levels of agreement between age readers at the NEFSC and NCDMF (31 and 46%). In 1996, research was conducted to determine inter-annular distances and to back-calculate mean length at age from scale samples collected on all NEFSC bottom trawl surveys (winter, spring and fall) for comparison with NCDMF samples. While mean length at age remained relatively constant from year to year, inter-annular distances increased sharply in the samples from the 1995-1996 winter surveys, and increased to a lesser degree in samples from other 1995-1996 surveys. As a result, further exchanges were suspended pending the resolution of an apparent aging problem.

Age samples from the winter 1997 bottom trawl survey, aged utilizing both scales and otoliths by only by one reader, indicated a similar pattern as the previous two winter surveys (i.e., several large age 1 individuals), and some disagreement between scale and otolith ages

obtained from the same fish. Because of these problems, a team of five experienced NEFSC readers was formed to re-examine the scales aged from the winter survey. After examining several hundred scales, the team determined that re-aging all samples from 1995-1997 would be appropriate, including all winter, spring, and fall samples from the NEFSC and MA DMF bottom trawl surveys and all samples from the commercial fishery. The age determination criteria remained the same as those developed at the 1990 summer flounder workshop (Almeida et al. 1992) and described in the aging manual utilized by NEFSC staff (Dery 1997). Only those fish for which a 100% agreement of all group members was attained were included in the revised database, however. The data from the re-aged database were used in analyses in the SAW 25 assessment (NEFSC 1997b).

A third summer flounder aging workshop was held at the NEFSC in February, 1999, to continue the exchange of age structures and review of aging protocols for summer flounder (Bolz et al. 2000). Participants at this workshop concluded that the majority of aging disagreements in recent NEFSC-NCDMF exchanges arose from the interpretation of marginal scale increments due to highly variable timing of annulus formation, and from the interpretation of first year growth patterns and first annulus selection. The workshop recommended regular samples exchanges between NEFSC and NCDMF, and further analyses of first year growth. Recently, Sipe and Chittenden (2001) concluded that sectioned otoliths were the best structure for aging summer flounder over the age range from 0 to 10 years. Since 2001, both scales and otoliths have routinely been collected in all NEFSC trawl surveys for fish larger than 60 cm, and studies are underway to determine the best structure to use for aging these large summer flounder. An exchange of NEFSC and NCDMF aging structures for summer flounder occurred again in 2006, after the SAW SDWG listed the age sample exchange as a high research priority. This exchange examined samples from fish aged 1 to 9 (23-76 cm total length) and determined that the current consistency of aging between NCDMF and the NEFSC is at an acceptable level.

Maturity

The maturity schedule for summer flounder used in the 1990 SAW (SAW 11) and subsequent stock assessments through 1999 was developed by the SAW 11 Working Group using NEFSC Fall Survey maturity data for 1978-1989 and mean lengths at age from the NEFSC fall survey (G. Shepherd, NEFSC, personal communication, July 1, 1990; NEFSC 1990; Terceiro 1999). The SAW 11 work indicated that the median length at maturity (50^{th} percentile, L_{50}) was 25.7 cm for male summer flounder, 27.6 cm for female summer flounder, and 25.9 cm for the sexes combined. Under the aging convention used in the SAW 11 and subsequent assessments (Smith *et al.* 1981, Almeida *et al.* 1992, Szedlmayer and Able 1992, Bolz *et al.* 2000), the median age of maturity (50^{th} percentile, A_{50}) for summer flounder was determined to be 1.0 years for males and 1.5 years for females. Combined maturities indicated that at peak spawning time in the autumn, 38% of age-0 fish are mature, 72% of age-1 fish are mature, 90% of age-2 fish are mature, 97% of age-3 fish are mature, 99% of age-4 fish are mature, and 100% of age-5 and older fish are mature. The maturities for age-3 and older were rounded to 100% in the SAW 11 and subsequent assessments.

In the past series of summer flounder assessments, it has been noted that the NEFSC maturity schedules have been based on simple gross morphological examination of the gonads; therefore, they may not accurately reflect (i.e., may overestimate) the true spawning potential of the summer flounder stock (especially for age-0 and age-1 fish). It should also be noted, however, that spawning stock biomass (SSB) estimates based on age-2 and older fish show the

same long term trends in SSB as estimates which include age 0 and 1 fish in the spawning stock. A research recommendation that the true spawning contribution of young summer flounder to the SSB be investigated has been included in the resulting research recommendations from summer flounder stock assessments since 1993 (NEFSC 1993). In light of the completion of a URI study to address this research recommendation, the maturity data for summer flounder for 1982-1998 were examined in the 2000 assessment (NEFSC 2000) to determine if changes in the maturity schedule were warranted.

The research at the University of Rhode Island (URI) by Drs. Jennifer Specker and Rebecca Rand Merson (hereafter referred to collectively as the "URI 1999" study) attempted to address the issue of the true contribution of young summer flounder to the spawning stock. The URI 1999 study examined the histological and biochemical characteristics of female summer flounder oocytes (1) to determine if age-0 and age-1 female summer flounder produce viable eggs, and (2) to develop an improved guide for classifying the maturity of summer flounder collected in NEFSC surveys (Specker *et al.* 1999, Merson *et al.* 2000). The URI 1999 study examined 333 female summer flounder (321 aged fish) sampled during the NEFSC Winter 1997 Bottom Trawl Survey (February 1997) and 227 female summer flounder (210 aged fish) sampled during the NEFSC Autumn 1997 Bottom Trawl Survey (September 1997) using radioimmunoassays to quantify the biochemical cell components characteristic of mature fish.

The NEFSC and URI 1999 maturity determinations disagreed for 13% of the 531 aged fish, with most (10%) of the disagreement due to NEFSC mature fish classified as immature by the URI 1999 histological and biochemical criteria. The URI 1999 criteria indicated that 15% of the age-0 fish were mature, 82% of the age-1 fish were mature, 97% of the age-2 fish were mature, and 100% of the age 3 and older fish were mature. When the proportions of fish mature at length and age were estimated by probit analysis, median length at maturity (50^{th} percentile, L_{50}) was estimated to be 34.7 cm for female summer flounder, with the following proportions mature at age: age-0: 30%, age-1: 68%, age-2: 92%, age-3: 98%, and age-4: 100%. Median age of maturity (50^{th} percentile, A_{50}) was estimated to be about 0.5 years. Based on this new information, SARC 31 (NEFSC 2000) considered 5 options for the summer flounder maturity schedule for the 2000 stock assessment:

1) No change, use the maturity schedule for combined sexes as in the SAW 11 and subsequent assessments (rounded to 0.38, 0.72, 0.90, 1.00, 1.00, and 1.00 as in the SAW 25 and Terceiro (1999) assessment analyses).

2) Consider only age-2 and older fish of both sexes in the SSB.

3) Knife edged, age-1 and older maturity for both sexes. This would eliminate age-0 fish of both sexes from the SSB, and assume that the proportions mature at age-1 "round" to 100%.

4) NEFSC 1982-1989, 1990-1998 for both sexes, assuming a 1:1 sex ratio in deriving a combined schedule.

5) NEFSC 1982-1989, 1990-1998 for males, URI 1999 for females, assuming a 1:1 sex ratio in deriving a combined schedule.

The 5 options produce the following maturity schedules for both sexes combined:

Option			Age			
	0	1	2	3	4	5+
1	0.38	0.72	0.90	1.00	1.00	1.00
2	0.00	0.00	0.90	1.00	1.00	1.00
3	0.00	1.00	1.00	1.00	1.00	1.00
4	0.45, 0.45	0.88, 0.82	0.97, 0.93	1.00, 0.98	1.00, 0.99	1.00, 1.00
5	0.29, 0.31	0.74, 0.76	0.95, 0.94	0.99, 0.98	1.00, 1.00	1.00, 1.00

SARC 31 concluded that some contribution to spawning from ages 0 and 1 should be included, eliminating options 2 and 3. The differences among remaining options 1, 4, and 5 were considered to be relatively minor, and so the SAW 11 schedule (Option 1) was retained for subsequent assessments (MAFMC 2001a, NEFSC 2002). SARC 31 recommended that more biochemical and histological work should be done for additional years to determine if the results of the URI 1999 study will be applicable over the full VPA time series. SARC 31 also noted the need for research to explore whether the viability of eggs produced by young, first time spawning summer flounder is comparable to the viability of eggs produced by older, repeat spawning summer flounder. In the 2005 SAW 41 work (NEFSC 2005), the maturity schedule was updated and broadened to include data from 1992-2004, covering the year range for individually measured and weighed fish sampled in NEFSC research surveys. The resulting combined sex maturity schedule (0.38, 0.91, 0.98, 1.00, 1.00, and 1.00; respectively for age-0 to 5+) was retained in the 2006 assessment and S&T peer review (Terceiro 2006b).

The SDWG examined the proportions of summer flounder mature at age from 1981-2007 as well as information on length and age at maturity from 1992-2007, and concluded that it was appropriate to retain the maturity schedule from the 2006 assessment. Using NEFSC Fall Survey maturity data from 1992-1997 and probit analysis, the median length at maturity (50^{th} percentile, L_{50}) was estimated as 27.0 cm for male summer flounder, 30.3 cm for female summer flounder, and 27.6 cm for the sexes combined. The median age of maturity (50^{th} percentile, A_{50}) for summer flounder was determined to be 1.1 years for males, 1.4 years for females, and 1.2 years for both sexes combined. These findings are consistent with the findings of SAW 11 and the URI 1999 study. In addition, an examination of the proportions of mature age-0 and age-1 fish did not indicate any trend which would warrant modification of the current maturity schedule (Figure 20).

3.1 Alternative approaches could consider separate Catch at age matrices for commercial and recreational fisheries, and resulting partial recruitment vectors for each fishery.

The SDWG considered the use of a single catch at age matrix as has been done in previous assessments, two matrices for retained and discarded components of the fishery, and as many as six matrices. These considerations are described in Sections 4.0 and 5.0 of this report.

3.2 Alternative approaches could consider regional differences (north, south) in catch at age matrices.

Exploratory analyses were conducted to examine if indeed some of the patterns observed in the summer flounder assessment (Terceriro 2006a, 2006b; i.e. retrospective pattern, large positive residuals primarily at ages 3 and 4 in NEFSC winter, spring, and CT, RI, and NJ indices) could be explained by changes in the spatial distribution of the commercial fishery and or the summer flounder stock. Therefore, the commercial landings data from 1967-2006 and NEFSC survey data were examined spatially. It should be noted that this data was compiled from a generalized data retrieval, therefore this numbers may differ slightly (within a few tons) from the assessment data tables.

Commercial landings were compiled by year, regional "division", and calendar quarter (1-4). While the data were examined by calendar quarter, for simplicity, the discussion of here focuses only on year and "division". These "divisions" were aggregations of the NEFSC commercial fishery statistical areas (SAs; Figure 22; units generally about 1 degree square) to allow for better investigation of regional differences. The following logical divisions were created based on the aggregation of statistical areas; Division 51 (Gulf of Maine) aggregates SAs 511-515; Division 52 (George's Bank) aggregates SAs 521-526, 561, and 562; Division 53 (Southern New England) aggregates SAs 533-539; Division 61 (Northern Mid-Atlantic Bight) aggregates SAs 611-616; Division 62 (Southern Mid-Atlantic Bight) aggregates SAs 621-629; Division 63 (Virginia/North Carolina region) aggregates SAs 631-636; and Division 99 is all other landings outside these 6 regions (SAs not reported).

There are three time periods worth noting that may influence the pattern exhibited in the commercial landings data: 1967-1981; 1982-1992, and 1993-2006. The period 1967-1981 is prior to any collection of the commercial fishery length-age-composition data, and is the period before the first comprehensive management measures were enacted in 1982. In addition, for 1967-1981 the set of commercial landings with SAs available is incomplete, relative to the total commercial landings reported, due to limited participation of the states in the Federal data collection program (i.e. the "weighout" system). As shown in Table 114, Division totals for the 1960s and 1970s are well below the commercial total reported in the assessment tables, and are dominated by landings reported for Divisions 52, 53, and 61. Most states did not fully participate until 1982; New York and New Jersey began participating in 1986 and North Carolina joined in 1997. Therefore, comparing this earliest period (pre-1982) with more recent two periods (post-1982) is not consistent.

The time period 1982-1992 represents an era of pre-quota management; quota management (output controls) have only been in place since 1993. These regulatory changes may be reflected in changes in the Divisions accounting for most of the commercial landings between these periods, if substantial changes in the spatial distribution of the commercial fishery were occurring.

In addition, these three periods roughly coincide with the pre-age-structured assessment period (1967-1981), the period of time when the stock is estimated to have been decline (1982-1992), and the period during which rebuilding plans have been in place and the stock has been expanding (1993-present). The overall expansion, contraction, and expansion again of the length and age structure of the stock would be expected to coincide with these three periods. Given the migratory nature of summer flounder, and of the behavior of larger/older fish migrating further North, one might expect to see some changes in the spatial distribution of large fish (e.g. ages 3

and 4, and older) in both the commercial data and survey over these periods. The divisions that accounted for the greatest proportion of commercial landings in a given year during the latter two time periods (1982-1992; 1993-2006) were Division 61 and 62, the areas of the Northern and Southern Mid-Atlantic Bight, respectively. Division 61 accounted for the highest commercial landings 9% of the time (1 out of 11 years) for the period 1982-1992, while Division 62 accounted for the highest landings 29% of the time (4 out of 14 years) during the period 1993-2006. This suggests a shift in the fishery northwards (Figure 23). Drawing further insight from this exploratory work would require de-construction of the commercial and recreational expanded length and age frequencies; one would expect to find larger/older fish in the commercial landings from the more Northerly Divisions (mostly Division 53–Southern New England), compared to the more Southerly Divisions (61-63). There may however, be limits to this exercise depending on the sample sizes for the length-age data during some years of the time series, particularly the earlier and mid-parts of the data collection series and if the additional factor of calendar quarter is included. In addition to examining the commercial landings data, the NEFSC survey data may provide insight into some of the patterns observed in the summer flounder assessment.

The NEFSC Spring survey data was compiled into two regions. These "regions" were aggregations of the NEFSC Spring survey strata (strata; Figure 24), with a Northern region aggregating strata 1-12 and a Southern region aggregating strata 61-76. These offshore strata are the standard suite of those used for calculation of that spring tuning index. Because of the low numbers of summer flounder caught in the strata on George's Bank, those strata are not used in calculation of the tuning indices and are not used in the exploratory analysis presenting here (Figure 25). As shown by Figure 26, indices of abundance over most of the last 40 years have generally been higher in the South, while the indices of biomass are comparable for the Northern and Southern strata. This is consistent with the expectation of older/larger fish being found in the North. Since around 2000, with the exception of 2004, both abundance and biomass have been higher in the North. An examination of length-frequencies for the period 2002-2004 by region (Northern versus Southern strata; Figure 27) are consistent with these findings and suggest that most of the differences in length frequencies appear between 40-50 cm, which are age-3 and age-4 fish.

The survey data do provide evidence of more older/larger fish being found in the NEFSC spring survey "Northern" strata (1-12) since around 2000. In addition, many of the Northern state-specific surveys show a similar pattern. This pattern appears to be more evident in the survey data than was shown in the commercial landings data examined. This exploratory analysis suggests that the development of assessment models which include a regional (spatial) component may be worthwhile and should continue to be included as a future research recommendation. It should be noted that this recommendation may be in conflict with TOR 2.1, which suggests development of integrated survey indices for use in the assessment.

3.3 Alternative approaches could consider potential gender differences in life span, growth rate, and natural mortality and implications of these factors for observed age- and length-specific sex ratios.

During the 2007 stock assessment update (SDWG 2007), it was noted that there is potential for change in certain biological parameters of the stock over the last few years.

Therefore, working group papers were developed (and summarized below) for this benchmark assessment to examine a variety of biological parameters and if there are changes in length-at-age, weight-at-age, and growth rates, and sex ratios (Working Papers 7 and 9; Appendix 3).

The first working paper examined trends in the NEFSC trawl data. Catches from the NEFSC trawl survey database (1992-2007) are subsampled and provide length, weight, age, and sex for summer flounder. Sample size at older ages was low, particularly during early years of this analysis corresponding to periods of lower abundance. The data were therefore limited to years and ages that had a sufficient sample size. Length at age calculations were developed from the NEFSC winter survey only and include 1999 to 2006, ages 0 through 4 for males, and 0 through 5 for females. Sample size for these years and ages are generally greater than 40 fish. Sex specific mean size at age was calculated for each year and SAS Proc REG (SAS 1990) was used to conduct regressions of size at age over time. The observed data were fit to a von Bertalanffy growth function using SAS Proc NLIN (SAS 1989a). Residuals were then resampled with replacement, by year, to develop 500 bootstrap datasets (Barker 2005), each of which was also fit using the von Bertalanffy growth function. Similarly, length-weight analysis was conducted using an allometric growth function and potential changes in weight-at-age were examined.

Mean lengths for males age 1 to 4 show no trends (given the limited data 1999-2006), and regression trends were not significant ($\alpha = 0.10$ level). Trends in mean length at age for females were similar to males for ages 0 to 4; however, female mean length at age 5 decreased significantly between 1999 and 2006.Fitting bootstrap data to the von Bertalanffy growth function resulted in unrealistic parameter estimates for males in 2000 and 2006 ($L\infty$=100,000 cm) and for females in 2000. Regression results, using the von Bertalanffy estimates, for male length at ages 0 to 10 (the approximate age range observed in survey data) showed no significant trends. Regression results indicate no significant trend in predicted length at age for females ages 0 to 4; however, predicted length at ages five and older decreased significantly between 1999 and 2006. Combined sex regression results using von Bertalanffy predicted length at age were consistent with results of mean length at age. Length:weight analysis was conducted using the same subset of years and ages described above. Sample size was generally above 40 fish and no significant trends were observed for weight at length for males or females.

Maximum age, as identified through review of NEFSC spring, winter, and fall survey data, indicated that the maximum age for males generally varied between age 4 and 5 from 1985-1995, while female maximum age ranged from age 6 to 8 (Figure 21). By 2000, the maximum age of males increased to between 8 and 9, where it remained stable until 2007 when one 12 year old male was captured. Female maximum age has increased steadily since 1995, with a peak of 14 years in 2005. Dery (1988) suggested males and females reached maximum ages of 7 and 12 years, respectively. While this is consistent with maximum ages observed in NEFSC trawl surveys from 1992 to 2000, recent data suggest that maximum ages of at least 12 for males and 15 for females is more appropriate. Additional years of reduced fishing pressure may result in even older observed maximum ages.

Sex ratio (*i.e.* percent female) at size was analyzed using SAS Proc GENMOD (SAS 1989b) with a normal distribution and a logit link function (*i.e.* a logistic regression). From 1992 to 1997 overall sex ratio was about 54% female, then increased from 53 to 58% of the stock in 1997 to 2000, where it remained stable for 3 years. In 2003, the ratio dropped to 51% female and has varied in recent years. Sex ratios by age showed a decrease in percent female since the mid 1990s across all ages, although the declines are more evident for ages 2+ .When data are

combined across years, logistic regression of percent female at size shows a 50:50 sex ratio at around 38 cm (15"). Fish smaller than this size are predominantly male, while larger fish are predominantly female. These findings are not new (*e.g.* Murawski and Figley 1977, Morse 1981), but this sexual dimorphism may have greater implications for management and stock rebuilding. For many ages, this decline has been observed over 15 years which is much longer than states have required large minimum sizes.

Natural mortality for each sex was estimated using 3 / T_{MAX} (Hoenig 1983), assuming maximum ages of 12 and 15 for males and females, respectively, and resulted in M=0.25 for males and M=0.20 for females Applying these to overall sex ratios to estimate annual M, M has remained relatively stable around 0.223, with a range of 0.221 in 2000 to 0.226 in 2005. A more comprehensive examination of methods to estimate M is available in Section 3.4.

Individual fecundity was estimated by applying the relationship of Morse (1981) to the mid-year length at age for females.

$$F = 0.0007975 * L^{3.402}$$

Mature females by age and year (in numbers) were determined by multiplying the VPA estimated abundance, sex ratios, and VPA input maturity schedule. Fecundity could only be evaluated for the years 1999 to 2006 due to low samples sizes. Theoretical fecundity of the stock increased from approximately 22.3 x 10^{12} eggs in 1999 to a maximum of over 36.5 x 10^{12} eggs in 2004, and decreased in to approximately 31.0 x 10^{12} eggs in 2006. Recruitment as calculated in the VPA remained relatively stable between 28 million and 38 million individuals, except for 2004 (17 million). The relationship between fecundity and recruitment is slightly negative, although this appears to be driven primarily by the 2004 data point (highest fecundity and lowest recruitment). It appears the increases in total abundance have outpaced any decreases in fecundity, resulting in theoretical stock fecundity increasing more than 50% from 1999 to 2004. Estimated fecundity declined in 2005 and 2006, coincident with slower stock growth; however, it is not clear there is a causal relationship.

In conclusion, this review of NEFSC trawl survey data do indicate that some life history parameters have changed since 1992; although many of the causal relationships have not be established. This descriptive information can be considered by the SDWG in development of the assessment, reference point calculations, and model projections.

A second working paper (summarized below) was developed to evaluate to describe information in the summer flounder biological data base (Working Paper 9; Appendix 3). This work attempted to answer the questions of whether the current data support development of and use of: 1) a sexually-explicit model for summer flounder 2) regionally-specific sex-at-age keys 3) differential natural mortality rate for male and female summer flounder or a nonlinear whole-stock natural mortality rate, or 4) regionally-specific age-length keys.

At the time of analysis, sex ratio data for young-of-the-year are not available prior to 1982; consequently analyses of sex ratio focus on 1982-2007. Due to data limitations, and regional variability in sex ratios as discussed in a subsequent section, data were excluded from southern New England north and also from Cape Hatteras south in this set of analyses as well as all age-year combinations where the number of sexed summer flounder is less than 20. For some analyses, data were parsed into six year groups with the central four being half-decadal (i.e. Year group 1 contains data from 1982-1985). The data suggest that young-of-the-year are dominantly male. A female-biased sex ratio for young-of-the-year summer flounder occurs only thrice in 26

years. The data also suggest a consistent change in sex ratio with age. Thus, summer flounder are consistently characterized by biased sex ratios regardless of age or half-decadal period within the time series and the direction of bias changes with age. In addition, the three years where females predominate in age-0 fish include the last two years. This is unexpected from the time series record. However, the sex ratio for age-1 fish from the 2006 cohort conforms with age-1 sex ratios from other years; thus, it is possible the 2006 young-of-the-year ratio is a sampling artifact. Second, the fraction of fish that are male at older age has increased over time, although remaining well below 0.5. This is particularly apparent for age-3 fish.

One explanation is that male fish are moderately more susceptible to the fishery at high fishing mortality rates. The dispersion of males and females as the cohort ages might support this first alternative. The same outcome would be obtained either if a reduction in natural mortality rate had occurred if the originating sex ratio was biased to a greater degree in favor of males. A number of potential reasons exist for the male-dominated sex ratios seen in young-of-the-year summer flounder. Females mature later than males. The observed females may under-represent the total number. The biological database also records undifferentiated fish. Assigning all of these fish to the female sex, however, does not markedly change the sex ratios summarized in the data. This suggests the maturity schedule along cannot explain the male-dominated sex ratios observed for age-0 fish. Young males may be more available to the survey. While this possibility cannot be excluded, the fact that females grow faster than males and that the male-biased sex ratios clearly are retained into age 2, albeit at diminishing intensity, suggest that availability is not an adequate explanation. Protandry would produce the observed age-dependent sequence of sex ratios. Protandry, however, is not reported in flatfish, and would almost assuredly have been observed were it to exist. Biased sex ratios have been observed by others in summer flounder, however. Morse (1981) and Smith and Daiber (1977) found that younger, smaller fish were much more likely to be male and that this trend quickly reversed with increasing age. Morse (1981) offers that an initially male-dominated sex ratio is necessary to offset an apparently higher natural mortality rate in males, thus promoting a more nearly 1:1 sex ratio in the spawning stock. One viable explanation for biased sex ratios in young-of-the-year summer flounder is temperature-dependent sex determination; this is consistent with some findings in the literature and has been observed in other flatfishes.

To examine this further by age, depth, region, and time, sex-ratio strata were allocated to three depth zones (<25 fm; 25-50 fm; >50 fm), five regions: southern New England (we included Georges Bank strata in this grouping), the northern Mid-Atlantic Bight, Delmarva, and the strata south of Cape Hatteras, and allocated to half-decadal year-groups: 1976-1980, 1981-1985, 1986-1990, 1991-1995, 1996-2000, 2001-2005, 2006-2007. We excluded all occurrences of age-year group, age-region, and age-depth combinations with sex ratios supported by a total count of males and females less than 30. ANOVAs were run by age using depth, year-group, and region as main effects. All interaction terms were included. Sex was implemented as a dependent variable by assigning a 0 to males and a 1 to females. Means, accordingly, were equivalent to the fraction female.

Examining the regional results for overall trends, it seems that the northern Mid-Atlantic and Delmarva regions have similar sex ratios regardless of age. In addition, the south Atlantic and southern New England regions have a tendency to be different from the Mid-Atlantic/Delmarva grouping, depending on age. When different, the southern New England and south Atlantic regions routinely have a higher fraction of males. This is what would be expected from the temperature-dependent determination of sex that produces an increase in fraction male

at the temperature extremes; however, sex determination in the first year of life militates against this explanation as the main effect of region is observed only later. Thus, alternative biological explanations or determinants from differential fishing mortality must be sought. The depth and year-group effects are, as yet, unexplained.

The gradual shift in sex ratio from male-dominated to female-dominated with increasing age might accrue from differential mortality or differential availability. A higher natural mortality rate in males could potentially be explained by some type of biological refuge for females; less time spent in a predatory window. Female summer flounder are known to grow at a faster rate than males and may therefore be less prone to predation (Poole 1961). However, male and female growth rates are similar until age 2, so such an explanation would not be warranted when considering the apparent differential natural mortality in fish younger than age 2. Some precedent exists for higher morality rates in male relative to female flatfish. Morse (1981) already proposed a higher natural mortality rate for males in summer flounder. Santos (1994) computed natural mortality rates for the four-spot megrim (*Lepidorhombus boscii*) by sex. The natural mortality rate for males was 0.41, and for females 0.34. Pearson and McNally (2005) also calculated mortality rates, using three different methods, for the sand sole, *Psettyichthys melanostictus*. The natural mortality rate for females ranged between 0.35 and 0.45, whereas the mortality rate for males was estimated to fall between 0.40 to 0.60.

Additional non-paramentric analyses (categorical ANOVAs) examined region, depth, and year group, with length as the dependent, ranked variable. Depth significantly impacted length-at-age for males and females, ages 1 through 3 and age 4 for females. At age 0, summer flounder are only present in shallow waters, and at age 5 and older, depth no longer influences length-at-age, for the most part. Tukey's studentized range tests show that fish in deeper water are larger at a given age than fish in shallower water. Length at age varied significantly with region for male and female summer flounder, ages 0-4, but not at older ages. When regions did group together they did so in a north-central, south-central trend. In other words, the southern New England region never grouped with the south Atlantic or Delmarva regions, and the south Atlantic never grouped with the northern Mid-Atlantic and southern New England regions. Year-group consistently affected length at age for male and female summer flounder until age 6. Year-group no longer impacted length at age for male summer flounder at age 6 and older, but continued to do so for female fish.

Not considering the influence of fishing mortality on age-at-length, these trends could suggest that summer flounder either grow at faster rates in deeper water and northern latitudes or that larger fish at age preferentially aggregate in these regions. Alternatively, in shallow waters and at southern latitudes larger fish may be more accessible to the fishery. While the fishery may not keep younger fish due to minimum size restrictions, younger fish may still be removed by the fishery as discard mortality. Whether it be a biological reason (e.g., differential growth rates) or a fishery-related reason (bigger fish at any age are more accessible in shallow/southern water), it seems clear that the average size of fish at age is larger in deeper/northern water than in shallow/southern water. However, significant interaction terms also occur commonly in fish 4 years or less in age and these involve both depth and region with relatively equal frequency and intensity. The frequency of significant interaction terms including depth and region suggests that regionality in the trends in age at length for summer flounder cannot facilely be explained simply in terms of depth and latitude. A more complex mixture of biology and, perhaps, relative fishing impact is likely to be required.

Analyses were conducted that focused on the age-length keys for the Delmarva and northern Mid-Atlantic region and, independently, on the three depth zones previously described, as these two regions were most similar in length at age. To compare keys efficiently, lengths were combined into 12 units, the central 10 being 5 cm; this yielded three keys for the three depth zones and two for the two regions. Each of these returned a significant result from a by-region or by-depth chi-square test, and from a Cochran-Mantel-Haenszel test controlling for depth or region. To directly compare two keys, we used Geary's C and Moran's I statistics on the set of residuals obtained by calculating the expected key structure in one array from the observed key structure in the other.

From this work, it was concluded that young-of-the-year summer flounder are dominantly male. Sex ratio changes gradually with age such that male frequencies over 0.5 occur infrequently by age 2 and rarely exceed 0.3 by age 4. The biased sex ratio at birth may be the result of temperature-dependent sex determination. In additional, this data suggests the need to implement a sex-explicit and/ or spatially-explicit model for summer flounder. The change in sex ratio with age also suggests that separate natural mortality rates be considered for male and female summer flounder stock assessment models with a higher natural mortality rate in males. Spatial variation in length-at-age suggests that a single age-length key is not likely to be representative across all regions and in different depths. The differential with region and depth suggests that differential fishing pressure cannot be excluded as the mechanism generating these differences. The male age-length relationships are move variable over depth and region than the female ones, but each varies significantly. The analyses suggest that a single age-length key may not adequately describe the stock, particularly for the males.

The SDWG considered the information and concluded that while there were some significant interactions among sex-ratios and length-at-age by depth, region, and time period, the patterns and frequency of significant terms suggest the explanatory variables are not being adequately characterized (grouped). Therefore, additional work is needed to address what factors may be appropriate to characterize the observed patterns before a sex-specific or spatially-explicit model can be developed. There are many factors that may be interacting to cause spatial differences in summer flounder length-at-age and sex-ratios, which could include sampling effects, fishing mortality patterns (fishery behavior within year and over time), temperature, and predation patterns. While these analyses focused on NEFSC survey strata, the patterns observed in the fishery catch data (for which there is no sex-information collect), could be different.

This SDWG did, however, consider the information on natural mortality rates, which is discussed in greater detail in the next section (section 3.4).

3.4 Alternative approaches could consider the strength of evidence for natural mortality rate used in the assessment; Update the estimate if appropriate.

Natural Mortality Rate

The instantaneous natural mortality rate (M) for summer flounder was assumed to be 0.2 in past assessments (SAW 20; NEFSC 1996a). In the SAW 20 work, estimates of M were derived using methods described by: 1) Pauly (1980) using growth parameters derived from NC-DMF age-length data and a mean annual bottom temperature (17.5^{o}C) from NC coastal waters; 2) Hoenig (1983) using a maximum age for summer flounder of 15 years; and 3) consideration of age structure expected in unexploited populations (5% rule, 3/M rule, e.g., Anthony 1982).

SAW 20 (NEFSC 1996a) concluded that M = 0.2 was a reasonable value given the mean (0.23) and range (0.15-0.28) obtained from the various analyses, and this value for M has been used in all subsequent assessments.

For this assessment, a working paper was prepared that reviewed longevity- and life-history based estimators of M. These sex and age-specific estimates of M were calculated from current summer flounder age and growth data (1976-2007) from the NEFSC trawl surveys. The complete working group paper (Working Paper 8) is provided in Appendix 3. A summary of the methods and conclusions from this paper are provided here. Longevity based estimators of M are sensitive to critical underlying assumptions which include the value of p, or the small proportion of the population surviving to a given maximum age, and the maximum observed age under no or low exploitation conditions. Using a t_{MAX} (maximum age) of 15 years for summer flounder, and the methods of Hoenig (1983) and Hewitt and Hoenig (2005), longevity based estimates of M for combined sexes ranged from 0.20 to 0.36 depending on whether a p=1.5% or p=5% was assumed. Other life-history based were examined and included Pauly (1980), Jensen (1996), Gunderson & Dygert (1988), and Gunderson (1997), with resulting estimates ranging from 0.20 to 0.45; although again these estimates are highly dependent on their underlying assumptions. Age-specific and size variable estimates of M, based on the work of Peterson & Wroblewski (1984), Chen & Watanabe (1989), Lorenzen (1996), Lorenzen (2000), ranged from 0.19 to 0.90, with the highest values obviously associated with age-0-1 fish (fish at smaller lengths). While these exercises provided a wide range of methods and M estimates to be considered, each estimate involved a suite of underlying assumptions which were debated. In addition, the modeling frameworks of ADAPT, ASAP, and SS2 (see sections 4.2-4.4) allow for log-likelihood profiling of M to determine which M estimate provides the best model fit. Based on this exercise using the base cases, M that minimized the log-likelihood is 0.35, 0.20, and 0.25 under the models ADAPT, ASAP, and SS2, respectively (Figure 76B). The estimate of M that results in the lowest MSR (likelihood) is clearly sensitive to model selection, as the BASE case inputs were similar across the three models.

The SDWG considered the different methods of estimating M and after lengthy discussion assumed a natural mortality rate (M) of 0.20 for females and 0.30 for males for this June 2008 assessment based mainly on recently observed maximum ages (tmax) in NEFSC survey data of 14 years (76 cm, in NEFSC Winter Survey 2005) for females and 12 years (63 cm, in NEFSC Spring Survey 2007) for males, and the expectation that larger and older fish are likely if fishing mortality rates are maintained near current rates over the next several years. The assumptions were guided by the work above as well as the SDWG working papers on summer flounder growth and maturity prepared by Brust, Powell, and Wong (Working papers 8,9,10; Appendix 3). A combined sex M-schedule at age was developed by assuming these initial M rates by sex, an initial proportion of females at age 0 of 0.40 derived from the NEFSC Fall survey indices by age and sex, and population abundance decline over time at the sex specific M rates. The final abundance weighted combined sex M-schedule at age ranged from 0.26 at age 0 to 0.24 at age 7+, with a mean of 0.25. Additional details on the sensitivity of the assessment to an increase in M are discussed in Section 6.6.

4.0 Compare results from alternative modeling approaches with those from the VPA model, to evaluate the robustness of VPA model results. Perform retrospective analyses of F, SSB, and recruitment for the models, and describe potential effects of retrospective patterns on assessment and rebuilding.

4.1 A Stock Production Model Incorporating Covariates (ASPIC)

The SDWG did not repeat an ASPIC analysis in this assessment. Past attempts to apply this modeling approach to the summer flounder assessment are described in greater detail below; estimates from the model were not considered to be robust and the associated biological reference points were therefore considered to be unreliable. In addition, approaches suggested in a submitted working paper (Working Paper 10, Appendix 4) were not considered by the SDWG to be the most appropriate approach for the current benchmark assessment. The SDWG determined that the extensive age-information available for summer flounder should be utilized for this assessment and other modeling frameworks provide greater flexibility in developing the underlying assumptions, that are implicitly determined based on which surplus production approach is selected.

The non-equilibrium surplus production model incorporating covariates (ASPIC; Prager 1994, 1995) can be used to estimate maximum sustainable yield (MSY) and other biological reference points. An ASPIC analysis applied to summer flounder using various state and federal agency survey biomass indices (the 1998 analysis) was previously reviewed by the NEFMC Overfishing Review Panel (Applegate et al. 1998). Based on total weighted mean squared error (MSE), the NEFSC spring and autumn biomass indices gave the best fit to the data in that analysis. However, the Overfishing Review Panel concluded that biological reference points estimated in the 1998 analysis for summer flounder were unreliable, due to the short time series of reliable catch estimates and lack of dynamic range in the input data (Applegate et al. 1998).

An ASPIC analysis using projected catch and NEFSC survey biomass indices through 1999 was reviewed in the 1999 assessment (Terceiro 1999). Model results were examined for sensitivity by employing a Monte Carlo search routine and by initializing over a broad range the values of MSY (10,000 to 50,000 mt) and the intrinsic rate of increase (r : 0.12 to 1.25). The ratio of initial to current biomass (B1 ratio) was assigned a starting value of 0.50. Overall, the 1999 ASPIC model results for summer flounder were not well defined and suggested the possibility of numerous local minima in the sums of squared errors (SSE) response surface. The Monte Carlo search algorithm was employed in an attempt to provide a better search of the SSE response surface, and the this generated a range of estimates of MSY from 19,000 mt to 58,000 mt and of r from 0.49 to 1.08. Due to the number of iterations needed to reach convergence (>25) and the probable number of local minima, these results also appeared to be unreliable. Thus, biological reference points for summer flounder estimated by the 1999 ASPIC analysis were not considered to be robust.

4.2 ADAPT Virtual population analysis (VPA)

Fishing mortality rates in 2006 and stock sizes in 2007 were estimated using the ADAPT method for calibration of the VPA (Parrack 1986, Gavaris 1988, Conser and Powers 1990) as implemented in the NOAA Fisheries Toolbox (NFT) ADAPT VPA version 2.7.7. As recommended by the MAFMC SSC Committee during the review of the Terceiro (1999) assessment and by the National Research Council review of the summer flounder assessment (NRC 2000), ages 0-6 were included in the analysis as true ages, with ages 7 and older combined as a plus group. An instantaneous natural mortality rate of M = 0.2 was assumed for all ages in all years. Maturities were retained from the last revisions made in the 2005 SAW 41 assessment (NEFSC 2005); maturities at age for all years were 38% for age-0, 91% for age-1, 98% for age-

2, and 100% for ages 3 and older. Stock sizes in 2007 were directly estimated for ages 1-6, while the age 7+ group was calculated from Fs estimated in 2006. Fishing mortality on the oldest true age (6) in the years prior to the terminal year was estimated from back-calculated stock sizes for ages 3-6. Fishing mortality on the age 7+ group was assumed equal to the fishing mortality for age 6. Winter, spring, and mid-year (e.g., RIDFW monthly fixed station, DEDFW and NJBMF) survey indices and all survey recruitment (age-0) indices were compared to population numbers of the same age at the beginning of the same year. Fall survey indices were compared to population numbers one year older at the beginning of the next year. Tuning indices were *a priori* unweighted.

A number of ADAPT VPA runs using were made to examine the sensitivity of the analysis to several revisions to data and analyses that have been incorporated in this assessment. These changes include a) revisions to the historical time series of recreational fishery data, including state of North Carolina catch type B2 estimates (run INIT), b) use of the exact catch equation, as opposed to the Pope's approximation used previously (run EXACT), c) revisions to the MADMF trawl survey indices due to changes in stratum area specification (run MASV), d) treatment of survey zero values as missing data (run NOFILL), e) use of only NEFSC survey data in calibration (run NOFILL_NEC), and f) use of all survey indices (run F08_ALL). Of these changes from the 2007 final run configuration, the analysis was most sensitive to the treatment of zeros as missing (change from the MASV to NOFILL run).

A total of 51 age-specific indices were initially considered as input for the ADAPT VPA calibration and other models. The ADAPT VPA was used as the platform to select the base set of indices to carry forward because the existing NFT ADAPT software has very useful diagnostic features for judging the calibration performance of the indices. The inclusion of each survey index was considered based on a pre-calibration correlation analysis among all indices, a post-F08_ALL indices run correlation analysis among the indices and resulting ADAPT VPA estimates of stock size, and an examination of the analytical diagnostics (including the precision of each survey index series, the partial variance accounted for by each index, patterns in residuals, and the mean squared residual (MSR) of the calibrated solution). Survey indices with trends that did not reasonably match corresponding patterns in abundance as estimated by other indices and/or the F08_ALL run were eliminated from the tuning configuration.

The DEDFW 30 foot trawl indices of abundance were considered to be reflective of local population trends and not stock level trends. On that basis and the large amount of variance that the DEDFW indices contributed to the overall model fit, the DEDFW 30 foot trawl ages 0-3 indices were dropped. The MADMF spring age 1, MADMF fall age 1 (tuned to age 2), CTDEP spring age 1, and RIDFW fall age-1 (tuned to age-2) indices correlated poorly with other regional indices and exhibited large CVs and partial variances and were also dropped. The RIDFW fall, MADMF seine survey, DEDFW 16 foot Estuary trawl, and NCDMF age 0 (young-of-year) indices were also dropped due to large partial variance and poor correlation with F08_ALL estimates of recruitment.

The final base run configuration (run F08_BASE) includes 39 survey indices at age. This base set of calibration indices was also used in subsequent runs of the other age-structured models (ASAP and SS2) considered in the assessment. Figures 28-30 compare the estimates of Spawning Stock Biomass (SSB; mt), recruitment at age 0 (R; 000s) and fully-recruited fishing mortality rate (F, ages 3-5) from the alternative ADAPT VPA run configurations with the final F08_BASE run.

The annual partial recruitment of age-1 fish decreased from near 0.50 during the first half of the VPA time series to less than 0.30 since 1994, and to less than 0.20 during 2000-2006; the partial recruitment of age-2 fish has decreased from 1.00 in 1993 to about 0.50 during 2002-2006. These decreases in partial recruitment at age are in line with expectations given recent changes in commercial and recreational fishery regulations. For these reasons, summer flounder are currently considered to be fully recruited to the fisheries at age 3, and fully recruited fishing mortality is expressed as the unweighted average of fishing mortality at age for ages 3 to 5. Fishing mortality calculated from the average of the currently fully recruited ages (3-5) varied between 0.94 and 2.13 during 1982-1997, then declined substantially and was estimated to be 0.44 in 2006 (Figure 30).

Summer flounder spawn in the late autumn and early winter (peak spawning on November 1), and age 0 fish recruit to the fishery during the autumn after they are spawned. For example, summer flounder spawned in autumn 1987 (from the November 1, 1987 spawning stock biomass) recruit to the fishery in autumn 1988, and appear in VPA tables as age 0 fish in 1988. The F08_BASE run indicates that the 1982 and 1983 year classes were the largest of the VPA series, at 73 and 79 million fish, respectively. The 1988 year class was the smallest of the series, at only 13 million fish. The 2006 year class is estimated at 31 million fish, below the time series average of 36 million (Figure 29). Spawning stock biomass (SSB; Age 0+) declined 71% between 1983 and 1989 (23,900 mt to 6,900 mt), but has increased six-fold to 41,700 mt in 2005, before falling slightly to 40,500 mt in 2006 (Figure 28).

Retrospective analysis of the summer flounder ADAPT VPA F08_BASE run was carried out for terminal catch years 1995-2006. The retrospective analysis indicates a pattern of overestimation of fully recruited F (ages 3-5) for 1995-1997, followed by a pattern of underestimation of F for 1998-2005, continuing the pattern observed in the last several assessments (NEFSC 2000, MAFMC 2001a, NEFSC 2002, NEFSC 2005, Terceiro 2006b, S&T 2006)(Figure 31). For the last three years, fishing mortality was underestimated by 42% for 2003, by 25% for 2004, and by 15% for 2005, relative to the terminal year 2006 estimates. Spawning stock biomass has been generally been overestimated in the last 3 years, by 54% for 2003, 23% for 2004, and 7% for 2005, relative to the terminal year 2006 estimates (Figure 32). There is no consistent retrospective pattern in the estimation of the abundance of age 0 fish over the last three years (Figure 33).

As the previously accepted, peer-reviewed assessment model, the 2006 NMFS S&T ADAPT VPA (Terceiro 2006b) has been updated through 2007. The updated run (VPA_2007) exhibited the same time series trends and retrospective characteristics as the 2006 NMFS S&T run. Using the ADAPT VPA model assuming constant M = 0.20, the stock is overfished and overfishing is occurring when compared to existing BRPs (ADAPT VPA F2007 = 0.311, 11% above the existing F BRP = Fmax = FMSY = 0.280; ADAPT VPA SSB2007 = 42,142 mt, 47% of the existing SSB BRP = SSBMSY = 89,411 mt).

4.3 Age Structured Assessment Program (ASAP)

Fishing mortality rates and stock sizes were estimated using the ASAP model as implemented in the NOAA Fisheries Toolbox (NFT) ASAP version 2.0.9. The catch at age, mean weights at age, maturity at age, and survey index calibration time series were input as in the ADAPT VPA F08_BASE run (see section 4.2.1). An instantaneous natural mortality rate of M = 0.2 was assumed for all ages in all years. Fishery selectivities (partial recruitment) were

estimated either at each age or by fitting a single (flat-topped) logistic curve. Winter, spring, and mid-year survey indices and all survey recruitment (age-0) indices were compared to population numbers of the same age at the beginning of the same year. Fall survey indices were compared to population numbers one year older at the beginning of the next year. In developing the ASAP2 F08_BASE run, lognormal error distributions were assumed for the total catch in weight, research survey catch at age calibration indices, internal Beverton-Holt stock-recruitment relationship and parameters, selectivity parameters, fishing mortality (Fmult) parameters, survey catchability parameters, and estimated stock numbers at age. A multinomial distribution was assumed for fishery catch at age. A number of additional initial model settings are required in ASAP, including specification of likelihood component emphasis factors (lambdas), size of deviation factors expressed as standard deviations, and penalty functions for extreme fishing mortality estimates. The settings were left at the default values in the first few runs, and changed as runs were developed.

Initial runs used a) the number of sampled commercial fishery trips (ranging from 30 per year in 1995 to 181 in 2006) as the lambda for the effective fishery age composition sample size (ESS), b) a total catch lambda of 10 and CV of 0.01, c) recruitment deviation lambda of 6.74 and CV of 0.5, d) Fmult lambda of 6.74 and CV of 0.9, e) survey index lambdas of 0.4 and CV of 0.9 for all indices and catchability deviations lambda of 10000 (i.e., constant) and CV of 0.9, f) s-r function lambdas of 6.74 and CV of 0.9, and g) N in year 1 lambda of 6.74 with CV of 0.9.

Run configurations adjusting the ESS, lambdas, survey CVs, and time blocks for the estimation of the fishery selectivity pattern were tested to judge the sensitivity of the analysis to these settings. The sequence of runs is summarized in Table 115. As a result of these tests, a) the ESS was set at 200, b) a total catch lambda was set at 10 with CV of 0.10, c) recruitment deviation lambda was set at 0.001 with CV of 0.5, d) Fmult lambda was set at 1.0 with CV of 0.9, e) survey index lambdas were set at 1.0 with CVs of NEC Winter = 0.15, NEC Spring = 0.25, and NEC Fall = 0.25, and catchability deviations lambda of 10000 (i.e., constant) and CVs of 0.9, f) s-r function lambdas were set at 0.001 with CVs of 0.9, and g) N in year 1 lambda was set at 1.0 with CV of 0.9. These settings provided a good fit to fishery total catch and age comps, reasonable fit to survey indices, and a smooth transition in F pattern through the selectivity break in 1994-1995, and resulted in run ASAP run SELEX_94_95 which was then renamed BASE for subsequent tuning.

The next steps were to a) include the additional state agency survey indices at age accepted for the base ADAPT VPA formulation, with initial lambdas set at 1.0 with CVs of 0.40, b) set s-r function lambdas and CVs to 0, and c) set the ESS to the numbers estimated in the BASE run. Subsequent tuning adjustments (runs T1 and T2) attempted to even out patterns in the estimated ESS and fishing mortality using changes in the at-age selectivity estimation (Table 116). Run T3 was fit using a single logistic pattern with a break at 1994/1995. This change provided a smoother F pattern, while maintaining the expected transition from full selection at age 2 in the first block (1982-1994) and full selection at age 3 in the second (1995-2006). Run T4 specified the survey CVs to more closely match the true time series means of CVs of the NEFSC and MADMF series (other state agency CVs not available), but this change failed to improve the model fit to the surveys, and degraded the fit to the fishery age compositions. Following guidance received from Ian Stewart of NMFS NWFSC (pers. comm.) and Chris Legault of NMFS NEFSC (pers. comm.), the final tuning step, run T5, increased the survey CVs by 1.5 to 2.0 times, to allow better fits to the survey indices while maintaining fit to the fishery age compositions. Changes in the stock size and fishing mortality estimates between the BASE

and T1 through T5 run configurations were small (Figures 34-36). This last tuning configuration, F08_BASE_T5, was used as the final ASAP base run.

The annual selection of age-1 fish decreased from about 0.54 during the first time block of selectivity estimation (1982-1994) to about 0.16 during the second block, 1995-2006. The annual selection of age-2 fish decreased from about 0.97 during the first time block of selectivity estimation (1982-1994) to about 0.72 during the second block, 1995-2006. These decreases in selection at age are in line with expectations given changes in commercial and recreational fishery regulations. For these reasons, summer flounder are currently considered to be fully recruited to the fisheries at age 3, and fully recruited fishing mortality is expressed as the unweighted average of fishing mortality at age for ages 3 to 7+. Fishing mortality varied between 1.04 and 1.93 during 1982-1997, then declined substantially and was estimated to be 0.38 in 2006 (Figure 36).

The F08_BASE_T5 run indicates that the 1983 year class was the largest of the series, at 83 million fish. The 1988 year class was the smallest of the series, at only 12 million fish. The 2006 year class is estimated at 34 million fish, below the time series average of 36 million (Figure 35). Spawning stock biomass (SSB; Age 0+) declined 73% between 1983 and 1989 (23,300 mt to 6,300 mt), but increased six-fold to 39,900 mt in 2003, before falling to 38,600 mt in 2006 (Figure 34).

Retrospective analysis of the summer flounder ASAP F08_BASE_T5 run was carried out for terminal catch years 1997-2006 – earlier terminal years were not advisable due to the constraints of the selectivity blocks (2-3 years are recommended in each block; Chris Legault, NMFS NEFSC, pers.comm.). The retrospective analysis indicates a pattern of underestimation of fully recruited F (ages 3+) for 1997-2005 (Figure 37). For the last three years, fishing mortality was underestimated by 38% for 2003, by 32% for 2004, and by 9% for 2005, relative to the terminal year 2006 estimates. Spawning stock biomass has been generally been overestimated in the last 3 years, by 60% for 2003, 44% for 2004, and 9% for 2005, relative to the terminal year 2006 estimates (Figure 38). There is no consistent retrospective pattern in the estimation of the abundance of age 0 fish since 1997 (Figure 39).

4.4 Stock Synthesis 2 (SS2)

Fishing mortality rates and stock sizes were estimated using the Stock Synthesis 2 (SS2) model as implemented in the NOAA Fisheries Toolbox (NFT) SS2 version 2.00o. The catch at age, maturity at age, and survey index calibration time series were input as in the ADAPT VPA F08_BASE run (see section 4.2.1). For the population biology component of the SS2 model runs, growth patterns were estimated for combined sexes from NEFSC survey biological data for the period from 1992-2007, age structure was set at ages 0-15, and length structure at lengths 10 to 79 cm. Growth rates were estimated as of January 1. An instantaneous natural mortality rate of M = 0.2 was assumed for all ages in all years. Fishery selectivity (partial recruitment) was generally estimated by fitting a single (flat-topped) logistic curve, although dome-shaped patterns were explored. Winter, spring, and mid-year survey indices and all survey recruitment (age-0) indices were compared to population numbers of the same age at the beginning of the same year. Fall survey indices were compared to population numbers one year older at the beginning of the next year. In developing the SS2 F08_BASE run, lognormal error distributions were assumed for the total catch in weight, research survey catch at age calibration indices, internal Beverton-Holt stock-recruitment parameters, selectivity parameters, fishing mortality

parameters, survey catchability parameters, and estimated stock numbers at age. When modeled with lognormal error, survey selectivity was specified as S = 1 for the relevant age or series of ages indexed by the survey. Normal error distributions were assumed for mean length at age and mean weight at age. A multinomial distribution was assumed for fishery catch at age.

A number of additional initial model settings are required in SS2, including specification of likelihood component emphasis factors (lambdas), size of deviation factors expressed as standard deviations, and penalty functions for extreme fishing mortality estimates. The lambdas were set at 1 for the likelihood components that were intended to influence model fit. Initial runs used a) the number of sampled commercial fishery trips (ranging from 30 per year in 1995 to 181 in 2006) as the lambda for the effective fishery age composition sample size (ESS), b) total catch lambda equal to the default value of 1, and c) initial CVs of 0.15 for the NEFSC Winter survey indices and 0.25 for the NEFSC Spring and Fall indices.

Initial runs used a single fishery catch at age matrix and NEFSC survey indices, and adjusted the number and timing of fishery selectivity blocks and the number of selectivity parameters estimated to judge the sensitivity of the analysis to these settings. The sequence of initial runs is summarized in Table 117.

These tests found that attempts to fit 3 parameters to describe a logistic selectivity pattern for the fishery generally resulted in gradients (a model fit diagnostic) that were too high. Fitting a single pattern for the entire 1982-2006 time series also generally provided gradients that were too high, or poor fits to the fishery age composition for some years in the early part of the time series. Initial runs with 3 time blocks and 1 or 2 selectivity parameters were judged to fit best. A second round of tests showed that the selectivity parameters for the first 2 periods were nearly the same and so subsequent runs included only 2 blocks: 1982-1994 and 1995-2006. Further testing indicated best fits for runs with 2 logistic selectivity parameters (SELEX pattern 20, parameters 1 (peak) and 3 (ascending limb width)), with a total catch weight lambda of 10 (Table 118). A third round of testing incorporated Working Group (WG) recommendations (Mark Maunder, Quantitative Resource Assessment LLC, pers. comm.) for general SS2 model settings, including estimation of R0, R1 deviations, testing of the start date for recruitment deviations, and testing of the effect of the s-r function lambda. These tests are summarized in Table 119., and provided a base configuration (F08_BASE) that would be subject to "tuning" by adjusting the observed ESS and survey index CVs.

The next steps were to include the additional state agency survey indices at age accepted for the base ADAPT VPA formulation and adjust likelihood component lambdas and survey index CVs. Survey CVs were re-set to 0.16 for the NEFSC Winter survey indices, 0.21 for the NEFSC Spring indices, 0.31 for the NEFSC Fall indices, 0.21 for the MADMF Spring and Fall indices (based on the average of the annual aggregate indices), and 0.40 for the CTDEP, RIDFW, NJDFW, DEDFW, MDDNR, VIMS, and NCDFW indices (no average values available; based on expectation that state survey indices at ages would be less precise than NEFSC surveys). The s-r function lambdas and CVs were set to 0 to remove the influence on the fit (as in the ASAP model building exercise), but allow internal estimation of the s-r function and reference points. The effects of these changes are summarized in Table 120 (run F08_BASE).

Following guidance received from Ian Stewart of NMFS NWFSC (pers. comm.) and Chris Legault of NMFS NEFSC (pers. comm.), the next step was to use the estimated ESS to observed sample size (OSS) ratio for the times series (1.863) to "tune" the model to the fishery age compositions by multiplying the input observed ESS by this ratio (run F08_BASE_T1). A

recommended second tuning step was to increase the survey CVs by 1.5 to 2.0 times (variance adjustment in absolute terms of +0.14, +0.19, and +0.20), to allow better fits to the survey indices while maintaining fit to the fishery age compositions (run F08_BASE_T2). The ESS/OSS ratio tuning step had a greater effect on the results than did increasing the survey CVs (Table 120). Changes in the stock size and fishing mortality estimates between the BASE, T1 and T2 run configurations are presented in Figures 40-42. This last tuning configuration, F08_BASE_T2, was used as the final SS2 base run.

The annual selection of age-1 fish decreased from about 0.51 during the first time block of selectivity estimation (1982-1994) to about 0.15 during the second block, 1995-2006. The annual selection of age-2 fish decreased from about 1.00 during the first time block of selectivity estimation (1982-1994) to about 0.68 during the second block, 1995-2006. These decreases in selection at age are very similar to those estimated for the same time blocks using the ASAP model (see section 4.3), and are in line with expectations given changes in commercial and recreational fishery regulations. For these reasons, summer flounder are currently considered to be fully recruited to the fisheries at age 3, and fully recruited fishing mortality is expressed as the unweighted average of fishing mortality at age for ages 3 to 7+. Fishing mortality calculated from the average of fully recruited ages 3-5 varied between 1.14 and 1.84 during 1982-1996, then declined substantially and was estimated to be 0.43 in 2006 (Figure 42).

The F08_BASE_T2 run indicates that the 1983 year class was the largest of the series, at 64 million fish. The 1988 year class was the smallest of the series, at only 10 million fish. The 2006 year class is estimated at 32 million fish, equal to the time series average of 32 million (Figure 41). Spawning stock biomass (SSB; Age 0+) declined 68% between 1983 and 1990 (28,900 mt to 9,200 mt), but increased four-fold to 39,200 mt in 2005, before falling to 38,800 mt in 2006 (Figure 40).

Retrospective analysis of the summer flounder SS2 F08_BASE_T2 run was carried out for terminal catch years 1997-2006 – earlier terminal years were not advisable due to the constraints of the selectivity blocks (2-3 years are recommended in each block; Ian Stewart, NMFS NWFSC, pers. comm.; Chris Legault, NMFS NEFSC, pers. comm.). The retrospective analysis indicates a pattern of underestimation of fully recruited F for 1997-2005 (Figure 43). For the last three years, fishing mortality was underestimated by 42% for 2003, by 37% for 2004, and by 12% for 2005, relative to the terminal year 2006 estimates. Spawning stock biomass has been generally been overestimated in the last 3 years, by 51% for 2003, 38% for 2004, and 8% for 2005, relative to the terminal year 2006 estimates (Figure 44). There is no consistent retrospective pattern in the estimation of the abundance of age 0 fish since 1997 (Figure 45).

4.5 Considerations for Model Selection

4.5.1 Comparative BASE Model Results

Fishing mortality rates in 2006 and stock sizes in 2007 were estimated using a) the ADAPT method for calibration of the VPA (Parrack 1986, Gavaris 1988, Conser and Powers 1990) as implemented in the NOAA Fisheries Toolbox (NFT) ADAPT VPA version 2.7.7, b) the ASAP model as implemented in the NOAA Fisheries Toolbox (NFT) ASAP version 2.0.13, and c) the Stock Synthesis 2 (SS2) model as implemented in the NOAA Fisheries Toolbox (NFT) SS2 version 2.00o. The catch at age, maturity at age, and survey index calibration time series

were input as in the ADAPT VPA F08_BASE run (see section 4.2.1), with fishery and survey data through 2006 (fishery) and 2007 (selected surveys) for ADAPT and through 2006 for ASAP and SS2. The ADAPT VPA was used as the platform to select the base set of indices to carry forward in the base case for all 3 models because the existing NFT ADAPT software has very useful diagnostic features for judging the calibration performance of the indices. The final base run configurations include 39 survey indices at age.

The ASAP and SS2 models require many additional assumptions and model settings as compared to the ADAPT VPA, including setting for emphasis factors (lambdas) and measures of deviation for the catch, survey and fishery age composition, and s-r function likelihood components. The base case ASAP and SS2 model configurations were developed in parallel fashion, although the experience gained in first developing the SS2 base case helped guide the ASAP base case formulation, especially with regards to the timing of selectivity blocks. Likewise, recommendations provided on the "tuning" of the SS2 model were adopted to guide the "tuning" of the ASAP model. Details are provided in section 4.3 for ASAP and section 4.4 for SS2. Figures 46-48 compare the estimates of Spawning Stock Biomass (SSB; mt), recruitment at age 0 (R; 000s) and fully-recruited fishing mortality rate (F, ages 3-5) from the base case configurations for the ADAPT VPA, ASAP, and SS2 models. In general, the 3 models provided similar results in terms of both the trend and current estimates of fishing mortality and stock size. The SS2 base case provided lower estimates of recruitment in the early years of the time series compared to the ADAPT VPA and ASAP models.

Retrospective analysis of the 3 models was carried out for terminal catch years 1995-2006 for the ADAPT VPA, and for 1997-2006 for ASAP and SS2 (1995-1996 were omitted to avoid estimation problems related to the selectivity block break between 1994 and 1995). For the ADAPT VPA over the last 3 years, fishing mortality was underestimated by 42% for 2003, by 25% for 2004, and by 15% for 2005, relative to the terminal year 2006 estimates. ADAPT VPA estimates of SSB were overestimated in the last 3 years, by 54% for 2003, 23% for 2004, and 7% for 2005, relative to the terminal year 2006 estimates. For ASAP over the last 3 years, fishing mortality was underestimated by 37% for 2003, by 32% for 2004, and by 9% for 2005, relative to the terminal year 2006 estimates. ASAP estimates of SSB were overestimated in the last 3 years, by 60% for 2003, 44% for 2004, and 9% for 2005, relative to the terminal year 2006 estimates. For SS2 over the last 3 years, fishing mortality was underestimated by 41% for 2003, by 37% for 2004, and by 12% for 2005, relative to the terminal year 2006 estimates. SS2 estimates of SSB were overestimated in the last 3 years, by 51% for 2003, 38% for 2004, and 8% for 2005, relative to the terminal year 2006 estimates. There was no consistent retrospective pattern in the estimation of the abundance of age 0 fish over the last three years for any of the 3 models.

Table 121 presents the calculated Mohn's rho diagnostic ([retro year estimate – current year estimate]/current year estimate) for the 3 models for SSB and F. If the cumulative value of rho is used to judge the performance of the model over the retrospective time interval, then the ASAP model performed best (smallest cumulative sum), with the ADAPT VPA and SS2 exhibiting more severe retrospective error in fishing mortality estimates (comparable larger cumulative sums). The ASAP model also exhibited the smallest retrospective error in SSB, followed by the SS2 and ADAPT VPA models. See the individual model sections (4.2-4.4) for the retrospective plots of F and SSB for each model.

Comparative BASE Model Characteristics (Pros and Cons)

ADAPT VPA

Pros: a) relatively simple model compared to the SCAA models, results dictated by the input data, within the constraints of the catch equation formulation, b) well developed bootstrap routine to estimate uncertainty of current year estimates, c) well developed interface with AGEPRO stochastic projection software.

Cons: a) current implementation lacks flexibility to model multiple fleets, multiple sexes, multiple areas, different selectivity assumptions, b) exhibits most severe retrospective error for the summer flounder data.

ASAP

Pros: a) current implementation is a moderately complex, flexible SCAA capable of modeling multiple fleets and multiple approaches to survey index modeling, b) well developed MCMC routine to estimate uncertainty of current year estimates, c) well developed interface with AGEPRO stochastic projection software, d) exhibits least severe retrospective error for the summer flounder data.

Cons: a) current implementation lacks flexibility to model multiple sexes or multiple areas.

SS2

Pros: a) current implementation is a very complex, flexible SCAA capable of modeling multiple fleets, multiple sexes, multiple areas, and multiple approaches to survey index modeling.

Cons: a) exhibits relatively severe retrospective error for the summer flounder data, b) current MCMC implementation lacks an interface with AGEPRO stochastic projection software.

4.5.2 Alternative ASAP and SS2 Model Configurations

ASAP

Alternative configurations of the ASAP v2.0.13 model were tested to investigate the sensitivity of the qualitative assessment conclusions to different ways of modeling the BASE case assessment data. In the BASE case, the fishery catch data are modeled as a single aggregate catch at age matrix, with multinomial error distribution, and a single, time-varying fishery selectivity pattern is estimated for the combined fisheries. In the BASE case, the survey indices at age are modeled as individual indices at age with lognormal error, and survey selectivity specified as S = 1 for the relevant age or series of ages indexed by the survey.

In the first alternative configuration (F08_MULTI), the six fishery catch at age components (NER [ME-VA] commercial landings, NC commercial landings, commercial trawl fishery discards, commercial scallop dredge fishery discards, recreational fishery landings, and recreational fishery discards) were modeled separately, each with a multinomial error assumption. Flat-topped (single logistic, asymptotic) time-varying selectivity patterns were modeled for landings; dome-shaped patterns were modeled for the discards. For the trawl and scallop discards the By-Age selectivity model, with S = 1 fixed at age 1 for the trawl fishery discards and S = 1 fixed at age 2 for the scallop fishery discards, was used to model a dome-shaped pattern that was constant for the time series. For the recreational discards, a time-

varying double logistic model was used to model a dome-shaped pattern. In the F08_MULTI configuration, survey indices were modeled as in the BASE case.

In the second alternative configuration (F08_SVAge comp), the survey indices at age were modeled with a multinomial error assumption when feasible (e.g., NEFSC Winter survey indices at age, ages 1-7+). A constant, flat-topped selectivity pattern was used for surveys with a full range of ages. The NEFSC Winter, Spring and Fall, CTDEP Fall, RI Monthly, and NJDFW Monthly survey indices at age were modeled in this manner. The MADMF Spring and Fall, CTDEP Spring, and RIDFW Fall surveys were modeled using the By-Age model for the selected ages included in the BASE case tuning set. The stand-alone age 0 recruitment index series (DEDFW Inland, MDDNR and VIMS) were modeled as in the BASE case (lognormal, S= 1). In the F08_SVAgecomp configuration, the single fishery catch at matrix was modeled as in the BASE case.

In the third configuration (F08_MULTI_SVAGE), the F08_MULTI and F08_SVAgecomp configurations were combined, so that the 6 fishery catch at age components were modeled as in the MULTI configuration, while the survey indices at age were modeled as in the SVAgecomp configuration.

Table 122 summarizes the run diagnostics and results for the three ASAP alternative runs. No "tuning" steps were undertaken for the three ASAP alternatives. The diagnostics for the SVAgecomp configuration was acceptable. The MULTI and MULTI_SVAGE configurations both exhibited problems in the commercial trawl and scallop fishery discard selectivity fits and S-R function parameter estimation (due to very high recruitment estimates at low SSB). The multiple fisheries ASAP configuration results were sensitive to the method of selectivity for the commercial discards, and the estimated age compositions did not match the observed discard at age well. If may not be feasible to model the trawl and scallop fishery discards as separate fleets. Alternatively, future work might consider methods to extend the commercial fishery discard series back to 1982.

None of the three ASAP alternatives provided solutions that significantly reduced that pattern of positive residuals in aggregate indices or indices at age (mainly ages 3-5) during the late 1990s/early 2000s that was apparent in the BASE case ADAPT VPA, ASAP, and SS2 models.

The SVAgecomp configuration estimates most closely matched the ASAP BASE case. The MULTI_SVAGE configuration usually provided the most variable and/or highest F estimates when compared to the BASE case and two other alternative configurations. Figures 49-51 compare the estimates of Spawning Stock Biomass (SSB; mt), recruitment at age 0 (R; 000s) and fully-recruited fishing mortality rate (F, ages 3-5) from the ASAP BASE case configuration (F08_BASE_T5) with the three ASAP alternatives.

SS2

Alternative configurations of the SS2 model were tested to investigate the sensitivity of the qualitative assessment conclusions to different ways of modeling the BASE case assessment data. In the BASE case, the fishery catch data are modeled as a single aggregate catch at age matrix, with multinomial error distribution, and a single, time-varying fishery selectivity pattern is estimated for the combined fisheries. In the BASE case, the survey indices at age are modeled as individual indices at age with lognormal error, and survey selectivity specified as S = 1 for the relevant age or series of ages indexed by the survey.

In the first alternative configuration (F08_MULTI), the six fishery catch at age components were modeled separately, each with a multinomial error assumption and a time-varying selectivity pattern. Flat-topped (single logistic, asymptotic) selectivity patterns were modeled for landings; dome-shaped patterns were modeled for the discards. In the F08_MULTI configuration, survey indices were modeled as in the BASE case.

In the second alternative configuration (F08_SVAge comp), the survey indices at age were modeled with a multinomial error assumption (e.g., NEFSC Winter survey indices at age, ages 1-7+) and a constant, flat-topped selectivity pattern. The NEFSC Winter, Spring and Fall, MADMF Spring and Fall, CTDEP Spring and Fall, RIDFW Fall and Monthly, and NJDFW Monthly survey indices at age were modeled in this manner. Stand-alone age 0 recruitment index series (DEDFW Inland, MDDNR and VIMS) were modeled as in the BASE case (lognormal, S= 1). In the F08_SVAgecomp configuration, the single fishery catch at matrix was modeled as in the BASE case.

In the third configuration (F08_MULTI_SVAGE), the F08_MULTI and F08_SVAgecomp configurations were combined, so that the 6 fishery catch at age components were modeled as in the MULTI configuration, while the survey indices at age were modeled as in the SVAgecomp configuration.

Table 123 summarizes the run diagnostics and results for the three alternative SS2 runs. No "tuning" steps were undertaken for the three SS2 alternatives. The diagnostics for all three alternatives were generally acceptable. However, some parameter bounds (constraints) were hit during fitting of the selectivity patterns, and these parameters would need to be fixed near these bounds if one of the alternatives were accepted as the final assessment model run. For the commercial discard fleets modeled with a dome, the selection for the older ages (beyond the age range of the input catch, ages 8 and older) appeared infeasible for both time blocks (either near S = 1 for trawls, or near S = 0.50 for scallop dredges). If may not be feasible to model the trawl and scallop fishery discards as separate fleets. Alternatively, future work might consider methods to extend the commercial fishery discard series back to 1982.

None of the three SS2 alternatives provided solutions that significantly reduced that pattern of positive residuals in aggregate indices or indices at age (mainly ages 3-5) during the late 1990s/early 2000s that was apparent in the BASE case ADAPT VPA, ASAP, and SS2 models. The fishery selectivity pattern for 1995-2006 estimated in the F08_SVAgecomp configuration was "steeper," with higher selectivity at age 2 (S = 0.85) and full recruitment (S = 1.0) by age 3, than in the F08_MULTI and F08_MULTI_SVAGE configurations, for which the landings selectivity patterns tended to have lower selection at age 2 (ranging from 0.30 to 0.65).

Figures 52-54 compare the estimates of Spawning Stock Biomass (SSB; mt), recruitment at age 0 (R; 000s) and fully-recruited fishing mortality rate (F, ages 3-5) from the SS2 BASE case configuration (F08_BASE_T2) with the three SS2 alternatives. The alternative configurations provided similar trends in fishing mortality and stock sizes, although the F08_BASE_T2 and F08_MULTI cases tended to estimate lower Fs and higher stock sizes over the time series. The exception was that the F08_MULTI_SVAGE configuration estimated the lowest F and highest stock sizes in 2005 and 2006.

4.5.3 More Alternative SS2 Model Configurations

More alternative configurations of the SS2 model were tested to investigate the sensitivity of the qualitative assessment conclusions to different ways of modeling the BASE

case assessment data. In this case, an alternative sex-structured assessment model was developed for summer flounder. The goal of the analysis was to more accurately represent the population dynamics (e.g. include sex-structure) and extract more of the information contained in the data. The stock assessment model was developed using Stock Synthesis II (Rick Methot, NMFS). It is a sex- and age-structured model. The model starts at an exploited stock size in 1976. The initial age-structure in 1976 is parameterized with substantial flexibility and independent of prior catch. Age 15 is used as a plus group for the dynamics. The catch and catch-at-age data is separated into six fisheries: main commercial fishery, North Carolina commercial fishery, commercial discards, scallop trawl discards, recreational, and recreational discards. The three NMFS trawl surveys are used as relative indices of abundance. Sex-specific catch-at-age data are included for the surveys. Combined sex catch-at-age data are included for the fisheries. Age 11 is used as a plus group for the catch-at-age data. Growth rates differ between males and females. Natural mortality is assumed constant over time and age, but can differ between males and females and is estimated in the model. The proportion female at age zero is assumed to be 0.4. All selectivity curves are dome-shaped except for the winter trawl survey. Fishery selectivities are length-based to accommodate different selectivities at age between the sexes due to differences in growth. Survey selectivities are age based, but the same for each sex. The fishery selectivities have different parameters starting in 1995, except the North Carolina fishery for which the new parameters start in 1989. The fishery selectivities have temporal variability to accommodate the changes in management (e.g. minimum legal size) and spatial differences in size of the fish. The MSY quantities are calculated using the age-specific fishing mortality averaged over 2005-2007.

Several sensitivity analyses were conducted to investigate the model assumptions.

- Assuming asymptotic selectivities for all survey and fisheries, except the discard fisheries. (asymptotic)
- Setting the steepness of the Beverton-Holt stock-recruitment relationship to 0.75 (h75)
- Fixing M at 0.2 for both females and males (M0.2)
- Fixing M at 0.2 and 0.3 for females and males, respectively. (M0.2M0.3)
- Fixing M at 0.2 for females and estimating M for males. (M0.2Mest)
- Using age-specific selectivity for the fisheries (Sage)
- Starting the model in 1982 (Start82)
- Using iterative reweighting to estimate the effective sample size for the catch-at-age data and the standard deviations for the surveys.

The results of the basecase model are much more optimistic than the ASAP assessment (Table 124). The estimates of natural mortality are much higher than currently used and the rate for males (0.54) is higher than the rate for females (0.29). The spawning biomass was estimated to have declined during the late 1970's and 1980's and then rebuilt to above the initial level by 2008 (Figure 55). The initial level in 1976 was about 30% of the unfished level, indicating that by 1976 the stock had already been substantially depleted (Figure MM1, Table 125). The current spawning biomass level is estimated to be above the level that corresponds to MSY and the current fishing mortality is estimated to be below the level that corresponds to MSY.

Based on the change in likelihood of >400 units, the MLE estimate of female natural mortality was statistically significantly different from 0.2 (Figure 56, Table 124) and results are dependent on the value of natural mortality (Table 124). The Male natural mortality was

consistently 0.25 units higher than the female natural mortality (x-axis of Figure 56, Table 124). This is presumably due to the information in the sex-specific survey catch-at-age data.

There is substantial scatter in the stock-recruitment estimates and there is no clear evidence of a stock-recruitment relationship (Figure 57). The sensitivity analysis with the steepness of the Beverton-Holt stock-recruitment relationship fixed at 0.75 fits the data significantly worse than the assessment without a stock recruitment relationship (Table 124). The estimates of natural mortality were higher than in the basecase.

The asymptotic selectivity and age based fishery selectivity sensitivity analyses fit the data significantly worse than the basecase, but the estimates of natural mortality are still substantially higher than used in the ASAP assessment and the results more optimistic (Table 124).

The sensitivity analysis that starts in 1982 provides similar results to the basecase (Table 124). The sensitivity that iteratively reweights the catch-at-age sample size and the standard deviations for the survey likelihoods estimates higher values for natural mortality and is generally more optimistic (Table 124).

All the sensitivities, except when the steepness of the stock-recruitment relationship is fixed at 0.75, estimate that the spawning biomass in 2008 is above the value that corresponds to MSY (Table 124). All sensitivities estimate that the current fishing mortality rate is less than that corresponding to MSY. The spawning biomass corresponding to MSY as a fraction of the unfished spawning biomass is low due to the lack of a stock-recruitment relationship (Table 124). Under current levels of fishing, the base case assessment estimates that continuing at that rate would produce a spawning biomass of about 40% of the unfished level (Table 125)

All of the model runs have positive definite hessians, but the maximum gradient was often larger than that used for the stopping criteria. In some cases a local minima was obtained and the model had to be rerun. Usually, the local minimum was obtained at an unrealistic parameter value (e.g. the estimate of natural mortality was unrealistically low).

4.6 Selected Modeling Approach

4.6.1 Model Selection Justification

After considerable debate focused mainly on the assumption for the natural mortality rate (M), use of a single or two-sex model, and the characteristics of fishery selection patterns, the SDWG concluded that the final assessment for 2008 would be conducted using the ASAP model with two fleets (combined landings modeled with a flat-topped [single logistic] pattern and combined discards modeled with a dome-shaped [double logistic] pattern), a single sex using a combined sex vector of M at age, and surveys configured as indices at age with a lognormal error assumption.

A two-fleet configuration was chosen because it allowed the landings and discards selectivity patterns to be modeled separately, judged to be an improvement over the single fleet F08_BASE runs (see Section 4.3). Six-fleet configurations were also considered in both ASAP and SS2 (Section 4.5.2). In ASAP multiple fleet configurations, landings were modeled with flat-topped patterns (single logistic, asymptotic) for two time periods (break between 1994/1995) and discards were modeled with dome-shaped patterns (double logistic or by-age) for the same periods. In a six-fleet single-sex configuration in ASAP, the fishery selectivity patterns were not well estimated as some parameter estimates were constrained by bounds during fitting, and so the SDWG concluded that a six-fleet model in ASAP could not be currently be constructed

without fixing some of the parameters. Comparable problems were encountered in a similarly constructed six-fleet single-sex SS2 model (Section 4.5.2). A six-fleet, two-sex model constructed in SS2 (Section 4.5.3) showed reduced estimation problems by modeling selection for the fleets as annual length-based double-logistic (domed) patterns, although some parameters were still constrained by bounds in model fitting. The domed-shaped patterns for both landings and discards fit better than flat-topped patterns in the SS2 six-fleet two-sex model. The SDWG concluded, however, that these strongly domed patterns and the "cryptic biomass" that was implied (biomass generated by the model that has not been observed in either the fishery or surveys) could not be accepted given the lack of supporting data or assumptions external to the model.

The two-sex configuration modeled in SS2 provided the ability to estimate differences in fishing mortality rates and stock size trends by sex (Section 4.5.3). However, the SDWG was unable to determine the effect on assessment results of modeling some of the surveys by sex, some as combined sexes, and the landings and discards as combined sexes. The ability to compile survey indices by sex is currently limited to the NEFSC surveys – much more future work will need to be completed by the SDWG to compile state survey indices by sex (which may be feasible since many of them are aged using NEFSC age-length keys).

A potentially more difficult task will be to re-compile the landings and discards at age by sex, because fishery dependent samples by sex are not available. The SDWG will need to perform future research to determine if a feasible approach can be developed to re-compile the fishery catch by sex.

The ADAPT VPA, ASAP and SS2 models provide comparable results when configured similarly (see Section 4.5.2). ASAP was chosen as the final model framework for the 2008 assessment mainly because ASAP a) provides the capability to model multiple fleets and multiple approaches to survey modeling, b) can incorporate data on changes in growth expressed as annual mean weights and maturity at age, c) exhibits the least severe retrospective pattern in a BASE run comparison among ADAPT VPA, ASAP, and SS2 (see section 4.5.1), d) provides a well developed MCMC routine to estimate the uncertainty of current year estimates and facilitate completion of TOR 5.0, and e) provides a well developed interface with the NOAA NFT AGEPRO stochastic projection software, to facilitate completion of TOR 8.0.

The SDWG assumed a natural mortality rate (M) of 0.20 for females and 0.30 for males based mainly on recently observed maximum ages (tmax) in NEFSC survey data of 14 years (76 cm, in NEFSC Winter Survey 2005) for females and 12 years (63 cm, in NEFSC Spring Survey 2007) for males, and the expectation that larger and older fish are likely if fishing mortality rates are maintained near current rates over the next several years. The assumptions were further guided by a) the 3/tmax (5% surviving to tmax at F = 0; Vetter 1988, Quinn and Deriso 1999) and 4.22/tmax (1.5% surviving to tmax at F = 0; Hewitt and Hoenig 2005) rule-of-thumb approaches, and b) the current SDWG working papers on summer flounder growth and maturity prepared by Brust, Powell, and Wong. A combined sex M-schedule at age was developed for use in ASAP by assuming these initial M rates by sex, an initial proportion of females at age 0 of 0.40 derived from the NEFSC Fall survey indices by age and sex, and population abundance decline over time at the sex specific M rates. The final abundance weighted combined sex M-schedule at age ranged from 0.26 at age 0 to 0.24 at age 7+, with a mean of 0.25. The new assumption for M (changed from M=0.2 for both sexes, all ages) resulted in substantial change in

the summer flounder assessment by rescaling to increase estimates of stock size, biomass and fishing mortality rates, when compared to previous assessments and current BASE case runs.

4.6.2 Final ASAP Model with Terminal Year 2006

Subsequent to the April 2008 SDWG meeting, the final ASAP two-fleet single-sex model run with terminal year 2006 was subject to a single tuning step, by revising the input fleet Observed Sample Size for the two fleets by the ESS/OSS ratio, as in SS2 tuning. The ratio for the landings fleet was 0.95, and so no change from the input value of 200 was made. The ratio for the discards fleet was 9.4, and so the input value was increased from 10 to 90. Additional tuning by increasing the input survey CVs was not done at this stage, since tuning of the ASAP F08_BASE case run indicated that the impact of that tuning was minimal. The F08_FINAL_T2006 run exhibits a retrospective pattern in recent years similar to those of the BASE case runs in the other models – underestimation of F and overestimation of SSB, with no strong pattern evident for recruitment at age 0 (Figures 58-60).

Summer flounder stock size (SSB, R) and fishing mortality (F) as estimated by the S&T 2006 ADAPT VPA assessment (one fleet, mean M = 0.2), the ASAP F08_BASE case model run (one fleet, mean M = 0.20), and the F08_FINAL_T2006 run (two fleets, mean M = 0.25) are summarized in Figures 61-63. The three runs provide similar long term trend in stock size and F, with the F08_FINAL_T2006 run providing intermediate results in terms of recent SSB in comparison to the other two, but higher recent levels of recruitment and F.

The F08_FINAL_T2006 run was also compared with sensitivity runs for four alternative specifications of the M-schedule: 1) F1_M3 - female M = 0.10, male M = 0.30, mean = 0.18, 2) F2_M2 - female M = 0.20, male M = 0.20, mean = 0.20, 3) F2_M4 - female M = 0.20, male M = 0.40, mean = 0.29, and 4) F2_M5 -female M = 0.20, male M = 0.50, mean = 0.33. The F08_FINAL_T2006 results are compared with those from the four M alternative runs in Figures 64-66. The rescaling of the stock size and fishing mortality rate estimates as mean M increases or decreases is readily apparent, while time series trends are the same. The F08_FINAL_T2006 results are intermediate with respect to the alternative assumption M runs. The final ASAP model with terminal year 2007 (The F08_FINAL_T2007) is provided in the following section (5.0).

5.0 Based on the "best" model or models, estimate fishing mortality rate, recruitment, spawning stock biomass, and total stock biomass for the current year and characterize the uncertainty of those estimates. If possible, also include estimates for earlier years with uncertainty estimates.

5.1 Final ASAP Model with Terminal Year 2007

The F08_FINAL_T2006 run was updated with fishery catches and research survey indices through 2007 to create run F08_T2007_T1. Input survey CVs were maintained at the same tuning step values as in the F08_FINAL_T2006 run (NEFSC Winter = 0.3, NEFSC Spring = 0.4, NEFSC Fall = 0.6, all State Agency = 0.6). The input Observed Sample Sizes (OSS) were maintained at 200 for the Landings but reset to 10 for the Discards, as in the initial T2006 runs. The F08_T2007_T1 results were then used to calculate the Effective Sample Size (ESS) for the two fleets; the resulting ESS/OSS ratio was then used to revise the input OSS to 173 for the

Landings (0.86 ESS/OSS ratio) and to 101 for the Discards (10.10 ESS/OSS ratio) to configure the F08_T2007_T2 run.

Results for the F08_FINAL_T2006, F08_T2007_T1, and F08_T2007_T2 runs are compared in Figures 67-69; the long term trends are very similar. The only significant differences occur between the T2006 and T2007 runs in stock sizes (SSB and R) during 2003-2006. The patterns in fishing mortality rates are nearly identical. Differences between the two T2007 tuning runs are also very minor. The ASAP F08_T2007_T2 configuration was adopted as the final assessment model run.

The F08_T2007_T2 run exhibits a retrospective pattern in recent years similar to those of the BASE case runs in the other models and the F08_FINAL_T2006 run – generally an underestimation of F and overestimation of SSB since 1997, with no strong pattern evident for recruitment at age 0 (Figures 70-72). Over the last 3 years, the annual retrospective change in fishing mortality has ranged from +30% to -5%; the annual retrospective change in SSB has ranged from -29% to +6%; the annual retrospective change in recruitment has ranged from +12% to +44%.

The F08_T2007_T2 run was also compared with sensitivity runs for four alternative specifications of the M-schedule: 1) F1_M3: female M = 0.10, male M = 0.30, mean = 0.18, 2) F2_M2: female M = 0.20, male M = 0.20, mean = 0.20, 3) F2_M4: female M = 0.20, male M = 0.40, mean = 0.29, and 4) F2_M5: female M = 0.20, male M = 0.50, mean = 0.33. The F08_T2007_T2 results are compared with those from the four M alternative runs in Figures 73-75. As with the T2006 runs, the rescaling of the stock size and fishing mortality rate estimates as mean M increases or decreases is readily apparent, while time series trends are the same. The F08_T2007_T2 results are intermediate with respect to the alternative assumption M runs. The results of likelihood profiling of M for the F08_T2007_T2 run indicates lower normalized MSR (greater likelihood) at higher M (Figure 76A). A comparison of these results to likelihood profiles of M for the ADAPT, ASAP, and SS2 BASE cases suggest the model preferred M (as indicted by lower likelihood) is highly sensitive to both model selection and configuration (Figure 76B).

Summary estimates for the 2008 assessment final model ASAP F08_T2007_T2 run are provided in Table 126, and population number and fishing mortality estimates at age are provided in Tables 127 and 128. The full report of the F08_T2007_T2 run is provided in the TOR 5 Appendix. Fishing mortality calculated from the average of the currently fully recruited ages (3-7+) was very high, varying between 1.143 and 2.042 during 1982-1996. The fishing mortality rate has declined to below 1.00 since 1996 and was estimated to be 0.288 in 2007 (Figure 77). There is an 80% probability that the fishing mortality rate in 2007 was between 0.253 and 0.325 (Figures 78 and 79). Spawning stock biomass (SSB) declined from 24,674 mt in 1982 to 7,017 in 1989, then increased to 43,932 mt by 2004. SSB was estimated to be 43,363 in 2007 (Figure 80). There is an 80% chance that SSB in 2007 was between 39,325 and 48,122 mt (Figures 81 and 82). The arithmetic average recruitment from 1982 to 2007 is 41.6 million fish at age 0. The 1982 and 1983 year classes are the largest in the VPA time series, at 73.5 and 81.6 million fish; the 1988 year class is the smallest at only 12.8 million fish. The 2007 year class is currently estimated to be about 40.0 million fish (Figure 80).

6.0 Examine and evaluate the role of the environment on past and present summer flounder recruitment success.

The SDWG has prepared two working group papers in support of this term of reference. The complete working group papers (Working Paper 11 and 12) are provided in Appendix 6,

with a summary of these papers provided and findings given below.

The first document explored the hypothesis that relatively cold water temperature, or some mechanism associated with cold and/or severe weather, is correlated with poor recruitment success for summer flounder. Therefore, the relationships between water temperature anomalies, NAO indices and metrics of summer flounder recruitment success were examined by applying the general approaches of Brodziak and O'Brien (2005) and Megrey et al. (2005) to summer flounder Recruit-Spawner (RS) data and relevant environmental data. Brodziak and O'Brien (2005) examined relationships between environmental indices and summer flounder Recruit-Spawner Anomalies (RSAs) and found the NAO winter index forward lagged by two years was a significant predictor of summer flounder RS ratios, with positive NAO anomalies (wet and mild winters) correlating with positive RSAs (high recruit survival rate).

Spawning stock biomass (SSB), Recruit-Spawner Anomalies (RSAs), and absolute recruitment estimates (VPA0; as suggested by Megrey et al (2005)), were computed using data from a version of the 2007 assessment update Virtual Population Analysis (VPA). NEFSC research survey surface and bottom water temperature anomalies for the Mid-Atlantic Bight North (MABN; Nantucket Shoals to Hudson Canyon) and South regions (MABS; Hudson Canyon to Cape Hatteras) were obtained from the NEFSC database and seasonal temperatures anomalies were computed for the two regions for winter/spring (season 1; January-June) and fall (July-December; lagged forward) for both surface and bottom water temperatures. North Atlantic Oscillation (NAO) climate index monthly values were obtained from the University of East Anglia database and winter (December-March) and fall (September- November) indices were computed (contemporary and forward lagged one or two years).

The current work first attempted to identify potentially significant relationships by using correlation analyses among the environmental factors and SSB, RSAs, and absolute estimates of recruitment (VPA0). A Generalized Additive Model (GAM; Hastie and Tibshirani 1990) was then used to model relationships for environmental (predictive) factors initially identified by the correlation analysis (significant at the $p = 0.10$ level). The GAM approach is a nonparametric regression technique that relaxes error distribution assumptions in modeling the relationships between independent predictive variables and dependent response variables; it was suggested by Daskalov (1999), Megrey et al. (2005), and Brodziak and O'Brien (2005) as an effective tool for modeling biological responses to environmental factors. The initial null predictive model in the GAM framework used smoothing splines with 3 degress of freedom for each predictive factor. Following the procedures suggested by Brodziak and O'Brien (2005), a stepwise model-selection process was applied to eliminate predictive factors from the model if they had a p-value $<= 0.20$, with the step repeated until only predictive factors with $p <= 0.20$ were included in the model. Finally, the time series of the environmental factors with best fitting GAM models were used in an exercise to investigate their performance as potential VPA recruitment calibration indices.

Prominent features of the summer flounder absolute recruitment series (VPA0) include the strong year class that recruited in 1983 and the two weak year classes that recruited in 1988 and 2005; the recruit-spawner anomaly (RSA) series exhibited generally positive anomalies before 1996, and the uniformly negative anomalies since. The strong negative RSAs in 1988 and 2005 correspond to the weak absolute magnitude of recruitments (VPA0) in those years. The pattern of relatively low (negative) RSA since 1995 is one that would be expected for a fish stock exhibiting a Beverton-Holt (1957) asymptotic stock-recruitment relationship as that stock grows toward SSBMSY (Terceiro 2006b).

Several of the regional, seasonal temperature anomalies exhibit significant statistical correlation over the time series. However, the initial GAMs related only those factors that exhibited the strongest statistical correlations; either absolute recruitment (VPA0) or recruit-spawner anomaly (RSA) to the Mid-Atlantic North and South region winter-spring bottom temperature anomalies (MAN_BT1 and MAS_BT2) and the fall and winter NAO Climate indices (NAO_FAL, NAO_FAL_1, and NAO_WIN). There were two final GAMs (GAM1 and GAM2) that were developed relating either the RSA or the VPA0 to predictive factors. The final GAM relating RSA to the predictive factors (GAM1) included only the NAO_WIN index as the predictive factor on the x-axis (i.e., $p <= 0.20$). Comparison of the observed NAO_WIN index and estimated RSA indicates a positive and fairly strong predicative relationship, consistent with the results of the correlation analysis.

The final GAM relating VPA0 to the predictive environmental factors included the Mid-Atlantic South region winter-spring bottom temperature anomaly (MAS_BT2) and the and the fall and winter NAO Climate indices (NAO_WIN and NAO_FAL_1; i.e., $p <= 0.20$). The NAO_WIN index emerged as a significant predictive factor for VPA0 in the GAM model, even though the correlation of this factor with VPA0 was not initially identified as significant ($r = 0.08$, $p = 0.72$). It should also be noted that the NAO_FAL index failed to be retained in the GAM (i.e., $p > 0.20$) even though NAO_FAL was significantly correlated with VPA0 ($r = 0.34$, $p = 0.09$). Under GAM2, the combined predictive fit of the retained predictive factors (x-axis) on the absolute magnitude of summer flounder recruitment (VPA0; y-axis) characterizes the strong 1983 year class and the weak 1988 and 2005 year classes relatively well. However, the relationship between VPA0 and the individual environmental factors is relatively weak as evidenced by the wide confidence intervals of the predicted VPA0.

The time series of predictive factors from the GAM2 model (NAO_WIN, NAO_FAL_1 and MAS_BT2) were included as indices of age 0 recruitment (VPA0) in three derivative configurations of the summer flounder ADAPT VPA F07_ALL run to investigate their performance as potential calibration indices (i.e., as proxy indices of recruitment). Inclusion of these predictive factors resulted in increases in the magnitude of the MSR for the alternative runs (MSR = Mean Squared Residual = total sum of squared residuals divided by degrees of freedom), indicating that the inclusion of these environmental factors as recruitment calibration indices degraded the overall fit of the VPA. Estimates of the strong 1983 and weak 1988 year classes, estimated in the converged (stabilized) part of the VPA, were unchanged by the inclusion of the environmental factors; however the estimates of the weak 2005 year class increased by up to 30% in the alternative runs and estimates of the average 2006 year class increased by up to 13% in the alternative runs.

In summary, the results of this work suggest there are relationships between commonly measured environmental factors such as regional water temperature anomalies and larger scale climate indices and metrics of summer flounder recruitment success. However, these relationships are no stronger than those currently modeled using research survey indices of abundance. Inclusion of these environmental factors in alternative configurations of the current summer flounder assessment VPA does not significantly change the pattern of the recruitment time series or increase the precision of current recruitment estimates. The inclusion of the environmental factors in other summer flounder population dynamics models would not be expected to improve the reliability of forecasts or biological reference points.

A second working group paper was developed and applied the time series approach of wavelet analysis to identify if a relationship exists between summer flounder spawning stock

biomass and recruitment estimates and two climatic signals that are considered significant in affecting oceanographic and estuarine processes in the Mid-Atlantic Bight. The North Atlantic Oscillation (NAO) is closely related to the Arctic Oscillation (AO) and primarily affects temperature; it has a well-described 8-year cycle and indications of a 4-yr periodicity that are superimposed on longer-term trends. The Pacific North American (PNA) has a well-described teleconnection with the El Niño-Southern Oscillation (ENSO) and has a dominant effect on precipitation and, thus, freshwater inflow, in the northeast region. These periodicities are known to profoundly effect estuarine oyster populations, including recruitment and mortality.

Monthly values for the NAO and PNA indices were obtained from the National Weather Service Climate Prediction Center. Spawning stock biomass (SSB) and absolute recruitment estimates (VPA0) were computed using data from a version of the 2007 assessment update Virtual Population Analysis (VPA).

Wavelet analysis was used to resolve localized variations in the strength of a signal (i.e., the wave) within a time series. With this approach, the original time series is decomposed into a time-frequency space, which allows the dominant components (i.e., the wavelets) that make up the wave to be identified. Soniat et al (2006) provide references to source the mathematical details of the technique. Earlier analyses by conducted by the Rutgers University group evaluated the use of a number of mother wavelets (e.g., Paul, Morlet). Comparison of the two mother wavelets show that, for applications of the type that follows, the Morlet wavelet provides adequate time resolution and superior frequency resolution over the results obtained from the Paul wavelet. As a consequence, the Morlet wavelet is used here. Four wavelet analyses were reported as representative of a number of different analyses. Each is a cross-wavelet analysis, equivalent to a cross-correlational analysis, comparing either the NAO or PNA to either the VPA0 or the spawner-recruit (VPA0/SSB) index.

No evidence exists for a relationship between the PNA and summer flounder recruitment. On the other hand, a relationship between the NAO and summer flounder recruitment is strongly supported. The 8-year periodicity, the dominant periodicity in the NAO, is identified as significantly correlated with an 8-year periodicity in the recruitment indices in all analyses. The significance level consistently exceeds $\alpha = 0.05$. No substantive phase shift occurs. The two periodicities are in near-synchrony so that high NAO and high recruitment indices occur more or less simultaneously. In most analyses, a 4-year periodicity also occurs, although sometimes at a weaker level of significance. This interaction is consistently associated with a phase shift between 1995 and 2000. Such phase shifts are frequently associated with substantive long-term changes in population dynamics. However, this periodicity was no longer significant after the long-term trend in the spawner-recruit data was eliminated. This suggests that the interaction of the two time series was primarily associated with subsets of the time series record. A detailed examination of the coherence over the time series suggests that the 4-year periodicity was stronger pre-1995 and post-2000 and that the phase shift was coincident with a decline in the significance of this periodicity during the intervening years.

The NAO is consistently associated with temperature shifts in the North Atlantic. The present analysis suggest that some portion of the variability in summer flounder recruitment since 1982 can be explained by this climate forcer and its expression in changes in the temperature regime experienced by the fish.

7.0 Biological Reference Points

7.1 Update or redefine biological reference points (BRPs; proxies for BMSY and FMSY), taking into account conclusions from earlier assessments and findings from TOR 6 (i.e., recruitment and the environment). Estimate uncertainty in BRPs. Comment on the scientific adequacy of existing and redefined BRPs.

Background

The calculation of biological reference points for summer flounder based on yield per recruit analysis using the Thompson and Bell (1934) model was first detailed in the 1990 Stock Assessment Workshop (SAW) 11 assessment (NEFC 1990). The 1990 analysis estimated that F_{max} = 0.23. In the 1997 SAW 25 assessment (NEFSC 1997), an updated yield per recruit analysis reflecting the partial recruitment pattern and mean weights at age for 1995-1996 estimated that F_{max} = 0.24. The analysis in the Terceiro (1999) assessment, reflecting partial recruitment and mean weights at age for 1997-1998, estimated that F_{max} = 0.263.

The Overfishing Definition Review Panel (Applegate *et al.* 1998) recommended that the Mid-Atlantic Fishery Management Council (MAFMC) base MSY proxy reference points on yield per recruit analysis, and this recommendation was adopted in formulating the FMP Amendment 12 Overfishing Definition (MAFMC 1999). These reference points were based on the 1999 assessment (Terceiro 1999) and followed what would later be described as the Anon-parametric approach@ (i.e., biomass reference points calculated as the product of biomass per recruit and a reference period recruitment level; NEFSC 2002a). The 1999 assessment indicated that $F_{threshold} = F_{target} = F_{max} = 0.263$, yield per recruit (Y/R) at F_{max} was 0.55219 kg/recruit, and January 1 Total Stock Biomass per recruit (TSB/R) at F_{max} was 2.8127 kg/recruit. The median number of summer flounder recruits estimated from the 1999 Virtual Population Analysis (VPA) for 1982-1998 was 37.844 million age-0 fish. Based on this median recruitment level, maximum sustainable yield (Y_{max} as a proxy for MSY) was estimated to be 20,897 mt (46 million lbs) at a Total Stock Biomass (TSB_{max} as a proxy for B_{MSY}) of 106,444 mt (235 million lbs). The biomass threshold, one-half TSB_{max} as a proxy for one-half B_{MSY}, was therefore estimated to be 53,222 mt (118 million lbs). The Terceiro (1999) reference points were retained in the 2000 SAW 31 assessment (NEFSC 2000) because of the stability of the input data and resulting biological reference point estimates.

The MAFMC Science and Statistical Committee (SSC) conducted a peer review of the summer flounder Overfishing Definition in concert with the 2001 assessment update (MAFMC 2001a, b). The SSC reviewed six analyses to estimate biological reference points for summer flounder conducted by members of the Atlantic States Marine Fisheries Commission (ASMFC) Summer Flounder Biological Reference Point Working Group. After considerable discussion, the SSC decided that although the new analyses conducted by the ASMFC Working Group had resulted in a wide range of estimates, they did not provide a reliable alternative set of reference points for summer flounder. The SSC therefore recommended that F_{target} remain F_{max} = 0.263 because a better estimate had not been established by any of the new analyses. The SSC also reviewed the biomass target (B_{MSY}) and threshold (one-half B_{MSY}) components of the Overfishing Definition and concluded that the new analyses did not justify an alternative estimate of the B_{MSY} proxy. The SSC endorsed the recommendations of SAW 31 which stated that Athe use of F_{max} as a proxy for F_{MSY} should be reconsidered as more information on the dynamics of growth in relation to biomass and the shape of the stock recruitment function

become available@ (NEFSC 2000). The SSC agreed that additional years of stock and recruitment data should be collected and encouraged further model development, including model evaluation through simulation studies. They also encouraged the evaluation of alternative proxies for biological reference points that might be more appropriate for an early maturing species like summer flounder and the development and evaluation of management strategies for fisheries where B_{MSY} is unknown. The SSC indicated that as the stock size increases, population dynamic processes that could reflect density dependent mechanisms should be more closely monitored and corresponding analyses should be expanded, i.e., rates of size and age, maturity, fecundity, and egg viability should be closely monitored as potential indicators of compensation at higher stock sizes. Finally, the SSC recommended that potential environmental influences on recruitment, including oceanographic changes and predation mortality, should be reevaluated as additional recruitment data become available. As a result of the SSC peer review (MAFMC 2001a) the Terceiro (1999) reference points were retained in the 2001 stock assessment (MAFMC 2001b). In the review of the 2002 stock assessment (NEFSC 2002b), SAW 35 concluded that revision of the reference points was not warranted at that time due to the continuing stability of the input data and resulting reference point estimates. The Terceiro (1999) reference points were subsequently retained in the 2003 (Terceiro 2003a) and 2004 (SDWG 2004) assessment updates.

The biological reference points for summer flounder were next peer-reviewed by the 2005 SAW 41, based on the 2005 assessment update using fishery data through 2004 and research survey data through 2004/2005 (NEFSC 2005). The SAW 41 Review Panel noted that the Beverton-Holt (Beverton and Holt, 1957; Mace and Doonan 1988; BH) model fit the observed stock-recruitment data well, and provided reference points comparable to those derived from a non-parametric (yield and biomass per recruit) approach. The SAW 41 Panel noted, however, that the quantity of observed stock-recruitment data was limited (22 years), and the data during the early part of the time series, when the SSB was at the lowest observed levels, indicated a level of recruitment near the estimated R_{max}, and exerted a high degree of leverage on the estimation of the model parameters. This leverage resulted in a high value (0.984) for the subsequently calculated steepness of the BH curve, outside of the $\pm$ one standard error interval of the estimate for Pleuronectid flatfish (0.8 ± 0.1) indicated by Myers (1999). The BH model results suggested that summer flounder SSB could fall to very low levels (<2,000 mt) and still produce recruitment near that produced at SSB_{MSY}. The SAW 41 Panel concluded a) that this result might not be reasonable for the long term, given the recent stock-recruitment history of the stock (i.e., production of a very poor year class in 1988), b) the BH model estimated parameters might prove to be sensitive to subsequent additional years of S-R data, especially if they accumulated at higher levels of SSB and recruitment in the near term, and c) the BH model fit might also be sensitive to the magnitude of recently estimated spawning stock and recruitment, given the recent retrospective pattern of overestimation of stock size evident in the assessment. The SAW 41 Panel recognized that the limited time series of observed stock-recruitment data impacted both reference point estimation approaches (non-parametric and parametric stock-recruitment model) in terms of the potential spawning stock biomass and recruitment levels that might be realized from the stock if fished at fishing mortality rates in the 0.2-0.3 range over the long term. Given these concerns, the SAW 41 Panel advised that the BH model estimates were not suitable for use as biological reference points for summer flounder, and recommended continued use of reference points developed using the non-parametric model approach. FMP biological reference points from the 2005 assessment were $F_{max} = F_{MSY} = 0.276$, $Y_{max} = MSY =$

19,072 mt (42.0 million lbs), TSB_{max} = B_{MSY} = 92,645 mt (204.2 million lbs), and biomass threshold of 0.5*TSB_{max} = 46,323 mt (102.1 million lbs; NEFSC 2005).

The most recent peer review of biological reference points for summer flounder occurred in 2006 and was conducted by the National Marine Fisheries Service (NMFS) Office of Science and Technology (S&T) (Methot 2006). The 2006 S&T Peer Review recommended using SSB, rather than TSB as in previous assessments, as the metric for the biomass reference point proxy. The product of the mean recruitment (37.010 million fish) and Y/R at F_{max} was 21,444 mt = 47.276 million lbs (current FMP Amendment 12 proxy for MSY); the product of the mean recruitment and SSB/R at F_{max} was 89,411 mt = 197.118 million lbs (current FMP Amendment 12 proxy for $B_{MSY;}$ Terceiro 2006b). The 2006 S&T Peer Review Panel (Methot 2006) recommended adoption of these biological reference points from the non-parametric approach for summer flounder, advising:

"The low level of recruitment observed in 2005 is essentially the same as the low 1988 recruitment, so it is within the range of recruitment fluctuation used in calculating the expected time to rebuild this stock. The Panel finds that the most representative approach to calculating BRPs and rebuilding rates would be to use the entire set of recruitments from 1982-2005. The average, not median, of these recruitments should be used for calculation of biological reference points because much of the stock's accumulated biomass comes from the larger recruitments. Random draws from this set of recruitments would provide a probability distribution of rebuilding rates that is consistent with the occasional occurrence of small recruitments (1988 and 2005) and large recruitments (1982-1987). There is no documented and obvious reason why recruitments were higher during 1982-1987. If such recruitment levels become more common as the stock rebuilds, then the stock may rebuild to an even higher level than is currently targeted. If such recruitment levels do not occur during the next few years of the rebuilding, then the rebuilding target may be not be achieved by the target time to rebuild. More precise forecasts than this are not feasible."

Estimation Methodology

The two biological reference point estimation approaches previously used in the 2005 SAW 41 (NEFSC 2005) and 2006 S&T Peer Review (Terceiro 2006b) assessments were again applied in the 2008 assessment work, so as to be potentially complementary and supportive and because using both should build confidence in the results. Objective application of either approach is often compromised by lack of sufficient observation on stock and recruitment over a range of biomass to provide suitable contrast. Thus, it is often necessary to extrapolate beyond the range of observation and to infer the shape of the stock-recruit relationship from limited and variable observations (NEFSC 2002a). The 2001 MAFMC SSC review of summer flounder reference points also noted this concern (MAFMC 2001a).

The non-parametric approach was to evaluate various statistical moments (mean, variance, percentiles) of the observed series of recruitment data and apply the estimated spawning stock biomass and yield per recruit associated with common F reference points to derive the implied spawning stock biomass and equilibrium total yield (landings plus discards). The biomass and yield per recruit models were fit using the NOAA Fisheries Toolbox (NFT) YPR version 2.7.2 software (NFT 2008a). The full time series of recruitment during 1982-2007 as estimated by the 2008 assessment final model ASAP F08_T2007_T2 run was used in the yield and spawning stock biomass calculations at fishing mortality reference points, as per the 2006 S&T Peer Review Panel recommendation. The non-parametric approach assumes that

compensatory mechanisms such as impaired growth, maturity, or recruit survival are negligible over the range of biomass considered (NEFSC 2002a). Once the F_{max} reference point (i.e., the F_{max} proxy for F_{MSY}) was determined, a long-term (100 year) stochastic projection of stock sizes and catches was done to provide better consistency between the estimated medians of the BRP calculations and shorter-term (e.g., 1-5 year) projections (Legault 2008 MS).

The parametric approach used fitted parametric stock-recruitment models along with yield and spawning biomass per recruit information to calculate MSY-based reference points following the procedure of Sissenwine and Shepherd (1987). Stock-recruitment models were fit using the NFT SRFIT version 6.3 software (NFT 2008b). Since a wide range of models (Beverton-Holt [BH] and Ricker [RK] models, incorporating autoregressive error, and Bayesian priors for various parameters) had been tested in the 2005 SAW 41 work, the current parametric model exercise was limited to the simple Beverton-Holt and Ricker models (Beverton and Holt 1957, Mace and Doonan 1988, Ricker 1954).

For the 2008 assessment, the ASAP F08_T2007_T2 model (where "ASAP": Age Structured Assessment Program; "F08": Fluke 2008; "T2007": terminal year 2007; and "T2": 2nd run) provides the basis for the 2008 proposed biological reference points and stock status. Average values of mean weights at age in the catch and stock, maturity schedule, and partial recruitment pattern for the period 2005-2007 were used as input for ages 0-7+ for BRP calculations (Table 129). In previous assessments (NEFSC 2005 and earlier) for older aged fish (ages 8-15) with very limited or missing samples, Gompertz functions based on younger ages were used to estimate mean weights for the older ages in the BRP calculations. However, the practice of extending the age structure to age 15 and use of Gompertz weights for the older ages results in inconsistency between the BRP biomass estimates based on long-term stochastic projections and shorter-term (e.g., 1-5 year) projections used for Total Allowable Landings (TAL) calculations (NEFSC 2002a, Legault 2008 MS). Therefore, to increase consistency between these two types of projections, the age range of the BRP and projection calculations as been set at 0-7+, with 8 additional ages (to age 15) included in the plus group calculation of yield and spawning biomass per recruit (NFT 2008a). The mean weight at age for the plus group (age 7+; ages 7 and older) was updated for this assessment in a new way, by using a weighted average of mean weights for ages 7-15 (observed catch weights for ages 7-10; calculated Gompertz weights for ages 11-15 as estimated from observed ages 0-10) based on the relative proportions at age given a 2007 total mortality rate of 0.55 (mean M = 0.25 + 2007 F = 0.30; this value is coincidently consistent with the proposed F35% proxy for FMSY).

2008 Assessment Biological Reference Points

Summer flounder stock size (SSB, R) and fishing mortality (F) as estimated by the S&T 2006 assessment (ADAPT VPA, terminal year 2005, one fleet, mean M = 0.2), the S&T 2006 ADAPT VPA assessment model updated with current catch data through 2007 (VPA_T2007; terminal year 2007, one fleet, mean M = 0.2), the F08_T2007_T2_M20 run (terminal year 2007, two fleets, mean M = 0.20), and the F08_T2007_T2 run (terminal year 2007, two fleets, mean M = 0.25) are summarized in Figures 83-85. The four runs provide similar long term trends in stock size and F, with the ASAP F08_T2007_T2 run using mean M = 0.25 generally providing higher stock sizes (SSB and R) since 1995 than the S&T 2006 ADAPT VPA, the ADAPT VPA_T2007, and ASAP F08_T2007_T2_M20 runs using mean M = 0.20.

The combined effects of the new assumption for M and the modeling of landings and discards as distinct fleets (which results in a slightly domed-shaped combined fishery selectivity

pattern) result in higher estimates of F reference points, lower estimates of MSY, lower estimates of SSB reference points, and improved stock status with respect to both the F and SSB reference points as compared to the S&T 2006 assessment (Tables 129-131). For the 2008 assessment, the ASAP F08_T2007_T2 model run provides the basis for the 2008 proposed biological reference points and evaluation of stock status that follows.

The reference points estimated from the parametric approach were suspect because the Beverton-Holt function steepness parameters were always very near 1.0 (Table 130). Therefore Fmax, F40%, and F35% (and their corresponding biomass reference points) from the non-parametric approach were considered as candidate proxies for FMSY and BMSY. Fmax has been used in previous assessments as the proxy for FMSY. The current estimate of Fmax using mean M = 0.25 and updated fishery selectivity and mean weights at age is relatively high (0.558) and the YPR to F relationship does not indicate a well defined peak (Figure 86). As a result, there is little gain in YPR (<5%) at fishing mortality rates higher than F35% = 0.310. However, the corresponding decline in SSBR between F35% = 0.310 (~1.48 kg/r) and Fmax = 0.558 (~0.93 kg/r) is about 37%. The WG concluded that F40% = 0.254 and F35% = 0.310 were candidate proxies that provided sufficient YPR (F40% YPR = 92% of Fmax YPR; F35% YPR = 97% of Fmax YPR) to allow for productive fisheries while also providing for substantial SSBR (F40% SSBR = 176% of Fmax SSBR; F35% SSBR = 155% of Fmax SSBR) to buffer against short-term declines in recruitment. Recommended proxies for FMSY and SSBMSY (Table 131) are F35% = 0.310 and the associated MSY (13,122 mt) and SSBMSY (60,074 mt) estimates from long-term stochastic projections. F40% (= 0.254) is recommended as a fishing mortality rate target for management.

Table 131 attempts to build a bridge between past and present assessments. The table includes results from the 2006 ADAPT VPA assessment (page 1 of Table 131; S&T 2006; Methot 2006, Terceiro 2006b), an updated ADAPT VPA run (page 2 of Table 131 "T2007"), and the 2008 ASAP assessment (page 3 of Table 131). Results are based on the non-parametric Biological Reference Point approach. For each assessment model, Table 131 also explores the sensitivity of assessment results to assumed natural mortality rate, M (M=0.25 is preferred). Compared to Page 1 of Table 131, Page 2 is based on two additional years of data. In addition Page 2 results are based on modeling decisions that were adopted for the 2008 assessment (e.g., handling of zeros in survey catches, the particular suite of survey indices included, and updated weights at age.).

7.2 Evaluate current stock status with respect to the existing BRPs, as well as with respect to updated or redefined BRPs (from TOR 7a).

The preferred age-structured assessment model for summer flounder changed from an ADAPT VPA model to a forward projecting ASAP model. A new value for natural mortality has been adopted, changing from a constant value of M = 0.20 to age- and sex-specific values that result in a mean value of M = 0.25. Biological reference points have therefore also been revised; the recommended proxy for FMSY changed from Fmax to F35%, and F40% is recommended as an Ftarget.

Based on the proposed 2008 assessment biological reference points (Table 131 – see 3rd page of Table, center column; Figure 87) the summer flounder stock is not overfished and overfishing is not occurring. Fishing mortality calculated from the average of the currently fully recruited ages (3-7+) ranged between 1.143 and 2.042 during 1982-1996. The fishing mortality

rate has declined to below 1.000 since 1996 and was estimated to be 0.288 in 2007, below the proposed fishing mortality reference point = F35% = FMSY = 0.310. There is an 80% probability that the fishing mortality rate in 2007 was between 0.253 and 0.325. Spawning stock biomass (SSB) declined from 24,674 mt in 1982 to 7,017 in 1989, then increased to 43,932 mt by 2004. SSB was estimated to be 43,363 in 2007, about 72% of the proposed SSB35% = SSBMSY reference point = 60,074 mt. There is an 80% chance that SSB in 2007 was between 39,325 and 48,122 mt.

The previously accepted, peer-reviewed 2006 NMFS S&T ADAPT VPA assessment model (Terceiro 2006b) has also been updated through 2007. Using that run of the VPA and assuming constant M = 0.20, the stock would be considered overfished and overfishing would be occurring when compared to existing BRPs (ADAPT VPA F2007 = 0.311, 11% above the existing F BRP = Fmax = FMSY = 0.280; ADAPT VPA SSB2007 = 42,142 mt, 47% of the existing SSB BRP = SSBMSY = 89,411 mt).

8.0 Stock Projections

8.1, 8.2, and 8.3: Recommend what modeling approaches and data should be used for conducting single and multi-year stock projections, computing TACs or TALs, and measures of uncertainty. If possible, provide numerical examples of short term projections (2-3 years) of biomass and fishing mortality rate, and characterize their uncertainty, under various TAC/F strategies. If possible, compare projected stock status to existing rebuilding or recovery schedules, as appropriate.

Stochastic projections were made to provide forecasts of stock size and catches in 2008-2012 consistent with the proposed biological reference points. The projections do not explicitly account for the recent retrospective pattern in the assessment, as per the 2006 S&T Peer Review advice (Terceiro 2006b). The projections assume that recent (2005-2007) patterns of discarding will continue over the time span of the projections. Different patterns that could develop in the future due to different trip and bag limits and fishery closures have not been evaluated. To increase consistency between the proposed reference points and stock projections, the input fishery selectivity pattern, M-pattern, and mean weights at age were configured in the same way (Table 132). One hundred projections were made for each of the 1000 MCMC realizations of 2008 stock sizes from the final assessment ASAP model F08_T2007_T2 run using NFT AGEPRO version 3.1.3 (NFT 2008). Future recruitment at age 0 was generated randomly from a cumulative density function of the F08_T2007_T2 run recruitment series for 1982-2007 (mean recruitment = 41.6 million fish).

If landings in 2008 are 7,153 mt (15.8 million lbs; the 2008 TAL) and discards are 885 mt (2.0 million lbs), the forecast estimates a median (50% probability) F in 2008 = 0.238 and a median SSB on November 1, 2008 of 46,992 mt, above the proposed biomass threshold of one-half SSBMSY = 30,037 mt (Table 133, Figure 87). Fishing at Frebuild = 0.274 in 2009 results in forecast median (50%ile) landings of 9,211 mt (20.3 million lbs); the corresponding 25%ile of landings is 8,653 mt (19.1 million lbs) (Table 133). Continued fishing at Frebuild = 0.274 during 2010-2012 is forecast to rebuild the stock to SSBMSY = 60,074 in 2012 (Figure 88). Fishing at F35% = 0.310 during 2009-2012 is forecast to result in SSB = 56,471 mt in 2012,

below the proposed SSBMSY (Figure 89). Fishing at F40% = 0.255 during 2009-2012 is forecast to result in SSB = 62,181 mt in 2012, above the proposed SSBMSY (Figure 90).

9.0 Review, evaluate and report on the status of the Research Recommendations offered in recent SARC reviewed assessments and in the 2006 "Methot" Review.

Major data and analytical needs for future assessments have been identified in the SAW 35 review of the 2002 assessment (NEFSC 2002a), the SDWG assessment updates for 2003 and 2004 (Terceiro 2003a; SDWG 2004), the SAW 41 assessment update (NEFSC 2005), the 2006 assessment and S&T peer review (Terceiro 2006a, 2006b; Methot et al. 2006), the SDWG 2007 assessment update, and by the SDWG for this current benchmark assessment (SDWG 2008). Research recommendations "never die", and are retained in these documents until they are addressed (completed). Therefore, these remaining recommendations have been subset as those that have been completed (between the last benchmark and the current assessment), in progress at present or to be addressed (previously identified), and new (identified by the SDWG for this benchmark assessment (SDWG 2008)).

9.1 Completed

9.1.1 2008 SDWG Responses to Summary Findings of the 2006 NMFS Office of Science and Technology Peer Review

1. Retain the non-parametric approach to biological reference points; there is insufficient contrast to estimate Spawner-Recruitment steepness.
The non-parametric reference points have been retained in this 2008 benchmark assessment.

2. For the non-parametric approach, use SSB to track status of the stock. This is a much more accurate proxy for the reproductive potential of the stock and is consistent with current consideration of spawner-recruitment models as possible replacement for the non-parametric approach. The past use of Jan 1 total stock biomass as the measure of reproductive potential over-represents the contribution of age 0 fish.

SSB has been used as the basis to track the status of the stock with respect to the biomass reference point.

3. Use long-term (1982-2005) average body weight-at-age for calculation of biological reference points. The recent downturn in mean weight-at-age is influenced by shifting sex ratio and should only be used for short-term TAL and SSB calculations.

Due to recent trends in the biological characteristics of the stock, the SDWG concluded that short-term (2005-2007) average body weight-at-age was more appropriate for calculation of biological reference points and projections in this 2008 benchmark assessment.

4. Discount the recent downtrend in recruits per spawner. Such a trend is exactly what is expected from near constant recruitment and reduced fishing mortality which allows more

spawning biomass per recruit. Further declines are expected as the stock approaches the rebuilt level.

5. Use the arithmetic mean (not median) of long-term (1982-2005) recruitment as the basis for the average level of recruitment expected from a rebuilt stock. Although the five highest recruitments in this time period occur in the first five years, there is no reason to discount the occasional occurrence of such recruitment levels from a rebuilt stock. Median recruitment underestimates the level of biomass expected from a rebuilt stock because most biomass comes from the larger recruitments.

With respect to Findings 4 & 5: as recommended, the recent downturn in R/SSB was discounted in the calculation of reference points in this 2008 benchmark assessment. The arithmetic mean of long-term (1982-2007) recruitment was used as the basis for the long term level of recruitment expected from a rebuilt stock in calculation of the reference points.

6. Revise the survey input to the VPA model so that observations of zero are replaced with a small positive value. This VPA model, as with most assessment models, fits to the logarithm of the observations so cannot explicitly deal with observations of zero. However, the current VPA practice of treating these observations as missing values is probably underestimating the degree to which the stock has rebuilt since the low level in 1990.

As recommended, survey inputs to the VPA model with zero values were replaced with small positive values in the 2007 update. Since then, work performed by the SDWG and Groundfish Assessment Review Meeting (GARM) working groups has indicated that zeros should not be filled with a small value, and so this practice (retain zeros – treat as missing values) has been re-instituted in this 2008 benchmark assessment. The assessment model is now ASAP.

7. Do not make an explicit adjustment for the retrospective pattern in the VPA results. The pattern diminishes in the last year, its cause is not clear, and past patterns in the opposite direction have also diminished after a few years. The several survey indices included in the model increased greatly during the late 1990s and the indices of the oldest age groups have continued to increase. The current model does not track these changes closely, so exploration of alternative models and data interpretations that better reconcile this recent pattern should be a higher priority than the retrospective pattern.

As recommended, no explicit adjustment for the retrospective pattern was made to the 2008 assessment model results or projections.

9.1.2 Other Completed Research Recommendations

1) Evaluate use of a forward calculating age-structured model for comparison with VPA. Forward models would facilitate use of expanding age/sex structure and allow inclusion of historical data. If sex-specific assessments are explored, the implications on YPR should also be investigated.

SDWG Response: This recommendation was addressed for the current (June 2008) benchmark assessment through modeling exercises utilizing the forward projecting models ASAP and SS2 (section 4.0 and 5.0 of this assessment report).

2) Evaluate trends in the regional components of the NEFSC surveys and contrast with the state surveys that potentially index components of the stock.

SDWG Response: This recommendation was addressed for the current (June 2008) benchmark assessment through TOR 2.1 (section 2.0) which examined the potential for an integrated index approach and TOR 3.2 which examined regional difference in the CAA data. There is very limited spatial and/or temporal overlap to allow for an equivalent comparison; therefore, the analyses that were completed were considered adequate.

3) Explore statistical methods to develop "combined" survey abundance indices (by age if possible) from state agency survey data, for use in calibration of analytical assessment models.

SDWG Response: This recommendation was addressed for the current (June 2008) benchmark assessment through TOR 2.1 (section 2.0) which examined the potential for an integrated index approach.

4) Consider examining alternative expansion factors (i.e, summer flounder landings, all species landings) for discards and subsequent effect on retrospective pattern.

SDWG Response: This recommendation was addressed for the current (June 2008) benchmark assessment under TOR 1.0 (section 1.0), although the conclusions of that working paper (Estimation of Commercial Fishery Discards of Summer Flounder: Update 2007 or Revise the 1989-2007 Time Series) recommend no change to the current methodology and additional research into the merits of other estimation methods.

5) Consider treating discards as a separate catch-at-age component, once the summer flounder assessment is implemented in a statistical catch at age framework.

SDWG Response: The current (June 2008) benchmark assessment examined separation of the catch-at-age into smaller components (multiple matrices) and utilized two matrices (retained and discarded fish) for the working group preferred model (section 4.0 and 5.0).

6) Present the VTR Party/Charter boat to MRFSS/FHS comparison in more detail, including stratification by state/federal waters for federal permit holders in the Party/Charter sector.

SDWG Response: A comparison of the VTR Party/Charter boat to MRFSS/FHS was presented in greater detail for the current (June 2008), while the latter part of this recommendation still needs to be addressed. No changes were made to the manner in which the recreational data were handled for this assessment.

7) Consider alternative weighting schemes to explore the sensitivity of the VPA calibration to perceived survey index outliers.

SDWG Response: The current (June 2008) benchmark assessment addressed this recommendation through TOR 2.1 (section 2.0) which examined the potential for an integrated index approach for the various state surveys, as well as the sensitivity of the assessment to different weighting schemes applied to those surveys.

8) For the maximum age plots, consider comparing the 90th percentile of max age, which may more effectively show time series trends (particularly for the males).

SDWG Response: While the working group did not specifically examine the 90th percentile of max age, a detailed examination of maximum age (by sex) was conducted for this benchmark assessment.

9) Explore the sensitivity of the VPA results to separating the summer flounder stock into multiple components.

SDWG Response: The current (June 2008) benchmark assessment examined the sensitivity of the assessment to configuration such as multiple catch components (ASAP and SS2) and sexes within the SS2 model (section 4.0).

9.2 To Be Addressed or In Progress

High

1) Develop a program to annually sample the length and age frequency of summer flounder discards from the recreational fishery.

SDWG Response: To date, ongoing programs are in place only in the MRFSS, MRFSS For-hire survey, ALS, Connecticut (CTDEP Volunteer Anglers), Maryland (MD-DNR Volunteer Anglers), to sample lengths of recreational discards. Progress has been made but more synoptic data are needed including the age- and sex-frequency.

2) The SDWG noted that more comprehensive collection of otoliths, for all components of the catch-at-age matrix, needs to be collected on a continuing basis for fish larger than 60 cm (~7 years). The collection of otoliths and the proportion at sex for all of the catch components could provide a better indicator of stock productivity.

SDWG Response: This recommendation has not been addressed and remains an ongoing data collection need.

3) The SDWG recommends that a reference collection of summer flounder scales and otoliths be developed to facilitate future quality control of summer flounder production aging. In addition, a comparison study between scales and otoliths as aging structures for summer flounder should be completed.

SDWG Response: An exchange of aging structures between NEFSC and NCDMF was completed and a report was reviewed by the 2007 SDWG, in response to a 2005 SAW 41 high

priority Research Recommendation. The SDWG noted that while the Fall 2006 aging exchange between NC-DMF and the NEFSC indicated that the current level of aging consistency between NC and NEFSC is acceptable, there is a need to conduct and fund these exchanges more frequently, on a schedule consistent with benchmark assessments.

4) The SDWG noted that the observed change in the sex ratio in NEFSC survey samples may result in the SSB estimates not translating as directly to egg production since there are more males proportionally in those older age-categories. Collecting information on overall fecundity for the stock, both egg condition and production may be a better indicator of stock productivity.

SDWG Response: This recommendation has not been addressed and remains an ongoing data collection need.

5) Investigate trends in sex ratios and mean lengths and weights of summer flounder in state agency and federal surveys catches.

SDWG Response: While these trends have not been examined in the state survey catches, these trends were examined in the NEFSC spring, autumn, and winter survey data. Additional work to examine and explain these trends in greater detail should be conducted.

Medium

6) Use NEFSC fishery observer age-length keys for 1994 and later years (as they become available) to supplement NEFSC survey data in aging the commercial fishery discard.

SDWG Response: This recommendation has not been addressed by the SDWG, as the age data are not yet available.

7) Consider use of management strategy evaluation techniques to address the implications of harvest policies that incorporate consideration of retrospective patterns (see ICES Journal of Marine Science issue of May 2007).

SDWG Response: This recommendation has not been addressed by the SDWG.

Low

8) Consider treating scallop closed areas as separate strata in calculations of summer flounder discards in the commercial fisheries.

SDWG Response: This recommendation has not been addressed.

9.3 New

The following major data and analytic needs for future assessments were identified by the SDWG in completing the 2008 June benchmark assessment.

1) Examine the sensitivity of the summer flounder assessment to the various unit stock hypotheses and evaluate spatial aspects of the stock to facilitate sex and spatially-explicit modeling of summer flounder.

2) Conduct further research to examine the predator-prey interactions of summer flounder and other species, including food habitat studies, to better understand the influence of these other factors on the summer flounder population.

3) Collect and evaluate information on the reporting accuracy of recreational discards estimates in the recreational fishery.

4) Examine male female ratio at age-0 and potential factors (eg. environmental) that may influence determination of that ratio.

5) Evaluate potential changes in fishery selectivity relative to the spawning potential of the stock; analysis should consider the potential influence of the recreational and commercial fisheries.

6) Collect data to determine the sex ratio for all of the catch components.

7) Determine the appropriate level for the steepness of the S-R relationship and investigate how that influences the biological reference points

10.0 Major sources of assessment uncertainty

The SDWG identified the following as ongoing sources of uncertainty in the current assessment.

1) The landings from the commercial fisheries used in this assessment assume no under reporting of summer flounder landings. Therefore, reported landings and associated effort from the commercial fisheries should be considered minimal estimates.

2) The recreational fishery landings and discards used in the assessment are estimates developed from the Marine Recreational Fishery Statistics Survey (MRFSS). While the estimates of summer flounder catch are considered to be among the most reliable produced by the MRFSS, they are subject to error. The MRFSS program has been reviewed; the program is being redesigned in light of the outcome of the NRC Review of the MRFSS methodology.

3) The length and age composition of the recreational discards are based on data from a limited geographic area (MRFSS, MRFSS For-hire survey, ALS, Connecticut (CTDEP Volunteer Anglers), Maryland (MD-DNR Volunteer Anglers). Sampling of recreational fishery discards on an annual, synoptic basis is needed.

4) The current estimate of M remains an ongoing source of uncertainty. M is highly influential on the assessment results and has a “rescaling affect” on SSB, F, R, point calculations, and the associated perception of current stock status.

5) Estimation of the mean weight at age for older fish (i.e. age 10+) remains an ongoing source of uncertainty.

6) Sex specific differences in life history parameters may have a affect on the assessment model.

ACKNOWLEDGMENTS

Special thanks to Jay Burnett and the staff of the NOAA Fisheries NEFSC Population Biology Branch for their timely preparation of the summer flounder ages used in this assessment.

Table 2. 1994 Summer flounder landings (mt, live and percent) from the Dealer Report data, Vessel Trip Report data, and the matched set, by state and month of landing (proration strata). Most landings for the first quarter of 1994 (Jan-Mar) were reported under the previous NER weighout system and are not included here; the total will therefore not match that for 1994 in Table 1.

Table 35. Number ('000) of summer flounder at age landed in the North Carolina commercial winter trawl fishery. The 1982-1987 NCDMF length samples were aged using NEFSC age-lengths keys for comparable times and areas (i.e., same quarter and statistical areas). Since 1987, the NCDMF length samples have been aged using NCDMF age-lengths keys.

Table 79. Estimated total landings (catch types A + B1, [000s]) of summer flounder by recreational fishermen. SHORE mode includes fish taken from beach/bank and man-made structures. P/C indicates catch taken from party/charter boats, while P/R indicates fish taken from private/rental boats. Proportional Standard Error (PSE) is for the TOTAL landings estimate.

Table 85. Recreational fishery sample size for summer flounder discard mortality assumption. Includes MRFSS landed fish sampling, American Littoral Society (ALS) reported released lengths, CT Volunteer Angler Survey (CTVAS) reported released lengths, MADMF party boat sampling (MADMF), NYDEC Party Boat Survey sampling (NYPBS), MDDNR Volunteer Angler Logs (MDVAL), and MRF For-Hire Survey (MRF FHS) reported released lengths. Number of MRFSS lengths is for landed fish measured that were less than the state or federal minimum landed size, and assumed to be indicative of the length frequency of the discarded catch. This length frequency was used to characterize the length frequency of the released catch. All other sources of released lengths were used to verify this assumption. In 2002 and 2003, samples of discarded summer flounder from CTVAS and NYPBS used to directly characterize the discard in those states. The MRF FHS began sampling in 2005. B2 mt estimates use NC from NCDMF (C. Batsavage, pers. comm.)

Table 86. Estimated recreational fishery discard at age of summer flounder (catch type B2). NC estimates by NCMDF. Discards during 1982-1996 allocated to age groups in same relative proportions as ages 0 and 1 in the subregional catch. Discards during 1997-2000 allocated to age groups in same relative proportions as fish less than the annual EEZ minimum size in the subregional catch. Discards in 2001-2007 allocated to age groups either in the same relative proportion as fish less than the minimum size in the respective state catch, and as indicate by state agency or ALS sampling of the released catch. All years assume 10% release mortality.

Table 92. NEFSC research trawl survey indices of abundance. Indices are stratified mean numbers (n) and weight (kg) per tow. Spring indices are for offshore strata 1-12 61-76; autumn indices are for offshore strata 1-2, 5-6, 9-10, 61, 65, 69, and 73. Winter indices (1992-2007) are for NEFSC offshore strata 1-3, 5-7, 9-11, 13-14, 16-17, 61-63, 65-67, 69-71, and 73-75. n/a = not available due to incomplete coverage (spring) or end of survey (winter). Note that door and vessel conversion factors are not significant; gear conversion factors have not been included due to limited sample size and extreme violation of underlying assumptions in experimental work.

Year	Spring (n)	Spring (kg)	Autumn (n)	Autumn (kg)

Table 115. Initial run configurations tested in building the ASAP model framework for summer flounder.

Run ID	Obj Func	Selex Blocks	Selex Est	Fishery ESS	SV CVs	SSB2006	F2006	Notes
SELEX_2_NEC	3958.1	2; 1994/1995	By Age; 0-3	Comm trips	0.40 all	21,248	0.81	Lambdas defaults
Next, iterated FISHERY ESS to find a reasonable constant level								
SELEX_2_NEC_300	4184.6	2; 1994/1995	By Age; 0-3	300	0.40 all	25,190	0.63	ESS set too high
SELEX_2_NEC_200	3007.3	2; 1994/1995	By Age; 0-3	200	NECW = 0.15 NECS = 0.25 NECF = 0.25	26,880	0.55	ESS Pattern even
Next, tested sensitivity to SELEX blocks; based on pattern in CAA								
SELEX_93_94	2979.8	2; 1993/1994	By Age; 0-3	200	same	29,570	0.49	Noisy F-pattern near break
SELEX_94_95	3007.3	2; 1994/1995	By Age; 0-3	200	same	26,880	0.55	Smooth F-pattern through break
SELEX_95_96	2972.8	2; 1995/1996	By Age; 0-3	200	same	24,183	0.64	Big shift in F-pattern at break
SELEX_96_97	2927.7	2; 1996/1997	By Age; 0-3	200	same	21,550	0.76	Big shift in F-pattern at break
SELEX_97_98	2975.8	2; 1997/1998	By Age; 0-3	200	same	22,700	0.70	Big shift in F-pattern at break
Therefore, retained 1994/1995 SELEX break for blocks								

Table 116. Tuning run configurations tested in building the ASAP model framework for summer flounder.

Starting Point is Run SELEX_94_95, based on diagnostics and fit chracterisitcs
Add agreed State SV Indices from ADAPT VPA F08_BASE Index selection exercise
Tuning of run using Fishery ESS and SV CVs, SELEX pattern
Catch Lambda = 10, all SVs = 1, all SELEX parms = 1, S-R = 0

Run ID	Obj Func	Selex Blocks	Selex Est	Fishery ESS	SV CVs	SSB2006	F2006	Notes
SELEX_94_95 (BASE)	3304.6	2; 1994/1995	By-Age; 0-3	200	NECW = 0.15 NECS, F = 0.25 State = 0.4	35,943	0.41	Large Spike in 1990 ESS, but F-pattern good Block 1 SELEX has "dip" at age 3
F08_BASE_T1 S-R function Lambdas set to 0	3238.2	2; 1994/1995	By-Age; 0-3	Input BASE Estimated	NECW = 0.15 NECS, F = 0.25 State = 0.4	36,625	0.40	Large Spike in 1990 ESS, but rest fit well Good fit to Fishery age-comps Block 1 SELEX still has "dip" at age 3
F08_BASE_T2	3309.6	2; 1994/1995	By-Age; 0-3	Average Block ESS (186, 181)	NECW = 0.15 NECS, F = 0.25 State = 0.4	36,200	0.41	Did not fix SELEX "dip"
F08_BASE_T3	3268.7	2; 1994/1995	Fit Single Logistic	Input BASE Estimated	NECW = 0.15 NECS, F = 0.25 State = 0.4	36,400	0.40	Fixed SELEX "dip" Block 1: S1 @ age 2 Block 2: S1 @ age 3
F08_BASE_T4	3621.5	2; 1994/1995	Fit Single Logistic	Input BASE Estimated	NECW = 0.16 NECS = 0.21 NECF = 0.31 MAS,F = 0.21 State = 0.40	38,044	0.38	Different spikes in ESS (85,89,92) Poorer fit to Fish age-comps Hard to discern sig. better fit to indices
F08_BASE_T5 Increased SV CVs by ~1.5-2X	2432.13	2; 1994/1995	Fit Single Logistic	Input BASE Estimated	NECW = 0.30 NECS = 0.40 NECF = 0.60 State = 0.60	38,570	0.38	One "unfit" spike in ESS (88) Slightly better fit to Fish age-comps Marginally better fit to indices

USED F08_BASE_T5 as basis for RETRO, MCMC, and BRPs

Table 117. Initial run configurations tested in building the SS2 model framework for summer flounder.

Run ID	Parm N	Like	Gradient	Selex	SSB2006	F2006
SELEX_1_p1	56	1525	0.001860	Est. peak @ 3-4	49,000	0.31
SELEX_1_p2	57	1226	7.486000	Est. peak @ 2	46,000	0.30
SELEX_1_p3	58	1226	2.214000	Est. peak @ 2	46,000	0.30
SELEX_1_p3A	*58*	*1197*	*0.005829*	*Allowed Dome @ 5+*	*67,000*	*0.33*
SELEX_2_p1	57	1561	0.000598	Est. peak @ 2 to 3	64,000	0.22
SELEX_2_p2	59	1233	0.002427	Est. peak @ 2 to 3	54,000	0.25
SELEX_2_p3	61	1234	5.255000	Est. peak @ 2 to 3	54,000	0.25

SELEX_3_p2	**61**	**1174**	**0.001670**	**Est peak @ 2 to 3**	**50,000**	**0.28**
SELEX_3_p3	64	1174	5.463000	Est peak @ 2 to 3	50,000	0.28

SELEX_2 time period are 1982-1988, 1989-2006
SELEX_3 time period are 1982-1988, 1989-1992, 1993-2006
All runs except SELEX_1_p3A fit logistic fishery selection

Attempts to fit 3 selex params: gradient too high
Attempts to fit 1 period: gradient too high, and/or relatively poor fit to fishery age comps
Runs with 3 time blocks and 1 or 2 SELEX params estimated fit fishery age comps best

Next step: alter dimensions of 3 periods, fit 1 or 2 SELEX params

Table 118. Second round of configurations tested in building the SS2 model framework for summer flounder.

Run ID	Parm N	Like	Gradient	Selex	SSB2006	F2006	
SELEX_3A time period are 1982-1988, 1989-1994, 1995-2006							
SELEX_3A_p1	58	1444	0.188900	age 3/4 to age 4/5	31,000	0.71	**NOTE; Hit Finitial constraint = F = 2.0**
SELEX_3A_p2	61	1170	0.013730	age 2 to 3	34,000	0.46	**NOTE: Periods 1 and 2 have nearly same selex pattern**
SELEX_2B time period are 1982-1994, 1995-2006							
SELEX_2B_p2	59	1171	0.000638	age 2 to 3	34,000	0.46	NOTE: Eff N to Obs N good; follows age comps well
CL100	59	1168	0.000318	age 2 to 3	33,600	0.47	NOTE: Eff N to Obs N good; follows age comps well
CL10	59	1147	0.000068	age 2 to 3	31,700	0.51	NOTE: Eff N to Obs N often >1; follows age comps well
CL1	59	1171	0.000638	age 2 to 3	33,800	0.46	NOTE: Eff N to Obs N good; follows age comps well

Table 119. Third round of configurations tested in building the SS2 model framework for summer flounder.

Run ID	Parm N	Like	Gradient	Selex	SSB2006	F2006	NOTES
Starting from SELEX_2B_p2_CL10							
Incorporate MMs recommendations to configure F08_NEC							
F08_NEC	68	1642	0.000200	age 2; 0.99 to 0.94	91,672	0.15	**Recruit (YOY) and Age-1 estimates do not follow indices**
Recruit devs begin in 1972							**SELEX barely changes**
Recruits devs follow S-R function							
Estimate R0 and R1 offset							
F08_NEC_SR1	58	647	0.000085	age 2; 0.99 to 0.94	92,200	0.15	**Recruit (YOY) and Age-1 estimates do not follow indices**
Recruit devs begin in 1982							**Allows more variability than F08_NEC, however**
							SELEX barely changes
F08_NEC_SR2	58	1152	0.000185	age 2; 0.99 to 0.70	31,627	0.54	**Recruit (YOY) and Age-1 estimates follow indices**
S-R function lambda set = 0.0001							**SELEX changes substantially (as expected)**
F08_NEC_SR3	59	1152	0.000424	age 2; 0.99 to 0.70	32,587	0.54	**Recruit (YOY) and Age-1 estimates follow indices**
S-R function lambda set = 0							**SELEX changes substantially (as expected)**
Estimate S-R steepness, R0, R1 offset							**Recruits in 1982-1983 low relative to other models**
							B-H Steepness = 0.93
F08_NEC_SR4	69	1145	0.000029	age 2; 0.99 to 0.70	31,803	0.54	**WARNING: Hessian not positive definite**
S-R function lambda set = 0							**B-H Steepness = 0.99**
Estimate S-R steepness, R0, R1 offset							**No improvement in SV fits**
Reset Recruit devs to begin in 1972							
So, go back to F08_NEC_SR3 and add State Indices to build F08_BASE							

Table 120. Tuning run configurations tested in building the SS2 model framework for summer flounder.

Run ID	Parm N	Like	Gradient	Selex	SSB2006	F2006	NOTES
Incorporate State SV Indices to F08_NEC_SR3 to build F08_BASE							
F08_BASE *S-R function lambda set = 0* *Estimate S-R steepness, R0, R1 offset* *Recruit devs to begin in 1982*	59	3026	0.000027	age 2; 0.99 to 0.77	44,430	0.34	**Recruit (YOY) and Age-1 estimates follow indices** **SELEX changes substantially (as expected)** **Recruits in 1982-1983 low relative to other models** **B-H Steepness = 0.92** **B-H Alpha ~45% higher than in ASAP T5 run**
F08_BASE_T1 *Used ESS/OSS ratio* *to tune Fishery age comps* ***Var. adj. = 1.863x***	59	3068	0.000077	age 2; 0.99 to 0.71	39,950	0.40	**Recruit (YOY) and Age-1 estimates follow indices** **SELEX changes substantially (as expected)** **Recruits in 1982-1983 low relative to other models** **B-H Steepness = 0.94** **B-H Alpha ~20% higher than in ASAP T5 run** **Improved ESS/OSS ratio**
F08_BASE_T2 *Increased SV CVs to 0.3, 0.4, 0.6* *(as in ASAP T5 run)* ***Var. Adj. = +0.14, +0.19, +0.20***	59	1050	0.000543	age 2; 0.99 to 0.68	38,820	0.43	**Recruit (YOY) and Age-1 estimates follow indices** **SELEX changes substantially (as expected)** **Recruits in 1982-1983 low relative to other models** **B-H Steepness = 0.94** **B-H Alpha ~30% higher than in ASAP T5 run** **Change due to SV CVs smaller than change due to ESS/OSS ratio** **Increased SV CV allows more fits thru CIs; doesn't fix 2000s resids** **Good fits to Fishery agecomps; no residual patterns**

Table 125. MSY related quantities from the sex-structured stock assessment model compared to arbitrary Spawning Biomass Ratio (SBR) targets. SBR is the spawning biomass relative to the spawning biomass in the absence of fishing. Fmult is the amount that the 2005-2007 average fishing mortality would have to be scaled to produce the associated SBR.

	Basecase	SBR = 0.3	SBR = 0.4

Northeast Fisheries Science Center Reference Documents

This series is a secondary scientific series designed to assure the long-term documentation and to enable the timely transmission of research results by Center and/or non-Center researchers, where such results bear upon the research mission of the Center (see the outside back cover for the mission statement). These documents receive internal scientific review, and most receive copy editing. The National Marine Fisheries Service does not endorse any proprietary material, process, or product mentioned in these documents.

All documents issued in this series since April 2001, and several documents issued prior to that date, have been copublished in both paper and electronic versions. To access the electronic version of a document in this series, go to *http://www.nefsc.noaa.gov/nefsc/publications/*. The electronic version is available in PDF format to permit printing of a paper copy directly from the Internet. If you do not have Internet access, or if a desired document is one of the pre-April 2001 documents available only in the paper version, you can obtain a paper copy by contacting the senior Center author of the desired document. Refer to the title page of the document for the senior Center author's name and mailing address. If there is no Center author, or if there is corporate (*i.e.*, non-individualized) authorship, then contact the Center's Woods Hole Laboratory Library (166 Water St., Woods Hole, MA 02543-1026).

This document's publication history is as follows: manuscript submitted for review July 24, 2008; manuscript accepted through technical review July 28, 2008; manuscript accepted through policy review July 28, 2008; and final copy submitted for publication July 28, 2008. Pursuant to section 515 of Public Law 106-554 (the Information Quality Act), this information product has undergone a pre-dissemination review by the Northeast Fisheries Science Center, completed on July 28, 2008. The signed pre-dissemination review and documentation is on file at the NEFSC Editorial Office. This document may be cited as:

SAW 47 Working Paper 1 (TOR 1) – Commercial Fishery Discards

December 10, 2007

Estimation of Commercial Fishery Discards of Summer Flounder: Update 2007 or Revise the 1989-2007 Time Series?

Background

In the 1993 SAW 23 assessment for summer flounder (NEFSC 1993), an analysis of variance of fishery observer data for summer flounder was used to identify stratification variables for an expansion procedure to estimate total landings and discards from the observer data kept and discard rates (weight per day fished) in the commercial fishery. Initial models included year, quarter, fisheries statistical division (2-digit area), area (divisions north and south of Delaware Bay), and tonnage class as main effects. Quarter and division consistently emerged as significant main effects without significant interaction with the year effect. The estimation procedure expanded transformation bias-corrected geometric mean catch (landings and discards) rates in year, quarter, and division strata by total days fished (days fished on trips landing any summer flounder by any mobile gear, including fish trawls and scallop dredges) to derive fishery landings and discards (hereafter called the "mean log ratio with correction" method). The "days fished" effort metric was found to correlate better with the observed summer flounder discards on a per trip basis than other potential expansion factors such as total summer flounder landings or total trip landings of all species. The use of fishery effort as the multiplier (raising factor) also allowed estimation of landings from the fishery observer data for comparison with dealer reported landings, to help judge the potential accuracy of the procedure and/or sample data.

For strata with no fishery observer sampling, catch rates from adjacent or comparable strata were substituted as appropriate (except for Division 51, which generally has very low catch rates and negligible catch). Estimates of discard were stratified by 2 gear types (scallop dredges; trawls) for years when data were adequate (1992 and later years). Estimates at length and age were stratified by gear for 1994-2000 and 2002-2006, again due to sample size considerations. Only 11 fish were sampled from the sea scallop dredge fishery 2001, and so the scallop dredge discards were assumed to have the same length and age composition as the trawl fishery discards in 2001.

The change in mid-1994 from the interview/weighout data reporting system to the VTR/mandatory dealer report system required a change in the estimation of effort (days fished) to estimate total discards. An initial examination of days fished and catch per unit effort (CPUE; landings per day fished) for cod conducted at SAW 24 (NEFSC 1997a) compared these quantities as reported in the full weighout and VTR data sets (DeLong *et al.*, 1997). This comparison indicated a shift to a higher frequency of short trips (trips with one or two days fished reported), and to a mode at a lower rate of CPUE. It was not clear at SAW 24 if these changes were due to the change in reporting system (units reported not comparable), or real changes in the fishery, and so effort data reported by the VTR system were not used

quantitatively in the SAW 24 assessments. In the SAW 25 assessment for summer flounder (NEFSC 1997b), a slightly different comparison was made. The port agent interview data for 1991-93 and merged dealer/VTR data for 1994-1996 (the matched set data), which under each system serve as the Asample@ to characterize the total commercial landings, were compared in relative terms (percent frequency). For summer flounder, the percent frequency of short trips (lower number of days fished per trip) increased during 1991-1996, but not to the degree observed for cod, and the mode of CPUE rates for summer flounder increased in spite of lower effort per trip. For the summer flounder fishery, these may reflect actual changes in the fishery, due to increased restrictions on allowable landings per trip (trip landings limits might lead to shorter trips) and stock size increases (higher CPUE). As for cod, however, the influence of each of these changes (reporting system, management changes, stock size changes) has not been quantified. Total days fished in the summer flounder fishery were comparable between 1989-1993 period and 1994. Since 1994, total days fished have ranged from 20,700 days in 1999 to 9,300 days in 2004, with a mean of about 12,000 days, a substantial decline relative to the 1989-1993 mean of 22,000 days. Because the effort measure is critical to the estimation of discards for summer flounder, the VTR data were used as the best data source to estimate summer flounder fishery days fished for 1994-2006.

Two adjustments were made to the dealer/VTR matched data subset days fished estimates to fully account for summer flounder fishery effort during 1994-2006. First, the landings to days fished relationship in the matched set was assumed to be the same for unmatched trips, and so the days fished total in each discard estimation stratum (2-digit area and quarter) was raised by the dealer to matched set landings ratio. This step in the estimation accounted for days fished associated with trips landing summer flounder, and provided an estimate of discard for trips landing summer flounder. Given the restrictions on the fishery however, there is fishing activity which results in summer flounder discard, but no landings, especially in the scallop dredge fishery. The days fished associated with these trips was accounted for by raising strata discard estimates by the ratio of the total days fished on trips catching any summer flounder (trips with landings and discard, plus trips with discard only) to the days fished on trips landing summer flounder (trips with landings and discard), for VTR trips reporting discard of any species (DeLong *et al.* 1997). For this step, it is necessary to assume that the discard rate (as indicated by the fishery observer data, which includes trips with discard but no landings, and which is used in previous estimation procedure steps) is the same for trips with only discards as for trips with both landings and discards.

This “mean log ratio with correction” estimation procedure has been used in every assessment since 1993, including the 2006 update (Terceiro 2006). Discard estimates using this method for 1989-2006 are summarized in Table 1 (see ASSESS estimates). Discards as a proportion of the fishery observer data estimated landings were highest in 2001 (53%), and lowest in 1995 and 1996 (5 and 7%). Estimates of landings from observer data ranged from +53% (1999) to -70% (2001) of the reported landings in the fisheries, with discards ranging from 41% (1990) to 6% (1995) of the reported landings (Tables 1-2). Total discards estimated for 2003, 2004, and 2005 were 10%, 4%, and 4% of the reported landings. Scallop dredge fishery discard to landed ratios are much higher than trawl fishery ratios, purportedly because of closures and trip limits. Although the scallop dredge landings of summer flounder are less than 5% of the total, the discards of summer flounder have been estimated to be of the same order of magnitude as in the trawl fishery (see ASSESS estimates, Table 1).

Estimation of discards for groundfish: GARM 2007

Rago et al. (2005) described methods recently adopted by the NEFSC to estimate the discards of trawl, gillnet, longline, scallop, and herring fisheries of the Northeast U.S. The Rago et al. (2005) work focused on the use of stratified discard to kept weight ratios (d/k) as the primary estimator, with the "d" portion for the stocks (or group of stocks) of interest, and the "k" portion most often for the kept of all species, or the species that comprised the dominant portion of the catch.

The method developed by Rago et al. (2005) was subsequently modified and used in an expanded exercise to develop discard estimates for 45 different fishing fleets and 60 fish stocks, encompassing all of the federally managed fisheries in the Northeast. This work is documented in Wigley et al. (2007) – the "SBRM Report." Recently, these general methods were reviewed as part of the Groundfish Assessment Review Meeting (GARM) 2007 Data Methods Workshop. The working paper of Wigley et al. (MS2007) documents revisions to the Rago et al (2005) and Wigely et al. (2007) methods, and provides details on the methodology used to develop the National Bycatch Report for 2005, and proposes this method for use in the GARM 2008 assessments for New England groundfish. That general estimation method is used in this work, and is hereafter called the National Bycatch Report Discard method 2 (NBRD2).

The working paper of Legault (MS2007), also prepared for the GARM 2007 Data Methods Workshop, presented results of simulations designed to rank the utility of different methods to estimate commercial fishery discards. Among the methods compared were the approach currently used in the Terceiro (2006) summer flounder assessment ("mean log ratio with correction" in Legault MS2007) and the Wigley et al. (MS2007) NBRD2 approach ("ratio of sums" in Legault MS2007). Legault (MS2007) concluded that the "mean log ratio with correction" was not a good estimator for total discards, due to the potential for large bias in the estimates; the Wigley et al. (MS2007) "ratio of sums" was recommended as a good estimator, with use of "all species kept" appearing to produce less biased results than kept of only the species of interest. The Wigley et al. (MS2007) "ratio of sums" estimation method (NBRD2) has been used here to estimate discards and landings of summer flounder in the trawl, scallop dredge, and sink gillnet fisheries at different spatial and temporal stratifications, for comparison with estimates made in the Terceiro (2006) stock assessment using the "mean log ratio with correction" (ASSESS) method.

Comparative Results

Trawl Fishery

Discard estimation results for the current method (ASSESS) and the proposed NBRD2 method for trawl gear are compared in Table 1 and Figure 1. Discard estimates in Figure 1 are plotted with +/- one standard error (1 SE) bars. Over the 18 year (1989-2006) time series, the NBRD2 method provides higher discard estimates in 14 years. Of those 14 years, the +/- 1 SE error bars of the NBRD2 estimates overlap those of the ASSESS estimates in 7 years, suggesting that the estimates are comparable in those years – i.e., the two methods produce comparable estimates in 7 of the 18 total years. In 3 of those 7 years, the estimates match very closely (1997, 1999, 2002).

In general, the coefficient of variation (CV) for discard estimates are smaller for NBRD2 discard ratios calculated at a region/quarter stratification than at wider temporal scales (annual or

semi-annual), and at the quarterly time stratification are comparable to, but generally slightly higher than, the ASSESS discard rate CVs (Table 1, Figure 1). The ASSESS discard rate data are from "more directed" observed summer flounder trips (trips must have summer flounder discard and/or landings to be included) and so the discard rates tend to be less variable than the wider universe of trips used in the NBRD2 approach. In addition, the ASSESS method effort expansion factor (days fished) is from VTR trips reporting summer flounder discard and/or landings, which tend to be more "directed" in nature than the "all species landings" (i.e., all trips) expansion factor used in the NBRD2 method. These combined factors generally result in slightly better precision of the ASSESS discard estimates, in spite of the smaller number of observed trips used to calculate the discard rates.

The estimation of landings from the two methods can potentially be used a means to verify the accuracy of the discard estimates. Landings estimation results for the ASSESS and NBRD2 methods and DEALER reported landings for trawl gear are compared in Table 2 and Figure 2. The ASSESS method estimates of trawl landings are closer to the DEALER reported landings in 12 of the 18 years. There are time blocks (ASSESS: 1989-1997, 2001-2003; NBRD2: 1998-2000, 2004-2006) during which one method performs better than the other. Over the 1989-2006 period, DEALER reported landings averaged 4,853 mt, NBRD2 estimates averaged 5,914 mt (+22% above DEALER), and ASSESS estimates averaged 4,602 mt (-5%). The precision of the ASSESS method landings estimates is consistently better than for the NBRD2 method, due to the same factors as for the discards.

Scallop Dredge Fishery

Discard estimation results for the current method (ASSESS) and the proposed NBRD2 method for trawl gear are compared in Table 1 and Figure 3. Discard estimates in the figure are plotted with +/- one standard error (1 SE) bars. Over the 15 year (1992-2006) time series, the NBRD2 method provides higher discard estimates in 12 years. Of those 12 years, the +/- 1 SE error bars of the NBRD2 estimates overlaps those of the ASSESS estimates in 4 years, suggesting that the estimates are comparable in those years – i.e., the two methods produce comparable estimates in 4 of the 15 total years. In 3 of those 4 years, the estimates match closely (1992, 1998, 2001).

In general, as with the trawl fishery estimates, the coefficient of variation (CV) for discard estimates are smaller for NBRD2 discard ratios calculated at the region/quarter stratification than at wider temporal scales (annual or semi-annual), and at the quarterly time stratification are comparable to the ASSESS discard rate CVs (Table 1, Figure 3). The ASSESS discard rate data are from more "directed" observed summer flounder trips (trips must have summer flounder discard and/or landings to be included) and so the discard rates tend to be less variable than the wider universe of trips used in the NBRD2 approach. In addition, the ASSESS method effort expansion factor (days fished) is from VTR trips reporting summer flounder discard and/or landings, which tend to be more "directed" (although still mainly bycatch in nature) than the "all scallop landings" (i.e., all scallop dredge trips) expansion factor used in the NBRD2 method. These combined factors generally result in slightly better precision of the ASSESS discard estimates, especially early in the time series when the total number of scallop dredge trips observed is small (< 50 trips annually).

The estimation of landings from the two methods can potentially be used a means to verify the accuracy of the discard estimates. Landings estimation results for the ASSESS and NBRD2 methods and DEALER reported landings for scallop dredge gear are compared in Table

2 and Figure 4. Summer flounder are generally a small bycatch in the scallop dredge fishery, and the DEALER reported landings have ranged from 25 to 284 mt over the series. The NBRD2 method estimates of summer flounder landings are closer to the DEALER reported landings in 12 of the 15 years. Over the 1992-2006 period, DEALER reported landings averaged 81 mt, NBRD2 estimates averaged 79 mt (-3%), and ASSESS estimates averaged 102 mt (+26%). The precision of the landings estimates are comparable for the two estimation methods over the time series.

Gillnet Fisheries

Discard estimates for the gillnet fishery (sink, drift, and anchor combined) have not previously been estimated in the summer flounder assessment, due to the small magnitude of summer flounder landings in the DEALER reported data and the small absolute magnitude of summer flounder discards in the gillnet observer data. The Wigley et al (2007) report indicated, however, that in 2005 about 25 mt of summer flounder were discarded in the gillnet fisheries (mainly using extra large mesh and targeting monkfish), and so in this exercise discard estimates were made using the NBRD2 method (Table 1, Figure 5). Discard estimates in the Figure 5 are plotted with +/- one standard error (1 SE) bars. Over the 13 year (1994-2006) time series, the NBRD2 method provides discard estimates of 1 to 37 mt annually, with quarterly time strata CVs ranging from 59% (1994) to 18% (2005). The NBRD2 discard estimates for the gillnet fishery are relatively imprecise (CV > 30% in 9 of 13 years) because summer flounder are encountered relatively rarely in the gillnet fishery, and both the observer discard and landings rates are highly variable.

Landings estimation results for the NBRD2 method and DEALER reported landings for gillnet gear are compared in Table 2 and Figure 6. In the gillnet fishery, summer flounder generally are a small bycatch, and the DEALER reported landings have ranged from 8 to 143 mt over the series. NBRD2 method estimates of gillnet landings generally do not match the DEALER reported landings very well over the 13 years; DEALER reported landings averaged 67 mt, while NBRD2 estimates averaged 29 mt (-57%). NBRD2 landings estimates for quarterly time strata have CVs ranging from 78% (1997) to 19% (2004), exceeding 30% in 8 of the 13 years.

Summary

This material was presented and discussed as part of a Post-GARM review session by the NEFSC Population Dynamic Branch (December 6, 2007). The results of that discussion are summarized as follows:

- GARM simulations suggested ASSESS method would prove to be positively biased…
- But, NBRD2 generally produced higher discard estimates for both trawl and scallop fisheries
- For trawl fishery NBRD2 discards average 900 mt; ASSESS discards average 500 mt
- ASSESS method precision was generally slightly better at region/quarter stratification
- ASSESS method estimates of trawl landings more consistently match DEALER over the 18 years (12 of 18 years); DEALER landings average 4,853 mt, NBRD2 estimates average 5,914 mt (+22%); ASSESS estimates average 4,602 mt (-5%)
- But, there are time blocks (ASSESS: 1989-1997, 2001-2003; NBRD2: 1998-2000, 2004-2006) during which one method performs better for the trawl fishery

- For scallop fishery NBRD2 discard estimates average 470 mt; ASSESS discards average 225 mt
- NBRD2 method estimates of scallop dredge landings more consistently match DEALER over the 15 years (12 of 15 years); DEALER landings average 81 mt, NBRD2 estimates average 79 mt (-3%); ASSESS estimates average 102 mt (+26%)
- For gillnet fishery NBRD2 discard estimates average 14 mt
- NBRD2 method estimates of gillnet landings generally don't match DEALER very well over the 13 years; DEALER averages 67 mt, NBRD2 averages 29 mt (-57%)
- The statistical diagnostics (i.e., CV indicating the precision of the discards and landings estimates) do not indicate that the NBRD2 approach represents an improvement over the current ASSESS method
- The verification method (i.e., matching the DEALER reported landings) do not indicate that the NBRD2 approach represents an improvement over the current method for trawl gear; the NBRD2 approach does seem to perform better than the current ASSESS approach for scallop dredge gear
- Given the lack of discard length frequency samples for summer flounder for gillnet gear, those discards may accounted for in the trawl fishery estimate by "raising" of the expansion factor
- Significantly more research into the sensitivity of the NBRD2 method to alternative stratification schemes is needed before the NBRD2 estimates are adopted in the assessment, and therefore…
- For now, make no changes to the discard estimation approach used in the assessment - update for 2008 benchmark assessment using the current ASSESS method
- For future work, focus on trawl and scallop dredge gear; try other approaches using sums of ratio (NBRD2) estimator, possibly with d/df for "directed" fluke trips (ASSESS) or for a "characteristic" group of landed species trips in the trawl fishery (e.g., fluke, scup, BSB, loligo, ilex, yellowtail flounder, winter flounder, cod, haddock, silver hake, etc.)

Table 1: Comparison of summer flounder estimated discards using the NBRD2 method for alternative stratification of the discard rate. For trawl gear (negear = 050-059), d/k =d_fluke/k_allspecies; for scallop dredge gear (negear = 132), d/k = d_fluke/k_scallop; for gillnet (negear = 100,110,500), d/k = d_fluke/k_allspecies. N (number) of OB trips is the same for stratification levels within years. ASSESS row provides the discard estimates (based on geometric means of trip discard/days_fished ratios) used in the current assessment; N OB trips are based on different criteria (required fluke catch) than current (NBRD2) method; no gillnet gear estimates made.

SAW 47 Working Paper 2 (TOR 1) – Commercial Discard Mortality

WORKING PAPER:

DISCARD MORTALITY OF SUMMER FLOUNDER IN THE INSHORE TRAWL FISHERY

SUMMARY

In 2007, Cornell University Cooperative Extension received a RSA grant to determine the discard mortality in the inshore summer flounder trawl fishery. Fieldwork was carried out successfully from May through October 2007 off Long Island, New York. Ten scientific trips were made on commercial draggers working the traditional mixed trawl fishery. A goal of the project was to determine discard mortality relative to tow duration, fish size, and the amount of time fish were on the deck of the vessel. Tows of 1, 2 and 3 hours in duration were conducted. Fish were culled both immediately (from 0-10 minutes on deck) and after being held on deck for a delayed period of time (25-35 minutes on deck). Approximately 20 live fish were removed from the immediate and delayed culls upon haul-back of each tow. These live fish were weighed, tagged, and graded by condition before being transferred to a flow through seawater holding system where they were held on deck for the duration of the trip. The total catch of fluke was weighed and sorted between live and dead at consistent intervals of time to determine the effect of culling for a long as it took to clear the deck. Other variables were examined including total catch weight, species composition of total catch, fish condition factors, gear size, water temperature and air temperature. Upon arrival at the dock, live fish were transferred to a dockside net pen holding system and monitored for mortality over a 14-day period. Discard mortality rates were calculated based on the live/dead fraction of fish sorted on deck as well as the mortality rate of the live fish held in the monitoring net pen system over a 14 day period. Mortality rates were calculated by tow duration, cull time and overall. Mortality rates for the one and two hour tows were less than for the three hour tow. Mortality rates for the immediate cull

and delayed cull were similar. Overall median mortality was similar to the value assumed in recent summer flounder assessments.

METHODS

The research design of this study was dictated by the specific proposal requirements, i.e. to conduct ten one-day fishing trips incorporating different gear types, and areas fished, reflective of the inshore mixed trawl fishery. The selection of gear, fishing area, target species was left to the participating commercial fisherman to determine in consultation with CCE. This was done with the hope of not skewing the results in any one given direction, by letting the natural conditions dictate the project activity to reflect a more realistic picture of the existing inshore trawl fishery including summer flounder. Ten research trips were completed and have met the design criteria outlined in the proposal. Each trip consisted of a one, two and three hour tow, with an immediate and delayed cull for each specific tow. A specific culling procedure was adopted, so as to maintain random sampling protocol. The following time line was used after haul back:

- 0-10 minutes (immediate cull) – collection of 20 live fish for cages plus sorting of live and dead fish from one half of the pile.
- 10-25 minutes – sorting of live and dead fish only.
- 25-35 minutes (delayed cull) – collection of 20 live fish for cages plus sorting of live and dead fish from second half of the pile.
- 35-50 minutes – sorting of live and dead fish only.

Processing the catch continued until all summer flounder were sorted by live or dead in 15 minute increments of time until all fish were sorted. In addition, all other species in each tow were recorded. For each of the three tows conducted, forty live fish randomly selected were tagged, weighed, measured and rated as to condition utilizing a scale of excellent, good, poor with specific trawl damage noted.

The live fish selected for the mortality monitoring component of the project were held during the trip in an on board holding system. Twenty live fish were selected from each cull time for each tow duration. 120 total live fish were held for each trip. The on board holding system and plan adopted was similar to that used in the commercial fishery for holding and transport of live fish. Two 35 cubic foot, 268 gallon capacity Bonar insulated holding containers were used in addition to 22 holding cages constructed of plastic coated wire. The live fish were placed in the cages, and the cages were stacked in the Bonar containers filled with seawater. Each Bonar container held up to eight cages, with each cage typically holding ten fish. This system allowed for optimum holding and transport of the fish. The cages kept the fish from sloshing in the containers, kept the weight of fish off of each other and allowed for maximum water flow around each individual fish.

Two (2) twelve volt battery operated aerator compressor systems utilizing four large capacity air stones per container were used to aerate the holding system. This method has proven to be very effective in terms of maintaining fish condition and was very practical for fish handling purposes. The on board holding system was continually monitored for water temperature and dissolved oxygen levels during each trip. Surface and bottom temperatures and dissolved oxygen were also monitored in the targeted fishing areas and correlated with the temperatures and oxygen levels in the on board holding system.

The ability to safely hold and monitor all study fish was necessary to fully measure summer flounder trawl discard mortality. Through consultation with aquaculture specialists, commercial fishermen and gear specialist we were able to design, construct and install a 15' diameter by 15' deep pentagon shaped net pen attached to a stake system incorporating a pulley rope system which allowed the raising and lowering of the net pen similar to a pound net installation. This design allowed easy access to stock and the ability to monitor and finally release study fish with minimum impact. The net pen was installed next to the Inlet Seafood Dock at Montauk. The location was adjacent to the Montauk Harbor Inlet and provided excellent water quality and good flushing and exchange with Block Island Sound.

At the end of each of the scheduled discard mortality harvest trips all fish held live in the on-board live holding system from each tow and cull, were transferred to the dockside net pen holding system. They were held in the net pen system for 14 days to monitor mortality. Scuba certified staff conducted net pen monitoring on days 1, 2, 3 and then every other day during the 14 day holding period. Information collected included dead fish vitals, fish tag numbers, surface and bottom water temperature/ DO levels. Scales and otoliths were also collected from dead fish.

On day 14 the net pen was lifted and all remaining fish including live fish, dead fish and control fish, were removed from the net pen. Tag information and fish condition index were recorded for all fish. All live control and experimental fish were released in adjacent waters. The net pen was then re-set and prepared to receive a new set of control fish as well as the new set of experimental fish being harvested on board the mortality harvest trip. We utilized two CCE crews on each day that we had a scheduled harvest trip (every 14 days). One crew went out on the trawler and performed all scientific components associated with the collection and harvest of fish. The other crew was the net pen shore side crew and took care of all scientific components related to: collecting and releasing fish from the net pen after their 14 day study; accepting and processing new control fish; transferring the new set of experimental fish into the net pen when the harvest vessel and crew returned to the dock at the end of the day. This two crew procedure provided for efficiency of the overall process and allowed us to stick to a schedule of a new harvest trip every 14 days in order to accomplish the number of trips needed before the end of October. Also, local baymen were hired to lift and re-set the net pen on each release day.

RESULTS

We calculated the cumulative mortality for each tow on trips 3-10 using the mortality on board and estimating the number of live fish culled that would have died using the 14-day survivorship observed in the dockside holding/monitoring pen. First, for each trip, tow, and cull time we calculated a weight for dead fish in the pen that was corrected for the mortality rate of control fish in the pen, $\hat{w}t_d$:

$$\hat{w}t_d = w_d - [(1 - surv_c)(w_d + w_l)] \qquad (1)$$

where w_d is the weight of dead fish in the pen, $surv_c$ is the fraction of control fish living after 14 days in the pen, and w_l is the weight of live fish released from the pen after 14 days.

The survivorship of live fish in the pen, SP, was determined as:

$$SP = wt_l / (wt_l + \hat{w} t_d) \quad (2)$$

The survivorships from equation (2) were used to calculate the ratio of survivorship between the immediate and delayed cull times, ΔS:

$$\Delta S = SP_{\tau=D} / SP_{\tau=I} \quad (3)$$

where $SP_{\tau=D}$ is the survivorship of fish in the pen at the delayed cull time and $SP_{\tau=I}$ is the survivorship of fish in the pen at immediate cull time.

We calculated the elapsed time between the immediate and delayed cull times, t as:

$$t = [(t_e - t_s)/2 + t_s]_{\tau=D} - [(t_e - t_s)/2 + t_s]_{\tau=I} \quad (4)$$

where t_e is the end of the time interval in question, from the time the net was brought onboard, and t_s is the start of the time interval in question, both in cumulative minutes.

The change in the survival fraction, ΔS, between the two cull times is converted to a rate, fm, that can be used to estimate the change from any other cull time, under the assumption that the rate is linear with time:

$$fm = (-\ln(\Delta S)) / t \quad (5)$$

Thus, to calculate the amount of surviving summer flounder, we apply this rate to each 10-15 minute cull period, using equation (4) to determine the elapsed time. Then, the estimated fish surviving, EL, is:

$$EL = \sum_{i=1}^{n} (L_{up} + L_p) e^{-fm \times t} \quad (6)$$

where L_{up} is the weight of live fish that were not placed into the pen and L_p is the weight of the live fish that were placed into the pen.

The estimated weight of dead fish for each tow, ED, is then:

$$ED = wt_c - EL \quad (7)$$

where wt_c is the total catch weight for all summer flounder.

Finally, the % mortality for the tow can be calculated as:

$$\%Mortality = ED/(ED + EL) \quad (8)$$

The discard mortality for each tow length duration, as well as for all tow durations combined, is shown in Table 1. These mortality rates are for the entire summer flounder catch for each tow duration and reflect the total mortality for each tow from the time the fish were dumped on deck until the deck is cleared. The median mortality for all tows combined at 78.7% is very close to the estimated overall discard mortality of 80% currently used in the summer founder assessment. The mean of 64.6% however is considerably less. Also the mean and median mortality rates for the one hour and two hour tows are considerably less than the currently estimated 80% mortality. In order to use a mortality rate representative of the overall inshore fishery for summer flounder, tow length parameters of the fishery should be evaluated. Observer data and VTR data should be analyzed for average tow time across the fishery. Our calculated mortality rate for the tow duration that is most representative of the Observer/VTR data could then be used in the assessment.

An *a posteriori* least squares means test on tow time shows that mortality was greater in 3-hour tows than 2-hour tows and greater in 2-hour tows than 1-hour tows. Additionally, 1-hour tows and 3-hour tows were significantly different from each other ($p = .0044$).

The calculated mortality by tow duration and cull time is shown in Table 2. All of these values are considerably different, for both the mean and median, from the currently used 80% rate and exhibit a considerable range. Interestingly there is not much difference between the overall mortality rate for all tows combined at the immediate cull and at the delayed cull.

Keywords: abundance indices, virtual population analysis, general linear models, summer flounder

ABSTRACT

Northeast United States fish stock assessments typically incorporate multiple abundance indices at age from several state and federal research survey programs. Peer reviews of these assessments have recommended investigation of methods to better integrate trends in abundance provided by survey indices, prior to their use in population model calibration. Exercises were performed to explore different approaches to the integration of survey indices for use in virtual population analysis calibration. General linear modeling of integrated indices of abundance provides a useful summarization of mean survey trends. However, an empirical example for summer flounder shows that the use of integrated indices as input to virtual population analysis calibration does not guarantee substantially more accurate or precise results than using the original survey indices. The greatest potential utility for the integrated index approach is in simple index-based assessments.

INTRODUCTION

Many of the Northeast United States fish stock assessments conducted by Northeast Regional (NER) Stock Assessment Workshop (SAW) Working Groups and Atlantic States Marine Fisheries Commission (ASMFC) Technical Committees incorporate abundance indices from several state and federal agency research survey programs. Typically, these indices of abundance are provided to the assessment process as annual or seasonal indices at age. Use of

these indices ranges from: a) isolated consideration in single-index based assessments (i.e., as measures of stock abundance in relation to an index based reference point; e.g., for scup, black sea bass, and the skate stocks); b) use of single indices in calibrated analyses (e.g., lobster in a Collie-Sissenwine model); and c) use of many indices from many surveys for a range of age classes in complex age-structured calibrated analyses (e.g., striped bass, bluefish, summer flounder, and winter flounder assessments).

Evaluation of the utility of indices for inclusion in complex models using many survey indcies has typically been accomplished by looking for common trends in abundance (i.e., signal) through: a) examination of time series plots; b) analysis of correlation (of lack thereof) between survey indices and between survey indices and population dynamics model results; c) outlier analysis; and d) consideration of the trend and magnitude of residuals (i.e., noise) when indices are included in population dynamics models. Multiple analyses with different sets of indices are often conducted to examine the sensitivity of results to inclusion of a given index series to determine the best analysis configuration to characterize stock status. Alternatively, all available abundance indices may be included in an analysis with the results most strongly influenced by those indices that statistically fit best within the analytical framework. Even given these approaches, with 50 or more indices of abundance at age to consider for inclusion in a complex age structured assessment, it can be difficult to discern general trends in abundance from the battery of available indices. The decision to include a given index time series at age can therefore often be subjective, based on a loose set of decision rules that may vary from one assessment to another.

Recent NER SAW peer reviews have recommended the investigation of methods to better integrate trends in stock abundance inferred from survey indices of abundance, prior to the inclusion of such indices in a population model calibration. For example, in the development of the NER index-based assessments for monkfish (NEFSC 1997), scup (NEFSC 1998) and skates (NEFSC 2000), extensive discussions occurred about which survey time series (i.e., NEFSC Spring or Fall) would best serve as the basis for biological reference points and the evaluation of stock status. A recent review of the NER summer flounder assessment (NEFSC 2002) included the following discussion:

- The SARC discussed the procedure for selecting survey indices used in the summer flounder VPA. The use of state surveys, which cover only a small component of the stock, was questioned. It was noted that YOY surveys may be variable due to the low numbers of fish caught per tow. The SARC requested that the standard error also be shown with the survey indices in the future. Whether differences in state surveys truly measure different trends in different components of the stock or whether differences are simply due to variation among survey was questioned.

and research recommendations:

- Explore the possibility of weighting survey indices used in VPA calibration by the areal coverage (i.e., in square kilometers) of the respective seasonal surveys.
- Evaluate trends in the regional components of the NEFSC surveys and contrast with the state surveys that potentially index components of the stock.@

A recent review of the NER black sea bass stock assessment (NEFSC 2004) also called for improved integration of survey indices to aid in the interpretation of stock abundance trends. That review recommended:

- More comprehensive evaluation of regional survey data is required to give more integrated indices of recruitment. For example, catch rates of recruits can be modeled as a function of location, time of year, and gear type in the surveys, to provide standardized indices, and
- Attempts should be made to extract as much information as possible from all time series considered using, for example, a GLM or GAM approach to combine the various surveys and gear types into a standardized index.

In a recent review of the NER bluefish stock assessment, the review panel (NEFSC 2004) recommended:

- There is a need for an integrated analysis of the many different research surveys for juvenile bluefish. The surveys cover different regions using different gear types and provide data on 0- and 1- group bluefish. It is recommended that serious consideration be given to... methods for standardizing and combining data from small scale intensive surveys with large scale less spatially intensive surveys, to give improved indices of recruitment.

Finally, another review of the NER summer flounder assessment (NEFSC 2005) recommended:

- Develop integrated survey indices by: combining the three NEFSC research trawl indices into a single annual abundance index, and combining state-run survey indices into a single annual abundance index.

In assessments like those for NER stocks of striped bass, bluefish, summer flounder, and winter flounder, the recommendations for development of integrated indices stem, in part, from the realization that the state agency survey data do not index trends for the entire stock, but merely components or substocks of the whole. While some state survey indices may, in fact, capture stock-wide trends, the peer-review panel research recommendations suggest that a method to statistically summarize and/or appropriately weight indices which are considered *a priori* to not adequately characterize stock-wide trends - to Aintegrate them@ - will provide more reliable and transparent results than if the indices were simply used in their original form in Virtual Population Analysis (VPA) calibration.

The integration of survey indices collected by different research sampling programs can be viewed as analogous to the standardization analysis of commercial fishing vessel rates in developing fishery-dependent indices of abundance. Viewed in that light, a General Linear Model framework (GLM; SAS Institute 1999) can be used in which deviations from the mean trend are modeled by defining various classification variables which are thought to account for the deviations. This general approach has been used in several NAFO groundfish stock assessments to integrate multiple fishery-independent survey indices of recruitment (e.g., Healey et al. 2001 and subsequent Greenland halibut assessments, and Stansbury et al. 2001 and subsequent Grand Banks cod assessments). In the current study, four exercises were constructed

to explore and illustrate different approaches to the integration of indices of abundance in VPA calibrations of NER assessments.

MATERIALS AND METHODS

Exercise 1: simple, simulated survey data

As GLM modeling results can be strongly influenced by the assumed nature of the underlying error structure of the data (Terceiro 2003), the first step was to determine the appropriate error assumption to apply to research survey data. The statistical characteristics of *positive* catch data for summer flounder (*Paralichthys dentatus*) from the NEFSC Winter Trawl Survey for 1992, 1998, and 2004 were examined. Compiled on a total catch (numbers per tow) basis, the summer flounder data appear to resemble a Poisson or negative binomial distribution, although the majority of the catches (closest to the origin of the plots) reasonably approximate a lognormal distribution (Figure 1). A K-S test indicated that any of these distributions might be appropriate, with slightly better fit indicated for the Poisson (slightly smaller deviations from the expected). Terceiro (2003) indicated that inclusion of zero catch events (trips or tows) in such distributions increases the likelihood that the Negative binomial distribution will fit best. Most of the analytical models currently used in Northeast U.S. stock assessments, however, assume a normal or lognormal error structure, due mainly to variance estimation considerations.

The next step was to illustrate how Acombining indices into an integrated index@ should workgiven simulated survey data with known statistical characteristics and patterns. To this end, survey catch per tow data were simulated for 15 years and 2 seasons, with means ranging from 8 to 100 fish per tow and corresponding Coefficients of Variation (CVs) of 150% (standard errors ranging from 12 to 150), under a Poisson error distribution assumption. One hundred catch per tow values were randomly simulated for each year/season combination, for a total of 15 years * 2 seasons * 100 tows = 3,000 total tows. The annual sequence of the seasonal abundance indices was ordered to provide a time series pattern of a period of high abundance followed by a steady decline, followed by a relatively rapid increase, and then a short term decline. This exercise provided two realistic seasonal time series of survey abundance indices with: a) known statistical properties; b) slightly different annual rank orders; and c) generated a significant correlation (r = 0.7) between the series comparable to that between the actual NEFSC Winter and Spring survey 1992-2005 time series for summer flounder (r = 0.66; NEFSC 2005).

The 3,000 simulated individual tows were used an input to a GLM model with year of sampling and survey season as the main effects classification variables. The goal was to derive an Aintegrated abundance index@ from the two independent survey series - i.e., the GLM reproduction of the simple mean of two independent series with known characteristics. Models were run under lognormal, Poisson (true), and Negative binomial error assumptions. Normalized, retransformed year effect model coefficients served as the annual indices of abundance. This exercise was intended to demonstrate that if the assumption about the error distribution is correct, the GLM model should exactly extract the simple mean of two known series - i.e., a simple form of an Aintegrated@ survey index.

Exercise 2: Simulation of integrated indices at age

This simulation extended Exercise 1 to create integrated age-based indices, as might be used in an age-structured population model calibration (e.g., a VPA). Exercise 2 also explored the issue of weighting indices by the geographical coverage of individual surveys, as recommended by peer reviews of the NER stock assessments (see the Introduction). The intent was to simulate the averaging of multiple, individual survey indices at age into single, integrated indices of abundance, and compare the performance of four different index treatments in VPA calibration.

Three substock populations were simulated using NFT Popsim (NFT 2005a). The substocks were simulated with common biological and fishery characteristics (e.g., partial recruitment to the fishery and magnitude and time series patterns of fishing and natural mortality), but with different initial proportions of the additive, total stock numbers in Year 1 at ages 0 (recruits) through age 6. The magnitude of the correlation between the three simulated indices (ranging from 0.3 to 0.4, or borderline significance at the alpha = 10% level for degrees of freedom of about 20 observations; Rohlf 1981) and between the three simulated indices and the true substock sizes (ranging from 0.5 to 0.7) was made comparable to that observed in recent summer flounder assessments (NEFSC 2005, Terceiro 2006) so as to lend realism to the simulation. In actual assessments, indices with a poorer correlation than these are generally excluded from the VPA calibrations in preliminary screening work (NEFSC 2005, Terceiro 2006). Error was incorporated into the catchability coefficient (q) of each of the three simulated substock abundance indices at recruiting age 0 for the 21 years (random error with CV = 100%, 100%, and 150%) to ensure a realistic degree of deviation from the True Total Stock (TTS) sizes. The catch from each substock was simulated without error, to isolate the effects in the VPA calibration caused solely by the treatment of the age 0 indices. The percentages that each substock accounted for of the TTS numbers was set at 50%, 40%, and 10%. The simulated catch and population numbers were summed to provide the TTS catch and population numbers.

To create an integrated index for use in the four VPA calibration treatments, the three 21 year time series of simulated age 0 indices were averaged to single integrated age 0 index series within GLM models. Both simple (unweighted) and stratified (area-weighted) integrated indices were compiled. This step was intended to reconfirm the conclusion of exercise 1, but on a index-at-age basis: to establish that the GLM can exactly extract the means, simple or stratified, of multiple input time series of indices of abundance to create an integrated index of age 0 abundance. The areal coverages of the respective surveys were set at (63%, 31%, and 6%) [different from the TTS percentages in numbers (50%, 40%, and 10%)] to explore the impact of such differences (i.e., what if the assumption that survey area coverage = percentage of total stock is wrong?) on integrated index modeling and VPA calibration.

In the final step of Exercise 2, the use of the four index treatments was explored in an ADAPT VPA (NFT 2005b) calibration for the TTS catch at age and the differences summarized. The normalized versions of all indices (each value divided by its= time series mean) were used to remove scale effects prior to calibration. Only the age 0 index treatments were used as VPA calibration indices. Stock sizes for ages 1-6 were calculated using the known, input fishing mortality rates and a partial recruitment vector. Both deterministic (one-time run) and stochastic (1000 bootstrap iterations of the age 0 index calibration residuals) VPA calibrations were explored.

The four age 0 index treatments were:

1) three age 0 substock indices, simple (unweighted)
2) three age 0 substock indices, stratified (area weighted in the VPA calibration)
3) one GLM integrated age 0 index, simple (unweighted)
4) one GLM integrated age 0 index, stratified (area weighted in the GLM)

Exercise 3: Real data GLM integrated indices of abundance at age

In Exercise 3, the GLM approach was used with actual research survey data to calculate integrated indices of abundance at age for use in VPA calibration. Data from a recent NER assessment (NEFSC 2005) for summer flounder were used as an empirical test case. The time series of years for the fishery catch and research survey indices was 1982-2003/2004; the VPA calibration used survey indices at age (0-7+) from three seasonal NEFSC trawl survey series and 12 seasonal state surveys. As previously noted in the Introduction, the analytical approach is analogous to a GLM standardization analysis of commercial fishing vessel catch per unit effort data: the Ayear@ main effect classification variable serves as the index of abundance, while the Asurvey@ classification variable is analogous to a Avessel@ classification variable, each with its= own time series of catch per unit effort that has some relationship to the underlying true abundance of the stock. The mean index of abundance is modeled as a log-linear function of the classification variables. The analysis could be expanded by including additional classification variables, such as the sampling gear type or tow duration, temporal variables (e.g., spring/fall; day/night) or environmental variables (e.g., water temperature anomalies). However, such details typically are not available for most assessments, and indices are most often presented as aggregate annual or seasonal indices at age. As configured here, the analysis provides average, or integrated, annual indices of abundance at age.

Examination of the observed distribution of the normalized summer flounder age 0 survey indices suggested that the indices were best characterized by either a lognormal or Poisson/Negative binomial distribution. The standard error of the indices is slightly less than the mean (mean = 1.0, standard error = 0.8, skew = 2.8), with a single data point accounting for the high skewness. K-S tests indicated that the Poisson and negative binomial expected distributions were the same, and slightly better than the expected lognormal distribution in fitting the observed mean and variance. Visual differences (observed minus expected) were similar for the three expected distributions. Since the indices were to be lognormal-transformed in the ADAPT VPA calibration (NFT 2005b), and the age 0 indices represent the largest group of indices with the greatest absolute value range (and hence provide the best age for which to reliably examine statistical properties), it was concluded that GLM modeling under a lognormal error distribution would be reasonable for all ages in this exercise.

GLM models were constructed for ages 0, 1, 2, 3, 4, and 5-7+. Main effects were limited to the year of sampling (1982, 1983...2004) and the identity of the survey (NEFSC age 1, NEFSC age 2...NEFSC age 5-7+). The resulting year effect coefficients, corrected for lognormal-transformation bias and re-transformed to the original scale, were used as a single index of abundance at age 0 input to the VPA calibration in place of the twelve original survey series. The input GLM age 0 vector was called GLM_YOY. The corresponding VPA run using this vector was called VPA_GLM0. In VPA_GLM0, for example, all of the original indices for all the other ages (1, 2, 3, 4, and 5-7+) were retained so that the effect of using the GLM_YOY vector could be isolated. The pattern was repeated as GLM vectors (GLM_1, GLM_2...GLM_5:7) for the other ages tested. A run using only the GLM vectors at age

(VPA_GLM) was also constructed. Results from these seven GLM integrated index run configurations were compared to the trends in stock size at age provided by the VPA calibration run (F04_ALL) using the original, full suite of indices at age.

Exercise 4: Real data GLM integrated indices at age, NEFSC vs. State

The 2005 SARC 41 Panel review of the NER summer flounder assessment (NEFSC 2005) recommended the development of integrated survey indices by combining the various seasonal NEFSC research trawl survey series indices at age into single annual abundance indices at age (e.g., NEFSC age 0 index, age 1 index, etc.), and likewise combining the state survey indices into a single annual abundance indices at age. In Exercise 4, the GLM approach was used with the same data as in Exercise 3 to construct integrated indices at age from the three seasonal NEFSC surveys (winter, spring and fall) and from the state surveys (MA, RI, CT, NJ, MD, VA, NC), for a total of twelve GLM integrated indices at age (NEFSC ages 0-5:7+; State ages 0-5:7+). Considering the series in this manner resulted in more inconsistent data in terms of the length of the series, and more frequent occurrence of >zero@ observations. Therefore, the resulting GLM integrated ANEFSC@ and AState@ indices exhibit a greater number of missing observations for some year and age combinations than did the six GLM integrated indices at age for all surveys combined constructed in Exercise 3. Given the extent of Exercise 3, comparisons in Exercise 4 were limited to a VPA calibration using the 12 GLM integrated indices (VPA_NEC_ST) and the VPA calibration (F04_ALL) using the original suite of indices at age.

RESULTS

Exercise 1: simple, simulated survey data

Table 1 shows the time series of annual means of the two simulated seasonal survey indices, the combined annual means of the two simulated series, and retransformed GLM year effect coefficients (annual indices of abundance) under lognormal, Poisson, and negative binomial error assumptions. As the two seasonal series were simulated with Poisson error, the expected result was that the retransformed Poisson coefficients would exactly match the combined mean of the two input series, while the lognormal and negative binomial results would differ slightly. For ease of comparison, all results were rescaled to the means of the respective series in the bottom of Table 1. The results demonstrate that if the error distribution is correctly specified, the GLM model can exactly reproduce the combined mean of averaged survey series.

Exercise 2: Simulation of integrated indices at age

The Year 1 numbers at age of the three substock populations (SS1, SS2, SS3) simulated using NFT Popsim (NFT 2005a) are presented in Table 2. The catch and population numbers were summed to provide the true total stock (TTS) catch and population numbers. The panels in Figure 2 show the relationship between the simulated age 0 population sizes in the three substocks and the respective simulated age 0 survey indices over the 21 year time series. Figure 3 presents the trends in age 0 stock size, age 1-6+ stock size, and age 0-6+ catch in the simulated VPA used to explore the sensitivity of the VPA calibration to different treatments of the age 0 indices.

The simulated integrated indices of age 0 abundance using simple arithmetic averaging and GLM modeling are presented in the upper section of Table 3. As noted earlier, Astratified@ equates to area weighted; rescaled indices (divided by the time series means) are presented in the lower section of Table 3. The results re-confirm those of Exercise 1, that given the correctly specified error distribution, the GLM model can exactly reproduce the combined mean of averaged survey series.

VPA calibration results for the four treatments of the age 0 indices (VPA1 = simple mean, VPA2 = stratified mean, VPA3 = simple GLM, and VPA4 = stratified GLM) differ from the True Total Stock (TTS) and also from each other mainly in the Auncoverged@ part of the VPA in Years 14-21 (Table 4). Because the area weights intentionally did not match the true substock percentages, the stratified mean (VPA2) and stratified GLM (VPA4) treatments generated calibration results that deviated more (both on an aggregated deviation and mean deviation basis), and correlated less well (Pearson r) than the simple mean (VPA1) and simple GLM (VPA3) treatments. Since the area weight was highest for SV1 (63%), the weighted index treatments (VPA2 and VPA4) correlated best with the SV1 index, and poorest with SV2 and SV3, than the simple mean (VPA1) and simple GLM (VPA3) treatments. In this exercise, the smoothing effect of the simple GLM model of the indices produced VPA calibrated stock sizes that deviated from the TTS sizes slightly less, on both aggregate and mean bases, than the simple mean treatment (Table 4, Figure 4).

VPA bootstrap results were qualitatively similar to the one-time runs, and with the focus on the Year 21 age 0 stock size estimates, show how the incorrect assumption of survey area coverage as a proxy for stock size percentages can provide inaccurate results. As in the one-time runs, the simple (unweighted) VPA1 and VPA3 bootstrap estimates more closely match the TTS size for age 0 in Year 21 than the stratified (area weighted) VPA2 and VPA4 estimates (Table 5). The smoothing effect of the GLM on the integrated age 0 index in the VPA3 calibration produces a larger deviation from the TTS size than the simple three index VPA1 calibration. Finally, while the VPA2 estimate (54,107) is most precise (CV = 0.11; due to the good correlation of estimated stock sizes and the SV1 index), it deviates most from the TTS size (92,000).

Exercise 3: GLM using real indices of abundance at age

The results for the age 0 indices in exercise 3 are first provided in the upper left panel of Figure 5, where the pattern of age 0 stock sizes indicated by the GLM model estimated year effect vector (the integrated index at age 0, GLM_YOY) is compared with the estimates from the VPA (VPA0_GLM0) when this single, integrated age 0 index is used in place of the 12 original indices to calibrate age 0 stock size. The overall patterns are similar, with highest recruitment at the start of the series and a poor year class in 1988. The major difference is in the rank order of the 1982/1983 and 1985/1986 year classes. The upper left panel of Figure 6 compares estimates of age 0 stock size from VPA_GLM0 (using the integrated index for age 0, and the original indices for ages 1 and older) with the VPA using the original survey series for all ages (F04_ALL). In the two VPAs, the estimates of age 0 abundance are nearly identical. Exercise 3 results for ages 1, 2, 3, 4 and 5-7+ are provided in the successive panels of Figures 5-6. A VPA calibration was also conducted using only the GLM integrated indices (i.e., 6 index series at ages 0-5:7+), and these results are presented in Figure 7.

In general, the GLM integrated indices at age diverged somewhat from the VPA_GLM estimates, due to the smoothing effect of the GLM and possibly due to process error caused by mis-specification of the true error structure. However, the VPA_GLM and F04_ALL estimates are nearly the same for all ages, diverging only in the most recent 2-3 years in the unconverged part of the VPA. This last finding reflects the substantial influence on stock size estimates of the input catch at age data and the convergence properties of the VPA model. The F04_ALL VPA calibration is characterized by a substantial retrospective pattern, with F underestimated and stock size overestimated over the unconverged part of the analysis. The retrospective patterns for F, SSB, and recruitment at age 0 (R) are nearly identical for the VPA_GLM calibration, indicating no improvement in this characteristic of the analysis by using integrated indices of abundance (Figure 8).

Exercise 3 results suggest that using GLM integrated indices may increase the difficulty of interpreting the uncertainty of the VPA estimates. VPA calibrations based on a limited number of externally derived GLM integrated indices are likely to have less total absolute variance than calibrations with multiple sets of indices; an example is the difference in the Residual Sums of Squares (RSS) and Mean Squared Residual (MSR) between the F04_ALL and VPA_GLM runs. The VPA_GLM MSR is about one-third of the F04_ALL MSR, indicating an overall Abetter fitting@ model (Table 6). However, the number of potential calibration residuals in the VPA_GLM run is also much lower (130 versus 937 in the F04_ALL run), and so estimates of individual stock sizes, and subsequently derived quantities such as Average F and Biomass, are less precise (a Adegrees of freedom@ phenomenon). This is evident in both the deterministic Nonlinear Least Squares (NLLS) and Bootstrap (1000 iterations; BOOT) results for the F04_ALL and VPA_GLM runs (Table 6).

Exercise 4: GLM Integrated Indices, NEFSC vs. State

Figure 9 compares the GLM integrated indices at age derived from the NEFSC survey indices at age are compared with those derived from state survey indices at age. Consistency in trend and rank order between the NEC and ST indices at age is poorest for ages 0 and 1, and best for ages 3 and 4, but overall is very similar across all ages. The use of the twelve GLM integrated indices at age in a VPA calibration, the VPA_NEC_ST run, produced estimates of stock size at age that were generally slightly lower than the F04_ALL run in the unconverged (most recent) years of the analysis. As a result, the estimated total stock size is slightly lower for the VPA_NEC_ST run compared to the F04_ALL estimate, and correspondingly the average fishing mortality rate (F) is slightly higher (Figure 10). Finally, as with the Exercise 3 comparison, the total variance (RSS) for the integrated index VPA_NEC_ST run is smaller than for the F04_ALL run. However, the VPA_NEC_ST run Mean Squared Residual (MSR) is higher than the F04_ALL run, indicating a slightly poorer fit. As well, the VPA_NEC_ST run provided larger CVs on the estimated parameters, in both the deterministic (NLLS) and bootstrap (BOOT) runs (Table 7). The overall fit of the NEC integrated indices was similar to the ST integrated indices, with the NEC integrated indices accounting for 51.5% of the total variance in the fit and the ST integrated indices 48.5%. NEC integrated indices at age fit better (i.e., smaller partial variance) for ages 2, 4, and 5-7+; the ST indices fit better for ages 0, 1, and 3 (Figure 11).

CONCLUSIONS

The results of Exercises 1 and 2 suggest that use of a lognormal error distribution in constructing integrated indices in a GLM framework can introduce some degree of process (model) error to these indices because of mis-specification of the true error distribution of survey catch data. Future developments should consider alternative error distribution assumptions. Such alternative assumptions, or use of non-parametric approaches such as General Additive Modeling (GAM), would also permit the use of Azero@ observations in the calibration which are generally treated as missing observations in lognormal models.

The inclusion of auxiliary information (e.g., environmental data) in the GLM modeling could theoretically improve the accuracy and utility of integrated indices. If fine-scale auxiliary data are available and have predictive utility, integration of indices at the tow or stratum level could be easily accomplished. Further research should consider alternative modeling frameworks such as GAM or ordination approaches such as Principal Components Analysis (PCA) which could incorporate non-parametric assumptions and smoothing. Results of exercises using real summer flounder data indicate that without the inclusion in the GLM model of significant main effects (beyond year of sampling and survey identity) that account for a large proportion of the variance of survey series at age from the simple overall means, use of a GLM to develop integrated indices at age provides no clear advantage over using the original indices as input to the VPA calibration. While the GLM integrated indices provide a useful summarization of mean survey trends, the use of integrated indices as VPA calibration input does not guarantee substantially more accurate or precise results than calibration using the original survey indices.

A number of stock assessments in the Northeast United States rely on a single, seasonal time series of survey indices, selected from among several candidate series, as the sole means of evaluating the status of the stock with respect to an index-based reference point. For those situations, the construction of an integrated index of abundance from several different time series could provide a more robust approach to the evaluation of the status of a stock. Therefore, the greatest potential utility for the integrated index approach may be for simple index-based assessments.

SAW 47 Working Paper 4 (TOR 2b) – Zero Filling

8 November 2006

Simulation Studies of Issues Associated with Filling Zeros in VPA Tuning Indices

by

Chris Legault and Al Seaver

Introduction

Recently, the 2006 assessment of summer flounder (Terceiro 2006) was subject to a NMFS Office of Science and Technology (S&T) Peer Review (Methot 2006). Among the recommendations made by the S&T Peer Review panel was the following:

The Panel finds that one immediate modification of the VPA is justifiable and reduces the retrospective pattern in stock size during 2003-2005. The VPA model currently treats survey observations of zero as missing values. An observation of zero for a particular age of fish in a particular survey year does not mean that there are no fish of that age in the stock, only that the number of survey samples was not sufficient to detect any fish of that age. This VPA model, as with most assessment models, tunes to the logarithm of the survey observations so cannot explicitly deal with observations of zero. However, treating these zeroes as missing values can result in a bias because time periods of low abundance are underrepresented in the data input to the assessment model. In the case of summer flounder, the result may be an underestimate of the degree to which the stock has rebuilt since the low levels that occurred around 1990. The committee did not discuss this issue during the Sept 14-15 meeting, so is not prepared to present a definitive solution. An interim approach would use a small value in place of the zeroes. A value equal to one sixth of the smallest observed positive value would be reasonable until a more complete statistical solution can be developed.

This recommendation departs from the standard practice in NEFSC assessments of treating zero values in tuning indices as missing values. To more fully understand the implications of this suggested change, two types of simulation analyses were conducted. The first is a simple spreadsheet example of how a single time series is impacted by different levels of fish detection and the implications for a full VPA. The second is a full simulation that generates many random sets of data for VPA from a known case, creates zeros for some of the indices in some years, and compares different methods for dealing with these zeros, including treating them as missing values, replacing the zeros with a fixed small value, and the one sixth of the smallest observation rule.

First Study: Impact of Zeros on One Time Series

A population that declined and then increased was created artificially. A catchability coefficient was applied to generate a survey time series exactly from the data. The values in the time series were rounded to two, one, and zero decimal places creating observations of zero for 2, 4, and 7 years, respectively (Table 1). A series of constants was added to the time series ranging from 0.0001 to 10 so that the holes were filled. A new catchability coefficient was calculated that minimized the difference between the true population and the observed survey time series which had been modified to fill the holes. This was done to show how a model would need to change the predicted values to more closely match the observed series. In this study, treating the index values as missing results in an exact match between the observed and predicted values, due to the formulation of the problem and so are not considered further.

The differences between observed and predicted values depend strongly on the constant added to the time series (Figs 1-3). Adding a large value, such as 10, causes the survey time series to flatten relative to the true population. A model would try to reduce the change in the population in this case. Conversely, adding a very small value, such as 0.0001, causes the survey time series to exhibit a stronger decline and recovery than the true population. In this case, a model would try to increase the changes in the population. Adding one sixth of the minimum observed value appears to be an objective way to determine a value that is not too big or too small for the round 2 case where only two zeros are replaced.

However, the more disturbing result seen in these simulations is that the addition of a constant value to replace the zeros in a survey time series artificially imposes a pattern that may not match the actual pattern in the population. This is most clearly seen in the round 0 case where seven zeros are filled with the same value even though the true population declines then increases during the seven year period.

Second Study: Simulation Analysis of Different Methods of Treating Zeros

A comparative study was performed using the POPCOMP length based population simulator tool and VPA version 2.3.3. The objective was to examine the effects of using indices of abundance with some portion of the index data treated as missing or alternatively replaced with an imputed value. Four scenarios were examined. In each case the simulated data were sampled to create 100 realizations of VPA input data and the results of the multiple realizations were compared in their ability to recover the true stock numbers and fishing mortality at age. The test was performed in such a manner as the VPA files created for each realization would be the same for each scenario except in the specified removal and alternative replacement of index data based on an input cut point.

The simulated population was loosely based on the summer flounder assessment with the population initially declining due to high F (>2) and then rebuilding as F was lowered to <0.5). The simulated population spans 24 years starting in 1982 and consisting of 8 age classes with the last age class acting as a plus group. Natural mortality was 0.2 for all ages and years. Both recruitment and fishing mortality vary widely over the time series. The growth projection matrix was created using von Bertalanffy growth coefficients and length bins ranging from 10 to 84 cm. A logistic equation was used for fishery selectivity at length. Catch was removed from the population based on the true F but samples were collected from four market categories based on size (sample sizes 65-133 per 100 metric tons) to introduce variability in the catch at length. Age-length keys were created based on sampling 25% of the observed lengths and an ageing error matrix was included to introduce variability in the catch at age (mis-aged proportions

ranged from 4% to 17%). The length-weight equation coefficients supplied to allow expansion of sampled catch to total landings, which had a small amount of variability relative to the true landings (CV = 0.01). Discards were not included in this simulation. This level of uncertainty in the catch at age is thought to be representative of the level associated with the summer flounder assessment. However, there is not a retrospective pattern observed when the simulated data are analyzed with VPA, so not all sources of uncertainty have been captured.

There was only one index generated for each age. The catchability for each index was chosen so that catchability increased with age (Table 2). The uncertainty was higher for the indices at younger ages than older ages (Table 2). The coefficients of variation were used to generate lognormally distributed error in the observed indices. The population trends, catchability coefficients, and coefficients of variation combined to produce different probabilities that a given index value would fall below 1.0 (Table 3). Index values below 1.0 were treated in four different ways:

- Case 1 - Actual values used
- Case 2 - Replaced with 0.0 and treated as missing
- Case 3 - Replaced with the arbitrary constant 0.01
- Case 4 - Replaced with 0.0 then a constant of 1/6 times the smallest non-zero element in the index vector added to all index vector elements including zeros.

The VPA input files generated for each realization were identical excepting that indices of abundance were altered by case.

The median values of F and N at age from the 100 realizations of the VPA model under the four cases of treating index values below 1.0 were compared with the true values from the simulated population (Tables 4-5 and Figs 4-5). Due to the convergence properties of VPA, the medians from the 4 cases are essentially identical for years 1982-1994, as seen in Figures 4-5, and so are not shown in Tables 4-5. The most striking feature seen in the tables and figures is the poor performance of Case 3 (replacing zeros with the arbitrary constant 0.01). The fishing mortality rates in Case 3 were well below the true values while the estimated population abundances were well above the true values. Case 3 clearly demonstrates the potential for introducing bias by replacing zeros in tuning index time series with an arbitrary constant. While not as clear, generally the Case 4 (add 1/6 of smallest non-zero element) estimates were more biased than the Case 2 (treat zeros as missing) estimates. The exception to this generality is seen in age 1 results where the VPA formulation had to be modified slightly to estimate only ages 3-8 in the terminal year +1 due to the lack of information for age 2 in the terminal year +1 when the index was zero. For older ages, Case 2 actually outperformed Case 1 (all data used) relative to the truth. It is not clear why this happened and may be an artifact of the bias introduced by the mis-ageing matrix used to generate the catch data. However, even if Case 1 is used as the basis for comparison, instead of the true values, Case 2 performs at least as well as Case 4 for all ages except age 1.

Discussion

An alternative method to determining the constant to use in place of zeros that was not considered in this exercise is provided by Berry (1987). The Berry approach consists of finding the constant that minimizes a function of the skewness plus kurtosis of the raw data. This

approach is not appropriate for use with tuning index data because the residuals are assumed to follow a lognormal distribution, not the raw observations.

While the 1/6 of the smallest non-zero approach appears to provide reasonable results in some cases, it is an arbitrary rule. In some situations, 1/5 or 1/7 of the smallest non-zero index value would perform better than 1/6. The main problem remains however. Filling zeros with a constant value, no matter how that constant is selected, creates a pattern that may not match reality. These simulations show that this approach can produce results further from the truth than treating zeros as missing values.

Of course, in reality the zeros do have information. Results should be checked to ensure that predicted values are not high when index is zero. If an assessment model predicts high abundance for a year-age combination that had a zero index, the model results should be questioned. However, adding incorrect information arbitrarily has the potential to bias the results, as demonstrated in these simulations.

Conclusions

The two simulation studies have demonstrated problems that can arise when tuning indices with zero values are replaced with arbitrary constants. This practice assumes that the correct magnitude can be chosen to fill the zeros and that it is better to provide the model with information that the index is low rather than treat the data as missing. Results demonstrate that this premise is not always correct. Thus, we recommend the NEFSC standard approach of treating zero values in tuning indices for VPA as missing values.

Some More Thoughts on Filling Zeros in Tuning Indices: A Simple Regression Example

by
Chris Legault

Introduction

The problem of zeros in tuning indices is that a lognormal error distribution is assumed. Since the logarithm of zero is undefined these zero tuning indices must be either treated as missing data or else be replaced by a positive value. One objective method to do this is to add 1/6 of the smallest non-zero value in the series to all values. The consequences of these two approaches are considered in a simple regression example.

Methods

A 26 year population time series was simulated with each value varying uniformly between zero and 50,000 fish. A catchability coefficient of 0.0001 was applied to generate the predicted index value. Lognormal noise with exp(std dev) of 0.2 was applied to the predicted values to generate the observed indices. If an observed index was below 0.5, then it was set to zero to mimic the problem of low abundance not being detected. The constant c was determined for each realization as 1/6 of the smallest non-zero value in the observed time series. Four time series of values were created, ln(obs), ln(obs+c), ln(pred), and ln(pred+c) where ln(obs) was missing when the observed value was zero. Two slopes were computed, one for ln(obs) vs ln(pred) denoted "missing" and the other for ln(obs+c) vs ln(pred+c) deonted "add c." Since in both cases the only source of error is the lognormal error assumed around the observed values, the expectation is that both lines will have slope equal to one. Random series of populations and observation errors were drawn 10,000 times and the two slopes computed for each realization.

Results

When zero observations were treated as missing, the slope was slightly negatively biased with mean 0.983 and 90% confidence interval (0.864, 1.109). When a constant of 1/6 the smallest non-zero value was added to all observed and predicted values, the slope was highly positively biased with mean 1.261 and 90% confidence interval (1.018, 1.483). Note that the 90% confidence interval for the "add c" case does not overlap one and has a range nearly twice as large as the "missing" case.

Discussion

The reason for this large disparity between the "missing" and "add c" results can be seen by examining an extreme example of the data used in the regressions (Figure 1). There were five observations that were replaced with c=0.094 causing the five ln(obs+c) values to all be -2.364 even though the associated ln(pred+c) values ranged from -1.265 to -0.307. These points do not fall on the line that would have been fit to the remaining data and are the source of the bias in the results. More typical results followed the same pattern but with less difference between the two slopes.

The constant was added to both observed and predicted data because to ensure an appropriate comparison. In a separate simulation I did not replace values less than 0.5 with zero and found nearly identical distributions for the "missing" and "add c" slopes. This demonstrates that filling of zeros causes the problem, not the addition of a constant.

In order for the "add c" approach to be unbiased, the constant would have to be selected for each realization such that the average of the ln(pred+c) was the same as ln(obs+c) for the values when obs=0. This cannot happen because the predicted values are positive while the observed values are by definition set to zero. Thus, adding a constant to all values when a zero is in the time series will always bias the results.

Conclusion

Filling observed zeros in tuning indices causes a bias relative to the true population that is much greater than the bias introduced by treating the zeros as missing in this simple regression example.

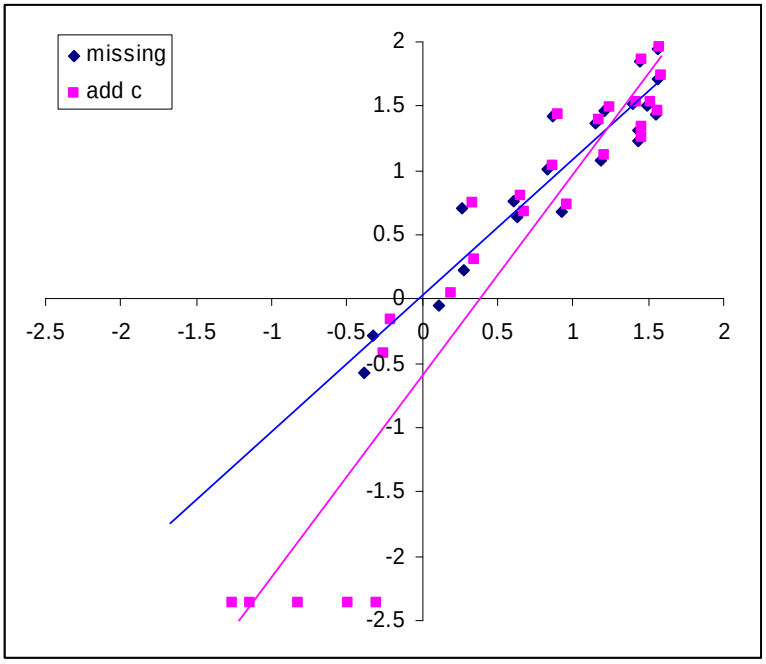

Figure 1. One realization of the "missing" and "add c" regressions. This example is extreme with "add c" slope slightly larger than the upper 90% confidence interval. The x-axis is either ln(pred) or ln(pred+c) and the y-axis is either ln(obs) or ln(obs+c).

The treatment of "zero" observations in the Summer Flounder ADAPT VPA calibration

by
Mark Terceiro

Introduction

The issue of how to treat "zero" observations in ADAPT VPA calibrations was addressed in a previous Southern Demersal Working Group (SDWG) working paper used in preparing the 2004 summer flounder assessment (SDWG 2003; beginning on page 8). That work responded to the 2002 SAW 35 (NEFSC 2002) summer flounder assessment Research Recommendation: *Explore the sensitivity of the VPA calibration to the addition of 1 and/or a small constant to values of survey series with "true zeros."* This recommendation stemmed from the nature of the ADAPT VPA calibration (tuning) algorithm, which includes natural logarithm (ln) transformation (i.e., assumption of a lognormal error distribution) of the input survey abundance indices prior to calibration. Some of the tuning series in the assessment include several "true zero" observations (as contrasted with years for which no sampling was performed) in their time series. Since "zeros" are treated as missing values in the ADAPT computations, a possible solution would be to add a constant to every value in these series to enable use of these "true zeros" as observations.

In the 2002 (NEFSC 2002) and 2003 (Terceiro 2003a) summer flounder assessments, the addition of the constant value of 1 was made for five age 0 recruitment indices: the MA DMF Seine, CT DEP fall trawl, RI DFW fall trawl, RI DFW monthly trawl, and DE DFW 16 foot bay trawl survey series (note that the latter series was not included in the final ADAPT VPA tuning configuration). No constant was added to survey series with "zero" observations for other age classes. The choice of the value of 1 as the additive constant was based on recommendations from statistical texts (e.g., Snedecor and Cochran 1967, Sokal and Rohlf 1981) for the ln-transformation of data.

Berry (1987) provides guidance on the objective selection of the appropriate value of the additive constant based on the statistical properties (skewness and kurtosis) of data series to be ln-transformed. Briefly, the method consists of 1) addition of a range of constants from very large (e.g., 100) to very small (e.g., 0.0001) to the original values in the series, 2) ln-transformation of the modified series, 3) calculation of the skewness and kurtosis of the modified series, and 4) summation of the absolute value of the skewness and kurtosis (providing the statistic g) of the modified series. The additive constant that minimizes g for a given series of data is the one that best minimizes the effect of outliers and normalizes residuals from the lognormal error distribution, hence best adhering to the assumption of the lognormal distribution. Work using the procedures suggested by Berry (1987) with recreational fishery catch rates as indices of abundance indicated that the additive constant of 1 was an appropriate value for those

data, typically with values between zero and 50 (Terceiro 2003b).

The SDWG (2003) work applied the method suggested by Berry (1987) to summer flounder age 0 surveys with "zero" observations. Of the five age 0 series with "zero" observations, the MA DMF series varies between 0 and 70, while the other four series contained small values that varied between 0 and 1. The 2003 work (SDWG 2003) found that for the MA DMF series, the additive constant of 1 minimized the value of *g*. For the other four series, *g* was minimized by small values of the additive constant ranging from 0.001 to 0.1, with an "average" best additive constant of 0.1. The SDWG (2003) therefore recommended use of the revised, varying (1 or 0.1) additive constants in future assessments, and this revision was made in the 2004-2006 assessment, for age 0 survey series only. No constant was added for survey series of other age classes, pending further research.

Recently, the 2006 assessment of summer flounder (Terceiro 2006a) was subject to a NMFS Office of Science and Technology (S&T) Peer Review (Methot 2006). Among the recommendations made by the S&T Peer Review panel was the following:

The Panel finds that one immediate modification of the VPA is justifiable and reduces the retrospective pattern in stock size during 2003-2005. The VPA model currently treats survey observations of zero as missing values. An observation of zero for a particular age of fish in a particular survey year does not mean that there are no fish of that age in the stock, only that the number of survey samples was not sufficient to detect any fish of that age. This VPA model, as with most assessment models, tunes to the logarithm of the survey observations so cannot explicitly deal with observations of zero. However, treating these zeroes as missing values can result in a bias because time periods of low abundance are underrepresented in the data input to the assessment model. In the case of summer flounder, the result may be an underestimate of the degree to which the stock has rebuilt since the low levels that occurred around 1990. The committee did not discuss this issue during the Sept 14-15 meeting, so is not prepared to present a definitive solution. An interim approach would use a small value in place of the zeroes. A value equal to one sixth of the smallest observed positive value would be reasonable until a more complete statistical solution can be developed.

As a result, a revised 2006 ADAPT VPA for summer flounder was developed for which the previous treatment of "zero" observations for age 0 indices was retained (additive constant of 1 for MA DMF seine survey, 0.1 for the CT DEP fall trawl, RI DFW fall trawl, RI DFW monthly trawl, and DE DFW 16 foot bay trawl surveys). For ages 1-7+ survey series with "zero" observations, a value equal to one-sixth of the minimum value in each series was used in place of the "zero" observations. Typically, the minimum non-zero value in these series was 0.01, and so the additive constant was 0.001667 (Terceiro 2006b).

Summer flounder 2006 ADAPT VPA

In this work, the Berry (1987) approach is applied to the summer flounder survey series for all ages with observed "zeros" to determine the best additive constant to use to remove these "zero" observations from the ADAPT VPA calibration data. Table 1 summarizes the statistical properties of the 24 survey series that were examined. The distributions of the surveys are characterized by non-zero values between 0.001 and 70, CVs that generally exceed 100%, positive skewness (long right hand tail), and significant kurtosis (high degree of peak, or contagion, near the mean). The proportion of "zeros" in the time series ranged from 1 of 31 = 3% (NEFSC Spring Age 3 index) to 13 of 28 = 46% (MA Fall 4).

Table 2 summarizes the results of the exercise for each group of age-specific indices. Values of *g* were minimized for constants between 0.001 and 100 (minimum values in ***bold italics***), for the age 0, 1, 2, 3, 4, and 5-7+ (aggregate) survey indices (number per tow or haul). There is no statistically significant correlation (Table 3) between the value of the additive constant that minimizes g and the statistical parameters listed in Table 1.

Age 0 Indices

For the five age 0 series, the *g* statistic was minimized by values of the additive constant ranging from 0.001667 to 1. The constant equated to one-sixth of the minimum non-zero observed value for 2 of the 5 series . The relationships between the additive constants and calculated values of *g* for the age 0 indices are shown in Figure 1.

Age 1 Indices

For the three age 1 series, the additive constant of 0.01 minimized the absolute value of *g*. The relationships between the additive constants and calculated values of *g* for the age 1 indices are shown in Figure 2.

Age 2 Indices

For the single age 2 series, the additive constant of 0.1 minimized the absolute value of *g*. The relationships between the additive constants and calculated values of *g* for the age 2 indices are shown in Figure 3.

Age 3 Indices

For the six age 3 series, the absolute value of the *g* statistic was minimized by values of the additive constant ranging from 0.001 to 100. The constant equated to one-sixth of the minimum non-zero observed value for 1 of the 6 series . The relationships between the additive constants and calculated values of *g* for the age 3 indices are shown in Figure 4.

Age 4 Indices

For the six age 4 series, the absolute value of the *g* statistic was minimized by values of the additive constant ranging from 0.001 to 1. The constant equated to one-sixth of the minimum non-zero observed value for 1 of the 6 series . The relationships between the additive constants and calculated values of *g* for the age 4 indices are shown in Figure 5.

Age 4/5-7+ Indices

For the three age 4/5-7+ series, the absolute value of the *g* statistic was minimized by values of the additive constant ranging from 0.001667 to 100. The constant equated to one-sixth of the minimum non-zero observed value for 1 of the 3 series . The relationships between the additive constants and calculated values of *g* for the age 4/5-7+ indices are shown in Figure 6.

Conclusion

There is no consistent pattern in the identification of the additive constant that minimizes the absolute value of Berry's (1987) *g* statistic. There is no strong relationship between the absolute magnitude of the index values, the length of the time series, the number of zeros, the magnitude of the smallest observed value, or any of the usual statistical moments of the series (mean, maximum, non-zero minimum, CV, skewness, kurtosis), and the value of the additive

constant that minimizes *g*. Further, while the "one-sixth" of the minimum observed value was identified as the "best" additive constant in 5 of the 24 (21%) cases examined, this level is not high enough to justify this approach as a reliable rule-of-thumb. In fact, the additive constant of 0.01 was identified as "best" for a higher percentage of series (6 of 24 = 25%). Given the inability to identify a constant that consistently minimizes *g*, the best rule is to maintain the current approach of making no adjustment and continue to treat "zero" observations as "missing."

APPENDIX 3

SAW 47 Working Paper 7 (TOR 3) – Life History Parameters

Evaluation of summer flounder life history parameters from NEFSC trawl survey data, 1992 – 2006.

Jeffrey C. Brust
New Jersey Division of Fish and Wildlife

April 2008

Background

In 2000, summer flounder stocks were determined to be overfished. Management of the species entered a ten year rebuilding period in order to increase abundance to sufficient levels. Recent stock assessments indicate that, although fishing mortality has decreased substantially and biomass is at the highest level ever recorded, the stock is still only about 50% of the target biomass. As the end of the rebuilding period nears and quotas continue to drop despite the high biomass, there has been growing concern that the stock assessment and/or biological reference points for the species are flawed.

During the 2007 stock assessment update, it was noted that there have been changes in certain biological parameters of the stock over the last few years. Among these are size at age and sex ratio. Changes in these and other parameters could affect population dynamics and rebuilding rates. The purpose of this paper is to review data collected during National Marine Fisheries Service, Northeast Fishery Science Center seasonal trawl surveys in order to investigate key biological parameters and evaluate potential implications on stock rebuilding and management of the species.

Methods

Data were obtained from the NEFSC trawl survey database. Since 1992, NEFSC finfish trawl surveys have occurred three to four times per year, and have recorded lengths, weights, ages, and sex from at least a subsample of summer flounder captured in the survey.

Length and weight at age

Evaluation of sample size at age revealed that sample size at older ages was very low, particularly during early years of the analysis. Data were therefore subset to years and ages that had a sufficient sample size.

Trends of size at age over time were evaluated in two ways. First, sex specific mean size at age was calculated for each year with sufficient sample size. SAS Proc REG (SAS 1990) was used to conduct regressions of size at age over time.

Second, observed data were fit to a von Bertalanffy growth function

$$L_t = L_\infty * (1 - e^{-(k*(t-t_0))})$$

to develop annual sex specific predicted length at age estimates using SAS Proc NLIN (SAS 1989a). For each year, residuals were resampled with replacement to develop 500 bootstrap datasets (Barker 2005), each of which was also fit using the von Bertalanffy growth function. Summary statistics were calculated for the parameter estimates, as well as predicted size at age. SAS Proc REG was used to perform regression analysis of mean predicted length at age over time.

For both methods, slope parameters of length at age over time were evaluated at the $\alpha = 0.10$ level.

Length-weight analysis was also conducted with SAS Proc NLIN using an allometric growth function.

$$W = \alpha L^\beta$$

For each year, residuals between observed and predicted weight at length were calculated and resampled to develop 500 bootstrap datasets which were also fit to the growth function. Summary statistics were calculated for the parameter estimates, as well as predicted weight at length. SAS Proc REG was used to evaluate trends in mean weight at length over time.

Maximum age, sex ratio, and natural mortality

Maximum age by sex was found by analytical review of the raw data, as were overall sex ratios and sex ratios by age. Sex ratio (*i.e.* percent female) at size was analyzed using SAS Proc GENMOD (SAS 1989b) with a normal distribution and a logit link function (*i.e.* a logistic regression).

Natural mortality for each sex was estimated using the approximation of 3 / T_{MAX} (Hoenig 1983). Annual estimates of natural mortality for the stock were determined using a weighted average of sex-specific natural mortality and annual sex ratio.

Fecundity

Individual fecundity was estimated by applying the fecundity:length relationship of Morse (1981) to the mid-year length at age for females.

$$F = 0.0007975 * L^{3.402}$$

Number of mature females by age and year were determined by multiplying the VPA estimated abundance at age by sex ratios at age and the VPA input maturity schedule. These were multiplied by fecundity at age and summed across ages to estimate total theoretical fecundity of the stock.

Results

Length and weight at age

The number of fish observed on trawl surveys was low for some ages and years, particularly during early years of the analysis. Data were therefore subset to years and ages where sample size was generally greater than 50 fish per year (all surveys combined). Prorating ages to the season fish were captured (assuming a January 1 birthdate) as done in earlier drafts resulted in low sample size for some seasons, but fitting equations using ages pooled across surveys in a year resulted in poor or unconverged fits for some years. As a result, length at age calculations (mean and von Bertalanffy) were conducted using samples from the winter survey only. The subset data include years from 1999 to 2006 and ages 0 through 4 for males and 0 through 5 for females. Sample size for these years and ages are generally greater than 40 fish (Table 1).

Mean lengths for males age 1 to 4 show no long term trends between 1999 and 2006 (Table 2, Figure 1), and regression results indicate no significant changes over time (Table 3). Trends in mean length at age for females were similar to males for ages 0 to 4; however, female mean length at age 5 decreased significantly between 1999 and 2006.

Fitting bootstrap data to the von Bertalanffy growth function resulted in unrealistic parameter estimates for males in 2000 and 2006 (Table 4). Bootstrap average maximum length for these years was approximately 100,000 cm. Although the mean estimated parameter values produce unrealistic estimates of length at age, specific bootstrap replicates with large maximum size estimates had correspondingly lower estimates of the growth parameter *k*, such that mean predicted length at age was not erratic for fish less than 8 years old. Regression results for length

at ages 0 to 10 (the approximate age range observed in survey data) showed no significant trends (Table 5, Figure 2).

Estimated von Bertalanffy parameters for females were also unrealistic in 2000, though much less so than for males (Table 6). Regression results indicate no significant trend in predicted length at age for ages 0 to 4; however, predicted length at ages five and older decreased significantly between 1999 and 2006 (Table 7, Figure 3). For both males and females, regression results using von Bertalanffy predicted length at age were consistent with results of mean length at age.

Length:weight analysis was conducted on the same subset of years and ages as age:length analysis. As before, sample size was generally above 40 fish (Table 8). No significant trends were observed for weight at length for males (Tables 9 and 10, Figure 4) or females (Tables 11 and 12, Figure 5).

Maximum age, sex ratio, and natural mortality

Between 1985 and 1995, maximum age for males generally varied between age 4 and 5, while female maximum age ranged from age 6 to 8 (Figure 6). By 2000, maximum age of males had increased to between 8 and 9, where it remained stable until 2007 when one 12 year old male was captured. Female maximum age has increased steadily since 1995, with a peak of 14 years in 2005.

From 1992 to 1997 overall sex ratio averaged approximately 54% female (Figure 7). From 1997 to 2000, females increased from 53 to 58% of the stock, where it remained stable for 3 years. In 2003, the ratio dropped to 51% female and has varied widely from 47 to 57% since then.

Natural mortality was estimated as a weighted average of sex ratio and sex-specific natural mortality. Using maximum ages of 12 and 15 for males and females, respectively, sex-specific natural mortality is estimated at 0.25 for males and 0.20 for females. Applying these to overall sex ratios, M has remained relatively stable around 0.223, with a range of 0.221 in 2000 to 0.226 in 2005 (Figure 7).

Sex ratios by age (Figure 8) show a general decrease in percent female at age since the mid 1990s for all ages, although the declines are more evident for ages 2 and above. For example, 3 year old fish have dropped from an average of 75% female during 1992 to 1994 to 56% female in 2004 to 2006. Four year old fish have dropped from 85% female to 62% female over the same time period.

Sex ratio at size data (discussed below) indicate that greater than 90% of fluke can be sexed by 25 cm. Von Bertalanffy estimates indicate that both males and females attain this size by age 1. By age 2 both males and females have recruited to the commercial fishery (36 cm, 14”), so age 1 is the only age where they are large enough to be sexed and experience no harvest pressure. Natural mortality for age 1 fish is generally stable between 0.225 and 0.23 from 1992 to 2002, but has increased to approximately 0.235 in recent years (Figure 9). Even though age 2 fish are exploited, the sex ratio averages approximately 50:50 up to 43 cm (17”, age 3), and both sexes are likely harvested in equal proportions. Natural mortality of age 2 fish shows a gradual increase from 0.216 to 0.23 from 1992 to 2005, before dropping sharply back to 0.224 in 2006. Average M for age 1 and 2 also shows a gradual increase over all years from 0.222 to approximately 0.23.

When data are combined across years, logistic regression of percent female at size shows a 50:50 sex ratio at around 38 cm (15”). Fish smaller than this size are predominantly male,

while larger fish are predominantly female (Figure 10). Using annual data, the 50% inflection ranges from 33 cm in 1992 and 1995 to 43 cm in 2003 and 2005 (Figure 11).

Combined data show that greater than 90% of all animals 25 cm and larger can be sexed. Sex ratio for fish 25-35 cm (*i.e.* able to be sexed but less than minimum size) has decreased from an average of 34.5% females for 1992-94 to 29.4% for 2004-06 (Figure 12). Natural mortality for fish in this size range has increased from an average of 0.233 for 1992-94 to 0.235 for 2004-06 (Figure 13). From 35 cm to 43 cm, the sex ratio is approximately 50:50, and fish in this size range are likely exploited in similar proportions. The sex ratio for fish 25 to 43 cm shows a decline from 48.4% female in 1992-1994 to 37.2% in 2004-2006. *M* for this size range has increased from 0.226 to 0.231 over the same time period.

Fecundity

Because of the concerns with sample size for age:length data, fecundity could only be evaluated for the years 1999 to 2006. Theoretical fecundity of the stock increased steadily from approximately 22.3 x 10^{12} eggs in 1999 to a maximum of over 36.5 x 10^{12} eggs in 2004 (Figure 14). Fecundity has decreased in each of the last two years, to approximately 31.0 x 10^{12} eggs in 2006. During this time period, recruitment (VPA output) has remained relatively stable between 28 million and 38 million individuals, except for 2004 where recruitment was estimated at only 17 million. The relationship between fecundity and recruitment is slightly negative, although this appears to be driven primarily by the 2004 data point (highest fecundity and lowest recruitment.

Discussion

Summer flounder biomass has increased substantially during the rebuilding period, yet managers continue to cut annual quotas in an attempt to reach established biomass reference points. This has led many managers and industry stakeholders to question the accuracy of the reference point targets. In recent months, evidence has been presented that summer flounder stocks may be experiencing changes in life history parameters, such as size at age and sex ratios. In addition, there have been implications that management measures themselves are impeding stock rebuilding by selectively harvesting larger individuals which are primarily female. This paper was undertaken to evaluate certain life history parameters and the implications they have on stock rebuilding.

Dery 1988 found males reached a maximum age of 7 years and females 12 years. This is generally consistent with maximum ages observed in NEFSC trawl surveys from 1992 to 2000. Since then, maximum ages of both males and females captured in the NEFSC trawl surveys have approximately doubled, likely as a result of reduced fishing mortality allowing fish to survive to older ages. Trawl data indicate that maximum ages of 12 for males and 15 for females may be more appropriate. As maximum ages for both sexes were observed in recent years, additional years of reduced fishing pressure may result in even older maximum ages. In addition, maximum ages may be confounded with survey catchability at size.

As identified by Terceiro (pers. comm.) length and weight at age do appear to have decreased in recent years. For males, decreases in length at age are not yet statistically significant, but may become so if the trend continues. For females, significant decreases in length at age have been observed for ages 5 and older. Although length:weight relationships

have not changed, decreased length at age results in lower weight at age, which may result in slower than anticipated rebuilding rates.

In recent months, many fishermen have expressed concern regarding the finding of the NEAMAP trawl survey that most fluke greater than 41 cm (16") are female. These findings are not new (*e.g.* Murawski and Figley 1977, Morse 1981), but this sexual dimorphism has greater implications for management and stock rebuilding as minimum size limits increase in an effort to reduce harvest. There does appear to be a general decline in the ratio of females to males observed in the trawl survey. However, for many ages this decline has been observed over 15 years, much longer than states have required large minimum sizes.

Natural mortality for summer flounder is generally approximated as $M = 0.2$ based on longevity information. Because summer flounder males and females appear to have different maximum ages, the sex ratio of the population could affect the overall stock natural mortality rate. The shift in sex ratio towards more males in recent years has led to a slight increase in natural mortality for the stock, but the increase does not appear substantial enough to affect rebuilding. However, estimates based on current data indicate that $M = 0.22$ might be a more appropriate estimate of overall natural mortality. A higher natural mortality rate would result in a higher F_{Target} and lower SSB_{Target} than currently estimated. Although this analysis provides evidence for a higher M, additional analyses should be conducted. The Hoenig (1983) approximation used in this paper is often criticized as being inadequate (*e.g.* Pascual and Iribarne 1993, Hewitt and Hoenig 2005). In addition, maximum ages captured by trawl in a stock that is undergoing rebuilding may be underestimated.

Morse (1981) found that length was the best indicator of fecundity in fluke. Changes in female length at age and management strategies directing effort to large females could affect fecundity of the stock. In general, however, increases in total abundance have outpaced any decreases in fecundity, resulting in theoretical stock fecundity increasing more than 50% from 1999 to 2004. Fecundity declined in 2005 and 2006, coincident with slower stock growth. However, additional years of data are necessary to determine if there is a causal relationship.

Conclusions

Review of NEFSC trawl survey data do indicate that certain life history parameters have changed since 1992. Length at age has decreased significantly for older females. Maximum ages have approximately doubled since 2000. Sex ratios have shifted towards higher proportions of males. Natural mortality based on longevity and sex ratio has increased slightly. Despite decreases in fecundity at age, overall theoretical stock fecundity was higher in 2006 than in 1999. The implications of these patterns in biological parameters should be reviewed and considered when evaluating potential management strategies for stock rebuilding.

SAW 47 Working Paper 8 (TOR 3) – Natural Mortality
A Review of Natural Mortality of Summer Flounder
Rich Wong

This report is a short review of the common models used to estimate natural mortality rates M for use in population dynamics modeling. The natural mortality models were categorized as either longevity- or life-history based estimators of M. Sex and age-specific estimates of M are given in Tables 1-3, calculated from model inputs from current summer flounder age and growth data (1976-2007) from the NMFS trawl survey.

Longevity-Based Estimators of Natural Mortality

Longevity-based estimators of natural mortality are derived from the underlying mathematical function describing population decline, $\frac{N_t}{N_0} = e^{-Zt}$. For unexploited stocks, 1) Z = M, and 2) $\frac{N_t}{N_0}$ approaches zero as t approaches a stock's maximum longevity. This is the basis for the rule of thumb (ROT) equation, $M = \frac{-\ln(P)}{t_{\max}}$. Only two variables, therefore, affect M given this ROT expression, 1) P, which represents some small proportion of the population that survives to a given maximum age, and 2) t_{max}, which should represent the maximum longevity of the stock (Hewitt and Hoenig 2005). The value of P is often set equal to 5% for population modeling purposes (e.g. blue crabs, summer flounder, tautog, bluefish, etc.) resulting in a more simplified expression, $M = \frac{\ln(0.05)}{t_{\max}} \approx \frac{3}{t_{\max}}$. However, aside from its common use in assessments, the value of P = 5% is not well supported by data (Hewitt and Hoenig 2005). Recently, Hewitt and Hoenig (2005) recommended a more empirically supported value of P = 1.5% based on a regression of Z and maximum observed age from 134 unexploited fish, mollusk, and cetacean stocks in earlier work by Hoenig (1983). Hoenig's (1983) regression, $\ln(Z) = 1.44 - 0.982\ln(t_{\max})$,

can be rearranged as $Z = \frac{e^{1.44}}{t_{max}^{0.982}} \approx \frac{4.22}{t_{max}}$. Ergo, P roughly equals 1.5% from the equation, ln(P) = -4.22. Estimates of M using the 5% ROT are 29% lower than the estimates from P = 1.5% (Figure 1). Predictably, outputs from population models are highly sensitive to estimates of M. Lower M inputs typically result in lower abundance estimates from population modeling and lower benchmarks from YPR analysis.

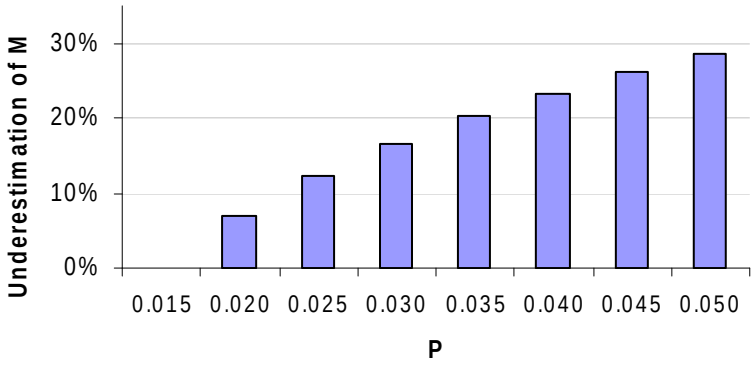

Figure 1. Underestimation of M relative to P = 1.5%.

In addition to the critical importance of P, using a maximum observed age collected from a highly exploited stock produces a biased underestimate of longevity and is in direct violation of the longevity-based M paradigm. As an example of how the maximum observed age can change over a short time period, the maximum observed age of Atlantic croaker increased from 6 to 12 since the early 1990s from age and growth studies in North Carolina, mirroring an increase in stock abundance over this period (pers. comm. R. Gregory, age/growth biologist NC Division of Marine Fisheries). If t_{max} were solely based on these age samples, the resulting estimates of M (using the 1.5% ROT) would have declined from 0.70 to 0.35 in less than 20 years. Despite the recent occurrence of older age classes, no specimen has yet been observed at the maximum age of 15 y recorded from scattered otoliths found in archaeological shell middens from a period of minimal exploitation (Hales and Reitz 1992).

The underestimation of longevity is a legitimate concern for stocks whose t_{max} is observed during a period of heavy exploitation. For example, for summer flounder at the current t_{max} = 15, the effect of potentially underestimating longevity by 1 to 5 years results in an overestimation of M by 6 to 32% (Figure 2). On the other hand, the consequence of using a P value up to 5% is the 29% reduction in M from the 1.5% ROT supported by Hoenig (1983) (Figure 1). The widespread use of P = 5% for stock assessment purposes, whether intentional or not, automatically accounts for an assumed ~4 year underestimation of longevity (assuming that P = 1.5% is the proper P value for the longevity-based ROT).

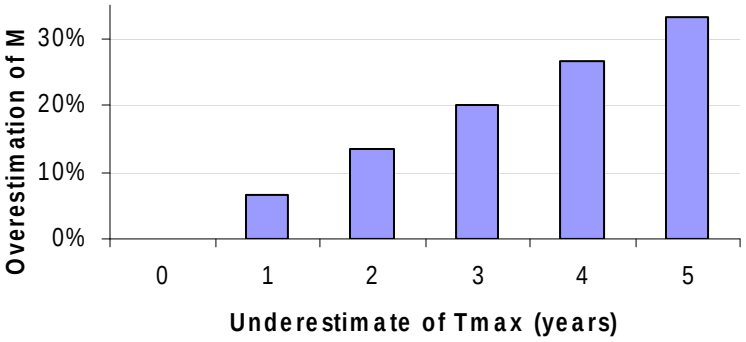

Figure 2. Effect of underestimating longevity by up to 5 years for summer flounder.

Life-History Based Estimators of Natural Mortality

Other methods of estimating M are based on specific life history characteristics from the species in question (Table 1; Figure 3). Pauly (1980) described M using von Bertalanffy growth parameters (L_{inf}, K) and water temperature based on data of 175 fish stocks. Jensen (1996) provides a modification of Pauly's (1980) model based solely on the correlation between M and K, providing the basis for the simplified equation, M = gK. The coefficient g was estimated as 1.598 (r^2 = 0.72) based on Pauly's (1980) data (Jensen 1996). Gunderson (1997) showed that M

could be predicted from reproductive effort from data of 28 fish stocks by the linear regression, M = 1.79*GSI (r^2 = 0.75). Variance of these life-history based estimates of M can be calculated given the known variances of model inputs (Gunderson et al. 2002).

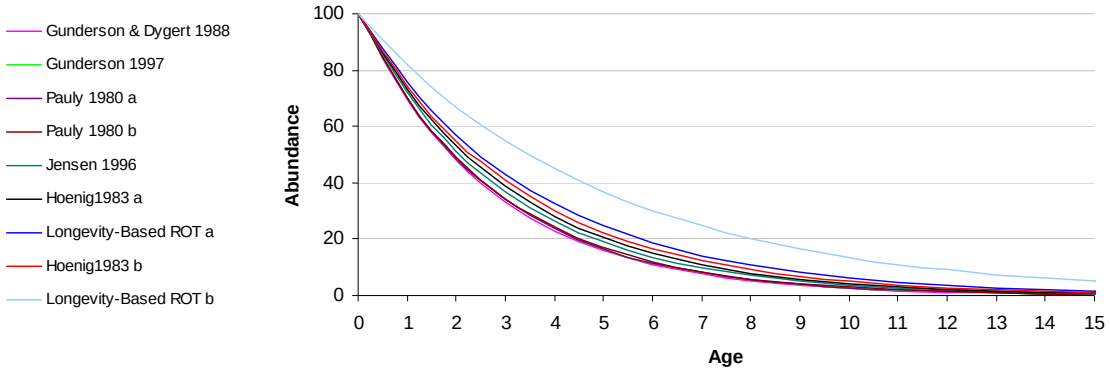

Figure 3. Survival curves from constant M estimates.

Other life-history based estimators of M provide for size-specific or age-based natural mortality rates (Tables 2, 3; Figures 4, 5, 6). Peterson and Wroblewski (1984) describe an inverse relationship between M and dry weight for juvenile and adult fishes. McGurk (1986) complemented this model by describing a steeper inverse M-dry weight relationship specific to fish eggs and larvae based on the linear regression of ln(M) and ln(dry weight) ($r = 0.58$, $P < 0.001$). Lorenzen (1996) describes a similar allometric relationship between body weight and natural mortality in juvenile and adult fish across different ecosystems. All of these size-dependent M rates can also be expressed as age-dependent M rates with necessary age and growth data. Chen and Watanabe (1989) estimate age-specific M rates based on known LVB growth parameters, accounting for higher natural mortality rates at early and senescent life history stages. Use of Lorenzen's (2000) approach, which is based on an allometric relationship between body length and M, combined with an assumption of longevity (ala the aforementioned

longevity-based ROTs) can provide for somewhat of a hybrid age-dependent-longevity-based natural mortality model (pers. comm. L. Brooks, NMFS).

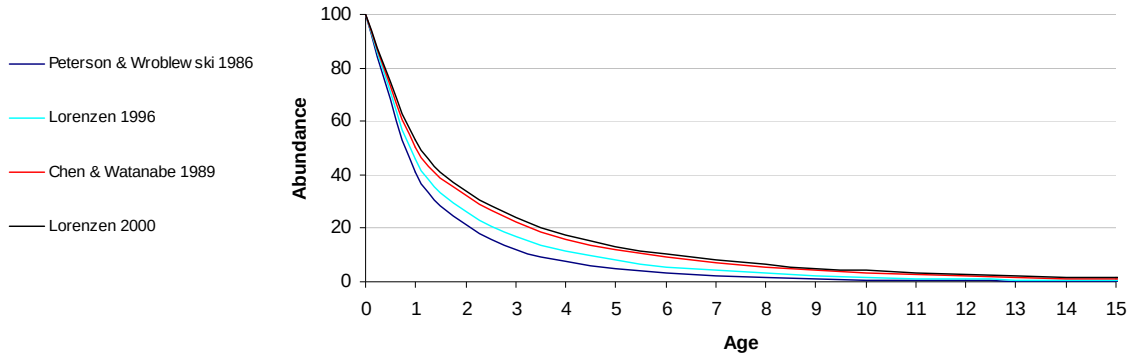

Figure 4. Survival curves from age-specific M estimates.

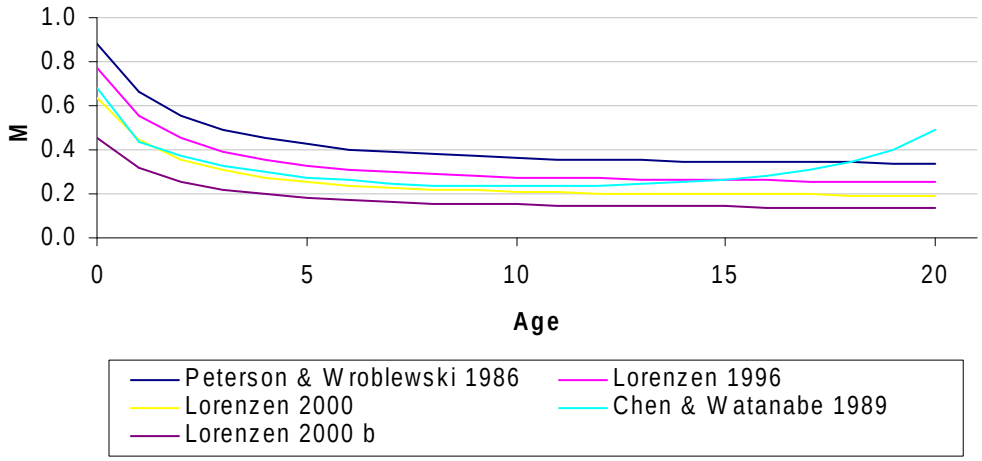

Figure 5. Age-specific M rates. Lorenzen 2000 is based on the 1.5% ROT, Lorenzen 2000 b is based on the 5% ROT.

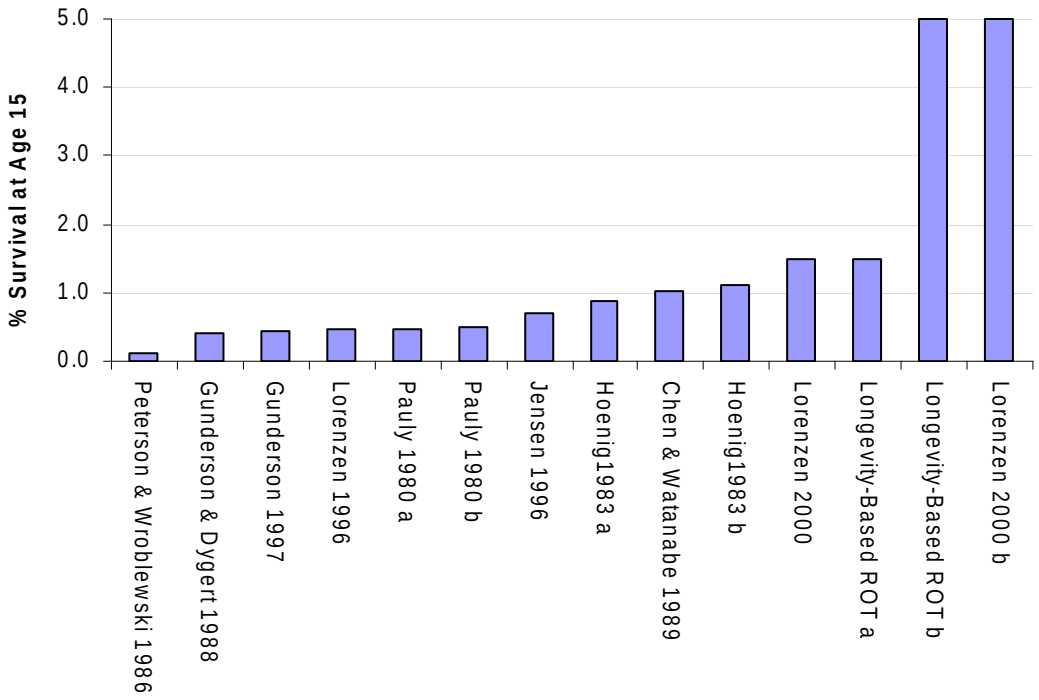

Figure 6. Percent survival at age = 15y.

Male-to-female demographics are very important considerations when combined-sex M rates are calculated. For example, size-at-age inputs for M models will likely differ from a combined-sex LVB growth trajectory versus the sex-weighted mean size-at-age observed in the population (Figure 6), resulting in potentially different M rates. Also, the time step chosen for calculating age-based M estimates can be influential particularly when estimates of natural mortality are much higher at early life stages. For example, survival after one year is 46% using a 1 year time step versus 44% using a 1/4 year step from size-based M rates calculated from the Lorenzen (1996) model (using the size at the mid-point of each time step).

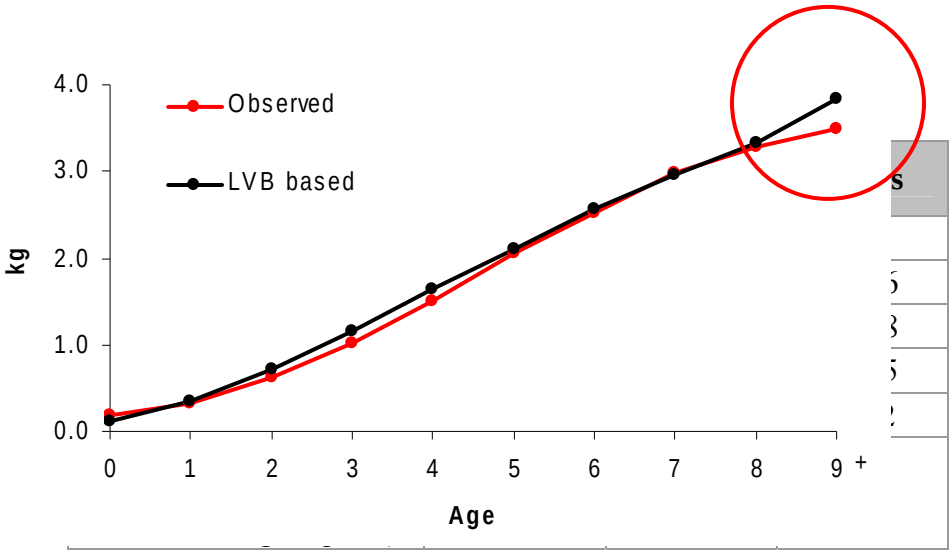

Figure 7. Observed mean weight-at-age from the NMFS trawl survey versus weight-at-age based on LVB length-at-age and L:W relationship.

Table 1. Estimates of constant natural mortality rates for summer flounder.

SAW 47 Working Paper 9 (TOR 3) – Analysis of Sex Ratios

Analysis of Trends in Sex Ratio, Implications for Natural Mortality, and Variation in Age-Length Keys in Summer Flounder

Eric N. Powell
Jason Morson

Haskin Shellfish Research Laboratory
Rutgers University

Introduction

The analyses described herein use the biological database for summer flounder. The goals of these analyses are to answer the following questions to the extent permitted by this database.

1. Does information exist in the sex-ratio data that would support the need to construct a sex-explicit model for summer flounder?
2. Does information exist in the sex-ratio data that would support the need to utilize regionally-specific sex-at-age keys?
3. Does information exist in the sex-ratio data that would support a differential natural mortality rate for male and female summer flounder or a nonlinear whole-stock natural mortality rate?
4. Does variation exist in the relationship of size and age that would support the need to utilize regionally-specific age-length keys?

Sex Ratio as a Function of Age

Methods and Results

Sex ratio data for young-of-the-year are not available prior to 1982; consequently analyses of sex ratio focus on 1982-2007. Due to data limitations, and regional variability in sex ratios as discussed in a subsequent section, we exclude data from southern New England north and also from Cape Hatteras south in this set of analyses. We also exclude all age-year combinations where the number of sexed summer flounder is less than 20. For some analyses, we have collected the data into six year groups with the central four being half-decadal. Year group 1 contains data from 1982-1985 and year group six for 2006-2007.

Table 1 shows the sex ratio by year and age for summer flounder. The year-group averages are in Table 2. Perusal of Table 1 elucidates two general trends.

First, the young-of-the-year are dominantly male. A female-biased sex ratio for young-of-the-year summer flounder occurs only thrice in 26 years, a frequency significantly different than the expected 50:50 split (binomial test, $P < 0.0005$). Furthermore, the fraction male for young-of-the-year fish frequently exceeds 0.6; in fact a sex ratio at least this divergent from 50:50

occurs in 17 of 26 years. The average number of age-0 fish sexed per year is 51.5. Given this average, a 50:50 male:female ratio by chance when measured would return a ratio of 60:40 or greater 7.56% of the time. The occurrence rate observed, 17 in 26, would not be expected to occur by chance (binomial test, $P < 0.0001$). Thus, young-of-the-year summer flounder are consistently over-represented by male fish.

Table 1. The fraction of summer flounder that are male at age for ages and years where the total number of summer flounder sexed was ≥20.

Year	Age 0	Age 1	Age 2	Age 3	Age 4	Age 5	Age 6	Age 7	Age8

2002	0.737	0.523	0.492	0.474	0.284	0.128	0.069		
2003	0.633	0.644	0.569	0.422	0.331	0.190	0.040	0.062	
2004	0.655	0.582	0.562	0.440	0.260	0.193	0.103	0.059	
2005	0.808	0.635	0.638	0.454	0.397	0.341	0.190		
2006	0.429	0.683	0.515	0.426	0.305	0.197	0.108	0.125	0.062
2007	0.286	0.581	0.666	0.441	0.250	0.196	0.250	0.067	

The second observation is a consistent change in sex ratio with age (Figure 1), such that male frequencies over 0.5 occur only 8 times in 25 cases in age-2 fish and ratios above 0.3 occur only 6 times in age-4 fish. In fact, of the sex ratios accumulated by year-group in Table 2, only one age and year-group pair was characterized by a sex ratio not significantly different from 50:50 male-to-female. Thus, summer flounder are consistently characterized by biased sex ratios regardless of age or half-decadal period within the time series and the direction of bias changes with age.

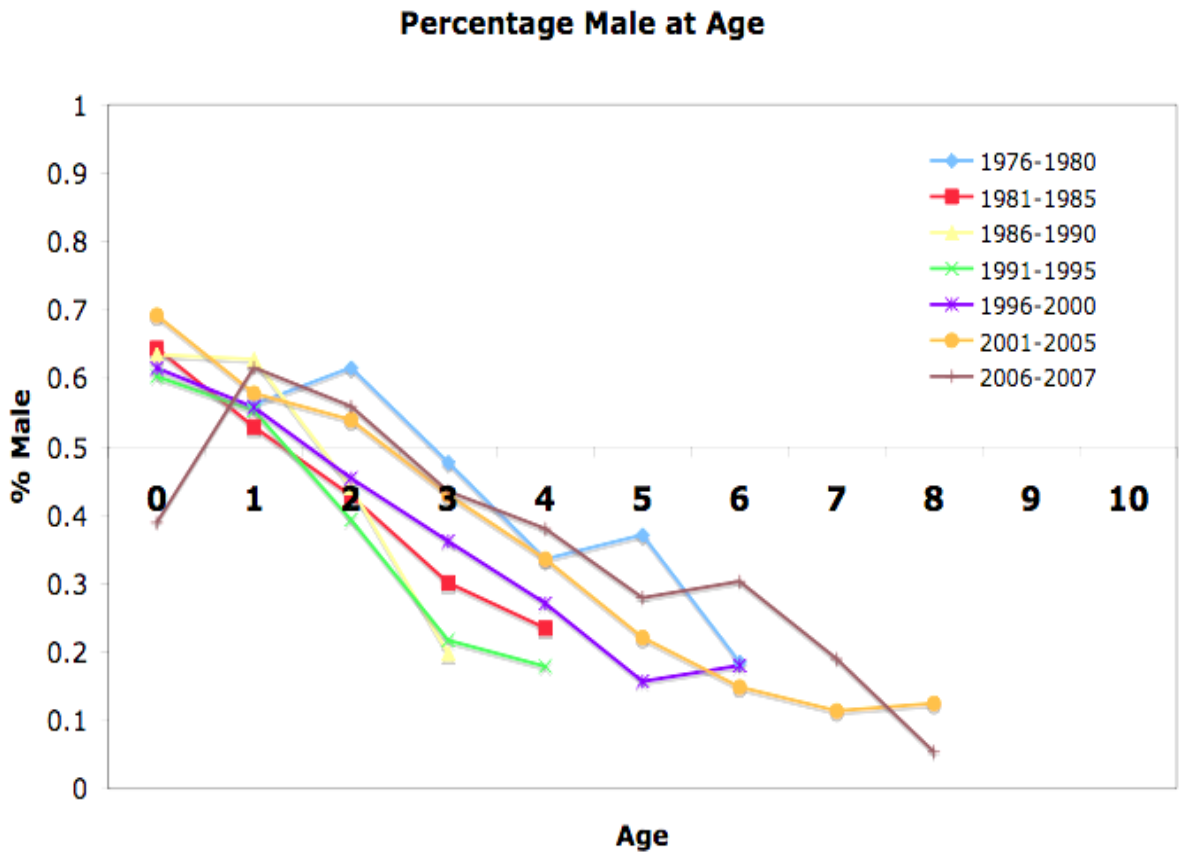

Figure 1. The percentage of the stock that is male by age, summarized by year-group.

Two additional observations are worthy of note. First, the three years where females predominate in age-0 fish include the last two years. This is unexpected from the time series record. However, the sex ratio for age-1 fish from the 2006 cohort conforms with typical age-1 sex ratios in being biased in favor of males. Thus, the aberrant 2006 young-of-the-year ratio is likely a sampling artifact. Second, the fraction of fish that are male at older age has increased over time, although remaining well below 0.5. This is particularly apparent for age-3 fish (Table 2). One explanation is that male fish are moderately more susceptible to the fishery at high fishing mortality rates, but two other explanations should first be considered. The same outcome would be obtained either if a reduction in natural mortality rate had occurred of if the originating sex ratio was biased to a greater degree in favor of males. Evidence in Table 1 does not strongly support the latter alternative. Evidence in a subsequent section does not support the penultimate option. The dispersion of males and females as the cohort ages, discussed in a subsequent section, might be interpreted to support the first alternative.

Table 2. The fraction of summer flounder that are male at age for ages and year groups where the total number of summer flounder sexed was ≥20. Parentheses indicate ratios not significantly different from an expected 50:50 split (binomial test, $\alpha = 0.05$).

Year Group	Age 0	Age 1	Age 2	Age 3	Age 4	Age 5	Age 6	Age 7	Age 8

Interpretation: Age-dependent Bias in Sex Ratio

A number of potential reasons exist for the male-dominated sex ratios seen in young-of-the-year summer flounder.

Females mature later than males. The observed females may under-represent the total number. The biological database records undifferentiated fish. Assigning all of these fish to the female sex, however, does not markedly change the data summarized in Table 2. Thus, maturity schedule cannot explain the male-dominated sex ratios observed for age-0 fish.

Young males may be more available to the survey. While this possibility cannot be excluded, the fact that females grow faster than males and that the male-biased sex ratios clearly are retained into age 2, albeit at diminishing intensity, suggest that availability is not an adequate explanation.

Protandry would produce the observed age-dependent sequence of sex ratios. Protandry, however, is not reported in flatfish, and would almost assuredly have been observed, were it to exist.

Biased sex ratios have been observed by others in summer flounder, however. Morse (1981) and Smith and Daiber (1977) found that younger, smaller fish were much more likely to be male and that this trend quickly reversed with increasing age. Morse (1981) offers that an initially male-dominated sex ratio is necessary to offset an apparently higher natural mortality rate in males, thus promoting a more nearly 1:1 sex ratio in the spawning stock.

The most viable explanation for biased sex ratios in young-of-the-year summer flounder is temperature-dependent sex determination. Temperature has been shown to influence sex ratios at the point of sexual differentiation in flatfish, not afterwards, and this influence of temperature seems to be a frequent characteristic of flounder species. For example, when barfin flounder, *Verasper moseri*, were reared at high temperatures (18°C for this species), all fish developed as males, whereas at 14°C, the sex ratio was close to 1:1 (Goto et al. 1999). Marbled sole, *Limanda yokohamae*, also show temperature-dependent sex determination; when the larvae were kept in 25°C water, the sex ratio was again strongly skewed towards males (Goto et al. 2000). Southern flounder, *Paralichthys lethostigma*, likewise develop a sex ratio skewed towards males when raised at higher (28°C) or lower (18°C) than optimal temperature, 23°C, which produces a 1:1 ratio (Luckenbach et al. 2003). Although little is known of the genetic determinants of sex, *Paralichthys olivaceus* uses an *XX* female/*XY* male system of genetic sex determination, yet high water temperatures (25-27.5°C) produce physiological males possessing an *XX* genotype.

Genetically determined males (*XY*) were never observed to develop into physiological females (Yamamoto 1999).

Among the flatfishes have been shown to exhibit temperature-dependent sex determination are two species of the same genus as summer flounder, the Japanese flounder or hirame, *Paralichthys olivaceus*,and the southern flounder, *Paralichthys lethostigma* (Yamamoto 1999; Luckenbach, et al.2003). Furthermore, in both cases, extreme temperatures result in a higher fraction of the young being male. This could potentially explain why a higher fraction of young-of-the-year summer flounder are found at the northern and southern edges of their range, as described subsequently.

Sex Ratio as a Function of Region and Depth

Methods and Results

For this analysis, we allocated strata to three depth zones (<25 fm; 25-50 fm; >50 fm). This division allocated sex-ratio data into approximately equivalent groups by data richness. Insufficient data were present to achieve a finer division of deeper-water strata. Strata were allocated to five regions: southern New England (we included Georges Bank strata in this grouping), the northern Mid-Atlantic Bight, Delmarva, and the strata south of Cape Hatteras. Finally, data were allocated to half-decadal year-groups: 1976-1980, 1981-1985, 1986-1990, 1991-1995, 1996-2000, 2001-2005, 2006-2007. We excluded all occurrences of age-year group, age-region, and age-depth combinations with sex ratios supported by a total count of males and females less than 30. ANOVAs were run by age using depth, year-group, and region as main effects. All interaction terms were included. Sex was implemented as a dependent variable by assigning a 0 to males and a 1 to females. Means, accordingly, were equivalent to the fraction female.

Table 3. Results of ANOVAs examining the impact of depth, region, and year-group on sex ratios at age. Blank cells indicate insufficient data. NS, non-significant at $\alpha = 0.05$. ×, an interaction term.

Age	Region	Depth	Year Group	Depth × Region	Depth × Year Group	Year Group × Region	Year Group × Depth × Region
0	NS		≤.001			NS	
1	NS	NS	NS	≤.001	NS	NS	0.01
2	0.05	≤.001	≤.001	≤.001	NS	≤.001	0.005
3	NS	0.002	≤.001	NS	NS	NS	0.005
4	≤.001	NS	0.01	NS	0.03	NS	NS
5	≤.001	NS	0.006	NS	NS	NS	NS
6	NS	NS	NS	NS	NS	NS	NS
7	NS	NS	NS	NS	NS	NS	NS

Depth significantly influenced sex ratio in summer flounder, ages 2 and 3 (Table 3). The catch of age-0 fish was insufficient in the deeper depth zones to analyze. Whereas depth was only significant for ages 2 and 3 in the ANOVA, Tukey's studentized range tests identified depth differences in sex ratios for ages 1 through 4. The presence of significant interaction terms, however, limits the interpretation of this *a posteriori* test. For these younger fish, exclusive of age 1, a tendency exists for the sex ratios to be more nearly 50:50 offshore (Figure 2). Age-1 males are distinctly proportionately more common offshore. At ages 5 and older, depth no longer impacts sex ratios significantly in summer flounder.

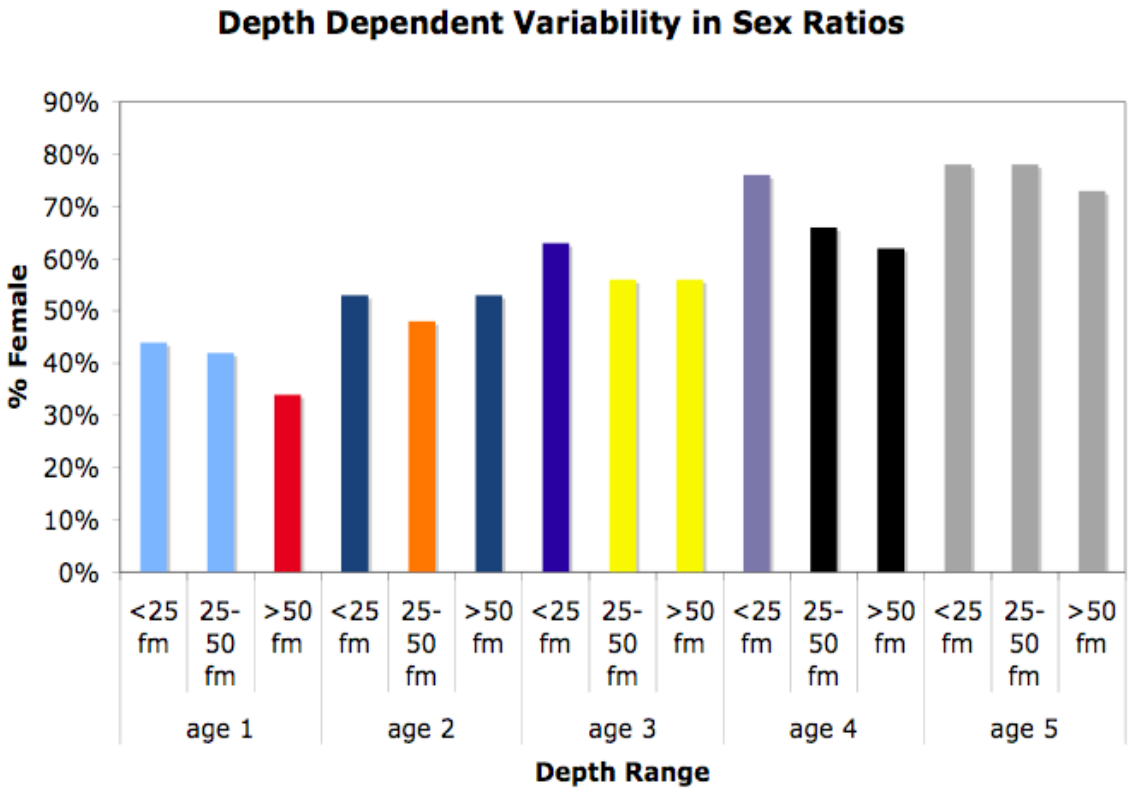

Figure 2. Mean percent female at age by depth. Bars within an age group with the same color were not significantly different in an *a posteriori* Tukey's test. ANOVA results are in Table 3

Sex ratios were significantly affected by region at age 2, but much more so for ages 4 and 5 (Table 3). The switch between depth and region as the dominant main effect between ages 3 and 4 is dramatic and suggests a differential segregation of the stock spatially as the fish age. Interaction terms were routinely significant between main effects for younger ages, but rarely significant after age 3. The change in significant main effect with age and the frequency of significant interaction terms including depth suggests that regionality in summer flounder sex ratios is not facilely explained simply in terms of depth and latitude. Tukey's studentized range tests document the tendency for the northern Mid-Atlantic and Delmarva regions to group together, while one of either the south Atlantic or southern New England regions differed significantly from the central region group (Figure 3). For the cases in which region was a significant main effect, a significantly lower fraction of females occurred in southern New England strata when compared to the Delmarva and northern Mid-Atlantic regions.

Year-group was highly significant for ages 0, 2, 3, 4, and 5. Tukey's studentized range tests clearly indicated a pattern for early years (1976-1980) and later years (2001-2007) to group together and for middle years (1981-1996) to group together (Figure 4). These groupings can be correlated with periods of low and high abundance. Furthermore, periods of lower abundance routinely had higher male ratios than periods of high abundance.

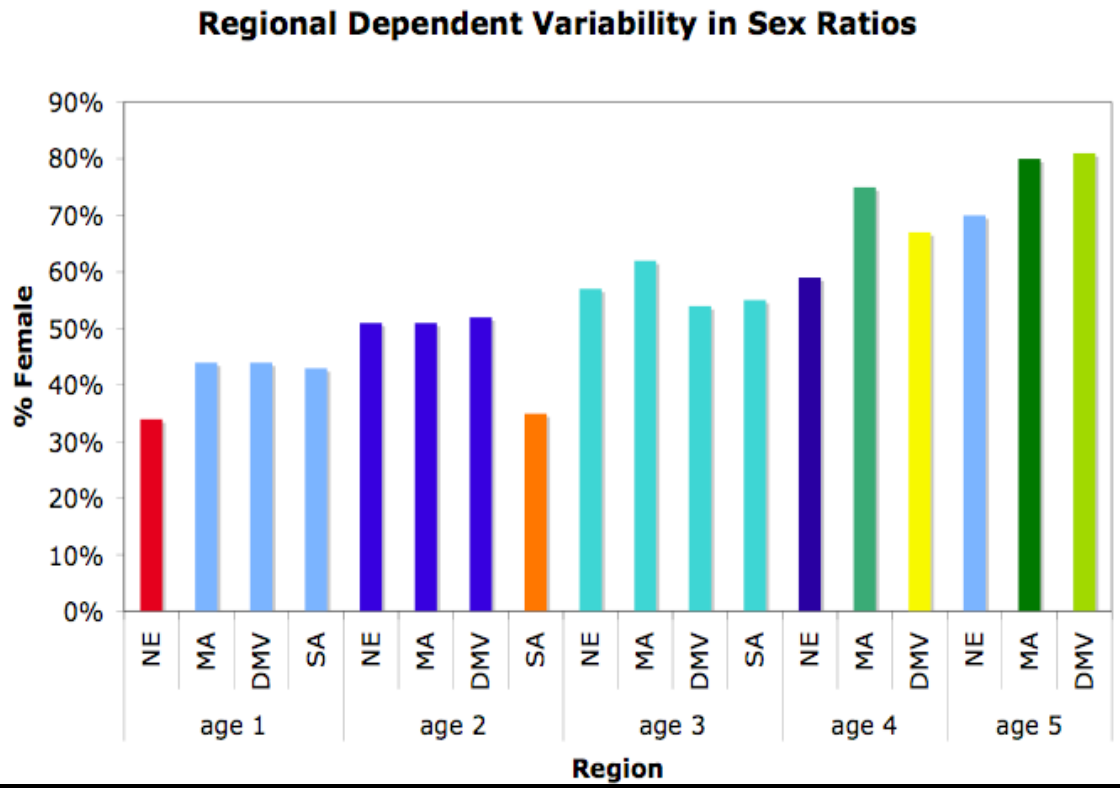

Figure 3. Mean percent female at age by region. Bars within an age group with the same color were not significantly different in an *a posteriori* Tukey's test. ANOVA results are in Table 3. NE, southern New England; MA, northern Mid-Atlantic; DMV, Delmarva; SA, south Atlantic.

Interpretation: Spatial Divergence in Sex Ratio

Examining the regional results for overall trends, it seems that the northern Mid-Atlantic and Delmarva regions have similar sex ratios regardless of age. In addition, the south Atlantic and southern New England regions have a tendency to be different from the Mid-Atlantic/Delmarva grouping, depending on age. When different, the southern New England and south Atlantic regions routinely have a higher fraction of males. This is precisely what would be expected from the temperature-dependent determination of sex that produces an increase in fraction male at the temperature extremes; however, sex determination in the first year of life militates against this explanation as the main effect of region is observed only later. Thus, alternative biological explanations or determinants from differential fishing mortality must be sought. The depth and year-group effects are, as yet, unexplained.

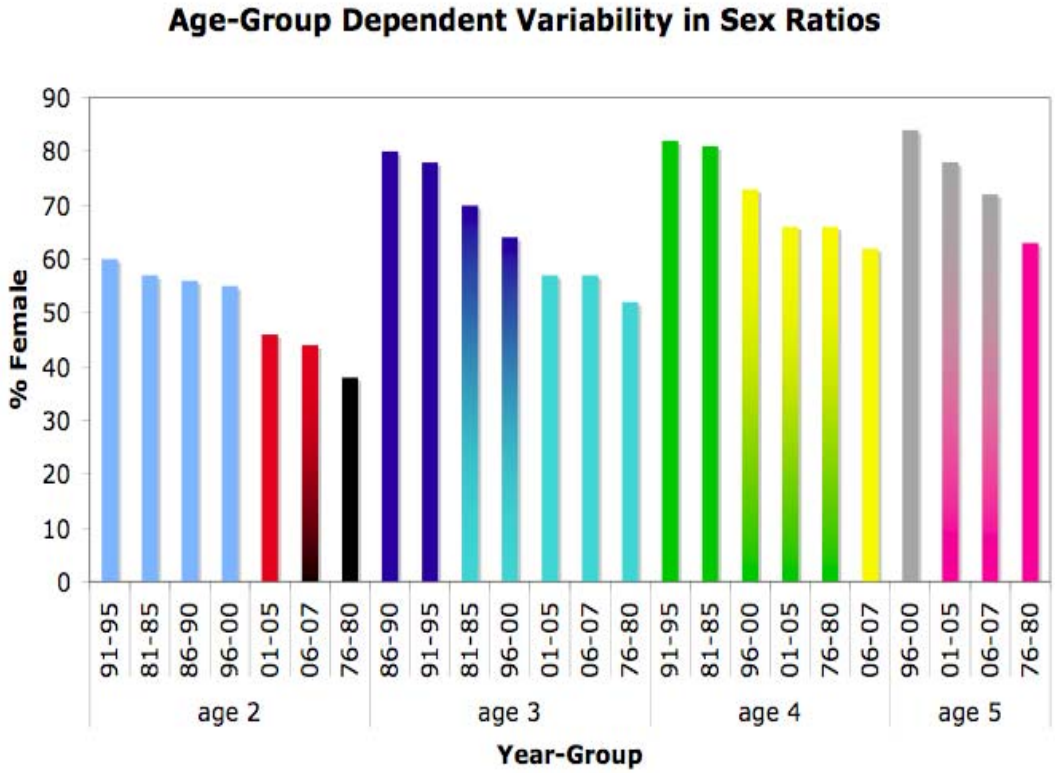

Figure 4. Mean percent female at age by year-group. Bars within an age group with the same color were not significantly different in an *a posteriori* Tukey's test. ANOVA results are in Table 3.

Sex Ratio-imposed Requirement on Relative Mortality Rate

Methods and Results

The gradual shift in sex ratio from male-dominated to female-dominated with increasing age might accrue from differential mortality or differential availability. The latter would seem unlikely, as the trends in sex ratio are consistent across a wide range of age groups.

The differential rate of natural mortality can be directly calculated from the information provided in Table 2. The calculation is based on the following governing equation:

$$N_{1_m} + N_{1_f} = N_{0_m} e^{-Z_m t} + N_{0_f} e^{-Z_f t} \tag{1}$$

where N is abundance of males m or females f, Z is total mortality rate, t is time, and numerals designate consecutive time periods. The equation can be converted to ratio form by dividing through by N_1:

$$1 = \frac{N_{0_m}}{N_1} e^{-Z_m t} + \frac{N_{0_f}}{N_1} e^{-Z_f t} \tag{2}$$

Equation (2) can be solved iteratively under the conditions that the sum of the two terms on the right-hand side closely approximate 1, that $N_{1_m} \le N_{0_m}$, and that $N_{1_f} \le N_{0_f}$.

Table 4. Relative natural mortality rates of male and female summer flounder calculated from the changes in sex ratios with age, by year-group, Delmarva and northern Mid-Atlantic region only, from equation (2).

Year Group	Male (Z_m)	Female (Z_f)
1976-1980	0.46	0.12
1981-1985	0.82	0.42
1986-1990	0.51	0.13
1991-1995	0.53	0.30
1996-2000	0.25	0.22
2001-2005	0.53	0.22
All years	0.62	0.22

Table 4 demonstrates that the change in sex ratio over the lifespan of a cohort requires a differential natural mortality rate, whereby males die at a much faster rate than females. The calculation is robust in measuring the relative mortality rate. The mortality rate for males is often twice that of females. Considering the entire dataset, all years combined, the natural mortality rate for males is about three times the female rate (Table 4). The calculation is less robust in measuring absolute natural mortality rate as any mortality process distributed evenly among the sexes would not impact an estimate based on varying sex ratios. Nevertheless, the female natural mortality rate of 0.22 for all years is remarkably similar to the assumed female natural mortality rate derived from estimates of female lifespan.

Interpretation: Sex-specific Natural Mortality Rate

The change in sex ratio with age requires that male and female summer flounder be modeled separately as far as natural mortality rate. In lieu of a sex-explicit model, a whole stock mortality rate might be employed, although this is less satisfactory. The natural mortality rate, derived thusly, is not linear, however (Table 5). We calculated this age-dependent rate using the equation:

$$Z_{m+f} = -\log\left(\frac{N_{0_m}}{N_{0_{m+f}}}e^{-Z_m t} + \frac{N_{0_f}}{N_{0_{m+f}}}e^{-Z_f t}\right) \quad (3)$$

Equation (3) was employed using age-independent mortality rates for males and females from Table 4, based on the observation of relatively constant mortality with age within sex inferred from Figure 5. Whole-stock natural mortality rates derived thusly vary from 0.45 for young-of-the-year summer flounder to 0.25 for fish age 7 and older (Table 5).

Table 5. Whole-stock mortality rate based on the age-dependency in sex ratio from 1976-2007 and the male and female natural mortality rates reported in Table 4.

Age 0	Age 1	Age 2	Age 3	Age 4	Age 5	Age 6	Age 7
0.447	0.424	0.394	0.362	0.316	0.286	0.262	0.245

A higher natural mortality rate in males could potentially be explained by some type of biological refuge for females. Female summer flounder are known to grow at a faster rate than males and may therefore be less prone to predation (Poole 1961). However, male and female growth rates are similar until age 2, so such an explanation would not be warranted when considering the apparent differential natural mortality in fish younger than age 2.

Some precedent exists for higher morality rates in male relative to female flatfish. Morse (1981) already proposed a higher natural mortality rate for males in summer flounder. Santos (1994) computed natural mortality rates for the four-spot megrim (*Lepidorhombus boscii*) by sex. The natural mortality rate for males was 0.41, and for females 0.34. Pearson and McNally (2005) also calculated mortality rates, using three different methods, for the sand sole, *Psettyichthys melanostictus*. The natural mortality rate for females ranged between 0.35 and 0.45, whereas the mortality rate for males was estimated to fall between 0.40 to 0.60.

Comparison of Age-Length Keys: Relationship of Length at Age with Region and Depth

Methods and Results

Tables 6 and 7 show the results of ANOVAs examining the relationship of depth, region, and year-group on length at age. For these analyses, the dependent variable, length, was ranked. Thus, the analysis is nonparametric. Depth significantly impacted length-at-age for males and females, ages 1 through 3 and age 4 for females. At age 0, summer flounder are only present in shallow waters, and at age 5 and older, depth no longer influences length-at-age, for the most part. Tukey's studentized range tests show that fish in deeper water are larger at a given age than fish in shallower water (Figure 6).

Length at age varied significantly with region for male and female summer flounder, ages 0-4, but not at older ages. Whereas Tukey's Studentized Range tests identified a tendency for some regions to group together at some ages, overall, fish are smaller in the south and get progressively larger at all ages, 0-4, northward (Figure 7). When regions did group together they did so in a north-central, south-central trend. In other words, the southern New England region never grouped with the south Atlantic or Delmarva regions, and the south Atlantic never grouped with the northern Mid-Atlantic and southern New England regions.

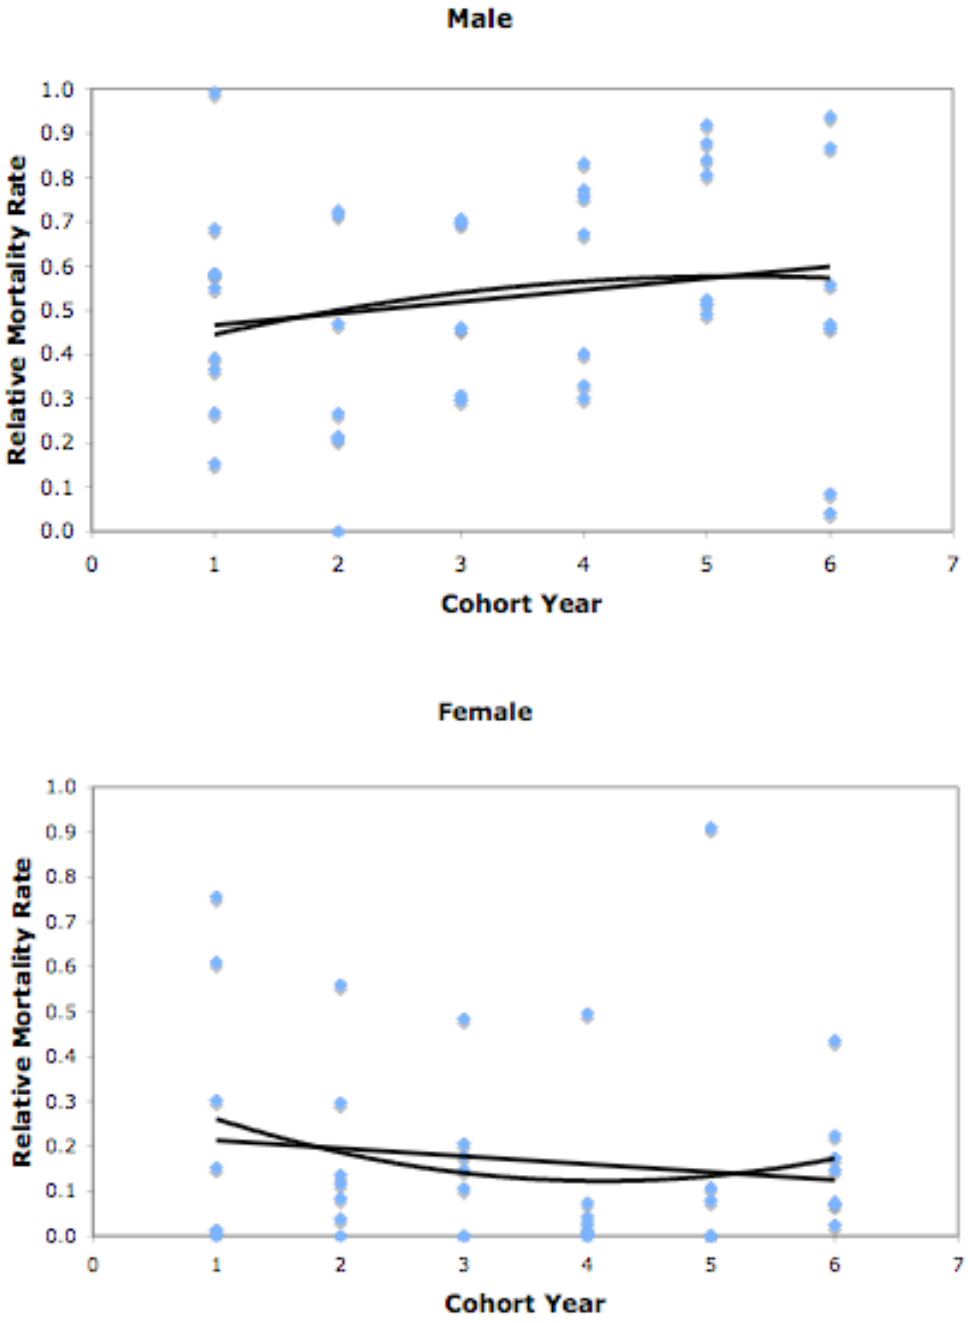

Figure 5. Trends in natural mortality rate by age for male and female summer flounder. Points are values from each of the years from 1976-2006 where sufficient data density permitted the estimate of within-cohort natural mortality rate at age. Neither polynomial nor linear curve fits transit a slope significantly at variance to zero.

Comparison of Age-Length Keys:Relationship of Length at Age with Region and Depth

Methods and Results

Tables 6 and 7 show the results of ANOVAs examining the relationship of depth, region, and year-group on length at age. For these analyses, the dependent variable, length, was ranked. Thus, the analysis is nonparametric. Depth significantly impacted length-at-age for males and females, ages 1 through 3 and age 4 for females. At age 0, summer flounder are only present in shallow waters, and at age 5 and older, depth no longer influences length-at-age, for the most part. Tukey's studentized range tests show that fish in deeper water are larger at a given age than fish in shallower water (Figure 6).

Length at age varied significantly with region for male and female summer flounder, ages 0-4, but not at older ages. Whereas Tukey's Studentized Range tests identified a tendency for some regions to group together at some ages, overall, fish are smaller in the south and get progressively larger at all ages, 0-4, northward (Figure 7). When regions did group together they did so in a north-central, south-central trend. In other words, the southern New England region never grouped with the south Atlantic or Delmarva regions, and the south Atlantic never grouped with the northern Mid-Atlantic and southern New England regions.

Disregarding the influence of fishing mortality on age-at-length, these trends indicate that summer flounder either grow at faster rates in deeper water and northern latitudes or that larger fish at age preferentially aggregate in these regions. Alternatively, in shallow waters and at southern latitudes larger fish may be more accessible to the fishery. While the fishery may not keep younger fish due to minimum size restrictions, younger fish may still be removed by the fishery as discard mortality. Whether it be a biological reason (e.g., differential growth rates) or a fishery-related reason (bigger fish at any age are more accessible in shallow/southern water), it seems clear that the average size of fish at age is larger in deeper/northern water than in shallow/southern water.

However, significant interaction terms also occur commonly in fish 4 years or less in age and these involve both depth and region with relatively equal frequency and intensity. The frequency of significant interaction terms including depth and region suggests that regionality in the trends in age at length for summer flounder cannot facilely be explained simply in terms of depth and latitude. A more complex mixture of biology and, perhaps, relative fishing impact is likely to be required. These trends are remarkably reminiscent of those observed earlier for sex ratio (Table 3).

Table 6. Results of ANOVAs examining the impact of depth, region, and year-group on male length for summer flounder. All regional data were included. Blank cells indicate insufficient data. NS, non-significant at $\alpha = 0.05$. ×, an interaction term.

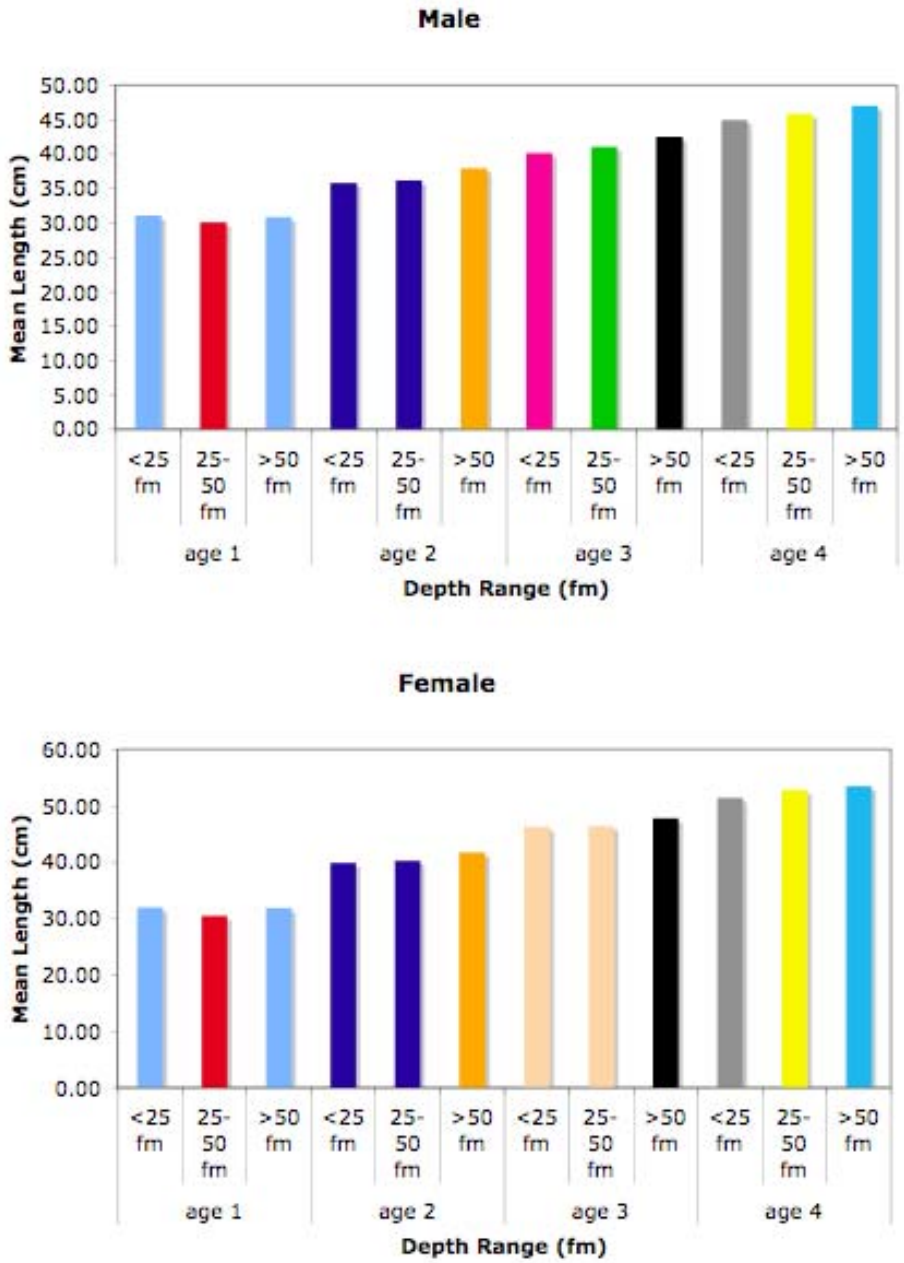

Figure 6. Mean length at age for male and female summer flounder. Bars within an age group with the same color were not significantly different in an *a posteriori* Tukey's test. ANOVA results are in Tables 6 and 7.

.

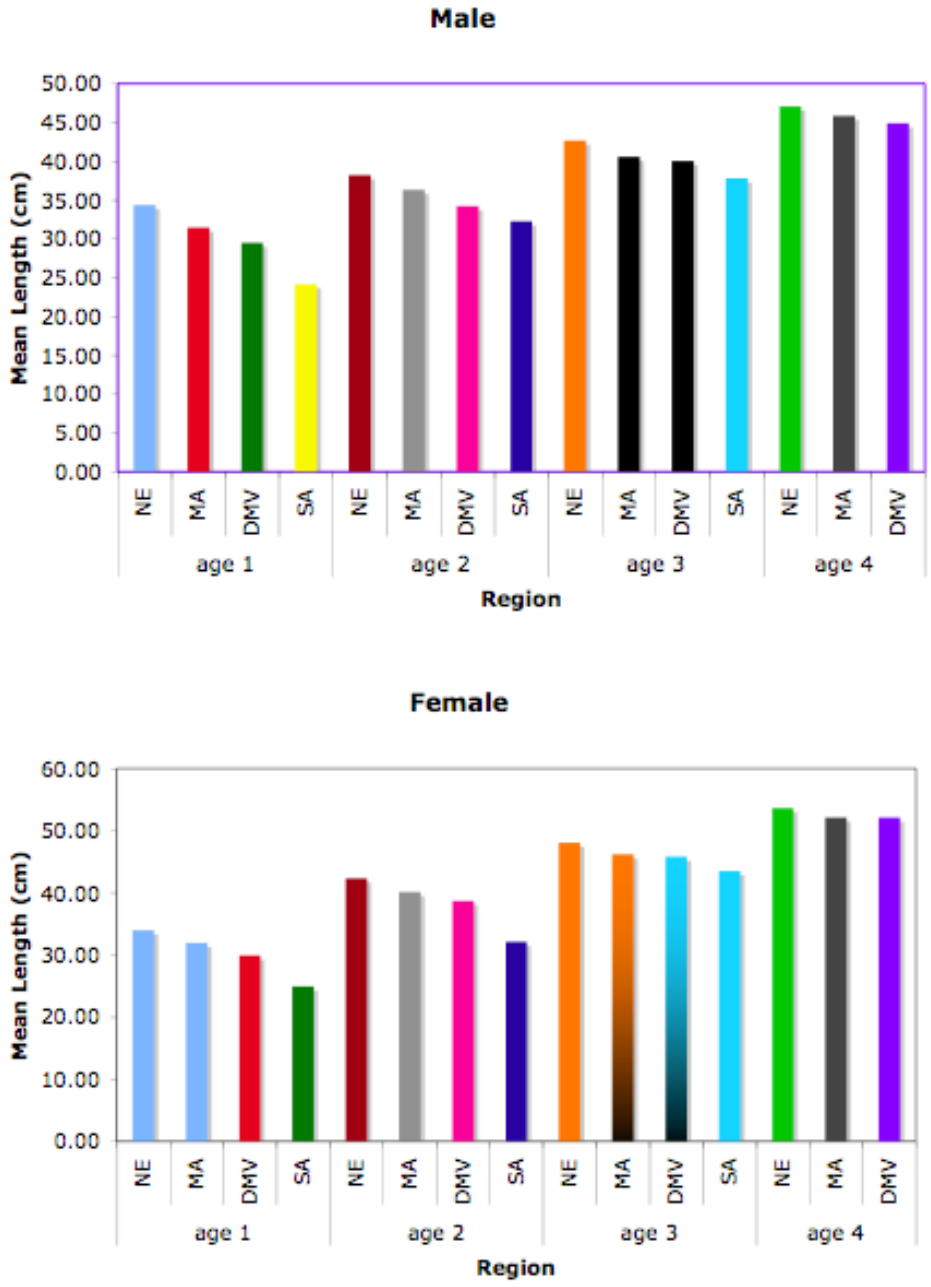

Figure 7. Mean length at age for male and female summer flounder. Bars within an age group with the same color were not significantly different in an *a posteriori* Tukey's test. ANOVA results are in Tables 6 and 7. NE, southern New England; MA, northern Mid-Atlantic; DMV, Delmarva; SA, south Atlantic

Disregarding the influence of fishing mortality on age-at-length, these trends indicate that summer flounder either grow at faster rates in deeper water and northern latitudes or that larger fish at age preferentially aggregate in these regions. Alternatively, in shallow waters and at southern latitudes larger fish may be more accessible to the fishery. While the fishery may not keep younger fish due to minimum size restrictions, younger fish may still be removed by the fishery as discard mortality. Whether it be a biological reason (e.g., differential growth rates) or a fishery-related reason (bigger fish at any age are more accessible in shallow/southern water), it seems clear that the average size of fish at age is larger in deeper/northern water than in shallow/southern water.

However, significant interaction terms also occur commonly in fish 4 years or less in age and these involve both depth and region with relatively equal frequency and intensity. The frequency of significant interaction terms including depth and region suggests that regionality in the trends in age at length for summer flounder cannot facilely be explained simply in terms of depth and latitude. A more complex mixture of biology and, perhaps, relative fishing impact is likely to be required. These trends are remarkably reminiscent of those observed earlier for sex ratio (Table 3).

Year-group consistently affected length at age for male and female summer flounder until age 6. Year-group no longer impacted length at age for male summer flounder at age 6 and older, but continued to do so for female fish. A few trends are clear in both males and females. First, summer flounder averaged much smaller at all ages in the period from 1976-1980 than any other year group. Additionally, year groups including years 1981-1985 and 2006-2007, generally group together as periods where size was smaller at age. Other year-groups are not consistently associated with small or large size-at-age groups. The former groupings are interesting because these periods are associated with relatively high abundance in comparison to the intermediate years. Additionally, a similar trend was noted in the sex ratio analyses.

Tables 8 and 9 repeat the ANOVAs of Tables 6 and 7, but restrict regional coverage to the two central regions, Delmarva and northern Mid-Atlantic. The frequency of significant main effects is much reduced in these ANOVAs relative to the earlier ones, although depth effects in particular continue to be present. Even for depth, significant main effects are less common, as are significant interaction terms, indicating that the central component of the stock offers a more spatially coherent picture than those portions near the northern and southern range limits.

Table 8. Results of ANOVAs examining the impact of depth, region, and year-group on male summer flounder length. Only the Mid-Atlantic and Delmarva regions were included. Blank cells indicate insufficient data. NS, non-significant at $\alpha = 0.05$. ×, an interaction term.

Age	Region	Depth	Year Group	Depth × Region	Depth × Year Group	Year Group × Region	Year Group × Depth × Region
0	≤.001		≤.001			NS	
1	NS	≤.001	≤.001	≤.001	≤.001	NS	NS
2	NS	≤.001	≤.001	NS	≤.001	NS	NS
3	NS	NS	≤.001	0.04	NS	NS	NS

Interpretation: Spatial Variation in Length-at-age

The ANOVAS of Tables 6-9 suggest that a single age-length key is not likely to be representative across all regions and in different depths. Furthermore, the differential with region and depth suggests that differential fishing pressure cannot be excluded as the mechanism generating these differences.

Table 9. Results of ANOVAs examining the impact of depth, region, and year-group on female summer flounder length. Only the Mid-Atlantic and Delmarva regions were included. Blank cells indicate insufficient data. NS, non-significant at $\alpha = 0.05$. ×, an interaction term.

Comparison of Age-Length Keys: Comparison of Key Structure Across Region and Depth

Methods and Results

These analyses focused on the age-length keys for the Delmarva and northern Mid-Atlantic region and, independently, on the three depth zones previously described, as these two regions were most similar in length at age. To compare keys efficiently, lengths were combined into 12 units, the central 10 being 5 cm intervals. Size 12 included fish ≥70 cm and size 1 included fish <20 cm. This yielded three age-length keys for the three depth zones and two for the two regions. Each of these returned a significant result from a by-region or by-depth chi-square test, and from a Cochran-Mantel-Haenszel test controlling for depth or region. Tests were conducted on doubly standardized arrays (columns and rows). These results are anticipated since the ages are not independently distributed with respect to lengths in these keys.

The commonest age at length translates a diagonal from the northwestern to the southeastern corner of the age-length array (age in columns, length in rows). This trend is consistent across keys. A same cell-to-same cell mapping evaluated by a Spearman's rank correlation test on doubly standardized arrays returned a significance level of $P < 0.0005$ or better for each pair-wise comparison (e.g., Delmarva vs northern Mid-Atlantic). This also is expected from the anticipated structure of the keys.

These two standard statistics are described because these approaches, plus the afore-described ANOVAs (Tables 6-9) represent typical statistical treatments of age-length data. None of them answer the query concerning equivalency of the age-length relationship documented by the distribution of ages at length in the two-dimensional array of the key.

To directly compare two keys, we used Geary's C and Moran's I statistics on the set of residuals obtained by calculating the expected key structure in one array from the observed key structure in the other. Each row was standardized, but a column standardization was not performed. Residuals were calculated for each array cell as $expected_{i,j} - observed_{i,j}$ where the expected values were obtained from the first of two paired arrays. The null hypothesis is that the residuals will be randomly distributed in x-y space. A statistical test revealing a non-random pattern in the residuals indicates that some portion of the two arrays under examination differ in the distribution of values among cells; that is, that the age-length relationship differs.

The test statistics were calculated following Cliff and Ord (1973) where:

$$Moran's\ I = \left(\frac{n}{W}\right)\frac{\sum_{i=1}^{n}\sum_{\substack{j=1 \\ i\neq j}}^{n} w_{ij} z_i z_j}{\sum_{i=1}^{n} z_i^2}\ ; \tag{4}$$

$$Geary's\ C = \left(\frac{n-1}{2W}\right)\frac{\sum_{i=1}^{n}\sum_{\substack{j=1 \\ i\neq j}}^{n} w_{ij}(x_i - x_j)^2}{\sum_{i=1}^{n} z_i^2} \tag{5}$$

and

$$W = \sum_{i=1}^{n}\sum_{\substack{j=1 \\ i\neq j}}^{n} w_{ij}\ ; \tag{6}$$

$$z_i = x_i - \bar{x}; \quad (7)$$

$n =$ number of samples; $x_i =$ datum of each sample i; and $w_{ij} =$ a weighting measure as described subsequently. Significance levels were calculated under the assumption of randomization (Jumars et al., 1977).

Calculation of Moran's I or Geary's C is contingent on the mathematical representation of the spatial relationship of the cell values (w_{ij}). We employed a King's moves weighting such that any two cells i and j located in the array at position k,l for i and at positions $k,l+1,\ k,l-1,\ k-1,\ l$, and $k+1,\ l$ for j were given $w_{ij} = 1.0$. For the remainder, $w_{ij} = 0$.

Moran's I is sensitive to the location of extreme departures from the mean ($x_i - \bar{x}$). The expected value of I for spatially randomly distributed samples is $-(n-1)^{-1}$, a number close to zero at high n (Cliff and Ord, 1973). High values of I occur if x_i and x_j are both, much above or much below the mean. Geary's C is sensitive to sample-to-sample variation ($x_i - x_j$). Values above 1.0 indicate negative spatial autocorrelation (i.e., neighboring values less similar than expected by chance), an even distribution. Values below 1.0 indicate positive spatial autocorrelation (i.e., neighboring values more similar than expected by chance), a patchy distribution.

Both statistics are provided; however the question at hand is the relationship of nearest neighbors in the array and thus a strong preference is given to Geary's C as the statistic best evaluating similarity between two age-length arrays.

An important question concerns the incorporation of zeros. The northeastern and southwestern corners of the arrays routinely contain zeros. These paired zeros increase the number of cells and thus bias the statistic in proportion to their importance, as they are a guaranteed characteristic of the array if formulated correctly. An additional concern is singleton zeros, as the residual obtained is less constrained than for cases with paired non-zero values. In our opinion, the most valid approach is to discount paired-zeros only. Results of comparison of three age-length keys for the three depths and two geographic regions are provided in Tables 10 and 11. These comparisons are based on the exclusion of paired-zero cells.

Table 10. Values of Geary's C and Moran's I and significance for the cases in which array cells characterized by paired zeros were excluded. Age-length keys compared were for males only. The first array in each array pair as listed is the parent array used to generate the expected values for the second array. Residuals were calculated for the second array. Significance values are Moran's I over Geary's C $\left(\frac{Moran's\ I}{Geary's\ C}\right)$. NS, not significant. For region, Delmarva was used as the parent array.

Array Pair	Moran's I	Geary's C	Significance
Depth 1 vs. 2	0.182	2.175	$\frac{P < 0.05}{P < 0.005}$
Depth 1 vs. 3	-0.005	2.281	$\frac{NS}{P < 0.005}$
Depth 2 vs. 3	0.164	0.932	$\frac{P < 0.005}{NS}$
Region	-0.090	2.353	$\frac{NS}{P < 0.005}$

Table 11. Values of Geary's C and Moran's I and significance for the cases in which array cells characterized by paired zeros were excluded. Age-length keys compared were for females only. The first array in each array pair as listed is the parent array used to generate the expected values for the second array. Residuals were calculated for the second array. Significance values are Moran's I over Geary's C $\left(\frac{Moran's\ I}{Geary's\ C}\right)$.

NS, not significant. For region, Delmarva was used as the parent array.

Array Pair	Moran's I	Geary's C	Significance
Depth 1 vs. 2	0.056	1.645	$\frac{NS}{P<0.01}$
Depth 1 vs. 3	0.174	1.392	$\frac{P<0.05}{P<0.10}$
Depth 2 vs. 3	0.026	0.890	$\frac{NS}{NS}$
Region	-0.013	1.573	$\frac{NS}{P<0.05}$

The trend with depth is exemplified by Table 12 in which is compared via residuals the arrays for depths 1 (<25 fm) and 3 (>50 fm). A negative residual indicates a higher value in the second array (>50 fm). Consistently, across size groups, the negative residuals occur at older ages indicating that male fish of a given size tend to be older at deeper depths. This is consistent with ANOVA results described earlier in Tables 6-9. Table 13 compares the male arrays for the two regions. In this case, the residual pattern is more complex; however, negative values tend to occur at younger ages for a given size, indicating that males tend to be older at size in the southern portion of the Mid-Atlantic Bight. This is also consistent with ANOVA results.

Table 12. Residual pattern for the comparison of and example age-length relationship in summer flounder males between arrays representing depths 1 and 3.

Length (cm)	Age 0	Age 1	Age 2	Age 3	Age 4	Age 5	Age 6
<20	54.43	-60.76	6.33

Interpretation

The male age-length relationships are more variable over depth and region than the female ones. Probably, this accrues from the higher natural mortality rates for the males which are also probably more variable spatially. The analyses suggest that a single age-length key may not be adequate, particularly for the males. However, comparison of model runs using different age-length keys would be needed to determine whether the observed variations are substantive for stock modeling. Regardless, the analyses again focus on the need to differentiate the two sexes and to investigate a spatially explicit model.

Conclusions and Recommendations

1. Young-of-the-year summer flounder are dominantly male. Sex ratio changes gradually with age such that male frequencies over 0.5 occur infrequently by age 2 and rarely exceed 0.3 by age 4. The biased sex ratio at birth is likely the result of temperature-dependent sex determination (TSD).
2. The age-dependency of sex ratio indicates the need to implement a sex-explicit model for summer flounder. Spatial variation in sex ratio suggests that a single sex-at-age key is not likely to be representative across all regions and in different depths.
3. The change in sex ratio with age also requires that separate natural mortality rates be used for male and female summer flounder stock assessment models. In lieu of a sex-explicit model, a whole stock mortality rate might be employed, although this is less satisfactory. The natural mortality rate, derived thusly, is not linear, but varies from 0.45 for age-0 fish to 0.25 for fish age 7 and older.
4. Higher natural mortality rate in male summer flounder is supported by published information on summer flounder and other flatfish.
5. Spatial variation in length-at-age suggests that a single age-length key is not likely to be representative across all regions and in different depths. The differential with region

and depth suggests that differential fishing pressure cannot be excluded as the mechanism generating these differences.

6. The male age-length relationships are move variable over depth and region than the female ones, but each varies significantly. The analyses suggest that a single age-length key may not adequately describe the stock, particularly for the males.

SUMMARY

In this report, a time series (1982-2006) of age aggregated (ages 1+) F and stock size estimates was derived for summer flounder from 1982 to 2006. A subset of tuning indices that significantly ($P < 0.01$) predicted the converged portion of the flounder time series (1982-2000) was used to project stock sizes for the non-converged portion (2001-2006) where the presence of retrospective bias from ADAPT was shown to systematically overestimate stock size. In addition, overfishing thresholds (Fmsy, Bmsy) were estimated for flounder by dynamic surplus production models. Finally, I examined the hypothesis that flounder stock rebuilding has been recently halted due mainly to enhanced predation and shifts in environmental factors. The stepwise regression analyses revealed that the recreational cpue index and the NEFSC spring trawl index were selected as the best predictors of mean ages 1+ numbers, biomass and SSB from 1982 to 2000. These regression models accounted for 62 to 89% of the variation in abundance over three converged periods (1982-1998, 1982-1999, 1982-2000), and were then used to project recent (2001-2006) ages 1+ abundance in an effort to address systematic retrospective bias during those years. The ADAPT model overestimated ages 1+ abundance by 35 to 50% in most years after 2000. Based on these analyses, the most reliable time series (1982-2006) of flounder abundance and SSB consisted of the converged portion (1982-2000) from ADAPT plus the predicted abundance and SSB estimates from 2001 to 2006 based on the predictive equations. This time series of stock size estimates was used in all subsequent analyses.

Biomass weighted fishing mortality (F) on ages 1+ flounder was high and variable before 1995, ranging from a low of 0.74 in 1994 to a high of 1.88 in 1988. After 1994, ages 1+ fishing mortality rates dropped considerably and remained relatively stable between 0.38 and 0.54. Ages 1+flounder biomass (mt) based on ADAPT was relatively high and stable from 1982 to 1987 at around 25 thousand mt, than flounder biomass dropped quickly to below 16 thousand mt from 1988 to 1994. Thereafter stock biomass began to rise and eventually reached about 30 thousand mt by 2001. Ages 1+ stock biomass remained relatively steady at around 30 thousand mt from 2001 to 2005, but the 2006 biomass level fell by 30% to 23 thousand mt. The dynamic Gompertz production model was a good fit to flounder surplus production data, but the model generated an anomalous residual pattern. As a result, several candidate predators (striped bass, bluefish and spiny dogfish) and

environmental variables (mean annual water temperatures and deviations in the winter NAO index) were added to the Gompertz model in a stepwise regression. Striped bass was the only additional variable selected to the Gompertz model at the $P < 0.02$ level. The extended Gompterz model with striped bass predatory effects explained over 83% of the variability in surplus production and, more importantly, removed the serial residual pattern noted from the original Gompertz model. This extended Gompertz production model was then used to estimate flounder overfishing thresholds (Fmsy, Bmsy). The resulting overfishing threshold (Fmsy) for flounder was 0.64 (80% C.I.: 0.51 to 0.77) and the biomass threshold was 32,500 mt (80% C. I: 25,900-39,200 mt). All of the ages 1+ fishing mortality (FW) rates (biomass weighted) on flounder from 1982 to 1994 exceeded the Fmsy threshold of 0.64, indicating that overfishing had occurred on flounder from 1982 to 1994. However, all subsequent FW estimates were below the Fmsy threshold, suggesting that overfishing was corrected by additional management measures imposed during the early to mid 1990's. Recent (2002-2005) biomass (mt) levels have approached my Bmsy threshold, but the 2006 biomass level of 22,900 mt represented a 30% drop and was well below the Bmsy threshold of 32,500 mt. Since fishing mortality rates (FW) have stabilized below Fmsy since 1995, the recent lack of stock rebuilding is likely due to enhanced striped bass predation and not overfishing. When the dome-shaped Ricker S-R model was fitted to the flounder S-R data, the model converged and the parameter estimates (A, Kp) were highly significant ($P < 0.0001$). However, the residual pattern from the Ricker Model looked almost exactly like the atypical residual pattern exhibited by the asymptotic Beverton-Holt S-R model. When striped bass abundance from 1982 to 2006 was added as a second explanatory variable, the extended Ricker model explained 91% of the recruitment variability, all three parameter estimates (A, Kp, c) were highly significant ($P < 0.0001$), and most importantly, the anomalous residual pattern observed in the basic Beverton-Holt and Ricker S-R models virtually disappeared. These finding are consistent with the Predation Hypothesis, indicating that surplus production and the transmission of age 0 recruits to the adult stock has been recently impeded due to a recent rise in striped bass predation. The management implications of successful stock rebuilding of summer flounder in the presence of rising predatory mortality are discussed.

INTRODUCTION

The most recent stock assessment for summer flounder (Terceiro 2006) concluded that overfishing on the coast-wide stock has occurred since at least 1982. Current (2006) spawning stock biomass based on the 2007 ADAPT (Terceiro 2007) run is about 6% below the biomass threshold, and the current fully recruited fishing mortality rate (F) is about 25% above the current Fmax threshold of 0.28. As indicated by Terceiro (2006), all ADAPT model runs conducted thus far have exhibited a pronounced and systematic retrospective bias for the terminal (most recent year) F and stock size estimates. Although the exact origin of retrospective bias is still unclear (ICES 2002), this problem occurs at some level in nearly all catch-at-age models. The ADAPT model for summer flounder almost always underestimated F and overestimated stock size for fully recruited fish in the last three to five years of the time series by a sizeable amount. Such a large systematic bias greatly confounds our ability to establish conservative quotas on the commercial fisheries and, more importantly, over-inflates the true pace of flounder stock rebuilding toward the SSB threshold of 44,760 mt. Given that the most recent (2002-2006)

biomass estimates from ADAPT have been consistently overestimated, the rate of stock rebuilding since 2002 may be much slower than previously suggested based on output from ADAPT.

The current target and overfishing thresholds for summer flounder are both expressed by an Fmax value of 0.28 based on the Thompson-Bell yield-per-recruit (YPR) model (Terceiro 2006). The threshold Fmax is assumed to be a suitable proxy for Fmsy when the shape of the stock-recruitment relationship is indeterminate. The YPR model assumes no density-dependence and constant age-specific somatic growth and natural mortality rates (M). The notion that Fmax closely approximates Fmsy under most conditions was challenged recently during a review of reference points for summer flounder conducted by the Mid Atlantic Fishery Management Council (MAFMC). Three reports (Gibson 2000; Crecco 2000; Armstrong 2000) from this meeting estimated Fmsy for summer flounder based on stock-recruitment and dynamic surplus production models that assume the presence of density-dependent mortality. All of their findings indicated that the range of Fmsy thresholds (Fmsy: 0.58-0.82) for summer flounder always exceeded the Fmax level of 0.28 used in the current assessment as did the range of Fmsy levels (Fmsy range: 0.45-0.69) reported earlier by Chang and Pacheco (1976). These findings strongly suggest that summer flounder are under some density-dependent control and are thus more resilient to fishing pressure than previously thought.

Over the last seven years, the stock-recruitment (S-R) relationship for flounder has been extensively examined (Terceiro 2000, 2006; Gibson 2000; Crecco 2000). Terceiro (2006) has shown that the residuals from all Beverton-Holt S-R model runs have exhibited a pronounced and consistent serial correlation over time. The residuals were all large and positive from 1983 to 1987, after which nearly all residuals switched to a negative direction. Gibson (2000) also noted a similar residual pattern for the dome-shaped form of the Shepherd (1982) S-R model, indicating that this serial correlation in residuals over time is widespread and not related to the shape of the S-R curve. The other potential cause for serial residuals is that the basic S-R model lacks an additional important explanatory variable such as an environmental or trophic factor. Given the uncertainty and controversy surrounding the effects of retrospective bias in ADAPT on current F and stock biomass, as well as the persistent occurrence of serial residuals from all current flounder S-R models, I argue here that a thorough examination of these issues are needed even if it occurs outside the normal Peer Review process. The need for such a review may appear unwarranted since the last eight flounder assessments have been upheld by Peer Review (Terceiro 2006). Nevertheless, the ramifications of persistent retrospective bias from ADAPT and residual anomalies from S-R models require more attention here and in future Peer Reviews.

In this report, a time series (1982-2006) of age aggregated (ages 1+) F and stock size estimates was derived from 1982 to 2006. The F and stock size estimates were expressed annually as ratios of landings and discards to ages 1+ abundance from the converged portion of the 2007 ADAPT run (Terceiro 2007). A subset of tuning indices that significantly ($P< 0.01$) predicted the converged numbers and biomass time series was then used to project stock sizes estimates for the non-converged portion (2001-2006) of the biomass, stock numbers and spawning stock biomass (SSB) time series. In addition, overfishing thresholds (Fmsy, Bmsy) were estimated for flounder by dynamic surplus production models. Finally, I examined the hypothesis that flounder surplus production and recruitment have recently fallen mainly due to enhanced predation and shifts in environmental factors.

METHODS

Method to Adjust Recent Stock Size for Retrospective Bias

Retrospective bias has been persistent in the most recent (> 2001) flounder abundance estimates from the ADAPT model (Terceiro 2006). In an effort to reduce the impact of retrospective bias, I developed a number of linear least squares predictive models based on the tuning indices and the mean ages 1+ biomass, mean ages 1+stock numbers and spawning stock biomass (SSB) values from the converged portion of the 2007 ADAPT run (Terceiro 2007), where retrospective bias was minimal. Annual mean ages 1+ biomass and SSB are direct outputs from ADAPT, but mean ages 1+ stock numbers are not. To estimate mean stock numbers according to the VPA manual (Alan Seaver, NEFSC pers. comm.), ages 1+ stock size estimates at the beginning of each year from ADAPT was multiplied by the quantity (1-exp (-Zt)/Zt), where Zt is the instantaneous total mortality estimate (numbers weighted) from ADAPT.

My approach involved the use of the Pearson correlation and stepwise regression analyses to relate all ages 1+ tuning indices in weight and number against average ages 1+ biomass, spawning stock biomass (SSB) and average ages 1+ numbers from the converged portion (1982-2000) of the VPA (Tables 1-3). Both the Pearson correlation and Stepwise regression methods were conducted in the Statistical Analysis System (SAS 2002). A subset of tuning indices was selected from this analysis that best predicted (maximum rsquare) stock size within the converged portion of the VPA. Before the predictive equation was accepted, residual diagnostics was performed on each model to determine whether or not serial correlations were evident between model residuals and time (1982-2000). The residuals from each predictive model were linearly regressed against time (years) and a significant serial correlation coefficient ($P < 0.05$) would indicate an abnormal residual pattern. This would indicate that the current model configuration was either incorrect or an additional explanatory variable was missing from the model. In addition, the partial correlation coefficients were examined for each explanatory variable from the stepwise model. If the model accurately predicted ($P < 0.01$) abundance trends over the converged portion and passed the residual test, it was then used to estimate ages 1+ abundance in number, biomass (mt) and SSB for the non-converged portion (from 2001 to 2006) of the time series.

Since the degree of retrospective bias declines backwards in time from the terminal stock estimate, the exact cutoff for the most recent value in the converged time series is somewhat subjective. It is clear that the degree of retrospective bias in the abundance time series diminished sharply prior to 2001. Thus, the time series of ages 1+ abundance and SSB from 1982-2000 was defined as the converged portion. This converged portion was therefore considered to be the most reliable time series of flounder abundance. This allowed the converged portion to be used as an unbiased dependent variable in the stepwise model, against which the tuning indices can be regressed in the stepwise model. The stepwise model was designed to screen out tuning indices that were poorly correlated ($P > 0.05$) to ages 1+abundance. The definition of the 1982-2000 time series of ages 1+ abundance as a time frame with which to ground truth the tuning indices is arbitrary. Retrospective bias in ages 1+ F and stock size was still discernible albeit at a low level as far back as 1998 (Terceiro 2007). As a result, to further examine how the 1982-2000 time frame might affect the choice of informative indices, the Pearson correlation and stepwise analyses were repeated for ages 1+ abundance and SSB from ADAPT for an additional two periods 1982-1998 and 1982-1999.

The theoretical foundation of this regression approach could be questioned by the fact that trawl survey indices were used to directly tune the 2007 ADAPT run. The potential influence of the tuning indices on the trend in ages 1+ abundance over the converged portion of ADAPT should be minimal. The overall trend in flounder abundance within the converged portion (1982-2000) is mainly influenced by the catch-at-age matrix, whereas more recent abundance estimates are mainly affected by trends in the tuning indices (Mohn 1999).The candidate abundance indices used in the Pearson correlation and stepwise regression analyses included 10 trawl survey indices and one additional recreational cpue index that has not been previously used to tune ADAPT (Tables 1 and 2). The trawl indices included ages 1+ number/tow from the 1982-2006 Massachusetts (MA) spring trawl survey, ages 1+ number/tow in the1982-2006 Rhode Island fall trawl survey, ages 1+ number/tow in the 1990-2006 Rhode Island fixed station trawl survey, ages 1+ number from the 1984-2006 Connecticut spring and fall trawl surveys, both ages 1+ number and kg/tow from the1982-2006 NEFSC spring and fall indices, both ages 1+ number and kg /tow from the 1992-2006 NEFSC winter trawl survey, ages 1+ number /tow from the 1989-2006 New Jersey trawl survey, ages 1+ number/tow from 1990 to 2006 for the Delaware trawl survey. A shorter (1990-2006) time series of flounder kg/tow data are also available for the Connecticut spring and fall surveys. At this time, there are no reported biomass (kg/tow) time series for trawl surveys in Massachusetts, Rhode Island, New Jersey and Delaware. A more extensive description of these 10 trawl survey indices is found in the 2006 assessment report (Terceiro 2007).

The new coast-wide recreational cpue index was derived based on a coast-wide recreational catch-effort ratio from 1982 to 2006:

$$RelNt = ATLN / Et. \qquad (1)$$

The coast-wide recreational catch (ATLN) (type A, B1 and B2) in numbers and recreational fishing effort (Et, trips) in equation (1) were based on the private boat sector of the MRFSS annual surveys (Table 1). Flounder catch and fishing effort data were confined to the private boat sector for two reasons. First, the flounder total catch and total effort estimates each year were derived with relatively high precision (proportional CV < 5% of the mean). Second, the private boat sector of the fishery is highly mobile and capable of catching flounder of all sizes throughout their range.

A second time series (1982-2006) of relative abundance indices in weight (RelWt) was also derived as a ratio of recreational catches (A, B1, B2) in weight (RelWt) to fishing effort (Et) (Table 2). The MRFSS has monitored weight (kg) data from only the harvest (A, B1) so weight data from released fish (B2) are not available. As a result, average weight for A, B1 and B2 catches was estimated indirectly as the average weight (kg) per flounder taken from the NEFSC spring and fall surveys from 1982-2006. The average weight (avwt) of a flounder was derived annually from the NEFSC spring and fall surveys as the average kg/tow index divided by the average number/tow index. The resulting weight index (RelWt) for the recreational fishery was expressed annually as the product of the relative abundance index in number (RelNt) and the average weight (avwt) from the spring and fall NEFSC trawl surveys.

The proposed recreational indices for flounder (RelNt and RelWt) are fishery dependent and thus not entirely independent of the total (sport, commercial and discards) coast-wide landings. However, the problem of colinearity between recreational indices and total coast wide landings should be relatively minor for two reasons. First, auto-correlation between the relative abundance

indices (RelNt and RelWt) and total harvest is minimized by the fact that private boat recreational catches (type A, B1 and B2) were used here rather than harvest (type A and B1) to derive the RelNt. The recreational catches are usually three to four times higher each year than the harvest after 1993. Second, in order to derive the recreational indices, the private boat catches (A, B1, B2) in the MRFSS were further divided by private boat fishing effort (Et). Note that the trend in Et from 1982 to 2006 was inversely related ($r = -0.53$, $P < 0.01$) to total coast-wide flounder harvest.

RESULTS

Each of the ages 1+ abundance indices for the three converged periods 1982-1998, 1982-1999 and 1982-2000 was correlated to the corresponding ages 1+ abundance in number and weight (mt) based on ADAPT (Tables 4 and 5). Regardless of the converged time frames (1982-1998, 1982-1999, 1982-2000), ages 1+ number/tow from the NEFSC spring and winter surveys, as well as the Massachusetts, Rhode Island and Delaware surveys were poorly ($P > 0.05$) correlated to ages 1+ stock size in number from the three converged portions (Table 4). The Rhode Island fixed station survey and Connecticut fall survey of ages 1+ abundance were significantly correlated ($P < 0.03$) to the 1982-2000 and 1982-1999 abundance estimates but not to ages 1+ abundance from the 1982-1998 period. All of the other surveys (NEFSC fall, Connecticut spring, New Jersey and the coast-wide recreational cpue (RelNt) were significantly ($P < 0.05$) correlated to ages 1+ abundance across the three converged periods. However, recreational cpue in number was consistently the most highly ($P < 0.0001$) correlated index to ages 1+ abundance across the three converged periods.

Results of the correlation analyses for biomass (Table 5) revealed that the NEFSC winter biomass indices were poorly correlated to ages 1+ biomass from the converged portions, whereas the Connecticut spring and fall indices were significantly ($P < 0.05$) correlated to ADAPT biomass from 1982 to 1999 and 1982-2000, but not for the period 1982-1998. The NEFSC spring and fall biomass (kg/tow) indices and the recreational cpue index in kg (RelWt) were highly correlated ($P < 0.05$) to ages 1+ biomass across the three converged periods (Table 4). The recreational index (RelWt) always exhibited the highest correlation ($P < 0.0001$) to ages 1+ abundance across the three converged periods.

Ages1+ biomass (mt) from the converged portion (1982-2000) was highly correlated ($P < 0.0001$) to spawning stock biomass (SSB). The correlation matrix (Table 5) indicated that all biomass indices except the NEFSC winter survey were significantly correlated to SSB levels from 1982 to 2000. As in the other comparisons, the recreational cpue (RelWt) was the most highly correlated ($P < 0.0001$) time series to the SSB for the converged portion (1982-2000).

Results from the stepwise regression that related ages 1+ abundance from the converged portion to the tuning indices revealed that the recreational cpue index was the only index selected as the best predictor of mean ages 1+ numbers, accounting for 62 to 68% of the variation in abundance over the three converged periods (1982-1998, 1982-1999, 1982-2000) (Table 6). None of the ten trawl survey indices were selected as a second predictor variable from the stepwise regression. The predictive equation that explained 68% of the variation in abundance from 1982-2000 (Figure 1) was:

$$\text{PredN} = 5.28 + 26.38 * \text{RelNt} . \quad (2)$$

The resulting residual pattern from equation (2) was random over time (P <0.15) (Figure 2), indicating that this predictive model was unbiased and a reliable predictor of abundance at least from 1982-2000. As a result, this model was used to predict ages 1+ flounder abundance from 2001 to 2006 in an effort to adjust recent ages 1+ abundance for systematic retrospective bias. Severe overestimation of ages 1+ stock size from ADAPT was clearly evident in recent years (2001-2006) (Figure 3). The lowest systematic bias occurred in 2001 (23.7%) and highest took place in 2003 (53.9%). The percentage bias for ages 1+ abundance was 50.5% in the terminal (2006) year. The most reliable time series (1982-2006) of ages 1+ abundance was considered to be the converged portion (1982-2000) of ages 1+ abundance from ADAPT plus the predicted ages 1+ abundance estimates from 2001 to 2006 based on equation (2).

Results from the stepwise regression of ages 1+ biomass (mt) from the converged portion and the tuning indices revealed that the recreational cpue index in weight (RelWt) and the NEFSC spring index (kg/tow) were together the best predictors of ages 1+ biomass for the three converged periods (1982-1998, 1982-1999, 1982-2000), each accounting for 87 to 88% of the variation (Table 6). The partial correlation coefficients were always much higher for the recreational cpue (0.77-0.80) than for the NEFSC spring indices (0.09-0.11). The predictive equation for the converged period 1982-2000 was:

$$\text{PredW} = 4.30 + 4.94^{*}\ \text{NEFSC} + 23.10^{*}\ \text{RelWt}, \quad (3)$$

which explained 88% of the variation in ages 1+ stock biomass from 1982-2000 (Figure 4). A plot of residuals was random (P <0.60) across the time series (Figure 5), indicating that the predictive model (equation 3) was unbiased. As a result, this model was used to predict ages 1+ flounder biomass from 2001 to 2006 in an effort to adjust ages 1+ biomass for retrospective bias (Figure 6). The percentage bias between the ADAPT stock biomass and the predicted (PredW) biomass from equation (3) was relatively low (1.5%) in 2001, but the bias generally increased in magnitude over time to the highest (45.5%) level in 2006, indicating that the terminal stock biomass estimate is severely overestimated by ADAPT. The most reliable time series (1982-2006) of ages 1+ biomass for further analyses was the converged portion (1982-2000) of ages 1+ biomass from ADAPT plus the predicted ages 1+ biomass estimates from 2001 to 2006 based on equation (3). This biomass time series was used in all subsequent surplus production modeling.

Stepwise regression analyses of SSB (mt) relating the converged portion of ADAPT to the tuning indices also revealed that the recreational cpue index in weight (RelWt) and the NEFSC spring index (kg/tow) were the best predictors of flounder SSB for the 1982-2000 period (Table 6), accounting for 79% of the variation in SSB (Figure 7). The partial correlation coefficient was much higher for the recreational cpue (0.67) than for the NEFSC spring indices (0.11). The predictive equation for SSB over the converged period 1982-2000 was:

$$\text{PredSSB} = 4.40 + 5.90^{*}\ \text{NEFSC} + 19.26^{*}\ \text{RelWt}. \quad (4)$$

The residuals based on the difference between observed and predicted SSB (PredSSB) were random (P <0.17) across the time series (Figure 8), indicating that the predictive model (equation 4) was unbiased. As a result, this model was used to predict flounder SSB from 2001 to 2006 in an effort to adjust SSB for retrospective bias (Figure 9). The percentage bias between the ADAPT stock biomass and the predicted (PredW) biomass from equation (4) was relatively low (-5.8%) in 2001, but the bias generally rose in magnitude over time to the highest (47.3%)

level in 2006. Based on this analysis, the most reliable time series (1982-2006) of flounder SSB for further analyses was the converged portion (1982-2000) of SSB from ADAPT plus the predicted SSB estimates from 2001 to 2006 based on equation (4) (Table 3). This SSB time series was used in all subsequent stock-recruitment analyses.

Approach to Estimate ages 1+ F and Surplus Production

In this analysis, age aggregated (ages 1+) fishing mortality (Ft) was derived annually on summer flounder from 1982 to 2006. The theoretical underpinnings of our approach is based on a simple re-arrangement of the Baranov catch equation (Ricker 1975, page 13, equation 1.17) with respect to F:

$$F = \text{Catch} / \text{Mean Stock Size}, \quad (5)$$

where: mean stock size is typically expressed as the average stock size in years t and t+1. The ages 1+ Ft estimates were based on the ratio of ages 1+ coast-wide (commercial and sport plus discards) landings (numbers) of flounder in year t (Catcht) to the corresponding ages 1+ abundance estimates (Nt, Nt+1) in year t and t+1:

$$Ft = Catcht / [(Nt + Nt+1)/2], \quad (6)$$

where: Nt and Nt+1 are the flounder ages 1+ abundance estimates from the converged portion (1982-2000) of ADAPT whereas Nt values from 2001 to 2006 represent the predictive values (equation 2). The landings and discards (Catcht, n*1000) of ages 1+ flounder (Table 2) in the numerator of equation (6) were derived earlier in the 2007 stock assessment (Terceiro 2007). Equation (6) is very similar to the equation introduced earlier by Sinclair (1998) except that he estimated relative exploitation:

$$Relu = Catch/ RelNt \quad (7)$$

instead of F. Because the 2007 abundance estimate (Nt) is not yet available, the Nt+1 value a year later in 2006 was assumed to be the same as the 2006 Nt abundance estimate. Ages 1+ F estimates via equation (6) do not consider temporal and spatial shifts in the age structure, so this approach is designed only to monitor age aggregated F values across time (1982-2006). Thus, the Ft values are uninformative about year-class and age-specific changes in F over the time series. However, since Ft estimates from equation (6) are expressed as a ratio of annual harvest to average abundance, the trend in ages 1+ F is not confounded by the assumption of constant natural mortality (M = 0.2) used explicitly to derive F estimates (F = Z – 0.2) in ADAPT and in other catch-age models.

Another time series (1982-2006) of biomass weighted F estimates for ages 1+ flounder was estimated from 1982 to 2006 as a ratio of ages 1+ landings and discards (mt) to the average ages 1+ biomass estimates in year t (Biot) and t+1 (Biot+1). As with the other analysis, Biot and Biot+1 represent the flounder ages 1+ biomass estimates from the converged portion (1982-2000) of ADAPT whereas the Biot estimates from 2001 to 2006 were derived from the predictive equation (equation 3).

A time series (1982-2006) of surplus production estimates in year t (SURPt) was also derived for flounder. As in Jacobson et al (2002), the SURPt values were expressed each year by subtracting flounder biomass in year t (BIOt) from the biomass in year t+1 (BIOt+1), and then adding the coast-wide harvest and discards (mt) (catcht):

$$SURPt = BIOt+1 - BIOt + Catcht. \quad (8)$$

Overfishing Thresholds (Fmsy, Bmsy)

Surplus production estimates have been used to monitor trends in per capita stock productivity for many exploited finfish populations (Jacobson et al 2002).). Having a time series (1982-2006) of flounder surplus production (SURPt) (Table 7) and stock biomass estimates in year t (Biot) (Table 7), updated Fmsy and Nmsy thresholds were estimated for flounder using the dynamic version of the Gompertz external surplus production model (Quinn and Deriso 1999; Jacobson et al 2002). Like stock-recruitment models, the theoretical foundation of production models assumes the existence of compensatory density-dependent mortality for finfish populations, a position widely held by most fish population ecologists (Wahle 2003). We selected the Gompertz form over the more widely used logistics equation because Yoshimoto and Clarke (1993) reported that under simulation conditions, the Gompertz model produced more realistic (positive) and stable overfishing thresholds than the logistics model. In the asymmetrical Gompertz model, surplus production estimates (SURPt) from 1982-2006 were regressed against biomass (Biot) and the product of the log flounder biomass and biomass (LogBiot*Biot) in a two variable linear regression model without a y-axis intercept:

$$SURPt = a*Biot + b * ((LogBiot)*Biot), \quad (9)$$

where: K – theoretical carrying capacity (mt) = exp (a / b);
MSY- maximum sustainable yield (mt) = (-b * K)/2.72;
Bmsy – stock size (mt) at MSY = K / 2.72;
Fmsy – instantaneous fishing mortality at MSY= MSY / Bmsy;
Fcoll – instantaneous fishing mortality at stock collapse = Fmsy *2.72.

Our ability to estimate precise Fmsy and Bmsy values in surplus production models are often plagued by the presence of outliers caused by moderate to high measurement errors. To minimize the effects of outliers, the Gompertz model (equation 9) was fitted as a linear robust regression model using the least trimmed squares regression (LTS) objective function as recommended by Rousseeuw and Van Driessen (2000). The parameter estimates (a, b) and resulting reference points (Fmsy, Bmsy, Fcoll) from the dynamic production model (equation 9) were derived from the ROBUSTREG procedure contained in the Statistical Analysis System (SAS 2002). The parameter estimates (a, b) and their standard errors based on least squares (LS) are highly prone to the presence of outliers. With robust linear regression like LTS, outlying observations are identified and automatically down-weighted, resulting in higher precision and greater overall stability of the parameter estimates (a, b) over those derived from ordinary least squares.

Before the overfishing thresholds (Fmsy, Bmsy) were estimated via equation (9), the pattern of residuals was examined for the presence of serial correlations over time. The residuals from an unbiased model should be distributed randomly over time. By contrast, a significant ($P < 0.05$) correlation between residuals and time (1982-2006) would indicate model misspecification. A serial correlation occurs when the residuals are all in one direction during say the first half of the time series then they switch abruptly in the opposite direction thereafter. This anomalous residual pattern could be due to an incorrect configuration of the production model (i. e. Logistics versus Gompertz), or perhaps, the model lacks an important explanatory variable. If the parameter estimates (a, b) of the model are statistically significant ($P <0.05$), and if the residual pattern from the model exhibited no serial correlation, the model was considered unbiased and used to estimate overfishing (Fmsy, Bmsy) thresholds.

To examine the hypothesis that flounder surplus production has recently been eroded by trophic and environmental factors, candidate predators such as striped bass, bluefish and spiny dogfish abundance (pred term) were included in the production model as an extra independent variable (Table 3). In addition, environmental variables such as annual mean water temperature and deviations in the winter North Atlantic Oscillation (NAO) index (environ term) from 1981 to 2006 (Table 3) were also added to the external production model:

$$SURPt = a*Biot + b * ((LogBiot)*Biot)+ c*(Pred\ of\ Environ), \qquad (10)$$

in a stepwise regression fashion. Since all female flounder reach sexual maturity by age 2 (Almeida et al 1992), water temperature and winter NAO values were lagged t-1 and t-2 years to coincide with flounder recruitment to the adult stock. Environmental disturbances have been proposed as a major process structuring ecological systems (Hollowed et al 2000), both by causing direct mortality and by changing the carrying capacity of the ecosystem. Bluefish, striped bass and spiny dogfish are major inshore finfish predators that have recently risen sharply in abundance along the Atlantic coast. Moreover, these finfish predators overlap the spatial and temporal distribution of flounder, and all are considered, to some extent, as potential candidate predators on flounder (Roundtree 1999). Striped bass is regarded as a voracious predator from the Mid and North Atlantic on menhaden, gizzard shad and herring (Hartman 1993). Larger (> 70 cm) striped bass, however, have been reported to switch their prey preference from herring and small menhaden to spot, flounder and weakfish in Chesapeake Bay (Hartman and Brandt 1995; Walter and Austin 2003). Bluefish (Pomatomous saltatrix) also prey upon a variety of finfishes including flounder throughout the Atlantic coast (Bowman et al 2000). Dogfish (Squalus acanthias) are found coast-wide and are regarded as a primary finfish predator of juvenile summer flounder (Rountree 1999).

Statistical evidence consistent with the predation hypothesis would be evident if the slope (c) for predation effects in equation (10) was negative and statistically significant ($P <0.05$). This would imply that enhanced predation has eroded flounder surplus production independent of fishery effects. Moreover, if the slope for predation effects is significant, the inclusion of the extra predation term in the model can greatly enhance the precision around the (a) and (b) parameters of equation (10), thus allowing more precise estimates of Fmsy and Bmsy thresholds. To test for potential joint effects of fishing (F) and trophic interactions on flounder productivity, residual plots against time were examined for the presence of serial correlations. Further statistical support for the predation hypothesis would exist, if the pronounced serial correlation

evident in the basic production model (equation 9) should disappear following the addition of predation effects to the model (equation 10).

Annual changes in coast-wide striped bass abundance (ages 7+) in numbers (Table 3) have been monitored annually from 1988 to 2006 by the ratio of ages 7+ harvest to the tag-based F derived from the catch equation approach (Versak 2007). In addition, a time series (1982-2006) of ages 8+ striped bass abundance has been derived recently from the Statistical Catch-at-Age model (Nelson 2007). Annual changes in spiny dogfish and bluefish from 1982 to 2006 were indexed here as cpue based on the coast-wide recreational catches in number (A, B1, B2) and coast-wide effort (trips) from the private boat fishery in the MRFSS surveys (Table 3). These trends in coast-wide recreational cpue of dogfish and bluefish were assumed to be informative about coast-wide changes in these stocks from 1982 to 2006. A time series (1982-2006) of average annual surface water temperatures was taken from a continuous temperature recorder in Long Island Sound located at the Millstone Nuclear Power Station, Waterford CT. Annual deviations in the winter NAO indices from 1982 to 2006 were taken from the NOAA web site.

Stock-Recruitment Effects

Over the last seven years, the stock-recruitment (S-R) relationship for flounder has been extensively examined (Terceiro 2000, 2006; Gibson 2000; Crecco 2000). Terceiro (2006) has argued that the asymptotic Beverton-Holt S-R model should be chosen over the parabolic Ricker S-R model based on theoretical grounds, despite the fact that the parabolic model was a better fit to stock-recruitment data (Gibson 2000). Terceiro (2006, 2007) has repeatedly shown that the residuals from all Beverton-Holt S-R model runs have exhibited a persistent serial correlation over time. The residuals were all high and positive from 1983 to 1987, then nearly all subsequent residuals switched to a negative direction. Since Gibson (2000) noted a similar anomalous residual pattern when flounder S-R data were fitted to the dome-shaped form of the Shepherd (1982) S-R model, this serial residual pattern is widespread and not related directly to the shape of the S-R curve. The other potential cause for the serial correlation in residuals is that the basic S-R model may lack an additional important explanatory variable such as environmental or predatory effects.

In this report, the shape and residual pattern of the flounder stock-recruitment relationship was further explored with the flexible Shepherd (1982) S-R model:

$$Rec = A * SSB / (1 + (SSB/ Kp)^{**}b), \quad (11)$$

where: A = the magnitude of compensatory reserve;

Kp = the flounder spawning stock biomass (mt) at which compensatory effects dominate;

b = the degree of compensatory density-dependent mortality;

Rec = estimated age 0 recruits from the most recent ADAPT run (Terceiro 2007) (Table 3);

SSB = estimated SSB from the converged portion (1982-2000) of ADAPT plus predicted SSB from the stepwise model from 2001-2006 (Table 3).

If the b parameter estimate in equation (11) is less than 1.0, the curve approximates a power function. If (b) is equal to 1.0, the S-R curve is consistent with the asymptotic Beverton-Holt model, whereas a (b) estimate greater than 1.0 is consistent with the parabolic Ricker type S-R curve. The entire time series (1982-2006) of flounder recruitment (Rec) based on the 2007

ADAPT run (Terceiro 2007) was fitted to equation (11) because Terceiro (2006) has shown that the degree of retrospective bias on recent recruitment estimates from ADAPT was relatively small. In order to explore the residual patterns from the Beverton-Holt and Ricker type S-R models, the S-R data were fitted to equation 11 holding the (b) parameter constant at 1.0 and 2.0, respectively. The remaining parameter estimates (A, Kp) from the S-R model (equation 11) were derived from the NLIN procedure (marquardt algorithm) contained in the Statistical Analysis System (SAS 2002).

Given the likely presence of outliers in the S-R data, the Shepherd S-R model was fitted as a nonlinear robust regression using the iterative reweighted least squares method outlined by Holland and Welsch (1978). The algorithm and rationale for this approach is described in SAS (2002). This re-weighting scheme is designed to detect outliers, thereby allowing the down weighting of S-R data from certain years in the model where model residuals, regardless of direction, exceeded a previously defined threshold level. As indicated by Holland and Welsch (1978), the choice of a threshold is subjective and always represents a trade-off between minimizing the variances around the parameters (A, Kp) and at the same time generating globally converged parameter estimates. As suggested by Holland and Welsch (1978), a range of threshold estimates was used initially and the final threshold value was selected that satisfied the trade-off between global convergence of all parameter estimates and parameter estimates with maximum precision and minimum variance. The two-step re-weighting approach always produced converged estimates (global estimates) that were within 10% of the parameter estimates (A, Kp) derived by the nonlinear least squares approach. However, the standard errors about the estimates based on iterative re-weighting were always 30 to 45% lower than the standard errors from the least squares method.

To examine for potential predatory and environmental effects on flounder recruitment and on the residuals from the S-R model, the Shepherd S-R model (equation 11) included an extra exponent (c) reflecting potential predation (pred) and environmental (environ) effects:

$$Rec = A * SSB / (1 + (SSB/ Kp)^{**}b) * \exp(c*pred, environ). \quad (12)$$

As in the surplus production analyses, candidate predators (pred) included striped bass, bluefish and spiny dogfish abundance (Table 3) were added separately to the model. Potential environmental variables (environ) included annual water temperature and deviations in the winter North Atlantic Oscillation (NAO) index. Statistical evidence consistent with the predation and environmental hypotheses would exist if the additional exponent (c) for predation and environmental effects in equation (12) was negative and statistically significant ($P < 0.05$). This would imply that biotic and abiotic factors external to the fishery have reduced recent age 0 recruitment over time. Further statistical support for the predation and environmental hypotheses would be evident, if the serial correlation in residuals evident in the basic Shepherd S-R model (equation 11) disappeared following the addition of predation or environmental effects to the S-R model (equation 12).

RESULTS

Ages 1+ Fishing Mortality (F) and Surplus Production (SURPt)

Ages 1+ fishing mortality estimates (FN) (catch weighted) were derived from 1982 to 2006 as the ratio of total annual landings (including discards) to average (t, t+1) ages 1+ abundance (Table 7). These FN estimates on ages 1+ flounder were high and variable before 1995, ranging from a low of 0.74 in 1982 to a high of 2.22 in 1988 (Figure10). After 1994, ages 1+ fishing mortality rates dropped considerably and remained relatively stable at around 0.50 thereafter.

Ages 1+ abundance in number from ADAPT was relatively high from 1982 to 1984, than flounder abundance fell quickly to the lowest level in the time series at 9.5 million fish in 1989 (Table 7, Figure 10). Ages 1+ abundance rose steadily after 1988 to a peak abundance of 33 million fish in 2000. Note that ages 1+ flounder stock sizes from 2001 to 2006 were predicted from equation 2 in order to adjust for retrospective bias from ADAPT. These predicted biomass levels fell slightly after 2000 and remained relatively stable thereafter at around 25 million fish.

Ages 1+ fishing mortality (FW) (biomass weighted) on flounder were again high and variable before 1995 (Table 7), ranging from a low of 0.74 in 1994 to a high of 1.88 in 1988 (Figure 11). Biomass weighted FW levels on ages 1+ flounder dropped steadily from 1994 through 2002 to below 0.38, but FW levels rose slightly thereafter to a peak of 0.54 in 2006.

Ages 1+flounder biomass (mt) based on ADAPT was relatively high and stable from 1982 to 1987 at around 25 thousand mt, than flounder biomass dropped quickly to below 16 thousand mt from 1988 to 1994 (Table 7, Figure 11). Thereafter stock biomass began to rise and eventually reached about 30 thousand mt by 2001. Ages 1+ stock biomass remained relatively steady at around 30 thousand mt from 2001 to 2005, but the 2006 biomass level fell by 30% to 23 thousand mt. Note that stock biomass from 2001 to 2006 was predicted by equation 3 in order to adjust for severe retrospective bias from ADAPT.

Surplus production (SURPt) estimates (mt) for flounder were derived via equation 8 from 1982-2006 (Table 7, Figure 12). Surplus production was highest during the early to mid-1980's despite the presence of high fishing mortality (F) rates (Figures 10 and 11). SURPt levels did fall steadily after 1986, presumably due to high fishing mortality, to the lowest level in the time series in 1990. SURPt levels for flounder increased by 20 to 30% after 1991 but never recovered to the pre 1987 levels despite the presence of relatively low and steady fishing mortality from 1997 to 2006 (Figures 10 and 11).

Overfishing Thresholds (Fmsy, Bmsy)

To estimate overfishing thresholds (Fmsy, Bmsy), flounder surplus production estimates from 1982 to 2006 (Figure 12) were fitted to flounder biomass via the Gompertz dynamic production model (equation 9). The Gompertz model accounted for 80% of the variation in surplus production and the parameter estimates (a, b) were determined with high precision (Table 8). However, the plot of model residuals indicated a severe ($P < 0.01$) serial correlation over time (Figure 13), indicating model misspecification. The residuals were large and positive from 1982 to 1986, then the residuals for most years shifted in the opposite direction. Even when the Logistics form of the surplus production model was used instead of Gompertz , the same serial residual pattern persisted over time, indicating that the residual problem was not due to the

configuration of the production model. Due to the clear residual problem with the basic Gompertz and Logistics models, they were not used to estimate overfishing thresholds for flounder.

Since a serial residual pattern persisted in the basic (equation 9) production model, the environmental-dependent form of the Gompertz model (equation 10) was used in the linear stepwise regression model with potential explanatory variables such as striped bass, bluefish and spiny dogfish, mean annual water temperature and winter NAO. The stepwise model selected striped bass abundance (either tag-based or SCAM estimates) as the only negative and significant ($P < 0.01$) explanatory variable (Table 9). No other variables were chosen at the $P < 0.05$ level.

When this extended production model was fitted to the robust regression procedure, all parameters (a, b, c) estimates were highly significant ($P < 0.0001$) (Table 8). This production model with striped bass effects explained 83% of the variation in flounder surplus production from 1982-2006. Moreover, the serial residual pattern present in the basic production model virtually disappeared (Figure 14) ($P < 0.49$) when striped bass abundance was added as a second variable to the production model. These findings are consistent with the Predation Hypothesis, indicating that flounder productivity has recently been eroded by enhanced striped bass predation.

This extended production model with striped bass predatory effects was then used to estimate flounder overfishing thresholds (Fmsy, Bmsy). The resulting overfishing threshold (Fmsy) for flounder was 0.64 (80% C.I.: 0.51 to 0.77) and the biomass threshold was 32,500 mt (80% C. I: 25,900-39,200 mt) (Table 8). All of the ages 1+ fishing mortality (FW) rates (biomass weighted) on flounder from 1982 to 1994 exceeded the Fmsy threshold of 0.64 (Figure 16), indicating that overfishing had occurred on flounder from 1982 to 1994. However, all subsequent FW estimates were below the Fmsy threshold, suggesting that overfishing was corrected by additional management measures imposed during the early to mid 1990's. By contrast, although ages 1+ biomass (mt) has risen steadily since 1989 (Figure 15), except for the 2001 ages 1+ stock biomass of 33,900 mt, all other ages 1+ biomass estimates have remained below the estimated Bmsy threshold of 32, 500 mt (Figure 16). Recent (2002-2005) biomass levels have approached the Bmsy threshold, but the 2006 biomass level of 22,900 mt represented a 30% drop and is well below the Bmsy threshold of 32,500 mt. Since fishing mortality rates (FW) have stabilized below the Fmsy threshold since 1995, the recent lack of stock biomass growth is likely due largely to enhanced striped bass predation and not overfishing.

Stock –Recruitment Effects

The Beverton-Holt version ($b = 1.0$) of the Shepherd S-R (equation 11) model was fitted to age 0 recruitment and spawning stock biomass (mt) estimates (Table 3) from 1982-2006 using iterative reweighted least squares regression. The S-R model converged but the parameter estimates (A, Kp) did not differ significantly ($P < 0.05$) from zero (Table 10, Figure 17). Moreover, the residual plot over time indicated the presence of significant ($P < 0.0005$) serial correlation in the residuals (Figure 18). The residuals were large and positive from 1982 to 1987 then the residuals became smaller and mostly negative (Figure 17), indicating model misspecification.

When the Ricker version ($b = 2.0$) of the S-R model was fitted to the S-R data (Table 3), the model converged and the parameter estimates (A, Kp) were highly significant ($P < 0.0001$)

(Table 10, Figure 19). However, the residual pattern from the Ricker Model (Figure 20) looked almost exactly like the atypical residual pattern from the Beverton-Holt S-R model. When bluefish and dogfish abundance, as well as lagged (t-1, t-2) mean annual temperature and lagged winter NAO were added separately to the extended Ricker model (equation 12), the resulting exponent (c) for each of these variables did not differ significantly ($P < 0.05$) from zero. However, when striped bass abundance was added as a second explanatory variable, the model explained 91% of the recruitment variation, all three parameter estimates (A, Kp, c) were highly significant ($P < 0.0001$) (Table 10, Figure 21) and, most importantly, the anomalous residual pattern seen in the basic Beverton-Holt and Ricker S-R models virtually disappeared (Figure 22). These finding are consistent with the Predation Hypothesis, indicating that the transmission of age 0 recruits to the adult stock has been recently impeded due to enhanced striped bass predation.

Management Implications and Scientific Advice

My results indicate that density-dependent processes play a much greater role in stabilizing flounder abundance than is assumed in the current stock assessment (Terceiro 2006). The main conclusion from the last stock assessment (Terceiro 2006) is that flounder have been overfished since at least 1982 despite the implementation of catch quotas on commercial fisheries beginning in 1990 and a steady decline in fishing mortality (F) since 1995. The current assessment results show that flounder stock biomass has not yet reached the biomass threshold of 44,760 mt because F has remained too high. The important conclusion from the last assessment that summer flounder have remained overfished for at least 25 years largely depends on the degree of compensatory density-dependent mortality inherent to the flounder stock. It is widely recognized that the magnitude of Fmsy and the level of resilience to exploitation depends on the degree of density-dependent compensation (Quinn and Deriso 1999). The current assessment has assumed that little if any compensation occurs for flounder and therefore used an Fmax of 0.28 from the YPR model as a proxy for Fmsy. In this report, Fmsy was estimated directly to be 0.64 based on the extended Gompterz model that assumes moderate to high density-dependent compensation. My findings indicate that the flounder were overfished before 1995 when ages 1+ F estimates exceeded my Fmsy, but that extensive management measures imposed during the early to mid 1990's enabled F to drop below the overfishing threshold. The very strong fit of both the production and dome-shaped Ricker models suggests that moderate to strong density-dependent mortality is evident in the summer flounder stock, allowing the flounder stock to absorb the effects of relatively high ($F < 0.64$) fishing mortality. My findings of moderate to high density-dependent compensation for summer flounder is consistent with their suite of life history traits that include early female maturation (age 2) (Almeida et al 1992), relatively rapid somatic growth and a relatively short lifespan (12 years) (Dery 1988). My Fmsy threshold of 0.64 is well within the range of Fmsy levels reported from four earlier studies (Chang and Pacheco 1976; Gibson 2000; Crecco 2000; Armstrong 2000). They reported Fmsy thresholds (Fmsy: 0.45-0.82) for summer flounder that always exceeded the Fmax level of 0.28 used in the current assessment, and were clearly closer to my Fmsy estimate of 0.64 based on the Gompertz production model. These earlier findings are consistent with my results, suggesting that summer flounder are under at least partial density-dependent control and are thus more resilient to fishing pressure than previously thought.

The possibility for further rebuilding of summer flounder biomass beyond the Bmsy level of 32,500 mt over the next five years is more uncertain due to the recent rise in predatory mortality. My findings indicate that the rapid build-up in stock biomass inferred from 2001 to 2006 based on ADAPT is overstated due to persistent retrospective bias. When the recent (2001-2006) abundance estimates from ADAPT were adjusted downward by 20 to 50% to account for retrospective bias, the rate of stock rebuilding after 2000 was minimal. My results suggest that enhanced predation by striped bass on young flounder provides the most plausible explanation for the recent stagnation of flounder population growth and age 0 recruitment to the adult stock. Moreover, the inclusion of striped bass effects in both the extended Ricker S-R and Gompertz models was the only variable examined thus far that removed the recurring residual problem that constantly plagued the Beverton-Holt S-R model in previous assessments (Terceiro 2006). The fact that the exponent for striped bass predation was negative and highly significant ($P < 0.0001$) in both the extended Ricker S- R and Gompertz surplus production models is not surprising, given that annual changes in age 0 recruitment largely govern the net changes in fish surplus production (Walters and Martell 2004).

It is widely recognized that statistical evidence (regression and production models) alone does not demonstrate causality, but recent empirical evidence is wholly consistent with the Predation Hypothesis involving striped bass. Due to the success of striped bass management, striped bass abundance has risen steadily to record levels in mid and north Atlantic coastal waters from 1993 to 2006 (Crecco 1994; Nelson 2007). The results of coast-wide tagging of striped bass since 1987 indicate that abundance of ages 7+ stripers has risen nearly four-fold coast-wide from 1998 to 2006 (Versak 2007). Moreover, coast-wide tag returns from Maine to North Carolina indicate that striped bass are found mostly in state waters (Versak 2007) that clearly overlap the temporal and spatial distribution of summer flounder. Since striped bass are known to consume finfish prey up to 60% of their own body length (Manooch 1973), it is reasonable to hypothesize that striped bass abundance has reached such high abundance that flounder population growth would be severely impeded by enhanced striped bass predation. Larger (> 70 cm) striped bass have been reported to switch their prey preference from herring and small menhaden to spot, flounder and weakfish in Chesapeake Bay (Hartman and Brandt 1995; Walter and Austin 2003). Striped bass grow rapidly to a large size (>90 cm) that can easily prey on smaller adult flounder, are highly piscivorous (Hartman 1993), and are efficient diurnal and nocturnal predators along inshore waters (Nelson et al 2006). Recent studies on river herring and American shad in the Connecticut River (Savoy and Crecco 2004), as well as the coast-wide weakfish stock assessment (Kahn et al 2005; Uphoff 2005) concluded that enhanced striped bass predation was the most reasonable hypothesis to explain the unexpected declines of these finfishes under low exploitation. Nelson et al (2006) reported that the average consumption level (mt) of Altantic menhaden by striped bass along the Massachusetts coast from 1997 to 2000 was 12 times greater than the total menhaden commercial landings (mt) from Massachusetts. Finally, Bax (1998), in a comprehensive review of finfish predatory effects, noted that finfish predation accounts for between 2 and 35 times the finfish losses (mt) reported annually to commercial fisheries throughout the world.

The management implications and long-term prognosis for flounder in the presence of enhanced striped bass predation are challenging and somewhat ambiguous. In the current assessment (Terceiro 2006), natural mortality (M) in both the ADAPT and YPR models was assumed constant at 0.20 for all ages and years. It is widely recognized from recent multispecies models (Hollowed et al 2000; Walters et al 2005) that the scientific foundation supporting the

constant M assumption in single species assessments is highly questionable, particularly for younger fish. Moreover, unless long-term tagging studies are conducted, there is no other way to scientifically verify the assumption of a fixed M estimate. Despite the lack of scientific foundation around the fixed M assumption, the constant M approach is used in nearly all single species assessments conducted along the Atlantic coast. The wide acceptance of constant M occurs because time varying M is often difficult to estimate with confidence, and because a constant M assumption greatly reduces the number of parameters to be estimated in age structured VPA models. The constant M assumption implies that no systematic shifts in finfish mortality and productivity associated with predation, inter-specific competition and environmental effects are possible. Thus, the constant M assumption greatly limits our ability to explore for enhanced predation effects that may result in a systematic rise in M particularly among younger and smaller prey, as well as temporal shifts in environmental factors that can adversely affect recruitment, somatic growth and maturation. Since the choice of a fixed M value can greatly affect the magnitude of the Fmax reference point, more detailed analyses are therefore required to determine whether or not M has change systematically over time due to enhanced predation and shifts in environmental variables. In future flounder stock assessments, the assumption that trophic and environmental effects are constant over time should be critically examined. The potential impacts of trophic and environmental effects on summer flounder should also be integrated into fisheries models and rigorously tested as a potential alternative hypothesis to the Overfishing Hypothesis.

The highly significant exponent (c) for striped bass predation from the extended Ricker S-R and Gompertz models is consistent with the presence of enhanced density-independent mortality although, under certain conditions, enhanced finfish predation can give rise to compensatory or even depensatory density-dependent mortality (Tsou and Collie 2001). In any event, increased predation should result in a systematic rise in M, particularly for smaller flounder. This phenomenon plus the apparent emergence of a flounder recruitment bottleneck between ages 0 and 1 makes stock rebuilding of flounder via further management measures an exceedingly difficult task. As indicated by Spencer and Collie (1997), fish stocks that are subject to moderate to severe predatory mortality, often undergo a sudden and persistent drop or prolonged stagnation in recruitment and surplus production over time even when fishing mortality rates have remained low for several years. Note that biomass weighted fishing mortality (FW) on ages 1+ flounder reported here have been below my estimated Fmsy threshold of 0.64 since 1995. If density-independent predation remains high, flounder recruitment and biomass may remain unresponsive to favorable climatic events and to further fishery management restrictions. The phenomenon of enhanced predation mortality could lead to a persistent stagnation in future flounder rebuilding unless predation pressure reverts back to pre 1998 levels.

There is a prevailing consensus that overfishing has had an adverse effect on many fish stocks throughout the world (Myers et al 1997; Hutchings and Reynolds 2004; Scheffer et al. 2001). However, the catch-at-age models traditionally used to estimate fishing mortality over time have almost always assumed a low and constant (M = 0.20) natural mortality rate. Under the assumption of low and constant M, a rise in total mortality (Z) over time is always construed as a rise in fishing mortality (F). Thus in nearly all single species assessments, projection models always predict rapid stock rebuilding following sizeable reductions in F. But if the wide-spread assumption of constant M is violated and M actually rises systematically over time due to enhanced predatory mortality, the results from projection models of rapid stock rebuilding would

be highly misleading. Clearly there are finfish stocks throughout the world where natural mortality (M) approximates 0.20 for some period of time or can otherwise vary without trend. But as shown here for flounder and elsewhere for American shad (Savoy and Crecco 2004) and weakfish (Kahn et al 2005; Uphoff 2005), a systematic rise in predatory mortality on age 0 flounder coupled with relatively low and stable fishing mortality (F) can either greatly extend the timetable for rebuilding, or can simply eliminate the likelihood of any stock rebuilding even after the imposition of stringent conservation measures. A similar case study linking a rise in natural mortality to the lack of stock rebuilding has been recently addressed for Northern cod stocks (Shelton et al 2006). Several cod stocks on the Grand Banks have been under a landings moratorium since 1996, but stock rebuilding of these depleted stocks has, as of 2006, not been realized. Shelton et al (2006) reported that the lack of stock rebuilding of eight cod stocks was attributed to a recent rise in natural mortality from 0.2 prior to 1990 to 0.4 to 0.8 due mainly to enhanced gray seal (Halichoerus grypus) predation. In the case of summer flounder, the probability of successful stock rebuilding via management intervention is reduced further by the emergence of a recruitment bottleneck at age 0 as indicated by results from the extended Ricker S-R model. Due to recent increases in the minimum size on flounder, age 0 flounder are now only slightly susceptible to direct harvest, so a coast-wide moratorium would have little if any impact on the recently emergent recruitment bottleneck.

Table 4. Pearson Correlation (r) Analyses between relative abundance (catch/tow) of each of the 11 candidate tuning indices and ages 1+ flounder abundance over the converged portion from ADAPT. This analysis was conducted on ages 1+ abundance over three converged time periods (1982-1998, 1982-1999, 1982-2000). An asterisk (*) indicates a statistically significant ($P < 0.05$) correlation between the ages 1+ tuning index and ages 1+ abundance.

Table 6. STEPWISE REGRESSION MODEL relating the 11 tuning indices to ages 1+ numbers, ages 1+ biomass and SSB for the three converged time periods (1982-1998, 1982-1999, 1982-2000). Flounder ages 1+ abundance, biomass and SSB from ADAPT were used as dependent variables. Independent variables selected by the stepwise model at the P < 0.05 level were the recreational cpue in number (RelNt) and weight (RelWt) and the NEFSC spring index in kg/tow (NMFSSk). The parameter estimates (Est) and their standard error (SE) are give as well as the coefficient of determination (r**2).

Table 8. Parameter estimates (a, b, c) for summer flounder derived from the Gompertz external production model with and without striped bass predation. The overfishing thresholds (F_{msy}, B_{msy}) were derived from the Gompertz model with striped bass effects. The models were fitted to the LTS Robust regression model. The standard error (SE) is given for each parameter estimate (a, b, Strip), as well as the coefficient of determination (r^2). Overfishing thresholds (F_{msy}, B_{msy}) are presented with 80% CI.

LTS Robust Regression Model Without Striped Bass

Parameter	Mean	SE	P
a	8.05	1.08	< 0.0001
b	-0.74	0.11	< 0.0001
r^2	0.80		

LTS Robust Regression With Striped Bass Effects

Parameter	Mean	SE	P
a	7.29	1.01	< 0.0001
b	-0.64	0.10	< 0.0001
c**	-1.36	0.34	<0.0001
r^2	0.83		

Threshold	Mean	80% Confidence Limit
F_{msy}	0.64	0.51 – 0.77
Fcoll	1.74	1.39 – 2.09
Bmsy	32,500 mt	29,900 – 39,200 mt

** c is the slope estimate for striped bass effects

TABLE 9. Stepwise model relating the abundance of three candidate predators (bluefish, striped bass and spiny dogfish) and two environmental variables (t and t-1 lagged mean annual water temperature and deviations in the winter NAO) to surplus production from the Gompertz Production model. The stepwise model selected striped bass abundance (SCAM based) as the only significant (P <0.02) explanatory variable. The standard error (SE) is given for each parameter estimate (a, b, c), as well as the coefficient of determination (r^2).

Least Squares Fit

Parameter	**Mean**	**SE**	**P**
a	7.84	1.20	< 0.0001
b	-0.70	0.12	< 0.0001
c**	-1.04	0.42	< 0.02
r^2	0.85		

** c is the slope estimate for striped bass effects

Table 10. Shepherd S-R Parameter estimates (A, Kp, c) for summer flounder with and without striped bass predation. The S-R models were fitted by nonlinear iterative re-weighted least squares regression. The shape parameter (b) was fixed at 1.0 for the Beverton-Holt model and at 2.0 for the dome-shaped Ricker model. The approximate standard error (SE) is given for each parameter estimate (a, Kp, Strip), as well as the coefficient of determination (r^2).

	Beverton-Holt			**Ricker**		
Parameter	**Mean**	**SE**	**P**	**Mean**	**SE**	**P**

 -- Non-Linear Least Squares Fit --

 Default Tolerances Used

 Scaled Gradient Tolerance      =    6.055454E-06
 Scaled Step Tolerance          =    3.666853E-11
 Relative Function Tolerance    =    3.666853E-11
 Absolute Function Tolerance    =    4.930381E-32

 VPA Method Options

 - Catchability Values Estimated as an Analytic Function of N
 - Catch Equation Used in Cohort Solution
 - Plus Group Backward Calculation Method Used
 - Rivard Weights Used for JAN-1 Biomass
 - Rivard Weights Calculation Used  3 Years for Terminal Year Plus One

 - Heincke Rule Used in F-Oldest Calculation
 - F-Oldest Calculation in Years Prior to Terminal Year
   Uses Stock Sizes in Ages  3 to  6
 - Calculation of Population of Age 0 In Year 2007
   =  CDF Using First Age Populations
      Year Range Applied =  1982 to  2005

 Stock Estimates
