Risk and Exposure Assessment to Support the Review of the SO_2 Primary National Ambient Air Quality Standards: Second Draft

EPA-452/P-09-003
March 2009

Risk and Exposure Assessment to Support the Review of the SO_2 Primary National Ambient Air Quality Standards: Second Draft

U.S. Environmental Protection Agency
Office of Air Quality Planning and Standards
Research Triangle Park, North Carolina

Disclaimer

This draft document has been prepared by staff from the Ambient Standards Group, Office of Air Quality Planning and Standards, U.S. Environmental Protection Agency. Any opinions, findings, conclusions, or recommendations are those of the authors and do not necessarily reflect the views of the EPA. This document is being circulated to obtain review and comment from the Clean Air Scientific Advisory Committee (CASAC) and the general public. Comments on this draft document should be addressed to Michael Stewart, U.S. Environmental Protection Agency, Office of Air Quality Planning and Standards, C504-06, Research Triangle Park, North Carolina 27711 (email: stewart.michael@epa.gov)

Table of Contents

List of Tables

List of Figures

List of Acronyms/Abbreviations

A/C	Air conditioning
AER	Air exchange rate
AERMOD	American Meteorological Society (AMS)/EPA Regulatory Model
AHS	American Housing Survey
APEX	EPA’s Air Pollutants Exposure model, version 4
ANOVA	One-way analysis of variance
ANPR	Advanced Notice of Proposed Rulemaking
AQS	EPA’s Air Quality System
AQCD	Air Quality Criteria Document
AS	Asthma symptoms
BRFSS	Behavioral Risk Factor Surveillance System
C	Cough
CAA	Clean Air Act
CAMD	EPA’s Clean Air Markets Division
CASAC	Clean Air Scientific Advisory Committee
CDC	Centers for Disease Control
CHAD	EPA’s Consolidated Human Activity Database
Clev/Cinn	Cleveland and Cincinnati, Ohio
CMSA	Consolidated metropolitan statistical area
CO	Carbon monoxide
COPD	Chronic Obstructive Pulmonary Disease
COV	Coefficient of Variation
C-R	Concentration-Response
CTPP	Census Transportation Planning Package
EDR	Emergency department visits for respiratory disease
EDA	Emergency department visits for asthma
EDAC	Emergency department visits for asthma – children
EPA	Environmental Protection Agency
HAAC	Hospital admissions for asthma - children
ER	Emergency room
EPA	United States Environmental Protection Agency
EOC	Exposure of Concern
FEV_1	Forced expiratory volume in the first second
GM	Geometric mean
GSD	Geometric standard deviation
GST	Glutathione *S*-transferase (e.g., GSTM1, GSTP1, GSTT1)
ID	Identification
ISA	Integrated Science Assessment
ISH	Integrated Surface Hourly Database
km	Kilometer
L95	Lower limit of the 95th confidence interval
LOEL	Lowest Observed Effect Level
m	Meter

max	Maximum
ME	Microenvironment
med	Median
min	Minimum
MSA	Metropolitan statistical area
NAAQS	National Ambient Air Quality Standards
NAICS	North American Industrial Classification System
NCEA	National Center for Environmental Assessment
NEI	National Emissions Inventory
NEM	NAAQS Exposure Model
NCDC	National Climatic Data Center
NHAPS	National Human Activity Pattern Study
NHIS	National Health Interview Survey
NO_2	Nitrogen dioxide
NO_x	Oxides of nitrogen
NWS	National Weather Service
NYC	New York City
NYDOH	New York Department of Health
O_3	Ozone
OAQPS	Office of Air Quality Planning and Standards
OR	Odds ratio
ORD	Office of Research and Development
ORIS	Office of Regulatory Information Systems identification code
POC	Parameter occurrence code
ppb	Parts per billion
PEN	Penetration factor
PM	Particulate matter
ppm	Parts per million
PRB	Policy-Relevant Background
PROX	Proximity factor
PVMRM	Plume Volume Molar Ratio Method
REA	Risk and Exposure Assessment
RECS	Residential Energy Consumption Survey
RIU	Rescue inhaler use
RR	Relative risk
SAS	Statistical Analysis Software
SB	Shortness of breath
SES	Social-economic status
SIC	Standard Industrial Code
SD	Standard deviation
Se	Standard error
SO_2	Sulfur dioxide
SO_3	Sulfur trioxide
SO_4^-	Sulfate
SO_x	Oxides of Sulfur
sRaw	Specific airway resistance
tpy	Tons per year

TRIM	EPA’s Total Risk Integrated Methodology
U95	Upper limit of the 95th confidence interval
UARG	Utility Air Regulatory Group
US DOT	United States Department of Transportation
US EPA	United States Environmental Protection Agency
USGS	United States Geological Survey

1.0 INTRODUCTION

The U.S. Environmental Protection Agency (EPA) is presently conducting a review of the primary, health based national ambient air quality standards (NAAQS) for sulfur dioxide (SO_2). Sections 108 and 109 of the Clean Air Act (The Act) govern the establishment and periodic review of the NAAQS. These standards are established for pollutants that may reasonably be anticipated to endanger public health and welfare, and whose presence in the ambient air results from numerous or diverse mobile or stationary sources. The NAAQS are to be based on air quality criteria, which are to accurately reflect the latest scientific knowledge useful in indicating the kind and extent of identifiable effects on public health or welfare that may be expected from the presence of the pollutant in ambient air. The EPA Administrator is to promulgate and periodically review, at five-year intervals, primary (health-based) and secondary (welfare-based) NAAQS for such pollutants. Based on periodic reviews of the air quality criteria and standards, the Administrator is to make revisions in the criteria and standards and promulgate any new standards as may be appropriate. The Act also requires that an independent scientific review committee advise the Administrator as part of this NAAQS review process, a function now performed by the Clean Air Scientific Advisory Committee (CASAC).

The first step in the SO_2 NAAQS review was the development of an integrated review plan. This plan presented the schedule for the review, the process for conducting the review, and the key policy-relevant science issues that would guide the review. The final integrated review plan was informed by input from CASAC, outside scientists, and the public. The integrated review plan for this review of the SO_2 primary NAAQS was presented in the Integrated Review Plan for the Primary National Ambient Air Quality Standard for Sulfur Dioxide (EPA, 2007a). This document was made available to the public on October 9, 2007 and can found at: http://www.epa.gov/ttn/naaqs/standards/so2/s_so2_cr_pd.html.

The second step in this review was a science assessment. A concise synthesis of the most policy-relevant science was compiled into an Integrated Science Assessment (ISA). The ISA was supported by a series of annexes that contained more detailed information about the scientific literature. The final ISA to support this review of the SO_2 primary NAAQS was presented in the Integrated Science Assessment for Oxides of Sulfur - Health Criteria, henceforth referred to as the ISA (EPA, 2008a). This document was made available to the public in

September 2008 and can found at: http://www.epa.gov/ttn/naaqs/standards/so2/s_so2_cr_pd.html.

The third step in this primary SO_2 NAAQS review is a risk and exposure assessment (REA) that describes exposures and characterizes risks associated with SO_2 emissions from anthropogenic sources. The plan for conducting the risk and exposure assessment to support the SO_2 primary NAAQS review was presented in the Sulfur Dioxide Health Assessment Plan: Scope and Methods for Exposure and Risk Assessment, henceforth referred to as the Health Assessment Plan (EPA, 2008b). This document was made available to the public in November 2007 and can be found at: http://www.epa.gov/ttn/naaqs/standards/so2/s_so2_cr_pd.html. The first draft SO_2 REA was informed by comments from the public and CASAC on the Health Assessment Plan, as well as the 1st and 2nd drafts of the ISA for SO_x. The first draft SO_2 REA developed estimates of human exposures and risks associated with recent ambient levels of SO_2 and levels that just met the current SO_2 standards. This first draft REA document was made available to the public in July 2008 and can be found at: http://www.epa.gov/ttn/naaqs/standards/so2/s_so2_cr_rea.html

The second draft SO_2 REA is this document and it has been informed by comments from CASAC and the public on the first draft REA, as well as findings and conclusions contained in the final ISA. This document develops estimates of human exposures and risks associated with: (1) recent ambient levels of SO_2, (2) levels that just meet the current SO_2 standards, and (3) levels that just meet potential alternative standards: defined in terms of indicator, averaging time, form, and level. This document also contains a policy assessment that will address the adequacy of the current SO_2 NAAQS and of potential alternative standards. More specifically, this policy assessment considers epidemiological, human exposure, and animal toxicological evidence presented in the ISA (EPA, 2008a), as well as the air quality, exposure, and risk characterization results presented in this document, as they relate to the adequacy of the current SO_2 NAAQS and potential alternative primary SO_2 standards (see Figure 1-1). This 2nd draft REA is to be followed by a final REA. The final REA will be informed by comments from CASAC and the public on the 2nd draft REA, as well as findings and conclusions contained in the final ISA.

The final step in the review of the SO_2 NAAQS will be the rulemaking process. This process will be informed by the risk and exposure information contained in the final REA, as well the scientific evidence described in the final ISA. The rulemaking process will also take into account CASAC advice and recommendations, as well as public comment on any policy options under consideration. Notably, EPA is now under a consent decree to complete its review of the SO_2 primary NAAQS by issuing a proposed rule no later than November 16, 2009 and a final rule by June 2, 2010.

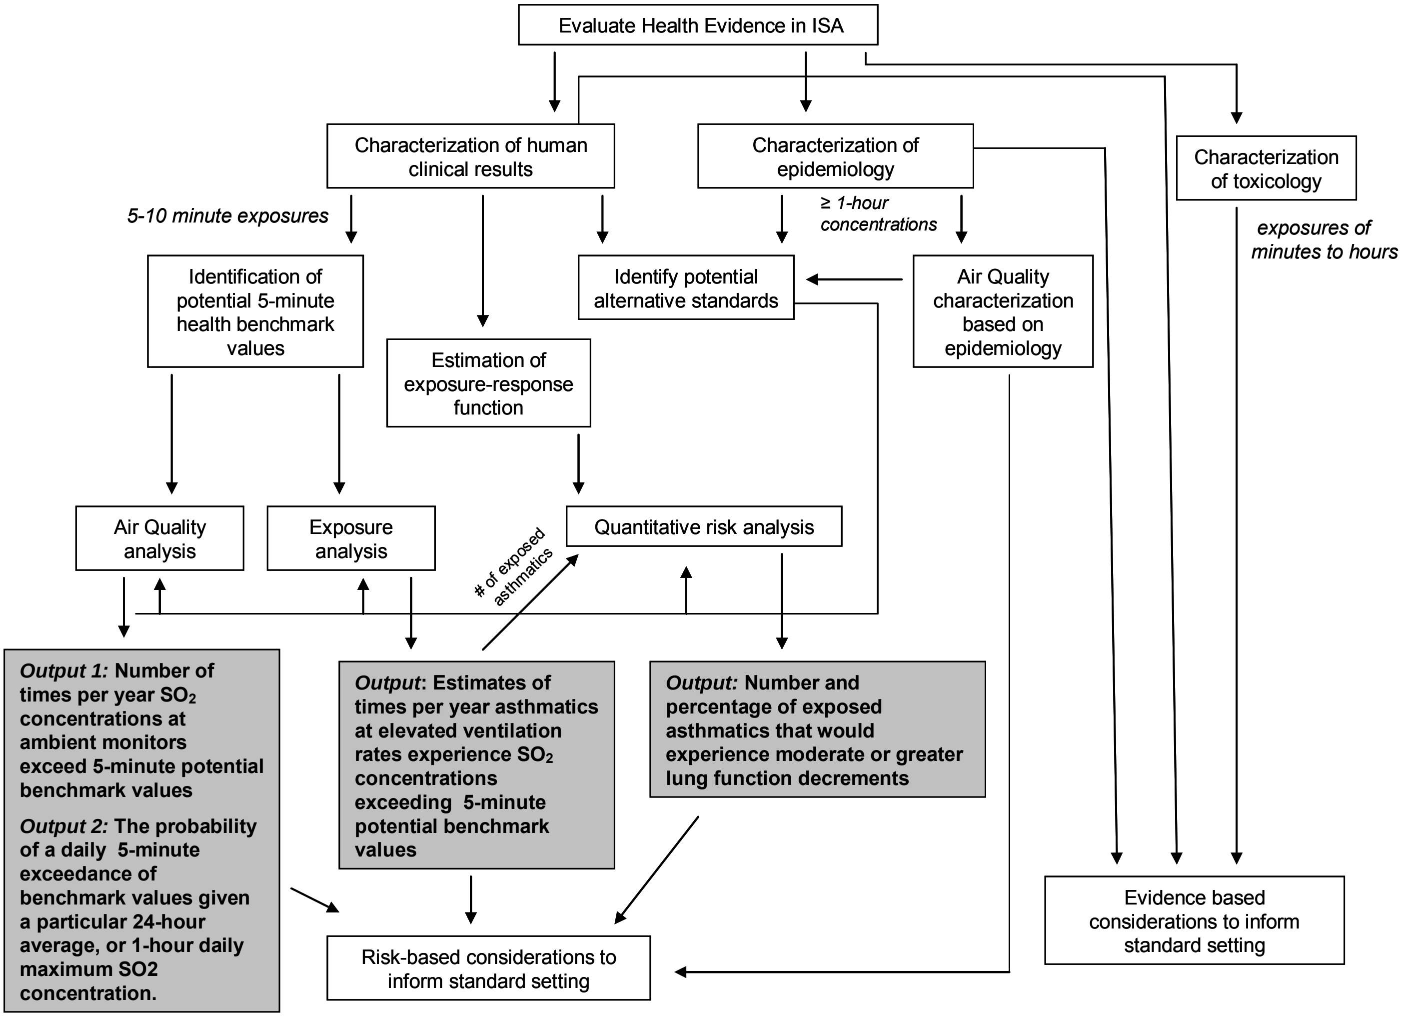

Figure 1-1. Overview of the analyses described in this document and their interconnections

As mentioned above, an initial step in the review process was the development of an integrated review plan. This plan identified policy relevant questions that would guide the review of the SO_2 NAAQS. These questions are particularly important for the REA because they provide a context for both evaluating health effects evidence presented in the ISA, as well as for selecting the appropriate analyses for assessing exposure and risks associated with current ambient SO_2 levels, and levels that just meet the current standards. These policy relevant questions are:

- Has new information altered/substantiated the scientific support for the occurrence of health effects following short- and/or long-term exposure to levels of SO_x found in the ambient air?
- Does new information impact conclusions from the previous review regarding the effects of SO_x on susceptible populations?
- At what levels of SO_x exposure do health effects of concern occur?
- Has new information altered conclusions from previous reviews regarding the plausibility of adverse health effects caused by SO_x exposure?
- To what extent have important uncertainties identified in the last review been reduced and/or have new uncertainties emerged?
- What are the air quality relationships between short-term and longer-term exposures to SO_x?

Additional questions will become relevant if the evidence suggests that revision of the current standard might be appropriate. These questions are:

- Is there evidence for the occurrence of adverse health effects at levels of SO_x different than those observed previously? If so, at what levels and what are the important uncertainties associated with that evidence?
- Do exposure estimates suggest that levels of concern for SO_x-induced health effects will occur with current ambient levels of SO_2, or with levels that just meet the current, or potential alternative standards? If so, are these exposures of sufficient magnitude such that the health effects might reasonably be judged to be important from a public health perspective? What are the important uncertainties associated with these exposure estimates?
- Do the evidence, the air quality assessment, and the risk/exposure assessment provide support for considering different standard indicators, averaging times, or forms?

- What range of levels is supported by the evidence, the air quality assessment, and risk/exposure assessment? What are the uncertainties and limitations in the evidence and assessments?

1.1 HISTORY

1.1.1 History of the SO_2 NAAQS

The first SO_2 NAAQS was established in 1971. At that time, a 24-hour standard of 0.14 ppm, not to be exceeded more than one time per year, and an annual standard of 0.03 ppm were judged to be both adequate and necessary to protect public health. The most recent review of the SO_2 NAAQS was completed in 1996 and focused on the question of whether an additional short-term standard (e.g., 5-minute) was necessary to protect against short-term, peak exposures. Based on the scientific evidence, the Administrator judged that repeated exposures to 5-minute peak SO_2 levels ($\geq$ 600 ppb) could pose a risk of significant health effects for asthmatic individuals at elevated ventilation rates. The Administrator also concluded that the likely frequency of such effects should be a consideration in assessing the overall public health risks. Based upon an exposure analysis conducted by EPA, the Administrator concluded that exposure of asthmatics to SO_2 levels that could reliably elicit adverse health effects was likely to be a rare event when viewed in the context of the entire population of asthmatics and therefore, did not pose a broad public health problem for which a NAAQS would be appropriate. On May 22, 1996, EPA's final decision not to promulgate a 5-minute standard and to retain the existing 24-hour and annual standards was announced in the Federal Register (61 FR 25566).

The American Lung Association and the Environmental Defense Fund challenged EPA's decision not to establish a 5-minute standard. On January 30, 1998, the Court of Appeals for the District of Columbia found that EPA had failed to adequately explain its determination that no revision to the SO_2 NAAQS was appropriate and remanded the decision back to EPA for further explanation. Specifically, the court required EPA to provide additional rationale to support the Agency judgment that 5-minute peaks of SO_2 do not pose a public health problem from a national perspective even though those peaks would likely cause adverse health impacts in a subset of asthmatics. In response, EPA has collected and analyzed additional air quality data focused on 5-minute concentrations of SO_2. These air quality analyses conducted since the last review will help inform the current review, which will answer the issues raised in the Court's remand of the Agency's last decision.

1.1.2 Health Evidence from the Previous Review

The 1982 Air Quality Criteria Document (AQCD) for Particulate Matter and Sulfur Oxides (EPA, 1982), and its subsequent addenda and supplement (EPA, 1986b, 1994a) presented an evaluation of SO_2 associated health effects primarily drawn from epidemiological and human clinical studies. In general, these documents identified adverse health effects that were likely associated with both short- (generally hours to days), and long-term (months to years) exposures to SO_2 at concentrations present in the ambient mixture of air pollutants. Moreover, these documents presented evidence for bronchoconstriction and respiratory symptoms in exercising asthmatics following controlled exposures to 5-10 minutes peak concentrations of SO_2.

Evidence drawn from epidemiological studies supported a likely association between 24-hour average SO_2 concentrations and daily mortality, aggravation of bronchitis, and small, reversible declines in children's lung function (EPA 1982, 1994a). In addition, a few epidemiological studies found an association between respiratory symptoms and illnesses and annual average SO_2 concentrations (EPA 1982, 1994a). However, it was noted that most of these epidemiological studies were conducted in years and cities where particulate matter (PM) counts were also quite high, thus making it difficult to quantitatively determine whether the observed associations were the result of SO_2, PM, or a combination of both pollutants.

Evidence drawn from clinical studies exposing exercising asthmatics to <1000 ppb SO_2 for 5-10 minutes found that these types of SO_2 exposures evoked health effects that were similar to those asthmatics would experience from other commonly encountered stimuli (e.g. exercise, cold/dry air, psychological stress, etc. (EPA, 1994a). That is, there was an acute-phase response characterized by bronchoconstriction and/or respiratory symptoms that occurred within 5-10 minutes of exposure but then subsided on its own within 1 to 2 hours. This acute-phase response was followed by a short refractory period where the individual was relatively insensitive to additional SO_2 challenges. Notably, the SO_2-induced acute-phase response was found to be ameliorated by the inhalation of beta-agonist aerosol medications, and to occur without an additional, often more severe, late-phase inflammatory response.

The 1994 supplement to the AQCD noted that of particular concern was the subset of asthmatics in these clinical studies that appeared to be hyperresponsive (i.e. those experiencing greater-than-average bronchoconstriction or respiratory symptoms at a given SO_2 concentration). Thus, for a given concentration of SO_2, EPA estimated the number of asthmatics likely to experience bronchoconstriction (and/or symptoms) of a sufficient magnitude to be considered a health concern. At 600 to 1000 ppb SO_2, EPA estimated that more than 25% of mild to moderate exercising asthmatics would likely experience decrements in lung function distinctly exceeding typical daily variations in lung function, or the response to commonly encountered stimuli (EPA, 1994a). Furthermore, the AQCD concluded that the severity of effects experienced at 600-1000 ppb was likely to be of sufficient concern to cause a cessation of activity, medication use, and/or the possible seeking of medical attention. In contrast, at 200 – 500 ppb SO_2, it was estimated that at most 10 – 20% of mild to moderate exercising asthmatics were likely to experience lung function decrements larger than those associated with typical daily activity, or the response to commonly encountered stimuli (EPA, 1994a).

1.1.3 Assessment from Previous Review

The risk and exposure assessment from the previous review of the SO_2 NAAQS qualitatively evaluated both the existing 24-hour (0.14 ppm) and annual standards (0.03 ppm), but primarily focused on whether an additional standard was necessary to protect against short-term (e.g., 5-minute) peak exposures. Based on the human clinical data mentioned above, it was judged that exposures to 5-minute SO_2 levels at or above 600 ppb could pose an immediate significant health risk for a substantial proportion of asthmatics at elevated ventilation rates (e.g., while exercising). Thus, EPA analyzed existing ambient monitoring data to estimate the frequency of 5-minute peak concentrations above 500, 600, and 700 ppb, the number of repeated exceedances of these concentrations, and the sequential occurrences of peak concentrations within a given day (SAI, 1996). The results of this analysis indicated that in the vicinity of local sources, several locations in the U.S. had a substantial number of 5-minute peak concentrations at or above 600 ppb.

In addition to the ambient air quality analysis, the previous review also included several annual exposure analyses that in general, combined SO_2 emission estimates from utility and non-utility sources with exposure modeling to estimate the probability of exposure to short-term peak

SO_2 concentrations. The first such analysis conducted by the Agency estimated the number of 5-minute exposures ≥ 500 ppb associated with four selected coal-fired power utilities (EPA, 1986a). An expanded analysis sponsored by the Utility Air Regulatory Group (UARG) considered the frequency of short-term exposure events that might result from the nationwide operation of all power utility boilers (Burton et al., 1987). Additionally, the probability of peak concentrations surrounding non-utility sources was the focus of another study conducted by the Agency (Stoeckenius et al., 1990). The resultant combined exposure estimates based on these early analyses indicated that between 0.7 and 1.8 percent of the total asthmatic population potentially could be exposed one or more times annually, while outdoors at exercise, to 5-minute SO_2 concentrations ≥ 500 ppb. It also was noted that the frequency of 5-minute exposures above the health effect benchmark of 600 ppb, while not part of the analysis, would be anticipated to be lower.

In addition to the early analyses mentioned above, two other analyses were considered in the prior review. The first was an exposure assessment sponsored by the UARG (Rosenbaum et al., 1992) that focused on emissions from fossil-fueled power plants. That study accounted for the anticipated reductions in SO_2 emissions after implementation of the acid deposition provisions (Title IV) of the 1990 Clean Air Act Amendments. This UARG-sponsored analysis predicted that these emission reductions would result in a 42% reduction in the number of 5-minute exposures to 500 ppb for asthmatic individuals (reducing the number of asthmatics exposed from 68,000 down to 40,000) in comparison with the earlier Burton et al. (1987) analysis. The second was a new exposure analysis submitted by the National Mining Association (Sciences International, Inc. 1995) that reevaluated non-utility sources. In this analysis, revised exposure estimates were provided for four of the seven non-utility source categories by incorporating new emissions data and using less conservative modeling assumptions in comparison to those used for the earlier Stoeckenius et al. (1990) non-utility analysis. Significantly fewer exposure events (i.e., occurrence of 5-minute 500 ppb or greater exposures) were estimated in this industry-sponsored revised analysis, decreasing the range of estimated exposures for these four sources by an order of magnitude (i.e., from 73,000-259,000 short-term exposure events in the original analysis to 7,900-23,100 in the revised analysis).

1.2 SCOPE OF THE RISK AND EXPOSURE ASSESSMENT FOR THE CURRENT REVIEW

1.2.1 Overview of the Second Draft Assessment

The second draft REA describes exposure and risks associated with recent ambient levels of SO_2, levels that just meet the current SO_2 standards, and levels that just meet potential alternative standards. This second draft REA also contains a policy discussion regarding the adequacy of the current SO_2 NAAQS, and potential alternative primary standards. A concise overview of the information, analyses, and policy discussion contained in this document is presented below.

Chapters 2-4 evaluate background information presented in the ISA that is relevant for conducting an exposure and risk assessment. This includes information on 1) human exposure to SO_2, 2) at-risk populations, and 3) health effects associated with short- and long-term exposures to SO_2. Chapter 5 presents in terms of indicator, averaging time, form, and level the potential alternative standards that will be used in the exposure and risk chapters of the document. Specifically, these potential alternative standards are 99th percentile 1-hour daily maximum SO_2 levels of 50, 100, 150, 200, and 250 ppb, and a 98th percentile 1-hour daily maximum SO_2 level of 200 ppb. Chapter 5 also describes the rationale for the selection of these potential alternative standards. In brief, the rationale takes into consideration both human exposure and epidemiological evidence from the ISA, as well as a qualitative analysis conducted by staff characterizing 98th and 99th percentile 1-hour daily maximum SO_2 levels in cities and time periods corresponding to key U.S. and Canadian hospitalization and ED visit studies for all respiratory causes and asthma (key studies are identified in Table 5-5 of the ISA). Chapter 6 is an overview of the technical analyses that will be presented in the subsequent chapters of this document. This chapter will also present rationale for the selection of specific health benchmark values derived from the human exposure literature.

Chapters 7-9 present the analytical portion of the document. Staff considered both evidence of bronchoconstriction and respiratory symptoms from human exposure studies, as well as CASAC advice on the first draft REA, and judged it appropriate to conduct a series of three analyses to estimate risks associated with 5-minute SO_2 exposures ranging from 100-400 ppb in exercising asthmatics (see Figure 1-1 and Chapter 6). Chapter 7 presents an air quality characterization that uses monitored and statistically estimated 5-minute ambient SO_2

concentrations as a surrogate for exposure. This analysis estimates the number of times per year measured or statistically estimated 5-minute peak SO_2 concentrations meet or exceed the potential health benchmark values of 100, 200, 300 and 400 ppb This air quality analysis is done under scenarios reflecting current air quality, air quality simulated to just meet the current standards, and air quality simulated to just meet potential alternative standards (i.e. 99th percentile 1-hour daily maximum SO_2 levels of 50, 100, 150, 200 and 250 ppb and an 98th percentile 1-hour daily maximum SO_2 level of 200 ppb). Chapter 8 presents results from exposure analysis case studies conducted in St Louis and Greene Counties Missouri. Notably, EPA is also attempting to extend its exposure and risk analyses to Alleghany County (Pittsburgh), Pennsylvania and Cuyahoga County (Cleveland), Ohio. However, as of this date we are still working to rectify technical issues involving disparities between dispersion model predicted SO_2 concentrations and measured SO_2 concentrations at fixed site monitors. If EPA is successful in resolving these technical issues, additional exposure and risk estimates for these areas will be included in the presentation to the CASAC Panel at the April 16-17 meeting. In this document, analyses conducted in St. Louis and Greene Counties provides estimates of the number and percent of asthmatics residing within 20 kilometers (km) of major SO_2 sources experiencing 5-minute exposures to 100, 200, 300, and 400 ppb SO_2, while at elevated ventilation rates under the air quality scenarios mentioned above (i.e. recent air quality, and air quality adjusted to just meet the current and alternative standards). Chapter 9 is a quantitative risk assessment that produces health risk estimates for the number and percent of exposed asthmatics (as determined by the exposure analysis; see Figure 1-1) that would experience moderate or greater lung function responses under the air quality scenarios previously described.

In addition to the technical analyses presented in Chapters 7-9, Chapter 10 integrates the scientific evidence and the air quality, exposure, and risk information as they pertain to informing decisions about the primary SO_2 NAAQS. More specifically, Chapter 10 considers the epidemiological, human exposure, and animal toxicological evidence presented in the ISA (EPA, 2008a), as well as the air quality, exposure, and risk characterization results presented in this document, as they relate to the adequacy of the current SO_2 NAAQS and potential alternative primary SO_2 standards.

1.2.2 Species of Sulfur Oxides Included in Analyses

The sulfur oxides include multiple gaseous (e.g., SO_2, SO_3) and particulate (e.g., sulfate) species. In considering what species of sulfur oxides are relevant to the current review of the SO_2 NAAQS, we note that the health effects associated with particulate species of sulfur oxides have been considered within the context of the Agency's review of the primary NAAQS for particulate matter (PM). In the most recent review of the NAAQS for PM, it was determined that size-fractionated particle mass, rather than particle composition, remains the most appropriate approach for addressing ambient PM. This conclusion will be re-assessed in the parallel review of the PM NAAQS; however, at present it would be redundant to also consider effects of particulate sulfate in this review. Therefore, the current review of the SO_2 NAAQS will focus on gaseous species of sulfur oxides and will not consider health effects directly associated with particulate sulfur oxide species. Additionally, of the gaseous species, EPA has historically determined it appropriate to specify the indicator of the standard in terms of SO_2 because other gaseous sulfur oxides (e.g. SO_3) are likely to be found at concentrations many orders of magnitude lower than SO_2 in the atmosphere, and because most all of the health effects and exposure information is for SO_2. The ISA has again found this to be the case, and therefore this REA will use SO_2 as a surrogate for all gaseous sulfur oxides.

2.0 OVERVIEW OF HUMAN EXPOSURE

In order to help inform the air quality, exposure, and risk analyses presented in Chapters 7-9, staff has briefly summarized relevant human exposure information from the ISA. After defining the concept of "integrated exposure," this chapter discusses major sources of SO_2 emissions. Characterizing these SO_2 sources helps identify the most relevant locations for conducting air quality, exposure, and health risk analyses. This Chapter then discusses ambient levels of SO_2 associated with 1-hour, 24-hour, and annual averaging times. SO_2 concentrations associated with these averaging times are relevant to the air quality, exposure, and risk analyses because the current SO_2 standards have 24-hour and annual averaging times, and EPA is considering potential alternative 1-hour averaging time standards (see section 5.3). In addition, this chapter contains a general description of the monitors reporting 5-minute SO_2 concentrations, as well a broad characterization of ambient 5-minute SO_2 levels (a more thorough discussion of these topics be found in Chapters 6 and 7). This discussion is particularly relevant to the analyses described in this document because the potential health effect benchmark levels and the outputs of the air quality, exposure, and risk assessments are presented with respect to a 5-minute averaging time (see section 6.2). More specifically, as previously described in section 1.2.1, outputs of the air quality analysis presented in Chapter 7 include the number of measured, or statistically estimated (see Chapter 6) 5-minute SO_2 concentrations that exceed 5-minute potential health effect benchmark levels. Similarly, the output of the exposure analysis in Chapter 8 is the number of exercising asthmatics exposed to 5-minute SO_2 concentrations above benchmark levels. Outputs of the exposure analysis (i.e. the number of exercising asthmatics exposed to 5-minute SO_2 concentrations above benchmark levels) are then used as inputs into the quantitative risk assessment in Chapter 9 to estimate the number and percent of exposed exercising asthmatics expected to experience a moderate or greater lung function response (see Figure 6-1).

In addition to providing information relevant to the air quality, exposure, and risk analyses presented in this document, this Chapter also provides information relevant to the Chapter 4 health discussion and the Chapter 10 policy assessment. That is, the current chapter highlights uncertainties involved with using ambient SO_2 concentrations as a surrogate for personal exposure in epidemiological studies, as well as the ISA's conclusions on this topic.

2.1 BACKGROUND

The integrated exposure of a person to a given pollutant is the sum of the exposures over all time intervals for all environments in which the individual spends time. People spend different amounts of time in different microenvironments and each microenvironment is characterized by different pollutant concentrations. There is a large amount of variability in the time that different individuals spend in different microenvironments, but on average people spend the majority of their time (about 87%) indoors. Most of this time spent indoors is spent at home with less time spent in an office/workplace or other indoor locations (ISA, Figure 2-21). In addition, people spend on average about 8% of their time outdoors and 6% of their time in vehicles. A potential consequence of multiple sources of exposure or microenvironments is the exposure misclassification that may result when total human exposure is not disaggregated between these various microenvironments. In epidemiological studies that rely on ambient pollutant levels as a surrogate for exposure to ambient SO_2, such misclassification may obscure the true relationship between ambient air pollutant exposures and health outcomes.

In addition to accounting for the times spent in different microenvironments, it is also important to note the duration of exposure experienced. This is important because health effects caused by long-term, low-level exposures may differ from those caused by relatively higher shorter-term exposures.

2.2 SOURCES OF SO_2

In order to estimate risks associated with SO_2 exposure, principle sources of the pollutant must first be characterized because the majority of human exposures are likely to result from the release of emissions from these sources. Anthropogenic SO_2 emissions originate chiefly from point sources, with fossil fuel combustion at electric utilities (~66%) and other industrial facilities (~29%) accounting for the majority of total emissions (ISA, section 2.1). Other anthropogenic sources of SO_2 include both the extraction of metal from ore as well as the burning of high sulfur containing fuels by locomotives, large ships, and non-road diesel equipment. Notably, almost the entire sulfur content of fuel is released as SO_2 or SO_3 during combustion. Thus, based on the sulfur content in fuel stocks, oxides of sulfur emissions can be calculated to a higher degree of accuracy than can emissions for other pollutants such as PM and NO_2 (ISA, section 2.1).

The largest natural sources of SO_2 are volcanoes and wildfires. Although SO_2 constitutes a relatively minor fraction (0.005% by volume) of total volcanic emissions, concentrations in volcanic plumes can be in the range of several to tens of ppm (thousands of ppb). Volcanic sources of SO_2 in the U.S. are limited to the Pacific Northwest, Alaska, and Hawaii. Emissions of SO_2 can also result from burning vegetation. The amount of SO_2 released from burning vegetation is generally in the range of 1 to 2% of the biomass burned and is the result of sulfur from amino acids being released as SO_2 during combustion.

2.3 AMBIENT LEVELS OF SO_2

Since the integrated exposure to a pollutant is the sum of the exposures over all time intervals for all environments in which the individual spends time, understanding the temporal and spatial patterns of SO_2 levels across the U.S is an important component of conducting air quality, exposure, and risk analyses. SO_2 emissions and ambient concentrations follow a strong east to west gradient due to the large numbers of coal-fired electric generating units in the Ohio River Valley and upper Southeast regions. In the 12 CMSAs that had at least 4 SO_2 regulatory monitors from 2003-2005, 24-hour average concentrations in the continental U.S. ranged from a reported low of ~1 ppb in Riverside, CA and San Francisco, CA to a high of ~12 ppb in Pittsburgh, PA and Steubenville, OH (ISA, section 2.4.4). In addition, inside CMSAs from 2003-2005, the annual average SO_2 concentration was 4 ppb (ISA, Table 2-8). However, spikes in hourly concentrations occurred; the mean 1-hour maximum concentration was 130 ppb, with a maximum value of greater than 700 ppb (ISA, Table 2-8).

In addition to considering 1-hour, 24-hour, and annual SO_2 levels in this document, examining the temporal and spatial patterns of 5-minute peaks of SO_2 is also important given that human clinical studies have demonstrated exposure to these peaks can result in adverse respiratory effects in exercising asthmatics (see Chapter 4). Although the total number of SO_2 monitors across the continuous U.S. can vary from year to year, in 2006 there were approximately 500 SO_2 monitors in the NAAQS monitoring network (ISA, section 2.5.2). State and local agencies responsible for these monitors are required to report 1-hour average SO_2 concentrations to the EPA Air Quality System (AQS). However, a small number of sites, only 98 total from 1997 to 2007, and not the same sites in all years—voluntarily reported 5-minute block average data to AQS (ISA, section 2.5.2). Of these, 16 reported all twelve 5-minute averages in each hour for at least part of the time between 1997 and 2007. The remainder reported only the maximum 5-minute average in each hour. When maximum 5-minute concentrations were reported, the absolute highest concentration over the ten-year period exceeded 4000 ppb), but for all individual monitors, the 99th percentile was below 200 ppb (ISA, section 2.5.2). Medians from these monitors reported data ranged from 1 ppb to 8 ppb, and the average for each maximum 5-minute level ranged from 3 ppb to 17 ppb. Delaware, Pennsylvania, Louisiana, and West Virginia had mean values for maximum 5-minute data exceeding 10 ppb (ISA, section 2.5.2). Among aggregated within-state data for the 16 monitors from which all 5-minute average intervals were reported, the median values ranged from 1 ppb to 5 ppb, and the means ranged from 3 ppb to 11 ppb (ISA, section 2.5.2). The highest reported concentration was 921 ppb, but the 99th percentile values for aggregated within-state data were all below 90 ppb (ISA, section 2.5.2).

EPA has generally conducted NAAQS risk assessments that focus on the risks associated with levels of a pollutant that are in excess of policy relevant background (PRB). Policy relevant background levels are defined as concentrations of a pollutant that would occur in the U.S. in the absence of anthropogenic emissions in continental North America (defined here as the United States, Canada, and Mexico). However, throughout much of the United States, SO_2 PRB levels are estimated to be at most 30 parts per trillion and contribute less than 1% to present day SO_2 concentrations (ISA, section 2.5.3). We note that in the Pacific Northwest and Hawaii, PRB concentrations can be considerably higher due to geothermal activity (e.g. volcanoes); in these areas, PRB can account for 70-80% of total SO_2 concentrations (ISA, section 2.5.3). Since we do not plan on conducting SO_2 risk assessments in areas with high background SO_2 levels due to natural sources, and the contribution of PRB is negligible in all other areas, EPA is addressing the risks associated with monitored and/or modeled ambient SO_2 levels without regard to PRB levels.

2.4 RELATIONSHIP OF PERSONAL EXPOSURE TO AMBIENT CONCENTRATIONS

To help inform the evaluation of the epidemiological evidence in Chapter 4 and the evidence-based considerations presented in Chapter 10, this section discusses the relationship of personal SO_2 exposure to ambient SO_2 concentrations. Many epidemiological studies rely on measures of ambient SO_2 concentrations as surrogates for personal exposure to ambient SO_2. Thus, it is important to consider the potential sources of error that are associated with using SO_2

measured by ambient monitors as a surrogate for personal exposure to ambient SO_2. Key aspects related to this issue include: (1) ambient and personal sampling issues, (2) the spatial variability of ambient SO_2 concentrations, and (3) the relationship between ambient concentrations and personal exposures as influenced by exposure factors (e.g. indoor sources).

Only a limited number of studies have focused on the relationship between personal exposure and ambient concentrations of SO_2, in part because ambient SO_2 levels have declined markedly over the past few decades. Indoor and outdoor SO_2 concentrations are often below detection limits for personal samplers[1] and in these situations, the ISA notes that associations between ambient concentrations and personal exposures are inadequately characterized (ISA, section 2.6.3.2). However, in studies with personal measurements above detection limits, the ISA states that a reasonably strong association was observed between personal SO_2 exposure and ambient concentrations (Brauer et al., 1989; Sarnat et al., 2006; described in ISA section 2.6.3.2). In addition, the ISA notes that no study has examined the relationship between concentrations measured at ambient monitors and the community average exposure: a relationship that is more relevant than that of ambient concentration to personal exposure for the majority of the epidemiological studies presented in the ISA (ISA, section 5.3).

Because epidemiological studies rely on ambient SO_2 measurements at fixed site monitors, there is concern about the extent to which instrument error could influence the results of these studies. That is, the SO_2 monitoring network was designed and put into place when SO_2 concentrations were considerably higher, and thus, well within the standard monitor's limits of detection. However, SO_2 concentrations have fallen considerably over the years and are currently at, or very near these monitors' lower limit of detection (~3 ppb). This introduces a degree of uncertainty because as monitors approach their detection limits there can be greater error in their measurements. The ISA states that it is unclear how uncertainties in measured SO_2 concentrations will change the effect estimates of epidemiological studies relying on these monitors (ISA, section 2.6.4.1). As an additional matter, staff notes that the lower detection limit of these monitors is not considered problematic with respect to attaining the standards because the current 24-hour and annual standards, as well as the potential alternative 1-hour maximum standards, are all well within the detection limits of the SO_2 NAAQS monitoring network.

---

[1] The lower limit of detection of personal samplers is ~60 ppb for 1-hour and ~5 ppb for 24-hour. A discussion of personal sampler detection limits can be found in section 2.6.2 of the ISA.

Uncertainty in epidemiological studies is also associated with the spatial and temporal variation of SO_2 across communities. The ISA finds that site-to-site correlations of SO_2 concentrations among monitors in U.S. cities ranges from very low to very high (ISA, section 2.6.4.1; ISA, Table 2-9). This suggests that at any given time, SO_2 concentrations at individual monitoring sites may not highly correlate with the average SO_2 concentration in the community. This could be the result of local sources (e.g. power plants) causing an uneven spatial distribution of SO_2, monitors being sited to represent concentrations near local sources, or effects related to terrain or weather (ISA, section 2.6.4.1). However, this type of error is not thought to bias epidemiological conclusions in a positive direction because it generally tends to reduce, rather than increase, the effect estimate (ISA, section 2.6.4.1).

In epidemiological studies, since people spend most of their time indoors, there is also uncertainty in the relationship between ambient concentrations measured by local monitors and actual personal exposure related to ambient sources. That is, the presence of indoor or nonambient sources of SO_2 could complicate the interpretation of associations between personal exposure and ambient SO_2 in exposure studies. Sources of indoor SO_2 are associated with the use of sulfur-containing fuels, with higher levels expected when emissions are poorly vented. In the U.S., the contribution of indoor sources is not thought to be a major contributor to overall SO_2 exposure because the only known indoor source is kerosene heaters and their use is not thought to be widespread (ISA, section 2.6.4.1).

As described above, the ISA finds that there is some error in epidemiological studies associated with ambient SO_2 concentrations being used as a surrogate for personal exposure. However, the ISA concludes that positive effect estimates in SO_2 community time-series or panel epidemiological studies would likely be stronger and less uncertain if these errors had been take into account (ISA, section 2.6.4.4.).

3.0 AT RISK POPULATIONS

3.1 OVERVIEW

The risk of an adverse health effect following exposure to a pollutant is dependent on a number of factors, such as the individual's personal attributes (age, gender, preexisting health conditions) and the toxic properties of the pollutant (e.g., as indicated by dose- or concentration-response relationships). Individuals in potentially sensitive groups are of concern, as they may experience adverse effects from lower levels of a pollutant compared to the general population or experience a greater impact with the same level of exposure. The term susceptibility generally encompasses innate (e.g. genetic) or acquired (age or disease) factors that make individuals more likely to experience pollutant-related health effects. In addition, some population groups are described as being particularly vulnerable to pollution-related health effects because their air pollution exposures are higher than those of the general population. Table 3-1 presents a list of factors that could potentially lead to increased susceptibility or vulnerability to air pollution in general. However it should be noted that currently, only a subset of these factors has been shown to lead to increased susceptibility or vulnerability to SO_2 specifically. Those groups identified in the ISA to be potentially susceptible and/or vulnerable to SO_2 exposure are described in greater detail below.

Table 3-1 Factors Potentially Contributing to Susceptibility or Vulnerability to Air Pollution in General (modified from Table 4-1 in the ISA)

Susceptibility Factors	Vulnerability Factors
Pre-existing disease (e.g. asthma)	Increased activity patterns
Genetic factors	Limited air conditioner use
Age	Increased exertion level
Gender	Work environment (e.g. outdoor workers)
Race	Lower SES
Ethnicity	Lower education level
Obesity	Residential location (e.g. living near sources)
Adverse birth outcomes (e.g. low birth rate)	Geographic location (e.g. east vs. west)

3.2 SUSCEPTIBILITY: PRE-EXISTING DISEASE

Both recent epidemiological and human clinical studies have strengthened the prior conclusion that individuals with pre-existing respiratory disease are likely more susceptible to the effects of SO_2 than the general public (ISA, section 4.2.1.1). Epidemiological studies have reported associations between ambient SO_2 concentrations and a range of respiratory symptoms in individuals with respiratory disease. Additionally, numerous controlled human exposure studies have found that exercising asthmatics are more responsive to the respiratory effects of SO_2 than healthy, non-asthmatic individuals. Specifically, clinical studies have demonstrated that in non-asthmatics, SO_2-attributible decrements in lung function have generally not been shown at concentrations <1000 ppb. In contrast, increases in respiratory symptoms and/or decrements in lung function have been shown in a significant proportion of exercising mild and moderate asthmatics following 5-10 minute exposures to SO_2 concentrations as low as 200-600 ppb (ISA, section 4.2.1.1).

The ISA also examined the possible effects of pre-existing cardiovascular disease (CVD) on SO_2 susceptibility. The ISA found that results from a limited number of epidemiological studies provided inconsistent evidence that individuals with pre-existing CVD were more susceptible than the general public to adverse health effects associated with ambient SO_2 exposure (ISA, section 4.2.1.2). Moreover, results from a single human clinical study found no evidence to suggest that patients with stable angina were more susceptible to SO_2- related health effects than healthy individuals. Overall, the ISA found the evidence for an association between pre-existing CVD and increased susceptibility to SO_2 related health effects to be inconclusive (ISA, section 4.2.1.2).

3.3 SUSCEPTIBILITY: GENETICS

The ISA noted that a consensus now exists among scientists that the potential association between genetic factors and increased susceptibility to ambient air pollution merits serious consideration. Several criteria must be satisfied in selecting and establishing useful links between polymorphisms in candidate genes and adverse respiratory effects. First, the product of the candidate gene must be significantly involved in the pathogenesis of the effect of interest, which is often a complex trait with many determinants. Second, polymorphisms in the gene must produce a functional change in either the protein product or in the level of expression of the protein. Third, in epidemiological studies, the issue of confounding by other genes or environmental exposures must be carefully considered (ISA section 4.2.2).

While many studies have examined the association between genetic polymorphisms and susceptibility to air pollution in general, only one study has specifically examined the effects of SO_2 exposure on genetically distinct subpopulations. Winterton et al. (2001) found a significant association between SO_2-induced decrements in Forced Expiratory Volume in the first second (FEV_1) and the homozygous wild-type allele in the promoter region of Tumor Necrosis Factor-α (TNF- α; AA, position -308). However, the ISA concluded that the overall body of evidence was too limited to reach a conclusion regarding the effects of SO_2 exposure on genetically distinct subpopulations at this time.

3.4 SUSCEPTIBILITY: AGE

The ISA identifies children (i.e., <18 years of age) and older adults (i.e. >65 years of age) as groups that are potentially more susceptible than the general population to the health effects associated with SO_2 exposure. In children, the developing lung is highly susceptible to damage from environmental toxicants as it continues to develop through adolescence. The basis for increased susceptibility in the elderly is unknown, but one hypothesis is that it may be related to changes in antioxidant defenses in the fluid lining the respiratory tract. The ISA found a number of epidemiological studies that observed increased respiratory symptoms in children associated with increasing SO_2 exposures. In addition, several studies have reported that the excess risk estimates for ED visits and hospitalizations for all respiratory causes, and to a lesser extent asthma, associated with a 10-ppb increase in 24-hour average SO_2 concentrations were higher for children and older adults than for all ages together (ISA, section 4.2.3). However, the ISA also notes that results from human exposure studies do not suggest that adolescents are more susceptible than adults to the respiratory effects of SO_2 (ISA, section 4.2.3). Overall, the ISA states that compared to the general population, there is limited evidence to suggest that children and older adults are more susceptible to the adverse respiratory effects of ambient SO_2 (ISA, section 4.2.3).

3.5 VULNERABILITY

Indoor and personal SO_2 concentrations are generally much lower than outdoor ambient concentrations. Therefore, people who spend most of their time indoors are generally less vulnerable to SO_2 related health effects than those who spend a significant amount of time outdoors. In addition, human clinical studies have demonstrated that decrements in lung function and respiratory symptoms occur at significantly lower SO_2 exposure levels in exercising asthmatics compared to resting asthmatics. Thus, individuals who spend a significant amount of time outdoors at elevated ventilation rates (e.g. while playing, or working) are expected to have increased vulnerability and therefore be at greater risk of experiencing SO_2-related health effects.

In addition to individuals who spend extended periods of time outdoors, the ISA also describes evidence that vulnerability to SO_2 exposure is associated with lower socioeconomic status (SES) (ISA section 4.2.5). Finkelstein et al. (2003) found that among people with below-median income, the relative risk for above-median exposure to SO_2 was 1.18 (95% CI: 1.11, 1.26); the corresponding relative risk among subjects with above-median income was 1.03 (95% CI: 0.83, 1.28). However, the ISA concludes that overall, the evidence is too limited to reach a conclusion regarding SES and exposure to SO_2 (ISA section 4.2.5).

3.6 NUMBER OF SUSCEPTIBLE OR VULNERABLE INDIVIDUALS

Large proportions of the U.S. population are likely to be at increased risk for SO_2-related health effects due to the potential susceptibilities and vulnerabilities mentioned above. In the United States, approximately 10% of adults and 13% of children have been diagnosed with asthma. Notably, the prevalence and severity of asthma is higher among certain ethnic or racial groups such as Puerto Ricans, American Indians, Alaskan Natives, and African Americans (ISA for NO_x, section 4.4). Furthermore, a higher prevalence of asthma among persons of lower SES and an excess burden of asthma hospitalizations and mortality in minority and inner-city communities have been observed. In addition, population groups based on age comprise substantial segments of individuals that may be potentially at risk for SO_2-related health impacts. Based on U.S. census data from 2000, about 72.3 million (26%) of the U.S. population are under 18 years of age, 18.3 million (7.4%) are under 5 years of age, and 35 million (12%) are 65 years of age or older. There is also concern for the large segment of the population that is potentially vulnerable to SO_2-related health effects because of increased time spent outdoors at elevated ventilation rates (e.g. those who work or play outdoors). Overall, the considerable size of the population groups at risk indicates that exposure to ambient SO_2 could have a significant impact on public health in the United States.

4.0 HEALTH EFFECTS

4.1 INTRODUCTION

The ISA along with its annexes integrates newly available epidemiological, human clinical, and animal toxicological evidence with consideration of key findings and conclusions from prior reviews to draw conclusions about the relationship between short- and long-term exposure to SO_2 and numerous human health endpoints. For these health effects, the ISA characterizes judgments about causality with a hierarchy (for discussion see ISA section 1.3.7) that contains the following five levels:

- Sufficient to infer a causal relationship
- Sufficient to infer a likely causal relationship (i.e., more likely than not)
- Suggestive but not sufficient to infer a causal relationship
- Inadequate to infer the presence or absence of a causal relationship
- Suggestive of no causal relationship

The ISA notes that these judgments about causality are informed by a series of aspects of causality that are based on those set forth by Sir Austin Bradford Hill in 1965 (ISA section 1.3.6). These aspects include strength of the observed association, availability of experimental evidence, consistency of the observed association, biological plausibility, coherence of the evidence, temporal relationship of the observed association, and the presence of an exposure-response relationship. A summary of each of the five levels of the hierarchy is provided in Table 1-2 of the ISA, which has also been included below (Table 4-1).

Table 4-1. Weight of Evidence for Causal Determination

Sufficient to infer a causal relationship	Evidence is sufficient to conclude that there is a causal relationship between relevant pollutant exposure and the outcome. Causality is supported when an association has been observed between the pollutant and the outcome in studies in which chance, bias, and confounding could be ruled out with reasonable confidence. That is, human clinical studies provide the strongest evidence for causality. Causality is also supported by findings from epidemiologic "natural experiments" or observational studies supported by other lines of evidence. Generally, determination is based on multiple studies from more than one research group.
Sufficient to infer a likely causal relationship (i.e., more likely than not).	Evidence is sufficient to conclude that there is a likely causal association between relevant pollutant exposures and the outcome. That is, an association has been observed between the pollutant and the outcome in studies in which chance, bias and confounding are minimized, but uncertainties remain. For example, observational studies show associations but confounding and other issues are difficult to address and/or other lines of evidence (human clinical, animal, or mechanism of action information) are limited or inconsistent. Generally, determination is based on multiple studies from more than one research group.
Suggestive, but not sufficient to infer a causal relationship	Evidence is suggestive of an association between relevant pollutant exposures and the outcome, but is weakened because chance, bias and confounding cannot be ruled out. For example, at least one high-quality study shows an association, while the results of other studies are inconsistent.
Inadequate to infer the presence or absence of a causal relationship	The available studies are inadequate to infer the presence or absence of a causal relationship. That is, studies are of insufficient quality, consistency or statistical power to permit a conclusion regarding the presence or absence of an association between relevant pollutant exposure and the outcome. For example, studies which fail to control for confounding or which have inadequate exposure assessment, fall into this category.
Suggestive of no causal relationship	The available studies are suggestive of no causal relationship. That is, several adequate studies, examining relationships between relevant population exposures and outcomes, and considering sensitive subpopulations, are mutually consistent in not showing an association between exposure and the outcome at any level of exposures. In addition, the possibility of a small elevation in risk at the levels of exposure studied can never be excluded.

For the purpose of characterizing SO_2-related health risks in the risk and exposure analyses, we have focused on health endpoints for which the ISA concludes that the available evidence is sufficient to infer a causal relationship. The ISA concludes that there is sufficient evidence to infer a causal relationship between respiratory morbidity and short-term exposure to SO_2 (ISA, section 5.2). This conclusion is based on the consistency, coherence, and plausibility of findings observed in controlled human exposure studies examining SO_2 exposures of 5-10 minutes, epidemiological studies mostly using 24-hour average exposures, and animal toxicological studies using exposures of minutes to hours (ISA, section 5.2). The evidence for causal associations between SO_2 exposure and other health endpoints is judged to be less convincing, at most suggestive but not sufficient to infer a causal relationship, and therefore will not be discussed in this chapter, but may be considered as part of the policy discussion in Chapter 10. Key conclusions reached in the ISA are listed below:

- **Sufficient to infer a causal relationship:**
    - Short-Term Exposure to SO_2 and Respiratory Morbidity
- **Suggestive but not sufficient to infer a causal relationship:**
    - Short-Term Exposure to SO_2 and Mortality
- **Inadequate to infer the presence or absence of a causal relationship**
    - Short-Term Exposure to SO_2 and Cardiovascular Morbidity;
    - Long-Term Exposure to SO_2 and Respiratory Morbidity;
    - Long-Term Exposure to SO_2 and Mortality ;
    - Long-Term Exposure to SO_2 and Other Morbidity;

A more detailed summary of these conclusions can be found in Table 5-3 of the ISA.

4.2 SHORT-TERM PEAK (<1-HOUR, GENERALLY 5-10 MINUTES) SO_2 EXPOSURES AND RESPIRATORY HEALTH EFFECTS

4.2.1 Overview

The ISA concludes that there is sufficient evidence to infer a causal relationship between respiratory morbidity and short-term (5-minutes to 24-hours) exposure to SO_2 (ISA, section 5.2). In large part, this determination is based on controlled human exposure studies demonstrating a relationship between short-term peak SO_2 exposures and adverse effects on the respiratory system in exercising asthmatics. Since the last review, several human clinical studies providing evidence of SO_2-induced decrements in lung function and increases in respiratory symptoms among exercising asthmatics have been published (ISA section 3.1.3). In addition, based in part on recent guidance from the American Thoracic Society (ATS) regarding what constitutes an adverse health effect of air pollution (ATS, 2000), the ISA also reviewed and analyzed key older studies along with those published since the last review. In their official statement, the ATS concluded that an air pollution-induced shift in a population distribution of a given health-related endpoint (e.g., lung function) should be considered adverse, even if this shift does not result in the immediate occurrence of illness in any one individual in the population (ATS 2000). The ATS also recommended that transient loss in lung function with accompanying respiratory symptoms attributable to air pollution should be considered adverse. However, the ISA cautions that symptom perception is highly variable among asthmatics even during severe episodes of asthmatic bronchoconstriction, and that an asymptomatic decrease in lung function may pose a significant health risk to asthmatic individuals as it is less likely that these individuals will seek treatment (ISA section 3.1.3). As in previous reviews, the ISA also concludes that at concentrations below 1000 ppb, healthy individuals are relatively insensitive to the respiratory effects of short-term peak SO_2 exposures (ISA, sections 3.1.3.1 and 3.1.3.2).

4.2.2 Respiratory Symptoms

The 1994 Supplement to the Second Addendum described multiple studies that evaluated respiratory symptoms (e.g. cough, wheeze, or chest tightness) following controlled exposures of asthmatic subjects to SO_2. Linn et al. (1983) reported that relative to exposure to clean air, exposure to SO_2 levels as low as 400 ppb for 5 minutes in exercising asthmatics resulted in a statistically significant increase in an overall respiratory symptoms score that included wheeze, chest tightness, cough, and substernal irritation. In an additional study, Linn et al. (1987) observed that 43% of asthmatics exhibited respiratory symptoms following exposure to 600 ppb SO_2 during a 10-minute period of exercise; this study also found that exposure to SO_2 concentrations of 400 ppb resulted in 15% of study subjects experiencing respiratory symptoms (ISA, 3.1.3.1). In addition, Balmes et al. (1987) reported that 7 out of 8 asthmatic adults at elevated ventilation rates developed respiratory symptoms following a 3-minute exposure via mouthpiece to 500 ppb SO_2 (ISA section 3.1.3.1). However, it should be noted that studies utilizing a mouthpiece exposure system cannot be directly compared to studies involving freely breathing subjects, as nasal absorption of SO_2 is bypassed during oral breathing, thus allowing a greater fraction of inhaled SO_2 to reach the tracheobronchial airways. As a result, individuals exposed to SO_2 through a mouthpiece are likely to experience greater respiratory effects from a given SO_2 exposure.

Controlled human exposure studies published since the 1994 Supplement to the Second Addendum have provided additional evidence of short-term peak SO_2 exposures resulting in respiratory symptoms in asthmatics at elevated ventilation rates (ISA, section 3.1.3.1). In a study conducted by Gong et al. (1995), unmedicated SO_2-sensitive asthmatics were exposed to 0-, 500- and 1000 ppb SO_2 for 10 minutes, while performing different levels of exercise (light, medium, or heavy). The authors found that respiratory symptoms increased with increasing SO_2

concentrations. Moreover, they found that exposure to 500 ppb SO_2 during light exercise evoked a more severe symptomatic response than heavy exercise in clean air. In addition, Trenga et al. (1999) observed a correlation between decreases in FEV_1 and increases in respiratory symptoms following 10-minute exposures to 500 ppb SO_2 by mouthpiece.

4.2.3 Lung function

The ISA notes that it has been clearly established that subjects with asthma are more sensitive to the respiratory effects of SO_2 exposure than healthy individuals (ISA, section 3.1.3.2). Asthmatic individuals exposed to SO_2 concentrations as low as 200-300 ppb for 5-10 min during exercise have been shown to experience moderate or greater bronchoconstriction, measured as an increase in specific airway resistance (sRaw) of ≥ 100% or decrease in FEV_1 of ≥ 15% after correction for exercise-induced responses in clean air (Bethel et al., 1983; Linn et al., 1983, 1984, 1987; 1988; 1990; Magnussen et al., 1990; Roger et al., 1985). Moreover, the ISA finds that among asthmatics, both the magnitude of SO_2-induced lung function decrements and the percent of individuals affected have been shown to increase with increasing 5- to 10-minute SO_2 exposures in the range of 200 to 1000 ppb.

The ISA finds supporting evidence for SO_2-induced decrements in lung function from more recently published studies. Gong et al. (1995) found that increasing SO_2 concentrations resulted in both a decrease in FEV_1, as well as an increase in sRaw. This same study found that increasing the concentration of SO_2 had a greater effect on sRaw and FEV_1 than increasing the level of exercise. In a separate study, following a 10-minute exposure to 500 ppb SO_2 by mouthpiece (see caveat in section 4.2.2), Trenga et al. (1999) observed that 25 out of 47 exercising adult asthmatics experienced a ≥ 8% decrease in FEV_1 versus baseline (mean decrease = 17.2%).

4.2.4 Decrements in Lung Function in the Presence of Respiratory Symptoms

SO_2-induced decrements in lung function (increased sRaw and decreased FEV_1) have frequently been associated with increases in respiratory symptoms among asthmatics at elevated ventilation rates (Balmes et al., 1987; Gong et al., 1995; Linn et al., 1983b; 1987; 1988; 1990). For example, Linn et al. (1987) exposed 40 asthmatics during 10-minute periods of exercise to 0, 200, 400, and 600 ppb SO_2 and the individual results were made available to EPA (Smith, 1994). In brief, this study found that after adjusting for effects of exercise in clean air, exposure to 600 ppb SO_2 resulted in 21 of the 40 subjects experiencing moderate or greater decrements in lung function. Of these 21 responders, 14 (67%) also experienced mild to severe respiratory symptoms. In the same study, 14 asthmatics experienced moderate or greater decrements in lung function in response to 400 ppb SO_2, five of whom (36%) also experienced mild to moderate respiratory symptoms. In addition, five asthmatics experienced moderate or greater decrements in lung function in response to 200 ppb SO_2 (i.e. the lowest concentration tested), one of whom (20%) also experienced mild respiratory symptoms.

4.2.5 Medication as an Effect Modifier

The ISA reports that quick-relief and long-term-control asthma medications have been shown to provide varying degrees of protection against SO_2-induced bronchoconstriction in mild and moderate asthmatics (ISA section 3.1.3.2 and Annex Table D-1). More specifically, while no therapy has been shown to completely eliminate SO_2-induced respiratory effects in exercising asthmatics, some short- and long-acting asthma medications are capable of significantly reducing SO_2-induced bronchoconstriction (Gong et al., 1996; 2001; Koenig et al., 1987; Linn et al., 1990). However, the ISA notes that asthma is often poorly controlled even among severe asthmatics due to inadequate drug therapy or poor compliance among those who are on regular medication (Rabe et al., 2004). Moreover, the ISA also notes that mild asthmatics, who constitute the majority of asthmatic individuals, are much less likely to use asthma medication than asthmatics with more severe disease (O'Byrne, 2007; Rabe et al., 2004). Therefore, the ISA finds that it is reasonable to conclude that all asthmatics (i.e. mild, moderate, and severe), are at high risk of experiencing adverse respiratory effects from SO_2 exposure (ISA section 3.1.3.2).

4.3 SHORT-TERM (≥ 1-HOUR, GENERALLY 24-HOUR) SO_2 EXPOSURE AND RESPIRATORY HEALTH EFFECTS

In addition to the human clinical evidence described above (section 4.2), the ISA also bases its causal determination for an association between exposure to short-term (5-minutes to 24-hour) SO_2 and respiratory morbidity on results from epidemiological studies. More specifically, this section will focus on the epidemiological results presented in the ISA with regard to respiratory symptoms, as well as hospitalization and ED visits for all respiratory causes and asthma. This is because the ISA emphasizes that epidemiological results from these studies provide "supporting evidence" for its determination of causality (ISA section 5.2).

4.3.1 Respiratory Symptoms

The ISA finds that the strongest epidemiological evidence for an association between short-term SO_2 concentrations and respiratory symptoms was in children, and comes from two large U.S. multi-city studies: the National Cooperative Inner-City Asthma Study (NCICAS; Mortimer et al., 2002; ISA section 3.1.4.1.), and the Childhood Asthma Management Program (CAMP; Schildcrout et al., 2006; ISA section 3.1.4.1). Both of these studies found significant associations between the level of SO_2 concentration and the risk of respiratory symptoms in asthmatic children (Mortimer et al., 2002; Schildcrout et al., 2006;). However, it should be noted that the Harvard Six Cities Study (Schwartz et al., 1994) suggested that the association between SO_2 and respiratory symptoms in children could be confounded by PM_{10}; the authors found that the effect of SO_2 was substantially diminished after adjustment for PM_{10} in copollutant models (ISA, section 3.1.4.1). These key studies are discussed in more detail below.

The National Cooperative Inner-City Asthma Study (NCICAS, Mortimer et al. 2002) included asthmatic children (n = 846) from eight U.S. urban areas and examined the relationship between respiratory symptoms and summertime air pollution levels. The strongest associations were found between morning symptoms (e.g. morning cough) and the median 3-hour average SO_2 concentrations during morning hours (8 a.m. to 11 a.m.)- following a 1- to 2-day lag (ISA, Figure 3-2). Three hour average concentrations in the morning hours ranged from 17 ppb in Detroit to 37 ppb in East Harlem, NY. This relationship remained robust and statistically significant in multi-pollutant models with ozone (O_3), and nitrogen dioxide (NO_2). When PM_{10} was also added to the model, the effect estimate was similar although no longer statistically significant (ISA, Figure 3-2), but the ISA notes that this loss of statistical significance could have been the result of reduced statistical power (only three of eight cities were included in this analysis) or collinearity resulting from adjustment of multiple pollutants (ISA, section 3.1.4.1).

The Childhood Asthma Management Program (CAMP, Schildcrout et al. 2006) examined the association between ambient air pollution and asthma exacerbations in children (n = 990) from eight North American cities. The median 24-hour average SO_2 concentrations (collected in seven of the eight study locations) ranged from 2.2 ppb in San Diego to 7.4 ppb in St. Louis. All lag structures were positively associated with an increased risk of asthma symptoms, but only the 3-day moving average was statistically significant (ISA, Figure 3-3). In joint-pollutant models with carbon monoxide (CO) and NO_2, the 3-day moving average effect estimates remained robust and statistically significant. In a joint-pollutant model with PM_{10}, the 3-day moving average effect estimate remained robust, but was no longer statistically significant (ISA Figure 3-3).

A longitudinal study of 1,844 schoolchildren during the summer months from the Harvard Six Cities Study suggested that the association between SO_2 and respiratory symptoms may potentially be confounded by PM_{10} (Schwartz et al., 1994). It should be noted that unlike the NCICAS and CAMP studies, this study was not limited to asthmatic children. The median 24-hour average SO_2 concentration during this period was 4.1 ppb (10th–90th percentile: 0.8, 17.9; maximum 81.9). SO_2 concentrations were found to be associated with cough incidence and lower respiratory tract symptoms. However, the effect of SO_2 was substantially reduced and no longer statistically significant after adjustment for PM_{10}. PM_{10} had the strongest association with respiratory symptoms, and the effect of PM_{10} remained robust in copollutant models. Because PM_{10} concentrations were correlated strongly to SO_2-derived sulfate particles ($r = 0.80$), the reduced SO_2 effect estimate may indicate that for PM_{10} dominated by fine sulfate particles, PM_{10} has a slightly stronger association than SO_2 to cough incidence and lower respiratory symptoms (ISA, section 3.1.4.1.1).

In addition to epidemiological studies examining the relationship between ambient SO_2 concentrations and respiratory symptoms in children, the ISA also describes studies that looked for associations between SO_2 levels and respiratory symptoms in adults (ISA, section 3.1.4.1). The ISA notes that compared to the number of epidemiological studies examining the association between SO_2 exposure and respiratory symptoms in children, fewer studies examined this association in adults. Moreover, results in adults were mixed; some studies demonstrated positive associations while others showed no relationship at ambient SO_2 levels (ISA, section 3.1.4.1).

4.3.2 ED Visits and Hospitalizations for All Respiratory Causes

Respiratory causes for ED and hospitalization visits typically include asthma, pneumonia, bronchitis, emphysema, upper and lower respiratory infections, as well as other minor categories. Overall, the ISA concludes that these studies provide evidence to support an association between ambient SO_2 concentrations and ED visits and hospitalizations for all respiratory causes (ISA, section 3.1.4.6). The ISA also finds that when analyses are restricted by age, the results among children (0-14 years) and older adults (65+ years) are mainly positive, but not always statistically significant (ISA, section 3.1.4.6). When all age groups are combined, the ISA finds that the results of studies are mainly positive; however, the excess risk estimates are generally smaller compared to children and older adults (ISA, Figure 3-6). Results from key epidemiological studies conducted in the U.S. and Canada are described below, and a more detailed discussion of both the U.S. and international epidemiological literature can be found in the ISA (ISA, section 3.1.4.6).

Wilson et al., (2005) examined the association between SO_2 levels and ED visits for all respiratory causes in Portland, ME (54,000 ED visits) and Manchester, NH (30,000 ED visits). The authors found a negative association in Portland when analyses were limited to children. In Portland, they found a positive and statistically significant 9% (95% CI: 5, 14) excess risk per 10 ppb increase in 24-hour average SO_2 in adults. Largest effects were observed among the elderly, with a 16% (95% CI: 7, 26) excess risk per 10 ppb increase in 24-hour average SO_2. When all ages were combined, a positive and statistically significant 7% (95% CI: 3, 12) excess risk per 10 ppb increase in 24-hour average SO_2 was observed in Portland. No relationship was observed between SO_2 concentrations and ED visits for all respiratory causes in Manchester in the analyses of all ages or any age-stratified group.

Schwartz (1995) conducted a study in New Haven, CT and Tacoma, WA evaluating the relationship between hospital admissions for all respiratory causes ($n \approx 8,800$ in New Haven and $n \approx 4,600$ in Tacoma) and ambient SO_2 concentrations in older adults (65+ years). The average 24-hour SO_2 concentration was 29.8 ppb in New Haven and 16.8 ppb in Tacoma. This study found positive associations between hospitalizations and SO_2, with a 2% (95% CI: 1, 3) excess risk in New Haven and 3% (95% CI: 1, 6) excess risk in Tacoma per 10 ppb increase in 24-hour average SO_2. Notably, the effect estimate for New Haven remained robust and statistically significant in two-pollutant models with PM_{10}, but in Tacoma was substantially reduced and no longer statistically significant (ISA, Figure 3-8). Additional evidence for an association between SO_2 exposure and hospital admissions for all respiratory causes in older adults was found in two studies conducted in Vancouver, BC. Fung et al., (2006) and Yang et al., (2003) both found positive associations between hospitalizations and 24-hour average SO_2 concentrations in older adults.

Peel et al., (2005) investigated the relationship between 1-hour maximum SO_2 concentrations and respiratory ED visits ($n \approx 480,000$) for all ages in Atlanta, GA. The mean 1-hour maximum SO_2 concentration was 16.5 ppb. A weak and statistically non-significant relationship was observed for respiratory ED visits. Specifically, Peel et al., (2005) found an excess risk of 1.6% (95% CI: −0.6, 3.8) per 40 ppb increase in 1-hour maximum SO_2. Tolbert et al (2007) recently reanalyzed the data from this study along with four additional years of data and found similar results.

4.3.3 Emergency Department Visits and Hospitalizations for Asthma

The ISA also finds evidence of an association between SO_2 levels and ED visits and hospitalizations for asthma. The document notes that most of the effect estimates associated with asthma ED visits are positive (suggesting an association with ambient SO_2), although few are statistically significant (ISA, section 3.1.4.6). In an analysis encompassing all ages, Wilson et al., (2005) found a statistically significant positive association between asthma ED visits and SO_2, with an 11% (95% CI: 2, 20) excess risk per 10 ppb increase in 24-hour average SO_2 in Portland, ME. In Manchester NH, the authors found a positive, although not statistically significant association with a 6% (95% CI: -4, 17) excess risk per 10 ppb increase in 24-hour average SO_2. Ito et al., (2007) also examined the association between SO_2 and asthma ED visits in all ages. This study was conducted in New York City and found a 6% (95% CI: 3, 10) excess risk per 10 ppb increase in 24-hour average SO_2 in all year analyses. Multipollutant analyses were conducted in data limited to the warm season only. While the SO_2 effect estimate was robust and remained statistically significant after adjustment for $PM_{2.5}$, O_3, and CO in two-pollutant models, it was found to diminish to null when adjusting for NO_2. Peel et al., (2005) also examined the association between asthma ED visits and ambient SO_2. This study was conducted in Atlanta and found a null association between ED visits for asthma and 1-hour maximum SO_2 levels. In addition to these ED studies, a hospital admissions study conducted by the New York Department of Health (NY DOH, 2006) found a statistically significant 10% (95% CI: 5, 15) excess risk for asthma hospital admissions per 10 ppb increase in 24-hour average SO_2 for residents of the Bronx, but a null association for those living in Manhattan.

In three Ohio cities, Jaffe et al., (2003) examined the association between SO_2 concentrations and asthma ED visits among asthmatics, aged 5-34 years. The mean 24-hour average SO_2 concentrations were 14 ppb in Cincinnati, 15 ppb in Cleveland, and 4 ppb in Columbus. A statistically significant association was observed in the multicity analysis. The authors found an excess risk of 6% (95% CI: 1, 11) per 10 ppb increase in 24-hour average SO_2. In the city-stratified analyses, statistically significant associations were observed for Cincinnati

(17% [95% CI: 5, 31]), but not in Cleveland (3% [95% [CI -4, 11]) or Columbus (13% [95% CI: -14, 49]).

Lin et al., (2004b) conducted a case-control study of children aged 0-14 years in Bronx County, NY. The authors examined the potential association between daily ambient SO_2 concentrations (categorized into quartiles of both average and maximum levels) and cases admitted into the hospital for asthma, or controls who were admitted for reasons other than asthma. The results of this study demonstrated that cases were exposed to higher daily average concentrations of SO_2 than controls. When the highest exposure quartile (>20 ppb, 24-h average SO_2) was compared with the lowest (2.9-9.4 ppb, 24-h average SO_2), the odds ratios (ORs) were strongest when a 3-day lag was employed (OR 2.16 [95% CI: 1.77, 2.65]). However, the results were positive and statistically significant for all lag days examined. Lin et al., (2005) observed a weak positive association between hospitalizations for asthma and SO_2 among girls, and a null association for boys in a Toronto, ON study (mean 24-h average SO_2 of 5.36 ppb [SD 5.90]). In addition to these hospitalization studies, Wilson et al. (2005) found a positive, but not statistically significant 5% (95% CI -12, 25) excess risk per 10 ppb increase in 24-hour average SO_2 for asthma ED visits in Portland, ME, and a positive, but not statistically significant 20% (95% CI -3, 49) excess risk in Manchester, NH among children aged 0-14 years.

5.0 IDENTIFICATION OF POTENTIAL ALTERNATIVE STANDARDS FOR ANALYSIS

5.1 INTRODUCTION

The primary goals of the SO_2 risk and exposure assessment described in this draft document are to estimate short-term exposures and potential human health risks associated with 1) recent levels of ambient SO_2; 2) SO_2 levels associated with just meeting the current standards; and 3) SO_2 levels associated with just meeting potential alternative standards. This section identifies potential alternative standards to be included in the quantitative analyses discussed in Chapters 7 through 9. The potential alternative standards to be analyzed are defined in terms of indicator, averaging time, form, and level and this chapter provides the rationale that was used for their selection

5.2 INDICTATOR

The SO_x include multiple gaseous (e.g., SO_2, SO_3) and particulate (e.g., sulfate) species. In considering the appropriateness of different indicators, we note that the health effects associated with particulate species of SO_x have been considered within the context of the health effects of ambient particles in the Agency's review of the PM NAAQS. Thus, as discussed in the integrated review plan (2007a), the current review of the SO_2 NAAQS is focused on the gaseous species of SO_x and will not consider health effects directly associated with particulate species of SO_x. Of the gaseous species, EPA has historically determined it appropriate to specify the indicator of the standard in terms of SO_2 because other gaseous sulfur oxides (e.g., SO_3) are likely to be found at concentrations many orders of magnitude lower than SO_2 in the atmosphere, and because most all of the health effects evidence and exposure information is related to SO_2. The final ISA has again found this to be the case and therefore, staff finds that SO_2 remains the most appropriate indicator for the alternative standards to be analyzed in this document.

5.3 AVERAGING TIME

Staff finds that the most robust evidence for SO_2-induced respiratory morbidity exists for exposure durations $\leq$ 1-hour. The strongest evidence for this finding comes from controlled human exposure studies that have consistently demonstrated that exposure to SO_2 for 5-10 minutes can result in significant bronchoconstriction and/or respiratory symptoms in exercising asthmatics (see section 4.2). In fact, the ISA describes the controlled human exposure studies as being the "definitive evidence" for its causal determination between SO_2 exposure and short-term respiratory morbidity (ISA, section 5.2). In addition to these controlled human exposure studies, there is a relatively small body of epidemiological evidence describing positive associations between 1-hour maximum SO_2 levels and respiratory symptoms as well as hospital admissions and ED visits for all respiratory causes and asthma (ISA, Tables 5.4 and 5.5). In addition to the 1-hour epidemiological evidence, there is a considerably larger body of epidemiological studies reporting associations between 24-hour average SO_2 levels and respiratory symptoms, as well as hospitalizations and ED visits; however, the ISA notes that it is possible that associations observed in these 24-hour studies are being driven, at least in part, by short-term peaks of duration < 24-hours of SO_2. More specifically, when describing epidemiological studies observing associations between ambient SO_2 and respiratory symptoms, the ISA states "that it is possible that these associations are determined in large part by peak exposures within a 24-hour period" (ISA, section 5.2). The ISA also states that the respiratory effects following peak SO_2 exposures in controlled human exposure studies provides a basis for a progression of respiratory morbidity that could result in increased ED visits and hospital admissions (ISA, section 5.2). It should also be noted that epidemiological studies conducted in Paris, France (Dab et al., 1996) and in Manhattan and Bronx, NY (NY DOH, 2006) used both 24-hour average and 1-hour daily maximum air quality levels and found similar effect estimates with regard to hospital admissions for all respiratory causes (Dab et al., 1996) and asthma ED visits (NY DOH, 2006). Finally, in addition to the controlled human exposure and epidemiological evidence, the ISA describes key toxicological studies with exposures ranging from minutes to hours resulting in decrements in lung function, airway inflammation, and/or hyperresponsiveness in laboratory animals (ISA, Table 5-2).

The scientific evidence described above suggests that at a minimum, averaging time(s) selected for further risk and exposure analyses should address respiratory effects associated with SO_2 exposures of ≤ 1-hour. We note that analyses conducted in the ISA demonstrate that at monitors measuring all twelve 5-minute SO_2 levels in an hour (n=16), there is a high Pearson correlation between the 5-minute maximum level and the corresponding 1-hour average SO_2 concentration, with only one monitor observing a correlation ≤ 0.9 (ISA, section 2.5.2; ISA, Table 2-12). Thus, for the purpose of conducting quantitative exposure and risk analyses staff concluded that the focus should be on potential alternative SO_2 standards with an averaging time of 1-hour. Staff believes that alternative standards with an averaging time of 1-hour will limit both 5-minute peak concentrations within an hour, as well as other peak SO_2 concentrations ($\geq$ 1-hour) that are likely in part, driving the respiratory outcomes described in epidemiological studies.

Staff also considered examining alternative 5-minute standards in the risk and exposure assessment, but concluded for several reasons that such an analysis would be of questionable utility in the decision-making process. We note that EPA historically conducts air quality, exposure, and risk analyses of alternative standards by adjusting measured, not modeled air quality data. This is an issue in evaluating alternative 5-minute standards for SO_2 because there were, and continue to be relatively few locations reporting 5-minute SO_2 concentrations. As described in Appendix A, from 1997-2007, there were a total of 98 monitors in 13 states and the District of Columbia measuring maximum 5-minute SO_2 concentrations in an hour. In comparison, there were 933 monitors in 49 states, the District of Columbia, Puerto Rico and the Virgin Islands measuring 1-hour SO_2 concentrations. Moreover, it is important to consider that those monitors reporting 5-minute concentrations do not represent data from a dedicated 5-minute monitoring network, but rather a voluntary submission of 5-minute values from monitors placed for the purpose of evaluating attainment of 24-hour and annual average SO_2 NAAQS. Thus, staff has little confidence that this limited set of data, from monitors sited for a different purpose, can provide the input required for a comprehensive air quality, exposure, and risk analysis of a much shorter averaging time standard. In fact, given the spatial heterogeneity of 5-minute peaks, and the aforementioned issues with monitor siting, staff is not confident (based on 5-minute monitoring data alone) that even in the 13 locations reporting 5-minute concentrations, that those reported values adequately reflect the extent to which 5-minute peaks are occurring in those areas.

While we have chosen to evaluate alternative 1-hour averaging time standards in the air quality, exposure, and risk chapters of this document, it does not preclude the possibility of considering 5-minute standards as part of the policy assessment discussion in Chapter 10, or during the rulemaking process. Consideration of potential alternative 5-minute standards could be based on evidence-based considerations, drawn from the discussion of the scientific evidence related to 5-10 minute exposures from the ISA, and presented below in Chapter 10.

5.4 FORM

In evaluating alternative forms of primary standards to be analyzed in the risk and exposure chapters, staff recognizes that it is important to have a form that: (1) reflects the health risks posed by elevated SO_2 concentrations and (2) achieves a balance between limiting the occurrence of peak concentrations and providing a stable and robust regulatory target. Consistent with judgments made in recent reviews of the PM (71FR61144) and O_3 (73 FR 16436) NAAQS, staff judges that a concentration-based form for the SO_2 standard would better reflect the health risks and would provide greater stability than a form based on expected exceedances. This is because a concentration-based form gives proportionally greater weight to 1-hour daily maximum values when concentrations are well above the level of the standard than to 1-hour daily maximum values when the concentrations are just above the level of the standard. In contrast, an expected exceedance form would give the same weight to a 1-hour daily maximum concentration that just exceeds the level of the standard as to a 1-hour daily maximum concentration that greatly exceeds the level of the standard. Therefore, a concentration-based form better reflects the continuum of health risks posed by increasing SO_2 concentrations (i.e. the percentage of asthmatics affected and the severity of the response increases with increasing SO_2 concentrations). The most recent review of the PM NAAQS (completed in 2006) judged that using a 98th percentile form averaged over 3 years provides an appropriate balance between limiting the occurrence of peak concentrations and providing a stable regulatory target (71 FR 61144). In that review, staff also considered other forms within the range of the 95th to the 99th percentiles. In making recommendations regarding the form, staff considered the impact on risk of different forms, the year-to-year stability in the air quality statistic, and the extent to which different forms of the standard would allow different numbers of days per year to be above the level of the standard in areas that achieve the standard. Based on these considerations, staff recommended either a 98th percentile form or a 99th percentile form. We have made similar judgments in identifying an appropriate range of forms for potential alternative 1-hour daily maximum SO_2 standards. As a result of these judgments, we have determined it appropriate here to consider 98th and 99th percentile SO_2 concentrations averaged over 3 years. We have judged that the 98th and 99th percentile, when combined with the range of alternatives identified for the level of a new 1-hour standard (see below), will likely offer a sufficient range of options to balance the objective of providing a stable regulatory target against the objective of limiting the occurrence of peak 5-minute to 1-hour SO_2 concentrations.

5.5 LEVEL

When considering the appropriate range of levels for alternative 1-hour daily maximum standards to analyze in the exposure and risk assessments described in this document, staff examined both the controlled human exposure and epidemiological evidence evaluated in the ISA. Controlled human exposure evidence demonstrates that there is a continuum of SO_2-related health effects following 5-10 minute peak SO_2 exposures in exercising asthmatics. That is, the ISA finds that the percentage of asthmatics affected and the severity of the response increases with increasing SO_2 concentrations. At concentrations ranging from 200 ppb-300 ppb, 5-30% percent of exercising asthmatics are likely to experience moderate or greater bronchoconstriction (ISA, Table 3-1). At concentrations $\geq$ 400 ppb, moderate or greater bronchoconstriction occurs in 20-60% of exercising asthmatics, and compared to exposures at 200-300 ppb, a larger percentage of subjects experience severe bronchoconstriction (ISA, Table 3-1). Moreover, at concentrations $\geq$ 400 ppb, moderate or greater bronchoconstriction was frequently accompanied with respiratory symptoms (ISA, Table3-1).

In addition to the controlled human exposure evidence, we also considered the epidemiological evidence, as well as an air quality analysis conducted by staff characterizing 1-hour daily maximum SO_2 air quality levels in cities and time periods corresponding to key U.S. and Canadian ED visit and hospital admission studies for all respiratory causes and asthma[2] (key studies are identified in Table 5-5 of the ISA). Figures 5-1 to 5-5 show standardized effect estimates and the 98th and 99th percentile 1-hour daily maximum SO_2 levels for locations and time periods corresponding to these key U.S. (Figures 5-1 to 5-4) and Canadian[3] (Figure 5-5)

---

[2] Authors of relevant U.S. and Canadian studies were contacted and air quality statistics from the study monitor that recorded the highest SO_2 levels were requested. In some cases, U.S. authors provided the AQS monitor IDs used in their studies and the statistics from the highest reporting monitor were calculated by EPA. In cases where U.S. authors were unable to provide the requested data (Schwartz 1995, Schwartz 1996, and Jaffe 2005), EPA identified the maximum reporting monitor from all monitors located in the study area and calculated the 98th and 99th percentile statistics (see Thompson 2009).

[3] The Canadian statistics presented in Figure 5-5 were calculated from a data set provided by Dr. Richard Burnett and were used for all relevant single city studies on which he was an author. Note that air quality statistics presented for Canadian studies are likely not directly comparable to those presented for U.S. studies. This is because SO_2 concentrations presented for Canadian studies represent the 98th and 99th percentile 1-hour daily maximum SO_2 concentrations across a given city, rather than concentrations from the single monitor that recorded the highest 98th and 99th percentile SO_2 levels in a given city (see Thompson, 2009).

studies. In general, staff finds that the results presented in these figures demonstrate that most of these epidemiological studies show positive, although frequently not statistically significant associations with SO_2. Furthermore, we find that Figures 5-1 to 5-5 demonstrate that positive effect estimates, including some that are statistically significant, are found in locations that span a broad range of 98th and 99th percentile 1-hour daily maximum SO_2 concentrations (98th percentile range: 19- 401 ppb; 99th percentile range: 21-457 ppb). Thus, staff finds it appropriate to utilize the 1-hour daily maximum air quality data presented in these figures to help inform both the upper and lower ranges of alternative SO_2 standards to be analyzed in the air quality, exposure, and risk assessments described in this REA.

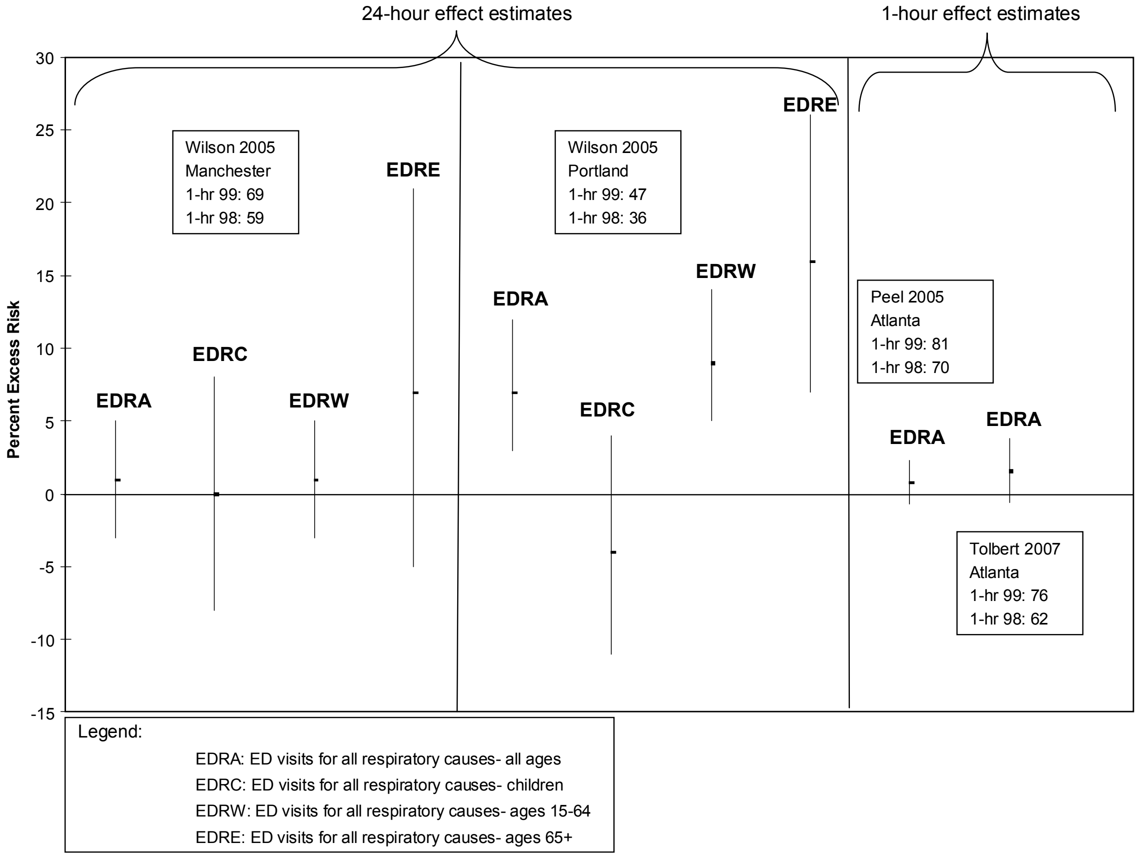

Figure 5-1. Effect estimates for U.S. all respiratory ED visit studies and associated 98th and 99th percentile 1-hour daily maximum SO_2 levels.

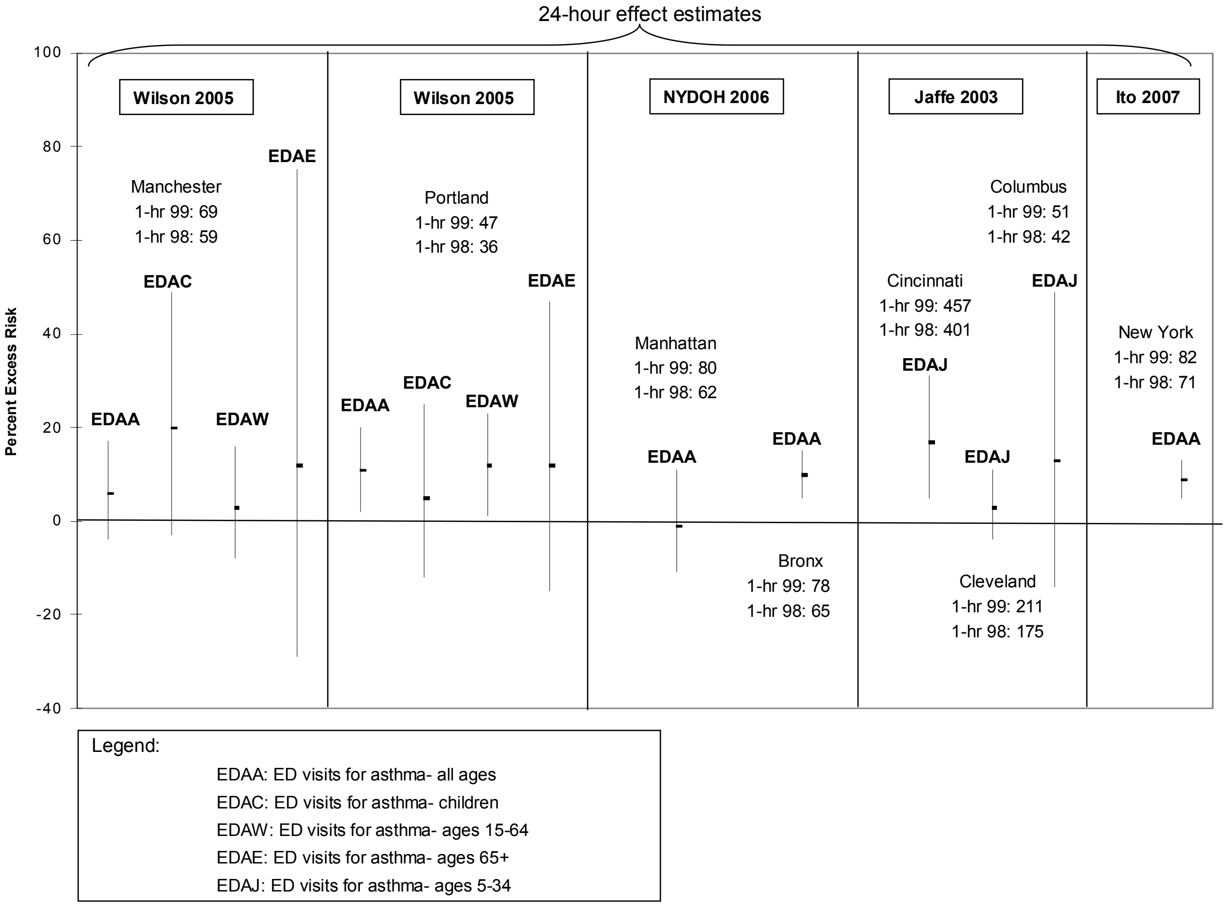

Figure 5-2. 24-hour effect estimates for U.S. asthma ED visit studies and associated 98th and 99th percentile 1-hour daily maximum SO_2 levels.

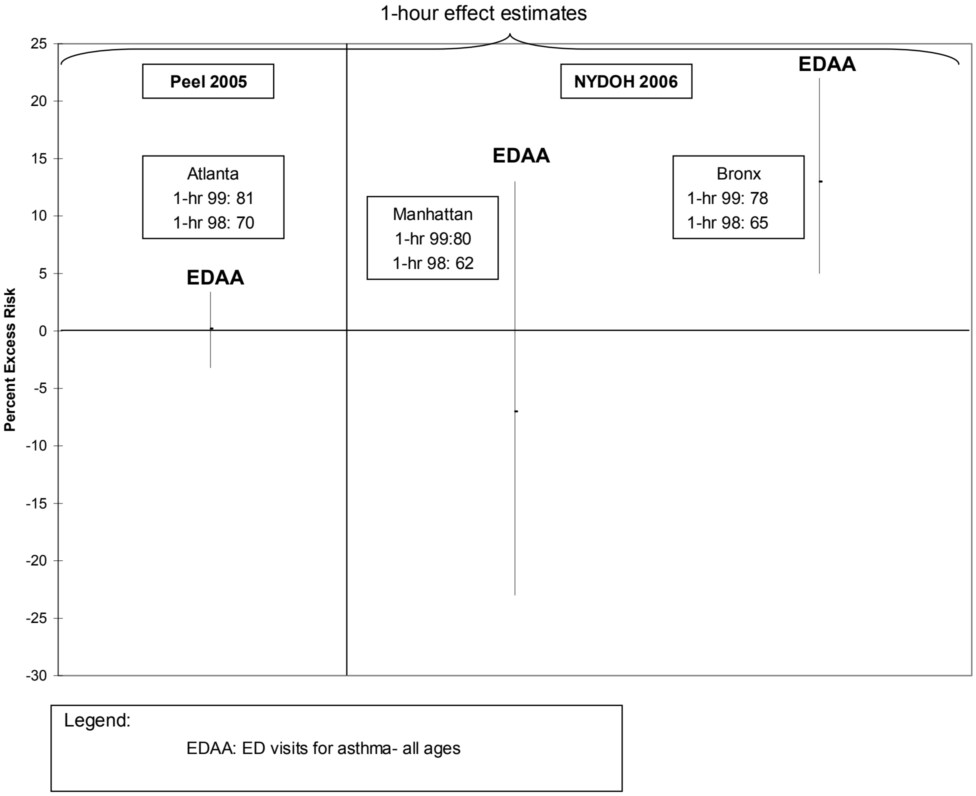

Figure 5-3. 1-hour effect estimates for U.S. asthma ED visit studies and associated 98th and 99th percentile 1-hour daily maximum SO_2 levels.

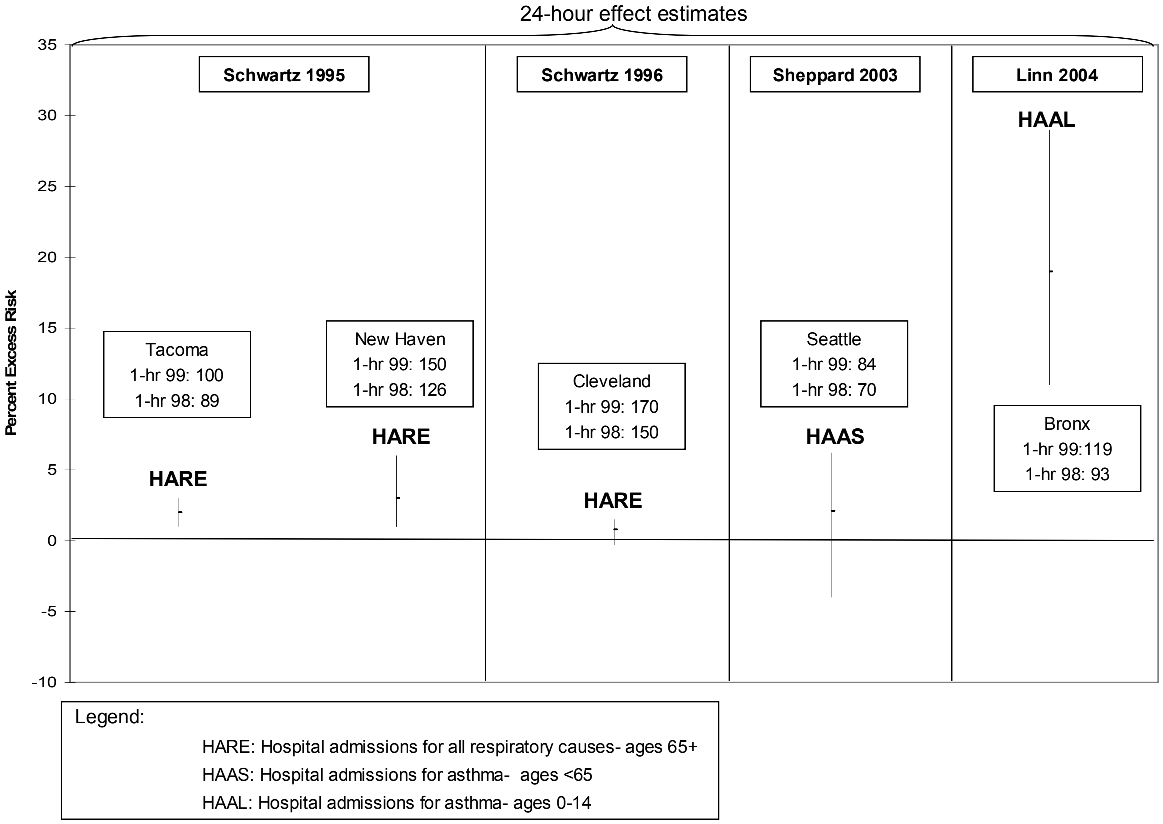

Figure 5-4. 24-hour effect estimates for U.S. hospitalization studies and associated 98th and 99th percentile 1-hour daily maximum SO_2 levels.[4]

---

[4] There were no key U.S. hospitalization studies with 1-hour effect estimates identified in Table 5-5 of the ISA

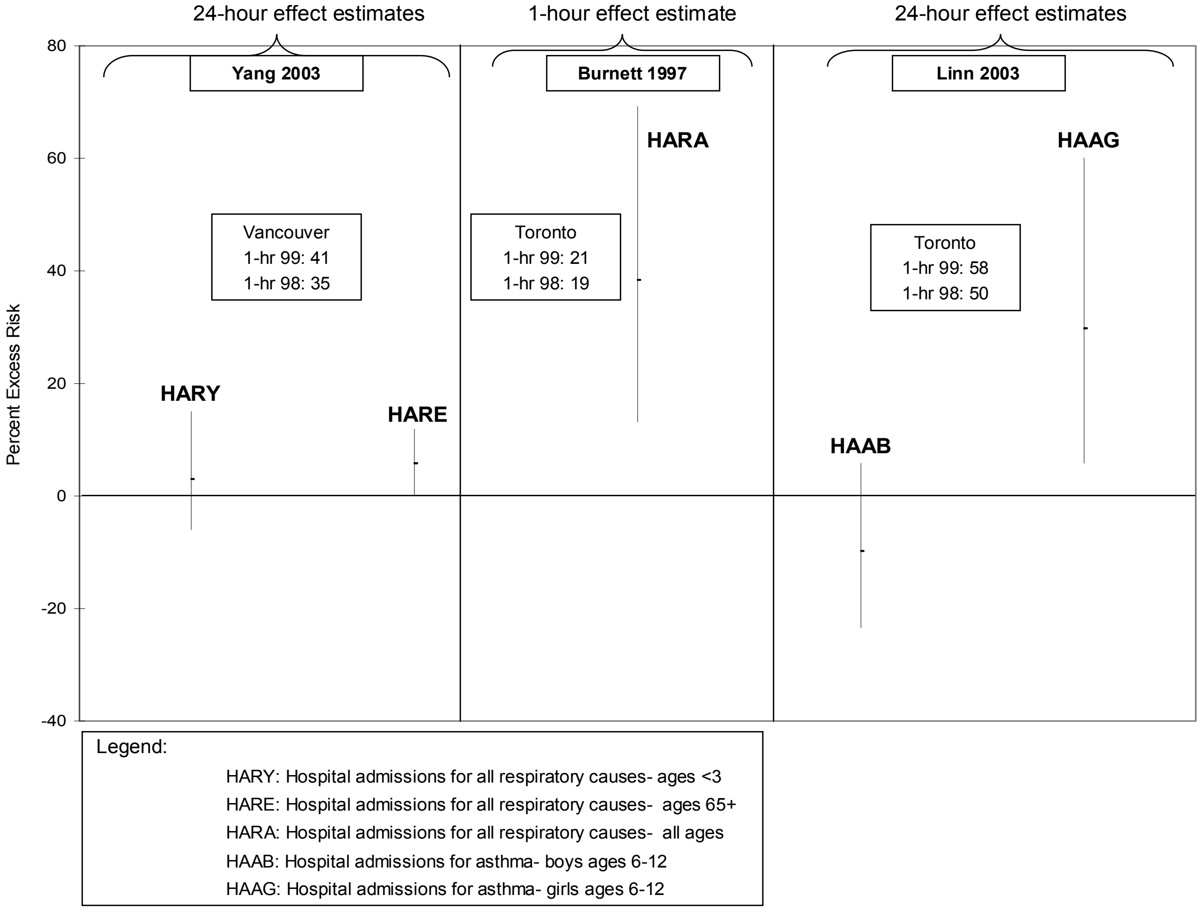

Figure 5-5. Effect estimates for Canadian ED visits and hospitalization studies and associated 98th and 99th percentile 1-hour daily maximum SO_2 levels.

The highest 99th percentile 1-hour daily maximum air quality levels were found in analyses conducted in the cities of Cincinnati (Figure 5-2), Cleveland (Figures 5-2 and 5-4) and New Haven (Figure 5-4). These studies showed positive associations[5] with respiratory-related hospital admissions or ED visits during time periods when 98th and 99th percentile 1-hour daily maximum SO_2 concentrations ranged from 126 ppb to 457 ppb. Notably, this range of 1-hour daily maximum SO_2 levels overlaps considerably with 5-10 minute SO_2 concentrations (≥ 200 ppb) that have consistently been shown in controlled human exposure studies to result in lung function responses in exercising asthmatics. Of particular concern are the air quality levels that were found in Cincinnati (Jaffe et al., 2003). The 98th and 99th percentile 1-hour daily maximum SO_2 concentrations were in excess of 400 ppb. Notably, levels ≥ 400 ppb have consistently been

---

[5] Results in Cincinnati (Jaffe et al., 2003) and New Haven (Schwartz et al., 1996) were statistically significant.

shown in human exposure studies to result in moderate or greater bronchoconstriction in the presence of respiratory symptoms in a considerable percentage of exercising asthmatics. As a result, staff judges that the upper bound of alternative standard levels to be analyzed should be 250 ppb. We find that it is reasonable to suggest that a 98th or 99th percentile 1-hour daily maximum standard at this level will both substantially limit the number of days when the 1-hour daily maximum SO_2 concentration is ≥ 200 ppb, while also potentially limiting the number of 5-10 minute SO_2 peaks ≥ 400 ppb.

In identifying the lower end of the range of alternative standards to be analyzed, staff again considered controlled human exposure and epidemiological evidence. However, with regard to the controlled human exposure evidence, several additional factors were considered. First, it is important to consider that the subjects in human exposure studies do not necessarily represent the most SO_2 sensitive asthmatics; that is, these studies included mild and moderate, but not severe asthmatics. Also while human clinical studies have been conducted in adolescents, younger children have not been included in these exposure studies, and thus, it is possible asthmatic children represent a population that is more sensitive to the respiratory effects of SO_2 than the individuals who have been examined to date. Moreover, it is important to consider that 5-30% of asthmatics who engaged in moderate or greater exertion experienced bronchoconstriction following exposure to 200-300 ppb SO_2, which is the lowest level tested in breathing chamber studies (ISA, Table 3-1)[6]. Thus, it is highly likely that a subset of the asthmatic population would also experience bronchoconstriction following exposure to levels lower than 200 ppb.

In addition to the consideration of controlled human exposure evidence mentioned above, we note that Figure 5-5 contains epidemiological analyses observing associations between ambient SO_2 concentrations and hospital admissions in Canadian cities where 1-hour daily maximum SO_2 levels were ≤ 41 ppb. More specifically, positive associations between SO_2 and hospital admissions were found in Toronto, (Burnett al., 1997) and Vancouver (Yang et. al., 2003) when 99th percentile 1-hour daily maximum SO_2 levels were approximately 21 ppb and 41 ppb, respectively. Moreover, in a U.S. study, Delfino et al., (2003) observed an association

---

[6] The ISA cites one chamber study with intermittent exercise where healthy and asthmatic children were exposed to 100 ppb SO_2 in a mixture with ozone and sulfuric acid. The ISA notes that compared to exposure to filtered air, exposure to the pollutant mix did not result in statistically significant changes in lung function or respiratory symptoms (ISA section 3.1.3.4)

between ambient SO_2 and respiratory symptoms in Hispanic children when the maximum 1-hour SO_2 concentration in Los Angeles was 26 ppb (ISA Table 5-4). However, it should be noted that the association reported in the Vancouver study was not statistically significant in either single, or multipollutant models with O_3, and the study did not examine the potential for confounding by PM (Figure 5-5; ISA Table 5-5). In addition, while the association observed in the Toronto study was statistically significant in a single pollutant model, the effect estimate was substantially diminished and no longer statistically significant in a multi-pollutant model with PM_{10} (ISA, Table 5-5). Finally, the epidemiological study conducted in Los Angeles (Delfino et al., 2003; ISA, Table 5-4) was very small (n=22), and did not examine potential confounding by co-pollutants. Thus, staff finds that this evidence alone is not sufficient to warrant inclusion of alternative 1-hour daily maximum standards at levels below 50 ppb in the risk and exposure assessments.

In contrast to the epidemiological evidence in cities and over time frames when 1-hour daily maximum SO_2 concentrations were < 46 ppb, staff finds relatively stronger evidence of an association between SO_2 and hospital admissions and ED visits in cities and over time frames when 98th and 99th percentile 1-hour daily maximum SO_2 concentrations ranged from 47 to 100 ppb (Figures 5-1 to 5-5). More specifically, the majority of epidemiological studies in this range observed positive associations between ambient SO_2 levels and increased hospital admissions and increased ED visits for all respiratory causes or asthma. Moreover, although most of these positive effect estimates were not statistically significant, there were some statistically significant results in single pollutant models (Portland, Wilson, 1995; Bronx, NYDOH, 2006; NYC, Ito, 2006; and Schwartz, 1995), as well as limited evidence of statistically significant associations in multi-pollutant models with PM[7] (Bronx, NYDOH, 2006; NYC, Ito, 2006; New Haven, Schwartz 1995). Given these epidemiological and air quality results, as well as the considerations mentioned above regarding the controlled human exposure evidence, staff concluded it was appropriate to examine a range of alternative standards in the air quality, exposure, and risk analyses that includes a level of 50 ppb as the lower bound. Staff believes that a 98th or 99th percentile 1-hour daily maximum standard at this level would both limit the

---

[7] In the NYDOH study (2006), the Bronx positive effect estimate remained statistically significant in the presence of $PM_{2.5}$. In Ito et al., (2006), the NYC positive effect estimate was statistically significant in the presence of $PM_{2.5}$ during the warm season. In Schwartz et al., (1995), the positive effect estimate in New Haven remained statistically significant in the presence of PM_{10}.

number of days when 1-hour daily maximum SO_2 levels are $\geq$ 50 ppb, while also limiting 5-10 minute peaks of $SO_2 \geq$ 100 ppb. Moreover, we note that a level of 50 ppb is substantially below the 98th and 99th percentile 1-hour daily maximum SO_2 levels observed in the Bronx during the NYDOH analysis and in NYC during the period analyzed by Ito et al., (2006): two studies where the SO_2 effect estimate remained robust and statistically significant in multi-pollutant models with $PM_{2.5}$ (ISA, Table 5-5).

6.0 OVERVIEW OF RISK CHARACTERIZATION AND EXPOSURE ASSESSMENT

6.1 INTRODUCTION

The assessments presented in the subsequent chapters of this document will characterize short-term exposures (i.e., 5-minutes) and potential health risks associated with: (1) recent ambient levels of SO_2, (2) levels associated with just meeting the current SO_2 NAAQS, and (3) levels associated with just meeting potential alternative standards (see chapter 5 of this document for the discussion of potential alternative standards). To characterize health risks, we will employ three approaches (Figure 6-1). With each approach, we will characterize health risks associated with the air quality scenarios mentioned above (i.e., recent air quality unadjusted, air quality adjusted to simulate just meeting the current standards, and air quality adjusted to simulate just meeting potential alternative standards). In the first approach, SO_2 air quality levels are compared to potential health effect benchmark values (see section 6.2) derived from the controlled human exposure literature (Chapter 7). In the second approach, modeled estimates of human exposure are compared to the same potential health effect benchmark values derived from the human exposure literature (Chapter 8). In the third approach, outputs from the exposure analysis are combined with exposure-response functions derived from the human clinical literature to estimate the number and percent of exposed asthmatics that would experience moderate or greater lung function responses under the different air quality scenarios (Chapter 9). A more detailed overview of each of these approaches to characterizing potential health risks is provided below (section 6.3), and each approach is described in more detail in their respective chapters and associated appendices. In addition, this chapter also describes important methodologies used throughout these analyses. That is, estimation of 5-minute SO_2 concentrations from 1-hour data (section 6.4) and adjustment of recent air quality to simulate just meeting the current, as well as potential alternative SO_2 standards (section 6.5).

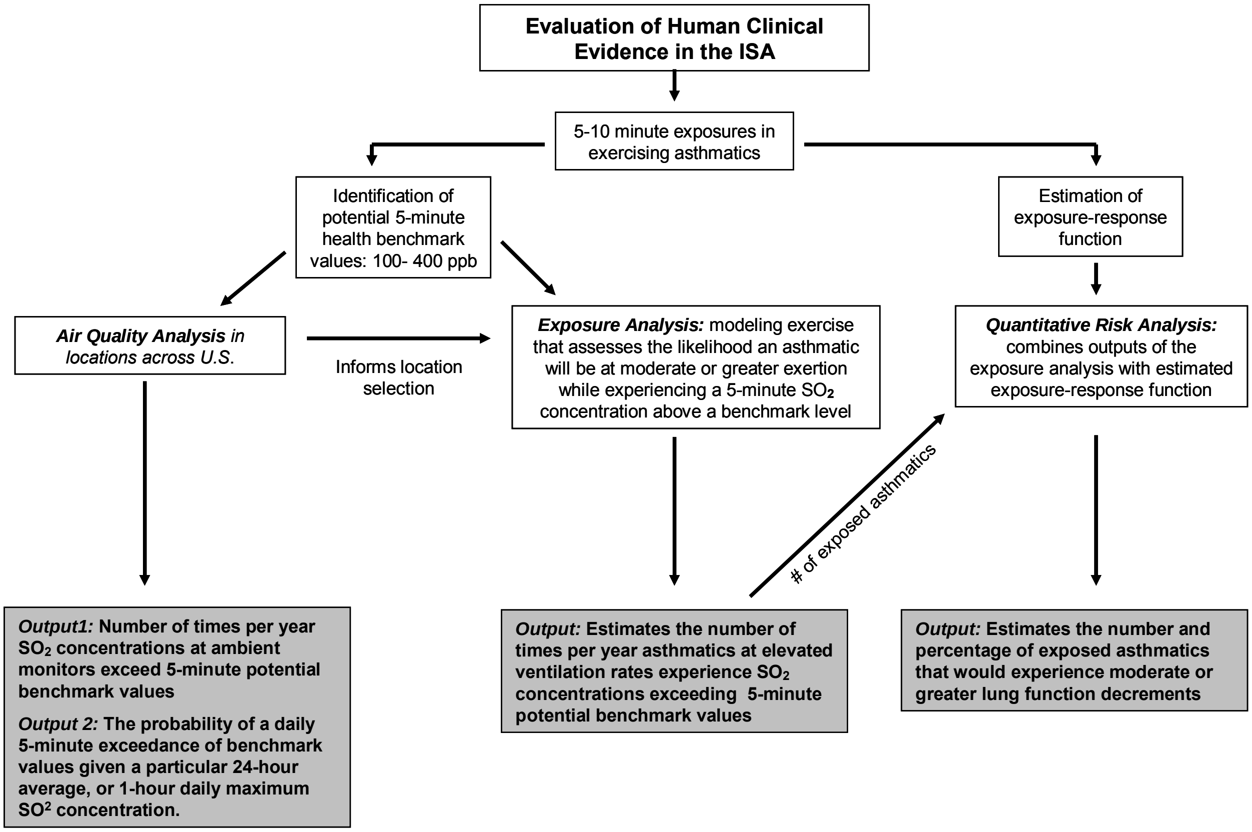

Figure 6-1. Overview of analyses addressing exposures and risks associated with 5-minute peak SO_2 exposures. All three outputs are calculated considering current air quality, air quality just meeting the current standards, and air quality just meeting potential alternative standards. Note: this schematic was modified from Figure 1-1.

6.2 POTENTIAL HEALTH EFFECT BENCHMARK LEVELS

Potential health benchmark values to be used in the air quality, exposure, and risk analyses are derived solely from the human exposure literature. This is primarily because concentrations used in clinical studies represent actual personal exposures rather than concentrations measured at fixed site ambient monitors. In addition, human exposure studies can examine the health effects of SO_2 in the absence of co-pollutants that can confound results in epidemiological analyses; thus, health effects observed in clinical studies can confidently be attributed to a defined exposure level of SO_2.

The ISA presents human exposure evidence demonstrating decrements in lung function in 5-30% of exercising asthmatics exposed to 200-300 ppb SO_2 for 5-10 minutes. However, it is important to note: (1) subjects in human exposure studies do not include individuals who may be most susceptible to the respiratory effects of SO_2, (e.g. severe asthmatics and children) and (2) given that 5-30% of exercising asthmatics experienced bronchoconstriction following exposure to 200 -300 ppb SO_2 (the lowest levels tested in free-breathing chamber studies), it is likely that a percentage of asthmatics would also experience bronchoconstriction following exposure to levels lower than 200 ppb. Considering this information, staff finds it appropriate to examine potential 5-minute benchmark values in the range of 100- 400 ppb. The lower end of the range considers the factors mentioned above, while the upper end of the range recognizes that 400 ppb represents the lowest concentration at which statistically significant decrements in lung function are seen in conjunction with statistically significant respiratory symptoms. Moreover, we note that this range of benchmark values is in general agreement with consensus CASAC comments on the first draft REA.

6.3 APPROACH FOR ASSESSING EXPOSURE AND RISK ASSOCIATED WITH 5-MINUTE PEAK SO_2 EXPOSURES

In the air quality characterization, we have compared SO_2 air quality with the potential health effect benchmark levels for SO_2. Scenario-driven air quality analyses were performed using ambient SO_2 concentrations for the years 1997 though 2006. All U.S. monitoring sites where 1-hour SO_2 data have been collected are represented by this analysis and, as such, the results generated are considered a broad characterization of national air quality and potential human exposures that might be associated with these concentrations. An advantage of this approach is its relative simplicity; however, there is uncertainty associated with the assumption that SO_2 air quality can serve as an adequate indication of exposure to ambient SO_2. Actual exposures will be influenced by factors not considered by this approach, such as the spatial and temporal variability in human activities.

In the second approach, we have used an inhalation exposure model to generate estimates of personal exposures. Estimates of personal exposure have also been compared to the potential SO_2 health benchmark levels as was done in the air quality characterization. This results in estimates of the number of individuals that are likely to experience exposures exceeding these benchmark levels. For this exposure analysis, a probabilistic approach was used to model individual exposures considering the time people spend in different microenvironments and the variable SO_2 concentrations that occur within these microenvironments across time, space, and microenvironment type. The model also accounts for activities that individuals perform within the microenvironments, allowing for estimation of exposures that coincide with varying activity levels. As such, this approach to assessing exposures was more resource intensive than evaluating ambient air quality; therefore, at this time staff has included the analysis of two specific locations in the U.S. (Greene County, MO. and St. Louis, MO.)[8]. Although the geographic scope of this analysis is restricted, the approach provides realistic estimates of SO_2 exposures, particularly those exposures associated with important emission sources of SO_2 and serves to complement the broad air quality characterization.

For the characterization of risks in both the air quality analysis and the exposure modeling analysis described above, staff has used a range of short-term potential health effect benchmarks. The levels of potential benchmarks are based on SO_2 exposure levels that have been associated with respiratory symptoms and decrements in lung function in exercising asthmatics during controlled human exposure studies (ISA, section 5.2; see above section 4.2 for discussion). Benchmark values of 100, 200, 300, and 400 ppb have been compared to both SO_2 air quality (measured and modeled 5-minute concentrations) and to estimates of SO_2 exposure. In characterizing the SO_2 air quality using ambient monitors, the output of the analysis is an estimate of the number of times per year specific locations experience 5-minute daily maximum levels of SO_2 that exceed a particular benchmark. When personal exposures are simulated, the output of the analysis is an estimate of the number of individuals at risk for experiencing daily maximum 5-minute levels of SO_2 of ambient origin that exceed a particular benchmark. An advantage of using potential health effect benchmark levels to characterize health risks is that the effects observed in controlled human exposure studies clearly result from SO_2 exposure. This is in contrast to health effects associated with SO_2 in epidemiologic studies, which may also be associated with pollutants that co-occur with SO_2 in the ambient air. Thus, when using epidemiologic studies as the basis for risk characterization, the unique contribution of SO_2 to a particular health effect may be difficult to quantify. A disadvantage of the potential benchmark approach is that the magnitude of the SO_2 effect on respiratory morbidity can vary considerably from individual to individual and not all asthmatics would be expected to respond to the same

---

[8] In the document titled *Risk and Exposure Assessment to Support the Review of the SO_2 Primary National Ambient Air Quality Standard: First Draft*, staff presented the results of an exposure analysis for Greene County (or Springfield, MO.) and several other source-based modeling domains. Based on CASAC comments received on that exposure analysis, we have refined our approach and applied those refinements to the Greene County analysis presented in this document and completed the exposure assessment in St. Louis which had been started at the time of the earlier draft.

levels of SO_2 exposure. Therefore, the public health impacts of SO_2-induced respiratory morbidity are difficult to quantify.

The third approach is a quantitative risk assessment combining outputs from the exposure analysis with estimated exposure-response functions based on data from controlled human exposure studies. This analysis estimates the percentage, and number of asthmatics likely to experience a given decrement in lung function associated with recent air quality and SO_2 levels adjusted to simulate just meeting the current, and potential alternative standards.

6.4 APPROACH FOR ESTIMATING 5-MINUTE PEAK SO_2 CONCENTRATIONS

Health effects evaluated in this REA include those associated with 5-10 minute peak concentrations of SO_2. While there are 98 ambient monitors that have reported 5-minute SO_2 concentrations some time during 1997-2007, the spatial and temporal representation is limited to a few states and often only a few years of monitoring. Most of these monitors report the 5-minute maximum SO_2 concentration occurring within an hour, though there were a few that reported all twelve continuous 5-minute SO_2 concentrations measured within the hour. The ambient monitors reporting continuous SO_2 values are limited to fewer locations and number of monitoring years, with sixteen monitors deployed within six US states and Washington DC, ten of which operated only during one year. The overwhelming majority of the SO_2 ambient monitoring data are for 1-hour average concentrations (upwards to 935 monitors), comprising a broad monitoring network that includes most U.S. states and territories. Because the health effects of greatest interest were associated with short-term exposures (5-10 minutes) and a greater number of monitors and monitor-years were available for the 5-minute maximum SO_2 concentrations than 10 minute concentrations, a model was developed to estimate 5-minute maximum SO_2 concentrations from the comprehensive 1-hour SO_2 ambient monitoring data.

Staff first reviewed the air quality characterization conducted in the prior SO_2 NAAQS review and supplementary analyses, where the relationship between the maximum 5-minute SO_2 concentration and the 1-hour average SO_2 concentration, or peak-to-mean ratios (PMRs) were initially evaluated and used to approximate 5-minute maximum SO_2 concentrations (EPA, 1986a; EPA, 1994b; SAI, 1995; Thompson, 2000). While the relationship between the two metrics is not expected to be linear, the temporal patterns in the two averaging times are consistent. Five-minute maximum SO_2 concentrations are often much greater than that of the corresponding 1-hour SO_2 concentrations, and observed increases in a given 1-hour SO_2 concentration often coincide with increases in the 5-minute maximum SO_2 concentration. As an example of this pattern, the time-series of 1-hour average and 5-minute maximum SO_2 concentrations measured at an ambient monitor across a 3-day period in 2005 is illustrated in Figure 6-2.

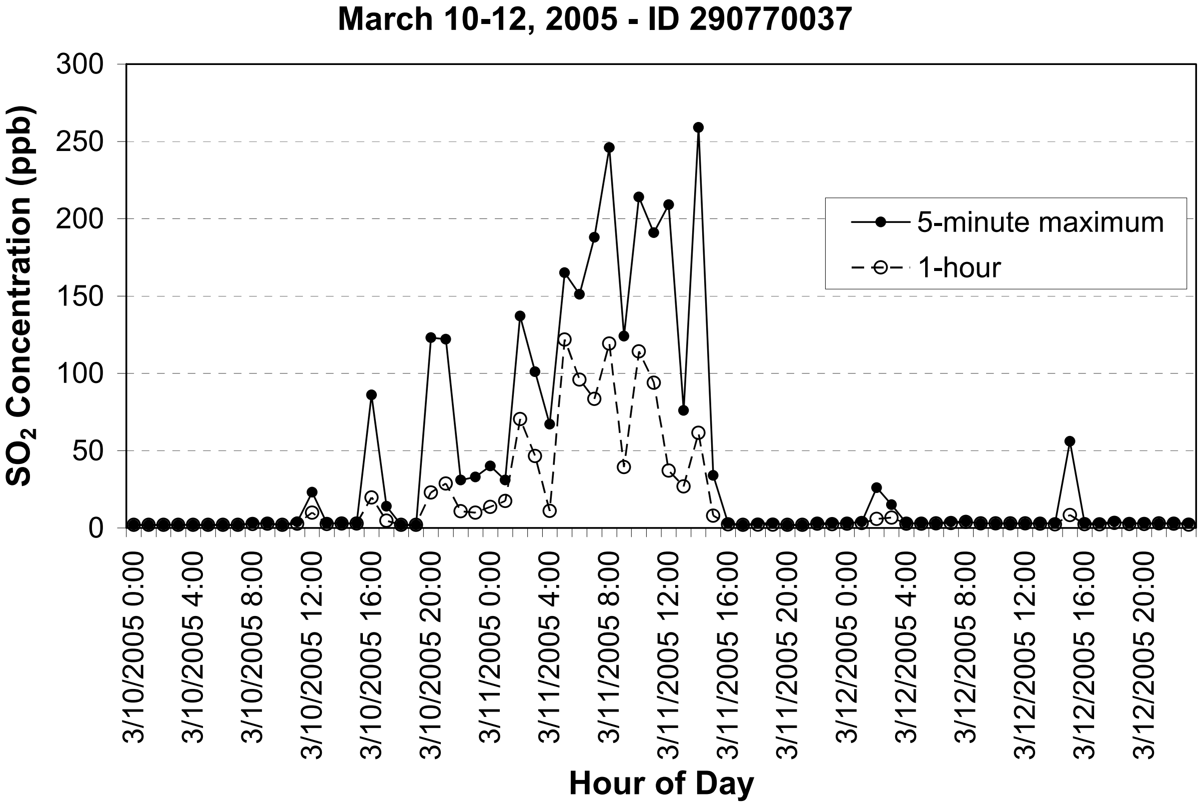

Figure 6-2. Example of an hourly time-series of measured 1-hour and measured 5-minute maximum SO_2 concentrations.

In general, PMRs were determined to be approximately two in some of the earlier studies and used in estimating 5-minute peak SO_2 concentrations; though for the exposure analyses conducted for the last NAAQS review, a distribution of PMRs was used with values of up to eleven (EPA, 1994b). In each of the analyses conducted previously, estimates of PMRs were derived using ambient monitoring data (i.e., where both 5-minute maximum and 1-hour average SO_2 were measured) and then used to estimate the occurrence of peak 5-minute SO_2 concentrations given a 1-hour ambient SO_2 concentration, generally as follows:

$$C_{\max-5} = PMR \times C_{1-hour} \qquad \text{equation (6-1)}$$

where,

C_{max-5} = estimated 5-minute maximum SO_2 concentration (ppb)

PMR = peak-to-mean ratio (PMR)

C_{1-hour} = measured 1-hour average SO_2 concentration

At the time of the last NAAQS review, there were very few monitors reporting 5-minute SO_2 data. In fact, distributions of PMRs from ambient monitors surrounding a single coal-fired power utility served as the primary source used in estimating 5-minute peak concentrations used in the exposure analyses (EPA, 1994b). As mentioned above, the PMRs were determined to be approximately two in these earlier studies; however, the ratio can vary depending on a several factors. It has been shown that there can be increased variability in the ratio with decreasing 1-hour average SO_2 concentrations, that is, there is a greater likelihood of values greater than two at low hourly average concentrations than expected at high hourly average concentrations (EPA, 1986a). It has also been argued that the occurrence of short-term peak concentrations at ambient monitors may be influenced by particular SO_2 emission sources (EPA, 1994b). Different sources may have variable emission amounts, temporal operating patterns (e.g., seasonal, time-of-day), facility maintenance, and other physical parameters (e.g., stack height, area terrain) that could contribute to variability in 5-minute maximum SO_2 concentrations. In addition, a sensitivity analysis conducted for copper-smelters determined that distance from the source was inversely proportional to the PMR in all three of the 1-hour mean stratifications evaluated (i.e., ≤ 0.04 ppm, 0.04 to ≤ 0.15 ppm, and >0.15 ppm), with the highest 1-hour category having the lowest range of PMR (Sciences International, 1995).[9]

There are some data available for the current SO_2 monitoring network regarding the type of sources that may be near the ambient monitors, the magnitude of emissions, the temporal variation in emissions, and distance from specific sources; however, staff determined that there was no practical way to define every ambient monitor as being exclusively influenced by a single source or a defined mix of sources. Given other conditions that may vary within a specific source category (monitor-to-source distances, local meteorology, operating conditions, etc.), staff

---

[9] In that analysis, normalized 1-hour SO_2 concentrations were obtained by dividing by the maximum hourly concentration.

also determined that there was no practical way to use such data quantitatively in the construction of the PMR statistical model and apply such a model to the 1-hour SO_2 ambient monitor data.

In recognizing the limited geographic span of the monitors reporting the 5-minute maximum SO_2 concentrations and the overall uncertainty regarding the amount of influence of a specific source on any given monitor, staff developed an approach based on hourly SO_2 concentration levels and the variability observed at the monitors reporting both the 5-minute maximum 1-hour average SO_2 concentrations. The main assumption in the approach is that the temporal and spatial pattern in SO_2 source emissions is influenced by the type of source(s) present, its operating conditions, and that the emission pattern(s) is reflected in the ambient SO_2 concentration distribution measured at the monitor. Thus, measures of concentration level and associated variability at each monitor were used as a surrogate for the variability in the source characteristics that may impact concentrations at a particular monitor. Each monitor reporting 5-minute maximum SO_2 concentrations was categorized based on the coefficient of variation (COV) of 1-hour average SO_2 concentrations and then used to estimate distribution of PMRs for range of 1-hour SO_2 concentrations. This approach is detailed in section 7.2.3.

6.5 APPROACH FOR SIMULATING THE CURRENT AND ALTERNATIVE STANDARDS

A primary goal of this draft of the risk and exposure assessments is to evaluate the ability of the current SO_2 standards (0.03 ppm annual average, 0.14 ppm 24-hour average) and potential alternative standards (99th percentile 1-hour daily maximum SO_2 levels of 50, 100, 150, 200, and 250 ppb, and 98th percentile 1-hour daily maximum SO_2 levels: 200 ppb; see chapter 5 of this document) to protect public health. In order to evaluate the ability of a specific standard to protect public health, ambient SO_2 concentrations need to be adjusted such that they simulate levels of SO_2 that just meet that standard. Such adjustments allow comparisons of the level of public health protection that could be associated with just meeting the current and potential alternative standards.

All areas of the United States currently have ambient SO_2 levels below the current annual standard (EPA, 2007c). One site in Northampton County, Pa., measured concentrations above the level of the 24-hour standard in 2006. Therefore, in order to evaluate whether the current standards adequately protect public health, nearly all SO_2 concentrations need to be adjusted upwards for all areas included in our assessment in order to simulate levels of SO_2 that would just meet the current standard levels. Similarly, to simulate a potential standard that is below current air quality levels, those current levels must be adjusted downward.

This procedure for adjusting ambient concentrations was necessary to provide insight into the degree of exposure and risk which would be associated with an increase in ambient SO_2 levels such that the levels were just at or near the current standards in the areas analyzed. Staff recognizes that it is extremely unlikely that SO_2 concentrations in any of the selected areas where concentrations have been adjusted would rise to meet the current NAAQS and that there is considerable uncertainty associated with the simulation of conditions that would just meet the current standards. Nevertheless, this procedure was necessary to assess the ability of the current standards, not current ambient SO_2 concentrations, to protect public health. This process of adjusting air quality to simulate just meeting a specific standard is described in more detail below.

6.5.1 Adjustment of Ambient Air Quality

Ambient SO_2 concentrations were characterized in Chapter 7 by considering air quality as is and several hypothetical air quality scenarios. Each of the hypothetical air quality scenarios had an ambient concentration target, derived from the form and level of the current NAAQS or from potential alternative standards. An overview of the approach used to adjust the ambient air quality is provided in the following, with additional details in the approach and application provided in section 7.2.4.

In developing a simulation approach to adjust air quality to meet a particular standard level, policy-relevant background (PRB) levels in the U.S. were first considered. As described in section 2.3, PRB is well below concentrations that might cause potential health effects at most locations. Policy-relevant background will not be considered separately in any characterization of health risk associated with *as is* air quality or air quality just meeting the current standards. In monitoring locations where PRB is expected to be of particular importance however (e.g., Hawaii County, HI) data will be noted as under possible influence of natural rather than anthropogenic sources and will not be used in analyses simulating air quality that would just meet the current or potential alternative standards.

While annual average concentrations have declined significantly over the time period of analysis, the variability in the concentrations (both the 5-minute and 1-hour SO_2 concentrations) have remained relatively constant. This trend is apparent when considering the air quality data collectively (section 7.4.3) and when considering individual locations (Rizzo, 2009). As an example, Figure 6-3 compares the pattern in daily maximum SO_2 1-hour concentration percentiles at the two ambient monitors in Beaver County PA that were in operation as far back as 1978 and are currently part of the monitoring network. Staff selected a recent year of data to constitute a low concentration year along with an historical year of data (1992) constituting a high concentration year (2007), each of the years were common to both monitors. As shown in the figure, the relationships between the low and high concentration years at each of the daily maximum concentration percentiles are mostly linear, with R^2 values above 0.98. Where deviation from linearity did occur in many of the comparisons performed, it occurred primarily at the extreme upper or lower portions of the distribution, often times at the maximum daily maximum or the minimum daily maximum 1-hour SO_2 concentration (Rizzo, 2009). In addition, the absolute values for simple linear regression intercepts were typically 1-3 ppb (Rizzo, 2008). This indicates that the rate of decrease in ambient air quality concentrations at the mean value for the monitors evaluated is consistent with the rate of change at the lower and upper daily maximum 1-hour concentration percentiles. This evaluation provides support for the use of a proportional approach to adjust current ambient concentrations to represent air quality under both the current and alternative standard scenarios.

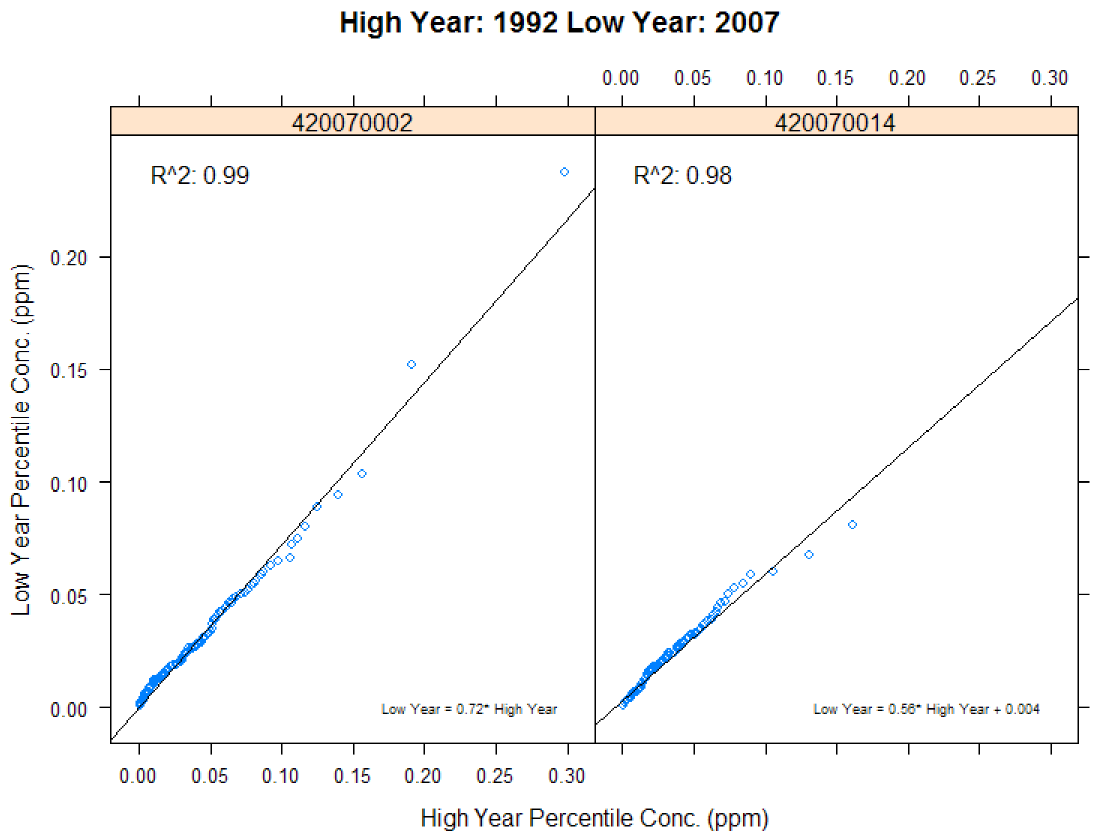

Figure 6-3. Comparison of measured daily maximum SO_2 concentration percentiles in Beaver County, PA for a high concentration year (1992) versus a low concentration year (2007) at two ambient monitors.

The current deterministic form of each standard was used to approximate concentration adjustment factors to simulate just meeting the current 24-hour and annual SO_2 NAAQS. The 24-hour standard of 0.14 ppm is not to be exceeded more than once per year, therefore, the second highest daily mean observed at each monitor was used as the target for adjustment. The rounding convention, which is part of the form of the standard, defines values up to 144 ppb as just meeting the 24-hour standard. The form of the current annual standard requires that the standard level of 0.03 ppm is not to be exceeded, therefore, the highest annual average concentration at each monitor served as the target for adjustment. With a rounding convention to the fourth decimal, values of up to 30.4 ppb would just meet the current standard. For each county (*i*) and year (*j*), 24-hour and annual SO_2 concentration adjustment factors (*F*) were derived by the following equation:

$$F_{ij} = S / C_{\max,ij} \qquad \text{equation (6-2)}$$

where,

F_{ij} = Adjustment factor derived from either the 24-hour or the annual average concentrations at monitors in location *i* for year *j* (unitless)

S = concentration values allowed that would just meet the current NAAQS (either 144 ppb for 24-hour or 30.4 ppb for annual average)

$C_{max,ij}$ = the maximum 2nd highest daily mean SO_2 concentration at a monitor in county *i* and year *j* or the maximum annual average SO_2 concentration at a monitor in location *i* and year *j* (ppb)

In these cases where staff simulated a proportional adjustment in ambient SO_2 concentrations using equation (6-2), it was assumed that the current temporal and spatial distribution of air concentrations (as characterized by the current air quality data) is maintained and increased SO_2 emissions contribute to increased SO_2 concentrations, with the highest monitor (in terms of annual averages) being adjusted so that it just meets either the current 0.03 ppm annual average standard or the 0.14 ppm 24-hour standard, whichever is the controlling standard.[10] Values for each air quality adjustment factor used for each location evaluated in the air quality and risk characterization are given in Appendix A (section A.3). For each county and calendar year, all the hourly SO_2 concentrations in a count were multiplied by the same constant value *F* to make the highest annual mean equal to 30.4 ppb or the 2nd highest 24-hour average equal to 144 ppb for that location and year.

For example, of five monitors measuring hourly SO_2 in Cuyahoga County for year 2001 (Figure 6-4, top), the maximum annual average concentration was 7.5 ppb (ID 390350060), giving an adjustment factor of $F = 30.4/7.5 = 4.06$ for that year. The 2nd highest 24-hour SO_2 concentration was 35.5 (ID 390350038) giving an adjustment factor of $F = 144/35.5 = 4.05$ for year 2001. Because the adjustment factor derived from the 24-hour concentration was lower, 4.05 was selected as the factor to adjust air quality to just meet the current standard. All 1-hour concentrations measured at all monitoring sites in Cuyahoga County were multiplied by 4.05,

---

[10] The controlling standard by definition would be the standard that allows air quality to just meet either the annual concentration level of 30.4 ppb (i.e., the annual standard is the controlling standard) or the 2nd highest 24-hour concentration level of 144 ppb (i.e, the 24-hour standard is the controlling standard). The factor selected is derived from a single monitor within each county (even if there is more than one monitor in the county) for a given year. A different (or the same) monitor in each county could be used to derive the factor for other years; the only requirement for selection is that it be the lowest factor, whether derived from the annual or 24-hour standard level.

resulting in an upward scaling of hourly SO_2 concentrations for that year. Therefore, one monitoring site in Cuyahoga County for year 2001 would have an 2nd highest 24-hour average concentration of 144 ppb, while all other monitoring sites would have a 2nd highest 24-hour average concentration below that value, although still proportionally scaled up by 4.05 (Figure 6-4, bottom). Then, using the adjusted hourly concentrations to simulate just meeting the current standard, the metrics of interest (i.e., annual mean SO_2 concentration, 24-hour average SO_2 concentration, 1-hour daily maximum SO_2 concentration, and the number of potential health effect benchmark exceedances) were estimated for each site-year.

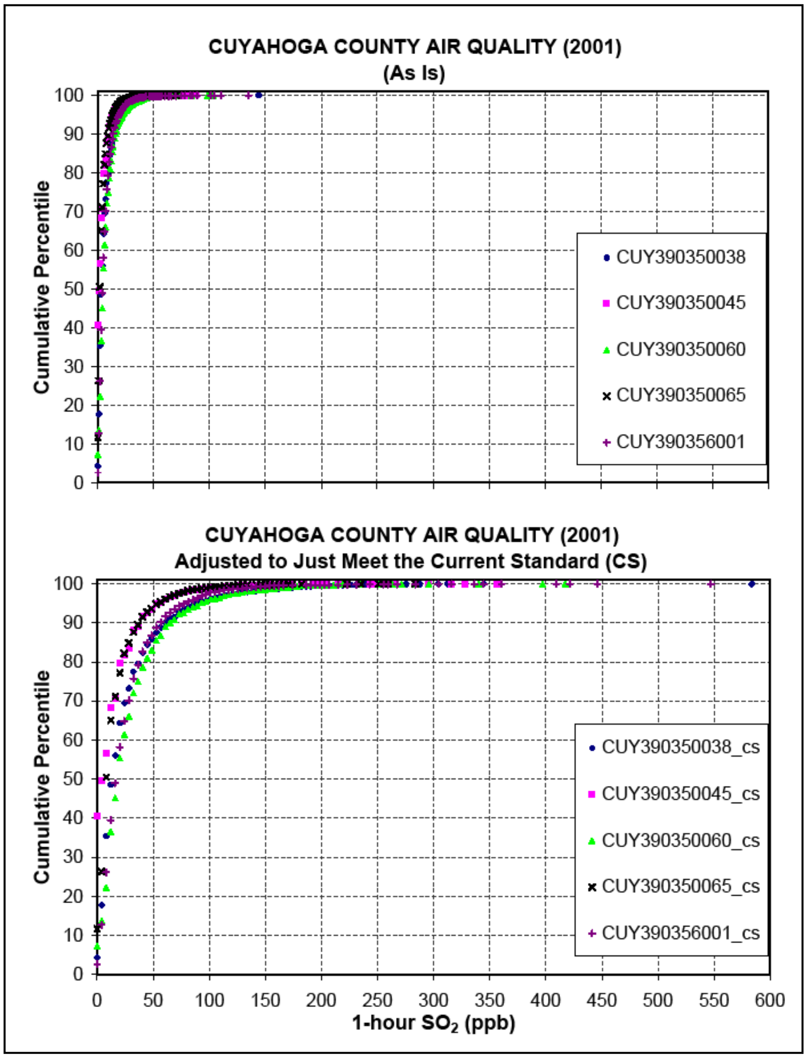

Figure 6-4. Distributions of hourly SO_2 concentrations at five ambient monitors in Cuyahoga County, as is (top) and air quality adjusted to just meet the current 24-hour SO_2 standard (bottom), Year 2001.

Proportional adjustment factors were also derived considering the form, averaging time, and levels of the potential alternative standards under consideration. Discussion regarding the staff selection of each of these components is provided in chapter 5 of this document. The 98th and 99th percentile 1-hour daily maximum SO_2 concentrations averaged across three years of monitoring were used in calculating the adjustment factors at each of five standard levels as follows:

$$F_{ikl} = S_l \Big/ \left(\frac{\sum_{j=1}^{3} C_{ijk}}{3} \right)_{\max,i} \qquad \text{equation (6-3)}$$

where,

F_{ikl} = SO_2 concentration adjustment factor (unitless) in location *i* given alternative standard percentile form *k* and standard level *l* across a 3-year period

S_l = Standard level *l* (i.e., 50, 100, 150, 200, and 250 ppb 1-hour SO_2 concentration (ppb))

C_{ijk} = Selected percentile *k* (i.e., 98th or 99th) 1-hour daily maximum SO_2 concentration at a monitor in location *i* (ppb) for each year *j*

As described above for adjustments made in simulating just meeting the current standards, it was assumed that the current temporal and spatial distribution of air concentrations (as characterized by the current SO_2 air quality data) is maintained and increased SO_2 emissions contribute to increased SO_2 concentrations, with the highest monitor (in terms of the 3-year average at the 98th or 99th percentile) being adjusted so that it just meets the level of the particular 1-hour alternative standard. Since the alternative standard levels range from 50 ppb through 250 ppb, both proportional upward and downward adjustments were made to the 1-hour ambient SO_2 concentrations. The values for each air quality adjustment factor used for each location evaluated in the air quality and risk characterization are given in Appendix A (section A.3). Due to the form of the alternative standards, the expected utility of such an analysis, and the limited time available to conduct the analysis, only the more recent air quality data were used (i.e., years 2001-2006). The 1-hour ambient SO_2 concentrations were adjusted in a similar manner described above for just meeting the current standard, however, due to the form of these standards, only one factor was derived for two 3-year periods (i.e., 2001-2003, 2004-2006), rather than one factor for each calendar year.

6.5.2 Adjustment of Potential Health Effect Benchmark Levels

Rather than proportionally modify the air quality concentrations used for input to the exposure modeling described in Chapter 8, staff applied a proportional adjustment to the potential health effect benchmark levels. The benchmark levels were adjusted rather than the air quality to reduce the processing time associated the modeling of several thousands of receptors in each of the large exposure modeling domains. In addition, because the adjustment procedure is proportional, the application of an adjustment of the selected benchmark level (i.e., division by the adjustment factor) is mathematically equivalent to a proportional adjustment of the air quality concentrations (i.e., multiplication by the adjustment factor). The same proportional approach used in the air quality adjustment described above was used in the exposure modeling to scale the benchmark levels to simulate just meeting the current and potential alternative standards. For example, an adjustment factor of 5.10 was determined for Cuyahoga County for year 2002 to simulate ambient concentrations just meeting the current standard, based on a 2nd highest 24-hour average SO_2 concentration of 28.2 ppb observed at an ambient monitor for that year (see Appendix A, section A.3). Therefore, the 5-minute potential health effect benchmark levels of 100, 200, 300, and 400 ppb were proportionally adjusted downward to 19.6, 39.2, 58.8, and 78.4 ppb, respectively for year 2002.

A comparison of the two procedures is presented in Figure 6-5 where air quality is adjusted to simulate just meeting the current annual standard (i.e., the controlling standard in this example) and where the benchmark is adjusted to simulate air quality that just meets the current standard with using the *as is* air quality. This example used the distribution of hourly SO_2 concentrations measured at one ambient monitor (ID 390350045) within the Cuyahoga County modeling domain for year 2002. Both the adjusted and unadjusted 1-hour SO_2 concentrations were input to the statistical model used to estimate 5-minute daily maximum SO_2 concentrations. If one were interested in the number of exceedances of 5-minute daily maximum SO_2 concentrations of 400 ppb under the current standard scenario for example, this would be equivalent to counting the number of exceedances of 5-minute daily maximum SO_2 concentrations of 78.4 ppb using the *as is* air quality.

For additional clarity, the same ambient air quality data are presented in Figure 6-6, only with expansion of the highest percentiles on the graph to allow for the visualization of the number of exceedances. In using the air quality adjusted to just meet the current standard, i.e., the *as is* air quality was adjusted upwards by a factor 5.10, there were 14 exceedances of a daily maximum 5-minute concentration of 400 ppb.[11] When considering the *as is* air quality without adjustment but with a downward adjustment of the benchmark by the same factor of 5.10, there are the same number of exceedances. This benchmark adjustment procedure was applied by staff in each of the exposure modeling domains to simulate just meeting the current and alternative standards. Additional details regarding derivation of the adjusted benchmark levels used in the exposure modeling are provided in chapter 8 of this document.

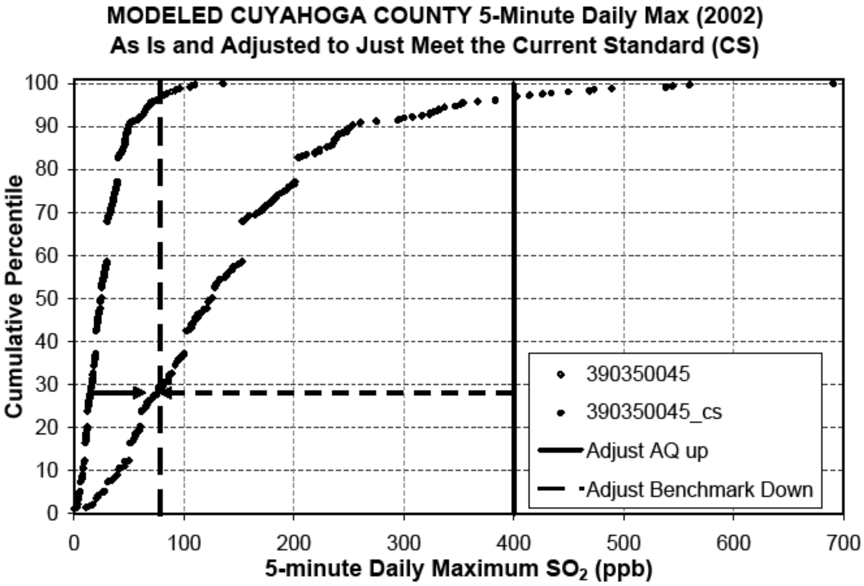

Figure 6-5. Comparison of adjusted ambient monitoring concentrations or adjusted benchmark level (dashed line) to simulate just meeting the current annual average standard at one ambient monitor in Cuyahoga County for year 2002.

---

[11] Only 12 points are observed in Figure 6-3 however, three peak concentrations were identical within each of the simulations.

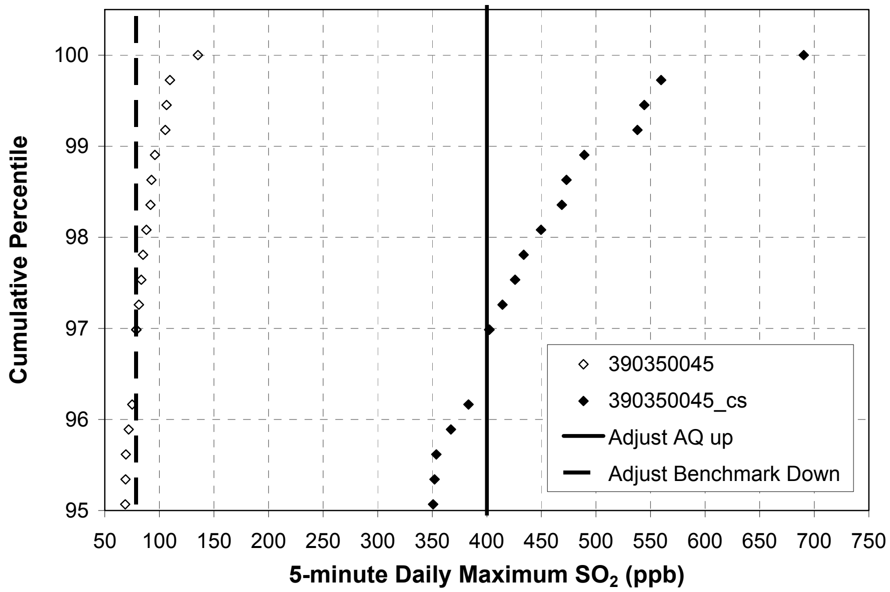

Figure 6-6. Comparison of the upper percentile modeled 5-minute daily maximum SO_2 for where 1-hour ambient SO_2 concentrations were adjusted and the benchmark level was adjusted to simulate just meeting the current annual standard at one ambient monitor in Cuyahoga County for year 2002. The complete distributions are provided in Figure 6-4.

7.0 AMBIENT AIR QUALITY AND BENCHMARK HEALTH RISK CHARACTERIZATION FOR 5-MINUTE PEAK SO_2 EXPOSURES

7.1 OVERVIEW

Ambient monitoring data for each of the years 1997 through 2007 were used in this analysis to characterize SO_2 air quality across the U.S. Measured air quality, as well as additional SO_2 concentrations derived from the measured air quality data, were used as an indicator of potential human exposure. While an ambient monitor measures SO_2 concentrations at a stationary location, the monitor may well represent the concentrations to which persons residing nearby are exposed. The quality of the extrapolation of ambient monitor concentration to personal exposure depends upon the spatial distribution of important emission sources, the siting of the ambient monitors, local meteorological conditions, and consideration of places that persons visit. It is within this context that the approach for characterizing ambient SO_2 air quality was designed by staff.

As previously mentioned, the ISA finds the evidence for an association between respiratory morbidity and SO_2 exposure to be “sufficient to infer a causal relationship” (ISA section 5.2). The ISA states that the “definitive evidence” for this conclusion comes from the results of human exposure studies demonstrating decrements in lung function and/or respiratory symptoms in exercising asthmatics following exposure to SO_2 levels as low as 200 to 300 ppb for 5-10 minutes (section 5.2). Accordingly, 5-minute potential health effect benchmark levels ranging from 100-400 ppb were derived from the human exposure literature (see section 6.2 for benchmark level rationale) and compared to measured and statistically modeled 5-minute ambient concentrations. A broad analysis is first presented that evaluates the potential health risk at all ambient monitors, and then for more detailed analyses, at monitors located within selected U.S. counties (see section 7.2.4). Both the number of the 5-minute benchmark exceedances in a year and the probability of benchmark exceedances given 1-hour daily maximum or 24-hour average concentrations were estimated.

All ambient monitors report hourly SO_2 concentrations; a subset of those report 5-minute maximum SO_2 concentrations as well, with a subset of these reporting continuous 5-minute SO_2 concentrations. Because there were essentially two distinct sample averaging times reported for the available ambient monitoring data (i.e., ambient monitors reporting 1-hour SO_2 concentration measurements alone and monitors reporting both 5-minute and 1-hour average SO_2 concentrations), the data used in the analyses were separated by staff as follows. The first set of ambient air quality data is from monitors reporting both 5-minute and 1-hour SO_2 concentrations. Staff (1) analyzed the ambient monitoring data for trends in 1-hour and 5-minute SO_2 concentrations, (2) counted the number of measured daily 5-minute maximum SO_2 concentrations above the potential health effect benchmark levels given the annual average SO_2 concentrations, (3) estimated the probability of benchmark exceedances given the 24-hour average and 1-hour daily maximum SO_2 concentrations, and (4) developed a statistical model to estimate 5-minute maximum SO_2 concentrations from 1-hour SO_2 concentrations (see section 7.2.3). The second set of ambient data was comprised of 1-hour SO_2 concentrations from the broader SO_2 monitoring network; therefore this set also includes 1-hour SO_2 concentrations from those monitors where 5-minute SO_2 data were reported, though the vast majority of the 1-hour data were from monitors that did not report 5-minute concentration measurements. Staff applied the statistical model that related 5-minute to 1-hour SO_2 measurements to this second set of ambient monitoring data to estimate 5-minute maximum SO_2 concentrations. As was done with the 5-minute SO_2 ambient measurement data, staff evaluated trends in SO_2 concentrations, counted the number of statistically modeled potential health effect benchmark exceedances in a day using the same longer-term averaging times, and estimated the probability of peak concentrations associated with 1-hour daily maximum and 24-hour average SO_2 concentrations.

Staff considered three scenarios in this REA to characterize the ambient SO_2 air quality. The first scenario involved an evaluation of the combined 5-minute and 1-hour SO_2 measurement data as they were reported, representing the conditions at the time of monitoring (termed in this assessment "*as is*"). The second scenario also considered the *as is* air quality; however in this scenario staff used the statistically modeled 5-minute SO_2 concentrations based on the 1-hour SO_2 measurements. This second scenario expands the geographic scope of the 5-minute air quality characterization in using the broader SO_2 monitoring network. The third scenario considered ambient 1-hour SO_2 concentrations simulated to just meeting the current NAAQS[12] and each of the potential alternative 1-hour daily maximum standard levels of 50, 100,

---

[12] For consistency, the concentration units in this chapter are reported as ppb, even though NAAQS have units of ppm. Just meeting the current NAAQS levels could either be meeting a 30 ppb annual average or the 140 ppb 24-

150, 200 and 250 ppb (see chapter 5 for details). The data used in this third scenario were limited to the most recent and comprehensive ambient monitoring data available (i.e., 2001-2006).[13] Due to the form of the alternative standards considered here (98th and 99th percentiles of the 1-hour daily maximum concentrations averaged over 3 years), the recent ambient monitoring data set was evaluated using two three-year groups, 2001-2003 and 2004-2006.[14] To summarize, the first scenario is the only scenario that used entirely 1-hour and 5-minute SO_2 measurement data. The second and third scenarios are common in that they both used a simulation procedure to estimate 5-minute concentrations from measured 1-hour SO_2 concentrations, while the third scenario also included an adjustment of the 1-hour SO_2 concentrations to just meet a particular standard level.

Staff expected there would be variability in the number of persons living within close proximity of each monitor (both the 5-minute and 1-hour SO_2 monitors) given the particular siting characteristics of the ambient monitors (e.g., either source- or population-oriented monitoring objectives). Therefore, we separated some of the air quality results within each scenario by using the population density surrounding each ambient monitor. First, each monitor was characterized by having one of three population densities (i.e., low, medium, and high), groupings defined by the three characteristic regions of the population distribution generated from the broader SO_2 monitoring network. Then, staff counted the number of 5-minute benchmark exceedances per year at each monitor, either measured or estimated depending on the scenario considered, and aggregated the monitors by the population density group. Rather than count the total number of 5-minute SO_2 concentrations above a particular benchmark, staff calculated the number of times in a year the daily 5-minute maximum SO_2 concentration exceeded a benchmark.[15]

---

hour average concentration (one allowed exceedance), whichever is the controlling standard at that ambient monitor (see section 6.5 and section 7.2.4).

[13] At the time of the initial data download from the AQS data mart, many of the monitors did not have complete years of data available for 2007, therefore the most recent data for most monitors was from 2006. These data are a subset of the broader ambient monitoring data set.

[14] A number of 3-year groups are within 2001-2006 (e.g., 2001-2003, 2002-2004, etc.) and a number of years of monitoring data are outside the 2001-2006 time frame that could have been used in an extended 3-year grouping of 2001-2006 air quality (e.g., 2000-2002). For convenience, the upper and lower groupings were chosen by staff to represent 3-year air quality within the 6-year period when considering just meeting the potential alternative standards.

[15] In the first draft SO_2 REA, as well as the early draft NO_2 REAs, all benchmark exceedances for any hour of the day were reported. The use of the daily maximum exceedance was selected in the final NO_2 REA as well in this

Because many of the SO_2 ambient monitoring sites used in this analysis are targeting public health monitoring objectives and the monitoring results are separated by population density groups, staff considers the results a broad characterization of national air quality and potential human exposures that might be associated with these scenario-driven concentrations. One of the outputs of this air quality characterization is an estimate of the number of times per year a monitor experienced daily 5-minute maximum levels of SO_2 above those that may cause adverse health effects in susceptible individuals (i.e., benchmark level exceedances). These counts are a useful metric in comparing one monitor or location to another and in identifying where and when frequent benchmark exceedances occur. The 1st draft SO_2 REA however indicated that the relationship between the annual average SO_2 concentration and the number of 5-minute benchmark exceedances was generally weak; therefore comparison of the number of exceedances in a year with the annual average SO_2 concentration is of limited use. This absence of a strong relationship highlights the ineffectiveness of long-term averaged concentrations in controlling short-term peak concentrations. In addition, while it was shown in the 1st draft SO_2 REA that the number of 5-minute maximum concentrations had an improved relationship with 24-hour average concentrations, [16] it was also shown that the number of peak concentrations was variable given a specific 24-hour average concentration. Often times the number of 5-minute maximum SO_2 concentrations above benchmark levels was zero for a wide range of 24-hour average SO_2 concentrations, while in other instances is could as many as five within the same range. In recognizing that there is variability in the number of 5-minute peak SO_2 concentrations associated with concentrations of longer-term averaging times, that a daily maximum 5-minute SO_2 concentration was the metric of interest, and that the potential alternative standards investigated use 1-hour daily maximum SO_2 concentrations, staff decided that a more appropriate comparison would be between the frequency of peak SO_2 concentrations and a given 1-hour daily maximum SO_2 concentration. Thus, the second output of this air quality characterization is presented as the probability of a benchmark exceedance given a daily maximum 1-hour SO_2 concentration. For comparison, the probability of a 5-minute benchmark

---

draft SO_2 REA to improve the temporal perspective for the metric (i.e, the number of daily maximum exceedances also gives the number of days in a year with an exceedance of a selected benchmark).

[16] In the first draft SO_2 REA, multiple exceedances within a day (if any) were counted. In this draft there is only one possible exceedance per day.

exceedance given a 24-hour average concentration is also provided to offer additional perspective on this averaging time.

7.2 APPROACH

There were five broad steps to characterize the SO_2 air quality. The first step involved compiling and screening the ambient air quality data collected since 1997 to ensure consistency with the SO_2 NAAQS requirements and for usefulness in this air quality characterization. Next, due to potential variable influence of SO_2 emission sources on ambient monitor concentrations, the monitors from each of the two data sets (i.e., combined 5-minute and 1-hour, broader 1-hour only) were categorized and evaluated according to their monitoring site attributes, including land use characteristics, location type, monitoring objective, distance to emissions sources, and population density. In addition, the variability in 5-minute and 1-hour SO_2 concentrations was evaluated and used to categorize each ambient monitor for use in development and application of the 5-minute maximum SO_2 statistical model. Then, criteria based on the measured concentrations proximity to the level of the current standards and the number of exceedances of potential health effect benchmark levels were used to identify specific locations for focused analysis. These locations served as the geographic centers of the current and potential alternative standard analyses. And finally, air quality metrics of interest (i.e., the number and probability of potential health effect benchmark exceedances) were calculated using the air quality data from each scenario.

The following provides an overview of the five steps used to characterize air quality and summarizes key portions of the analysis. Briefly, the five steps include: 1) an air quality data screening; 2) evaluation of site characteristics of ambient SO_2 monitors; 3) development of a statistical model to estimate 5-minute maximum SO_2 concentrations; 4) selection of locations to evaluate the current and potential alternative standard scenarios; and 5) generation of air quality metrics. Details regarding the ambient monitors used for characterizing air quality and associated descriptive meta-data are provided in Appendix A-1.

7.2.1 Air Quality Data Screening

SO_2 air quality data and associated documentation from the years 1997 through 2007 were downloaded from EPA's Air Quality System for this analysis (EPA, 2007c, d). Data obtained were used as reported; there were no substitutions performed for any missing or zero concentration data. The available SO_2 ambient monitoring data, collected over either 5-minute or 1-hour averaging times, are summarized in Table 7-1. The 5-minute SO_2 monitoring data existed in either one of two forms; the single highest 5-minute concentration occurring in a 1-hour period (referred to here as max-5 data set), or all twelve 5-minute concentrations within a 1-hour period (referred to here as continuous-5 data set).

Table 7-1. Summary of all available 5-minute and 1-hour SO_2 ambient monitoring data, years 1997-2007, pre-screened.

Sample Type	Number of Monitors	Number of States[1]	Years in Operation	Number of Measurements
Max-5	104	13 + DC	1997-2007	3,457,057
Continuous-5	16	6 + DC	1999-2007	3,328,725
1-hour	935	49 + DC, PR, VI	1997-2007	47,206,918

Notes:
[1] DC=District of Columbia, PR=Puerto Rico, VI=Virgin Islands.

Staff evaluated the data for inconsistencies and duplication. The reported measurement units varied within each of the data sets, therefore the staff converted all concentrations to parts per billion (ppb). Next staff screened each of the three data sets listed in Table 7-1 for where monitor IDs had multiple parameter occurrence codes (POCs) and identical monitoring times; this could indicate that SO_2 concentrations were measured simultaneously at a given location. These duplicate measures could either result from co-location of ambient monitors (i.e., more than one instrument) or from duplicate reporting of ambient concentrations (i.e., the 5-minute maximum concentration in the max-5 data set is the same as the maximum 5-minute concentration reported from the continuous-5 data set). As a result of this evaluation and additional concentration level screening (see below), staff constructed several data sets for analysis in this REA and summarized in Table 7-2 and is described below.

Table 7-2. Analytical data sets generated using the continuous-5, max-5, and 1-hour ambient SO_2 monitoring data, following screening.

Sample Type	Within Set Duplicates (n)	Available Data (n)	Combined Set Duplicates (n)		Final Combined Max-5 Data (n)	Final Combined 1-hour (n)	Final Combined Max-5 & 1-hour (n)
Max-5	300,438	3,156,619	29,058		3,410,763		2,367,686
Continuous-5 with 1-hour[1]	0	283,202[2]		258,457		47,213,385[3]	
1-hour	0	47,188,640					

Notes:

[1] 1-hour concentrations from continuous-5 data were calculated from all 5-minute values within the hour.

[2] The number of 5-minute maximum samples.

[3] There were a total of 24,745 unique 1-hour values added from the continuous-5 monitors.

1. Simultaneously reported/measured ambient SO_2 data

Two data sets were constructed that had multiple 5-minute SO_2 measurements collected at the same monitoring location and time for:

- max-5 duplicates (i.e., simultaneous measurements of 5-minute maximum SO_2 concentrations from co-located max-5 monitors; n=300,438)
- max-5 and continuous-5 duplicates (i.e., simultaneous 5-minute maximum SO_2 concentrations reported in max-5 and continuous-5 datasets; n=29,058)

A third data set was constructed that had simultaneous 1-hour SO_2 measurements collected at the same monitoring location and time for:

- 1-hour duplicates (i.e., from 1-hour SO_2 monitors and from averaging the continuous-5 monitors; n=258,457)

Each of these duplicate data sets were used for quality assurance purposes only, the evaluation of which is presented in Appendix A-2. The duplicate values were not used in the statistical model development or for any other 5-minute SO_2 concentration analysis.

2. Combined 5-minute and 1-hour ambient SO_2 data

A complete set of 5-minute maximum SO_2 concentrations,[17] generated from the max-5 data set and from the maximum 5-minute concentrations reported by the continuous-5 monitors, was then combined with their corresponding measured 1-hour SO_2 concentrations (see below). Then, the combined data were screened for validity, recognizing that the combined max-5 and 1-hour SO_2 data set may have certain anomalies (e.g., 5-minute maximum SO_2 concentrations < 1-hour mean SO_2 concentration). A value of 1 was selected as the lower bound peak-to-mean ratio (PMR), accepting the possibility that the 5-minute maximum concentrations (and all other 5-minute concentrations within the same hour) may be identical to the 1-hour average concentration. A PMR of <12 was selected as the upper bound since it would be a mathematical impossibility to generate a value at or above that given there are twelve 5-minute measurements within any 1-hour period.[18] This screening resulted in a total of nearly 2.4 million values comprising the combined 5-minute maximum and 1-hour SO_2 concentration data set. Staff used this data set to develop a statistical model (section 7.2.3) and in characterizing the measured 5-minute maximum ambient air quality. Details on the monitors used and site attributes (e.g., latitude, longitude, operating years, monitoring objective) are provided in Appendix A-1.

3. Broader 1-hour ambient SO_2 data

This data set was comprised of all 1-hour SO_2 data, whether obtained from the 1-hour ambient monitoring data set or from averaging 5-minute concentrations from the continuous-5 data set. The raw 1-hour data from a total of 935 ambient monitors were first screened for negative concentrations (n=3,555) and for where concentrations were less than 0.1 ppb (n=14,723). The refined 1-hour data were then combined with the 1-hour average concentrations obtained from the continuous 5-monitors. Staff retained the 1-hour average concentrations from the continuous-5 monitors where duplicate values existed. This was done to better maintain the relationship between the 5-minute maximum and 1-hour SO_2 concentrations. Staff removed duplicate 1-hour values identified at each monitoring location originating from the 1-hour and

---

[17] A single 5-minute and 1-hour SO_2 concentration was used in each of data set 2 and 3. The criteria for selection of a particular value was first based on whether the 1-hour concentration was calculated from the continuous-5 data (where present) followed by the monitor ID POC that had the greatest overall number of samples.

[18] As the 5-minute maximum concentration approaches infinity, the other 11 concentrations measured in the hour comparatively tend towards zero, giving a maximum $PMR = Peak/Mean = C_{max}/[(C_{max} + (C_{others} \rightarrow 0) \times 11)/12] < 12$.

continuous-5 monitors for separate analysis (Appendix A-2). The remaining 1-hour SO_2 data set (with duplicate 1-hour values removed) was then combined with the complete 5-minute maximum data set described above (with duplicate 5-minute maximum SO_2 values removed). Staff used this data set in developing the statistical model to estimate 5-minute maximum SO_2 concentrations (section 7.2.3).

Additional screening of the 1-hour SO_2 data set was performed using a 75% completeness criterion. For a monitor to have a valid year of data, first, valid days were selected as those with at least 18 hours of data. Then, each monitor was required to have 75% of each calendar quarter with complete days (either 68 or 69 days per quartile). This 75% completeness criterion was applied to the available monitoring data to generate 4,692 valid site-years of data obtained from 809 ambient monitors. The number of valid monitoring site-years available as a result of this screening is presented in Table 7-3, effectively encompassing ambient SO_2 monitoring in 48 US States, Washington DC, Puerto Rico and the US Virgin Islands over years 1997 through 2006.[19] This data set was used in the second data air quality characterization scenario that considered the measured *as is* 1-hour SO_2 concentrations with statistically modeled 5-minute maximum concentrations. Details on the monitors used and site attributes (e.g., latitude, longitude, operating years, monitoring objective) are provided in Appendix A-1.

---

[19] Based on the version date of the files downloaded from EPA's AQS data mart (6/20/2007), all 1-hour SO_2 data from 2007 were less than complete. In addition, two monitors located in Hawaii County, HI were identified in the 1st draft REA as having concentrations influenced by natural sources. Therefore, monitor IDs 150010005 and 150010007, while meeting the completeness criteria, were removed from the valid 1-hour SO_2 data set due to the influence of volcanic activity on measured SO_2 concentrations at these locations. Alaska had no SO_2 monitors during the period of analysis.

7.2.2 Site Characteristics of Ambient SO_2 Monitors

The siting of the monitors is of particular importance, recognizing that proximity to local sources could have an influence on the measured SO_2 concentration data and subsequent interpretation of the air quality characterization. Staff evaluated the attributes of monitors within each of the two data sets; the first data set comprised of monitors that reported 5-minute maximum SO_2 concentrations, and the second generated from monitors within the broader SO_2 monitoring network and having valid 1-hour SO_2 concentrations. Two points are worthy of mention for this analysis; the first being the number of monitors and the second being the potential for differences in types of sources influencing each monitor. While there is overlap in the measurement of 5-minute maximum and its associated 1-hour SO_2 concentration at some locations (n=98), the remainder of SO_2 monitors with valid data (n=711) are sited in other locations where 5-minute SO_2 measurements have not been reported. Staff evaluated the ambient monitor attributes within each data set because there may be influential attributes in the subset of data used to develop the statistical model (i.e., monitors reporting 5-minute maximum SO_2 concentrations) that are not applicable to the broader SO_2 monitoring network.

First staff evaluated the specific monitoring site characteristics provided in AQS, including the monitoring objective, measurement scale, and predominant land-use. Additional features such as proximity to SO_2 emission sources and the population residing within various distances of each monitor were estimated using monitoring site and emission source geographic coordinates and U.S Census data. Each of these attributes is summarized here to provide perspective on the attributes of where 5-minute maximum SO_2 concentrations were reported versus the attributes of the broader SO_2 monitoring network. A more thorough discussion of the ambient monitoring network is provided in Chapter 2. Individual monitor site characteristics are given in Appendix A-1.

The monitoring objective meta-data field describes the nature of the monitor in terms of its attempt to generally characterize health effects, the presence of point sources, regional transport, or welfare effects. In recognizing that there were variable numbers of ambient monitors in operation and variation in the number of valid site-years available for each data set, the monitoring objectives were weighted by the number of site-years. This was done to provide perspective on the air quality characterization results that are based on the total site-years of data available, not just the number of ambient monitors. In addition, the monitors can have more than one objective. Where multiple objectives were designated, staff selected a single objective to characterize each monitor using the following order: population exposure, source-oriented, high concentration, general/background, unknown. All other objectives (whether known or indicated as “none”) were grouped by staff into an “Other” category. Figure 7-1 summarizes the monitoring objectives for each monitoring data set. Each of the data sets had a large proportion of site-years that would target public health objectives through the population exposure and highest concentration categories, though the monitors in the broader SO_2 monitoring network had a greater percentage than the monitors reporting both 5-minute maximum and 1-hour SO_2 concentrations. The monitors reporting 5-minute concentrations had approximately twice the percentage of site-years from source-oriented monitors when compared with the broader SO_2 monitoring network.

Similarly, the overall measurement scale of the monitors used for the air quality characterization in each location was evaluated based on the weighting of valid site-years of data. The measurement scale represents the air volumes associated with the monitoring area dimensions. While a monitor can have multiple objectives, each monitor typically has only one measurement scale. Figure 7-1 summarizes the measurement scales for the monitoring site-years comprising each data set. Both data sets had their greatest proportion of monitoring site-years associated with neighborhood measurement scales (500 m to 4 km), though monitors recording 1-hour concentrations had about 22 percentage points greater than the monitors reporting 5-minute maximum concentrations. Furthermore, monitors reporting 5-minute values had a larger proportion of site-years of data characterized at an urban (4 to 50 km) and regional scale (50 km to 1,000 km) compared with the broader SO_2 monitoring network.

The land-use meta-data indicate the prevalent land-use within ¼ mile of the monitoring site. Figure 7-2 summarizes the land-use surrounding monitors that reported 5-minute maximum concentrations and the broader 1-hour SO_2 monitoring network. Over half of the site-years are from residential and industrial areas and are of similar proportions for both data sets considered. The greatest difference in the surrounding land-use was for the number of site-years associated with monitors sited in agricultural and commercial areas. The monitors reporting 5-minute maximum SO_2 concentrations had about 10 percentage points more site-years from monitors within agricultural areas and 10 percentage points less in commercial areas when compared to the respective land use of the broader SO_2 monitoring network.

The setting is a general description of the environment within which the site is located. Figure 7-2 summarizes the setting of each data set. For monitors reporting 5-minute concentrations, the greatest proportion of site-years is from ambient monitors with a rural setting (49%). Most of the site-years in the broader SO_2 monitoring network were from monitors within a suburban setting (40%).

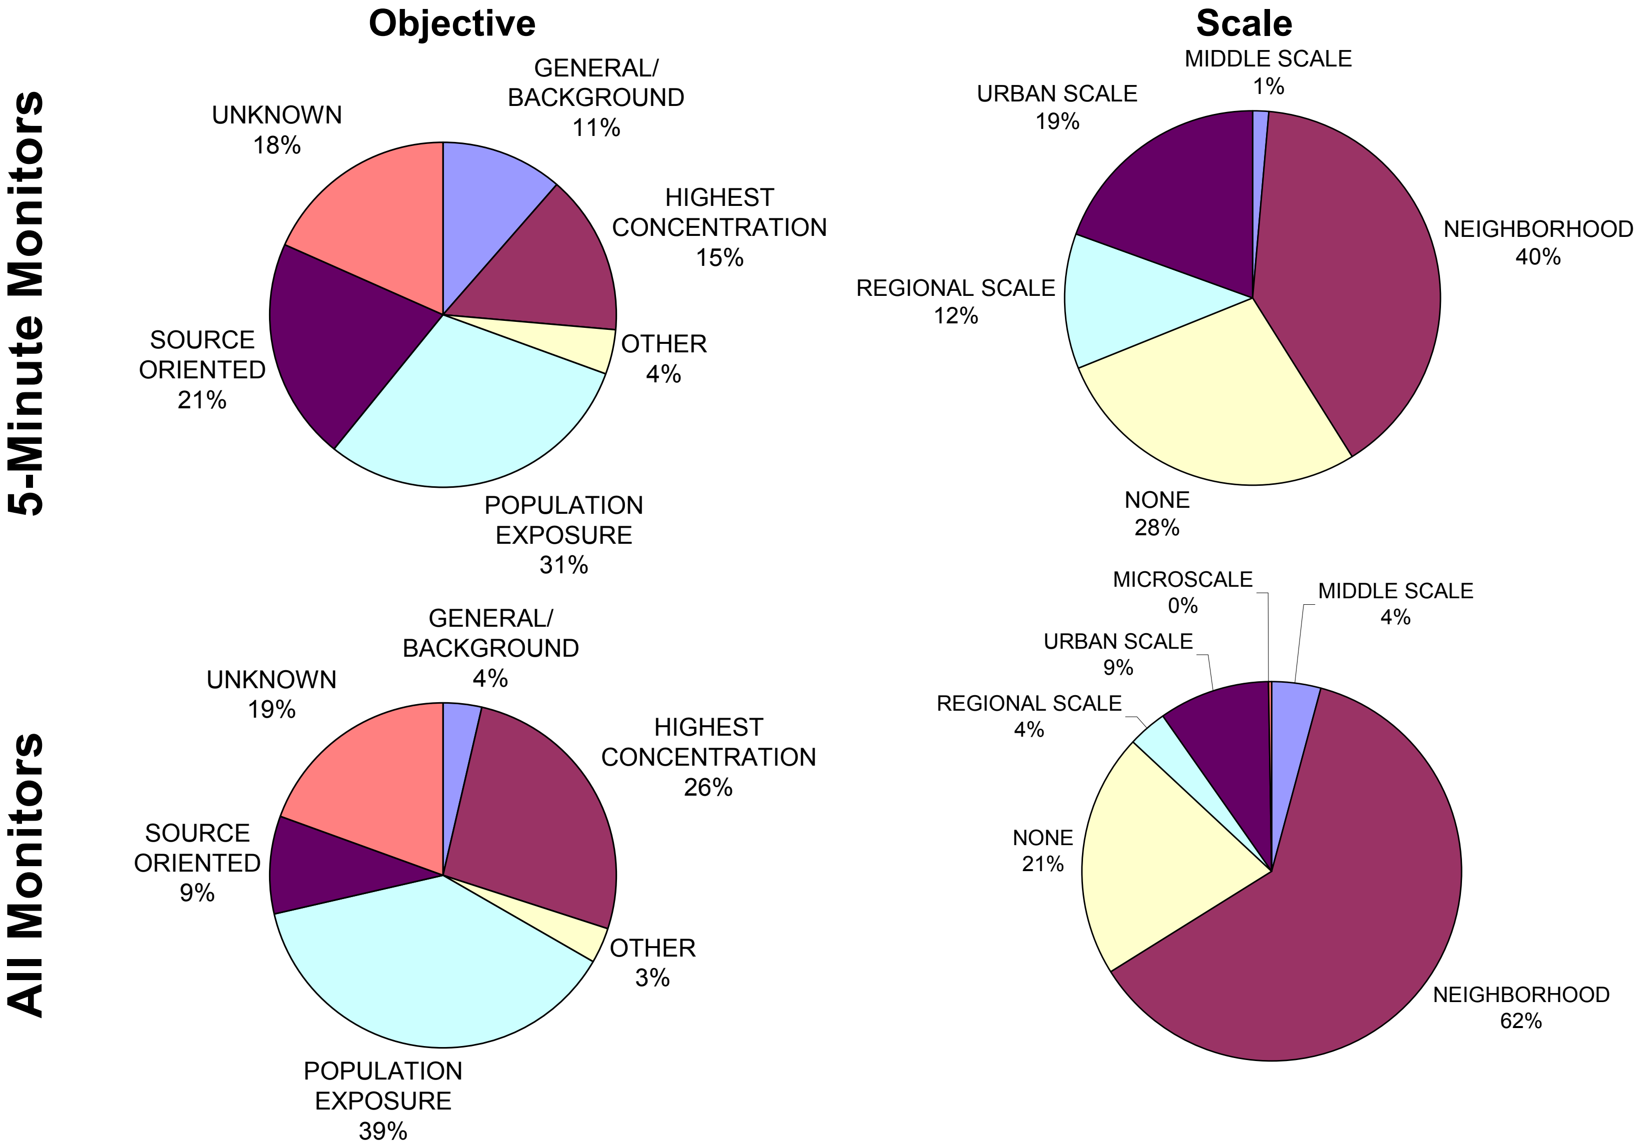

Figure 7-1. Distribution of site-years of data considering monitoring objectives and scale: monitors that reported 5-minute maximum SO_2 concentrations (top) and the broader SO_2 monitoring network (bottom).

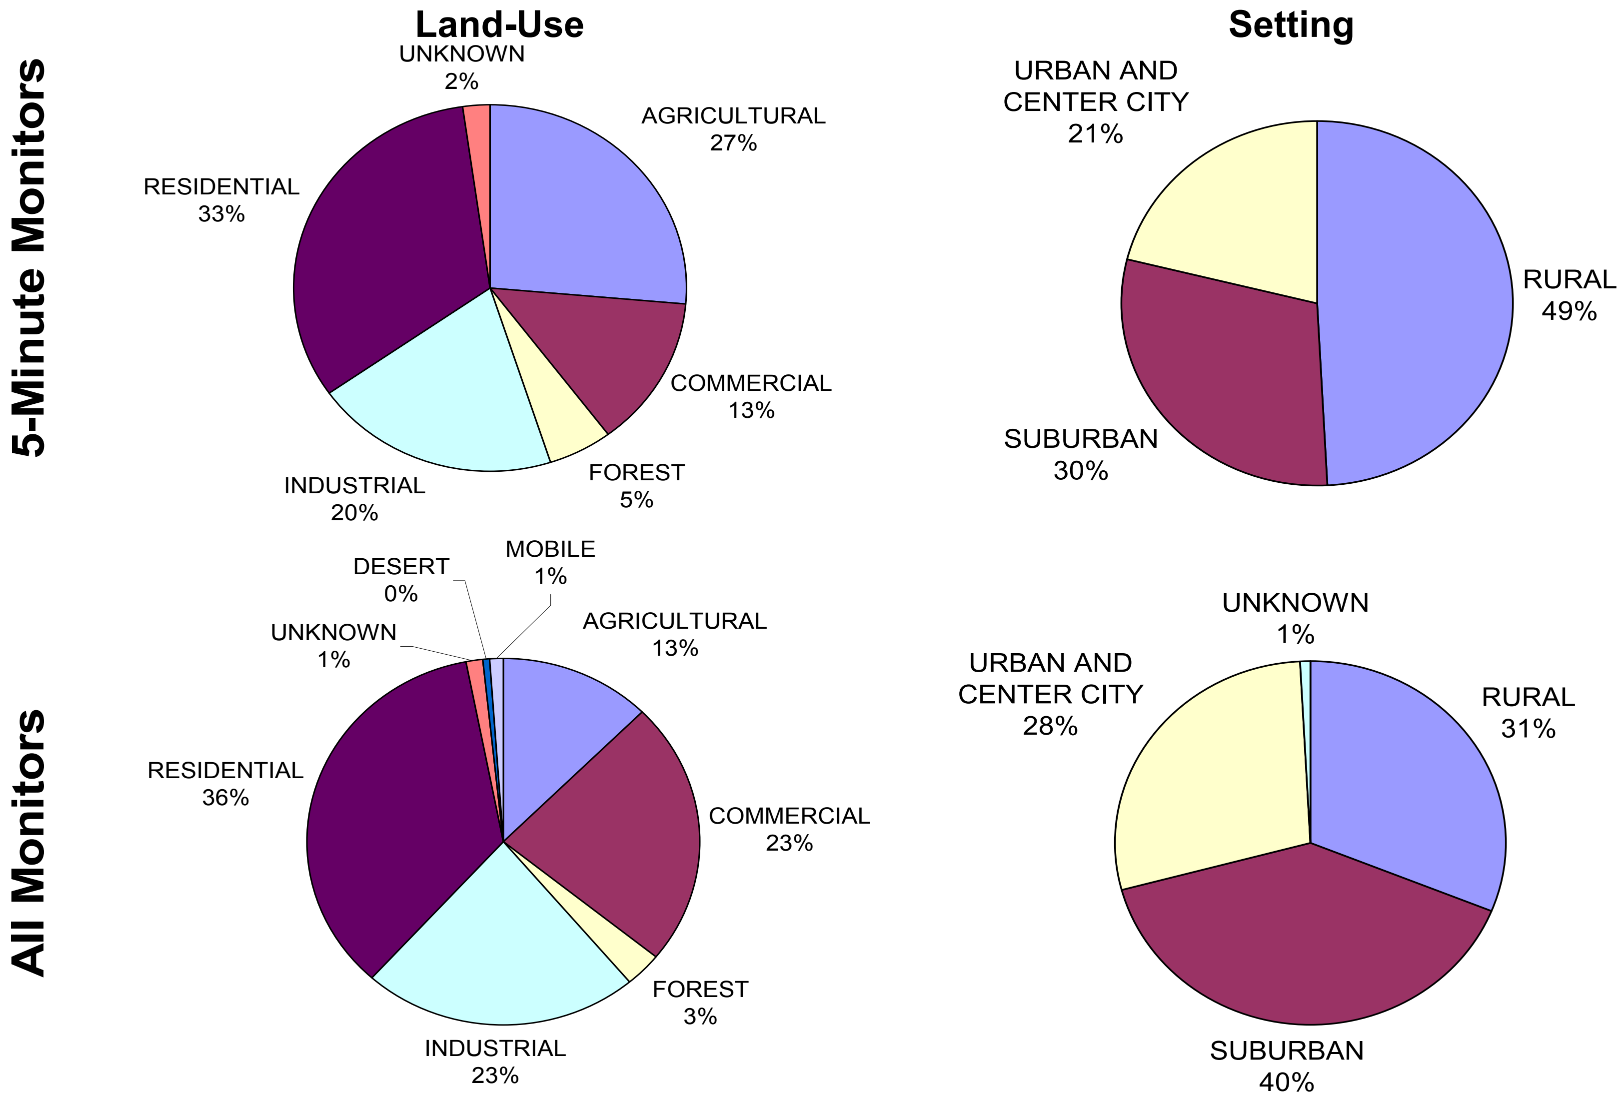

Figure 7-2. Distribution of site-years of data considering land-use and setting: monitors that reported 5-minute maximum SO_2 concentrations (top) and the broader SO_2 monitoring network (bottom).

Stationary sources (in particular, power generating utilities using fossil fuels) are the largest contributor to SO_2 emissions in the U.S. (ISA). First, staff determined the distances, amounts of, and types of stationary source emissions associated with each of the ambient SO_2 monitors. Then, staff selected the sources in close proximity of each monitor to identify whether there are differences in the distribution of emission sources that could affect the monitored concentrations. Stationary sources emitting > 5 tons per year (tpy) SO_2 and within 20 km of each monitor were identified using data from the 2002 National Emissions Inventory (NEI).[20] Details on the number of sources, the distribution of emissions, and the method for determining the distances to each individual ambient monitor are provided in Appendix A-1.

The total SO_2 source emissions within 20 km of every monitor were summed by their source descriptions; the top eight source types were selected for evaluation followed by a summing of all other remaining source types in a final source description group ("other"). These emission results are presented in Figure 7-3 for the monitors reporting 5-minute maximum SO_2 concentrations and for the broader SO_2 monitoring network. A comparison of the sources located within 20 km of monitors comprising both data sets indicates strong similarity in the types of sources present. Approximately 70% of the stationary source emissions local to monitors comprising either data set originate from fossil fuel power generation.[21] Similarity in emission contributions from several other source categories is also evident (e.g., petroleum refineries, iron and steel mills, cement manufacturing). One of the largest distinctions between the sources surrounding the two data sets is the emission contribution from primary smelters. There were greater source emissions from smelters located within 20 km of the monitors reporting 5-minute maximum SO_2 concentrations (8.8%) than within 20 km of the broader SO_2 monitoring network (1.1%). A second difference between the two sets of data existed in the emission contribution from a combined power generation, transmission and distribution description; this source category contributes approximately 11% to emissions proximal monitors in the broader SO_2 monitoring network compared with only 2% at monitors measuring 5-minute SO_2 concentrations.

[20] 2002 National Emissions Inventory Data & Documentation. Office of Air Quality Planning and Standards, Research Triangle Park, NC. Available at: http://www.epa.gov/ttn/chief/net/2002inventory.html.

[21] This emission category was summed from fossil fuel power generation (NEI code 221112) and hydroelectric utilities (NEI code 221111). Hydroelectric utility SO_2 emissions arise from power generating facility operations that require fossil fuel combustion (e.g., diesel-fueled backup generators).

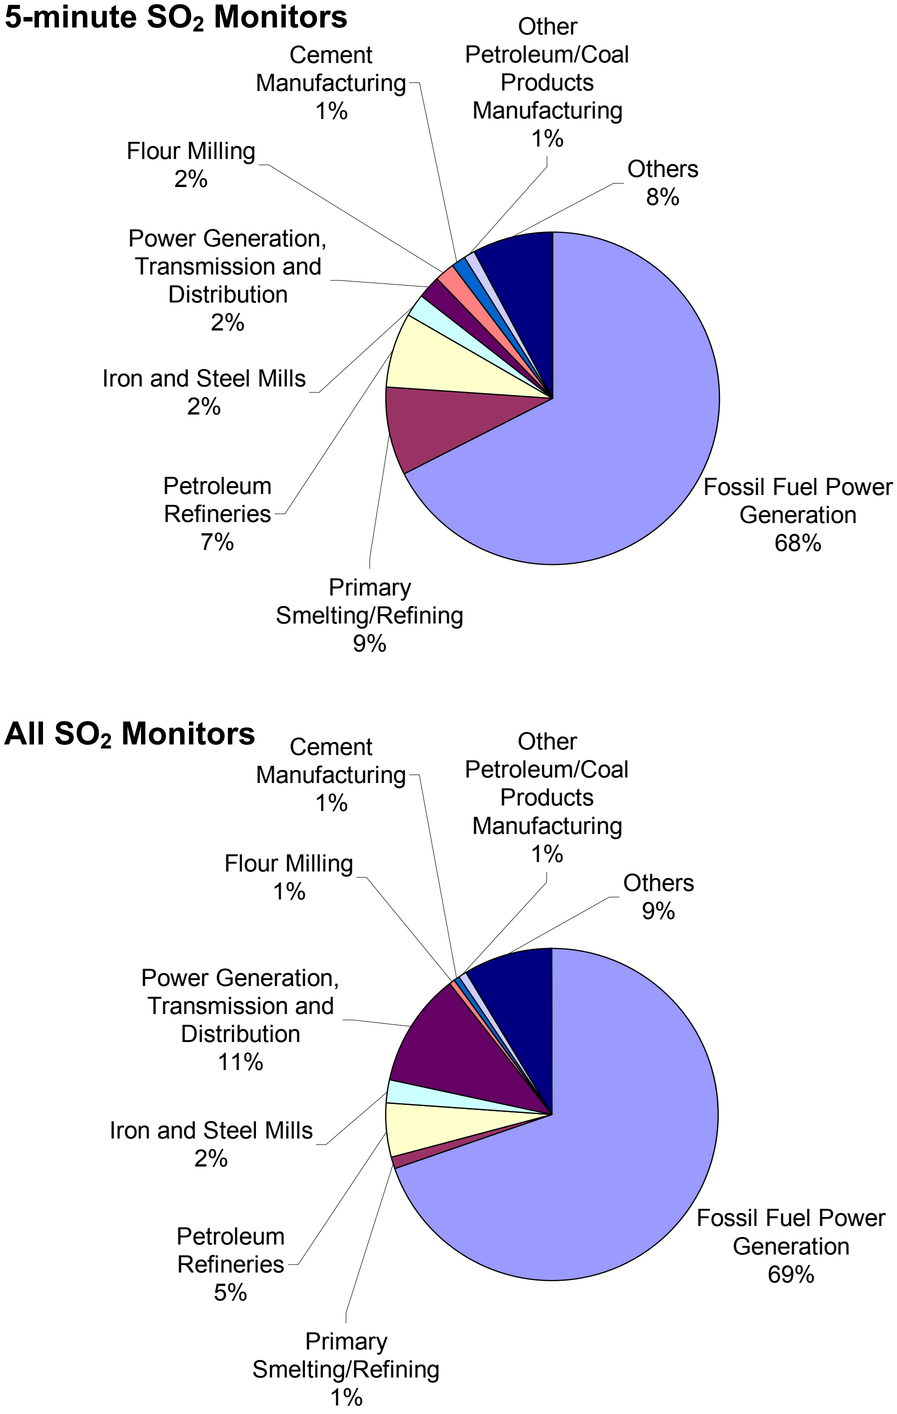

Figure 7-3. The percent of total SO_2 emissions of sources located within 20 km of ambient monitors: monitors reporting 5-minute maximum SO_2 concentrations (top) and the broader SO_2 monitoring network (bottom).

And finally, the population residing within four buffer distances of each ambient monitor was estimated using ArcView. First, staff obtained block group population data from the US Census and converted the location of each block group polygon to single central point. Then buffers were created around each monitor location at progressive 5 km distances to a final buffer distance of 20 km. The total population was estimated by summing the population of all block group centroids that fell within the monitor buffers. An example of the population distribution represented by the monitors comprising each data set is given by Figure 7-4, with the population within each of the buffer distances given in Appendix A-1. In general, the shape of the population distribution was similar for each data set, though as a whole, the monitors reporting 5-minute SO_2 concentrations tended to be sited in locations with lower population density when considering any of the population buffers. Staff created population density groups of *low*, *mid*, and *high* to categorize all ambient monitors using the population distribution within 5 km, by generally apportioning each data set into three equal sample size groupings. The low-population density group included those monitors with populations under 10,000 persons. Mid-population density included those monitors with between 10,000 and 50,000 persons, while the high-population density group was assigned to monitors with greater than 50,000 persons within a 5 km buffer. These population density groups of low, medium, and high were used in separating some of the air quality characterization results.

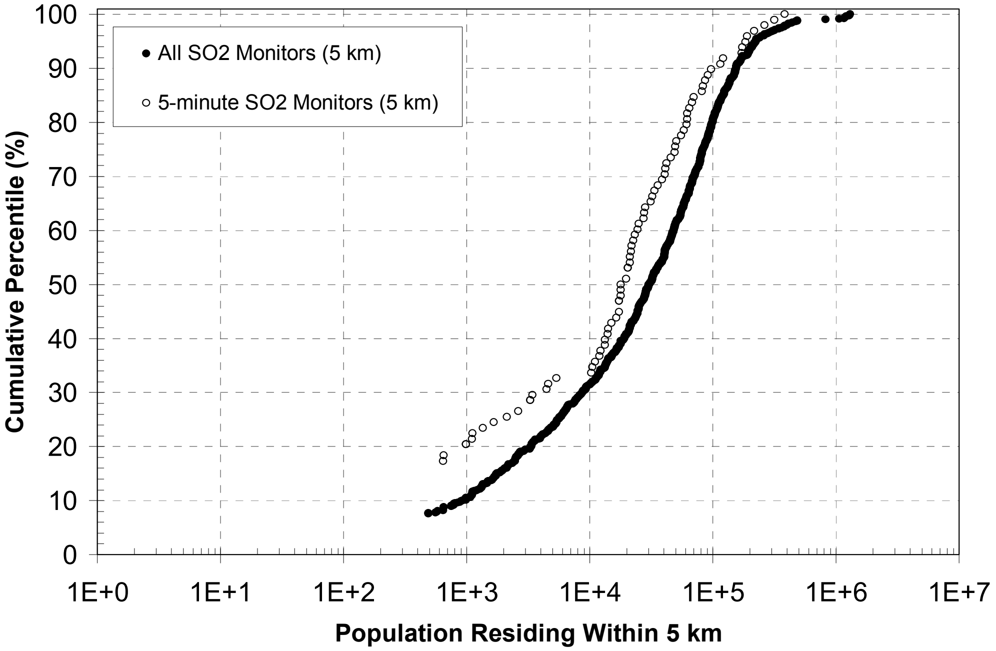

Figure 7-4. Distribution of the population residing within a 5 km radius of ambient monitors: monitors reporting 5-minute maximum SO_2 concentrations and the broader SO_2 monitoring network.

7.2.3 Statistical model to estimate 5-minute maximum SO_2 concentrations

As described earlier, staff noted there were a limited number of ambient monitors that reported 5-minute maximum SO_2 concentrations. The majority of the SO_2 monitoring network reports 1-hour average SO_2 concentrations. Staff developed a statistical model to extend the 5-minute SO_2 air quality characterization to locations where 5-minute concentrations were not reported. The statistical model was briefly introduced in section 6.4; this section details the development of the statistical model designed to estimate 5-minute maximum SO_2 concentrations from 1-hour SO_2 concentrations, using the combined 5-minute maximum and 1-hour SO_2 measurement data set.

Fundamental to the model are the peak-to-mean ratios or PMRs. Peak-to-mean ratios are derived by dividing the 5-minute maximum SO_2 concentration by the 1-hour average SO_2 concentration. These derived PMRs can be useful in estimating 5-minute maximum SO_2 concentrations when only the 1-hour concentration is known. The PMRs derived from monitoring data can be variable however, and are likely dependent on local source emissions, site meteorology, and other influential factors. Each of these factors will have variable influence on the measured concentrations at ambient monitors. Therefore, to develop a useful tool for extrapolating from the measured data, at a minimum, the approach needed to account for variation in ambient concentration. It is within this context that the statistical model was developed.

Staff selected the variability in SO_2 concentrations at each individual ambient monitor as a collective surrogate for source emissions, source types, and/or distance to sources in developing a purposeful application of the statistical model to the broader 1-hour SO_2 measurement data. Many of the meta-data described in section 7.2.2, while useful for qualitatively describing the SO_2 monitoring network, were not considered robust in quantifying how sources could influence monitored concentrations, particularly when many monitor characteristics are unknown, missing, or potentially mischaracterized. In addition, while individual source types, emissions, and distances to the monitors are presented as quantitative measures, use of this data can be problematic knowing that 1) source characteristics can change over time, 2) it is largely unknown what source(s) influence many of the ambient monitors and by how much, 3) there is uncertainty in source emission estimates, and 4) even similar source types will not have the same emission characteristics. There may be several ways to extrapolate between the two data sets, however staff decided that the measured concentrations had the most to offer in efficiently designing the linkage between the statistical model and the broader SO_2 ambient monitoring data set given the strong relationships between averaging times, concentration variability, and the frequency of peak concentrations. Where possible, staff compared the relevant monitor attributes described in section 7.2.2 with selected variability metrics used in developing and applying the statistical model.

The purpose of the first analysis that follows is to determine an appropriate variable to reasonably connect the statistical model derived from 5-minute and 1-hour concentrations to any 1-hour SO_2 concentration data set where there are no 5-minute SO_2 measurements. Staff first evaluated variability metrics associated with 5-minute and 1-hour SO_2 ambient monitoring concentrations as a basis for linking the statistical model to 1-hour concentrations. Next, staff generated distributions of PMRs for use in estimating 5-minute concentrations. Then the statistical model was applied to where 5-minute measurements were reported and evaluated using cross-validation.

7.2.3.1 Relationship Between 5-minute and 1-hour SO_2 Concentrations

Because the statistical model employs 5-minute and 1-hour SO_2 concentrations, staff evaluated the relationship between the concentrations for the two averaging times. The monitors reporting all twelve 5-minute concentrations within the hour were used for this analysis (n=16). First, all of the continuous-5 minute data available for each monitor were averaged to generate a single 5-minute mean concentration (both in an arithmetic and geometric mean form) and their respective standard deviations, yielding a total of 16 monitor-specific 5-minute SO_2 values.[22] Staff performed a second calculation to generate similar statistics using the continuous-5 data, though a 1-hour averaging time was of interest. To obtain the 1-hour statistics, the twelve 5-minute SO_2 concentrations were averaged to generate 1-hour mean SO_2 concentrations for each monitor, which were then averaged to generate a single 1-hour mean SO_2 concentration (both in an arithmetic and geometric mean form) and their corresponding standard deviations, yielding a total of 16 monitor-specific 1-hour SO_2 values.

Staff selected the coefficient of variation (COV)[23] and geometric standard deviation (GSD) as metrics used to compare concentration variability in both 1-hour and 5-minute averaging times, each of which are illustrated in Figure 7-5. As expected, a strong direct linear relationship exists between the variability in 5-minute and 1-hour SO_2 concentrations at each monitor. Even with the limited geographic representation (these monitors are from only six U.S. States and Washington DC), there is a wide range in the observed concentration variability for both the 5-minute and associated hourly measurements (i.e., COVs range from about 75 – 300%, GSDs range from about 1.7 – 3.7). In general, this analysis demonstrates that variability in 5-minute SO_2 concentrations is directly related to the variability in 1-hour SO_2 concentrations, and these measures of variability may be used as to describe the potential variability in concentrations measured at any ambient SO_2 monitor, similarly for either the 1-hour or 5-minute measured concentrations. Note that there is a difference in the slope of the two lines, indicating that there is not a direct linear relationship between the COV and GSD. This means that in characterizing the variability at any ambient monitor, an identified COV (e.g., either low or high COV) does not necessarily correspond to the same GSD characterization.

---

[22] Each of the 16 continuous-5 monitors was characterized by four statistics, arithmetic and geometric means and their respective standard deviations.

[23] The COV used here is calculated by dividing the standard deviation by the arithmetic mean, then multiplying by 100.

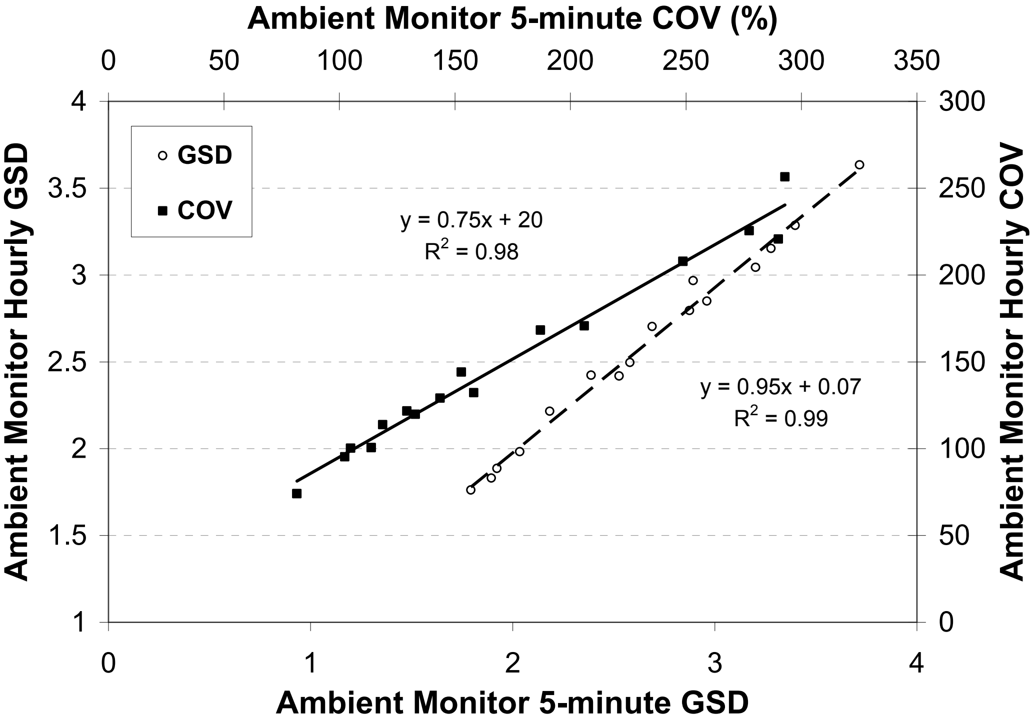

Figure 7-5. Comparison of hourly and 5-minute concentration COVs and GSDs at sixteen monitors reporting all twelve 5-minute SO_2 concentrations over multiple years of monitoring.

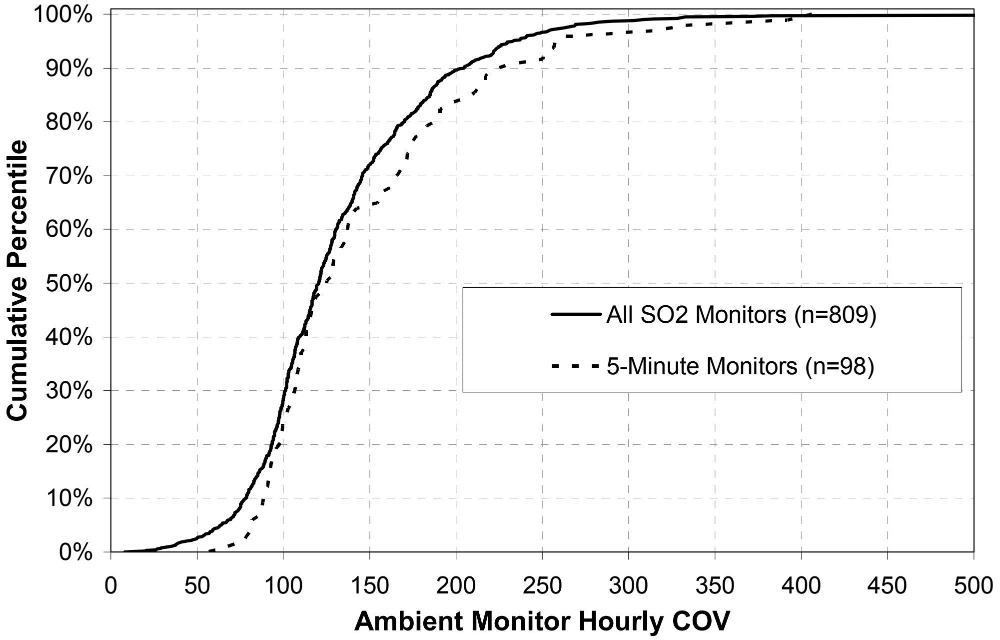
Next, staff compared the variability in 1-hour SO_2 concentrations using data from the monitors reporting 5-minute maximum SO_2 concentrations the broader SO_2 monitoring network. The objective of this evaluation was to determine if the observed hourly concentration variability was similar for the two sets of data. Four statistics were generated for each ambient monitor using the 1-hour SO_2 concentrations, with the variability at each represented by its COV and GSD. Figure 7-6 illustrates the cumulative density functions (CDFs) for the hourly COVs and GSDs at each of the 98 monitors that reported 5-minute maximum SO_2 concentrations (i.e., the data set used for developing the statistical model) and the 809 monitors from the broader SO_2 monitoring network (i.e., the final 1-hour SO_2 data set with complete years). While the subset of monitors reporting the 5-minute maximum SO_2 concentrations exhibit greater variability in hourly concentration at most percentiles of the distribution, the overall shape and span of the distribution is very similar to monitors within the broader SO_2 monitoring network using either variability metric. The similarity in variability distributions could indicate that the monitor proximity to sources, the magnitude and temporal profile of source emissions, and the types of sources affecting concentrations at either set of data (i.e., the monitors reporting 5-minute SO_2

concentrations versus the broader SO_2 monitoring network) are similar. This, combined with the meta-data evaluation and the source type, distance, and emissions analysis that indicated similar source type emission proportions between the two sets of ambient monitoring data (7.2.2), provides support for using concentration variability as a variable to extrapolate information from the 5-minute SO_2 monitors to the 1-hour SO_2 monitors.



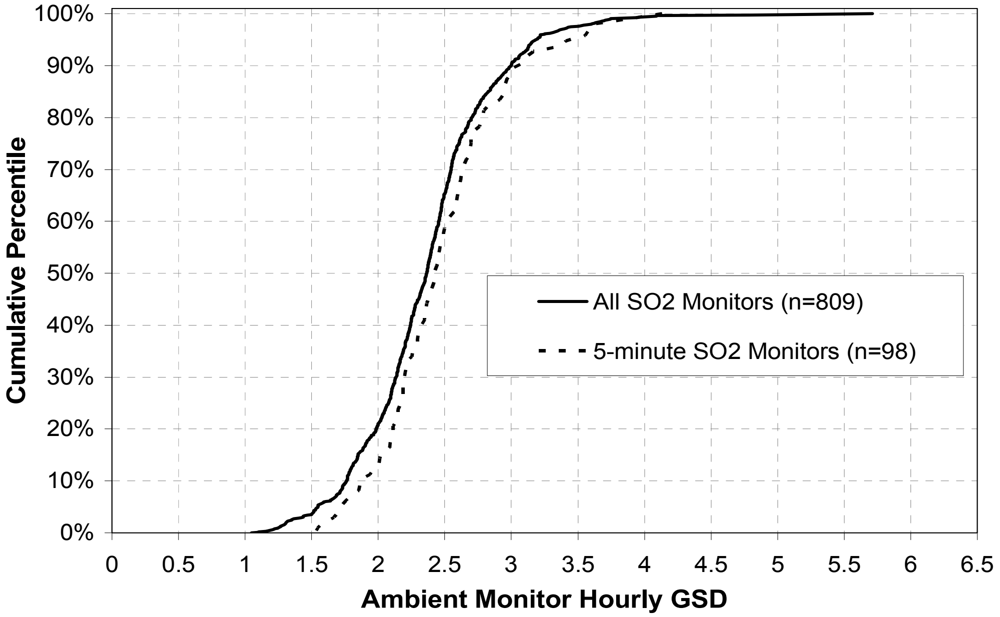


Figure 7-6. Cumulative density functions (CDFs) of hourly COVs (top) and GSDs (bottom) at ambient monitors: monitors reporting 5-minute maximum SO_2 concentrations and the broader SO_2 monitoring network.

7.2.3.2 Development of Peak-to-Mean Ratio (PMR) Distributions

A key variable in the statistical model to estimate the 5-minute maximum SO_2 concentrations where only 1-hour average SO_2 concentrations were measured is the peak-to-mean ratio (PMR). Peak-to-mean ratios are obtained by dividing the 5-minute maximum SO_2 concentration occurring within an hour by the 1-hour SO_2 concentration. The use of a PMR or distributions of PMRs in estimating 5-minute maximum SO_2 concentrations is not new to the current NAAQS review. Both individual PMRs and distributions of PMRs were used in the previous NAAQS review in characterizing 5-minute SO_2 air quality (Thrall et al, 1982; EPA, 1986a; 1994b; Thompson 2000) and in estimating human exposures to 5-minute SO_2 concentrations (Burton et al. 1987; EPA, 1986a, 1994b; Stoeckenius et al. 1990; Rosenbaum et al., 1992; Sciences International, 1995). In this review, staff generated distributions of PMRs to characterize 5-minute SO_2 air quality and in estimating 5-minute SO_2 exposures (chapter 8). The distributions of PMRs used here build upon recent PMR analyses conducted by Thompson (2000).[24] In the current PMR analysis, staff developed several distributions of PMRs using more recent 5-minute SO_2 monitoring data (through 2007) and used concentration level and variability as categorical variables in defining the distributions of PMRs.

Concentration variability has been identified as a potential attribute in characterizing sources affecting concentrations measured at the ambient monitors (section 7.2.3.1). Instead of designing a continuous function from the variability distribution, staff chose to use categorical variables to describe the monitors comprising each data set. The approach involved the creation of variability bins, such that PMR data from several monitors would comprise each bin. Staff decided this approach would better balance the potential number of PMRs available in generating the distributions of PMR given the variable number of samples collected and years of monitoring at monitors that reported the 5-minute maximum SO_2 concentrations (Appendix A-2). Using the hourly COV or GSD distributions in Figure 7-6, staff assigned one of three COV or GSD bins to each of the 98 monitors reporting the 5-minute maximum SO_2 concentrations: for COV, the bins were defined as low ($COV \leq 100\%$), mid ($100\% < COV \leq 200\%$), and high ($COV > 200\%$). These three COV bins were selected to capture the upper and lower tails of the variability distribution and a mid-range area.[25] Similarly and based on the same percentile ranges selected for the COV, three GSD bins were selected as follows: low ($GSD \leq 2.17$), mid ($2.17 < GSD \leq 2.94$), and high ($GSD > 2.94$.

In addition, the level of the 1-hour mean SO_2 concentration has been identified as an important consideration in defining an appropriate PMR distribution to use in estimating 5-

---

[24] In the Thompson (2000) analysis, a single distribution of PMRs was employed based on 6 ratio bins and assumed independence between the ratio and the 1-hour SO_2 concentration.

[25] For monitors reporting the 5-minute maximum SO2 concentrations, these groupings corresponded to approximately the 25th and the 84th percentile of the variability distribution.

minute maximum SO_2 concentrations (EPA, 1986a). Therefore, staff further stratified the PMRs by seven 1-hour mean concentration ranges: 1-hour mean < 5 ppb, 5 ≤ 1-hour mean < 10 ppb, 10 ≤ 1-hour mean < 25 ppb, 25 ≤ 1-hour mean < 75 ppb, 75 ≤ 1-hour mean < 150 ppb, 150 ≤ 1-hour mean < 250 ppb, and 1-hour mean > 250 ppb. Staff selected these 1-hour concentration stratifications to maximize any observed differences in the PMR distributions within a given variability and concentration bin and to limit the total possible number of PMR distributions for computational manageability. While PMR distributions were generated for 1-hour SO_2 concentrations < 5 ppb, it should be noted that any estimated 5-minute maximum SO_2 concentration would be below that of the lowest potential health effect benchmark level of 100 ppb.

Based on the concentration variability and 1-hour concentration bins, staff generated a total of 19 separate PMR distributions.[26] Due to the large number of PMRs available for several of the variability and concentration bins, all of the empirical data were summarized into distributions using the cumulative percentiles ranging from 0 to 100, by increments of 1. Figure 7-7 illustrates two patterns in the PMR distributions when comparing the different stratification bins. First, the monitors with the highest COVs or GSDs contain the highest PMRs at each of the percentiles of the distribution (bottom graph of each variability bin in Figure 7-7) when compared with monitors from the other two variability bins (top and middle graphs), while the mid-range variability bins (middle graph) had a greater proportion of higher PMRs than the low variability bin (top graph). These distinctions in the PMR distributions are consistent with the results illustrated in Figure 7-5, that is, the variability in the hourly average concentrations is directly related to the variability in the short-term concentrations.

---

[26] Although there were a total of 21 PMR distributions possible (i.e., 3 × 7), the COV < 100% and GSD <2.17 categories had only three 1-hour concentrations above 150 ppb. Therefore, the two highest concentration bins do not have a distribution, and concentrations > 75 ppb constituted the highest concentration bin in the low COV or low GSD bins. All PMR distributions are provided in Appendix A-3.

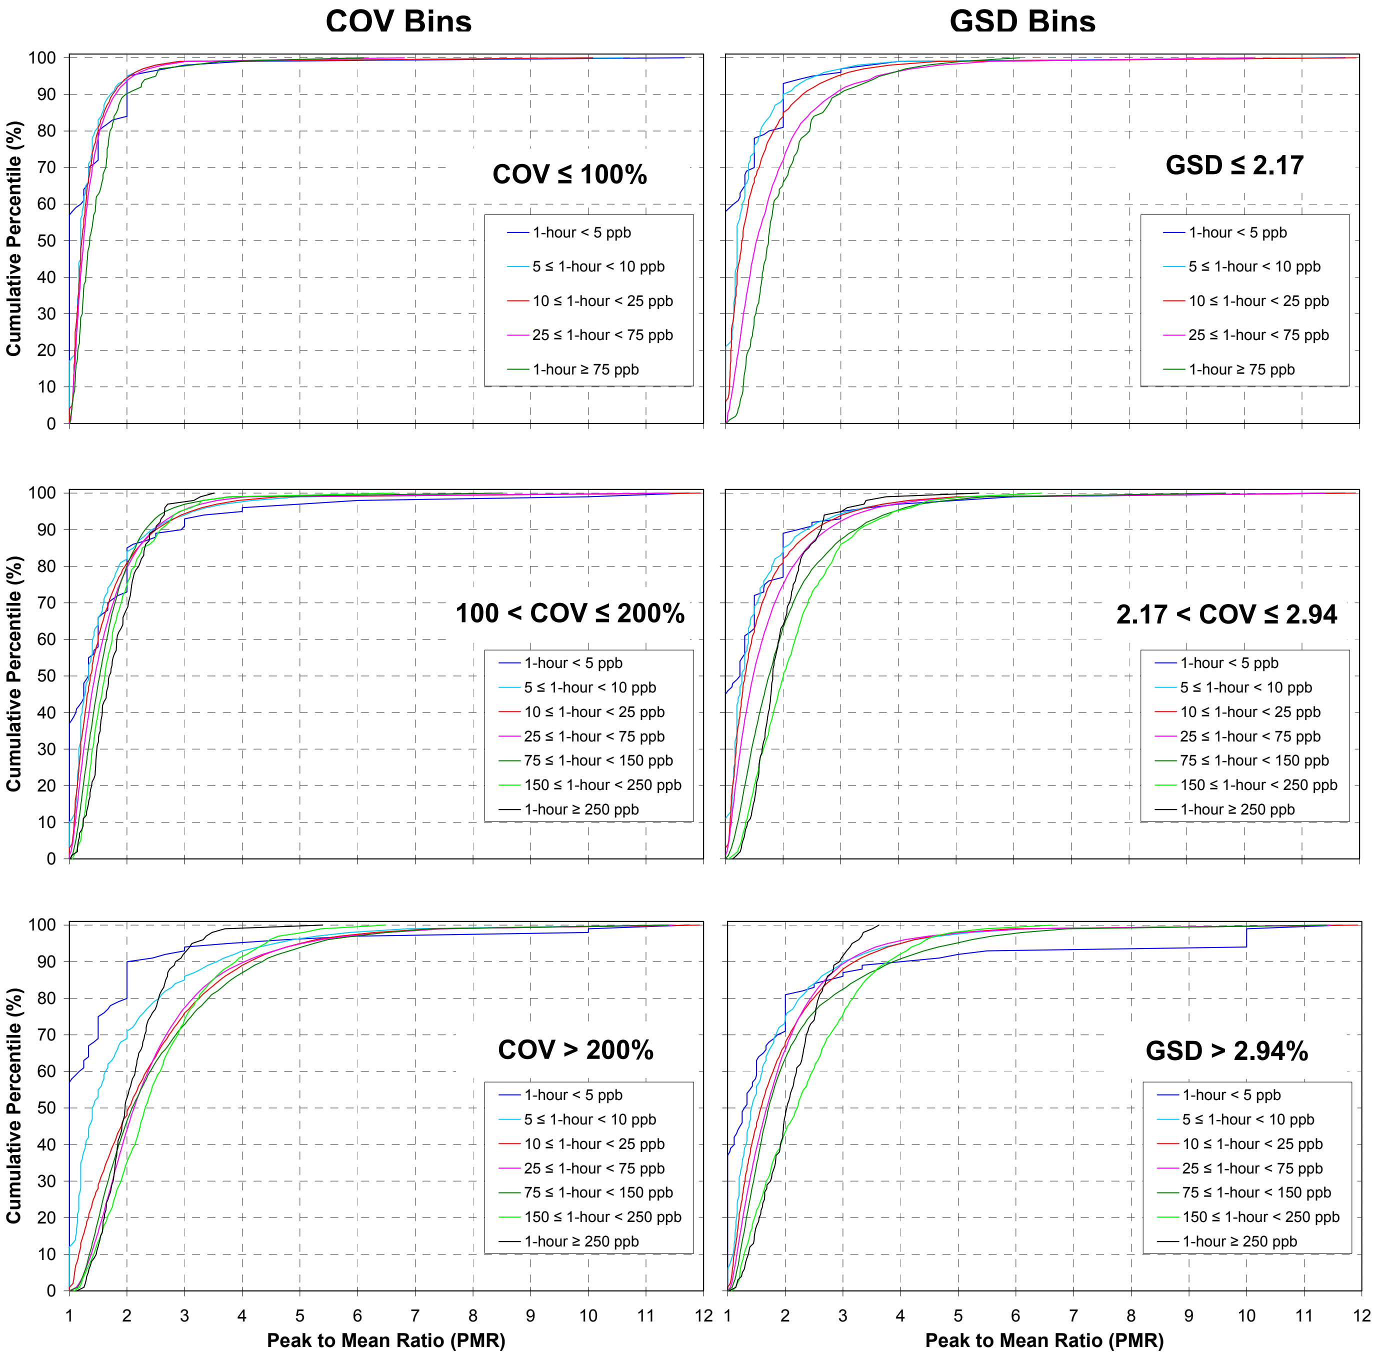

Figure 7-7. Peak-to-mean ratio (PMR) distributions for three COV and GSD variability bins and seven 1-hour SO_2 concentration stratifications.

Second, differences were observed in the PMR distributions within each variability bin when stratified by 1-hour SO_2 concentration. This is most evident in the highest variability bin (bottom graph of Figure 7-7); the highest 1-hour concentration category (> 250 ppb) had lower PMRs at each of the distribution percentiles compared with the PMR distributions derived for the lower concentration categories, most prevalent at the upper percentiles of the distribution. In fact, the maximum PMRs for the > 250 ppb concentration bin were only 5.4 and 3.6 for the COV and GSD high variability bin, respectively, compared with maximum PMRs of about 11.5 at many of the other concentration bins. Again, this inverse relationship between the PMR and concentration level has been shown by other researchers (EPA, 1986a). The stratification of PMRs by the 1-hour concentration was done to avoid applying high PMRs calculated from low hourly concentrations to high hourly concentrations. The observed patterns in the PMR distributions support the staff selection of variability bins and 1-hour concentration stratifications in controlling for the aberrant assignment of PMRs to particular 1-hour concentrations.

Staff compared the assigned concentration variability bin at each monitor with two ambient monitoring site characteristics described in section 7.2.2. First, the total emissions within 20 km of each monitor were compared with the assigned concentration variability bin. This comparison was performed using the monitors reporting 5-minute maximum SO_2 concentrations and the broader SO_2 monitoring network (Figure 7-8). A pattern of increased emissions associated with increasing concentration variability bin is common with both the COV and GSD bins, though more prominent in the COV bins. In general, this indicates the variability bins may be useful as a surrogate for local source emission characteristics.

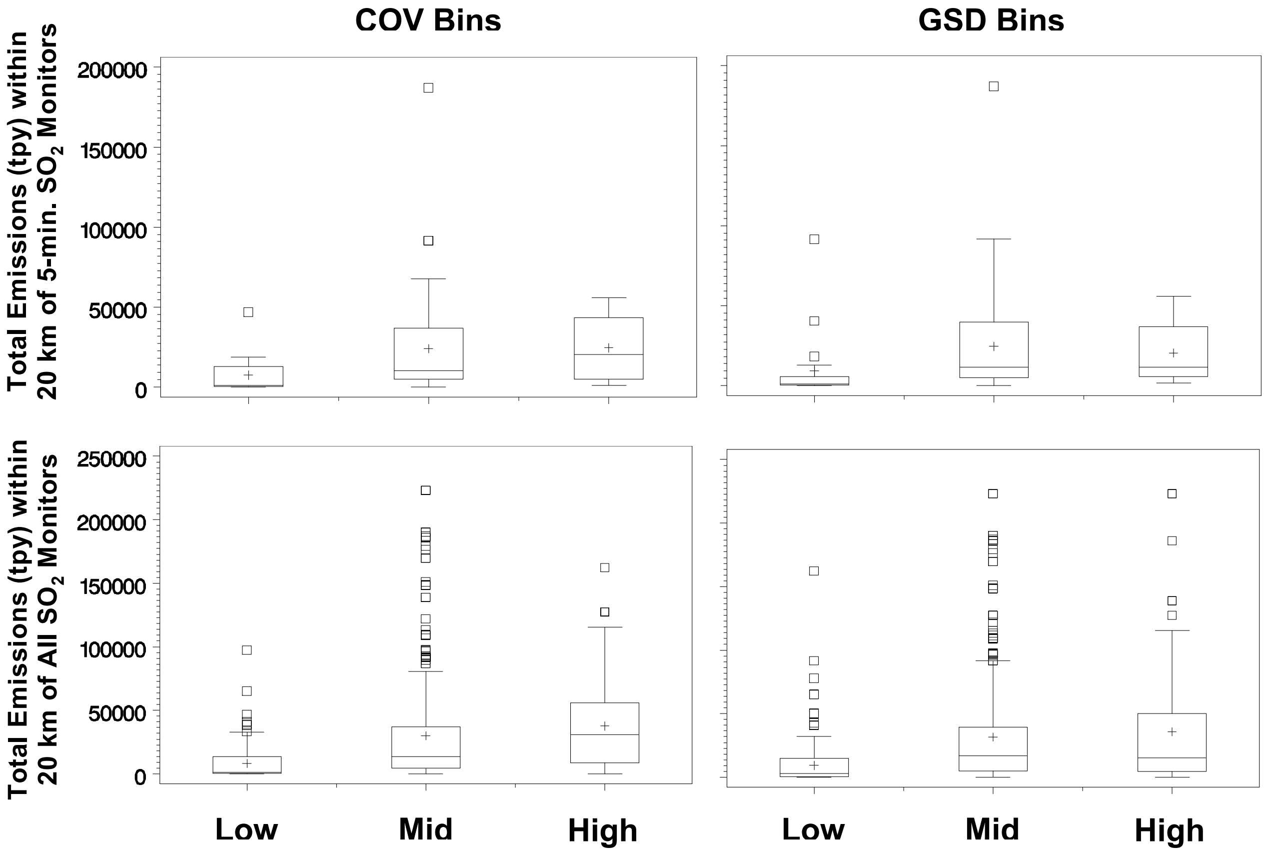

Figure 7-8. Distribution of total SO_2 emissions (tpy) within 20 km of monitors by COV (left) and GSD (right) concentration variability bins: monitors reporting 5-minute maximum SO_2 concentrations (top) and the broader SO_2 monitoring network (bottom).

The second ambient monitoring site characteristic compared with the selected concentration variability bins was the monitoring objective, principally when it was noted as source-oriented. Staff calculated the percent of monitors in each variability bin that were identified as source-oriented using the two sets of data; the set comprised of monitors that reported 5-minute maximum SO_2 concentrations and those within the broader SO_2 monitoring network. In general, there is an increasing percent of monitors characterized as source oriented in the higher concentration variability bins when using either the COV or GSD metrics (Figure 7-9), though the pattern is more consistent with the COV metric than with the GSD metric. This comparison also indicates that the concentration variability metric may be useful as a surrogate for local source emission characteristics.

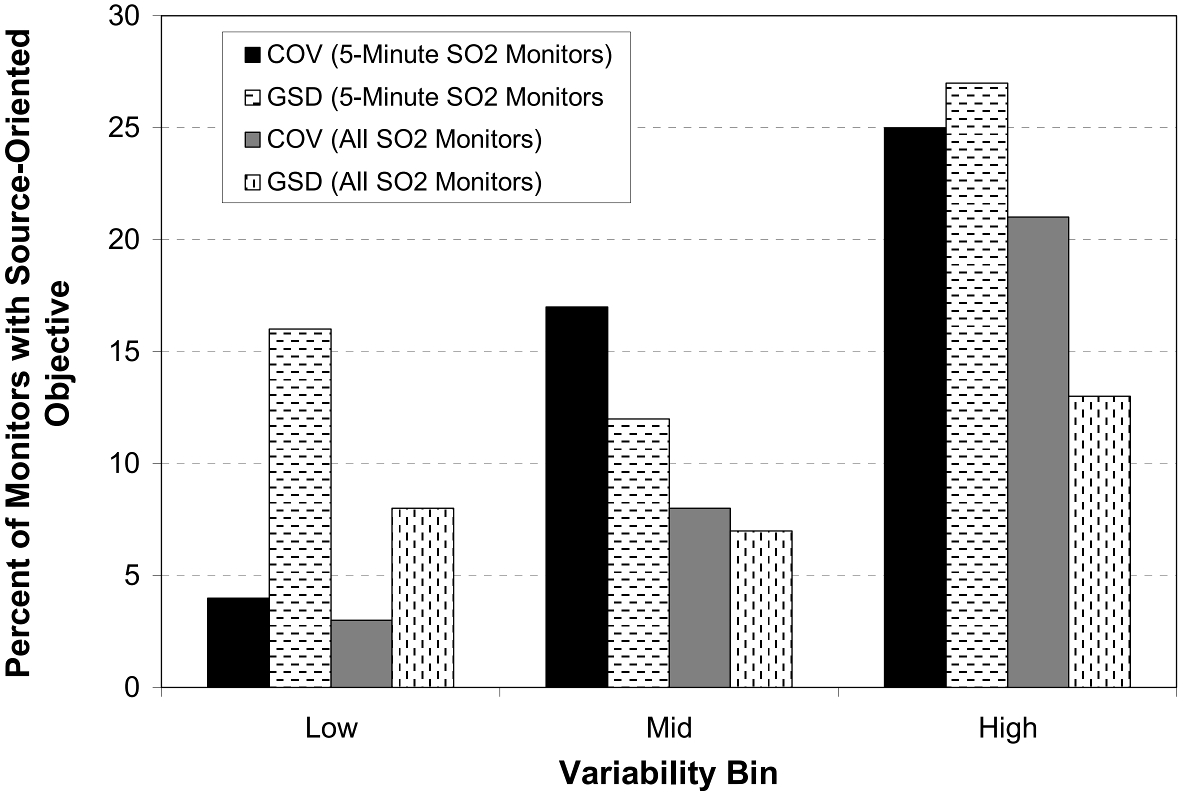

Figure 7-9. Percent of monitors within each concentration variability bin where the monitoring objective was source-oriented: monitors reporting 5-minute maximum SO_2 concentrations (solid) and the broader SO_2 monitoring network (slotted).

7.2.3.3 Application of Peak to Mean Ratios (PMRs)

As described above regarding the monitors reporting 5-minute maximum SO_2 concentrations, staff characterized the monitors within the broader SO_2 monitoring network (n=809) were also characterized by their respective hourly concentration variability and placed in one of the three COV bins (COV ≤ 100%, 100% < COV ≤ 200%, and COV > 200%) and GSD bins (GSD ≤ 2.17, 2.17 < GSD ≤ 2.94, and GSD > 2.94). Based on the monitor's assigned concentration variability bin (either from the COV or GSD, not mixed) and the 1-hour SO_2 concentration, PMRs can be randomly sampled[27] from the appropriate PMR distribution to estimate a 5-minute maximum SO_2 concentrations using the following equation:

---

[27] The random sampling was based selection of a value from a uniform distribution {0,100}, whereas that value was used to select the PMR from the corresponding distribution percentile value.

$$C_{\max-5} = PMR_{ij} \times C_{i,1-hour} \qquad \text{equation (7-1)}$$

where,

C_{max-5} = estimated 5-minute maximum SO_2 concentration (ppb) for each hour

PMR_{ij} = peak-to-mean ratio (PMR) randomly sampled from the *i* concentration variability and *j* 1-hour mean SO_2 concentration distribution

$C_{i,1-hour}$= measured 1-hour average SO_2 concentration at an *i* concentration variability monitor

As a result of this calculation, every 1-hour ambient SO_2 concentration has an estimated 5-minute maximum SO_2 concentration.[28] These data were then summarized using the output metrics described in section 7.2.5.

7.2.3.4 Evaluation of Statistical Model Performance

Staff evaluated the performance of the statistical model using cross-validation (Stone, 1974). Details of the evaluation are provided in Langstaff (2009). Briefly, PMR distributions were estimated using 97 of the 98 monitors that reported both the 1-hour and 5-minute maximum SO_2 concentrations. All ambient monitors were characterized using the same variability bins and 1-hour concentrations were characterized by the same stratifications described in section 7.2.3.2. Then staff used the newly constructed PMR distributions to predict the 5-minute maximum SO_2 concentrations at the monitor not included in developing the PMR distributions using equation 7-1. This modeling was performed 98 times, i.e., removing every single monitor (one monitor at a time), generating new PMR distributions, and predicting 5-minute maximum SO_2 concentrations at the removed monitor. Staff then compared the predicted and measured daily 5-minute maximum SO_2 concentrations to generate a distribution of model prediction errors (e.g., median errors, median absolute errors) and general model statistics (i.e., the root mean square error or RMSEs, and R^2, a measure of the amount of variance explained by the model).

Four statistical models were evaluated: the two variability bins (COV and GSD) using all percentiles of the PMR distributions and the two variability bins without the minimum and maximum percentiles of the PMR distributions. The models were evaluated at the benchmark

---

[28] When the 1-hour SO_2 concentration was > 0, otherwise the 5-minute maximum SO_2 concentration was estimated as zero).

concentration levels as well as at selected percentiles in the 5-minute SO_2 concentration distribution. In comparing the model predictions, the model using variability bins defined by the COV and excluding the minimum and maximum percentiles had the lowest prediction errors (e.g., see Table 7-4).[29] Based on these results, staff used this COV model (excluding the 0th and 100th percentiles of the PMR distribution) to estimate 5-minute maximum SO_2 concentrations from 1-hour SO_2 concentrations.

---

[29] Table 7-4 presents a few of the prediction error statistics used to compare each of the models, though several other prediction errors were evaluated (e.g., the 75th and 99th). Each of these were consistent with results presented, that is the alt. COV model had the lowest error when compared with the other models evaluated. See Langstaff (2009) for the additional percentile comparisons for each of the models.

Table 7-4. Comparison of prediction errors and model variance parameters for the four models evaluated.

Benchmark Level (ppb)	Model[1]	Median Prediction Error[2]	RMSE	R^2
100	COV	2.6	18.9	0.72
	alt. COV	0.4	14.1	0.81
	GSD	2.5	24.8	0.48
	alt. GSD	0.3	19.8	0.63
200	COV	1	10.7	0.66
	alt. COV	0.1	8.6	0.74
	GSD	1.3	12.8	0.49
	alt. GSD	0.4	10.2	0.64
300	COV	0.6	6.5	0.73
	alt. COV	0	5.6	0.78
	GSD	0.6	8.2	0.55
	alt. GSD	0.1	7.1	0.64
400	COV	0.3	4.5	0.76
	alt. COV	0	3.9	0.8
	GSD	0.3	6	0.55
	alt. GSD	0	5.5	0.61

Notes:

[1] The "alt." abbreviation denotes the alternative model was used: the minimum and maximum percentiles of the PMR distributions were not used.

[2] The absolute value of the prediction differences is calculated (predicted minus the observed number of exceedances in a year), generating a distribution of prediction errors. The value reported here is the (50th percentile) of that distribution.

Staff performed additional evaluations using the prediction errors associated with the statistical model. Additional percentiles of the prediction error distribution were calculated to estimate the magnitude and direction of the model bias. Table 7-5 summarizes the prediction errors for each benchmark level. When considering paired percentiles (e.g., the 25th and the 75th or prediction intervals) and the 50th percentile as a pivot point (there is no bias here), there appears to be over-estimation bias at each of the benchmark levels. For example, there is a greater overestimation of the 400 ppb benchmark level at the 95th percentile (i.e., 5 exceedances), than compared with the under estimation at the 5th percentile (i.e., 1 exceedance). However, there is good agreement in the predicted versus observed number of exceedances, whereas 90%

of the predicted exceedances of 400 ppb were within -1 to 5 exceedances per year. There is a wider range in the prediction intervals at the lower benchmark levels, partly a function of the greater number of exceedances at the lower benchmark levels rather than the degree of agreement (Table 7-5). At the extreme ends of the distribution for each of the benchmarks, the agreement between the predicted and observed exceedances widens, indicating that for some site-years (approximately 2%), the number of exceedances can be over- or under-estimated by 20 to 50 days in a year.

Table 7-5. Prediction errors of the statistical model used in estimating 5-minute maximum SO_2 concentrations above benchmark levels.

	Prediction Error at Benchmark Level[1]			
Percentile	**100**	**200**	**300**	**400**
1	-31	-17	-18	-19
5	-15	-7	-3	-1
25	-1	0	0	0
50	0	0	0	0
75	7	1	1	0
95	32	20	10	5
99	48	43	26	14
	Mean Number of Benchmark Exceedances[2]			
	100	**200**	**300**	**400**
Observed	148	81	69	56
Predicted	150	100	67	45

Notes:

[1] The percentiles are based on the distribution of predicted minus the observed values for each benchmark. Units are the number of exceedances per year.

[2] This is the average of all site-years. Units are the number of exceedances per year.

7.2.4 Locations to Evaluate the Current and Potential Alternative Standard Scenarios

As discussed in section 6.4, staff needed to adjust the air quality concentrations to allow for comparison of the level of public health protection that could be associated with just meeting the current and potential alternative standards. A proportional approach was selected based on the mostly linear relationship between older high concentration years of air quality when compared with recent low concentration years at several locations (Rizzo, 2009). Staff limited the analysis to particular locations using designated geographic boundaries (not just the monitors themselves). Counties were used to define the locations of interest in these alternative air quality standard scenarios. Use of a county is consistent with current policies on the designation of appropriate boundaries of non-attainment areas (Meyers, 1983). Further, to maintain a computationally manageable data set given the number of air quality scenarios (i.e., eight) and potential health effect benchmark levels investigated (i.e., four), staff used the recent ambient monitoring data, specifically years 2001 through 2006.[30]

The first criterion used to select locations was based on monitors that had a high number of daily 5-minute maximum SO_2 concentrations at or above the potential health effect benchmark levels. Ambient monitors located in two counties in Missouri (Iron and Jefferson) had the most frequently measured daily 5-minute maximum SO_2 concentrations above the potential health effect benchmarks (see Appendix A-5). While there were limited data available from these ambient monitors (4 and 2 years did not met the completeness criteria out of 8 total site-years for each of Jefferson and Iron counties, respectively), it was decided by staff that lack of a complete year should not preclude their use in this focused analysis given the high number of measured daily 5-minute maximum SO_2 concentrations at these monitors. All other monitoring data used in this focused analysis were selected from where 1-hour ambient monitoring met the completeness criteria described in section 7.2.1.

Staff selected an additional 38 counties based on the relationship of the ambient SO_2 concentrations within the county to the current annual and daily NAAQS to expand the number of counties investigated to a total of 40.[31] Mean multiplicative factors were calculated using the form and level of each standard (annual average or 2nd highest 24-hour concentration) in comparison with the measured SO_2 concentrations. First, for each county (*i*) and year (*j*), 24-hour and annual SO_2 concentration adjustment factors (*F*) were derived by the following equation:

$$F_{ij} = S / C_{\max,ij} \qquad \text{equation (7-2)}$$

where,

---

[30] As described in the section 7.2.1, at the time the 1-hour concentrations were downloaded, none of the monitors had a complete year of data for 2007. All data from 2007 were excluded from the 1-hour monitor simulations.

[31] In the 1st draft SO2 REA, a total of 20 counties were selected for the current standard scenario only.

F_{ij} = Adjustment factor derived from either the 24-hour or the annual average concentrations at monitors in county *i* for year *j* (unitless)

S = concentration values allowed that would just meet the current standards (either 144 ppb for 24-hour or 30.4 ppb for annual average)

$C_{max,ij}$ = 2nd highest daily mean SO_2 concentration at a monitor in county *i* and for year *j* or the maximum annual average SO_2 concentration at a monitor in county *i* and for year *j* (ppb)

Two initial criteria to be met for selection included having at least two monitors operating in the county for at least five of the six possible years of monitoring.[32] The mean daily and mean annual factor for each county was calculated by averaging the site-years available at each monitor, with the selection of the lowest mean factor retained to characterize the county. Each county was then ranked in ascending order based on this selected mean factor. The 38 counties were selected from the top 38 values, that is, those counties having the lowest mean adjustment factors. The 40 counties selected and the mean factors used to select each location given the above selection criteria are provided in Table 7-6.

---

[32] In the 1st draft SO_2 REA, having at least three monitors for all six years of the monitoring period was required. These earlier criteria were relaxed to allow for additional locations that may have ambient concentrations close to the current and daily standard levels.

Table 7-6. Counties selected for evaluation of air quality adjusted to just meeting the current and potential alternative SO_2 standards.

State	County[1]	Mean Factor	Closest Standard[2]
Arizona	Gila	3.44	A
Delaware	New Castle	2.80	D
Florida	Hillsborough	3.81	D

	Wayne	3.07	D

Notes:

[1] Listed counties were selected based on lowest mean concentration adjustment factor, derived from at least 2 monitors per year for years 2001-2006.

[2] Ambient concentrations were closest to either the annual (A) or daily (D) NAAQS level.

[3] County selected based on frequent 5-minute benchmark level exceedances.

Following the selection of the 40 counties, staff retained the adjustment factors calculated for each monitoring site-year (not the mean factor that was used for the county selection) to simulate air quality just meeting the current standard (either the daily or annual factor, whichever was lower). These adjustment factors are given in Appendix A, Table A.4-1. When simulating a proportional adjustment in ambient SO_2 concentrations using the factors generated by equation (7-2), staff assumed that the current temporal and spatial distribution of air concentrations (as characterized by the current air quality data) was maintained and that increased SO_2 emissions would contribute to increased SO_2 concentrations. For the daily averages, the 2nd highest monitor concentration would be adjusted so that it meets the current 140 ppb, 24-hour average standard (144 ppb considering the rounding convention). For the annual average concentration, the maximum monitor concentration would be adjusted so that it meets the current 30 ppb, annual average standard (30.4 ppb considering the rounding convention). For each county and calendar year, all the hourly ambient monitoring concentrations in the county were multiplied by the same constant value F (whichever adjustment value was lower) determined for that county and year. For example, of the seven monitors measuring SO_2 in Allegheny County, PA for year 2003, the 2nd highest 24-hour mean concentration was 64.6 ppb, giving an adjustment factor of $F_{daily} = 144/64.6 = 2.23$ for that year. This is lower than the adjustment factor calculated considering the maximum annual average concentration for that year ($F_{annual} = 30.4/11.9 = 2.54$). All hourly concentrations measured at all monitoring sites in that county would then be multiplied by 2.23, resulting in an upward scaling of all hourly SO_2 concentrations for that year. Therefore, one monitoring site in Allegheny County, Pa. for year 2003 would have the 2nd highest 24-hour average concentration at 144 ppb, while all other monitoring sites would have their 2nd highest daily average concentrations below that value, although still proportionally scaled up by 2.23. Using the adjusted hourly concentrations to simulate just meeting the current standard (either the daily or annual average standard), 5-minute maximum SO_2 concentrations were estimated using equation (7-1). Then, air quality characterization metrics of interest were estimated for each monitoring site and year as described in section 7.2.5.

Similarly, staff generated air quality adjustment factors for evaluating the potential alternative standards described in chapter 5. The 98th and 99th percentile 1-hour daily maximum

SO_2 concentrations averaged across three years of monitoring were used in calculating the adjustment factors at each of five standard levels as follows:

$$F_{ikl} = S_l / \left(\frac{\sum_{j=1}^{3} C_{ijk}}{3} \right)_{\max,i} \qquad \text{equation (7-3)}$$

where,

F_{ikl} = SO_2 concentration adjustment factor (unitless) in county *i* given alternative standard percentile form *k* and standard level *l* across a 3-year period

S_l = Standard level *l* (i.e., 50, 100, 150, 200, and 250 ppb 1-hour SO_2 concentration (ppb))

C_{ijk} = Selected percentile *k* (i.e., 98th or 99th) 1-hour daily maximum SO_2 concentration at a monitor in county *i* (ppb) for each year *j*

As described above for adjustments made in simulating just meeting the current standards, staff assumed that the current temporal and spatial distribution of air concentrations (as characterized by the current SO_2 air quality data) is maintained and increased SO_2 emissions contribute to increased SO_2 concentrations, with the highest monitor (in terms of the 3-year average at the 98th or 99th percentile) being adjusted so that it just meets the level of the particular 1-hour alternative standard. Since the alternative standard levels range from 50 ppb through 250 ppb, both proportional upward and downward adjustments were made to the 1-hour ambient SO_2 concentrations. The values for each percentile (i.e., 98th or 99th) 1-hour daily maximum SO_2 concentration averaged over three years at a monitor in the selected counties are given in Appendix A, Table A.4-2. Staff adjusted the 1-hour ambient SO_2 air quality in a similar manner described above for just meeting the current standard, however, due to the form of these standards, only one factor was derived for two 3-year periods (i.e., 2001-2003, 2004-2006) and applied to the individual years within the 3-year group, rather than one factor for each calendar year as was done with just meeting the current standard. Using the adjusted hourly concentrations to simulate just meeting each of the potential alternative standards, staff estimated

5-minute maximum SO_2 concentrations using equation (7-1). Then, air quality characterization metrics of interest were estimated for each site and year as described in section 7.2.5.

7.2.5 Air Quality Concentration Metrics

For each of the three air quality characterization scenarios considered, several concentration metrics were calculated; these included the annual average, 24-hour, and 1-hour daily maximum SO_2 concentrations for each site-year of data and the number of exceedances of the potential health effect benchmark levels. The numbers of daily maximum 5-minute concentration exceedances were counted (i.e., either 1 or none per day) rather than total number of exceedances (i.e., which confounds numbers of exceedances and days with exceedances). To characterize the relationship between the number of 5-minute benchmark exceedances and the ambient concentrations, staff generated two types of analyses given the different concentration averaging times.

The first analysis compares the annual average SO_2 concentration and the number of daily 5-minute maximum SO_2 concentrations above the benchmark levels in a year. The output of this is the number of days per year a monitor had a measured or modeled exceedance, given an annual average SO_2 concentration. In general, these results are graphically depicted in this REA, though most of the individual results displayed in the figures are provided in Appendix A-5. When considering the 40 counties used for detailed analysis, the results are presented at the county-level, some of which had multiple ambient monitors. Therefore, the results for the monitors within counties were aggregated to generate mean values representing the central tendency of the county's concentrations and numbers of benchmark exceedances.

The second analysis provides the probability of potential health effect benchmark exceedances associated with concentrations of short-term averaging times. It was proposed in chapter 5 that the 1-hour daily maximum SO_2 concentration would be of an appropriate averaging time in controlling the number of daily 5-minute maximum SO_2 concentrations. Staff analyzed such a relationship using the measured 5-minute and 1-hour ambient SO_2 concentrations to determine if this indeed was the case. A tally was made every time a daily 5-minute maximum SO_2 concentration occurred during the same hour of the day as the 1-hour daily maximum SO_2 concentration. The results of this analysis, separated by benchmark exceedance level, are given in Table 7-7. The co-occurrence of daily 5-minute maximum and 1-

hour daily maximum SO_2 concentrations is greater than 70% at each of the benchmark levels indicating a strong relationship between the two concentrations.

Table 7-7. The co-occurrence of daily 5-minute maximum and 1-hour daily maximum SO_2 concentrations using measured ambient monitoring data.

Concentration/Level	Co-occurring 5-minute and 1-hour daily maximums (n)	Total 5-minute Daily Maximums (n)	Percent Co-occurring (%)
All concentrations	106,115	130,296	81.4
> 100 ppb	6,192	8,817	70.2
> 200 ppb	2,030	2,793	72.7
> 300 ppb	1,067	1,476	72.3
> 400 ppb	700	961	72.8

Given the form of the current standard (i.e., the 24-hour average) and the potential alternative standards (1-hour daily maximum) and the frequency of 5-minute SO_2 benchmark exceedances (i.e., either one or none per concentration), the probability of the exceedance can be calculated for any of the air quality scenarios considered (using either measured or modeled daily 5-minute maximum SO_2 concentrations). First, concentration data (24-hour average or 1-hour daily maximum) were categorized by using concentration midpoints, separated by 10 ppb bins. For example a concentration of 53 ppb would be included in the 50 ppb bin, while a concentration of 55 ppb would fall within the 60 ppb bin. Then, the presence or absence of a daily 5-minute benchmark exceedance given the number of values in each concentration bin (that originate from all monitoring concentrations in the range of the bin) was used to estimate the probability of an exceedance. For example, if there were 237 exceedances of the 300 ppb benchmark level out of 1,265 instances of a 24-hour average binned concentration of 90 ppb, the probability of a 300 ppb benchmark exceedance would be 237/1,265 × 100 = 19% given a 24-hour concentration of around 90 ppb.

As mentioned earlier, these probability results were separated into one of three population density groups; either low (≤ 10,000 persons within 5 km), mid (10,001 to ≤ 50,000 persons within 5 km), or high (> 50,000 persons within 5 km). Staff hypothesized that there may be different exceedance probabilities in dense population areas compared with locations having fewer residents given the siting characteristics of the monitors with regard to the presence of emission sources. This separation of the monitoring results by the surrounding population should be useful in appropriately characterizing the air quality because the monitoring data are used as indicator of potential human exposure; the results from monitors sited within greater population densities should be more representative of potential population exposure.

In constructing the probability curves, staff noted there were fewer samples with increasing concentrations (either 1-hour daily maximum or 24-hour average). Having too few samples generated instability in the calculated probabilities at the highest 1-hour or 24-hour concentrations. For example, there were very few measured 1-hour daily maximum SO_2 concentrations above the 130 ppb bin considering the high population density group (Table 7-8). A total of 116 1-hour daily maximum SO_2 concentrations out of 26,983 were scattered across the bins of 140 through 620 ppb, either indicating the presence or absence of a 300 ppb benchmark exceedance. There are increasing probabilities of benchmark exceedances with increasing 1-hour daily maximum SO_2 concentration starting at 100 ppb; however, at certain higher concentrations (shaded area of Table 7-8) there are lower estimated probabilities of exceedances than the preceding lower 1-hour daily maximum SO_2 concentration. If using the probability data alone in Table 7-8, this would imply that at 1-hour daily maximum concentrations of about 210 – 230 ppb, the likelihood of an exceedance is less than that when considering 1-hour daily maximum concentrations between 190 – 200 ppb. This is likely not the case, and in this instance, the estimated probabilities are more a function of the sample sizes (no more than 3 samples per bin in this case) rather than the 1-hour daily maximum SO_2 concentrations. Therefore, in viewing the occurrence of this issue at small sample sizes, staff selected concentration bins having at least thirty 1-hour daily maximum (or 24-hour average) concentrations (whether it was all, none, or a mixture of exceedances) for inclusion in the probability curves.

Table 7-8. Example of how the probability of exceeding a 300 ppb 5-minute benchmark would be calculated given 1-hour daily maximum SO_2 concentration bins.

Daily Maximum 1-hour bin	Number of times: With no exceedances	With 1 exceedance	Probability of Exceedance (%)
100	71	0	0
110	45	2	4
120	43	1	2
130	34	1	3
140	17	1	6
150	15	2	12
160	11	4	27
170	10	2	17
180	8	3	27
190	1	4	80
200	1	3	75
210	1	0	0
220	1	2	67
230	2	0	0
240	0	2	100
250	0	2	100
260	0	4	100
270	0	2	100

7.3 RESULTS

7.3.1 Measured 5-minute Maximum and Measured 1-Hour SO_2 Concentrations at Ambient Monitors – *As Is* Air Quality

In this first scenario staff analyzed the *as is* air quality, solely based on the SO_2 ambient monitor measurements. Ambient monitoring data were evaluated at the 98 locations where both the hourly and 5-minute maximum SO_2 concentrations were reported for years 1997 through 2007. Due to the large size of the data set (i.e., 471 site-years), staff summarized the number of potential health effect benchmark exceedances in a series of figures. This analysis centered on the relationship between various concentration averaging times and the daily 5-minute maximum SO_2 concentration exceedances. Descriptive statistics for the measured daily 5-minute maximum and the 1-hour SO_2 concentrations are provided in Appendix A-5 and in the SO_x ISA section 2.5.2, the latter of which includes additional discussion of the spatial and temporal variability of the 5-minute maximum and continuous 5-minute SO_2 concentrations.

First, staff evaluated the occurrence of the daily 5-minute maximum SO_2 concentration exceedances in a year. Figure 7-10 compares the number of daily 5-minute maximum SO_2 concentrations above the potential health effect benchmark levels along with the corresponding annual average SO_2 concentration from each max-5 monitor. Overall, the frequency of daily 5-minute maximum SO_2 concentrations above the potential health effect benchmark levels in a year is low. Given the data in Table 7-6, no more than 7% of total measured days had a daily 5-minute maximum SO_2 concentrations above the 100 ppb benchmark, while approximately 2%, 1%, and 0.7% of days had a daily 5-minute maximum SO_2 concentrations above the 200, 300, and 400 ppb levels, respectively. None of the monitors in this data set had annual average SO_2 concentrations above the current NAAQS of 30 ppb. However, several of the monitors in several years frequently had daily 5-minute maximum SO_2 concentrations above the potential health effect benchmark levels. Many of those monitors where frequent exceedances occurred had annual average SO_2 concentrations between 5 and 15 ppb, with little to no correlation between the annual average SO_2 concentration and the number of daily 5-minute maximum SO_2 concentrations above the potential health effect benchmark levels. The data are useful in determining the number of days in a year a particular monitor had a daily maximum exceedance of a selected benchmark level, however from a practical perspective, the annual average concentration would be ineffective at controlling daily 5-minute maximum SO_2 concentrations given the observed weak relationships.

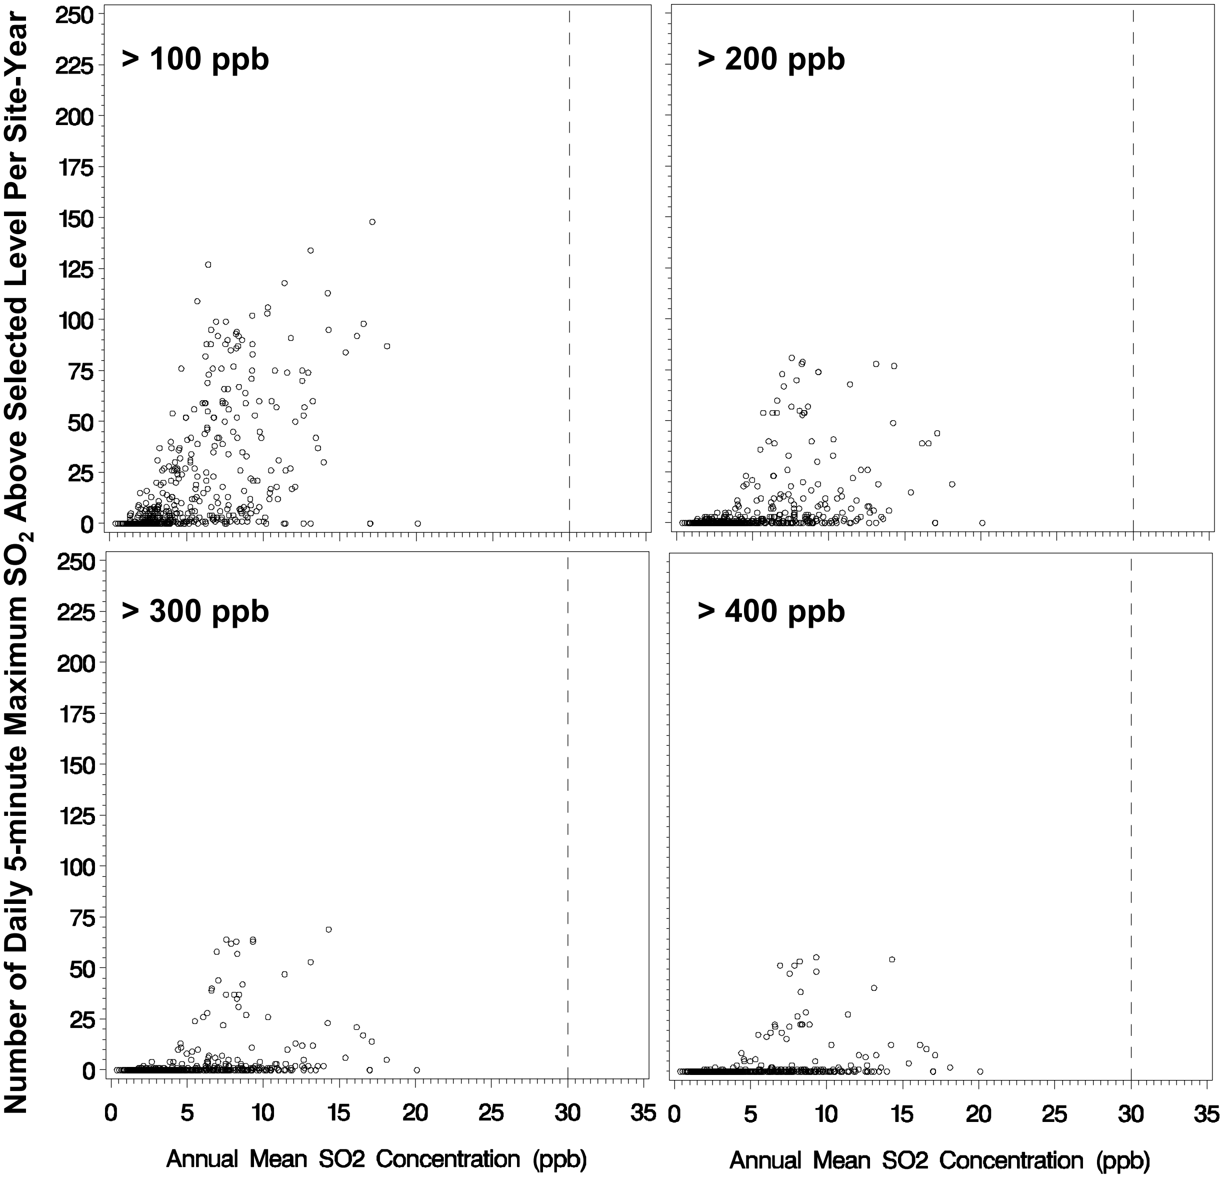

Figure 7-10. The number of measured daily 5-minute maximum SO_2 concentrations above potential health effect benchmark levels per year at 98 monitors given the annual average SO_2 concentration, 1997-2007 air quality as is. The level of the annual average SO_2 NAAQS of 30 ppb is indicated by the dashed line.

The probability of potential health effect benchmark exceedances was estimated using the combined 5-minute maximum and 1-hour measurement data set and considering the 24-hour average and 1-hour daily maximum SO_2 concentrations. Figure 7-11 presents the probability results using the 24-hour average SO_2 concentrations, separated by the three population densities. There is an increasing probability of daily 5-minute maximum SO_2 concentration exceedances with increasing 24-hour average concentrations at each of the potential health effect benchmark levels and each of the population density groups. Some deviation from increasing probability occurs near the end of the curves in the monitors cited within mid-population density areas, and as discussed earlier, it is likely a function of the small sample size rather than 24-hour SO_2 concentrations. Monitors sited in the low-population density area exhibit a steeper slope on each of the probability curves when compared with the other density groups, indicating a greater probability of exceedance given the same 24-hour concentration. For example, the probability of exceeding a daily 5-minute maximum concentration of 200 ppb is 30% at the low-population density monitors given a 24-hour average concentration of about 20 ppb, while at the mid- and high-population density monitors the probability is only about 14% and 3%, respectively. There is a small probability (about 10%) of exceedance of the 300 and 400 ppb in the high-population density areas given a 24-hour average concentration of about 40 ppb, though at monitors sited in the low-population areas this probability is between 50% and 60%. At a 24-hour average concentration of approximately 60 ppb, it is estimated that the probability of a daily 5-minute maximum above 100 ppb is at or near 100% considering any of the population density groups.

Figure 7-12 presents similar relationships using the 5-minute and 1-hour ambient measurement data, only the probabilities are associated with the 1-hour daily maximum SO_2 concentrations. A pattern of increasing probability with increasing 1-hour daily maximum SO_2 concentration is present considering each of the benchmark levels and population densities, along with steeper slopes noted for the low-population density group when compared with the higher population density groups. Note that while there is uncertainty regarding an extrapolation beyond the measured 1-hour daily maximum SO_2 concentrations, one can be assured that the probability of an exceedance of a daily 5-minute maximum SO_2 concentration of 400 ppb is 100% given a 1-hour daily maximum SO_2 concentration of 400 ppb (and so on for the other 5-minute benchmark/1-hour daily maximum SO_2 concentration combinations).[33] The shape of the

---

[33] Technically, if all 5-minute concentrations were exactly 400 ppb, the 1-hour average concentration would be 400 ppb and the 5-minute maximum would not actually exceed 400 ppb. However, note that probability of exceeding the 100 or 200 ppb benchmarks approaches 100% at less than a 1-hour daily maximum of 100 an 200 ppb, respectively (Figure 7-11).

curves beyond the measured data to the peak level though can only be informed by additional measurement or modeling, the latter being performed in subsequent sections.

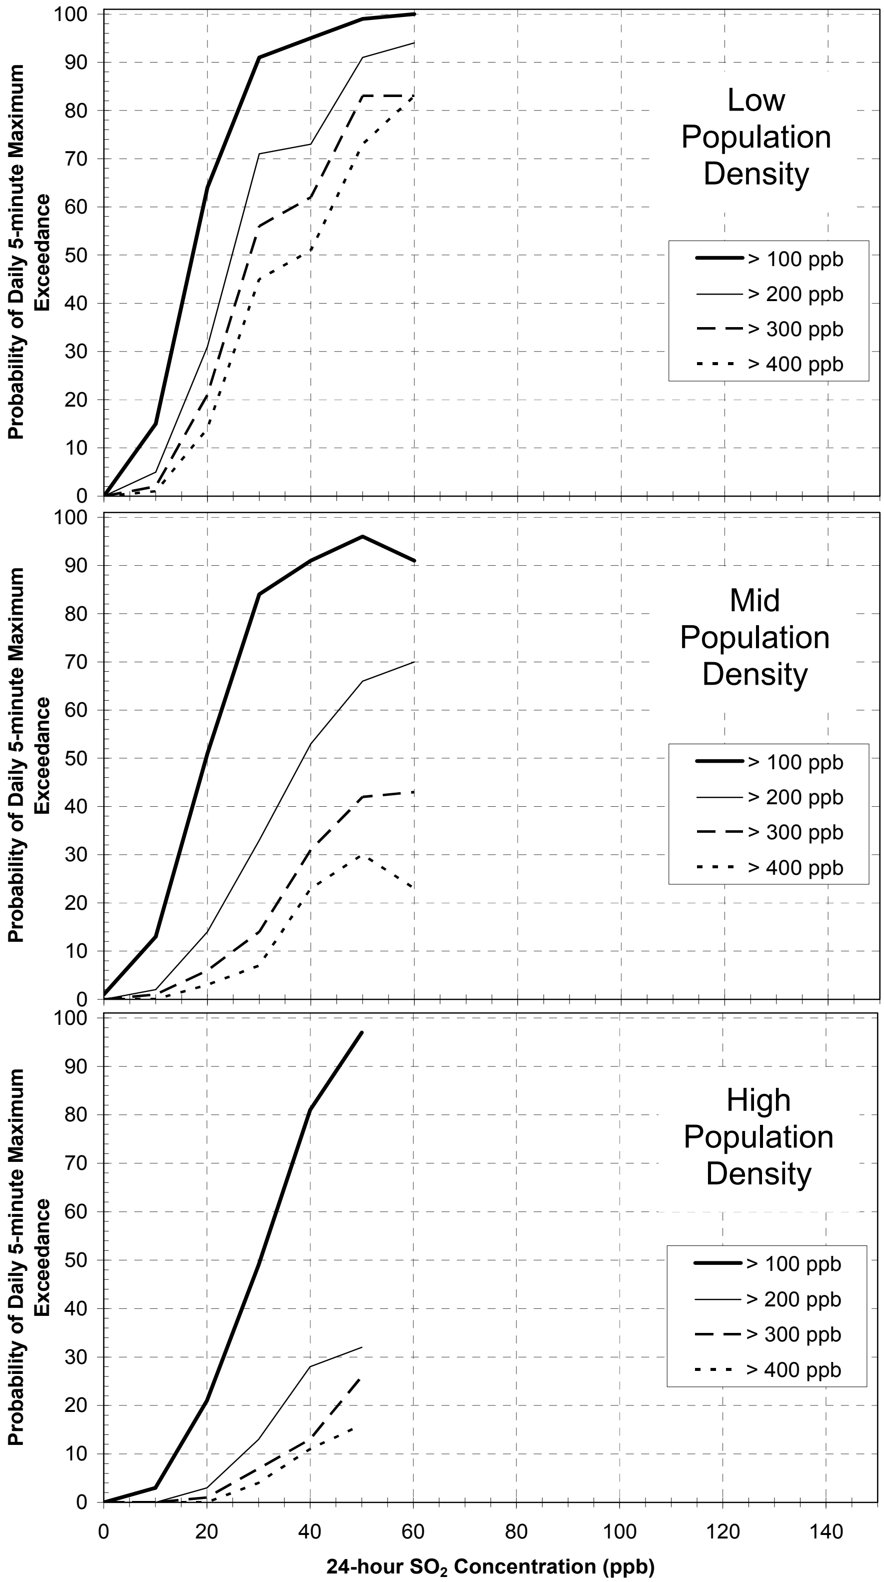

Figure 7-11. Probability of daily 5-minute maximum SO_2 concentrations above potential health effect benchmark levels given 24-hour average SO_2 concentrations, 1997-2007 air quality as is. Both the 5-minute maximum concentrations and 1-hour concentrations were from measurements collected at 98 ambient monitors and then separated by population density within 5 km of monitors.

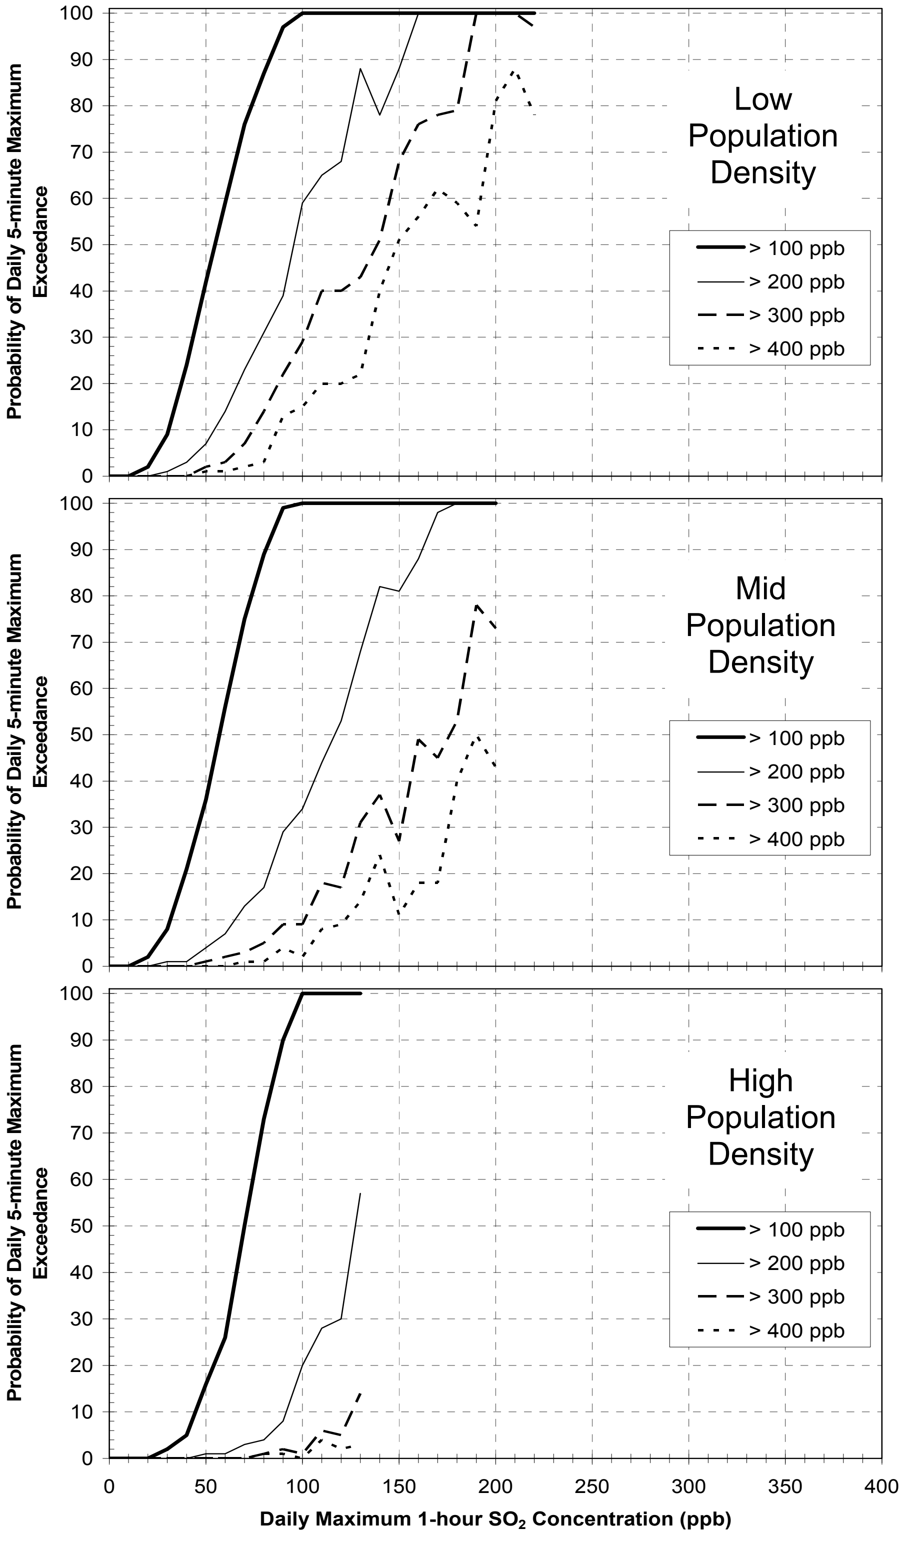

Figure 7-12. Probability of daily 5-minute maximum SO_2 concentrations above potential health effect benchmark levels given 1-hour daily maximum SO_2 concentrations, 1997-2007 air quality as is. Both the 5-minute maximum concentrations and 1-hour concentrations were from measurements collected at 98 ambient monitors and then separated by population density within 5 km of monitors.

7.3.2 Measured 1-Hour and Modeled 5-minute Maximum SO_2 Concentrations at All Ambient Monitors – *As Is* Air Quality

Results for this second scenario analyzing the *as is* air quality are based on a combination of measurement and modeled data. As described in section 7.2.3, a statistical model was applied to 1-hour ambient SO_2 measurements to estimate 5-minute maximum SO_2 concentrations. This was done because there are a greater number monitors in the broader SO_2 monitoring network compared to subset of monitors reporting the 5-minute maximum SO_2 concentrations. This larger monitoring data set included 809 ambient monitors in operation at some time during the years 1997 through 2006 that met the completeness criteria described in section 7.2.1. This data set includes 4,692 site-years of data, and combined with the estimated 5-minute SO_2 concentrations using the measured 1-hour values, allowed for a comprehensive characterization of the hourly and 5-minute SO_2 air quality at ambient monitors located across the U.S. Descriptive statistics for the measured 1-hour SO_2 concentrations are provided in the SO_x ISA section 2.5.1 including additional discussion of the spatial and temporal variability in 1-hour SO_2 concentrations.

Twenty separate simulations were performed to estimate the 5-minute maximum SO_2 concentration associated with each 1-hour measurement. The individual simulation results were combined to generate a mean estimate for the number of daily 5-minute benchmark exceedances. The modeled (5-minute maximum) and measurement (1-hour) data were analyzed in a similar manner as performed on the measured 5-minute maximum and 1-hour SO_2 concentrations described in section 7.3.1. The results provided in this section were generated using the modeled daily 5-minute maximums and the measured hourly SO_2 concentrations at 1-hour, 24-hour, and annual averaging times.

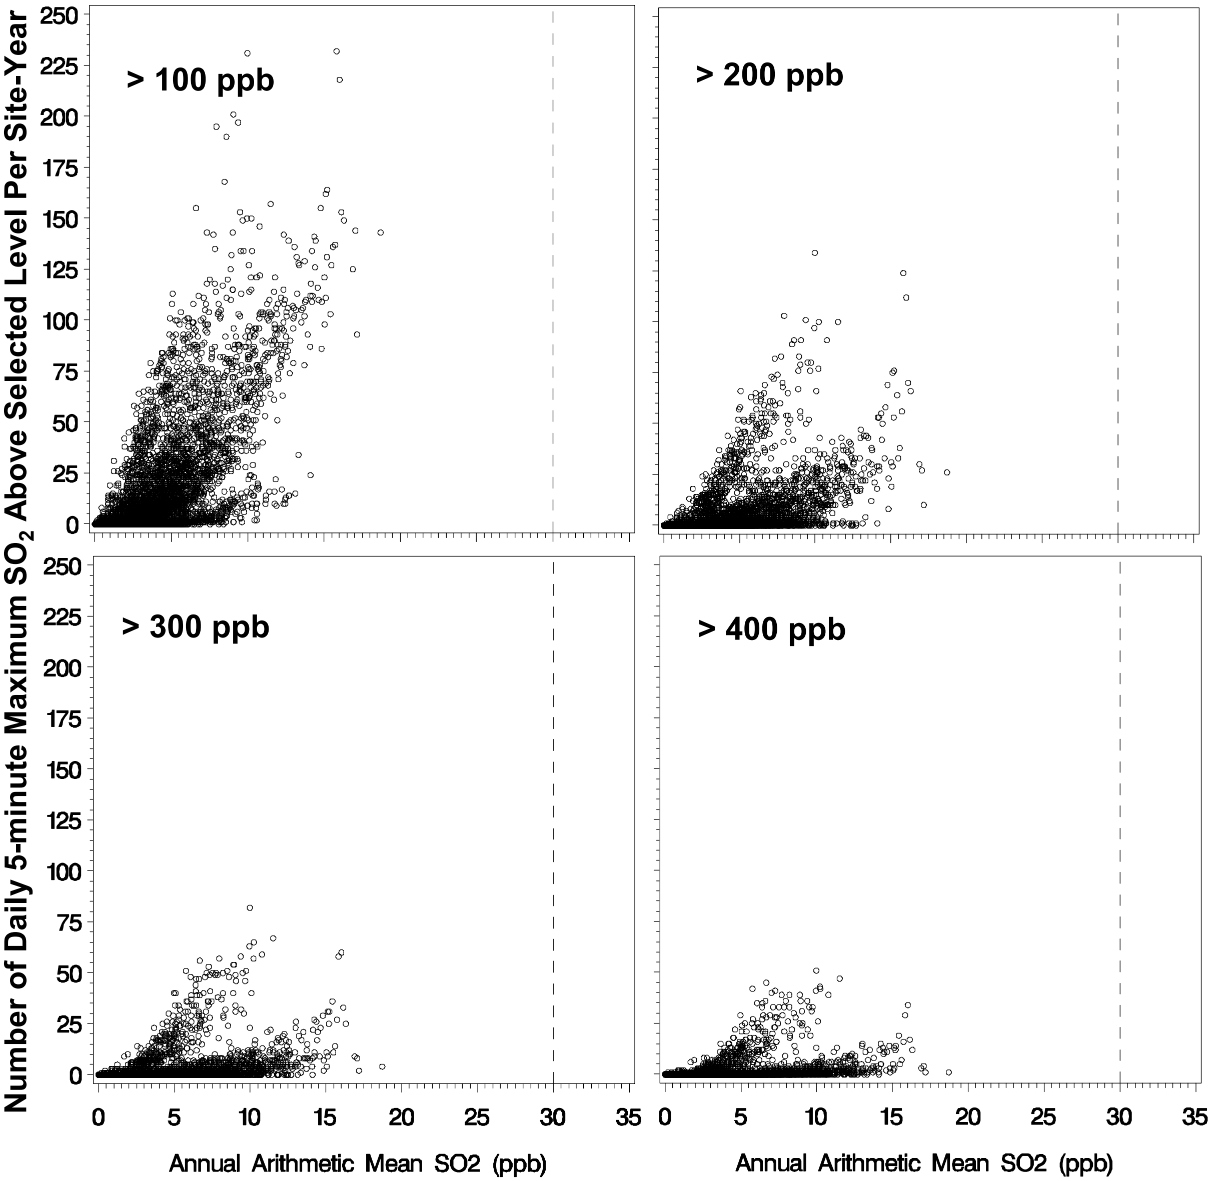

Figure 7-13. The number of modeled daily 5-minute maximum SO_2 concentrations above potential health effect benchmark levels per year at 809 ambient monitors given the annual average SO_2 concentration, 1997-2006 air quality as is. The level of the annual average SO_2 NAAQS of 30 ppb is indicated by the dashed line.

The occurrence of the modeled daily 5-minute maximum SO_2 concentrations was first evaluated with regard to the annual average SO_2 concentrations calculated from the 1-hour measurements. Figure 7-13 compares the number of daily 5-minute maximum SO_2 concentrations above the potential health effect benchmark levels with the annual average SO_2 concentration from each monitoring site-year of data. Fewer than 5% of total days had an estimated daily 5-minute maximum SO_2 concentration above the 100 ppb benchmark, while approximately 1%, 0.5%, and 0.2% of days had a 5-minute peak above the 200, 300, and 400 ppb levels, respectively. None of the monitors in this data set had annual average SO_2 concentrations at or above the level of the current annual NAAQS (30 ppb). However as described above, several of the monitors in several years had estimated 5-minute SO_2 concentrations above the potential health effect benchmark levels. Many of those monitors where frequent exceedances occurred had annual average SO_2 concentrations between 10 and 20 ppb, with a pattern of increasing numbers of benchmark exceedances with increasing annual average concentrations, most prominent at the 100 ppb benchmark level, though progressively less of a relationship present at each the subsequent benchmark levels.

Figure 7-14 presents the probability of benchmark exceedances using the modeled daily 5-minute maximum SO_2 concentrations, exhibiting patterns similar to the measured daily 5-minute maximum results (Figure 7-11). Again, low-population density probability curves are steeper than both the higher population density curves at each to the benchmark levels considered. The modeled probability curves though are slightly steeper than was observed with the measurement data when considering the 100 ppb benchmark level. For example, at a 24-hour average concentration of about 20 ppb, the probabilities for the low-, mid-, and high-population densities using all measurement data is 60, 50, and 20%, respectively (Figure 7-11). At the same 24-hour average and benchmark concentrations, the probability of an exceedance is 70, 60 and 30% when considering the modeled 5-minute maximum concentrations (Figure 7-14). At the higher benchmark levels however (e.g., 300 and 400 ppb), the slopes appear to be consistent between the measured and modeled 5-minute maximum data, where comparable 24-hour average concentrations exist. In using the broader SO_2 monitoring network to estimate daily 5-minute maximum SO_2 concentrations, there is insight as to the potential shape of each probability curve at greater 24-hour average concentrations. The upper range of 24-hour concentrations extends to around 70 – 100 ppb, while at the monitors reporting 5-minute maximum concentrations the maximum 24-hour average concentrations extend to at most between 50 and 60 ppb.

Similar patterns in the probability curves are exhibited when considering a 1-hour daily maximum concentration (Figure 7-15). In comparing these short-term probability curves with corresponding 24-hour probability curves (Figure 7-14), the overall slopes using the 1-hour daily maximums are steeper. This means that changes in 1-hour daily maximum SO_2 concentration (either up or down) will effectively result in larger changes in the probability of exceedances when compared with the 24-hour average probability curves, given a similar concentration shift. Again, a wider range of 1-hour daily maximum concentrations is observed in using the broader monitoring network when compared with the results using the monitors reporting the 5-minute maximum SO_2 concentrations (see Figure 7-12), giving greater ability to discern the probability of benchmark exceedances at higher 1-hour daily maximum SO_2 concentrations.

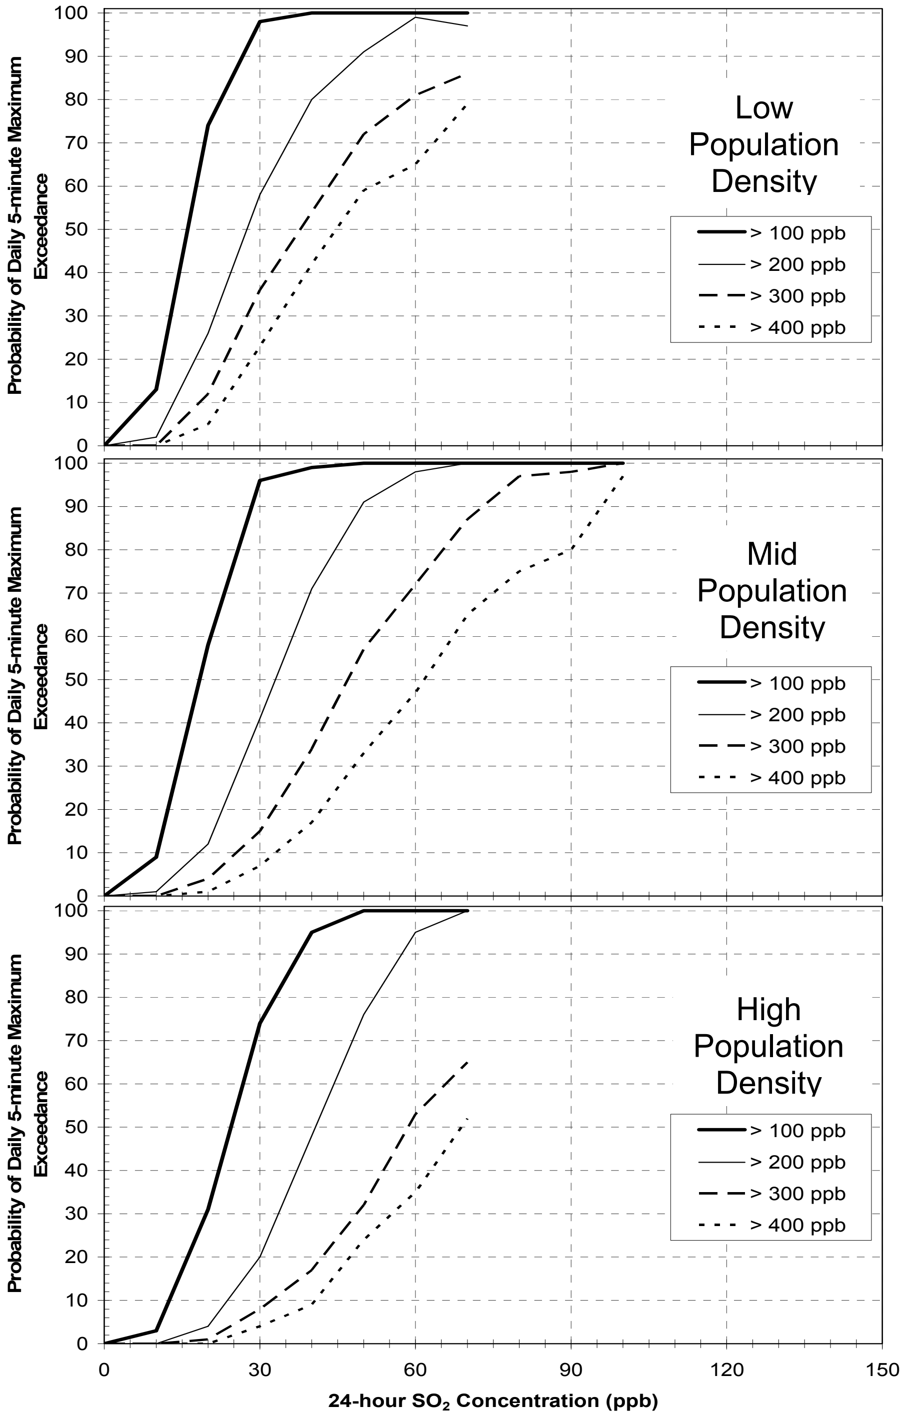

Figure 7-14. Probability of daily 5-minute maximum SO_2 concentrations above potential health effect benchmark levels given 24-hour average SO_2 concentrations, 1997-2006 air quality as is. The 5-minute maximum concentrations were modeled from 1-hour measurements collected at 809 ambient monitors and then separated by population density within 5 km of monitors.

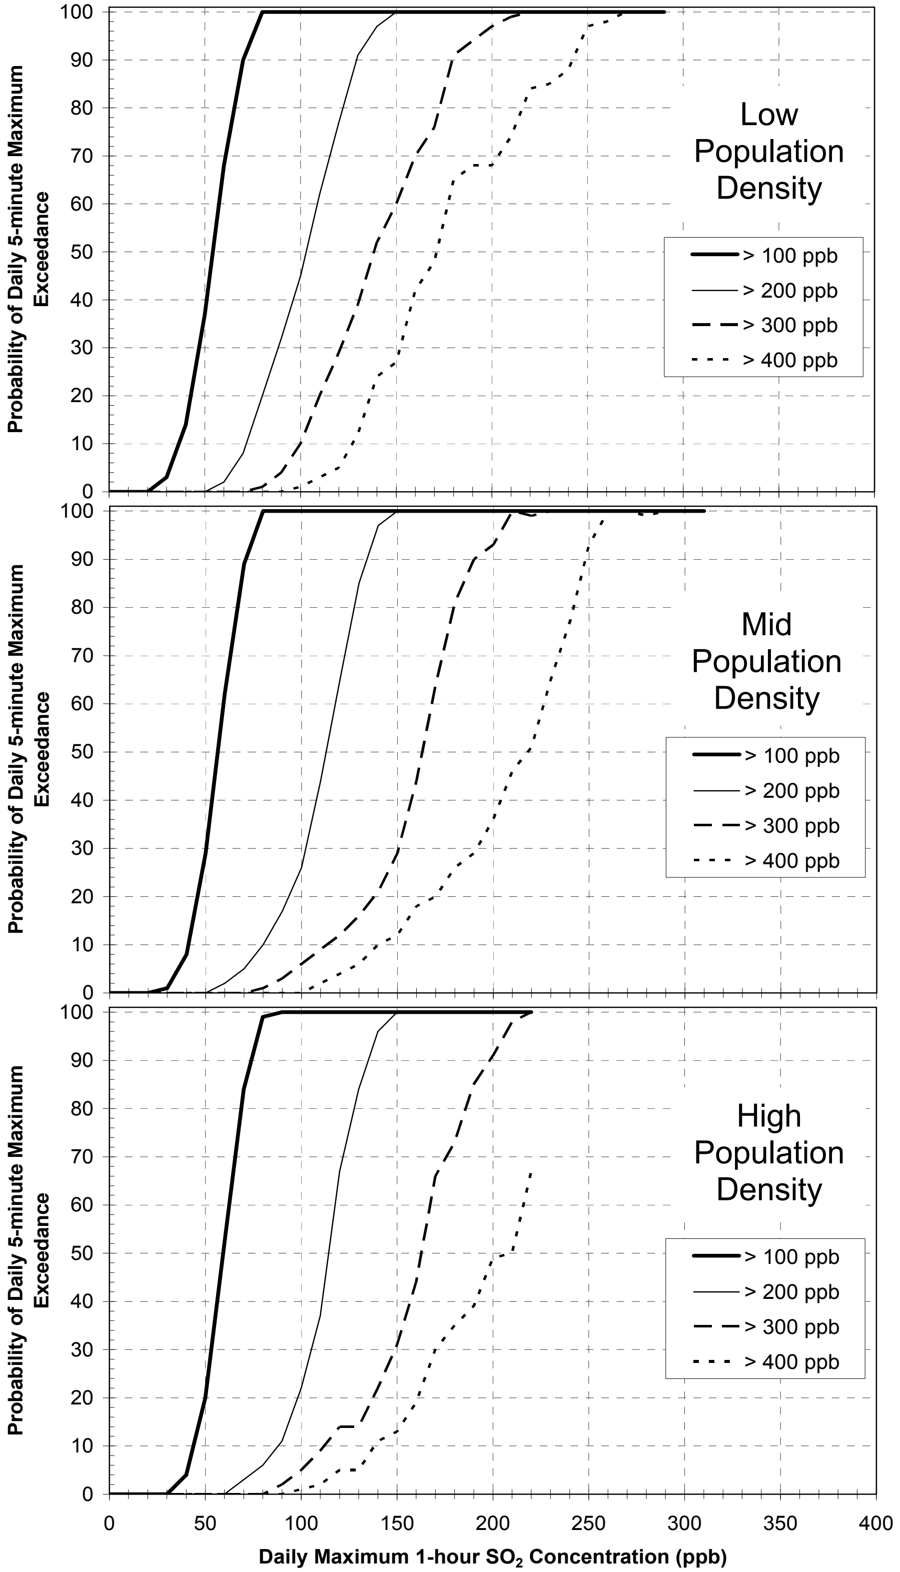

Figure 7-15. Probability of daily 5-minute maximum SO_2 concentrations above potential health effect benchmark levels given 1-hour daily maximum SO_2 concentrations, 1997-2006 air quality as is. The 5-minute maximum concentrations were modeled from 1-hour measurements collected at 809 ambient monitors and then separated by population density within 5 km of monitors.

7.3.3 Modeled 1-Hour and Modeled 5-minute Maximum SO_2 Concentrations at Ambient Monitors in 40 Counties – Air Quality Adjusted to Just Meet the Current and Potential Alternative Standards

Staff selected forty counties for detailed analyses that included an evaluation of ambient concentration distributions and the estimated numbers of exceedances of the potential health effect benchmark levels using as is air quality and air quality adjusted to just meeting the current and alternative standards. The counties were selected using criteria discussed in section 7.2.4; 38 counties having 1-hour ambient monitor SO_2 concentrations nearest the current NAAQS levels, and two counties having a high frequency of measured daily 5-minute maximum SO_2 concentrations above the potential health effect benchmark levels. The 1-hour SO_2 measurement data were from 128 ambient monitors and totaled 610 site-years of monitoring, a subset of data from the broader SO_2 monitoring network (see section 7.3.2). Staff evaluated multiple alternative air quality scenarios by first adjusting the 1-hour ambient monitoring concentrations (section 7.4). Then, staff performed twenty simulations to estimate the 5-minute maximum SO_2 concentration associated with each 1-hour adjusted concentration using the statistical model described in section 7.2.3. These simulation results were combined to generate a mean estimate for each of the metrics of interest (e.g., the number of daily 5-minute maximum SO_2 concentrations > 200 ppb) selected here as the best estimate from the twenty simulations.

First staff evaluated the relationship between the short-term peak concentrations and the level of the current annual SO_2 NAAQS in the selected counties. Figure 7-16 presents the number of 5-minute daily maximum SO_2 concentrations above the potential health effect benchmark levels along with the corresponding annual average concentration from each site-year using air quality adjusted to just meeting the current SO_2 standards. None of the monitors in the selected counties had annual average concentrations above the level of the current NAAQS (30 ppb) by design[34], however there are many more site-years with modeled daily 5-minute maximum SO_2 concentrations above the potential health effect benchmark levels. There are a decreasing number of exceedances with increasing benchmark concentrations, though there is a greater proportion of monitors with exceedances when considering concentrations adjusted to just meeting the current standard than when using the *as is* air quality (e.g., see Figure 7-13). With the concentration adjustment procedure, there is a stronger relationship between the annual

---

[34] The current annual SO_2 NAAQS is 30 ppb. Concentrations of up to 30.4 ppb are possible due to a rounding convention. This is why there are several data points just to the right of the dashed line in Figure 7-16.

average concentrations and the number of benchmark exceedances than observed previously with the as is air quality however, the strength of that relationship weakens with increasing benchmark levels.

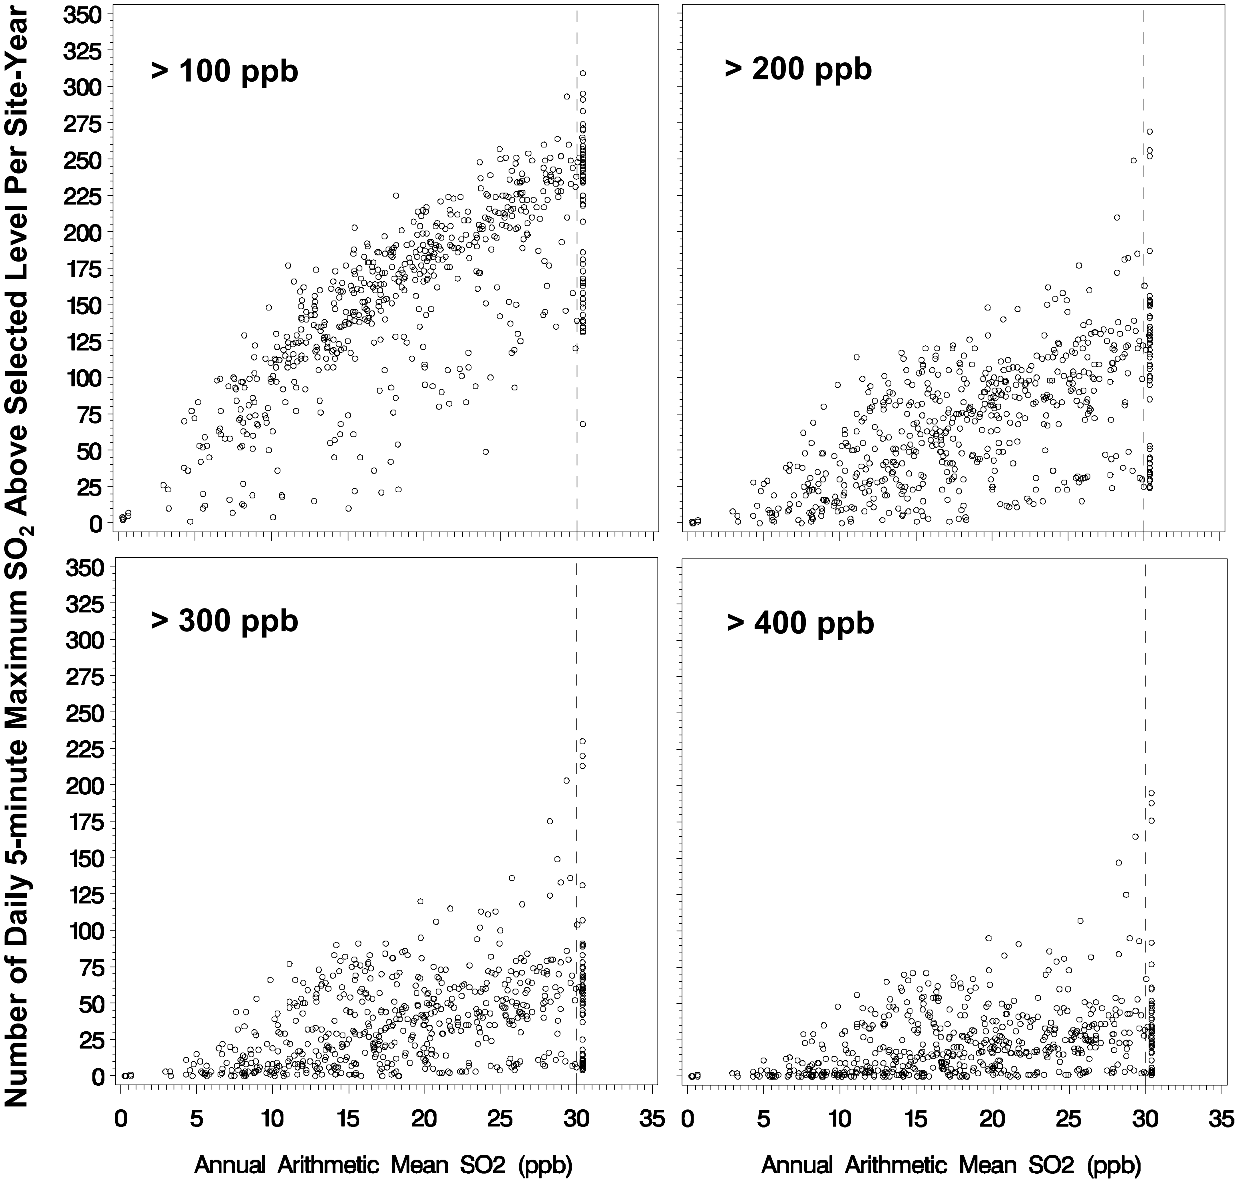

Figure 7-16. The number of modeled daily 5-minute maximum SO_2 concentrations above potential health effect benchmark levels per year at 128 ambient monitors in 40 selected counties given the annual average SO_2 concentration, 2001-2006 air quality adjusted to just meet the current NAAQS. The level of the annual average SO_2 NAAQS of 30 ppb is indicated by the dashed line.

Similar relationships are present between the annual average SO_2 concentrations and the number of benchmark exceedances when considering the potential alternative standards. Each of the potential alternative standards had a unique adjustment factor to simulate the alternative air quality. Based on the direction (either >1 or <1) and magnitude of the adjustment factor used, the estimated number of 5-minute benchmark exceedances was within the range of results generated using the *as is* air quality or the air quality adjusted to just meet the current standard. For example, a comparison of the annual average SO_2 concentrations and number of daily 5-minute maximum exceedances of 200 ppb is presented in Figure 7-17 for six air quality scenarios: four of the 99th percentile 1-hour daily maximum potential alternative standards (i.e., the 100, 150, 200, and 250 ppb); the air quality adjusted to just meet the current standards; and *as is* air quality.

Clearly, in using the air quality adjustment procedure combined with the statistical model to estimate 5-minute maximum SO_2 concentrations, the current standard air quality scenario allows for the greatest estimated number of potential health effect benchmark exceedances in a year (Figure 7-17). However, at a minimum the annual standard does provide protection against annual average concentrations above the level of the current standard. While there were fewer 5-minute benchmark exceedances using the 1-hour daily maximum forms of a potential standard, two of the levels (1-hour daily maximums of 200 and 250 ppb) did not prevent annual average concentrations from exceeding the current annual standard (Figure 7-17). High annual average concentrations become less of an issue when considering the lower levels of the 1-hour daily maximum standards. Even though the 99th percentile 1-hour daily maximum standards of 100 or 150 ppb allow for greater annual average concentrations than when considering *as is* air quality, all but one site-year are below the level of the current annual standard and there are fewer estimated daily 5-minute benchmark exceedances. These results further demonstrate the stronger relationship 5-minute peak concentrations have with 1-hour SO_2 concentrations than with annual average concentrations.

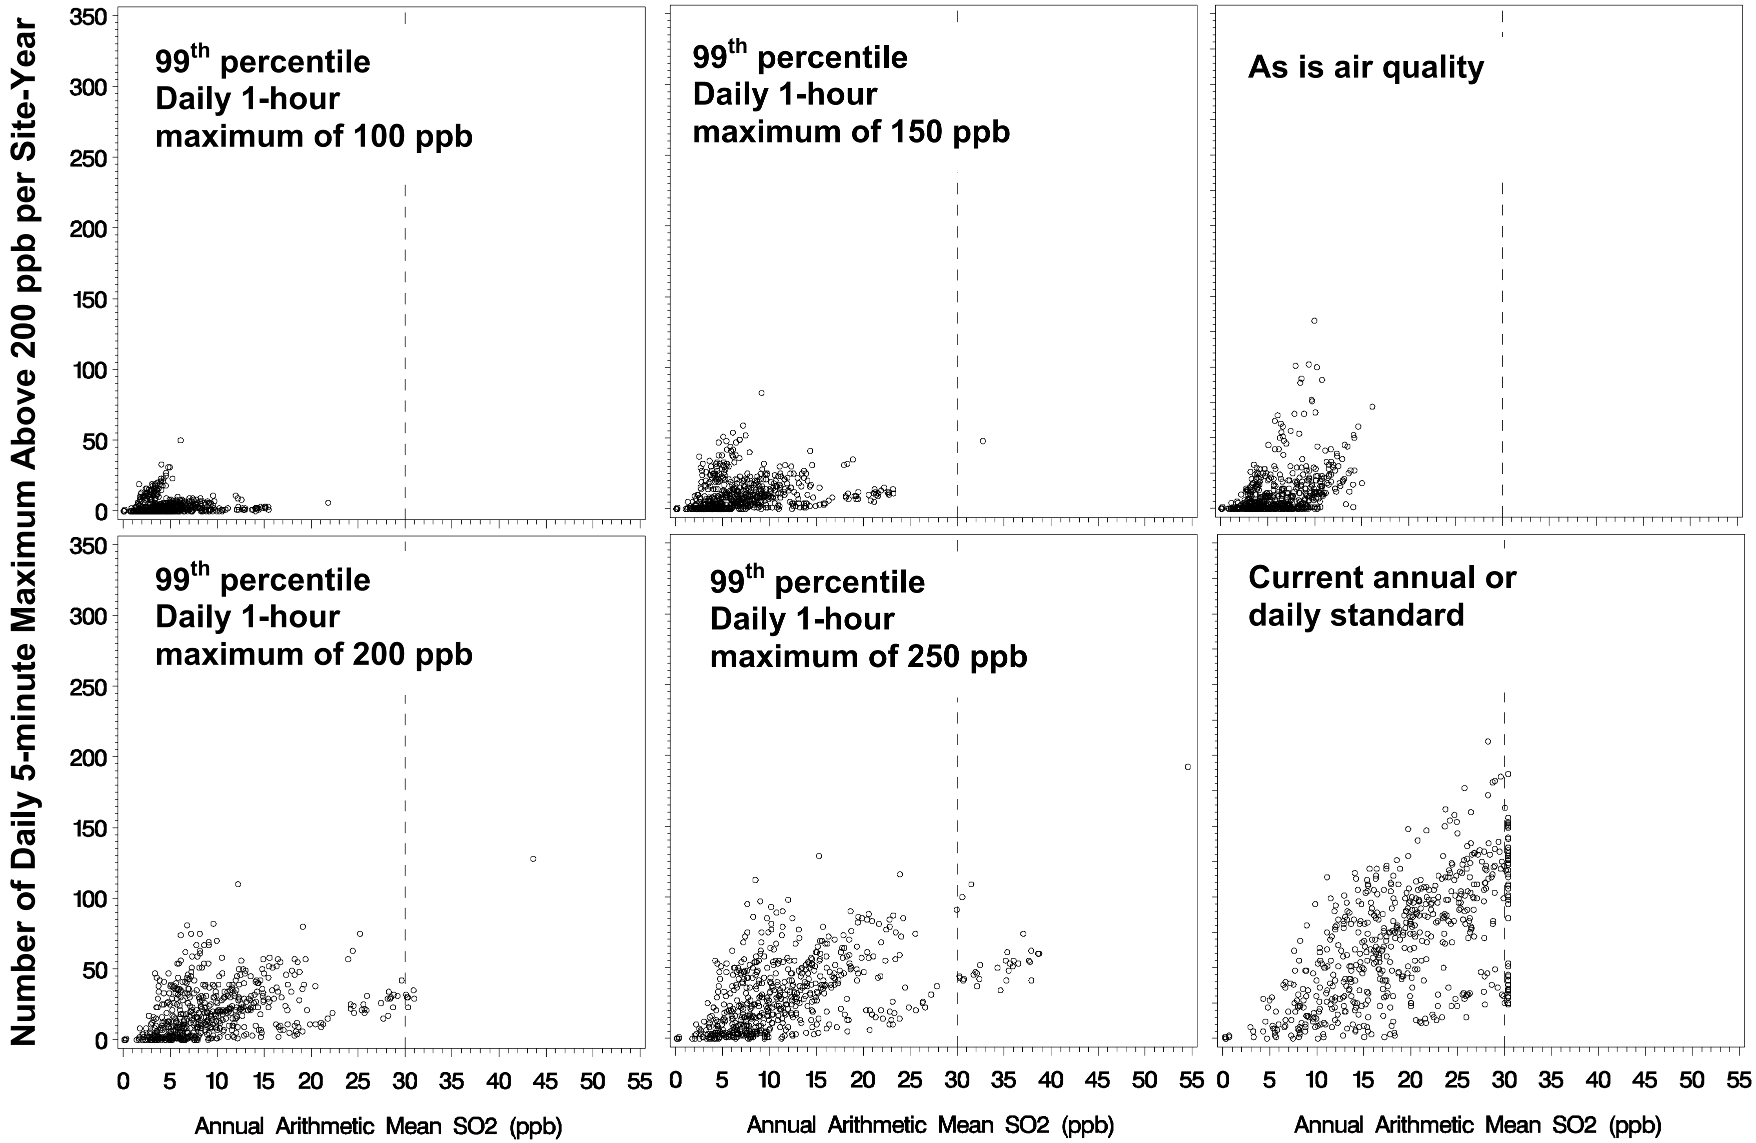

Figure 7-17. The number of modeled daily 5-minute maximum SO_2 concentrations above 200 ppb per year at 128 ambient monitors in 40 selected counties given the annual average SO_2 concentration, 2001-2006 air quality as is and that adjusted to just the current and four potential alternative standards (text in graph indicate standard evaluated). The level of the annual average SO_2 NAAQS of 30 ppb is indicated by the dashed line.

Table 7-9. Percent of days having a modeled daily 5-minute maximum SO_2 concentration above the potential health effect benchmark levels given air quality as is and air quality adjusted to just meeting the current and each of the potential alternative standards.

Air Quality Scenario[1]	Percent of Days With Daily 5-minute Maximum SO_2 Concentrations Above Benchmark Levels			
	> 100 ppb	> 200 ppb	> 300 ppb	> 400 ppb
As Is	9.1	2.4	0.9	0.5
CS	41.0	17.2	9.1	5.3
99-50	0.7	0.0	0.0	0.0
99-100	4.5	0.7	0.2	0.0
99-150	10.6	2.2	0.7	0.3
99-200	17.2	4.5	1.6	0.7
99-250	23.6	7.4	2.9	1.3
98-200	22.5	6.9	2.6	1.2

Notes:
[1] As is air quality is unadjusted; CS is air quality adjusted to just meet the current standard; x-y are the x^{th} percentile form of a 1-hour daily maximum level of y.

Staff summarized the frequency of daily 5-minute maximum SO_2 concentrations within the 40-county data set for additional comparisons of the air quality scenarios. Table 7-9 presents the percent of all days above each of the benchmark levels considering each of the air quality scenarios. Again, the scenario where air quality just meets the current standard has the greatest percent of days with benchmark exceedances. With each progressive decrease in the 1-hour daily maximum SO_2 concentration levels of the potential alternative standards, there are fewer days with benchmark exceedances. The percent of days with benchmark exceedances using *as is* air quality was between a potential 1-hour daily maximum alternative standard level of 100 – 150 ppb (99th percentile form).

Staff also evaluated two forms of the potential alternative standards: the 99th and 98th percentile forms, each having a 1-hour daily maximum level of 200 ppb. For example, Figure 7-18 indicates that nearly all site-years have a greater number of daily 5-minute maximum SO_2 concentrations above 100 ppb given the 98th percentile form when compared with a 99th percentile form at the same level. This is expected given the number of allowable 1-hour SO_2 concentrations above the 200 ppb level for each of the percentile forms. On average, the 98th percentile form allowed for approximately 46, 68, 84, and 86% more benchmark exceedances considering the 100, 200, 300, and 400 ppb benchmark levels, respectively when compared with the 99th percentile form.

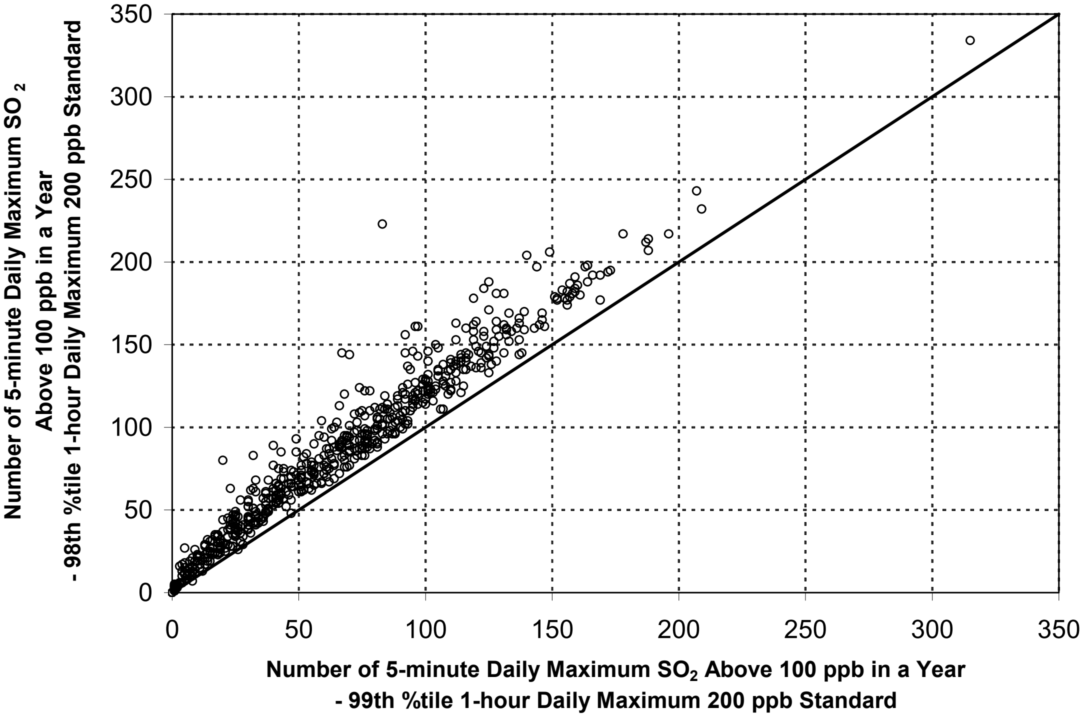

Figure 7-18. The number of modeled daily 5-minute maximum SO_2 concentrations above 100 ppb per year given the 99th and 98th percentile forms at a 1-hour daily maximum level of 200 ppb, using the 40-county air quality data set.

Staff approximated the probability of potential health effect benchmark exceedances given the adjusted air quality scenarios and short-term averaging times. Again, patterns in the curves were consistent with what was observed and described previously; monitors within low-population density areas had steeper probability curves compared with those in higher population density areas. Further, there were similarities in the shape and the steepness of the curves when comparing the adjusted air quality probability curves with the curves developed from the corresponding *as is* air quality. For example, Figure 7-19 presents the probability of 5-minute benchmark exceedances using *as is* air quality and air quality adjusted to just meet the current standard, given 1-hour daily maximum SO_2 concentrations. In general, all of the corresponding 100 and 200 ppb probability curves for all of the air quality scenarios follow a similar pattern. However, the estimated probabilities of exceeding the 300 and 400 ppb benchmark levels using the adjusted air quality were lower than when using the *as is* air quality given a similar 1-hour daily maximum concentration, most notable at monitors sited in low- and high population density areas. This is likely a function of the non-linear form of the statistical model used to estimate the 5-minute maximum SO_2 concentrations, the proportional adjustment procedure to simulate alternative standards, and the air quality characterization metric.

When adjusting the 1-hour SO_2 concentrations upwards using a proportional factor, a corresponding proportional increase in the number of exceedances does not necessarily follow. The statistical model uses multiple distributions of PMRs, not linearly related to 1-hour SO_2 concentrations. Certainly, the total number of days in a year with benchmark exceedances will increase with an upward adjustment of air quality, and does so as observed in Figure 7-17. However, the greatest proportion of monitoring days within any of the air quality scenarios is comprised of days without an exceedance. The frequency of exceedances of the higher benchmarks is already very low; the few added days with estimated exceedances of 300 or 400 ppb using the simulated air quality is not proportional to the universal increase in hourly concentrations applied to all 1-hour concentrations, therefore the probability curves tend to be less steep with the upward 1-hour concentration adjustments. Furthermore, days already having an exceedance are only counted once, that is, if there were an exceedance on a given day using the as is air quality, it is likely that the same day would also have an exceedance using the adjusted air quality, only it is associated with a greater 1-hour (or 24-hour average) concentration. Again, the 1-hour concentrations are increased without proportional increases in the probability of exceedances when comparing the two scenarios. Conversely, it could also be argued that there may be an increased probability of daily 5-minute exceedances of 300 and 400 ppb when using air quality with a relatively low concentration distribution (such as with the as is air quality) compared with a distribution of higher concentrations (such as with the current standard scenario). However, it should be noted that the total number of benchmark level exceedances in a year (and the absence of exceedances at the same high 1-hour daily maximum concentration) under either of these scenarios would be very few, with far fewer numbers of exceedances associated with the relatively low concentration air quality.

This discussion of probability curves can be extended to each of the potential alternative standards. For example, Figure 7-20 illustrates a range in each of the probability curves given each of the adjusted air quality scenarios and using monitors sited within high-population density areas. The 100 and 200 ppb benchmark level probability curves exhibit a narrow range across each of the adjusted air quality scenarios. While the estimated 300 and 400 ppb probability curves are wider than the 100 and 200 ppb curves, there is still agreement in the estimated probabilities at many of the 1-hour daily maximum SO_2 values. The range in probability curves tended to be widest at the lowest probabilities/1-hour daily maximum SO_2 concentrations within a given benchmark, likely indicating an increased uncertainty in the relationship between exceedance of the daily 5-minute maximum SO_2 concentrations of 300 and 400 ppb and 1-hour daily maximum SO_2 concentrations less than 130 ppb and 180 ppb, respectively.

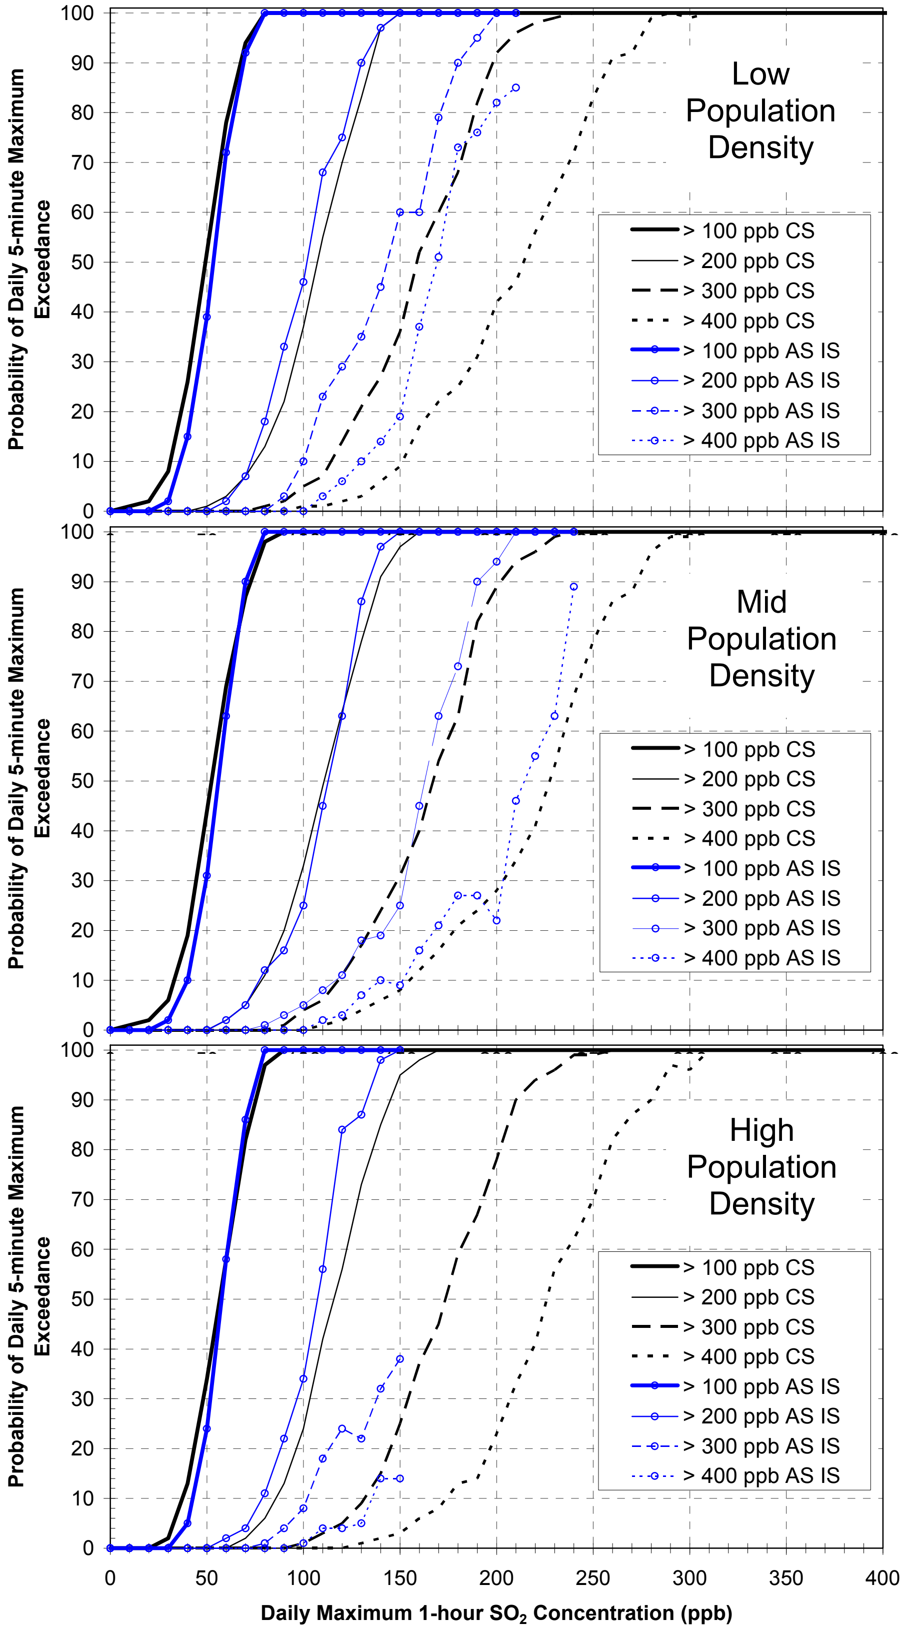

Figure 7-19. Probability of daily 5-minute maximum SO_2 concentrations above potential health effect benchmark levels given 1-hour daily maximum SO_2 concentrations, 2001-2006 air quality as is and that adjusted to just meet the current NAAQS. The 5-minute maximum concentrations were modeled from 1-hour measurements collected at 128 ambient monitors from 40 selected counties and then separated by population density within 5 km of monitors.

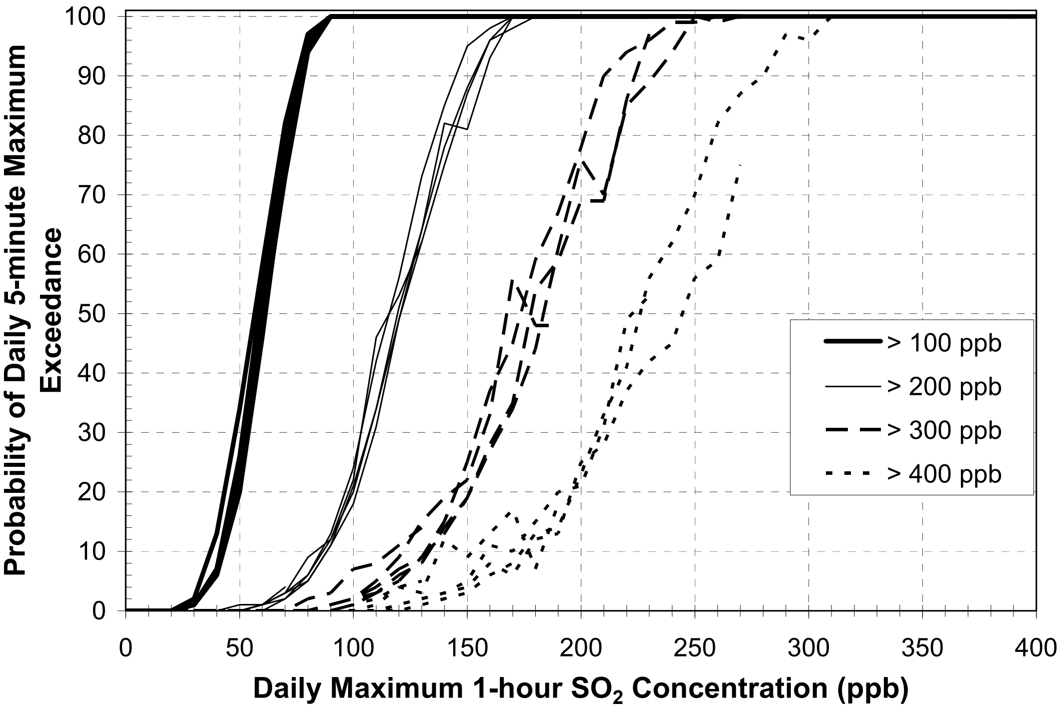

Figure 7-20. Probability of daily 5-minute maximum SO_2 concentrations above potential health effect benchmark levels given 1-hour daily maximum SO_2 concentrations, 2001-2006 air quality adjusted to just meet the current and each of the potential alternative standards. The 5-minute maximum concentrations were modeled from 1-hour measurements collected at 128 ambient monitors from 40 selected counties, high-population density within 5 km of monitors.

While there are similarities in the probability of daily 5-minute maximum benchmark exceedances for each of the potential alternative standard scenarios given either the 1-hour daily maximum or 24-hour average SO_2 concentrations, there are large differences in the total number of exceedances given a particular county and air quality scenario. Table 7-10 presents the mean number of days in a year where the daily 5-minute maximum SO_2 concentration was above 100 ppb in each of the 40 selected counties and for all air quality scenarios. In considering the highest potential alternative standard levels of 200 and 250 ppb (1-hour daily maximum) and the current standard air quality, counties such as Hudson NJ, Tulsa OK, and Wayne WV were estimated to have the greatest number of benchmark exceedances. On average it is estimated that between 100 and 200 days of the year there would be daily 5-minute maximum SO_2 concentrations above 100 ppb in these counties. Most of the other locations though had fewer than 100 exceedances in a year, particularly when considering the two potential alternative 1-hour daily maximum standards. Air quality simulating just meeting the current standard was associated with the greatest number of estimated exceedances at most locations. This consistent pattern was observed with each of the benchmark levels (see below) again indicating the limited influence the current standard has on the estimated number of 5-minute benchmark exceedances. In addition, the number of exceedances using a 98th percentile 1-hour daily maximum alternative standard level of 200 ppb was similar to the 99th percentile using a 250 ppb 1-hour concentration level considering any of the 5-minute benchmarks. Decreases in the potential alternative standard level corresponded with decreases in the number of exceedances. Most counties have fewer mean estimated 5-minute benchmark exceedances of 100 ppb using air quality adjusted to just meeting the 99th percentile daily 1-hour maximum concentration of 100 ppb, than estimated using the *as is* air quality.

There were fewer estimated exceedances of 200 ppb given the 1-hour daily maximum potential alternative standards than compared with the current standard scenario (Table 7-11). Most counties had fewer than forty days with 5-minute maximum SO_2 concentrations above 200 ppb, even at the 250 ppb 1-hour daily maximum level; though the number of exceedances was typically double that using air quality simulating just meeting the current standard. With progressive decreases in the 1-hour daily maximum standard level, the number of days with 5-minute maximum SO_2 concentrations also decreases. In most counties, the estimated number of exceedances using *as is* air quality was within that estimated using 1-hour daily maximum standard levels of 100 and 200 ppb (approximately 10-20 per year). The 99th percentile 1-hour daily maximum concentration level of 50 was associated with the fewest days with 5-minute maximum SO_2 concentrations above 200 ppb. On average most locations had zero exceendaces of the 200 ppb benchmark level.

Similar results are presented for each the 300 ppb (Table 7-12) and the 400 ppb (Table 7-13) 5-minute benchmark levels, though the difference in the number of exceedances between the current standard and the other air quality scenarios is much greater than was observed for the lower benchmark levels. Most counties had a 5-fold (or greater) number of days with daily 5-minute maximum SO_2 concentrations above 300 or 400 ppb when considering air quality just meeting the current standard compared with air quality adjusted to just meet the 99th percentile 1-hour daily maximum level of 250 ppb. The number of exceedances given *as is* air quality was still within the range of values estimated using the potential standard levels of 100 and 200 ppb; in most counties it was fewer than 10 days per year. Most counties did not have any estimated daily 5-minute maximum SO_2 concentrations above 400 ppb given a 99th percentile 1-hour daily maximum of 100 ppb, while 75% of the counties had 1 or fewer exceedances of 300 ppb considering this same potential alternative standard.

Table 7-10. Mean number of modeled daily 5-minute maximum concentrations above 100 ppb per year in 40 selected counties given 2001-2006 air quality as is and air quality adjusted to just meet the current and alternative standards.

7.4 UNCERTAINTY ANALYSIS

The approach for evaluating uncertainty was adapted from guidelines outlining how to conduct a qualitative uncertainty characterization (WHO, 2008). First, the key sources of the assessment that contribute to uncertainty are identified, and the rationale for why they are included is discussed. Second, a qualitative characterization follows for the types and components of uncertainty, resulting in a summary describing, for each source of uncertainty, the level and direction of influence the uncertainty may have on the air quality characterization results.

The overall characterization of uncertainty is qualitatively evaluated by considering the degree of severity of the uncertainty, implied by the relationship between the source of the uncertainty and the output of the air quality characterization. To the extent possible, an appraisal of the knowledge base (e.g., the accuracy of the data used, acknowledgement of data gaps) and evaluation of the decisions made (e.g., selection of particular model forms) is also included in this uncertainty rating. The characterization is subjectively scaled by staff using a designation of low, medium, and high. Briefly, a *low* level of uncertainty suggests large changes within the source of uncertainty would have only a small effect on the results, there is completeness and scientific consistency in the knowledge base, and decisions made regarding the particular source of uncertainty would be widely accepted. A designation of *medium* implies that a change within the source of uncertainty would likely have a proportional effect on the results; there may be limited scientific backing, and limited selection of inputs or models to choose from. A characterization of *high* implies that a small change in the source would have a large effect on results, there may be inconsistencies present in the scientific support, and assumptions made would be considered unusual and restrictive by others.

The bias direction indicates how the source of uncertainty has been judged to influence estimated concentrations, either the concentrations are likely *over*- or *under-estimated*. In the instance where two or more types or components of uncertainty are present that potentially offset the direction of influence, the bias has been judged as *both*. An *unknown* bias has been assigned where there was no evidence reviewed to judge the direction of uncertainty bias associated with the source. Table 7-14 provides a summary of the sources of uncertainty identified in the air quality characterization, the level of uncertainty, and the overall judged bias of each. A discussion regarding each of these sources of uncertainty and how conclusions were drawn is given in the sections that follow.

Table 7-14. Summary of qualitative uncertainty analysis for the air quality and health risk characterization.

Source	Type	Concentration/ Exceedance Bias Direction	Characterization of Uncertainty
Air Quality Data	Database quality	Both	Low
Ambient Measurement	Interference	Both	Medium
Temporal Representation	Scale	None - Unknown	Medium
	Missing data	Both	Low
	Years evaluated	Unknown	Low
Spatial Representation	Scale	Unknown	Medium - High
Air Quality Adjustment	Proportional approach used	Unknown	Moderate
	Spatial scale	Over	Low - Moderate
Statistical Model using PMRs	Data Screening	Both	Low
	Temporal Variation in PMRs	Unknown	Low
	Distribution form of PMRs	Unknown	Low
	Accuracy	Both	Low - Moderate
	Reproducibility	Both	Low
Ambient as Indicator of Exposure	Scale	Over	Moderate
Health Benchmarks	Averaging time	Unknown	Low
	Susceptibility	Under	Moderate

7.4.1 Air Quality Data

One basic assumption is that the AQS SO_2 air quality data used are quality assured already. Methods exist for ensuring the precision and accuracy of the ambient monitoring data (e.g., EPA, 1983). Reported concentrations contain only valid measures, since values with quality limitations are not entered to the system, removed following determination of being of lower quality or flagged. There is likely no selective bias in retention of data that is not of reasonable quality if the data are in error; it is assumed that selection of high concentration poor quality data would be just as likely as low concentration data of poor quality. Given the numbers of measurements used for this analysis, it is likely that even if a few low quality data are present in the data set, they would not have any significant effect on the results presented here. In addition, a quantitative analysis of available simultaneous measures in Appendix A-3 indicated little to no bias in measured concentrations or in the selection of one particular simultaneous measurement over another. There are no alternative data sets available that are as comprehensive, and where monitoring data are available that are not included in the AQS, it is expected that given the same methods and quality assurances, they would be complementary to the data existing in the AQS. Therefore, the air quality data and database used likely contributes minimally to the uncertainty level, there is low uncertainty in the knowledge base, and the uncertainty in the subjectivity of choices is also considered low.

Temporally, some of the ambient monitoring data used in this analysis had both the 5-minute maximum and 1-hour concentrations reported and appropriately accounted for variability in concentrations that are commonly observed for SO_2. When employing the completeness criteria discussed in section 7.2, data were assured as representative of either a valid day or year. In addition, having more than one ambient monitor accounted for some of the spatial variability in selected counties. However, the degree of representation of the monitoring data used in this analysis can be evaluated from several perspectives, one of which is how well the temporal and spatial variability are represented. In particular, missing 5-minute maximum or hourly measurements at a monitor may introduce bias (if there are specific periods within a day, month or a year that influence measured values) and reduce certainty in the estimations. Furthermore, the spatial representativeness will be poor if the monitoring network is not dense enough to resolve the spatial variability (causing increased uncertainty) or if the monitors are not effectively distributed to reflect population exposure (causing a bias). Additional uncertainty regarding temporal and spatial representation by the monitors is expanded below.

7.4.2 Measurement Technique for Ambient SO_2

One source of uncertainty in SO_2 air quality data is due to interference with other compounds. The ISA notes several sources of positive and negative interference that could increase the uncertainty in the measurement of ambient SO_2 concentrations (ISA, sections 2.3.1 and 2.3.2). Many of the identified sources (e.g., polycyclic aromatic hydrocarbons, stray light, collisional quenching) were described as having limited impact on SO_2 measurement due to the presence of instrument controls that prevent the interference. The actual impact on any individual monitor though is unknown; the presence of either negative or positive interference, and the degree of interference contributed by one or the other, has not been quantified for any ambient monitor. In addition, it is not known whether there is a concentration dependence on the amount of interference. This may be an important uncertainty in considering the air quality concentrations adjusted to just meet the current and potential alternative standards. While reported ambient monitoring concentrations could be either over- or under-estimated, it is probably minimal given instrument controls. The uncertainty is characterized as medium given the limited quantitative evidence to judge the degree of bias at any individual ambient monitor.

7.4.3 Temporal Representation

Data are valid 5-minute and 1-hour average SO_2 measurements and are of the same temporal scale as identified potential health effect benchmarks where 5-minute measurements were reported. There are frequent missing values within a given valid year that may reduce the degree of certainty in concentration distributions and model estimations; however, given the level of the benchmark concentrations and the low frequency of benchmark exceedances, it is likely of negligible consequence. Bias may be introduced if some seasons, day-types (e.g., weekday/weekend), or times of the day (e.g., nighttime or daytime) are not equally represented. This type of bias may be present in the combined 5-minute and 1-hour measurement data set because all of the available data were used without considering the standard 75% completeness criteria. Staff elected to use all of the data rather than further reducing the already limited number of samples and locations represented by the 5-minute SO_2 measurement data. The 5-minute measurement data set did undergo screening that improved the quality of the data set, including the removal of duplicate reporting/measurements, concentrations < 0.1 ppb, and any concentrations resulting in technically impossible PMRs. For the analyses performed using the broader SO_2 monitoring network and the 40-county analysis, a valid year of ambient monitoring was based on 75 percent complete hours/day and days/quarter, and having all four complete quarters/year. Therefore, these potential biases resultant from missing data are likely to have been removed from these data sets.

Data were not interpolated in the analysis; missing data were not substituted with estimated values and concentrations reported as zero were used as is. For the missing data, it is assumed here that missing values are not systematic, i.e., high concentrations would be absent as well low concentrations in equal proportions. There are methods available that can account for time-of-day, day-of-week, and seasonal variation in ambient monitoring concentrations. However, if a method were selected it would have to not simply interpolate the data, but accurately estimate the probability of peak 1-hour SO_2 concentrations that could occur outside the predictive range of the method. It was judged that if such a method was available or one was developed to substitute data, it would likely add to a similar level of uncertainty as not choosing to substitute the missing values. Again, this can be viewed as having a limited effect on uncertainty because using the validity criteria should select for the most representative and complete ambient monitoring data sets possible. In using the concentrations reported as zero, there is likely a negligible effect on uncertainty in the analyses resulting from not estimating any extremely low (e.g., <1 ppb) 1-hour concentrations, since the concentrations of interest are well above 1 ppb.

There may be bias and added uncertainty if the years and concentrations vary significantly between monitors and across the two averaging times. When using older monitoring data, the assumption is that the sources present at that time have similar emissions and emission profiles as the current sources, adding uncertainty to results if this is not the case. Monitoring sites across the U.S. have changed over time, with a trend of decreasing number of monitors most evident for those reporting the 5-minute maximum SO_2 concentrations (Figure 7-21). Five-minute SO_2 concentrations have been reported in fewer monitors than the 1-hour SO_2 concentrations; generally only a few years of data exist for 5-minute SO_2 concentrations (Appendix A, Table A.1-1). This is the reason why, given the limited number of measurements, all of the 5-minute maximum SO_2 data were used in developing the statistical relationships and for the model evaluation without meeting 75% completeness criteria. In addition, the use of the older ambient monitoring data (e.g., pre-2001) in some of the analyses here carries the assumption that the sources present at that time are the same as current sources, potentially adding to uncertainty if this is were not the case. The variability in monitoring concentrations (both the 1-hour and 5-minute maximum SO_2) does not change significantly across most monitoring years (i.e., years 1997 though 2004) and have a comparable range between the two averaging times (Figure 7-22). There is some compression in the range of COVs considering some of the more recent years of data, most notable for year 2007, possibly affected by the reduction in the number of ambient monitors in operation rather than a reduction in the temporal variability in 5-minute or 1-hour concentrations at particular monitors. Furthermore, the selection of a subset of the recent air quality (2001-2006) for detailed analyses may reduce the potential impact from changes in national- or location-specific source influences and is judged to have a minimal bias in representing air quality concentrations for those selected years. Therefore, due to the limited variation in temporal trends in COV for both 5-minute and 1-hour

SO_2, the overall impact to uncertainty is expected to be low for analyses performed using the monitoring data set that spans several years.

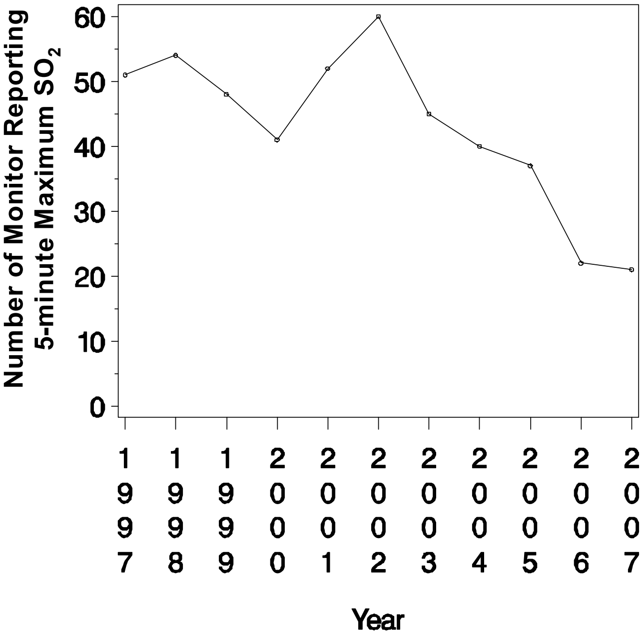

Figure 7-21. Temporal trends in the number of ambient monitors in operation per year for monitors reporting both 5-minute and 1-hour SO_2 concentrations

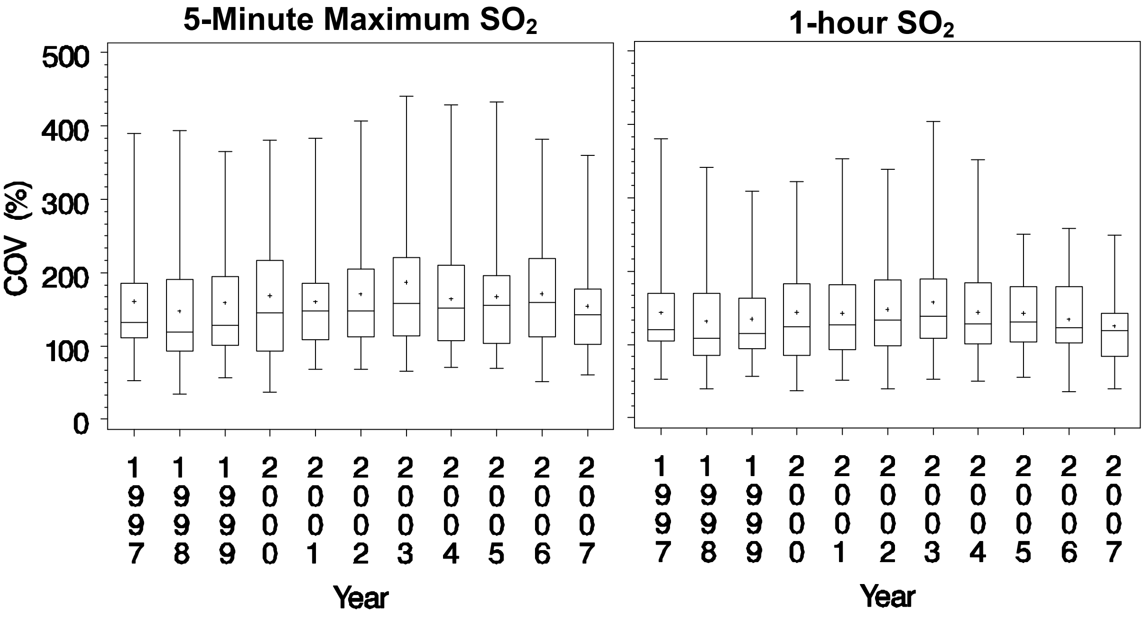

Figure 7-22. Temporal trends in the coefficient of variability (COV) for 5-minute maximum and 1-hour concentrations at the 98 monitors that reported both 5-minute and 1-hour SO_2 concentrations

7.4.4 Spatial Representation

The ambient monitoring data are assumed to be spatially representative of the locations analyzed in this REA because the monitors are used in determining whether areas meet or do not meet the NAAQS. However, relative to the physical area, staff recognizes there are only a small number of monitors, particularly when considering the set of monitors that reported 5-minute maximum SO_2. When considering 1-hour ambient monitoring at the county level, data were assumed to be spatially representative of those particular locations analyzed here. This includes areas between the 1-hour ambient monitors that may or may not be influenced by similar local sources of SO_2. For these reasons, the uncertainty due to the spatial networks may be moderate, although the SO_2 monitoring network design should have addressed these issues within the available resources and other monitoring constraints. Portions of the air quality characterization used all monitors meeting the 75 percent completeness criteria, without taking into account the monitoring objectives, scale, or land use. Thus, there may be a further lack of spatial representation and contribution to uncertainty due to either the inclusion or exclusion of monitors that are near local source emissions of SO_2 resultant from the validity screening. Bias will depend on ambient monitoring objectives, monitoring scale, and whether there is large variability in monitoring surface, i.e., areas of differing terrain that are not adequately represented by the current distribution of monitors. The direction of this bias is largely unknown due to the differences in the true representativeness of the network and the particular terrain in each location.

In addition, because the monitors reporting 5-minute concentrations are not part of a designed 5-minute SO_2 monitoring network but are entirely voluntary, it is largely unknown what the direction of bias and magnitude of uncertainty may be for the results generated using these monitors. In comparing the emission sources in close proximity to the monitors reporting 5-minute maximum versus the broader SO_2 monitoring network , similar distributions were observed in the types of sources and the total emissions potentially impacting both sets of data. This could indicate that the relationships derived from monitors reporting 5-minute SO_2 concentrations and applied to the broader monitoring network does not add to uncertainty when considering the ambient monitoring data wholly. In comparing individual monitors, there are varying numbers and types of sources within given distances of each monitor, each potentially contributing in varying proportions to the measured SO_2 concentrations at each monitor. There could be added uncertainty in extrapolating relationships derived from any one monitor and applied to other ambient monitors with dissimilar source types and total emissions. However, the method of applying both concentration level and variability measures to each hourly concentration at each monitor should have accounted for some of the variability anticipated by the presence differing source types and emissions. Additional discussion on the use of the monitors reporting 5-minute data is given below in section 7.4.6. Based on the similarity in the emission sources surrounding the group of monitors in each data set, it is judged that there is at most a moderate uncertainty associated with the spatial representation of the monitors reporting 5-minute SO_2 concentrations with unknown bias.

7.4.5 Air Quality Adjustment Procedure

There is uncertainty in the air quality adjustment procedures due to the uncertainty of the true relationship between the adjusted concentrations that are simulating a hypothetical scenario and the *as is* air quality. The adjustment factors used for the current and the potential alternative standards each assumed that all hourly concentrations will change proportionately at each ambient monitoring site. Two principal uncertainties are discussed, namely uncertainty regarding the proportional approach used and the universal application of the approach to all ambient monitors within each location.

Different sources have different temporal emission profiles, so that equally applied changes to the concentrations at the ambient monitors to simulate hypothetical changes in emissions may not correspond well within all portions of the concentration distribution. When adjusting concentrations upward to just meeting the current standard, the proportional adjustment used an equivalent multiplicative factor derived from the annual mean or daily mean concentration and equally applied that factor to all portions of the concentration distribution, i.e., the upper tails were treated the same as the area of central tendency. This may not necessarily reflect changes in an overall emissions profile that may result from, for example, an increase in the number of sources in a location. It is possible that while the mean concentration measured at an ambient monitor may increase with an increase in the source emissions affecting concentrations measured at the monitor, the tails of the hourly concentration distribution might not have the same proportional increase. The increase could be greater or it could be less than that observed at the mean, dependent largely on the type of sources and inherent operating conditions. Adjusting the ambient concentrations upwards to simulate the potential alternative standards also carries a similar level of uncertainty although the multiplicative factors were derived from the upper percentiles of the 1-hour daily maximum SO_2 concentrations, rather than the mean, and then applied to the 1-hour SO_2 concentrations equally. If there are deviations from proportionality, the magnitude of the bias is likely related to the magnitude of the concentration adjustment. There is likely greater uncertainty in the results for evaluating the current and the 250 ppb 99th percentile alternative standards which have the highest adjustment factors, than when considering the 50 ppb and 100 ppb 99th percentile alternative standard which have the lowest adjustment factors.

In each of these instances of adjusting the concentrations upwards, one could argue that there may be an associated over-estimation in the concentrations at the upper tails of the distributions, possibly leading to over-estimation in the numbers of exceedances of benchmark levels. An analysis was performed on monitors within seven counties used in the air quality characterization to investigate how distributions of hourly nitrogen dioxide concentrations have changed over time (Rizzo, 2009). The analysis indicates that a proportional approach can be appropriate in simulating higher concentrations at most monitoring sites, since historically, SO_2 concentrations have decreased linearly across the entire concentration distribution at each of the monitoring sites and counties evaluated.

At some of monitoring sites analyzed however, there were features not consistent with a completely proportional relationship, including deviation from linearity primarily at the maximum or minimum percentile concentrations, some indication of curvilinear relationships, and the presence of either a positive or negative regression intercept (Rizzo, 2009). Where multiple monitors were present in a location, there tended to be a mixture of each of these conditions including proportionality (e.g., see Figure 7-23). Not all of the counties analyzed as part of the air quality characterization were included in the evaluation. It was also assumed that the analysis conducted for the seven counties would reflect what may be observed at the other counties if evaluated for trends in concentration over long periods of time. Further, there is uncertainty in adjusting concentrations upwards or downwards considering assumptions regarding future source emission scenarios and how these would relate to observed trends in current and historical air quality. The uncertainty about future source emission control scenarios is largely unknown.

Universal application of the proportional simulation approach for each of the counties and within each county was done for consistency and was designed to preserve the inherent variability in the concentration distribution. There is uncertainty regarding emission changes that would affect the concentrations at the design monitor having the highest concentration (e.g., the highest annual mean, 98th or 99th percentile 1-hour concentration) that may not necessarily affect other lower concentration sites proportionately. This could result in either over- or under-estimations in the number of exceedances at lower concentration sites within a county where the current or alternative standard scenarios were evaluated. For example, Figure 7-23 shows the daily maximum 1-hour SO_2 concentration percentiles for five ambient monitors in Allegheny County PA, where each of the ambient monitors were in operation for years 1998 and 2007. While all five of the monitors generally demonstrate features of proportionality, the difference in regression slopes indicates that the rate of change in the concentration distribution was not equal when comparing these monitors for these two monitoring years.

Given the limited deviations in linearity and proportionality at each monitor site that may result in both over- or under-estimations in concentrations following either an adjustment upwards or downwards and the limited time and resources available to develop a new universal approach that addresses each of the observed deviations, staff judged the proportional approach used to simulate just meeting the current and alternative standards as adequate and appropriate for the scenario considered. The uncertainty is judged moderate, given the differences in the rate of change in concentrations over time and limited deviations from linearity/proportionality at individual monitoring sites, each of which could add to either an over- or underestimation bias.

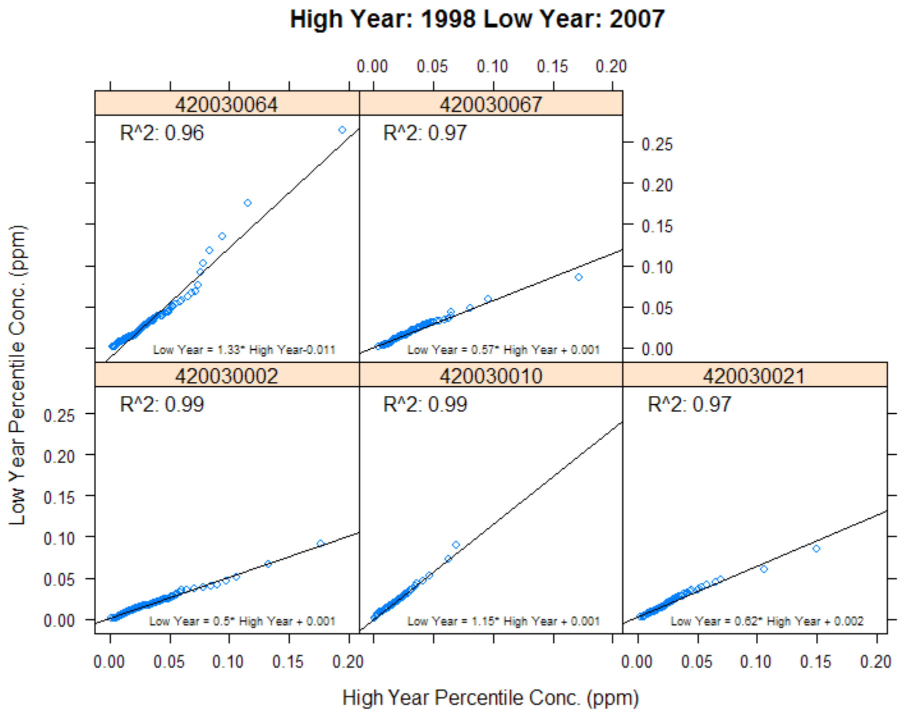

Figure 7-23. Comparison of measured daily maximum SO_2 concentration percentiles in Allegheny County PA for one high concentration year (1998) versus a low concentration years (2007) at five ambient monitors.

7.4.6 Statistical Model Used for Estimating 5-minute SO_2 Concentrations

Four components of uncertainty were identified regarding the statistical model: the screening of the PMR data, the temporal representation of data used in the statistical model development, the accuracy of the model in predicting daily 5-minute maximum concentrations and the reproducibility of the model predictions.

Staff identified data for removal from the combined 5-minute and 1-hour ambient measurement data set using the PMR. The calculation of PMRs less than 1 implies the 5-minute peak is less than the 1-hour average, a physical impossibility, and values >12 are a mathematical impossibility. The 5-minute ambient monitoring data were screened for values outside of these bounds[35], increasing confidence in the relevance of PMRs used for development of the statistical model. While a total of 40,665 data points were excluded from the data set using the PMR criterion, this comprised less than 2% of the data available to develop the PMR relationship. It is

---

[35] It is possible to have a PMR equal to 12. The value is achievable with one 5-minute concentration above zero and the other eleven 5-minute values reporting concentrations of zero. Data used in developing the statistical relationship were screened for the values with a PMR equal to 12 however since it could not be used by the AERMOD/APEX modeling. It is of little consequence because the distributions chosen in estimating the 5-minute concentrations included the 1st through the 99th percentiles, not the minimum and maximum values.

assumed that the criterion used for the data removal is not biased, only directed towards identifying unrealistic 5-minute and 1-hour concentration combinations. Therefore, given the few data removed from further analysis and recognizing there would be reduced uncertainty offered in using a data set comprised of PMRs with realistic bounds, the uncertainty associated with the screening of the 5-minute data is low.

The use of all screened 5-minute maximum SO_2 data (1997 to 2007) in developing distributions of PMRs assumes that the source emissions present at that time of measurement are similar to other year source emissions, possibly adding to uncertainty in estimated exceedances in areas where source emissions have or have not changed over time. However, as noted with the concentration variability, the PMRs do not have any apparent trend with monitoring year and have averaged around 1.6 using the 5-minute maximum measurement data (Figure 7-24). This indicates that the use of the older ambient monitoring data in developing the statistical model may have a negligible impact on the predicted concentrations.

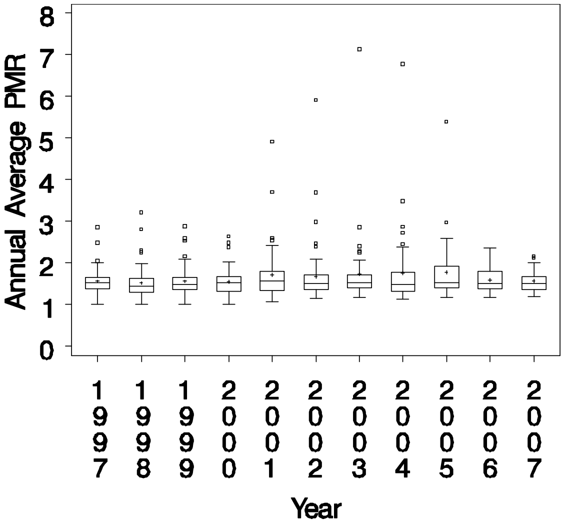

Figure 7-24. Distributions of annual average peak-to-mean ratios (PMRs) derived from the 98 monitors reporting both 5-minute maximum and 1-hour SO_2 concentrations, Years 1997 through 2007.

The PMRs distributions for each COV and concentration bin were represented by a non-parametric form condensed to single percentiles, with each value from the distribution having an equal probability of selection. While there may be other distribution forms that could be alternatively selected, staff judged that use of a fitted distribution would not improve the representation of the true population of PMRs compared with a non-parametric form, and that there would likely be no reduction in the uncertainty of estimated number of exceedances if using a parameterized distribution. While many of the PMR distributions were similar to a lognormal distribution (for example Figure 7-25), 93 of 95 possible statistical tests performed indicated the distributions were statistically distinct ($p<0.01$) from any of the tested forms (i.e., normal, lognormal, Weibull, gamma, and exponential) (see Figure 7-26 as an example). The PMRs derived from monitors having the greatest COV (all concentration bins) and those derived from the lowest concentration bins (all COV bins) were most common in exhibiting atypical distribution forms. While there is uncertainty associated with the use of the empirically-derived data in representing the true population of PMRs, assuming a fitted distribution would not be without its own uncertainties. For example, using a lognormal distribution may underestimate the observed frequency of certain values of PMRs while overestimating others. For PMR distributions that are of similar form with the lognormal distribution, it is likely that the small variation in PMRs selected from a fitted lognormal distribution would have only limited impact to the estimated 5-minute maximum SO_2 concentrations. For distributions exhibiting no similarities to any parametric distribution, experimental justification criteria would need to be developed in selecting the most appropriate form of the distribution, likely requiring multiple test iterations, potentially yielding distributions with more uncertainty than those of a non-parametric form (WHO, 2008). Each of these additional evaluations and iterations would require time and resources not available to staff. Furthermore, the sample sizes for many of the PMR distributions used are well above 1,000 (only 5 of the 19 distributions had fewer than 1,000), with all above 100 samples, providing support that the true distribution may be well-represented by the non-parametric form. Each of these factors mentioned (uncertainty in the form of the distribution, limits on time and resources available, and numbers of samples available) were considered and it was decided by staff that the non-parametric distribution derived from the measurement data would be appropriate.

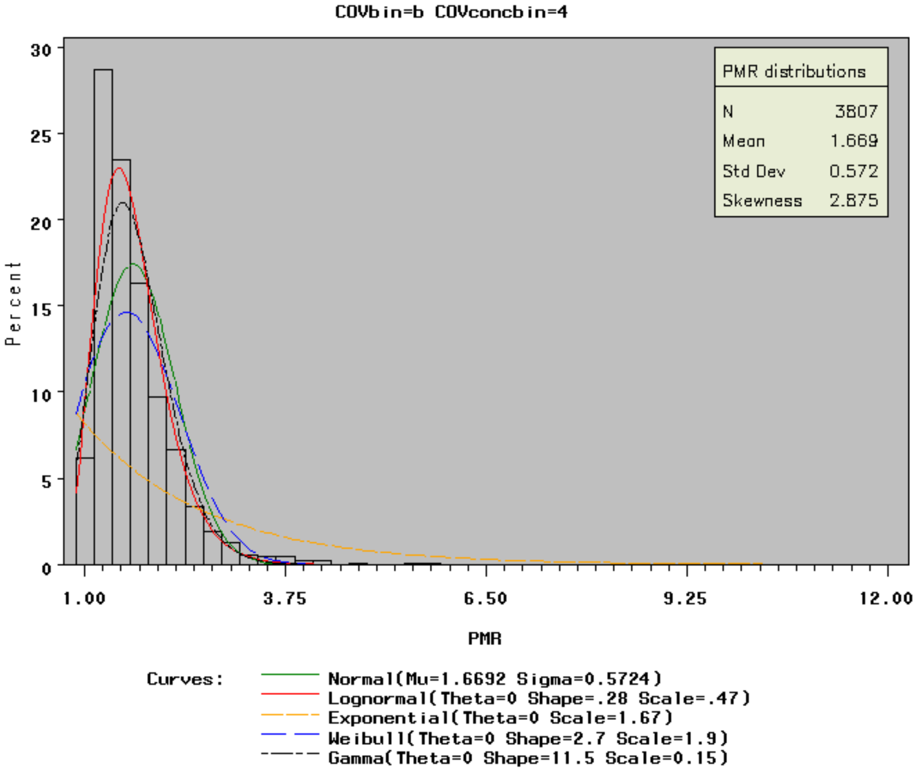

Figure 7-25. Example histogram of peak-to-mean ratios (PMRs) compared with four fitted distributions derived from monitors reporting the 5-minute maximum and 1-hour SO_2 concentrations: monitors with medium level variability and 1-hour concentrations between 75 and 150 ppb.

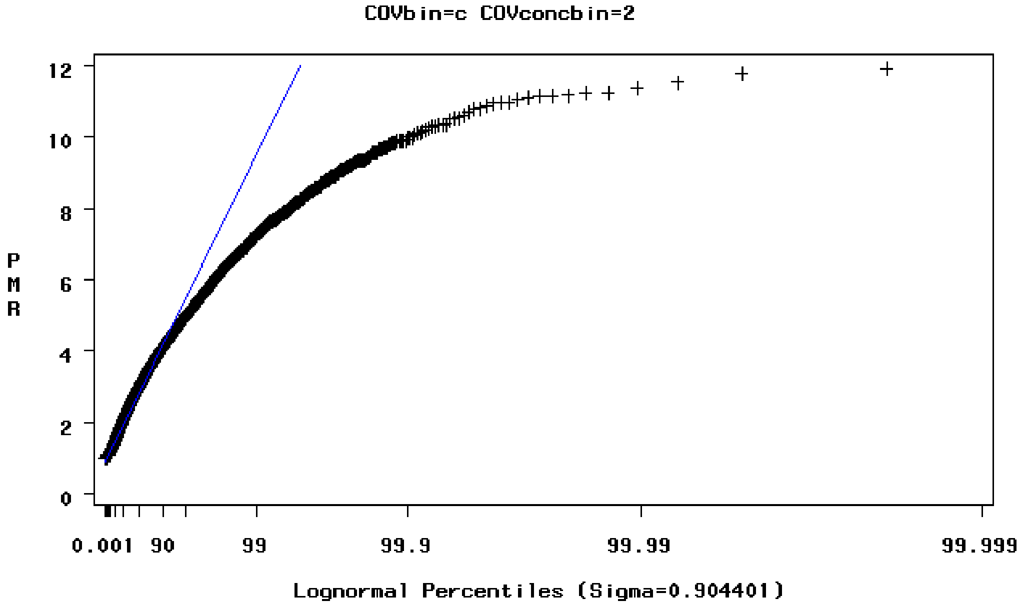

Figure 7-26. Example of a measured peak-to-mean ratio (PMRs) distribution with the percentiles of a fitted lognormal distribution.

The accuracy in the predicted daily 5-minute maximum SO_2 concentrations above each of the benchmark levels was evaluated using measured concentrations. The results indicated that on average, the statistical model performed well in estimating of these short-term peak concentrations (section 7.2.3.4). However, the evaluation indicated the estimated number of daily 5-minute maximum SO_2 concentrations above the any of the benchmark levels could be either over- or under-estimated by as many as 20 to 50 days in the year. These model prediction errors were limited to several site-years from a few monitors. Figure 7-27 presents the model predicted and observed number of benchmark exceedances at each of the benchmark levels. While there is generally uniform agreement between the predicted and observed values at the 100 ppb benchmark, there is some deviation in the agreement at the highest and lowest number of exceedances for the 200, 300, and 400 ppb benchmark levels. For example, there were a few site-years without any observed daily 5-minute maximum SO_2 concentrations above 400 ppb, although the statistical model predicted between 2-15 days in a year. This could indicate that a few of the site-years may have moderate overestimations in the estimated number of daily 5-minute maximum SO_2 concentrations, where the estimated number of exceedances is 15 or less. In addition, site-years with the greatest number of observed exceedances of 400 ppb (about 50 per year) were consistently underestimated by about 30%. This could imply that when the estimated number of daily 5-minute maximum SO_2 concentrations above 400 ppb is at 40 per year, the underestimate may be as large as 15 days per year. Neither of these situations appeared related to a source type; additional monitors sited in the same area impacted by similar source types had good agreement between the observed and predicted concentrations. At the monitor with the greatest number of measured benchmark exceedances (ID 290930030) and largest over-prediction error, complex terrain may be an influential factor. A nearby monitor (ID 290930031) sited in open, flat terrain and close to the major source of emissions (about 1.7 km) had small prediction errors. The other monitor (ID 290930030) is about 4.6 km from the same primary smelter, but located at the base of a ridge running between the source and the monitoring site. These results suggests that when considering any individual monitor, there may be factors not accounted for by the statistical model that are important in estimating benchmark exceedances. Based on the results of the model evaluation, the greatest uncertainty in the number of benchmark exceedances for individual monitors is likely at the lower and upper tails of the prediction distribution. However, in evaluating the estimated number of benchmark exceedances at most of the other monitoring site-years (i.e., about 90% of the data set) and at all of the benchmark levels, the uncertainty in the predicted number of exceedances as a whole is likely low.

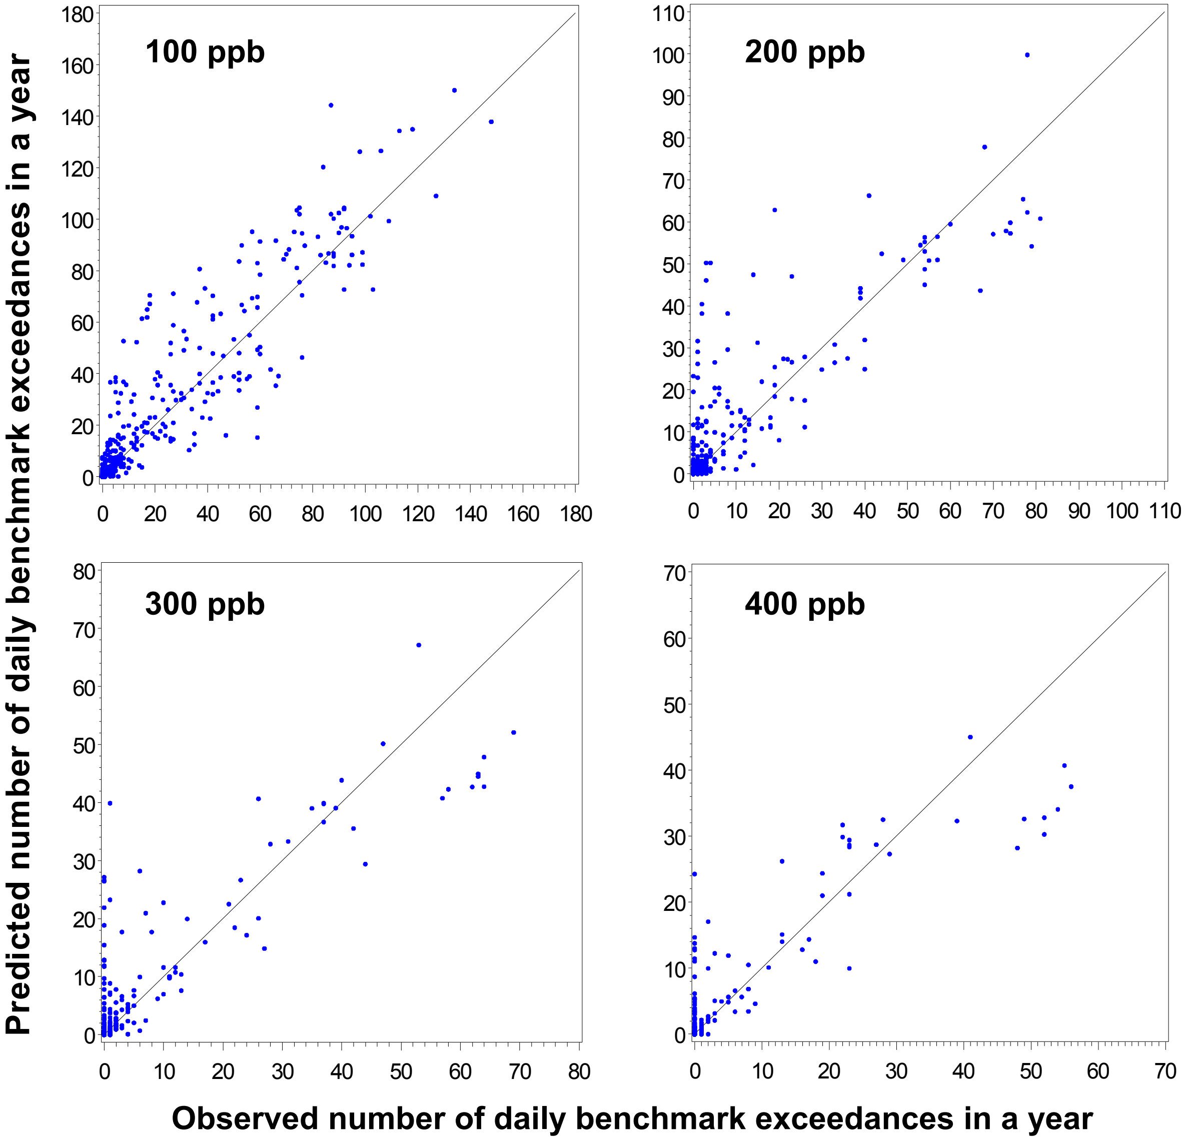

Figure 7-27. Comparison of observed and predicted number of daily benchmark exceedances in a year at monitors reporting 5-minute maximum SO_2 concentrations.

Reproducibility in the model estimates was evaluated by performing multiple model runs. For the sake of efficiency, a limit of 20 simulations per air quality scenario was selected as sufficient to generate stable estimates of 5-minute concentrations where the statistical modeling was performed. This determination was based on a series of sensitivity runs conducted using the 40-county *as is* air quality data set. First, ten independent model runs were performed using 20 simulations in each run. A simulation is where each monitor has all of its years of 1-hour data used in estimating 5-minute maximum concentrations; this is repeated 20 times and used to generate a mean number of daily 5-minute maximum SO_2 concentration exceedances for each year. This model run was repeated 10 times to generate the 10 runs of 20 simulations. Then an additional model run was performed, only this time it was comprised of 100 simulations using the same air quality data set. Estimated mean exceedances from this larger model simulation run were compared with the 10 independent 20 model simulation runs to evaluate differences between the runs. The absolute difference in the number of exceedances between the single 100 simulation run and each of the ten 20 simulation runs for each site-year (n=610) was calculated. The distribution of the differences in the estimated number of exceedances of the potential health effect benchmark levels is provided in Figure 7-28. For each of the potential benchmark levels, there is little to no difference in using a 100 model simulation versus a 20 model simulation per run. All of the differences in the number of exceedances are centered at zero, with a very few site-years exhibiting prediction differences greater than one. There may be a small overestimation bias in estimating daily 5-minute maximum concentrations above 100 ppb when using a 20 model simulation run compared with a 100 model simulation run, however the difference for most of the site years is at most 1 exceedance. Of the 610 site-years simulated in each run, over 70% were within at least one exceedance when considering the 100 ppb level, while about 95% were within at least two estimated exceedances (Table 7-15). At the higher benchmark levels the agreement improves, with nearly 98% of all model run site-years with a two or fewer exceedance difference between the 100 and 20 model simulation runs. Run-to-run variability is also limited, indicating that a single independent 20 model simulation run would consistently estimate the mean number of benchmark exceedances.

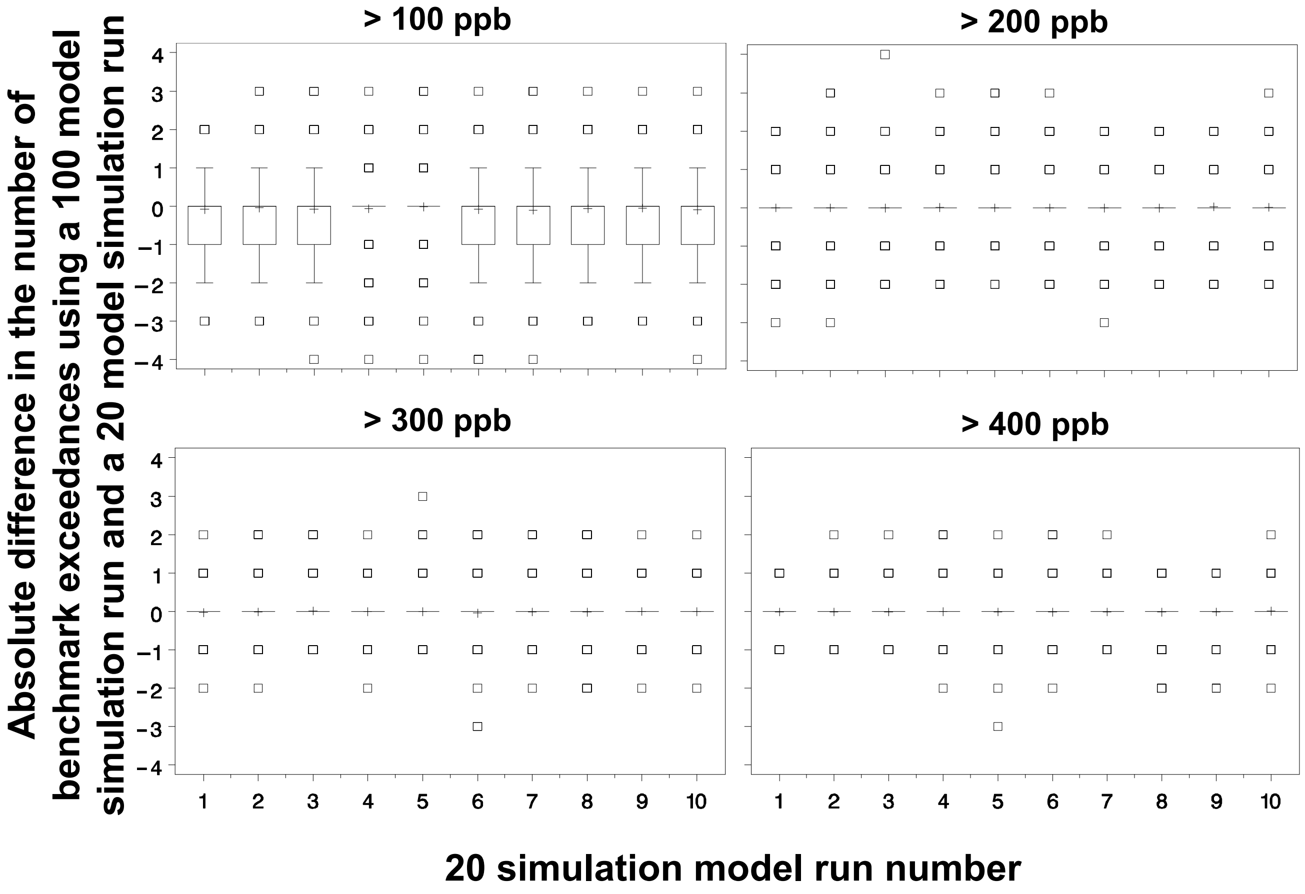

Figure 7-28. Distributions of the calculated difference between estimated concentration exceedances using a single 100 model simulation run and those estimated using ten independent 20 model simulation runs. Box represents the inner quartile range (IQR, or the 25th to 75th percentile), + indicates the mean, whiskers are 1.5 times the IQR.

Table 7-15. The percent of site-years with a difference in the number of modeled exceedances using a 100 model simulation run versus a 20 model simulation run.

Difference in Estimated Yearly Exceedances	Potential Health Effect Benchmark Level Compared			
	> 100 ppb	> 200 ppb	> 300 ppb	> 400 ppb
≤ 1	71.5 - 73.8	82.6 - 85.6	91.1 - 93.1	93.8 - 95.4
≤ 2	94.6 - 97.5	97.9 - 99.3	99 - 99.8	99.7 - 100

In further analyzing the reproducibility of the statistical model, ninety-five percent prediction intervals (95-PI) about the median number of daily 5-minute maximum benchmark exceedances were generated for each monitor in the forty counties selected for detailed analysis, using the model simulations for the as is air quality scenario, for each year simulated, and for each potential health effect benchmark level. Percentile distributions were calculated from the 100 model simulation run using the number of estimated exceedances at each monitor, with the 2.5th, 50th, and 97.5th percentile values retained. First, the estimated median peak values were ranked for each site-year and used to represent the central tendency. Then, the 2.5th and 97.5th percentile predictions were used to construct the 95-PI about the ranked median estimates (i.e., 97.5th value minus 2.5th value = 95th prediction interval).

Figure 7-29 presents the results of this sensitivity analysis for the number of days with 5-minute benchmark exceedances per site-year in the selected counties when using the as is air quality data. The 95-PI spans about 15 and is generally consistent across a wide range of estimated number of potential health effect benchmark exceedances and for each benchmark level, indicating little bias in the estimation procedure at any individual site-year. When a few exceedances are estimated (e.g., 7 or less in a year), the 95-PI tends to include an estimate of zero, suggesting that when a monitor contains this few estimated mean or median number of exceedances, the certainty in the prediction may be limited. This is evident when considering the lowest percentiles of the distribution, that of course varies with each given benchmark level. For example, just over 15 percent of site-years have a 95-PI that includes zero exceedances of the 100 ppb benchmark. Even though there may have been a positive number (say 3 or 4) of mean or median estimated exceedances for a percentage of these site-years, zero exceedances is still a reasonable prediction. Compared to the benchmark of 100 ppb, far fewer monitors have mean exceedances of 300 ppb greater than zero, with around 80 percent either having a 95-PI that includes zero or a mean estimate of zero exceedances. Where the estimated exceedances of any of the benchmarks in a year are greater than or equal to about 10, the 95-PI excludes a value of zero, indicating greater certainty about the estimated mean or median number of exceedances being different from zero. This is most evident in the number of estimated days with 5-minute maximum concentrations above 100 ppb, where most of the site-years (about 80%) likely have about 10 exceedances in a year. The other benchmark levels also have 95-PI that does not include zero exceedances, albeit at a lower percentage of the total site-years.

Similarly, Figure 7-30 presents the 95-PI generated at the county level. These intervals were generated using the mean estimates of each benchmark percentile (i.e., the 2.5th, the 50th, and the 97.5th) by county for each year. The 95-PI have a smaller range than when considering individual site-years, spanning approximately 10 exceedances, suggesting a mean prediction of about 5 or more exceedances likely excludes the possibility of zero estimated exceedances.

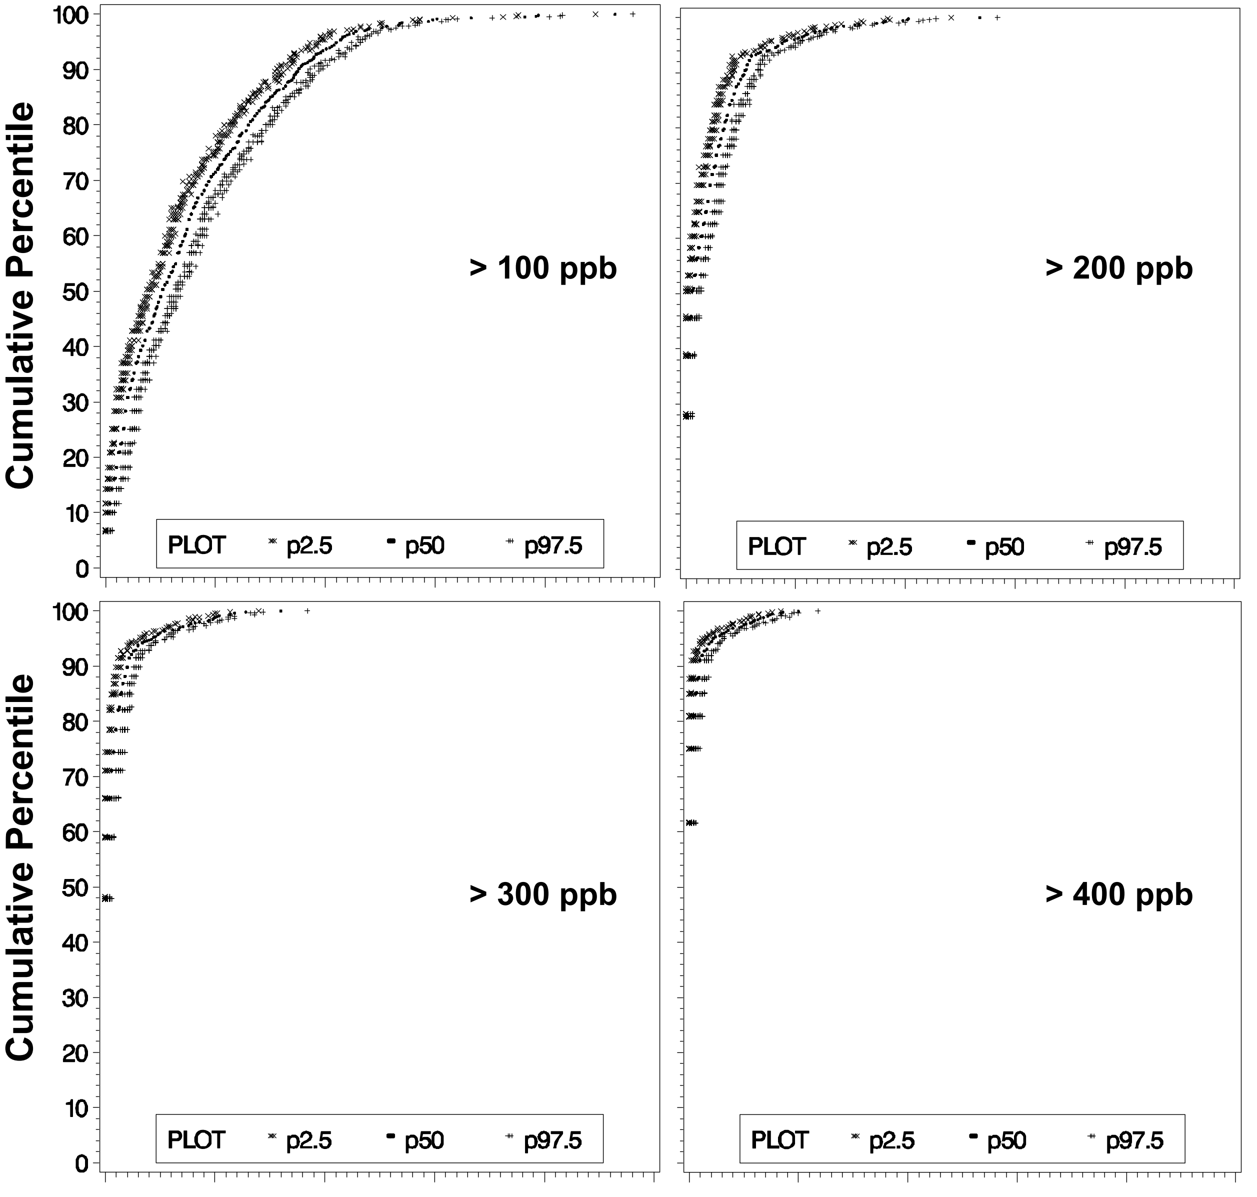

Figure 7-29. 95% prediction intervals for the number of modeled daily 5-minute maximum SO_2 concentrations in a year above potential health effect benchmark levels by each monitor, Years 2001 through 2006 for 40 selected counties, air quality data as is.

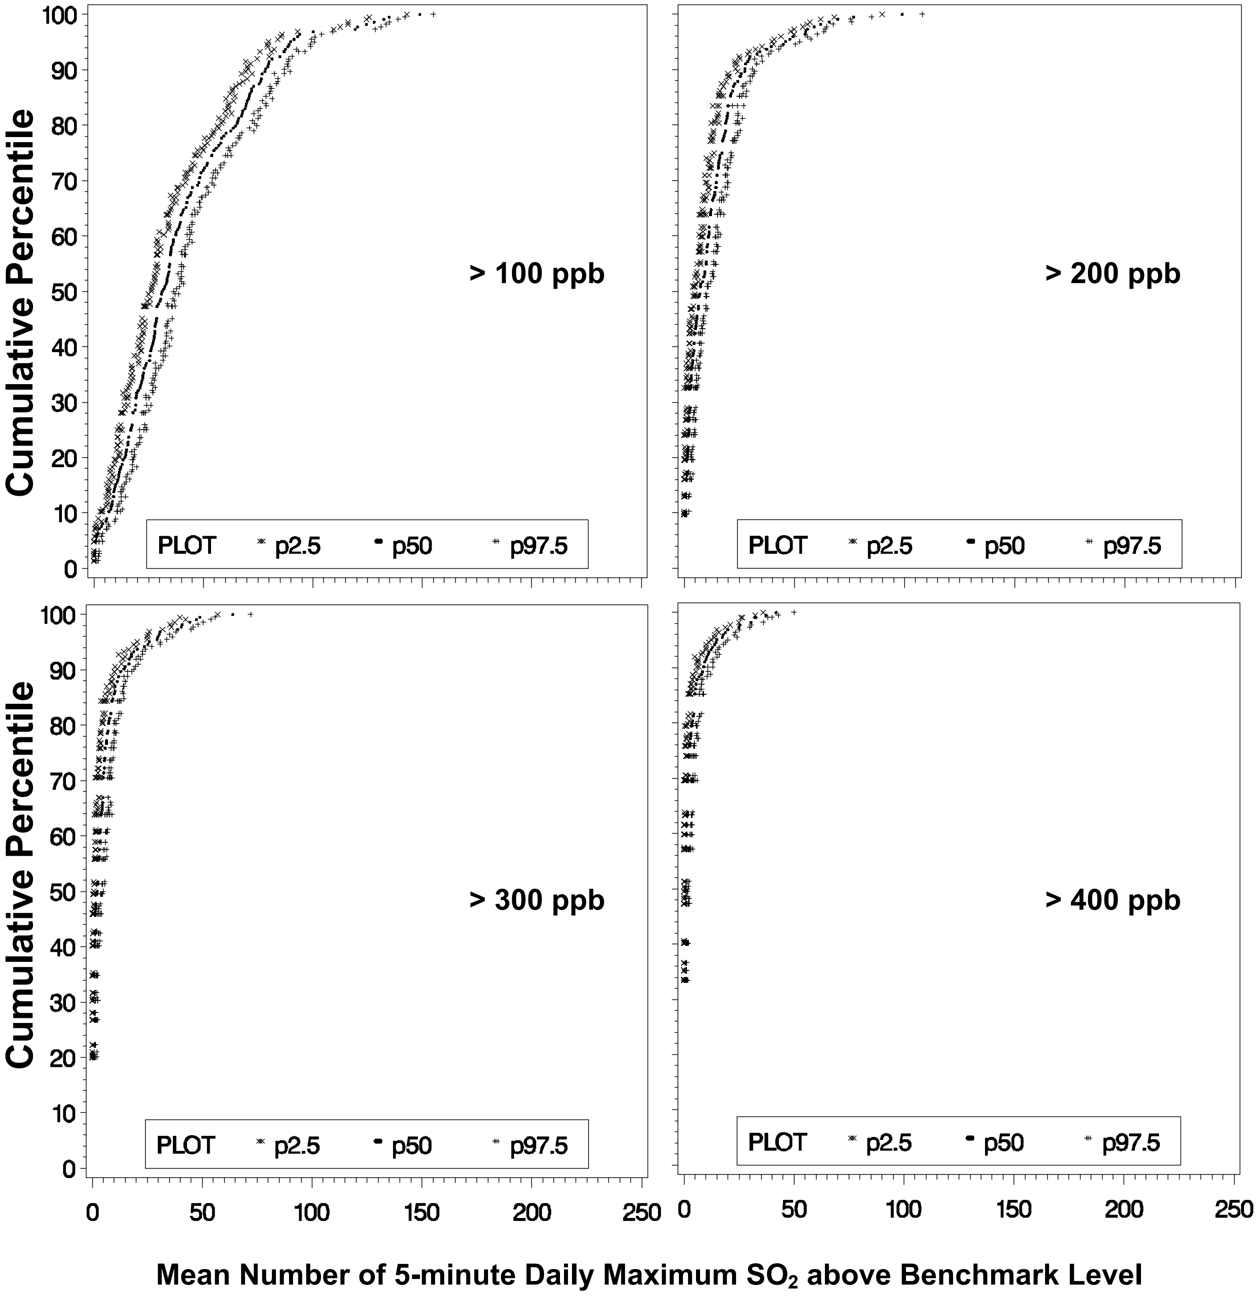

Figure 7-30. 95% prediction intervals for the number of modeled daily 5-minute maximum SO_2 concentrations in a year above potential health effect benchmark levels by each county, Years 2001 through 2006 for 40 selected counties, air quality data as is.

7.4.7 Ambient Monitor to Exposure Representation

Human exposure is characterized by contact of a pollutant with a person, and as such, the air quality characterization assumes that the ambient monitoring concentrations can serve as a surrogate for exposure. The ISA reports that personal exposure measurements (PEM) are of limited use since ambient concentrations are typically below the detection limit of the personal samplers. There is no method to quantitatively assess the relationship between 5-minute ambient monitoring data and 5-minute personal exposures, particularly since personal exposures are time-averaged over hours or days, and never by 5-minute averages. Therefore the fraction of actual 5-minute maximum personal exposure concentrations attributed to 5-minute maximum ambient is unknown and thus adds to uncertainty when using ambient as an indicator of human exposure.

An evaluation in the ISA indicates the relationship between longer-term averaged ambient monitoring concentrations and personal exposures is strong, particularly when ambient concentrations are above the limit of detection. The strength of the relationship between personal and ambient concentrations is supported further by the limited presence of indoor sources of SO_2; much of an individuals' personal exposure is of ambient origin. However, SO_2 personal exposure concentrations are reportedly a small fraction of ambient concentrations. This is because local outdoor SO_2 concentrations are typically half that of the ambient monitoring SO_2 concentrations, and indoor concentrations about half that of the local outdoor SO_2 concentrations (ISA). Therefore, while the relationship between personal exposures and ambient is strong, the use of monitoring data as a surrogate for exposure would likely lead to an overestimate in the number of peak concentrations those individuals might encounter. While the magnitude of the uncertainty about the true relationship between actual human exposure and any given ambient monitor short-term concentration exceedance is unknown, it is likely to be a moderate level given the large difference between the longer-term PEM and the ambient concentrations.

7.4.8 Health Benchmark

The choice of potential health effect benchmarks, and the use of those benchmarks to assess risks, can add to uncertainty in the risk assessment results. For example, the potential health effect benchmarks used were from studies where volunteers were exposed to SO_2 for varying lengths of time. Typically, the SO_2 exposure durations in the controlled human studies were between 5 and 10 minutes. This may add to uncertainty in the characterization of risk using the air quality because the potential health effect benchmark levels were compared to concentration exceedances over a 5-minute time period. If there were a difference in the response rate for a given concentration level and averaging time, the use of a 5-minute averaging time could either over- or under-estimate risks. The true dose-response relationship may be dependent on both the combined concentration level and the exposure duration, that is, it is possible that a particular response rate observed at a 10-minute exposure level of concentration x may be similar to that of a 5-minute exposure level equal to or greater than concentration x. In this hypothetical scenario, if benchmarks were derived from 10 minute exposures and applied in the evaluation of 5-minute ambient concentrations, the potential risk may well be over-estimated. However, the ISA did not distinguish between health effects observed following either 5- or 10-minute exposures. Therefore the potential bias is unknown, and given similarity in studies using either 5- or 10-minute exposures, the overall uncertainty is judged low.

In addition, the human exposure studies evaluated airways responsiveness in mild to moderate asthmatics. For ethical reasons, adults with severe asthma and younger asthmatics. Severe asthmatics and/or asthmatic children may be more susceptible than mild asthmatic adults to the effects of SO_2 exposure. Therefore, the potential health effect benchmarks based on these studies could underestimate risks in populations with greater susceptibility. This assumption likely adds a moderate level of uncertainty to the relevance of the particular health effect benchmark levels.

7.5 KEY OBSERVATIONS

Presented below are key observations resulting from the SO_2 air quality characterization:

- For unadjusted *as is* air quality at ambient monitors measuring 5-minute maximum concentrations, nearly 70% of the 471 site-years analyzed had at least one daily 5-minute maximum concentration above 100 ppb and over 100 site-years had ≥ 25 days with a daily 5-minute maximum concentration above 100 ppb. Less than half (44%) of the site-years had at least one daily 5-minute maximum concentration above 200 ppb and only 36 site-years had ≥ 25 days with a daily 5-minute maximum concentration above 200 ppb. Approximately 25% and 17% of the 471 site-years analyzed had at least one daily 5-minute maximum concentration above 300 and 400 ppb, respectively, with 23 and 12 site-years having ≥ 25 days with a daily 5-minute maximum concentration above 300 and 400 ppb, respectively (Appendix A, Table A.5-1).

- For any of the air quality scenarios considered, the probability of exceeding the 5-minute maximum benchmark levels was consistently greater at monitors sited in low-population density areas compared with high-population density areas. In addition, the probability of any 5-minute benchmark exceedance was consistently related to either a 24-hour average or 1-hour daily maximum concentration.
- For unadjusted air quality in the 40 counties selected for detailed analysis, most counties are estimated to have, on average, fewer than 50 days per year where the daily 5-minute maximum ambient SO_2 concentrations are > 100 ppb. Most counties are estimated to have, on average, 25 days per year with daily 5-minute maximum ambient SO_2 concentrations > 200 ppb. Very few counties are estimated to have more than ten days with 5-minute maximum SO_2 concentrations > 300 ppb, while nearly half did not have any days with 5-minute maximum SO_2 concentrations > 400 ppb (Tables 7-10 to 7-13).
- When air quality is adjusted to simulate just meeting the current annual standard in the 40 counties selected for detailed analysis, a hypothetical scenario requiring air quality to be adjusted upward, all locations evaluated are estimated to have multiple days per year where 5-minute maximum ambient SO_2 concentrations are > 100 ppb. Most counties are estimated to have, on average, 100 days or more per year with 5-minute maximum ambient SO_2 concentrations > 100 ppb, while eight of the forty counties are estimated to have 200 days or more per year with 5-minute maximum ambient SO_2 concentrations > 100 ppb. Fewer benchmark exceedances are estimated to occur with higher benchmark levels. For example, only five counties are estimated to have 60 or more days per year with 5-minute maximum ambient SO_2 concentrations that exceed 300 ppb (Table 7-12) and only four counties are estimated to 50 or more days per year with 5-minute maximum ambient SO_2 concentrations that exceed 400 ppb.
- In all counties, potential alternative standard levels of 100 and 150 ppb are estimated to result in fewer days per year than the current standards and the potential alternative standard levels of 200 and 250 ppb with daily 5-minute

maximum SO_2 concentrations > 300 and > 400 ppb (Tables 7-12 and 7-13). When considering the potential 1-hour daily maximum potential alternative standard levels of 100 and 200 ppb, corresponding annual average SO_2 concentrations were typically between 3 and 15 ppb, similar to a range of concentrations using unadjusted air quality (Appendix A). When considering the potential alternative standard levels of 200 and 250 ppb, corresponding annual average SO_2 concentrations were typically between 10 and 30 ppb, similar to the range of concentrations observed when using adjusted air quality that just meets the current annual standard.

8.0 EXPOSURE ANALYSIS

8.1 OVERVIEW

This section documents the methodology and data staff used in the inhalation exposure assessment and associated health risk characterization for SO_2 conducted in support of the current review of the SO_2 primary NAAQS. Two important components of the analysis include the approach for estimating temporally and spatially variable SO_2 concentrations and simulating human contact with these pollutant concentrations. The approach was designed to better reflect exposures that may occur near SO_2 emission sources, not necessarily reflected by the existing ambient monitoring data alone.

Staff used a combined air quality and exposure modeling approach to generate estimates of 5-minute maximum, 24-hour, and annual average SO_2 exposures within Greene County, MO. and portions of the St. Louis Metropolitan Statistical Area (MSA) for the year 2002. AERMOD, an EPA recommended dispersion model, was used to estimate 1-hour ambient SO_2 concentrations using emissions estimates from stationary, non-point, and port sources. The Air Pollutants Exposure (APEX) model, EPA's human exposure model, was used to estimate population exposures using the census block level hourly SO_2 concentrations estimated by AERMOD. Staff used the person-based exposure profiles to generate the number of 5-minutes daily maximum exposure events in an entire year.

Exposure and potential health risk were characterized considering recent air quality conditions (*as is*), for air quality adjusted to just meet the current SO_2 standards (0.030 ppm, annual average; 0.14 ppm, 24-hour average), and for just meeting potential alternative standards (see Chapter 5). Specifically, the number of times an individual experienced a daily maximum 5-minute exposure concentration in excess of 100 ppb through 800 ppb was estimated. The exposures for each individual were estimated over an entire year therefore, multiple occurrences of exceedances were estimated, giving the number of days per year with an exceedance of the potential health effect benchmark levels.

The approaches used for assessing exposures in Greene County and St. Louis are described below. Additional model input data and supporting discussion of APEX modeling are provided in Appendix B. Briefly, the discussion in this Chapter includes the following:

- description of the inhalation exposure model and associated input data used for Green County and St. Louis;
- evaluation of estimated SO_2 air quality concentrations and exposures; and
- assessment of the quality and limitations of the input data for supporting the goals of the SO_2 NAAQS exposure and risk characterization.

The overall flow of the exposure modeling process performed for this SO_2 NAAQS review is illustrated in Figure 8-1. Several models were used in addition to APEX and AERMOD including emission factors and meteorological processing, as well as a number of data bases and literature sources to populate the model input parameters. Each of these are described within this Chapter, supplemented with additional details in Appendix B.

8.2 OVERVIEW OF HUMAN EXPOSURE MODELING USING APEX

The EPA has developed the APEX model for estimating human population exposure to criteria and air toxic pollutants. APEX serves as the human inhalation exposure model within the Total Risk Integrated Methodology (TRIM) framework (EPA 2009a; 2009b). APEX was recently used to estimate population exposures in 12 urban areas for the O_3 NAAQS review (EPA, 2007d; 2007e) and in estimating population NO_2 exposures in Atlanta as part of the NO_2 NAAQS review (EPA, 2008d).

APEX is a probabilistic model designed to account for sources of variability that affect people's exposures. APEX simulates the movement of individuals through time and space and estimates their exposure to a given pollutant in indoor, outdoor, and in-vehicle microenvironments. The model stochastically generates a sample of simulated individuals using census-derived probability distributions for demographic characteristics. The population demographics are drawn from the year 2000 Census at the tract, block-group, or block level, and a national commuting database based on 2000 census data provides home-to-work commuting flows. Any number of simulated individuals can be modeled, and collectively they approximate a random sampling of people residing in a particular study area.

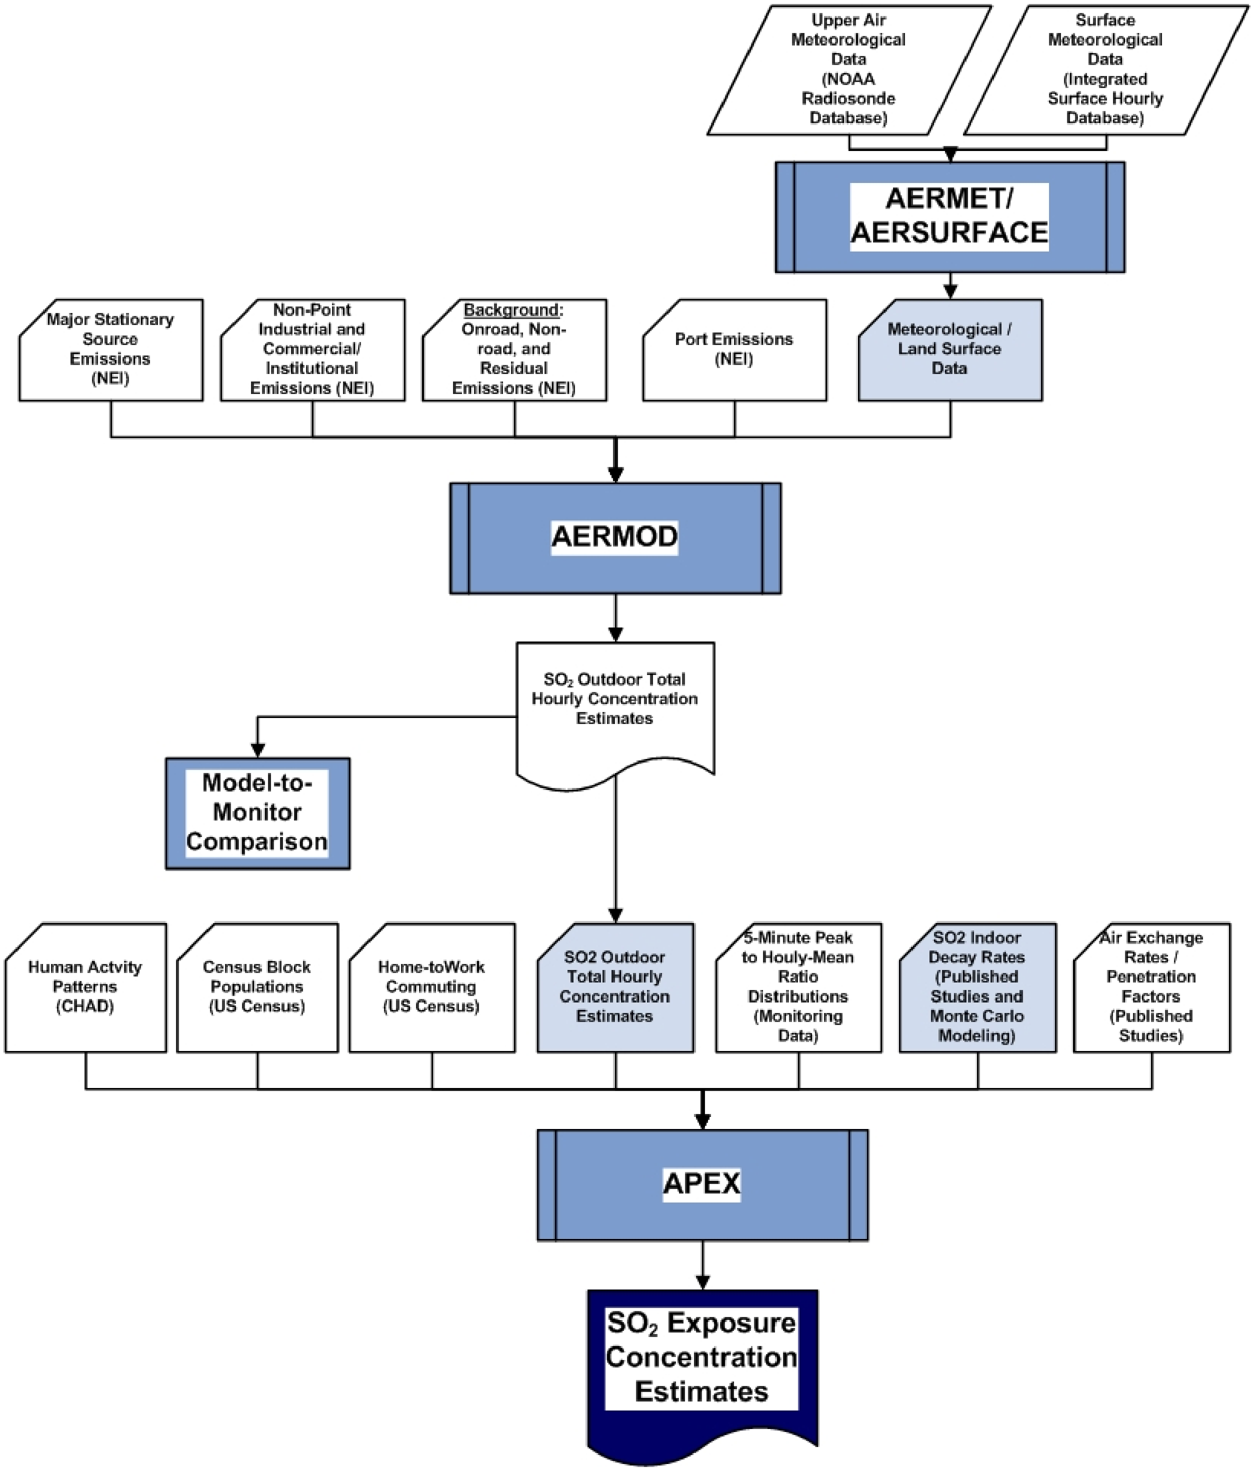

Figure 8-13. General process flow used for SO_2 exposure assessment.

Daily activity patterns for individuals in a study area, an input to APEX, are obtained from detailed diaries that are compiled in the Consolidated Human Activity Database (CHAD) (McCurdy et al., 2000; EPA, 2002). The diaries are used to construct a sequence of activity events for simulated individuals consistent with their demographic characteristics, day type, and season of the year, as defined by ambient temperature regimes (Graham and McCurdy, 2004). The time-location-activity diaries input to APEX contain information regarding an individuals' age, gender, race, employment status, occupation, day-of-week, daily maximum hourly average temperature, the location, start time, duration, and type of each activity performed. Much of this information is used to best match the activity diary with the generated personal profile, using age, gender, employment status, day of week, and temperature as first-order characteristics. The approach is designed to capture the important attributes contributing to an individuals' behavior, and of likely importance in this assessment (i.e., time spent outdoors) (Graham and McCurdy, 2004). Furthermore, these diary selection criteria give credence to the use of the variable data that comprise CHAD (e.g., data collected were from different seasons, different states of origin, etc.).

APEX has a flexible approach for modeling microenvironmental concentrations, where the user can define the microenvironments to be modeled and their characteristics. Typical indoor microenvironments include residences, schools, and offices. Outdoor microenvironments include for example near roadways, at bus stops, and playgrounds. Inside cars, trucks, and mass transit vehicles are microenvironments which are classified separately from indoors and outdoors. APEX probabilistically calculates the concentration in the microenvironment associated with each event in an individual's activity pattern and sums the event-specific exposures within each hour to obtain a continuous series of hourly exposures spanning the time period of interest. The estimated microenvironmental concentrations account for the contribution of ambient (outdoor) pollutant concentration and influential factors such as the penetration rate into indoor microenvironments, air exchange rates, decay/deposition rates, proximity to important outdoor sources, and indoor source emissions. Each of these influential factors are dependent on the microenvironment modeled, available data to define model inputs, and estimation method selected by the model user. And, because the modeled individuals represent a random sample of the population of interest, the distribution of modeled individual exposures can be extrapolated to the larger population within the m0deling domain.

The exposure modeling simulations can be summarized by five steps, each of which is detailed in the subsequent sections of this document. Briefly, the five steps are as follows:

1. **Characterize the study area**. APEX selects the census blocks within a study area – and thus identifies the potentially exposed population – based on user-defined criteria and availability of air quality and meteorological data for the area.
2. **Generate simulated individuals**. APEX stochastically generates a sample of hypothetical individuals based on the demographic data for the study area and estimates anthropometric and physiological parameters for the simulated individuals.
3. **Construct a sequence of activity events**. APEX constructs an exposure event sequence spanning the period of the simulation for each of the simulated individuals using time-location-activity pattern data.
4. **Calculate 5-minute and hourly concentrations in microenvironments**. APEX users define microenvironments that people in the study area would visit by assigning location codes in the activity pattern to the user-specified microenvironments. The model calculates 5-minute and hourly concentrations of a pollutant in each of these microenvironments for the period of simulation, based on the user-provided microenvironment descriptions, the hourly air quality data, and peak-to-mean ratios (PMRs; see section 7.2.3). Microenvironmental concentrations are calculated for each of the simulated individuals.
5. **Estimate exposures**. APEX estimates a concentration for each exposure event based on the microenvironment occupied during the event. In this assessment, APEX estimated 5-minute exposures. These exposures can also be averaged by clock hour to produce a sequence of hourly average exposures spanning the specified exposure period. The values may be further aggregated to produce daily, monthly, and annual average exposure values.

8.3 CHARACTERIZATION OF STUDY AREAS

8.3.1 Study Area Selection

The selection of areas to include in the exposure analysis takes into consideration the availability of ambient monitoring, the presence of significant and diverse SO_2 emission sources, population demographics, and results of the ambient air quality characterization. Although it could be useful to characterize SO_2 exposures nationwide, because the exposure modeling approach is both time and labor intensive, a regional and source-oriented approach was selected to make the analysis tractable and with the goal of focusing on areas most likely to have elevated SO_2 peak concentrations and with sufficient data to conduct the analysis.

A broad study area was first identified based on the results of a preliminary screening of the 5-minute ambient SO_2 monitoring data that were available. The state of Missouri was one of only a few states reporting both 5-minute maximum and continuous 5-minute SO_2 ambient monitoring data (14 total monitors), as well as having over thirty monitors in operation at some time during the period from 1997 to 2007 that measured 1-hour SO_2 concentrations. In addition, the air quality characterization described in Chapter 7 estimated frequent exceedances above the potential health effect benchmark levels at several of the 1-hour ambient monitors. In a ranking of estimated SO_2 emissions reported in the National Emissions Inventory (NEI), Missouri ranked 7th out of all U.S. states for the number of stacks with annual emissions greater than 1,000 tons. These stack emissions were associated with a variety source types such as electrical power generating units, chemical manufacturing, cement processing, smelters, and emissions associated with port operations.

In the 1st draft SO_2 REA, several modeling domains were characterized within the selected state of Missouri to assess the feasibility of the modeling methods. These modeling domains were defined as areas within 20 km of a major point source of SO_2 emission. While modeled air quality and exposure results were generated for several of these domains in the 1st draft REA, changes in the methodology used in this 2nd draft REA precluded additional analysis for most of the domains. Staff judged the availability of relevant ambient monitoring data within the model domain as essential in evaluating model performance, increasing confidence in the predicted air quality and exposure modeling results. For example, when comparing the modeled air quality to ambient monitoring data in Greene County in the 1st draft REA, it was judged by staff that non-point source emissions may contribute to a large proportion of measured ambient concentrations. Addressing non-point source emissions then added a layer to the already complex modeling performed, further limiting the potential number of locations analyzed. Second, to assess the impact of potential alternative standards, baseline conditions (as is) need to be known, again requiring ambient monitoring data. Because Greene County had a number of ambient monitors and most of the model input data were already well-defined, it was selected for additional modeling in the 2nd draft REA. Further, staff decided that modeling a large urban area would be advantageous in combining both large emission sources and large potentially exposed populations. Modeling for St. Louis, MO was already underway at the time of the 1st draft REA, therefore it was decided that modeling in this domain should be continued and expanded for other sources for this 2nd draft REA.

8.3.2 Study Area Descriptions

8.3.2.1 Greene County

The greater Springfield, MO, Metropolitan Statistical Area (MSA) consists of five counties in southwestern Missouri including Christian, Dallas, Greene, Polk, and Webster counties. The only city in the region with a population greater than 150,000 is Springfield, in Greene County. Greene County has a total area of approximately 678 mi^2 (1,756 km^2). Due to the complexity of the air quality and exposure modeling to be performed in this exposure assessment and the focus on receptors within 20 km of stationary sources, the modeling domain was limited to Greene County (see Figure 8-2). The Springfield-Branson Regional Airport (WBAN 13995) served as the source of meteorological data used in the Greene County modeling domain.

8.3.2.2 St. Louis Area

The greater St. Louis Metropolitan Statistical Area (MSA) is the 18th largest MSA in the United States and includes the independent City of St. Louis; the Missouri counties of St. Louis, St. Charles, Jefferson, Franklin, Lincoln, Warren, and Washington; as well as the Illinois counties of Madison, St. Clair, Macoupin, Clinton, Monroe, Jersey, Bond, and Calhoun. The total MSA has an area of approximately 8,846 mi^2 (22,911 km^2). Due to the complexity of the air quality and exposure modeling performed in this exposure assessment and the focus on receptors within 20 km of stationary sources, staff limited the modeling domain to three counties directly surrounding the city of St. Louis: St. Louis City, St. Louis County, and St. Charles County (see Figure 8-3). These three counties comprise much of the urban center of the St. Louis MSA, with a combined population of 1,151,094 (2000 Census), which is approximately 45 percent of the Greater St. Louis MSA population.

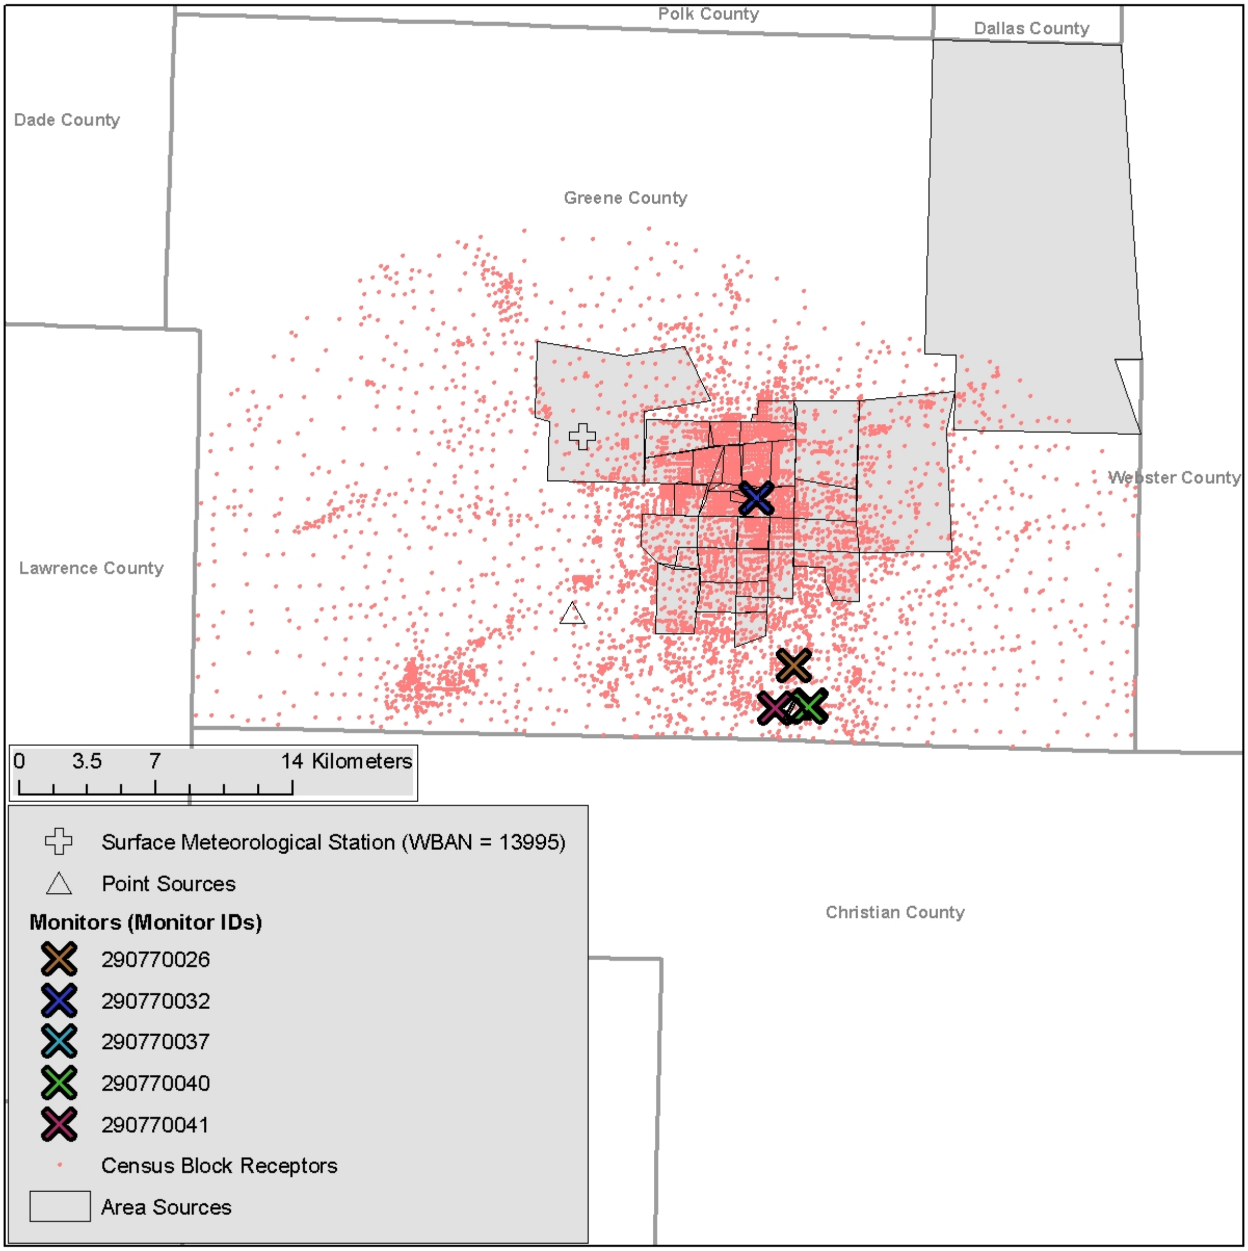

Figure 8-2. Modeling domain for Greene County MO, along with identified emissions sources, air quality receptors, ambient monitors, and meteorological station.

The St. Louis modeling domain reported on here was assembled from three separate modeling domains described in the 1st Draft SO_2 REA, aggregated to utilize the most reliable hourly meteorological data available (St. Louis International-Lambert Field; WBAN 13994). It was then reduced to just the three counties of the urban core. Figure 8-3 shows the modeling domain for the greater St. Louis, MO area.

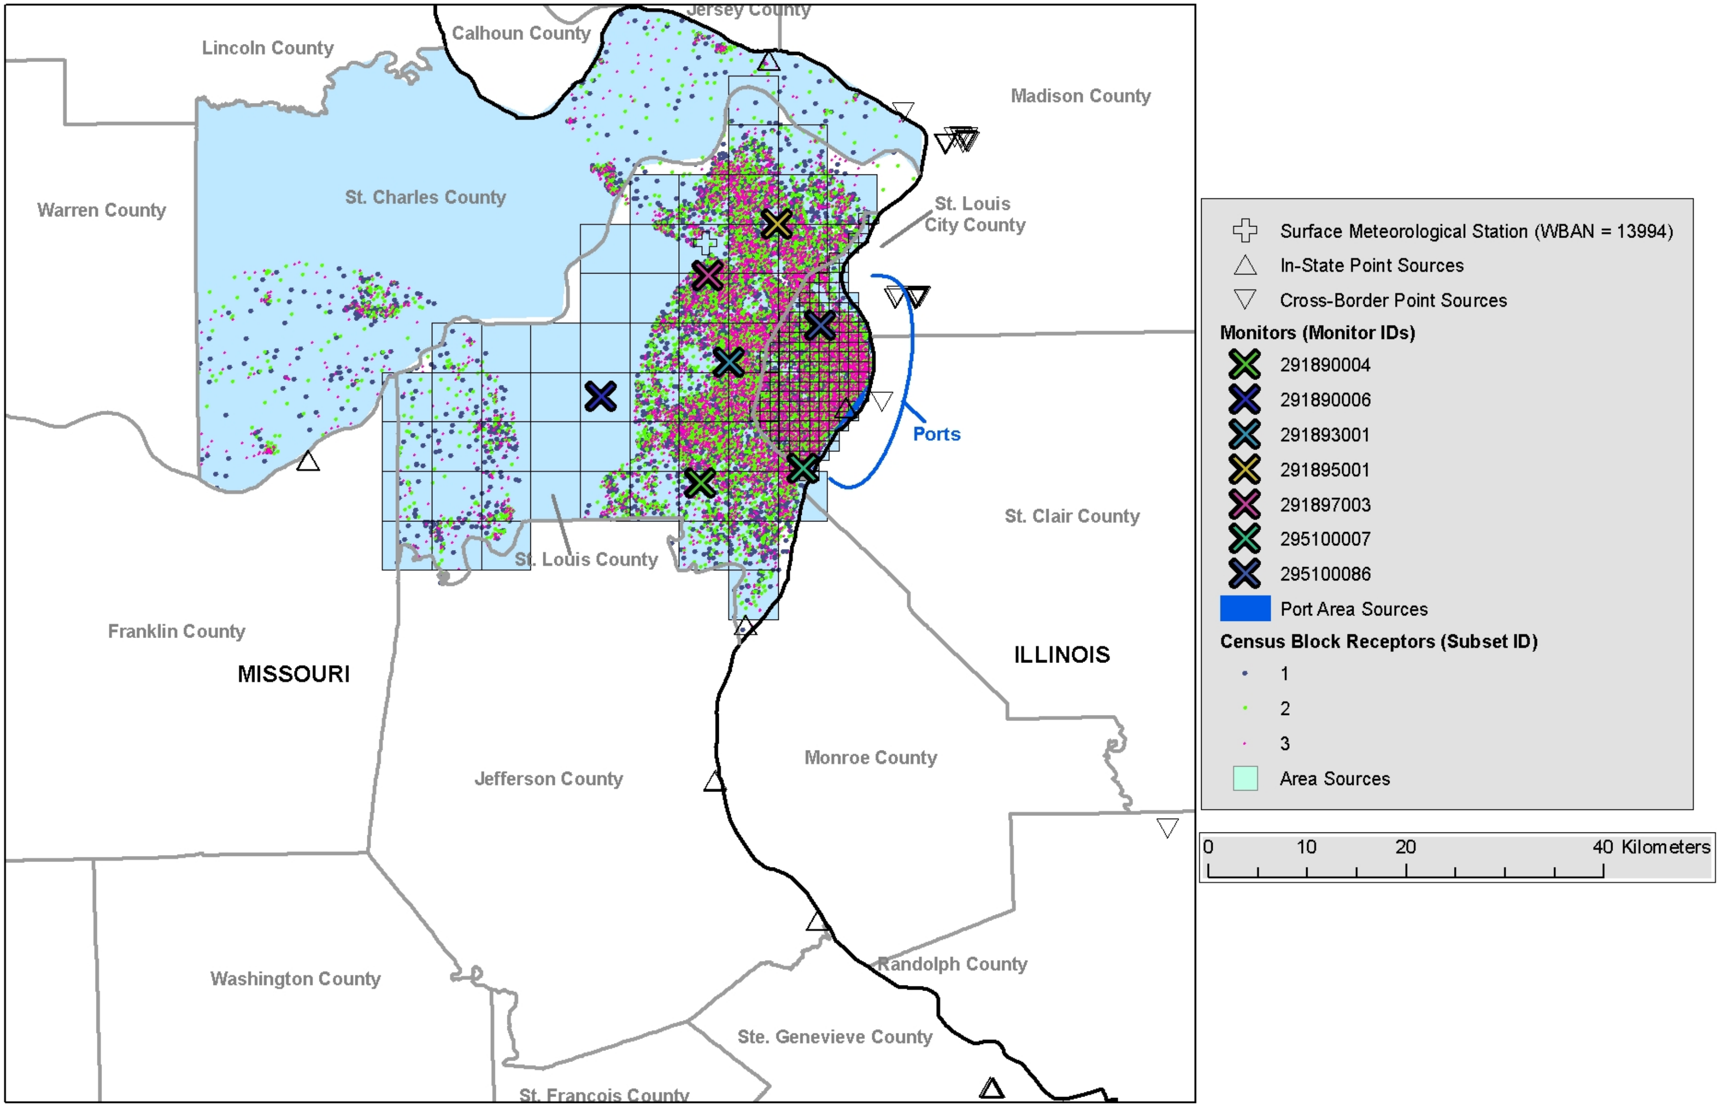

Figure 8-3. Three county modeling domain for St. Louis, MO, along with identified emissions sources, air quality receptors, ambient monitors, and meteorological station.

8.3.3 Time Period of Analysis

Calendar year 2002 was simulated for both modeling domains to characterize the most recent year of emissions data available for the study locations. Year 2002 temperature and precipitation used in the dispersion modeling was compared with 30-year climate normal period data from 1978 through 2007. For Greene County, 2002 was similar to the 30-year normal (56.2 °F compared to 56.3 °F) though drier than the 30-year normal (37.8 in. compared to 40.2 in.). For St. Louis, 2002 was warmer on average than the 30-year normal (57.9 °F compared to 56.8 °F) and received an annual rainfall total that was similar with the 30-year normal (40.9 in. compared to 39.1 in.). See Appendix B, Attachment 1 for further details.

8.3.4 Populations Analyzed

The exposure assessment included the total population residing in each modeled area and population subgroups that were considered more susceptible as identified in the ISA. These population subgroups include:

- Asthmatic children (5-18 years in age)
- All Asthmatics (all ages)

In addition, based on the observed responses in the human clinical trials, all asthmatic exposures were characterized only when the individual was at moderate or greater exertion levels during the exposure events.

8.4 CHARACTERIZATION OF AMBIENT HOURLY AIR QUALITY DATA USING AERMOD

8.4.1 Overview

Air quality data used for input to APEX were generated using AERMOD, a steady-state, Gaussian plume model (EPA, 2004). For both modeling domains, the following steps were performed.

1. **Collect and analyze general input parameters.** Meteorological data, processing methodologies used to derive input meteorological fields (e.g., temperature, wind speed, precipitation), and information on surface characteristics and land use are needed to help determine pollutant dispersion characteristics, atmospheric stability and mixing heights.
2. **Define sources and estimate emissions.** The emission sources modeled included:

    a. Major stationary emission sources within the domain,
    b. Major stationary emission sources outside the domain (cross-border stacks)
    c. Non-point source area emissions,
    d. Emissions from ports, and
    e. Background sources not otherwise captured.

However, note that not all source categories were present in both modeling domains.

3. **Define air quality receptor locations**. Two sets of receptors were identified for the dispersion modeling, including ambient monitoring locations (where available) and census block centroids.

4. **Estimate concentrations at receptors**. Full annual time series of hourly concentration were estimated for 2002 by summing concentration contributions from each of the emission sources at each of the defined air quality receptors.

Estimated hourly concentrations output from AERMOD were then used as input to the APEX model to estimate population exposure concentrations. Details regarding both modeling approaches and input data used are provided below. Supplemental information regarding model inputs and methodology is provided in Appendix B.

8.4.2 General Model Inputs

8.4.2.1 Meteorological Inputs

All meteorological data used for the AERMOD dispersion model simulations were processed with the AERMET meteorological preprocessor, version 06341. The National Weather Service (NWS) served as the source of input meteorological data for AERMOD. Tables 8-1 and 8-2 list the surface and upper air NWS stations chosen for the two areas. A potential concern related to the use of NWS meteorological data is the often high incidence of calms and variable wind conditions reported for the Automated Surface Observing Stations (ASOS) in use at most NWS stations. A variable wind observation may include wind speeds up to 6 knots, but the wind direction is reported as missing. The AERMOD model currently cannot simulate dispersion under these conditions. To reduce the number of calms and missing winds in the surface data for each of the four stations, archived one-minute winds for the ASOS stations were used to calculate hourly average wind speed and directions, which were used to supplement the standard archive of winds reported for each station in the Integrated Surface Hourly (ISH) database. Details regarding this procedure are described in Appendix B, Attachment 1.

Table 8-1. Surface stations for the SO_2 study areas.

Area	Station	Identifier	WMO (WBAN)	Latitude[1]	Longitude[1]	Elevation (m)	Time Zone[2]
Greene County	Springfield-Branson Regional AP	SGF	724400 (13995)	37.23528	-93.40028	387	6
St. Louis	Lambert-St. Louis International AP	STL	724340 (13994)	38.7525	-90.37361	161	6

Notes:
[1] Latitude and longitude are the best approximation coordinates of the meteorological towers.
[2] Time zone is the offset from UTC/GMT to LST in hours.

Table 8-2. Upper air stations for the SO_2 study areas.

Area	Station	Identifier	WMO (WBAN)	Latitude	Longitude	Elevation (m)	Time Zone[1]
Greene County	Springfield-Branson Regional AP	SGF	724400 (13995)	37.23	-93.40	394	6
St. Louis	Lincoln-Logan County AP, IL	ILX	724340 (4833)	40.15	-89.33	178	6

Notes:
[1] Time zone is the offset from UTC/GMT to LST in hours.

8.4.2.2 Surface Characteristics and Land Use Analysis

The AERSURFACE tool (US EPA, 2008e) was used to determine surface characteristics (albedo, Bowen ratio, and surface roughness) for input to AERMET. Surface characteristics were calculated for the location of the ASOS meteorological towers, approximated by using aerial photos and the station history from the National Climatic Data Center (NCDC). A draft version of AERSURFACE (08256) that utilizes 2001 National Land Cover Data (NLCD) was used to determine the surface characteristics for this application since the 2001 land cover data will be more representative of the meteorological data period than the 1992 NLCD data supported by the current version of AERSURFACE available on EPA's SCRAM website. All stations were considered at an airport. Monthly seasonal assignments were defined as shown in Table 8-3 and because the AERSURFACE default seasonal assignments were not used, the surface characteristics were output by month.

Table 8-3. Seasonal monthly assignments.

8.4.3 Stationary Sources Emissions Preparation

8.4.3.1 Emitting Sources and Locations

Point Sources

Point sources at major facilities were identified and paired to a representative surface meteorological station. Any stacks listed as in the same location with identical release parameters within a certain resolution (typically to the nearest integer value) were aggregated into a single stack to simplify modeling but retain all emissions. For this analysis, major facilities were defined as those with an SO_2 emission total exceeding 1,000 tpy in 2002. Within such facilities, every stack emitting more than one tpy was included in the modeling inventory. This process resulted in the identification of 11 (combined) stacks in Greene County and 38 (combined) stacks in St. Louis. Additionally, 45 (combined) stacks were identified across the state border that could influence concentrations in St. Louis. These cross-border stacks were modeled the same as the within-state stacks. The locations of all emitting stacks were corrected based on GIS analysis. This was necessary because many stacks in the NEI are assigned the same location, which often corresponds to a location in the facility – such as the front office – rather than the actual stack locations. To correct for this, stack locations were reassigned manually with the Microsoft® Live Maps® Virtual Earth® tool to visually match stacks from the NEI database to their locations within the facilities using stack heights as a guide to stack identification. All release heights and other stack parameters were taken from the values listed in the NEI. Table B-3-1 (in Appendix B) lists all stacks in both domains.

Port-Related Sources

Only the St. Louis domain has relevant port emissions. The Port of St. Louis is one of the Nation's largest inland river ports. Activity from this port was modeled as fourteen area sources along the waterfront. All port-related emission sources were considered as non-point area emissions with boundaries based on GIS analysis of aerial photographic images. A release height of 5.0 m with a plume initial vertical standard deviation (σ_{zi}) of 2.33 m was used in all cases to represent emissions from Category 1 and 2 commercial marine vessels. Port emission strength was taken from the NEI for appropriate activity within St. Louis City and allocated uniformly by emission density for all harbor areas. That is, all ports were modeled with the same emission density. The emission profile was taken as the seasonal hourly value from the EMS-HAP model.

Non-Point Sources

Non-point sources constitute industrial, commercial and institutional facilities as identified in the NEI. Emissions from non-point sources in Greene County are identified for each tract in the County. In Greene County, spatial allocation factors (SAFs) from EPA's EMS-HAP data base[36] were used to disaggregate the county-wide emissions from the NEI to census tracts. Tracts with total non-point emission densities greater than 12 tons per year/square mile were digitized and characterized as non-point source area polygons. These tracts accounted for about 87% of the total non-point source emissions in Greene Co.

The release height for non-point area sources are 10.0 m with initial vertical dispersion (σ_{zi}) of 4.67 m for rural tracts and 20.0 m with σ_{zi} of 9.34 m for rural tracts. Because these sources are not well-defined, the release parameters were derived by conducting sensitivity runs to characterize model performance at the ambient monitor locations.

For the St. Louis domain, staff chose a slightly different approach to characterize non-point emissions sources. During model-to-monitor comparisons, it became clear that the spatial allocation of county-wide non-point emissions to tracts, based on SAFs, resulted in an inaccurate spatial pattern of emissions. Therefore, the spatial resolution of non-point sources in this domain was retained at the county level. However, to improve the numerical representation of these emissions in the model, the two counties with the highest non-point source emissions – St. Louis

---

[36] The SAFs were derived from land use data.

City and St. Louis County – were subdivided into regular grid cells. St. Louis County grid cells were 5 km by 5 km; St. Louis City grid cells were 1 km by 1 km, more closely approximating the smaller and denser census tracts in that region. All county-wide non-point source emissions were spatially allocated uniformly to the grid cells. St. Charles County was modeled as a single area source, with edges approximating the full county boundaries.

The release parameters for the St. Louis domain varied according to the urban and rural designation of individual grid cells. Rural grid cells have a release height of 10 m and initial dispersion length of 4.67 m. Urban grid cells have a release height of 20 m and initial dispersion length of 9.34 m.

Background Sources

For the Greene County domain, background sources were assembled to account for any emissions not otherwise included. These were comprised of any point sources in facilities not meeting the 1,000 tpy selection criteria and any residual non-point sources, as well as on-road and non-road mobile sources. In addition, all emission sources in neighboring Christian County were modeled as a rural, county-wide non-point area source with uniform density. Both background sources were characterized as county-wide polygon rural area sources with release heights of 10.0 m and initial dispersion length of 4.67 m.

For the St. Louis domain, emissions from residual point sources, on-road mobile sources, and non-road mobile sources were combined with the county-wide non-point sources as described above. Thus, no separate background sources were simulated.

8.4.3.2 Urban vs. Rural Designations

AERMOD regulatory default settings were employed in each model domain. Therefore, no chemical decay is assumed for rural sources, while urban sources experience a 4-hour half-life. For urban sources, additional dispersion is simulated at night to account for increased surface heating within an urban area under stable atmospheric conditions. The magnitude of this effect is weakly proportional to the urban area population.

Point Sources

Urban or rural designations for point sources were made according to EPA guidance based on the land use within 3 km of the source. The 2001 NLCD database was used to make this determination. Table 8-4 lists the land use categories in the 2001 NLCD.

Table 8-4. NLCD2001 land use characterization.

Category	Land Use Type	Category	Land Use Type
11	Open Water	73	Lichens
12	Perennial Ice/Snow	74	Moss
21	Developed, Open Space	81	Pasture/Hay
22	Developed, Low Intensity	82	Cultivated Crops
23	Developed, Medium Intensity	90	Woody Wetlands
24	Developed, High Intensity	91	Palustrine Forested Wetland[1]
31	Barren Land (Rock/Sand/Clay)	92	Palustrine Scrub/Shrub Wetland[1]
32	Unconsolidated Shore[1]	93	Estuarine Forested Wetland[1]
41	Deciduous Forest	94	Estuarine Scrub/Shrub Wetland[1]
42	Evergreen Forest	95	Emergent Herbaceous Wetlands
43	Mixed Forest	96	Palustrine Emergent Wetland (Persistent) [1]
51	Dwarf Scrub	97	Estuarine Emergent Wetland[1]
52	Shrub/Scrub	98	Palustrine Aquatic Bed[1]
71	Grassland/Herbaceous	99	Estuarine Aquatic Bed[1]
72	Sedge/Herbaceous		

Notes:
[1] Coastal NLCD class only.

Each stack where more than half the land use within 3 km fell into categories 21-24 were designated as urban. These categories are consistent with those considered developed by AERSURFACE.[37]

Non-Point Sources

Non-point area sources were defined as rural or urban using a similar methodology as that for the point sources. As noted in the 2008 AERMOD Implementation Guide[38], in some cases, a population density is more appropriate than a land use characterization. Therefore, non-point area sources were evaluated from both a land use and population density perspective.

In Greene County, area sources were defined as corresponding to the census tract boundaries. Each tract was then considered urban or rural by considering both the population density and land use fraction from NLCD2001. If the population density was greater than 750/ km^2 or the developed land use categories 22-24 throughout the tract was greater than 50 percent,

[38] *AERMOD IMPLEMENTATION GUIDE*, AERMOD Implementation Workgroup, US EPA, OAQPS, Air Quality Assessment Division, Research Triangle Park, NC, Revised January 9, 2008,

the tract was designated as urban. In addition, if a tract was surrounded by urban tracts it was designated as urban, since the emissions from such a tract would likely be subject to urban dispersion conditions.

As explained above, for the St. Louis domain, the counties with the greatest non-point emissions – St. Louis City and St. Louis County – were subdivided into regular grid cells, while St. Charles County was represented as a polygon area source with its political boundaries. The urban or rural designation was then assigned to each based on population density. St. Charles County and all but eleven of the 5 km grid cells in St. Louis County were designated rural; the remaining cells in St. Louis County and all of St. Louis City were designated urban.

Port-Related Sources

Only the St. Louis domain has relevant port emissions. The fourteen port-related non-point area sources described above were designated urban, given their location in the urban core along the waterfront and their associated industrial activities.

Background Sources

Background area sources for Greene County were classified with the same procedures for non-point area sources. Both Greene and Christian counties were designated rural.

8.4.3.3 Source Terrain Characterization

All corrected locations for the final list of major facility stacks in St. Louis and Green County domains were processed with a pre-release version of the AERMAP terrain preprocessing tool. This version is functionally equivalent to the current release version of the tool (version 08280). In particular, this updated version allows use of 1 arc-second terrain data from the USGS Seamless Server[39] which allows for more highly resolved values of the source and receptor heights as well as the hill height scales.

Terrain height information for point sources was processed through AERMAP with input data taken from the USGS server. For all area sources (non-point and background source types), the outputs from AERMAP were modified. In these cases, rather than using a single point to represent these large areas, the terrain height for each vertex of the area was estimated with AERMAP. The terrain height for the entire source polygon was then characterized as the average terrain height from all vertices.

8.4.3.4 Emissions Data Sources

Point Sources

Data for the parameterization of major facility point sources in the two modeling domains comes primarily from three sources: the 2002 NEI (EPA, 2007f), Clean Air Markets Division (CAMD) Unit Level Emissions Database (EPA, 2007g), and temporal emission profile information contained in the EMS-HAP (version 3.0) emissions model.[40] The NEI database contains stack locations, emissions release parameters (i.e., height, diameter, exit temperature, exit velocity), and annual SO_2 emissions. The CAMD database has information on hourly SO_2 emission rates for all the electric generating units in the US, where the units are the boilers or equivalent, each of which can have multiple stacks.[41] These two databases generally contain complimentary information, and were first evaluated for matching facility data. However, CAMD lacks SO_2 emissions data for facilities other than electric-generating units. To convert annual total emissions data from the NEI into hourly temporal profiles required for AERMOD, a three tiered prioritization was used, as follows.

1. CAMD hourly concentrations to create relative temporal profiles.
2. EMS-HAP seasonal and diurnal temporal profiles for source categorization codes (SCCs).
3. Flat profiles.

Details of these processes are as follows:

Tier 1: CAMD to NEI Emissions Alignment and Scaling

Of the 94 major facility stacks within the model domains identified above (11 in Greene County and 45 cross-border and 38 within-state in the St. Louis domain), 35 (11 in Greene County and 7 cross-border and 17 in-state in the St. Louis domain) were able to be matched directly to sources within the CAMD database. Stack matching was based on the facility name, Office of Regulatory Information Systems (ORIS) identification code (when provided) and facility total SO_2 emissions. For these stacks the relative hourly profiles were derived from the hourly values in the CAMD database, and the annual emissions totals were taken from the NEI.

---

[40] http://www.epa.gov/ttn/chief/emch/projection/emshap30.html

[41] The CAMD database also contains hourly NO_2 emission data for both electric generating units and other types of industrial facilities. In the case of facilities for which CAMD has hourly NO_2 data but not SO_2 data, SO_2 relative temporal profiles could be approximated by NO_2 temporal profiles. However, there were no such cases for MO facilities.

That is, hourly emissions in the CAMD database were scaled to match the NEI annual total emissions.

Tier 2: EMS-HAP to NEI Emissions Profiling

Of the 94 major facility stacks within the two MO domains, 38 stacks (all of which are cross-border stacks in the St. Louis domain) could not be matched to a stack in the in the CAMD database, but had SCC values that corresponded to SCCs that have temporal profiles included in the EMS-HAP emissions model. In these cases, the SCC-specific seasonal and hourly variation (SEASHR) values from the EMS-HAP model were used to characterize the temporal profiles of emissions for each hour of a typical day by season and day type.

Tier 3: Other Emissions Profiling

Of the 94 major facility stacks within the two MO model domains, 21 (all from the St. Louis in-state domain) could not be matched to a stack in CAMD database, or to profiles in the EMS-HAP model by SCC code. In these cases, a flat profile of emissions was assumed. That is, emissions were assumed to be constant for all hours of every day, but with an annual total that equals the values from the NEI. A summary of the point source emissions used for the two modeling domains is given in Table 8-5. Appendix B, Table B-3-1 contains all 94 stacks within the modeling domains and the data source used to determine their emissions profiles.

Nearly all of the point sources in both domains were accounted for directly in the dispersion modeling. Table 8-5 shows the point source contribution captured directly within each modeling domain.

Port-Related Sources

Ports were the only non-road sector explicitly simulated in either modeling domain. Only the St. Louis domain had port emissions. All relevant port emissions were directly captured, comprising 51 percent of the total non-road emissions for the domain. Emission profiles for port-related activity were taken from the EMS-HAP model for sectors matching the modeled activity. Table 8-5 shows the port source contribution modeled directly within each modeling domain and compares it to the total non-road emissions.

Non-Point and Background Sources

Non-point polygon area sources were developed to capture non-point commercial/institutional and industrial emissions within the domains, as specified in the NEI.

For the St. Louis domain, all non-point emissions were included either in gridded area sources over St. Louis City and St. Louis County or a polygon area source over St. Charles County, as described above. For the Greene County domain, commercial/institutional and industrial non-point area source polygons were created to represent the individual census tracts within the county that captured approximately 87 percent of the relevant emissions countywide from the NEI. Other non-point sources, as well as on-road mobile and non-road mobile sources were included in the background source

Because non-point area source and background area source temporal profiles are unknown, profiles were derived that provided a best-fit match between the model predictions and monitor data. Figures 8-4 and 8-5 show the diurnal emissions profiles derived for both the St. Louis and Greene County domains compared to other profiles derived from commonly used emissions models. Table 8-5 shows the non-port source contribution modeled directly within each modeling domain and compares it to the total non-point emissions.[42]

Table 8-5. Summary of NEI emission estimates and total emissions used for dispersion modeling in Greene County and St. Louis modeling domains.

	Point Sources			Area Sources			Non-road Sources		
Modeling Domain	NEI Emissions (tpy)	Modeled Emissions (tpy)	(%)	NEI Emissions (tpy)	Modeled Emissions (tpy)	(%)	NEI Emissions (tpy)	Modeled Emissions (tpy)	(%)
Greene Co.	9,255	9,047	98%	2,055	1,781	87%	N/A	N/A	N/A
St. Louis	70,016	68,656	98%	15,137	15,137	100 %	3,058	1,559	51%

---

[42] Table 8-5 does not have the relevant background contribution for each domain. This is because the total background in each domain includes not only the counties in the modeling domain (three in the St. Louis domain and one in the Greene County domain), but also adjacent counties that could influence concentrations within the modeling domain. In those cases, the total countywide emissions are included in the background. Thus, directly expressing those values would be confusing and are thus omitted.

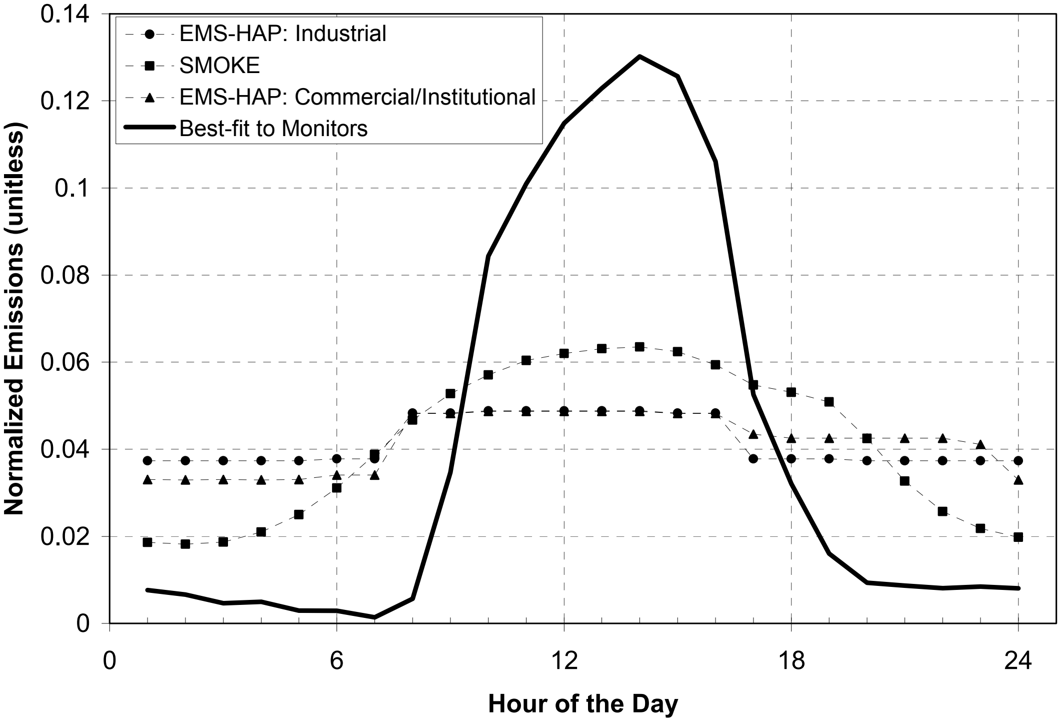

Figure 8-4. Derived best-fit non-point area source diurnal emission profile for the St. Louis domain, compared to other possible profiles.

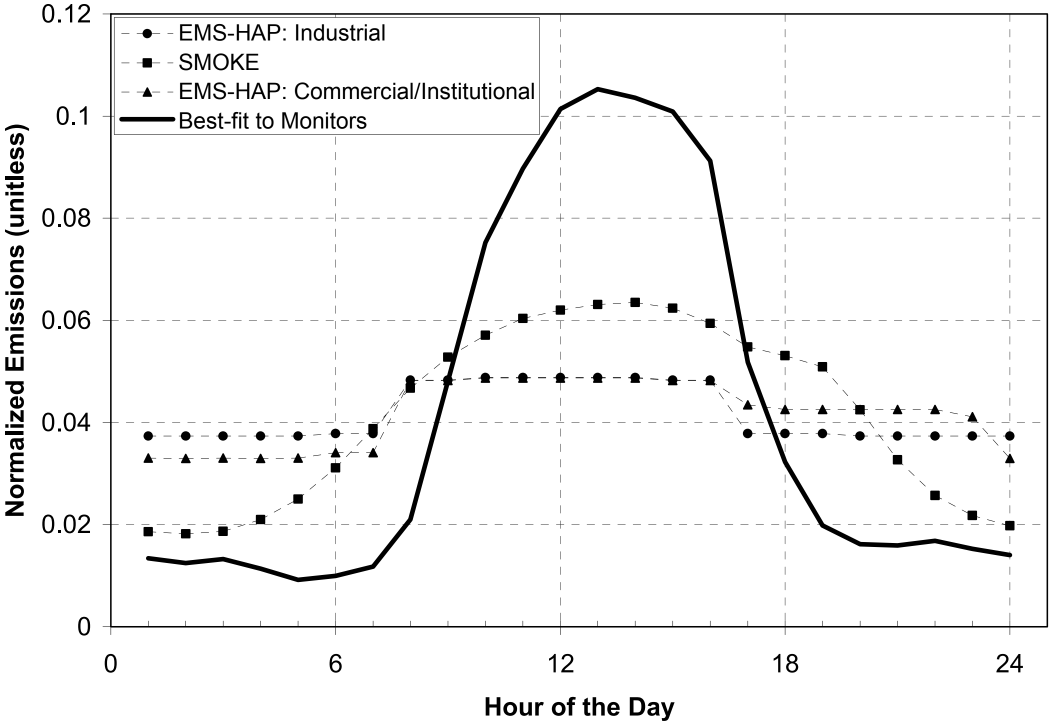

Figure 8-5. Derived best-fit non-point area source diurnal emission profile for the Greene County domain, compared to other possible profiles.

8.4.4 Receptor Locations

Two sets of receptors were chosen to represent the locations of interest within each of the modeling domains. The first set was selected to represent the locations of the residential population of the modeling domain. These receptors were US Census block centroids in the Greene County and St. Louis modeling domains, (Figures 8-2 and 8-3, respectively), that lie within 20 km (12 miles) of any of the major facility stacks.[43] Each of these receptors was modeled at ground level. A total of 17,703 receptors were selected in the St. Louis domain and a total of 5,359 receptors were selected in the Greene County domain.

The second set of receptors included the locations of the available ambient SO_2 monitors. These receptors were used in evaluating the dispersion model performance. In Greene County, there were five ambient monitors with valid ambient monitoring concentrations (Figure 8-2). Within the three St. Louis counties, there were seven monitors (Figure 8-3).

8.4.5 Modeled Air Quality Evaluation

The hourly SO_2 concentrations estimated from each of the sources within a modeling domain were combined at each receptor. These concentration predictions were then compared with the measured concentrations at ambient SO_2 monitors. Rather than compare concentrations estimated at a single modeled receptor point to the ambient monitor concentrations, a distribution of concentrations was developed for the predicted concentrations for all receptors within a 4 km distance of the monitors. Further, instead of a comparison of central tendency values (mean or median), the modeled and measurement concentration distributions were used for comparison.

As an initial comparison of modeled versus measured air quality, all modeled receptors within 4 km of each ambient monitor location were used to generate a prediction envelope.[44] This envelope was constructed based on selected percentiles from the modeled concentration distribution at each receptor for comparison to the ambient monitor concentration distribution.

---

[43] The block centroids used for this analysis are actually population-weighted locations reported in the ESRI data base. They were derived from geocoded addresses within the block taken from the Acxiom Corporation InfoBase household database (Skuta and Wombold 2008; ESRI 2008). These centroids differ from the "internal points" reported by the US Census, which are often referred to as centroids because they are designed to represent the approximate geographic center of the block.

[44] 500 m to 4 km is the area of representation of a neighborhood-scale monitor, according to EPA guidance.

The 2.5th and 97.5th percentiles from all monitor distribution percentiles[45] were selected to create the lower and upper bounds of the envelope. The full 1-hour distributions for the ambient measurement data, the modeled monitor receptor,[46] and the prediction envelope were compared using their respective cumulative density functions (CDFs). When illustrating the cumulative percentiles, only concentrations above the 80th percentile 1-hour concentration were shown because over 80% of the 1-hour SO_2 concentrations were less than 5 ppb (concentrations generally not of interest).

A second comparison between the modeled and monitored data was performed to evaluate the diurnal variation in SO_2 concentrations. AERMOD receptor concentrations during each hour-of-the-day were averaged (i.e., 365 values for hour 1, 365 values for hour 2, and so on) to generate an annual average SO_2 concentration for each hour at each modeled receptor. Prediction envelopes were constructed similar to that described above from modeled receptors located within 4 km of each ambient monitor. The measured ambient monitoring data was also averaged to generate the diurnal profile. Then, annual averaged concentrations for the ambient measurement data, the modeled monitor receptor, and the prediction envelope were plotted by hour-of-the-day for comparison.

8.4.5.1 Greene County Modeled Air Quality Evaluation

For Greene County, there were five monitors used for comparison with the AERMOD concentration estimates. The distribution of the modeled 1-hour SO_2 concentrations estimated for the monitor receptor, the receptor envelope (i.e., all receptors within 4 km of monitor receptor), and the hourly concentration distribution measured at each ambient monitor are provided in Figures 8-6 to 8-8. Data used to generate the figures is provided in Appendix B.

When considering the total hourly distribution or CDFs, most of the monitor concentration distributions are completely bounded by the modeled distributions. At some of the upper percentiles of the distributions, the deviations were of varying direction (over- or under-prediction) and magnitude. For example, monitor ID 290770026 (Figure 8-6) exhibits higher

---

[45] As an example, suppose there are 1,000 receptors surrounding a monitor, each receptor containing 8,760 hourly values used to create a concentration distribution. Then say the 73rd percentile concentration prediction is to be estimated for each receptor. The lower bound of the 73rd percentile of the modeled receptors would represented by the 2.5th percentile of all the calculated 73rd percentile concentration predictions, i.e., the 25th highest 73rd percentile concentration prediction across the 1,000 73rd percentile values generated from all of the receptors. Note that at any given percentile along either of the envelope bounds as well as at the central tendency distribution (the receptor 50th percentile), the concentration from a different receptor may be used.

[46] The *modeled monitor* is the modeled air quality at the ambient monitoring location.

measured concentrations at the upper percentiles of the distribution that extend above the AERMOD prediction envelope, however the deviation occurred beyond the 99th percentile (maximum observed =114 ppb, AERMOD P97.5 = 101 ppb). At monitor ID 290770032 (Figure 8-6), the measured concentrations fall below the prediction envelope, beginning just above the 95th percentile 1-hour concentration.

Even though ambient monitors 290770040 and 290770041 (Figure 8-2) are located approximately 150 m from one another, they exhibited very different measured concentrations at the extreme upper percentiles (Figure 8-7). The greatest difference is in comparing the maximum observed concentrations; 203 ppb versus 33 ppb. The AERMOD predictions followed a similar pattern at the upper percentiles, i.e., the modeled concentrations for the monitor location were greater (50 to 100%) at monitor ID 290770040 when compared with 290770041, but not nearly as great as a difference noted at the maximum measured concentrations. The AERMOD prediction envelope was similar for both of these monitors, encompassing the ambient measured concentrations from the 80th through the 99th percentiles for both, while completely enveloping all 1-hour concentrations at monitor ID 290770041.

The pattern in the AERMOD modeled concentrations at the monitor location and the ambient measurement concentration distribution for monitor ID 290770037 is nearly identical and the only difference observed is that the measured concentrations are greater at each of the upper percentiles. Much of the measured distribution falls within the AERMOD prediction envelope, with deviation occurring at the maximum concentration.

The diurnal pattern observed at each of the ambient monitors is represented well by the modeled concentrations; in general concentrations are elevated during the midday hours and lowest during the late-night and early-morning hours. In addition, most of the measured concentrations fall within the AERMOD prediction envelopes at all hours of the day, with a few exceptions. For example, all observed concentrations for monitor ID 290770032 are below that of the upper AERMOD prediction envelope, though at monitor ID 290770026, measured concentrations are above those modeled during the early-morning and late-night hours (Figure 8-6). Much of the deviation during these hours-of-the-day is likely a result of the concentrations at or below the 80th percentile, where measured concentrations were always greater than any of the predicted concentrations at corresponding percentiles of the distribution. While the prediction envelopes encompassed the diurnal pattern observed at monitor IDs 290770040 and 290770041

(Figure 8-7), the modeled concentrations at the monitor location results were not equally representative. The diurnal pattern and magnitude of concentrations was well reproduced at monitor ID 290770041, while modeled concentrations at the monitor location during the midday and evening hours were greater than the measured concentrations at monitor ID 290770040.

8.4.5.2 St. Louis Modeled Air Quality Evaluation

For St. Louis, there were seven monitors used for comparison with the AERMOD concentration estimates. The distribution of the modeled 1-hour SO_2 concentrations estimated for the monitor receptor, the receptor envelope (i.e., all receptors within 4 km of monitor receptor), and the hourly concentration distribution measured at each ambient monitor are provided in Figures 8-9 to 8-12. Data used to generate the figures is provided in Appendix B.

There are distinct differences in the comparison of modeled versus measured concentration distributions at ambient monitoring locations in St. Louis when compared with Greene County. Most noticeable is the width of the prediction envelopes; St. Louis prediction envelopes were not as wide as those generated for Greene County. This indicates that, in comparison with the Greene County modeling domain, there is less spatial variability in the concentrations modeled at receptors surrounding the ambient monitoring locations in St. Louis. This is likely a result of the emission source contributions; four of five ambient monitors in Green County were primarily influenced by point sources, while most of the concentration contribution in St. Louis monitors was from area source emissions.

The modeled concentrations at the monitor locations and ambient measured concentration distributions showed better overall agreement at the St. Louis monitors, though many of the measured concentrations are outside of the prediction envelopes. For example, at monitor ID 291890006 all measured concentrations up to the 99th percentile fell below the prediction envelope (Figure 8-9) (the maximum was within). Note however that the difference in the measured concentrations was only about 1 ppb when compared with concentrations at any of the envelope percentiles and at most 2 ppb when compared with the modeled concentrations at the monitor receptor. In addition, because most of these under-predictions occur at concentrations well below levels of interest, it is not of great consequence. At the upper percentiles, many of the ambient concentrations fell within the prediction envelopes; 6 of 7 monitors at the maximum percentile were within, 3 of 7 monitors at the 99th percentile were within, and 4 of 7 monitors at the 95th percentile were within the prediction envelopes. Where measured upper percentile concentrations were outside of the prediction envelopes, it was consistently beneath the 2.5th prediction, possibly indicating some over-prediction bias at these monitors at certain percentiles of the distribution. When comparing the AERMOD monitor concentrations with the measured ambient concentrations between the 80th and 99th percentile of the distribution, most of the predicted values were greater than the measured concentrations. The magnitude of this over-prediction ranged from about 1 to 2 ppb, although one monitor had a 7 ppb difference at the 99th percentile. Predictions at the maximum concentrations were more balanced; 4 of the 7 monitors had over-predictions, while all predictions (under or over) were approximately with 10 to 35 ppb of the measured concentrations.

The diurnal pattern was reproduced at the St. Louis monitoring locations, with some of the prediction envelopes encompassing much of the measured ambient concentrations (e.g., Figure 8-9, monitor ID 291890004; Figure 8-11 monitor ID 291897003). Again where deviation did occur at a few of the monitors, the contribution of the lower concentrations (i.e., mostly those beneath the 90th percentile) likely played a role in the magnitude of the disagreement. This can be seen at monitor ID 291890006 (Figure 8-10) where most (99%) of the predicted concentrations are consistently above the measure concentrations by 1 to 2 ppb. It is not surprising to see that the difference in comparing the measured versus modeled diurnal profile at every hour-of-the-day is also between 1 to 2 ppb.

8.4.4.3. Using unadjusted AERMOD predicted SO_2 concentrations

The SO_2 concentrations estimated using AERMOD do not have significant bias, save for small overestimation primarily observed at the lowest concentrations and some difficulty in reproducing the maximum concentrations. Most ambient monitoring concentrations fell within the modeled prediction envelopes constructed of modeled receptors surrounding the monitor. In generating the modeled air quality, staff made judgments in appropriately modifying model inputs including an adjustment of the area source temporal emission profile to improve the comparison of the model predictions with the measurement data. Staff went through several iterations of evaluating the model performance in each modeling domain following model input adjustments to obtain the current modeled air quality results. Given the time and resources to perform this assessment, the good agreement in the model-to-monitor comparisons, the degree of confidence in the dispersion modeling system, the spatial representation of the monitors compared with receptors modeled, and the number of comparisons available, staff did not perform any further adjustments to the modeled concentrations to improve the relationship between modeled versus measured concentration at each monitor. Additional details on the staff's reasoning are provided in section 8.11.

8.5 SIMULATED POPULATION

The population subgroups included in this exposure assessment are asthmatics and asthmatic children. Evaluating exposures of the exposure of this group with APEX requires the estimation of children's asthma prevalence rates. The proportion of the population of children characterized as being asthmatic was estimated by statistics on asthma prevalence rates recently used in the NAAQS review for O_3 (US EPA, 2007d). See Appendix B, Attachment 2 for details in the derivation. Specifically, an analysis of data provided in the National Health Interview Survey (NHIS) for 2003 (CDC, 2007) generated age and gender specific asthma prevalence rates for children ages 0-17. Adult asthma prevalence rates were estimated by gender and for each particular modeling domain based on Missouri regional data (MO DOH, 2002). Table 8-6 provides a summary of the asthma prevalence used in the exposure analysis, stratified by age and gender.

The total population simulated within the two modeling domains was approximately 1.4 million persons, of which there was a total simulated population of about 130,000 asthmatics. The model simulated over 360,000 children ages 5 through 17, of which there were nearly 50,000 asthmatics. The individual populations for each modeling domain and subpopulation of interest are provided in Table 8-7. For comparison, the MO Department of Health (2003) reports the following 2003 asthma prevalence rates by county for all ages as follows; Greene (10.2%), St. Charles (8.8%); St. Louis (5.8%), and St. Louis City (16.4%) which amounts to a county population-weighted value of 8.8%, similar to the 9.3% modeled here using APEX.

Table 8-6. Asthma prevalence rates by age and gender used in Greene County and St. Louis modeling domains.

Modeling Domain (Region)	Age[1]	Asthma Prevalence (%)[2]	
		Females	Males
Greene Co. and St. Louis (Midwest)	0	7.0	3.1
	1	7.1	6.3
	2	7.3	10.8
	3	7.5	15.8
	4	8.1	21.6
	5	9.5	17.8
	6	9.2	12.8
	7	9.0	12.1
	8	8.6	12.8
	9	11.0	14.7
	10	16.2	17.7
	11	19.6	19.0
	12	21.2	19.5
	13	17.0	16.9
	14	14.0	16.8
	15	13.3	18.0
	16	14.0	20.1
	17	16.5	23.7
Greene Co.	>17	10.7	6.1
St. Louis	>17	9.3	5.3

Notes:
[1] Ages 0-17 from the National Health Interview Survey (NHIS) for 2003 (CDC, 2007); ages >17 from (MO DOH, 2002).

Table 8-7. Population modeled in Greene County and St. Louis modeling domains.

Modeling Domain	Population		Asthmatic Population	
	All Ages	Children (5 – 18)	All Ages	Children (5 – 18)

8.5.1 Characterizing Ventilation Rates

Human activities are variable over time, a wide range of activities are possible even within a single hour of the day. The type of activity an individual performs, such as sleeping or jogging, will influence their breathing rate. The ISA indicates that adverse lung function responses associated with short-term peak exposures at levels below 1,000 ppb occurs with moderate to heavy exertion levels. Therefore, ventilation rates needed to be defined to further characterize exposures of interest. The target ventilation for adults (both a mix of males and females) experiencing effects from 5-10 minute SO_2 exposures from most of the controlled human exposure studies was between 40-50 L/min. Since there were limited controlled human exposure study data available for asthmatic children, the ventilation targets needed to be adjusted. As was done in the O_3 NAAQS review (EPA, 2007d), target ventilation rates were normalized to body surface area (BSA) to allow for such an extrapolation from adults to children. The resulting normalization yields an equivalent ventilation rate (EVR). Since BSA was not measured in the controlled human exposure studies and the data were reported as grouped, median estimates for males (1.94 m^2) and females (1.69 m^2) were obtained from EPA (1997) and averaged to normalize the target ventilation rates. Therefore, an EVR = 40/1.81 = 22 L/min-m^2 was used to characterize the minimum target ventilation rate of interest. Individuals at or above an EVR of 22 L/min-m^2 (children or adult) would be characterized as performing activities at or above a moderate ventilation rate.

8.6 CONSTRUCTION OF LONGITUDINAL ACTIVITY SEQUENCES

Exposure models use human activity pattern data to predict and estimate exposure to pollutants. Different human activities, such as spending time outdoors, indoors, or driving, will result in varying pollutant exposure concentrations. To accurately model individuals and their exposure to pollutants, it is critical to understand their daily activities. EPA's CHAD provides data for where people spend time and the activities performed. Typical time-activity pattern data available for inhalation exposure modeling consist of a sequence of location/activity combinations spanning 24-hours, with 1 to 3 diary-days for any single study individual.

The exposure assessment performed here requires information on activity patterns over a full year. Long-term multi-day activity patterns were estimated from single days by combining the daily records using an algorithm that represents the day-to-day correlation of activities for individuals. The algorithm first uses cluster analysis to divide the daily activity pattern records into groups that are similar, and then select a single daily record from each group. This limited number of daily patterns is then used to construct a long-term sequence for a simulated individual, based on empirically-derived transition probabilities. This approach is intermediate between an assumption of no day-to-day correlation (i.e., re-selection of diaries for each time period) and perfect correlation (i.e., selection of a single daily record to represent all days).

Details regarding the algorithm and supporting evaluations are provided in Appendix B, Attachments 3 and 4.

8.7 CALCULATING MICROENVIRONMENTAL CONCENTRATIONS

Probabilistic algorithms are used to estimate the pollutant concentration associated with each exposure event. The estimated pollutant concentrations account for temporal and spatial variability in ambient (outdoor) pollutant concentration and factors affecting indoor microenvironment, such as a penetration, air exchange rate, and pollutant decay or deposition rate. APEX calculates air concentrations in the various microenvironments visited by the simulated person by using the ambient air data estimated for the relevant blocks/receptors, the user-specified algorithm, and input parameters specific to each microenvironment. The method used by APEX to estimate the microenvironmental concentration depends on the microenvironment, the data available for input to the algorithm, and the estimation method selected by the user. The current version of APEX calculates hourly concentrations in all the microenvironments at each hour of the simulation for each of the simulated individuals using one of two methods: by mass balance or a transfer factors method. Details regarding the algorithms used for estimating specific microenvironments and associated input data derivations are provided in Appendix B.

Briefly, the mass balance method simulates an enclosed microenvironment as a well-mixed volume in which the air concentration is spatially uniform at any specific time. The concentration of an air pollutant in such a microenvironment is estimated using the following processes:

- Inflow of air into the microenvironment
- Outflow of air from the microenvironment
- Removal of a pollutant from the microenvironment due to deposition, filtration, and chemical degradation
- Emissions from sources of a pollutant inside the microenvironment.

A transfer factors approach is simpler than the mass balance model, however, most parameters are derived from distributions rather than single values to account for observed variability. It does not calculate concentration in a microenvironment from the concentration in the previous hour as is done by the mass balance method, and the transfer factors approach contains only two parameters. A proximity factor is used to account for proximity of the microenvironment to sources or sinks of pollution, or other systematic differences between concentrations just outside the microenvironment and the ambient concentrations (at the measurements site or modeled receptor). The second parameter, a penetration factor, quantifies the amount of outdoor pollutant penetrates into the microenvironment.

8.7.1 Approach for Estimating 5-Minute Maximum SO_2 Concentrations

The 5-minute peak concentrations were estimated probabilistically considering the empirically-derived PMR CDFs developed from recent 5-minute ambient monitoring data (see section 7.2). Thus for every 1-hr concentration estimated at each receptor, an associated 5-minute maximum SO_2 concentration was generated.

The approach is designed to generate the maximum 5-minute SO_2 concentrations to use in evaluating exceedances of the potential health effects benchmarks. In general, it is not an objective to estimate each of the other eleven 5-minute concentrations within the hour with a high degree of certainty. While the occurrence of multiple peak concentrations above benchmark levels within an hour is possible, the potential health effect benchmark levels are related to single peak exposures within a day. The APEX model originally used 1-hour ambient SO_2 concentrations as input prior to the calculation of microenvironmental concentrations. The current APEX model now can use ambient concentrations of almost any time step, including down to 5-minutes. The file size was an issue with this approach however, since each of the thousands of receptor files generated by AERMOD would be increase by a factor of twelve, creating both disk space and processing difficulties. An algorithm was incorporated into the flexible time-step APEX model to estimate the 5-minute maximum SO_2 concentrations real-time using the 1-hour SO2 concentration, an appropriate PMR (section 7.2), and equation 7-1. The additional eleven 5-minute concentrations within an hour at each receptor were approximated using the following:

$$X = \frac{n\overline{C} - P}{n-1} \qquad \text{equation (8-1)}$$

where,

X = 5-minute concentration in each of non-peak concentration periods in the hour at a receptor (ppb)

$\overline{C}$ = 1-hr mean concentration estimated at a receptor (ppb)

P = estimated peak concentration at a receptor (ppb) estimated probabilistically using equation 7-1.
n = number of time steps within the hour (12)

In addition to the level of the maximum concentration, the actual time of when the contact occurs with a person is also of importance. There is no reason to expect a temporal relationship of the peak concentrations within the hour, thus clock times for peak values were estimated randomly (i.e., any one of the 12 possible time periods within the hour). The PMR assignment also assumes a standard frequency during any hour of the day.

8.7.2 Microenvironments Modeled

In APEX, microenvironments represent the exposure locations for simulated individuals. For exposures to be estimated accurately, it is important to have realistic microenvironments that match closely to the locations where actual people spend time on a daily basis. As discussed above, the two methods available in APEX for calculating pollutant levels within microenvironments were mass balance or a transfer factors approach. Table 8-8 lists the microenvironments used in this study, the calculation method used, and the type of parameters used to calculate the microenvironment concentrations.

Table 8-8. List of microenvironments modeled and calculation methods used.

Microenvironment	Calculation Method	Parameter Types used [1]
Indoors – Residence	Mass balance	AER and DE
Indoors – Bars and restaurants	Mass balance	AER and DE
Indoors – Schools	Mass balance	AER and DE
Indoors – Day-care centers	Mass balance	AER and DE
Indoors – Office	Mass balance	AER and DE
Indoors – Shopping	Mass balance	AER and DE
Indoors – Other	Mass balance	AER and DE
Outdoors – Near road	Factors	PR
Outdoors – Public garage - parking lot	Factors	PR
Outdoors – Other	Factors	None
In-vehicle – Cars and Trucks	Factors	PE and PR
In-vehicle - Mass Transit (bus, subway, train)	Factors	PE and PR

[1] AER=air exchange rate, DE=decay-deposition rate, PR=proximity factor, PE=penetration factor

8.7.3 Microenvironment Descriptions

8.7.3.1 Microenvironment 1: Indoor-Residence

The Indoor-Residence microenvironment uses several variables that affect SO_2 exposure: whether or not air conditioning is present, the average outdoor temperature, the SO_2 removal rate, and an indoor concentration source.

Air conditioning prevalence rates

Since the selection of an air exchange rate distribution is conditioned on the presence or absence of an air-conditioner, for each modeled area the air conditioning status of the residential microenvironments is simulated randomly using the probability that a residence has an air conditioner. A value of 95.5% was calculated to represent the air conditioning prevalence rate in both Greene County and St. Louis, using the data and survey weights for St. Louis, MO. obtained from the American Housing Survey of 2003 (AHS, 2003a; 2003b).

Air exchange rates

Air exchange rate data for the indoor residential microenvironment were the same used in APEX for the most recent O_3 NAAQS review (EPA, 2007d; see Appendix B, Attachment 5). Briefly, data were reviewed, compiled and evaluated from the extant literature to generate location-specific AER distributions categorized by influential factors, namely temperature and presence of air conditioning. In general, lognormal distributions provided the best fit, and are defined by a geometric mean (GM) and standard deviation (GSD). To avoid unusually extreme simulated AER values, bounds of 0.1 and 10 were selected for minimum and maximum AER, respectively.

Briefly, AER data were reviewed, compiled, and evaluated from the extant literature to generate location-specific AER distributions categorized by influential factors, namely, location, temperature, and presence of A/C. The AER data obtained was limited in the number of samples, particularly when considering these influential factors. When categorizing by temperature, a range of temperatures was used to maintain a reasonable number of samples within each category to allow for some variability within the category, while still allowing for differences across categories. Several distribution forms were investigated (i.e., exponential, log-normal, normal, and Weibull) and in general, lognormal distributions provided the best fit. Fitted lognormal distributions were defined by a geometric mean (GM) and standard deviation

(GSD). Because no fitted distribution was available specifically for St. Louis or Greene County, distributions were selected from other locations thought to have similar characteristics, qualitatively considering factors that might influence AERs including the age composition of housing stock, construction methods, and other meteorological variables not explicitly treated in the analysis, such as humidity and wind speed patterns. To avoid unusually extreme simulated AER values, bounds of 0.1 and 10 were selected for minimum and maximum AER, respectively. Table 8-9 summarizes the distributions used by A/C prevalence and temperature categories. See Appendix B, Attachment 5 for additional details.

Table 8-9. Geometric means (GM) and standard deviations (GSD) for air exchange rates by A/C type and temperature range.

A/C Type[1]	Temp (ºC)	N	GM	GSD
Central or Room A/C	<=10	179	0.9185	1.8589
	10-20	338	0.5636	1.9396
	20-25	253	0.4676	2.2011
	25-30	219	0.4235	2.0373
	>30	24	0.5667	1.9447
No A/C	<=10	61	0.9258	2.0836
	10-20	87	0.7333	2.3299
	>20	44	1.3782	2.2757

Notes:
[1] All distributions derived from data reported in non-California cities. See Appendix B, Attachment 5 for details in the data used and distribution derivation.

SO_2 Removal Rate

Staff estimated distributions of indoor SO_2 deposition rates by applying a Monte Carlo sampling approach to configurations of indoor microenvironments of interest. The relative composition of particular surface materials (e.g., painted wall board, wall paper, wool carpet, synthetic carpet, synthetic floor covering, cloth) within various sized buildings were probabilistically modeled to estimate 1,000 SO_2 deposition rates that in turn were used to parameterize lognormal distributions (Table 8-10). The modeling was fundamentally based on a review of SO_2 deposition conducted by Grontoft and Raychaudhuri (2004) for a variety of building material surfaces under differing conditions of relative humidity. Details on the data used and derivation of removal rates are provided in Appendix B, section 4.

Table 8-10. Final parameter estimates of SO_2 deposition distributions in several indoor microenvironments modeled in APEX.

Microenv-ironment	Heating or Air Conditioning in Use				Air Conditioning Not in Use (Summertime Ambient Morning Relative Humidity of 90%)			
	Geom. Mean (hr^{-1})	Geom. Stand. Dev. (hr^{-1})	Lower Limit (hr^{-1})	Upper Limit (hr^{-1})	Geom. Mean (hr^{-1})	Geom. Stand. Dev. (hr^{-1})	Lower Limit (hr^{-1})	Upper Limit (hr^{-1})
Residence	3.14	1.11	2.20	5.34	13.41	1.11	10.31	26.96
Office	3.99	1.04	3.63	4.37	N/A	N/A	N/A	N/A
School/ Day Care Center	4.02	1.02	3.90	4.21	N/A	N/A	N/A	N/A
Restaurant	2.36	1.28	1.64	4.17	N/A	N/A	N/A	N/A
Other Indoors	2.82	1.21	1.71	4.12	N/A	N/A	N/A	N/A
Notes: N/A not applicable, assumed by staff to always have A/C in operation.								

8.7.3.2 Microenvironments 2-7: All Other Indoor Microenvironments

The remaining five indoor microenvironments, which represent Bars and Restaurants, Schools, Day Care Centers, Office, Shopping, and the broadly defined Other Indoor microenvironments, were all modeled using the same data and functions. An air exchange rate distribution (GM = 1.109, GSD = 3.015, Min = 0.07, Max = 13.8) was based on an indoor air quality study (Persily et al, 2005). This is the same distribution in APEX used for the most recent O_3 NAAQS review (EPA, 2007d). See Appendix B, Attachment 5 for details in the data used and derivation. The SO_2 removal rates were estimated as explained in section 8.7.3.1, and described in more detail in Appendix B, section 4. The resulting lognormal distributions are presented in Table 8-10. These microevironments all assumed to all have air-conditioning.

8.7.3.3 Microenvironments 8-10: Outdoor Microenvironments

All outdoor microenvironmental concentrations are well represented by the modeled concentrations. Therefore, both the penetration factor and proximity factor for this microenvironment were set to 1.

8.7.3.4 Microenvironments 11 and 12: In Vehicle- Cars and Trucks, and Mass Transit

There were no available measurement data for SO_2 penetration factors, therefore the penetration factors used were developed from NO_2 data provided in Chan and Chung (2003) and used in the recent NO_x NAAQS review (EPA, 2008d). Inside-vehicle and outdoor NO_2 concentrations were measured with for three ventilation conditions, air-recirculation, fresh air intake, and with windows. Mean values range from about 0.6 to just over 1.0, with higher values associated with increased ventilation (i.e., window open). A uniform distribution U{0.6, 1.0} was selected for the penetration factor for Inside-Cars/Trucks due to the limited data available to describe a more formal distribution and the lack of data available to reasonably assign potentially influential characteristics such as use of vehicle ventilation systems for each location. Mass transit systems, due to the frequent opening and closing of doors, was assigned a uniform distribution U{0.8, 1.0} based on the reported mean values for fresh-air intake (0.796) and open windows (1.032) on urban streets.

8.8 EXPOSURE MEASURES AND HEALTH RISK CHARACTERIZATION

APEX calculates exposure as a time-series of exposure concentrations that a simulated individual experiences during the simulation period. APEX calculates exposure by identifying concentrations in the microenvironments visited by the person according to the composite diary. In this manner, a time-series of event exposures are found. Then, the time-step exposure concentration at any clock hour during the simulation period is calculated using the following equation:

$$C_i = \frac{\sum_{j=1}^{N} C_{time-step\,(j)}\, t_{(j)}}{T} \qquad \text{equation (8-2)}$$

where,

C_i = Time-step exposure concentration at clock hour *i* of the simulation period (ppm)

N = Number of events (i.e., microenvironments visited) in time-step *i* of the simulation period.

$C_{time-step(j)}$ = Time-step concentration in microenvironment *j* (ppm)

$t_{(j)}$ = Time spent in microenvironment *j* (minutes)

T = Length of time-step (or 5 minutes in this analysis)

From the time-step exposures, APEX calculates time-series of 5-minute, 1-hour, 24-hour, and annual average exposure concentrations that a simulated individual would experience during the simulation period. APEX then statistically summarizes and tabulates the 5-minute time-step (or daily, or annual average) exposures. From this, APEX can calculate two general types of exposure estimates: counts of the estimated number of people whose exposure exceeded a specified SO_2 concentration level 1 or more times in a year and the number of times per year that they are so exposed; the latter metric is in terms of person-occurrences or person-days. The former highlights the number of individuals whose exposure exceeded at least *one or more* times per modeling period the health effect benchmark level of interest. APEX can also report counts of individuals with multiple exposures. This person-occurrences measure estimates the number of times per season that individuals are exposed to the exposure indicator of interest and then accumulates these estimates for the entire population residing in an area.

In this exposure assessment, APEX tabulates and displays the two measures for exposures above levels ranging from 0 to 800 ppb by 50 ppb increments for all exposures. These results are tabulated for the population and subpopulations of interest.

8.8.1 Adjustment for Just Meeting the Current and Alternative Standards

We used a different approach to simulate just meeting the current and alternative standards than was used in the Air Quality Characterization (see section 7.2.4). In this case, instead of adjusting upward[47] the air quality concentrations, to reduce computer processing time, we adjusted the health effect benchmark levels by the same factors described for each specific modeling domain and simulated year (Table 8-11). Since it is a proportional adjustment, the end effect of adjusting concentrations upwards versus adjusting benchmark levels downward within the model is the same. The same follows for where as is concentrations were in excess of an alternative standard level (e.g., 50 ppb for the 99th percentile averaged over three years), only the associated benchmarks are adjusted upwards (i.e., a higher threshold concentration that would simulate lower exposures).

---

[47] To evaluate the current and most of the alternative standards proposed, ambient concentrations were lower than air quality that would just meet the standards.

Table 8-11. Exposure concentrations and adjusted potential health effect benchmark levels used by APEX to simulate just meeting the current and potential alternative standards in the Greene County and St Louis modeling domains.

Modeling Domain	Form[1]	Level[2]	Exposure Concentrations and Adjusted Potential Health Effect Benchmark Levels (ppb)[3]

Notes:

[1] The form of the standard used to adjust the air quality. 98 is the 98th percentile 1-hour daily maximum alternative standard, 99 is the 99th percentile 1-hour daily maximum alternative standard, CS is either the current annual average or 24-hour NAAQS (whichever had the lowest factor), AS IS is unadjusted air quality.

[2] The level of the potential alternative standards, i.e., the 1-hour daily maximum at the noted percentile of the distribution.

[3] Exposure levels were defined in 50 ppb increments from 0 through 800 ppb even though the selected potential health effect benchmark levels were 100 to 400 ppb in 100 ppb increments.

8.9 EXPOSURE MODELING AND HEALTH RISK CHARACTERIZATION RESULTS

Exposure results are presented for simulated asthmatic populations residing in the two modeling domains in Missouri. Five-minute daily maximum SO_2 exposures were estimated for each day for year 2002. These short-term exposures were evaluated for all asthmatics and asthmatic children when the exposure corresponded with moderate or greater activity levels. The number of daily maximum 5-minute SO_2 exposures that were at or above any level from 0 through 800 ppb in 50 ppb increments was estimated by APEX. Therefore, depending on the concentration level, an individual would have at most one exceedance of a particular level per day, or 365 per year, provided that the person was at a moderate (or higher) exertion level while exposed.

Multiple air quality scenarios were evaluated, including unadjusted air quality (termed as is), air quality adjusted to just meet the current NAAQS, and air quality adjusted to just meet several potential alternative 1-hr daily maximum standards. Exposure results are presented in a series of figures that allow for simultaneous comparison of exposures associated with each air quality scenario. Four types of results are provided for each modeling domain: (1) the number of persons in the simulated subpopulation exposed at or above selected levels 1 or more times in a year, (2) the percent of the simulated subpopulation exposed at or above selected levels 1 or more times in a year, (3) the total number of days in a year the simulated subpopulation is exposed (or person days) at or above selected levels, and (4) the percent of time associated with the exposures at or above the selected levels. Tables summarizing all of the exposure results for each modeling domain, air quality scenario, exposure level, and subpopulation are provided in Appendix B, section 4.

8.9.1 Asthmatic Exposures to 5-minute Daily Maximum SO_2 in Greene County

When considering the lowest 5-minute benchmark level of 100 ppb, approximately one thousand asthmatics are estimated to be exposed at least once in the year 2002 while at moderate or greater exertion and when considering the current standard air quality scenario (top of Figure 8-13). Each of the potential alternative 1-hr standard air quality scenarios as well as the as is air quality scenario result in fewer asthmatics exposed when compared with the current standard scenario, and progressively fewer persons were exposed with decreases in the 1-hour daily maximum concentration levels of the potential alternative standards. The 99th percentile 1-hour daily maximum standard levels of 50 and 100 ppb produced the same number of persons with 5-minute daily maximum exposures at or above 100 ppb as the as is air quality (i.e., 13). With progressive increases in exposure level, there were corresponding decreases in the number of individuals exposed. None of the asthmatics had a 5-minute daily maximum exposure above 100 ppb when considering the as is air quality scenario. Asthmatic children exhibited similar patterns in the estimated number of exposures at each of the exposure levels, though comprising a large proportion of the total asthmatics exposed (bottom of Figure 8-13).

The difference between all asthmatics and asthmatic children is best demonstrated by comparing the percent of the subpopulation exposed. Asthmatic children have nearly double the percentage of the subpopulation exposed at any of the benchmark levels considered when compared with that of all asthmatics (Figure 8-14). For example, approximately 1% of asthmatic children experience at least one 5-minute daily maximum exposure at or above 200 ppb in a year in considering the current standard scenario, while approximately 0.6% of all asthmatics experienced a similar exposure. As observed with the numbers of persons exposed, a lower estimated percent of persons was exposed at the higher benchmark levels, though again, the current standard scenario contains the greatest percent of asthmatics exposed when compared with the other air quality scenarios.

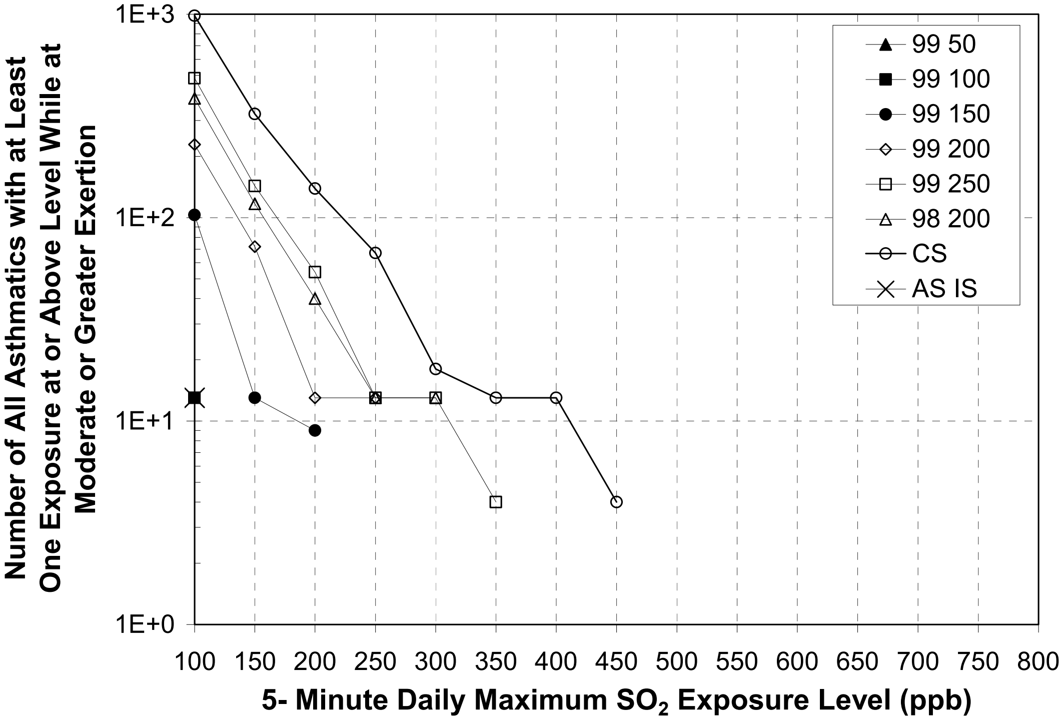
The number of person days or occurrences of exposures is greater than the number of persons exposed, indicating that some of the simulated asthmatics had more than one 5-minute daily maximum exposure above selected benchmark levels (Figure 8-15). For example, when considering all asthmatics and the current standard scenario, there were approximately 22 person days with exposures at or above 300 ppb. This corresponds with the 18 asthmatics estimated to experience at least one 5-minute daily maximum SO_2 concentration above this level, indicating that a number of persons had experienced at least 2 benchmark exceedances in the year. For both subpopulations considered, there were no estimated exposures above 300 ppb when considering the 99th percentile 1-hour daily maximum alternative standard level of 200 ppb.

Staff evaluated the microenvironments where the peak exposures frequently occurred. There were very few persons exposed considering the as is air quality, though 99% or greater experienced their 5-minute daily maximum exposure in an outdoor microenvironment (i.e., outdoors or outdoors near-roads) when considering any of the benchmark levels. For the current standard air quality scenario, approximately 7% of persons were exposed to the 100 ppb benchmark level indoors (i.e., primarily in the persons residence), though with increasing benchmark level (e.g., 300 ppb) the percent of persons with any benchmark exceedances indoors approached zero (i.e., > 99% occurred outdoors). The inside vehicle microenvironment also comprised a small percent of the cases where the exposures above selected levels occurred; at most 2% of benchmark exceedances occurred inside vehicles at some of the lowest benchmark levels.

8.9.2 Asthmatic Exposures to 5-minute Daily Maximum SO_2 in St. Louis

The patterns in the number of persons (either asthmatics or asthmatic children) exposed in St. Louis were different to that observed in Greene County; a greater number of persons were estimated exposed in St. Louis at each of the corresponding benchmark levels and air quality scenarios (Figure 8-16). For example, nearly 80,000 asthmatics were estimated to experience at least one 5-minute daily maximum SO_2 concentration at or above 100 ppb when considering the current standard scenario compared to the one thousand asthmatics estimated in Greene County (section 8.9.1). In addition, there were more persons exposed to the higher benchmark levels in St. Louis compared with Greene County. For example, none of the asthmatics were exposed to a 5-minute daily maximum SO_2 concentration above 450 ppb in Greene County considering any of the air quality scenarios. In St. Louis many of the air quality scenarios had persons with exceedances of 450 ppb; the estimated number of persons experiencing at least one 5-minute daily maximum SO_2 concentration above 450 ppb ranged from a low of 16 (the 99th percentile 1-hour daily maximum standard level of 100 ppb) to over 10,000 (the current standard air quality scenario). Note though, in considering the as is air quality scenario, none of the asthmatics in St. Louis had exceedances of a 450 ppb exposure level.

There were also differences in the estimated percent of asthmatics and asthmatic children exposed to concentrations above the benchmark levels in St. Louis when compared with Greene County. For example, over 40% of asthmatic children were estimated to experience a 5-minute daily maximum exposure above 300 ppb in St. Louis considering the current standard air quality scenario, while less than 1% of asthmatic children in Greene County experienced a similar exposure (Figure 8-17). Just as observed with the Greene County estimates though, there were



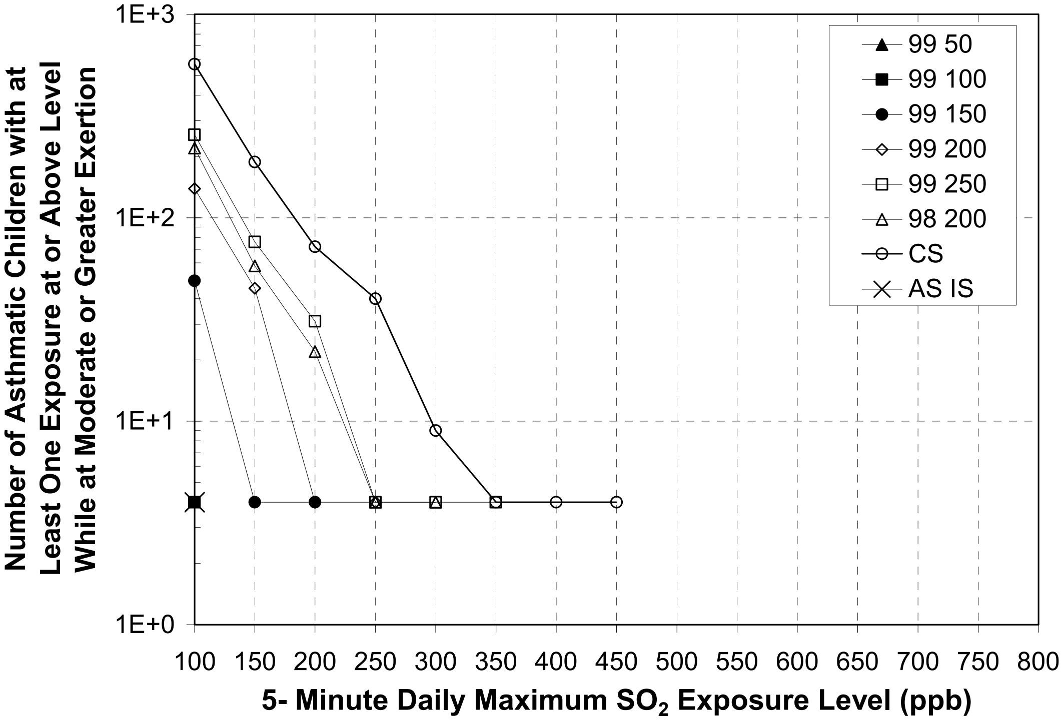


Figure 8-13. Number of all asthmatics (top) and asthmatic children (bottom) with 5-minute daily maximum SO$_2$ exposures above selected exposure levels in Greene County, year 2002 air quality as is and adjusted to just meeting the current and potential alternative standards.

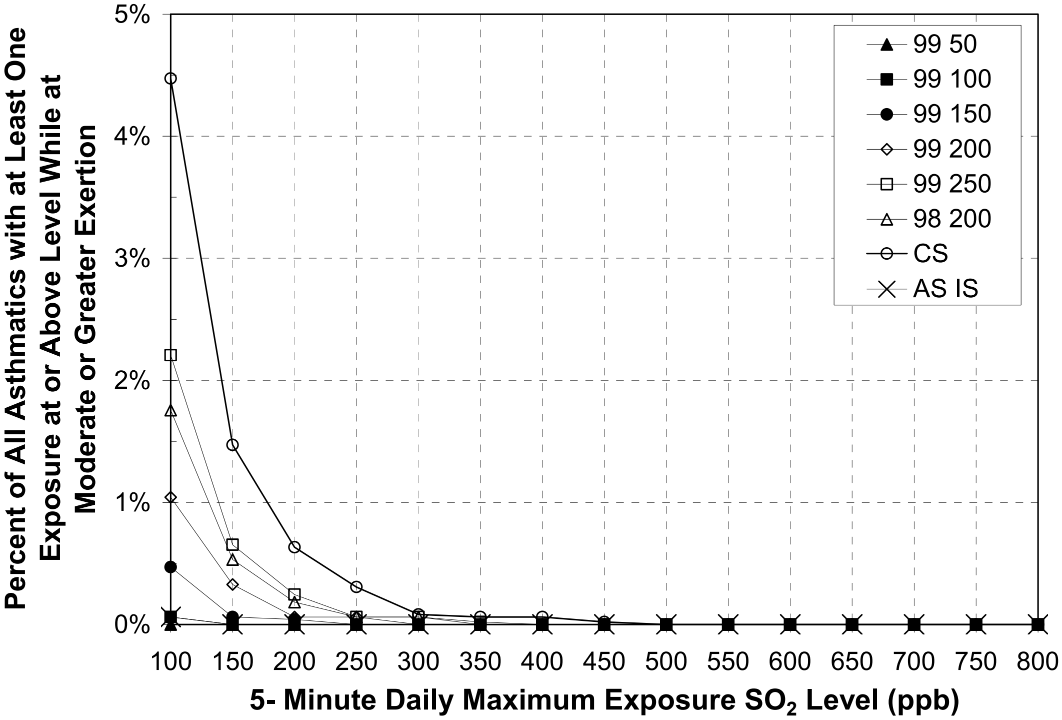

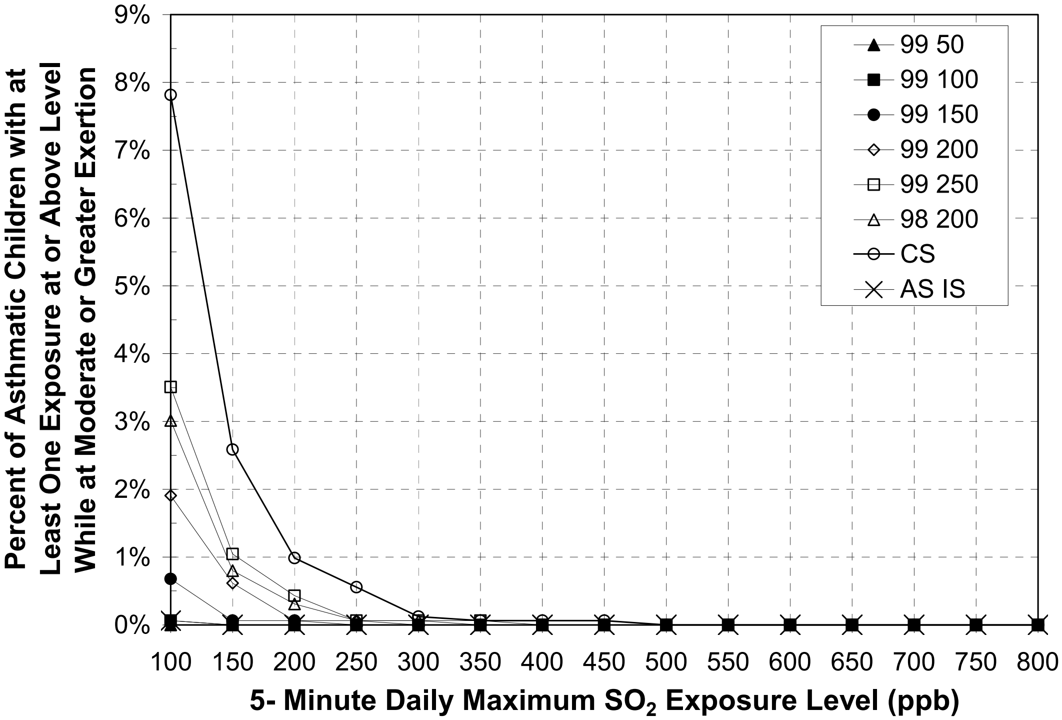

Figure 8-14. Percent of all asthmatics (top) and asthmatic children (bottom) with 5-minute daily maximum SO_2 exposures above selected exposure levels in Greene County, year 2002 air quality as is and adjusted to just meeting the current and potential alternative standards.

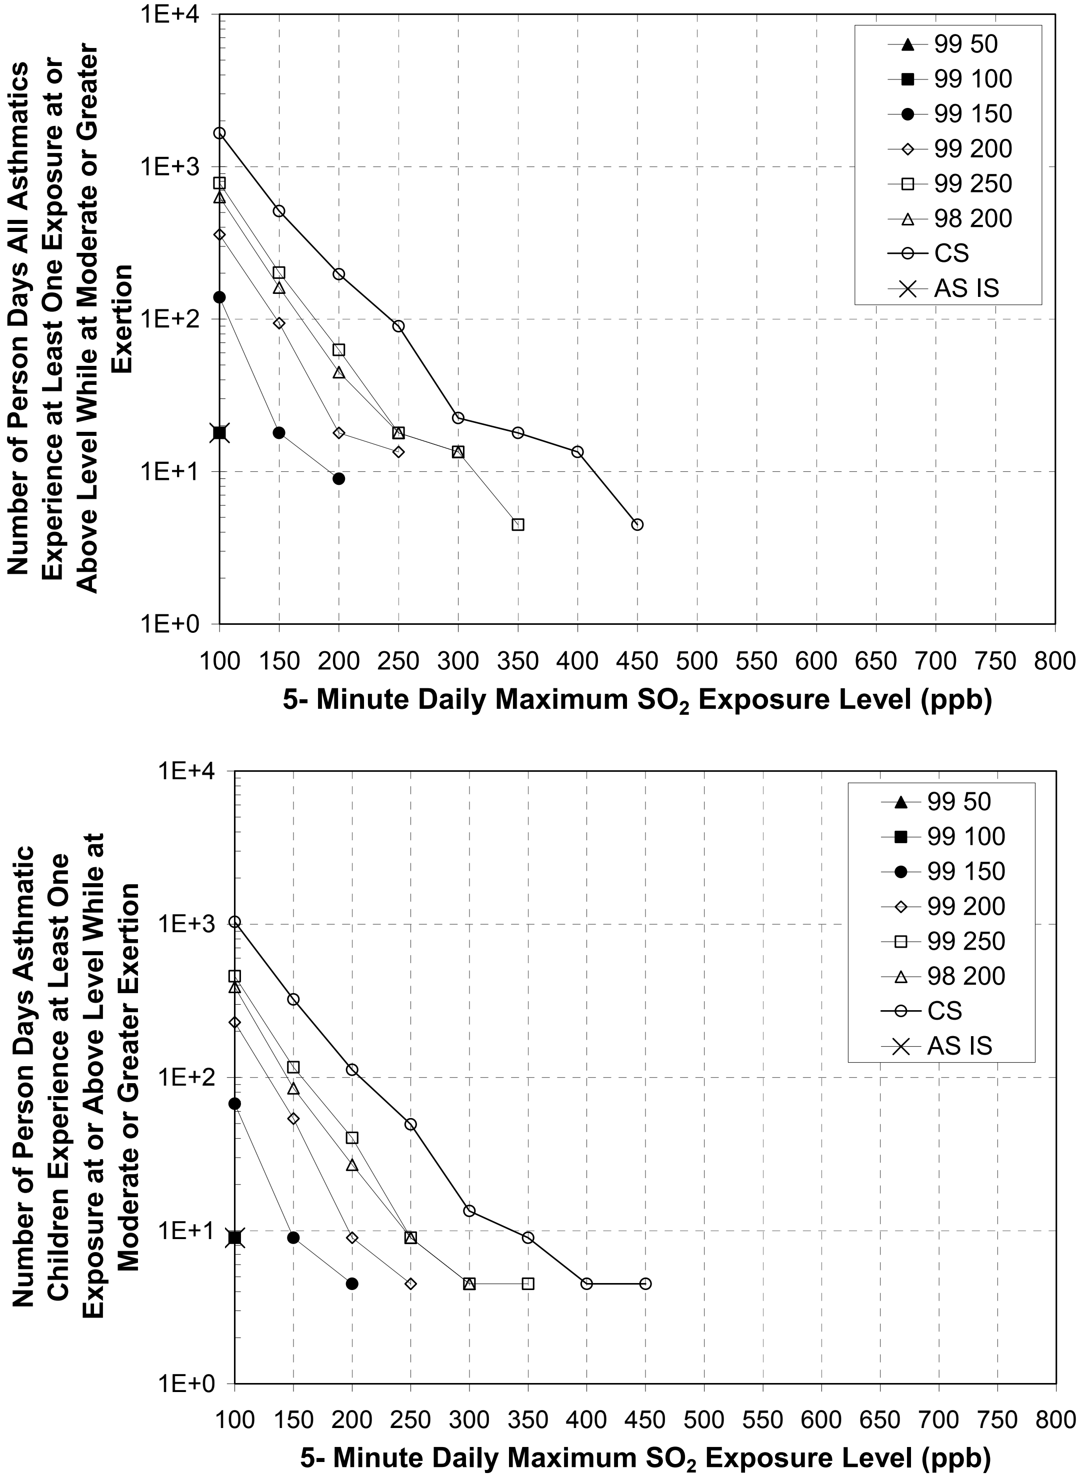

Figure 8-15. Number person days all asthmatics (top) and asthmatic children (bottom) experience 5-minute daily maximum SO_2 exposures above selected exposure levels in Greene County, year 2002 air quality as is and adjusted to just meeting the current and potential alternative standards.

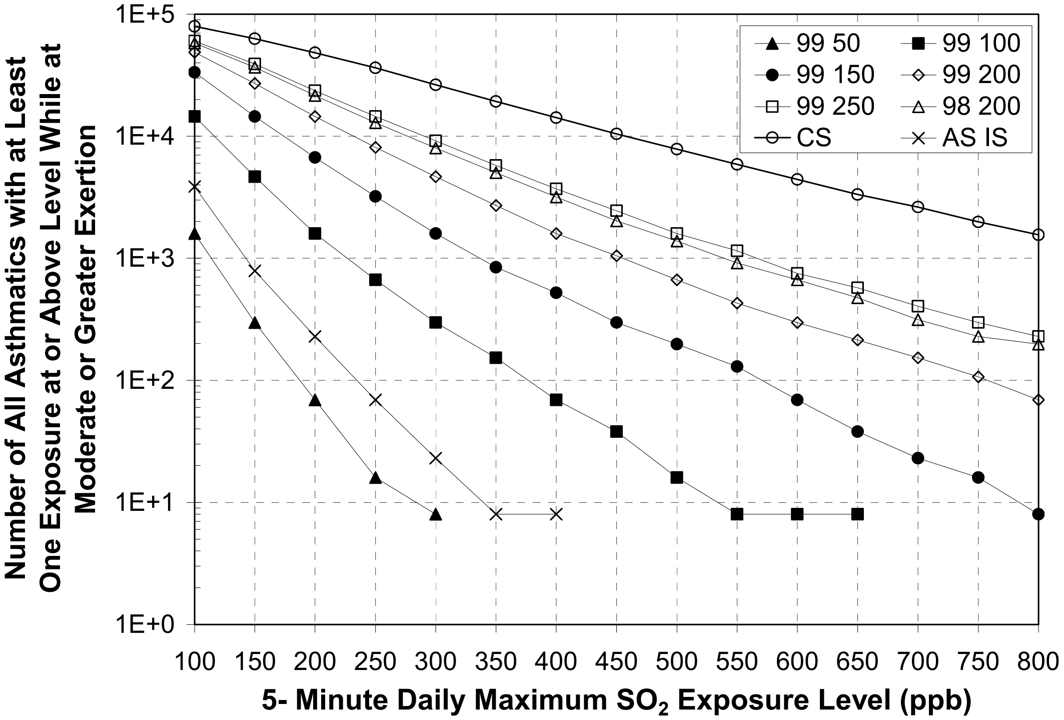
decreases in the percent of persons exposed with decreases in the 1-hour daily maximum level of the potential alternative standards. For example, less than 3% of asthmatic children were estimated to have at least one 5-minute daily maximum exposure above 300 ppb when considering a 99th percentile 1-hour daily maximum standard level of 150 ppb.

The discussion regarding the patterns observed in the number of persons exposed in St. Louis can be extended to the number of person days (i.e., both a greater number and at higher benchmark levels when compared with Greene County). In addition, St. Louis had a greater number of persons with multiple exceedances when compared with Greene County (Figure 8-18). For example, given the 22 person days at or above 300 ppb in Greene County experienced by the 18 asthmatics considering the current standard air quality, on average this amounts to approximately 1.2 exposures per year. In contrast, approximately 26,000 asthmatics had nearly 50,000 person days at the same benchmark level and air quality scenario in St. Louis; on average each person is estimated to experience 1.9 exceedances in a year.

Staff also evaluated the microenvironments where the peak exposures occurred in St. Louis, and again, there were differences when compared with the exposures in Greene County. In St. Louis, there were a greater percentage of benchmark exceedances within indoor and inside vehicle microenvironments, although overall still comprising a small percentage of where the exceedances were occurring. At the 100 ppb benchmark level, approximately 10% of the exposures occur within indoor microenvironments (i.e., principally inside residences) and about 5% occur inside vehicles considering as is air quality (Figure 8-19). The percentage increases when considering air quality adjusted to just meeting the current standard, with approximately 30% of benchmark exceedances of 100 ppb occurring indoors and 20% occurring inside vehicles. Just beyond the benchmark level of 400 ppb, nearly all of the exceedances occur outdoors when considering the as is air quality, while indoor microenvironments still contribute to around 10% of exceedances up to a 5-minute daily maximum exposure level of 800 ppb. For comparison, air quality adjusted to just meet a 99th percentile 1-hour daily maximum standard level of 150 ppb is also shown, and falls within the range of values provided by the as is and current standard scenarios.



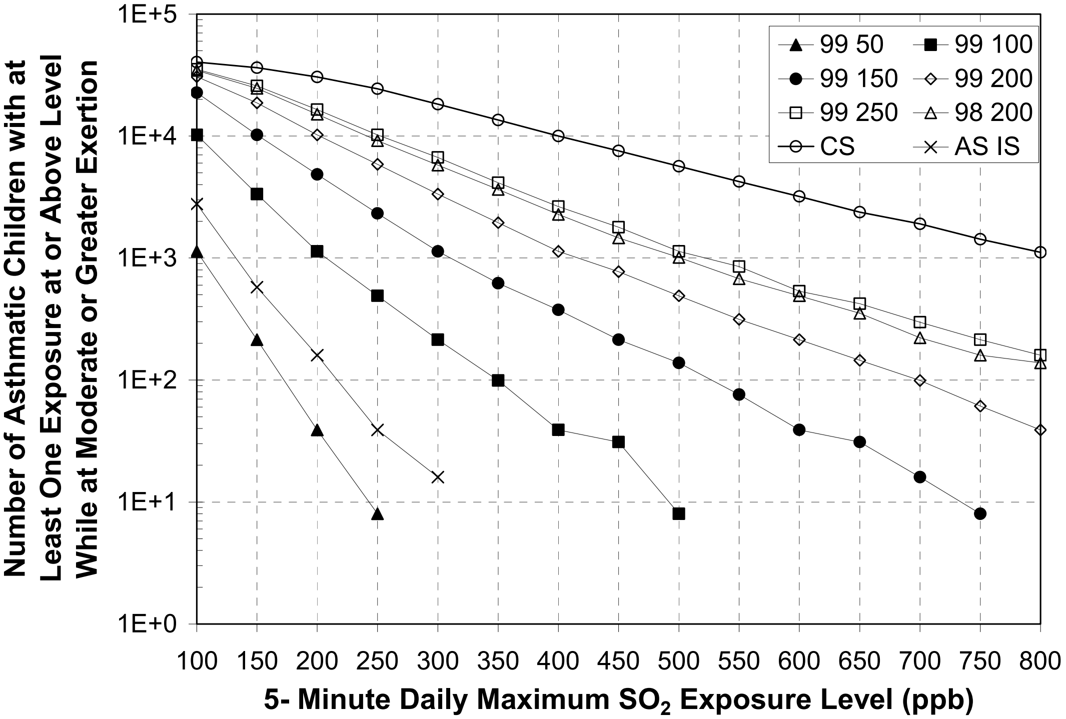


Figure 8-16. Number of all asthmatics (top) and asthmatic children (bottom) with 5-minute daily maximum SO$_2$ exposures above selected exposure levels in St. Louis, year 2002 air quality as is and adjusted to just meeting the current and potential alternative standards.

8.10 REPRESENTATIVENESS OF EXPOSURE RESULTS

8.10.1 Introduction

Due to time and resource constraints the exposure assessment evaluating the current and alternative standards was only applied to the two locations in Missouri. A natural question is how representative are the estimates from this assessment of exposures in Greene County and St. Louis to other areas in the United States with elevated peak SO_2 concentrations. To address this question, additional data were compiled and analyzed to provide perspective on how representative the exposure modeling results might be for other areas. Because most estimated exceedances were associated with the outdoor microenvironments, this analysis and discussion is centered on time spent outdoors to allow for comparison of the two modeling domains with several other broad regions. In addition, the distribution of asthma prevalence rates in the U.S. is also discussed.

8.10.2 Time spent outdoors

The time spent outdoors by children age 5-17 was calculated from CHAD-Master[48] for five regions of the country. The U.S. states used in the air quality characterization (Chapter 7) were of interest, which already includes Missouri (representing the two exposure modeling domains). Staff analyzed the outdoor time by broad geographic regions because it was thought that the regional climate would have influence on each population. In addition, most of the location descriptors are already broadly defined to protect the identity of persons in CHAD; finer spatial scale such as at a city-level is uncommon. Table 8-12 has the States used to identify CHAD diaries available to populate a data set for each of the five regions. Staff further separated the diaries by time-of-year (school year versus summer)[49] and the day-of-week (weekdays versus weekends), both important factors influencing time spent outdoors (Graham and McCurdy, 2004). Summer days were not separated by day of week; staff assumed that the variation in outdoor time during the summer would not be greatly influenced by this factor for children. The results for time spent outdoors in each region are given in the attached Table 8-13.

---

[48] Currently available through EPA at mccurdy.tom@epa.gov.

49 A traditional school year was considered (months of September-May); summer months included June-August.

Table 8-12. States used to define five regions of the U.S. and characterize CHAD data diaries.

Region	States
Mid-Atlantic (MA)	New York, New Jersey, Delaware, Maryland, District of Columbia, Virginia, West Virginia, Pennsylvania
Midwest (MW)	Ohio, Iowa, Missouri, Illinois, Indiana, Kentucky
Northeast (NE)	Maine, New Hampshire, Vermont, Massachusetts, Connecticut, Rhode Island
Southeast (SE)	North Carolina, South Carolina, Georgia, Florida, Tennessee, Alabama, Mississippi, Arkansas, Louisiana
Southwest (SW)	Nevada, Utah, Colorado, Arizona, New Mexico, Texas, Oklahoma

Participation rates for the selected time of year and day of week groupings were similar for each of the regions. In general, a smaller percent of children spend time outdoors during the school year (about 45-50%) compared to the summer (about 70-77%). There was no apparent pattern in the day-of week participation rates considering the school year days. However, children did spend more time outdoors on weekend days compared to weekdays at all percentiles of the distribution and within all regions. In addition, children consistently spent more time outdoors during summer days within all regions. There were few differences in outdoor time when comparing each of the regions. Children in Northeastern States had the widest range in the distributions for time spent outdoors. In this region of the U.S., children spent the least amount of time outdoors during the school-year days-of-the-week and the greatest amount of time outdoors on average during the summer. Based on this analysis, it is not expected that the results generated for the two Missouri modeling domains would be largely different from results generated in most areas of the U.S. when considering time spent outdoors, though there may be differences in exposures estimated in Northeastern states. [50] Depending on when the peak exposure events occur in the year, the exposures estimated in these states may be lower or higher.

---

[50] Note however that all of the Northeastern data have the fewest number of person days available, in particular the summer days (n=23).

Table 8-13. Time spent outdoors for children ages 5-17 using CHAD diaries.

Region	Time of Year	Day of Week	Doers[1]		Time Spent Outdoors (minutes)							
			(n)	(%)	Mean	SD	Min	Med	P95	Max	GM	GSD
MA	school	weekdays	400	45	113	97	1	90	301	700	73	3.0

		weekends	593	52	157	126	1	123	404	810	112	2.5
	summer	all	244	70	185	147	5	150	480	935	135	2.4
SW	school	weekdays	253	46	119	106	1	90	315	650	80	2.8
		weekends	232	50	162	142	7	120	405	1390	116	2.4
	summer	all	273	76	187	137	2	150	450	840	136	2.5

Notes:

[1] Doers are those engaged in the particular activity, in this case those children that had at least 1 minute of outdoor time recorded in their CHAD time-location-activity diary. The participation rate (%) was estimated by the total number of persons in each subgroup (not included). The *n* indicates the person-days of diaries used to calculate the outdoor time statistics.

8.10.3 Asthma Prevalence

Staff compared regional asthma prevalence statistics for children <18 years in age and all persons. For children, the estimated age-adjusted percents of ever having asthma are presented in Table 8-13 using data from Dey et al. (2004). There are similar prevalence rates for asthmatic children in three of the four regions of the U.S. (Midwest, South, and West), suggesting that exposure analyses conducted in these broader regions may result in similar distributions in the percent of asthmatics exposed to the two Missouri modeling domains used in this assessment. The Northeastern U.S. has a higher percentage of asthmatic children. This suggests that there may be a greater percentage of peak exposures to asthmatic children in the Northeast than compared with the percent modeled in St. Louis or Greene County, holding all other influential variables are constant (e.g., time spent outdoors, a similar air quality distribution).

Staff weighted the BRFSS 2002 state-level adult asthma prevalence rates (self-reported) to generate prevalence rates for five U.S regions (Table 8-15).[51] Similar rates (between 7.6-

---

[51] http://www.cdc.gov/asthma/brfss/02/current/tableC1.htm. Regions were mapped using Table 8-12.

7.9%) were estimated for three of the five regions (Mid-Atlantic, Midwest, and the Southwest), suggesting that exposure analyses conducted in these broader regions may result in similar distributions in the percent of asthmatics exposed to the two Missouri modeling domains used in this assessment. Consistent with that observed for asthmatic children, the Northeastern U.S. has the greatest percent of asthmatic adults. The Southeastern states on average were estimated to have the lowest adult asthma prevalence. This suggests that there may be a greater percentage of peak exposures to asthmatic adults in the Northeast and a lower percentage of peak exposures in the Southeast when compared with the percent modeled in St. Louis or Greene County, holding all other influential variables are constant (e.g., time spent outdoors, a similar air quality distribution).

Table 8-14. Asthma prevalence rates for children in four regions of the U.S.

Region	Asthma Prevalence[1] (%)
Northeast	15.2
Midwest	11.6
South	11.9
West	11.1

Notes:
[1] prevalence is based on the question, "Has a doctor or other health professional ever told you that [child's name] had asthma?'" (Dey et al., 2004)

Table 8-15. Asthma prevalence rates for adults in five regions of the U.S.

Region[1]	Asthma Prevalence[2] (%)
Mid-Atlantic	7.9
Midwest	7.7
Northeast	8.9
Southeast	6.9
Southwest	7.6

Notes:
[1] Table 8-12 was used in mapping the states to regions.

8.11 UNCERTAINTY ANALYSIS

The methods and the model used in this exposure assessment conform to the most contemporary modeling methodologies available. APEX is a powerful and flexible model that allows for the realistic estimation of air pollutant exposure to individuals. Since it is based on human time-location-activity diaries and accounts for the most important variables known to affect exposure (where people are located and what they are doing), it has the ability to effectively approximate actual exposure conditions. In addition, the input data selected were the best available data to generate the exposure results. However, there are constraints and uncertainties with the modeling approaches and the input data that limit the realism and accuracy of the modeling results.

Uncertainties and assumptions associated with SO_2 specific model inputs, their utilization, and application are discussed in the following sections. Analyses for certain components of APEX performed previously in other NAAQS reviews (see EPA, 2007d; Langstaff, 2007) that are relevant to the SO_2 NAAQS review are only summarized below. This includes a sensitivity analyses performed on the CHAD data base using O_3 exposures and an analysis of the air exchange rate data.

Following the same general approach described in section 7.8 and adapted from WHO (2008), a qualitative analysis of the components contributing to uncertainty in the exposure results was performed. This includes an identification of the important uncertainties, an indication of the potential bias direction, and a scaling of the uncertainty using *low*, *medium*, and *high* categories. Even though uncertainties in AERMOD concentrations predictions are an APEX input uncertainty, they are addressed separately here for clarity. Table 8-16 summarizes the results of the qualitative uncertainty analysis conducted by staff for the SO_2 exposure assessment.

Table 8-16. Summary of qualitative uncertainty analysis for the exposure assessment.

Source	Type	Concentration/ Exceedance Bias Direction	Characterization of Uncertainty
AERMOD Inputs and Algorithms	Algorithms	unknown	Low
	Meteorological data	unknown	Low – Medium
	Area source emission profiles, temporal and spatial	both	Medium
APEX Inputs and Algorithms	Population data base	both	Low
	Commuting data base	both	Low - Medium
	CHAD data base	both	Low - High
	Longitudinal profile	both	Low
	Meteorological data	both	Low
	Air exchange rates	unknown	Medium
	A/C prevalence	none	Low
	Indoor decay distribution	unknown	Low
	Multiple peaks	under	Low - Medium
	Asthma prevalence rate	unknown	Low

8.11.1 Dispersion Modeling Uncertainties

Air quality data used in the exposure modeling was determined through use of EPA's recommended regulatory air dispersion model, AERMOD (version 07026 (EPA, 2004)), with meteorological data and emissions data discussed above. Parameterization of meteorology and emissions in the model were made in as accurate a manner as possible to ensure best representation of air quality for exposure modeling. Thus, the resulting air quality values are likely free of systematic errors to the best approximation available through application of modeled data.

An analysis of uncertainty associated with application of a model is generally broken down into two main categories of uncertainty: 1) model algorithms, and 2) model inputs. While it is convenient to discuss uncertainties in this context, it is also important to recognize that there is some interdependence between the two in the sense that an increase in the complexity of model algorithms may entail an increase in the potential uncertainty associated with model inputs.

8.11.1.1 AERMOD Algorithms

The AERMOD model was promulgated by in 2006 as a “refined” dispersion model for near-field applications (with plume transport distances nominally up to 50 kilometers), based on a demonstration that the model produces largely unbiased estimates of ambient concentrations across a range of source characteristics, as well as a wide range of meteorological conditions and topographic settings (Perry, *et al.*, 2005; EPA, 2003). While a majority of the 17 field study databases used in evaluating the performance of AERMOD are associated with elevated plumes from stationary sources (typically power plants), a number of evaluations included low-level releases. Moreover, the range of dispersion conditions represented by these evaluation studies provides some confidence that the fundamental dispersion formulations within the model will provide robust performance in other settings.

AERMOD is a steady-state, straight-line plume model, which implies limitations on the model’s ability to simulate certain aspects of plume dispersion. For example, AERMOD treats each hour of simulation as independent, with no memory of plume impacts from one hour to the next. As a result, AERMOD may not adequately treat dispersion under conditions of atmospheric stagnation or recirculation when emissions may build up within a region over several hours. This could lead to a bias toward underprediction by AERMOD during such periods. On the other hand, AERMOD assumes that each plume may impact the entire domain for each hour, regardless of whether the actual transport time for a particular source-receptor combination exceeds an hour. While these assumptions imply some degree of physically unrealistic behavior when considering the impacts of an individual plume simulation, their importance in terms of overall uncertainty will vary depending upon the application. The degree of uncertainty attributable to these basic model assumptions is likely to be more significant for individual plume simulations than for a cumulative analysis based on a large inventory. This question deserves further investigation to better define the limits and capabilities of a modeling system such as AERMOD for large scale exposure assessments such as this. The evidence provided by the model-to-monitor comparisons presented in section 8.4.5 is encouraging as to the viability of the approach in this application when adequate meteorological and other inputs are available. However, each modeling domain and inventory will present its own challenges and will require a separate assessment based on the specifics of the application.

One of the improvements in the AERMOD model formulations relative to the ISCST model which it replaced is a more refined treatment of enhanced turbulence and other boundary layer processes associated with the nighttime heat island influence in urban areas. The magnitude of the urban influence in AERMOD is scaled based on the urban population specified by the user. Since the sensitivity of AERMOD model concentrations to the user-specified population is roughly proportional to population to the 1/4th power, this is not a significant source of uncertainty. The population areas of interest for this application are also well-defined, reducing any uncertainty associated with specification of population or with defining the extent of the modeling domain to be treated as urban.

While the AERMOD model algorithms are not considered to be a significant source of uncertainty for this assessment, the representativeness of modeled concentrations for any application are strongly dependent on the quality and representativeness of the model inputs. The main categories of model inputs that may contribute to bias and uncertainty are emission estimates and meteorological data. These issues are addressed in the following sections.

8.11.1.2 Meteorological Inputs

Details regarding the representativeness of the meteorological data inputs for AERMOD are addressed separately in section 8.4.2. One of the main issues associated with representativeness is the sensitivity of the AERMOD model to the surface roughness of the meteorological tower site used to process the meteorological data for use in AERMOD relative to the surface roughness across the full domain of sources. This issue has been shown to be more significant for low-level sources due to the importance of mechanical shear-stress induced turbulence on dispersion for such sources. A previous application of the AERMOD model to support the REA for the NO_2 NAAQS review (EPA, 2008d) provided an opportunity for a direct assessment of this issue by comparing AERMOD modeled concentrations based on processed meteorological data from the Atlanta Hartsfield airport (ATL) with concentrations based on processed meteorological data from a SEARCH monitoring station located on Jefferson Street (JST) near Georgia Tech. The ATL data were representative of an open exposure, low roughness, site typical for an airport meteorological station. The JST data were representative of a higher roughness exposure more typical of many locations within an urban area. Surface roughness lengths were generally about an order of magnitude higher at the JST site relative to the ATL site. A comparison of AERMOD modeled concentrations for the mobile source NO_x

inventory, representing near ground-level emissions, showed relatively good agreement in modeled concentrations based on the two sets of meteorological inputs, at least for the peak of the concentration distribution at four monitor locations across the modeling domain. This suggests that the sensitivity of AERMOD model results to variations in surface roughness may be less significant than commonly believed, provided that meteorological data inputs are processed with surface characteristics appropriate for the meteorological site.

8.11.1.3 Area source temporal and spatial emission profiles

Details regarding the modeling of non-point and background area sources in AERMOD are addressed in Section 8.4.3. In the case of SO2, the area source emissions category for AERMOD represents a cumulative approximation of several small point sources, such as small commercial/industrial boilers, which are too small to be represented as individual sources within the existing emissions inventories. Given the lack of detailed information regarding the location and release characteristics of these small emission sources, estimated emissions are typically aggregated at a county level within the emission inventories. Given these limitations in terms the emission inventory, two of the main uncertainties associated with modeling these sources are the temporal and spatial profiles used in simulating their releases. Lacking detailed location information, the emissions are assumed to be uniformly distributed across a specified area, typically at a county or census tract level since the emissions are aggregated at the county level and allocated spatially using population as one of the surrogates. An additional uncertainty associated with the area source category for SO_2 emissions is the likelihood that the actual emissions may be associated with buoyancy that cannot be explicitly treated the area source algorithm within the dispersion model. At best, the anticipated effect of plume buoyancy can be reflected on average through the release height assigned to the area source.

As discussed in Section 8.4.3, all emissions in the regions of interest were simulated, either through their representative group (point sources, port-related sources, or other non-point area sources) or through cumulative background sources. Staff obtained emission strengths from the 2002 National Emissions Inventory (NEI) however, only annual total emissions at the county level are provided. To better parameterize these emissions for the hourly, census block-level dispersion modeling conducted here, we relied on additional data and an algorithm to optimize model performance based on model-to-monitor comparisons.

Additional data on the spatial distribution of non-point emissions was used to allocate county-wide to census tract values for the Greene County domain. Staff used the spatial allocation factors (SAFs) from EPA's EMS-HAP database. Emissions within each modeled tract were simulated as uniform over the tract, while emissions outside the modeled tracts and other residual emissions were characterized as uniform over an entire county. The performance obtained by using tract-level sources in Greene County was verified by model-monitor comparisons. In the St. Louis area, model performance evaluations using factors from the EMS-HAP database made it apparent that some factors were mischaracterizing the allocations. Thus, in the St. Louis area, spatial bias was avoided by modeling emissions with a uniform density throughout each of the counties of interest. In both cases, using spatially uniform emissions resolved to the finest level the input data allows eliminates spatial bias and reduces overall uncertainty.

Unlike point sources, where the temporal profile was based largely on direct observations via the CAMD database, these non-point emission profiles are based on generalized emissions surrogates and may not well represent specific source or local group of sources. Model performance evaluations of diurnal profiles showed that temporal factors based on these models inadequately represented the true, aggregate, temporal release profile. Unlike spatial allocations, however, uniformly distributing the emissions in time resulted in significantly worse model performance than using these sample profiles. In order to account for these uncertainties in the temporal profiles of area source emissions, an algorithm was developed to determine the optimal temporal emission release profile in each area. Examination of the diurnal profiles of modeled and monitored concentrations with uniform and with EMS-HAP emission profiles for monitors in locations dominated by area sources showed that, while monitored concentrations increased during the daytime, modeled concentrations actually decreased. An examination of the dispersion characteristics showed that increased dilution during the daytime overcame the small increase in emission strength predicted using emissions models such as EMS-HAP that lack locally specific information. Thus, it is reasonable to conclude that emissions in the St. Louis and Greene County areas should show a more pronounced diurnal cycle than is reflected in the standardized temporal profiles.

To determine the most representative average non-point area source emission profile across each modeling domain, we first selected monitors where ambient concentrations were expected to be primarily influenced by area sources. Due to their locations relative to sources, all but one monitor (290770032) in Greene County indicated ambient concentrations were primarily influenced by point source emissions. In St. Louis, all seven ambient monitors (291890004, 291890006, 291893001, 291895001, 291897003, 295100007, and 295100086) indicated significant influence from area source emissions. Next, simulations were conducted with all sources modeled in detail – except area sources, which were modeled with uniform emission profiles. A weighting function was then determined based on the modeled error for each hour of the day at the one Greene County monitor and as an average of the errors at the seven individual St. Louis area monitors. In both cases, the error function was defined as the ratio of the total observed concentration, minus the total concentration due to all non-point sources, to the concentration predicted by the non-point sources alone. This diurnal error function was then normalized such that its average value is unity. Finally, a corrected non-point emission profile was determined by combining this normalized weighting function with the uniform emission profile.

This method of determining an appropriate, local, non-point source emission profile has the advantage of preserving total emissions reflected in the emission inventory while deducing what the actual temporal emission profile from these local sources should be, based on the observed trends in each region. Essentially, it derives an emission profile that best agrees with observations when coupled with local meteorology and dispersion. This is justified given the lack of detail regarding emission characteristics of local area sources. Because there is large uncertainty in the emission characteristics in the sources being modeled, this approach effectively mitigates the effect of that uncertainty on the modeling results by application of a systematic approach to minimize discrepancies between predicted and observed values.

8.11.2 Exposure Modeling Uncertainties

8.11.2.1 Population Data Base

The population and commuting data are drawn from U.S. Census data from the year 2000. This is a high quality data source for nationwide population data in the U.S. however, the data do have limitations. The Census used random sampling techniques instead of attempting to reach all households in the U.S., as it has in the past. While the sampling techniques are well established and trusted, they may introduce uncertainty to exposure results. The Census has a quality section (http://www.census.gov/quality/) that discusses these and other issues with

Census data. It is likely the bias within this data would not affect the results in any particular direction, and given the use of the sampled demographics to represent the simulated population, it is expected that the uncertainty in the exposure results from this source is low.

8.11.2.2 Commuting Data Base

Commuting pattern data were derived from the 2000 U.S. Census. The commuting data address only home-to-work travel. A few simplifying assumptions needed to be made to allow for practical use of this data base to reflect a simulated individual's commute. First, there were a few commuter identifications that necessitated a restriction of their movement from a home block to a work block. This is not to suggest that they never travelled on roads, only that their home and work blocks were the same. This includes the population not employed outside the home, individuals indicated as commuting within their home block, and individuals that commute over 120 km a day. This could lead to either over- or under-estimations in exposure if they were in fact to visit a block with either higher or lower SO_2 concentrations. Given that the number of individuals who meet these conditions is likely a small fraction of the total population and that the bias is likely in either direction, the overall uncertainty is considered low.

Second, although several of the APEX microenvironments account for time spent in travel, the travel is assumed to always occur in basically a composite of the home and work block. No other provision is made for the possibility of passing through other census blocks during travel. This could also contribute to bias in either direction, dependent on the number of blocks the simulated individual would actually traverse and the spatial variability of the concentration across different blocks. This could potentially affect a large portion of the population, since we expect that at the block level, many persons would have a commute transect that included more than two blocks, although the actual number of persons and the number of blocks per commute and the spatial variability across blocks has not been quantified. In addition, the commuting route (i.e., which roads individuals are traveling on during the commute) is not accounted for. This may bias the exposure results in either direction, with some individual under-estimated and others over-estimated.

Furthermore, the estimation of block-to-block commuter flows relied on the assumption that the frequency of commuting to a workplace block within a tract is proportional to the amount of commercial and industrial land in the block. This assumption may introduce a bias in overestimating exposures if 1) the blocks with greater commercial/industrial land density also have greater concentrations when compared with lower density commercial/industrial density blocks, and 2) most persons commute to lower commercial/industrial density blocks. It should also be noted that recent surveys, notably the National Household Transportation Survey (NHTS), have found that most trips taken and most VMT accrued by households are non-work trips, particularly social/recreational and shopping-related travel (Hu and Reuscher, 2004). This constitutes an unquantified source of uncertainty that is not be addressed by the Census commuter dataset. However, because most benchmark exceedances occur outdoors the overall impact to uncertainty is likely low.

8.11.2.3 Human Time-Location-Activity Pattern Data

The CHAD time-location activity diaries used are the most comprehensive source of such data and realistically represent where individuals are located and what they are doing. The diaries are sequential records of each persons activities performed and microenvironments visited. There are however, uncertainties in the exposure results as a result of the CHAD diaries used for simulating individuals. First, much of the data used to generate the daily diaries were collected in surveys conducted over 20 years ago. While the trends in people's daily activities may not have changed much over the years, it is certainly possible that some differences do exist such as the amount of time spent outdoors, time spent performing activities at a particular level of exertion, and the microenvironments where moderate or greater exertion is likely to occur. It would be extremely difficult to determine real differences in the distribution of these factors that may influence SO_2 exposure. Much of the data available to test such differences is survey-based. The survey methods used to collect data twenty years ago are not consistent with survey methods used today. If there are observed differences, it is likely an affect of the survey methods rather than changes in population activities.

Second, the CHAD data are taken from numerous surveys that were performed for different purposes. Some of these surveys collected only a single diary-day while others went on for several days. Some of the studies were designed to not be representative of the U.S. population, although a large portion of the data is from National surveys. In addition, study collection periods occur at different times of the year, possibly resulting in seasonal differences. This could add uncertainty to the results if there are characteristics of the survey population that are distinct from the simulated population.

The CHAD diaries that are selected from APEX to represent the Greene County and St. Louis population are not all from these cities, the State of Missouri, or from the Midwest, albeit some of the diaries may be. As stated above, most of the diaries are from National surveys, therefore there are diaries from locations other than Greene County and St. Louis that are used to simulate the modeled population. A few of the limitations associated with the use of diaries from different locations or seasons are corrected by the approaches used in the exposure modeling. For example, diaries used are weighted by population demographics (i.e., age and gender) for a particular location and temperature is used as a classification variable to account for its affect on human activities.

A sensitivity analysis was recently performed to evaluate the affect of using different CHAD studies has on APEX results for the recent O_3 NAAQS review (see Langstaff (2007) and EPA (2007d)). Briefly, O_3 exposure results were generated using APEX with all of the CHAD diaries and compared with results generated from running APEX using only the CHAD diaries from the National Human Activity Pattern Study (NHAPS), a nationally representative study in CHAD. There was agreement between the APEX exposure results for the 12 metropolitan areas evaluated (one of which was St. Louis), whether all of CHAD or only the NHAPS component of CHAD is used. The absolute difference in percent of persons above a particular concentration level ranged from -1% to about 4%, indicating that the exposure model results are not being overly influenced by any single study in CHAD. It is likely that similar results would be obtained here for SO_2 exposures, although it remains uncertain due to different averaging times (5-minute vs. 8-hour average). This is not to suggest that the uncertainty is low in using all of the CHAD data to represent the Greene County and St. Louis areas, but that similar results would be obtained in using the diaries available, so long as the population was appropriately stratified and certain characteristics influencing exposure were considered.

In addition, due to limitations in the data summaries output from the current version of APEX, certain exposure data could only be output for the entire population modeled (i.e., all persons - includes asthmatics and healthy persons of all ages) rather than the particular subpopulation. The exposure results for time spent in microenvironments at or above a potential health effect benchmark level was estimated from the total persons simulated (not just asthmatics) and is assumed by staff to be representative of the asthmatic population in the modeling results. This is a reasonable modeling assumption because the asthmatic population does not have its microenvironmental concentrations and activities estimated any differently from those of the total population. There is however uncertainty in the use of all CHAD diaries in simulating all individuals without considering the health status of the surveyed population and the simulated population if health status affects an important element of how persons are exposed. In this assessment it was shown that the most important microenvironments for contacting the 5-minute peak concentration were those that were outdoors. Therefore, if there is a difference in the time spent outdoors (e.g., total time, time-of-day) between asthmatics and healthy individuals, there may be a greater uncertainty in the estimated number of asthamtics exposed than if there were no difference.

This assumption of modeling asthmatics similarly to healthy individuals (i.e., using the same time-location-activity profiles) is supported by the findings of van Gent et al. (2007), at least when considering children 7-10 years in age. These researchers used three different activity-level measurement techniques; an accelerometer recording 1-minute time intervals, a written diary considering 15-minute time blocks, and a categorical scale of activity level. Based on analysis of 5-days of monitoring, van Gent et al. (2007) showed no difference in the activity data collection methods used as well as no difference between asthmatic children and healthy children when comparing their activity levels. Activity level is directly correlated with time spent outdoors.

There is also the possibility that information regarding bad air quality may affect the activities performed by the asthmatic population. There has been some research regarding significant “averting behavior” i.e., there is a reduction in time spent outdoors when the individual is informed of the potential for bad air quality days (e.g., Bresnahan, et al. 1997; Mansfield, 2005), though one study reviewed by staff reported no effect on outdoor time (e.g., Yen et. al. 2004). Of the limited studies reviewed by staff, most were focused on the population response to ozone (or smog) air pollution alerts. The strength of the relationship between ozone air quality and the occurrence of short-term SO_2 pollution events modeled here is not known at this time. In addition, being informed of the potential air pollution event was an important factor in whether there was a reported reduction in outdoor time for either asthmatic children or non-asthmatic children (Mansfield et al., 2005). Parents of asthmatic children checked air quality alerts more frequently than parents of non-asthmatic children and, though reported as statistically significant, only about 25% of parents of asthmatics checked the air quality on a daily basis

(Mansfield et. al., 2005). Therefore, if there is averting behavior in response to air pollution events, it is largely uncertain the degree to which an asthmatics SO_2 exposure would be altered. It is likely that there would be a reduction in the estimated number of asthmatics exposed if there were a strong relationship between an ozone air pollution event and an SO_2 air pollution event and the frequency of averting behavior was accounted for by APEX, though the reduction is likely to be small given the apparently limited degree of awareness.

8.11.2.4 Longitudinal Profile

APEX creates seasonal or annual sequences of daily activities for a simulated individual by sampling human activity data from more than one subject. Each simulated person essentially becomes a composite of several actual people in the underlying activity data. Certain aspects of the personal profiles are held constant, though in reality they change as an individual ages. This is only important for simulations with long timeframes, particularly when simulating young children (e.g., over a year or more).

The cluster algorithm used in constructing longitudinal profiles was evaluated against a sequence of available multiday diaries sets collected as part of the Harvard Southern California Chronic Ozone Exposure Study (Xue et al. 2005, Geyh et al. 2000). Briefly, the activity pattern records were characterized according to time spent in each of 5 aggregate microenvironments: indoors-home, indoors-school, indoors-other, outdoors, and in-transit. The predicted value for each stratum was compared to the value for the corresponding stratum in the actual diary data using a mean normalized bias statistic. See Appendix B, Attachment 3 and 4 for details. The evaluation indicated the cluster algorithm can replicate the observed sequential diary data, with some exceptions. The predicted time-in-microenvironment averages matched well with the observed values. For combinations of microenvironment/age/gender/season, the normalized bias ranges from –35% to +41%. Sixty percent of the predicted averages have bias between –9% and +9%, and the mean bias across any microenvironment ranges from -9% to +4%. Although, on occasion there were large differences in replicating variance across persons and within-person variance subsets, about two-thirds of the predictions for each case were within 30% of the observed time spent in each microenvironment.

The longitudinal approach used in the exposure assessment was an intermediate between random selection of diaries (a new diary used for every day for each person in the year) and perfect correlation (same diary used for every day for each person in the year). The cluster algorithm used here was previously compared with two other algorithms, one that used random sampling and the other employing diversity (*D*) and autocorrelation (*A*) statistics (see EPA, 2007g for details on this latter algorithm). The number of persons with at least one or more exposure to a given O_3 concentration was about 30% less when using the cluster algorithm than when using random sampling, while the number of multiple exposures for those persons exposed was greater using the cluster algorithm (by about 50%). The algorithm employing the *D* and *A* statistics exhibited similar patterns, although were lower in magnitude when compared with random sampling (about 5% fewer persons with one or more exposures, about 15% greater multiple exposures). These exposure results using the cluster algorithm in APEX appeared to be the result of a greater correlation of diaries selected in comparison with the other two algorithms. This outcome conforms to an expectation of correlation between the daily activities of individuals. While the evaluation was performed using 8-hour O_3 as the exposure output it is expected that similar results would be obtained for 5-minute SO_2 exposures. That is, the characteristics of the diaries that contribute greatly to any pollutant exposure above a given threshold (e.g., time spent outdoors, vehicle driving time, time spent indoors) are likely a strong component in developing each longitudinal profile. Given these results and that the REA is not necessarily focused on health effects resulting from multi-day exposures, the particular longitudinal approach used likely contributes minimally to uncertainty. See Appendix B, Attachments 3 and 4 for further details in the cluster algorithm and the evaluations performed.

8.11.2.5 Meteorological Data

Meteorological data are taken directly from monitoring stations in the assessment areas. It is assumed that most of the data used are error free and have undergone required quality assurance review. One strength of these data is that it is relatively easy to see significant errors if they appear in the data. Because general climactic conditions are known for the simulated area, it would have been apparent upon review if there were outliers in the dataset, and at this time none were identified. If there were a bias in the data, it would be expected to be limited in extend and randomly occurring, therefore contributing to both under and over-estimations equally to a marginal degree. To reduce the number of calms and missing winds in the 1-hour MET data, archived one-minute winds for the ASOS stations in each model domain were used to calculate hourly average wind speed and directions. This approach reduces the number of estimated zero concentrations that would be output by AERMOD if not supplemented by the additional wind data, thus preventing a downward bias in the predicted 1-hour SO_2 concentrations.

There are limitations in the use of the meteorological data in APEX. APEX only uses one temperature value per day in selecting an appropriate CHAD diary and indoor microenvironment air exchange rate. Because the model does not represent hour-to-hour variations in meteorological conditions throughout the day, there may be uncertainty in some of the exposure estimates for indoor microenvironments (see the next section).

8.11.2.6 Air Exchange Rates (AER)

The residential air exchange rate (AER) distributions used to estimate indoor exposures contribute to uncertainty in the exposure results. Three components of the AER analyzed previously by EPA (2007d) include 1) the extrapolation of air exchange rate distributions between-CMSAs, 2) analysis of within-CMSA uncertainty due to sampling variation, and 3) the uncertainty associated with estimating daily AER distributions from AER measurements with different averaging times. The results of those previous investigations are briefly summarized here. See Appendix B, Attachments 6 and 7 for details in the data used to generate the AER and the uncertainty analyses performed.

Extrapolation of AER among locations

Air exchange rate (AER) distributions were assigned in the APEX model, as described in the indoors-residential microenvironment. Because location-specific AER data for St. Louis and Greene County were not available and that there were no AER data from cities thought to have similar influential characteristics affecting AER[52], staff constructed an aggregate distribution of the available AER data from cities outside California to represent the distribution of AERs in St. Louis and Greene County (see Appendix B, Attachment 6).

In the absence of location-specific data for the microenvironments modeled by APEX within each model domain, only limited uncertainty analyses were performed. To assess the uncertainty associated with deriving AERs from one city and applying those to another city, between-location uncertainty was evaluated by examining the variation of the geometric means and standard deviations across several cities and originating from several different studies. The evaluation showed a relatively wide variation across different cities in their AER geometric

---

[52] Such potential influential factors would include age, composition of housing stock, construction methods used, and other meteorological variables not explicitly treated in the analysis, such as humidity and wind speed patterns.

means and standard deviations, stratified by air-conditioning status, and temperature range. For example, Figure 8-20 Illustrates the GM and GSD of AERs estimated for several cities in the U.S. where A/C was present and within the temperature range of 20-25 °C. The wide range in GM and GSD pairs implies that the modeling results may be very different if the matching of modeled location to a particular study location was changed. For example, the SO_2 exposure estimates may be sensitive to use of an alternative distribution, say those in New York City, compared with results generated using the aggregate non-California AER distributions. It is possible though that the true distribution could be more similar to the selected distribution from all non-California cities than that of the specific locations given the population of available AER data. It is unclear as to the direction of bias given the limited number of data available for comparison. It is possible that the impact to the number of exceedances is low, given that most of the exceedances occurred outdoors for most of the air quality scenarios evaluated.

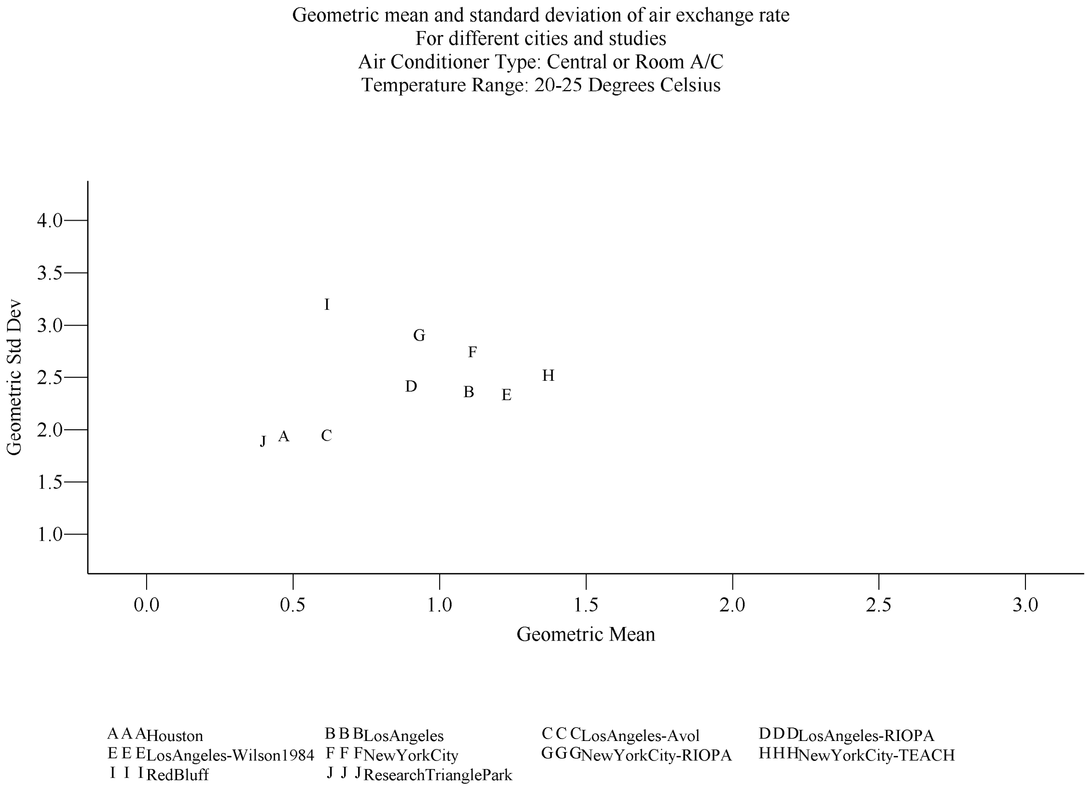

Figure 8-20. Example comparison of estimated geometric mean and geometric standard deviations of AER (h^{-1}) for homes with air conditioning in several cities.

Within location uncertainty

There is also variation in AERs within studies for the same location (e.g., Outside California data), but this is much smaller than the observed variation across different CMSAs. This finding tends to support the approach of combining different studies for a CMSA, where data were available. The within-city uncertainty was assessed by using a bootstrap distribution to estimate the effects of sampling variation on the fitted geometric means and standard deviations for the non-California data used to represent the St. Louis and Greene County AERs. These bootstrap distributions assess the uncertainty due to random sampling variation. They do not address other uncertainties such as the lack of representativeness of the available study data or the variation in the lengths of the AER monitoring periods. Because only the GM and GSD were used, the bootstrap analyses does not account for uncertainties about the true distributional shape, which may not necessarily be lognormal.

One-thousand bootstrap samples were randomly generated for each AER subset (of size N), producing a set of 1,000 geometric mean (GM) and geometric standard deviation (GSD) pairs. The analysis of the non-California city data used to represent Greene County and St. Louis indicated that the GSD uncertainty for a given AER temperature group tended to have a range within ±0.3 fitted GSD (hr^{-1}), with smaller intervals surrounding the GM (i.e, about ± 0.10 fitted GM (hr^{-1}) (Figure 8-21). Broader ranges were generated from the bootstrap simulation for AER distributions used for Greene County and St. Louis homes without A/C (Figure 8-22), although both still within ±0.5 of the fitted GM and GSD values. See Appendix B, Attachment 6 for further details.

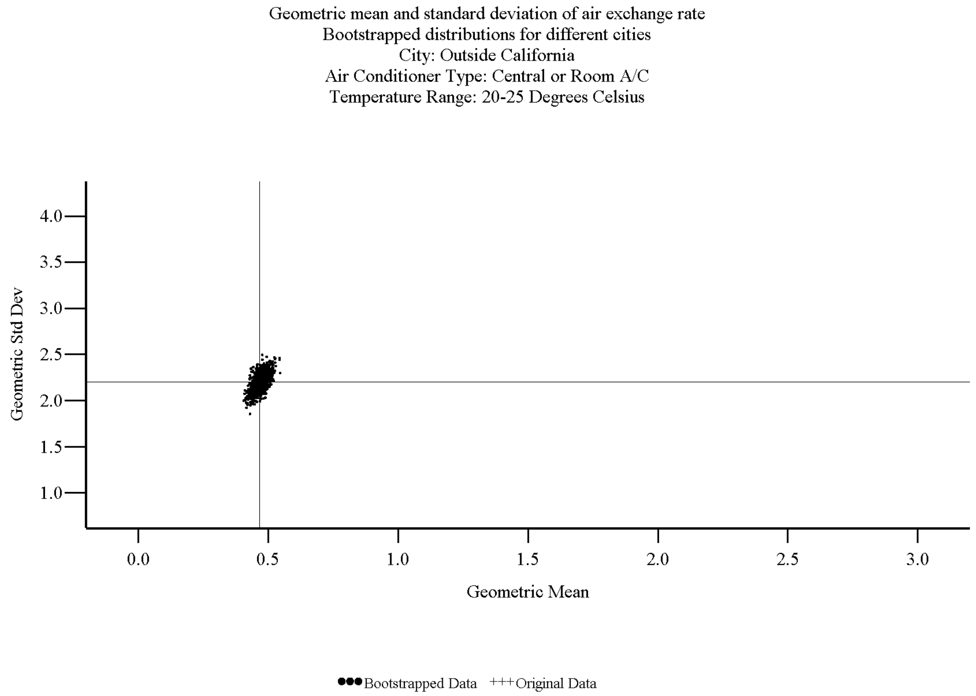

Figure 8-21. Example of boot strap simulation results used in evaluating random sampling variation of AER (h-1) distributions (data from cities outside California).

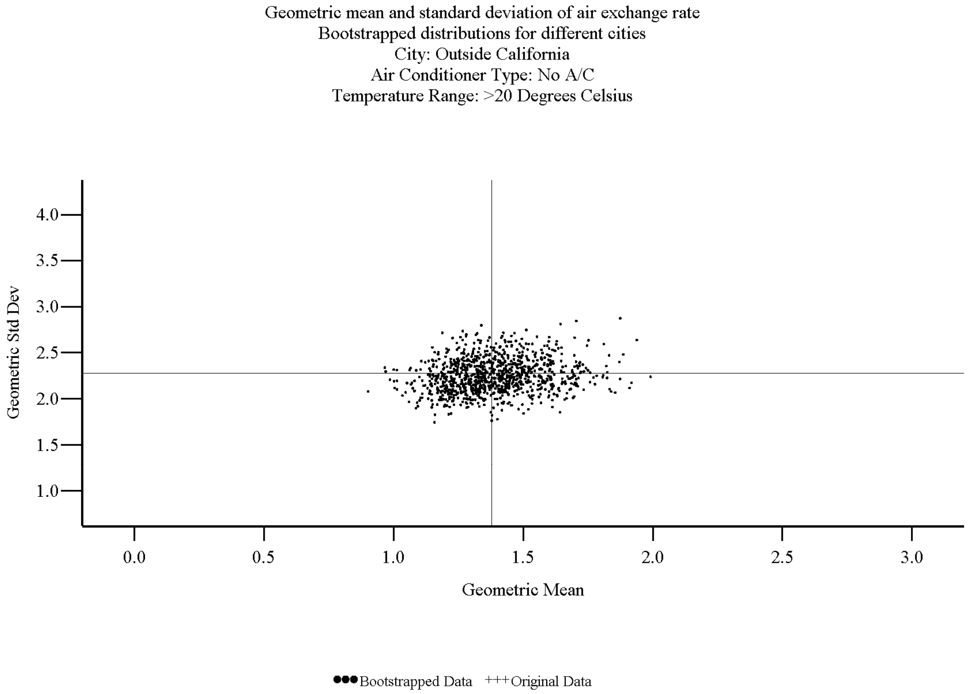

Figure 8-22. Example of boot strap simulation results used in evaluating random sampling variation of AER (h-1) distributions (data from cities outside California).

Variation in AER measurement averaging times

Although the averaging periods for the air exchange rates in the study data varied from one day to seven days, the analyses did not take the measurement duration into account and treated the data as if they were a set of statistically independent daily averages. To investigate the uncertainty of this assumption, correlations between consecutive 24-hour air exchange rates measured at the same house were investigated using data from the Research Triangle Park Panel Study (Appendix B, Attachment 7). The results showed extremely strong correlations, providing support for the simplified approach of treating multi-day averaging periods as if they were 24-hour averages.

8.11.2.7 Air Conditioning Prevalence

Because the selection of an air exchange rate distribution is conditioned on the presence or absence of an air-conditioner, the air conditioning status of the residential microenvironment was simulated randomly using the probability that a residence has an air conditioner, i.e., the residential air conditioner prevalence rate. For this study we used location-specific data for St. Louis (AHS, 2003a; 2003b) and applied that data to Greene County as well. EPA (2007d) details the specification of uncertainty estimates in the form of confidence intervals for the air conditioner prevalence rate, and compares these with prevalence rates and confidence intervals developed from the Residential Energy Consumption Survey (RECS) of 2001 for several aggregate geographic subdivision (e.g., states, multi-state Census divisions and regions) (EIA, 2001).

Briefly, Air conditioning prevalence rates were 95.5% for St. Louis, with reported standard errors of 1.7% (AHS, 2003a; 2003b). Estimated 95% confidence intervals were also small and span approximately 6.5 percentage points (AHS, 2003a; 2003b). The RECS prevalence estimate for Census Divisions was 92% (ranging between 86.4% and 98.4%), while the Census Region prevalence estimate was 83.6% (ranging between 80.0% and 87.2%). This suggests that the air conditioning prevalence used, while likely being representative of a city in Missouri, may be overestimated for non-urban locations. The magnitude of uncertainty associated with the estimated A/C prevalence and the impact to estimated exposures is likely low.

8.11.2.8 Indoor Decay

There may be uncertainty added to the exposure results when considering the estimated parameters, the form (i.e., lognormal) and limits (limited by the bounds of the measurement data) of the distribution used to represent indoor decay. The data used to develop the distribution were obtained from a review of several studies that analyzed SO_2 removal for a variety of building material surfaces (Grontoft and Raychaudhuri, 2004). Potential influential factors such as humidity and air exchange rate were accounted for in developing and applying the removal distributions within the indoor microenvironments. The distributions were based on a large empirical data base and likely well represent expected SO_2 removal within indoor microenvironments.

However, several assumptions were made to characterize the likely materials used within a simulated indoor microenvironment, some of which were data-based, others in the absence of supporting data, were based solely on professional judgment. Staff performed a Monte Carlo simulation using the removal data and 1,000 simulated indoor rooms of buildings to effectively generate a distribution of SO_2 removal rates, weighted by the approximated room configurations and proportion of materials present. There are many assumptions staff made that could be modified with newly available data, particularly where inputs were based on professional judgment. It is largely unknown what the current direction of bias is in the absence of new or refined input data. While some of the assumptions used may add to uncertainty, the magnitude of the uncertainty is likely low given the relative contribution of the indoor microenvironments to exposure concentrations above the potential health effect benchmark levels.

8.11.2.9 Occurrence of Multiple Exceedances Within an Hour

The statistical model described in section 7.2 was used within APEX to estimate a single 5-minute maximum SO_2 concentration for every hour. However, multiple short-term peak concentrations above selected levels are possible within any hour. Analysis of the 5-minute continuous monitoring data indicates that multiple occurrences of 5-minute concentrations above the 100, 200, 300, and 400 ppb within the same hour can be common. Using the continuous monitoring data obtained from years 1997-2007, multiple peak concentrations (i.e., 2 or more) at or above 400 ppb within the same hour occurred with a 61% frequency (Table 8-17). The frequency of multiple exceedances was similar for the lower 5-minute SO_2 concentration levels, where 63, 56, and 53% of the time there were two or more exceedances within the same hour at the 100, 200, and 300 ppb benchmark levels, respectively. These results may suggest that a single peak approach for estimating the 5-minute daily maximum SO_2 concentrations alone as a surrogate for all possible peak exposure events may lead to an underestimate in the number of potential exposures.

Table 8-17. Number of multiple exceedances of potential health effect benchmark levels within an hour.

Number of Exceedances of 5-minute SO_2 in 1-hour[1]	Number of Hours with Multiple 5-minute SO_2			
	> 100 ppb	> 200 ppb	> 300 ppb	> 400 ppb
1	1248	267	76	26
2	658	122	31	20
3	411	78	21	7
4	257	35	10	5
5	242	28	6	4
6	153	25	4	1
7	125	14	5	1
8	89	11	2	1
9	64	6	3	1
10	49	6	1	1
11	50	3	0	0
12	73	5	1	0
Total	**3419**	**600**	**160**	**67**

Notes:
[1] The analysis is based on the 16 monitors reporting all 5-minute SO_2 concentrations in an hour (n=3,328,725).

In using the data in Table 8-17 alone, the potential underestimation bias may be somewhat overstated however, particularly when considering the benchmark levels of 200, 300, and 400 ppb. A detailed analysis of the multiple exceedances by monitor indicated that one of the monitors (ID 420070005) was highly influential in generating the values in Table 8-17, contributing greatly to the multiple peak occurrences at the higher benchmark levels. This Beaver, PA urban-scale monitor is identified as population-based, within a rural setting, and having agricultural land use (Appendix A). Five of eight of the sources located within 20 km of this monitor had SO_2 emissions <250 tpy, one smelter emitting about 7,000 tpy was within 2.5 km, and two power generating facilities located approximately 3.4 and 7.5 km from the monitor had SO_2 emissions of 3,000 and 30,000 tpy, respectively. Of the number of hours having multiple exceedances, monitor 420070005 contributed to 61, 73, and 80% of the hours with multiple peaks >200, >300, and >400 ppb, respectively. Following removal of this monitor from the full data set, the occurrence of multiple exceedances of each the 200, 300, and 400 ppb benchmark lowered to approximately 40% of all hours having co-occuring peaks.

This suggests there may be added uncertainty in the exposure results if the continuous monitoring data were used to design an approach for estimating multiple exceedances within an hour. These data were only from 16 ambient monitors, each having a limited number of monitoring years. The analyses above indicated that one of the monitors contributed to most of the hours with multiple peak concentrations. How this one monitor (as well as any other monitor having multiple exceedances) reflects what may occur at the APEX modeled receptors in St. Louis and Greene County (or other different locations) is largely unknown. There is no simple extrapolation possible using the continuous monitoring data because the time of the peak (and hence multiple peak) concentrations modeled are not known with respect to the simulated individuals' time spent outdoors.

The PMR statistical model is based on both concentration and variability measures, implemented by APEX in estimating a single maximum 5-minute SO_2 concentration for every hour at every receptor. This is based on known concentration and variability relationships described in section 7.2. While APEX can model all twelve 5-minute concentrations, staff chose to normalize the eleven remaining 5-minute concentrations within an hour to the 1-hour mean concentration. This decision was based largely on the size of the air quality files used (thousands of receptors across a year) that already required a time consuming post-processing step prior to input in APEX and ultimately, the run time associated with the exposure model simulations. Estimating the 5-minute maximum SO_2 concentrations and the other 11 concentrations within APEX was more efficient than pre-processing all twelve 5-minute SO_2 concentrations.

There is bias in having all eleven other 5-minute SO_2 concentrations normalized to the mean; the exposure simulation could *miss* a persons exposure that might have occurred if in fact there are multiple peak concentrations within the same hour (a likely event given the continuous monitoring data, roughly between 40-60%). The CHAD time-location-activity diaries used in APEX are fixed, that is, the modeled time spent outdoors is based on the actual time (and amount) recorded by the surveyed individual. APEX models exposure on a minute-by-minute basis; if most persons spend time outdoors for a short time (e.g., 5-minutes), then it is possible that persons are not realistically encountering peak concentrations given the normalization of the eleven 5-minute SO_2 concentrations. Therefore, staff analyzed outdoor activities in the CHAD diaries used by APEX to determine the duration of time spent outdoors for each outdoor event.

Figure 8-23 illustrates the distribution of time spent outdoors, given activity outdoor events defined by clock-hour increments (already part of the CHAD design). Thirty-five percent of all outdoor events are for the entire hour; if the event corresponds with the same hour as a simulated peak concentration, there would be no underestimation bias associated with exposure occurring during these events. Therefore, occurrence of multiple peaks within an hour is potentially not an issue for 35% of the peak exposure events that occur outdoors. However, at each of the other outdoor events, there is a probability of underestimating the exposure, given by the duration of the event divided by 60 minutes. For example, approximately 15% of outdoor events were 30 minutes. If these outdoor events occurred at the time where there was a second estimated peak concentration in the same hour, there is a 50% chance that the exposure is missed. The probability of missing a potential exposure increases with decreasing duration of the outdoor event and, given the data in Figure 8-23, this could be a frequent occurrence (i.e., about 65% of outdoor events may have some probability of missing an exposure). This analysis does not account for multiple outdoor events that may increase an individual's chance of a daily maximum exposure exceedance, regardless of the event duration. It also assumes the each of the outdoor events evaluated have an equal probability of occurring at the time of the peak concentration, which may or may not be the case. In addition, the outdoor time distribution is based on all of the CHAD diary days, potentially not the same distribution of diaries that were used in the APEX exposure simulations.

A better method to determine the potential number of missing exposures is to model the exposures using two input data sets: air quality with all continuous 5-minute measurements, and air quality having the measured 5-minute maximum and the eleven other 5-minute concentrations within the hour normalized to the 1-hour mean. Staff constructed a data set using measurements from the continuous-5 ambient monitoring. While there were two monitors reporting continuous 5-minute measurements in Greene County (monitor IDs 290770037 and 290770026), there were only two years with exceedances of the 200 ppb benchmark level, and no exceedances of the 300 or 400 ppb benchmarks. To explore the maximum effect of multiple peak concentrations within an hour, staff used two years of data from monitor ID 420070005, noted above as having the greatest number of benchmark exceedances in a year (years 2002 and 2005 were selected).

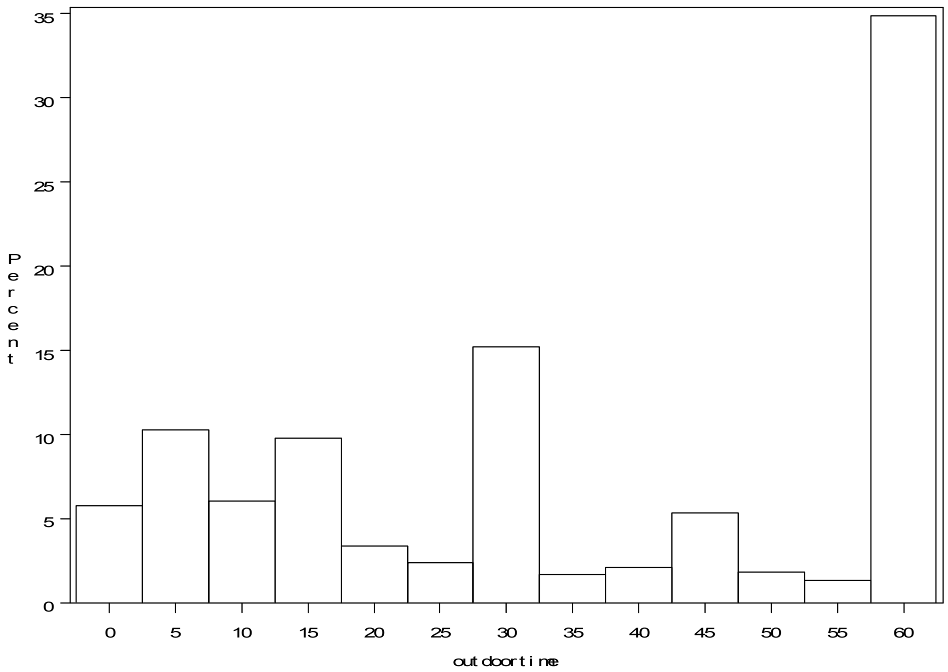

Figure 8-23. Duration of time spent outdoors (in minutes) using all CHAD events

First, staff replaced missing concentrations (approximately 5% of each year) using the time-of-day monthly averaged SO_2 concentration. This data set served as the multiple peak air quality data set to be tested; all measured 5-minute concentrations were used as is. Next, staff constructed a similar data set, only this second data set had the maximum measured 5-minute concentration retained and all other eleven 5-minute concentrations within the hour were normalized using the 1-hour mean. This single peak data set reflects what was being modeled by APEX. Each of the data sets were used as the air quality input to APEX simulation, controlling for all model sampling, the algorithms used, microenvironments modeled, and persons simulated. The only difference in the two runs was the air quality input. Fifty thousand persons were simulated using APEX, 13% of which were asthmatic children. Figure 8-24 illustrates the percent of asthmatic children exposed to selected 5-minute maximum concentrations for each of the two scenarios; a multiple peak scenario and a single maximum peak concentration, using two site-years of continuous monitoring data with the greatest number of benchmark exceedances. As expected, there are more asthmatic children exposed when considering the occurrence of multiple peaks in an hour. The difference in the percent of asthmatic children exposed at each of the benchmark levels is small, about 2-5 percentage points differ between the two simulations. However, considering the percent difference in the numbers of persons exposed at most of the benchmarks levels, the simulations using the single peak air quality method had between 20-35% fewer persons exposed than the multiple peak simulation. Similar results were generated in simulations using the site-year with the 2nd highest number of exceedances only the underestimation using the single peak method was about 15-30% (Figure 8-25). Based on these analyses, at most the estimated number of persons exposed in St. Louis and Greene County are underestimated by 35% when using a single peak method. The actual amount of underestimation is likely smaller given that these results were generated using site-years of monitoring data having the greatest numbers of exceedances and contributing significantly to the high frequency of multiple peak exceedances.

The location where exposures occur may also be influenced by the presence or absence of multiple peak concentrations. In particular, the modeled indoor 5-minute maximum concentrations may be markedly diluted if the indoor air exchange rate is low and all eleven other 5-minute values within the same hour are normalized to the 1-hour mean concentration. APEX estimates all microenvironmental concentrations using a mass balance method for 5-minute time-steps (equation 8-2) that accounts for estimated microenvironmental concentrations from the previous time-step (EPA, 2009b). While dilution of the indoor air is not an unusual circumstance considering the physical process modeled, it is possible that the number of exposure events from indoor sources is underestimated when the prior time-step concentration is artificially reduced.

Staff evaluated the microenvironments where peak exposures occurred, by aggregating the time 5-minute exposures occurred into three broad microenvironmental groups: indoors, outdoors, and in-vehicles. A comparison of the APEX simulations using the two air quality input simulations (i.e., multiple peak versus single peak, monitor 420070005 – year 2002) and considering how often peak exposures occur indoors is presented in Figure 8-26. The differences in the percent of indoor exposure exceedances are consistent with the design of the model and the particular input data used. For exposures less than the 400 ppb level, a greater percent of the overall exposures occur indoors using the single peak method than compared with the multiple peak data set. For exposures at or above the 400 ppb level, a smaller percent of the overall exposures occur indoors using the single peak method than compared with the multiple peak data set. In fact, the multiple peak simulation had indoor peak exposures at levels not observed using the single peak method. This is likely a function of the normalized concentrations, that when used in the mass balance equation as the prior time-step microenvironmental concentration, the microenvironmental concentration at time *t* is less than what would be expected.

While this analysis and its findings are encouraging, context is needed to assign relevance to the current exposure analyses in St. Louis and Greene County. As stated earlier, the data set used had the greatest number of benchmark exceedances, designed by staff to observe the effect that multiple peaks within the hour has on estimated exposures. The observed differences in the contribution from the indoor microenvironment may be more appropriately applied in discussions regarding air quality scenarios with high concentrations distributions (e.g., air quality adjusted to just meeting the current standard, Figure 8-19). While the differences in the highest benchmarks exceedances are likely of greatest interest when investigating the possibility of missing exposure events, it should be noted that the greatest proportion of exposure events still occur outdoors (in this simulation, >70% of exposures above 400 ppb occurred outdoors). In addition, the differences observed at the lower benchmarks indicated the role of indoor exposures was fairly similar. At most the difference was four percentage points, with the multiple peak simulation having a consistently lower contribution of exceedances from indoor exposures.

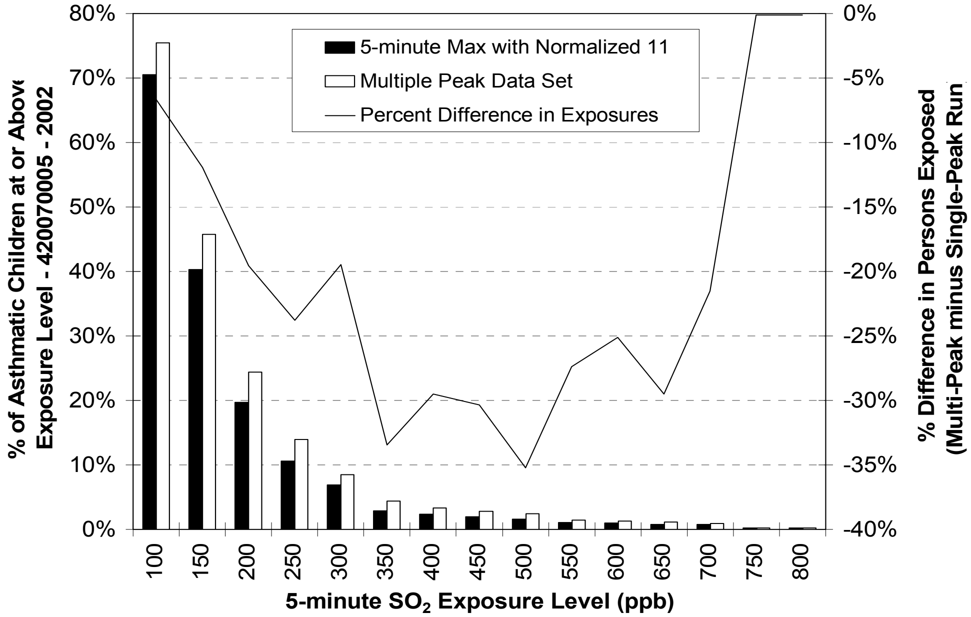

Figure 8-24. Percent of asthmatic children above given exposure level for two APEX simulations: one using multiple peak concentrations in an hour, the other assuming a single peak concentration. Continuous 5-minute monitoring data (ID 42007005, year 2002) were used as the air quality input.

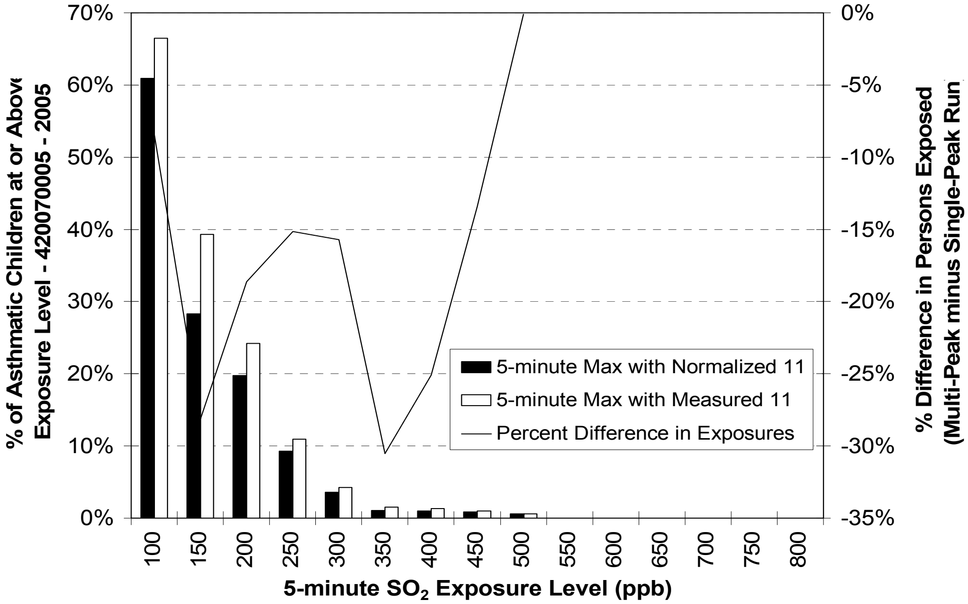

Figure 8-25. Percent of asthmatic children above given exposure level for two APEX simulations: one using multiple peak concentrations in an hour, the other assuming a single peak concentration. Continuous 5-minute monitoring data (ID 42007005, year 2005) were used as the air quality input.

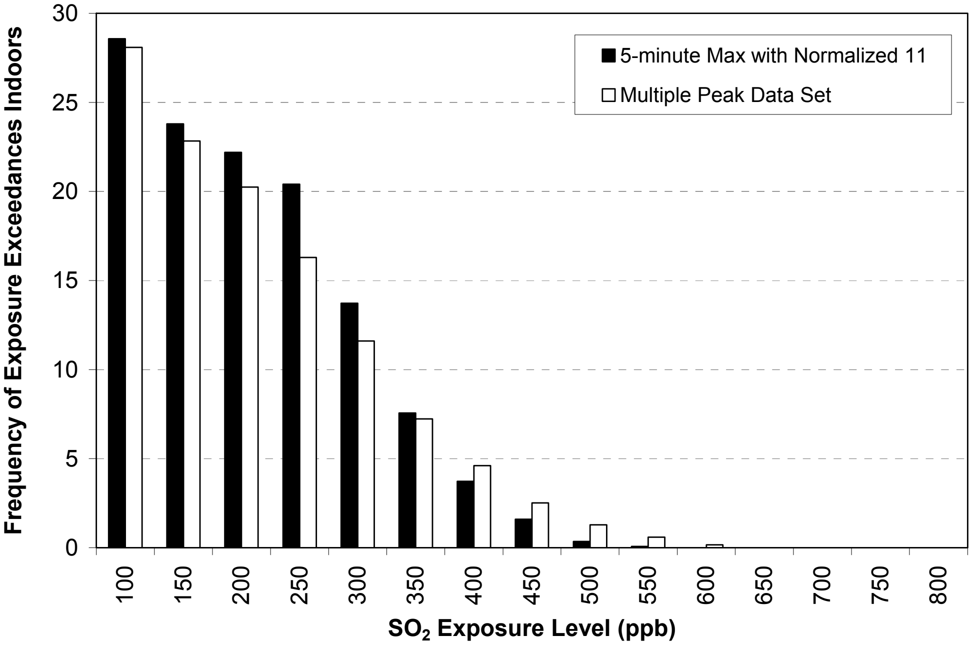

Figure 8-26. Frequency of exposure exceedances indoors for two APEX simulations: one using multiple peak concentrations in an hour, the other assuming a single peak concentration. Continuous 5-minute monitoring data (ID 42007005, year 2002) were used as the air quality input.

8.11.2.10 Asthma Prevalence Rate

The best estimate of asthma prevalence used in this analysis was generated using a comprehensive and widely used data set (CDC, 2007). Staff judged that variability in the asthma prevalence based on age was an important attribute to represent in simulating SO_2 exposures, one of the principal reasons for selection of the particular data set. There are however limitations in using the data that may add to uncertainty in the generated exposure results. The percent of asthmatics simulated by APEX using a combined regional (children by age) and local (adults all ages) prevalence was comparable with an independent estimate of the percent of asthmatics within the four counties modeled (9.3% versus 8.8% of the population, respectively). Therefore, the uncertainty in the overall total percent of asthmatics exposed is likely low, particularly in Greene County. In Greene County, 9.8% of the simulated population was asthmatic and compares well with the 10.2% asthma prevelance reported by MO DOH (2003). However, the asthma prevalence across the three county domain in St. Louis was variable, with St. Louis City County having a high estimated prevalence rate (16.4%) and St Louis County having a much lower prevalence rate (5.8%). This variable distribution was not represented in the exposure modeling simulation; all children and adults in each of the counties used the data summarized in Table 8-6. Therefore in St. Louis County, the asthma prevalence may have been underestimated, while in St. Louis County the asthma prevalence may have been overestimated. This may add to uncertainty in the total number of asthmatics exposed in St. Louis (not the percent of asthmatics exposed), though the direction of bias is largely unknown because individual county level exposures are not output by the model.

9.0 HEALTH RISK ASSESSMENT FOR LUNG FUNCTION RESPONSES IN ASTHMATICS ASSOCIATED WITH 5-MINUTE PEAK EXPOSURES

9.1 INTRODUTION

In the previous review, it was clearly established that subjects with asthma are more sensitive to the respiratory effects of SO_2 exposure than healthy individuals (ISA, section 3.1.3.2). As discussed above in section 4.2, asthmatics exposed to SO_2 concentrations as low as 200-300 ppb for 5-10 minutes during exercise have been shown to experience significant bronchoconstriction, measured as an increase in sRaw (≥100%) or decrease in FEV_1 (≥15%) after correction for exercise-induced responses in clean air. These studies exposed asthmatic volunteers to SO_2 in the absence of other pollutants that often confound associations in the epidemiological literature. Therefore, these controlled human exposure studies provide direct evidence of a causal relationship between exposure to SO_2 and respiratory health effects. Staff judges the controlled human exposure evidence presented in the ISA with respect to lung function effects in exercising asthmatic subjects as providing an appropriate basis for conducting a quantitative risk assessment for this health endpoint and exposure scenario.

A brief description of the approach used to conduct this health risk assessment is presented below. More detailed discussion of the approach can be found in the risk assessment technical support document, included as Appendix C to this document. The goals of this SO_2 risk assessment are: (1) to develop health risk estimates of the number and percent of the asthmatic population that would experience moderate or greater lung function decrements in response to 5-minute daily maximum peak exposures while engaged in moderate or greater exertion for several air quality scenarios (described below); (2) to develop a better understanding of the influence of various inputs and assumptions on the risk estimates; and (3) to gain insights into the risk levels and patterns of risk reductions associated with meeting several alternative 1-hour daily maximum SO_2 standards. Health risks have been estimated for the following three scenarios: (1) recent ambient levels of SO_2, (2) air quality adjusted to simulate just meeting the current 24-hour standard, and (3) air quality adjusted to simulate just meeting several alternative 1-hour standards.

As discussed in Chapter 8, the geographic scope of the assessment includes selected locations encompassing a variety of SO_2 emission source types in two areas within the state of Missouri (i.e., Greene County and St. Louis). These areas were identified based on the results of a preliminary screening of the 5-minute ambient SO_2 monitoring data that were available. The state of Missouri was one of only a few states having both 5-minute maximum and continuous 5-minute SO_2 ambient monitoring, as well as having over 30 1-hour SO_2 monitors in operation at some time during the period from 1997 to 2007. In addition, the air quality characterization, described in Chapter 7, estimated frequent exceedances above the potential health effect benchmark levels at several of the 1-hour ambient monitors. In a ranking of estimated SO_2 emissions reported in the National Emissions Inventory (NEI), Missouri ranked 7th for the number of stacks with > 1000 tpy SO_x emissions out of all U.S. states. These stack emissions were associated with a variety of source types such as electrical power generating units, chemical manufacturing, cement processing, and smelters. For all these reasons, the current SO_2 lung function risk assessment focuses on Missouri and, within Missouri, on those areas within 20 km of a major point source of SO_2 emissions in Greene County and the St. Louis area.

9.2 DEVELOPMENT OF APPROACH FOR 5-MINUTE LUNG FUNCTION RISK ASSESSMENT

The lung function risk assessment is based on the health effects information evaluated in the ISA and discussed above in Chapter 4. The basic structure of the risk assessment reflects the fact that we have available controlled human exposure study data from several studies involving volunteer asthmatic subjects who were exposed to SO_2 concentrations at specified exposure levels while engaged in moderate or greater exertion for 5- or 10-minute exposures. As discussed in the ISA (section 3.1.3.5), among asthmatics, both the magnitude of SO_2-induced lung function decrements and the percent of individuals affected have been shown to increase with increasing 5- to 10-minute SO_2 exposures in the range of 200 to 1,000 ppb. Therefore, for the SO_2 lung function risk assessment we have developed probabilistic *exposure-response* relationships based on these data. The analysis was based on the combined data set consisting of all available individual data that describe the relationship between a measure of personal exposure to SO_2 and measures of lung function recorded in these studies. For the purposes of this risk assessment, all of the individual data, including both 5- and 10-minute exposure duration, were combined and treated as representing 5-minute responses. These probabilistic exposure-response relationships were then combined with 5-minute daily maximum peak exposure estimates for mild and moderate asthmatics engaged in moderate or greater exertion associated with the various air quality scenarios mentioned above. A more detailed description of the exposure assessment that was the source of the estimated daily maximum 5-minute peak exposures under moderate or greater exertion is provided above in Chapter 8.

9.2.1 General Approach

The major components of the lung function health risk assessment are illustrated in Figure 9-1. As shown in Figure 9-1, under the lung function risk assessment, exposure estimates for mild and moderate asthmatics for a number of different air quality scenarios (i.e., recent year of air quality, just meeting the current 24-hour standard, just meeting alternative standards) are combined with probabilistic exposure-response relationships derived using a combined data base consisting of data from several controlled human exposure studies to develop risk estimates. The air quality and exposure analysis components that are integral to this risk assessment are discussed in greater detail in Chapters 7 and 8 of this document and in the Exposure Assessment TSD. Only the air quality and exposure aspects affecting the scope of the lung function risk assessment are briefly discussed in section 9.2.2. A description of the overall approach to estimating the exposure-response relationship is included in section 9.2.3 below.

Two types of risk measures were generated for the lung function risk assessment. The first type included estimates of the number and percentage of all asthmatics (or asthmatic children) experiencing one or more occurrences of a defined lung function response associated with 5-minute exposures to SO_2 while engaged in moderate or greater exertion under a given air quality scenario. The second type of risk measure generated for each defined lung function response is the number of occurrences of the lung function response in asthmatics (or asthmatic children) in a year associated with 5-minute exposures under moderate or greater exertion under a given air quality scenario. Since asthmatic school age children are a subset of all asthmatics, the risk estimates presented for these two groups should not be combined.

To obtain risk estimates associated with SO_2 concentrations under different scenarios, we estimated expected risk given the personal exposures associated with SO_2 concentrations under each scenario – i.e., associated with

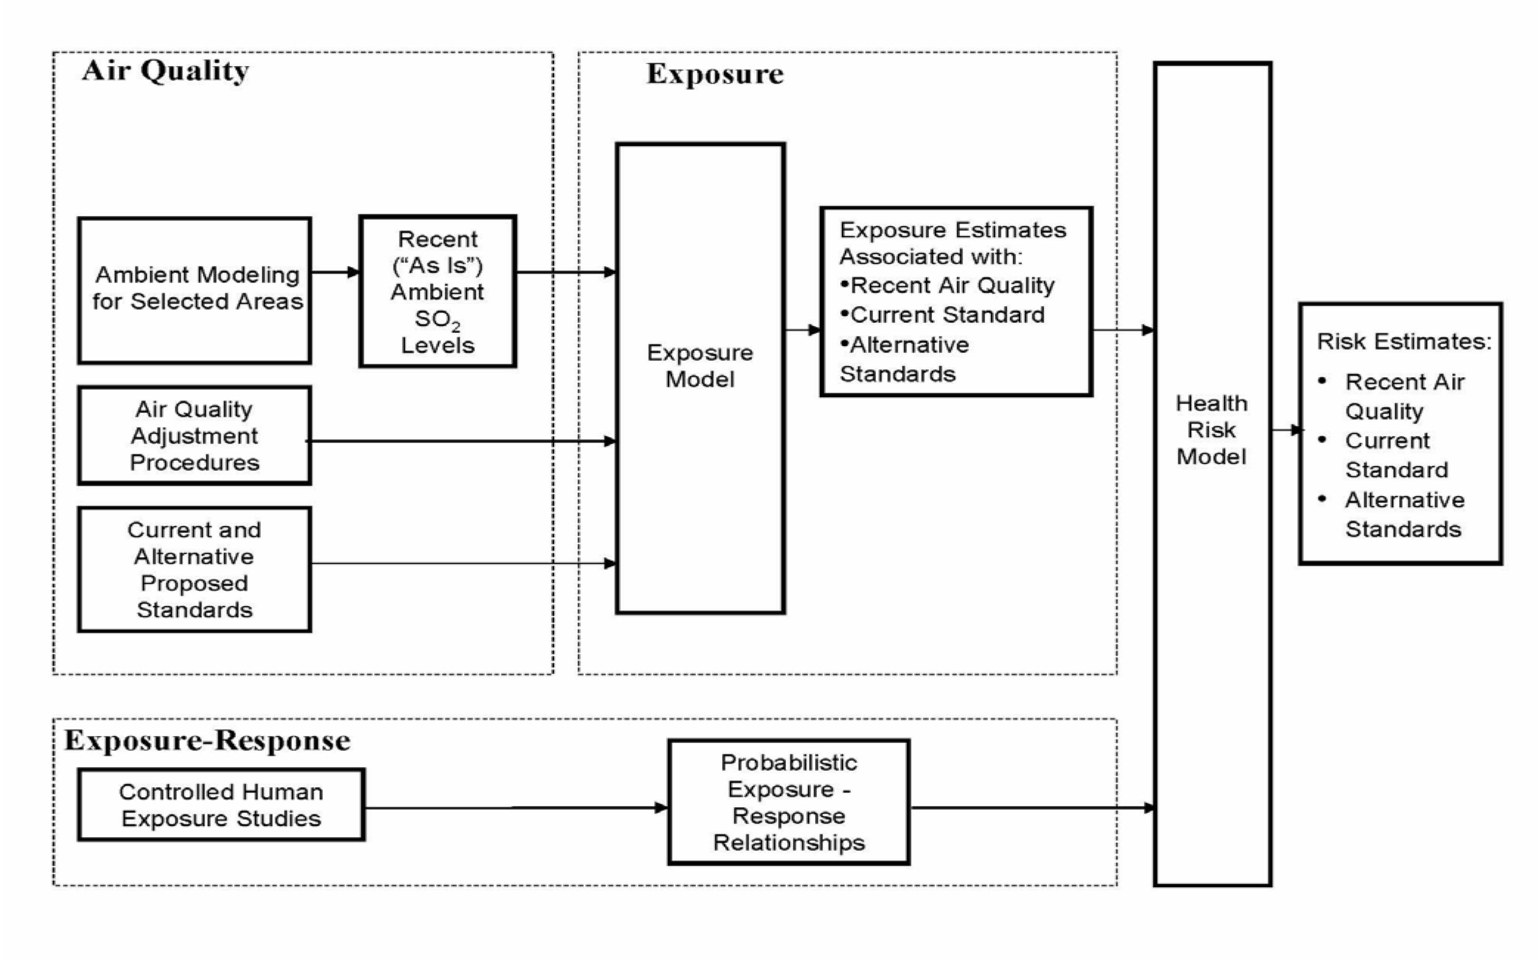

Figure 9-1. Major Components of 5-Minute Peak Lung Function Health Risk Assessment Based on Controlled Human Exposure Studies

- "as is" ambient SO_2 concentrations representing a recent year,
- SO_2 air quality levels simulating just meeting the current 24-hour and annual standards, and
- SO_2 air quality levels simulating just meeting specified alternative 1-hour standards.

Note that, in contrast to the headcount risk estimates calculated for the O_3 health risk assessment, the headcount risk estimates calculated for the SO_2 health risk assessment do not subtract out risk given the personal exposures associated with estimated policy-relevant background ambient SO_2 concentrations. This is because policy-relevant background SO_2 concentrations are estimated to be at most 30 parts per trillion and they contribute less than 1% to present day SO_2 ambient concentrations (ISA, section 2.4.6).

The first measure of risk (i.e., the number or percent of individuals in the designated population to experience at least one lung function response in a year) is calculated as follows:

1) From the exposure modeling described in Chapter 8, we obtain the number of individuals exposed at least once to x ppb SO_2 or higher, for x = 0, 50, 100, etc.;

2) We then calculate the number of individuals exposed at least once to SO_2 concentrations within each SO_2 exposure bin defined above;

3) We then multiply the number of individuals in each exposure bin by the response probability corresponding to the midpoint of the exposure bin; and

4) We sum the results across all of the bins.

Because response probabilities are calculated for each of several percentiles of a probabilistic exposure-response distribution, estimated numbers of individuals with at least one SO_2-related lung function response are similarly percentile-specific. For example, the kth percentile number of individuals, Y_k associated with SO_2 concentrations under a given air quality scenario is:

$$Y_k = \sum_{j=1}^{n} NI_j \; x \; (R_k \mid e_j) \qquad \text{(equation 9-1)}$$

where:

e_j = (the midpoint of) the jth category of personal exposure to SO_2, given "as is" ambient SO_2 concentrations;

NI_j = the number of individuals who highest exposure is to e_j ppb SO_2, given ambient SO_2 concentrations under the specified air quality scenario.

$RR_k \mid e_j$ = the kth percentile response rate at SO_2 concentration e_j; and

n = the number of intervals (categories) of SO_2 personal exposure concentration.

The kth percentile estimate of the total number responding is then calculated by multiplying the kth percentile risk by the number of people in the relevant population. An example is given in Table 9-1, for the median (i.e., 50th percentile) risk estimate using personal exposures associated with a 99th percentile 100 ppb 1-hour daily maximum SO_2 standard for asthmatics in the St. Louis modeling domain. We note that this calculation assumes that individuals who do not respond at the highest SO_2 concentration to which they are exposed will not respond to any lower SO_2 concentrations to which they are exposed.

Table 9-1. Example Calculation of the Number of Asthmatics in St. Louis Engaged in Moderate or Greater Exertion Estimated to Experience At Least One Lung Function Response (Defined as an Increase in sRaw ≥ 100%) Associated with Exposure to SO_2 Concentrations Just Meeting a 99th percentile, 1-Hour 100 ppb Standard

SO_2 Exposure Bin			Number of Asthmatics with At Least One Exposure in Bin	Probability of Response at Midpoint SO_2 Level	Estimated Number of Asthmatics Experiencing at Least One Lung Function Response
Lower Bound	Upper Bound	Midpoint (1)	(2)	(3)	=(2) x (3)
0	0.05	0.025	53711	0.00406	218
0.05	0.1	0.075	34236	0.02334	799
0.1	0.15	0.125	9835	0.05162	508
0.15	0.2	0.175	3059	0.08563	262
0.2	0.25	0.225	929	0.12300	114
0.25	0.3	0.275	368	0.16220	60
0.3	0.35	0.325	145	0.20210	29
0.35	0.4	0.375	84	0.24190	20
0.4	0.45	0.425	31	0.28060	9
0.45	0.5	0.475	22	0.31830	7
0.5	0.55	0.525	8	0.35430	3
0.55	0.6	0.575	0	0.38850	0
0.6	0.65	0.625	0	0.42090	0
0.65	0.7	0.675	8	0.45150	4
0.7	0.75	0.725	0	0.46600	0
0.75	0.8	0.775	0	0.49380	0
		Total :	102436	Total:	2032

The second type of risk measure, the number of occurrences of a defined lung function response in the designated population (i.e., asthmatics or asthmatic children) in a year associated with SO_2 concentrations under a given air quality scenario is calculated as follows:

1) From the exposure modeling described in Chapter 8, we obtain the number of exposure occurrences among the population at and above each benchmark level (i.e., 0,ppb, 50 ppb, 100 ppb, etc.);

2) We then calculate the number of exposure occurrences within each 50 ppb exposure "bin" (e.g., < 50 ppb, 50-100 ppb, etc.)[53];

3) We then multiply the number of occurrences in each exposure bin by the response probability corresponding to the midpoint of the exposure bin; and

4) We sum the results across all of the bins.

Similar to the first type of risk measure discussed above, because response probabilities are calculated for each of several percentiles of a probabilistic exposure-response distribution, estimated numbers of occurrences are similarly percentile-specific. The k^th^ percentile number of occurrences, O_k, associated with SO_2 concentrations under a given air quality scenario is:

$$O_k = \sum_{j=1}^{n} N_j \, x \, (R_k \mid e_j) \qquad \text{(equation 9-2)}$$

where:

e_j = (the midpoint of) the j^{th} category of personal exposure to SO_2;

N_j = the number of exposures to e_j ppb SO_2, given ambient SO_2 concentrations under the specified air quality scenario;

$R_k \mid e_j$ = the k^{th} percentile response probability at SO_2 concentration e_j; and

n = the number of intervals (categories) of SO_2 personal exposure concentration.

An example calculation is given in Table 9-2.

---

[53] The final exposure bin was from 0.75 to 0.8 ppm SO_2. In at least one of the alternative standard scenarios, there were a few individuals whose exposure was greater than 0.8 ppm. For anyone whose exposure exceeded 0.8 ppm, we assumed a final bin from 0.8 to 0.85 ppm, and assigned them the midpoint value of that bin, 0.825 ppm. This will result in a slight downward bias in the estimate of risk.

Table 9-2. Example Calculation of Number of Occurrences of Lung Function Response (Defined as an Increase in sRaw ≥ 100%), Among Asthmatics in St. Louis Engaged in Moderate or Greater Exertion Associated with Exposure to SO_2 Concentrations that Just Meet a 99^{th} Percentile 1-Hour, 100 ppb Standard

9.2.2 Exposure Estimates

As noted above, exposure estimates used in the lung function risk assessment were obtained from running the APEX exposure model for the population of individuals with asthma for selected locations encompassing a variety of SO_2 emission source types within two areas in the state of Missouri (i.e., St. Louis and Greene County). Chapter 8 provides additional details about the inputs and methodology used to estimate 5-minute daily maximum peak SO_2 exposures while engaged in moderate or greater exertion for the asthmatic population in these two areas. These 5-minute exposure estimates for asthmatic children and adult asthmatics have been combined separately with probabilistic exposure-response relationships for lung function response associated with 5-minute SO_2 exposures. Only the highest 5-minute peak exposure (with moderate or greater exertion) on each day has been considered in the lung function risk assessment, since the controlled human exposure studies have shown an acute-phase response that was followed by a short refractory period where the individual was relatively insensitive to additional SO_2 challenges.

As described in section 8.8.1, instead of adjusting upward[54] the air quality concentrations to simulate just meeting the current SO_2 standards and potential alternative 1-hr daily maximum standards, to reduce computer processing time, the exposure assessment simulated exposures associated with just meeting various standards by adjusted the health effect benchmark levels by the same factors described for each specific modeling domain and simulated year (see Table 8-11). Since it is a proportional adjustment, the end effect of adjusting concentrations upwards versus adjusting benchmark levels downward within the model is the same. The same follows for where as is concentrations were in excess of an alternative standard level (e.g., 50 ppb for the 99th percentile averaged over three years), only the associated benchmarks are adjusted upwards (i.e., a higher threshold concentration that would simulate lower exposures).

9.2.3 Exposure-Response Functions

Similar to the approach used in the ozone lung function risk assessment (Abt Associates, 2007), we have used a Bayesian Markov Chain Monte Carlo approach to estimate probabilistic exposure-response relationships for lung function decrements associated with 5-minute daily maximum peak exposures while engaged in moderate or greater exertion using the WinBUGS software (Spiegelhalter et al., 1996).[55] The combined data set includes all available individual data from controlled human exposure studies of mild-to-moderate asthmatic individuals exposed for 5- or 10-minutes while engaged in moderate or greater exertion. As noted above, for the purposes of this risk assessment, all of the individual response data, including both 5- and 10-minute exposure durations, have been combined and treated as representing 5-minute responses. Table 9-2 summarizes the available controlled human exposure data that have been used to develop the probabilistic exposure-response relationships for the lung function risk assessment.

The combined data set from Linn et al. (1987, 1988, 1990), Bethel et al. (1983, 1985), Roger et al. (1985), and Kehrl et al. (1987), summarized in Table 9-2, provide data with which to estimate exposure-response relationships between responses defined in terms of sRaw and 5-

---

[54] To evaluate the current and most of the alternative 1-hr standards analyzed, “as is” ambient concentrations were lower than air quality that would just meet the standards.

[55] See Gleman et al. (1995) or Gilks et al. (1996) for an explanation of these methods.

minute exposures to SO_2 at levels of 200, 250, 300, 400, 500, 600, and 1,000 ppb.[56] As noted above, two definitions of response have been used: (1) an increase in sRaw ≥ 100% and (2) an increase in sRaw ≥ 200%.

Likewise, the combined data set from Linn et al. (1987, 1988, 1990), summarized in Table 9-3, provide data with which to estimate exposure-response relationships between responses defined in terms of FEV_1 and 5-minute exposures to SO_2 at levels of 200, 300, 400, and 600 ppb. As noted above, two definitions of response have been used: a decrease in $FEV_1 \geq 15\%$ and a decrease in $FEV_1 \geq 20\%$.

Before being used to estimate exposure-response relationships for 5-minute exposures, the data from these controlled human exposure studies were corrected for the effect of exercising in clean air to remove any systematic bias that might be present in the data attributable to an exercise effect and this correction is reflected in the summary of the response data provided in Table 9-3.[57] Generally, this correction for exercise in clean air is small relative to the total effects measures in the SO_2-exposed cases.

We considered two different functional forms for the exposure-response functions: a 2-parameter logistic model and a probit model. In particular, we used the data in Table 9-3 to estimate the logistic function,

$$y(x;\ \beta,\gamma) = \frac{1}{(1+e^{\beta+\gamma^{*}\ln(x)})} \qquad \text{(equation 9-3)}$$

and the probit function,

$$y(x;\beta,\gamma) = \frac{1}{(2\pi)^{1/2}} \int_{-\infty}^{\beta+\gamma\ln(x)} e^{-t^2/2}\,dt \qquad \text{(equation 9-4)}$$

---

[56] Data from Magnussen et al. (1990) were not used in the estimation of sRaw exposure-response functions because exposures in this study were conducted using a mouthpiece rather than a chamber.

[57] Corrections were subject-specific. A correction was made by subtracting the subject's percent change (in FEV_1 or sRaw) under the no-SO_2 protocol from his or her percent change (in FEV_1 or sRaw) under the given SO_2 protocol, and rounding the result to the nearest integer. For example, if a subject's percent change in sRaw under the no-SO_2 protocol was 110.12% and his percent change in sRaw under the 0.6 ppm SO_2 protocol was 185.92%, then his percent change in sRaw *due to SO_2* is 185.92% - 110.12% = 75.8%, which rounds to 76%.

Table 9-3. Percentage of Asthmatic Individuals in Controlled Human Exposure Studies Experiencing SO_2-Induced Decrements in Lung Function.

[1] Data presented from all references from which individual data were available. Percentage of individuals who experienced greater than or equal to a 100, 200, or 300% increase in specific airway resistance (sRaw), or a 15, 20, or 30% decrease in FEV_1. Lung function decrements are adjusted for effects of exercise in clean air (calculated as the difference between the percent change relative to baseline with excersise/SO_2 and the percent change relative to baseline with excerise/clean air). Quality control of data was performed by two EPA staff scientists.

[2] Responses of mild and moderate asthmatics reported in Linn et al. (1987) have been combined. Data reported only for the first 10 min period of exercise in the first round of exposures.

[3] Analysis includes data from only mild (1988) and moderate (1990) asthmatics who were not receiving supplemental medication.

[4] One subject was not exposed to 1,000 ppb due to excessive wheezing and chest tightness experienced at 500 ppb. For this subject, the values used for 500 ppb were also used for 1,000 ppb under the assumptions that the response at 1,000 ppb would be equal to or greater than the response at 500 ppb..

[5] Indicates studies in which exposures were conducted using a mouthpiece rather than a chamber.

Source: ISA, Table 3-1 (EPA, 2008c, p.3-10).

for each of the four lung function responses defined above, where x denotes the SO_2 concentration (in ppm) to which the individual is exposed, ln(x) is the natural logarithm of x, y denotes the corresponding probability of response (increase in sRaw $\geq$ 100% or $\geq$ 200% or decrease in $FEV_1 \geq$ 15% or $\geq$ 20%), and β and γ are the two parameters whose values are estimated.[58]

We assumed that the number of responses, s_i, out of N_i subjects exposed to a given SO_2 concentration, x_i, has a binomial distribution with response probability given by equation (9-3) when we assume the logistic model and equation (9-4) when we assume the probit model. The likelihood function is therefore

$$L(\beta,\gamma;data) = \prod_i \binom{N_i}{s_i} y(x_i;\beta,\gamma)^{s_i}\,[1-y(x_i;\,\beta,\gamma)]^{N_i-s_i} \quad . \qquad \text{(equation 9-5)}$$

In some of the controlled human exposure studies, subjects were exposed to a given SO_2 concentration more than once. However, because there were insufficient data to estimate subject-specific response probabilities, we assumed a single response probability (for a given definition of response) for all individuals and treated the repeated exposures for a single subject as independent exposures in the binomial distribution.

For each model, we derived a Bayesian posterior distribution using this binomial likelihood function in combination with uniform prior distributions for each of the unknown parameters.[59] We used 4,000 iterations as the "burn-in" period followed by 10,000 iterations, a number sufficient to ensure convergence of the resulting posterior distribution. Each iteration corresponds to a set of values for the parameters of the logistic or probit exposure-response function.

For any SO_2 concentration, x, we could then derive the n^{th} percentile response value, for any n, by evaluating the exposure-response function at x using each of the 18,000 sets of parameter values. The resulting median (50th percentile) exposure-response functions based on the 2-parameter logistic and probit models are shown

---

[58] For ease of exposition, the same two Greek letters are used to indicate two unknown parameters in the logistic and probit models; this does not imply, however, that the values of these two parameters are the same in the two models.

[59] We used the following uniform prior distributions for the 2-parameter logistic model: $\beta \sim U(-10, 0)$; and $\gamma \sim U(-10,0)$; we used the following normal prior distributions for the probit model: $\beta \sim N(0, 1000)$; and $\gamma \sim N(0,1000)$.

together, along with the data used to estimate these functions, for increases in sRaw $\geq$ 100% and $\geq$ 200% and decreases in $FEV_1 \geq$ 15% and $\geq$ 20% in Figures 9-2, 9-3, 9-4, and 9-5, respectively. The 2.5th percentile, median, and 97.5th percentile curves, along with the response data to which they were fit, are shown separately for each of the eight combinations of (four) response definitions and (two) exposure-response models in Appendix C.

We note that there were only limited data with which to estimate the logistic and probit exposure-response functions, and that the logistic and probit models both appear to fit the data equally well. We also note that since the data being fit has already been corrected to account for the lung function response due to exercise in clean air, then the response must by definition be zero associated with 0 ppm SO_2 exposure. As one observes in Figures 9-2 through 9-5 there is very little difference in the exposure-response relationship between the two models, particularly at concentrations at and below about 0.6 ppm. Since nearly all of the risk is attributable to exposures below the 0.6 ppm level, we have chosen to use the 2-parameter logistic exposure-response functions to develop the risk estimates associated with exposure to SO_2 under the different air quality scenarios considered.

9.3 LUNG FUNCTION RISK ESTIMATES

In this section, we present and discuss risk estimates associated with several air quality scenarios, including a recent year of air quality as represented by 2002 monitoring data. In addition, risk estimates are presented for several hypothetical scenarios, equivalent to adjusting air quality upward to simulate just meeting the current annual SO_2 24-hour standard and to adjusting air quality (either up or down) to simulate just meeting potential alternative 98th and 99th percentile daily maximum 1-h standards. As discussed previously in Chapter 5, potential alternative 1-h standards with levels set at 50, 100, 150, 200, and 250 ppb have been included in the risk assessment. Only selected risk estimates are presented in this section and additional risk estimates are presented in Appendix C. Throughout this section and Appendix C the uncertainty surrounding risk estimates resulting from the statistical uncertainty in the SO_2 exposure-response relationships due to sampling error is characterized by ninety-five percent credible intervals around estimates of occurrences, number of asthmatics experiencing one or more lung function responses, and percent of total incidence that is SO_2-related.

Risk estimates for selected lung function responses for all asthmatics and asthmatic children associated with 5-minute exposures to ambient SO_2 concentrations while engaged in moderate or greater exertion are presented in Tables 9-4 through 9-9. Tables 9-4 through 9-6 are for all asthmatics and Tables 9-7 through 9-9 are for asthmatic children. Each table includes risk estimates for both Greene County and St. Louis, Missouri. As discussed in section 9.2.3, the risk assessment included two types of lung function responses (i.e., sRaw and FEV_1) and two levels of response for each type of lung function response (≥ 100 and 200% increase for sRaw and ≥ 15 and 20% decrease for FEV_1). Risk estimates using sRaw as the measure of lung function response are included in this section and additional risk estimates using FEV_1 as the indicator of lung function response are included in Tables 4-3, 4-4, 4-7, and 4-8 in Appendix C.

Tables 9-4 and 9-5 summarize the estimated number and percent of asthmatics that would experience 1 or more lung function responses in a year, where lung function response was defined as ≥ 100% and ≥ 200% increase in sRaw, in all asthmatics associated with ambient 5-minute SO_2 exposures estimated to occur under “as is” air quality (i.e., air quality based on 2002 monitored and modeled SO_2 air quality data) and under air quality representing just meeting the current SO_2 standards and several alternative 1-hour daily maximum SO_2 standards. Tables 9-7 and 9-8 present the same types of estimates for asthmatic children. The median estimates are presented in each cell of the table with the 95% credible intervals based on statistical uncertainty surrounding the SO_2 coefficient in the exposure-response relationship shown in parentheses below the median estimates.

Tables 9-6 and 9-9 summarize the estimated number of occurrences of two defined levels of lung function response (≥ 100% and ≥ 200% increase in sRaw) in all asthmatics and in asthmatic children, respectively, associated with ambient 5-minute SO_2 exposures estimated to occur under "as is" air quality (i.e., air quality based on 2002 monitored and modeled SO_2 air quality data) and under air quality representing just meeting the current SO_2 standards and several alternative 1-hour daily maximum SO_2 standards.

The current primary SO_2 standards include a 24-hour standard set at 0.14 parts per million (ppm), not to be exceeded more than once per year, and an annual standard set at 0.03 ppm, calculated as the arithmetic mean of hourly averages. In St. Louis, SO_2 concentrations that are predicted to occur if the current standards were just met are substantially higher than "as is" air quality (based on 2002 monitoring and modeling data) and also substantially higher than they would be under any of the alternative 1-hr standards considered in this analysis. Consequently, the levels of response that would be seen if the current standard were just met are well above the levels that would be seen under the "as is" air quality scenario or under any of the alternative 1-hr standards – for asthmatics and for asthmatic children, and for all four definitions of lung function response. We also note that the only standard resulting in decreases in lung function responses relative to the "as is" scenario is the 50 ppb, 99th percentile 1-hr daily maximum standard.

**The "as is" exposure scenario was based on monitoring and modeling using 2002 air quality information.

***The current primary SO_2 standards include a 24-hour standard set at 0.14 parts per million (ppm), not to be exceeded more than once per year, and an annual standard set at 0.03 ppm, calculated as the arithmetic mean of hourly averages.

As an illustration of the changes in the number of occurrences of sRaw increases ≥ 100% in all asthmatics across the range of standards analyzed in the St. Louis modeling domain, under the current SO_2 standards the median estimate is 117,900. These estimated occurrences decrease for increasingly more stringent alternative 1-hour standards with the 50 ppb, 99th percentile daily maximium 1-hour standard, the most stringent alternative standard analyzed, reducing the median estimated number of occurrences of this lung function response to 41,300. The pattern of reductions observed for all asthmatics is similar to that observed in asthmatic children.

The estimated occurrences of sRaw responses are much lower in Greene County due both to a smaller population as well as fewer exposure occurrences of elevated 5-minute SO_2 concentrations. We also note that the differences in estimated occurrences of lung function responses associated with all of the air quality scenarios analyzed are much smaller for Greene County than in St. Louis. The minimal differences observed in Greene County among the air quality scenarios analyzed is due to the relatively small differences in the distribution of exposures while engaged in moderate or greater exertion among the air quality scenarios analyzed.

Figures 9-7 (a) and (b) show the contribution of different exposure "bins" or intervals to the total estimated occurrences of SO_2-related lung function responses to 5-minute SO_2 exposures for asthmatics and asthmatic children, respectively, in the St. Louis modeling domain using ≥ 100% increases in sRaw as the indicator of lung function response. Figures 9-8 (a) and (b) show the percent of asthmatics and asthmatic children, respectively, engaged in moderate or greater exertion in St. Louis, MO estimated to experience at least one lung function response in a year, defined as an increase in sRaw ≥ 100%, attributable to exposure to SO_2 in each exposure "bin." Figure 9-6 displays the legend for Figures 9-7 and 9-8 indicating the exposure bins used in the figures. Similar figures are included in Appendix C for lung function responses defined in terms of ≥ 15% and ≥ 20% decrements in FEV_1 for both asthmatics and asthmatic children.

As one observes in Figures 9-8 (a) and (b), for total occurrences of lung function response the pattern of the contribution of exposures from different concentration intervals is very similar. Of course the magnitude of occurrences is smaller for asthmatic children since they are a subset of all asthmatics. For the two most stringent alternative standards, nearly all of the SO_2-related risk is attributable to exposures in the lowest exposure interval (i.e., < 50 ppb), and for the remaining alternative 1-hr standards most of the SO_2-related risk is attributable to

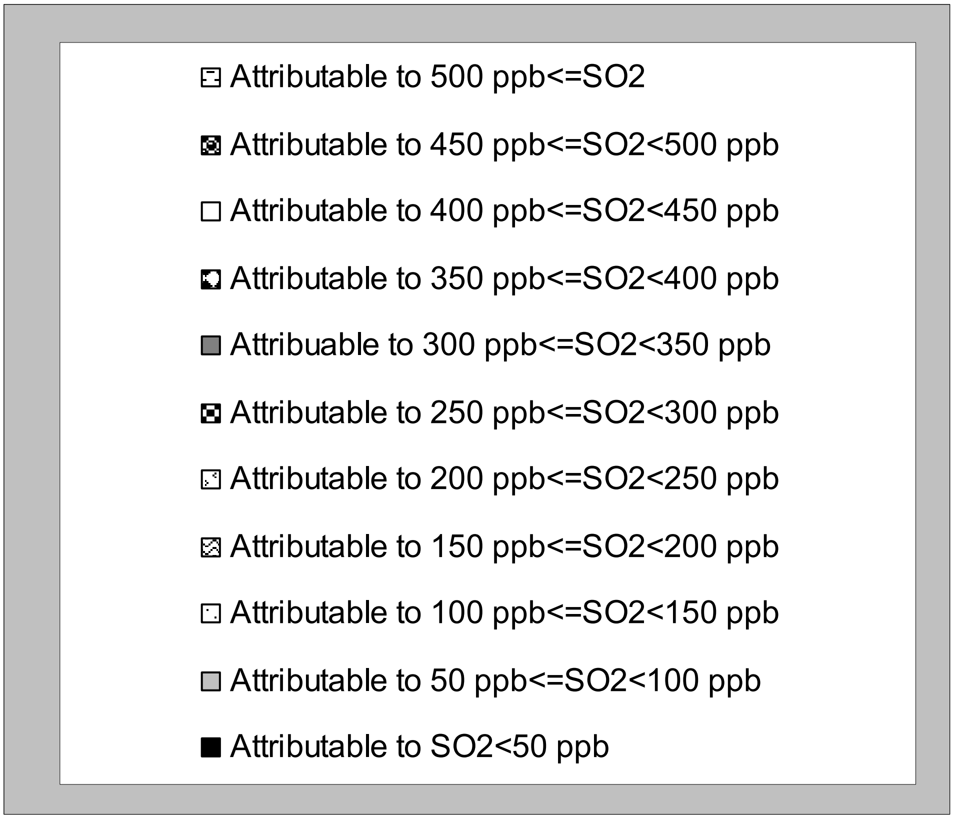

Figure 9-6. Legend for Figures 9-7 and 9-8 Showing Total and Contribution of Risk Attributable to SO2 Exposure Ranges.

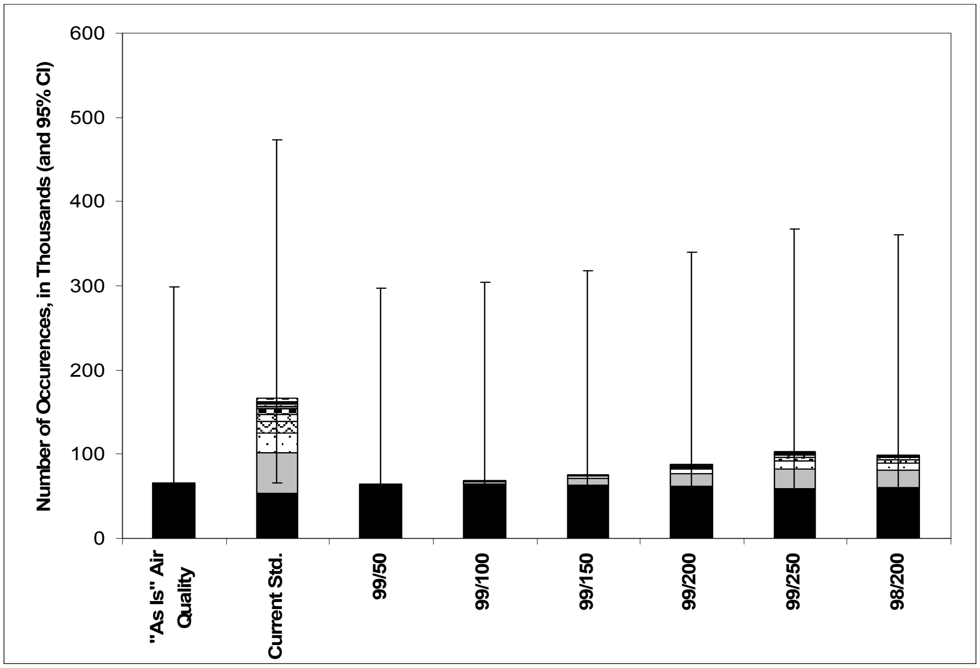
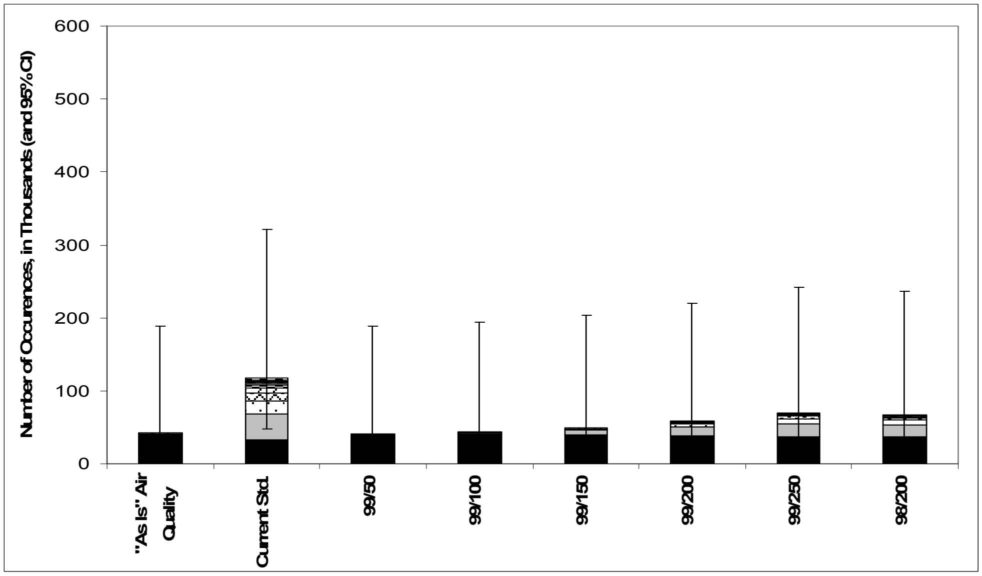
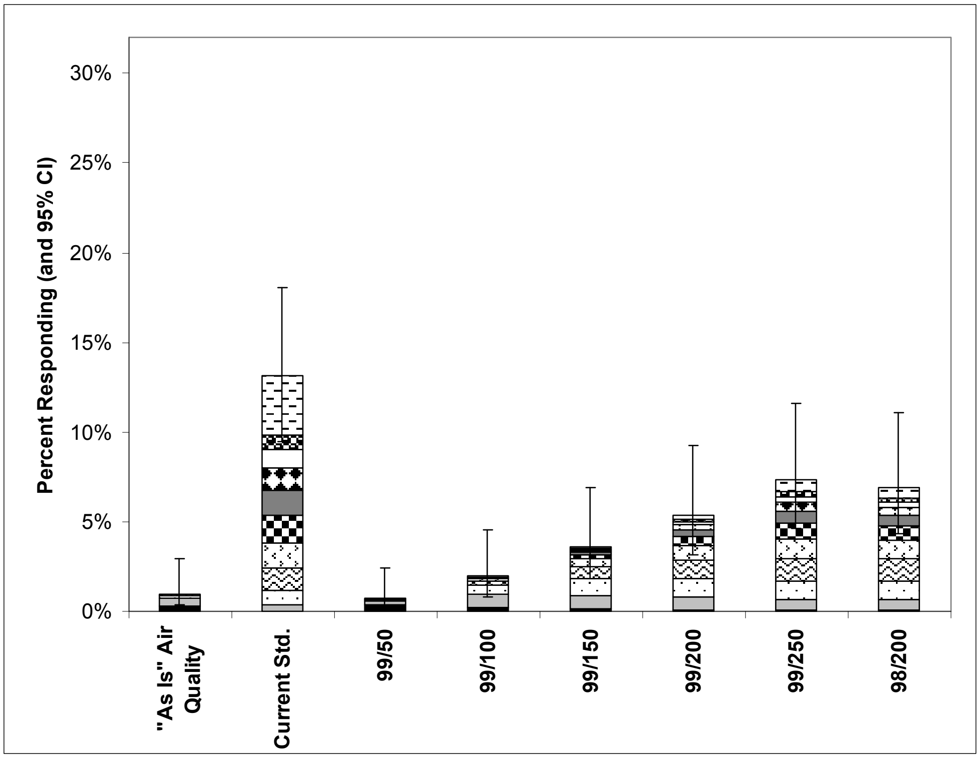


a) Asthmatics

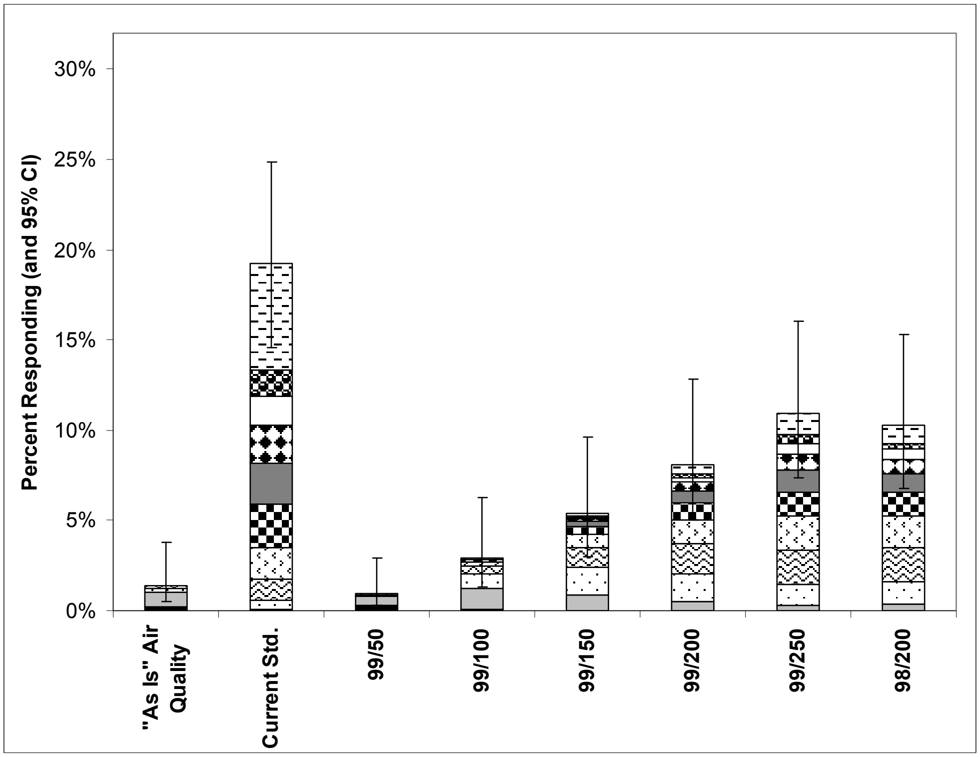


b) Asthmatic children

Figure 9-7. Estimated Annual Number of Occurrences of Lung Function Response (Defined as ≥ 100% increase in sRaw) for Asthmatics and Asthmatic Children Associated with Short-Term (5-minute) Exposures to SO_2 Concentrations Associated with Alternative Air Quality Scenarios – Total and Contribution of 5-Minute SO_2 Exposure Ranges (see Figure 9-6 for legend).



a) Asthmatics



b) Asthmatic children

Figure 9-8. Estimated Percent of of Asthmatics and Asthmatic Children Experiencing One or More Lung Function Responses (Defined as ≥ 100% increase in sRaw) Per Year Associated with Short-Term (5-minute) Exposures to SO_2 Concentrations Associated with Alternative Air Quality Scenarios – Total and Contribution of 5-Minute SO_2 Exposure Ranges (see Figure 9-6 for legend).

exposures < 100 ppb.

We note that, while in several air quality scenarios the great majority of occurrences of lung function response are in the lowest exposure bin, the numbers of individuals with at least one lung function response attributable to exposures in that lowest bin are typically quite small. This is because the calculation of numbers of individuals with at least one lung function response uses individuals' highest exposure only. While individuals may be exposed mostly to low SO_2 concentrations, many are exposed at least occasionally to higher levels. Thus, the percentage of individuals in a designated population with at least one lung function response associated with SO_2 concentrations in the lowest bin is likely to be very small, since most individuals are exposed at least once to higher SO_2 levels. For example, defining lung function response as an increase in sRaw ≥ 100%, under a scenario in which SO_2 concentrations just meet an alternative 1-hour 99th percentile 100 ppb standard, about 93 percent of occurrences of lung function response among asthmatics in St. Louis are associated with SO_2 exposures in the lowest exposure bin (0 – 50 ppb). However, the lowest SO_2 exposure bin accounts for only about 0.2 percent of asthmatics estimated to experience at least 1 SO_2-related lung function response. For this very small percent of the population, the lowest exposure bin represents their highest SO_2 exposures under moderate exertion in a year. Thus Figure 9-7(a) shows virtually all of the occurrences among asthmatics in St. Louis associated with the lowest SO_2 exposure bin; however, Figure 9-8 (a) shows a relatively small proportion of asthmatics in St. Louis experiencing at least one response to be experiencing those responses because of exposures in that lowest exposure bin.

Finally, we observe that the risks are greater for asthmatic children than all asthmatics in terms of percentage of the population experiencing lung function responses in terms of population responding 1 or more times per year.

9.3 CHARACTERIZING UNCERTAINTY AND VARIABILITY

An important issue associated with any population health risk assessment is the characterization of uncertainty and variability (see section 7.4 for definition of uncertainty and variability). Our approach to characterizing uncertainty includes both qualitative and quantitative elements. From a quantitative perspective, the statistical uncertainty surrounding the estimated SO_2 exposure-response relationships due to sampling error are reflected in the credible intervals that have been provided for the risk estimates in this document. Following the same general approach described in section 7.4 and 8.11, the approach for qualitatively evaluating uncertainty was adapted from guidelines outlining how to conduct a qualitative uncertainty characterization (WHO, 2008). This includes an identification of the important uncertainties, an indication of the potential bias direction, and a scaling of the uncertainty using *low, medium,* and *high* categories.

The bias direction indicates how the source of uncertainty was judged to influence estimated lung function responses associated with SO_2 5-minute exposures, either the estimated number or percent of asthmatics experiencing 1 or more lung function responses and total occurrences are likely “over-“ or “under-estimated”. In the instance where two or more types or components of uncertainty result in offsetting direction of influence, the bias was judged as “both.” An “unknown” bias was assigned where there was no evidence reviewed to judge the uncertainty associated with the source. Table 9-10 provides a summary of the sources of uncertainty identified in the health risk assessment, the level of uncertainty, and the overall judged bias of each. A brief summary discussion regarding those sources of uncertainty not already examined in Chapters 7 and 8 is included in the comments section of Table 9-10.

The 5-minute daily maximum exposure estimates for asthmatics and asthmatic children while engaged in moderate or greater exertion is an important input to the lung function response risk assessment. A qualitative characterization of uncertainties associated with the exposure model and the inputs to the exposure model are summarized in Table 8-13 and discussed in section 8.11.

With respect to variability, the lung function risk assessment incorporates some of the variability in key inputs to the analysis by its use of location-specific inputs for the exposure analysis (e.g., location specific population data, air exchange rates, air quality, and temperature data). The extent to which there may be variability in exposure-response relationships for the populations included in the risk assessment residing in different geographic areas is currently unknown. Temporal variability also is more difficult to address, because the risk assessment focuses on some unspecified time in the future. To minimize the degree to which values of inputs to the analysis may be different from the values of those inputs at that unspecified time, we have used the most current inputs available.

Table 9-10. Characterization of Key Uncertainties in the Lung Function Response Health Risk Assessment for St. Louis and Greene County, Missouri

Uncertainty	Direction of Bias	Level of of Uncertainty	Comments
AERMOD Inputs and Algorithms	Unknown	Low-Medium	See Table 8-13 and section 8.12.1
Exposure Model (APEX) Inputs and Algorithms	Unknown	Medium	See Table 8-13 and section 8.12.2
Spatial representation	Unknown	Medium - High	See discussion in section 7.4.4
Air quality adjustment	Unknown	Medium	See discussion in section 7.4.5
Causality	None	Low	The SO_2-related lung function responses have been observed in controlled human exposure studies and, thus there is little uncertainty that SO_2 exposures are responsible for the observed lung function responses.
Use of 2-parameter logistic model to estimate probabilistic exposure-response relationships	Overestimate	Low – within range of data Medium – for levels well below 200 ppb	It was necessary to estimate responses at SO_2 levels both within the range of exposure levels tested (i.e., 200 to 1,000 pppb) as well as below the lowest exposure levels used in free-breathing controlled human exposure studies (i.e., below 200 ppb). We have developed probabilistic exposure-response relationships using two different functional forms (i.e., probit and 2-parameter logistic). As shown in Figures 9-2 through 9-5, the two functional forms result in very similar probabilistic exposure-response relationships for the four health response definitions, and therefore, we used only the logistic model to estimate risks. For the risks attributable to exposure levels below 200 ppb, there is greater uncertainty.
Use of 5- and 10-minute lung function response data to estimate 5-minute lung function risk estimates	Overestimate	Low	The 5-minute lung function risk estimates are based on a combined data set from several controlled human exposure studies, most of which evaluated responses associated with 10-minute exposures. However, since some studies which evaluated responses after 5-minute exposures found responses occurring as early as 5-minutes after exposure, we are using all of the 5- and 10-minute exposure data to represent responses associated with 5-minute exposures. We do not believe that this approach appreciably impacts the risk estimates.
Use of exposure-response data from studies of mild/moderate asthmatics to	Underestimate	Medium	The data set that was used to estimate exposure-response relationships included mild and/or moderate asthmatics. There is uncertainty with regard to how well the population of mild and moderate asthmatics included in the series of SO_2 controlled human exposure studies represent the distribution of mild and moderate asthmatics in the U.S. population. As indicated in the ISA (p. 3-9), the subjects studied

Uncertainty	Direction of Bias	Level of of Uncertainty	Comments
represent all asthmatics			represent the responses “among groups of relatively healthy asthmatics and cannot necessarily be extrapolated to the most sensitive asthmatics in the population who are likely more susceptible to the respiratory effects of exposure to SO_2."
Reproducibility of SO_2-induced lung function response	Unknown	Low	The risk assessment assumes that the SO_2-induced responses for individuals are reproducible. We note that this assumption has some support in that one study (Linn et al., 1987) exposed the same subjects on two occasions to 0.6 ppm and the authors reported a high degree of correlation ($r > 0.7$ for mild asthmatics and $r > 0.8$ for moderate asthmatics, $p < 0.001$), while observing much lower and nonsignificant correlations ($r = 0.0 – 0.4$) for the lung function response observed in the clean air with exercise exposures.
Use of adult asthmatic lung function response data to estimate exposure-response relationships for asthmatic children	Unknown	Low to Medium	Because the vast majority of controlled human exposure studies investigating lung function responses were conducted with adult subjects, the risk assessment relies on data from adult asthmatic subjects to estimate exposure-response relationships that have been applied to all asthmatic individuals, including children. The ISA (section 3.1.3.5) indicates that there is a strong body of evidence that suggests adolescents may experience many of the same respiratory effects at similar SO_2 levels, but recognizes that these studies administered SO_2 via inhalation through a mouthpiece rather than an exposure chamber. This technique bypasses nasal aborption of SO_2 and can result in an increase in lung SO_2 uptake. Therefore, the uncertainty is greater in the risk estimates for asthmatic children.
Exposure history	Unknown	Low	The risk assessment assumes that the SO_2-induced response on any given day is independent of previous SO_2 exposures. For some pollutants (e.g., ozone) prior exposure history can lead to both enhanced and diminished lung function responses depending on the pattern of exposure. This type of information is not available for SO_2 lung function responses.
Assumed no interaction effect of other co-pollutants on SO_2-related lung function responses	Underestimate	Low to Medium	Because the controlled human exposure studies used in the risk assessment involved only SO_2 exposures, it is assumed that estimates of SO_2-induced health responses are not affected by the presence of other pollutants (e.g., $PM_{2.5}$, O_3, NO_2).

9.4 KEY OBSERVATIONS

Presented below are key observations related to the risk assessment for lung function responses in asthmatics and asthmatic children associated with 5-minute exposures to SO_2 while engaged in moderate or greater exertion:

- Lung function responses estimated to result from 5-minute exposures to SO_2 were estimated for two areas in Missouri (i.e., Greene County and St. Louis) for 2002 air quality and for air quality adjusted to simulate just meeting the current suite of annual and 24-hour SO_2 standards and just meeting several alternative 1-hour daily maximum SO_2 standards. While we would expect some differences in estimated SO_2-related lung function responses across different locations due to differences in populations, asthma prevalence rates, location and types of SO_2 sources, and various factors affecting exposure, we believe that the risk estimates do provide a useful perspective on the likely overall magnitude and pattern of lung function responses associated with various SO_2 air quality scenarios in areas within the U.S. that have significant SO_2 point and area sources.

- Only the 50 ppb/99th percentile daily maximum 1-hr standard is estimated to reduce risks in one of the two modeling domains (i.e., St. Louis) relative to the "as is" air quality scenario.

- With respect to total occurrences of lung function responses, where response is defined as $\geq$ 100% increase in sRaw, most of the estimated risk for the St. Louis modeling domain for the potential 1-hr standard alternatives analyzed is due to exposures at and below 100 ppb and for the most stringent standards analyzed (i.e., 50 and 100 ppb), most of the estimated risk is due to exposures at and below 50 ppb.

- In terms of estimated percentage of asthmatics or asthmatic children experiencing 1 or more lung function responses, risks are greater for asthmatic children and risks are attributed to a broader range of exposure intervals, as high as 500 ppb, for some of the standards considered in the assessment.

- Important uncertainties and limitations associated with the risk assessment which were discussed above in section 9.3 and which should be kept in mind as one considers the quantitative risk estimates include:
  - uncertainties affecting the exposure estimates which are described in section 8.11 and which are an important input to the risk assessment;
  - uncertainties related to how changes in population, activity patterns, air quality, and other factors over time might impact the exposure estimates which are an important input to the risk assessment;
  - uncertainties associated with the air quality adjustment procedure that was used to simulate just meeting the current annual and several alternative 1-h daily maximum standards;

- statistical uncertainty due to sampling error which is characterized in the assessment;
- uncertainty about the shape of the exposure-response relationship for lung function responses at levels well below 200 ppb, the lowest level examined in free-breathing single pollutant controlled human exposure studies;
- uncertainty with respect to how well the estimated exposure-response relationships reflect asthmatics with more severe disease than those tested in chamber studies;
- uncertainty about whether the presence of other pollutants in the ambient air would enhance the SO_2-related responses observed in the controlled human exposure studies;
- uncertainty about the extent to which the risk estimates presented for the two modeled areas in Missouri are representative of other locations in the U.S. with significant SO_2 point and area sources.

10.0 EVIDENCE- AND EXPOSURE/RISK-BASED CONSIDERATIONS RELATED TO THE PRIMARY SO_2 NAAQS

10.1 INTRODUCTION

This chapter considers the scientific evidence in the ISA (EPA, 2008a) and the air quality, exposure and risk characterization results presented in this document as they relate to the adequacy of the current SO_2 primary NAAQS and potential alternative primary SO_2 standards. The available scientific evidence includes epidemiologic, controlled human exposure, and animal toxicological studies. The SO_2 air quality, exposure, and risk analyses described in Chapters 7-9 of this document include characterization of air quality, exposure, and health risks associated with recent SO_2 concentrations and with SO_2 concentrations adjusted to simulate scenarios just meeting the current suite of standards and potential alternative 1-hour standards. In considering the scientific evidence and the exposure- and risk-based information, we have also considered relevant uncertainties. Section 10.2 of this Chapter presents our general approach to considering the adequacy of the current standards and potential alternative standards. Sections 10.3 and 10.4 focus on evidence- and exposure-/risk-based considerations related to the adequacy of the current 24-hour and annual standards respectively, while section 10.5 focuses on such considerations related to potential alternative standards (in terms of the indicator, averaging time, form, and level).

These considerations are intended to inform the Agency's policy assessment of a range of options with regard to the SO_2 NAAQS. We note that the final decision on retaining or revising the current SO_2 primary standard, taking into account the Agency's policy assessment, is largely a public health policy judgment. A final decision will draw upon scientific information and analyses about health effects, population exposure and risks, and policy judgments about the appropriate response to the range of uncertainties that are inherent in the scientific evidence and analyses. Our approach to informing these judgments, discussed more fully below, is based on a recognition that the available health effects evidence reflects a continuum consisting of ambient levels at which scientists generally agree that health effects are likely to occur through lower levels at which the likelihood and magnitude of the response become increasingly uncertain. This approach is consistent with the requirements of the NAAQS provisions of the Act and with how EPA and the courts have historically interpreted the Act. These provisions require the

Administrator to establish primary standards that, in the Administrator's judgment, are requisite to protect public health with an adequate margin of safety. In so doing, the Administrator seeks to establish standards that are neither more nor less stringent than necessary for this purpose. The Act does not require that primary standards be set at a zero-risk level but rather at a level that avoids unacceptable risks to public health, including the health of at risk populations.

10.2 GENERAL APPROACH

This section describes the general approach that staff is taking to inform decisions regarding the need to retain or revise the current SO_2 NAAQS. The current standards, a 24-hour average of 0.14 ppm, not to be exceeded more than one time per year, and an annual average of 0.03 ppm were retained by the Administrator in the most recent review completed in 1996 (61 FR 25566). The decision to retain the 24-hour standard was largely based on an assessment of epidemiological studies that supported a likely association between 24-hour average SO_2 exposure and daily mortality, aggravation of bronchitis, and small, reversible declines in children's lung function (EPA 1982, 1994a). Similarly, the decision to retain the annual standard (see section 10.4) was largely based on an assessment of epidemiological studies finding an association between respiratory symptoms/illnesses and annual average SO_2 concentrations (EPA 1982, 1994a).

The previous review of the SO_2 NAAQS also questioned whether an additional short-term standard (e.g., 5-minute) was necessary to protect against short-term peak SO_2 exposures. Based on the scientific evidence, the Administrator judged that repeated exposures to 5-minute peak levels ≥ 600 ppb could pose a risk of significant health effects for asthmatic individuals at elevated ventilation rates (61 FR 25566). The Administrator also concluded that the likely frequency of such effects should be a consideration in assessing the overall public health risks. Based upon an exposure analysis conducted by EPA (see section 1.1.3), the Administrator concluded that exposure of asthmatics to SO_2 levels that could reliably elicit adverse health effects was likely to be a rare event when viewed in the context of the entire population of asthmatics, and therefore did not pose a broad public health problem for which a NAAQS would be appropriate (61 FR 25566). On May 22, 1996, EPA published its final decision to retain the existing 24-hour and annual standards and not to promulgate a 5-minute standard (61 FR 25566). The decision not to set a 5-minute standard was ultimately challenged by the American Lung Association and remanded back to EPA for further explanation on January 30, 1998 by the DC

Court of Appeals (see section 1.1.1). Specifically, the court required EPA to provide additional rationale to support the Agency judgment that 5-minute peaks of SO_2 do not pose a public health problem when viewed from a national prospective even though those peaks would likely cause adverse health effects in a subset of exposed asthmatics.

To inform the range of options that the Agency will consider in the current review of the primary SO_2 NAAQS, the general approach we have adopted builds upon the approaches used in reviews of other criteria pollutants, including the most recent reviews of the Pb, O_3, and PM NAAQS (EPA, 2007i; EPA, 2007e; EPA, 2005). As in these other reviews, we consider the implications of placing more or less weight or emphasis on different aspects of the scientific evidence and the exposure/risk-based information, recognizing that the weight to be given to various elements of the evidence and exposure/risk information is part of the public health policy judgments that the Administrator will make in reaching decisions on the standard.

A series of general questions frames our approach to considering the scientific evidence and exposure/risk-based information. First, our consideration of the scientific evidence and exposure/risk-based information with regard to the adequacy of the current standard is framed by the following questions:

- To what extent does evidence and exposure/risk-based information that has become available since the last review reinforce or call into question evidence for SO_2-associated effects that were identified in the last review?

- To what extent has evidence for different health effects and/or sensitive populations become available since the last review?

- To what extent have uncertainties identified in the last review been reduced and/or have new uncertainties emerged?

- To what extent does evidence and exposure/risk-based information that has become available since the last review reinforce or call into question any of the basic elements of the current standard?

To the extent that the available evidence and exposure/risk-based information suggests it may be appropriate to consider revision of the current standards, we consider that evidence and information with regard to its support for consideration of a standard that is either more or less protective than the current standard. This evaluation is framed by the following questions:

- Is there evidence that associations, especially causal or likely causal associations, extend to ambient SO_2 concentrations as low as, or lower than, the concentrations that have previously been associated with health effects? If so, what are the important uncertainties associated with that evidence?

- Are exposures above benchmark levels and/or health risks estimated to occur in areas that meet the current standard? If so, are the estimated exposures and health risks important from a public health perspective? What are the important uncertainties associated with the estimated risks?

To the extent that there is support for consideration of a revised standard, we then consider the specific elements of the standard (indicator for gaseous SOx, averaging time, form, and level) within the context of the currently available information. In so doing, we address the following questions:

- Does the evidence provide support for considering a different indicator for gaseous SO_x?

- Does the evidence provide support for considering different averaging times?

- What ranges of levels and forms of alternative standards are supported by the evidence, and what are the associated uncertainties and limitations?

- To what extent do specific averaging times, levels, and forms of alternative standards reduce the estimated exposures above benchmark levels and risks attributable to SO_2, and what are the uncertainties associated with the estimated exposure and risk reductions?

The following discussion addresses the questions outlined above and presents staff's conclusions regarding the scientific evidence and the exposure-/risk-based information specifically as they relate to the current and potential alternative standards. This discussion is intended to inform the Agency's consideration of policy options that will be presented during the rulemaking process, together with the scientific support for such options. Sections 10.3 and 10.4 consider the adequacy of the current standards while section 10.5 considers potential alternative standards in terms of indicator, averaging time, form, and level. Each of these sections considers key conclusions as well as the uncertainties associated with the evidence and exposure/risk analyses.

10.3 ADEQUACY OF THE CURRENT 24-HOUR STANDARD

10.3.1 Introduction

In the last review of the SO_2 NAAQS, retention of the 24-hour standard was based largely on epidemiological studies conducted in London in the 1950's and 1960's. The results of those studies suggested an association between 24-hour average levels of SO_2 and increased daily mortality and aggravation of bronchitis when in the presence of elevated levels of PM (53 FR14927). Additional epidemiological evidence suggested that elevated SO_2 levels were associated with the possibility of small, reversible declines in children's lung function (53 FR14927). However, it was noted that in the locations where these epidemiological studies were conducted, high SO_2 levels were usually accompanied by high levels of PM- thus making it difficult to disentangle the individual contribution each pollutant had on these health outcomes. It was also noted that rather than 24-hour average SO_2 levels, the health effects observed in these studies may have been related, at least in part, to the occurrence of shorter-term peaks of SO_2 within a 24-hour period (53 FR14927).

10.3.2 Evidence-based considerations

In discussing the adequacy of the current 24-hour NAAQS, we first note the conclusions presented in the ISA with regard to short-term SO_2 effects on mortality and respiratory morbidity. As mentioned above, the previous review described positive associations between SO_2 and mortality, when in the presence of elevated PM levels. In this review, based on numerous studies conducted since the last review, the ISA characterizes the evidence of an association between short-term ($\geq$ 1-hour) SO_2 levels and mortality as being "suggestive of a causal relationship." The ISA consistently finds positive associations between short-term SO_2 levels and mortality, but these effect estimates are generally diminished in multi-pollutant models- an indication that results may be confounded by the presence of co-pollutants (ISA Table 5-3).

With respect to respiratory morbidity, the previous review of the SO_2 NAAQS described possible associations between 24-hour SO_2 levels and small reversible declines in children's lung function and aggravation of bronchitis. The current ISA concludes that there is sufficient evidence to infer "a causal relationship between respiratory morbidity and short-term exposure to SO_2 (ISA section 5.2)." The ISA states that the strongest evidence for this judgment is from human exposure studies demonstrating increased respiratory symptoms and decreased lung function in exercising asthmatics exposed for 5-10 minutes to ≥ 200 ppb SO_2 (ISA section 5.2). Supporting this conclusion is a larger body of epidemiological studies published since the last review observing associations between ≥1-hour SO_2 concentrations and respiratory symptoms, ED visits, and hospital admissions (ISA section 5.2).

In considering the adequacy of the current 24-hour standard, we further note that many epidemiological studies demonstrating positive associations between ambient SO_2 and respiratory symptoms, ED visits, and hospitalizations were conducted in areas where SO_2 concentrations met the level of the current 24-hour (as well as the annual; see section 10.4) NAAQS. With regard to these epidemiological studies, we note that the ISA characterizes the evidence for respiratory effects as consistent and coherent. The evidence is consistent in that associations are reported in studies conducted in numerous locations and with a variety of methodological approaches (ISA, section 5.2). It is coherent in the sense that respiratory symptoms results from short-term (≥ 1-hour) epidemiological studies are generally in agreement with respiratory symptom results from controlled human exposure studies of 5-10 minutes. These results are also coherent in that the respiratory effects observed in controlled human exposure studies of 5-10 minutes provides a basis for a progression of respiratory morbidity that could lead to the ED visits and hospitalizations observed in epidemiological studies (ISA section 5.2). Moreover, the ISA states that several of the more precise effect estimates in these studies are statistically significant (ISA, section 5.2).

However, it should be noted that interpretation of the epidemiological literature is complicated by the fact that SO_2 is but one component of a complex mixture of pollutants present in the ambient air. The matter is further complicated by the fact that SO_2 is a precursor to sulfate, which can be a principle component of PM. Ultimately, this uncertainty calls into question the extent to which effect estimates from epidemiological studies reflect the independent contributions of SO_2 to the adverse respiratory outcomes assessed in these studies. In order to provide some perspective on this uncertainty, the ISA evaluates epidemiological studies that employ multi-pollutant models. The ISA concludes that these analyses indicate that although copollutant adjustment has varying degrees of influence on SO_2 effect estimates, the effect of SO_2 on respiratory health outcomes appears to be generally robust and independent of the effects of gaseous copollutants, including NO_2 and O_3 (ISA, section 5.2). With respect to PM_{10}, evidence of an independent SO_2 effect on respiratory health is less consistent, with about half of the positive ED visit and hospitalization results becoming negative (although result were not statistically significantly negative) after inclusion of PM_{10} in regression models (ISA section 3.1.4.6). In epidemiological studies of respiratory symptoms, inclusion of PM_{10} in multipllutant models often resulted in the SO_2 effect estimate losing statistical significance (although the effect estimate may have remained positive, and relatively unchanged; ISA section 3.1.4.1). The ISA also concludes that SO_2-effect estimates generally remained robust in the limited number of studies that included $PM_{2.5}$ and/or $PM_{10-2.5}$ in multipolutant models (ISA section 3.1.4.6). Taken together, the ISA finds studies employing multi-pollutant models do suggest that SO_2 has an independent effect on respiratory morbidity outcomes (ISA, section 5.2). Thus, the results of experimental and epidemiological studies form a plausible and coherent data set that supports a relationship between SO_2 exposures and respiratory morbidity endpoints.

10.3.3 Air Quality, exposure and risk-based considerations

In addition to the evidence-based considerations described above, staff has considered the extent to which exposure- and risk-based information can inform decisions regarding the adequacy of the current 24-hour SO_2 standard, taking into account key uncertainties associated with the estimated exposures and risks. For this review, we have employed three approaches. In the first approach, SO_2 air quality levels were used as a surrogate for exposure. In the second approach, modeled estimates of human exposure were developed for all asthmatics and asthmatic children living in Greene County, MO and the St. Louis modeling domain in MO. Notably, this second approach considers time spent in different microenvironments, as well as time spent at elevated ventilation rates. In each of the first two approaches, health risks have been characterized by comparing estimates of air quality or exposure to potential 5-minute health effect benchmarks These benchmarks are based on controlled human exposure studies involving known SO_2 exposure levels and corresponding decrements in lung function, and/or increases in respiratory symptoms in asthmatics at elevated ventilation rates (e.g. while exercising; see section 6.2 for further discussion of benchmark levels). In addition to these analyses, staff also conducted a quantitative risk assessment for lung function responses associated with 5-minute exposures to characterize SO_2-related health risks. This assessment combined outputs from the exposure analysis with estimated exposure-response functions derived from the controlled human exposure literature to estimate the number, and percent of exposed asthmatics that would experience moderate or greater lung function responses per year and to estimate the total number of occurrences of these lung function responses per year (Chapter 9).

In making judgments as to whether SO_2-induced effects should be regarded as adverse to the health of individuals, staff has relied upon the guidelines published by the American Thoracic Society (ATS) (ATS 2000) and conclusions from the ISA. The ATS notes that an air pollution-induced shift in a population distribution of a given health-related endpoint (e.g., lung function) should be considered adverse, even if this shift does not result in the immediate occurrence of illness in any one individual in the population (ATS 2000). The ATS also recommends that transient loss in lung function with accompanying respiratory symptoms attributable to air pollution be considered adverse. However, the ISA cautions that symptom perception is highly variable among asthmatics even during severe episodes of asthmatic bronchoconstriction, and that an asymptomatic decrease in lung function may pose a significant health risk to asthmatic individuals as it is less likely that these individuals will seek treatment (ISA section 3.1.3). In addition, regarding decrements in lung function and respiratory symptoms, we note the following:

- 5-30% of exercising asthmatics will experience moderate or greater lung function decrements (i.e. ≥ 100% increase in sRaw and/or a ≥ 15% decrease in FEV_1) following exposure to 200- 300 ppb SO_2 for 5-10 minutes (ISA, section 3.1).

- 20-60% of exercising asthmatics will experience moderate or greater lung function decrements (i.e ≥ 100% increase in sRaw and/or a ≥ 15% decrease in FEV_1) following exposure to 400- 1000 ppb SO_2 for 5-10 minutes (ISA, Table 5-3).

- At concentrations ≥ 400 ppb, moderate or greater statistically significant decrements in lung function are frequently associated with respiratory symptoms (ISA, section 3.1).

- Over 20 million people in the U.S. have asthma (ISA, for NOx, Table 4.4-1).

Overall, based on the ATS guidance mentioned above and the potential size of the population affected, staff suggests that the Agency may want to consider moderate or greater SO_2-induced lung function decrements (i.e. lung function responses) and/or related increases in respiratory symptoms as representing adverse health effects for the asthmatic population.

10.3.3.1 Key Uncertainties

The way in which exposure and risk results will inform ultimate decisions regarding the SO_2 standard will depend upon the weight placed on each of the analyses when uncertainties associated with those analyses are taken into consideration. Sources of uncertainty associated with each of the analyses (air quality, exposure, and quantitative risk) are briefly presented below and are described in more detail in Chapters 7-9 of this document. Although we are discussing these uncertainties within the context of the adequacy of the 24-hour standard, they apply equally to consideration of the annual, as well as alternative 1-hour standards.

Air Quality Analysis

A number of key uncertainties should be considered when interpreting air quality results with regard to decisions on the standards. Such uncertainties are highlighted below, and these, as well as other sources of uncertainty are discussed in greater depth in section 7.4 of this document.

- In order to simulate just meeting the current standards, and many of the alternative 1-hour standards, an upward adjustment of recent ambient SO_2 concentrations was required. We note that this adjustment does not reflect a judgment that levels of SO_2 are likely to increase under the current standard or any of the potential alternative standards under consideration. Rather, these adjustments reflect the fact that the current standard, as well as some of the alternatives under consideration, could allow for such increases in ambient SO_2 concentrations. In adjusting air quality to simulate just meeting these standards, we have assumed that the overall shape of the distribution of SO_2 concentrations would not change. While we believe this is a reasonable assumption in the absence of evidence supporting a different distribution and we note that available analyses support this approach (Rizzo, 2008), we recognize this as an important uncertainty. It may be an especially important uncertainty for those scenarios where considerable upward adjustment is required to simulate just meeting one or more of the standards.

- In recognizing the limited geographic span of monitors reporting 5-minute maximum SO_2 levels, staff developed an approach to statistically estimate 5-minute SO_2 concentrations from 1-hour average SO_2 concentrations. This method uses monitors that reported both 5-minute and 1-hour average SO_2 concentrations and the associated variability in their measurements (from the years 1997-2007) as a surrogate for variability in source characteristics that may impact SO_2 levels at a given monitor. As a result, this method assumes that source emissions present at the time of the measurement are similar to more recent source emissions. This could add uncertainty in the number of estimated exceedances in areas where source emissions have changed. However, peak-to-mean ratios (PMRs) do not show any apparent trend with monitoring year and have averaged around 1.6 when considering the 5-minute measurement data over the period analyzed. This indicates that the use of the older ambient monitoring data in developing the statistical model used for estimating 5-minute concentrations may have a negligible impact on the predicted concentrations. In addition, there is uncertainty in the extent to which the relationships used to estimate 5-minute maximum concentrations from measured 1-hour average concentrations reflects the actual relationship in the locations and over the time periods of interest. However, we note general agreement between analyses restricted to the subset monitors where 5-minute maximum levels were actually reported, and corresponding analyses where statistically estimated 5-minute maximum concentrations were derived from monitors reporting 1-hour concentrations (e.g. see Figures 7-12 and 7-15). Thus, measured and modeled results in the air quality analysis appear to be in general agreement.

- The human exposure studies that form the basis for potential health effect benchmark levels include mild and moderate asthmatics. For ethical reasons, more severely affected asthmatics are not included in these analyses. This is important because severe asthmatics may be more susceptible than mild or moderate asthmatics to the respiratory effects of SO_2 exposure. Therefore, the potential health effect benchmarks based on these studies could underestimate risks in populations with greater susceptibility. Although approaches to classifying asthma severity differ, some estimates indicate that over half of asthmatics could be classified as moderate or severe (Fuhlbrigge et al., 2002; Stout et al., 2006).

St Louis and Green Counties Exposure Analysis

A number of key uncertainties should be considered when interpreting the St. Louis and Greene County exposure results with regard to decisions on the standards. Such uncertainties are highlighted below, and these, as well as other sources of uncertainty are also discussed in greater depth in section 8.11 of this document.

- Details regarding the modeling of non-point and background area sources in AERMOD are addressed in section 8.4.3. In brief, two of the main uncertainties associated with these sources are the temporal and spatial profiles used in simulating their releases. Staff obtained emission strengths from the 2002 National Emissions Inventory (NEI). However, only annual total emissions at the county level are provided. Thus, to better parameterize these emissions for the hourly, census block-level dispersion modeling, we relied on additional data and an optimization algorithm (described in section 8.4.3). Overall, the uncertainties associated with the temporal and spatial profiles of SO_2 emissions is characterized as a medium uncertainty and is thought to bias concentrations of SO_2 in both directions (see Table 8-13).

- Commuting pattern data were derived from the 2000 U.S. Census. The commuting data addresses only home-to-work travel. A few simplifying assumptions needed to be made to allow for practical use of this data base to reflect a simulated individual's commute. First, there were a few commuter identifications that necessitated a restriction of their movement from a home block to a work block. This is not to suggest that they never travelled on roads, only that their home and work blocks were the same. This includes the population not employed outside the home, individuals indicated as commuting within their home block, and individuals that commute over 120 km a day. This could lead to either over- or under-estimations in exposure if they were in fact to visit a block with either higher or lower SO_2 concentrations. Given that the number of individuals who meet these conditions is likely a small fraction of the total population, and that the bias with respect to SO_2 exposures above health benchmark levels is likely in either direction, the overall uncertainty is considered low.

- Although several of the APEX microenvironments account for time spent in travel, the travel is assumed to always occur in basically a composite of the home and work block. No other provision is made for the possibility of passing through other census blocks during travel. This could contribute to bias in SO_2 exposures above benchmark levels in either direction. In addition, the commuting route (i.e., which roads individuals are traveling on during the commute) is not accounted for and this may also contribute to bias in either direction.

- The best estimate of asthma prevalence was generated using a comprehensive data set that provides variability in asthma prevalence rates based on age (CDC, 2007). However, it is possible that this data overestimates asthma prevalence rates in some areas while underestimating it in others. It is unknown how this uncertainty would bias exposure results.

St Louis and Green Counties Quantitative Risk Analysis

A number of key uncertainties should be considered when interpreting the St. Louis and Greene County quantitative risk estimated for lung function responses with regard to decisions on the standards. Such uncertainties are highlighted below, and these, as well as other sources of uncertainty are also discussed in greater depth in section 9.3 of this document.

- It was necessary to estimate responses at SO_2 levels below the lowest exposure levels used in the controlled human exposure studies (i.e., below 200 ppb). We have developed probabilistic exposure-response relationships using two different functional forms (i.e., probit and 2-parameter logistic), but nonetheless there remains greater uncertainty in responses below 0.2 ppm because of the lack of experimental data.

- The risk assessment assumes that the SO_2-induced responses for individuals are reproducible. We note that this assumption has some support in that one study (Linn et al., 1987) exposed the same subjects on two occasions to 600 ppb and the authors reported a high degree of correlation while observing a much lower correlation for the lung function response observed in the clean air with exercise exposure.

- Because the vast majority of controlled human exposure studies investigating lung function responses were conducted with adult subjects, the risk assessment relies on data from adult asthmatic subjects to estimate exposure-response relationships that have been applied to all asthmatic individuals, including children. The ISA (section 3.1.3.5) indicates that there is a strong body of evidence that suggests adolescents may experience many of the same respiratory effects at similar SO_2 levels, but recognizes that these studies administered SO_2 via inhalation through a mouthpiece (which can result in an increase in lung SO_2 uptake) rather than an exposure chamber. Therefore, the uncertainty is greater in the risk estimates for asthmatic children.

- Because the controlled human exposure studies used in the risk assessment involved only SO_2 exposures, it is assumed that estimates of SO_2-induced health responses are not affected by the presence of other pollutants (e.g., $PM_{2.5}$, O_3, NO_2).

10.3.3.2 Assessment Results

As previously mentioned, the ISA finds the evidence for an association between respiratory morbidity and SO_2 exposure to be "sufficient to infer a causal relationship" (ISA section 5.2) and that the "definitive evidence" for this conclusion comes from the results of controlled human exposure studies demonstrating decrements in lung function and/or respiratory symptoms in exercising asthmatics (ISA, section 5.2). Accordingly, the exposure and risk analyses presented in this document focused on exposures and risks associated with 5-minute peaks of SO_2 in excess of potential health effect benchmark values derived from the human exposure literature. These potential health effect benchmark levels span a range of 100 to 400 ppb. In brief, the 400 ppb benchmark represents the lowest exposure level in free breathing chamber studies at which moderate or greater lung function responses are consistently accompanied by respiratory symptoms in exercising asthmatics. The 100 ppb benchmark takes into consideration that the LOEL for moderate or greater lung function decrements in exercising asthmatics participating in free breathing chamber studies is 200 ppb, but that the asthmatics participating in these studies might not represent the most SO_2 sensitive population (e.g. severe asthmatics are excluded from these studies). Additional discussion concerning the selection of the potential health effect benchmark levels can be found in section 6.2 of this document.

Air Quality Assessment

The results of our air quality assessment provide additional perspective on the public health impacts of exposure to ambient levels of SO_2. In considering these results, we first note that the benchmark values derived from the controlled human exposure literature are associated with a 5-minute averaging time, but very few monitors in the U.S. report measured 5-minute concentrations since it is not required. As a result, staff developed a statistical relationship to estimate the highest 5-minute level in an hour, given a reported 1-hour average SO_2 concentration (see section 7.2.3). Thus, many of the outputs of the air quality analysis are presented with respect to statistically estimated 5-minute concentrations in excess of potential health effect benchmark values. Results of these analyses, as they relate to the adequacy of the current standards, are discussed below.

A key output of the air quality analysis (i.e. where air quality serves as a surrogate for exposure) is the predicted number of statistically estimated 5-minute daily maximum SO_2 concentrations above benchmark levels given air quality simulated to just meet the level of the current 24-hour or annual SO_2 standards, whichever is controlling for a given county. Under this scenario, in 40 counties selected for detailed analysis, we note that the predicted mean number of 5-minute daily maximum concentrations > 400 ppb ranges from 1-102 days per year, with most counties in this analysis experiencing a mean of at least 20 days per year when 5-minute daily SO_2 concentrations exceed 400 ppb (Table 7-13). In addition, the predicted mean number of 5-minute daily maximum concentrations >200 ppb ranges from 22-171 days per year, with about half of the counties in this analysis experiencing ≥ 70 days per year when 5-minute daily maximum SO_2 concentrations exceed 400 ppb (Table 7-11).

Exposure Assessment

When considering the Missouri exposure results as they relate to the adequacy of the current standard, we focus on the number of asthmatics at elevated ventilation rates estimated to experience at least one benchmark exceedence given air quality that is adjusted upward to simulate just meeting the current 24-hour standard (i.e. the controlling standard in St. Louis). We note that in these analyses, if SO_2 concentrations are such that the St Louis area just meets the current standard, approximately 13% (~14,000) of asthmatics would be estimated to experience at least one SO_2 exposure concentration greater than or equal to the 400 ppb benchmark level while at elevated ventilation rates (Figure 8-17). Similarly, approximately 46% (~48,000) of asthmatics would be expected to experience at least one SO_2 exposure concentration greater than or equal to the 200 ppb benchmark level while at elevated ventilation rates. When the St. Louis results are restricted to asthmatic children at elevated ventilation rates, approximately 25% (~10,000) and 73% (~31,000) of these children would be estimated to experience at least one SO_2 exposure concentration greater than or equal to the 400 ppb and 200 ppb benchmark levels, respectively (Figure 8-17).

In Greene County, results of the exposure analysis indicate that when air quality is adjusted to just meet the current 24-hour standard, considerably fewer asthmatics are exposed to SO_2 concentrations in excess of benchmark levels. An estimated <0.1% (13) and 0.6% (139) of asthmatics at elevated ventilation rates would be expected to experience at least one SO_2 exposure concentration greater than or equal to the 400 ppb and 200 ppb benchmarks respectively (Figure 8-14). When the Greene County results are restricted to asthmatic children at elevated ventilation rates, approximately <0.1% (4) and 0.9% (72) of these children would be estimated to experience at least one SO_2 exposure concentration greater than or equal to the 400 ppb and 200 ppb benchmark levels respectively (Figure 8-14).

Risk results

When considering the St. Louis risk results as they relate to the adequacy of the current standard, we note the percent of asthmatics at elevated ventilation rates likely to experience at least one lung function response given air quality that is adjusted upward to simulate just meeting the current standards. Under this scenario, 13.1% (~13,000) of exposed asthmatics at elevated ventilation rates are estimated to experience at least one moderate lung function response (defined as an increase in sRaw ≥ 100% (Table 9-5)). Furthermore, 5.4% (~5,500) of exposed asthmatics at elevated ventilation rates are estimated to experience at least one large lung function response (defined as an increase in sRaw ≥ 200% (Table 9-5)). We also note that estimates from this analysis indicate that the percentage of exposed asthmatic children in the St. Louis modeling domain estimated to experience at least one moderate or large lung function response is somewhat greater than the percentage for the asthmatic population as a whole (Table 9-8).

When considering the Greene County risk results, as in the exposure analysis, we note that compared to St. Louis, there are far fewer exposures in Greene County, and therefore, there are far fewer numbers of asthmatics predicted to have a given lung function response. That is, in Greene County 1% (210) of exposed asthmatics at elevated ventilation rates are estimated to experience at least one moderate lung function response (Table 9-5). Furthermore, 0.3% (70) of exposed asthmatics at elevated ventilation rates are estimated to experience at least one large lung function response (Table 9-5). Similar to St. Louis, the percentage of exposed asthmatic children estimated to experience at least one moderate or large lung function response is greater than the percentage for the asthmatic population as a whole (Table 9-8).

10.3.3.3 Conclusions regarding the adequacy of the 24-hour standard

As noted above, several lines of scientific evidence are relevant to consider when making a decision regarding the adequacy of the current 24-hour standard to protect the public health. These include causality judgments made in the ISA, as well as the human exposure and epidemiological evidence supporting those judgments. In particular, we note that numerous epidemiological studies reporting positive associations between ambient SO_2 and respiratory morbidity endpoints were conducted in locations that met the current 24-hour standard. To the extent that these considerations are emphasized, the adequacy of the current standard to protect the public health would clearly be called into question. This suggests consideration of a revised 24-hour standard and/or that an additional shorter-averaging time standard may be needed to provide additional health protection for sensitive groups, including asthmatics and individuals who spend time outdoors at elevated ventilation rates. Moreover, this conclusion also suggests that an alternative SO_2 standard(s) should protect against health effects ranging from lung function responses and increased respiratory symptoms following 5-10 minute peak SO_2 exposures, to increased respiratory symptoms and respiratory-related ED visits and hospital admissions associated with SO_2 exposures $\geq$1-hour.

In examining the exposure- and risk-based information with regard to the adequacy of the current 24-hour SO_2 standard to protect the public health, we note that the results described above (and in more detail in Chapters 7-9) indicate risks associated with air quality adjusted upward to simulate just meeting the current standard that can reasonably be judged important from a public health perspective. Therefore, exposure- and risk-based considerations reinforce the scientific evidence in supporting the conclusion that consideration should be given to revising the current 24-hour standard and/or setting a new shorter averaging time standard (e.g. 1-hour) to provide increased public health protection, especially for sensitive groups (e.g. asthmatics), from SO_2-related adverse health effects.

10.4 ADEQUACY OF THE CURRENT ANNUAL STANDARD

10.4.1 Introduction

In the last review of the SO_2 NAAQS, retention of the annual standard was largely based on an assessment of qualitative evidence gathered from a limited number of epidemiological studies. The strongest evidence for an association between annual SO_2 concentrations and adverse health effects in the 1982 AQCD was from a study conducted by Lunn et al (1967). The authors found that among children a likely association existed between chronic upper and lower respiratory tract illnesses and annual SO_2 levels of 70 -100 ppb in the presence of 230-301 ug/m^3 black smoke. Three additional studies described in the 1986 Second Addendum also suggested that long-term exposure to SO_2 was associated with adverse respiratory effects. Notably, studies conducted by Chapman et al. (1985) and Dodge et al. (1985) found associations between long-term SO_2 concentrations (with or without high particle concentrations) and cough in children and young adults. However, it was noted that there was considerable uncertainty associated with these studies because they were conducted in locations subject to high, short-term peak SO_2 concentrations (i.e. locations near point sources); therefore it was difficult to discern whether this increase in cough was the result of long-term, low level SO_2 exposure, or repeated short-term peak SO_2 exposures.

It was concluded in the last review that there was no quantitative rationale to support a specific range for an annual standard (EPA, 1994b). However, it was also found that while no single epidemiological study provided clear quantitative conclusions, there appeared to be some consistency across studies indicating the possibility of respiratory effects associated with long-term exposure to SO_2 just above the level of the existing annual standard (EPA, 1994b). In addition, air quality analyses conducted during the last review indicated that the short-term standards being considered (1-hour and/or 24-hour) could not by themselves prevent long-term concentrations of SO_2 from exceeding the level of the existing annual standard in several large urban areas. Ultimately, both the scientific evidence and the air quality analyses were used by the Administrator to conclude that retaining the existing annual standard was requisite to protect human health.

10.4.2 Evidence-based considerations

The ISA presents numerous studies published since the last review examining possible associations between long-term SO_2 exposure and mortality and morbidity outcomes. This includes discussion of additional epidemiological studies examining possible associations between long-term SO_2 exposure and respiratory effects in children (in part, the basis for retaining the annual standard in the last review; see section 10.4.1). In addition, the ISA presents results from epidemiological and animal toxicological studies published since the last review examining possible associations between long-term ambient SO_2 concentrations and adverse respiratory, cardiovascular, and birth outcomes, as well as carcinogenesis. The current ISA also discusses the possible association between long-term SO_2 exposure and mortality.

As an initial consideration with regard to the adequacy of the current annual standard, staff notes that the evidence relating long-term (weeks to years) SO_2 exposure to adverse health effects (respiratory morbidity, carcinogenesis, adverse prenatal and neonatal outcomes, and mortality) is judged to be "inadequate to infer the presence or absence of a causal relationship" (ISA, Table 5-3). That is, the ISA finds this health evidence to be of insufficient quantity, quality, consistency, or statistical power to make a determination as to whether SO_2 is truly associated with these health endpoints (ISA Table1-2). With respect specifically to respiratory morbidity in children, the ISA presents recent epidemiological evidence of an association with long-term exposure to SO_2 (ISA section 3.4.2). However, the ISA finds the strength of these epidemiological studies to be limited because of 1) variability in results across studies with respect to specific respiratory morbidity endpoints, 2) high correlations between long-term average SO_2 and co-pollutant concentrations, particularly PM, and 3) a lack of evaluation of potential confounding (ISA section 3.4.2.1). In addition, the ISA finds that results from animal toxicological studies do not provide strong biological plausibility for an association between long-term ambient SO_2 concentrations and respiratory morbidity (ISA, Table 5-3). Thus, the current evidence does not provide support for an annual SO_2 standard for purposes of protecting against long-term health effects.

We also note that many epidemiological studies demonstrating positive associations between 1- to 24-hour ambient SO_2 concentrations and respiratory symptoms, ED visits, and hospitalizations, were conducted in areas where ambient SO_2 concentrations were well below the current annual NAAQS. This evidence suggests that the current annual standard is not providing adequate protection against health effects associated with shorter-term SO_2 concentrations.

10.4.3 Risk-based considerations

Results of the risk characterization based on the air quality assessment provide additional insight into the adequacy of the current annual standard. Analyses in this document describe the extent to which the current annual standard provides protection against 5-minute peaks of SO_2 in excess of potential health effect benchmark levels. Figure 7-10 counts the number of *measured* 5-minute daily maximum SO_2 concentrations above the 100 -400 ppb benchmark levels for a given annual average SO_2 concentration. None of the monitors in this data set contained annual average SO_2 concentrations above the current NAAQS, but several of the monitors in several of the years frequently reported 5-minute daily maximum concentrations above the potential health effect benchmark levels. Many of these monitors where frequent exceedances are reported had annual average SO_2 concentrations between 5 and 15 ppb, with little to no correlation between the annual average SO_2 concentration and the number of 5-minute daily maximum concentrations above potential health effect benchmark levels. This suggests that the annual standard adds little in the way of protection against 5-minute peaks of SO_2 (see section 7.3.1).

10.4.4 Conclusions regarding the adequacy of the current annual standard

As noted, the ISA concludes that the evidence relating long-term (weeks to years) SO_2 exposure to adverse health effects (respiratory morbidity, carcinogenesis, adverse prenatal and neonatal outcomes, and mortality) is "inadequate to infer the presence or absence of a causal relationship" (ISA, Table 5-3). The ISA also reports that many epidemiological studies demonstrating positive associations between short-term (≥1-hour) SO_2 concentrations and respiratory symptoms, as well as ED visits and hospitalizations, were conducted in areas where annual ambient SO_2 concentrations were well below the level of the current annual NAAQS. In addition, analyses conducted in this REA suggest that the current annual standard is not providing protection against 5-10 minute peaks of $SO_{2.}$ Taken together, the scientific evidence and the risk and exposure information suggest that the current annual SO_2 standard does not provide adequate protection from the health effects associated with shorter-term exposures to SO_2 and that consideration should be given to revoking the annual standard in conjunction with setting an appropriate short-term standard(s).

10.5 POTENTIAL ALTERNATIVE STANDARDS

10.5.1 Indicator

In the last review, EPA focused on SO_2 as the most appropriate indicator for ambient SO_x. This was in large part because other gaseous sulfur oxides (e.g. SO_3) are likely to be found at concentrations many orders of magnitude lower than SO_2 in the atmosphere, and because most all of the health effects and exposure information was for SO_2. The current ISA has again found this to the case, and while the presence of gaseous SO_x species other than SO_2 has been recognized, no alternative to SO_2 has been advanced as being a more appropriate surrogate for ambient gaseous SO_x. Importantly, controlled human exposure studies and animal toxicology studies provide specific evidence for health effects following exposure to SO_2. Epidemiological studies also typically report levels of SO_2, as opposed to other gaseous SO_x. Because emissions that lead to the formation of SO_2 generally also lead to the formation of other SO_x oxidation products, measures leading to reductions in population exposures to SO_2 can generally be expected to lead to reductions in population exposures to other gaseous SO_x. Therefore, meeting an SO_2 standard that protects the public health can also be expected to provide some degree of protection against potential health effects that may be independently associated with other gaseous SO_x even though such effects are not discernable from currently available studies indexed by SO_2 alone. Given these key points, staff judges that the available evidence supports the retention of SO_2 as the indicator in the current review.

10.5.2 Averaging Time

The current 24-hour and annual averaging times for the primary SO_2 NAAQS were originally set in 1971. As previously described, (section 10.3.1) the 24-hour NAAQS was based on epidemiological studies that observed associations between 24-hour average SO_2 levels and adverse respiratory effects and daily mortality (EPA 1982, 1994b). The annual standard was supported by a few epidemiological studies that found an association between adverse respiratory effects and annual average SO_2 concentrations (EPA 1982, 1994b). Based on currently available evidence, the issue of averaging time is being reconsidered in the current review. In order to inform these judgments, staff has considered causality judgments from the ISA, results from experimental and epidemiological studies, and SO_2 air quality correlations. These considerations are described in more detail below.

10.5.2.1 Evidence-based considerations

As an initial consideration regarding the most appropriate averaging time (e.g., short-term, long-term, or a combination of both) for alternative SO_2 standard(s), we note that the ISA finds evidence relating long-term (weeks to years) SO_2 exposures to adverse health effects to be "inadequate to infer the presence or absence of a causal relationship" (ISA, Table 5-3). In contrast, the ISA judges evidence relating short-term (5-minutes to 24-hours) SO_2 exposure to respiratory morbidity to be "sufficient to infer a causal relationship" and short-term exposure to SO_2 and mortality to be "suggestive of a causal relationship" (ISA, Table 5-3). Taken together, these judgments most directly support standard averaging time(s) that focus protection on SO_2 exposures from 5-minutes to 24-hours.

In considering the level of support available for specific short-term averaging times, we first note the strength of evidence from human exposure and epidemiological studies. Human clinical studies exposed exercising asthmatics to 5-10 minute peak concentrations of SO_2 and consistently found decrements in lung function and/or respiratory symptoms. Importantly, the ISA describes the controlled human exposure studies as being the "definitive evidence" for its causal association between short-term (5-minutes to 24-hours) SO_2 exposure and respiratory morbidity (ISA section 5.2). Supporting the human clinical evidence is a relatively small body of epidemiological evidence describing positive associations between 1-hour maximum SO_2 levels and respiratory symptoms as well as hospital admissions and ED visits for all respiratory causes and asthma (ISA tables 5.4 and 5.5). In addition to the 1-hour epidemiological evidence, there is a considerably larger body of epidemiological studies reporting associations between 24-hour average SO_2 levels and respiratory symptoms, as well as hospitalizations and ED visits for all respiratory causes and asthma. However, as in the last review, there remains considerable uncertainty as to whether these associations are due to 24-hour average SO_2 exposures, or exposure (or multiple exposures) to short-term peaks of SO_2 within a 24-hour period. That is, the ISA notes that it is possible that associations observed in these 24-hour studies are being driven, at least in part, by short-term peaks of SO_2. More specifically, when describing epidemiological studies observing associations between ambient SO_2 and respiratory symptoms, the ISA states "that it is possible that these associations are determined in large part by peak exposures within a 24-hour period" (ISA, section 5.2). The ISA also states that the respiratory effects following 5-10 minute SO_2 exposures in controlled human exposure studies provides a basis for a progression of respiratory morbidity that could result in increased ED visits and hospital admissions (ISA, section 5.2).

The controlled human exposure evidence described above provides support for an averaging time that protects against 5-10 minute peak exposures. Results from the epidemiological evidence provides support for both 1-hour and 24-hour averaging times. However, it is worth noting that the effects observed in epidemiological studies may least be in part, especially in 24-hour epidemiological studies, due to shorter-term peaks of SO_2. Overall, the evidence mentioned above suggests that a primary concern with regard to averaging time is the level of protection provided against 5-10 minute peak SO_2 exposures. Additionally, even though there is a greater degree of uncertainty, the evidence described above also suggests it would be appropriate to consider the ability of averaging times under consideration to protect against both 1-hour daily maximum and 24-hour average SO_2 concentrations.

10.5.2.2 Risk-based considerations

The shortest averaging time for a current primary SO_2 standard is 24-hours. It is therefore instructive to evaluate the potential for a standard based on 24-hour average SO_2 concentrations to provide protection against 5-minute peak SO_2 exposures. Table 10-1 reports the ratio between 99th percentile 5-minute maximum and 99th percentile 24-hour average SO_2 concentrations for 42 monitors reporting measured 5-minute data from 2004-2006. Across this set of monitors in 2004, ratios of 99th percentile 5-minute maximum to 99th percentile 24-hour average SO_2 concentrations spanned a range of 2.0 to 14.1, with an average ratio of 6.7 (Table 10-1). These results suggests that a standard based on 24-hour average SO_2 concentrations would not likely be an effective or efficient approach for addressing 5-minute peak SO_2 concentrations. That is, using a 24-hour average standard to address 5-minute peaks would likely result in over controlling in some areas, while under controlling in others. In addition, it is important to note that this analysis also suggests that a 5-minute standard would not likely be an effective or efficient means for controlling 24-hour average SO_2 concentrations.

Table 10-1 also reports the ratios between 99th percentile 5-minute maximum and 99th percentile1-hour daily maximum SO_2 levels from this set of monitors. Compared to the ratios discussed above (5-minute maximum to 24-hour average), there is far less variability between 5-minute maximum and 1-hour daily maximum ratios. More specifically, 39 of the 42 monitors had 99th percentile 5-minute maximum to 99th percentile 1-hour daily maximum ratios in the range of 1.4 to 2.5 (Table 10-1). The remaining 3 monitors had ratios of 3.6, 4.2 and 4.6 respectively. Overall, this relatively narrow range of ratios suggests that a standard with a 1-hour averaging time would be more efficient and effective at limiting 5-minute peaks of SO_2 than a standard with a 24-hour averaging time. In addition, these results also suggest that a 5-minute standard could be a relatively effective means of controlling 1-hour daily maximum SO_2 concentrations.

Table 10-1 Ratios of 99th percentile 5-minute maximums to 99th percentile 24-hour average and 1-hour daily maximum SO_2 concentrations for monitors reporting measured 5-minute data from years 2004-2006[60]

[60] 5-minute maximum, 1-hour daily maximum, and 24-hour average 99th percentile values were calculated for each year a given monitor was in operation from 2004-2006. If a monitor was in operation for multiple years over that span, 99th percentile values were calculates for each year, averaged, and then the appropriate ratio was determined.

As noted, the strongest evidence for SO_2-induced respiratory effects is associated with an averaging time of 5-10 minutes. Furthermore, as mentioned above epidemiological studies of respiratory symptoms and ED visits and hospitalizations for all respiratory causes and asthma provide evidence for SO_2-associated respiratory effects at averaging times ranging from 1 to 24-hours. Notably, there is a greater degree of uncertainty associated with the epidemiological literature because: (1) results of these studies are generally positive, but often not statistically significant in single pollutant models; (2) only a limited subset of these studies investigated potential confounding by co-pollutants; and (3) it is very possible that associations observed in these studies are being driven at least in part, by short-term peaks of SO_2 within a 24-hour period. Despite these uncertainties, since the majority of the epidemiological literature is associated with a 24-hour averaging time, staff finds that it would be instructive to evaluate the potential of the 1-hour daily maximum standards analyzed in this REA to provide protection against 24-hour average SO_2 exposures. The 99th percentile 24-hour average SO_2 concentrations in cities where key U.S. ED visit and hospitalization studies (for all respiratory causes and asthma) were conducted ranged from 16 ppb to 115 ppb (Thomson, 2009). Moreover, effect estimates that remained statistically significant in multipollutant models with PM were found in cities with 99th percentile 24-hour average SO_2 concentrations ranging from approximately 36 ppb to 64 ppb. Table 10-2 suggests that a 99th percentile 1-hour daily maximum standard set at a level of 50-100 ppb would limit 99th percentile 24-hour average SO_2 concentrations observed in epidemiological studies where statistically significant results were observed in multi-pollutant models with PM. That is, given a 50 ppb 99th percentile 1-hour daily maximum standard, none of the 39 counties analyzed would be expected to have 24-hour average SO_2 concentrations ≥ 36 ppb; and, given a 100 ppb 99th percentile 1-hour daily maximum standard, only 5 of the 39 counties (Linn, Union, Bronx, Fairfax, and Wayne) included in this analysis would be estimated to have 99th percentile 24-hour average SO_2 concentrations ≥ 36 ppb. This analysis was also done for the years 2005 and 2006 and similar results were found (Appendix D).

Table 10-2. 99th percentile 24-hour average SO_2 concentrations for 2004 given just meeting the alternative 1-hour daily maximum standards analyzed in the risk assessment (note: concentrations in ppb).

As an additional matter, we note that a 99th percentile 1-hour daily maximum standard at a level of 50-150 ppb could have the effect of maintaining SO_2 concentrations below the level of the current 24-hour and annual standards (see Table 10-3). That is, under these alternative standard scenarios (using 2004 air quality data), there would be no counties in this analysis with a 2nd highest 24-hour average greater than 140 ppb. Similarly, under these alternative standard scenarios, there would be no counties in this analysis with an annual SO_2 concentration in excess of the current annual standard (0.03 ppm; see Table 10-4). These analyses were also done with air quality from the years 2005 and 2006 and similar results were found (Appendix D).

Table 10-3. 2nd highest 24-hour average SO_2 concentrations (i.e. the current 24-hour standard) for 2004 given just meeting the alternative 1-hour daily maximum standards analyzed in the risk assessment (note: concentrations in ppb).[61]

[61] 99th percentile 1-hour daily maximum concentrations were determined for each monitor in a given county for years 2004-2006. These concentrations were averaged, and the monitor with the highest average in a given county was determined. Based on this highest average, all monitors in a given county were adjusted to just meet the potential alternative standards defined above, and for each of the years, the 2nd highest 24-hour maximum concentration was identified. Iron County did not meet completeness criteria for all years and is therefore not part of this analysis.

Table 10-4. Annual average SO_2 concentrations for 2004 given just meeting the alternative 1-hour daily maximum standards analyzed in the risk assessment (note: concentrations in ppb).[62]

[62] 99th percentile 1-hour daily maximum concentrations were determined for each monitor in a given county for years 2004-2006. These concentrations were averaged, and the monitor with the highest average in a given county was determined. Based on this highest average, all monitors in a given county were adjusted to just meet the potential alternative standards defined above, and for each of the years, the annual concentration was calculated. Iron county did not meet completeness criteria for all years and is therefore not part of this analysis.

10.5.2.3 Conclusions regarding averaging time

Staff finds that the scientific evidence and the air quality analyses most support an averaging time of 1-hour. We first note that the ISA finds a causal relationship between ambient SO_2 exposure and respiratory morbidity, and that this conclusion is based on both human exposure studies of 5-10 minutes, as well as supporting evidence from epidemiological studies ranging from 1 to 24-hours. This evidence suggests that an appropriate averaging time should protect against SO_2 concentrations ranging from 5-minutes to 24-hours. Importantly, the air quality analyses presented above demonstrate that it is likely that an alternative 99th percentile (see form discussion in 10.5.3) 1-hour daily maximum standard at an appropriate level (see level discussion in 10.5.4) will substantially diminish: (1) 5-10 minute peaks of SO_2 shown in human exposure studies to result in respiratory symptoms and/or decrements in lung function in exercising asthmatics, (2) 99th percentile 1-hour daily maximum air quality concentrations in cities observing positive effect estimates in epidemiological studies of hospital admissions and ED visits for all respiratory causes and asthma, and (3) 99th percentile 24-hour average air quality concentrations found in U.S. cities where ED visit and hospitalization studies (for all respiratory causes and asthma) observed statistically significant associations in multi-pollutant models with PM (i.e. 99th percentile 24-hour average SO_2 concentration $\geq$ 36 ppb). Taken together, staff concludes that a 1-hour daily maximum standard, set at an appropriate level, would likely provide protection against the range of health outcomes associated with averaging times from 5-minutes to 24-hours.

We note that based solely on the controlled human exposure evidence, staff also considered a 5-minute averaging time. Staff's initial view does not favor such an approach. It is legitimate to consider the stability of the design of pollution control programs in considering the elements of a NAAQS, since more stable programs are more effective, and hence result in enhanced public safety. Here, staff has concerns about the stability of a 5-minute averaging time and standard. Specific concerns relate to the number of monitors needed and the placement of such monitors given the temporal and spatial heterogeneity of 5-minute SO_2 concentrations. Moreover, staff is concerned that compared to longer averaging times (e.g. 1-hour, 24-hour), year to year variation in 5-minute SO_2 concentrations is likely to be substantially more temporally and spatially diverse. Consequently, staff initially judges that a 5-minute averaging time would not provide a stable regulatory target and therefore, is not the preferred approach to provide adequate public health protection. However, as noted above, staff 's provisional view is that a 1-hour averaging time, given an appropriate form (see 10.5.3) and level (see 10.5.4), will adequately control 5-minute SO_2 exposures (see 10.5.4.2) and provide a more stable regulatory target than setting a 5-minute standard.

10.5.3 Form

When evaluating alternative forms in conjunction with specific levels, staff considers the adequacy of the public health protection provided by the combination of level and form to be the foremost consideration. In addition, we recognize that it is important to have a form that is reasonably stable and relatively insulated from the impacts of extreme meteorological events. A standard set with a high degree of instability could have the effect of reducing public health protection because shifting in and out of attainment due to meteorological conditions could disrupt an area's ongoing implementation plans and associated control programs.

Controlled human exposure evidence demonstrates that there is a continuum of SO_2 related health effects in exercising asthmatics following 5-10 minute peak SO_2 exposures. That is, the ISA finds that the percentage of asthmatics affected and the severity of the response increases with increasing SO_2 concentrations. Therefore, as noted in Chapter 5 and consistent with recent reviews of the O_3 and PM NAAQS, we focus this review on concentration-based forms averaged over 3 years. This is because a concentration-based form gives proportionally greater weight to 1-hour daily maximum values when concentrations are well above the level of the standard than to 1-hour daily maximum values when the concentrations are just above the level of the standard. In contrast, an expected exceedance form would give the same weight to a 1-hour daily maximum concentration that just exceeds the level of the standard as to a 1-hour daily maximum concentration that greatly exceeds the level of the standard. Therefore, a concentration-based form better reflects the continuum of health risks posed by increasing SO_2 concentrations (i.e. the percentage of asthmatics affected and the severity of the response increases with increasing SO_2 concentrations). Concentration-based forms also provide greater regulatory stability than a form based on allowing only a single expected exceedance.

In considering specific concentration-based forms, we recognize the importance to minimize the number of days per year that an area could exceed the standard level and still attain the standard. Given this, we have focused on 98th and 99th percentile forms averaged over 3 years. With regard to these alternative forms, staff notes in most locations analyzed, the 99th percentile form of a 1-hour daily maximum standard would correspond to the 4th highest daily maximum concentration in a year, while a 98th percentile form would correspond approximately to the 7th to 8th highest daily maximum concentration in a year (Table 10-5; see Thompson, 2009 for methods). Staff also notes that the air quality analyses indicate that a 99th percentile form could be appreciably more effective at limiting 5-minute peak SO_2 concentrations than a 98th percentile form. For example, in all but one of the 40 counties selected for detailed analyses, a 99th percentile 1-hour daily maximum standard at 200 ppb allows less days per year of 5-minute daily maximum SO_2 concentrations > 400 ppb than the corresponding 98th percentile standard (see Table 7-11).[63] Taken together, staff finds provisionally that the scientific evidence and the risk and exposure analyses suggest consideration be given primarily to a 1-hour daily maximum standard with a 99th percentile form.

---

[63] In Alleghany County, both a 98th and 99th percentile 1-hour daily maximum standard at 200 ppb would be estimated to allow 2 days of 5-minute daily maximum SO_2 concentrations > 400 ppb.

10.5.4 Level

In considering alternative standard levels that would provide greater protection than that afforded by the current standard against SO_2-related adverse health effects, staff has taken into account scientific evidence from both experimental and epidemiological studies, as well as the uncertainties and limitations in that evidence. In particular, we have considered the extent to which controlled human exposure studies provide evidence for a lowest-observed-effects level (LOEL) and the extent to which epidemiological studies provide evidence for potential effect thresholds and/or for positive associations that extend down to the lower levels of SO_2 concentrations observed in studies. We note that the scientific evidence can provide insights into alternative standard levels only within the context of specific averaging times and forms. Therefore, while this section considers the evidence as it relates to alternative levels, such considerations assume particular averaging times and forms (see sections 10.5.2 and 10.5.3).

10.5.4.1 Evidence-based consideration

Human Clinical

Controlled human exposure results demonstrate that there is a continuum of SO_2 related health effects following 5-10 minute peak SO_2 exposures in exercising asthmatics. That is, the ISA finds that the percentage of asthmatics affected and the severity of the response increases with increasing SO_2 concentrations. At concentrations ranging from 200 - 300 ppb, the lowest levels tested in free breathing chamber studies, 5-30% percent of exercising asthmatics are likely to experience moderate or greater bronchoconstriction. At concentrations $\geq$ 400 ppb, moderate or greater bronchoconstriction occurs in 20-60% of exercising asthmatics, and compared to exposures at 200- 300 ppb, a larger percentage of subjects experience severe bronchoconstriction. At concentrations $\geq$ 400 ppb, statistically significant moderate or greater bronchoconstriction is frequently accompanied by respiratory symptoms.

With regard to the controlled human exposure evidence as it relates to alternative standard levels, several additional factors must be considered. First, it is important to note that the subjects in human exposure studies do not represent the most SO_2 sensitive asthmatics; that is, these studies included mostly mild and some moderate, but not severe asthmatics. Also, children have not been included in free-breathing controlled human exposure studies, and thus, it is possible asthmatic children represent a population that is more sensitive to the respiratory effects of SO_2 than the individuals who have been examined to date. Moreover, it is important to consider that 5-30% of asthmatics who engaged in moderate or greater exertion experienced bronchoconstriction following exposure to 200- 300 ppb SO_2, which is the lowest level tested in free-breathing chamber studies. Thus, it is likely that a subset of the asthmatic population would also experience bronchoconstriction following exposure to levels lower than 200 ppb. We also note this effect could have important public health implications due to the large size of the asthmatic population in the United States (see section 3.6).

Epidemiological

When evaluating the epidemiologic literature for its potential to inform decisions on standard level, we note that the ISA describes the evidence for the presence of an effects threshold as inconclusive (ISA, section 4.1.3). While some epidemiological studies found the concentration-response relationship to be linear, other studies found a marked increase in SO_2 related respiratory effects at higher SO_2 concentrations (ISA, section 4.1.3). However, the ISA urges caution when interpreting studies finding a marked increase in respiratory effects at higher SO_2 concentrations because these results were based on a few potentially influential data points (i.e., 24-hour SO_2 concentrations above the 90th percentile; ISA, section 4.1.3). In the absence of a clear threshold, our discussion of alternative standard levels will focus on the range of 1-hour daily maximum SO_2 concentrations observed in cities where key U.S. and Canadian epidemiological studies of ED visits and hospitalizations were conducted.

Figures 5-1 to 5-5 (see Chapter 5) show standardized effect estimates and the 98th and 99th percentile concentrations of 1-hour daily maximum SO_2 levels for locations and time periods for which key U.S. (Figures 5-1 to 5-4) and Canadian (Figure 5-5) ED visit and hospitalization studies were conducted**.** The highest 99th percentile 1-hour daily maximum air quality levels were found in analyses conducted in the cities of Cincinnati (Figure 5-2), Cleveland (Figures 5-2 and 5-4), and New Haven (Figure 5-4). These studies showed positive associations with respiratory-related hospital admissions or ED visits during time periods when 99th percentile 1-hour daily maximum SO_2 concentrations ranged from 150 to 457 ppb. Notably, this range of 1-hour daily maximum SO_2 levels overlaps considerably with 5-10 minute SO_2 concentrations ($\geq$ 200 ppb) that have consistently been shown in controlled human exposure studies to result in decrements in lung function in exercising asthmatics. Of particular concern are the air quality levels that were found in Cincinnati. The 98th and 99th percentile 1-hour daily maximum SO_2 concentrations were in excess of 400 ppb. Notably, levels $\geq$ 400 ppb have consistently been shown in human clinical studies with 5-10 minute exposures to result in statistically significant moderate or greater bronchoconstriction in the presence of respiratory symptoms in a considerable percentage of exercising asthmatics.

With regard to the lowest levels of SO_2 observed in cities where positive effect estimates were observed in epidemiological studies, we first note that Figure 5-5 contains epidemiological studies reporting associations between ambient SO_2 concentrations and hospital admissions in Canadian cities where 99th percentile, 1-hour daily maximum SO_2 levels were ≤ 46 ppb. Specifically, 99th percentile, 1-hour daily maximum SO_2 levels for hospital admission studies conducted in Toronto (Burnett et al., 1997) and Vancouver (Yang et al., 2003) were approximately 21 ppb, and 41 ppb, respectively. Moreover, in a U.S. analysis, Delfino et al. (2003) reported an association between ambient SO_2 and respiratory symptoms in Hispanic children when the maximum 1-hour SO_2 concentration in Los Angeles was 26 ppb (ISA Table 5-4). However, it should be noted that the Vancouver study was not statistically significant in either single, or multipollutant models with O_3, and that the study did not examine the potential for confounding by PM (Figure 5-5; ISA, Table 5-5). In addition, while the Toronto study was statistically significant in a single pollutant model, the effect estimate was substantially diminished and no longer statistically significant in a multi-pollutant model with PM_{10} (ISA, Table 5-5). Finally, the epidemiological study conducted in Los Angeles (Delfino et al., 2003; ISA, Table 5-4) was very small (n=22), and did not examine potential confounding by co-pollutants. Thus, staff finds that this evidence considered by itself is not sufficient to warrant consideration of alternative 1-hour daily maximum standards at levels below 50 ppb.

In contrast to the epidemiological evidence in cities where 99th percentile 1-hour daily maximum SO_2 concentrations were < 47 ppb, staff finds relatively stronger evidence of an association between SO_2 and hospital admissions and ED visits for all respiratory causes and asthma in cities where 99th percentile 1-hour daily maximum SO_2 concentrations were ≥ 47 ppb (Figures 5-1 to 5-5). More specifically, the majority of epidemiological studies in this range observed positive associations between ambient SO_2 levels and hospital admissions and ED visits for all respiratory causes or asthma. Moreover, although most of these positive effect estimates were not statistically significant, there were some statistically significant results in single pollutant models (Portland, Wilson, 1995; Bronx, NYDOH, 2006; NYC, Ito, 2006; and Schwartz, 1995), as well as limited evidence of statistical significance in multi-pollutant models with PM (Bronx, NYDOH, 2006; NYC, Ito, 2006; New Haven, Schwartz 1995).

10.5.4.2 Exposure- and risk-based considerations

Staff's consideration of exposure- and risk-based information as it relates to alternative levels for the primary SO_2 NAAQS builds upon our conclusions, discussed above in sections 10.3.3.3 and 10.4.4, that the overall body of scientific evidence clearly calls into question the adequacy of the current standards to protect the public health. Therefore, we have judged it appropriate to consider a range of alternative levels that would improve upon the level of protection provided by the current standard. As noted in Chapter 5, this range of levels (50- 250 ppb) is based on results from controlled human exposure and epidemiologic studies. When considering this range of levels given recent air quality, we note that all of the potential alternative 1-hour daily maximum SO_2 standard levels would be estimated to result in counties in the U.S. with air quality above the level of the given alternative standard (Table 10-6; Thompson, 2008). In contrast, given recent air quality, all counties in the U.S. meet the current 24-hour and annual standards. Thus, to varying extents, all potential alternative 1-hour daily maximum standards would represent increased protection against ambient SO_2 concentrations compared to the current standards.

Table 10-6. Percent of counties that may be above the level of alternative standards (based on years 2004-2006)

Alternative Standards and Levels (ppb)	Percent of counties, total and by region not likely to meet a given standard								
	Total Counties (population in millions)	Northeast	Southeast	Industrial Midwest	Upper Midwest	Southwest	Northwest	Southern CA	Outside Regions
Number of counties with monitors	**211 (96.5)**	**52**	**40**	**75**	**19**	**7**	**9**	**6**	**3**

200	1 (0.4)	0	0	1	0	14	0	0	33

The results of the air quality analyses are presented in Chapter 7 of this document. The outputs of these analyses include estimates of the number of daily exposures greater than or equal to benchmark levels. These estimates are based on as-is air quality and air quality that has been adjusted to simulate just meeting the current and potential alternative standards. In considering the results presented Chapter 7, we note the following key points with respect to exceedences of the 200 and 400-ppb benchmark levels. We highlight these benchmark levels because (1) 400 ppb represents the lowest concentration in human exposure studies where statistically significant moderate or greater lung function decrements are frequently accompanied by respiratory symptoms, (2) 200 ppb is the LOEL for moderate or greater decrements in lung function in free-breathing human exposure studies, and (3) taken together, the human exposure evidence suggests that the 1-hour daily maximum SO_2 standard level should be set low enough to significantly reduce the number of 5-10 minute peaks in excess of 200 ppb, and thus provide even greater protection against peaks in excess of 400 ppb.

- When air quality is simulated to just meet the current standards in 40 counties selected for detailed analysis, all locations are estimated to have between 21-171 days per year where 5-minute daily maximum SO_2 concentrations exceed 200 ppb. Moreover, most counties are estimated to have $\geq$ 50 days per year where 5-minute daily maximum SO_2 concentrations exceed 200 ppb (Table 7-11).

- When air quality is simulated to just meeting the current standards in the 40 counties selected for detailed analysis, all locations are estimated to have between 1-102 days per year when 5-minute daily maximum SO_2 concentrations exceed 400 ppb. Moreover, most counties will have > 20 days per year where 5-minute daily maximum SO_2 concentrations exceed 400 ppb (Table 7-13)

- In all counties selected for detailed analysis, simulating just meeting the 99th percentile alternative standard levels of 50, 100 and 150 ppb results in fewer estimated days per year when 5-minute daily maximum SO_2 concentrations exceed the 200 and 400 ppb benchmarks compared to just meeting the current standards (Tables 7-11 and 7-13).

- In all counties selected for detailed analysis, compared to the current standards, simulating just meeting the 99th percentile alternative standard level of 200 ppb results in fewer estimated days per year when 5-minute daily maximum SO_2 concentrations exceed 200 ppb, and in all but three counties, results in fewer exceedences of the 400 ppb benchmark (under the current, and 200 ppb alternative standards, Bronx, Union, and Fairfax Counties would have the same number of exceedences of the 400 ppb benchmark (Tables 7-11 and 7-13).

- In Bronx, Union, Hudson, and Fairfax Counties simulating just meeting the 99th percentile 1-hour daily maximum standard of 250 ppb results in more exceedences of the 200 ppb benchmark than just meeting the current standard. Similarly, this 250 ppb alternative standard results in these counties experiencing more exceedences of the 400 ppb benchmark than just meeting the current standard (Tables 7-11 and 7-13).

- In all counties selected for detailed analysis, a 99th percentile 1-hour daily maximum standard of 50 ppb would be estimated to result in at most 2 days/year where 5-minute maximum SO_2 concentrations were ≥ 200 ppb, and 0 days/year where 5-minute maximum SO_2 concentrations were ≥ 400 ppb (Tables 7-11 and 7-13).

- In all counties selected for detailed analysis, a 99th percentile 1-hour daily maximum standard of 100 ppb would be estimated to result in at most 13 days/year where 5-minute maximum SO_2 concentrations were ≥ 200 ppb, and at most 2 days/year where 5-minute maximum SO_2 concentrations were ≥ 400 ppb (Tables 7-11 and 7-13).

- In all counties selected for detailed analysis, a 99th percentile 1-hour daily maximum standard of 150 ppb would be estimated to result in at most 24 days/year where 5-minute maximum SO_2 concentrations were ≥ 200 ppb, and at most 7 days/year where 5-minute maximum SO_2 concentrations were ≥ 400 ppb (Tables 7-11 and 7-13).

The results of the St Louis and Greene County exposure assessments are presented in Chapter 8 of this document. In Figures 8-13 through 8-17, we present estimates of the percent and number of asthmatics in St. Louis and Greene Counties expected to experience SO_2 exposure concentrations at or above our potential health benchmark levels for the year 2002, given unadjusted air quality and air quality that has been adjusted to simulate just meeting the current and potential alternative standards. In considering the results presented in those figures, we note the following key points (values in parentheses represent the numbers of asthmatics exposed):

- In St. Louis under the current standards, about 46% (~48,000) and 13% (~14,000) of asthmatics at elevated ventilation rates would be estimated to experience at least one exposure greater than or equal to the 200 ppb and 400 ppb benchmarks, respectively (Figures 8-16 and 8-17).

- In St. Louis, 99th percentile 1-hour daily maximum standards of 50 ppb, 100 ppb, 150 ppb, and 200 ppb would be estimated to result in ≤ 1% (69), 1.5% (~1,600), 6.4% (~7,000) and 13.7% (~14,000), respectively, of asthmatics at elevated ventilation rates experiencing at least one exposure greater than or equal to the 200 ppb benchmark respectively (Figures 8-16 and 8-17).

- In St. Louis, 99th percentile 1-hour daily maximum standards of 50 ppb, 100 ppb and 150 ppb would be estimated to result in <1% of asthmatics at elevated ventilation rates experiencing at least one exposure greater than or equal to the 400 ppb benchmark (Figure 8-17).

- In St. Louis, a 99th percentile 1-hour daily maximum standard of 200 ppb would be estimated to result in 1.5% (~1,600) of asthmatics at elevated ventilation rates experiencing at least one exposure greater than or equal to the 400 ppb benchmark (Figures 8-16 and 8-17).

- When results are restricted to asthmatic children, similar trends are found with respect to exceedences of the 200 ppb and 400 ppb benchmark levels under the current and 99th percentile 1-hour daily maximum standards (Figure 8-17).

- In Greene County, although all of the alternative 99th percentile 1-hour daily maximum standards are estimated to be more protective than the current standards, <1% of asthmatics at elevated ventilation rates are estimated to experience at least one exposure greater than or equal to the 200 ppb and 400 ppb benchmarks under all air quality scenarios. At most, 139 and 13 asthmatics at elevated ventilation rates would be expected to experience at least one exposure over the 200 or 400 ppb benchmark respectively (Figures 8-13 and 8-14).

- In Greene County, under the current standards, about 1.0% (72) and <1% (<10) of asthmatic children at elevated ventilation rates would be estimated to experience at least one exposure greater than or equal to the 200 ppb and 400 ppb benchmarks, respectively (Figures 8-13 and 8-14).

- In Greene County, under all of the 1-hour daily maximum alternative standards, <35 asthmatic children at elevated ventilation rates would be estimated to experience at least one exposure greater than or equal to the 200 ppb benchmark (Figure 8-13).

The results of the St Louis and Greene County risk assessment are presented in Chapter 9 of this document. In Tables 9-4 and 9-5 we present estimates of the number and percent of exposed asthmatics likely to experience moderate or greater lung function responses. In considering the results from these tables we note the following key points (values in parentheses represent the numbers of asthmatics):

- In the St. Louis modeling domain the median percentage of exposed asthmatics at elevated ventilation rates estimated to experience at least one moderate decrement in lung function defined as a ≥ 100% increase in sRaw is 13.1% (~13,500) under the current standards.

- In the St. Louis modeling domain the median percentage of exposed asthmatics at elevated ventilation rates estimated to experience at least one ≥ 100% increase in sRaw is 0.7% (730), 1.9% (~2,000), 3.6 % (~3,700), and 5.4% (~5,500) given a 50 ppb, 100 ppb, 150 ppb, and 200 ppb 99th percentile 1-hour daily maximum standard, respectively.

- In the St. Louis modeling domain the median percentage of exposed asthmatics at elevated ventilation rates estimated to experience at least one large decrement in lung function defined as a ≥ 200% increase in sRaw is 5.4% (~5,500) under the current standard.

- In the St. Louis modeling domain the median percentage of exposed asthmatics at elevated ventilation rates estimated to experience at least one ≥ 200% increase in sRaw is 0.2% (230), 0.7% (670) 1.3% (~1,300) and 2% (~2,000) given a 50 ppb, 100 ppb, 150 ppb, and 200 ppb 99th percentile 1-hour daily maximum standard respectively.

- Similar trends are found in the St. Louis modeling domain with respect to the median percentages of exposed asthmatic children at elevated ventilation rates expected to experience at least one ≥ 100% or ≥ 200% increase in sRaw.

- Similar trends are found in the St. Louis modeling domain in exposed asthmatics and asthmatic children at elevated ventilation rates when moderate or large lung function decrements are defined in terms of FEV_1 rather than sRaw (Table 9-8 and Appendix C Tables 4-7, 4-8, 4-11, and 4-12).

- In Greene County under the current standard the median percentage of exposed asthmatics at elevated ventilation rates estimated to experience at least one ≥ 100% increase in sRaw is 1% (210).

- In Greene County the median percentage of exposed asthmatics at elevated ventilation rates estimated to experience at least one ≥ 100% increase in sRaw is 0.4% (80), 0.4% (90), 0.5 % (100), and 0.6% (120) given a 50 ppb, 100 ppb, 150 ppb, and 200 ppb 99th percentile 1-hour daily maximum standard, respectively.

- In Greene County under the current standard the median percentage of exposed asthmatics at elevated ventilation rates estimated to experience at least one ≥ 200% increase in sRaw is 0.3% (70).

- In Greene County, using a 2-Parameter Logistic function, the median percentage of exposed asthmatics at elevated ventilation rates estimated to experience at least one ≥ 200% increase in sRaw is 0.1% (30), 0.1% (30), 0.2 % (30), and 0.2% (40) given a 50 ppb, 100 ppb, 150 ppb, and 200 ppb 99th percentile 1-hour daily maximum standard, respectively.

10.5.4.3 Conclusions regarding level

Taken together, staff provisionally concludes that the evidence and exposure and risk information reasonably support a 1-hour daily maximum standard within a range of 50- 150 ppb. Controlled human exposure evidence has consistently demonstrated increases in respiratory symptoms and/or decrements in lung function in exercising asthmatics following 5-10 minute SO_2 exposures ≥ 200 ppb. At concentrations ≥ 400 ppb, human exposure studies have demonstrated that decrements in lung function are frequently accompanied with respiratory symptoms. Suggestive evidence for health effects associated with this range of SO_2 concentrations can also be found in epidemiological studies. That is, our air quality analysis based on key U.S. and Canadian hospital admission and ED visit studies identified in the ISA indicates positive effect estimates have been observed in cities where 99th percentile 1-hour daily maximum SO_2 concentrations were also between 200- 400 ppb. At a minimum, these multiple lines of evidence suggest that a 99th percentile 1-hour daily maximum standard should be lower than 200 ppb. Moreover, given that the definitive evidence for the ISA's causal determination is the controlled human exposure evidence, staff believes that the level of a 1-hour daily maximum SO_2 standard should be low enough to significantly limit the number of 5-minute peaks ≥ 200 ppb. Thus, we note results from the air quality and risk analyses indicate that a 1-hour daily maximum standard ranging from 50- 150 ppb would provide substantial protection against 5-minute peaks ≥ 200 ppb. For a given county in our detailed air quality analysis, it is estimated that air quality just meeting a 1-hour daily maximum standard set at a level of 50 ppb, 100 ppb, or 150 ppb would result in at most 2, 13, or 24 days per year respectively, when 5-minute daily maximum SO_2 concentrations would be ≥ 200 ppb (Table 7-11). We also note that results from the St. Louis exposure analysis indicate that air quality just meeting a 50 ppb, 100 ppb, or 150 ppb 1-hour daily maximum standard, respectively, would result in a corresponding < 0.1% (69), 1.5% (~1,600), or 6.4% (~7,000) of asthmatics at elevated ventilation rates experiencing at least one 5-minute daily maximum exposure ≥ 200 ppb. In the Greene County exposure analysis, it is estimated that < 10 exercising asthmatics would be expected to experience an SO_2 exposure ≥ 200 ppb given a 1-hour daily maximum standard set at 50, 100, or 150 ppb. Finally, results of the St. Louis quantitative lung function response risk assessment estimate that the median percentage of asthmatics at elevated ventilation rates estimated to experience at least one ≥ 100% increase in sRaw (a moderate lung function decrement) is 0.7% (730), 1.9% (~2,000) and 3.6 % (~3,700) given air quality just meeting a 50 ppb, 100 ppb, and 150 ppb 99th percentile 1-hour daily maximum standard, respectively.

In further informing this range of SO_2 standard levels, we again consider the epidemiological evidence, as well as the air quality analysis conducted by staff characterizing 99th percentile 1-hour daily maximum SO_2 concentrations in cities corresponding to key U.S. and Canadian epidemiological studies (identified in the ISA). We first note that there are important sources of uncertainty associated with the results of the epidemiological literature (see section

10.5.2.2). However, we also note that the ISA does conclude that SO_2 likely has an independent effect on the respiratory outcomes observed in these studies (ISA, section 5.2). As previously described, positive associations between ambient SO_2 and hospital admissions and ED visits for all respiratory causes and asthma were observed in cities where 99th percentile 1-hour daily maximum SO_2 concentrations were ≥ 47 ppb. Notably, this range includes three studies where statistically significant results in multi-pollutant models with PM were observed. Studies conducted in NYC, NY (Ito et al., 2007), Bronx, NY (NYDOH, 2006), and New Haven, CT (Schwartz et al., 1995) observed statistically significant results in multi-pollutant models with PM when 99th percentile 1-hour daily maximum SO_2 concentrations were 82 ppb, 78 ppb, and 150 ppb, respectively. However, in Tacoma, WA (Schwartz et al., 1995), when the 99th percentile 1-hour daily maximum SO_2 concentration was 100 ppb, the positive SO_2 effect estimate was substantially reduced and no longer statistically significant in a multi-pollutant model with PM. In addition, we note that several other studies reported positive and sometimes statistically significant SO_2 effect estimates in cities where 99th percentile 1-hour SO_2 concentrations ranged from 70-100 ppb (Figures 5-1 to 5-5). Thus, if the epidemiological results are emphasized, they could reasonably support a 99th percentile 1-hour daily maximum standard in the lower end of the standard range, that is, from 70 ppb -100 ppb. Moreover, if emphasis is placed on the *99th percentile 24-hour average SO_2 concentrations* observed in cities where the epidemiological studies mentioned above were conducted, we note that a 50 ppb (and to a lesser extent the100 ppb) 99th percentile 1-hour daily maximum standard would likely provide protection against the range of 99th percentile 24-hour average SO_2 concentrations in cities where statistically significant associations in multi-pollutant models with PM were observed (i.e. ≥ 36 ppb; see section 10.5.2.2).

In addition to using the epidemiological results, uncertainties in the controlled human exposure evidence could also be used to further inform consideration of standards within this 50 -150 ppb range of alternative standard levels. For example, if emphasis is placed on the uncertainty that the participants in human exposure studies do not represent the most SO_2 sensitive individuals, consideration could be given to a 1-hour daily maximum standard level that provides increased protection against peaks < 200 ppb to provide a margin of safety for these SO_2 sensitive individuals. In this case, we would note that in the St. Louis exposure analysis, compared to a standard level of 100 or 150 ppb, a 1-hour daily maximum standard of 50 ppb would likely result in substantially fewer asthmatics at elevated ventilation rates experiencing SO_2 concentrations ≥ 100 ppb. That is, given a 50 ppb, 100 ppb, and 150 ppb 1-hour daily maximum standard, 1.5% (~1,600), 13.7%, (~14,000) and 31% (~33,000) of asthmatics at elevated ventilation rates would be expected to experience at least one SO_2 concentrations ≥ 100 ppb, respectively.

On the other hand, if emphasis is placed on the uncertainties associated with the controlled human exposure results at the lowest levels, it could be argued that the upper end of this range of alternative standard levels could be sufficient to protect public health. That is, the ISA notes that while decrements in lung function have been demonstrated to occur in free breathing chamber studies as low as 200 ppb, it also notes that results of chamber studies exposing exercising asthmatics to 200-300 ppb are not statistically significant, nor are they frequently accompanied with respiratory symptoms (ISA, section 4.1.1). Thus, an argument could be made that a 99th percentile 1-hour daily maximum SO_2 standard should predominantly provide protection against 5-10 minute SO_2 concentrations ≥ 400 ppb (i.e. the lowest concentration in free-breathing chamber studies where statistically significant respiratory effects have been observed). In this instance, staff notes that results of the St. Louis exposure analysis indicate that a 99th percentile 1-hour daily maximum standard at levels ranging from 100 -150 ppb, would be estimated to result in <1% (~80) and <1% (~500) of asthmatics at elevated ventilation rates experiencing at least one exposure greater than or equal to the 400 ppb benchmark, respectively (Figure 8-17).

Given the above considerations, staff's initial views are that selecting a level from within this range will be based on the relative weight given to different types of information from the exposure and risk assessment, as well as to the evidence, and the uncertainties associated with the evidence and assessments. Finally, staff recognizes that the particular level selected will also have implications for retaining or revoking the current 24-hour and/or annual standards. That is, if the alternative standard selected would be expected to prevent ambient SO_2 concentrations from exceeding the levels of the current standards, it could reasonably be suggested that the current NAAQS be revoked. However, if the alternative standard selected is not expected to prevent ambient SO_2 concentrations from exceeding the levels of the current standards, it would be appropriate to consider retaining the current NAAQS.

Appendix A: Supplement to the SO_2 Air Quality Characterization

This appendix contains supplementary information on the SO_2 ambient monitoring data used in the air quality characterization described in Chapter 7 of the SO_2 REA. Included in this appendix are spatial and temporal attributes important for understanding the relationship between the ambient monitor and those sources affecting air quality measurements.

In section A.1, important spatial characteristics described include the physical locations of the ambient monitors (e.g., U.S. states, counties, territories, and cities). Temporal attributes of interest include, for example, the number of samples collected, sample averaging times, and years of monitoring data available. Attributes of the monitors that reported both the 5-minute maximum and the 1-hour SO_2 concentrations are given in Tables A.1-1 and A.1-2, while the supplemental characteristics of the broader ambient monitoring network are given in Table A.1-3 and A.1-4. The method for calculating the proximity of the ambient monitors follows, along with the distance and emission results summarized in Table A.1-5.

Section A.2 details the analyses performed on simultaneous concentrations, some of which are the result of co-located monitoring instruments, others the result of duplicate reporting. Simultaneous measurements were identified by staff using monitor IDs and multiple concentrations present given the hour-of-day on each available date. Staff estimated a relative percent difference between the simultaneous measurements at each monitor.

Section A-3 has the tables summarizing the COV and GSD peak-to-mean ratio (PMRs). Section A-4 has tables summarizing the individual factors used in adjusting ambient air quality to just meet the current and potential alternative SO_2 air quality standards. Section A-5 summarizes measured 1-hour and 5-minute maximum concentrations at the 98 monitors reporting both averaging times.

A-1 Spatial and Temporal Attributes of Ambient SO_2 Monitors

Table A.1-1. Meta-data for ambient monitors reporting 5-minute maximum and corresponding 1-hour SO_2 concentrations.

Notes:

[1] Population bins: low (≤10,000); mid (10,001 to 50,000); hi (>50,000) using population within 5 km of ambient monitor.

[2] COV bins: a (≤100%); b (>100 to ≤200); c (>200).

[3] GSD bins: a (≤2.17); b (>2.17 to ≤2.94); c (>2.94).

[4] Sum of emissions within 20 km radius of ambient monitor based on 2002 NEI.

Table A.1-3. Meta-data for ambient monitors in the broader SO_2 monitoring network.

Notes:

[1] Population bins: low (≤10,000); mid (10,001 to 50,000); hi (>50,000) using population within 5 km of ambient monitor.

[2] COV bins: a (≤100%); b (>100 to ≤200); c (>200).

[3] GSD bins: a (≤2.17); b (>2.17 to ≤2.94); c (>2.94).

[4] Sum of emissions within 20 km radius of ambient monitor based on 2002 NEI.

A.1.2 Analysis of SO_2 Emission Sources Surrounding Ambient Monitors

Distances of the 5-minute and 1-hour ambient monitoring sites to stationary sources emitting SO_2 were estimated using data from the 2002 National Emissions Inventory[1] (NEI). The NEI database reports emissions of SO_2 in tons per year (tpy) for 98,667 unique emission sources at various points of release. The release locations were all taken from the latitude longitude values within the NEI. First, all SO_2 emissions were summed for identical latitude and longitude entries while retaining source codes for the emissions (e.g., Standard Industrial Code (SIC), or North American Industrial Classification System (NAICS)). Therefore, any facility containing similar emission processes were summed at the stack location, resulting in 32,521 observations. These data were then screened for sources with emissions greater than 5 tpy, yielding 6,104 unique SO_2 emission sources. Locations of these stationary source emissions were compared with ambient monitoring locations using the following formula:

$$d = \arccos(\sin(lat_1) \times \sin(lat_2) + \cos(lat_1) \times \cos(lat_2) \times \cos(lon_2 - lon_1)) \times r$$

where

d = distance (kilometers)
lat_1 = latitude of a monitor (radians)
lat_2 = latitude of source emission (radians)
lon_1 = longitude of monitor (radians)
lon_2 = longitude of source emission (radians)
r = approximate radius of the earth (or 6,371 km)

Location data for monitors and sources provided in the AQS and NEI data bases were given in units of degrees therefore, these were first converted to radians by dividing by 180/π. For each monitor, source emissions within 20 km of the monitor were retained.

Table A.1-5 contains the summary of the distance of stationary source emissions to each of the monitors in the broader SO_2 monitoring network. There were varying numbers of sources emitting >5 tpy of SO_2 and located within a 20 km radius for many of the monitors. Some of the monitors are point-source oriented, that is, sited to measure ambient concentrations potentially

---

influenced by a specific single sources (e.g., Missouri monitor IDs 290210009, 290210011, 290930030), or by several sources (e.g., Pennsylvania monitor IDs 420030021, 420030031) of varying emission strength. A few of the monitors contained no source emissions >5 tpy (e.g., Iowa monitor IDs 191770005, 191770006).

Table A.1-5. Distance of ambient SO_2 monitors (all used in analysis) to stationary sources emitting > 5 tons of SO_2 per year, within a 20 kilometer distance of monitoring site, and SO_2 emissions associated with those stationary sources.

Notes:

[1] Mean, std , min, p2.5, p50, p97.5, max are the arithmetic average, standard deviation, minimum, 2.5th, 50th, 97.5th percentiles, and maximum distances and emissions.

[2] There were no emissions above 5 tpy for sources located within 20 km of the monitors sited in Puerto Rico and the Virgin Islands.

A.2 Analysis Duplicate SO_2 Values at Ambient Monitor Locations

During the screening of each of the ambient monitoring data sets, it became evident that simultaneous measurements were present. Staff analyzed the duplicate SO_2 measurements to discern if there were any differences in the reported/measured values because ultimately only one value would be selected for use in each of the final screened data sets. Staff was not interested in whether multiple monitors were present at a particular monitoring site or if there were duplicate reporting of SO_2 concentrations, only to determine that the selection of a particular value used in the final data sets were not biased.

In selecting which of the duplicate concentrations to use for final REA data sets, staff made the following judgements. First, the ambient monitor POC containing the greatest number of samples was used to populate the max-5 data set. Second, where continous-5 measurements were available and coincided with max-5 measurements, staff selected the 5-minute maximum SO_2 concentration from the continuous-5 data set. And finally, where continuous-5 data were available and used to estimate a 1-hour average SO_2 concentration that coincided with a reported 1-hour ambient monitor concentration, the continuous-5 1-hour average concentration was used. Staff designed the following analyses to explore the effect the selection of one concentration over another may have on the final data set used.

Staff calculated the relative percent difference (RPD) for each duplicate concentration, considering measurements within the 5-max data set (n=300,438), duplicate reporting between the continuous-5 and the max-5 data sets (n=29,058), and duplicate values between the 1-hour and the continuous-5 data sets (n=258,457), separately. We anticipated that small fluctuations in concentration between the duplicate data would have a greater influence on the RPD at lower concentrations than at higher concentrations. Therefore, staff separated the duplicate values into concentration groups for this analysis. Two groups were constructed; one with concentrations ≤ 10 ppb and the other conrtaining concentrations > 10 ppb. The following formula calculates the RPD for each duplicate value:

$$RPD = \frac{(C_1 - C_2)}{(C_1 + C_2)} \times 200 \qquad \text{equation A.2-1}$$

where,

RPD = Relative percent difference (%)

C_1 = First SO_2 concentration value

C_2 = Second SO_2 concentration value

Depending on the difference in concentration, the value for the calculated RPD could be as low as -200 or as high +200, indicating the maximum difference between any two values, while an RPD of zero indicates no difference. The sign of the value can also indicate the direction of bias when comparing the first concentration to the second.

In the first comparison (i.e., the within max-5 duplicates), C_1 was selected as the ambient monitor containing the overall greater sample size/duration. Table A.2-1 summarizes the distribution of RPDs for where duplicate values of SO_2 concentrations were less than 10 ppb within the max-5 monitoring data set. On average, there were relatively small differences in the duplicate values reported at each of the monitoring locations. Most duplicate values were within +/-67% of one another, although some were noted at or above 100% (absolute difference). In considering that these maximum 5-minute SO_2 concentrations are well below that of potential interest in the exposure and risk analysis, this degree of agreement between the two values at these concentration levels is acceptable.

Table A.2-1. Distribution of the relative percent difference (RPD) between duplicate 5-minute maximum SO_2 values at max-5 monitors, where concentrations were ≤ 10 ppb.

Monitor ID	n	Relative Percent Difference (%)[1]						
		mean	std	min	p5	p50	p95	max
290210009	25868	0	34	-196	-50	0	67	100
290210011	22247	-7	22	-143	-40	0	18	67
290930030	54904	8	34	-181	-40	0	67	100
290930031	48417	-14	29	-122	-67	0	67	67

290990018	17025	2	25	-156	-40	0	67	100
291630002	11528	-3	34	-164	-40	0	67	67

Notes:
[1] the mean, std, min, p5, p50, p95, max are the arithmetic average, standard deviation, minimum, 5th, median, 95th, and maximum, respectively.

When considering duplicate values > 10 ppb, the RPD was much lower at each of the monitors (Table A.2-2). Most of the RPDs are within +/-10%, indicating excellent agreement among the duplicate values. A small negative bias may exist with selection of the monitor with the greatest number of samples as the base monitor, but on average the difference was typically less than 3%.

Table A.2-2. Distribution of the relative percent difference (RPD) between duplicate 5-minute maximum SO_2 values at max-5 monitors, where concentrations were > 10 ppb.

		Relative Percent Difference (%)[1]

290990018	2626	0	6	-81	-7	0	10	32
291630002	1195	-6	32	-137	-133	0	11	29

Notes:
[1] the mean, std, min, p5, p50, p95, max are the arithmetic average, standard deviation, minimum, 5th, median, 95th, and maximum, respectively.

Staff also analyzed data where the max-5 sampling times corresponded with the continuous-5 monitoring at the same location. Of the 29,058 duplicate measurement values, only 312 contained different values among the two sample types (i.e, a non-zero RPD). This indicates that the majority of the data are duplicate values reported in each of the two data sets. Since there were very few samples with RPDs deviating from zero (i.e., 1.1%), the following analysis included only the samples that had a non-zero difference and at any concentration levels. The distribution for the RPD given these monitors and duplicate monitoring events is provided in Table A.2-3. On average there may be a small positive bias in selecting the continuous-5 monitoring concentrations where differences existed, however given that there were only 1% of samples that differed among the two data sets, the overall impact to the below estimation procedure is determined as negligible. In addition, selection of the continuous-5 measurement preserves the relationship between the actual 5-minute maximum and the calculated 1-hour concentration derived from the multiple 5-minute measurements that occurred within the hour, not adding to uncertainty regarding the true relationship between the 1-hour and 5-minute maximum concentrations.

Table A.2-3. Distribution of the relative percent difference (RPD) between simultaneous 5-minute SO_2 maximum values in the max-5 and continuous-5 data sets, where concentrations > 0 ppb.

Monitor ID	n[1]	Relative Percent Difference (%)[2]						
		mean	std	min	p5	p50	p95	max
301110066	76	26	57	-143	-117	16	133	160
301110079	149	27	48	-178	-67	29	67	164
301110082	47	25	52	-67	-67	29	67	186
301110083	40	78	64	-120	-53	67	160	160

Notes:

[1] This distribution is for the number of samples where the RPD was non-zero. The majority of the duplicate measures (n=28,746) were identical.

[2] the mean, std, min, p5, p50, p95, max are the arithmetic average, standard deviation, minimum, 5th, median, 95th, and maximum, respectively.

In the last comparison (i.e., the 1-hour concentration duplicates), the 1-hour concentration from the continous-5 ambient monitors was selected as C_1 in equation A.2-1. Table A.2-4 summarizes the distribution of RPDs for where duplicate measurements of SO_2 concentrations were less than 10 ppb within the max-5 monitoring data set. While nearly 20% had no difference between the duplicate values, on average, there were greater differences in the duplicate 1-hour values at most of the monitors than was observed for the 5-minute duplicates. Nearly 20% of the concentrations were noted at or above 100% one another (absolute difference), however all of these were due to where reported values were zero at the 1-hour monitor and concentrations of 1 ppb were reported for the continuous-5 monitor. This factor contributes to the observed positive bias at most of the monitors, however in considering that these 1-hour SO_2 concentrations are below that of potential interest in the exposure and risk analysis, this degree of limited agreement between the two data sets at these concentration levels should be acceptable.

Table A.2-4. Distribution of the relative percent difference (RPD) between duplicate 1-hour SO_2 values in the continuous-5 and 1-hour data sets, where concentrations were ≤ 10 ppb.

Notes:
[1] the mean, std, min, p5, p50, p95, max are the arithmetic average, standard deviation, minimum, 5th, median, 95th, and maximum, respectively.

When considering duplicate 1-hour concentrations > 10 ppb, the RPD was much lower at each of these same monitors (Table A.2-5). Most RPD distributions were within +/-5%, indicating excellent agreement among the duplicate 1-hour values at concentrations above 10 ppb. A very small positive bias may exist with selection of the continuous-5 monitor data for use in the air quality characterization when compared with the reported 1-hour concentrations, but on average, the difference was typically less than 1% when considering concentrations above 10 ppb.

Table A.2-5. Distribution of the relative percent difference (RPD) between duplicate 1-hour SO_2 values in the continuous-5 and 1-hour data sets, where concentrations were > 10 ppb.

A.3 Peak-To-Mean Ratio Distributions

Peak-to-mean ratios (PMR) were calculated using the measured values for each the 5-minute maximum and 1-hour SO_2 concentrations. PMRs were seperated into 19 groups[2] based on the observed variability (3 bins) and concentrations ranges (7 bins) in measured 1-hour ambient monitor concentrations (n=2,367,686). Table A.3-1 summarizes the PMR distributions used for estimating 5-minute maximum concentrations from 1-hour measurements where ambient monitors were characterized by the 1-hour coefficient of variation (COV). These are the PMR distributions used in the statistical modeling of 5-minute maximum SO_2 concentrations in the air quality characterization and in the exposure modeling. Table A.3-2 summarizes the PMR distributions used for estimating 5-minute maximum SO_2 concentrations from 1-hour measurements where ambient monitors were characterized by the 1-hour coefficient of variation (GSD). Peak-to-mean ratios estimated by categorizing the ambient monitors by GSD were used only in evaluating an alternative method of estimating 5-minute SO_2 concentrations.

---

[2] Although there are 21 PMR distributions possible (i.e., 3 × 7), the COV < 100% and GSD <2.17 categories had only three 1-hour concentrations above 150 ppb. Therefore, the two highest concentration bins do not have a distribution, and concentrations > 75 ppb constituted the highest concentration bin in the low COV or low GSD bins.

Table A.3-1. Distribution of 5-minute maximum peak to 1-hour mean SO_2 concentration ratios (PMRs) using ambient monitors categorized by 1-hour coefficient of variation (COV) and 1-hour mean concentration.

	GSD ≤ 100%					100% < GSD ≤ 200%							COV > 200 %

Notes:

[1] 1-hour SO_2 concentration bins are: 0 = 1-hour mean < 5 ppb; 2 = 5 ≤ 1-hour mean < 10 ppb; 2 = 10 ≤ 1-hour mean < 25 ppb; 3 = 25 ≤ 1-hour mean < 75 ppb; 4 = 75 ≤ 1-hour mean < 150 ppb ; 5 = 150 ≤ 1-hour mean 250 ppb; 6 = 1-hour mean > 250 ppb.

[2] pct – *x* indicates the percentile of the distribution.

[3] *n* is the number of 5-minute maximum and 1-hour SO_2 measurements used to develop distribution.

Table A.3-2. Distribution of 5-minute maximum peak to 1-hour mean SO_2 concentration ratios (PMRs) using ambient monitors categorized by 1-hour geometric standard deviation (GSD) and 1-hour mean concentration.

Notes:

[1] 1-hour SO_2 concentration bins are: 0 = 1-hour mean < 5 ppb; 2 = 5 ≤ 1-hour mean < 10 ppb; 2 = 10 ≤ 1-hour mean < 25 ppb; 3 = 25 ≤ 1-hour mean < 75 ppb; 4 = 75 ≤ 1-hour mean < 150 ppb ; 5 = 150 ≤ 1-hour mean 250 ppb; 6 = 1-hour mean > 250 ppb.

[2] pct – *x* indicates the percentile of the distribution.

[3] *n* is the number of 5-minute maximum and 1-hour SO_2 measurements used to develop distribution.

A.4 Factors Used in Adjusting Air Quality to Just Meet the Current and Potential Alternative SO2 Air Quality Standards

The adjustment factors used for simulating just meeting particular forms and levels of SO_2 standards are described here in two sections. This was done given the difference in how the adjustment factors were derived and applied to each of the air quality scenarios and given the number of factors generated for the potential alternative standards. The first section includes the factors used for adjusting air quality to just meet the current standards (either the 24-hour or annual average), while the second section note the concentrations used in deriving the factors applied to simulate just meeting potential alternative standards.

A.4.1 Adjustment factors for just meeting the current standard

Both annual and daily adjustment factors were calculated for all selected counties in evaluating the current annual and daily standards however, the lowest value of the two was selected for use in adjusting concentrations (see REA section 7.2.4). The adjustment factors for each county, year, and the standard from which the factors were derived is given in Table A.4-1. In addion, the coefficient of variation (i.e., COV) was used as a measure to indicate the variability associated with each of the calculated factors when considering all of the monitors in a county. Within a given year, the COV generally indicates the extent of spatial variability in ambient concentrations, considering the number of monitors in operation. Variation in the COV across different years can indicate the temporal variability in a county however, year-to-year differences in the number and location of ambient monitors may confound this comparison. Lower COVs indicate similarity in that concentration metric in the county, while higher values indicate less homogeneity in concentrations (whether spatially or temporally).

Table A.4-1. Adjustment factors used in simulating air quality just meeting the current SO_2 NAAQS in selected counties by year.

Notes:

[1] Ambient SO_2 concentrations were closest to either the annual (A) or daily (D) NAAQS level.

A.4.2 Adjustment factors for just meeting the potential alternative standards

Five potential alternative standards (i.e., 50, 100, 150, 200, and 250 ppb daily maximum 1-hour) given a 99th percentile form and one alternative standard (200 ppb daily maximum 1-hour) given a 98th percentile form were selected for evaluation (for details, see REA chapter 5). Adjustment factors were derived for each of two 3-year groups of recent air quality (i.e., 2001-2003 and 2004-2006). For the sake of brevity, only the maximum 3-year averaged concentrations for each of the percentile forms are provided in Table A.4-2, rather than all of the adjustment factors. The actual adjustment factors used in simulating air quality can be derived for each of the concentration levels by dividing by the county concentration for each year goup. For example, the adjustement factor applied to the 2002 hourly mean concentrations in New Castle DE to simulate just meeting a 99th percentile daily maximum 1-hour of 100 ppb is 100/164 = 0.61. That is to say, to meet this particular standard, the hourly concentrations need to be adjusted downward by a factor of 0.61. The COV is also used to represent the temporal variability over the three years of monitoring (where such data exist).

Table A.4-2. Concentrations used in developing adjustment factors when simulating air quality just meeting potential alternative SO_2 NAAQS in selected counties by year.

Notes:

[1] Two monitors in the county had the same average 98th percentile daily 1-hour maximum concentrations. Concentrations, monitoring years, and COVs for both monitors are indicated.

A.5 Supplementary Results Tables for 5-minute Measurement Data

Table A.5-1. Annual average SO_2 concentrations and number of measured 5-minute daily maximum SO_2 concentrations above potential health effect benchmark levels. Data used were from 98 monitors that reported both the 5-minute maximum and 1-hour SO_2 concentrations for years 1997 through 2007.

Appendix B: Supplement to the SO_2 Exposure Assessment

B-1 OVERVIEW

This appendix contains supplemental descriptions of the methods and data used in the SO_2 exposure assessment, as well as detailed results from the exposure analyses performed. First, a broad description of the exposure modeling approach is described (section B-2), applicable to the two exposure modeling domains conducted to date: Greene County, Mo. and St. Louis, MO. Supplementary input data used in AERMOD are provided in section B-3, as well as the model predictions and ambient monitor measurements in each modeling domain. Section B-4 has additional input and output data for APEX. A series of Attachments follow, further documenting some of the data sources and modeling approaches used, as well as previously conducted uncertainty analyses on selected input parameters in APEX.

B-2 HUMAN EXPOSURE MODELING USING APEX

The Air Pollutants Exposure model (APEX) is a personal computer (PC)-based program designed to estimate human exposure to criteria and air toxic pollutants at the local, urban, and consolidated metropolitan levels. APEX, also known as TRIM.Expo, is the human inhalation exposure module of EPA's Total Risk Integrated Methodology (TRIM) model framework (US EPA, 1999), a modeling system with multimedia capabilities for assessing human health and ecological risks from hazardous and criteria air pollutants. It is developed to support evaluations with a scientifically sound, flexible, and user-friendly methodology. Additional information on the TRIM modeling system, as well as downloads of the APEX Model, user's guide, and other supporting documentation, are on EPA's Technology Transfer Network (TTN) at http://www.epa.gov/ttn/fera.

B-2.1 History

APEX was derived from the National Ambient Air Quality Standards (NAAQS) Exposure Model (NEM) series of models, developed to estimate exposure to the criteria pollutants (e.g., carbon monoxide (CO), ozone O_3). In 1979, EPA began by assembling a database of human activity patterns that could be used to estimate exposures to indoor and outdoor pollutants (Roddin et al., 1979). These data were then combined with measured outdoor concentrations in NEM to estimate exposures to CO (Biller et al., 1981; Johnson and Paul, 1983). In 1988, OAQPS began to incorporate probabilistic elements into the NEM methodology and use activity pattern data based on various human activity diary studies to create an early version of probabilistic NEM for O_3 (i.e., pNEM/O_3). In 1991, a probabilistic version of NEM was extended to CO (pNEM/CO) that included a one-compartment mass-balance model to estimate CO concentrations in indoor microenvironments. The application of this model to Denver, Colorado has been documented in Johnson et al. (1992). Additional enhancements to pNEM/O_3 in the early- to mid-1990's allowed for probabilistic exposure assessments in nine urban areas for the general population, outdoor children, and outdoor workers (Johnson et al., 1996a; 1996b; 1996c). Between 1999 and 2001, updated versions of pNEM/CO (versions 2.0 and 2.1) were developed that relied on activity diary data from EPA's Consolidated Human Activities Database (CHAD) and enhanced algorithms for simulating gas stove usage, estimating alveolar ventilation rate (a measure of human respiration), and modeling home-to-work commuting patterns.

The first version of APEX was essentially identical to pNEM/CO (version 2.0) except that it was capable of running on a PC instead of a mainframe. The next version, APEX2, was substantially different, particularly in the use of a personal profile approach (i.e., simulation of individuals) rather than a cohort simulation (i.e., groups of similar persons). APEX3 introduced a number of new features including automatic site selection from national databases, a series of new output tables providing summary exposure and dose statistics, and a thoroughly reorganized method of describing microenvironments and their parameters. Most of the spatial and temporal constraints of pNEM and APEX1 were removed or relaxed by version 3.

The version of APEX used in this exposure assessment is APEX4.3, described in the APEX User's Guide and the APEX Technical Support Document (US EPA, 2009a; 2009b) and referred to here as the APEX User's Guide and TSD. This latest version has the added flexibility of addressing user defined exposure timesteps within an hour.

B-2.2 APEX Model Overview

A **microenvironment** is a three-dimensional space in which human contact with an environmental pollutant takes place and which can be treated as a well-characterized, relatively homogeneous location with respect to pollutant concentrations for a specified time period.

APEX estimates human exposure to criteria and toxic air pollutants at the local, urban, or consolidated metropolitan area levels using a stochastic, microenvironmental approach. The model randomly selects data for a sample of hypothetical individuals from an actual population database and simulates each hypothetical individual's movements through time and space (e.g., at home, in vehicles) to estimate their exposure to a pollutant. APEX simulates commuting, and thus exposures that occur at home and work locations, for individuals who work in different areas than they live.

APEX can be conceptualized as a simulated field study that would involve selecting an actual sample of specific individuals who live in (or work and live in) a geographic area and then continuously monitoring their activities and subsequent inhalation exposure to a specific air pollutant during a specific period of time.

The main differences between APEX and an actual field study are that in APEX:

- The sample of individuals is a virtual sample, not actual persons. However, the population of individuals appropriately balanced according to various demographic variables and census data using their relative frequencies, in order to obtain a representative sample (to the extent possible) of the actual people in the study area

- The activity patterns of the sampled individuals (e.g., the specification of indoor and other microenvironments visited and the time spent in each) are assumed by the model to be comparable to individuals with similar demographic characteristics, according to activity data such as diaries compiled in EPA's Consolidated Human Activity Database (or CHAD; US EPA, 2002; McCurdy et al., 2000)
- The pollutant exposure concentrations are estimated by the model using a set of user-input ambient outdoor concentrations (either modeled or measured) and information on the behavior of the pollutant in various microenvironments;
- Variation in ambient air quality levels can be simulated by either adjusting air quality concentrations to just meet alternative ambient standards, or by reducing source emissions and obtaining resulting air quality modeling outputs that reflect these potential emission reductions, and
- The model accounts for the most significant factors contributing to inhalation exposure – the temporal and spatial distribution of people and pollutant concentrations throughout the study area and among microenvironments – while also allowing the flexibility to adjust some of these factors for alternative scenarios and sensitivity analyses.

APEX is designed to simulate human population exposure to criteria and air toxic pollutants at local, urban, and regional scales. The user specifies the geographic area to be modeled and the number of individuals to be simulated to represent this population. APEX then generates a personal profile for each simulated person that specifies various parameter values required by the model. The model next uses diary-derived time/activity data matched to each personal profile to generate an exposure event sequence (also referred to as *activity pattern* or *diary*) for the modeled individual that spans a specified time period, such as one year. Each event in the sequence specifies a start time, exposure duration, geographic location, microenvironment, and activity performed. Probabilistic algorithms are used to estimate the pollutant concentration associated with each exposure event. The estimated pollutant concentrations account for the effects of ambient (outdoor) pollutant concentration, penetration factors, air exchange rates, decay/deposition rates, and proximity to emission sources, depending on the microenvironment, available data, and estimation method selected by the user. Because the modeled individuals represent a random sample of the population of interest, the distribution of modeled individual exposures can be extrapolated to the larger population. Additional discussion regarding the five basic exposure modeling steps noted in the SO_2 REA are described in sections that follow.

B-2.2.1 Study Area Characterization

The APEX study area has traditionally been on the scale of a city or slightly larger metropolitan area, although it is now possible to model larger areas such as combined statistical areas (CSAs). In the exposure analyses performed as part of this NAAQS review, the study area is defined by either a single or a few counties. The demographic data used by the model to create personal profiles is provided at the census block level. For each block the model requires demographic information representing the distribution of age, gender, race, and work status within the study population. Each block has a location specified by latitude and longitude for some representative point (e.g., geographic center). The current release of APEX includes input files that already contain this demographic and location data for all census tracts, block groups, and blocks in the 50 United States, based on the 2000 Census. In this assessment, exposures were evaluated at the block level.

Air Quality Data

Air quality data can be input to the model as measured data from an ambient monitor or that generated by air quality modeling. This exposure analysis used modeled air quality data, whereas the principal emission sources included both mobile and stationary sources as well as fugitive emissions. Air quality data used for input to APEX were generated using AERMOD, a steady-state, Gaussian plume model (US EPA, 2004). The following steps were performed using AERMOD.

In APEX, the ambient air quality data are assigned to geographic areas called districts. The districts are used to assign pollutant concentrations to the blocks/tracts and microenvironments being modeled. The ambient air quality data are provided by the user as hourly time series for each district. As with blocks/tracts, each district has a representative location (latitude and longitude). APEX calculates the distance from each block/tract to each district center, and assigns the block/tract to the nearest district, provided the block/tract representative location point (e.g., geographic center) is in the district. Each block/tract can be assigned to only one district. In this assessment the district was synonymous with the receptor modeled in the dispersion modeling.

Meteorological Data

Ambient temperatures are input to APEX for different sites (locations). As with districts, APEX calculates the distance from each block to each temperature site and assigns each block to the nearest site. Hourly temperature data are from the National Climatic Data Center Surface Airways Hourly TD-3280 dataset (NCDC Surface Weather Observations). Daily average and 1-hour maxima are computed from these hourly data.

There are two files that are used to provide meteorological data to APEX. One file, the meteorological station location file, contains the locations of meteorological data recordings expressed in latitude and longitude coordinates. This file also contains start and end dates for the data recording periods. The temperature data file contains the data from the locations in the temperature zone location file. This file contains hourly temperature readings for the period being modeled for the meteorological stations in and around the study area.

B-2.2.2 Generate Simulated Individuals

APEX stochastically generates a user-specified number of simulated persons to represent the population in the study area. Each simulated person is represented by a personal profile, a summary of personal attributes that define the individual. APEX generates the simulated person or profile by probabilistically selecting values for a set of profile variables (Table B-2-1). The profile variables could include:

- Demographic variables, generated based on the census data;
- Physical variables, generated based on sets of distribution data;
- Other daily varying variables, generated based on literature-derived distribution data that change daily during the simulation period.

APEX first selects demographic and physical attributes for each specified individual, and then follows the individual over time and calculates his or her time series of exposure.

Table B-2-1. Examples of profile variables in APEX.

Variable Type	Profile Variables	Description
Demographic	Age	Age (years)
	Gender	Male or Female
	Home block	Block in which a simulated person lives
	Work tract	Tract in which a simulated person works
	Employment status	Indicates employment outside home
Physical	Air conditioner	Indicates presence of air conditioning at home
	Gas Stove	Indicates presence of gas stove at home

Population Demographics

APEX takes population characteristics into account to develop accurate representations of study area demographics. Specifically, population counts by area and employment probability estimates are used to develop representative profiles of hypothetical individuals for the simulation.

APEX is flexible in the resolution of population data provided. As long as the data are available, any resolution can be used (e.g., county, census tract, census block). For this application of the model, census block level data were used. Block-level population counts come from the 2000 Census of Population and Housing Summary File 1 (SF-1). This file contains the 100-percent data, which is the information compiled from the questions asked of all people and about every housing unit.

As part of the population demographics inputs, it is important to integrate working patterns into the assessment. In the 2000 U.S. Census, estimates of employment were developed by census information (US Census Bureau, 2007). The employment statistics are broken down by gender and age group, so that each gender/age group combination is given an employment probability fraction (ranging from 0 to 1) within each census tract. The age groupings used are: 16-19, 20-21, 22-24, 25-29, 30-34, 35-44, 45-54, 55-59, 60-61, 62-64, 65-69, 70-74, and >75. Children under 16 years of age were assumed to be not employed.

Since this analysis was conducted at the census block level, block level employment probabilities were required. It was assumed that the employment probabilities for a census tract apply uniformly to the constituent census blocks.

Commuting

In addition to using estimates of employment by tract, APEX also incorporates home-to-work commuting data. Commuting data were originally derived from the 2000 Census and were collected as part of the Census Transportation Planning Package (CTPP) (US DOT, 2007). The data used contain counts of individuals commuting from home to work locations at a number of geographic scales. These data were processed to calculate fractions for each tract-to-tract flow to create the national commuting data distributed with APEX. This database contains commuting data for each of the 50 states and Washington, D.C.

Commuting within the Home Tract

The APEX data set does not differentiate people that work at home from those that commute within their home tract.

Commuting Distance Cutoff

A preliminary data analysis of the home-work counts showed that a graph of log(flows) versus log(distance) had a near-constant slope out to a distance of around 120 kilometers. Beyond that distance, the relationship also had a fairly constant slope but it was flatter, meaning that flows were not as sensitive to distance. A simple interpretation of this result is that up to 120 km, the majority of the flow was due to persons traveling back and forth daily, and the numbers of such persons decrease rapidly with increasing distance. Beyond 120 km, the majority of the flow is comprosed of persons who stay at the workplace for extended times, in which case the separation distance is not as crucial in determining the flow.

To apply the home-work data to commuting patterns in APEX, a simple rule was chosen. It was assumed that all persons in home-work flows up to 120 km are daily commuters, and no persons in more widely separated flows commute daily. This meant that the list of destinations for each home tract was restricted to only those work tracts that are within 120 km of the home tract. When the same cutoff was performed on the 1990 census data, it resulted in 4.75% of the home-work pairs in the nationwide database being eliminated, representing 1.3% of the workers. The assumption is that this 1.3% of workers do not commute from home to work on a daily basis. It is expected that the cutoff reduced the 2000 data by similar amounts.

Eliminated Records

A number of tract-to-tract pairs were eliminated from the database for various reasons. A fair number of tract-to-tract pairs represented workers who either worked outside of the U.S.

(9,631 tract pairs with 107,595 workers) or worked in an unknown location (120,830 tract pairs with 8,940,163 workers). An additional 515 workers in the commuting database whose data were missing from the original files, possibly due to privacy concerns or errors, were also deleted.

Commuting outside the study area

APEX allows for some flexibility in the treatment of persons in the modeled population who commute to destinations outside the study area. By specifying “KeepLeavers = No” in the simulation control parameters file, people who work inside the study area but live outside of it are not modeled, nor are people who live in the study area but work outside of it. By specifying “KeepLeavers = Yes,” these commuters are modeled. This triggers the use of two additional parameters, called LeaverMult and LeaverAdd. While a commuter is at work, if the workplace is outside the study area, then the ambient concentration is assumed to be related to the average concentration over all air districts at the same point in time, and is calculated as:

$$Ambient\ Concentrat\ ion = LeaverMult\ \times avg\,(t) + LeaverAdd \qquad \text{equation (B-1)}$$

where:

Ambient Concentration = Calculated ambient air concentrations for locations outside of the study area (ppm or ppm)
LeaverMult = Multiplicative factor for city-wide average concentration, applied when working outside study area
avg(t) = Average ambient air concentration over all air districts in study area, for time *t* (ppm or ppm)
LeaverAdd = Additive term applied when working outside study area

All microenvironmental concentrations for locations outside of the study area are determined from this ambient concentration by the same function as applies inside the study area.

Block-level commuting

For census block simulations, APEX requires block-level commuting file. A special software preprocesser was created to generate these files for APEX on the basis of the tract-level commuting data and finely-resolved land use data. The software calculates commuting flows between census blocks for the employed population according equation (B-2).

$$Flow_{block} = Flow_{tract} \times F_{pop} \times F_{land} \qquad \text{equation (B-2)}$$

where:

$Flow_{block}$ = flow of working population between a home block and a work block.
$Flow_{tract}$ = flow of working population between a home tract and a work tract.
F_{pop} = fraction of home tract's working population residing in the home block.
F_{land} = fraction of work tract's commercial/industrial land area in the work block

Thus, it is assumed that the frequency of commuting to a workplace block within a tract is proportional to the amount of commercial and industrial land in the block.

Profile Functions

A *Profile Functions* file contains settings used to generate results for variables related to simulated individuals. While certain settings for individuals are generated automatically by APEX based on other input files, including demographic characteristics, others can be specified using this file. For example, the file may contain settings for determining whether the profiled individual's residence has an air conditioner, a gas stove, etc. As an example, the *Profile Functions* file contains fractions indicating the prevalence of air conditioning in the cities modeled in this assessment (Figure B-2-1). APEX uses these fractions to stochastically generate air conditioning status for each individual. The derivation of particular data used in specific microenvironments is provided below.

B-2.2.3 Longitudinal Activity Pattern Sequences

Exposure models use human activity pattern data to predict and estimate exposure to pollutants. Different human activities, such as spending time outdoors, indoors, or driving, will have varying pollutant exposure concentrations. To accurately model individuals and their exposure to pollutants, it is critical to understand their daily activities.

The Consolidated Human Activity Database (CHAD) provides data for where people spend time and the activities performed. CHAD was designed to provide a basis for conducting multi-route, multi-media exposure assessments (McCurdy et al., 2000). The data contained within CHAD come from multiple activity pattern surveys with varied structures (Table B-2-2), however the surveys have commonality in containing daily diaries of human activities and personal attributes (e.g., age and gender).

There are four CHAD-related input files used in APEX. Two of these files can be downloaded directly from the CHADNet (http://www.epa.gov/chadnet1), and adjusted to fit into the APEX framework. These are the human activity diaries file and the personal data file, and are discussed below. A third input file contains metabolic information for different activities listed in the diary file, these are not used in this exposure analysis. The fourth input file maps five-digit location codes used in the diary file to APEX microenvironments; this file is discussed in the section describing microenvironmental calculations (Section B-2.2.4.4).

Personal Information file

Personal attribute data are contained in the CHAD questionnaire file that is distributed with APEX. This file also has information for each day individuals have diaries. The different variables in this file are:

- The study, person, and diary day identifiers
- Day of week
- Gender
- Employment status
- Age in years
- Maximum temperature in degrees Celsius for this diary day
- Mean temperature in degrees Celsius for this diary day
- Occupation code

- Time, in minutes, during this diary day for which no data are included in the database

Diary Events file

The human activity diary data are contained in the events file that is distributed with APEX. This file contains the activities for the nearly 23,000 people with intervals ranging from one minute to one hour. An individuals' diary varies in length from one to 15 days. This file contains the following variables:

- The study, person, and diary day identifiers
- Start time of this activity
- Number of minutes for this activity
- Activity code (a record of what the individual was doing)
- Location code (a record of where the individual was)

Table B-2-2. Summary of activity pattern studies used in CHAD.

Study Name	Location	Study time period	Ages	Persons	Person -days	Diary type /study design	Reference

Construction of Longitudinal Activity Sequences

Typical time-activity pattern data available for inhalation exposure modeling consist of a sequence of location/activity combinations spanning a 24-hour duration, with 1 to 3 diary-days for any single individual. Exposure modeling requires information on activity patterns over longer periods of time, e.g., a full year. For example, even for pollutant health effects with short averaging times (e.g., SO_2 5-minute average concentration) it may be desirable to know the frequency of exceedances of a concentration over a long period of time (e.g., the annual number of exceedances of a 24-hour average SO_2 concentration of 100 ppb for each simulated individual).

Long-term multi-day activity patterns can be estimated from single days by combining the daily records in various ways, and the method used for combining them will influence the variability of the long-term activity patterns across the simulated population. This in turn will influence the ability of the model to accurately represent either long-term average high-end exposures, or the number of individuals exposed multiple times to short-term high-end concentrations.

A common approach for constructing long-term activity patterns from short-term records is to re-select a daily activity pattern from the pool of data for each day, with the implicit assumption that there is no correlation between activities from day to day for the simulated individual. This approach tends to result in long-term activity patterns that are very similar across the simulated population. Thus, the resulting exposure estimates are likely to underestimate the variability across the population, and therefore, underestimate the high-end exposure concentrations or the frequency of exceedances.

A contrasting approach is to select a single activity pattern (or a single pattern for each season and/or weekday-weekend) to represent a simulated individual's activities over the duration of the exposure assessment. This approach has the implicit assumption that an individual's day-to-day activities are perfectly correlated. This approach tends to result in long-term activity patterns that are very different across the simulated population, and therefore may over-estimate the variability across the population.

Cluster-Markov Algorithm

A new algorithm has been developed and incorporated into APEX to represent the day-to-day correlation of activities for individuals. The algorithms first use cluster analysis to divide the daily activity pattern records into groups that are similar, and then select a single daily record from each group. This limited number of daily patterns is then used to construct a long-term sequence for a simulated individual, based on empirically-derived transition probabilities. This approach is intermediate between the assumption of no day-to-day correlation (i.e., re-selection for each time period) and perfect correlation (i.e., selection of a single daily record to represent all days).

The steps in the algorithm are as follows.

1. For each demographic group (age, gender, employment status), temperature range, and day-of-week combination, the associated time-activity records are partitioned into 3

groups using cluster analysis. The clustering criterion is a vector of 5 values: the time spent in each of 5 microenvironment categories (indoors – residence; indoors – other building; outdoors – near road; outdoors – away from road; in vehicle).

2. For each simulated individual, a single time-activity record is randomly selected from each cluster.
3. A Markov process determines the probability of a given time-activity pattern occurring on a given day based on the time-activity pattern of the previous day and cluster-to-cluster transition probabilities. The cluster-to-cluster transition probabilities are estimated from the available multi-day time-activity records. If insufficient multi-day time-activity records are available for a demographic group, season, day-of-week combination, then the cluster-to-cluster transition probabilities are estimated from the frequency of time-activity records in each cluster in the CHAD data base.

Details regarding the Cluster-Markov algorithm and supporting evaluations are provided in Attachments 3 and 4.

B-2.2.4 Calculating Microenvironmental Concentrations

Probabilistic algorithms estimate the pollutant concentration associated with each exposure event. The estimated pollutant concentrations account for the effects of ambient (outdoor) pollutant concentration, penetration factor, air exchange rate, decay/deposition rate, and proximity to microenvironments can use the transfer factors method while the others use the mass balance emission sources, depending on the microenvironment, available data, and the estimation method selected by the user.

APEX calculates air concentrations in the various microenvironments visited by the simulated person by using the ambient air data for the relevant blocks, the user-specified estimation method, and input parameters specific to each microenvironment. APEX calculates hourly concentrations in all the microenvironments at each hour of the simulation for each of the simulated individuals using one of two methods: by mass balance or a transfer factors method.

Mass Balance Model

The mass balance method simulates an enclosed microenvironment as a well-mixed volume in which the air concentration is spatially uniform at any specific time. The following processes are used estimate the concentration of an air pollutant in such a microenvironment:

- Inflow of air into the microenvironment

- Outflow of air from the microenvironment
- Removal of a pollutant from the microenvironment due to deposition, filtration, and chemical degradation
- Pollutant emissions inside the microenvironment.

Table B-2-3 lists the parameters required by the mass balance method to calculate concentrations in a microenvironment. A proximity factor ($f_{proximity}$) is used to account for differences in ambient concentrations between the geographic location represented by the ambient air quality data (e.g., a regional fixed-site monitor or modeled concentration) and the geographic location of the microenvironment (e.g., near a roadway). This factor could take a value either greater than or less than 1. Emission source (ES) represents the emission rate for the emission source and concentration source (CS) is the mean air concentration resulting from the source. $R_{removal}$ is defined as the removal rate of a pollutant from a microenvironment due to deposition, filtration, and chemical reaction. The air exchange rate ($R_{air\ exchange}$) is expressed in air changes per hour.

Table B-2-3. Mass balance model parameters.

Variable	Definition	Units	Value Range
$f_{proximity}$	Proximity factor	unitless	$f_{proximity} \geq 0$
CS	Concentration source	ppb	$CS \geq 0$
$R_{removal}$	Removal rate due to deposition, filtration, and chemical reaction	1/hr	$R_{removal} \geq 0$
$R_{air\ exchange}$	Air exchange rate	1/hr	$R_{air\ exchange} \geq 0$
V	Volume of microenvironment	m^3	$V > 0$

The mass balance equation for a pollutant in a microenvironment is described by:

$$\frac{dC_{ME}(t)}{dt} = \Delta C_{in} - \Delta C_{out} - \Delta C_{removal} + \Delta C_{source} \qquad \text{equation (B-3)}$$

where:

$dC_{ME}(t)$ = Change in concentration in a microenvironment at time t (ppb),

ΔC_{in} = Rate of change in microenvironmental concentration due to influx of air (ppb/hour),

ΔC_{out} = Rate of change in microenvironmental concentration due to outflux of air (ppb/hour),

$\Delta C_{removal}$ = Rate of change in microenvironmental concentration due to removal processes (ppb/hour), and

ΔC_{source} = Rate of change in microenvironmental concentration due to an emission source inside the microenvironment (ppb/hour).

Within the timestep selected, each of the rates of change, ΔC_{in}, ΔC_{out}, $\Delta C_{removal}$, and ΔC_{source}, is assumed to be constant. At each timestep of the simulation period, APEX estimates the equilibrium, ending, and mean concentrations using a series of equations that account for concentration changes expected to occur due to these physical processes. Details regarding these equations are provided in the APEX TSD (US EPA, 2009b). The calculation continues to the next timestep by using the end concentration for the previous timestep as the initial microenvironmental concentration. A brief description of the input parameters estimates used for microenvironments using the mass balance approach is provided below.

Factors Model

The factors method is simpler than the mass balance method. It does not calculate concentration in a microenvironment from the concentration in the previous hour and it has fewer parameters. Table B-2-4 lists the parameters required by the factors method to calculate concentrations in a microenvironment without emissions sources.

Table B-2-4. Factors model parameters.

Variable	Definition	Units	Value Range
$f_{proximity}$	Proximity factor	unitless	$f_{proximity} \geq 0$
$f_{penetration}$	Penetration factor	unitless	$0 \leq f_{penetration} \leq 1$

The factors method uses the following equation to calculate the timestep concentration in a microenvironment from the user-provided hourly air quality data:

$$C_{ME}^{timestep} = C_{ambient} \; x \; f_{proximity} \; x \; f_{penetration} \qquad \text{equation (B-4)}$$

where:

$C_{ME}^{timestep}$ = Timestep concentration in a microenvironment (ppb)

$C_{ambient}$ = Timestep concentration in ambient environment (ppb)

$f_{proximity}$ = Proximity factor (unitless)

$f_{penetration}$ = Penetration factor (unitless)

The ambient NO_2 concentrations are from the air quality data input file. The proximity factor is a unitless parameter that represents the proximity of the microenvironment to a monitoring station. The penetration factor is a unitless parameter that represents the fraction of pollutant entering a microenvironment from outside the microenvironment via air exchange. The development of the specific proximity and penetration factors used in this analysis are discussed below for each microenvironment using this approach.

Microenvironments Modeled

In APEX, microenvironments represent the exposure locations for simulated individuals. For exposures to be estimated accurately, it is important to have realistic microenvironments that match closely to the locations where actual people spend time on a daily basis. As discussed above, the two methods available in APEX for calculating pollutant levels within microenvironments are: 1) factors and 2) mass balance. A list of microenvironments used in this study, the calculation method used, and the parameters used to calculate the microenvironment concentrations can be found in Table B-2-5.

Each of the microenvironments is designed to simulate an environment in which people spend time during the day. CHAD locations are linked to the different microenvironments in the *Microenvironment Mapping* File (see below). There are many more CHAD locations than microenvironment locations (there are 113 CHAD codes versus 12 microenvironments in this assessment), therefore most of the microenvironments have multiple CHAD locations mapped to them.

Table B-2-5. List of microenvironments and calculation methods used.

Microenvironment		Calculation Method	Parameter Types used [1]
No.	Name		
1	Indoors – Residence	Mass balance	AER and DE
2	Indoors – Bars and restaurants	Mass balance	AER and DE
3	Indoors – Schools	Mass balance	AER and DE
4	Indoors – Day-care centers	Mass balance	AER and DE
5	Indoors – Office	Mass balance	AER and DE
6	Indoors – Shopping	Mass balance	AER and DE
7	Indoors – Other	Mass balance	AER and DE
8	Outdoors – Near road	Factors	PR
9	Outdoors – Public garage - parking lot	Factors	PR
10	Outdoors – Other	Factors	None
11	In-vehicle – Cars and Trucks	Factors	PE and PR
12	In-vehicle - Mass Transit (bus, subway, train)	Factors	PE and PR
0	Not modeled		

[1] AER=air exchange rate, DE=decay-deposition rate, PR=proximity factor, PE=penetration factor

Mapping of APEX Microenvironments to CHAD Diaries

The *Microenvironment Mapping* file matches the APEX Microenvironments to CHAD Location codes. Table B-2-6 gives the mapping used for the APEX simulations.

Table B-2-6. Mapping of CHAD activity locations to APEX microenvironments.

```
CHAD Loc.  Description                            APEX micro

B-2.2.5 Exposure Calculations

APEX calculates exposure as a time series of exposure concentrations that a simulated individual experiences during the simulation period. APEX determines the exposure using hourly ambient air concentrations, calculated concentrations in each microenvironment based on these ambient air concentrations (and indoor sources if present), and the minutes spent in a sequence of microenvironments visited according to the composite diary. The hourly exposure concentration at any clock hour during the simulation period is determined using the following equation:

$$C_i = \frac{\sum_{j=1}^{N} C_{ME(j)}^{timestep} \quad t_{(j)}}{T} \qquad \text{equation (B-5)}$$

where:

C_i = Hourly exposure concentration at clock hour i of the simulation period (ppb)

N = Number of events (i.e., microenvironments visited) in clock hour i of the simulation period.

$C_{ME(j)}^{timestep}$ = Timestep concentration in microenvironment j (ppm)

$t_{(j)}$ = Time spent in microenvironment j (minutes)

T = Length of timestep (minutes)

From the timestep exposures, APEX calculates time series of 1-hour, 8-hour and daily average exposures that a simulated individual would experience during the simulation period. APEX then statistically summarizes and tabulates the timestep, hourly, 8-hour, and daily exposures. Note that if the APEX timestep is greater than an hour, the 1-hour and 8-hour exposures are not calculated and the corresponding tables are not produced. Exposures are calculated independently for all pollutants in the simulation.

From the timestep exposures, APEX can calculate the time-series of 1-hour, 8-hour, and daily average exposures that a simulated individual would experience during the simulation period. APEX then statistically summarizes and tabulates the timestep (or hourly, daily, annual average) exposures. In this analysis, the exposure indicator is 5-minute exposures above potential health effect benchmark levels. From this, APEX can calculate two general types of exposure estimates: counts of the estimated number of people exposed to a specified SO_2 concentration level and the number of times per year that they are so exposed; the latter metric is typically expressed in terms of person-occurrences or person-days. The former highlights the number of individuals exposed at least *one or more* times per modeling period to the health effect benchmark level of interest. APEX can also report counts of individuals with multiple exposures. This person-occurrences measure estimates the number of times per season that individuals are exposed to the exposure indicator of interest and then accumulates these estimates for the entire population residing in an area.

APEX tabulates and displays the two measures for exposures above levels ranging from any number of benchmark levels, by any increment (e.g., 0 to 800 ppb by 50 ppb increments for 5-minute exposures). These exposure results are tabulated for the population and subpopulations of interest.

Exposure Model Output

All of the output files written by APEX are ASCII text files. Table B-2-7 lists each of the output data files written for these simulations and provides descriptions of their content. Additional output files that can produced by APEX are given in Table 5-1 of the APEX User's Guide, and include hourly exposure, ventilation, and energy expenditures, and even detailed event-level information, if desired. The names and locations, as well as the output table levels (e.g., output percentiles, cut-points), for these output files are specified by the user in the simulation control parameters file.

Table B-2-7. Example of APEX output files.

Output File Type	Description
Log	The *Log* file contains the record of the APEX model simulation as it progresses. If the simulation completes successfully, the log file indicates the input files and parameter settings used for the simulation and reports on a number of different factors. If the simulation ends prematurely, the log file contains error messages describing the critical errors that caused the simulation to end.
Profile Summary	The *Profile Summary* file provides a summary of each individual modeled in the simulation.
Microenvironment Summary	The *Microenvironment Summary* file provides a summary of the time and exposure by microenvironment for each individual modeled in the simulation.
Sites	The *Sites* file lists the tracts, districts, and zones in the study area, and identifies the mapping between them.
Output Tables	The *Output Tables* file contains a series of tables summarizing the results of the simulation. The percentiles and cut-off points used in these tables are defined in the simulation control parameters file.

Notes:

[1] UTM Zone 15 values in all cases.

[2] Three methods were possible to convert annual total emissions data from the NEI into hourly temporal profiles required for AERMOD, based on availability of data:

Tier 1: CAMD hourly concentrations to create relative temporal profiles.
Tier 2: EMS-HAP seasonal and diurnal temporal profiles for source categorization codes (SCCs).
Tier 3: Flat profiles

Notes:

[1] UTM Zone 15 values in all cases.

[2] Three methods were possible to convert annual total emissions data from the NEI into hourly temporal profiles required for AERMOD, based on availability of data:

Tier 1: CAMD hourly concentrations to create relative temporal profiles.
Tier 2: EMS-HAP seasonal and diurnal temporal profiles for source categorization codes (SCCs).
Tier 3: Flat profiles

B-3.2 AERMOD Air Quality Evaluation Data

Table B-3-2. Measured ambient monitor SO_2 concentration distributions and the modeled monitor receptor and receptors within 4 km of the ambient monitors in Greene County for year 2002.

Notes:

[1] AERMOD concentrations are for the given percentile (p2.5 = 2.5th; p50 = 50th; p97.5 = 97.5th) of the modeled distribution of all modeled air quality receptors within 4 km of ambient monitor. *AERMOD monitor* is the concentration prediction at the ambient monitor location using AERMOD.

Table B-3-3. Measured ambient monitor SO_2 concentration diurnal profile and the modeled monitor receptor and receptors within 4 km of the ambient monitors in Greene County for year 2002.

B-4 SUPPLEMENTAL APEX EXPOSURE MODELING DATA

B-4.1 APEX Input Data Distributions for SO_2 deposition

In recognizing the relationship between SO_2 deposition rate and various surface types within indoor microenvironments and that the presence of these surfaces would vary in proportions dependent on the microenvironment, staff estimated the APEX input SO_2 deposition rate distributions using a Monte Carlo sampling approach. First, 1,000 different hypothetical indoor microenvironments were simulated, each with a different ratio of wall area to floor area and furniture area to floor area. Based on these ratios, surface area to volume ratios were estimated in each sample indoor microenvironment. Then, surface area to volume ratios were used to convert the deposition velocities to deposition rates in hr^{-1} by dividing the velocities by the surface area to volume ratio and then making an appropriate unit conversion. And finally, the deposition rate for each surface type was combined using a weighted average to estimate an effective deposition rate, as follows:

$$D_{eff} = \frac{D_{floor} + D_{ceiling} * \frac{A_{ceiling}}{A_{floor}} + D_{furniture} * \frac{A_{furntiture}}{A_{floor}}}{1 + \frac{A_{ceiling}}{A_{floor}} + \frac{A_{furniture}}{A_{floor}}} \qquad \text{equation (B-6)}$$

where D denotes deposition rate, A denotes area of the indoor microenvironment, and D_{eff} is the effective deposition rate. If more than one surface type is present in the sample indoor microenvironment (e.g. both carpet and non-carpeted floors), these values were first averaged using the fraction of the room that contains each. Details regarding the data used for estimating the SO_2 deposition rate within simulated indoor microenvironments are provided in the following sections.

B-4.1.1 Surface deposition data and surface type mapping

Staff obtained SO_2 deposition velocities from a literature review conducted by Grøntoft and Raychaudhuri (2004). These authors categorized the data by several relative humidities and considering several different surface types. Staff mapped the surface classes reported in Grøntoft and Raychaudhuri (2004) to surface types typically found within indoor microenvironments (Table B-4-1).

Table B-4-1. Classification of SO_2 deposition data for several microenvironmental surfaces.

Surface Category	**Surface Type**	**Surface Class**[1]	**Deposition in cm/s**[1]		
			50% Relative Humidity	**70% Relative Humidity**	**90% Relative Humidity**
Floor	Carpet	Average of the wool and synthetic carpet values	0.0625	0.075	0.117
	Floor	Synthetic Floor Covering – medium worn	0.007	0.015	0.032
Ceiling	Ceiling Tile	Coarse composite panels	0.14	0.15	0.18
	Ceiling Wallboard	Treated gypsum wallboard	0.048	0.16	0.27
Wall	Wallpaper	Wall paper	0.036	0.043	0.068
	Wall Wallboard	Treated gypsum wallboard	0.048	0.16	0.27
	Wood paneling	Surface treated wood work and wall boards	0.014	0.047	0.078
Furniture	Furniture	Cloth	0.019	0.023	0.036

Notes:
[1] Obtained from Table 6 of Grøntoft and Raychaudhuri (2004).

B-4.1.2 Indoor Microenvironment Configurations

Because the configuration of rooms within a building will affect the wall area to floor area ratio, staff first estimated the areas of several indoor microenvironments. Staff had to make several assumptions due to the limited availability of data. The first broad assumption was that a single room within the indoor microenvironment could represent all potential rooms within the particular building type. Secondly, staff assumed all rooms were square to calculate the area distributions. Additional assumptions specific to the type of indoor microenvironment are provided below, along with the estimated indoor microenvironment area distributions.

Residential area distributions

In residences, the American Housing Survey (AHS, 2008) provides a matrix that gives the number of survey homes within a given total square footage and a given number of rooms category. Staff converted the data to probabilities using the total number of homes in each category (Table B-4-2). In calculating the room area using these distributions, a series of two independent random numbers were used to select a square footage category and then to find the number of rooms within that square footage category, accounting for the inherent correlation of the number of rooms in a given building with the total square footage. Staff derived a representative room area by dividing the square footage by the number of rooms.

Table B-4-2. Distributions used to calculate a representative room size in an indoor residential microenvironment.

		Square Footage					
		250	**750**	**1250**	**1750**	**2250**	**2750**
	Cumulative probability for each square footage class →	**0.01**	**0.10**	**0.35**	**0.60**	**0.77**	**1.00**
Cumulative probability for number of rooms within each square footage class ↓	**Rooms**						
	1	0.07	0.00	0.00	0.00	0.00	0.00
	2	0.13	0.00	0.00	0.00	0.00	0.00
	3	0.40	0.07	0.01	0.00	0.00	0.00
	4	0.64	0.47	0.13	0.04	0.02	0.01
	5	0.81	0.80	0.54	0.28	0.15	0.08
	6	0.90	0.94	0.86	0.65	0.41	0.23
	7	0.97	0.98	0.96	0.90	0.71	0.46
	8	0.99	0.99	0.99	0.98	0.92	0.71
	9	0.99	1.00	1.00	0.99	0.98	0.87
	10	1.00			1.00	1.00	1.00

Non-residential area distributions

An office can contain many different rooms, each with either one or two occupants (usually a smaller office) or a collection of cubicles (usually a larger office).

Staff used the Building Assessment Survey and Evaluation study (BASE; US EPA, 2008a) to generate representative office areas for simulated buildings. The BASE data provided the mean, standard deviation, minimum, and maximum of the total square footage and the number of people per square meter of occupied space (Table B-4-3).[1] Based on this, staff represented the data as a normal distribution and set the lower and upper limits using the minimum and maximum observations. BASE (US EPA, 2008a) also provides the average number of occupants in private or semi-private work areas (40%) compared to shared space (60%).[2] Staff assumed that the private and semi-private offices have an average of two people in each and the shared spaces have an average of six people in each. In calculating the area, two independent random numbers were used to select the total floor area and the number of occupants in that floor area. The total square footage of the office was then divided by the number of rooms to obtain the representative office area.

For schools, the distribution of the total building square footage is available from the Commercial Building Energy Consumption Survey (CBECS; US DOE, 2003); however, information on the number of rooms in each square footage class is not available. As an alternate data source, information was available on the range of the square footage of a typical school classroom (600 to 1,400 square feet) to generate a uniform distribution bounded by these extremes (NCBG, 2008; US Army Corps of Engineers, 2002). For restaurants and other buildings, staff assumed that the entire building was one room; therefore, the CBECS (US DOE, 2003) provided data for this building category to estimate square footage distributions (Table B-4-3).

Table B-4-3. Distributions used to calculate representative room size for non-residential microenvironments.

Microenvironment	Parameter 1[a]	Parameter 2[b]	Parameter 3[c]	Parameter 4[d]	Distribution Type
Office, Building size (ft^2)	16,632	8,035	4,612	69,530	Normal
Office, number of people per m^2.	4.0	1.5	1.5	8.5	Normal

[2] http://www.epa.gov/iaq/base/pdfs/test_space_characteristics/tc-1.pdf

School (ft^2)	600	1,400	N/A	N/A	Uniform
Restaurant (ft^2)	5,340	31	668	42,699	Lognormal
Other Buildings (ft^2)	3,750	24	750	18,796	Lognormal

Notes:
[a] Mean for normal, geometric mean for lognormal, lower limit for uniform distribution.
[b] Standard deviation for normal, geometric standard deviation for lognormal, upper limit for uniform.
[c] Minimum value for normal and lognormal.
[d] Maximum value for normal and lognormal.

Additional specifications

Two additional specifications were required to calculate the room volumes and surface areas: the ceiling heights and surface area of furniture within the rooms. Table B-4-4 provides the data values and sources used to estimate each of these variables.

Table B-4-4. Ceiling heights and furniture surface area to floor ratios for simulated indoor microenvironments.

Indoor Microenvironment	Ceiling Height[a]	Furniture Surface Area to Floor Ratio
Residence	8 ft	2[b]
Office	10 ft	4[c]
School	10 ft	4[c]
Restaurant	10 ft	4[c]
Other Buildings	10 ft	4[c]

Notes:
[a] Assumed by staff.
[b] Thatcher et al. (2002) and Singer et al. (2002).
[c] The surface area to volume ratio was assumed higher in the commercial microenvironments than in residences. A value of 4 was selected since it kept the range of total surface area to volume ratio within a typical range of 2 to 4 (Lawrence Berkeley National Laboratory., 2003).

B-4.1.3 Surface type probabilities

Following the calculation of the basic dimensions of the simulated room, staff performed additional probabilistic sampling to specify the surface types present. In some microenvironments, it is possible that only a single surface type be present (e.g., a public access building likely contains only hard floors and no carpet). However, in other cases, a typical building may have multiple surface types (e.g., a residence may have a mixture of both hard floor and carpet). Thus, in each microenvironment, staff estimated a probability of occurrence for each surface type. If more than one surface type is possible at the same time, then staff also approximated the fraction of each. Table B-4-5 summarizes both the probabilities and fractions assumed by staff for each microenvironment.

B-4.1.4 Final SO_2 deposition distributions

Following the estimation of the room dimensions and surface types within each simulated indoor microenvironment, an effective deposition rate was estimated for all 1,000 sample buildings. The geometric mean and geometric standard deviation were calculated across all 1,000 samples and used to parameterize a lognormal distribution (Table B-4-6). In applying these to the relative humidity conditions in the study areas, staff assumed that the relative humidity is below 50% when the air conditioning or heating unit is on. If the building has no air conditioner, the ambient summer humidity was used (90 % in the morning, 50% in the afternoon). Staff also assumed that all non-residential buildings had air-conditioning.

As far as mapping to the APEX microenvironments, residences, offices, and restaurants are explicitely modeled microenvironments. The daycare microenvironment used the school deposition distribution, while other indoor microenvironments (i.e., shopping or other) used the other building deposition distribution.

Table B-4-5. Probability of occurrence and fractional quantity for surface types in indoor micronenvironments.

Indoor Microenvironment	Floor		Ceiling		Wall		
	Carpet	Hard floor	Wallboard	Ceiling Tile	Wallboard	Wallpaper	Wood Paneling
Residence	P = 1 F = N{0.52, 0.23}[a]	P = 1 F = 1 - fraction carpeted[a]	P = 1[c]	P = 0[c]	P = 1 F= 5/6 if wallpaper is present[c]	P = 0.225 F= 1/6 if wallpaper is present[d]	P = 0[c]
Office	P = 1 F = 5/6 if hard floor present[c]	P = 0.34 F= 1/6 if hard floor is present[b]	P = 0[c]	P = 1[c]	P = 1 F is adjusted if wallpaper and/or wood paneling is present[c]	P = 0.11 F= 1/6 if wallpaper is present[b]	P = 0.13 F = 1/6 if wood paneling is present[b]
School	P = 0[c]	P = 1[c]	P = 0[c]	P = 1[c]	P = 1[c]	P = 0[c]	P = 0[c]
Restaurant	P = 0.1[d]	P = 0.9[d]	P = 0.55[d]	P = 0.45[d]	P = 1 F is adjusted if wallpaper and/or wood paneling is present[c]	P = 0.09 F = 1/2 if wallpaper is present[d]	P = 0.25 F = 1/10 If wood paneling is present[d]
Other Buildings	P = 0.1[d]	P = 0.9[d]	P = 0.19[d]	P = 0.81[d]	P = 1 F is adjusted if wallpaper and/or wood paneling is present[c]	P = 0.09 F = 1/2 if wallpaper is present[d]	P = 0.045 F=1/10 if wood paneling is present[d]

Notes:

[a] US EPA, 2008b.

[b] BASE study, Table 4 (US EPA, 2008a); the fraction of 1/6 is based on professional judgment.

[c] Assumed by staff.

[d] Source Ranking Database (SRD, US EPA, 2004b). The fraction of buildings value in the database was used to specify a probability each surface type occurs in the microenvironment. SRD names were matched to the APEX environments. Most categories in the SRD have the same fraction of building values. To map to the necessary surface types: Carpet – Networx represented carpet; Ceiling tile represented ceiling tile; vinyl coated wallpaper represented wallpaper; and Hardwood plywood paneling represented wood paneling. Fractions were assumed by staff. Then, probabilities in the remaining surface types were calculated assuming either only one type could be present or multiple types could be present.

Table B-4-6. Final parameter estimates of SO_2 deposition distributions in several indoor microenvironments modeled in APEX.

Microenv-ironment	Heating or Air Conditioning in Use				Air Conditioning Not in Use (Summertime Ambient Morning Relative Humidity of 90%)			
	Geom. Mean (hr^{-1})	Geom. Stand. Dev. (hr^{-1})	Lower Limit (hr^{-1})	Upper Limit (hr^{-1})	Geom. Mean (hr^{-1})	Geom. Stand. Dev. (hr^{-1})	Lower Limit (hr^{-1})	Upper Limit (hr^{-1})
Residence	3.14	1.11	2.20	5.34	13.41	1.11	10.31	26.96
Office	3.99	1.04	3.63	4.37	N/A	N/A	N/A	N/A
School	4.02	1.02	3.90	4.21	N/A	N/A	N/A	N/A
Restaurant	2.36	1.28	1.64	4.17	N/A	N/A	N/A	N/A
Other Buildings	2.82	1.21	1.71	4.12	N/A	N/A	N/A	N/A
Notes: N/A not applicable, assumed by staff to always have A/C in operation.

Re: EPA 68D01052, Work Assignment 3-08. Analysis of NHIS Asthma Prevalence Data

---

This memorandum describes our analysis of children's asthma prevalence data from the National Health Interview Survey (NHIS) for 2003. Asthma prevalence rates for children aged 0 to 17 years were calculated for each age, gender, and region. The regions defined by NHIS are "Midwest," "Northeast," "South," and "West." For this project, asthma prevalence was defined as the probability of a Yes response to the question CASHMEV: "Ever been told that … had asthma?" among those that responded Yes or No to this question. The responses were weighted to take into account the complex survey design of the NHIS survey. Standard errors and confidence intervals for the prevalence were calculated using a logistic model, taking into account the survey design. Prevalence curves showing the variation of asthma prevalence against age for a given gender and region were plotted. A scatterplot smoothing technique using the LOESS smoother was applied to smooth the prevalence curves and compute the standard errors and confidence intervals for the smoothed prevalence estimates. Logistic analysis of the prevalence curves shows statistically significant differences in prevalence by gender and by region. Therefore we did not combine the prevalence rates for different genders or regions.

Logistic Models

NHIS survey data for 2003 were provided by EPA. One obvious approach to calculate prevalence rates and their uncertainties for a given gender, region, and age is to calculate the proportion of Yes responses among the Yes and No responses for that demographic group, weighting each response by the survey weight. Although that approach was initially used, two problems are that the distributions of the estimated prevalence rates are not well approximated by normal distributions, and that the estimated confidence intervals based on the normal approximation often extend outside the [0, 1] interval. A better approach is to use a logistic transformation and fit a model of the form:

$$\text{Prob (asthma)} = \exp(\text{beta}) / (1 + \exp(\text{beta})),$$

where beta may depend on the explanatory variables for age, gender, or region. This is equivalent to the model:

Beta = logit {prob (asthma) } = log { prob (asthma) / [1 – prob (asthma)] }.

The distribution of the estimated values of beta is more closely approximated by a normal distribution than the distribution of the corresponding estimates of prob (asthma). By applying a logit transformation to the confidence intervals for beta, the corresponding confidence intervals for prob (asthma) will always be inside [0, 1]. Another advantage of the logistic modeling is that it can be used to compare alternative statistical models, such as models where the prevalence probability depends upon age, region, and gender, or on age and region but not gender.

A variety of logistic models for asthma prevalence were fit and compared, where the transformed probability variable beta is a given function of age, gender, and region. SAS's SURVEYLOGISTIC procedure was used to fit the logistic models, taking into account the NHIS survey weights and survey design (stratification and clustering).

The following Table G-1 lists the models fitted and their log-likelihood goodness-of-fit measures. 16 models were fitted. The Strata column lists the four possible stratifications: no stratification, by gender, by region, by region and gender. For example, "4. region, gender" means that separate prevalence estimates were made for each combination of region and gender. As another example, "2. gender" means that separate prevalence estimates were made for each gender, so that for each gender, the prevalence is assumed to be the same for each region. The prevalence estimates are independently calculated for each stratum.

Table G-1. Alternative logistic models for asthma prevalence.

Model	Description	Strata	- 2 Log Likelihood	DF
1	1. logit(prob) = linear in age	1. none	54168194.62	2
2	1. logit(prob) = linear in age	2. gender	53974657.17	4
3	1. logit(prob) = linear in age	3. region	54048602.57	8
4	1. logit(prob) = linear in age	4. region, gender	53837594.97	16
5	2. logit(prob) = quadratic in age	1. none	53958021.20	3
6	2. logit(prob) = quadratic in age	2. gender	53758240.99	6
7	2. logit(prob) = quadratic in age	3. region	53818198.13	12
8	2. logit(prob) = quadratic in age	4. region, gender	53593569.84	24
9	3. logit(prob) = cubic in age	1. none	53849072.76	4
10	3. logit(prob) = cubic in age	2. gender	53639181.24	8
11	3. logit(prob) = cubic in age	3. region	53694710.66	16
12	3. logit(prob) = cubic in age	4. region, gender	53441122.98	32
13	4. logit(prob) = f(age)	1. none	53610093.48	18

Model	Description	Strata	- 2 Log Likelihood	DF
14	4. logit(prob) = f(age)	2. gender	53226610.02	36
15	4. logit(prob) = f(age)	3. region	53099749.33	72
16	4. logit(prob) = f(age)	4. region, gender	52380000.19	144

The Description column describes how beta depends upon the age:

Linear in age: Beta = $\alpha + \beta \times \text{age}$, where α and β vary with the strata.
Quadratic in age: Beta = $\alpha + \beta \times \text{age} + \gamma \times \text{age}^2$ where α β and γ vary with the strata.
Cubic in age: Beta = $\alpha + \beta \times \text{age} + \gamma \times \text{age}^2 + \delta \times \text{age}^3$ where α β, γ, and δ vary with the strata.
f(age) Beta = arbitrary function of age, with different functions for different strata

The category f(age) is equivalent to making age one of the stratification variables, and is also equivalent to making beta a polynomial of degree 16 in age (since the maximum age for children is 17), with coefficients that may vary with the strata.

The fitted models are listed in order of complexity, where the simplest model (1) is an unstratified linear model in age and the most complex model (16) has a prevalence that is an arbitrary function of age, gender, and region. Model 16 is equivalent to calculating independent prevalence estimates for each of the 144 combinations of age, gender, and region.

Table G-1 also includes the -2 Log Likelihood, a goodness-of-fit measure, and the degrees of freedom, DF, which is the total number of estimated parameters. Two models can be compared using their -2 Log Likelihood values; lower values are preferred. If the first model is a special case of the second model, then the approximate statistical significance of the first model is estimated by comparing the difference in the -2 Log Likelihood values with a chi-squared random variable with r degrees of freedom, where r is the difference in the DF. This is a likelihood ratio test. For all pairs of models from Table G-1, all the differences are at least 70,000 and the likelihood ratios are all extremely statistically significant at levels well below 5 percent. Therefore the model 16 is clearly preferred and was used to model the prevalences.

The SURVEYLOGISTIC model predictions are tabulated in Table G-2 below and plotted in Figures 1 and 3 below. Also shown in Table G-2 and in Figures 2 and 4 are results for smoothed curves calculated using a LOESS scatterplot smoother, as discussed below.

The SURVEYLOGISTIC procedure produces estimates of the beta values and their 95 % confidence intervals for each combination of age, region, and gender. Applying the inverse logit transformation,

Prob (asthma) = exp(beta) / (1 + exp(beta)),

converted the beta values and 95 % confidence intervals into predictions and 95 % confidence intervals for the prevalence, as shown in Table G-2 and Figures 1 and 3. The standard error for the prevalence was estimated as

$$\text{Std Error } \{\text{Prob (asthma)}\} = \text{Std Error (beta)} \times \exp(-\text{ beta}) / (1 + \exp(\text{beta}))^2,$$

which follows from the delta method (a first order Taylor series approximation).

Loess Smoother

The estimated prevalence curves shows that the prevalence is not a smooth function of age. The linear, quadratic, and cubic functions of age modeled by SURVEYLOGISTIC were one strategy for smoothing the curves, but they did not provide a good fit to the data. One reason for this might be due to the attempt to fit a global regression curve to all the age groups, which means that the predictions for age A are affected by data for very different ages. We instead chose to use a local regression approach that separately fits a regression curve to each age A and its neighboring ages, giving a regression weight of 1 to the age A, and lower weights to the neighboring ages using a tri-weight function:

$$\text{Weight} = \{1 - [\ |\text{age} - A| / q\ ]^3\},\ \text{ where } |\text{ age} - A| <= q.$$

The parameter q defines the number of points in the neighborhood of the age a. Instead of calling q the smoothing parameter, SAS defines the smoothing parameter as the proportion of points in each neighborhood. We fitted a quadratic function of age to each age neighborhood, separately for each gender and region combination. We fitted these local regression curves to the beta values, the logits of the asthma prevalence estimates, and then converted them back to estimated prevalence rates by applying the inverse logit function exp(beta) / (1 + exp(beta)). In addition to the tri-weight variable, each beta value was assigned a weight of $1 / [\text{std error (beta)}]^2$, to account for their uncertainties.

The SAS LOESS procedure was applied to estimate smoothed curves for beta, the logit of the prevalence, as a function of age, separately for each region and gender. We fitted curves using the choices 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, and 1.0 for the smoothing parameter in an effort to determine the optimum choice based on various regression diagnostics.3,4

---

3 Two outlier cases were adjusted to avoid wild variations in the “smoothed” curves: For the West region, males, age 0, there were 97 children surveyed that all gave No answers to the asthma question, leading to an estimated value of -15.2029 for beta with a standard error of 0.14. For the Northeast region, females, age 0, there were 29 children surveyed that all gave No answers to the asthma question, leading to an estimated value of -15.2029 for beta with a standard error of 0.19. In both cases the raw probability of asthma equals zero, so the corresponding estimated beta would be negative infinity, but SAS’s software gives -15.2029 instead. To reduce the impact of these outlier cases, we replaced their estimated standard errors by 4, which is approximately four times the maximum standard error for all other region, gender, and age combinations.

4 With only 18 points, a smoothing parameter of 0.2 cannot be used because the weight function assigns zero weights to all ages except age A, and a quadratic model cannot be uniquely fitted to a single value. A smoothing parameter of 0.3 also cannot be used because that choice assigns a neighborhood of 5 points only (0.3 × 18 = 5, rounded down), of which the two outside ages have assigned weight zero, making the local quadratic model fit exactly at every point except for the end points (ages 0, 1, 16 and 17). Usually one uses a smoothing parameter below one so that not all the data are used for the local regression at a given x value.

Quantities predicted in these smoothing parameter tests were the predicted value, standard error, confidence interval lower bound and confidence interval upper bound for the betas, and the corresponding values for the prevalence rates.

The polygonal curves joining values for different ages show the predicted values with vertical lines indicating the confidence intervals in Figures 3 and 4 for smoothing parameters 0 (i.e., no smoothing) and 0.5, respectively. Note that the confidence intervals are not symmetric about the predicted values because of the inverse logit transformation.

Note that in our application of LOESS, we used weights of 1 / [std error (beta)] ^{2}, so that $\sigma^2 = 1$ for this application. The LOESS procedure estimates σ^2 from the weighted sum of squares. Since in our application we assume $\sigma^2 = 1$, we multiplied the estimated standard errors by 1 / estimated σ, and adjusted the widths of the confidence intervals by the same factor.

Additionally, because the true value of σ equals 1, the best choices of smoothing parameter should give residual standard errors close to one. Using this criterion the best choice varies with gender and region between smoothing parameters 0.4 (3 cases), 0.5 (2 cases), 0.6 (1 case), and 0.7 (1 case).

As a further regression diagnostic the residual errors from the LOESS model were divided by std error (beta) to make their variances approximately constant. These approximately studentized residuals, ‘student,’ should be approximately normally distributed with a mean of zero and a variance of $\sigma^2 = 1$. To test this assumption, normal probability plots of the residuals were created for each smoothing parameter, combining all the studentized residuals across genders, regions, and ages. The plots for smoothing parameters seem to be equally straight for each smoothing parameter.

The final regression diagnostic is a plot of the studentized residuals against the smoothed beta values. Ideally there should be no obvious pattern and an average studentized residual close to zero. The plots indeed showed no unusual patterns, and the results for smoothing parameters 0.5 and 0.6 seem to showed a fitted LOESS close to the studentized residual equals zero line.

The regression diagnostics suggested the choice of smoothing parameter as 0.4 or 0.5. Normal probability plots did not suggest any preferred choices. The plots of residuals against smoothed predictions suggest the choices of 0.5 or 0.6. We therefore chose the final value of 0.5. These predictions, standard errors, and confidence intervals are presented in tabular form below as Table G-2.

DATE: February 29, 2008

SUBJECT: The Cluster-Markov algorithm in APEX

Background

The goals of population exposure assessment generally include an accurate estimate of both the average exposure concentration and the high end of the exposure distribution. One of the factors influencing the number of exposures at the high end of the concentration distribution is time-activity patterns that differ from the average, e.g., a disproportionate amount of time spent near roadways. Whether a model represents these exposure scenarios well depends on whether the treatment of activity pattern data accurately characterizes differences among individuals.

Human time-activity data for population exposure models are generally derived from demographic surveys of individuals' daily activities, the amount of time spent engaged in those activities, and the ME locations where the activities occur. Typical time-activity pattern data available for inhalation exposure modeling consist of a sequence of location/activity combinations spanning a 24-hour duration, with 1 to 3 records for any single individual. But modeling assessments of exposure to air pollutants typically require information on activity patterns over long periods of time, e.g., a full year. For example, even for pollutant health effects with short averaging times (e.g., ozone 8-hour average) it may be desirable to know the frequency of exceedances of a threshold concentration over a long period of time (e.g., the annual number of exceedances of an 8-hour average ozone concentration of 0.07 ppm for each simulated individual).

Long-term activity patterns can be estimated from daily ones by combining the daily records in various ways, and the method used for combining them will influence the variability of the long-term activity patterns across the simulated population. This in turn will influence the ability of the model to accurately represent either long-term average high-end exposures, or the number of individuals exposed multiple times to short-term high-end concentrations.

A common approach for constructing long-term activity patterns from short-term records is to re-select a daily activity pattern from the pool of data for each day, with the implicit assumption that there is no correlation between activities from day to day for the simulated individual. This approach tends to result in long-term activity patterns that are very similar across the simulated population. Thus, the resulting exposure estimates are likely to underestimate the variability across the population, and therefore, underestimate the high-end concentrations.

A contrasting approach is to select a single activity pattern (or a single pattern for each season and/or weekday-weekend) to represent a simulated individual's activities over the modeling period. This approach has the implicit assumption that an individual's day to day activities are perfectly correlated. This approach tends to result in long-term activity patterns that are very different across the simulated population, and therefore may over-estimate the variability across the population.

The Cluster-Markov Algorithm

Recently, a new algorithm has been developed and incorporated into APEX that attempts to more realistically represent the day-to-day correlation of activities for individuals. The algorithms first use cluster analysis to divide the daily activity pattern records into groups that are similar, and then select a single daily record from each group. This limited number of daily patterns is then used to construct a long-term sequence for a simulated individual, based on empirically-derived transition probabilities. This approach is intermediate between the assumption of no day-to-day correlation (i.e., re-selection for each time period) and perfect correlation (i.e., selection of a single daily record to represent all days).

The steps in the algorithm are as follows.

- For each demographic group (age, gender, employment status), temperature range, and day-of-week combination, the associated time-activity records are partitioned into 3 groups using cluster analysis. The clustering criterion is a vector of 5 values: the time spent in each of 5 microenvironment categories (indoors – residence; indoors – other building; outdoors – near road; outdoors – away from road; in vehicle).
- For each simulated individual, a single time-activity record is randomly selected from each cluster.
- Next the Markov process determines the probability of a given time-activity pattern occurring on a given day based on the time-activity pattern of the previous day and cluster-to-cluster transition probabilities. The cluster-to-cluster transition probabilities are estimated from the available multi-day time-activity records. (If insufficient multi-day time-activity records are available for a demographic group, season, day-of-week combination, then the cluster-to-cluster transition probabilities are estimated from the frequency of time-activity records in each cluster in the CHAD data base.).

Figure 1 illustrates the Cluster-Markov algorithm in flow chart format.

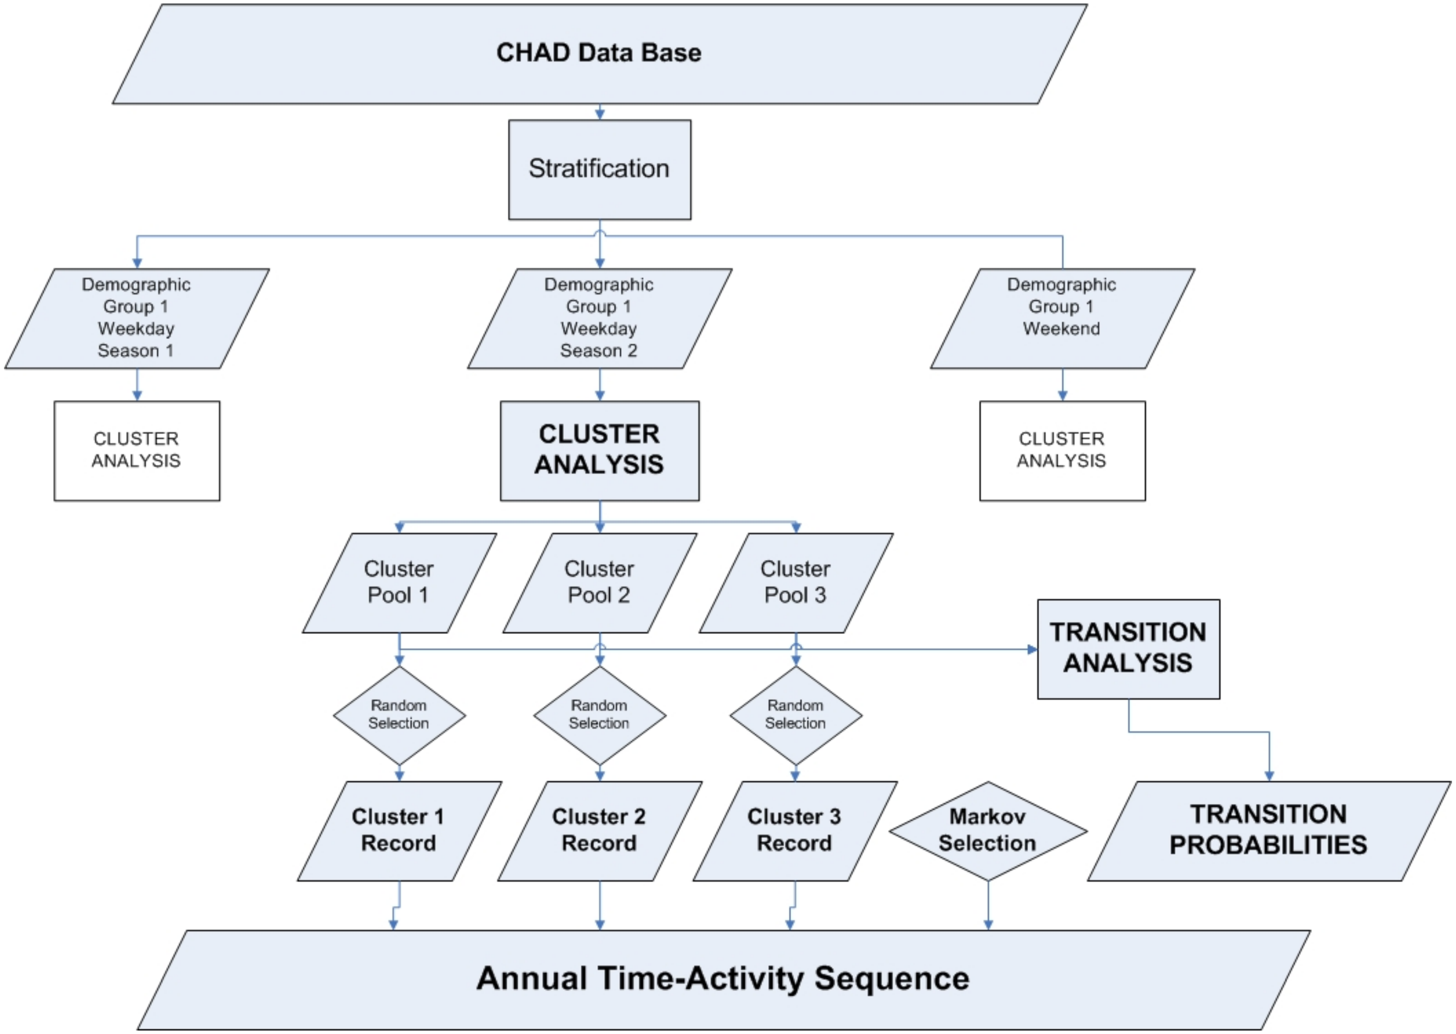

Figure 1. Flow chart of Cluster-Markov algorithm used for constructing longitudinal time-activity diaries.

Evaluation of modeled diary profiles versus observed diary profiles

The Cluster-Markov algorithm is also incorporated into the Hazardous Air Pollutant Exposure Model (HAPEM). Rosebaum and Cohen (2004) incorporated the algorithm in HAPEM and tested modeled longitudinal profiles with multi-day diary data sets collected as part of the Harvard Southern California Chronic Ozone Exposure Study (Xue et al. 2005, Geyh et al. 2000). In this study, 224 children in ages between 7 and 12 yr were followed for 1 year from June 1995 to May 1996, for 6 consecutive days each month. The subjects resided in two separate areas of San Bernardino County: urban Upland CA, and the small mountain towns of Lake Arrowhead, Crestline, and Running Springs, CA.

For purposes of clustering the activity pattern records were characterized according to time spent in each of 5 aggregate microenvironments: indoors-home, indoors-school, indoors-other, outdoors, and in-transit. For purposes of defining diary pools and for clustering and calculating transition probabilities the activity pattern records were divided by day type (i.e., weekday, weekend), season (i.e., summer or ozone season, non-summer or non-ozone season), age (7-10 and 11-12), and gender.

Week-long sequences (Wednesday through Tuesday) for each of 100 people in each age/gender group for each season were simulated. To evaluate the algorithm the following statistics were calculated for the predicted multi-day activity patterns and compared them with the actual multi-day diary data.

- For each age/gender group for each season, the average time in each microenvironment
- For each simulated person-week and microenvironment, the average of the within-person variance across all simulated persons. (The within-person variance was defined as the variance of the total time per day spent in the microenvironment across the week.)
- For each simulated person-week the variance across persons of the mean time spent in each microenvironment.

In each case the predicted statistic for the stratum was compared to the statistic for the corresponding stratum in the actual diary data. The mean normalized bias for the statistic, which is a common performance measure used in dispersion model performance and was also calculated as follows.

$$NBIAS = \frac{100}{N}\sum_{1}^{N}\frac{(predicted - observed)}{observed}$$

The predicted time-in-microenvironment averages matched well with the observed values. For combinations of microenvironment/age/gender/season the normalized bias ranges from –35% to +41%. Sixty percent of the predicted averages have bias between –9% and +9%, and the mean bias across any microenvironment ranges from -9% to +4%. Fourteen predictions have positive bias and 23 have negative bias.

For the variance across persons for the average time spent in each microenvironment, the bias ranged from –40% to +120% for any microenvironment/age/gender/season. Sixty-five percent of the predicted variances had bias between –22% and +24%. The mean normalized bias across any microenvironment ranged from –10% to +28%. Eighteen predictions had positive bias and 20 had negative bias.

For the within-person variance for time spent in each microenvironment, the bias ranged from –47% to +150% for any microenvironment/age/gender/season. Seventy percent of the predicted variances had bias between –25% and +30%. The mean normalized bias across any microenvironment ranged from –11% to +47%. Twenty-eight predictions had positive bias and 12 had negative bias, suggesting some tendency for overprediction of this variance measure.

The overall conclusion was that the proposed algorithm appeared to be able to replicate the observed data reasonably well. Although some discrepancies were rather large for some of the "variance across persons" and "within-person variance" subsets, about two-thirds of the predictions for each case were within 30% of the observed value. A detailed description of the evaluation using HAPEM is presented in Attachment 4.

Comparison of Cluster-Markov approach with other algorithms

As part of the application of APEX in support of US EPA's recent review of the ozone NAAQS several sensitivity analyses were conducted (US EPA, 2007). One of these was to make parallel simulations using each of the three algorithms for constructing multi-day time-activity sequences that are incorporated into APEX.

Table 1 presents the results for the number of persons in Atlanta population groups with moderate exertion exposed to 8-hour average concentrations exceeding 0.07 ppm. The results show that the predictions made with alternative algorithm Cluster-Markov algorithm are substantially different from those made with simple re-sampling or with the Diversity-Autocorrelation algorithm ("base case"). Note that for the cluster algorithm approximately 30% of the individuals with 1 or more exposure have 3 or more exposures. The corresponding values for the other algorithms range from about 13% to 21%.

Table 2 presents the results for the mean and standard deviation of number of days/person with 8-hour average exposures exceeding 0.07 ppm with moderate or greater exertion. The results show that although the mean for the Cluster-Markov algorithm is similar to the other approaches, the standard deviation is substantially higher, i.e., the Cluster-Markov algorithm results in substantially higher inter-individual variability.

Table 1. Sensitivity to longitudinal diary algorithm: 2002 simulated counts of Atlanta general population and children (ages 5-18) with any or three or more 8-hour ozone exposures above 0.07 ppm concomitant with moderate or greater exertion (after US EPA 2007).

Population Group	One or more exposures			Three or more exposures		
	Simple re-sampling	Diversity-Autocorrelation	Cluster-Markov	Simple re-sampling	Diversity-Autocorrelation	Cluster-Markov
General Population	979,533	939,663 (-4%)	668,004 (-32%)	124,687	144,470 (+16%)	188,509 (+51%)
Children (5-18)	411,429	389,372 (-5%)	295,004 (-28%)	71,174	83,377 (+17%)	94,216 (+32%)

Table 2. Sensitivity to longitudinal diary algorithm: 2002 days per person with 8-hour ozone exposures above 0.07 ppm concomitant with moderate or greater exertion for Atlanta general population and children (ages 5-18) (after US EPA 2007).

Population Group	Mean Days/Person			Standard Deviation		
	Simple re-sampling	Base case	Cluster-Markov	Simple re-sampling	Base case	Cluster-Markov
General Population	0.332	0.335 (+1%)	0.342 (+3%)	0.757	0.802 (+6%)	1.197 (+58%)
Children (5-18)	0.746	0.755 (+1%)	0.758 (+2%)	1.077	1.171 (+9%)	1.652 (+53%)

ATTACHMENT 4: TECHNICAL MEMORANDUM ON THE EVALUATION CLUSTER-MARKOV ALGORITHM

TECHNICAL MEMORANDUM

TO: Ted Palma, US EPA

FROM: Arlene Rosenbaum and Jonathan Cohen, ICF Consulting

DATE: November 4, 2004

SUBJECT: Evaluation of a multi-day activity pattern algorithm for creating longitudinal activity patterns.

BACKGROUND

In previous work ICF reviewed the HAPEM4 modeling approach for developing annual average activity patterns from the CHAD database and recommended an approach to improve the model's pattern selection process to better represent the variability among individuals. This section summarizes the recommended approach. (For details see Attachment 3)

Using cluster analysis, first the CHAD daily activity patterns are grouped into either two or three categories of similar patterns for each of the 30 combinations of day type (summer weekday, non-summer weekday, and weekend) and demographic group (males or females; age groups: 0-4, 5-11, 12-17, 18-64, 65+). Next, for each combination of day type and demographic group, category-to-category transition probabilities are defined by the relative frequencies of each second-day category associated with each given first-day category, where the same individual was observed for two consecutive days. (Consecutive day activity pattern records for a single individual constitute a small subset of the CHAD data.)

To implement the proposed algorithm, for each day type and demographic group, one daily activity pattern per category is randomly selected from the corresponding CHAD data to represent that category. That is, if there are 3 cluster categories for each of 3 day types, 9 unique activity patterns are selected to be averaged together to create an annual average activity pattern to represent an individual in a given demographic group and census tract.

The weighting for each of the 9 activity patterns used in the averaging process is determined by the product of two factors. The first is the relative frequency of its day type, i.e., 0.18 for summer weekdays, 0.54 for non-summer weekdays, and 0.28 for weekends.

The second factor in the weighting for the selected activity pattern is determined by simulating a sequence of category-types as a one-stage Markov chain process using the transition probabilities. The category for the first day is selected according to the relative frequencies of each category. The category for the second day is selected according to the category-to-category transition probabilities for the category selected for the first day. The category for the third day is selected according to the transition probabilities for the category selected for the second day. This is repeated for all days in the day type (65 for summer weekdays, 195 for non-summer weekdays, 104 for weekends), producing a sequence of daily categories. The relative frequency of the category-type in the sequence associated with the selected activity pattern is the second factor in the weighting.

PROPOSED ALGORITHM STEPS

The proposed algorithm is summarized in Figure 1. Each step is explained in this section.

Data Preparation

Step 1: Each daily activity pattern in the CHAD data base is summarized by the total minutes in each of five micro-environments: indoors – residence; indoors – other building; outdoors – near road; outdoors – away from road; in vehicle. These five numbers are assumed to represent the most important features of the activity pattern for their exposure impact.

Step 2: All CHAD activity patterns for a given day-type and demographic group are subjected to cluster analysis, resulting in 2 or 3 cluster categories. Each daily activity pattern is tagged with a cluster category.

Step 3: For each day-type and demographic group, the relative frequency of each day-type in the CHAD data base is determined.

Step 4: All CHAD activity patterns for a given day-type and demographic group that are consecutive days for a single individual, are analyzed to determine the category-to-category transition frequencies in the CHAD data base. These transition frequencies are used to calculate category-to-category transition probabilities.

For example, if there are 2 categories, A and B, then

P_{AA} = the probability that a type A pattern is followed by a type A pattern,

P_{AB} = the probability that a type A pattern is followed by a type B pattern ($P_{AB} = 1 – P_{AA}$),

P_{BB} = the probability that a type B pattern is followed by a type B pattern, and

P_{BA} = the probability that a type B pattern is followed by a type A pattern ($P_{BA} = 1 – P_{BB}$).

Activity Pattern Selection

For each day-type and demographic group in each census tract:

Step 5: One activity pattern is randomly selected from each cluster category group (i.e., 2 to 3 activity patterns)

Creating Weights for Day-type Averaging

For each day-type and demographic group in each census tract:

Step 6: A cluster category is selected for the first day of the day-type sequence, according to the relative frequency of the cluster category days in the CHAD data set.

Step 7: A cluster category is selected for each subsequent day in the day-type sequence day by day using the category-to-category transition probabilities.

Step 8: The relative frequency of each cluster category in the day-type sequence is determined.

Step 9: The activity patterns selected for each cluster category (Step 5) are averaged together using the cluster category frequencies (Step 8) as weights, to create a day-type average activity pattern.

Creating Annual Average Activity Patterns

For each demographic group in each census tract:

Step 10: The day-type average activity patterns are averaged together using the relative frequency of day-types as weights, to create an annual average activity pattern.

Creating Replicates

For each demographic group in each census tract:

Step 11: Steps 5 through 10 are repeated 29 times to create 30 annual average activity patterns.

EVALUATING THE ALGORITHM

The purpose of this study is to evaluate how well the proposed one-stage Markov chain algorithm can reproduce observed multi-day activity patterns with respect to demographic group means and inter-individual variability, while using one-day selection.

In order to accomplish this we propose to apply the algorithm to observed multi-day activity patterns provided by the WAM, and compare the means and variances of the predicted multi-day patterns with the observed patterns.

Current APEX Algorithm

Because the algorithm is being considered for incorporation into APEX, we would like the evaluation to be consistent with the approach taken in APEX for selection of activity patterns for creating multi-day sequences. The APEX approach for creating multi-day activity sequences is as follows.

Step1: A profile for a simulated individual is generated by selection of gender, age group, and home sector from a given set of distributions consistent with the population of the study area.

Step 2: A specific age within the age group is selected from a uniform distribution.

Step 3: The employment status is simulated as a function of the age.

Step 4: For each simulated day, the user defines an initial pool of possible diary days based on a user-specified function of the day type (e.g., weekday/weekend) and temperature.

Step 5: The pool is further restricted to match the target gender and employment status exactly and the age within 2A years for some parameter A. The diary days within the pool are assigned a weight of 1 if the age is within A years of the target age and a weight of w (user-defined parameter) if the age difference is between A and 2A years. For each simulated day, the probability of selecting a given diary day is equal to the age weight divided by the total of the age weights for all diary days in the pool for that day.

Approach to Incorporation of Day-to-Day Dependence into APEX Algorithm

If we were going to incorporate day-to-day dependence of activity patterns into the APEX model, we would propose preparing the data with cluster analysis and transition probabilities as described in Steps 1-4 for the proposed HAPEM 5 algorithm, with the following modifications.

- For Step 2 the activity patterns would be divided into groups based on day-type (weekday, weekend), temperature, gender, employment status, and age, with cluster analysis applied to each group. However, because the day-to-day transitions in the APEX activity selection algorithm can cross temperature bins, we would propose to use broad temperature bins for the clustering and transition probability calculations so that the cluster definitions would be fairly uniform across temperature bins. Thus we would probably define the bins according to season (e.g., summer, non-summer).
- In contrast to HAPEM, the sequence of activity patterns may be important in APEX. Therefore, for Step 4 transition probabilities would be specified for transitions between days with the same day-type and season, as in HAPEM, and also between days with different day-types and/or seasons. For example, transition probabilities would be specified for transitions between summer weekdays of each category and summer weekends of each category.

Another issue for dividing the CHAD activity records for the purposes of clustering and calculating transition probabilities is that the diary pools specified for the APEX activity selection algorithm use varying and overlapping age ranges. One way to address this problem would be to simply not include consideration of age in the clustering process, under the assumption that cluster categories are similar across age groups, even if the frequency of each cluster category varies by age group. This assumption could be tested by examination of the cluster categories stratified by age group that were developed for HAPEM5. If the assumption is found to be valid, then the cluster categories could be pre-determined for input to APEX, while the transition probabilities could be calculated within APEX during the simulation for each age range specified for dairy pools.

If the assumption is found to be invalid, then an alternative approach could be implemented that would create overlapping age groups for purposes of clustering as follows. APEX age group ranges and age window percentages would be constrained to some maximum values. Then a set of overlapping age ranges that would be at least as large as the largest possible dairy pool age ranges would be defined for the purposes of cluster analysis and transition probability calculation. The resulting sets of cluster categories and transition probabilities would be pre-determined for input into APEX and the appropriate set used by APEX for each diary pool used during the simulation.

The actual activity pattern sequence selection would be implemented as follows. The activity pattern for first day in the year would be selected exactly as is currently done in APEX, as described above. For the selecting the second day's activity pattern, each age weight would be multiplied by the transition probability P_{AB} where A is the cluster for the first day's activity pattern and B is the cluster for a given activity pattern in the available pool of diary days for day 2. (Note that day 2 may be a different day-type and/or season than day 1). The probability of selecting a given diary day on day 2 is equal to the age weight times P_{AB} divided by the total of the products of age weight and P_{AB} for all diary days in the pool for day 2. Similarly, for the transitions from day 2 to day 3, day 3 to day 4, etc.

Testing the Approach with the Multi-day Data set

We tested this approach using the available multi-day data set. For purposes of clustering we characterized the activity pattern records according to time spent in each of 5 microenvironments: indoors-home, indoors-school, indoors-other, outdoors (aggregate of the 3 outdoor microenvironments), and in-transit.

For purposes of defining diary pools and for clustering and calculating transition probabilities we divided the activity pattern records by day type (i.e., weekday, weekend), season (i.e., summer or ozone season, non-summer or non-ozone season), age (6-10 and 11-12), and gender. Since all the subjects are 6-12 years of age and all are presumably unemployed, we need not account for differences in employment status. For each day type, season, age, and gender, we found that the activity patterns appeared to group in three clusters.

In this case, we simulated week-long sequences (Wednesday through Tuesday) for each of 100 people in each age/gender group for each season, using the transition probabilities. To evaluate the algorithm we calculated the following statistics for the predicted multi-day activity patterns for comparison with the actual multi-day diary data.

- For each age/gender group for each season, the average time in each microenvironment
- For each age/gender group, season, and microenvironment, the average of the within-person variance across all simulated persons (We defined the within-

person variance as the variance of the total time per day spent in the microenvironment across the week.)

- For each age/gender group, season, and microenvironment, the variance across persons of the mean time spent in that microenvironment

In each case we compared the predicted statistic for the stratum to the statistic for the corresponding stratum in the actual diary data.5

We also calculated the mean normalized bias for the statistic, which is a common performance measure used in dispersion model performance and which is calculated as follows.

$$NBIAS = \frac{100}{N}\sum_{1}^{N}\frac{(predicted - observed)}{observed} \quad \%$$

RESULTS

Comparisons of simulated and observed data for time in each of the 5 microenvironments are presented in Tables 1 – 3 and Figures 2-5.

Average Time in Microenvironment

Table 1 and Figure 2 show the comparisons for the average time spent in each of the 5 microenvironments for each age/gender group and season. Figure 3 shows the comparison for all the microenvironments except indoor, home in order to highlight the lower values.

Table 1 and the figures show that the predicted time-in-microenvironment averages match well with the observed values. For combinations of microenvironment/age/gender/season the normalized bias ranges from –35% to +41%. Sixty percent of the predicted averages have bias between –9% and +9%, and the mean bias across any microenvironment ranges from -9% to +4%. Fourteen predictions have positive bias and 23 have negative bias. A Wilcoxon signed rank test that the median bias across the 40 combinations = 0 % was not significant (p-value = 0.40) supporting the conclusion of no overall bias.

Variance Across Persons

Table 2 and Figure 4 show the comparisons for the variance across persons for the average time spent in each microenvironment. In this case the bias ranges from –40% to +120% for any microenvironment/age/gender/season. Sixty-five percent of the predicted variances have bias between –22% and +24%. The mean normalized bias across any microenvironment ranges from –10% to +28%. Eighteen predictions have positive bias and 20 have negative bias. Figure 4 suggests a reasonably good match of predicted to observed

---

5 For the diary data, because the number of days per person varies, the average of the within-person variances was calculated as a weighted average, where the weight is the degrees of freedom, i.e., one less than the number of days simulated. Similarly, the variance across persons of the mean time was appropriately adjusted for the different degrees of freedom using analysis of variance.

variance in spite of 2 or 3 outliers. A Wilcoxon signed rank test that the median bias across the 40 combinations = 0 % was not significant (p-value = 0.93) supporting the conclusion of no overall bias.

Within-Person Variance for Persons

Table 3 and Figure 5 show the comparisons for the within-person variance for time spent in each microenvironment. In this case the bias ranges from –47% to +150% for any microenvironment/age/gender/season. Seventy percent of the predicted variances have bias between –25% and +30%. The mean normalized bias across any microenvironment ranges from –11% to +47%. Twenty-eight predictions have positive bias and 12 have negative bias, suggesting some tendency for overprediction of this variance measure. And indeed a Wilcoxon signed rank test that the median bias across the 40 combinations = 0 % was very significant (p-value = 0.01) showing that the within-person variance was significantly overpredicted. Still, Figure 4 suggests a reasonably good match of predicted to observed variance in most cases, with a few overpredicting outliers at the higher end of the distribution. So although the positive bias is significant in a statistical sense (i.e., the variance is more likely to be overpredicted than underpredicted), it is not clear whether the bias is large enough to be important.

CONCLUSIONS

The proposed algorithm appears to be able to replicate the observed data reasonably well, although the within-person variance is somewhat overpredicted.

It would be informative to compare this algorithm with the earlier alternative approaches in order to gain perspective on the degree of improvement, if any, afforded by this approach.

Two earlier approaches were:

1. Select a single activity pattern for each day-type/season combination from the appropriate set, and use that pattern for every day in the multi-day sequence that corresponds to that day-type and season.
2. Re-select an activity pattern for each day in the multi-day sequence from the appropriate set for the corresponding day-type and season.

Goodness-of-fit statistics could be developed to compare the three approaches and find which model best fits the data for a given stratum.

ATTACHMENT 5: TECHNICAL MEMORANDUM ON ANALYSIS OF AIR EXCHANGE RATE DATA

ICF INTERNATIONAL

DRAFT MEMORANDUM

To: **John Langstaff**

From: **Jonathan Cohen, Hemant Mallya, Arlene Rosenbaum**

Date: **September 30, 2005**

Re: **EPA 68D01052, Work Assignment 3-08. Analysis of Air Exchange Rate Data**

EPA is planning to use the APEX exposure model to estimate ozone exposure in 12 cities / metropolitan areas: Atlanta, GA; Boston, MA; Chicago, IL; Cleveland, OH; Detroit, MI; Houston, TX; Los Angeles, CA; New York, NY; Philadelphia, PA; Sacramento, CA; St. Louis, MO-IL; Washington, DC. As part of this effort, ICF Consulting has developed distributions of residential and non-residential air exchange rates (AER) for use as APEX inputs for the cities to be modeled. This memorandum describes the analysis of the AER data and the proposed APEX input distributions. Also included in this memorandum are proposed APEX inputs for penetration and proximity factors for selected microenvironments.

Residential Air Exchange Rates

Studies. Residential air exchange rate (AER) data were obtained from the following seven studies:

> **Avol:** Avol et al, 1998. In this study, ozone concentrations and AERs were measured at 126 residences in the greater Los Angeles metropolitan area between February and December, 1994. Measurements were taken in four communities: Lancaster, Lake Gregory, Riverside, and San Dimas. Data included the daily average outdoor temperature, the presence or absence of an air conditioner (either central or room), and the presence or absence of a swamp (evaporative) cooler. Air exchange rates were computed based on the total house volume and based on the total house volume corrected for the furniture. These data analyses used the corrected AERs.
>
> **RTP Panel:** Williams et al, 2003a, 2003b. In this study particulate matter concentrations and daily average AERs were measured at 37 residences in central North Carolina during 2000 and 2001 (averaging about 23 AER measurements per residence). The residences belong to two specific cohorts: a mostly Caucasian, non-smoking group aged at least 50 years having cardiac defibrillators living in Chapel Hill; a group of non-smoking, African Americans aged at least 50 years with controlled hypertension living in a low-to-moderate SES neighborhood in Raleigh. Data included the daily average outdoor temperature, and the number of air conditioner units (either central or room). Every residence had at least one air conditioner unit.
>
> **RIOPA:** Meng et al, 2004, Weisel et al, 2004. The Relationship of Indoor, Outdoor, and Personal Air (RIOPA) study was undertaken to estimate the impact of outdoor sources of air toxics to indoor concentrations and personal exposures. Volatile organic compounds,

carbonyls, fine particles and AERs were measured once or twice at 310 non-smoking residences from summer 1999 to spring 2001. Measurements were made at residences in Elizabeth, NJ, Houston TX, and Los Angeles CA. Residences in California were randomly selected. Residences in New Jersey and Texas were preferentially selected to be close (< 0.5 km) to sources of air toxics. The AER measurements (generally over 48 hours) used a PMCH tracer. Data included the daily average outdoor temperature, and the presence or absence of central air conditioning, room air conditioning, or a swamp (evaporative) cooler.

TEACH: Chillrud at al, 2004, Kinney et al, 2002, Sax et al, 2004. The Toxic Exposure Assessment, a Columbia/Harvard (TEACH) study was designed to characterize levels of and factors influencing exposures to air toxics among high school students living in inner-city neighborhoods of New York City and Los Angeles, CA. Volatile organic compounds, aldehydes, fine particles, selected trace elements, and AER were measured at 87 high school student's residences in New York City and Los Angeles in 1999 and 2000. Data included the presence or absence of an air conditioner (central or room) and hourly outdoor temperatures (which were converted to daily averages for these analyses).

Wilson 1984: Wilson et al, 1986, 1996. In this 1984 study, AER and other data were collected at about 600 southern California homes with three seven-day tests (in March and July 1984, and January, 1985) for each home. We obtained the data directly from Mr. Wilson. The available data consisted of the three seven-day averages, the month, the residence zip code, the presence or absence of a central air conditioner, and the presence or absence of a window air conditioner. We matched these data by month and zip code to the corresponding monthly average temperatures obtained from EPA's SCRAM website as well as from the archives in www.wunderground.com (personal and airport meteorological stations). Residences more than 25 miles away from the nearest available meteorological station were excluded from the analysis. For our analyses, the city/location was defined by the meteorological station, since grouping the data by zip code would not have produced sufficient data for most of the zip codes.

Wilson 1991: Wilson et al, 1996. Colome et al, 1993, 1994. In this 1991 study, AER and other data were collected at about 300 California homes with one two-day test in the winter for each home. We obtained the data directly from Mr. Wilson. The available data consisted of the two-day averages, the date, city name, the residence zip code, the presence or absence of a central air conditioner, the presence or absence of a swamp (evaporative) cooler, and the presence or absence of a window air conditioner . We matched these data by date, city, and zip code to the corresponding daily average temperatures obtained from EPA's SCRAM website as well as from the archives in www.wunderground.com (personal and airport meteorological stations). Residences more than 25 miles away from the nearest available meteorological station were excluded from the analysis. For our analyses, the city/location was defined by the meteorological station, since grouping the data by zip code would not have produced sufficient data for most of the zip codes.

Murray and Burmaster: Murray and Burmaster (1995). For this article, Murray and Burmaster corrected and compiled nationwide residential AER data from several studies conducted between 1982 and 1987. These data were originally compiled by the Lawrence Berkeley National Laboratory. We acknowledge Mr. Murray's assistance in obtaining these data for us. The available data consisted of AER measurements, dates, cities, and degree-days. Information on air conditioner presence or absence was not available.

Table A-1 summarizes these studies.

For each of the studies, air conditioner usage, window status (open or closed), and fan status (on or off) was not part of the experimental design, although some of these studies included information on whether air conditioners or fans were used (and for how long) and whether windows were closed during the AER measurements (and for how long).

As described above, in the following studies the homes were deliberately sampled from specific subsets of the population at a given location rather than the entire population: The RTP Panel study selected two specific cohorts of older subjects with specific diseases. The RIOPA study was biased towards residences near air toxics sources. The TEACH study focused on inner-city neighborhoods. Nevertheless, we included all these studies because we determined that any potential bias would be likely to be small and we preferred to keep as much data as possible.

Table A-1. Summary of Studies of Residential Air Exchange Rates

Comments			CA sample was a random sample of homes. NJ and TX homes were deliberately chosen to be near to ambient sources.	Restricted to inner-city homes with high school students.	Contemporaneous temperature data obtained for these analyses from SCRAM and www.wunderground.com meteorological data.	Contemporaneous temperature data obtained for these analyses from SCRAM and www.wunderground.com meteorological data.	

We compiled the data from these seven studies to create the following variables, of which some had missing values:

- Study
- Date
- Time – Time of the day that the AER measurement was made
- House_ID – Residence identifier
- Measurement_ID – Uniquely identifies each AER measurement for a given study
- AER – Air Exchange Rate (per hour)
- AER_Duration – Length of AER measurement period
- Have_AC – Indicates if the residence has any type of air conditioner (A/C), either a room A/C or central A/C or swamp cooler or any of them in combination. "Y" = "Yes." "N" = "No."
- Type_of_AC1 – Indicates the types of A/C or swamp cooler available in each house measured. Possible values: "Central A/C" "Central and Room A/C" "Central or Room A/C" "No A/C" "Swamp + (Central or Room)" "Swamp Cooler only" "Window A/C" "Window and Evap"
- Type_of_AC2 – Indicates if a house measured has either no A/C or some A/C. Possible values are "No A/C" and "Central or Room A/C."
- Have_Fan – Indicates if the house studied has any fans
- Mean_Temp – Daily average outside temperature
- Min_Temp – Minimum hourly outside temperature
- Max_Temp – Maximum hourly outside temperature
- State
- City
- Location – Two character abbreviation
- Flag – Data status. Murray and Burmaster study: "Used" or "Not Used." Other studies: "Used"; "Missing" (missing values for AER, Type_of_AC2, and/or Mean_Temp); "Outlier".

The main data analysis was based on the first six studies. The Murray and Burmaster data were excluded because of the absence of information on air conditioner presence. (However, a subset of these data was used for a supplementary analysis described below.) .

Based on our review of the AER data we excluded seven outlying high AER values – above 10 per hour. The main data analysis used all the remaining data that had non-missing values for AER, Type_of_AC2, and Mean_Temp. We decided to base the A/C type variable on the broad characterization "No A/C" versus "Central or Room A/C" since this variable could be calculated from all of the studies (excluding Murray and Burmaster). Information on the presence or absence of swamp coolers was not available from all the studies, and, also importantly, the corresponding information on swamp cooler prevalence for the subsequent ozone modeling cities was not available from the American Housing Survey. It is plausible that AER distributions depend upon the presence or absence of a swamp cooler. It is also plausible that AER distributions also depend upon whether the residence specifically has a central A/C, room or window A/C, or both. However we determined to use the broader A/C type definition, which in effect assumes that the exact A/C type and the presence of a swamp cooler are approximately proportionately represented in the surveyed residences.

Most of the studies had more than one AER measurement for the same house. It is reasonable to assume that the AER varies with the house as well as other factors such as the temperature. (The A/C type can be assumed to be the same for each measurement of the same house). We expected the temperature to be an important factor since the AER will be affected by the use of the available ventilation (air conditioners, windows, fans), which in turn will depend upon the outside meteorology. Therefore it is not appropriate to average data for the same house under different conditions, which might have been one way to account for dependence between multiple measurements on the same house. To simplify the data analysis, we chose to ignore possible dependence between measurements on the same house on different days and treat all the AER values as if they were statistically independent.

Summary Statistics. We computed summary statistics for AER and its natural logarithm LOG_AER on selected strata defined from the study, city, A/C type, and mean temperature. Cities were defined as in the original databases, except that for Los Angeles we combined all the data in the Los Angeles ozone modeling region, i.e. the counties of Los Angeles, Orange, Ventura, Riverside, and San Bernardino. A/C type was defined from the Type_of_AC2 variable, which we abbreviated as “NA” = “No A/C” and “AC” = “Central or Room A/C.” The mean temperature was grouped into the following temperature bins: -10 to 0 ºC, 0 to 10 ºC, 10 to 20 ºC, 20 to 25 ºC, 25 to 30 ºC, 30 to 40 ºC.(Values equal to the lower bounds are excluded from each interval.) Also included were strata defined by study = “All” and/or city = “All,” and/or A/C type = “All” and/or temperature bin = “All.” The following summary statistics for AER and LOG_AER were computed:

- Number of values
- Arithmetic Mean
- Arithmetic Standard Deviation
- Arithmetic Variance
- Deciles (Min, 10th, 20th … 90th percentiles, Max)

These calculations exclude all seven outliers and results are not used for strata with 10 or fewer values, since those summary statistics are extremely unreliable.

Examination of these summary tables clearly demonstrates that the AER distributions vary greatly across cities and A/C types and temperatures, so that the selected AER distributions for the modeled cities should also depend upon the city, A/C type and temperature. For example, the mean AER for residences with A/C ranges from 0.39 for Los Angeles between 30 and 40 ºC to 1.73 for New York between 20 and 25 ºC. The mean AER for residences without A/C ranges from 0.46 for San Francisco between 10 and 20 ºC to 2.29 for New York between 20 and 25 ºC. The need to account for the city as well as the A/C type and temperature is illustrated by the result that for residences with A/C and between 20 and 25 ºC, the mean AER ranges from 0.52 for Research Triangle Park to 1.73 for New York. Statistical comparisons are described below.

Statistical Comparisons. Various statistical comparisons were carried out between the different strata, for the AER and its logarithm. The various strata are defined as in the Summary Statistics section, excluding the "All" cases. For each analysis, we fixed one or two of the variables Study, City, A/C type, temperature, and tested for statistically significant differences among other variables. The comparisons are listed in Table A-2.

Table A-2. Summary of Comparisons of Means

Comparison Analysis Number.	Comparison Variable(s) "Groups Compared"	Stratification Variable(s) (not missing in worksheet)	Total Comparisons	Cases with significantly different means (5 % level)	
				AER	Log AER
1.	City	Type of A/C AND Temp. Range	12	8	8
2.	Temp. Range	Study AND City	12	5	5
3.	Type of A/C	Study AND City	15	5	5
4.	City	Type of A/C	2	2	2
5.	City	Temp. Range	6	5	6
6.	Type of A/C AND Temp. Range	Study AND City	17	6	6

For example, the first set of comparisons fix the Type of A/C and the temperature range; there are twelve such combinations. For each of these twelve combinations, we compare the AER distributions across different cities. This analysis determines whether the AER distribution is appropriately defined by the A/C type and temperature range, without specifying the city. Similarly, for the sixth set of comparisons, the study and city are held fixed (17 combinations) and in each case we compare AER distributions across groups defined by the combination of the A/C type and the temperature range.

The F Statistic comparisons compare the mean values between groups using a one way analysis of variance (ANOVA). This test assumes that the AER or log(AER) values are normally distributed with a mean that may vary with the comparison variable(s) and a constant variance. We calculated the F Statistic and its P-value. P-values above 0.05 indicate cases where all the group means are not statistically significantly different at the 5 percent level. Those results are summarized in the last two columns of the above table "Summary of Comparisons of Means" which gives the number of cases where the means are significantly different. Comparison analyses 2, 3, and 6 show that for a given study and city, slightly less than half of the comparisons show significant differences in the means across temperature ranges, A/C types, or both. Comparison analyses 1, 4, and 5 show that for the majority of cases, means vary significantly across cities, whether you first stratify by temperature range, A/C type, or both.

The Kruskal-Wallis Statistic comparisons are non-parametric tests that are extensions of the more familiar Wilcoxon tests to two or more groups. The analysis is valid if the AER minus the group median has the same distribution for each group, and tests whether the group medians are equal. (The test is also consistent under weaker assumptions against more general alternatives) The P-values show similar patterns to the parametric F test comparisons of the means. Since the logarithm is a strictly increasing function and the test is non-parametric, the Kruskal-Wallis tests give identical results for AER and Log (AER).

The Mood Statistic comparisons are non-parametric tests that compare the scale statistics for two or more groups. The scale statistic measures variation about the central value, which is a non-parametric generalization of the standard deviation. Specifically, suppose there is a total of N AER or log(AER) values, summing across all the groups. These N values are ranked from 1 to N, and the j'th highest value is given a score of $\{j - (N+1)/2\}^2$. The Mood statistic uses a one way ANOVA statistic to compare the total scores for each group. Generally, the Mood statistics show that in most cases the scale statistics are not statistically significantly different. Since the logarithm is a strictly increasing function and the test is non-parametric, the Mood tests give identical results for AER and Log (AER).

Fitting Distributions. Based on the summary statistics and the statistical comparisons, the need to fit different AER distributions to each combination of A/C type, city, and temperature is apparent. For each combination with a minimum of 11 AER values, we fitted and compared exponential, log-normal, normal, and Weibull distributions to the AER values.

The first analysis used the same stratifications as in the above "Summary Statistics" and "Statistical Comparisons" sections. Results are not reported for all strata because of the minimum data requirement of 11 values. Results for each combination of A/C type, city, and temperature (i.e., A, C, and T) were analyzed. Each combination has four rows, one for each fitted distribution. For each distribution we report the fitted parameters (mean, standard deviation, scale, shape) and the p-value for three standard goodness-of-fit tests: Kolmogorov-Smirnov (K-S), Cramer-Von-Mises (C-M), Anderson-Darling (A-D). Each goodness-of-fit test compares the empirical distribution of the AER values to the fitted distribution. The K-S and C-M tests are different tests examining the overall fit, while the Anderson-Darling test gives more weight to the fit in the tails of the distribution. For each combination, the best-fitting of the four distributions has the highest p-value and is marked by an x in the final three columns. The mean and standard deviation (Std_Dev) are the values for the fitted distribution. The scale and shape parameters are defined by:

- Exponential: density = $\sigma^{-1} \exp(-x/\sigma)$, where shape = mean = σ
- Log-normal: density = $\{\sigma x \sqrt{(2\pi)}\}^{-1} \exp\{ -(\log x - \zeta)^2 / (2\sigma^2)\}$, where shape = σ and scale = ζ. Thus the geometric mean and geometric standard deviation are given by $\exp(\zeta)$ and $\exp(\sigma)$, respectively.
- Normal: density = $\{\sigma\sqrt{(2\pi)}\}^{-1} \exp\{ -(x - \mu)^2 / (2\sigma^2)\}$, where mean = μ and standard deviation = σ
- Weibull: density = $(c/\sigma) (x/\sigma)^{c-1} \exp\{-(x/\sigma)^c\}$, where shape = c and scale = σ

Generally, the log-normal distribution was the best-fitting of the four distributions, and so, for consistency, we recommend using the fitted log-normal distributions for all the cases.

One limitation of the initial analysis was that distributions were available only for selected cities, and yet the summary statistics and comparisons demonstrate that the AER distributions depend upon the city as well as the temperature range and A/C type. As one option to address this issue, we considered modeling cities for which distributions were not available by using the AER distributions across all cities and dates for a given temperature range and A/C type.

Another important limitation of the initial analysis was that distributions were not fitted to all of the temperature ranges due to inadequate data. There are missing values between temperature ranges, and the temperature ranges are all bounded. To address this issue, the temperature ranges were regrouped to cover the entire range of temperatures from minus to plus infinity, although obviously the available data to fit these ranges have finite temperatures. Stratifying by A/C type, city, and the new temperature ranges produces results for four cities: Houston (AC and NA); Los Angeles (AC and NA); New York (AC and NA); Research Triangle Park (AC). For each of the fitted distributions we created histograms to compare the fitted distributions with the empirical distributions.

AER Distributions for The First Nine Cities. Based upon the results for the above four cities and the corresponding graphs, we propose using those fitted distributions for the three cities Houston, Los Angeles, and New York. For another 6 of the cities to be modeled, we propose using the distribution for one of the four cities thought to have similar characteristics to the city to be modeled with respect to factors that might influence AERs. These factors include the age composition of housing stock, construction methods, and other meteorological variables not explicitly treated in the analysis, such as humidity and wind speed patterns. The distributions proposed for these cities are as follows:

- Atlanta, GA, A/C: Use log-normal distributions for Research Triangle Park. Residences with A/C only.
- Boston, MA: Use log-normal distributions for New York
- Chicago, IL: Use log-normal distributions for New York
- Cleveland, OH: Use log-normal distributions for New York
- Detroit, MI: Use log-normal distributions for New York
- Houston, TX: Use log-normal distributions for Houston
- Los Angeles, CA: Use log-normal distributions for Los Angeles
- New York, NY: Use log-normal distributions for New York
- Philadelphia, PA: Use log-normal distributions for New York

Since the AER data for Research Triangle Park was only available for residences with air conditioning, AER distributions for Atlanta residences without air conditioning are discussed below.

To avoid unusually extreme simulated AER values, we propose to set a minimum AER value of 0.01 and a maximum AER value of 10.

Obviously, we would be prefer to model each city using data from the same city, but this approach was chosen as a reasonable alternative, given the available AER data.

AER Distributions for Sacramento and St. Louis. For these two cities, a direct mapping to one of the four cities Houston, Los Angeles, New York, and Research Triangle Park is not recommended because the cities are likely to be too dissimilar. Instead, we decided to use the distribution for the inland parts of Los Angeles to represent Sacramento and to use the aggregate distributions for all cities outside of California to represent St. Louis. The results for the city Sacramento were obtained by combining all the available AER data for Sacramento, Riverside, and San Bernardino counties. The results for the city St. Louis were obtained by combining all non-California AER data.

AER Distributions for Washington DC. Washington DC was judged likely to have similar characteristics both to Research Triangle Park and to New York City. To choose between these two cities, we compared the Murray and Burmaster AER data for Maryland with AER data from each of those cities. The Murray and Burmaster study included AER data for Baltimore and for Gaithersburg and Rockville, primarily collected in March. April, and May 1987, although there is no information on mean daily temperatures or A/C type. We collected all the March, April, and May AER data for Research Triangle Park and for New York City, and compared those distributions with the Murray and Burmaster Maryland data for the same three months.

The results for the means and central values show significant differences at the 5 percent level between the New York and Maryland distributions. Between Research Triangle Park and Maryland, the central values and the mean AER values are not statistically significantly different, and the differences in the mean log (AER) values are much less statistically significant than between New York and Maryland. The scale statistic comparisons are not statistically significantly different between New York and Maryland, but were statistically significantly different between Research Triangle Park and Maryland. Since matching central and mean values is generally more important than matching the scales, we propose to model Washington DC residences with air conditioning using the Research Triangle Park distributions, stratified by temperature:

- Washington DC, A/C: Use log-normal distributions for Research Triangle Park. Residences with A/C only.

Since the AER data for Research Triangle Park was only available for residences with air conditioning, the estimated AER distributions for Washington DC residences without air conditioning are discussed below.

AER Distributions for Washington DC and Atlanta GA Residences With No A/C. For Atlanta and Washington DC we have proposed to use the AER distributions for Research Triangle Park. However, all the Research Triangle Park data (from the RTP Panel study) were from houses with air conditioning, so there are no available distributions for the “No A/C” cases. For these two cities, one option is to use AER distributions fitted to all the study data for residences without A/C, stratified by temperature. We propose applying the “No A/C” distributions for modeling these two cities for residences without A/C. However, since Atlanta and Washington DC residences are expected to be better represented by residences outside of California, we instead propose to use the "No A/C" AER distributions aggregated across cities outside of California, which is the same as the recommended choice for the St. Louis "No A/C" AER distributions.

A/C Type and Temperature Distributions. Since the proposed AER distribution is conditional on the A/C type and temperature range, these values also need to be simulated using APEX in order to select the appropriate AER distribution. Mean daily temperatures are one of the available APEX inputs for each modeled city, so that the temperature range can be determined for each modeled day according to the mean daily temperature. To simulate the A/C type, we obtained estimates of A/C prevalence from the American Housing Survey. Thus for each city/metropolitan area, we obtained the estimated fraction of residences with Central or Room A/C (see Table A-3), which gives the probability p for selecting the A/C type "Central or Room A/C." Obviously, 1-p is the probability for "No A/C." For comparison with Washington DC and Atlanta, we have included the A/C type percentage for Charlotte, NC (representing Research Triangle Park, NC). As discussed above, we propose modeling the 96-97 % of Washington DC and Atlanta residences with A/C using the Research Triangle Park AER distributions, and modeling the 3-4 % of Washington DC and Atlanta residences without A/C using the combined study No A/C AER distributions.

Table A-3. Fraction of residences with central or room A/C (from American Housing Survey)

CITY	SURVEY AREA & YEAR	PERCENTAGE
Atlanta	Atlanta, 2003	97.01
Boston	Boston, 2003	85.23
Chicago	Chicago, 2003	87.09
Cleveland	Cleveland, 2003	74.64
Detroit	Detroit, 2003	81.41
Houston	Houston, 2003	98.70
Los Angeles	Los Angeles, 2003	55.05
New York	New York, 2003	81.57
Philadelphia	Philadelphia, 2003	90.61
Sacramento	Sacramento, 2003	94.63
St. Louis	St. Louis, 2003	95.53
Washington DC	Washington DC, 2003	96.47
Research Triangle Park	Charlotte, 2002	96.56

Other AER Studies

We recently became aware of some additional residential and non-residential AER studies that might provide additional information or data. Indoor / outdoor ozone and PAN distributions were studied by Jakobi and Fabian (1997). Liu et al (1995) studied residential ozone and AER distributions in Toronto, Canada. Weschler and Shields (2000) describes a modeling study of ventilation and air exchange rates. Weschler (2000) includes a useful overview of residential and non-residential AER studies.

AER Distributions for Other Indoor Environments

To estimate AER distributions for non-residential, indoor environments (e.g., offices and schools), we obtained and analyzed two AER data sets: "Turk" (Turk et al, 1989); and "Persily" (Persily and Gorfain 2004; Persily et al. 2005).

The earlier "Turk" data set (Turk et al, 1989) includes 40 AER measurements from offices (25 values), schools (7 values), libraries (3 values), and multi-purpose (5 values), each measured using an SF6 tracer over two- or four-hours in different seasons of the year.

The more recent "Persily" data (Persily and Gorfain 2004; Persily et al. 2005) were derived from the U.S. EPA Building Assessment Survey and Evaluation (BASE) study, which was conducted to assess indoor air quality, including ventilation, in a large number of randomly selected office buildings throughout the U.S. The data base consists of a total of 390 AER measurements in 96 large, mechanically ventilated offices; each office was measured up to four times over two days, Wednesday and Thursday AM and PM. The office spaces were relatively large, with at least 25 occupants, and preferably 50 to 60 occupants. AERs were measured both by a volumetric method and by a CO2 ratio method, and included their uncertainty estimates. For these analyses, we used the recommended "Best Estimates" defined by the values with the lower estimated uncertainty; in the vast majority of cases the best estimate was from the volumetric method.

Another study of non-residential AERs was performed by Lagus Applied Technology (1995) using a tracer gas method. That study was a survey of AERs in 16 small office buildings, 6 large office buildings, 13 retail establishments, and 14 schools. We plan to obtain and analyze these data and compare those results with the Turk and Persily studies.

Due to the small sample size of the Turk data, the data were analyzed without stratification by building type and/or season. For the Persily data, the AER values for each office space were averaged, rather using the individual measurements, to account for the strong dependence of the AER measurements for the same office space over a relatively short period.

Summary statistics of AER and log (AER) for the two studies are presented in Table A-4.

Table A-4. AER summary statistics for offices and other non-residential buildings

Study	Variable	N	Mean	Std Dev	Min	25th %ile	Median	75th %ile	Max
Persily	AER	96	1.9616	2.3252	0.0712	0.5009	1.0795	2.7557	13.8237
Turk	AER	40	1.5400	0.8808	0.3000	0.8500	1.5000	2.0500	4.1000
Persily	Log(AER)	96	0.1038	1.1036	-2.6417	-0.6936	0.0765	1.0121	2.6264
Turk	Log(AER)	40	0.2544	0.6390	-1.2040	-0.1643	0.4055	0.7152	1.4110

The mean values are similar for the two studies, but the standard deviations are about twice as high for the Persily data. The proposed AER distributions were derived from the more recent Persily data only.

Similarly to the analyses of the residential AER distributions, we fitted exponential, log-normal, normal, and Weibull distributions to the 96 office space average AER values. The results are shown in Table A-5.

Table A-5. Best fitting office AER distributions from the Persily et al. (2004, 2005)

Scale	Shape	Mean	Std_Dev	Distribution	P-Value Kolmogorov-Smirnov	P-Value Cramer-von Mises	P-Value Anderson-Darling
1.9616		1.9616	1.9616	Exponential	0.13	0.04	0.05
0.1038	1.1036	2.0397	3.1469	Lognormal	0.15	0.46	0.47
		1.9616	2.3252	Normal	0.01	0.01	0.01
1.9197	0.9579	1.9568	2.0433	Weibull		0.01	0.01

(For an explanation of the Kolmogorov-Smirnov, Cramer-von Mises, and Anderson-Darling P-values see the discussion residential AER distributions above.) According to all three goodness-of-fit measures the best-fitting distribution is the log-normal. Reasonable choices for the lower and upper bounds are the observed minimum and maximum AER values.

We therefore propose the following indoor, non-residential AER distributions.

- AER distribution for indoor, non-residential microenvironments: Lognormal, with scale and shape parameters 0.1038 and 1.1036, i.e., geometric mean = 1.1094, geometric standard deviation = 3.0150. Lower Bound = 0.07. Upper bound = 13.8.

Proximity and Penetration Factors For Outdoors, In-vehicle, and Mass Transit

For the APEX modeling of the outdoor, in-vehicle, and mass transit micro-environments, an approach using proximity and penetration factors is proposed, as follows.

Outdoors Near Road

Penetration factor = 1.

For the Proximity factor, we propose using ratio distributions developed from the Cincinnati Ozone Study (American Petroleum Institute, 1997, Appendix B; Johnson et al. 1995). The field study was conducted in the greater Cincinnati metropolitan area in August and September, 1994. Vehicle tests were conducted according to an experimental design specifying the vehicle type, road type, vehicle speed, and ventilation mode. Vehicle types were defined by the three study vehicles: a minivan, a full-size car, and a compact car. Road types were interstate highways (interstate), principal urban arterial roads (urban), and local roads (local). Nominal vehicle speeds (typically met over one minute intervals within 5 mph) were at 35 mph, 45 mph, or 55 mph. Ventilation modes were as follows:

- Vent Open: Air conditioner off. Ventilation fan at medium. Driver's window half open. Other windows closed.
- Normal A/C. Air conditioner at normal. All windows closed.
- Max A/C: Air conditioner at maximum. All windows closed.

Ozone concentrations were measured inside the vehicle, outside the vehicle, and at six fixed site monitors in the Cincinnati area.

The proximity factor can be estimated from the distributions of the ratios of the outside-vehicle ozone concentrations to the fixed-site ozone concentrations, reported in Table 8 of Johnson et al. (1995). Ratio distributions were computed by road type (local, urban, interstate, all) and by the fixed-site monitor (each of the six sites, as well as the nearest monitor to the test location). For this analysis we propose to use the ratios of outside-vehicle concentrations to the concentrations at the nearest fixed site monitor, as shown in Table A-6.

Table A-6. Ratio of outside-vehicle ozone to ozone at nearest fixed site[1]

Road Type[1]	Number of cases[1]	Mean[1]	Standard Deviation[1]	25th Percentile[1]	50th Percentile[1]	75th Percentile[1]	Estimated 5th Percentile[2]
Local	191	0.755	0.203	0.645	0.742	0.911	0.422
Urban	299	0.754	0.243	0.585	0.722	0.896	0.355
Interstate	241	0.364	0.165	0.232	0.369	0.484	0.093
All	731	0.626	0.278	0.417	0.623	0.808	0.170

1. From Table 8 of Johnson et al. (1995). Data excluded if fixed-site concentration < 40 ppb.
2. Estimated using a normal approximation as Mean – 1.64 × Standard Deviation

For the outdoors-near- road microenvironment, we recommend using the distribution for local roads, since most of the outdoors-near-road ozone exposure will occur on local roads. The summary data from the Cincinnati Ozone Study are too limited to allow fitting of distributions, but the 25th and 75th percentiles appear to be approximately equidistant from the median (50th percentile). Therefore we propose using a normal distribution with the observed mean and standard deviation. A plausible upper bound for the proximity factor equals 1. Although the normal distribution allows small positive values and can even produce impossible, negative values (with a very low probability), the titration of ozone concentrations near a road is limited. Therefore, as an empirical approach, we recommend a lower bound of the estimated 5th percentile, as shown in the final column of the above table. Therefore in summary we propose:

- Penetration factor for outdoors, near road: 1.

- Proximity factor for outdoors, near road: Normal distribution. Mean = 0.755. Standard Deviation = 0.203. Lower Bound = 0.422. Upper Bound = 1.

Outdoors, Public Garage / Parking Lot

This micro-environment is similar to the outdoors-near-road microenvironment. We therefore recommend the same distributions as for outdoors-near-road:

- Penetration factor for outdoors, public garage / parking lot: 1.
- Proximity factor for outdoors, public garage / parking lot: Normal distribution. Mean = 0.755. Standard Deviation = 0.203. Lower Bound = 0.422. Upper Bound = 1.

Outdoors, Other

The outdoors, other ozone concentrations should be well represented by the ambient monitors. Therefore we propose:

- Penetration factor for outdoors, other: 1.
- Proximity factor for outdoors, other: 1.

In-Vehicle

For the proximity factor for in-vehicle, we also recommend using the results of the Cincinnati Ozone Study presented in Table A-6. For this microenvironment, the ratios depend upon the road type, and the relative prevalences of the road types can be estimated by the proportions of vehicle miles traveled in each city. The proximity factors are assumed, as before, to be normally distributed, the upper bound to be 1, and the lower bound to be the estimated 5th percentile.

- Proximity factor for in-vehicle, local roads: Normal distribution. Mean = 0.755. Standard Deviation = 0.203. Lower Bound = 0.422. Upper Bound = 1.
- Proximity factor for in-vehicle, urban roads: Normal distribution. Mean = 0.754. Standard Deviation = 0.243. Lower Bound = 0.355. Upper Bound = 1.
- Proximity factor for in-vehicle, interstates: Normal distribution. Mean = 0.364. Standard Deviation = 0.165. Lower Bound = 0.093. Upper Bound = 1.

To complete the specification, the distribution of road type needs to be estimated for each city to be modeled. Vehicle miles traveled (VMT) in 2003 by city (defined by the Federal-Aid urbanized area) and road type were obtained from the Federal Highway Administration. (http://www.fhwa.dot.gov/policy/ohim/hs03/htm/hm71.htm). For local and interstate road types, the VMT for the same DOT categories were used. For urban roads, the VMT for all other road types was summed (Other freeways/expressways, Other principal arterial, Minor arterial, Collector). The computed VMT ratios for each city are shown in Table A-7.

Table A-7. Vehicle Miles Traveled by City and Road Type in 2003 (FHWA, October 2004)

FEDERAL-AID URBANIZED AREA	FRACTION VMT BY ROAD TYPE		
	INTERSTATE	URBAN	LOCAL
Atlanta	0.38	0.45	0.18
Boston	0.31	0.55	0.14
Chicago	0.30	0.59	0.12
Cleveland	0.39	0.45	0.16
Detroit	0.26	0.63	0.11
Houston	0.24	0.72	0.04
Los Angeles	0.29	0.65	0.06
New York	0.18	0.67	0.15
Philadelphia	0.23	0.65	0.11
Sacramento	0.21	0.69	0.09
St. Louis	0.36	0.45	0.19
Washington	0.31	0.61	0.08

Note that a “Federal-Aid Urbanized Area" is an area with 50,000 or more persons that at a minimum encompasses the land area delineated as the urbanized area by the Bureau of the Census. Urbanized areas that have been combined with others for reporting purposes are not shown separately. The Illinois portion of Round Lake Beach-McHenry-Grayslake has been reported with Chicago.

Thus to simulate the proximity factor in APEX, we propose to first select the road type according to the above probability table of road types, then select the AER distribution (normal) for that road type as defined in the last set of bullets.

For the penetration factor for in-vehicle, we recommend using the inside-vehicle to outside-vehicle ratios from the Cincinnati Ozone Study. The ratio distributions were summarized for all the data and for stratifications by vehicle type, vehicle speed, road type, traffic (light, moderate, or heavy), and ventilation. The overall results and results by ventilation type are shown in Table A-8.

Table A-8. Ratio of inside-vehicle ozone to outside-vehicle ozone[1]

Ventilation[1]	Number of cases[1]	Mean[1]	Standard Deviation[1]	25th Percentile[1]	50th Percentile[1]	75th Percentile[1]	Estimated 5th Percentile[2]
Vent Open	226	0.361	0.217	0.199	0.307	0.519	0.005
Normal A/C	332	0.417	0.211	0.236	0.408	0.585	0.071
Maximum A/C	254	0.093	0.088	0.016	0.071	0.149	0.000[3]
All	812	0.300	0.232	0.117	0.251	0.463	0.000[3]

1. From Table 7 of Johnson et al.(1995). Data excluded if outside-vehicle concentration < 20 ppb.
2. Estimated using a normal approximation as Mean – 1.64 × Standard Deviation
3. Negative estimate (impossible value) replaced by zero.

Although the data in Table A-8 indicate that the inside-to-outside ozone ratios strongly depend upon the ventilation type, it would be very difficult to find suitable data to estimate the ventilation type distributions for each modeled city. Furthermore, since the Cincinnati Ozone Study was scripted, the ventilation conditions may not represent real-world vehicle ventilation scenarios. Therefore, we propose to use the overall average distributions.

- Penetration factor for in-vehicle: Normal distribution. Mean = 0.300. Standard Deviation = 0.232. Lower Bound = 0.000. Upper Bound = 1.

Mass Transit

The mass transit microenvironment is expected to be similar to the in-vehicle microenvironment. Therefore we recommend using the same APEX modeling approach:

- Proximity factor for mass transit, local roads: Normal distribution. Mean = 0.755. Standard Deviation = 0.203. Lower Bound = 0.422. Upper Bound = 1.
- Proximity factor for mass transit, urban roads: Normal distribution. Mean = 0.754. Standard Deviation = 0.243. Lower Bound = 0.355. Upper Bound = 1.
- Proximity factor for mass transit, interstates: Normal distribution. Mean = 0.364. Standard Deviation = 0.165. Lower Bound = 0.093. Upper Bound = 1.
- Road type distributions for mass transit: See Table A-6
- Penetration factor for mass transit: Normal distribution. Mean = 0.300. Standard Deviation = 0.232. Lower Bound = 0.000. Upper Bound = 1.

ATTACHMENT 6. TECHNICAL MEMORANDUM ON THE UNCERTAINTY ANALYSIS OF RESIDENTIAL AIR EXCHANGE RATE DISTRIBUTIONS

ICF INTERNATIONAL

MEMORANDUM

To: John Langstaff, EPA OAQPS

From: Jonathan Cohen, Arlene Rosenbaum, ICF International

Date: June 5, 2006

Re: Uncertainty analysis of residential air exchange rate distributions

---

This memorandum describes our assessment of some of the sources of the uncertainty of city-specific distributions of residential air exchange rates that were fitted to the available study data. City-specific distributions for use with the APEX ozone model were developed for 12 modeling cities, as detailed in the memorandum by Cohen, Mallya and Rosenbaum, 2005[6] (Appendix A of this report). In the first part of the memorandum, we analyze the between-city uncertainty by examining the variation of the geometric means and standard deviations across cities and studies. In the second part of the memorandum, we assess the within-city uncertainty by using a bootstrap distribution to estimate the effects of sampling variation on the fitted geometric means and standard deviations for each city. The bootstrap distributions assess the uncertainty due to random sampling variation but do not address uncertainties due to the lack of representativeness of the available study data, the matching of the study locations to the modeled cities, and the variation in the lengths of the AER monitoring periods.

Variation of geometric means and standard deviations across cities and studies

The memorandum by Cohen, Mallya and Rosenbaum, 2005[7] (Attachment 5 of this report) describes the analysis of residential air exchange rate (AER) data that were obtained from seven studies. The AER data were subset by location, outside temperature range, and the A/C type, as defined by the presence or absence of an air conditioner (central or window). In each case we chose to fit a log-normal distribution to the AER data, so that the logarithm of the AER for a given city, temperature range, and A/C type is assumed to be normally distributed. If the AER data has geometric mean GM and geometric standard deviation GSD, then the logarithm of the AER is assumed to have a normal distribution with mean log(GM) and standard deviation log(GSD).

Table D-1 shows the assignment of the AER data to the 12 modeled cities. Note that for Atlanta, GA and Washington DC, the Research Triangle Park, NC data for houses with A/C was used to represent the AER distributions for houses with A/C, and the non-California data for houses without A/C was used to represent the AER distributions for houses without A/C. Sacramento, CA AER distributions were estimated using the AER data from the inland California counties of

---

[7] *Op. Cit.*

Sacramento, Riverside, and San Bernardino; these combined data are referred to by the City Name "Inland California." St Louis, MO AER distributions were estimated using the AER data from all states except for California and so are referred to be the City Name "Outside California."

Table D-1. Assignment of Residential AER distributions to modeled cities

Modeled city	AER distribution
Atlanta, GA, A/C	Research Triangle Park, A/C only
Atlanta, GA, no A/C	All non-California, no A/C ("Outside California")
Boston, MA	New York
Chicago, IL	New York
Cleveland, OH	New York
Detroit, MI	New York
Houston, TX	Houston
Los Angeles, CA	Los Angeles
New York, NY	New York
Philadelphia, PA	New York
Sacramento	Inland parts of Los Angeles ("Inland California")
St. Louis	All non-California ("Outside California")
Washington, DC, A/C	Research Triangle Park, A/C only
Washington, DC, no A/C	All non-California, no A/C ("Outside California")

It is evident from Table D-1 that for some of the modeled cities, some potentially large uncertainty was introduced because we modeled their AER distributions using available data from another city or group of cities thought to be representative of the first city on the basis of geography and other characteristics. This was necessary for cities where we did not have any or sufficient AER data measured in the same city that also included the necessary temperature and A/C type information. One way to assess the impact of these assignments on the uncertainty of the AER distributions is to evaluate the variation of the fitted log-normal distributions across the cities with AER data. In this manner we can examine the effect on the AER distribution if a different allocation of study data to the modeled cities had been used.

Even for the cities where we have study AER data, there is uncertainty about the fitted AER distributions. First, the studies used different measurement and residence selection methods. In some cases the residences were selected by a random sampling method designed to represent the entire population. In other cases the residences were selected to represent sub-populations. For example, for the RTP study, the residences belong to two specific cohorts: a mostly Caucasian, non-smoking group aged at least 50 years having cardiac defibrillators living in Chapel Hill; a group of non-smoking, African Americans aged at least 50 years with controlled hypertension living in a low-to-moderate SES neighborhood in Raleigh. The TEACH study was restricted to residences of inner-city high school students. The RIOPA study was a random sample for Los Angeles, but was designed to preferentially sample locations near major air toxics sources for Elizabeth, NJ and Houston TX. Furthermore, some of the studies focused on different towns or cities within the larger metropolitan areas, so that, for example, the Los Angeles data from the Avol study was only measured in Lancaster, Lake Gregory, Riverside, and San Dimas but the Los Angeles data from the Wilson studies were measured in multiple cities in Southern California. One way to assess the uncertainty of the AER distributions due to variations of study methodologies and study sampling locations is to evaluate the variation of the fitted log-normal distributions within each modeled city across the different studies.

We evaluated the variation between cities, and the variation within cities and between studies, by tabulating and plotting the AER distributions for all the study/city combinations. Since the original analyses by Cohen, Mallya and Rosenbaum, 2005 clearly showed that the AER distribution depends strongly on the outside temperature and the A/C type (whether or not the residence has air conditioning), this analysis was stratified by the outside temperature range and the A/C type. Otherwise, study or city differences would have been confounded by the temperature and A/C type differences and you would not be able to tell how much of the AER difference was due to the variation of temperature and A/C type across cities or studies. In order to be able to compare cities and studies we could not use different temperature ranges for the different modeled cities as we did for the original AER distribution modeling. For these analyses we stratified the temperature into the ranges <= 10, 10-20, 20-25, and >25 ºC and categorized the A/C type as “Central or Window A/C” versus ‘No A/C,” giving 8 temperature and A/C type strata.

Table D-2 shows the geometric means and standard deviations by city and study. These geometric mean and standard deviation pairs are plotted in Figure D-1 through D-8. Each figure shows the variation across cities and studies for a given temperature range and A/C type. The results for a city with only one available study are shown with a blank study name. For cities with multiple studies, results are shown for the individual studies and the city overall distribution is designated by a blank value for the study name.

* For a given city, if AER data were available from only one study, then the study name is missing. If AER data were available for two or more studies, then the overall city distribution is shown in the row where the study name is missing, and the distributions by study and city are shown in the rows with a specific study name.

** The geometric standard deviation is undefined if the sample size equals 1.

In general, there is a relatively wide variation across different cities. This implies that the AER modeling results would be very different if the matching of modeled cities to study cities was changed, although a sensitivity study using the APEX model would be needed to assess the impact on the ozone exposure estimates. In particular the ozone exposure estimates may be sensitive to the assumption that the St. Louis AER distributions can be represented by the combined non-California AER data. One way to address this is to perform a Monte Carlo analysis where the first stage is to randomly select a city outside of California, the second stage picks the A/C type, and the third stage picks the AER value from the assigned distribution for the city, A/C type and temperature range. Note that this will result in a very different distribution to the current approach that fits a single log-normal distribution to all the non-California data for a given temperature range and A/C type. The current approach weights each data point equally, so that cities like New York with most of the data values get the greatest statistical weight. The Monte Carlo approach gives the same total statistical weight for each city and fits a mixture of log-normal distributions rather than a single distribution.

In general, there is also some variation within studies for the same city, but this is much smaller than the variation across cities. This finding tends to support the approach of combining different studies. Note that the graphs can be deceptive in this regard because some of the data points are based on very small sample sizes (N) ; those data points are less precise and the differences would not be statistically significant. For example, for the No A/C data in the range 10-20 ºC, the Los Angeles TEACH study had a geometric mean of 2.32 based on only nine AER values, but the overall geometric mean, based on 390 values, was 0.75 and the geometric means for the Los Angeles Avol, RIOPA, Wilson 1984, and Wilson 1991 studies were each close to 0.75. One noticeable case where the studies show big differences for the same city is for the A/C houses in Los Angeles in the range 20-25 ºC where the study geometric means are 0.61 (Avol, N=32), 0.90 (RIOPA, N=26) and 1.23 (Wilson 1984, N=215).

Bootstrap analyses

The 39 AER subsets defined in the Cohen, Mallya, and Rosenbaum, 2005 memorandum (Appendix A of this report) and their allocation to the 12 modeled cities are shown in Table D-3. To make the distributions sufficiently precise in each AER subset and still capture the variation across temperature and A/C type, different modeled cities were assigned different temperature range and A/C type groupings. Therefore these temperature range groupings are sometimes different to those used to develop Table D-2 and Figure D-1 through D-8.

The GM and GSD values that define the fitted log-normal distributions for these 39 AER subsets are shown in Table D-4. Examples of these pairs are also plotted in Figures D-9 through D-19, to be further described below. Each of the example figures D-9 through D-19 corresponds to a single GM/GSD “Original Data” pair. The GM and GSD values for the “Original Data” are at the intersection of the horizontal and vertical lines that are parallel to the x- and y-axes in the figures.

To evaluate the uncertainty of the GM and GSD values, a bootstrap simulation was performed, as follows. Suppose that a given AER subset has N values. A bootstrap sample is obtained by sampling N times at random with replacement from the N AER values. The first AER value in the bootstrap sample is selected randomly from the N values, so that each of the N values is equally likely. The second, third, …, N'th values in the bootstrap sample are also selected randomly from the N values, so that for each selection, each of the N values is equally likely. The same value can be selected more than once. Using this bootstrap sample, the geometric mean and geometric standard deviation of the N values in the bootstrap sample was calculated. This pair of values is plotted as one of the points in a figure for that AER subset. 1,000 bootstrap samples were randomly generated for each AER subset, producing a set of 1,000 geometric mean and geometric standard deviation pairs, which were plotted in example Figures D-9 through D-19.

The bootstrap distributions display the part of the uncertainty of the GM and GSD that is entirely due to random sampling variation. The analysis is based on the assumption that the study AER data are a random sample from the population distribution of AER values for the given city, temperature range, and A/C type. On that basis, the 1,000 bootstrap GM and GSD pairs estimate the variation of the GM and GSD across all possible samples of N values from the population. Since each GM, GSD pair uniquely defines a fitted log-normal distribution, the pairs also estimate the uncertainty of the fitted log-normal distribution. The choice of 1,000 was made as a compromise between having enough pairs to accurately estimate the GM, GSD distribution and not having too many pairs so that the graph appears as a smudge of overlapped points. Note that even if there were infinitely many bootstrap pairs, the uncertainty distribution would still be an estimate of the true uncertainty because the N is finite, so that the empirical distribution of the N measured AER values does not equal the unknown population distribution.

In most cases the uncertainty distribution appears to be a roughly circular or elliptical geometric mean and standard deviation region. The size of the region depends upon the sample size and on the variability of the AER values; the region will be smallest when the sample size N is large and/or the variability is small, so that there are a large number of values that are all close together.

The bootstrap analyses show that the geometric standard deviation uncertainty for a given CMSA/air-conditioning-status/temperature-range combination tends to have a range of at most from “fitted GSD-1.0 hr^{-1}” to “fitted GSD+1.0 hr^{-1}”, but the intervals based on larger AER sample sizes are frequently much narrower. The ranges for the geometric means tend to be approximately from “fitted GM-0.5 hr^{-1}” to “fitted GM+0.5 hr^{-1}”, but in some cases were much smaller.

The bootstrap analysis only evaluates the uncertainty due to the random sampling. It does not account for the uncertainty due to the lack of representativeness, which in turn is due to the fact that the samples were not always random samples from the entire population of residences in a city, and were sometimes used to represent different cities. Since only the GM and GSD were used, the bootstrap analyses does not account for uncertainties about the true distributional shape, which may not necessarily be log-normal. Furthermore, the bootstrap uncertainty does not account for the effect of the calendar year (possible trends in AER values) or of the uncertainty due to the AER measurement period; the distributions were intended to represent distributions of 24 hour average AER values although the study AER data were measured over a variety of measurement periods.

To use the bootstrap distributions to estimate the impact of sample size on the fitted distributions, a Monte Carlo approach could be used with the APEX model. Instead of using the Original Data distributions, a bootstrap GM, GSD pair could be selected at random and the AER value could be selected randomly from the log-normal distribution with the bootstrap GM and GSD.

ATTACHMENT 7. TECHNICAL MEMORANDUM ON THE DISTRIBUTIONS OF AIR EXCHANGE RATE AVERAGES OVER MULTIPLE DAYS

ICF
INTERNATIONAL

MEMORANDUM

To: John Langstaff, EPA OAQPS
From: Jonathan Cohen, Arlene Rosenbaum, ICF International
Date: June 8, 2006
Re: Distributions of air exchange rate averages over multiple days

---

As detailed in the memorandum by Cohen, Mallya and Rosenbaum, 2005[8] (Appendix A of this report) we have proposed to use the APEX model to simulate the residential air exchange rate (AER) using different log-normal distributions for each combination of outside temperature range and the air conditioner type, defined as the presence or absence of an air conditioner (central or room).

Although the averaging periods for the air exchange rates in the study databases varied from one day to seven days, our analyses did not take the measurement duration into account and treated the data as if they were a set of statistically independent daily averages. In this memorandum we present some analyses of the Research Triangle Park Panel Study that show extremely strong correlations between consecutive 24-hour air exchange rates measured at the same house. This provides support for the simplified approach of treating all averaging periods as if they were 24-hour averages.

In the current version of the APEX model, there are several options for stratification of time periods with respect to AER distributions, and for when to re-sample from a distribution for a given stratum. The options selected for this current set of simulations resulted in a uniform AER for each 24-hour period and re-sampling of the 24-hour AER for each simulated day. This re-sampling for each simulated day implies that the simulated AERs on consecutive days in the same microenvironment are statistically independent. Although we have not identified sufficient data to test the assumption of uniform AERs throughout a 24-hour period, the analyses described in this memorandum suggest that AERs on consecutive days are highly correlated. Therefore, we performed sensitivity simulations to assess the impact of the assumption of temporally independent air exchange rates, but found little difference between APEX predictions for the two scenarios (i.e., temporally independent and autocorrelated air exchange rates).

---

[8] Cohen, J., H. Mallya, and A. Rosenbaum. 2005. Memorandum to John Langstaff. *EPA 68D01052, Work Assignment 3-08. Analysis of Air Exchange Rate Data*. September 30, 2005.

Distributions of multi-day averages from the RTP Panel Study

The RTP Panel study included measurements of 24-hour averages at 38 residences for up to four periods of at least seven days. These periods were in different seasons and/or calendar years. Daily outside temperatures were also provided. All the residences had either window or room air conditioners or both. We used these data to compare the distributions of daily averages taken over 1, 2, 3, .. 7 days.

The analysis is made more complicated because the previous analyses showed the dependence of the air exchange rate on the outside temperature, and the daily temperatures often varied considerably. Two alternative approaches were employed to group consecutive days. For the first approach, A, we sorted the data by the HOUSE_ID number and date and began a new group of days for each new HOUSE_ID and whenever the sorted measurement days on the same HOUSE_ID were 30 days or more apart. In most cases, a home was measured over four different seasons for seven days, potentially giving 38 × 4 = 152 groups; the actual number of groups was 124. For the second approach, B, we again sorted the data by the HOUSE_ID number and date, but this time we began a new group of days for each new HOUSE_ID and whenever the sorted measurement days on the same HOUSE_ID were 30 days or more apart or were for different temperature ranges. We used the same four temperature ranges chosen for the analysis in the Cohen, Mallya, and Rosenbaum, 2005, memorandum (Appendix A): <= 10, 10-20, 20-25, and > 25 ºC. For example, if the first week of measurements on a given HOUSE_ID had the first three days in the <= 10 ºC range, the next day in the 10-20 ºC range, and the last three days in the <= 10 ºC range, then the first approach would treat this as a single group of days. The second approach would treat this as three groups of days, i.e., the first three days, the fourth day, and the last three days. Using the first approach, the days in each group can be in different temperature ranges. Using the second approach, every day in a group is in the same temperature range. Using the first approach we treat groups of days as being independent following a transition to a different house or season. Using the second approach we treat groups of days as being independent following a transition to a different house or season or temperature range.

To evaluate the distributions of multi-day air exchange rate (AER) averages, we averaged the AERs over consecutive days in each group. To obtain a set of one-day averages, we took the AERs for the first day of each group. To obtain a set of two-day averages, we took the average AER over the first two days from each group. We continued this process to obtain three-, four-, five-, six-, and seven-day averages. There were insufficiently representative data for averaging periods longer then seven days. Averages over non-consecutive days were excluded. Each averaging period was assigned the temperature range using the average of the daily temperatures for the averaging period. Using Approach A, some or all of the days in the averaging period might be in different temperature ranges than the overall average. . Using Approach B, every day is in the same temperature range as the overall average. For each averaging period and temperature range, we calculated the mean, standard deviation, and variance of the period average AER and of its natural logarithm. Note than the geometric mean equals *e* raised to the power Mean log (AER) and the geometric standard deviation equals *e* raised to the power Std Dev log (AER). The results are shown in Tables E-1 (Approach A) and E-2 (Approach B).

Table E-1. Distribution of AER averaged over K days and its logarithm. Groups defined by Approach A.

Temperature (ºC)	K	Groups	Mean AER	Mean log(AER)	Std Dev AER	Std Dev log(AER)	Variance AER	Variance log(AER)

Using both approaches, Tables E-1 and E-2 show that the mean values for the AER and its logarithm are approximately constant for the same temperature range but different averaging periods. This is expected if the daily AER values all have the same statistical distribution, regardless of whether or not they are independent. More interesting is the observation that the standard deviations and variances are also approximately constant for the same temperature range but different averaging periods, except for the data at > 25 ºC where the standard deviations and variances tend to decrease as the length of the averaging period increases. If the daily AER values were statistically independent, then the variance of an average over K days is given by Var / K, where Var is the variance of a single daily AER value. Clearly this formula does not apply. Since the variance is approximately constant for different values of K in the same temperature range (except for the relatively limited data at > 25 ºC), this shows that the daily AER values are strongly correlated. Of course the correlation is not perfect, since otherwise the AER for a given day would be identical to the AER for the next day, if the temperature range were the same, which did not occur.

Table E-2. Distribution of AER averaged over K days and its logarithm. Groups defined by Approach B.

These arguments suggest that, based on the RTP Panel study data, to a reasonable approximation, the distribution of an AER measurement does not depend upon the length of the averaging period for the measurement, although it does depend upon the average temperature. This supports the methodology used in the Cohen, Mallya, and Rosenbaum, 2005, analyses that did not take into account the length of the averaging period.

The above argument suggests that the assumption that daily AER values are statistically independent is not justified. Statistical modeling of the correlation structure between consecutive daily AER values is not easy because of the problem of accounting for temperature effects, since temperatures vary from day to day. In the next section we present some statistical models of the daily AER values from the RTP Panel Study.

Statistical models of AER auto-correlations from the RTP Panel Study

We used the MIXED procedure from SAS to fit several mixed models with fixed effects and random effects to the daily values of AER and log(AER). The fixed effects are the population average values of AER or log(AER), and are assumed to depend upon the temperature range. The random effects have expected values of zero and define the correlations between pairs of measurements from the same Group, where the Groups are defined either using Approach A or Approach B above. As described above, a Group is a period of up to 14 consecutive days of measurements at the same house. For these mixed model analyses we included periods with one or more missing days. For all the statistical models, we assume that AER values in different Groups are statistically independent, which implies that data from different houses or in different seasons are independent.

The main statistical model for AER was defined as follows:

$$\begin{aligned}\text{AER} = {} & \text{Mean(Temp Range)} + \text{A(Group, Temp Range)} \\ & + \text{B(Group, Day Number)} + \text{Error(Group, Day Number)}\end{aligned}$$

Mean(Temp Range) is the fixed effects term. There is a different overall mean value for each of the four temperature ranges.

A(Group, Temp Range) is the random effect of temperature. For each Group, four error terms are independently drawn from four different normal distributions, one for each temperature range. These normal distributions all have mean zero, but may have different variances. Because of this term, there is a correlation between AER values measured in the same Group of days for a pair of days in the same temperature range.

B(Group, Day Number) is the repeated effects term. The day number is defined so that the first day of a Group has day number 1, the next calendar day has day number 2, and so on. In some cases AER's were missing for some of the day numbers. B(Group, Day Number) is a normally distributed error term for each AER measurement. The expected value (i.e., the mean) is zero. The variance is V. The covariance between B(Group g, day i) and B(Group h, day j) is zero for days in different Groups g and h, and equals $V \times \exp(d \times |i-j|)$ for days in the same Group. V and d are fitted parameters. This is a first order auto-regressive model. Because of this term, there is a correlation between AER values measured in the same Group of days, and the correlation decreases if the days are further apart.

Finally, Error(Group, Day Number) is the Residual Error term. There is one such error term for every AER measurement, and all these terms are independently drawn from the same normal distribution, with mean 0 and variance W.

We can summarize this rather complicated model as follows. The AER measurements are uncorrelated if they are from different Groups. If they are in the same Group, they have a correlation that decreases with the day difference, and they have an additional correlation if they are in the same temperature range.

Probably the most interesting parameter for these models is the parameter d, which defines the strength of the auto-correlation between pairs of days. This parameter d lies between -1 (perfect negative correlation) and +1 (perfect positive correlation) although values exactly equal to +1 or -1 are impossible for a stationary model. Negative values of d would be unusual since they would imply a tendency for a high AER day to be followed by a low AER day, and vice versa. The case d=0 is for no auto-correlation.

Table E-3 gives the fitted values of d for various versions of the model. The variants considered were:

- model AER or log(AER)
- include or exclude the term A(Group, Temp Range) (the “random” statement in the SAS code)
- use Approach A or Approach B to define the Groups

Since Approach B forces the temperature ranges to be the same for very day in a Group, the random temperature effect term is difficult to distinguish from the other terms. Therefore this term was not fitted using Approach B.

Table E-3. Autoregressive parameter d for various statistical models for the RTP Panel Study AERs.

Dependent variable	Include A(Group, Temp Range)?	Approach	d
AER	Yes	A	0.80
AER	No	A	0.82
AER	No	B	0.80
Log(AER)	Yes	A	0.87
Log(AER)	No	A	0.87
Log(AER)	No	B	0.85

In all cases, the parameter d is 0.8 or above, showing the very strong correlations between AER measurements on consecutive or almost consecutive days.

Impact of accounting for daily average AER auto-correlation

In the current version of the APEX model, there are several options for stratification of time periods with respect to AER distributions, and for when to re-sample from a distribution for a given stratum. The options selected for this current set of simulations resulted in a uniform AER for each 24-hour period and re-sampling of the 24-hour AER for each simulated day. This re-sampling for each simulated day implies that the simulated AERs on consecutive days in the same microenvironment are statistically independent. Although we have not identified sufficient data to test the assumption of uniform AERs throughout a 24-hour period, the analyses described in this memorandum suggest that AERs on consecutive days are highly correlated.

Therefore, in order to determine if bias was introduced into the APEX estimates with respect to either the magnitudes or variability of exposure concentrations by implicitly assuming uncorrelated air exchange rates, we re-ran the 2002 base case simulations using the option to not re-sample the AERs. For this option APEX selects a single AER for each microenvironment/stratum combination and uses it throughout the simulation.

The comparison of the two scenarios indicates little difference in APEX predictions, probably because the AERs pertain only to indoor microenvironments and for the base cases most exposure to elevated concentrations occurs in the “other outdoors” microenvironment. Figures E-

1 and E-2 below present the comparison for exceedances of 8-hour average concentration during moderate exertion for active person in Boston and Houston, respectively.

Sulfur Dioxide Health Risk Assessment

1 INTRODUCTION

The U.S. Environmental Protection Agency (EPA) is presently conducting a review of the national ambient air quality standards (NAAQS) for sulfur dioxide (SO_2). Sections 108 and 109 of the Clean Air Act (Act) govern the establishment and periodic review of the NAAQS. These standards are established for pollutants that may reasonably be anticipated to endanger public health and welfare, and whose presence in the ambient air results from numerous or diverse mobile or stationary sources. The NAAQS are to be based on air quality criteria, which are to accurately reflect the latest scientific knowledge useful in indicating the kind and extent of identifiable effects on public health or welfare that may be expected from the presence of the pollutant in ambient air. The EPA Administrator is to promulgate and periodically review, at five-year intervals, "primary" (health-based) and "secondary" (welfare-based) NAAQS for such pollutants.[1] Based on periodic reviews of the air quality criteria and standards, the Administrator is to make revisions in the criteria and standards, and promulgate any new standards, as may be appropriate. The Act also requires that an independent scientific review committee advise the Administrator as part of this NAAQS review process, a function performed by the Clean Air Scientific Advisory Committee (CASAC).

EPA's plan and schedule for this SO_2 NAAQS review is presented in the "Integrated Plan for Review of the Primary National Ambient Air Quality Standards for Sulfur Oxides" (U.S. EPA, 2007a). The plan discusses the preparation of two key components in the NAAQS review process: an Integrated Science Assessment (ISA) and risk/exposure assessments. The ISA critically evaluates and integrates scientific information on the health effects associated with exposure to oxides of sulfur (SO_x) in the ambient air. The risk/exposure assessments develop, as appropriate, quantitative estimates of human exposure and health risk and related variability and uncertainties, drawing upon the information summarized in the ISA.

In May 2008 EPA's National Center for Environmental Assessment (NCEA) released a draft version of the "Integrated Science Assessment for Oxides of Sulfur – Health Criteria, henceforth referred to as the draft ISA (U.S. EPA, 2008a). In June 2008, EPA's Office of Air Quality Planning and Standards (OAQPS) released a first draft of its "Risk and Exposure Assessment to Support the Review of the SO_2 Primary National Ambient Air Quality Standard," henceforth referred to as the 1st draft REA (U.S. EPA, 2008b). Both of these documents were reviewed by the CASAC SO_2 Panel on July 30-31, 2008. Based on its review of the draft ISA, OAQPS decided to expand the health risk assessment to include a quantitative assessment of lung function responses indicative of

---

[1] Section 109(b)(1) [42 U.S.C. 7409] of the Act defines a primary standard as one "the attainment and maintenance of which in the judgment of the Administrator, based on such criteria and allowing an adequate margin of safety, are requisite to protect the public health."

bronchoconstriction experienced by asthmatic subjects associated with 5 to 10 minute exposures to SO_2 while engaged in moderate or greater exertion. In September 2008, NCEA released the final version of the ISA, "Integrated Science Assessment for Oxides of Sulfur – Health Criteria, henceforth referred to as the ISA (U.S. EPA, 2008c).

SO_2 is one of a group of compounds known as sulfur oxides (SO_x), which include multiple chemicals (e.g., SO_2, SO, SO_3). However only SO_2 is present at concentrations significant for human exposures and the ISA indicates there is limited adverse health effect data for the other gaseous compounds. Therefore, as in past NAAQS reviews, SO_2 is considered as a surrogate for gaseous SO_x species in this assessment, with the secondarily formed particulate species (i.e., sulfate or SO_4) addressed as part of the particulate matter (PM) NAAQS review.

In the previous review, concluded in 1996, it was clearly established that subjects with asthma are more sensitive to the respiratory effects of SO_2 exposure than healthy individuals (ISA, section 3.1.3.2). Asthmatics exposed to SO_2 concentrations as low as 0.2-0.3 ppm for 5-10 minutes during exercise have been shown to experience significant bronchoconstriction, measured as an increase in specific airway resistance (sRaw) ($\geq$100%) or a decrease in forced expiratory volume in one second (FEV_1) ($\geq$15%) after correction for exercise-induced responses in clean air.

The basic structure of the SO_2 health risk assessment described in this document reflects the fact that we have available controlled human exposure study data from several studies involving volunteer asthmatic subjects who were exposed to SO_2 concentrations at specified exposure levels while engaged in moderate or greater exertion for 5- or 10-minute exposures.[2] The risk assessment estimates lung function risks for (1) recent ambient levels of SO_2, (2) air quality adjusted to simulate just meeting the current primary 24-hour and annual standards,[3] and (3) air quality adjusted to simulate just meeting selected alternative 1-hour standards in selected locations encompassing a variety of SO_2 emission source types in the Greene County and the St. Louis area within Missouri.

The SO_2 health risk assessment builds upon the methodology, analyses, and lessons learned from the assessments conducted for the last SO_2 NAAQS review in 1996, as well as the methodology and lessons learned from the health risk assessment work conducted for the recently concluded O_3 NAAQS review (Abt Associates, 2007a) – in particular, the assessment of risk based on controlled human exposure studies described in Chapter 3 of that document. The SO_2 risk assessment is based on our current understanding of the SO_2 scientific literature as reflected in the evaluation provided in the final ISA.

---

[2] An additional characterization of risk may involve use of concentration-response functions, if sufficient and relevant epidemiological data are identified in the ISA to support development of functions that are related to ambient SO_2 concentrations.

[3] There is a 3-hr secondary standard as well. However, this risk assessment is taking into account only the primary standards. The current primary SO_2 standards include a 24-hour standard set at 0.14 parts per million (ppm), not to be exceeded more than once per year, and an annual standard set at 0.03 ppm, calculated as the arithmetic mean of hourly averages.

The goals of this SO_2 health risk assessment are: (1) to develop health risk estimates of the number and percent of the asthmatic population in the selected study area locations that would experience moderate or greater lung function decrements in response to daily 5-minute maximum peak exposures while engaged in moderate or greater exertion for a recent year of air quality and under a scenario in which the SO_2 concentrations are adjusted to simulate just meeting the current 24-hour standard; (2) to develop a better understanding of the influence of various inputs and assumptions on the risk estimates; and (3) to gain insights into the risk levels and patterns of risk reductions associated with air quality simulating just meeting alternative 1-hour SO_2 standards. The risk assessment is intended as a tool that, together with other information on lung function and other health effects evaluated in the SO_2 ISA, can aid the Administrator in judging whether the current primary standards protect public health with an adequate margin of safety, or whether revisions to the standards are appropriate.

Preliminary considerations and the basic structure of the risk assessment are described in section 2. Section 3 describes the methods used, and section 4 presents the results of the risk assessment.

2 PRELIMINARY CONSIDERATIONS

The health risk assessment described in this document estimated lung function decrements (measured as increases in sRaw or decreases in FEV_1) associated with SO_2 exposures under several scenarios: (1) recent ambient levels of SO_2, (2) air quality adjusted to simulate just meeting the current 24-hour and annual standards, and (3) air quality adjusted to simulate just meeting several alternative 1-hour standards. In this section we address preliminary considerations. Section 2.1 briefly discusses the broad empirical basis for a relationship between SO_2 exposures and adverse health effects. Section 2.2 describes the basic structure of the risk assessment. Finally, section 2.3 addresses air quality considerations.

2.1 The Broad Empirical Basis for a Relationship Between SO_2 and Adverse Health Effects

The ISA concludes that the health evidence "is *sufficient to infer a causal relationship between respiratory morbidity and short-term exposure* to SO_2" (ISA, p. 3-33). In support of this conclusion, the ISA notes the following:

> The strongest evidence for this causal relationship comes from human clinical studies reporting respiratory symptoms and decreased lung function following peak exposures of 5-10 min duration to SO_2. These effects have been observed consistently across studies involving exercising mild to moderate asthmatics. Statistically significant decrements in lung function accompanied by respiratory symptoms including wheeze and chest tightness have been clearly demonstrated following exposure to 0.4-0.6 ppm SO_2. Although studies have not reported statistically significant respiratory effects following exposure to 0.2-0.3 ppm SO_2, some asthmatic subjects (5-30%) have been shown to experience moderate to large decrements in lung function at these exposure concentrations.
>
> A larger body of evidence supporting this determination of causality comes from numerous epidemiological studies reporting associations with respiratory symptoms, ED visits, and hospital admissions with short-term SO_2 exposures, generally of 24-h avg. Important new multicity studies and several other studies have found an association between 24-h avg ambient SO_2 concentrations and respiratory symptoms in children, particularly those with asthma.…
>
> … Collectively, the findings from both human clinical and epidemiological studies provide a strong basis for concluding a causal relationship between respiratory morbidity and short-term exposure to SO_2.

2.2 Basic Structure of the Risk Assessment

As noted above, this SO_2 health risk assessment is based on controlled human exposure studies involving volunteer subjects who were exposed while engaged in different exercise regimens to specified levels of SO_2 under controlled conditions for 5 or 10 minute periods. The responses measured in these studies were measures of lung function decrements, including increases in SRaw and decreases in FEV_1. We used probabilistic exposure-response relationships, based on analysis of individual data, that describe the relationships between a measure of personal exposure to SO_2 and the measure(s) of lung function recorded in these studies. These probabilistic exposure-response relationships were combined with daily 5-minute maximum peak exposure estimates associated with the air quality scenarios mentioned above for mild and moderate asthmatics engaged in moderate or greater exertion. Estimates of personal exposures to varying ambient concentrations associated with several air quality scenaros including recent air quality levels, and air quality levels simulating just meeting the current SO2 primary standard and several alternative primary 1-hour standards were derived through exposure modeling. The details of the exposure modeling are described in Chapter 8 and Appendix B of the second draft Risk and Exposure Assessment document (EPA, 2009).

The characteristics that are relevant to carrying out a risk assessment based on controlled human exposure studies can be summarized as follows:

- A risk assessment based on controlled human exposure studies uses exposure-response functions, and therefore requires as input (modeled) personal exposures to SO_2.

- Controlled human exposure studies, carried out in laboratory settings, are generally not specific to any particular real world location. A controlled human exposure studies-based risk assessment can therefore appropriately be carried out for any location for which there are adequate air quality data on which to base the modeling of personal exposures.

The methods for the SO_2 risk assessment are discussed in section 3 below. The risk assessment was implemented within a new probabilistic version of TRIM.Risk, the component of EPA's Total Risk Integrated Methodology (TRIM) model that estimates human health risks.[4]

2.3 Air Quality Considerations

The SO_2 health risk assessment estimates lung function risks associated with (1) "as is" ambient levels of SO_2, (2) air quality simulating just meeting the current 24-hour

---

[4] TRIM.Risk was most recently applied to EPA's O_3 health risk assessment. A User's Guide for the Application of TRIM.Risk to the O_3 health risk assessment (Abt Associates, 2007b) is available online at: http://epa.gov/ttn/fera/data/trim/trimrisk_ozone_ra_userguide_8-6-07.pdf.

and annual standards, and (3) air quality simulating just meeting several alternative 1-hour standards in a recent year (2002) in two selected locations encompassing a variety of SO_2 emission source types in Greene County, Missouri and St. Louis, Missouri.

In order to estimate health risks associated with just meeting the current 24-hour and annual standards and alternative 1-hour SO_2 standards, it is necessary to estimate the distribution of short-term (5-minute) SO_2 concentrations that would occur under any given standard. Since compliance with the current SO_2 standards is based on a single year, air quality data from 2002 were used to determine the change in SO_2 concentrations required to meet the current standards. Estimated design values were used to determine the adjustment necessary to just meet the current 24-hour and annual standards. The approach to simulating just meeting the current standards and alternative 1-hour standards is described in section 8.8.1 of the second draft Risk and Exposure Assessment document (EPA, 2009).

The risk estimates developed for the recently concluded PM and O_3 NAAQS reviews represented risks associated with PM and O_3 levels in excess of estimated policy-relevant background (PRB) levels in the U.S. PRB levels have been historically defined by EPA as concentrations of a pollutant that would occur in the U.S. in the absence of anthropogenic emissions in continental North America (defined as the United States, Canada, and Mexico). The ISA notes that PRB SO_2 concentrations are below 10 parts per trillion (ppt) over much of the United States and are generally less than 30 ppt. With the exception of a few locations on the West Coast and locations in Hawaii, where volcanic SO_2 emissions cause high PRB concentrations, PRB contributes less than 1% to present-day SO_2 concentrations in surface air. Since PRB is well below concentrations that might cause potential health effects, there was no adjustment made for risks associated with PRB concentrations in the current SO_2 health risk assessment.

3 METHODS

The major components of the SO_2 lung function risk assessment are illustrated in Figure 3-1. The air quality and exposure analysis components that are integral to the risk assessment are discussed in Chapters 6 and 7, respectively, of the 2nd draft REA. As described in the ISA and the 2nd draft REA, there are numerous controlled human exposure studies reporting lung function decrements (as measured by increases in SRaw and/or decreases in FEV_1) among mild and/or moderate asthmatic adults associated with short-term (5 or 10 minute) peak exposures to various levels of SO_2 while engaged in moderate or greater exercise. The SO_2 lung function risk assessment focuses on these lung function responses among asthmatic children and adults.

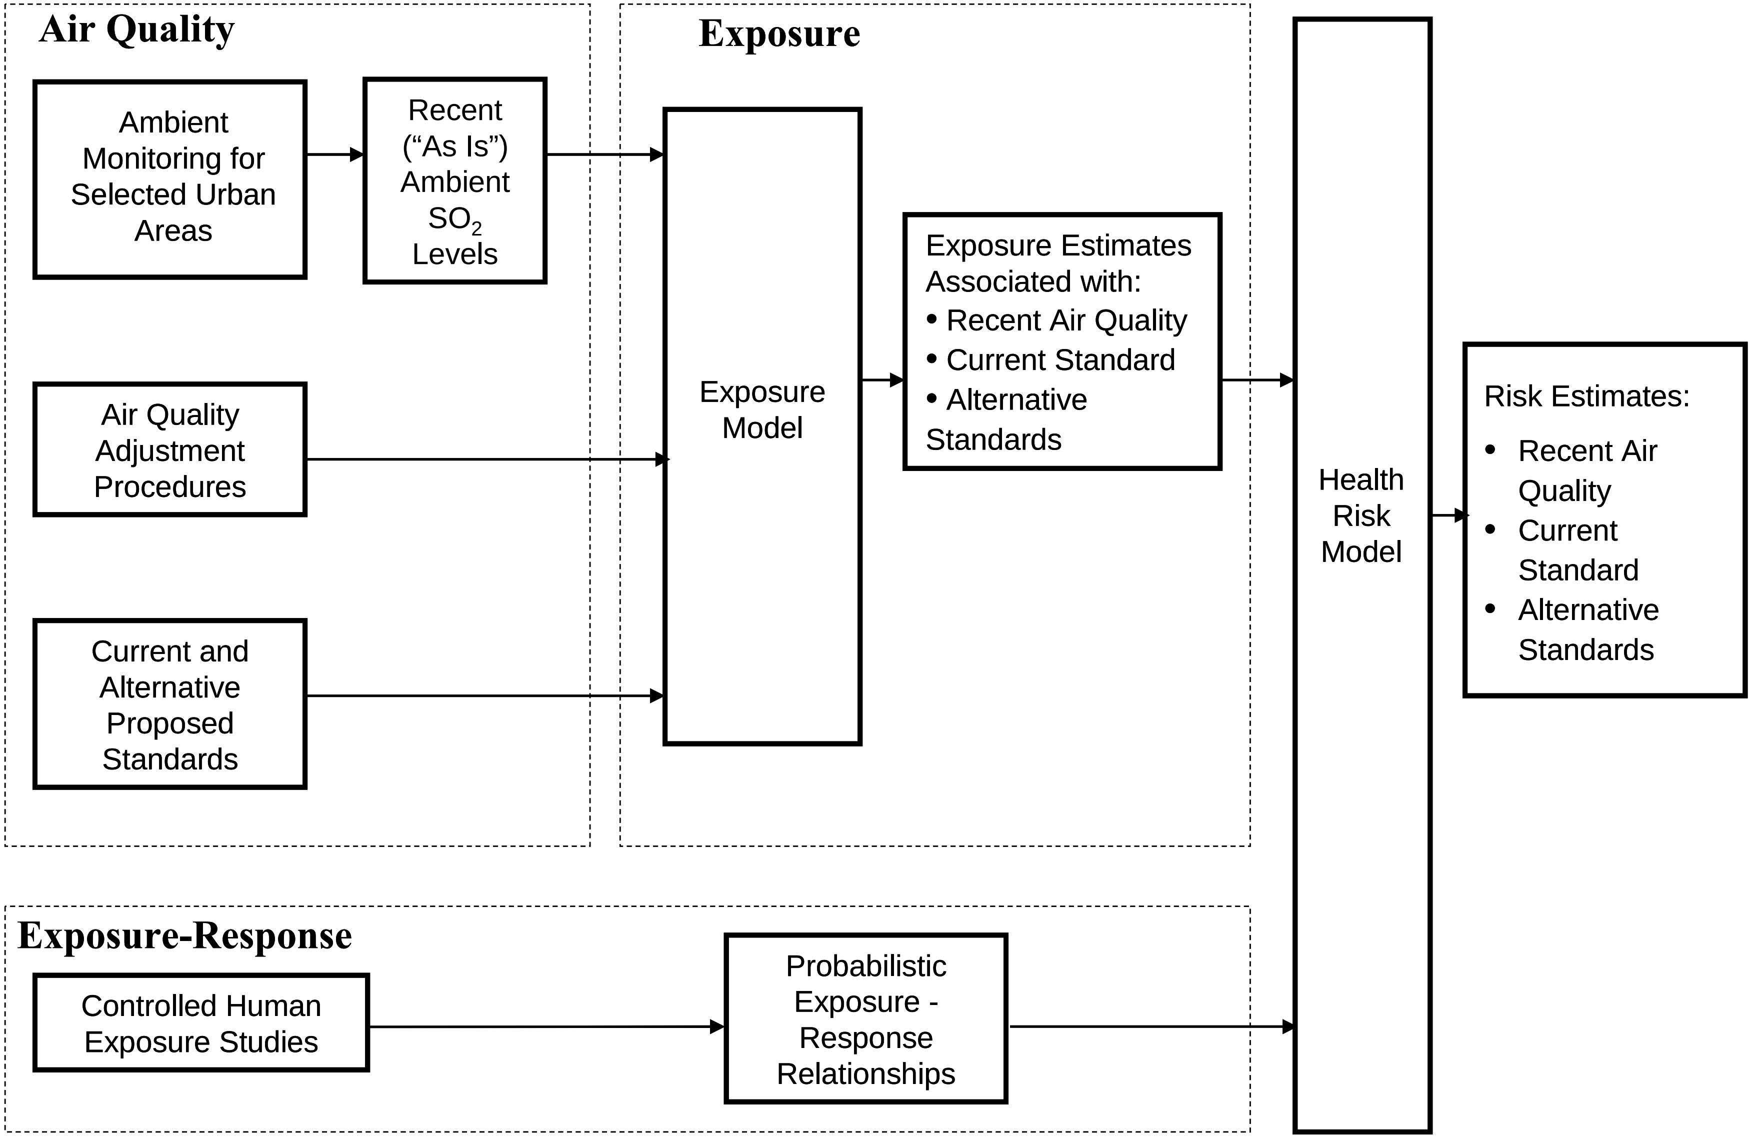
3.1 Selection of health endpoints and target population

The ISA concluded that there is sufficient evidence to infer a causal relationship between respiratory morbidity and short-term exposure to SO_2 (ISA, section 5.2). This determination was based in large part on controlled human exposure studies demonstrating a relationship between short-term (5- or 10-minute) peak SO_2 exposures and adverse effects on the respiratory system in exercising asthmatics. More specifically, the ISA found consistent evidence from numerous controlled human exposure studies demonstrating increased respiratory symptoms (e.g. cough, chest tightness, wheeze) and decrements in lung function in a substantial proportion of exercising asthmatics (generally classified as mild to moderate asthmatics) following short-term peak exposures to SO_2 at concentrations ≥ 0.4 ppm. As in previous reviews, the ISA also concluded that at concentrations below 1.0 ppm, healthy individuals are relatively insensitive to the respiratory effects of short-term peak SO_2 exposures (ISA, sections 3.1.3.2). Therefore, the SO_2 lung function risk assessment focuses on asthmatics. Exposure estimates for asthmatic children and adult asthmatics were combined separately with probabilistic exposure-response relationships (described below) for lung function response associated with daily 5-minute maximum peak exposures while engaged in moderate or greater exertion.[5]

---

[5] Only the highest 5-minute peak exposure (with moderate or greater exertion) on each day will be considered in the lung function risk assessment, since the controlled human exposure studies have shown an acute-phase response that was followed by a short refractory period where the individual was relatively insensitive to additional SO_2 challenges.

Figure 3-1. Components of SO_2 Health Risk Assessment Based on Controlled Human Exposure Studies



Two measures of lung function response – specific airway resistance (sRaw) and forced expiratory volume in one second (FEV_1) – have been used in the controlled human exposure studies that have focused on the effects of exposure to SO_2 on exercising asthmatics. Negative effects are measured as the percent increase in sRaw or the percent decrease in FEV_1. As explained below, we estimated exposure-response relationships for four different definitions of response:

- An increase in sRaw ≥ 100%
- An increase in sRaw ≥ 200%
- A decrease in FEV_1 ≥ 15%
- A decrease in FEV_1 ≥ 20%.

3.2 Development of exposure-response functions

We used a Bayesian Markov Chain Monte Carlo approach to estimate probabilistic exposure-response relationships for lung function decrements associated with 5- or 10-minute exposures at moderate or greater exertion, using the WinBUGS software (Spiegelhalter et al. (1996)). For an explanation of these methods, see Gelman et al. (1995) or Gilks et al. (1996). We treated both 5- and 10-minute exposures as if they were all 5-minute exposures.

The combined data set from Linn et al. (1987, 1988, 1990), Bethel et al. (1983, 1985), Roger et al. (1985), and Kehrl et al. (1987) provide data with which to estimate exposure-response relationships between responses defined in terms of sRaw and 5- or 10-minute exposures to SO_2 at levels of 0.2, 0.25, 0.3, 0.4, 0.5, 0.6, and 1.0 ppm.[6] As noted above, two definitions of response were used: (1) an increase in sRaw ≥ 100% and (2) an increase in sRaw ≥ 200%.

The combined data set from Linn et al. (1987, 1988, 1990) provide data with which to estimate exposure-response relationships between responses defined in terms of FEV_1 and 5- or 10-minute exposures to SO_2 at levels of 0.2, 0.3, 0.4, and 0.6 ppm. As noted above, two definitions of response were used: a decrease in FEV_1 ≥ 15% and a decrease in FEV_1 ≥ 20%.

Before being used to estimate exposure-response relationships for 5-minute exposures, the data from these controlled human exposure studies were corrected for the effect of exercising in clean air to remove any systematic bias that might be present in the data attributable to an exercise effect.[7] Generally, this correction for exercise in clean air is small relative to the total effects measures in the SO_2-exposed cases. The resulting study-specific results, based on the corrected data, are shown in Table 3-1.

---

[6] Data from Magnussen et al. (1990) were not used in the estimation of sRaw exposure-response functions because exposures in this study were conducted using a mouthpiece rather than a chamber.

[7] Corrections were subject-specific. A correction was made by subtracting the subject's percent change (in FEV_1 or sRaw) under the no-SO_2 protocol from his or her percent change (in FEV_1 or sRaw) under the given SO_2 protocol, and rounding the result to the nearest integer. For example, if a subject's percent change in sRaw under the no-SO_2 protocol was 110.12% and his percent change in sRaw under the 0.6 ppm SO_2 protocol was 185.92%, then his percent change in sRaw *due to* SO_2 is 185.92% - 110.12% = 75.8%, which rounds to 76%.

Table 3-1. Study-Specific SO_2 Exposure-Response Data for Lung Function Decrements

Study and SO_2 Level	Increase in sRaw ≥ 100%		Increase in sRaw ≥ 200%		Decrease in FEV_1≥15%		Decrease in FEV_1≥20%

*Data from Magnussen et al. (1990) were not used in the estimation of sRaw exposure-response functions because exposures in this study were conducted using a mouthpiece rather than a chamber.

We considered two different functional forms for the exposure-response functions: a 2-parameter logistic model and a probit model. In particular, we used the data in Table 3-1 to estimate the logistic function,

$$y(x;\ \beta,\gamma) = \frac{1}{(1+e^{\beta+\gamma*\ln(x)})} \tag{3-1}$$

and the probit function,

$$y(x;\beta,\gamma) = \frac{1}{(2\pi)^{1/2}} \int_{-\infty}^{\beta+\gamma\ln(x)} e^{-t^2/2}dt \tag{3-2}$$

for each of the four lung function responses defined above, where *x* denotes the SO_2 concentration (in ppm) to which the individual is exposed, ln(*x*) is the natural logarithm of *x*, *y* denotes the corresponding probability of response (increase in sRaw $\geq$ 100% or $\geq$ 200% or decrease in $FEV_1 \geq 15\%$ or $\geq$ 20%), and β and γ are the two parameters whose values are estimated.[8]

We assumed that the number of responses, s_i, out of N_i subjects exposed to a given SO_2 concentration, x_i, has a binomial distribution with response probability given by equation (3-1) when we assume the logistic model and equation (3-2) when we assume the probit model. The likelihood function is therefore

$$L(\beta,\gamma;data) = \prod_i \binom{N_i}{s_i} y(x_i;\beta,\gamma)^{s_i}\,[1-y(x_i;\ \beta,\gamma)]^{N_i-s_i}\ .$$

In some of the controlled human exposure studies, subjects were exposed to a given SO_2 concentration more than once. However, because there were insufficient data to estimate subject-specific response probabilities, we assumed a single response probability (for a given definition of response) for all individuals and treated the repeated exposures for a single subject as independent exposures in the binomial distribution.

For each model, we derived a Bayesian posterior distribution using this binomial likelihood function in combination with uniform prior distributions for each of the unknown parameters.[9] We used 4000 iterations as the "burn-in" period followed by a sufficient number of iterations to ensure convergence of the resulting posterior density. Each iteration corresponds to a set of values for the parameters of the logistic or probit exposure-response function.

---

[8] For ease of exposition, we use the same two Greek letters to indicate two unknown parameters in the logistic and probit models; this does not imply, however, that the values of these two parameters are the same in the two models.

[9] We used the following uniform prior distributions for the 2-parameter logistic model: $\beta \sim U(-10, 0)$; and $\gamma \sim U(-10,0)$; we used the following normal prior distributions for the probit model: $\beta \sim N(0, 1000)$; and $\gamma \sim N(0,1000)$.

For any SO_2 concentration, *x*, we could then derive the n^{th} percentile response value, for any *n*, by evaluating the exposure-response function at *x* using each of the 18,000 sets of parameter values. The resulting median (50th percentile) logistic and probit exposure-response functions are shown together, along with the data used to estimate these functions, for increases in sRaw $\geq$ 100% and $\geq$ 200% and decreases in $FEV_1 \geq$ 15% and $\geq$ 20% in Figures 3-2, 3-3, 3-4, and 3-5, respectively.

As can be seen in Figures 3-2 through 3-5, there were only limited data with which to estimate the logistic and probit exposure-response functions, and in all cases it wasn't clear that one function fit the data better than the other. In fact, for each of the four lung function response definitions there was little difference between the estimated logistic and probit models. Because the estimated exposure-response functions based on these two models were so similar to each other, for each of the four lung function definitions, and because the risk results from the two models for the same lung function definition would thus be almost the same, we used only one of the models, the logistic, to estimate the risks associated with exposure to SO_2 under the different air quality scenarios considered. The 2.5th percentile, median, and 97.5th percentile logistic exposure-response curves, along with the response data to which they were fit, are shown separately for each of the four response definitions in Appendix A.

Figure 3-2. Bayesian-Estimated Median Exposure-Response Functions: Increase in sRaw ≥ 100% for 5-Minute Exposures of Asthmatics Engaged in Moderate or Greater Exertion

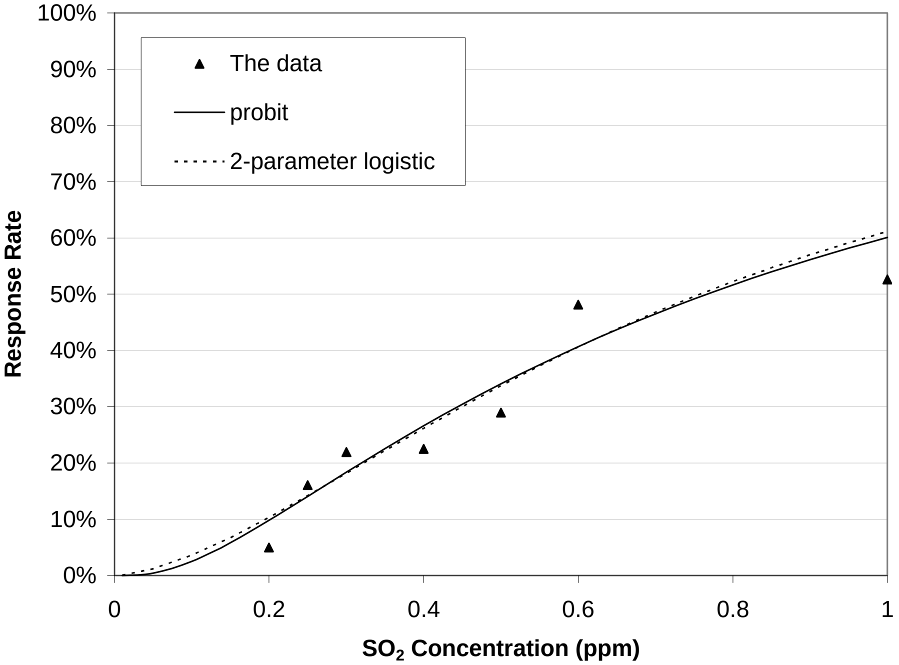

Figure 3-3. Bayesian-Estimated Median Exposure-Response Functions: Increase in sRaw ≥ 200% for 5-Minute Exposures of Asthmatics Engaged in Moderate or Greater Exertion

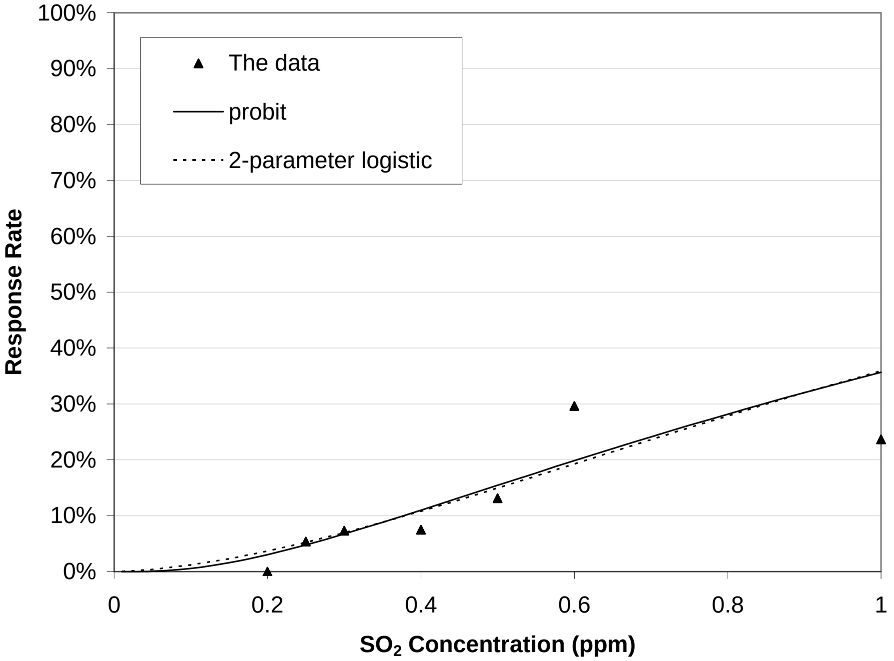

Figure 3-4. Bayesian-Estimated Median Exposure-Response Functions: Decrease in $FEV_1 \geq 15\%$ for 5-Minute Exposures of Asthmatics Engaged in Moderate or Greater Exertion

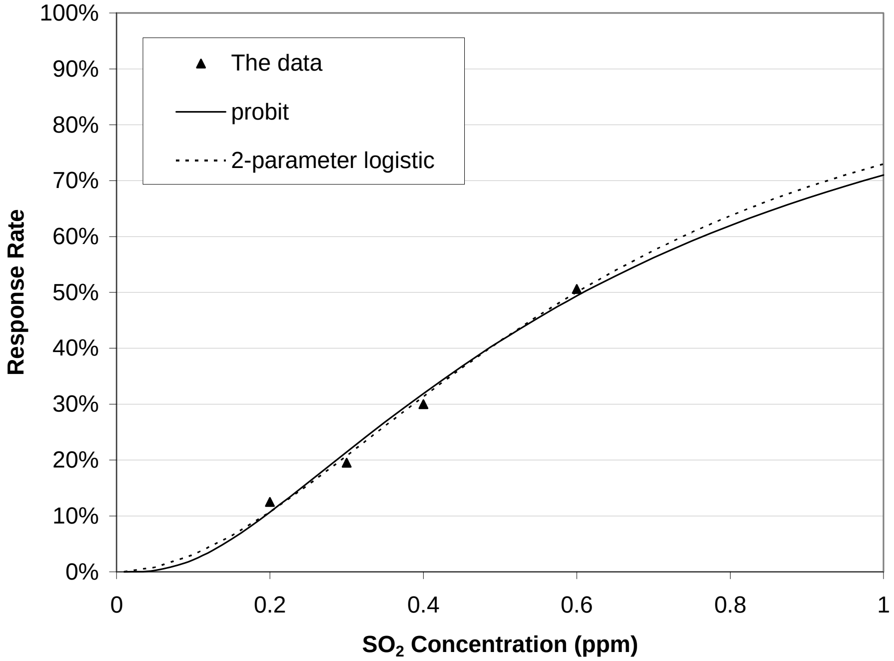

Figure 3-5. Bayesian-Estimated Median Exposure-Response Functions: Decrease in $FEV_1 \geq 20\%$ for 5-Minute Exposures of Asthmatics Engaged in Moderate or Greater Exertion

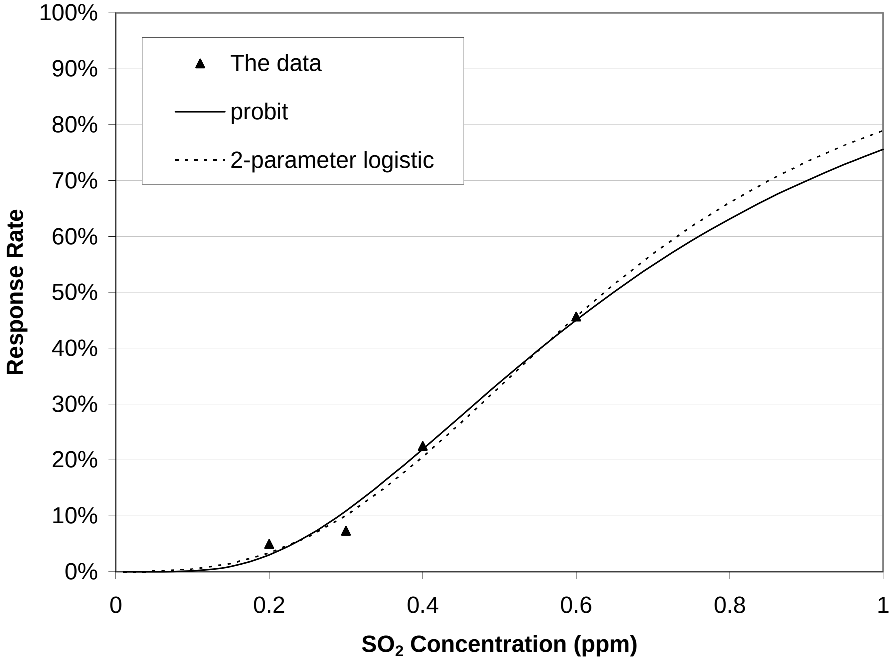

3.2.1 Calculation of risk estimates

We generated two measures of risk for each of the lung function response definitions. The first measure of risk is simply the number of occurrences of the lung function response in the designated population (e.g., asthmatics) in a year associated with SO_2 concentrations under a given air quality scenario. To calculate this measure of risk we started with the number of exposures among the population that are at or above each benchmark level (i.e., 0 ppb, 50 ppb, 100 ppb, etc.), estimated from the exposure modeling. From this we calculated the number of exposures within each 50 ppb exposure "bin" (e.g., < 50 ppb, 50 – 100 ppb, etc.).[10] We then calculated the number of occurrences of lung function response by multiplying the number of exposures in an exposure bin by the response probability (given by our logistic exposure-response function for the specified definition of lung function response) associated with the midpoint of that bin and summing the results across the bins.

Because response probabilities are calculated for each of several percentiles of a probabilistic exposure-response distribution, estimated numbers of occurrences are similarly percentile-specific. The k^{th} percentile number of occurrences, O_k, associated with SO_2 concentrations under a given air quality scenario is:

$$O_k = \sum_{j=1}^{n} N_j \, x \, (R_k \mid e_j) \qquad (3\text{-}3)$$

where:

e_j = (the midpoint of) the jth category of personal exposure to SO_2;

N_j = the number of exposures to e_j ppb SO_2, given ambient SO_2 concentrations under the specified air quality scenario;

$R_k \mid e_j$ = the k^{th} percentile response probability at SO_2 concentration e_j; and

n = the number of intervals (categories) of SO_2 personal exposure concentration.

An example calculation is given in Table 3-2.

---

[10] The final exposure bin was from 750 to 800 ppb SO_2. In at least one of the alternative standard scenarios, there were exposures greater than 800 ppb. For any exposures that exceeded 800 ppb, we assumed a final bin from 800 to 850 ppb, and assigned them the midpoint value of that bin, 825 ppb. This will result in a slight downward bias in the estimate of risk.

Table 3-2. Example: Calculation of Number of Occurrences of Lung Function Response, Defined as an Increase in sRaw ≥ 100%, Among Asthmatics in St. Louis Engaged in Moderate or Greater Exertion Associated with Exposure to SO_2 Concentrations that Just Meet an Alternative 1-Hour 99th Percentile 100 ppb Standard

SO_2 Exposure Bin			Number of Exposures (2)	Probability of Response at Midpoint SO_2 Level (3)	Expected Number of Occurrences of Lung Function Response =(2) x (3)
Lower Bound	Upper Bound	Midpoint (1)			
0	0.05	0.025	16519000	0.00406	67067
0.05	0.1	0.075	136621	0.02334	3189
0.1	0.15	0.125	15760	0.05162	814
0.15	0.2	0.175	3826	0.08563	328
0.2	0.25	0.225	1051	0.12300	129
0.25	0.3	0.275	413	0.16220	67
0.3	0.35	0.325	175	0.20210	35
0.35	0.4	0.375	83	0.24190	20
0.4	0.45	0.425	31	0.28060	9
0.45	0.5	0.475	24	0.31830	8
0.5	0.55	0.525	8	0.35430	3
0.55	0.6	0.575	0	0.38850	0
0.6	0.65	0.625	0	0.42090	0
0.65	0.7	0.675	8	0.45150	4
0.7	0.75	0.725	0	0.46600	0
0.75	0.8	0.775	0	0.49380	0
Total Number of Exposures:			16677000	Expected Number of Occurrences:	71672

The second measure of risk generated for each lung function response definition is the number of individuals in the designated population to experience at least one lung function response in a year associated with SO_2 concentrations under a specified air quality scenario. The calculation of this measure of risk is similar to the calculation of the first measure of risk – however, here we started with estimates, from the exposure modeling, of the number of individuals exposed at least once to *x* ppb SO_2 or higher, for $x = 0, 50, 100$, etc. From this we calculated the number of individuals exposed at least once to SO_2 concentrations within each SO_2 exposure bin defined above. We then multiplied the numbers of individuals in an exposure bin by the response probability (given by our logistic exposure-response function for the specified definition of lung function response) corresponding to the midpoint of the exposure bin, and summed the results across the bins.

Because response probabilities are calculated for each of several percentiles of a probabilistic exposure-response distribution, estimated numbers of individuals with at least one lung function response are similarly percentile-specific. The kth percentile number of individuals, Y_k, associated with SO_2 concentrations under a given air quality scenario is:

$$Y_k = \sum_{j=1}^{n} NI_j \; x \; (R_k \mid e_j) \tag{3-4}$$

Where e_j, $R_k \mid e_j$, and *n* are as defined above, and NI_j is the number of individuals whose highest exposure is to e_j ppb SO_2, given ambient SO_2 concentrations under the specified air quality scenario. An example calculation is given in Table 3-3.

Table 3-3. Example: Calculation of the Number of Asthmatics in St. Louis Engaged in Moderate or Greater Exertion Estimated to Experience at Least One Lung Function Response, Defined as an Increase in sRaw ≥ 100%, Associated with Exposure to SO_2 Concentrations that Just Meet an Alternative 1-Hour 99th Percentile 100 ppb Standard

SO_2 Exposure Bin			Number of Asthmatics with At Least One Exposure in Bin (2)	Probability of Response at Midpoint SO_2 Level (3)	Estimated Number of Asthmatics Experiencing at Least One Lung Function Response =(2) x (3)

0.25	0.3	0.275	368	0.16220	60
0.3	0.35	0.325	145	0.20210	29
0.35	0.4	0.375	84	0.24190	20
0.4	0.45	0.425	31	0.28060	9
0.45	0.5	0.475	22	0.31830	7
0.5	0.55	0.525	8	0.35430	3
0.55	0.6	0.575	0	0.38850	0
0.6	0.65	0.625	0	0.42090	0
0.65	0.7	0.675	8	0.45150	4
0.7	0.75	0.725	0	0.46600	0
0.75	0.8	0.775	0	0.49380	0
		Total :	102436	Total:	2032

Note that this calculation assumes that individuals who do not respond at the highest SO_2 concentration to which they are exposed will not respond to any lower SO_2 concentrations to which they are exposed.

Note also that, in contrast to the risk estimates calculated for the O_3 health risk assessment, the risk estimates calculated for the SO_2 health risk assessment do not subtract out risk given the personal exposures associated with estimated policy relevant background (PRB) ambient SO_2 concentrations, because PRB SO_2 concentrations are so low (see section 2.3).

3.2.2 Selection of urban areas

Although it would be useful to characterize SO_2-related lung function risks associated with "as is" SO_2 ambient concentrations and SO_2 concentrations that just meet the current and alternative SO_2 standards nationwide, because the modeling of personal exposures is both time and labor intensive, a regional and source-oriented approach was selected instead. The selection of areas to include in the exposure analysis, and therefore the risk assessment, took into consideration the availability of ambient monitoring, the desire to represent a range of geographic areas considering SO_2 emission sources, population demographics, general climatology, and results of the ambient air quality characterization.

The first area of interest was initially identified based on the results of a preliminary screening of the 5-minute ambient SO_2 monitoring data that were available. The state of Missouri was one of only a few states having both 5-minute maximum and continuous 5-minute SO_2 ambient monitoring, as well as having over 30 1-hour SO_2 monitors in operation at some time during the period from 1997 to 2007. In addition, the air quality characterization, described in Chapter 6 of the 1st draft REA, estimated frequent exceedances above the potential health effect benchmark levels at several of the 1-hour ambient monitors. In a ranking of estimated SO_2 emissions reported in the National Emissions Inventory (NEI), Missouri ranked 7th for the number of stacks with > 1000 tpy SO_x emissions out of all U.S. states. These stack emissions were associated with a variety of source types such as electrical power generating units, chemical manufacturing, cement processing, and smelters. For all these reasons, the current SO_2 lung function risk assessment focuses on Missouri and, within Missouri, on those areas within 20 km of a major point source of SO_2 emissions in Greene County and the St. Louis area.

3.2.3 Addressing variability and uncertainty

Any estimation of risks associated with "as is" SO_2 concentrations or with SO_2 concentrations that just meet the current or alternative SO_2 standards should address both the variability and uncertainty that generally underlie such an analysis. *Uncertainty* refers to the lack of knowledge regarding the actual values of model input variables (parameter uncertainty) and of physical systems or relationships (model uncertainty – e.g., the shapes of exposure-response and concentration-response functions). The goal of the analyst is to reduce uncertainty to the maximum extent possible. Uncertainty can be reduced by improved measurement and improved model formulation. In a health risk assessment, however, significant uncertainty often remains.

The degree of uncertainty can be characterized, sometimes quantitatively. For example, the statistical uncertainty surrounding the estimated SO_2 coefficients in the exposure-response functions is reflected in confidence or credible intervals provided for the risk estimates.

As described in section 3.2 above, we used a Bayesian Markov Chain Monte Carlo approach to estimate exposure-response functions as well as to characterize uncertainty attributable to sampling error based on sample size considerations. Using this approach, we could derive the n^{th} percentile response value, for any n, for any SO_2concentration, x, as described above (see section 3.2). Because our exposure estimates were generated at the midpoints of 0.05 ppm intervals (i.e., for 0.025 ppm, 0.075 ppm, etc.), we derived 2.5th percentile, 50th percentile (median), and 97.5th percentile response estimates for SO_2 concentrations at these midpoint values. The 2.5th percentile and 97.5th percentile response estimates comprise the lower and upper bounds of the credible interval around each point estimate (median estimate) of response.

In addition to uncertainties arising from sampling variability, other uncertainties associated with the use of the exposure-response relationships for lung function responses are briefly summarized below. Additional uncertainties with respect to the exposure inputs to the risk assessment are described in section 7.1 of the 2nd draft REA. The main additional uncertainties with respect to the approach used to estimate exposure-response relationships include:

- Length of exposure. The 5-minute lung function risk estimates are based on a combined data set from several controlled human exposure studies, most of which evaluated responses associated with 10-minute exposures. However, since some studies which evaluated responses after 5-minute exposures found responses occurring as early as 5-minutes after exposure, we used all of the 5- and 10- minute exposure data to represent responses associated with 5-minute exposures. We do not believe that this approach would appreciably impact the risk estimates.

- Exposure-response for mild/moderate asthmatics. The data set that was used to estimate exposure-response relationships included mild and/or moderate asthmatics. There is uncertainty with regard to how well the population of mild and moderate asthmatics included in the series of controlled human exposure studies represent the distribution of mild and moderate asthmatics in the U.S. population. As indicated in the ISA (p. 3-9), the subjects studied represent the responses “among groups of relatively healthy asthmatics and cannot necessarily be extrapolated to the most sensitive asthmatics in the population who are likely more susceptible to the respiratory effects of exposure to SO_2."

- Extrapolation of exposure-response relationships. It was necessary to estimate responses at SO_2 levels below the lowest exposure levels used in free-breathing controlled human studies (i.e., 0.2 ppm). We did not include alternative models that incorporate hypothetical population thresholds, given the lack of evidence supporting the choice of potential hypothetical threshold levels. As discussed later in this document, we have presented information on the contribution of different exposure intervals to the total estimated lung function risk. This information provides insights on how much of the estimated risk is attributed to SO_2 exposures at the lower exposure levels (i.e., 0 to 50 ppb, 50 to 100 ppb, 100 to 150 ppb, etc.). One can use this information to get a rough sense of the SO_2-related risk that would exist under alternative threshold assumptions.

- Reproducibility of SO_2-induced responses. The risk assessment assumed that the SO_2-induced responses for individuals are reproducible. We note that this assumption has some support in that one study (Linn et al., 1987) exposed the same subjects on two occasions to 0.6 ppm and the authors reported a high degree of correlation ($r > 0.7$ for mild asthmatics and $r > 0.8$ for moderate asthmatics, $p < 0.001$), while observing much lower and nonsignificant correlations ($r = 0.0 – 0.4$) for the lung function response observed in the clean air with exercise exposures.

- Age and lung function response. Because the vast majority of controlled human exposure studies investigating lung function responses were conducted with adult subjects, the risk assessment relies on data from adult asthmatic subjects to estimate exposure-response relationships that were applied to all asthmatic individuals, including children. The ISA (section 3.1.3.5) indicates that there is a strong body of evidence that suggests adolescents may experience many of the same respiratory effects at similar SO_2 levels, but recognizes that these studies administered SO_2 via inhalation through a mouthpiece rather than an exposure chamber. This technique bypasses nasal absorption of SO_2 and can result in an increase in lung SO_2 uptake. Therefore, the uncertainty will be greater in the risk estimates for asthmatic children.

- Exposure history. The risk assessment assumed that the SO_2-induced response on any given day is independent of previous SO_2 exposures.

- Interaction between SO_2 and other pollutants. Because the controlled human exposure studies used in the risk assessment involved only SO_2 exposures, it was assumed that estimates of SO_2-induced health responses would not be affected by the presence of other pollutants (e.g., $PM_{2.5}$, O_3, NO_2).

Variability refers to the heterogeneity in a population or parameter. Even if there is no uncertainty surrounding inputs to the analysis, there may still be variability. For example, there may be variability among exposure-response functions describing the relationship between SO_2 and lung function in different locations. This variability does not imply uncertainty about the exposure-response function in any location, but only that these functions are different in the different locations, reflecting differences in the populations and/or other factors that may affect the relationship between SO_2 and the associated health endpoint. In general, it is possible to have uncertainty but no variability (if, for instance, there is a single parameter whose value is uncertain) or variability but little or no uncertainty (for example, people's heights vary considerably but can be accurately measured with little uncertainty).

The SO_2 lung function risk assessment addresses variability-related concerns by using location-specific inputs for the exposure analysis (e.g., location-specific population data, air exchange rates, air quality and temperature data). The extent to which there may be variability in exposure-response relationships for the populations included in the risk assessment residing in different geographic areas is currently unknown.

Temporal variability is more difficult to address, because the risk assessment focuses on some unspecified time in the future. To minimize the degree to which values of inputs to the analysis may be different from the values of those inputs at that unspecified time, we are using the most current inputs available.

4 Results

The results of the SO_2 risk assessment are presented in Tables 4-1 through 4-12. Each table includes results for both of the locations included in the risk assessment and for all of the air quality scenarios considered. Tables 4-1 and 4-2 show the numbers of occurrences of lung function response in a year, defined in terms of sRaw, for asthmatics and for asthmatic children, respectively, engaged in moderate or greater exertion associated with SO_2 concentrations under each of the different air quality scenarios considered in each of the two locations. Tables 4-3 and 4-4 show the corresponding results when lung function response is defined in terms of FEV_1. Tables 4-5 and 4-6 show the numbers of asthmatics and asthmatic children, respectively, engaged in moderate or greater exertion estimated to experience at least one lung function response in a year, defined in terms of sRaw, under each of the different air quality scenarios in each of the two locations. Tables 4-7 and 4-8 show the corresponding results when lung function response is defined in terms of FEV_1. Finally, Tables 4-9 through 4-12 show results analogous to those shown in Tables 4-5 through 4-8, only as percentages of all asthmatics (asthmatic children) engaged in moderate or greater exertion.

In addition, responses attributable to exposure to SO_2 within different concentration ranges are shown in Figures 4-1 through 4-8. The exposure ranges are in 50 ppb increments – i.e., $SO_2 < 50$ ppb, 50 ppb $\leq SO_2 < 100$ ppb, 100 ppb $\leq SO_2 < 150$ ppb, … , $SO_2 \geq 500$ ppb. Figures 4-1a and b show the percent of asthmatics engaged in moderate or greater exertion in Greene Co., MO and St. Louis, MO, respectively, estimated to experience at least one lung function response in a year, defined as an increase in sRaw ≥ 100%, attributable to exposure to SO_2 in each exposure "bin." Figures 4-2a and b show the corresponding percents for asthmatic children engaged in moderate or greater exertion in each location, respectively. Figures 4-3a and b, and 4-4a and b, show the corresponding percents for asthmatics and asthmatic children, respectively, when lung function response is defined as a decrease in FEV1≥ 15%. Figures 4-5a and b show the number of occurrences of lung function response, defined as an increase in sRaw ≥ 100%, among asthmatics engaged in moderate or greater exertion attributable to exposure to SO_2 in each exposure "bin." Figures 4-6a and b show the corresponding numbers of occurrences among asthmatic children. Finally, Figures 4-7a and b and 4-8a and b show the corresponding numbers of occurrences of lung function response for asthmatics and asthmatic children, respectively, when lung function response is defined as a decrease in FEV1≥ 15%. Figure 4-9 shows the legend that is used in Figures 4-1 through 4-8.

Table 4-1. Number of Occurrences (in Hundreds) of Lung Function Response (Defined in Terms of sRaw) Among Asthmatics Engaged in Moderate or Greater Exertion Associated with Exposure to "As Is" SO_2 Concentrations, SO_2 Concentrations that Just Meet the Current Standards, and SO_2 Concentrations that Just Meet Alternative Standards*

Location	"As is" SO_2 Concentrations**	SO_2 Concentrations that Just Meet the Current Standards***	SO_2 Concentrations that Just Meet Alternative nth Percentile 1-Hr Daily Maximum Standards, with Levels (in ppb) of m (Standard Denoted n/m):					
			99/50	99/100	99/150	99/200	99/250	98/200
Response = Increase in sRaw >= 100%								
Greene County, MO	125 (24 - 572)	127 (25 - 577)	125 (24 - 572)	125 (24 - 572)	125 (24 - 573)	126 (24 - 573)	126 (24 - 575)	126 (24 - 574)
St. Louis, MO	657 (128 - 2985)	1672 (663 - 4740)	652 (125 - 2975)	686 (141 - 3041)	762 (176 - 3184)	880 (234 - 3398)	1036 (315 - 3673)	997 (295 - 3604)

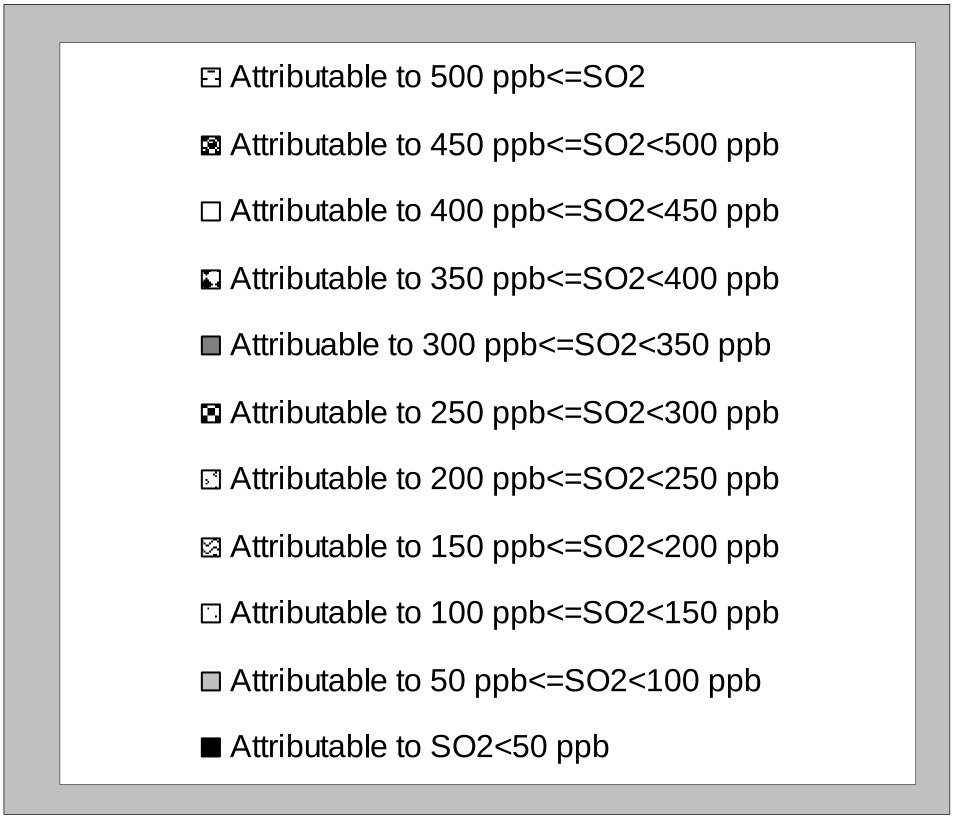
Figure 4-9. Legend for Figures 4-1 - 4-8.



The current primary SO_2 standards include a 24-hour standard set at 0.14 parts per million (ppm), not to be exceeded more than once per year, and an annual standard set at 0.03 ppm, calculated as the arithmetic mean of hourly averages. In St. Louis, SO_2 concentrations that are predicted to occur if the current standards were just met are substantially higher than "as is" air quality (based on 2002 monitoring and modeling data) and also substantially higher than they would be under any of the alternative 1-hr standards considered in this analysis. Consequently, the levels of response that would be seen if the current standard were just met are well above the levels that would be seen under the "as is" air quality scenario or under any of the alternative 1-hr standards – for asthmatics and for asthmatic children, and for all four definitions of lung function response.

For example, of the estimated approximately 102,400 asthmatics engaged in moderate or greater exertion in St. Louis, about 13,500 (or 13.1%) are estimated to have at least one lung function response, defined as an increase in sRaw ≥ 100%, if the current standards were just met. Under "as is" air quality conditions, the corresponding number is about 1,000 (1%). Only the most stringent alternative 99th percentile 1-hr standard, set at 50 ppb (denoted "99/50" in the above tables of results), is predicted to lower the numbers of responders below the levels estimated under the "as is" scenario. As the alternative 1-hr standards become less stringent (i.e., as the level is raised from 50 ppb to 100 ppb, to 150 ppb, etc.), the numbers responding correspondingly rise.

The pattern seen in St. Louis for lung function response, defined as an increase in sRaw ≥ 100%, is also seen for the other definitions of lung function response. For example, of the estimated roughly 102,400 asthmatics engaged in moderate or greater exertion, 750 are estimated to have at least one lung function response, defined as a decrease in $FEV_1 \geq 15\%$, under the "as is" air quality scenario; the corresponding number (percent) if the current standards were just met is about 15,200 (14.9%); the corresponding numbers for the alternative 1-hr standards denoted 99/50, 99/100, 99/150, 99/200, 99/250, and 98/200 are about 500 (0.5%), 1700 (1.7%), 3500 (3.4%), 5600 (5.4%), 7900 (7.7%), and 7400 (7.2%), respectively.

Although the basic pattern across air quality scenarios seen in St. Louis is repeated in Greene County, the impact of changing from one air quality scenario to another is substantially dampened in Greene County. This is because of the different patterns of exposures in the two locations. In St. Louis there is a wide range of SO_2 concentrations to which asthmatics are exposed under the current standards scenario – i.e., substantial percentages of asthmatics are exposed to relatively higher concentrations of SO_2 under this scenario. There is thus much room for improvement. Under the most stringent alternative 1-hr standard (99/50), much of that exposure is pushed down to the lowest SO_2 concentration "bins." Under the current standards scenario, for example, only about 22 percent of asthmatics in St. Louis have exposures no greater than 100 ppb; under the most stringent alternative 1-hr standard (99/50), that increases to 98 percent.

In Greene County, in contrast, about 95 percent of asthmatics have exposures no greater than 100 ppb under the current standards scenario. There is therefore little room for improvement. Under the most stringent alternative 1-hr standard (99/50), that 95 percent becomes 100 percent. The situation is even more extreme for person days of exposure. Under the current standards scenario, 99.9 percent of person days of exposure are to ≤ 100 ppb SO_2 in Greene County; the corresponding figure for St. Louis is 95.2 percent.

The generally lower levels of SO_2 to which asthmatics in Greene County are exposed, relative to asthmatics in St. Louis, and the corresponding greater preponderance of responses associated with the lowest SO_2 concentration "bins" in Greene County, can be readily seen in Figures 4-1 through 4-8.[11]

Although the numbers are smaller for asthmatic children (because the underlying populations are smaller), the patterns seen in St. Louis and in Greene County across the different air quality scenarios, and the comparisons between the two locations, are fairly similar for asthmatic children as for asthmatics for all lung function response definitions.

---

[11] In several cases, responses associated with exposures in SO_2 bins cannot be seen in the figures, because the percent responding, or numbers of occurrences of lung function response are so small. We chose to scale the y-axis the same on all comparable figures to facilitate comparisons between figures. This meant, however, that some "response bars" essentially became visually undetectable.

In general, however, the percentages of asthmatic children engaged in moderate or greater exertion who experience at least one lung function response, for each of the different lung function response definitions, tend to be greater than the corresponding percentages of asthmatics. This presumably is a reflection of the greater amount of time spent outdoors by asthmatic children relative to adults.

Finally, we note that, while in several air quality scenarios the great majority of occurrences of lung function response are in the lowest exposure bin, the numbers of individuals with at least one lung function response attributable to exposures in that lowest bin are typically quite small. This is because the calculation of numbers of individuals with at least one lung function response uses individuals' highest exposure only. While individuals may be exposed mostly to low SO_2 concentrations, many are exposed at least occasionally to higher levels. Thus, the percentage of individuals in a designated population with at least one lung function response associated with SO_2 concentrations in the lowest bin is likely to be very small, since most individuals are exposed at least once to higher SO_2 levels. For example, defining lung function response as an increase in sRaw $\geq$ 100%, under a scenario in which SO_2 concentrations just meet an alternative 1-hour 99th percentile 100 ppb standard, about 93 percent of occurrences of lung function response among asthmatics in St. Louis are associated with SO_2 exposures in the lowest exposure bin (0 – 50 ppb). However, the lowest SO_2 exposure bin accounts for only about 0.2 percent of asthmatics estimated to experience at least 1 SO_2-related lung function response. For this very small percent of the population, the lowest exposure bin represents their highest SO_2 exposures under moderate exertion in a year. Thus Figure 4-5b shows virtually all of the occurrences among asthmatics in St. Louis associated with the lowest SO_2 exposure bin; however, Figure 4-1b shows a relatively small proportion of asthmatics in St. Louis experiencing at least one response to be experiencing those responses because of exposures in that lowest exposure bin.
