Combination of CDF and D0 Measurements of the Single Top Production Cross Section

The Tevatron Electroweak Working Group ¹
for the CDF and DØ Collaborations

Abstract

We report a combination of the CDF and D0 measurements of the inclusive single top quark production cross section in the s - and t -channels, σ_{s+t} , in $p\bar{p}$ collisions at a center of mass energy of 1.96 TeV. The total integrated luminosity included in CDF's analysis is 3.2 fb^{-1} and D0's analysis has 2.3 fb^{-1} . A Bayesian analysis is used to extract the cross section from the distributions of multivariate discriminants provided by the collaborations. For a top quark mass $m_t = 170 \text{ GeV}/c^2$, we measure a cross section of $2.76_{-0.47}^{+0.58} \text{ pb}$. We extract the CKM matrix element $|V_{tb}| = 0.88 \pm 0.07$ with a 95% C.L. lower limit of $|V_{tb}| > 0.77$.

¹The Tevatron Electroweak Working Group can be contacted at tev-ewwg@fnal.gov.
More information can be found at <http://tevewwg.fnal.gov>.

1 Introduction

In the standard model (SM), top quarks are expected to be produced singly in $p\bar{p}$ collisions through s -channel or t -channel exchange of a virtual W boson [1]. The reasons for studying single top quarks are compelling: the production cross section is directly proportional to the square of the CKM matrix [2] element $|V_{tb}|$, and the cross section measurement is sensitive to fourth-generation models, models with flavor-changing neutral currents, and other new phenomena [3]. The main backgrounds to the single top final state are W +jets production, $t\bar{t}$ production, and QCD multijet production. Electroweak production of single top quarks is a difficult process to measure because the expected production cross section ($\sigma_{s+t}^{\text{theory}} \sim 2.9 - 3.5$ pb [4, 5]) is much smaller than those of the background processes, and it is also smaller than the uncertainty on the total background. The presence of only one top quark in the event provides fewer features to use in separating the signal from background, compared with measurements of top pair production ($t\bar{t}$), which was first observed in 1995 [6].

The CDF and D0 collaborations have developed a variety of sophisticated multivariate techniques that take advantage of the differences in the kinematic distributions between signal and backgrounds. These have successfully been used to observe the process, at the 5.0 standard deviation level of significance, separately by D0 [7] and by CDF [8]. Further details of these analyses are given in earlier publications presenting evidence for single top production in smaller samples of data [9, 10, 11].

Because the presence of single top production has been firmly established by the two collaborations and due to the computational difficulty of computing the significance of the two in combination, we do not perform a hypothesis test of the combined results. The cross section measurements, however, remain limited in precision by the sizes of the data samples collected by the two collaborations, and thus a combination of the results provides a more precise measurement and also stronger constraints on the CKM matrix element $|V_{tb}|$.

2 Method

The CDF and D0 collaborations both measure the single top cross section and extract $|V_{tb}|$ using a Bayesian statistical analysis. We use the same method here to combine the two measurements. The CDF and D0 collaborations use independently developed computer programs for performing the calculation, and we have verified that both codes reproduce the individual experiment results. Since the two codes produce consistent results we use the D0 code here to obtain the combined Tevatron results. CDF and D0 have exchanged histograms of their final multivariate discriminants for the observed data and all signals and backgrounds in each analysis channel. Furthermore, all systematic uncertainties – those on the predicted rates, histogram shapes, and bin-by-bin independent Monte Carlo statistical uncertainties, have been exchanged as well.

Rate and shape uncertainties are categorized by their source for use in evaluating correlations, between signals and/or backgrounds within a channel, between channels, and between experiments. Sources of systematic uncertainty that are common to the measurements of the two collaborations have been assigned 100% correlation, and other sources of uncertainty are assumed to be uncorrelated. A list of systematic uncertainties is given in Table 3 and discussed in more detail below.

The method used for extraction of the cross section chosen by the collaborations is a Bayesian technique [12]. The posterior probability density is given by

$$p(\sigma_{s+t}) = \int L(\text{data}|\sigma_{s+t}, \{\theta\})\pi(\sigma_{s+t})\pi(\{\theta\})d\{\theta\}, \quad (1)$$

where L is the joint likelihood function of all bins in all histograms

$$L = \prod_{\text{bins, channels}} \frac{(s_i + b_i)^{n_i} e^{-(s_i + b_i)}}{n_i!}, \quad (2)$$

$\{\theta\}$ is the set of nuisance parameters (such as integrated luminosity, b -tag efficiency, and other rate and shape parameters), and $\pi(\{\theta\})$ is the product of the priors encoding the systematic uncertainties on $\{\theta\}$. The predictions for the number of signal events (s_i) and background events (b_i) depend on the values of the nuisance parameters.

The prior density for the signal cross section is taken to be a nonnegative flat prior, $\pi(\sigma_{s+t}) = 1/\sigma_{\text{max}}$ for $\sigma \geq 0$, and $\pi(\sigma) = 0$ otherwise. Here, σ_{max} is the highest signal cross section axis point (7 pb for the combination). The priors on $\{\theta\}$ are truncated Gaussians, where the truncations are introduced so as not to allow negative predictions of s_i or b_i for any template in any bin. The integral over $d\{\theta\}$ is performed through numerical integration.

We quote the measured cross section as the value that maximizes the posterior likelihood, and the uncertainty as the shortest interval containing 68% of the posterior area.

In addition to the above, the D0 code uses a Gamma prior for the MC statistics uncertainty, reflecting the Poisson nature of MC statistics, and having the additional advantage that an analytic solution to the integral in Eq. 1 exists. This does not bias the cross section but reduces the computing time considerably.

The combination procedure includes all channels from both collaborations in the Bayesian analysis, including correlations of systematic uncertainties between experiments. We combine the CDF super-discriminant, the CDF missing transverse energy (\cancel{E}_T) plus jets analysis, and the D0 combination discriminant. While there are some differences in the detailed treatments of uncertainties, the CDF and D0 codes give results consistent with each other when run over the individual inputs. We have verified this by running the D0 code over the CDF inputs.

Table 1 (Table 2) lists the measured cross sections with and without systematic uncertainties for the two ingredients to the CDF combination as well as the CDF combination result, both

Table 1: Results summary for CDF’s ℓ +jets super-discriminant analysis, \cancel{E}_T +jets analysis, and CDF’s total combination, comparing the CDF code to the D0 code. This is for the published CDF measurements at $m_t = 175 \text{ GeV}/c^2$.

Analysis	Cross Section (pb) CDF Calculation	Cross Section (pb) D0 Recalculation
No systematic uncertainties		
Super-discriminant	$2.29^{+0.46}_{-0.43}$	$2.29^{+0.45}_{-0.43}$
\cancel{E}_T +jets	$4.18^{+1.43}_{-1.35}$	$4.19^{+1.41}_{-1.37}$
Combined	$2.49^{+0.43}_{-0.43}$	$2.48^{+0.44}_{-0.42}$
Including systematic uncertainties		
Super-discriminant	$2.1^{+0.6}_{-0.5}$	$2.1^{+0.6}_{-0.5}$
\cancel{E}_T +jets	$4.9^{+2.5}_{-2.2}$	$5.2^{+2.3}_{-2.1}$
Combined	$2.3^{+0.6}_{-0.5}$	$2.3^{+0.6}_{-0.5}$

Table 2: Results summary for CDF’s ℓ +jets super-discriminant analysis, \cancel{E}_T +jets analysis, and CDF’s total combination, comparing the CDF code to the D0 code. This is for the re-calculation corresponding to $m_t = 170 \text{ GeV}/c^2$ and includes all systematic uncertainties.

Analysis	Cross Section (pb) CDF Calculation	Cross Section (pb) D0 Recalculation
Super-discriminant	$2.17^{+0.56}_{-0.55}$	$2.12^{+0.59}_{-0.54}$
\cancel{E}_T +jets	$5.0^{+2.6}_{-2.3}$	$5.4^{+2.8}_{-2.7}$
Combined	$2.35^{+0.56}_{-0.50}$	$2.29^{+0.60}_{-0.54}$

for the original CDF calculation and the recalculation using the D0 code, for a top quark mass of $m_t = 175 \text{ GeV}/c^2$ ($m_t = 170 \text{ GeV}/c^2$). The D0 code reproduces the CDF results, indicating that all inputs and uncertainties are being read properly.

Different conventions have been used by the CDF and D0 analyses for the top quark mass and the theoretical single top cross section. CDF assumes $m_t = 175 \text{ GeV}/c^2$ in its extraction of the central value of the single top production cross section, while D0 assumes $m_t = 170 \text{ GeV}/c^2$. The current world average top mass is $173.1 \pm 1.3 \text{ GeV}/c^2$ [13]. CDF includes in its p -value calculation and the $|V_{tb}|$ limit the uncertainty in m_t and thus all rate and shape uncertainties have been evaluated for the single top signal templates and the $t\bar{t}$ background templates. D0 does not have single top or $t\bar{t}$ samples for $m_t = 175 \text{ GeV}/c^2$, so CDF has shifted its predictions to $m_t = 170 \text{ GeV}/c^2$, and thus the results quoted here assume $m_t = 170 \text{ GeV}/c^2$. The discriminant shapes and normalizations have been shifted for s-channel and t-channel signal as well as for $t\bar{t}$ background. The $t\bar{t}$ background cross section at $m_t = 170 \text{ GeV}/c^2$ is $7.91 \pm 0.95 \text{ pb}$ [14]. Other background normalizations that weakly depend on $t\bar{t}$ have not been modified. This has

a small impact on the measured cross section as can be seen in Table 2.

The other difference in convention is the choice of theoretical cross section to compare the measurement with. CDF chooses Harris and Sullivan’s next-to-leading order (NLO) calculation with cross sections of $\sigma_s^{\text{theory}} = 0.99 \pm 0.07$ pb and $\sigma_t^{\text{theory}} = 2.15 \pm 0.24$ pb at $m_t = 170$ GeV/ c^2 [4], while D0 chooses Kidonakis’ NLO plus soft-gluon corrections calculation with cross sections of $\sigma_s^{\text{theory}} = 1.12 \pm 0.05$ pb and $\sigma_t^{\text{theory}} = 2.34 \pm 0.13$ pb [5]. This choice has no effect on the measured cross section, but it does affect the extraction of $|V_{tb}|$ and its limits. We report both extractions of $|V_{tb}|$ here.

3 Systematic Uncertainties

The complete set of systematic uncertainties and their correlations from the CDF and D0 analyses have been included in the combination. They are categorized in Table 3.

The systematic error categories in Table 3 mainly follow those used for the Tevatron top mass combination [13] aiming to lump together sources of systematic uncertainty that share the same or similar origin as well as the same correlation between the two experiments. Each error category is briefly described below.

Luminosity from detector: That part of the luminosity uncertainty that comes from the uncertainty on the luminosity detector acceptance and efficiency. It is uncorrelated between CDF and D0.

Luminosity from cross section: That part of the luminosity uncertainty that comes from the uncertainty of the inelastic and diffractive cross sections. It is correlated between CDF and D0.

Signal modeling: The systematic uncertainty arising from uncertainties in the modeling of the single top signal. This includes uncertainties from variations in the ISR, FSR, and PDF descriptions. It also includes difference in the hadronization models. It is correlated between CDF and D0.

Background from MC: The systematic uncertainty arising from uncertainties in modeling of the different background sources that are correlated between CDF and D0. It includes $t\bar{t}$ and diboson normalization uncertainties obtained from theoretical calculations.

Background from data: The systematic uncertainty arising from uncertainties in modeling of the different background sources that are obtained using data-driven methods and are uncorrelated between CDF and D0. It includes the uncertainty on the W +jets and Wbb/Wcc normalization, scale factor and shape as well as the uncertainty on the multijet modeling and normalization. It also includes the uncertainty due to MC statistics.

Detector modeling: The systematic uncertainty arising from the uncertainty on the event detection efficiencies for object identification and MC mismodeling of data. It is uncorrelated between CDF and D0.

b-tagging: The systematic uncertainty coming from the uncertainty on the b-tagging and mistag rate and shape modeling. It is uncorrelated between CDF and D0.

dJES: The part of the JES uncertainty which originates from limitations in the calibration data samples used. For CDF this corresponds to uncertainties associated with the η -dependent JES corrections which are estimated using di-jet data events. For D0 this includes uncertainties in the calorimeter response for light jets, uncertainties from η - and p_T -dependent JES corrections, and other small contributions. It is uncorrelated between CDF and D0.

Table 3: Sources of systematic uncertainty in the CDF and D0 single top analyses, together with the rate range for each uncertainty and whether the shape effect on the final discriminant is considered for each uncertainty or not.

Systematic Uncertainty	CDF		D0		Correlated between the two experiments
	Rate	Shape	Rate	Shape	
Luminosity from detector	4.5%		4.6%		
Luminosity from cross section	4.0%		4.0%		•
Signal modeling	2.2–19.5%	•	3.5–13.6%		•
Background from MC	12.1–12.4%	•	15.1 %		•
Background from data	17–40%	•	13.7–54%	•	
Detector modeling	0–9%	•	7.1 %		
b-tagging	0–29%	•	2–30%	•	
dJES	0–16%	•	0.1–13.1%	•	

We do not include the small uncertainty due to the top quark mass as our result is computed at $m_t = 170 \text{ GeV}/c^2$. We also do not include the systematic uncertainty on the single top cross section theory prediction when measuring the cross section, but we do include it as an additional systematic when extracting $|V_{tb}|$.

4 Results

Figure 1 shows the posterior probability distribution of the combined CDF and D0 analyses, and Table 4 lists the measured cross section.

Table 4: Measured single top cross section and $|V_{tb}|$ value and lower limit for two different theory cross sections.

measured cross section	$2.76^{+0.58}_{-0.47}$ pb
$ V_{tb} $, $\sigma_{s+t}^{\text{theory}} = 3.46$ pb	0.88 ± 0.07
$ V_{tb} $ 95% C.L. limit, $\sigma_{s+t}^{\text{theory}} = 3.46$ pb	0.77
$ V_{tb} $, $\sigma_{s+t}^{\text{theory}} = 3.14$ pb	0.91 ± 0.08
$ V_{tb} $ 95% C.L. limit, $\sigma_{s+t}^{\text{theory}} = 3.14$ pb	0.79

Figure 1: The posterior probability distribution of the combined CDF and D0 analyses.

The most probable value of the combined s -channel and t -channel cross sections is $2.76^{+0.58}_{-0.47}$ pb for a top quark mass of $170 \text{ GeV}/c^2$. This value lies in between the CDF measurement of $2.35^{+0.56}_{-0.50}$ pb and the D0 measurement of 3.94 ± 0.88 pb as expected. The combination improves the cross section uncertainty from about 22% for each experiment to 19% for the combination. We have also computed the compatibility of the two measurements with each other, based on the uncorrelated systematic uncertainties, and find that they are 1.6 standard deviations apart.

In order to extract information about $|V_{tb}|$ from the combined data, we assume that the off-diagonal CKM matrix elements $|V_{ts}|$ and $|V_{td}|$ are much smaller than $|V_{tb}|$, but we do not make assumptions about the unitarity of the 3×3 CKM matrix, allowing for a fourth generation of quarks. We obtain the $|V_{tb}|^2$ posterior by dividing the measured cross section by the theoretical single top cross section for $V_{tb} = 1$ and a top quark mass of $170 \text{ GeV}/c^2$.

Figure 2: The posterior probability distribution of the combined CDF and D0 analyses for $|V_{tb}|$. The right plot shows only the posterior, V_{tb} measurement and limit using a theory cross section of 3.46 pb .

We obtain $|V_{tb}| = 0.91 \pm 0.08$ using the theoretical calculation of $\sigma_{s+t}^{\text{theory}} = 3.14 \times |V_{tb}|^2 \text{ pb}$ of Harris and Sullivan, and $|V_{tb}| = 0.88 \pm 0.07$ using the theoretical calculation $\sigma_{s+t}^{\text{theory}} = 3.46 \times |V_{tb}|^2 \text{ pb}$ of Kidonakis. We limit $|V_{tb}| > 0.79$ at the 95% C.L. assuming a flat prior in $|V_{tb}|^2$ from 0 to 1 using the calculation of Harris and Sullivan, and limit $|V_{tb}| > 0.77$ at the 95% C.L. using the calculation of Kidonakis. The two $|V_{tb}|$ posteriors are shown in Figure 2. In comparison, the CDF extraction of $|V_{tb}|$ at $175 \text{ GeV}/c^2$ is 0.91 ± 0.14 and the D0 extraction of $|V_{tb}|$ at $170 \text{ GeV}/c^2$ is 1.07 ± 0.12 . The relative $|V_{tb}|$ uncertainty improves from 14% (CDF) and 11% (D0) to 8% for the combination, more than for the cross section due to the square root dependence.

5 Summary

We combine the CDF and D0 measurements of the single top production cross section σ_{s+t} including the effects of all correlated and uncorrelated systematic uncertainties. The combined

measurement is $\sigma_{s+t} = 2.76^{+0.58}_{-0.47}$ pb, in agreement with the SM expectation. A summary of the cross section measurements is shown in Figure 3. From this we obtain measurements of $|V_{tb}|$ using two different theory cross section normalizations for a top quark mass of 170 GeV/ c^2 . We find $|V_{tb}| = 0.88 \pm 0.07$ for a cross section of $\sigma_{s+t}^{\text{theory}} = 3.46 \times |V_{tb}|^2$ pb and set a 95% C.L. lower limit of $|V_{tb}| > 0.77$.
