MIREX HAZARDS TO FISH, WILDLIFE, AND INVERTEBRATES: A SYNOPTIC REVIEW

by
Ronald Eisler

Patuxent Wildlife Research Center
U.S. Fish and Wildlife Service
Laurel, MD 20708

SUMMARY

Mirex (dodecachlorooctahydro - 1,3,4 - metheno - 2H - cyclobuta (c, d) pentalene) has been used extensively in pesticidal formulations to control the imported fire ant (*Solenopsis invicta*), and as a flame retardant in electronic components, plastics, and fabrics. One environmental consequence of mirex was the severe damage recorded to fish and wildlife in nine Southeastern States and the Great Lakes, especially Lake Ontario. In 1978, the U.S. Environmental Protection Agency banned all further use of mirex, partly because of the hazards it imposed on nontarget biota. These included delayed mortality and numerous birth defects in aquatic and terrestrial fauna; tumor formation; histopathology; wildlife population alterations; adverse effects on reproduction, early growth, and development; high biomagnification and persistence; degradation into toxic metabolites; movement through aquatic and terrestrial environmental compartments; disrupted mammalian energy metabolism; and detection of residues in human milk and adipose tissues.

Among susceptible species of aquatic organisms, significant damage effects were recorded when concentrations of mirex in water ranged from 2 to 3 ppb. Evidence suggested that sensitive species of wildlife are adversely affected at 0.1 ppm of dietary mirex. For comparison, current tolerance limits for mirex in food for human consumption range from 0.01 ppm for raw agricultural commodities to 0.1 ppm for eggs, milk, and animal fat to 0.4 ppm for various seafood products. Additional research is needed on the fate of mirex degradation products and their effects on natural resources. Further, it is strongly recommended that environmental use of all mirex replacement compounds be preceded by intensive ecological and toxicological evaluation. (Eisler, R. 1985. Mirex hazards to fish, wildlife, and invertebrates: a synoptic review. U.S. Fish and Wildlife Service Biological Report 85 (1.1), Contaminant Hazard Reviews Report No. 1. 42 pp.)

Table of Contents

TABLES

INTRODUCTION

Fish and wildlife resources associated with approximately 51 million ha (125 million acres) in the Southeastern United States, and with the Great Lakes, especially Lake Ontario, have been negatively affected by intensive or widespread use of mirex, a chlorinated hydrocarbon compound (Waters et al. 1977; Bell et al. 1978; Kaiser 1978; NAS 1978; Lowe 1982). Contamination of the Southeast and of Lake Ontario by mirex probably occurred between 1959 and 1978. During that period, mirex was used as a pesticide to control the imported fire ant (*Solenopsis invicta*), which infested large portions of Alabama, Arkansas, Florida, Georgia, Louisiana, Mississippi, North Carolina, South Carolina, and Texas. Under the trade name of Dechlorane, mirex was used as a fire retardant in electronic components, fabrics, and plastics; effluents from manufacturing processes resulted in the pollution of Lake Ontario.

Regulatory agencies, environmentalists, and the general public became concerned as evidence accumulated demonstrating that mirex was associated with high death rates, numerous birth defects, and tumors, and that it disrupted metabolism in laboratory mammals, birds, and aquatic biota. Mirex also tends to bioaccumulate and to biomagnify at all trophic levels of food chains. Field studies corroborated the laboratory

findings and showed that mirex appeared to be one of the most stable and persistent organochlorine compounds known, being resistant to chemical, photolytic, microbial, metabolic, and thermal degradation processes. Upon degradation, a series of potentially hazardous metabolites are formed, although it is generally acknowledged that the fate and effects of the degradation products are not fully understood. Mirex was also detected in human milk and adipose tissues at low concentrations, the levels related to the degree of environmental contamination.

In 1978, the U.S. Environmental Protection Agency banned all uses of mirex. It is probable, however, that mirex and its metabolites will continue to remain available to living organisms in this country for at least 12 years, although some estimates range as high as 600 years. In this account, I briefly review the evidence leading to the ban of mirex, with emphasis on afflicted natural resources, and provide current recommendations for the protection of fish and wildlife resources. It is part of a continuing series of synoptic reviews prepared in response to requests for information from environmental specialists of the U.S. Fish and Wildlife Service.

CHEMICAL PROPERTIES

Mirex is a white, odorless, free-flowing, crystalline, nonflammable, polycyclic compound composed entirely of carbon and chlorine; the empirical formula is $C_{10}Cl_{12}$, and the molecular weight 545.54 (Hyde 1972; Waters et al. 1977; Bell et al. 1978; NAS 1978; Menzie 1978; Kaiser 1978). In the United States, the common chemical name is dodecachlorooctahydro-1,3,4 - metheno - 2H - cyclobuta(c,d)pentalene; the systematic name is dodecachloropentacyclo $5.3.0.0^{2,6}.0^{3,9}.0^{4,8}$decane. Mirex was first prepared in 1946, patented in 1955 by Allied Chemical Company, and introduced in 1959 as GC 1283 for use in pesticidal formulations against hymenopterous insects, especially ants. It was also marketed under the trade name of Dechlorane for use in flame retardant coatings for various materials. Mirex is also known as ENT 25719 (Tucker and Crabtree 1970), CAS 2385-85-5 (Schafer et al. 1983), Dechlorane 510, and Dechlorane 4070 (Kaiser 1978). Technical grade preparations of mirex consists of 95.19% mirex and less than 2.58×10^{-7} % contaminants, mostly kepone $C_{10}Cl_{10}0$ (NAS 1978).

Mirex is comparatively soluble in various organic solvents, such as benzene, carbon tetrachloride and xylene, with solubilities ranging from about 4,000 to 303,000 ppm (mg/L). However, mirex has a very low solubility in water, not exceeding 1.0 ppb (µg/L) in freshwater or 0.2 ppb in seawater (Bell et al. 1978). In biological systems, mirex lipophilicity would account for the high concentrations observed in fatty tissues and reserves.

Mirex, which is composed of 22% carbon and 78% chlorine, is highly resistant to chemical, thermal, and biochemical degradation. It is reportedly unaffected by strong acids, bases, and oxidizing agents, and is resistant to photolysis in hydrocarbon solvents, but less so in aliphatic amines. Thermal decomposition begins at about 550°C and is rapid at 700°C; degradation products include hexachlorobenzene, hexachlorocyclopentadiene, and kepone. Several additional degradation products of mirex have been isolated, but not all have been identified (Holloman et al. 1975; Menzie 1978). At least one photodegradation product, the 8-monohydro analog, sometimes accumulates in sediments and animals, but the fate and effects of these photoproducts is unclear (Cripe and Livingston 1977).

Mirex is rapidly adsorbed onto various organic particles in the water column, including algae, and eventually is removed to the sediments. Not surprisingly, mirex has a long half-life in terrestrial and aquatic sediments; large fractional residues were detected at different locations 12 and 5 years after initial application (Bell et al. 1978). Some degradation of mirex to the 10-monohydro analog was reported in anaerobic sewage sludge after 2 months in darkness at 30°C (Menzie 1978). Other studies with mirex-contaminated anaerobic soils, anaerobic lake sediments, and soil microorganisms showed virtually no bacterial degradation over time (Jones and Hodges 1974). In Lake Ontario, mirex from contaminated sediments remained available to lake organisms for many years and, as judged by present sedimentation rates, mirex may continue to be bioavailable for 200 to 600 years in that system (Scrudato and DelPrete 1982). Disappearance of mirex from baits over a 12-month period was about 41% for those exposed on the ground, 56% from those exposed in soil, and 84% from those exposed in pond water (de la Cruz and Lue 1978b). Mirex disappearance was probably related to uptake by biological organisms, as has been demonstrated in marine ecosystems contaminated with mirex (Waters et al.

1977), and not to degradation.

Mirex is a highly stable chlorinated hydrocarbon with lipophilic properties, and its accumulation and persistence in a wide variety of nontarget biological species has been well documented. The biological half-life of mirex reportedly ranges from 30 days in quail to 130 days in fish and to more than 10 months in the fat of female rats (Menzie 1978); this subject area is further developed later. At this juncture, it is sufficient to state that most authorities agree on two points: there is little evidence of significant mirex metabolism; and mirex ranks among the more biochemically stable organic pesticides known.

TOXICITY

AQUATIC ORGANISMS

Aquatic organisms are comparatively resistant to mirex in short term toxicity tests. Among various species of freshwater biota, LC-50 (96 h) values were not obtained at the highest nominal concentrations tested of 1,000 ppb for insects, daphnids, and amphipods (Johnson and Finley 1980; Sanders et al. 1981) and 100,000 ppb for five species of fish (Johnson and Finley 1980). Similar results were reported for other species of freshwater invertebrates (Muncy and Oliver 1963; Lue and de la Cruz 1978) and fishes (Van Valin et al. 1968), although waterborne mirex at concentrations of 1,000 ppb was lethal to postlarval freshwater prawns (*Macrobrachium rosenbergerii*) in 24 h (Eversole 1980). It is probable that bioavailable concentrations from the water in each test did not exceed 1.0 ppb. However, delayed mortality frequently occurs for extended periods after exposure, and the potential for adverse effects at the population level remains high (NAS 1978). Latent biocidal properties of mirex were documented for fish (Van Valin et al. 1968; Koenig 1977) and crustaceans (Ludke et al. 1971; Hyde 1972; Cripe and Livingston 1977). Crustaceans were the most sensitive group examined. For example, the crayfish (*Procambarus blandingi*) immersed in nominal concentrations of 0.1 to 5.0 ppb mirex for periods of 6 to 144 h died 5 to 10 days after initial exposure (Ludke et al. 1971). Immature crayfish were more sensitive than adults, and mortality patterns were similar when mirex was administered in the water or in baits (Ludke et al. 1971).

BIRDS AND MAMMALS

Acute oral toxicity of mirex to warm blooded organisms was low, except for rats and mice, which died 60 to 90 days after treatment with 6 to 10 mg mirex/kg body weight (Table 1). Birds were comparatively resistant. The red-winged blackbird (*Agelaius phoeniceus*) was unaffected at 100 mg mirex/kg body weight, even though it was considered the most sensitive of 68 species of birds tested with 998 chemicals for acute oral toxicity, repellency, and hazard potential (Schafer et al. 1983).

Mortality due to dietary mirex is variable among species, although high death rates were usually associated with high dietary concentrations and long exposure periods (Table 2). One significant effect of mirex fed to breeding adult chickens, voles, and rats was a decrease in survival of the young (Naber and Ware 1965; Shannon 1976; Waters et al. 1977; Chu et al. 1981). Prairie voles (*Micropterus ochrogaster*) fed diets containing 15 ppm of mirex bred normally, but all pups died by day 21 (Shannon 1976). Survival of the pups of prairie voles decreased in the first litter when the diet of the parents contained 10 ppm mirex, in the second litter when it contained 5 ppm, and in the third litter when it contained 0.1, 0.5, 0.7, or 1.0 ppm (Shannon 1976).

Table 1. Acute oral toxicity of mirex to birds and mammals.

Organism	Dose, in mg/kg body weight	Mortality	Reference
Mice, *Mus* sp.	5	None, 60 days posttreatment	Gaines and Kimbrough 1969
Rat, female, *Rattus* sp.	6	50%, 90 days posttreatment	Gaines and Kimbrough 1969
Mice	10	100%, 60 days posttreatment	Gaines and Kimbrough 1969
Red-winged blackbird	100	None	Schafer et al. 1983
Mice	100-132	50% in 10 days	Fujimori et al. 1983
Common quail, *Coturnix coturnix*	300	12-30%	Stickel 1963
Rat, male	306	Some	Hyde 1972
Mice	330	50%	Waters et al. 1977

Rat, female	365	50%, 14 days posttreatment	Gaines and Kimbrough 1969
Rat, male	400	Lowest fatal dose	NAS 1978
Rat, female	500	Lowest fatal dose	NAS 1978
European starling, *Sturnus vulgaris*	562	None	Schafer et al. 1983
Rat, female	600	Some	Hyde 1972
Rabbit, *Lepus* sp.	800[a]	50%	Waters et al. 1977
Dogs, *Canis* sp.	1000	None	Larson et al. 1979
Ring-necked pheasant, *Phasianus colchicus*	1400-1600	50%	Waters et al. 1977
Mallard, *Anas platyrhynchos*	2400	None	Tucker and Crabtree 1970
Japanese quail, *Coturnix coturnix japonica*	10,000	50%	Waters et al. 1977

Table 2. Dietary toxicity of mirex to vertebrate organisms.

Organism	Mirex dietary concentration, in ppm	Exposure interval	Percent mortality	Reference
Mallard	1.0	25 weeks	6.2	Hyde 1972
Old-field mouse, *Peromyscus polionotus*	1.8	60 weeks	20.0	Wolfe et al. 1979
Mice	5.0	30 days	Some	Chernoff et al. 1979
Prairie vole	5.0-15	90 days	Some	Shannon 1976
Old-field mouse	17.8	60 weeks	91.7	Wolfe et al. 1979
Beagle dog	20	13 weeks	None	Larson et al. 1979
Pinfish, Lagodon *rhomboides*	20	20 weeks	None	Lowe 1982
Prairie vole	25	90 days	100	Shannon 1976
Rat	25	30 days	Some	Chernoff et al. 1979
Rat	50	14 days	None	NAS 1978
Mice	50	14 days	100	NAS 1978
Coho salmon	50	12 weeks	None	Leatherland et al. 1979
Beagle dog	100	13 weeks	Some	Larson et al. 1979
Mallard	100	25 weeks	27.4	Hyde 1972
Channel catfish	400	4 weeks	None	McCorkle et al. 1979
Ring-necked pheasant	1540	5 days	50.0	Heath et al. 1972
Common bobwhite, *Colinus virginianus*	2511	5 days	50.0	Heath et al. 1972
Japanese quail	5000	5 days	20.0	Heath et al. 1972
Mallard ducklings	5000	5 days	None	Heath et al. 1972

SUBLETHAL EFFECTS

AQUATIC ORGANISMS

The maximum acceptable toxicant concentration (MATC) values calculated for mirex and various freshwater species were <2.4 ppb for amphipods (*Gammarus* sp.), based on growth inhibition at higher concentrations (Sanders et al. 1981); 2 to 3 ppb for fathead minnows (*Pimephalas promelas*), as judged by disruption of swim bladder hydroxyproline content, vitamin C metabolism, and bone collagen (Mehrle et al. 1981); 34 ppb for fathead minnows, based on impaired reproduction (Buckler et al. 1981); and >34 ppb for daphnids (*Daphnia* sp.) and midges (*Chaoborus* sp.), predicated on daphnid reproduction and midge emergence (Sanders et al. 1981). Other mirex-induced sublethal effects included reduced photosynthesis in freshwater algae (Hollister et al.

1975), gill and kidney histopathology in the goldfish *Carassius auratus* (Van Valin et al 1968), reduced growth in the bluegill *Lepomis macrochirus* (Van Valin et al. 1968), cessation of reproduction in *Hydra* sp. (Lue and de la Cruz 1978), and disrupted behavior in the blue crab *Callinectes sapidus* (Shannon 1976) and the marine annelid *Arenicola cristata* (Schoor and Newman 1976). McCorkle et al. (1979) showed that channel catfish (*Ictalurus punctatus*) are particularly resistant to high dietary concentrations of mirex; juveniles fed 400 ppm mirex for 4 weeks showed no significant changes in enzyme-specific activities of brain, gill, liver, or muscle. However, yearling coho salmon (*Oncorhynchus kisutch*) fed 50 ppm mirex for 3 months showed significant reduction in liver weight and whole body lipid content (Leatherland et al. 1979). Additional studies with coho salmon and rainbow trout (*Salmo gairdneri*) fed 50 ppm mirex for 10 weeks demonstrated a significant depression in serum calcium, and significant elevation of skeletal magnesium in salmon; trout showed no measurable changes in calcium and magnesium levels in serum, muscle, or skeleton, although growth was reduced, muscle water content was elevated, and muscle lipid content was reduced (Leatherland and Sonstegard 1981). Interaction effects of mirex with other anthropogenic contaminants are not well studied, despite the observations of Koenig (1977) that mixtures of DDT and mirex produced more than additive deleterious effects on fish survival and reproduction.

BIRDS

Among captive American kestrels (*Falco sparverius)* fed 8 ppm mirex for 69 days by Bird et al. (1983), there was a marked decline in sperm concentration and a slight compensatory increase in semen volume, but an overall net decrease of 70% in sperm number. These investigators believed that migratory raptors feeding on mirex-contaminated food organisms could ingest sufficient toxicant to lower semen quality in the breeding season which, coupled with altered courtship, could reduce the fertility of eggs and the reproductive fitness of the individual. Altered courtship in ring-necked doves (*Streptopelia capicola*) fed dietary organochlorine compounds was reported by McArthur et al. (1983).

Most investigators, however, agree that comparatively high dietary concentrations of mirex had little effect on growth, survival, reproduction, and behavior of nonraptors, including chickens (*Gallus* sp.), mallards, several species of quail, and red-winged blackbirds. For domestic chickens, levels up to 200 ppm dietary mirex were tolerated without adverse effects on various reproductive variables (Waters et al. 1977), but 300 ppm mirex for 16 weeks was associated with reduced chick survival, and 600 ppm for 16 weeks reduced hatching by 83% and chick survival by 75% (Naber and Ware 1965). Mallard ducklings experienced temporary mild ataxia and regurgitation when given a single dose of 2,400 mg/kg body weight but not when given 1,200 mg/kg or less (Tucker and Crabtree 1970). Mallards fed up to 100 ppm mirex for prolonged periods showed no significant differences from controls in egg production, shell thickness, shell weight, embryonation, hatchability, or duckling survival (Hyde 1972). However, in other studies with mallards fed 100 ppm dietary mirex, eggshells were thinned and duckling survival was reduced (Waters et al. 1977), suggesting that 100 ppm dietary mirex may not be innocuous to mallards. No adverse effects on reproduction were noted in the common bobwhite at 40 ppm dietary mirex (Kendall et al. 1978), or in two species of quail fed 80 ppm mirex for 12 weeks (Waters et al. 1977). Red-winged blackbirds were not repelled by foods contaminated with mirex, but consumed normal rations (Schafer et al. 1983); a similar observation was recorded for bobwhites (Baker 1964).

MAMMALS

Mirex has considerable potential for chronic toxicity since it is only partly metabolized, is eliminated very slowly, and is accumulated in the fat, liver, and brain. The most common effects observed in small laboratory mammals fed mirex included weight loss, enlarged livers, altered liver enzyme metabolism, and reproductive failure. Mirex reportedly crossed placental membranes and accumulated in fetal tissues. Among the progeny of mirex-treated mammals, developmental abnormalities included cataracts, heart defects, scoliosis, and cleft palates (NAS 1978).

Mirex has caused liver tumors in mice and rats and must be considered a potential human carcinogen (Waters et al. 1977; NAS 1978). Long-term feeding of 50 and 100 ppm of mirex to rats of both sexes was associated with liver lesions that included neoplastic nodules and hepatocellular carcinomas; neither sign was found in controls (Ulland et al. 1977).

Adults of selected mammalian species showed a variety of damage effects of mirex: enlarged livers in rats at 25 ppm dietary mirex (Gaines and Kimbrough 1969) or at a single dose of 100 mg/kg body weight (Ervin

1982); liver hepatomas in mice at 10 mg mirex/kg body weight daily (Innes et al. 1969); decreased incidence of females showing sperm in vaginal smears, decreased litter size, and thyroid histopathology in rats fed 5 ppm dietary mirex since weaning (Chu et al. 1981); elevated blood and serum enzyme levels in rats fed 0.5 ppm mirex for 28 days (Yarbrough et al. 1981); and diarrhea, reduced food and water consumption, body weight loss, decreased blood glucose levels, and disrupted hepatic microsomal mixed function oxidases in mice receiving 10 mg/kg daily (Fujimori et al. 1983). In studies of field mice, decreased litter size was observed at 1.8 ppm dietary mirex, and complete reproductive impairment at 17.6 ppm after 6 months (Wolfe et al. 1979). At comparatively high sublethal concentrations of mirex, various deleterious effects were observed: thyroid histopathology and decreased spermatogenesis in rats fed 75 ppm mirex for 28 days (Yarbrough et al. 1981); abnormal blood chemistry, enlarged livers, reduced spleen size, and loss in body weight of beagles fed 100 ppm for 13 weeks (Larson et al. 1979); and decreased hemoglobin, elevated white blood cell counts, reduced growth, liver histopathology, and enlarged livers in rats fed 320 ppm for 13 weeks (Larson et al. 1979).

Cataract formation, resulting in blindness, in fetuses and pups from maternal rats fed comparatively low concentrations of dietary mirex is one of the more insidious effects documented. Mirex fed to maternal rats at 6 mg/kg body weight daily on days 8-15 of gestation, or at 10 mg/kg daily on days 1-4 postpartum, caused cataracts in 50% of fetuses on day 20 of gestation, and in 58% of pups on day 14 postpartum (Rogers 1982). Plasma glucose levels were depressed in fetuses with cataracts, and plasma proteins were depressed in neonates; both hypoproteineia and hypoglycemia are physiological conditions known to be associated with cataracts (Rogers 1982). Mirex-associated cataractogenicity has been reported in female pups from rats fed 5 ppm dietary mirex since weaning (Chu et al. 1981), in rat pups from females consuming 7 ppm dietary mirex on days 7-16 of gestation or 25 ppm in diets for 30 days prior to breeding (Chernoff et al. 1979), and in mice fed 12 ppm dietary mirex (Chernoff et al. 1979). Offspring born to mirex-treated mothers, but nursed by nontreated mothers showed fewer cataracts (Waters et al. 1977). Other fetotoxic effects in rats associated with dietary mirex included: edema and undescended testes (Chernoff et al. 1979); lowered blood plasma proteins, and heart disorders, including tachycardia and blockages (Grabowski 1981); and, as noted by Kavlock et al (1982), hydrocephaly; decreases in weight of brain, lung, liver, and kidney; decreases in liver glycogen, kidney proteins and alkaline phosphatase; and disrupted brain DNA and protein metabolism.

In prairie voles exposed continuously to dietary mirex of 0.5, 0.7, 1.0, 5.0, or 10.0 ppm, the numbers of litters produced decreased (Shannon 1976). Maximum number of litters per year were four at 1.0 ppm dietary mirex; three at 5.0 ppm; and two at 10.0 ppm. Furthermore, the number of offspring per litter also decreased progressively. Concentrations as low as 0.1 ppm in the diet of adults were associated with delayed maturation of pups and with an increase in number of days required to attain various behavioral plateaus such as bar-holding ability, hind-limb placing, and negative geotaxis (Shannon 1976). On the basis of residue data from field studies, as is shown later, these results strongly suggest that mirex was harmful to the reproductive performance and behavioral development of prairie voles at environmental levels approaching 4.2 g mirex/ha, a level used to control fire ants before mirex was banned.

BIOACCUMULATION

AQUATIC ORGANISMS

All aquatic species tested accumulated mirex from the medium and concentrated it over ambient water levels by factors ranging up to several orders of magnitude; uptake was positively correlated with nominal dose in the water column (Table 3). Other investigators have reported bioconcentration factors from water of 8,025X in daphnids (Sanders et al. 1981), 12,200 in bluegills (Skaar et al. 1981), 56,000 in fathead minnows (Huckins et al. 1982), and 126,600 in the digestive gland of crayfish (Ludke et al. 1971). Rapid uptake of mirex by marine crabs, shrimps, oysters, killifishes, and algae was reported after the application of mirex baits to coastal marshes (Waters et al. 1977; Cripe and Livingston 1977). Mirex was also accumulated from the diet (Table 3; Ludke et al. 1971; Zitko 1980) but not as readily as from the medium. Mirex may also be accumulated from contaminated sediments by marine teleosts (Kobylinski and Livingston 1975), but such accumulation has not been established conclusively. Although terrestrial plants, such as peas and beans, accumulate mirex at field application levels, mangrove seedlings require environmentally high levels of 11.2 kg mirex/ha before accumulation occurs (Shannon 1976).

There is general agreement that aquatic biota subjected to mirex-contaminated environments continue to accumulate mirex, and that equilibrium is rarely attained before death of the organism from mirex poisoning or

from other causes. There is also general agreement that mirex resists metabolic and microbial degradation, exhibits considerable movement through food chains, and is potentially dangerous to consumers at the higher tropic level (Hollister et al. 1975; NAS 1978; Mehrle et al. 1981). Marine algae, for example, showed a significant linear correlation between amounts accumulated and mirex concentrations in the medium. If a similar situation existed in nature, marine unicellular algae would accumulate mirex and, when grazed upon, act as passive transporters to higher trophic food chain compartments (Hollister et al. 1975). The evidence for elimination rates of mirex from aquatic biota on transfer to mirex-free media is not as clear. Biological half-times of mirex have been reported as 12 h for daphnids (Sanders et al. 1981), more than 28 days for fathead minnows (Huckins et al. 1982), about 70 days in Atlantic salmon (*Salmo salar*) (Zitko 1980), 130 days for mosquitofish (*Gambusia affinis)*, and 250 days for pinfish (as quoted in Skea et al. 1981). However, Skea et al. (1981) averred that biological half-times may be much longer if organism growth is incorporated into rate elimination models. For example, brook trout *(Salvelinus fontinalis*) fed 29 ppm mirex for 104 days contained 6.3 mg/kg body weight or a total of 1.1 mg of mirex in whole fish. At day 385 postexposure, after the trout had tripled in body weight, these values were 2.1 mg/kg body weight, an apparent loss of 67%; however, on a whole fish basis, trout contained 1.2 mg, thus showing essentially no elimination on a total organism basis (Skea et al. 1981).

No mirex degradation products were detected in whole fathead minnow or in hydrosoils under aerobic or anaerobic conditions (Huckins et al. 1982). In contrast, three metabolites were detected in coastal marshes after mirex bait application, one of which, photomirex, was accumulated by fish and oysters (Cripe and Livingston 1977). The fate and effects of mirex photoproducts in the environment is unclear and merits additional research.

The significance of mirex residues in various tissues is unresolved, as is the exact mode of action of mirex and its metabolites. Minchew et al. (1980) and others indicated that mirex is a neurotoxic agent, with a mode of action similar to that of other chlorinated hydrocarbon insecticides, such as DDT. In studies with crayfish and radiolabeled mirex, mirex toxicosis was associated with neurotoxic effects that included hyperactivity, uncoordinated movements, loss of equilibrium, and paralysis (Minchew et al. 1980). Before death, the most significant differences in mirex distributions in crayfish were the increases in concentrations in neural tissues, such as brain and nerve cord, by factors up to 14X (or 0.4 ppm) in low-dose groups held in solutions containing 7.4 ppb mirex, and up to 300X (or 6.2 ppm) in high-dose groups held in solutions with 74.0 ppb. With continued exposure, levels in the green gland and neural tissues approached the levels in the hepatopancreas and intestine (Table 3). Schoor (1979) also demonstrated that mirex accumulates in the crustacean hepatopancreas, but suggested that other tissues, such as muscle and exoskeleton, have specific binding sites that, once filled, shunt excess mirex to hepatopancreas storage sites.

Table 3. Bioaccumulation of mirex from ambient medium or diet by selected species.

Habitat, organism, and tissue	Mirex concentration in ppb in medium (M), or in ppm in diet (D)	Exposure period	Bioconcentration factor	Reference[a]

BIRDS AND MAMMALS

Like aquatic organisms, birds and mammals accumulated mirex in tissue lipids, and the greater accumulations were associated with the longer exposure intervals and higher dosages (Table 3). Sexual condition of the organism may modify bioconcentration potential. For example, in adipose fat of the bobwhite, males contained 10X dietary levels and females only 5X dietary levels; the difference was attributed to mirex loss through egg laying (Kendall et al. 1978).

Data on excretion kinetics of mirex are incomplete. Prairie voles fed mirex for 90 days contained detectable whole body levels 4 months after being placed on a mirex-free diet (Shannon 1976). Levels of mirex in voles after 4 months on uncontaminated feed were still far above levels in their mirex diets. Humans living in areas where mirex has been used for ant control contained 0.16 to 5.94 ppm in adipose fat; 60% of the mirex was excreted and most of the rest was stored in body tissues, especially fat (28%), and in lesser amounts of 0.2 to 3% in muscle, liver, kidney, and intestines (Waters et al. 1977). Almost all excretion of mirex takes place through feces; less than 1% is excreted in urine and milk. The loss rate pattern is biphasic; the fast phase was estimated at 38 h and the slow phase at up to 100 days. Mirex binds firmly to soluble liver proteins and appears to be retained in fatty tissues, a property that may contribute to its long biological half-life. Chickens given single doses of mirex at 30 mg/kg intravenously or 300 mg/kg orally demonstrated a biphasic decline in blood concentrations (Ahrens et al. 1980). The fast component, constituting about 25% of the total, was lost during the first 24 h; the loss of the slow component was estimated to be at a constant rate of about 0.03% daily, suggesting a half-life of about 3 years. Growing chicks fed 1 or 10 ppm dietary mirex for 1 week lost the compound rather rapidly; disappearance half-times were 25 days for skin and 32 days for fat (Ahrens et al. 1980). It is clear that much additional research is warranted on loss rate kinetics of this persistent compound and its metabolites.

MIREX IN THE SOUTHEASTERN UNITED STATES

Between 1961 and 1975, about 400,000 kg of mirex were used in pesticidal formulations, of which approximately 250,000 kg were sold in the Southeastern U.S. for control of native and imported fire ants (*Solenopsis* spp.); most of the rest was exported to Brazil for use in fire ant control in that country (NAS 1978). Mirex was also used to control big-headed ant populations in Hawaiian pineapple fields (Bell et al. 1978), Australian termites (Paton and Miller 1980), South American leaf cutter ants, South African harvester termites, and, in the U.S., western harvester ants and yellow jackets (Shannon 1976). Chemical control measures for imported fire ants began in the Southeastern United States during the 1950s with the use of heptachlor, chlordane, and dieldrin. The large mounds built by ants in cultivated fields were believed to interfere with mowing and harvesting operations, the “vicious sting” of the insects presented a hazard to workers harvesting the crops, and the species was considered to be a pest in school playgrounds and homes (Lowe 1982). In 1965, the use of organochlorine insecticides to control fire ants was discontinued, due partly to their high acute toxicity to nontarget biota and their persistence. Previously used compounds were replaced by mirex 4X bait formulations, consisting of 0.3% mirex by weight, dissolved in 14.7% soybean oil, and soaked into corncob grits

(85%). Initially, the 4X baits were broadcast from low flying airplanes at a total yearly rate of 1.4 kg bait/ha (1.25 lbs total bait/acre) or 4.2 g mirex/ha. Usually, three applications were made yearly. More than 50 million ha in nine Southeastern States were treated over a 10-year period. Later, dosages were modified downward, and mirex was applied to mounds directly. Ecologically sensitive areas, such as estuaries, prime wildlife habitats, heavily forested areas, and State and Federal parks, were avoided. In 1977, for example, the formulation was changed to 0.1% mirex and the application rate lowered to 1.12 g/ha; about 8,200 kg of the lower concentration bait were manufactured in 1977 (Bell et al. 1978). Under ideal aerial application conditions, about 140 particles of mirex-impregnated bait were distributed/m^2. When an infested area is treated, the bait is rapidly scavenged by the oil-loving fire ant workers, placed in the mound, and distributed throughout the colony, including queen and brood, before any toxic effects become evident; death occurs in several days to weeks. The exact mode of action is unknown, but is believed to be similar to that of other neurotoxic agents, such as DDT (Waters et al. 1977; NAS 1978).

Widespread use of mirex may lead to altered population structure in terrestrial systems, with resurgence or escalation of nontarget pests due to selective mirex-induced mortality of predators (NAS 1978). For example, populations of immature horn flies and rove beetles, two species of arthropods normally preyed upon by fire ants, were higher in mirex-treated areas than in control areas (Howard and Oliver 1978). Conversely, other species, such as crickets, ground beetles, and various species of oil-loving ants, were directly affected and populations were still depressed or eliminated 14 months posttreatment (NAS 1978), whereas fire ants recovered to higher than pretreatment levels, as judged by mound numbers and mound size (Summerlin et al. 1977).

Field results from aquatic and terrestrial ecosystems receiving mirex bait formulations indicated, with minor exceptions, that mirex accumulates sequentially in food complexes and concentrates in animals at the higher trophic levels. In both ecosystems, omnivores and top carnivores contained the highest residues (Hyde 1972; Shannon 1976; Waters et al. 1977; de la Cruz and Lue 1978a; Hunter et al. 1980). In South Carolina, where the 4X formulation was used to control fire ants from 1969 to 1971, mirex was translocated from treated lands to nearby marshes and estuarine biota, including crustaceans, marsh birds, and raccoons (Lowe 1982). Juvenile marine crustaceans showed delayed toxic effects after ingesting mirex baits, or after being exposed to low concentrations in seawater. About 18 months posttreatment, mirex residues of 1.3 to 17.0 ppm were detected in shrimp, mammals, and birds (Table 4); however, 24 months after the last mirex treatment, less than 10% of all samples collected contained detectable residues (Lowe 1982). A similar study was conducted in pasturelands of bahia grass (*Paspalum notatum*) (Markin 1981). Within a month after application, the target fire ant colonies were dead. Of the 4.2 g mirex/ha applied to the 164 ha block, 100% was accounted for on day 1, 63% at 1 month, and 3% at 1 year (Table 5). Unaccounted mirex residues could include loss through biodegradation; through movement out of the study area by migratory insects, birds, other fauna, and ground water; and through photodecomposition and volatilization (Markin 1981).

Mirex residues in bobwhites from South Carolina game management area were documented after treatment with 4.2 g mirex/ha (Kendall et al. 1977). Pretreatment residues in bobwhites ranged from nondetectable to 0.17 ppm mirex in breast muscle on a dry weight basis, and 0.25 to 2.8 ppm in adipose tissues on a lipid weight basis. Mirex residues in adipose tissue increased up to 5X within 1 month posttreatment and declined thereafter; however, another residue peak was noted in the spring after mirex treatment and corresponded with insect emergence (Kendall et al. 1977).

Heavily treated watershed areas in Mississippi were investigated by Wolfe and Norment (1973) and Holcombe and Parker (1979). After treatment, mirex residues were elevated in crayfish and stream fish; among mammals, residues were highest in carnivores and insectivores, lower in omnivores, and lowest in herbivores (Wolfe and Norment 1973). Mirex residues in liver and eggs were substantially higher in the box turtle *(Terrapene carolina)* an omnivorous feeder, than in the herbivorous slider turtle (*Chrysemys scripta*); mirex did not accumulate for protracted periods in tissues of these comparatively long-lived reptiles (Holcombe and Parker 1979). Among migratory reptiles, mirex was detected in only 11% of the eggs of the loggerhead turtle (*Caretta caretta*) and not at all in eggs of the green turtle (*Chelonia mydas*) corrected during summer 1976 in Florida (Clark and Krynitsky 1980). However, DDT or its isomers were present in all eggs of both species, and PCB's were detected in all loggerhead turtle eggs. The low levels of mirex and other organochlorine contaminants suggest that these turtles, when not nesting, live and feed in areas remote from Florida lands treated with mirex

and other insecticides (Clark and Krynitsky 1980).

Table 4. Mirex residues in water, sediments, and fauna in a South Carolina coastal marsh 18 months after application of 4.2 g/ha (after Lowe 1982).

Sample	Maximum mirex residues, in ppm	Percent samples with mirex residues

[a]Grit now included with pasture soil.

[b]Mounds badly weathered, not possible to identify.

A 10-5 bait formulation containing 0.1% mirex was designed to make more of the toxicant available to the fire ant and less to nontarget biota. In one study, the 10-5 formulation was applied to a previously untreated 8,000-ha area near Jacksonville, Florida, infested with fire ants (Wheeler et al. 1977). The bait was applied by airplane at 1.12 kg/ha, or 1.12 g mirex/ha. Insects accumulated mirex to the greatest extent during the first 6 months after application, and most of the mirex was lost by 12 months (Table 6); other invertebrates accumulated only low levels during the first 9 months, and no residues were detected after 12 months. Fish also showed low concentrations for 9 months and no detectable residues afterward; amphibians contained detectable residues after 12 months, but not at 24; reptiles contained measurable, but low, residues for the entire 24-month study period. Mammals had higher residue levels than reptiles, particularly in fat, whereas birds contained low to moderate residues (Table 6). After 24 months, mirex was found infrequently and only at low concentrations in birds, mammals, reptiles, and insects. It was concluded that 10-5 mirex formulations were as effective in controlling fire ants as the 4X formulation and that residues in nontarget species were reduced from that following 4X treatment, or were lacking (Wheeler et al. 1977).

Eggs of the American crocodile (*Crocodylus acutus*) from the Florida Everglades contained up to 2.9 ppm fresh weight of DDE and 0.86 ppm of PCB'S, but less than 0.02 ppm mirex (Hall et al. 1979). Livers of the deep sea fish (*Antimora rostrata*) collected in 1971-74 from a depth of 2,500 m off the U.S. east coast, contained measurable concentrations of DDT and its degradation products, and dieldrin, but no mirex (Barber and Warlen 1979).

MIREX IN THE GREAT LAKES

Between 1959 and 1975, 1.5 million kg of mirex were sold, of which 74% or more than 1.1 million kg were predominantly Dechlorane, a compound used in flame-resistant polymer formulations of electronic components and fabrics (Bell et al., 1978; NAS 1978). The total amounts are only approximate because almost half the mirex sold from 1962 to 1973 could not be accounted for (NAS 1978). Kaiser (1978) reported that all fish species in Lake Ontario were contaminated with mirex, and that concentrations in half the species exceeded the Food and Drug Administration guideline of 0.1 ppm; other aquatic species had mirex residues near this level. Reproduction of the herring gull (*Larus argentatus*) on Lake Ontario was poor; mirex levels were an order of magnitude higher in gull eggs from Lake Ontario than in eggs from other Great Lakes locations (Kaiser 1978). It was concluded that the probable source of contamination was a chemical manufacturer that used mirex (Dechlorane) as a flame retardant, and that only Lake Ontario was contaminated (Kaiser 1978; NAS 1978).

Gilman et al. (1977, 1978) observed poor reproductive success and declines in colony size of the herring gull at Lake Ontario at a time when dramatic increases of this species were reported along the Atlantic seaboard. In 1975, herring gull reproduction in Lake Ontario colonies was about one-tenth that of colonies on the other four Great Lakes. In addition, in Lake Ontario colonies, there were reductions in nest site defense, in number of eggs per clutch, in hatchability of eggs, and in chick survival. Hatching success of Lake Ontario gull eggs was 23 to 26%, compared with 53 to 79% for eggs from other areas. Analysis of herring gull eggs from all colonies for organochlorine compounds and mercury demonstrated that eggs from Lake Ontario colonies had mean mirex levels of 5.06 ppm fresh weight (range, 2.0-18.6), or about 10X more mirex than any other colony. Mean PCB and mercury levels were up to 2.8X and 2.3X higher, respectively, in gull eggs from Lake Ontario than in those from other colonies, but only mirex levels could account for the colony declines (Gilman et al. 1977, 1978). As judged by log-linear regression models, the half-life for mirex in herring gull eggs was 1.9 to 2.1 years, or essentially none was lost during egg incubation (Weseloh et al. 1979). Reproductive success of the Lake Ontario herring gull colonies improved after the early 1970s, an improvement that was directly paralleled by a decline in mirex, other organochlorine pesticides, and PCB's (Weseloh et al. 1979).

Table 6. Mirex residues in fauna near Jacksonville, Florida, at various intervals posttreatment following single application of 1.12 g mirex/ha (after Wheeler et al. 1977).

2,8-dihydromirex	0.016	0.4
$C_{10}Cl_{10}H_2$(II), possibly 3,8-dihydromirex	0.011	0.3
Total	3.872	100

The fate of mirex in the environment and the associated transfer mechanisms have not been well defined (NAS 1978). One of the more significant works on this subject area was that by Norstrom et al. (1978), who documented levels of mirex and its degradation products in herring gull eggs collected from Lake Ontario in 1977 (Table 7). They concluded that photodegradation was the only feasible mechanism for production of the degradation compounds, although mirex and its photoproducts rapidly become sequestered in the ecosystem and protected from further degradation. Norstrom et al. (1980) found mirex degradation products in herring gull eggs from all of the Great Lakes, and suggested that a high proportion of mirex and related compounds in herring gull eggs from Lakes Erie and Huron originated from Lake Ontario fish, whereas lower levels in eggs from Lakes Superior and Michigan originated from other sources. Mirex in sediments was considered an unlikely source because it was not being recycled into the ecosystem at an appreciable rate.

Biomagnification of mirex through food chains was investigated by Norstrom et al. (1978). Their basic assumption was that both herring gulls and coho salmon ate alewives (*Alosa pseudoharengus)* and rainbow smelt (*Osmerus mordax*). Mirex residues in these organisms, in parts per million fresh weight, were 4.4 in gull eggs, 0.23 in salmon muscle, 0.10 in salmon liver, and 0.09 in whole alewives and smelt retrieved from stomachs of salmon. Bioconcentration factors (BCF) from prey to predator ranged up to 50, and those from water to gull egg were estimated to be near 25 million (Table 8). Norstrom et al. (1978) indicated that salmon muscle and gull eggs are complementary indicators of organochlorine contamination in the Great Lakes.

Among Great Lakes fishes, the highest mirex value recorded was 1.39 ppm in whole eels (*Anguilla* sp.) collected from Lake Ontario (NAS 1978). This was substantially in excess of the tolerated limit of 0.3 ppm for human consumption (NAS 1978). High mirex values were also reported in chinook salmon *(Oncorhynchus tshawytscha)* and coho salmon from South Sandy Creek, a tributary of Lake Ontario, during autumn 1976; as a consequence, possession of all fish from that area was prohibited by the State of New York (Farr and Blake 1979). The significance of mirex residues in salmonid fishes is unclear. Skea et al. (1981), in laboratory studies with brook trout, showed that whole body residues of 6.3 ppm fish weight were not associated with adverse effects on growth or survival and speculated that long-lived species, such as the lake trout (*Salvelinus namaycush*), would probably continue to accumulate mirex in Lake Ontario as long as they were exposed, and may continue to contain residues for most of their lives, even after the source has been eliminated.

There was no widespread mirex contamination of urban environments near Lake Ontario as a result of Dechlorane use, although local contamination of the Lake Ontario area was high when compared with other Great Lake areas (NAS 1978). Among humans living in the Great Lakes area, there was great concern that mother's milk might be contaminated, owing to the high lipophilicity of mirex. Bush (1983) found mirex concentrations in mother's milk from residents of New York State to be 0.07 ppb in Albany, 0.12 in Oswego, and 0.16 in Rochester, confirming that mirex was present in human milk but that concentrations were sufficiently low to be of little toxicological significance. It is noteworthy that none of the mothers had eaten Lake Ontario fish or any freshwater fish, and only a few had eaten marine fishes (Bush 1983). For a 5-kg infant consuming 500 g of milk daily, this amount would approximate a dietary intake of 0.01 µg mirex/kg body weight daily (Bush 1983) or about 1/10,000 of the lowest recorded dietary value causing delayed maturation in prairie voles (Shannon 1976). It is not known if a safety factor of 10,000 is sufficient to protect human health against delayed toxic effects of mirex, but it now appears reasonable to believe that it is.

Table 8. Biomagnification of mirex in Great Lakes food chains (after Norstrom et al. 1978).

From	To	Bioconcentration factor
Water	Whole rainbow smelt or whole alewife	500,000
Water	Muscle of coho salmon	1,500,000
Water	Egg of herring gull	25,000,000
Alewife and smelt	Salmon muscle	2.6
Alewife and smelt	Gull egg	50.0

MIREX IN OTHER GEOGRAPHIC AREAS

Mirex residues were determined in birds collected Nationwide or from large geographic areas of the United States; however, aside from the Southeast and the Great Lakes, concentrations were low, considered nonhazardous, and occurred in a relatively small proportion of the samples collected (Cain and Bunck 1983).

Among wings of mallards and American black ducks (*Anas rubripes)* collected from the four major flyways during 1976-77, mirex concentrations were highest and percent occurrence greatest in samples from the Atlantic Flyway: mallards, 50% occurrence, 0.14 ppm fresh weight; black ducks, 19% and 0.04 ppm (White 1979). Data for mallards collected from other flyways follow: Mississippi, 29% and 0.03 ppm; Central, 14% and 0.06 ppm; and Pacific 4% and 0.03 ppm (White 1979). Carcasses of several species of herons found dead or moribund Nationwide from 1966 to 1980 were analyzed for a variety of common organochlorine pesticides by Ohlendorf et al. (1981); they detected mirex in less than 15% of the carcasses, a comparatively low frequency, and only in nonhazardous concentrations. However, about 20% of all herons found dead or moribund had lethal or hazardous concentrations of dieldrin or DDT. In bald eagles *(Haliaeetus leucocephalus)* found dead Nationwide, elevated mirex levels were recorded in carcass lipids (24.0 ppm) and in fresh brain tissues (0.22 ppm) (Barbehenn and Reichel 1981). Among endangered species such as the bald eagle, it was determined that the most reliable indicator for assessing risk of organochlorine compounds was the ratio of carcass to brain residues on a lipid weight basis (Barbehenn and Reichel 1981). Wings from American woodcocks (*Philohela minor*) collected from 11 States in 1970-71 and 14 States in 1971-72 were analyzed for mirex and other compounds by McClane et al. (1978). Mirex residues in the 1971-72 wings showed the same geographical pattern of recovery as those observed in 1970-71: residues were highest in the Southern States and New Jersey, and lowest in the Northern and Midwestern States. Mirex residues were significantly lower in 1971-72 than in 1970-71. As judged by the analysis of wings of immature woodcocks in Louisiana, mirex residues were significantly lower in immatures than in adults: 2.48 ppm lipid weight vs. 6.20 ppm (McLane et al. 1978).

Mirex and other organochlorine compounds in eggs of anhingas (*Anhinga anhinga*) and 17 species of waders (including herons, egrets, bitterns, ibises, and storks) were measured in various locations throughout the Eastern United States during 1972 and 1973 (Ohlendorf et al. 1979). The highest mean concentration of 0.74 ppm mirex, range 0.19 to 2.5, was found in eggs of the green heron (*Butorides striatus*) from the Savannah National Wildlife Refuge in South Carolina; a single egg of the cattle egret (*Bubulcus ibis*) analyzed from there contained 2.9 ppm mirex. However, the overall frequency of mirex occurrence was higher in eggs collected from the Great Lakes region (24%) than in those from the South Atlantic Coast (15.6%), inland areas (10.7%), Gulf Coast (4.4%), or North Atlantic region (3.2%).

Measurable mirex residues were detected in migratory birds collected from a variety of locations, including areas far from known sources or applications of mirex. For example, 22% of all eggs from 19 species of Alaskan seabirds collected in 1973-76 contained mirex. The highest concentration was 0.044 ppm in eggs of a fork-tailed storm petrel (*Oceanodroma furcata*) from the Barren Islands. Mirex residues were low compared with those of other organochlorine compounds (Ohlendorf et al. 1982). Eggs from the clapper rail (*Rallus longirostris*) collected in New Jersey from 1972—74 contained 0.16 to 0.45 ppm mirex (Klaas et al. 1980). Eggs from the greater black-backed gull (*Larus marinus)* collected from Appledore Island, Maine, in 1977 contained up to 0.26

ppm, but no mirex was detected in eggs of common eider (*Somateria mollissima)* or herring gull from the same area (Szaro et al. 1977). The greater black-backed gull is an active carnivore; 36-52% of its diet consists of small birds and mammals, whereas these items compose less than 1% in eider and herring gull diets. The higher mirex levels in black-backed gulls is attributed to its predatory feeding habits (Szaro et al. 1979). In New England, eggs of the black-crowned night-heron (*Nycticorax nycticorax)* contained between 0.28 and 0.66 ppm mirex wet weight in 1973; in 1979, this range was 0.11-0.37 ppm (Custer et al. 1983). Falcon eggs contained detectable mirex; levels were highest in the pigeon hawk (*Falco columbarius*) (0.25 ppm) and in the peregrine falcon (*Falco peregrinus*) (0.43 ppm), two species that feed on migratory birds or migrate to mirex-impacted areas (Kaiser 1978). Active mirex was also found in eggs of a cormorant (*Phalacrocorax* sp.) from the Bay of Fundy on the Atlantic coast; the suspected source of contamination was the southern wintering range (Kaiser 1978).

Mirex residues in 20 great horned owls *(Bubo virginianus)* found dead or dying in New York State in 1980-82 contained concentrations of mirex and PCB's higher than those reported for great horned owls elsewhere (Stone and Okoniewski 1983). Owls in “poor flesh” contained higher residues than those in “good flesh”; these values were 6.3 vs. 0.07 for brain, and 5.56 vs. 0.12 ppm for liver (Stone and Okoniewski 1983).

CURRENT RECOMMENDATIONS

Before the banning of mirex for all uses in 1978, the tolerance limits in food for human consumption were 0.1 ppm for eggs, milk, and fat of meat from cattle, goats, hogs, horses, poultry, and sheep, and 0.01 ppm for all other raw agricultural commodities (Waters et al. 1977; Buckler et al. 1981). Higher limits of 0.3 ppm mirex in fish and shellfish and 0.4 ppm in crabs were tolerated (NAS 1978). However, mirex concentrations as low as 0.1 ppm in diets of adult prairie voles were associated with delayed maturation of pups, and with significant delays in the attainment of various early development behaviors such as bar-holding ability, hind-limb placing, and negative geotaxis (Shannon 1976). It is not known whether or not prairie voles can serve as a model for protection of health of humans or various wildlife species. In the absence of supporting data, however, it seems prudent now to establish a dietary threshold of mirex at some level lower than 0.1 ppm. A maximum concentration of 0.01 ppm total dietary mirex, which is the current recommended level for most raw agricultural commodities, appears reasonable and conservative for the protection of fish, wildlife, and human health. This value could be modified as new data become available.

Although mirex is extremely persistent in the environment, recent data indicate that some degradation occurs and that some of the degradation products, such as photomirex, are biologically active. Accordingly, additional research is warranted on the fate and effects of mirex degradation products, with special emphasis on biomagnification through aquatic and terrestrial food chains.

Alternate means of controlling imported fire ants are under consideration. One approach has been to reduce the concentrations of active mirex in bait formulations from the current 0.3% to some lower, but effective, level. Paton and Miller (1980) demonstrated that mirex baits containing 0.07% mirex were effective in controlling Australian termites, reporting a 90% kill in 9 days; baits containing as little as 0.01% mirex were also reported effective, although termite mortality was delayed considerably. Waters et al. (1977) indicated that alternate chemical control agents, such as chloropyrifos, diazinon, dimethoate, or methyl bromide may be suitable and that nonbiocidal chemicals, such as various pheromones and hormones, which are capable of disrupting reproductive behavior of fire ants, are also under active consideration. Another proposal was to modify mirex chemically to a more water soluble and rapidly degradable product (Waters et al. 1977). The formulation Ferriamicide, which consisted of 0.05% mirex, ferrous chloride, and a small amount of long-chain alkyl amines, was formulated in baits during 1978-79 for ant control (Lowe 1982). Ferriamicide degraded within a few days after initial application; however, approval was revoked in 1980 when it was learned that the toxicity of various degradation products to mammals, especially that of photomirex, exceeded that of 4X bait formulations (Lowe 1982). In 1980, the use of Amdro (tetrahydro-5,5-dimethyl-2 (lH)-pyrimidine) was conditionally approved by the U.S. Environmental Protection Agency (Lowe 1982). Amdro reportedly has good ant control properties, degrades rapidly in sunlight, has a biological half life of less than 24 h, is nonmutagenic, and is relatively nontoxic to other than targeted species, except fish. Amdro was more acutely toxic than mirex to fish.

Mirex replacements should not manifest the properties that led to the discontinuance of mirex for all uses; namely, delayed mortality in aquatic and terrestrial fauna; numerous birth defects; tumor formation; histopathology; adverse effects on reproduction, early growth, and development; high biomagnification and persistence; disrupted energy metabolism; degradation into toxic metabolites; population alterations; and movement through aquatic and terrestrial environmental compartments. It is emphasized that mirex replacement compounds must be thoroughly tested before widespread application in the environment; if testing is incomplete, it is almost certain that the Nation's fish and wildlife resources will be adversely affected.

CADMIUM HAZARDS TO FISH, WILDLIFE, AND INVERTEBRATES: A SYNOPTIC REVIEW

By
Ronald Eisler

Patuxent Wildlife Research Center
U.S. Fish and Wildlife Service
Laurel, MD 20708

SUMMARY

Cadmium contamination of the environment is especially severe in the vicinity of smelters and urban industrialized areas. There is no evidence that cadmium, a relatively rare heavy metal, is biologically essential or beneficial; on the contrary, cadmium is a known teratogen and carcinogen, a probable mutagen, and has been implicated as the cause of severe deleterious effects on fish and wildlife. The freshwater biota is the most sensitive group; concentrations of 0.8 to 9.9 ug Cd/L (ppb) in water were lethal to several species of aquatic insects, crustaceans, and teleosts, and concentrations of 0.7 to 570 ppb were associated with sublethal effects such as decreased growth, inhibited reproduction, and population alterations. These effects were most pronounced in waters of comparatively low alkalinity. Marine organisms were more resistant than freshwater biota. Decapod crustaceans, the most sensitive saltwater group, died at concentrations of cadmium in seawater ranging from 14.8 to 420 ppb. Sublethal effects to marine animals recorded at Cd concentrations of 0.5 to 10 ppb included decreased growth, respiratory disruption, altered enzyme levels, and abnormal muscular contractions; effects were usually most obvious at relatively low salinities and high temperatures. Freshwater and marine aquatic organisms accumulated measurable amounts of cadmium from water containing Cd concentrations not previously considered hazardous to public health or to many species of aquatic life; i.e., 0.02 to 10 ppb.

Mammals and birds are comparatively resistant to the biocidal properties of cadmium. The lowest oral doses producing death in rats and guinea pigs ranged from 150 to 250 mg Cd/kg body weight (ppm). Although mallards and chickens tolerated 200 ppm of cadmium in diets for protracted periods, kidney cadmium exceeded 130 ppm fresh weight under this regimen, a concentration considered life-threatening to some organisms. Sublethal effects of cadmium in birds, which were similar to those in other animals, included growth retardation, anemia, and testicular damage; however, these effects were observed at higher concentrations than in aquatic biota. Although the evidence is incomplete, wildlife populations, especially migratory birds that feed on crops growing on fields fertilized with municipal sewage sludges, may be exposed to considerable risk of harmful effects from cadmium.

It is now conservatively estimated that adverse effects on fish or wildlife are either pronounced or probable when cadmium concentrations exceed 3 ppb in fresh water, 4.5 ppb in saltwater, 100 ppb in the diet, or 100 g Cd/m^3 in air. Cadmium residues in vertebrate kidney or liver that exceed 10 ppm fresh weight or 2 ppm whole body fresh weight should be viewed as evidence of probable Cd contamination; residues of 200 ppm fresh weight kidney, or more than 5 ppm whole animal fresh weight, are probably life-threatening to the organism. (Eisler, R. 1985. Cadmium hazards to fish, wildlife , and invertebrates: a synoptic review. U.S. Fish and Wildlife Service Biological Report 85 (1.2), Contaminant Hazard Reviews Report No. 2. 46 pp.)

Table of Contents

TABLES

INTRODUCTION

There is no evidence that cadmium (Cd) is biologically essential or beneficial; on the contrary, it has been implicated as the cause of numerous human deaths and various deleterious effects in fish and wildlife. In sufficient concentration, it is toxic to all forms of life, including microorganisms, higher plants, animals, and man. It is a relatively rare metal, usually present in small amounts in zinc ores, and is commercially obtained as an industrial by-product of the production of zinc, copper, and lead. Major uses of cadmium are in electroplating, in pigment production, and in the manufacture of plastic stabilizers and batteries. Anthropogenic sources of cadmium include smelter fumes and dusts, the products of incineration of Cd-bearing materials and fossil fuels, fertilizers, and municipal wastewater and sludge discharges; concentrations are most likely highest in the localized regions of smelters or in urban industrialized areas (Hammons et al. 1978; Hutton 1983b). Industrial consumption of cadmium in the United States, estimated at 6,000 metric tons in 1968, is increasing; projected use in the year 2000 is about 14,000 tons, primarily for electroplating of motor parts and in the manufacture of batteries. The cadmium load in soils and terrestrial biota in other industrialized countries also appears to be increasing; it is currently of great concern in Scandinavia (Tjell et al. 1983), Germany (Markard 1983), and the United Kingdom (Hutton 1983a).

This account summarizes ecological and toxicological aspects of cadmium in the environment, with special reference to game fish and migratory waterfowl and their predators and prey. It also provides recommendations for the protection of sensitive species of wildlife and aquatic biota. It is part of a continuing series of synoptic reviews prepared in response to requests for information from environmental specialists of the U.S. Fish and Wildlife Service.

ENVIRONMENTAL CHEMISTRY AND BACKGROUND RESIDUES

Cadmium is a silver-white, blue-tinged, lustrous metal that melts at 321°C and boils at 765°C. This divalent element has an atomic weight of 112.4 and an atomic number of 48. It is insoluble in water, although its chloride and sulphate salts are freely soluble (Windholz et al. 1976). The availability of Cd to living organisms from their immediate physical and chemical environs depends on numerous factors, including adsorption and desorption rates of cadmium from terrigenous materials, pH, Eh, chemical speciation, and many other modifiers. The few selected examples that follow demonstrate the complex behavior of Cd in freshwater systems.

Adsorption and desorption processes are likely to be major factors in controlling the concentration of cadmium in natural waters and tend to counteract changes in the concentration of cadmium ions in solution (Gardiner 1974). Adsorption and desorption rates of cadmium are rapid on mud solids and particles of clay, silica, humic material, and other naturally occurring solids. Concentration factors for river muds varied between 5,000 and 500,000 and depended mainly on the type of solid, the particle size, the concentration of cadmium present, the duration of contact, and the concentration of complexing ligands; humic material appeared to be the main component of river mud responsible for adsorption (Gardiner 1974). Changes in physicochemical conditions, especially pH and redox potential, that occur during dredging and disposal of Cd-polluted sediments may increase chemical mobility and, hence, bioavailability of sediment-bound Cd (Khalid et al. 1981). For example, cadmium in Mississippi River sediments spiked with radiocadmium was transformed from potentially available organic forms to more mobile and readily available dissolved and exchangeable forms (i.e., increased bioavailability) under regimens of comparatively acidic pH and high oxidation (Khalid et al. 1981). The role of dissolved oxygen and aquatic plants on Cd cycling was studied in Palestine lake, a 92-ha eutrophic lake in Kosciusko County, Indiana, a long-term recipient of cadmium and other waste metals from an electroplating plant. The maximum recorded concentration of dissolved Cd in the water column was 17.3 ppb; for suspended particulates, it was 30.3 ppb (Shephard et al. 1980). During anaerobic conditions in the lake's hypolimnion, a marked decrease in the dissolved fraction and a corresponding increase in the suspended fraction were noted. The dominant form of cadmium was free, readily bioavailable, cadmium ion, Cd^{2+}; however, organic complexes of Cd, which are comparatively nonbioavailable, made up a significant portion of the total dissolved Cd. Cadmium levels in sediments of Palestine Lake ranged from 1.5 ppm in an uncontaminated area of the lake to 805 ppm near the outlet of a metal-bearing ditch that entered the lake (McIntosh et al. 1978). The dominant form of Cd in sediments was a carbonate. Levels of Cd in water varied over time and between sites, but usually ranged from 0.5 to 2.5 ppb. It is possible that significant amounts of cadmium are transferred from the sediments into rooted aquatic macrophytes and later released into the water after macrophyte death (natural or herbicide-induced), particularly in heavily contaminated systems. In Palestine Lake, Cd levels in pondweed

(*Potomogeton crispus*), a rooted aquatic macrophyte, were about 90 ppm dry weight; a maximum burden of 1.5 kg was retained by the population of *P*. *crispus* in the lake (McIntosh et al. 1978). Release of the total amount could raise water concentrations by a maximum of 1 ppb. This amount was considered negligible in terms of the overall lake Cd budgets; however, it might have limited local effects. As judged by these and other complexities regarding Cd bioavailability, it appears that the organism remains the ultimate arbiter of its environment, regardless of the source of cadmium and its geophysical surroundings.

Background levels of cadmium in uncontaminated, nonbiological compartments extended over several orders of magnitude (Korte 1983). Concentrations (ppb) of cadmium reported ranged from 0.05 to 0.2 in freshwater, up to 0.05 in coastal seawater, from 0.01 to 0.1 in open ocean seawater, up to 5,000 in riverine and lake sediments, 30 to 1,000 in marine sediments, 10 to 1,000 in soils of nonvolcanic origin, up to 4,500 in soils of volcanic origin, 1 to 600 in igneous rock, up to 100,000 in phosphatic rock, and 0.001 to 0.005 $\mu g/m^3$ in air (Korte 1983). Where Cd is comparatively bioavailable, these values are very near those that have been shown to produce harmful effects in sensitive biological species, as will be discussed later.

Cadmium, unlike synthetic compounds, is a naturally occurring element, and its presence has been detected in more than 1,000 species of aquatic and terrestrial flora and fauna. Concentrations of cadmium in a few selected species of biota are shown in Table 1; more extensive documentation was presented by Hammons et al. (1978), NRCC (1979), Jenkins (1980), and Eisler (1981). At least six trends are evident from Table 1. First, marine biota generally contained significantly higher cadmium residues than their freshwater or terrestrial counterparts, probably because total cadmium levels are higher in seawater. Second, cadmium tends to concentrate in the viscera of vertebrates, especially the liver and kidneys. Third, concentrations of Cd are higher in older organisms than in younger stages; this relationship is especially pronounced in carnivores and marine vertebrates (Eisler 1984). Fourth, higher concentrations reported for individuals of a single species collected at several locations are almost always associated with proximity to industrial and urbanized areas or to point source discharges of Cd-containing wastes. Fifth, background levels of cadmium in crops and other plants are usually <1.0 mg/kg (ppm). Little is known about the Cd concentrations required to reduce plant yields; however, plants growing in cadmium-contaminated soils contain abnormally high residues that may be detrimental to plant growth and to animal and human consumers. And finally, it is apparent from Table 1 that species analyzed, season of collection, ambient Cd levels, and sex of organism all probably modify Cd concentrations.

The relationship between reported tissue cadmium concentrations of “unstressed” populations and hazard to the organism or its consumer is not well documented. For example, cadmium in eggs of successful nests of Cooper's hawks collected in Arizona and New Mexico ranged from 0.015 to 0.24 ppm fresh weight (FW); concentrations were higher in eggs from unsuccessful nests (Snyder et al. 1973). Cadmium concentrations in livers of breeding birds were higher in two declining colonies of puffins in St. Kilda and Clo Mor (12.9-22.3 ppm, dry weight) than in colonies of puffins from other areas, or in livers of other seabirds examined (Parslow et al. 1972); however, the link to cadmium requires elucidation. Among marine teleosts, whole body levels exceeding 5 ppm FW or 86 ppm ash weight (AW) in laboratory-stressed fish suggested that death would follow within 4 weeks (Eisler 1971). Marine bivalve molluscs occasionally contain more than 13 ppm of Cd in soft parts FW (Table 1), a level considered acutely toxic to human consumers (Zaroogian and Cheer 1976). The significance of cadmium residues to organism health is further developed later.

Table 1. Cadmium concentrations in field collections of selected species of flora and fauna. Values shown are in mg Cd/kg fresh weight (FW), dry weight (DW), or ash weight (AW).

ACUTE TOXICITY

A substantial toxicological data base for cadmium and freshwater biota demonstrates that ambient cadmium water concentrations exceeding 10 ppb are associated with high mortality, reduced growth, inhibited reproduction, and other adverse effects. Inasmuch as the current recommended drinking water criterion for human health protection is 10 ppb cadmium (EPA 1980), it is noteworthy that several species of freshwater aquatic insects, crustaceans, and teleosts exhibited significant mortality at cadmium concentrations of 0.8 to 9.9 ppb during exposures of 4 to 33 days; mortality generally increased as exposure time increased, water hardness decreased, and organism age decreased (Table 2).

Resistance to cadmium is higher in marine than in freshwater organisms; survival usually is higher at the lower temperatures and higher salinities for any given level of cadmium in the medium. Decapod crustaceans are the most sensitive marine group in short-term tests; LC-50 (96 h) values ranged from 320 to 420 ppb for the grass shrimp (*Palaemonetes vulgaris*), the hermit crab (*Pagurus longicarpus*), and the sand shrimp (*Crangon crangon*) (Eisler 1971). Studies of longer duration demonstrated that survival of shrimp groups was low at >250 ppb during 6 weeks of exposure and that hermit crab deaths were recorded at 60 ppb after 6 weeks, although some survivors remained at 10 weeks when the studies ended (Pesch and Stewart 1980). In another study, an LC-50 range of 14.8 to 19.5 ppb Cd was reported for two species of mysid shrimp subjected to “lifetime” (i.e., 23 to 27 days) exposure to cadmium salts (Gentile et al. 1982).

Birds are comparatively resistant to the biocidal properties of cadmium. Adult drake mallards (*Anas platyrhynchos*) fed up to 200 ppm cadmium in the diet for 90 days all survived with no loss of body weight (White and Finley 1978). Laying hens fed 200 ppm dietary Cd also survived; egg production was suppressed at that concentration but not at lower concentrations tested (White and Finley 1978). Marine and terrestrial animals, including ducks, have been shown to be particularly abundant in a wildlife community associated with a marine sewer outfall (Brown et al. 1977); these animals were contaminated with high levels of cadmium, as well as zinc and copper, but were apparently protected from the deleterious effects of high metal body burdens by metallothioneins. Amounts of these metal-binding proteinaceous metallothioneins and heavy metal loading appear to depend primarily on the degree of pollution and secondarily on the species of animal and its position in the food web. Ducks contained the highest levels of metallothioneins of all groups examined (Brown et al. 1977). Mammals are also comparatively resistant to cadmium. The lowest oral dose, in mg/kg body weight of cadmium (as fluroborate) producing death, was 250 in rats and 150 (as cadmium fluoride) in guinea pigs (EPA 1980).

Table 2. Lethal concentrations (LC) of cadmium to freshwater biota during various exposure intervals. Concentrations shown are in µg Cd/L (ppb) of medium fatal to 10% or 50% of test organisms.

SUBLETHAL EFFECTS

Studies of 30 to 60 days duration with three comparatively sensitive species of freshwater fishes demonstrated that concentrations of >1 and <3 ppb cadmium in water of low alkalinity caused reductions in growth, survival, and fecundity of brook trout, the most sensitive species tested (Table 3). Under conditions of increasing alkalinity, the maximum allowable cadmium concentration range for brook trout increased to >7 and <12 ppb; a similar case was made for the walleye (Table 3).

Among all species of freshwater biota examined, cadmium concentrations of 0.47 to 5.0 ppb were associated with decreases in standing crop, decreases in growth, inhibition of reproduction, immobilization, and population alterations (Table 4). There is an abundant technical literature documenting numerous sublethal effects at higher Cd concentrations; however, these were excluded from the present account if the effects were observed at >10.0 ppb, the currently recommended criterion for drinking water.

For marine organisms, ambient Cd levels between 0.5 and 10.0 ppb resulted in decreases in growth, respiratory disruption, molt inhibition, shortened life span of F1 generation crustaceans, altered enzyme levels, and abnormal muscular contractions. Effects, in general, were more pronounced at the lower salinities and higher temperatures tested (Table 4).

Table 3. Maximum allowable toxicant concentrations (MATC) of cadmium to sensitive species of freshwater teleosts (after Brungs et al. 1978).

Organism and exposure period (days)	Water alkalinity, in mg $CaCO_3$/L	MATC, in µg Cd/L or ppb medium
Brook trout, *Salvelinus fontinalis*		
60	30	>1-<3

Channel catfish, *Ictalurus punctatus*		
60	34	>11-<17
60	172	>12-<17
Walleye, *Stizostedion vitreum vitreum*		
30	33	>9-<25
30	172	>86.7

Sublethal effects in birds are similar to those in other species and include growth retardation, anemia, and testicular damage (Hammons et al. 1978). However, harmful damage effects were observed at higher concentrations when compared to aquatic biota. For example, Japanese quail fed 75 ppm Cd in diet developed bone marrow hypoplasia, anemia, and hypertrophy of both heart ventricles at 6 weeks (Richardson et al. 1974). In zinc-deficient diets, effects were especially pronounced and included all of the signs mentioned plus testicular

hypoplasia; a similar pattern was evident in cadmium-stressed quail on an iron-deficient diet. In all tests, 1% ascorbic acid in the diet prevented Cd-induced effects in Japanese quail (Richardson et al. 1974). Adult male white leghorn chickens given 2 ppm $CdSO_4$ daily by intraperitoneal injection for 15 to 22 days, or a total dose of 60 mg Cd per chicken, developed anemia, an enlarged heart, myocardial infarction, and other abnormalities (Sturkie 1973). Testicular damage was observed in ringdoves 20 days after intramuscular injection of 6.6 ppm Cd body weight (Richardson et al. 1974); in domestic pigeons, however, testicular damage was observed after a single subcutaneous injection of only 0.5 ppm (Sarker and Mondal 1973), and cardiovascular disease developed after exposure to 600.0 ppb in drinking water (Revis et al. 1981). In mallard ducklings fed 20 ppm dietary cadmium for 12 weeks, blood chemistry was altered, and mild to severe kidney lesions developed (Cain et al. 1983). Altered avoidance behavior in the form of hyperresponsiveness was observed in young American black ducks (*Anas rubripes*) produced from parents fed 4 ppm dietary cadmium for about 4 months before egg laying; this behavioral effect was observed only at comparatively low dietary cadmium levels and is considered harmful to wild birds (Heinz and Haseltine 1983). Cadmium readily reacts with sulfhydral groups and may compete, especially with zinc, for binding sites on proteins and, thus, may inhibit a variety of enzymatic reactions. The addition of zinc, iron, ascorbic acid, calcium, or selenium to diets ameliorated Cd damage effects, whereas the addition of lead or mercury exacerbated them (Hammons et al. 1978).

Among small laboratory mammals it appears that physiologically bound cadmium is more effective than $CdCl_2$ in producing metabolic iron irregularities. For example, in young mice fed oysters containing 1.8 ppm of Cd for 28 days, hematocrit and hemoglobin values were depressed and other blood chemistry factors were altered (Siewicki et al. 1983). Diets containing intrinsic oyster Cd at 1.8 ppm were more effective in producing hematopoietic alterations than were diets containing $CdCl_2$ at 3.6 ppm Cd (Siewicki et al. 1983).

Table 4. Sublethal effects of cadmium to selected species of aquatic biota

A study by Beyer et al. (1985) of metal contamination in wildlife from the vicinity of two zinc smelters in Palmerton, Pennsylvania, demonstrated the difficulties in interpretation of cadmium residues from biota in the presence of other potentially hazardous metal contaminants (Table 5). The soil litter horizon at Palmerton was heavily contaminated with lead (2,700 ppm), zinc (24,000 ppm), copper (440 ppm), and cadmium (710 ppm). Invertebrates that fed on soil litter or soil organic matter, such as earthworms, slugs, and millipedes, were rare or absent in the vicinity of the smelters but not at more distant sampling sites (Table 5). Concentrations of all metals tended to be higher in these invertebrates than in other invertebrate groups collected. Amphibians and reptiles were also rare or absent at the Palmerton site, but not at more distant stations. Mean concentrations, in ppm dry weight, of cadmium were highest in carrion insects (25), followed by fungi (9.8), leaves (8.1), shrews (7.3), moths (4.9), mice (2.6), songbirds (2.5), and berries (1.2). By contrast, average concentrations of lead, in ppm dry weight, were highest in shrews (110), followed by songbirds (56), leaves (21), mice (17), carrion insects (14), moths (4.3), berries (4), and fungi (3.7). Evidence for lead poisoning in shrews included high residues in kidney (280 ppm wet weight) and reduced blood enzyme levels. In addition, livers from two cuckoos from Palmerton had lead concentrations of 18 and 25 ppm wet weight; however, the cuckoos and other songbirds appeared to be healthy. Concentrations of zinc and copper tended to be highest in the same organisms that contained the highest concentrations of cadmium, emphasizing the importance of documenting organism body burdens of all suspected contaminants before significance is attributed to any single component. Beyer et al. (1985) demonstrated that only a small portion of all metals measured in the soil became incorporated into plant foliage and suggested that most of the metal contamination detected in biota came from aerial deposition.

In human tissues, there was a significant increase in cadmium burdens in the years 1897-1939 vs. 1980. cadmium content in the renal cortex portion of the kidney increased by a factor of 47 during this interval, and whole body burden increased by a factor near 5 (Drasch 1983). The significance of this increase is not fully clear; however, recent work has suggested that cadmium and lead are associated with increased risk of heart-related death, even in the light of known conventional causes of such fatalities (Voors et al. 1982). Similar data for wildlife are lacking, and this clearly indicates an area for additional research.

Table 5. Cadmium residues, in mg/kg dry weight (ppm), in soil, flora, and fauna collected near two zinc smelters in Palmerton, Pennsylvania (from Beyer et al. 1985).

Soil and category of plants and animals	Direction and distance of areas from smelter emissions	
	Downwind about 2.1 km	Upwind 9.7 km
Soil

BIOACCUMULATION

Biological half times of cadmium in humans is lengthy. Based on body burden and excretion data, Cd may remain in the human body 13 to 47 years. Although Cd is excreted primarily in urine and feces, cadmium tends to increase in concentration with age of the organism and eventually acts as a cumulative poison (Hammons et al. 1978). These phenomena have not been documented adequately in wildlife species.

Freshwater and marine aquatic organisms accumulate cadmium from water containing Cd concentrations not previously considered hazardous to public health or to many species of aquatic life (Table 6). In American oysters, held for 40 weeks in flowing seawater containing 5.0 ppb of Cd, edible meats contained 13.6 ppm Cd fresh weight, a level considered to be an emetic threshold for human consumers (Zaroogian and Cheer 1976). These oysters retained virtually all accumulated cadmium (12.5 ppm) during a 16-week posttreatment immersion in clean seawater (Zaroogian 1979). Emetic thresholds for Cd in oysters were surpassed in 5 weeks at 25 ppb and in only 2 weeks at 100 ppb (Shuster and Pringle 1969). There is considerable variation in the ability of teleost tissues to accumulate cadmium from the ambient medium. Among rainbow trout, for example, exposed for 2 weeks to 9 ppb Cd, bioconcentration factors (BCF) were 260 for gill, 17 for liver, 26 for kidney, and zero for spleen and heart tissues (Roberts et al. 1979). At slightly higher ambient Cd levels of 10 ppb and exposure for 3 months, BCF values were substantially higher: 1,740 for gill, 4,900 for liver, 740 for kidney, 160 for spleen, and 100 for heart tissues (Roberts et al. 1979). The evidence for cadmium transfer through various trophic levels suggests that only the lower trophic levels exhibit biomagnification. In the freshwater food chain extending from the alga *Chlorella vulgaris*, to the cladoceran *Daphnia magna*, to the teleost *Leucospius delineatus*, it was demonstrated that algae held 10 days in water containing 10 ppb of cadmium contained 30 ppm dry weight, up from 4.5 ppm at the start (Ferard et al. 1983). Cladocerans feeding on cadmium-loaded algae for 20 days contained 32 ppm Cd dry weight, up from 1.4 ppm at the start. However, fish fed Cd-contaminated cladocerans for 4 days showed no change in body burdens.

Table 6. Bioconcentration of cadmium from ambient medium by selected species of aquatic biota.

[a]Each reference applies to the values in the same row and in the rows that follow for which no other reference is indicated.

In laboratory studies with chipping sparrows fed radiocadmium-109 in their diets for 3 weeks, it was demonstrated that cadmium became localized in the liver and kidneys (Anderson and Van Hook 1973). During posttreatment on a radiocadmium-free diet, there was an initial rapid drop in radioactivity, and the remaining radiocadmium had an estimated biological half-life of 99 days (Anderson and Van Hook 1973). Marine killifish containing radiocadmium-115m lost 90% of the accumulated radiocadmium during a 6-month posttreatment observation period; the liver usually contained 75 to 80% of the total body dose at any time (*Fundulus heteroclitus* (L.) (Eisler 1974). Mallards fed 200 ppm Cd in the diet for about 13 weeks all survived but levels in liver and kidney were elevated at 110 and 134 ppm fresh weight, respectively (White and Finley 1978). Mallard ducklings fed only 20 ppm dietary cadmium for 12 weeks contained 42 ppm Cd in the liver (Cain et al. 1983).

The exact mechanism of acute cadmium poisoning is unknown, but, among teleosts, it depends in part on exposure period, concentration of Cd in the medium, and water temperature and salinity. Under conditions of high Cd concentration and short exposure, the gill seems to be the primary site of damage and accumulation; under conditions of prolonged exposure and low Cd levels, the intestine, kidney, and possibly other tissues were measurably affected. Retention of cadmium by teleosts depends on tissue biomagnification potential, length of postexposure recovery period, and other factors. The significance of comparatively low concentrations of cadmium in tissues of fish, other aquatic organisms, and wildlife, and the implications for organism health, is not fully understood. Although numerous physical, chemical, and biological factors demonstrably modify uptake and

retention of cadmium by fish and wildlife (Hammons et al. 1978; EPA 1980; Eisler 1981, 1984), the significance of relatively high cadmium residues to animal and plant health is difficult to interpret. There is some evidence, however, that life-threatening concentrations are 200 ppm Cd fresh weight in the renal cortex portion of the mammalian kidney (Hammons et al. 1978) and 5.0 ppm fresh weight whole body of estuarine teleosts (Eisler 1974).

TERATOGENESIS, MUTAGENESIS, CARCINOGENESIS

Teratogenic effect on animals appears to be greater for cadmium than for other metals, including lead, mercury, copper, indium, and arsenic (Ferm and Layton 1981). Among amphibians, frog embryos reared in 5,000 to 7,500 ppb Cd showed nonclosure of the neural tube (Ferm and Layton 1981). In embryos of fathead minnows from adults reared in water containing 37 to 57 ppb Cd, and from eggs transferred directly to such media, percent hatching was reduced, deformities were increased, and various blood clots developed (Pickering and Gast 1972). Embryos of the bluegill (*Lepomis macrochirus*) held in water at 80 ppb Cd or more showed edema, microcephalia, and malformed caudal fins (Eaton 1974). Eggs of a marine killifish (*Fundulus heteroclitus*) were little affected at up to 10,000 ppb of cadmium (Weis and Weis 1977). Caudal and hindlimb abnormalities were observed in chickens following injection of eggs with 0.1 to 1.0 ppm of cadmium chloride; excess zinc appeared to have a protective effect (Ferm and Layton 1981). Rats subjected to >6 mg Cd per kg body weight daily during pregnancy produced fetuses with jaw defects, cleft palates, club feet, and pulmonary hyperplasia (Ferm and Layton 1981). Among hamsters, cadmium administration was associated with embryonic tail defects; effects were synergized by salts of lead or mercury and antagonized by selenium (Ferm and Layton 1981). No conclusive evidence of Cd teratogenesis in humans is available.

From a variety of studies in which mice and bacteria were used as models, it appears likely that cadmium has mutagenic effects. Mice injected with 3 or 6 mg $CdCl_2$/kg body weight showed changes in chromosome number 12 h later; similar changes were observed in hamsters at 1.5 to 3.0 mg/kg (Ferm and Layton 1981). Very high dosages (>100 mg/kg) produced chromosomal abnormalities in plant seeds. Also, $CdCl_2$ had a mutagenic effect on indicator strains of *Salmonella* bacteria. However, the evidence for these effects is still diffuse and often contradictory (Ferm and Layton 1981).

Laboratory studies with mice and rats have conclusively demonstrated that the injection of cadmium metal or salts causes malignancies (sarcoma) at the site of injection and testicular tumors; however, the simultaneous administration of zinc is protective against sarcoma and interstitial cell tumor development (EPA 1980). Among humans, the available epidemiological evidence is not sufficient to conclude that cadmium is definitely implicated as a carcinogen (EPA 1980; Nomiyama 1982).

CURRENT RECOMMENDATIONS

Proposed limits for cadmium in water, food, and air for protection of human health and aquatic life are shown in Table 7. It is noteworthy that the current upper limit of 10.0 ppb of cadmium in drinking water for human health protection is not sufficient to protect many species of freshwater biota against the biocidal properties of cadmium or against sublethal effects, such as reduced growth and inhibited reproduction. Ambient water quality criteria formulated for protection of freshwater aquatic life state that, for total recoverable cadmium, the criterion, in µg/L, is the numerical value given by e to the power (1.05 (ln (hardness))-8.53) as a 24-h average and the concentration, in ppb, should never exceed the numerical value given by e to the power (1.05 (ln (hardness)) -3.73). Thus, at water hardnesses of 50, 100, and 200 mg/L as $CaCO_3$, the criteria are 0.012, 0.025, and 0.051 ppb, respectively, and the concentration of total recoverable cadmium should never exceed 1.5, 3.0, and 6.3 ppb, respectively. Unfortunately, data are accumulating that demonstrate that even these comparatively rigorous criteria are not sufficient to protect the most sensitive species of freshwater insects, plants, crustaceans, and teleosts. It now appears that levels in excess of 3.0 ppb of cadmium in freshwater are potentially hazardous to aquatic biota and that levels near 1.0 ppb are cause for concern in waters of low alkalinity. Not listed in Table 7, but still recognized as proposed criteria (EPA 1973), are the comparatively high levels of 10.0 ppb allowed for agricultural use on all soils (except neutral and alkaline soils, which may be irrigated with water having levels as high as 50.0 ppb) and public water supplies for livestock purposes, which may not exceed 50.0 ppb of cadmium.

The saltwater aquatic life protection criterion of 4.5 ppb seems adequate to prevent death, but will not prevent potentially deleterious physiological effects, including disrupted respiration in crustaceans and teleost. Incidentally, at 5.0 ppb of cadmium, the lowest concentration critically examined, oysters biomagnify ambient levels to concentrations hazardous to human consumers and possibly other animal consumers. The maximum allowable saltwater concentration (MAC) during a 24-h period was recommended as 59.0 ppb (Table 7). However, death of various species of marine crustaceans was reported at 60.0 ppb after exposure for 6 weeks and at 14.8 to 19.5 ppb after 23 to 27 days. Furthermore, a MAC of 59 ppb may be met with daily discharges of 59 ppb for 2 h and no discharge of cadmium for the rest of the day. The effects of exposure of marine life to 59 ppb of cadmium salts for 2 h daily for protracted periods have not yet been investigated. Accordingly, seawater concentrations in excess of 4.5 ppb of total cadmium at any time should be considered as potentially hazardous to marine life, until additional data prove otherwise.

Food is recognized as the major source of cadmium in humans, except in comparatively rare cases of occupational air exposure. The recommended upper limit for cadmium in food is 75 µg/day (Table 7). On the basis of an absorption factor of 0.1 (EPA 1980), a total of 7.5 µg Cd will be retained daily. A 70-kg adult ingests an estimated 0.75 kg of food daily, which suggests that human diets should not exceed 100 µg/kg. Ducks, geese, and other species of wildlife, unlike adult humans, may consume 6 to 7% of their total body weight daily and may graze extensively on crops directly affected by sewage and other wastes containing high Cd residues. Feeding studies with mallards indicated that diets containing 200 mg Cd/kg produced no obvious deleterious effects after 13 weeks. At the end of that study, however, kidney cadmium levels under those conditions were about 134 ppm fresh weight, a level near the 200 ppm fresh weight designated a “critical threshold” (and presumably life-threatening) for the renal cortex portion of the human kidney. Field observations on ducks and laboratory studies are not strictly comparable. Under field conditions, birds and other wildlife may consume food containing high Cd levels, but it is almost certain that these diets also contain other potentially harmful contaminants, as well as metals or compounds that may ameliorate cadmium toxicity. The significance of foods containing complex mixtures of contaminants and their resultant toxicological interactions are imperfectly understood. Until other data become available, wildlife dietary levels exceeding 100 µg Cd/kg diet fresh weight on a sustained basis should be viewed with caution.

Current recommendations for cadmium in air and human health protection under the worst scenario (Table 7) assume that total daily air intake is 27.14 m^3 for an adult human who spends about 6.3 h in occupational exposure to air containing 100 µg Cd/m^3 (EPA 1980). Under these conditions, a 70-kg adult would retain about 361 µg Cd/day, based on an absorption factor of 0.5 (EPA 1980), and most of this Cd would probably be translocated to the kidney; a critical threshold level of 200 mg Cd/kg in the kidney would be reached in about 1.52 years. It is not now known whether respiration rates of wildlife, particularly birds, are comparable to those of humans, or whether cadmium absorption energetics are similar, or whether wildlife species that frequent point sources of air contaminated by high Cd levels for protracted periods are at greater risk than humans. Evidence given by Beyer et al. (1985) demonstrated that flora and fauna in the vicinity of industrial smelters were affected by Cd and its associated heavy metals. This strongly suggest that current recommendations for cadmium levels under occupational air exposure should be revised downward for wildlife protection.

Finally, the issue of the significance of cadmium residues in various body parts requires resolution. At this time, it appears that cadmium residues in the vertebrate kidney or liver that exceed 10.0 mg/kg fresh weight or 2.0 mg/kg in whole body fresh weight should be viewed as evidence of probable cadmium contamination. Elevated levels of 13.0 to 15.0 ppm Cd tissue fresh weight probably represent a significant hazard to animals of the higher trophic levels, and residues of 200 ppm fresh weight kidney or more than 5.0 ppm whole animal fresh weight should be considered life-threatening.

Table 7. Current recommendations for cadmium in water, food, and air (adapted from EPA 1980).

Ecosystem, environmental compartment, and other variables		Cadmium concentration[a]
Water		µg/1
Freshwater aquatic life protection		
at water hardness, in mg $CaCO_3$/1, of		
50		1.5
100		3.0
200		6.3
Saltwater aquatic life protection		
24-h average		4.5
Maximum allowable concentration		59.0
Human health protection		
Best case		0.5
Average case		1.3
Worst case		10.0
Food	µg/day	µg/kg diet/day
Human health protection[b]		
Best case	12	16
Average case	30	40
Worst case	75	100
Air		$\mu g/m^3$
Human health protection		
Best case, ambient exposure		0.001
Average case, ambient exposure		0.03
Worst case		
Occupational exposure		100.0
Ambient exposure		0.4

[a]Units of concentration shown apply to the ecosystem concerned (water, food, air).

[b]Assumes consumption of 0.75 kg food per day by 70 kg adult.

CARBOFURAN HAZARDS TO FISH WILDLIFE, AND INVERTEBRATES: A SYNOPTIC REVIEW

by
Ronald Eisler

Patuxent Wildlife Research Center

Laurel, MD 20708

SUMMARY

Carbofuran (2, 3-dihydro-2, 2-dimethyl-7-benzofuranyl methyl carbamate) and other carbamate compounds, together with organophosphorus compounds, have virtually replaced the more persistent and hazardous organochlorine systemic pesticides used in agriculture. In general, carbofuran effectively controls insects through an anticholinesterase mode of action. Compared with chlorinated hydrocarbon insecticides, it has a relatively short residual life in the environment, degrades rapidly, and is almost completely excreted by nontarget organisms. Carbofuran degradation is complex and demonstrably modified by numerous biological and physicochemical factors; little is known of the biological properties of the degradation products, especially nitrosated metabolites, in relation to chronic toxicity, teratogenicity, mutagenicity, or carcinogenicity.

At currently recommended application rates and in present formulations, carbofuran has caused sporadic, and sometimes extensive, field kills of fish, wildlife, and invertebrates. In short-term laboratory tests, significant death rates were observed at concentrations of about 200 ppb carbofuran (in water) for sensitive species of aquatic biota, 238 ppb (acute oral, µg/kg body weight) and 190,000 ppb (dietary, µg/kg diet) for birds, and 2000 ppb (acute oral) and 100,000 ppb (dietary) for mammals. Among representative indicator species, harmful and sometimes life-threatening effects of carbofuran have been recorded for fish at nominal water concentrations of >15 ppb and for aquatic invertebrates at >2.5 ppb. For birds and mammals, harmful effects were observed at 10 to 50 ppb in the diet and 1000 ppb in drinking water. For comparison, the "safe" level of carbofuran in meat products for human consumption is 50 ppb. Current maximum permissible aerosol levels of 0.05 ppb (50.0 $\mu g/m^3$) carbofuran appear sufficient to protect wildlife; however, evidence suggests that aerosol concentrations should never exceed 2 ppb. Plants are significantly more resistant to carbofuran than are invertebrates and higher organisms. Carbofuran hazards to migratory waterfowl may be reduced by prohibiting granular formulations containing more than 3% active ingredients. In rice culture, carbofuran should be applied before the fields are flooded and after the peak of bird migration. Since annual domestic use of carbofuran exceeds 3.2 million kg (7 million pounds), it appears that additional research is merited on the biotic effects of various formulations of carbofuran, especially flowable formulations, and on applications to crops other than rice, such as corn, alfalfa, and hay.

TABLES

ACKNOWLEDGMENTS

I thank V. Adomaitis, L.R. DeWeese, C.J. Henny, and J.B. Hunn for reviewing the manuscript; P.H. Eschmeyer and C.I. Short for editorial services; L. Garrett, M. Shawe, and B. Graff for library services; and J. Cyphers and I. Moore for secretarial help.

INTRODUCTION

Carbofuran is a broad spectrum systemic insecticide that is currently registered for use on agricultural crops such as alfalfa (*Medicago sativa*), peanuts (*Arachis hypogaea*), rice (*Oryza sativa*), sugar cane (*Saccharum officinarum*), and especially corn (*Zea mays*) Anon. 1971; Dorough 1973; Palmer and Schlinke 1973; EPA 1976; Finlayson et al. 1979; Flickinger et al. 1980). Carbofuran, together with other carbamate compounds, organophosphorus insecticides, and pyrethroids, are the major substitutes for the more persistent pesticides such as DDT, chlordane, and heptachlor. In 1974, domestic carbofuran use was slightly over 3.2 million kg (7 million pounds) active ingredients, most of which was applied to control corn pests (EPA 1976). As a group, the carbamates, including carbofuran, have controlled insects effectively: their residual life in the environment is relatively short; excretion from the animal body is comparatively rapid and almost quantitative; and the terminal residues produced are polar and formed by chemical processes normally considered as steps in metabolic detoxication.

However, at recommended application rates, which range from 0.28 to 10.9 kg active ingredients/ha (0.25 to 9.7 lb/acre), and in a variety of formulations, carbofuran has been held responsible for sporadic kills of fish, wildlife, beneficial insects, and terrestrial and aquatic invertebrates. For example, among birds that only occasionally consume domestic crops, carbofuran applied to vegetables reportedly killed about 1400 ducks, largely green-winged teal (*Anas carolinensis*), pintail (*A. acuta*), and American wigeon (*A. americana*) in British Columbia between 1973 and 1975 (Flickinger et al. 1980). Carbofuran applied to alfalfa killed 2450 American wigeons at one California location in 1974 (Stickel 1975), 500 Canada geese (*Branta canadensis*) in southern Oklahoma in 1976, 1000 wigeons in Kansas in 1976, and more than 1063 wigeons in California in 1976-1977 (Flickinger et al. 1980). Secondary poisoning of red-shouldered hawks (*Buteo lineatus*) was reported after the application of carbofuran to Maryland cornfields (Balcomb 1983). Aerial application to flooded rice fields in various portions of Texas between 1970 and 1975 at the rate of 0.56 kg/ha resulted in deaths of three species of sandpipers (*Erolia* spp.) and red-winged blackbirds (*Agelaius phoeniceus*), as well as frogs, crayfish, leeches, earthworms, and four species of fish; however, no carbofuran residues were detectable among survivors 2 to 11 days postexposure (Flickinger et al. 1980).

In this account, I summarize the technical literature documenting environmental hazards associated with carbofuran, with special emphasis on game fish and migratory birds, and provide recommendations for protection of sensitive species of fish and wildlife. It is part of a continuing series of synoptic reviews prepared in response to requests for information from environmental specialists of the U.S. Fish and Wildlife Service.

CHEMICAL PROPERTIES AND PERSISTENCE

Carbofuran (2, 3-dihydro-2, 2-dimethyl-7-benzofuranyl methyl carbamate) is also known as Furadan, Bay 70142, CAS 1563-66-2, Curaterr, D-1221, ENT-27164, and FMC 10242 (Johnson and Finley 1980) and Niagara NIA-10242 (Leuck et al. 1968). Carbofuran has a molecular weight of 221.25 and a melting point of 150-152°C; it is comparatively stable under neutral or acidic conditions, but degrades rapidly in alkaline media (Anon. 1971). This white, crystalline, solid of empirical formula $C_{12}H_{l5}NO_3$ is soluble at concentrations up to 700 ppm (mg/l) in water, but at < 30 ppm in various organic solvents. It degrades at >130° and supports combustion if ignited (FMC 1979). The compound is available as a wettable powder, a granular formulation, and in solution as a flowable formulation (Anon. 1971; EPA 1976).

Pharmacologically, carbofuran inhibits cholinesterase, resulting in stimulation of the central, parasympathetic, and somatic motor systems. Acute toxic clinical effects resulting from carbofuran exposure in animals and humans appear to be completely reversible and have been successfully treated with atropine sulfate. However, treatment should occur as soon as possible after exposure because acute carbofuran toxicosis can be fatal; younger age groups of various species are more susceptible than adults (Finlayson et al. 1979). Carbofuran labels indicate that application is forbidden to streams, lakes, or ponds. In addition, manufacturers have stated that carbofuran is poisonous if swallowed, inhaled, or absorbed through the skin; users are cautioned not to breathe carbofuran dust, fumes, or spray mist; and treated areas should be avoided for at least 2 days (Anon. 1971). Three points are emphasized at this juncture. First, some carbofuran degradation products have not been identified. Second, toxicologic, mutagenic, carcinogenic, and teratogenic properties of most carbofuran degradation products have not been satisfactorily evaluated. And third, numerous physical, chemical, and biological vectors modify carbofuran degradation processes, as well as biological uptake, retention, and translocation. Each of these points is developed in greater detail later.

Carbofuran is metabolized by hydroxylation and hydrolysis in plants, insects, and mammals (Metcalf et al. 1968). The primary transformation product in most plants appears to be 3-hydroxycarbofuran. However, levels of 3-hydroxycarbofuran and other degradation products in plants are influenced by numerous factors, including plant age, soil type, pesticide formulation, application method and rate, and weather conditions, as is shown later. Oxidation of unconjugated 3-hydroxycarbofuran yields 3-ketocarbofuran, which is, in turn, rapidly hydrolyzed to the much less toxic 3-ketocarbofuran phenol. Accordingly, 3-ketocarbofuran is not likely to be detected as a terminal residue in plants above trace levels. Residue analyses indicated that carbofuran and 3-hydroxycarbofuran are the compounds that occur most often in plant tissues after treatment (Finlayson et al. 1979). In measurement of carbofuran and its degradation products in corn at 117 and 149 days after carbofuran application (Table 1), the decrease of 62% in the total carbamate residues detected between silage and harvest was attributed to cessation of root uptake, volatilization from drying plant surfaces, and further degradation to phenolic compounds. No losses of carbofuran or 3-hydroxycarbofuran were detected in fortified corn silage after storage at minus 18°C for 1 year (Finlayson et al. 1979).

Variation in content of carbofuran and its degradation products was evident among crop species (Finlayson et al. 1979). Strawberries (*Fragaria vesca*), for example, contained higher residues of phenol than of' either carbamate or hydroxy products. Carbofuran can persist in Mugho pine needles for at least 2 years at insecticidally-active concentrations. This unequal distribution of carbofuran in different parts of a plant has also been observed for tobacco (*Nicotiana tabacum*), in which more of the compound was in large leaves than in the tops of plants, suggesting that carbofuran moved in the plant fluids to the point of greatest transpiration in the leaves.

Carbofuran in animals may also be hydrolyzed to produce carbofuran-7-phenol; hydrolysis of the 3-hydroxyderivitive leads to formation of 3-hydrocarbofuran-7-phenol. Other degradation products include N-hydroxymethyl carbofuran and, as in plants, 3-hydroxy and 3-ketoderivitives. All of these compounds may become conjugated and excreted by animals in urine and, presumably, bile (Metcalf et al. 1968; Finlayson et al. 1979). At least 10 metabolites of carbofuran are known at present; their interrelations are shown in detail by Menzie (1978).

In water, the carbofuran degradation rate is strongly influenced by pH (Chapman and Cole 1982). The time to 50% degradation of carbofuran in water was 3.2 years at pH 4.5, 13.3 years at pH 5.0 and 6.0, 1.9 months at pH 7.0, and only 1 week at pH 8.0. The rate of carbofuran loss is also influenced by sunlight, trace impurities, and temperature, but not as dramatically as by pH (Seiber et al. 1978).

Persistence of carbofuran in soils is a function of many factors, including pesticide formulation, rate and method of application, soil type, pH, rainfall, temperature, moisture content, and microbial populations (Ahmad et al. 1979; Deuel et al. 1979; Finlayson et al. 1979; Fuhremann and Lichtenstein 1980; Gorder et al. 1982). Results of several studies indicate that loss from soil samples also takes place at low temperatures when air drying is used; this loss may present a problem to chemists who are unable to conduct analyses immediately after samples are collected (Finlayson et al. 1979). Soil pH is one of the more extensively documented variables affecting degradation; it may become increasingly important as acidic precipitation (acid rain) increases. Carbofuran decomposes rapidly at pH levels >7.0, but becomes increasingly stable as pH decreases. The hydrolysis half-life is about 16 years at a soil pH of 5.5; the half-lives are about 35, 6, and 0.25 days at pH levels of 7.0, 8.0, and 9.0, respectively (Finlayson et al. 1979). Similar results were reported by Getzin (1973), Caro et al. (1976), Seiber et al. (1978), and, in Table 2, by Chapman and Cole (1982). Temperature and moisture content of soils were both positively related to degradation of carbofuran to 3-hydroxycarbofuran, 3-ketocarbofuran, carbofuran phenol, and 3-ketocarbofuran phenol. In general, an increase in temperature from 15° to 27°C had a greater influence on degradation than did an increase from 27° to 35°C, although 27° to 35° was the range in which maximum degradation rates were observed (Ou et al. 1982). Similar results were recorded by Caro et al. (1976), Seiber et al. (1978), and Gorder et al. (1982).

The role of soil bacteria in carbofuran degradation is unclear. Most investigators agree that carbofuran is hydrolyzed to its phenol, which is immediately bound to soil constituents and then metabolized by microorganisms, either slowly (Getzin 1973; Siddaramappa et al. 1978) or rapidly, especially when associated with a *Pseudomonas* sp. isolate (Felsot et al. 1981). Others believe that carbofuran is degraded primarily by chemical hydrolysis, in which bacterial processes assume a negligible role (Venkateswarlu and Sethunathan 1978; Finlayson et al. 1979). Evidence exists demonstrating that soil microbial populations increased by up to 3

times following application of carbofuran (Mathur et al. 1976, 1980); that prior treatment with carbofuran produced rapid degradation attributed to acclimatized soil bacteria (Felsot et al. 1981); that estuarine bacteria are comparatively resistant to carbofuran (Brown et al. 1975); that sterilized soils did not show evidence of carbofuran degradation (Felsot et al. 1981); and that degradation to carbofuran phenol was most rapid under anaerobic conditions (Venkateswarlu and Sethunathan 1978). It appears that additional research is required on bacterial degradation of carbofuran, with special emphasis on acid-resistant strains.

LETHAL EFFECTS

GENERAL

In acute toxicity tests with aquatic organisms, LC-50 (96h) values, with only one exception, exceeded 130 ppb. The exception was the larva of a marine crab with an LC-50 (96h) value of 2.5 ppb. In tests of longer duration with fish, safe concentrations were estimated to range between 15 and 23 ppb. Among the most sensitive species of birds tested, the acute oral LD-50 was 238 ppb (µg/kg body weight), the dietary carbofuran LD-50 value was 190 ppm, dermal LD-50's exceeded 100 ppm, and the LC-100 value in drinking water was 2 ppm. Mammals were comparatively resistant, having LD-50 acute oral toxicities >2 ppm, a dietary LD-38 of 100 ppm after 8 months, and dermal LD-50's >120 ppm. However, only 2 ppb as an aerosol killed 50% of rhesus monkeys in 6 hours, and 40 ppb killed all pheasants within 5 minutes. Bees and earthworms were relatively sensitive to carbofuran, but test conditions were sufficiently different to preclude a strict comparison with vertebrate species. Among photosynthetic species, concentrations of 200 ppm carbofuran partly inhibited germination of rice seeds, but not other species tested, after exposure for 24 hours. Effects of carbofuran on plants are considered negligible when contrasted to faunal damage effects.

AQUATIC ORGANISMS

Among freshwater organisms, LC-50 values for carbofuran ranged from 130 to 14,000 ppb in tests of 72 to 96 hours; fish were the most sensitive and worms the most resistant (Table 3). A relatively narrow toxic range for carbofuran in the climbing perch (*Anabas testudineus*) was indicated by the LC-0 (120 hour) value of 560 ppb and the LC-100 (24 hour) value of 1560 ppb (Bakthavasalam and Reddy 1981). It is noteworthy that carbofuran was not as toxic to aquatic biota as were various cyclodiene chlorinated hydrocarbon insecticides, almost all of which were subsequently withdrawn from commercial use and replaced by carbofuran and other carbamates, and organophosphorus and other compounds.

In flow-through toxicity tests with the marine sheepshead minnow (*Cyprinodon variegatus*), LC-50 values had stabilized by day 60 of exposure with no significant mortality afterwards; however, the LC-50 value was 386 ppb at 96 hours, or 7.8 times greater than that (49 ppb) at 131 days (Table 3). At concentrations up to 49 ppb, carbofuran did not significantly affect the growth of parent fish nor the number of eggs produced. But mortality of fry from fish exposed to 23 and 49 ppb was measurably greater than that of controls (Parrish et al. 1977). On the basis of these and other observations that indicate that growth of surviving fry in all concentrations was not affected and that carbofuran was degraded rapidly in seawater and in sheepshead minnows, it was concluded that the MATC (maximum allowable toxicant concentration) for carbofuran and sheepshead minnow lies between 15 and 23 ppb (Parrish et al. 1977). This observation is similar to that of Caldwell (1977), who demonstrated that adult Dungeness crabs (*Cancer magister*) showed no deleterious effects on growth, survival, or reproduction during exposure to 25 ppb of carbofuran for 69 days. Larvae of Dungeness crabs were substantially more sensitive than adults in 96-hour tests (Table 3). In addition, Caldwell (1977) indicated that 1.5 ppb of carbofuran inhabited swimming ability in zoeal stages of Dungeness crabs and 1.0 ppb inhibited molting and prevented metamorphosis to more advanced larval stages. These observations require verification because mortality in control groups was high, a typical problem in bioassays with larvae of marine invertebrates.

BIRDS AND MAMMALS

Acute oral toxicities of carbofuran to birds ranged from 238 ppb (µg/kg body weight) for fulvous whistling-ducks (*Dendrocygna bicolor*) to 38,900 ppb for domestic chickens (Table 4). The fulvous whistling-duck has been listed as endangered since 1972 by the Texas Organization for Endangered Species (Flickinger et al. 1980). Concentrations of 1 ppm of carbofuran in drinking water of the ducks caused symptoms of intoxication in 7 days, and 2 ppm was lethal in the same period (Tucker and Crabtree 1970). Acute symptoms of carbofuran poisoning in birds, which may persist for up to 7 days, include a loss in muscular coordination, wings crossed high over the back, head nodding, vocal sounds, salivation, tears, diarrhea, immobility with wings spread,

labored breathing, eye pupil constriction, arching of back, and arching of neck over back; death may occur within 5 minutes after ingestion (Tucker and Crabtree 1970). Among mallards (*Anas platyrhynchos*), sensitivity to carbofuran was greater in ducklings than in older birds (Table 4); this relation appears to hold true for other birds for which data are available. Acute oral toxicities of carbofuran to various species of mammals ranged from 2000 ppb in mice to 34,500 ppb in rats (Table 4). Mammals were generally more resistant than birds to acute biocidal properties of carbofuran.

Carbofuran administered to birds in the diet for 5 days, plus 3 days postexposure on an untreated diet, produced 50% kill values of 140 to 1459 ppm dietary carbofuran; younger birds were more sensitive than older ones (Table 5). Food consumption in groups of Japanese quail (*Coturnix japonica*) with high carbofuran-induced mortality was markedly depressed during the first 3 days of treatment (Hill and Camardese 1982). Red-winged blackbirds, the most sensitive bird species tested in food repellency tests, consumed a normal ration of food contaminated with carbofuran (Schafer et al. 1983). As a result, carbofuran has a high potential for causing acute poisoning episodes in birds (Schafer et al. 1983). Field application of carbofuran granules to corn, at planting, in Maryland during 1980 was presumed to be responsible for deaths of songbirds (order Passeriformes) and white-footed mice (*Peromyscus leucopus*); all organisms contained high levels of carbofuran in the gastrointestinal tract and liver, suggesting extensive feeding in treated fields (Balcomb et al. 1984a). A similar situation occurred in Perry, Florida, after treatment of pine seed orchards (Overgaard et al. 1983). Laboratory studies with house sparrows (*Passer domesticus*) and red-winged blackbirds demonstrated that ingestion of a single carbofuran granule is fatal to either species (Balcomb et al. 1984a,b). In groups of old-field mice (*Peromyscus polionotus*) fed 100 ppm dietary carbofuran for 8 months, mortality was 38%; however, growth, development and behavior was normal among survivors from this group and their offspring (Wolfe and Esher 1980). In a preliminary study with rats and old-field mice fed 100 ppm of dietary carbofuran, parents lost weight (but none died), and the survival of young was reduced (Wolfe and Esher 1980).

Aerosol toxicity of carbofuran to warm-blooded animals ranged from about 2 ppb for rhesus monkeys to 110 ppb for rats (Table 6). These values substantially exceed the established Threshold Limit Value (TLV) of 0.05 ppb (50.0 ug/m^3) for protection of human health (Draper et al. 1981). The TLV is a time-weighted concentration for a 40-hour work week that nearly all workers can withstand without adverse effects, including eye and skin irritations and other minor irritations. Inhalation doses to humans were estimated during and immediately after aerial spraying of Furadan 4-Flowable at the rate of 446 g active ingredients carbofuran/ha, a concentration that generally controls most pests. During aerial sprayings of this level, the concentration of carbofuran in ambient air did not exceed 0.0033 ppb at any location (Draper et al. 1981), suggesting that most birds and wildlife are afforded a high degree of protection during aerial spraying at current recommended dosages. Studies with rats subjected to 1.2 ppb carbofuran aerosols for 50-70 minutes showed a substantial (55%) decrease in red blood cell cholinesterase 10 minutes posttreatment and a return to normal levels in 2 hours (Ferguson et al. 1982). After 8 hours, a maximum of 55% of the carbofuran was excreted by respiration (38%) or in the urine (12%) or feces (5%); the remainder was located primarily in the liver and gastrointestinal tract. Plasma half-lives in rats for carbofuran (36 minutes) and 3-hydroxycarbofuran (62 minutes) were similar to those previously determined after oral and intravenous exposures (Ferguson et al. 1982).

Dermal toxicity of carbofuran to birds and mammals is comparatively low. The LD-50 dermal values ranged from about 1000 ppm in cattle (Palmer et al. 1981) down to 100 ppm in birds; i.e., house sparrows and queleas (Schafer et al. 1983); rats and rabbits were intermediate in sensitivity at 120 and 885 ppm, respectively (Draper et al. 1981). Birds contaminated by carbofuran spray could possibly ingest significant amounts while preening (Finlayson et al. 1979), but such ingestion has not been demonstrated. For humans, the maximum potential dermal exposure based on exposed face, hands, forearms, back and front of the neck, and "V" of the chest is 3.1 mg (Draper et al. 1981) or 0.04 ppm for a person weighing 70 kg. This relationship suggests that human populations would be at greater risk than wildlife populations under current carbofuran spray application protocols.

Secondary poisoning of avian raptors with carbofuran is a recent and disturbing event (Balcomb 1983). Consider the case of a female red-shouldered hawk in adult plumage weighing 683 g, found in a cornfield near Beltsville, Maryland, in May, 1981. The field had been treated the previous day with Furadan 10 granules (10% carbofuran), applied at 1.12 kg/ha active ingredients. The bird was entirely paralyzed except for some head and neck movement, salivating a brown fluid, and respiring in rapid pants. These signs are consistent with those

observed in birds dosed in the laboratory with carbofuran. Stomach contents contained remains of a northern short-tailed shrew (*Blarina brevicauda*) and a common grackle (*Quiscalus quiscula*). A total of 96.6 ug of carbofuran was extracted from the gastrointestinal tract and stomach contents and tissues. Judging by the body weight of the hawk, and an LD-50 range of 0.26 to 5.6 mg/kg in various nondomesticated birds (Table 4), this amount of carbofuran would constitute between 2.5 and 59% of the known LD-50 values; however, carbofuran in birds is readily absorbed from the gut and widely transported in the body. Accordingly, the amount of toxicant extracted from the digestive tract was probably only a portion of that ingested by the hawk. In the same cornfield, at the same time, a smaller adult red-shouldered hawk (possibly the female's mate) was found that showed similar, but less severe, signs. Within 24 hours, it appeared to have recovered completely and was released. As judged by carbofuran residues in small mammals and birds at this site, the residues present in the digestive tract of the female hawk, and the nature of the toxic symptoms observed, the two red-shouldered hawks were probably poisoned by carbofuran acquired from small vertebrate prey or scavenged from the treated areas (Balcomb 1983).

TERRESTRIAL INVERTEBRATES

At recommended field application rates of granular carbofuran formulations, some losses of earthworms, springtails, and other soil-inhabiting organisms should be expected; spray and dust formulations adversely affect honeybees and other airborne crop pollinators (Finlayson et al. 1979). Bees are extremely susceptible to carbofuran. In one study with honeybees (*Apis* spp.), subjected to high levels of carbofuran, some young adults in the contaminated hive were unable to emerge from their cells, and those that did emerge remained weak and unfed. Eventually, the hive became vulnerable to invasion by the greater wax moth (*Galleria melonella*), an insect that subsequently destroyed the entire hive (Keener and Pless 1974). The LD-50 dose for honeybees was estimated at 0.16 ug/bee. If 1.12 kg carbofuran/ha were uniformly distributed at a height of 10 m, flying bees could encounter a lethal dose in only 2 seconds (Atkins et al. 1976).

Studies with susceptible and selectively bred carbofuran-resistant houseflies (*Musca domestica*) indicated that LD-50 values for susceptible and resistant strains were 0.1 and 1.3 ug/insect, respectively (Dorough 1973). Resistant flies contained up to 34% more cholinesterase than susceptible strains and could excrete carbofuran almost twice as fast (Dorough 1973). Carbofuran resistance among pestiferous insects is not yet widely known or adequately documented.

Among earthworms, the characteristic symptoms of carbofuran poisoning were rigidity, immobility, lesions, and segmental swelling, as well as cholinesterase inhibition (Stenerson et al. 1973). Worms maintained in soils to which commercial applications of carbofuran had been applied developed two types of lesions within 72 hours: multisegmental swelling that often ulcerated, causing death of the worm, and a discrete nodular mass protruding from the surface of the worm (Sileo and Gilman 1975). The LC-50 values were 0.5 ppm at 5 hours for *Lumbricus herculeus* (Lebrun et al. 1981), but 2.4 and 13.0 ppm at 5 days for *Lumbricus terrestris* and *Eisenia foetida*, respectively; the differences in sensitivity were attributed to a greater excretion rate of carbofuran by Eisenia (Gilman and Vardanis 1974). When applications of carbofuran to soils was 9.1 kg/ha, 50% of the *Lumbricus* died in 72 hours (Ruppel and Laughlin. 1977). At lower application rates of 2 kg/ha, populations of two species of Australian earthworms were reduced; juvenile stages were most severely affected (Martin 1980). The loss of earthworms could result in reduced food for many wildlife species.

Finlayson et al. (1979) indicated that some species of birds might absorb a lethal dose of carbofuran through foraging on poisoned invertebrates. For example, the woodcock (*Philohela minor*) which preys intensively on earthworms, may consume up to 50% of its body weight (about 125 g of food) per day. If each worm contained 1.3 ppm carbofuran, a woodcock would then ingest 0.16 mg of carbofuran or the equivalent of 0.65 mg/kg body weight (Finlayson et al. 1979), an oral dose lethal to many bird species. To date, secondary poisoning of woodcocks has not been verified under controlled conditions.

PLANTS

Carbofuran was more toxic to blue-green alga (*Nostoc muscorum*) at pH 5 to 6 than at pH 7.5 to 10; toxicity was lessened under conditions of reduced illumination and low population density (Kar and Singh 1978). All effects were observed at comparatively high carbofuran concentrations of 25 to 100 PPM.

Seeds of okra (*Abelmoschus esculentus*) treated with carbofuran, at 1, 3, or 5% active ingredient carbofuran by weight of seed, germinated normally after 90 days of storage (Gaikwad and Pawar 1979). After 6 months of storage, however, germination was measurably reduced at all carbofuran treatments. Okra plants developed normally except for a reduction in plumule length, but this effect was also observed among okra seeds tested with a wide variety of agricultural chemicals.

The effect of carbofuran on the germination of seeds of cotton (*Gossypium hirsutum*), rice, and groundnut (*Arachis hypogea*) were investigated by Arunachalam and Lakshmanan (1982), in rice seeds exposed for 24 hours to 100 or 200 ppm carbofuran, germination decreased 8 and 23%, respectively; seeds of the other two species were not affected at these exposure rates. Treated rice seedlings that germinated grew two to three times faster than controls, especially in the roots and leaves; no reasons were offered to account for these differences in rice plants. Carbofuran residues in seeds of the three test species exposed for 24 hours to 100 ppm carbofuran ranged from 17.5 to 28.1 ppm; at 200 ppm carbofuran these values ranged from 24.0 to 30.4 ppm. At 72 hours posttreatment, residues had declined markedly to 0.1 to 4.7 ppm in the groups treated with 100 ppm carbofuran and 2.3 to 3.8 ppm in the groups treated with 200 ppm. Observed growth promotion effects in certain plants by carbofuran and some of its metabolites may be due to effects on plant oxidase systems, rather than on insecticidal or nematocidal properties of the compound; however, the source of the effects has not been demonstrated conclusively (Finlayson et al. 1979).

SUBLETHAL EFFECTS

GENERAL

Most investigators agree that carbofuran degrades or is biotransformed rapidly, with negligible accumulations in biota. Numerous studies have demonstrated that carbofuran, at high sublethal concentrations, was capable of disrupting enzyme and lipid metabolism, but that effects were reversible with no observable permanent damage. Three major data gaps appear still to exist. First, latent biochemical and physiological effects that appear at substantial intervals posttreatment have not been explained. Second, interaction of carbofuran with other environmental compounds, especially other agricultural chemicals, are largely unknown, and the effects may cause more than additive damage. Third, and most important, data are scarce or lacking on chronic toxicity, teratogenicity, mutagenicity, and carcinogenicity of the degradation products of carbofuran, especially degradation products that may also form nitroso compounds; nitrosated carbofuran metabolites, for example, are demonstrably mutagenic.

AQUATIC ORGANISMS

Carbofuran reportedly disrupts enzyme and lipid metabolism in fishes and may not degrade as rapidly under field conditions as suggested by laboratory studies. However, most investigators argue that carbofuran, under current application rates, does not accumulate to a significant extent in aquatic systems and rapidly degrades under field and model microcosm study conditions.

In studies with the African catfish (*Mystus vittatus*) exposed to 31 or 62 ppb of carbofuran for 30 days, serum transaminases were significantly elevated (Verma et al. 1981a). In comparison with catfish exposed to concentrations of 21 ppb or less during the same period, there were also significant depressions in alkaline phosphatase activity in the liver; acid phosphatase activity in the liver, kidneys, and gills; and gulucose-6-phosphatase in the liver and kidneys (Verma et al. 1981b). In climbing perch, mean lipid levels in muscle and liver were elevated after exposure to an LC-0 (120 hour) dose of 560 ppb carbofuran for 120 hours; a similar pattern was observed following exposure to an LC-100 (24 hour) concentration of 1560 ppb for 6 hours (Bakthavasalam and Reddy 1981). Carbofuran-induced alterations have also been documented in serum chemistry of the African catfish during immersion in 21 ppb for 30 days (Verma et al. 1982b); in brain acetylcholinesterase activity of climbing perch and milkfish (*Channa punctatus*) 30 days after exposure to high sublethal levels for 48 hours (Jash and Bhattacharya 1983); and in blood and tissue enzyme and ammonia levels in the air-breathing catfish (*Clarias batrachus*) 1 month after exposure for 30 days to 500 ppb carbofuran (Mukhopadhyay et al. 1982). In field studies with *Trichogaster pectoralis*, a fish extensively cultured in flooded Malaysian rice paddies, (Gill (1980) found that the degradation of carbofuran in the liver was slower than that reported for laboratory animals and suggested that caution be exercised in the extrapolation of rates of carbofuran oxidative hydroxylation activity from laboratory organisms to fishes cultured in rice fields.

On the other hand, negligible accumulations of carbofuran were observed in egg masses of the caddisfly (*Triaenodus tardus*) during immersion for 120 hours in water containing 8 ppb of carbofuran . ; the low uptake was apparently related to the low partition coefficient of carbofuran (Bellick and Fels 1981). Rapid equilibrium and low accumulation was also reported for the sheepshead minnow (*Cyprinodon variegatus*); in a 28-day flow-through study, maximum tissue concentrations were measured between days 3 to 10 when upper concentration factors of 5 to 20X were recorded (Parrish et al. 1977). Field applications of carbofuran in farm ponds in Arkansas and Kansas were associated with low. mortality in fish (Davey et al. 1976) or negligible effects on fish and plankton (Klaassen and Kadoum 1979). Kansas farm ponds subjected to 25 ppb of carbofuran contained 10.6 ppb in surface waters 1 day later, but nondetectable residues thereafter; residues were <0.4 ppb at 1 day in mud, zooplankton, and fish (Klaassen and Kadoum 1979). Farm ponds treated with 50 ppb of carbofuran after 3 days contained 15 ppb carbofuran in surface water and 26 to 46 ppb in mud, but nondetectable residues in biota; no measurable residues were found in any sample after 25 days (Klaassen and Kadoum 1979). When atrazine at 300 ppb was applied in combination with 50 ppb carbofuran, carbofuran was detectable in surface water at 23 days posttreatment at 1.5 ppb, but not in the soil, biota, or any other compartment (Klaassen and Kadoum 1979).

Koeppe and Lichtenstein (1982), in a well-designed agromicrocosm study, evaluated the influence of percolating water on soils containing 3.6 ppm of radiolabeled (C-14) carbofuran. After 3 weeks, 49% of the carbofuran had been removed with percolating water from soils, and 37% was later recovered from soils and corn. In nonpercolated soils, 80% of the carbofuran was still associated with soils and corn. The aquatic components, including water, lake mud, plants (*Elodea*), and fish (the guppy *Poecilia*), contained 25% of the soil-applied carbofuran, although 49% had been- initially added to the aquariums by way of percolated water. This loss of 24% was attributed partly to the degradation of carbofuran to $C0_2$. About 75% of all the radiocarbon was in lake mud, most of it unextractable. Carbofuran was the major compound recovered from control and percolated soils, accounting for 39 and 15%, respectively; 3-ketocarbofuran and 3-hydroxycarbofuran were identified as the major metabolites. The addition of captafol, a fungicide, to carbofuran-treated soils resulted in a more rapid disappearance of the insecticide from terrestrial soils and reduced uptake by corn. The addition of EPTC, a herbicide, had no measurable effect on terrestrial components, but EPTC and captafol both caused increased recoveries of C-14 labeled carbofuran residues from lake bottom mud. In another study, radiolabeled carbofuran was applied at 1.12 kg/ha to a model ecosystem containing seedling sorghum plants (*Sorghum halopense*) saltmarsh caterpillar larvae (*Estigmene acrea*), the alga *Oedogonium cardiacum*, freshwater clams (*Corbicula manilensis*), crabs (*Uca minax*), a cladoceran (*Daphnia* sp.), mosquito larvae, unidentified species of frogs and snails, and the freshwater macrophyte *Elodea canadensis* (Yu et al. 1979). Carbofuran was rapidly, but not completely, degraded in water to carbofuranphenol, 3-ketocarbofuran, 3-hydroxycarbofuranphenol, N - hydroxy - methyl carbofuran, 3-hydroxycarbofuran, and several unknown compounds. Carbofuran was highly toxic to crabs, clams, and *Daphnia* immediately after application to the model ecosystem, but all animals, except one crab, survived restocking 20 days later.

The freshwater bivalve molluscs *Glebula rotundata* and *Rangia cuneata* absorbed waterborne carbofuran but did not appear to concentrate it (Zakour 1980). Both species of clams were very tolerant, even though symptoms of poisoning, such as shell gaping, foot extension, and incoordination, were evident when carbofuran exposures were high (75 ppm). *Glebula* converted injected radiolabeled carbofuran to a variety of free metabolites, primarily hydrolysis products, and also polar carbofuran metabolites that were not degraded by conditions known to hydrolyze glycosidic conjugates. These polar metabolites may contain some type of amino acid moiety. The rate of carbofuran metabolism by *Glebula* was slower than that reported for most other animals, but was more rapid than that of plants and microorganisms (Table 7). Bacterial metabolism of carbofuran was negligible in both *in vivo* and *in vitro* studies with bivalve molluscs (Zakour 1980).

BIRDS

Birds may encounter carbofuran through respiratory, dermal, and oral routes. Depending on the dietary requirements of particular species, ingestion of contaminated vegetables and poisoned invertebrates may be important exposure routes (Finlayson et al. 1979). Carbofuran may prove harmful alone or in combination with other substances. For example, male Japanese quail fed 0.5 ppm dietary carbofuran for 18 weeks exhibited a 79% inhibition of plasma cholinesterase activity (Dieter and Ludke 1978). The reduction was slightly greater (84%) when carbofuran was fed in combination with 0.05 ppm dietary morsodren, a methyl mercury compound, although morsodren had no measurable effect on cholinesterase activity when fed alone at that dosage. Since

many species of fish-eating birds frequently contain 0.05 ppm of mercury in various tissues, interaction effects of mercury with carbofuran and other cholinesterase-inhibiting compounds may produce synergistic, deleterious effects (Dieter and Ludke 1978).

Low oral dosages or high dietary levels of carbofuran produced no permanent damage effects in northern bobwhites. A single oral dose of 2 mg carbofuran/kg body weight did not affect brain cholinesterase levels at 48 hours, or growth, metabolic efficiency, or metabolized energy at 8 days (Solomon and Robel 1980). The activities of bobwhites fed 131 ppm dietary carbofuran for 14 days was reduced, but this effect was temporary and recovery was complete within 14 days on a carbofuran-free diet. The temporarily reduced activity was attributed to the rapid metabolic breakdown of carbofuran (Robel et al. 1983).

Among laying white leghorn hens, 80% of a single oral dose of 2.7 mg carbofuran/kg body weight was eliminated in feces within 10 days (Hicks et al. 1970). All eggs contained detectable carbofuran; the highest concentration of 0.13 ppm developed on day 4. Residues in liver and kidney were about 2.6 ppm at 6 hours but declined to 0.2 ppm in 24 hours. Muscle and fat contained about 0.3 ppm at 6 hours and <0.l ppm at 24 hours. Hicks et al. (1970) indicated that hydroxylation of carbofuran and hydrolysis of the carbamate ester were the predominant pathways in the metabolism of carbofuran by laying hens; similar results were obtained at single oral doses of 2.7 or 0.3 mg carbofuran/kg body weight.

MAMMALS

Among larger mammals, carbofuran is associated with a variety of stress symptoms, including increased salivation, muscle tremors, prostration, labored breathing, loss of appetite and (in rare cases) death. These symptoms were observed in 1- to 2-week old calves given single doses of carbofuran at 0.25-5.0 mg/kg body weight orally or 0.05-0.1% dermally, in cattle yearlings at 1.0-5.0 mg/kg orally or 0.1% dermally, and in sheep at 2.5-5.0 mg/kg orally (Palmer and Schlinke 1973). All survivors had completely recovered at 5 days posttreatment. Lactating cows fed corn silage containing 1.4-3.9 ppm carbofuran for 8 weeks, or about 74 mg carbofuran daily, showed no decrease in blood cholinesterase; furthermore, no carbofuran residues were detected in the milk (Leuck et al. 1968). Other studies with lactating cows dosed orally with carbofuran (Dorough and Ivie 1968; Ivie and Dorough 1968) showed almost complete excretion in 10 days, mostly through urine (94%), feces (0.7%) and milk (0.2%). Carbofuran metabolites in urine, feces, and excreted milk included the 3-hydroxy-, 3-keto-, and 3-hydroxy-N-hydroxymethyl derivatives, both conjugated and free, and unknown constituents, perhaps carbon dioxide formed by carbofuran hydrolysis.

In investigations of the effects of carbofuran or its metabolites on mice and rats, pregnant mice receiving 0.01 or 0.5 mg dietary carbofuran/kg daily throughout gestation gave birth to viable, overtly normal offspring at term (Barnett et al. 1980). Significant elevation of serum immunoglobins was measured in 101-day old male offspring of female parents receiving 0.5 mg/kg dietary carbofuran. This effect was not observed at day 400 or 800. In female offspring from the group receiving 0.01 mg/kg carbofuran, serum immunoglobins were significantly depressed at day 101, but not thereafter (Barnett et al. 1980). Disturbances in immunoglobulin contents may decrease immunocompetence and, thus, indirectly contribute to morbidity and premature mortality. In rats fed comparatively high dietary levels of 30 ppm carbofuran for 90 days, with mean daily intake of 1.97 mg carbofuran/kg body weight, growth was significantly reduced and ventral prostate gland metabolism of RNA, DNA, and protein was altered (Shain et al. 1977). Prenatal exposure of mice to 0.01 mg carbofuran/kg body weight daily, administered orally during gestation, resulted in persistent postnatal endocrine dysfunction in adults; specifically, the impairment of hepatic metabolism and elevation of plasma corticosterone (Crammer et al. 1978). Unexpectedly, however, at a higher dose of 0.05 mg/kg, there were no significant differences from controls, and the endocrine function of tested mice was normal. In female rats given a single dose of 0.05 mg carbofuran per kg body weight orally on the 18th day of gestation, acetylcholinesterase (AchE) activity decreased significantly in maternal and fetal blood and in the maternal liver within 1 hour (Cambon et al. 1979). At higher dosages of 0.25 and 2.5 mg/kg, AchE was also depressed in the fetal liver and in the maternal and fetal brains; the effects were not measurable 24 hours postadministration.

Carbamate pesticides can easily be converted to N-nitroso derivatives in the presence of sodium nitrite under acidic conditions. The N-nitroso form of carbofuran could possibly be formed in the human stomach (Nelson et al. 1981). Since carbofuran is used routinely on a variety of crops and nitrite is a common component of the human diet and is present in human saliva, nitrosation of carbamates under conditions simulating those in the human stomach is possible. Lijinsky and Schmal (1978) tested nitrosocarbofuran and

five other nitrosated carbamate pesticides for carcinogenicity in rats. Nitrosocarbofuran, at 16.5 mg/kg body weight administered orally once weekly for 23 weeks, was the most toxic compound tested and caused the death of several animals by liver damage early in the experiment. Among survivors, nitrosocarbofuran was the most carcinogenic, as judged by the numbers of carcinomas and tumors that developed. Nitrosation rates of carbofuran in the environment are not now adequately documented, but conceivably could represent an environmental risk to wildlife. Surprisingly, nitrosocarbofuran was among the least mutagenic compounds tested in rats; no obvious explanation is available of the differences in carcinogenic and mutagenic properties (Lijinsky and Schmal 1978). It is noteworthy that data on chronic toxicity, teratogenicity, mutagenicity, and carcinogenicity of degradation products of carbofuran, especially carbofuran-7-phenol, and 3-hydroxycarbofuran-7-phenol are either scarce or lacking (Finlayson et al. 1979); a similar case is made for nitrosocarbofuran and other degradation products of carbofuran which may also form nitroso compounds. More recent work (Nelson et al. 1981) indicated that nitrosated 3-hydroxycarbofuran and 3-ketocarbofuran produced mutagenic responses in bacterial strains of *Salmonella typhimurium* and chromosome aberrations in ovary cells of Chinese hamsters. Nitrosocarbofuran and 3-hydroxynitrosocarbofuran also induced large numbers of sister chromatid exchanges in the same cells. Furthermore, nitroso derivatives of carbofuran were considerably more active than nitroso forms of other carbamate pesticides in producing mutagenicity in *Salmonella* (Nelson et al. 1981). On the other hand, technical formulations of the parent carbofuran were neither genotoxic nor mutagenic to bacteria, yeast, or corn (Gentile et al. 1982).

TERRESTRIAL INVERTEBRATES

In decomposing the dead organic matter in a deciduous forest ecosystem, the detritus food chain may account for more than half the energy flowing through the ecosystem. Carbofuran can significantly disturb decomposition rates of litter communities, with profound consequences for nutrient recycling and incorporation of organic matter into the soils. For example, application of 0.29 kg/ha of carbofuran to a red maple (*Acer rubrum*) litter community near Ottawa, Canada, reduced daily decomposition rates by about 40%; all of the groups of macrodecomposers present, including Collembola, Acarina, Lepidoptera, Coleoptera, Diplopoda, and Annelida, have been shown to be susceptible to carbofuran and may have been affected by the treatment (Weary and Merriam 1978).

CURRENT RECOMMENDATIONS

In Canada, for regulatory purposes, the tolerance level for carbofuran in animal tissues or food, feed, and fiber crops is based on the total carbamate content of the sample, as indicated by total carbofuran, 3-hydroxycarbofuran, 3-ketocarbofuran, and their conjugates (Finlayson et al. 1979), presumably carbofuran phenol, 3-ketocarbofuran phenol , and 3-hydroxycarbofuran phenol. In the United States, the tolerance level is based on carbofuran and four metabolites: 3-hydroxycarbofuran; carbofuran phenol; 3-hydroxycarbofuran phenol; and 3-ketocarbofuran phenol (EPA 1976). Carbofuran levels considered safe range from 0.05 ppm (including 0.02 ppm carbofuran metabolites) in meat, fat, and meat by-products to 40.0 ppm (including 20.0 ppm carbofuran metabolites) in alfalfa hay; intermediate values are 0.1 ppm in milk, 0.2 ppm in corn grain, and 25.0 ppm in corn fodder and forage (EPA 1976). No recommended carbofuran level is currently being promulgated by any regulatory agency for the protection of sensitive species of aquatic biota and wildlife.

On the basis of evidence presented herein, I conservatively estimate that, in terms of total carbofuran in water, damage is possible to aquatic invertebrates at >2.5 ppb and to teleosts at >15 ppb. These levels could he attained during a heavy rainfall shortly after carbofuran treatment of adjacent fields. Among sensitive species of warm-blooded animals, dietary concentrations as low as 10 ppb have demonstrable effects, which were measurable only after extended periods postingestion; for comparison, this level is about 1/5 that allowed in meat by-products for human consumption. Current maximum permissible aerosol levels of 0.05 ppb (50 ug/m^3) appear sufficient to protect wildlife with the proviso that concentrations not exceed 2.0 ppb at any time.

Sporadic kills of migratory birds were associated with carbofuran formulations containing 3% active ingredients (a.i.). For example, migratory sandpipers died after eating Furadan 3 G granules (3% a.i.) applied to rice crops in Texas (Flickinger et al. 1980). The granules probably were ingested while the sandpipers were probing and skimming the surface of wet soil for insects and crustaceans. Other species of migratory waterfowl may have mistaken the small size and density of Furadan granules for seed, particularly in areas where concentrations of granules were abundant after misuse and careless applications. It appears that granular carbofuran formulations need to be developed that contain less than 3% a.i. in order to protect waterfowl, yet

still maintain their effectiveness against target organisms. In rice field pest control, carbofuran should be applied before the fields are flooded and delayed to avoid peak bird migration. Research also appears warranted on the effects on fish and wildlife of the numerous carbofuran formulations used, especially liquid spray formulations (flowables), and on applications to crops other than rice, such as corn, alfalfa, and hay.

Additional long-term research is urgently needed on potential impacts of degradation products of carbofuran on sensitive species of aquatic organisms and wildlife, with special attention to nitrosated carbofuran metabolites. Such data are now scarce or lacking. Research is also needed on chemical and biological interactions of carbofuran with other agricultural chemicals applied to the same locations, which are imperfectly understood. Finally, researchers must elucidate the significance of metabolic upset recorded in various species of laboratory mammals at considerable periods after carbofuran insult.

SUMMARY

Toxaphene (chlorinated camphene, 67-69% chlorine) is a broad-spectrum insecticide which, until recently, was one of the most heavily-used agricultural chemicals on a global scale, especially against pests of cotton. It is extremely persistent in soil and water, with documented half-times of 9 to 11 years; however, in air and in warm-blooded organisms, toxaphene degradation is rapid with half-times of 15 and 3 days, respectively. Toxaphene is especially hazardous to nontarget marine and freshwater organisms, with death recorded at ambient water concentrations substantially below 10 ug/l, and adverse effects observed on growth, reproduction, and metabolism at water concentrations between 0.05 and 0.3 ug/l. Aquatic organisms readily accumulate toxaphene from the ambient medium and diet, sometimes spectacularly, retain it for lengthy periods, and biomagnify the chemical through food chains. These phenomena could account for the numerous fish kills recorded after toxaphene application, as well as the high residues measured in fish from the Rio Grande Valley in southern Texas and other locations of high agricultural use of toxaphene. Atmospheric vectors, including prevailing winds and rainfall, may transport toxaphene hundreds of kilometers from known point sources of application. This, in part, would explain the levels of 5 to 10 mg/kg whole body wet weight recorded in various species of fish from the Great Lakes.

Based on estimated environmental exposure levels, toxaphene does not appear to constitute a major threat to warm-blooded animals, including migratory birds and other wildlife, domestic poultry and livestock, small laboratory mammals, and humans. Wildlife typically contain low or nondetectable levels of toxaphene, except for some species of fish-eating raptors, and the frequency of occurrence is low when compared with that of other organochlorine agricultural compounds. However, toxaphene has been implicated as a human carcinogen and mutagen at relatively high test dosages and was associated with some bird kills following aerial applications.

In water, the concentration of toxaphene considered safe for protection of freshwater life is conservatively estimated to lie between 0.008 and 0.013 ug/l; for marine life, it is 0.07 ug/l. This is in sharp contrast to the current recommended drinking water criterion for human health protection of 5.0 to 8.8 ug/l. Similarly, residues in fish tissue in excess of 0.4 to 0.6 mg/kg wet weight may be hazardous to fish health and should be considered as presumptive evidence of significant environmental contamination, although fish may contain up to 5.0 mg/kg before they are considered hazardous to human consumers. At present, other existing criteria for human health protection, which range in various foods from 0.1 mg/kg for sunflower seeds to 7.0 mg/kg in meat, fats, and citrus fruits, also appear adequate to safeguard sensitive species of wildlife.

In 1982, the U.S. Environmental Protection Agency cancelled the registrations of toxaphene for most uses. However, current stocks of toxaphene may be used, with restrictions, through 1986. Furthermore, considerable, but unknown, quantities of toxaphene previously discharged into the environment over the past several decades may remain undegraded and potentially available to living resources. Accordingly, we recommend, to all natural resources managers, that toxaphene application is contraindicated if there is a history of extensive prior treatment with toxaphene in their jurisdictional areas, if alternative control methods are available, or if there is no clear threat to crop production or to the health of livestock and humans.

INTRODUCTION

Environmental hazards and increasing public concerns associated with toxaphene (chlorinated camphene, 67-69% chlorine) are documented in a series of useful review articles (Pollock and Kilgore 1978; EPA 1980a; Cohen et al. 1982; Rice and Evans 1984). Although toxaphene was introduced in the mid-1940's as a new insecticide, only a few years elapsed before it was being used commercially on a large scale to effectively control a variety of pests. In the mid-1950's, toxaphene was first used in ponds, lakes, and streams as a piscicide. By 1966, toxaphene was the chemical of choice in fish eradication programs in Canada and second in the United States after rotenone (Lennon et al. 1970). Its use for this purpose was discontinued in the 1960's due to its lengthy persistence in water, high acute toxicity to aquatic biota, and significant bioaccumulation and biomagnification in various environmental compartments. By 1974, cumulative world use of toxaphene, mainly against insect pests of cotton, was estimated at 450,000 metric tons. Production of toxaphene declined from 1973 to 1980; however, annual consumption in 1980 was estimated at 105,000 tons, thus qualifying toxaphene as one of the most heavily-utilized agricultural chemicals worldwide. Until recently, toxaphene was extensively applied in California to control fruitworms on tomatoes, bollworm on cotton, and a wide range of pestiferous insects that infested alfalfa, broccoli, celery, beans, clover, lettuce, cauliflower, and pears. In time, toxaphene-resistant strains of cotton pests, including bollworm and lygus bug, appeared in California, Texas, Egypt, and India. In November, 1982, most registered uses of toxaphene were cancelled by the U.S. Environmental Protection Agency (EPA), although existing available stocks may be used through 1986 (EPA 1982). Prior to the EPA action, similar actions that banned or restricted toxaphene use had been implemented in a number of countries, including Canada, England, Sweden, Finland, Denmark, France, Switzerland, Hungary, Italy, Egypt, and Algeria (Cohen et al. 1982).

In this account, we briefly summarize available information on the environmental fate and effects of toxaphene, with special emphasis on gamefish, migratory birds, and their predators and prey. The recommendations on current and proposed safe limits for toxaphene residues in air, water, and biota are reviewed. This effort is part of a continuing series of synoptic reviews on contaminant hazards to natural resources and was prepared in response to informational requests from environmental specialists of the U.S. Fish and Wildlife Service.

ENVIRONMENTAL CHEMISTRY

The commercial production of toxaphene involves the reaction of camphene, chlorine activated by ultraviolet radiation, and certain catalysts to yield chlorinated camphene with a chlorine content of 67 to 69% by weight. This product is a relatively stable material composed of a mixture of structurally similar compounds and isomers. Of the 177 components, 26 have been isolated but only 10 have been identified; these 26 components comprise 40% of the toxaphene. Information on chemical properties and the fate and effects of the remaining components is missing or incomplete (Cohen et al. 1982). Several components that have been tested are more toxic to houseflies than the technical mixture, especially di-, tri-, and tetrachlorobornane compounds (Pollock and Kilgore 1978). Technical toxaphene is a yellow, waxy solid of empirical formula $C_{10}H_{10}Cl_8$ and an average molecular weight of 414. Toxaphene is soluble in water to 3 mg/l and is readily soluble in fats and organic solvents, based on its high partition coefficient of 10 to the power 3.3-6.4. Toxaphene has a tendency to adsorb on sediments and to bioaccumulate in aquatic organisms.

Because toxaphene consists of numerous compounds, it seems inappropriate and misleading to continue using the name toxaphene to describe this insecticide. We now know that chemical properties, such as solubility, toxicity, volatility, and other properties, are the sum of the individual contribution of many different compounds in differing relative amounts. A 50-fold difference between toxicities of toxaphene components can occur, and, with a wide range in the polarity of different fractions, there probably are also significant solubility differences. In addition, the composition of toxaphene changes with time, and residues in fat are not of the same composition as parent toxaphene (Pollock and Kilgore 1978). The metabolism of toxaphene has been an area of limited research activity, owing to the analytical difficulties involved in detecting a multicomponent substance (Pollock and Kilgore 1978). However, toxaphene has been reported more often in biological samples in recent years. This increased recognition is probably due to better analytical methods for toxaphene analysis (Ribick et al. 1982), greater awareness by analysts, and the continuing widespread use of toxaphene while use of potentially interfering organochlorine insecticides has slowly decreased.

Toxaphene was available as an emulsifiable concentrate, wettable power, or dust. The commercial product is relatively stable but may decay upon prolonged exposure to sunlight, alkalis, or temperatures above 120°C. Toxaphene is also known as chlorinated camphene, Synthetic 3956, Octachlorocamphene, Alltox, Geniphene, Toxakil (Negherbon 1959), polychlorocamphene, camphechlor, Clor Chem T-590, Cristoxo, Moto, Phenacide, Phenatox, Strobane-T, Toxon 63, and Vapotone (Johnson and Finley 1980). Chemically, it is known as a mixture of various chlorinated camphenes (Tucker and Crabtree 1970).

Toxaphene residues have been detected in various environmental compartments hundreds of kilometers distant from known applications of this insecticide. Prevailing winds, rainfall, and sediment runoff probably account for substantial portions of this transport. Rainfall, for example, has been implicated as a significant toxaphene vector in South Carolina estuaries (Harder et al. 1980). During and immediately after the summer use season, toxaphene levels in rain exceeded, by several times, the concentrations reported to produce bone damage in fish under controlled laboratory conditions. Toxaphene becomes sorbed to soils when it is used in agriculture; therefore, a major mode of toxaphene transport in areas planted continuously in cotton is through sediment loss in runoff (McDowell et al. 1981). Measurements indicated a linear relation between toxaphene yield and sediment yield in runoff water. Atmospheric transport of toxaphene is well documented. Air samples from the western North Atlantic contained measurable levels of toxaphene at distances up to 1,200 km from the nearest point source of application on land (Bidleman and Olney 1975). Similarly, Nationwide monitoring of toxaphene in fish showed increases during 1970-74 (Schmitt et al. 1981), especially in areas where the insecticide was not used, suggesting that atmospheric transport is essential to widespread distribution. Airborne toxaphene is resistant to photodecomposition; however, selective volatilization of toxaphene components is a major cause of degradation resulting in an estimated half-time of 15 days while in the atmosphere (Cohen et al. 1982).

Toxaphene degrades more rapidly in most environmental compartments than other chlorinated pesticides, such as DDT and dieldrin (Matsumura 1978). Toxaphene persistence and degradation in soil, water, and biota is modified by numerous and disparate biological and abiotic factors. In lakes, toxaphene persistence was significantly related to lake depth, stratification, and turnover, but not related to surface area, pH, temperature, sunlight, and oxygen (Cohen et al. 1982). Data from studies where toxaphene was used to control nongame fish in lakes suggest that it may persist in water from several months to more than 9 years. For example, two mountain lakes in Oregon that were treated with toxaphene in fish eradication programs remained toxic for 1 to 6 years (Terrierre et al. 1966). Davis Lake, a shallow lake rich in aquatic life, which was treated with 88 ug/l toxaphene, could be restocked with rainbow trout (*Salmo gairdneri*) within 1 year when water toxaphene levels were 0.63 ug/l. Trout grew rapidly, although whole body burdens up to 24 mg/kg were recorded. Miller Lake, a deep, biologically sparse lake, was treated with 40 ug/l toxaphene; trout could not be restocked for 6 years until water levels had dropped to 0.8 ug/l toxaphene. Toxaphene at 50 ug/l was used to eradicate fish from Clayton Lake, New Mexico (Kallman et al. 1962). Water concentrations of 1.0 ug/l were measured 250 days post-treatment, but the lake remained toxic for 9 months, with restocking possible only after 12 months. Residues in fish surviving treatment were 3.5 mg/kg whole body wet weight shortly after exposure and 0.3 mg/kg about 5 months postapplication. Some lakes treated with toxaphene to kill fish have remained toxic for 3 to 4 years (Webb 1980). In another study (Johnson et al. 1966), lake water that contained 1.0 ug/l toxaphene (9 years after toxaphene treatment) supported healthy fish populations. In this lake, particulate matter contained 70 ug of toxaphene/kg, and plankton contained 15,000 ug/kg. However, there were changes in gas chromatographic profiles of toxaphene residues taken from the lakes, suggesting that the parent toxaphene had been altered or degraded into compounds with lower environmental hazards to biota. Clearly, this subject area merits additional research effort.

In soils, toxaphene can persist for lengthy periods, with microbial degradation occuring under aerobic and anaerobic conditions (Cohen et al. 1982). Pimentel (1971) reported that toxaphene, applied at 140 mg/kg of soil persisted for more than 6 years; when applied at 50 mg/kg, half the toxaphene was measurable after 11 years. Further, in sandy loam soils, 45% of the toxaphene remained 14 years after initial application of 100 mg/kg. Some investigators suggest that toxaphene degradation is more rapid under anaerobic conditions (Pollock and Kilgore 1978). Thus, toxaphene in anaerobic salt marsh sediments generally degraded within a few days to shorter-lived components (Williams and Bidleman 1978). Toxaphene accumulated only slightly in anaerobic marsh soils not flooded daily by tides (Gallagher et al. 1979), and the highest pesticide concentrations were associated with roots of dead plants.

Degradation of toxaphene in plant, air, and soil samples was evident following toxaphene application of 9

kg/ha to a San Joaquin Valley, California, cotton field (Seiber et al. 1979). Cotton leaves contained 661 mg toxaphene/kg immediately after application and 135 mg toxaphene/kg after 58 days, with the greatest loss attributed to components of highest volatility. Air samples were essentially the same at 2 and 14 days postapplication (1.8-1.9 ug/m^3); this was attributed to a corresponding enrichment of volatile components. Top soil samples immediately after application and 58 days later contained 13.1 and 6.4 mg/kg, respectively; loss was primarily via vaporization, but at least one component was significantly degraded. One year later, soil cores and irrigation ditch samples showed extensive toxaphene degradation resulting in a selective decline of some components; anaerobic reduction occurred in these environmental compartments.

In rats, the half-time of toxaphene (time to 50% excretion) was 1 to 3 days. If the trend persisted, virtually all toxaphene would be eliminated in five half-lives. Elevated blood toxaphene levels in a human subject who had eaten catfish fillets containing 52 mg of toxaphene/kg dropped 67% in 11 days. By 14 days after the initial measurement, toxaphene blood levels were below analytical detection limits (EPA 1980a).

RESIDUES IN FIELD POPULATIONS

National contaminant monitoring surveys, conducted in the period 1974-76, show that toxaphene was detected in about 6% of all fish sampled; this is a higher percentage than recorded in fruits, vegetables, poultry, and meat (Ludke and Schmitt 1980). Fish collected Nationwide at 109 stations between 1976 and 1979 had measurable toxaphene residues at about 60% of all stations sampled; concentrations in fish from the Great Lakes stations exceeded those in fish from most of the rest of the United States, including locations within the cotton-growing areas (Schmitt et al. 1983). Lake trout (*Salvelinus namaycush*) from Lake Michigan typically contained 5 to 10 mg of toxaphene/kg whole body on a wet weight basis; lake trout from Lake Huron contained 9 mg/kg. These residues are considered harmful to various sensitive species of freshwater teleosts (Schmitt et al. 1983). Since relatively little toxaphene has been used in the Great Lakes region when compared to cotton-growing areas in the mid-South, Northeast, and Southeast, it is postulated that atmospheric transport from areas to the south and southwest are the sources of toxaphene contamination in the Great Lakes (Schmitt et al. 1983).

Freshwater fishes of the Arroyo Colorado, a major waterway traversing the lower Rio Grande Valley in Southern Texas, were highly contaminated with toxaphene and DDE residues when compared to fish collected elsewhere in the Valley; toxaphene concentrations ranged up to 31.5 mg/kg wet weight in whole fish composite samples (Table 1). These values were within or above the range producing adverse effects in sensitive species of fish. In addition, toxaphene residues in carcasses of fish-eating birds contained up to 3 mg/kg toxaphene (Table 1). Unlike fishes, avian species readily metabolize and excrete toxaphene, so that little accumulation occurs in tissues; in any event, these levels of toxaphene in carcasses of piscivorous birds are probably biologically insignificant (White et al. 1983). In the Arroyo Colorado area, toxaphene was being used, to some extent, on crops such as cotton, not only as an insecticide, but as a carrier for more effective chemicals. Another possible source of contamination is a former pesticide plant at Mission, Texas, near the headwaters of the Arroyo Colorado. Soil at this site contained high concentrations of various pesticides, including toxaphene. Contaminant laden runoff from this site could eventually reach the Arroyo from storm sewers and other water diversion facilities. The contaminated Arroyo Colorado, in turn, empties into the Laguna Madre, one of the more important breeding and nursery grounds for fish and wildlife in the United States. The Texas Department of Health, in an advisory to consumers, has stated that consumption of fishes from the Arroyo Colorado, especially blue catfish *(Ictalurus furcatus*) and gizzard shad (*Dorosoma cepedianum*), is not advised (White et al. 1983)

Birds, unlike fish, generally contained low or nondetectable levels of toxaphene, and the frequency of occurrence was relatively low when compared with that of other organochlorine pesticides. This generalization held for eggs of the osprey (*Pandion haliaetus*) collected in southern New Jersey in 1974 (Wiemeyer et al. 1978); carcasses of 103 skinned shorebirds from Corpus Christi, Texas, during winter 1976-77 (White et al. 1980); eggs of the brown pelican (*Pelecanus occidentalis*) from 1971-76 in Louisiana (Blus (et al. 1979); and eggs of clapper rail (*Rallus longirostris*), purple gallinules (*Porphyrula martinica*), and limpkins (*Aramus guarauna*) from the Southeast in 1972-74 (Klass et al. 1980). Among 105 herons found dead Nationwide since 1976, only nine contained measurable quantities of toxaphene; for DDE, PCB'S, dieldrin, and DDD, these frequencies were 96, 90, 37 and 35, respectively (Ohlendorf et al. 1981). Levels of toxaphene and other organochlorines in canvasbacks (*Aythya valisineria*) from Chesapeake Bay, Maryland, during 1973-76 were below the levels known to cause problems in other species (White et al. 1979). However, adipose tissues from 55 male wild turkeys (*Meleagris gallopavo*) killed during the 1974 hunting season in southern Illinois contained 0.2 to 0.9 mg/kg of toxaphene (Bridges and Andrews 1977), suggesting that certain species of birds may

selectively accumulate low concentrations of toxaphene.

Two bird kills reported in California have been attributed to toxaphene poisoning (Pollock and Kilgore 1978). In one case, the apparent route of exposure was from contaminated fish, with bird poisoning the result of toxaphene biomagnification in the food chain. In that case, algae contained 0.1 to 0.3 mg toxaphene/kg wet weight, snails and daphnids 0.2, fish 3 to 8, and fish-eating birds 39 mg/kg. The latter value is substantially in excess of 3 mg/kg, a concentration considered biologically insignificant to fish-eating birds (White et al. 1983). The second incident involved some birds that were apparently killed by toxaphene when it was used to control grasshoppers on a shortgrass range. At 2 to 3 weeks postspray, bird carcasses contained 0.1 to 9.6 mg toxaphene/kg.

Biomagnification of toxaphene through food webs was clearly demonstrated in 16 species of organisms collected from oxbow lakes in northeastern Louisiana during 1980 (Neithammer et al. 1984). Without exception, residues were highest (3.6 mg/kg whole body wet weight, range 1.7 to 5.5) in tertiary consumers, such as green-backed heron (*Butorides striatus*), various species of snakes, spotted gar (*Lepisosteus oculatus*), and largemouth bass (*Micropterus salmoides*). Secondary consumers, such as bluegill (*Lepomis macrochirus*) blacktail shiner (*Notropis venustus*), and yellow-crowned night-heron (*Nycticorax violaceus*), contained lower residues (0.9 mg/kg wet weight, range 0.7 to 1.2). Primary consumers, including crayfish (*Procambarus* spp.) and threadfin shad (*Dorosoma petenense*), contained the lowest levels (0.8 mg/kg wet weight, range 0.6 to 1.0) of all consumer groups. Toxaphene levels were not detectable in water and sediments from these oxbow lakes.

LETHAL EFFECTS

Toxaphene is extremely toxic to freshwater and marine biota. In laboratory tests of 96 hours duration, 50% mortality was recorded for the most sensitive species of freshwater and marine teleosts, marine crustaceans, and freshwater insects at nominal water concentrations of less than 10 ug/l of toxaphene, and, in several cases, less than 1 ug/l (Table 2). Bioassays of longer duration, based on exposure of aquatic organisms for the entire or most of the life cycle, produced significant adverse effects on growth, survival, and reproduction at toxaphene concentrations between 0.025 and 1.0 ug/l (Table 3). Based on its high toxicity and extensive use, it is not suprising that toxaphene was considered a major cause of Nationwide fish kills in 1977 (EPA 1980b).

Warm-blooded organisms are relatively resistant to toxaphene, as determined from results of short-term tests involving oral, dermal, and dietary routes of administration. In acute oral toxicity tests with birds and mammals, LD-50 values ranged between 10 and 160 mg/kg body weight (Table 4). The acute oral toxicities of toxaphene to rats, mice, dogs, guinea pigs, cats, rabbits, cattle, goats, and sheep extended from 25 to 270 mg/kg body weight (Pollock and Kilgore 1978; EPA 1980a); these values are in good agreement with those shown in Table 4. Dermal toxicities of toxaphene ranged from 250 mg/kg body weight for rabbits and 930 mg/kg for rats to 25,000 mg/kg for cattle (Pollock and Kilgore 1978). As was true for acute oral and dermal toxicity data, comparatively high levels of dietary toxaphene were required, i.e., 538 to 828 mg/kg diet, to produce significant death rates in various species of birds (Heath et al. 1972). In their study on four species of gamebirds, each aged 2 weeks, Heath et al. (1972) fed them diets containing graded concentrations of toxaphene for 5 days, followed by 3 days of untreated food. LD-50 values at the end of day 8 were 828 mg toxaphene/kg diet for northern bobwhite, 686 for Japanese quail (*Coturnix coturnix japonica*), 542 for ring-necked pheasant (*Phasianus colchicus*), and 538 for mallard (*Anas platyrhynchos*). It appears that toxaphene is not a major hazard to bird survival at previously recommended field application rates (Hoffman and Albers 1984). However, at toxaphene levels not considered life-threatening to birds and mammals, fetotoxic effects have been recorded. For example, ring-necked pheasants fed 100 mg/kg dietary toxaphene produced eggs with significantly reduced hatch over controls; similarly, toxaphene administered orally to pregnant rats and mice during organogenesis caused fetal toxicity at 15 mg/kg body weight (Pollock and Kilgore 1978).

Some human deaths, especially those of children, have been reported following the ingestion of toxaphene-contaminated foods (EPA 1980a). Known toxaphene residues in food items of victims ranged from 9.7 to 47 mg/kg; a total dose of 2 to 7 g of toxaphene is considered acutely toxic to a 70 kg adult. For comparison purposes, a 4.5 kg bird would probably die after consumption of 45 to 450 mg of toxaphene.

SUBLETHAL EFFECTS

Among sensitive species of marine and freshwater fish and invertebrates, water concentrations of 0.054 to 0.299 ug/l of toxaphene were associated with growth inhibition, reduced reproduction, backbone abnormalities, or histopathology (Table 5). Aquatic biota are capable of spectacular accumulations of toxaphene from the medium; factors ranged between 1,270 and 52,000X those of water under laboratory conditions (Table 6). A similar pattern was observed in Big Bear Lake, California, where toxaphene was applied at 200 ug/l to eradicate goldfish (Pimentel 1971). Biomagnification factors of 365 were calculated for plankton, 1,000 for goldfish, and 8,500 in pelican fat, representing residues of 73 mg/kg toxaphene in phytoplankton, 200 in goldfish, and 1,700 in pelican fat. Accumulation of toxaphene by various species of fish food organisms is dependent on exposure time and concentration. For example, insect nymphs subjected to 20 ug/l of toxaphene for <24 hours did not accumulate doses lethal to fish; however, algae, diatoms, and protozoan ciliates held for 24 hours in 20 ug/l toxaphene solutions, and *Daphnia magna* held 120 hours in 10 ug/l, were lethal when fed to fish (Schoettger and Olive 1961).

Fish accumulated part-per-million toxaphene concentrations in various tissues within a few days when placed in toxaphene-treated lakes that contained less than 1.0 ug/l (Cohen et al. 1982). Freshwater teleosts experienced acute and chronic effects when whole body levels were in excess of 0.4 mg/kg but less than 5 mg/kg (this latter value being the Food and Drug Administration "action level" for human consumption; Cohen et al. 1982). Thus, groups of brook trout eggs containing 900 ug toxaphene/kg had drastically reduced survival when compared to controls (Cohen et al. 1982), and brook trout tissue residues exceeding 400 ug toxaphene/kg were associated with reductions in growth, abnormal bone development, and reduced fecundity (Mayer and Mehrle 1977). Fathead minnows containing more than 400 ug toxaphene/kg grew more slowly than controls (Mayer and Mehrle 1977); similar results were reported in channel catfish fry containing 600 to 3,400 ug toxaphene/kg (Mayer and Mehrle 1977). Toxaphene retention by aquatic organisms is relatively lengthy when compared to mammals. In one case, eastern oysters (*Crassostrea virginica*) held for 24 weeks in 10 ug/l toxaphene solutions contained 32.4 mg/kg in soft tissues; after 16 weeks in noncontaminated seawater, oysters still contained 3.0 mg/kg (Pollock and Kilgore 1978).

Sublethal effects of toxaphene observed in mammals, small laboratory animals, and birds were similar to those recorded for aquatic organisms; however, there was general agreement that effects were induced at much higher concentrations. In domestic white leghorn chickens, for example, toxaphene at 100 mg/kg in the diet for 30 weeks did not significantly alter egg production, hatchability, or fertility, although some bone deformation and kidney lesions were recorded (Bush et al. 1977). The highest dietary dose of toxaphene fed to chickens in life-time exposure studies, which produced no effect on any parameter measured, ranged between 3.8 and 5 mg/kg (Bush et al. 1977). Several studies with the American black duck (*Anas rubripes*) produced effects similar to those recorded in chickens. In one study, ducklings that were fed diets containing 10 or 50 mg of toxaphene/kg for 90 days had reduced growth and impaired backbone development (Mehrle et al. 1979). Collagen, the organic matrix of bone, was significantly decreased in cervical vertebrae of ducklings fed the 50 ppm toxaphene diet. Calcium concentrations increased in vertebrae of ducklings fed either 10 or 50 mg/kg dietary toxaphene; effects were observed only in female ducklings. In a long-term feeding study lasting 19 months, which included two breeding seasons, American black ducks, fed 10 or 50 mg toxaphene/kg in a dry mash diet, showed no significant differences when compared to control birds in survival, egg production, fertility, hatchability, eggshell thickness, or growth and survival of young (Haseltine et al. 1980). The only negative effects recorded included weight loss among treated males during summer and a slight delay in the number of days required to complete a clutch. Carcass toxaphene residues, which seldom exceeded 0.5 mg/kg, were found in only one duck fed the 50 mg/kg diet (Haseltine et al. 1980), suggesting low body accumulations in American black duck. However, toxaphene residues were present in the liver of all birds fed toxaphene. At dietary concentrations of 10 or 50 mg/kg, there was no change in avoidance behavior of young American black ducks (Heinz and Finley 1978), which, if interrupted, is considered life-threatening.

Ring-necked pheasants (*Phasianus colchicus*) fed diets containing 300 mg toxaphene/kg showed decreases in egg deposition, egg hatch, food intake, and weight gain; at 100 mg/kg, all of these parameters, except reduced hatch, were the same as controls (Pollock and Kilgore 1978). In a field study, aerial applications of a DDT-toxaphene mixture in southwestern Idaho during 1970, at recommended concentrations to control pests, had no major impact on penned or feral ring-necked pheasants (Messick et al. 1974), suggesting that conformance with recommended application rates should be endorsed whenever possible. However, we emphasize that recommended toxaphene application rates, until recently, varied widely and depended, in part,

on the pest species to be controlled, the number and type of other pesticides applied jointly, and climatic conditions. Laboratory studies with mallard eggs suggest that recommended toxaphene application rates in excess of 1.12 kg/ha, which is generally exceeded in most cases, may produce severe embryotoxic effects, including dislocated joints and poor growth (Hoffman and Eastin 1982).

Northern bobwhite fed 5 mg/kg dietary toxaphene for 4 months showed thyroid hypertrophy (Pollock and Kilgore 1978) and interference with the ability of bobwhites to discriminate patterns (Kreitzer 1980). In the latter investigation, Kreitzer fed 10 or 50 mg/kg dietary toxaphene to 3-day old bobwhites for 20 weeks and found that toxaphene-treated birds made 50% more errors than controls on initial testing. These effects appeared as early as 30 days after toxaphene exposure. In a second test, there was no difference between experimentals and controls, indicating that the ability to learn these tasks was not permanently impaired.

Rats, mice, dogs, deer, sheep, and cattle are all relatively resistant to toxaphene. No-effect levels of 20 to 25 mg/kg dietary toxaphene were documented during multigeneration exposure of rats and during 2-year feeding studies with mice and dogs (EPA 1980a). No effects were observed in monkeys over a 2-year period during which they were fed diets containing 0.7 ppm toxaphene (Pollock and Kilgore 1978). However, carcinogenic responses have been induced in mice and rats by toxaphene when residues in the diet exceeded 50 mg/kg during lifetime exposure (EPA 1980a). "These results, together with the positive mutagenic response (to *Salmonella* bacteria) constitute substantial evidence that toxaphene is likely to be a human carcinogen" (EPA 1980a). Penned and wild deer fed toxaphene at 1,000 mg/kg appeared normal but showed a decreased digestion rate, which was attributed to a decrease in rumen bacteria (Schwartz and Nagy 1974). Steers fed alfalfa hay containing 306 mg toxaphene/kg for 19 weeks stored 772 mg/kg in abdominal fat and 27 mg/kg in lean meat without apparent ill effects, demonstrating the lipophilicity of toxaphene and the relatively low accumulation rates. For sheep under an identical regimen, these values were 317 mg/kg in fat and 36 mg/kg in meat (Pollock and Kilgore 1978).

RECOMMENDATIONS

In November, 1982 the U.S. Environmental Protection Agency cancelled the registration of toxaphene for most uses and, thus, joined a growing number of Nations in Western Europe, Scandinavia, North America, and North Africa that previously initiated similar actions. With some restrictions, toxaphene presently may be used domestically for treatment of scabies in cattle and sheep; controlling sporadic infestations of armyworms, cutworms, and grasshoppers on cotton, corn, and small grains; and, in Puerto Rico and the Virgin Islands, to control mealy bugs, pineapple gummosis moths, and banana weevils. Existing stocks of toxaphene may be used through 1986 for control of sicklepod in soybeans and peanuts, for insects in corn cultivated without tillage, and for pests of dry and southern peas (EPA 1982).

Although toxaphene is not markedly hazardous to most wildlife species for which data were available, the decision to withdraw or curtail agricultural uses of toxaphene was popular with most natural resource managers. Their concerns, apparently shared by others, were based, in part, on the following observations. First, toxaphene causes death and deleterious effects to nontarget aquatic biota at extremely low concentrations, i.e., <1.0 ug/l. Second, toxaphene is persistent in soils, water, and other environmental compartments, with residence times measured in years. Third, toxaphene accumulates in aquatic organisms and biomagnifies through food chains. Fourth, toxaphene is widely-distributed, even when the initial application point is hundreds of kilometers distant; transport is presumably by atmospheric and other vectors. Fifth, technical difficulties continue to exist in the chemical analysis of toxaphene, a 177-isomer compound. Sixth, there is an imperfect understanding of the fate and effects of individual toxaphene components. Seventh, there is inadequate knowledge of interaction effects of toxaphene with other agricultural chemicals (especially when mixtures are applied simultaneously) and with other persistent compounds in aquatic ecosystems, such as PCB'S, DDT and its isomers, and petroleum. Finally, there is the perception that suitable alternative pesticidal chemicals are available, including some carbamates, organophosphorus compounds, and synthetic pyrethroids.

At present, available stocks of toxaphene may be used throughout 1986. However, large but unknown quantities of toxaphene that were discharged into the environment over the past several decades remain undegraded and potentially bioavailable. Also, knowledge of toxaphene ecotoxicology is incomplete or inadequate. Accordingly, we recommend to fish and wildlife managers that they review all current and proposed uses of this compound in their jurisdictional areas. Specifically, we recommend that toxaphene use should not be permitted if there is a history of extensive prior treatment with toxaphene, if alternative control methods are available, or if there is no clear threat to crop existence or to health of livestock and humans. Current limits for

toxaphene residues in air, water, biota, and other environmental compartments for the protection of fish, livestock, and human health are summarized in Table 7. The concentration of toxaphene in seawater considered safe for marine life protection is 0.07 ug/l; for sensitive freshwater species this lies between 0.008 and 0.013 ug/l. This contrasts sharply with the current recommended drinking water criterion for human health protection of 5.0 to 8.8 ug/l. Other existing criteria for human health protection, which range in various foods from 0.1 to 7.0 mg/kg, appear adequate at this time to protect sensitive species of wildlife. We emphasize that these values, and others shown in Table 7, are considered criteria and not administratively-legislated standards.

Adult	5,400	32
Egg		
Longnose killifish	1,270	14
Longnose killifish	3,700	52

Table 7. Current recommendations on toxaphene concentrations (EPA 1980a).

Environmental or other factor	Allowable concentration
Freshwater life protection[a]	0.013 µg/1 (24-hour average); 1.6 µg/1 maximum at any time
Saltwater life protection	0.07 µg/1 maximum at any time
Fish tissues	5.0 mg/kg maximum, wet weight basis; 0.4 to 0.6 µg/kg maximum, wet weight basis (Mayer and Mehrle 1977)
Fat of meat from livestock	7.0 mg/kg
Milk and milk products, fat weight basis	0.5 mg/kg
Sunflower seeds	0.1 mg/kg wet weight basis
Citrus fruits	5.0-7.0 mg/kg wet weight basis (Canada); 0.4 mg/kg wet weight (W. Germany, Netherlands)
Drinking water	5.0-8.75 µg/1
Safe daily dose: human	3.4 µg/kg body weight
Acceptable daily intake: human	1.25 µg/kg body weight
Daily intake from air: human	0.00018 µg/kg body weight

[a]The International Joint Commission of the United States and Canada recommended a water standard of 0.008 µg/1 for protection of freshwater aquatic life. This standard is based on the study by Mayer et al. (1975), who found that toxaphene at 0.039 µg/1 in water, caused a significant increase in mortality and a significant decrease in growth of surviving brook trout fry over a 90-day period. The standard of 0.008 µg/1 is obtained by applying an application factor of 5.

SELENIUM HAZARDS TO FISH, WILDLIFE, AND INVERTEBRATES: A SYNOPTIC REVIEW

By

Ronald Eisler

Patuxent Wildlife Research Center
U.S. Fish and Wildlife Service
Laurel, MD 20708

SUMMARY

Ecological and toxicological aspects of selenium (Se) in the environment are reviewed, including its chemistry, background residues in biological and other materials, and toxic, sublethal, and latent effects (including the effects of Se deficiency). Recommendations are presented, including proposed Se criteria for protection of sensitive species of fish and wildlife.

Most authorities agree on five points. First, Se deficiency is not as well documented as Se poisoning, but may be equally significant. Second, Se released as a result of anthropogenic activities (including fossil fuel combustion and metal smelting), as well as that in naturally seleniferous areas, poses the greatest threat of poisoning to fish and wildlife. Third, additional research is required on chemical and biological transformations among valence states, allotropic forms, and isomers of Se. Fourth, Se metabolism and degradation are both significantly modified by interaction with various heavy metals, agricultural chemicals, microorganisms, and numerous physicochemical factors, and until these interactions are resolved it will be difficult to meaningfully interpret Se residues in various tissues. And fifth, documented biological responses to Se deficiency or to selenosis vary widely, even among closely related taxonomic groups.

It is generally agreed that Se deficiency may be prevented in fish, small laboratory mammals, and livestock by feeding diets containing 50 to 100 ppb of Se. The concentration range of total inorganic selenite currently recommended for aquatic life protection--35 ppb in freshwater to 54 ppb in marine waters--is below the range of 60 to 600 ppb that is fatal to sensitive aquatic species. In freshwater, it is also below the range of 47 to 53 ppb associated with growth inhibition of freshwater algae, anemia and reduced hatching in trout, and shifts in species composition of freshwater algae communities. Accordingly, current recommendations for Se with respect to aquatic life appear to afford an adequate measure of protection. However, some studies have shown that Se water concentrations of 9 to 12 ppb are associated with inhibited reproduction of certain freshwater teleosts, suggesting that the current Se criterion for protection of freshwater life should be revised downward. Also, high bioconcentration and accumulation of Se from water by numerous species of algae, fish, and invertebrates is well documented at levels of 0.015 to 3.3 ppb, which are substantially below the recommended range of 35 to 54 ppb. The significance of Se residues in aquatic biota is still unclear, and more research appears to be needed on Se pharmacokinetics in aquatic environments.

Aerosol concentrations exceeding 4.0 ug Se/m^3 are considered potentially harmful to human health; however, no comparable data base for birds and other wildlife species is available at this time.

Selenium in natural foods is less toxic than are purified forms of Se. The consensus is that Se toxicity is prevented in livestock if dietary Se concentrations do not exceed 5,000 ppb in natural forage, or 2,000 ppb in feeds supplemented with purified Se. Minimum toxic concentrations of Se in the rat (a sensitive species), fed diets containing natural Se were 1,400 ppb of Se as judged by evidence of liver changes, and 3,000 ppb as estimated from longevity and histopathology; these values were only 350 and 750 ppb, respectively, when diets low in natural Se were fortified with purified Se. The evidence is incomplete for migratory waterfowl and other birds, but diets containing more than 5,000 ppb of Se are demonstrably harmful.

INTRODUCTION

Selenium (Se) was first identified as an element in 1817 by the Swedish chemist Berzelius. It is now firmly established that Se is beneficial or essential in amounts from trace to part-per-billion concentrations for humans and some plants and animals, but toxic at some concentrations present in the environment. Selenium deficiency was recently reported among cattle grazing in the Florida Everglades, which showed evidence of anemia, slow growth, and reduced fertility (Morris et al. 1984). Conversely, calves of Indian buffaloes died of Se poisoning after eating rice husks grown in naturally seleniferous soils (Prasad et al. 1982); severe reproductive and developmental abnormalities were observed in aquatic birds nesting at Se-contaminated irrigation drainwater ponds in the San Joaquin Valley, California (Ohlendorf et al. 1986); and fish contained high body burdens of Se and failed to reproduce in a lake receiving dissolved Se by way of a power plant fly ash sluice water return (Cumbie and Van Horn 1978). Selenium poisoning is an ancient and well-documented disease (Rosenfeld and Beath 1964). Signs of it were reported among domestic livestock by Marco Polo in western China near the borders of Turkestan and Tibet in about the year 1295; among livestock, chickens, and children in Columbia, South America, by Father Pedro Simon in 1560; among human adults in Irapuato, Mexico, in about 1764; and among horses of the U.S. Cavalry in South Dakota in 1857 and again in 1893 (Rosenfeld and Beath 1964). In 1907-08, more than 15,000 sheep died in a region north of Medicine Bow, Wyoming, after grazing on seleniferous plants. The incidents have continued, and the recent technical literature abounds with isolated examples of selenosis among domestic animals.

Selenium has been the subject of many reviews (Rosenfeld and Beath 1964; Frost 1972; Sandholm 1973; Zingaro and Cooper 1974; Frost and Ingvoldstad 1975; Anon. 1975; NAS 1976; Harr 1978; EPA 1980; Lo and Sandi 1980; Shamberger 1981; Wilber 1980, 1983; Fishbein 1977, 1983; NRC 1983; Reddy and Massaro 1983). These authorities agree that Se is widely distributed in nature, being especially abundant with sulfide minerals of various metals, such as iron, lead, and copper. The major source of environmental Se is the weathering of natural rock. The amount of Se entering the atmosphere as a result of anthropogenic activities is estimated to be 3,500 metric tons annually, of which most is attributed to combustion of coal; however, aside from highly localized contamination, the contribution of Se by man's activities is small in comparison with that attributable to natural sources. Collectively, all authorities agree that Se may favorably or adversely affect growth, survival, and reproduction of algae and higher plants, bacteria and yeasts, crustaceans, molluscs, insects, fish, birds, and mammals (including humans). Most acknowledge that sensitivity to Se and its compounds is extremely variable in all classes of organisms and, except for some instances of Se deficiency or of selenosis, metabolic pathways and modes of action are imperfectly understood. For example, selenium “indicator” plants can accumulate Se to concentrations of thousands of parts per million without ill effects; in these plants Se promotes growth, whereas in crop plants accumulations as low as 25 to 50 ppm may be toxic. Thus, plants and waters high in Se are considered potentially hazardous to livestock and to aquatic life and other natural resources in seleniferous zones.

In this account I briefly review the technical literature on ecological and toxicological aspects of selenium (with emphasis on fish and wildlife and their predators and prey), and provide current recommendations for the protection of sensitive species of concern to the U.S. Fish and Wildlife Service. This is part of a continuing series of synoptic reviews prepared in response to informational requests from environmental specialists of the Service.

ENVIRONMENTAL CHEMISTRY

Selenium is characterized by an atomic weight of 78.96, an atomic number of 34, a melting point of 271°C, a boiling point of 685°C, and a density of 4.26-4.79. Chemical properties, uses, and environmental persistence of selenium were documented by a number of researchers whose works constitute the major source material for this section: Rosenfeld and Beath (1964); Bowen (1966); Lakin (1973); Stadtman (1974, 1977); Frost and Ingvoldstad (1975); Chau et al. (1976); Harr (1978); Wilber (1980, 1983); Zieve and Peterson (1981); Robberecht and Von Grieken (1982); Cappon and Smith (1982); and Nriagu and Wong (1983).

There was general agreement on four points. First, that selenium chemistry is complex, and that additional research is warranted on chemical and biochemical transformations among valence states, allotropic forms, and isomers of selenium. Second, that selenium metabolism and degradation is significantly modified by interaction with heavy metals, agricultural chemicals, microorganisms, and a variety of physicochemical factors. Third, that anthropogenic activities (including fossil fuel combustion and metal smelting) and naturally seleniferous areas pose the greatest hazards to fish and wildlife. And fourth, that selenium deficiency is not as well documented as

Se poisoning, but may be equally significant. These points are developed here in greater detail.

Selenium chemistry is complex (Rosenfeld and Beath 1964; Harr 1978; Wilber 1983). In nature, selenium exists: as six stable isotopes (Se-74,-76,-77,-78,-80, and -82), of which Se-80 and -78 are the most common, accounting for 50 and 23.5%, respectively; in three allotropic forms; and in five valence states. Changes in the valence state of Se from -2 (hydrogen selenide) through 0 (elemental Se), +2 (selenium dioxide), +4 (selenite), and +6 (selenate) are associated with its geologic distribution, redistribution, and use. Soluble selenates occur in alkaline soils, are slowly reduced to selenites, and are then readily taken up by plants. In drinking water, selenates represent the dominant chemical species. Selenites are less soluble than the corresponding selenates and are easily reduced to elemental Se. In seawater, selenites are the dominant chemical species under some conditions (Cappon and Smith 1981). Selenium dioxide is formed by combustion of elemental Se present in fossil fuels or rubbish. Selenium is the most strongly enriched element in coal, being present as an organoselenium compound, a chelated species, or as an adsorbed element. On combustion of fossil fuels, the sulfur dioxide formed reduces the selenium to elemental Se.

Elemental Se is insoluble and largely unavailable to the biosphere, although it is still capable of satisfying metabolic nutritional requirements. Hydrogen selenide is highly toxic (at 1-4 ppb in air), unstable, acidic, and irritative. Selenides of mercury, silver, copper, and cadmium are very insoluble, although their insolubility may be the basis for the reported detoxification of methylmercury by dietary selenite, and for the decreased heavy metal toxicity associated with selenite. Metallic selenides are thus biologically important in sequestering both Se and heavy metals in a largely unavailable form.

In areas of acid or neutral soils, the amount of biologically available Se should steadily decline. The decline may be accelerated by active agricultural or industrial practices. In dry areas, with alkaline soils and oxidizing conditions, elemental Se and selenides in rocks and volcanic soils may oxidize sufficiently to maintain the availability of biologically active selenium. Concentrations of selenium in water are a function of selenium levels in the drainage system and of water pH. In Colorado, for example, streams with pH 6.1-6.9 usually contain <1 ppb of Se, but those with pH 7.8-8.2 may contain 270 to 400 ppb (Lakin 1973).

Selenium volatilizes from soils at rates that are modified by temperature, moisture, time, season of year, concentration of water-soluble selenium, and microbiological activity. Conversion of inorganic and organic selenium compounds to volatile selenium compounds (such as dimethyl selenide, dimethyl diselenide, and an unknown compound) by microorganisms has been observed in lake sediments of the Sudbury area of Ontario. This conversion may have been effected by pure cultures of *Aeromonas*, *Flavobacterium*, *Pseudomonas*, or an unidentified fungus, all of which are found in methylated lake sediments. Production of volatile selenium is temperature dependent. Compared with the amount of $(CH_3)_2$ Se produced at an incubation temperature of 20°C, 25% less was produced at 10°C and 90% less at 4°C. Details of Se reduction and oxidation by microorganisms are not clear. One suggested mechanism for selenite reduction in certain microorganisms involves attachment to a carrier protein and transformation from selenite to elemental Se, which in turn may be oxidized to selenite by the action of *Bacillus* spp., as one example. It is apparent that much additional research on this problem is warranted.

Selenium is an essential nutrient for some plants and animals; it constitutes an integral part of the enzyme glutathione peroxidase and may have a role in other biologically active compounds, especially vitamin E and the enzyme formic dehydrogenase. Some animals require Se-containing amino acids (viz. selenocysteine, selenocystine, selenomethionine, selenocystathionine, Se-methylselenocysteine, and Se-methylselenomethionine), but reportedly are incapable of producing them. Selenium also forms part of certain proteins, including cytochrome C, hemoglobin, myoglobin, myosin, and various ribonucleoproteins. It now appears that selenates and selenites are absorbed by plants, reduced, and then incorporated in amino acids synthesis. The biological availability of Se is higher in plant foods than in foods of animal origin (Lo and Sandi 1980). The net effect of soil, plant, and animal metabolism is to convert Se to inert and insoluble forms such as elemental Se, metallic selenides, and complexes of selenite with ferric oxides.

Selenium was used in the early 1900's as a pesticide to control plant pests, and is still used sparingly to control pests of greenhouse chrysanthemums and carnations (Rosenfeld and Beath 1964). It has been used to control cotton pests (in Trinidad), mites and spiders that attack citrus, and mites that damage apples. Although no insect-resistant strains have developed, the use of selenium pesticides has been discontinued, owing to their stability in soils and resultant contamination of food crops, their high price, and their proven toxicity to mammals

and birds. Selenium shampoos, which contain about 1% selenium sulfide, are still used to control dandruff in humans and dermatitis and mange in dogs. Selenium is used extensively in the manufacture and production of glass, pigments, rubber, metal alloys, textiles, petroleum, medical therapeutic agents, and photographic emulsions.

Air and surface waters generally contain nonhazardous concentrations of Se. Significant increases of Se in specific areas are attributed exclusively to industrial sources, and to leaching of groundwater from seleniferous soils. In the United States, about 4.6 million kg of selenium are released annually into the environment: 33% from combustion of fossil fuels, 59% from industrial losses, and 8% from municipal wastes. Of the total, about 25% is in the form of atmospheric emissions, and the rest in ash. Mining and smelting of copper-nickel ores at Sudbury, Ontario, Canada, alone releases about 2 metric tons of Se to the environment daily, and probably represents the greatest point source of Se release in the world. In 1977, 680,000 kg of Se was produced at Sudbury, but only about 10% was recovered, suggesting that about 90% was lost to the environment. Of the amount lost, perhaps 50 metric tons was dispensed into the atmosphere, probably as selenium dioxide (airborne Se levels 1-3 km from Sudbury were as high as 6.0 $\mu g/m^3$). The rest was probably associated with mine tailings, wastewater, and scoria, and is a local source of Se contamination, most notably in lakes. The present annual rates of Se accumulation in lake sediments in the Sudbury area range from 0.3 to 12.0 mg/m^2; these deposition rates exceed those of pre-colonial times by factors of 3 to 18, and are among the highest recorded in North America (Nriagu and Wong 1983).

Selenium is a serious hazard to livestock and probably to people in a wide semiarid belt that extends from inside Canada southward across the United States into Mexico (NRC 1983). Selenium tends to be present in large amounts in areas where the soils have been derived from Cretaceous rocks. Total Se in such soils averages about 5 ppm, but is sometimes as high as 80 ppm. Lack of rainfall has prevented the solution of the Se minerals and the removal of their salts in drainage waters. In some areas, modern fertilization practices and the buildup of sulfates in the soil due to acid precipitation partly lessen the availability of Se to plants and forage crops. In the United States, highly seleniferous natural areas (200-300 ppb in forage) are most abundant in the Rocky Mountain and High Central Plains areas; areas with lower concentrations (20-30 ppb) in forage are typical in the Pacific Northwest and the Southeast. However, huge variations are not uncommon from one specific location to another. Among plants, primary and secondary selenium accumulators are almost always implicated in cases of acute or chronic selenium poisoning of livestock. Primary Se accumulator plants, such as various species of *Astragalus*, *Oonopsis*, *Stanelya*, *Zylorhiza*, and *Machaeranthera*, may require 1 to 50 ppm Se in either soil or water for growth, and may contain 100 to 10,000 ppm Se as a glutamyl dipeptide or selanocystanthionine. Secondary accumulator plants (representative genera: *Astor*, *Gutierrezia*, *Atriplex*, *Grindelia*, *Castilleja*, and *Comandra*) grow in either seleniferous or nonseleniferous soils and may contain 25-100 ppm Se. Nonaccumulator plants growing on seleniferous soils contain 1-25 ppm fresh weight of Se. Meat and eggs of domestic animals may contain 8-9 ppm of Se in seleniferous areas, compared with 0.01-1.0 ppm in nonseleniferous areas. Tissues from animals maintained on high-Se feeds generally contain 3-5 ppm Se fresh weight vs. up to 20 ppm in animals dying of Se poisoning (Harr 1978).

Selenium is nutritionally important as an essential trace element, but is harmful at slightly higher concentrations. Although normal Se dietary levels required to ensure human health range from 0.04 to 0.1 ppm, toxicity may occur if food contains as little as 4.0 ppm. Minimum Se concentrations required are usually higher in livestock than in humans. In areas with highly seleniferous soils, excess Se is adsorbed onto a variety of plants and grains and can be fatal to grazing livestock. There is general agreement, however, that selenium inadequacy can be of greater concern to health than is selenium toxicity. Studies in humans and small animals indicated that Se deficiency (in part) underlies various chronic diseases, increasing susceptibility to cancer, arthritis, hypertension, heart disease, and possibly periodontal disease and cataracts. Selenium reportedly protects mammals and some birds against the toxic effects of mercury, cadmium, arsenic, thallium, and the herbicide paraquat (Hill 1975; Wilber 1983). There is no doubt that high dietary levels of these compounds, as well as of salts of copper, zinc, and silver, contribute to selenium deficiency effects. However, too little is known of the chemical mechanisms to enable scientists to account for these phenomena. Selenium has a comparatively short effectual biological life in various species of organisms for which data are available. Studies with radioselenium-75 indicated that its biological half-life is 10 to 64 days: 10 in pheasants, 13 in guppies and voles, 15 in ants, 27 in eels, 28 in leeches, and 64 in earthworms (Wilber 1983). Many investigators concluded that the greatest current and direct use of selenium is in the transportation of grains grown in seleniferous areas to Se-deficient areas as animal and human food.

BACKGROUND CONCENTRATIONS

Selenium concentrations in nonbiological materials extend over several orders of magnitude (Table 1). In terrestrial materials, concentrations in excess of 5 ppm Se are routinely recorded in meteorites, copper-nickel ores, coal and other fossil fuels, lake sediments in the vicinity of a nickel-copper smeltery, and in sediments of fly ash settling ponds. Water concentrations exceeding 50 ppb Se have been documented in groundwater, especially in areas with seleniferous soils, in sewage wastes, in irrigation drain water, and in water of fly ash settling ponds. Selenium concentrations in air samples were >0.5 $\mu g/m^3$ in the vicinity of Se production plants, and these were at least 500 times higher than in a control area. As a result of natural and anthropogenic processes, comparatively high concentrations of selenium in nonbiological materials may pose significant risks to fish and wildlife (this point is discussed later).

Selenium concentrations in representative species of freshwater, marine, and terrestrial flora and fauna are listed in Table 2. Additional information on body and tissue burdens of selenium was given by Birkner (1978), Jenkins (1980), Lo and Sandi (1980), Eisler (1981), and Wilber (1983). It is emphasized that, for all organisms, Se concentrations tended to be significantly higher when collected from locales having certain characteristics: highly seleniferous soils or sediments (*in* Comparative studies of food and environmental contamination. Int. Atomic Energy Agency, Vienna.de Goeij et al. 1974; Birkner 1978; Speyer 1980; Wilber 1983); high human population densities (Beal 1974); heavy accumulations of Se-laden wastes, such as effluents from systems used to collect fly ash scrubber sludge or bottom ash (Cumbie and Van Horn 1978; Sorensen et al. 1982, 1984); and Se-contaminated subsurface irrigation drainwater (Ohlendorf et al. 1986). There is evidence that Se concentrations are positively correlated with mercury residues in piscivorous mammals (Reijnders 1980; Wren 1984) and teleosts (Ganther et al. 1972; Leonzio et al. 1982), although the evidence for teleosts is conflicting (Tamura et al. 1975; Speyer 1980; Maher 1983), and that Se varies seasonally in crustaceans (Zafiropoulos and Grimanis 1977). In general, concentrations of Se in various tissues are usually higher in older than in younger organisms; among marine vertebrates, Se increases were especially pronounced among the older specimens of predatory, long-lived species (Eisler 1984).

All reported Se levels in tissues of marine invertebrates and plants have been less than 2 ppm Se on a wet weight basis, or 12 ppm dry weight. Higher levels are routinely recorded in liver and kidney tissues of marine and coastal vertebrates, including teleosts, birds, and mammals. Livers from adult seals were comparatively rich in selenium (Table 2); however, high concentrations in liver of maternal California sea lions were not reflected in liver of newborn pups (Martin et al. 1976). Mean concentrations of Se in kidneys of seven species of coastal birds collected from the highly industrialized Corpus Christi, Texas, area usually varied between 1.7 and 5.6 ppm Se fresh weight, but were 10.2 ppm in one bird. According to White et al. (1980), Se concentrations of this magnitude may be sufficient to impair reproduction in shorebirds.

Selenium levels in freshwater biota are relatively low, compared with those in their marine counterparts. In freshwater organisms, about 36% of the total Se was present as selenate, and the rest as selenite and selenide. In marine samples, only 24% of the total Se was present as selenate (Cappon and Smith 1982). The implications of this difference are not now understood, but have great relevance in the ability of Se to complex and detoxify various potentially toxic heavy metals, such as mercury and cadmium. In the most recent Nationwide monitoring of selenium and other contaminants in freshwater fishes, Se ranged from 0.05 to 2.9 ppm (fresh weight, whole fish) and averaged about 0.6 ppm; stations where concentrations in fish exceeded 0.82 ppm (>85th percentile) were in three areas: Atlantic coastal streams; Mississippi River system; and California (May and McKinney 1981). Among fish from Atlantic coastal streams, those from the Delaware River near Camden, New Jersey, had elevated whole body concentrations (i.e., >1.0 and <3.0 ppm Se), which were attributed to the industrialized character of the river. In the Big Horn and Yellowstone Rivers, high Se concentrations in fish may result from geologic sources of the element, including coal, phosphate, and sedimentary rock. Fish from the South Platte River near Denver, Colorado, may receive Se from industrial effluents, or from natural and anthropogenic activities associated with the removal of deposits of coal, barite, and sulfur. In California, where Se was elevated in fish from the San Jouquin River, it was speculated that Selocide, an Se-containing pesticide registered for use on citrus fruits in the 1960's, may have been a source, although contaminated irrigation drain water was considered a more likely possibility (Ohlendorf et al. 1986).

Among terrestrial plants, selenium accumulations in species of *Aster*, *Astragalus*, and several other genera are sometimes spectacularly high (Table 2). *Astragalus* is the most widely distributed. About 24 of its more than 200 species are Se accumulators that require Se to grow well . The highest reported Se concentration in plants

was 15,000 ppm dry weight, in loco weed, *Astragalus racemosus* (Wilber 1983). Consumption of these and other Se-accumulating forage plants by livestock has induced illness and death from selenium poisoning. Even at much lower concentrations, Se may harm animals that eat considerable amounts of the forage. Plants that accumulate Se tend to be deeper rooted than the grasses and survive more severe aridity, thus remaining (unfortunately) as the principal forage for grazing in time of drought (Wilber 1983).

Table 2. Selenium concentrations in field populations of selected species of flora and fauna. Values shown are in total Se (mg/kg, or ppm) fresh weight (FW), dry weight (DW), or ash weight (AW). Hyphenated numbers show range and single numbers the mean; where both appear, the range is in parentheses.

DEFICIENCY AND PROTECTIVE EFFECTS

Selenium is a critical nutrient and a key component of several enzymes. There is a general consensus that Se deficiency in livestock is increasing in many countries, resulting in a need for added Se in the food. Selenium deficiency is considered by some researchers to constitute a greater threat to health than selenium poisoning. Studies with animals and humans have suggested that Se deficiency, in part, underlies susceptibility to cancer, arthritis, hypertension, heart disease, and possibly periodontal disease and cataracts (Frost and Ingvoldstad 1975; Shamberger 1981; Robberecht and Von Grieken 1982). These linkages have not yet been demonstrated conclusively; for example, eye lens cataract was induced in 10-day-old male rats by selenate, selenite, selenomethionine, and selenocystine, presumably through interference with glutathione metabolism (Ostadalova and Babicky 1980). On the other hand, adverse effects of Se inadequacy have been clearly documented for a wide variety of organisms, including bacteria, protozoans, Atlantic salmon, rainbow trout, Japanese quail, ducks, poultry, rats, dogs, horses, sheep, swine, cattle, antelopes, gazelles, deer, monkeys, and humans (Jensen 1968; Frost and Ingvoldstad 1975; *Methanococcus vanniellii*: culture and effects of selenium and tungsten on growth. J. Bacteriol. 130:1404-1406.

Jones and Stadtman 1975; Fishbein 1977; Harr 1978; Kaiser et al. 1979; Hilton et al. 1980; Shamberger 1981; Bovee and O'Brien 1982; Robberecht and Von Grieken 1982; NRC 1983; Levander 1983, 1984; Morris et al. 1984). Selenium deficiency, whether induced experimentally by use of low Se feeds supplemented with alpha tocopherol or by chronic ingestion of low Se diets, has caused a number of maladies: high embryonic mortality in cattle and sheep; anemia in cattle; poor growth and reproduction in sheep and rats; reduced viability of newly hatched quail; nutritional myopathy (white muscle disease) in sheep, swine, and cattle; hepatic necrosis and lameness in dogs, horses, and breeding bulls; hair loss and sterility in rat offspring; and spermatozoan abnormalities in rats. Deficiencies were usually prevented or reversed by supplements with sodium selenate or selenite at 100 ppb Se in the diet, or 20 µg Se/kg body weight administered parenterally.

The availability of Se to plants may be lessened by modern agricultural practices, eventually contributing to Se deficiency in animal consumers. For example, fertilizers containing nitrogen, sulfur, and phosphorus all influence Se uptake by plants through different modes of action, the net effect being a reduction in Se uptake (Frost and Ingvoldstad 1975). The buildup of sulfur (as sulfates) in the soil, due to acid rain, fertilizers, and other sources, interferes with Se accumulation by crops (Frost and Ingvoldstad 1975). In addition, high dietary levels of various heavy metals (including copper, zinc, silver, and mercury) contribute to Se deficiency in animals (Frost and Ingvoldstad 1975; Harr 1978), presumably as a result of Se binding with the metal into biologically unavailable forms (Harr 1978; Kaiser et al. 1979).

The protective action of selenium against the adverse or lethal effects induced by various metals and metalloids is well documented for a wide variety of plant and animal species. Among marine organisms, for example, selenium protects against toxic levels of mercury in algae (Gotsis 1982), shrimp (Lucu and Skreblin 1982), crabs and oysters (Glickstein 1978), fish (Sheline and Schmidt-Nielsen 1977), and mammals (Koeman et al. 1975). Similar observations have been recorded for copper and marine algae (Gotsis 1982); cadmium and freshwater snails (Wilber 1983), marine crabs (Bjerragaard 1982), earthworms (Helmke et al. 1979; Beyer et al. 1982), and rats (Harr 1978); mercury or methylmercury and rats (Cappon and Smith 1982), eggs of lake trout (Klaverkamp et al. 1983b), freshwater teleosts (Kim et al. 1975, 1977) and (temporarily) Japanese quail (El-Bergearmi et al. 1977, 1982; Beijer and Jernelov 1978); and arsenic and freshwater and marine teleosts (Luten et al. 1980; Orvini et al. 1980). Not all tests were conclusive. Studies with some species of freshwater teleosts demonstrated negligible antagonism of Se against mercury (Klaverkamp et al. 1983a) or cadmium (Duncan and Klaverkamp 1983). Selenium reportedly protects mammals and poikilotherms against poisoning by thallium, the herbicide paraquat, cadmium, mercury, lead, arsenic, and copper (Wilber 1983).

Reasons, to account for the antagonism of Se and heavy metals (here mercury is used as an example) include dietary source and chemical form of Se, influence of sulfur, biological translocation of Se or mercury to less critical body parts, and chemical linkage of Se to mercury on a linear basis. The exact mode of interaction is probably complex and has not yet been resolved. In regard to diet, Se of animal origin and in the form of selenate is less effective than Se from plant and inorganic sources in preventing methylmercury neurotoxicity in experimental animals (Cappon and Smith 1982). Disruption of sulfur metabolism by Se, the sulfur being replaced by seleno-amino acids and other cell constituents containing Se in living organisms, is one probable cause of Se poisoning. It is conceivable that Se-Hg compounds formed within the organism would be sufficiently

nonreactive biologically to interfere with sulfur kinetics, presumably -SH groups (Koeman et al. 1975; Beijer and Jernelov 1978; Cappon and Smith 1982; Gotsis 1982). Differential redistribution of Se or Hg to less critical body parts may partly account for observed antagonisms. Pretreatment of marine minnows with Se protects against Hg poisoning and causes a marked redistribution of Hg among organs, presumably to non-critical body parts, and this transfer may partly account for the observed Se-Hg antagonisms in that species (Sheline and Schmidt-Nielsen 1977). Some investigators have reported that Se results in increased Hg accumulations. Increased retention of Hg and other metals may lead to a higher level of biomagnification in the food chain and higher body burden in the individual, which might counteract the positive effect of decreased intoxication (Beijer and Jernelov 1978). Extensive research is under way on the chemical linkage of Se and Hg. In marine mammals and humans, Se and Hg concentrations are closely related, almost linearly in a 1:1 molar ratio, but this relation blurs in teleosts in which Se is in abundance, and fails in birds (Koeman et al. 1975; Beijer and Jernelov 1978; Orvini et al. 1980; Cappon and Smith 1982).

TOXICITY

MAMMALS AND BIRDS

“The element selenium can be traced in an orderly sequence from its origin in the earth's crust to specific geological formation, to distribution of specific genera and groups of plants which require the element for their growth, to the accumulation in vegetation, and to its subsequent toxicity to birds or mammals that consume the seleniferous foods” (Rosenfeld and Beath 1964). Selenium poisoning in livestock, discussed here, was largely extracted from reviews by Rosenfeld and Beath (1964), Frost (1972), Fishbein (1977), Harr (1978), Shamberger (1981), NRC (1983), and Wilber (1983).

In livestock, there are three basic types of selenium poisoning: acute, resulting from consumption (usually in a single feeding) of a sufficient quantity of highly seleniferous weeds; “blind staggers,” from consumption of moderately toxic amounts of seleniferous weeds over an extended period of time; and "alkali disease," caused by the consumption of moderately seleniferous grains and forage grasses over a period of several weeks to months.

Acute poisoning is associated with plant materials containing 400 to 800 ppm Se: sheep died when fed amounts of plant material ranging from 8 to 16 g/kg body weight, or about 3.2 to 12.8 mg Se/kg body weight. The minimum lethal dose of Se administered orally as selenite (mg Se per kg body weight) ranged from 3.3 for horses and mules to 11 for cattle and 15 for swine. Other modes of administration were more toxic, e.g., 2 and 1.2 mg Se/ kg body weight given subcutaneously killed swine in 4 hours and 5 days, respectively; and 1.5-6.0 mg Se/kg body weight given intravenously or intraperitoneally to rats and rabbits were fatal. Accidental toxicosis of sheep and cattle from overtreatment with commercial mixtures of Se salts and vitamin E are also documented for Australia and New Zealand. Acute Se poisoning in domestic livestock is characterized by abnormal movements, lowered head, drooped ears, diarrhea, elevated temperature, rapid pulse, labored breathing, bloating with abdominal pain, increased urination, and dilated pupils. Before death, which is due to respiratory failure, there is complete prostration and lethargy. Duration of illness extends from a few hours to several days, depending on the toxicity of plant material ingested. In these cases, Se is distributed by the circulatory system to all body organs, the concentrations being highest in liver, blood, kidney, spleen and brain, and lowest in muscle, skin, hair and bone. Elimination is primarily in the urine; smaller quantities are excreted with the feces, breath, perspiration, and bile. Postmortem examinations indicate many pathological changes in the heart, lungs, rumen, liver, kidney, and other organs. No effective treatment is known for counteracting toxic effects of large amounts of ingested selenium.

Chronic selenosis may be induced by dietary exposure to natural selenite, selenate, or seleniferous feedstuffs at dietary concentrations between 1 ppm (rat) and 44 ppm (horse), or from water containing 0.5 to 2.0 ppm of Se. Cattle fed 0.5 mg Se/kg body weight 3 times weekly lost their appetite; sheep fed up to 75 mg selenite daily developed myocardial degeneration and fibrosis, pulmonary congestion, and edema. The minimum toxic concentration of Se in lifetime exposure of rats (a comparatively sensitive species) fed Se-deficient diets fortified with Se was 0.35 mg Se/kg diet, as judged by changes in liver chemistry; and 0.75 mg Se/kg diet, as judged by longevity, and histological changes in heart, kidney, and spleen. These concentrations are 10 times the nutritional threshold for Se, and about 25% of the minimum lifetime exposure to Se in natural feedstuffs that produces similar effects under the same experimental conditions. Signs of chronic selenosis include skin lesions, lymph channel inflammation, loss of hair and nails, anemia, enlarged organs (spleen, pancreas, liver), fatigue, lassitude, and dizziness. “Blind staggers” is characterized by anorexia, emaciation, and sudden collapse, followed by death. Typically, the upper intestinal tract is ulcerated. In “alkali disease,” in cattle,

hogs, and horses that had eaten seleniferous grains, the signs were deformation and sloughing of the hooves, hair loss, lassitude, erosion of the articular cartilages, reduced conception, increased reabsorption of fetuses, and degeneration of heart, kidney, and liver. It is likely that Se displaces sulfur in keratin, resulting in structural changes in hair, nails, and hooves (Fishbein 1977).

Among birds, it appears that domestic chickens are extremely sensitive to Se; reduced hatching of eggs was recorded at 7 to 9 ppm Se in feed (Ort and Latshaw 1978). Similar results were observed by El-Bergearmi et al. (1977) in Japanese quail at 6 and 12 ppm dietary selenite. Studies in progress at the Patuxent Wildlife Research Center with adult mallards indicated that 100 ppm dietary selenium (as sodium selenite) was fatal within one month, but that survival was high at 25 ppm after 3 months. Poor egg hatchability was recorded in the 25 ppm selenite group, but not in the 10 ppm selenite group; however, hatching percent was reduced in eggs of adults fed 10 ppm of Se as selenomethionine (Dr. G. Heinz, pers. comm.). It appears obvious that additional research is needed on the toxicology of organoselenium compounds.

Selenosis in warm blooded organisms is modified by numerous factors, including method of administration, chemical form of Se, dietary composition, and age and needs of the organism. For example, Se administered in natural feedstuffs is only about one-fourth as toxic as are similar exposures in water or purified feeds (Harr 1978). Concurrent ingestion of minerals and rough or high protein feeds reduces Se toxicity, and exposure by diet is less toxic than exposure parenterally or by inhalation.

Many compounds are known to prevent or reduce toxic effects of subacute and chronic selenosis in pigs, beef cattle, and other warmblooded organisms. A partial list includes arsenic, strychnine sulfate, tungsten, germanium, antimony, beet pectin, high-fat diets, ACTH injections, sulfate, increased dietary proteins, lactalbumin, ovalbumin, wheat protein, dried brewer's yeast, desiccated liver, linseed oil meal, glucosamine, hemocysteine, creatine, methionine, and choline. Not all of these compounds afforded equal protection against various Se formulations; the reasons for the difference are not clear, but it appears that the subject of selenoprotective agents warrants additional research effort.

AQUATIC ORGANISMS

Among sensitive species of aquatic organisms, death was observed at water concentrations between 60 and 600 ppb Se; early life history stages that were subjected to comparatively lengthy exposures accounted for most of these data (Table 3). Latent mortality after exposure to comparatively high Se concentrations has been documented, but not extensively. For example, all embryos of the zebrafish (*Brachydanio rerio*) survived exposure to 3,000 ppb of Se during development, but more than 90% of the resultant larvae died soon after hatching; at 1,000 ppb, survival was similar to that in controls (Niimi and LaHam 1975). It has been suggested (EPA 1980) that selenite is more toxic than selenate and is preferentially concentrated over selenate by mussels, *Mytilus galloprovincialis* (Measures and Burton 1980). Selenite is generally more toxic to early life history stages and effects are most pronounced at elevated temperatures (Klaverkamp et al. 1983a). Also, Se salts may be converted to methylated forms by microorganisms, and these are readily accumulated by aquatic vertebrates (Klaverkamp et al. 1983a). Among freshwater algae species, it has been demonstrated that selenite, selenate, selenomethionine, and selenopurine are all toxic, but that sulphur, as sulphate, has a significant protective role against Se toxicity (Kumar and Prakash 1971). Numerous additional chemical compounds and mixtures probably protect against Se toxicity, much as Se protects against toxic effects of mercury salts and other chemicals, but data are sparse on Se protective agents.

Almost 50 years ago, Ellis et al. (1937) recorded a long list of signs of selenium poisoning in teleosts: loss of equilibrium, lethargy, contraction of dermal chromatophores, loss of coordination, muscle spasms, protruding eyes, swollen abdomen, liver degeneration, reduction in blood hemoglobin and erythrocyte number, and increase in white blood cells. Sorensen et al. (1984), observed most of these signs in Se-poisoned green sunfish together with elevated liver Se concentrations, reduced blood hematocrit, enlarged liver, histopathology of kidney and heart, swollen gill lamellae with extensive cellular vacuolization, and necrotic and degenerating ovarian follicles.

Table 3. Toxicity of selenium salts to aquatic biota. Values shown are in µg/l (ppb) in medium fatal to 50% of the organisms during exposure for various intervals.

SUBLETHAL AND LATENT EFFECTS

Results of laboratory studies and field investigations with fish, mammals, and birds have led to general agreement that elevated concentrations of selenium in diet or water were associated with reproductive abnormalities including congenital malformations, selective bioaccumulation by the organism, and growth retardation. Not as extensively documented, but nevertheless important, are reports of selenium-induced chromosomal aberrations, intestinal lesions, shifts in species composition of freshwater algal communities, swimming impairment of protozoans, and behavioral modifications.

AQUATIC ORGANISMS

In green sunfish from a lake in North Carolina receiving selenium (as fly ash wastes from a coal-fired power station), reproduction failed and the population declined markedly. In these fish, Se levels were elevated in liver (up to 21.4 ppm fresh weight) and other tissues; kidney, heart, liver, and gill showed histopathology; and blood chemistry was altered. Ovaries of fish had numerous necrotic and ruptured egg follicles that may have contributed to the population extinction (Sorensen et al. 1984). It is probable that Se uptake by plankton (containing 41-97 ppm dry weight) from lake water (9-12 ppb) introduced Se to the food chain where it ultimately reached elevated levels in fish through biomagnification (Cumbie and Van Horn 1978). In laboratory tests, however, eggs of common carp hatched normally when incubated in media containing 5,000 ppb of Se (Huckabee and Griffith 1974), as did eggs of lake trout (*Salvelinus namaycush)* at 10,000 ppb of Se (Klaverkamp et al. 1983b). In frogs (*Xenopus laevis*), cranial and vertebral deformities and lowered survival were documented during development in water with Se concentrations of 2,000 ppb or higher (Browne and Dumont 1979).

At water concentrations of 47 to 53 ppb, Se was associated with anemia and reduced hatch of rainbow trout (Hodson et al. 1980), growth retardation of freshwater green algae (Hutchinson and Stokes 1975; Klaverkamp et al. 1983a), and shifts in species composition of freshwater algal communities (Patrick 1978). At 250 ppb Se, growth was reduced in rainbow trout fry after exposure for 21 d (Adams 1976), and goldfish demonstrated an avoidance response after 48 h (Weir and Hine 1970). At Se water concentrations of 7,930-11,000 ppb, growth

was inhibited in freshwater and marine algae (Patrick 1978; EPA 1980), and swimming rate was reduced in the protozoan *Tetrahymena pyriformis* (Bovee and O'Brien 1982). Eggs of channel catfish exposed to certain metals (including cadmium, mercury, and copper) produced an increased percentage of albino fry; however, eggs exposed to 250 ppb Se produced fry with normal pigmentation (Westernman and Birge 1978).

A significant number of chromosomal aberrations was induced in the edible goby, *Boleophthalmus dussumieri*, by Se after intramuscular and water exposures (Krishnaja and Rege 1982). Intramuscular injections of Se as low as 0.1 mg/kg body weight, or 3,200 ppb in the water column, were associated with a marked enhancement of polyploid cells 76-96 h postadministration; some deaths were recorded at higher test concentrations. Selenite was more effective than selenate in inducing chromosomal aberrations. The authors concluded that a relatively narrow range of Se concentrations lead to a mutagenic rather than a lethal effect.

Accumulation of Se by aquatic organisms is highly variable. In short-term (48 h) laboratory tests at Se water concentrations of 0.015 to 3.3 ppb, Nassos et al. (1980) reported biological concentration factors (BCF) of 460 for mosquitofish to 32,000 for a freshwater gastropod; values were intermediate for daphnids (2,100), plankton (2,600), and *Fundulus kansae* (3,300), the freshwater killifish. High BCF's (>680) were recorded for freshwater diatoms subjected to maximum concentrations of 40 ppb Se (Patrick 1978). Livers from rainbow trout and brown trout may contain from 50 to 70 ppm Se fresh weight during lifetime exposure in seleniferous (12.3-13.3 ppb) water, and have BCF values of 3,759 to 5,691 (Kaiser et al. 1979); BCF values were 361 to 390 for skin, and about 180 for muscle (Kaiser et al. 1979). In short-term exposures, most of the Se was probably adsorbed to the body surface (Fowler and Benayoun 1976c), and was then rapidly lost on transfer to Se-free media (Browne and Dumont 1979). In longer exposures, the BCF values in aquatic organisms were lower after immersion in high ambient Se concentrations over extended periods. Thus, marine crabs exposed to a water concentration of 250 ppb of Se for 29 days accumulated Se over water concentration level by a factor of 25 for carapace, and 3.8 for gill; accumulations in muscle and hepatopancreas were negligible. Cadmium in solution enhanced Se uptake (Bjerragaard 1982). Exposure of common carp to 1,000 ppb Se for 85 days resulted in a whole body BCF of 6; additional studies of 7 weeks exposure plus 7 weeks postexposure at Se concentrations between 500 and 5,000 ppb (Sato et al. 1980) yielded a BCF range of 0.6 (5,000 ppb) to 1.8 (500 ppb). Highest BCF's in carp were 50 for kidney and 80 for liver after exposure of the fish to 100 ppb Se for 7 weeks plus 7 weeks in Se-free media. For carp, Se tended to accumulate in kidney, liver, gill, gall bladder, heart, bone, and muscle, in that general order (Sato et al. 1980). Studies with freshwater organisms collected from a farm pond contaminated by fly ash with high Se levels (Furr et al. 1979), and with marine bivalves and nereid worms held for 4 months in seawater flowing through coal fly ash containing 6,200 ppb Se (Ryther et al. 1979), showed that accumulation was slight. Contrasted to this are the observations of Cherry et al. (1976) and Ohlendorf et al. (1986). Cherry and his coworkers collected mosquitofish from a drainage system that received high coal fly ash concentrations at one end and thermal discharges at the other; mosquitofish contained up to 9.0 ppm Se whole body fresh weight. Of 40 elements examined, only Se, zinc, and calcium were accumulated in excess of the levels measured in the water. Ohlendorf et al. found mean residues of 172 ppm dry weight (range 110-280 ppm) in whole mosquitofish from irrigation drainwater ponds contaminated by about 300 ppb of Se; based on a wet/dry factor of 4, the BCF for whole mosquitofish was >91.

Selenium accumulation is modified by water temperature, age of the organism, organ or tissue specificity, mode of administration, and other factors. In the marine mussel, *Mytilus galloprovincialis*, an increase in water temperature from 13 to 29°C doubled the BCF in 13 days (Fowler and Benayoun 1976b). Mussels preferentially accumulated selenite over selenate (Fowler and Benayoun 1976b); however, mussels did not reach a steady state in 63 days (Fowler and Benayoun 1976c), indicating that Se kinetics in some species are difficult to elucidate in short-term studies. Accumulation rates were higher in small than in large mussels (Fowler and Benayoun 1976b), as they were in freshwater teleosts (Furr et al. 1979). However, the reverse was documented for marine mammals and teleosts (Eisler 1984). When Se was available from both the diet and the medium, concentrations were highest in liver, kidney, and gills of teleosts (Sorensen et al. 1982; Furr et al. 1979; Kaiser et al. 1979), exoskeleton of crustaceans (Fowler and Benayoun 1976c; Bjerragaard 1982), and visceral mass and gills of molluscs (Fowler and Benayoun 1976c). When Se was administered in food to marine shrimps, concentrations were highest in viscera and exoskeleton, suggesting that ingested Se is readily translocated from internal to external tissues (Fowler and Benayoun 1976c). Concentrations of Se in crustaceans usually were higher in fecal pellets than in the diet; fecal pellets may represent a possible biological mechanism for downward vertical transport of Se in the sea (Fowler and Benayoun 1976a), as well as in freshwater environments.

The time for 50% excretion of accumulated Se has ranged from 13 to 181 days in various species of marine and freshwater fauna. Biological half-life of Se accumulated from the medium has been estimated at 28 days for carp (Sato et al. 1980), 37 days for the marine euphausid crustacean *Meganyctiphanes norvegica* (Fowler and Benayoun 1976a), 63 to 81 days for the marine mussel *Mytilus galloprovincialis* (Fowler and Benayoun 1976b), 58 to 60 days for the marine shrimp *Lysmata caudata* (Fowler and Benayoun 1976b), and, as reviewed by Stadtman (1974, 1977), 13 days for guppies, 27 days for eels, and 28 days for leeches. Studies by Lemly (1982a) with bluegills and largemouth bass showed elevated tissue levels after exposure to 10 ppb of Se for 120 days. Time for 50% excretion in 30-day elimination trials was about 15 days from gill and erythrocytes; however, there was essentially no elimination from spleen, liver, kidney, or muscle. It appears that research is needed on preferential tissue retention of Se and its implications for biochemical and metabolic transport mechanisms.

TERRESTRIAL INVERTEBRATES

Concentrations of Se decreased in whole earthworms from 22.4 to 15.0 ppm (dry weight) as the rate of sludge application increased from 15 to 60 metric tons/ha. Concentrations of Se in soil and sludge were 0.3 and 0.5 ppm dry weight, respectively (Helmke et al. 1979). Other studies indicated that some metals, notably cadmium, decreased in worms living in soils amended with sewage sludge but that Se concentrations were not affected (Beyer et al. 1982). The biological half life of Se in earthworms is estimated to be 64 days, a period consistent with values of 10 to 81 days documented for ants, birds, mammals, and aquatic biota (Stadtman 1974, 1977).

BIRDS

Embryos of the domestic chicken (*Gallus domesticus)* are extremely sensitive to Se. The hatchability of eggs is reduced by concentrations of Se in feeds(6 to 9 ppm) that were too low to produce poisoning in other avian species. Dietary Se excess was associated with decreased egg weight, decreased egg production and hatchability, anemia, elevated kidney Se residues in chicks, and a high incidence of grossly deformed embryos with missing or distorted eyes, beaks, wings and feet (Ort and Latshaw 1978; Harr 1979). Selenomethionine was more effective than sodium selenite in raising the Se content of tissues and eggs (Moksnes 1983). Until recently, there was little credible evidence that selenium adversely affected wild birds. However, Ohlendorf et al. (1986) reported severe reproductive effects in ducks (*Anas* spp.), American coot (*Fulica americana*), and other species of aquatic birds nesting at irrigation drainwater ponds in the San Joaquin Valley, California. Water in these ponds contained abnormally high concentrations of about 300 ppb of Se, but low or non-detectable levels of silver, chromium, arsenic, cadmium, mercury, lead, and zinc. Of 347 nests examined from this site, about 40% had at least one dead embryo and about 20% had at least one embryo or chick with obvious external anomalies, including missing or abnormal beaks, eyes, wings, legs, or feet. In addition, brain, heart, liver, and skeletal anomalies were recorded. Concentrations of selenium (ppm, dry weight) were 2-110 in eggs and 19-130 in livers of birds, 12-79 in plants, 23-200 in invertebrates, and 110-280 in fish from the ponds, or 7 to 130 times those found at a nearby control area. It was concluded that Se was the probable cause of poor reproduction and developmental abnormalities in the aquatic nesting birds, due to interference with their reproductive processes. The concentrations of Se in breast muscle of coots were sufficiently high (up to 11.0 ppm fresh weight) to induce State agencies to post the area, advising against the consumption of more than one meal per week of this species, or of any coots by children or pregnant women (Ohlendorf et al. 1986).

In studies at the Patuxent Wildlife Research Center, Dr. G. Heinz (pers. comm.) is evaluating effects of dietary Se on mallard reproduction. Ducks given diets containing 100 ppm of inorganic selenite usually died within a month; for some time before death they exhibited reduced food intakes (bordering on repellence) and significant weight loss. In birds receiving 25 ppm, survival was high after 3 months, but growth and reproduction were dramatically reduced. Teratogenic effects were evident at 3 months in ducklings of mallards receiving 10 ppm, and preliminary evidence suggested that selenomethionine at 10 ppm dietary Se was more effective than inorganic selenite in producing developmental abnormalities. Ducks and their progeny appeared normal after 3 months of exposure to 5 ppm and less of dietary selenite.

MAMMALS

Harr (1978) and NRC (1983) summarized nonlethal effects of selenium on mammals, including reproductive anomalies. Selenosis caused congenital malformations in rats, mice, swine, and cattle. In general, young born to females with selenosis were emaciated and unable to nurse. Mice given Se in drinking water reproduced normally for three generations, but litters were fewer and smaller when compared to controls, pups were runts with high mortality before weaning, and most survivors were infertile.

In rats, selenium did not induce cirrhosis or neoplasia; however, intestinal lesions were observed among those fed diets containing 0.8 to 1.0 ppm Se during lifetime exposure. The threshold requirement for optimal rat nutrition under similar conditions is about 0.08 ppm, again demonstrating the relatively narrow range separating selenium deficiency from selenium poisoning. Absorption of oral radioselenite by rats was as high as 95 to 100%. A single dose of radioselenite concentrated in the pancreas, intestine, erythrocytes, liver, kidney and testes, in that general order; tissue distributions from chronic exposure were similar. As expected, levels of Se in poisoned rats were highest in liver and kidney. Rats, and probably other mammals, can regulate dietary Se accumulations. Dietary concentrations in excess of 54-84 ppb were usually excreted in urine; however, when Se intake exceeded 1,000 ppb, pulmonary excretion was active. Excretion of Se in feces, bile, saliva, and hair appears to be relatively constant regardless of the amount of exposure. Yonemoto et al. (1983) demonstrated that some selenotoxic effects in mice, including abortion and maternal death, were prevented by prior treatment with vitamin E, but exacerbated by reduced glutathione; the mechanisms for these interactions are unknown, and merit additional research.

Table 4. Proposed selenium criteria for prevention of Se deficiency and for protection against selenosis.

Criterion	Selenium concentration	Reference
PREVENTION OF		
SE DEFICIENCY		
Rainbow troup, *Salmo gairdneri*		
(water levels of 0.4 ppb Se)	70 ppb in diet	Hilton et al. 1980
Poultry	30-50 ppb in diet	Fishbein 1977

CURRENT RECOMMENDATIONS

All investigators appear to agree on four points. First, that insufficient selenium in the diet may have harmful and sometimes fatal consequences. Second, that exposure to grossly elevated levels of Se in the diet or water, is inevitably fatal over time to terrestrial and aquatic organisms. Third, that there is a comparatively narrow concentration range separating effects of selenium deficiency from those of selenosis. And fourth, that additional fundamental and basic research is required on selenium metabolism, physiology, recycling, interactions with other compounds or formulations, and chemical speciation in order to elucidate its nutritive role as well as its toxic effects. Accordingly, the proposed selenium criteria shown in Table 4 for prevention of Se deficiency and for protection of aquatic life, livestock, crops, and human health, should be viewed as guidelines, pending acquisition of additional, more definitive, data.

Regarding Se deficiency, it appears that diets containing 50 to 100 ppb Se provide adequate protection to humans and to various species of fish, small laboratory mammals, and livestock (Table 4). Factors contributing to Se deficiency in crops include increasing use of agricultural fertilizers and increasing atmospheric fallout of sulfur; furthermore, foliar applications of selenate, although efficient in raising Se levels in plants, have only

short-term value (Frost and Ingvoldstad 1975). There is a general consensus that Se deficiency in livestock in many countries is increasing, resulting in a need for added Se in the food chain.

Current recommendations for protection of freshwater aquatic life are that inorganic selenite concentrations in the water should not exceed 35 ppb on a daily average, or 260 ppb at any time (Table 4). These values are higher for saltwater life: 54 ppb daily average, 410 ppb at any time. The concentration range of 35 to 54 ppb recommended for protection of aquatic life is below the range of 60 to 600 ppb that is fatal to various sensitive species of marine and freshwater fauna, and in this respect affords an adequate measure of protection. It is very near the range (47 to 53 ppb) that has been associated with growth inhibition of freshwater algae, anemia and reduced hatch in rainbow trout, and shifts in species composition of freshwater algal communities. But studies by Cumbie and Van Horn (1978) and Sorensen et al. (1984) showed that water concentrations of 9 to 12 ppb of Se were associated with reduced reproduction of freshwater fishes, and their results strongly indicated that some downward modification of the Se freshwater aquatic life protection criterion may be appropriate. Furthermore, high bioconcentration and accumulation of Se from the water column by numerous species of algae, fish, and invertebrates is well documented at levels between 0.015 and 3.3 ppb, which is substantially below the recommended range of 35 to 54 ppb. The significance of Se residues in aquatic biota in terms of bioavailability and Se receptor sites is imperfectly understood, and it appears that much additional research is warranted on Se pharmacokinetics in aquatic environments.

Livestock appear to be protected against selenosis provided that their diets contain less than 4,000 ppb of natural (i.e., nonsupplemented) selenium (Table 4). This concentration is somewhat higher than levels reported for rats (Wilber 1983). Minimum toxic concentrations of Se in lifetime exposure of rats given diets containing natural Se were 1,400 ppb dietary Se, as judged by evidence of liver changes, and 3,000 ppb as estimated from longevity and histological changes in heart, kidney, and spleen. These values were only 350 and 750 ppb, respectively, when rat diets contained purified, rather than natural, Se. This relationship emphasizes that accidental poisoning of livestock, and presumably fish and wildlife, may occur when soils are deliberately supplemented with purified Se, or when soils or aquifers are contaminated as a result of faulty waste disposal practices. Although the concentration of <50 ppb for livestock drinking water and irrigation water for crop protection is inconsistent with that of < 35 ppb for aquatic life protection, neither livestock nor crops appear threatened at the higher level. Since many waterways that abut agricultural lands or areas of high anthropogenic loadings of Se contain valuable and desirable aquatic species, it would appear that some downward modification of the current livestock drinking water concentration of Se is necessary.

Recent field studies demonstrated that migratory waterfowl were heavily and adversely affected while nesting at Se-contaminated irrigation drainwater ponds in California, where food chain organisms contained between 12,000 and 280,000 ppb of Se. The source and fate of Se in irrigation drainwater ponds are largely unknown; they must be determined so that alternate technologies for Se control can be implemented to protect waterfowl in that geographical region.

Aerosol concentrations in excess of 4.0 µg Se/m^3 are potentially harmful to human health (Harr 1978); concentrations in excess of this value (6.0 µg Se/m^3) were regularly encountered in the vicinity of the smeltery at Sudbury, Canada (Nriagu and Wong 1983). It is not now known whether respiration rates of wildlife, particularly birds, are comparable to those of humans, or whether Se absorption energetics are similar, or whether wildlife species that frequent point sources of air contaminated by high Se levels for protracted periods are at greater risk than humans. Until additional and more conclusive data become available, aerosol concentrations of less than 4.0 µg Se/m^3 are recommended for the protection of sensitive species of wildlife.

Acute lethal doses for livestock species ranged from 3,300 µg/kg body weight of Se for horses and mules to 15,000 µg/kg for swine; appetite loss in cattle was noted at 500 µg/kg. For humans, the maximum tolerance level is usually set at 500 µg of Se daily (Lo and Sandi 1980), and the “safe” level at 200 µg/day (Shamberger 1981). Selenium dietary levels for man should not exceed 5,000 ppb; however, recommended maximum dietary levels in other mammals ranged from 1,000 ppb for rats to 4,000 ppb for horses. For all species, including man, there is a tendency to list Se dosage levels in terms of “natural” and “supplemented” levels, with the tacit understanding that “natural” levels are about one-fourth as toxic as “supplemented” values. Given the complexities of Se metabolism and speciation, it appears that greater precision and clarity are necessary in formulating Se criteria if these criteria are to become administratively enforced standards through passage of appropriate legislation.

CHROMIUM HAZARDS TO FISH, WILDLIFE, AND INVERTEBRATES: A SYNOPTIC REVIEW

by
Ronald Eisler

Patuxent Wildlife Research Center
U.S. Fish and Wildlife Service
Laurel, MD 20708

SUMMARY

Ecological and toxicological aspects of chromium (Cr) in the environment are reviewed, including its chemistry, background residues in biological and abiotic materials, beneficial and protective properties, and toxic and sublethal effects. Recommendations are presented, including proposed criteria for protection of sensitive species of wildlife and aquatic organisms.

Most authorities agree on eight points: (1) chromium levels are elevated in soil, air, water, and biota in the vicinity of electroplating and metal finishing industries, publicly owned municipal treatment plants, tanneries, oil drilling operations, and cooling towers; (2) hexavalent chromium (Cr+6) is the most biologically active Cr chemical species, although little is known about the properties of organochromium compounds, water soluble species, or their interactions in complex mixtures; (3) chromium chemistry is imperfectly understood, and existing analytical methodologies are inadequate for quantification of Cr species and ionic states; (4) chromium is an essential trace element in humans and some species of laboratory animals, but the data base is incomplete for other groups of organisms; (5) at high environmental concentrations, Cr is a mutagen, teratogen, and carcinogen; (6) no biomagnification of Cr has been observed in food chains, and concentrations are usually highest at the lowest trophic levels; (7) toxic and sublethal properties of Cr are modified by a variety of biological and abiotic factors; and (8) sensitivity to Cr varies widely, even among closely related species. As reported here, adverse effects of Cr to sensitive species have been documented at 10.0 ug/L (ppb) of Cr+6 and 30.0 ug/L of Cr+3 in freshwater and 5.0 ug/L of Cr+6 in saltwater and, to wildlife, 5.1 and 10.0 mg of Cr+6 and Cr+3, respectively, per kilogram of diet (ppm). Tissue levels in excess of 4.0 mg total Cr/kg dry weight should be viewed as presumptive evidence of Cr contamination, although the significance of tissue Cr residues is unclear. Some of these findings are in sharp contrast to Cr criteria proposed by regulatory agencies.

This report should be cited as:

TABLES

INTRODUCTION

Environmental effects of chromium (Cr) have been extensively reviewed (NAS 1974; Steven et al. 1976; Snyder et al. 1977; Towill et al. 1978; Taylor and Parr 1978Langard and Norseth 1979; Post and Campbell 1980; Hatherill 1981; Ecological Analysts 1981). These authorities agree that Cr is used widely in domestic and industrial products and that some of its chemical forms, primarily hexavalent chromium (Cr+6) and trivalent chromium (Cr+3), are toxic. In North America, thousands of tons of Cr ore and concentrates are imported annually for the production of stainless steels, chrome plated metals, pigments for inks and paints, and a wide variety of chemicals. Reports from Europe, Scandinavia, Asia, and North America all emphasize the high incidence of lung cancer and other respiratory diseases among workers involved in the manufacture of chromates. Others document that land dumping of wastes from chromate production and electroplating operations have been responsible for groundwater contamination; that discharge of Cr wastes into streams and lakes has caused damage to aquatic ecosystems and accidental poisoning of livestock; and that large amounts of Cr+3 and Cr+6 are reintroduced into the environment as sewage and solid wastes by the disposal of consumer products containing Cr.

In this account I briefly review the ecological and toxicological effects of Cr to fish and wildlife, with emphasis on migratory species, their predators, and their prey, and also provide current recommendations for the protection of sensitive species of concern to the U.S. Fish and Wildlife Service. This report is part of a continuing series of synoptic reviews prepared in response to informational requests from FWS environmental specialists.

ENVIRONMENTAL CHEMISTRY

The annual world production of chromium is estimated at 7 million metric tons; most of the ore, in the form of chromite ($FeOCr_2O_3$), is produced by the USSR and the Republic of South Africa. In the United States, chromium is used principally in metallurgy and chemical industries (Langard and Norseth 1979). Although natural mobilization of Cr by weathering processes is estimated at 32 thousand tons/year, the amounts of Cr added to the environment as a result of anthropogenic activities are far greater. New York City alone contributes about 440 tons of Cr annually to the environment (Steven et al. 1976). Major atmospheric emissions of Cr are from the chromium alloy and metal producing industries; lesser amounts come from coal combustion, municipal incinerators, cement production, and cooling towers (Towill et al. 1978). Atmospheric emissions contribute 4 to 6 times more Cr to aquatic ecosystems than do liquid wastes (Ecological Analysts 1981). In aquatic environments, the major sources of chromium are the electroplating and metal finishing industries and publicly owned treatment plants; relatively minor sources (other than localized contamination) are iron and steel foundries, inorganic chemical plants, tanneries, textile manufacturing, and runoff from urban and residential areas (Towill et al. 1978; Ecological Analysts 1981). Chromium in phosphates used as fertilizers may be an important source of Cr in soil, water, and some foods (Langard and Norseth 1979). In general, elevated levels of Cr in biological or other samples have been positively correlated with increased industrial and other uses of the element—especially uses associated with plating and foundry applications, chemical manufacturing, and corrosion inhibition (Taylor and Parr 1978).

Chromium, in the crystalline form, is a steel-gray, lustrous, hard metal characterized by an atomic weight of 51.996, an atomic number of 24, a density of 7.14, a melting point of 1900°C, and a boiling point of 2642°C. Four Cr isotopes occur naturally—Cr-50 (4.3%), -52 (83.8%), -53 (9.6%), and -54 (2.4%)—and seven are man-made. Elemental Cr is very stable, but is not usually found pure in nature. Chromium can exist in oxidation states ranging from -2 to +6, but is most frequently found in the environment in the trivalent (+3) and hexavalent (+6) oxidation states. The +3 and +6 forms are the most important because the +2, +4, and +5 forms are unstable and are rapidly converted to +3, which in turn is oxidized to +6 (Towill et al. 1978; Langard and Norseth 1979; Ecological Analysts 1981).

Most compounds prepared from chromite ore contain Cr in the more stable +3 and +6 states. The Cr in essentially all environmentally important Cr compounds is in one of these two oxidation states. Chromium in biological materials is usually in the +3 form (Langard and Norseth 1979), and is the form that functions as an essential element in mammals by maintaining efficient glucose, lipid, and protein metabolism (Steven et al. 1976). In general, the toxicity of trivalent chromium to mammals is low because its membrane permeability is poor and it is noncorrosive; further, there is little tendency for Cr+3 to biomagnify in food chains in the inorganic form. However, organo-trivalent Cr compounds may have significantly different accumulation tendencies

although little is known about these compounds (Steven et al. 1976). Hexavalent chromium is more toxic than the +3 form because its oxidizing potential is high and it easily penetrates biological membranes (Steven et al. 1976; Taylor and Parr 1978; Langard and Norseth 1979; Ecological Analysts 1981). Most of the Cr+6 found in nature is a result of domestic and industrial emissions (Steven et al. 1976). Interaction of +6 chromic oxide, dichromate, or chromate compounds with organic compounds can result in reduction to the comparatively less toxic trivalent form (Taylor and Parr 1978).

Little is known about the relation between concentrations of total Cr in a given environment and biological effects on the organisms living there. Depending on the physical and chemical state of the Cr, the same element concentration has a wide variety of mobilities and reactivities and thus has different effects (Steven et al. 1976). Chromium toxicity to aquatic biota is significantly influenced by abiotic variables such as hardness, temperature, pH, and salinity of water; and biological factors such as species, life stage, and potential differences in sensitivities of local populations (Ecological Analysts 1981). In both freshwater and marine environments, hydrolysis and precipitation are the most important processes that determine the fate and effects of chromium, whereas adsorption and bioaccumulation are relatively minor (Ecological Analysts 1981). Both Cr+3 and Cr+6 can exist in water with little organic matter; Cr+6 is usually the major species in seawater (Towill et al. 1978). Under oxygenated conditions, Cr+6 is the dominant dissolved stable Cr species in aquatic systems. The hexavalent form exists as a component of a complex anion that varies with pH and may take the form of chromate (CrO_4^{-2}), hydrochromate ($HCrO_4^{-1}$), or dichromate ($Cr_2O_7^{-2}$). These ionic Cr+6 forms are highly soluble in water and thus mobile in the aquatic environment. All stable Cr+6 anionic compounds strongly oxidize organic matter on contact and yield oxidized organic matter and Cr+3 (Ecological Analysts 1981). Trivalent Cr tends to form stable complexes with negatively charged inorganic or organic compounds, and thus is unlikely to be found uncomplexed in aqueous solution if anionic or particulate compounds (such as decaying plant or animal tissues, or silt or clay particles) are present (Steven et al. 1976; Pfeiffer et al. 1980; Ecological Analysts 1981). Precipitated Cr+3 hydroxides remain in the sediments under aerobic conditions; under low pH and anoxic conditions, however, Cr+3 hydroxides may solubilize and remain as ionic Cr+3 unless oxidized to Cr+6 through mixing and aeration (Ecological Analysts 1981). Among estuarine sediments, Cr content tends to be highest in those of small grain size and high organic and iron content; concentrations in European estuaries ranged from 3.9 mg/kg in intertidal sands to 162.0 mg/kg in anaerobic muds (Rehm et al. 1984). Adsorption of Cr by sediments is salinity-dependent; adsorption is greatest at salinities of 0.1 to 1.0 ‰ (Mayer and Schick 1981). Colloidal iron strongly scavenges Cr+3 from river water; flocculation of the colloids when they are mixed with seawater, coupled with lack of removal of the colloids to the sediments by gravitational settling or scavenging by suspended sediments, promotes the flux of Cr+3 through the estuary to the open ocean (Mayer et al. 1981).

The solubility and potential bioavailability of waste Cr added to soils through sewage sludge, animal manures, and industrial wastewater are modified by soil pH and organic complexing substances (James and Bartlett 1983a, 1983b). Although soil pH can affect oxidation rates of Cr+6 to Cr+3, organic complexes appear to play a more significant role. For example, organically complexed Cr+3 added to soils may remain soluble for at least a year, whereas the free Cr+3 metal ion in the absence of soluble complexing ligands quickly becomes adsorbed, or hydrolyzed and precipitated. The biological effects of organochromium compounds, which are not well documented, appear to be high-priority subjects for further research.

All toxic effects of Cr+6 seem to be related to the strong oxidizing action of chromates, and all biological interactions of chromates seem to result in reduction to the Cr+3 form and subsequent coordination to organic molecules (Langard and Norseth 1979).

Data on the environmental cycling of Cr are lacking, and those on the biochemistry of Cr are incomplete and sparse (Towill et al. 1978); it is clear that these two subjects merit additional research. Furthermore, there is increasing concern about the uncertainties in the analysis of some types of biological and environmental samples (Towill et al. 1978; Taylor and Parr 1978). For example, collaborating laboratories have reported order-of-magnitude differences in persistence of Cr in standard bovine liver. Until more is learned about the reasons for these differences, caution should be exercised in interpreting past analytical results.

BACKGROUND CONCENTRATIONS

Chromium concentrations in selected nonbiological materials are elevated in the vicinity of industrial operations and municipal waste treatment facilities where chromium is a significant component of wastes discharged into the environment (Tables 1 and 2). The bioavailability of Cr in these materials was mentioned earlier, but the mechanism still remains largely unknown. It is generally agreed that suspended particulates are a major source of transport in aquatic systems, that most Cr in soil and sediment is unavailable to living organisms, that Cr+6 in air and water is hazardous to fish and wildlife, and that the grossly elevated levels of Cr (especially inorganic fractions) in sludge components may have serious implications to wildlife when the sludge is applied to croplands.

Concentrations of Cr in representative species of plants and animals collected worldwide are shown in Table 3. Additional and more comprehensive data were given by Jenkins (1980) and Eisler (1981). Chromium concentrations in species of individual taxonomic groups tended to be elevated when collection localities were near electroplating plants, tanneries, oil drilling operations, sewage outfalls, drift cooling towers, dump sites, or other sources of Cr-containing wastes that were being discharged into the environment.

Among marine algae and invertebrates, for example, comparatively high concentrations of Cr were recorded in algae, clams, and annelids from the vicinity of electroplating plants; in crabs collected near an ocean dump site receiving large quantities of metals; and in algae and echinoderms near urbanized areas in Puerto Rico. Grossly elevated levels of Cr were also noted (Table 3) in selected plasma fractions of tunicate blood, in scales from a few species of teleosts, and in corals from Cr-rich areas containing high concentrations of scandium and titanium; however, these accumulations were not attributed to anthropogenic activities. Many factors are known to modify Cr levels. In marine molluscs, as one example, Cr concentrations tended to increase with the age of the organism (Eisler et al. 1978), but uptake was significantly inhibited at high salinities (Olson and Harrel 1973). Accidental contamination of field samples by metal particles in the samples, rust from stainless hydrowire, or flaking paint from the hull of the collecting ship may also constitute significant sources of elevated Cr residues (Martin and Knauer 1973). In terrestrial ecosystems, elevated Cr levels were reported in cotton rats and plants collected near drift cooling towers and in earthworms and plants from sludge-amended soils (Table 3). However, the high levels of Cr reported in the hair of pronghorns and elk (Table 3) require verification.

A major source of concern at present is the accuracy and precision of chromium analyses in biological samples. One interlaboratory calibration study, involving 87 laboratories, showed that an oyster homogenate averaged 1.1 ppm dry weight, with a standard deviation of 0.5 ppm (Fukai et al. 1978). This means that about 67% of the laboratories were in the range of 0.6 to 1.6 ppm and about 33% of the laboratories reporting were outside this range. It seems clear that more rigorous and more standardized sample preparation techniques and analyses for chromium are needed.

BENEFICIAL AND PROTECTIVE PROPERTIES

Chromium is essential for normal metabolism of insulin and glucose in humans (Langard and Norseth 1979) and for regulating carbohydrate metabolism in mammals (Preston et al. 1976; Onkelinx 1977; Gale 1978; Towill et al. 1978; Post and Campbell 1980). Chromium deficiency has been described in rats, guinea pigs, and squirrel monkeys; signs include reduced growth, decreased life span, elevated serum cholesterol, increased formation of aortic plaques, and signs resembling those of diabetes mellitus. Subjecting Cr-deficient animals to stress can exacerbate the signs (Preston et al. 1976). In humans, Cr deficiency has been suggested as a possible factor in the incidence of diabetes and atherosclerosis. Autopsy data from 31 areas of the world suggested that many Americans, but few non-Americans, were deficient in Cr. One characteristic feature of Cr levels in human tissues is a decline with increasing age (Onkelinx 1977).

Table 1. Chromium concentration in nonbiological materials collected worldwide.

Sample (units in parentheses)	Concentration	Reference[a]
Terrestrial (mg/kg)		
Earth's crust	100–300	1
"	mean, 125	2
Soils	5–300	3
"	trace to 250	2

Chromium is beneficial but not essential to growth in higher plants. Residues in plants seldom exceed a few parts per million, except in plants living on infertile serpentine soils containing high Cr concentrations, or grown on soils amended with sewage sludge. Plants with elevated Cr residues show no toxic effects, although concentrations in excess of 1 ppm in the aqueous medium may inhibit germination of the seed and growth of roots and shoots (Towill et al. 1978).

Chromium has proved effective in counteracting the deleterious effects of cadmium in rats and of vanadium in chickens. High mortality rates and testicular atrophy occurred in rats subjected to an intraperitoneal injection of cadmium salts; however, pretreatment with Cr ameliorated these effects (Stacey et al. 1983). In chickens, 10 ppm of dietary Cr counteracted adverse effects on albumin metabolism and egg shell quality induced by 10 ppm of vanadium salts (Jensen and Maurice 1980).

Additional research on the beneficial aspects of Cr in living resources appears warranted, especially where the organism is subjected to complex mixtures containing Cr and other potentially toxic heavy metals.

TOXICITY

GENERAL

Biocidal properties of chromium salts to aquatic organisms are modified, sometimes by an order of magnitude or more, by a variety of biological and abiotic factors. These include the species, age, and developmental stage of the organism; the temperature, pH, salinity, and alkalinity of the medium; interaction effects of Cr with other contaminants; duration of exposure; and chemical form of Cr tested. For hexavalent chromium, LC-50 (96 h) values for sensitive freshwater and marine species were between 445 and 2,000 ppb. For trivalent chromium, LC-50 (96 h) concentrations were 2,000 to 3,200 ppb for sensitive freshwater organisms and 3,300 to 7,500 ppb for marine biota.

Among warm-blooded organisms, hexavalent chromium was fatal to dogs in 3 months at 100 ppm in their food and killed most mammalian experimental animals at injected doses of 1 to 5 mg Cr/kg body weight, but had no measurable effect on chickens at dietary levels of 100 ppm over a 32-day period. Trivalent chromium compounds were generally less toxic than hexavalent chromium compounds, but significant differences may occur in uptake of anionic and cationic Cr+3 species, and this difference may affect survival.

AQUATIC ORGANISMS

Records of acute toxicities of hexavalent and trivalent chromium salts to representative species of aquatic life (Table 4) make it clear that Cr+6 is the more toxic to freshwater biota in comparatively soft and acidic waters, that younger life stages are more sensitive than older organisms, and that 96 h is insufficient to attain stable mortality patterns. There are at least five ionic species of hexavalent Cr, of which two—the hydrochromate ion and the chromate ion—are the predominant species and probably the agents that are toxic to freshwater life (Van der Putte et al. 1981b). However, water pH dramatically affects the concentration of each: as pH decreased from 7.8 to 6.5 the hydrochromate ion increased by a factor of about 3, and the chromate ion decreased by a factor of about 6.8 (Van der Putte et al. 1981b). More research is needed to fully elucidate chromium's mode of action. The organisms most sensitive to Cr+6, as judged by 96-h LC-50 values, were freshwater crustaceans and rotifers, and marine crustaceans, for which LC-50 values were 445 to 3,100 ppb;

longer exposures of 28 to 84 days produced LC-50 values of 200 to 500 ppb (Table 4). Other investigators had confirmed that Cr+6 is more toxic to freshwater daphnids and teleosts in water of comparatively low alkalinity, low pH, and low total hardness (Muller 1980). In marine teleosts, the toxicity of Cr+6 increased at elevated temperatures; furthermore, Cr was additive in toxicity when present as a component in a complex mixture of cadmium, zinc, and Cr+6 salts, (Negelski 1976).

For trivalent chromium and freshwater biota, toxicity was significantly increased in comparatively soft waters; this pattern was especially pronounced for daphnids (Table 4). Among freshwater teleosts, survival was reduced at comparatively low pH (EPA 1980). Also, organisms exposed previously to Cr+3 salts were not unusually sensitive or resistant when subjected to additional Cr+3—suggesting that they were unable to acclimatize or to become sensitized to Cr+3 (Stevens and Chapman 1984). As judged by 96-h LC-50 values, Cr+3 was toxic to sensitive freshwater organisms at concentrations of 2,000-3,000 ppb, or slightly less toxic than Cr+6 (Table 4). Toxicity of Cr+3, like that of Cr+6 increased with increasing exposure in rainbow trout. However, Cr+3 was significantly less toxic than Cr+6 in freshwater to salmon fingerlings, and was dramatically less toxic than Cr+6 to polychaetes and crustaceans (but not to molluscs or teleosts) in saltwater (Table 4).

Table 4. Acute toxicities of hexavalent and trivalent chromium to aquatic life.

Maximum acceptable toxicant concentrations (MATC) of chromium to aquatic life were derived from life cycle or partial life cycle exposures, and expressed as the highest concentration tested having no significant adverse effect on the characteristics measured—usually survival, growth, and reproduction—and the lowest concentration at which these effects were observed. For Cr and freshwater teleosts, MATC values ranged from as low as 51 to 105 ppb in rainbow trout to as high as 1,000 to 31,950 ppb in fathead minnows (Table 5). The most sensitive saltwater organism tested was a polychaete worm with a MATC range of 17 to 38 ppb (Table 5). For Cr+3 the MATC range for freshwater organisms was 47 to 1,400 ppb, which was quite similar to that for Cr+6 for freshwater life. No MATC data were available for Cr+3 and marine biota.

TERRESTRIAL INVERTEBRATES

Data on toxicity of Cr to terrestrial invertebrates are sparse. Studies conducted in India showed that a concentration of 10 to 15 ppm of Cr+6 in irrigation water, when applied to soils for agricultural purposes, was lethal to two species of earthworms in 58 to 60 days (Soni and Abbasi 1981; Abbasi and Soni 1983).

Table 5. Maximum acceptable toxicant concentration (MATC) values for hexavalent and trivalent chromium to aquatic life based on life cycle or partial life cycle exposures.

MAMMALS AND BIRDS

Acute and chronic adverse effects of chromium to warm-blooded organisms are caused mainly by Cr+6 compounds; there is little conclusive evidence of toxic effects caused by Cr+2 or Cr+3 compounds (Langard and Norseth 1979). Most investigators agree that chromium in biological materials is probably always in the trivalent state, that greatest exposures of Cr+3 in the general human population are through the diet (but no adverse effects have been reported from such exposures), and that no organic trivalent chromium complexes of toxicological importance have been described. Studies with guinea pigs fed Cr+3 for 21 weeks at concentrations up to 50 ppm dietary Cr+3 showed no adverse effects (Preston et al. 1976). Domestic cats were apparently

unaffected after exposure to aerosol levels of 80 to 115 mg Cr+3/m^3 for 1 h daily for 4 months, or after consuming diets with high amounts of chromic (Cr+3) salts over a similar period (Langard and Norseth 1979). When chromium was administered by injection, trivalent salts were substantially less toxic than hexavalent salts in producing effects in embryos of golden hamsters (Gale 1978). A similar pattern was evident in mice and in embryos of chickens. The LD-50's for mice were 260 mg/kg body weight for Cr+3, but only 5 mg/kg body weight for Cr+6 (Steven et al. 1976). For chicken embryos, the LD-50 values (mg/kg body weight) were 22.9 for Cr+3 and 1.7 for Cr+6 (Ridgeway and Karnofsky 1952). However, survival was depressed in young American black ducks fed 10 or 50 ppm dietary Cr+3 for 10 weeks—suggesting that black duck broods along the Atlantic coast (an area of high anthropogenic chromium discharge) may be adversely affected if they remain in contaminated areas for extended periods (Haseltine et al. 1985). In the black duck study, the authors administered chromium in the form of $CrK(SO_4)_2$ 12 H_2O; absorption of this anionic trivalent chromium compound (and an anionic hexavalent Cr compound) through black duck intestine was superior to that of cationic forms (Eastin et al. 1980).

Steven et al. (1976), in studies with Cr+6 and dogs, showed that 100 ppm in food for 3 months was fatal, that 11.2 ppm in drinking water was not lethal over a 4-year period (although significant accumulation was observed), and that 6.0 ppm in drinking water for 4 years had no measurable effects. In rats, 1,000 ppm dietary Cr+6 represented the toxic threshold, but all animals survived 134 ppm Cr+6 in drinking water for 3 months (Steven et al. 1976). For most mammalian experimental animals, including mice, dogs, rabbits, cats, and guinea pigs, the minimum injected fatal dose of Cr+6 ranged from 1 to 5 mg/kg body weight—although doses of 0.2 to 0.5 mg/kg body weight produced marked kidney damage (Steven et al. 1976). Repeated sublethal injections of Cr+6 did not promote tolerance in mice, but rather decreased the minimum lethal dose, suggesting that the animals were unable to develop tolerance to repeated chromium exposures (Steven et al. 1976). Investigators have not yet been able to identify a specific hexavalent Cr compound, or group of compounds, that could account for the most pronounced biological activity (Langard and Norseth 1979). A lethal oral dose of Cr+6 for a 14-year-old boy was estimated to be 10 mg/kg body weight—much lower than that tolerated by test animals on a repeated basis over a period of several months (Steven et al. 1976). Domestic chickens appear to be more resistant than mammals. No adverse effects were observed in chickens exposed to 100 ppm dietary Cr+6 in a 32-day study (Bosomer et al. 1961), although embryolethal and teratogenic effects have been observed in the range of 0.2 mg/kg (Gilani and Marano 1979) to 1.7-22.9 mg/kg (Ridgeway and Karnofsky 1952), depending on the method of administration.

SUBLETHAL EFFECTS

GENERAL

Under laboratory conditions, chromium is mutagenic, carcinogenic, and teratogenic to a wide variety of organisms, and Cr+6 has the greatest biological activity. However, information is lacking on the biological activities of water soluble Cr+3 compounds, organochromium compounds, and their ionic states. Aquatic plants and marine polychaete worms appear to be the most sensitive groups tested. In exposures to Cr+6, growth of algae was inhibited at 10.0 ppb, and reproduction of worms at 12.5 ppb. At higher concentrations, Cr+6 is associated with abnormal enzyme activities, altered blood chemistry, lowered resistance to pathogenic organisms, behavioral modifications, disrupted feeding, histopathology, osmoregulatory upset, alterations in population structure and species diversity indices, and inhibition of photosynthesis. Not all sublethal effects observed were permanent, but the potential for acclimatization of organisms to Cr is not well documented. The great variability among species and tissues in the accumulation or concentration of Cr is attributed partly to the route of administration, partly to the concentration of Cr and its chemical species, and partly to numerous biotic and physicochemical modifiers. High accumulations of Cr have been recorded among organisms from the lower trophic levels, but there is little evidence of biomagnification through food chains. Marine bivalve molluscs, for example, accumulated measurable concentrations at ambient water concentrations of 5.0 ppb of Cr+6, but the significance of Cr residues in molluscs and other organisms is not well understood. Depuration of accumulated Cr among organisms differs markedly, but usually follows a complex multicompartmental excretion pattern.

AQUATIC ORGANISMS: FRESHWATER

BACTERIA

The role of sewage bacteria in Cr kinetics and cycling is unresolved and promises to be a fruitful field of research. Of 362 bacterial isolates from Cr+6 liquid sanitary sewage and chemical waste sludges, only 1—an

isolate of *Arthrobacter* sp.—could tolerate 400 ppm of Cr+6 (Coleman and Paran 1983); however, this isolate could not effectively accumulate Cr at low ambient levels of 5 ppm of Cr+6, whereas *Agrobacter* sp., another isolate, could. Hexavalent Cr in a wide array of forms showed dose dependent responses for mutagenic activity in the bacterium *Salmonella typhimurium* (Del Carratore et al. 1984); moreover, among 56 metal compounds tested, Cr+6 elicited the strongest mutagenic responses in *Bacillus subtilis* (Hatherill 1981). In some tests, Cr+3 was genetically active, but only when present as a stable organic complex (Del Carratore et al. 1984).

ALGAE AND MACROPHYTES

Growth of freshwater algae was reduced at Cr+6 concentrations of 10 ppb for *Chlamydomonas reinhardi* and >45 ppb for other species tested; effects were most pronounced in water of low alkalinity (EPA 1980). Frond growth of the common duckweed, *Lemna minor*, the most sensitive aquatic plant tested, was reduced at 10 ppb Cr+6 in days (Mangi et al. 1978). Jouany et al. (1982) reported that a green alga, *Chlorella vulgaris*, biomagnified Cr+6 from the medium about 1000X in 28 days at ambient concentrations of 300 ppb; growth was inhibited at 445 ppb Cr+6 in 96 hours, and adenosine triphosphate (ATP) production was reduced at 470 ppb in 24 hours. At 10 ppb Cr+6 in the medium, bioconcentration factors for the chlorophytes *Hydrodictyon reticulatum* and *Oedogonium* sp. ranged from 200 to 600X in 14 days (Mangi et al. 1978). Accumulation of Cr by living and dead plant tissue is extensive, uptake linearly approximating concentration on a logarithmic basis (Mangi et al. 1978).

Trivalent chromium is far less effective than Cr+6 in producing root weight inhibition in Eurasian watermilfoil, *Myriophyllum spicatum*: 9,900 ppb Cr+3 vs. 1,900 ppb Cr+6 (EPA 1980).

INVERTEBRATES

Hexavalent chromium was associated with adverse effects in invertebrates of widely separated taxa: reduced survival and fecundity of the cladoceran *Daphnia magna* at a concentration of 10 ppb and exposure for 32 days (EPA 1980); growth inhibition of the protozoan *Chilomonas paramecium* at 1,100-3,000 ppb at temperatures of 10-30 °C during exposures of 19-163 h (Honig et al. 1980); abnormal movement patterns of larvae of the midge *Chironomus tentans* at 100 ppb in 48 h (Catalan 1982); and a temporary decrease in hemolymph glucose levels in the freshwater prawn *Macrobrachium lamarrei* surviving 1,840 ppb Cr+6 for 96 h (Murti et al. 1983).

Trivalent Cr was less effective than Cr+6 in reducing fecundity of *Daphnia magna*: 44 ppb Cr+3 vs. 10 ppb Cr+6 (EPA 1980). Annelid worms (*Tubifex* sp.) accumulated about 1 ppm Cr during exposure for 2 weeks in sediments containing 175 ppm Cr+3, suggesting that benthic invertebrates have only a limited ability to accumulate chromium from sediments or clays (Neff et al. 1978).

FISH

Among sensitive species of freshwater teleosts, Cr+6 concentrations of 16 to 21 ppb in the medium resulted in reduced growth of rainbow trout and chinook salmon fingerlings during exposure of 14 to 16 weeks, and altered plasma cortisol metabolism in rainbow trout after 7 days; locomotor activity in bluegills increased after 2 weeks in 50 ppb Cr+6 (EPA 1980). Long-term exposure of rainbow trout by Calamari et al. (1982) for 180 days to high, but environmentally realistic, concentrations of 0.2 ppm Cr+6 resulted in elevated levels of Cr in kidney (3.5 mg/kg fresh weight), liver (2.0), and muscle (0.6); after 90 days in Cr-free media, Cr levels were 1.6, 1.3, and 0.5, respectively. Time required to reach median asymptotic uptake ranged from 36 to 55 days for various tissues; extrapolated values for almost complete equilibrium were 237 to 365 days (Calamari et al. 1982). The rudd (*Scardinus erythrophthalmus*), exposed to Cr+6 for 24 hours, did not accumulate detectable levels of Cr in tissues during exposure to 16 ppm, but did during exposures to 20 ppm; the kidney contained the highest residues—10.3 mg Cr/kg fresh weight (Van Hoof and Van San 1981).

At high environmental concentrations of Cr+6 (i.e., 2.0 ppm in water) and at alkaline pH, concentrations in rainbow trout tissues were greatest in gill, liver, kidney, and digestive tract; after transfer of the fish to Cr-free media, residues tended to remain high in kidney and liver; concentration in gill tissues tended to be greater at pH 7.8 than at pH 6.5 (Van der Putte et al. 1981a). Studies with perfused gills showed that the transfer of Cr was directly coupled with the transfer of oxygen from the external solution to the internal perfusion medium and that this transfer was significantly more rapid at pH 6.5 than at alkaline pH (Van der Putte and Part 1982). Uptake rate of Cr+6 was rapid, equilibrium usually being reached in 2 to 4 days of exposure for various tissues,

except for gill, which continued to accumulate Cr with increasing exposure at acidic pH. In rainbow trout, the excretion pattern was biphasic. The biological half-life of the short-lived component (34% of the total Cr) was 1.0 day, and that of the long-lived component was 25.6 days (Van der Putte et al. 1981a). Other sublethal effects were observed in freshwater teleosts following Cr+6 insult. In the snakehead (*Channa punctatus*), enzyme activities were altered in a wide variety of organs and tissues after exposure for 30 days to 2.6 ppm (Sastry and Sunita 1984); the effects became life threatening after exposure for 120 days (Sastry and Tyagi 1982; Sastry and Sunita 1982,1983). In the mud skipper (*Boleophthalmus dussumieri*), chromosomal aberrations in the gill increased after injection of 1.0 mg/kg body weight, or exposure to 24 ppm in the medium for 24 h (Krishnaja and Rege 1982). In juvenile coho salmon (*Oncorhynchus kisutch*), disease resistance and serum agglutinin production both decreased after 2 weeks in water containing 0.5 ppm (Sugatt 1980b). In seaward migrating coho salmon, salinity tolerance and serum osmolality were impaired during exposure to 0.23 ppm Cr+6 for 4 weeks (Sugatt 1980a).

Chromium uptakes and effects in teleosts were modified significantly by many biological and abiotic variables, including water temperature and pH, the presence of other contaminants or compounds, and sex and tissue specificity. In rainbow trout, only males showed significant changes in liver enzyme activity during exposure to 0.2 ppm Cr+6 for 6 months; the effects were intensified by the presence of nickel and cadmium salts in solution (Arillo et al. 1982). Rainbow trout are able to regulate Cr somewhat, either actively, by reduced absorption or increased excretion, or passively, by the limitation of binding sites for Cr *in vivo* (Buhler et al. 1977). Tests with goldfish and high Cr+6 concentrations indicated that toxic and sublethal effects were more pronounced at comparatively high water temperatures and reduced pH; further, Cr residue levels were abnormally high in dead or moribund fish, suggesting that residue values from dead or dying fish should be interpreted with extreme caution (Riva et al. 1981). In rainbow trout, acute Cr poisoning caused morphological changes in gills, kidney, and stomach tissues at pH 7.8, but only in the gills at pH 6.5 (Van der Putte et al. 1981b). Chromium uptake in trout increased when 10 ppb of ionic cadmium was present in solution (Calamari et al. 1982)—again demonstrating that uptake patterns are not necessarily predictable for single components in complex mixtures.

AQUATIC ORGANISMS: MARINE

ALGAE AND MACROPHYTES

Algae and higher plants accumulated chromium from seawater by factors up to 8,600 (Van As et al. 1973), and from solutions containing 50 ppm Cr by a factor of 18 in 48 h (Sivalingam 1978). Algae also accumulated Cr from sewage sludge, showing increases in Cr of 25 to 60 mg/kg dry weight (Montgomery et al. 1978). The unusually high Cr concentrations observed in some species of algae and macrophytes from Narragansett Bay, Rhode Island (Phelps et al. 1975) and from Puerto Rico (Bernhard and Zattera 1975) almost certainly came from chromium wastes discharged from electroplaters (in Narragansett Bay) and from other anthropogenic sources (in Puerto Rico). A similar situation probably exists wherever grossly elevated Cr levels are observed.

Although chromium is abundant in primary producers, there is little evidence of biomagnification through marine food chains consisting of herbivores and carnivores (Osterberg et al. 1964). Baptist and Lewis (1969) followed the transfer of assimilated and unassimilated radiochromium through an experimental food chain that included phytoplankton, brine shrimp, postlarval fish, and adult fish. When chromium was successively transferred through each of the four trophic levels, concentrations declined after each transfer. Comparisons of the results from the food chain with laboratory studies on chromium uptake from seawater suggest that the food chain, despite the successive declines, was generally the more efficient pathway for uptake of chromium by all trophic levels.

Among sensitive species of marine algae, concentrations of 10 ppb of Cr+6 partly inhibited growth of *Olisthodiscus lutens*. All cultures, including those in which growth was inhibited, contained viable, active (75%) cells at the end of 10 days. Inhibitory effects were reversed by chelators such as EDTA (Mahoney 1982), suggesting that naturally occurring ligands and sequestering agents in seawater may alleviate the toxicity of Cr+6, and perhaps other metals. In the giant kelp (*Macrocystis pyrifera*), photosynthesis was inhibited 20% in 5 days at 1,000 ppb of Cr+6, and 50% in 4 days at 5,000 ppb (EPA 1980); this kelp appears to be one of the more resistant aquatic plants.

MOLLUSCS

Edible tissues of commercially important North American molluscs contained 0.1 to 0.6 mg Cr/kg fresh weight (Hall et al. 1978). Although this concentration is in general agreement with molluscan data from other geographic areas (Eisler 1981), Shuster and Pringle (1968) reported values (mg Cr/kg fresh weight) in edible portions as high as 3.4 in oysters (*Crassostrea virginica*), 5.8 in hardshell clams (*Mercenaria mercenaria*), and 5.0 in softshell clams (*Mya arenaria*). The ability of marine molluscs to accumulate Cr far in excess of that in ambient seawater was documented by Papadopoulu (1973), who found that the Cr concentration in 5 species of bivalves from Greek waters exceeded that in seawater by 16,000 times (*Pinna nobilis*) to 260,000 times (*Astralium rogosum*). No deleterious health effects have been reported among consumers of molluscs that contained occasional high Cr residues. Anthropogenic and natural chromium gradients in sediments or the water column were reflected in the wide range of values reported for this element in field collections of clams (Phelps et al. 1975; Eisler et al. 1978) and mussels (Alexander and Young 1976; Fowler and Oregioni 1976; Lande 1977; Karbe et al. 1977).

Two factors known to modify Cr accumulations in molluscs are the weight of the organism and the salinity of the medium. Concentrations of Cr in clams were reported to decrease with increasing body weight (Eisler et al. 1978) and increasing salinity (Olson and Harrel 1973). Accumulation of Cr by oysters (*Crassostrea gigas*) was independent of sediment Cr levels and dependent on organism size—suggesting some homeostatic regulation of this metal (Ayling 1974). In a 20-week laboratory study of chromium accumulation rates by oysters (Shuster and Pringle (1969) continuously subjected the animals to seawater solutions containing 50 or 100 ppb Cr+6. After 5, 10, or 20 weeks in 50 ppb, maximum whole body concentrations (mg Cr/kg fresh weight) were 2.4, 3.7, and 6.3, respectively (up from control values of <0.12); in 100 ppb, the values were 4.4 (5 weeks), 6.4 (10 weeks), and 11.5 (20 weeks). Preston (1971) concluded that *C. virginica*, under laboratory conditions, accumulated Cr more readily by direct absorption from the medium than from ingestion of radiochromium-labeled algae (*Chlamydomonas* spp.). In natural environments, however, Cr concentration is likely to be greater in the food supply than in the water. As a consequence, food might be the primary source of Cr to oysters, even though accumulation occurs more readily by direct absorption (Preston 1971).

Clams, oysters, and mussels accumulate Cr from the medium or from contaminated sediments at comparatively low concentrations. For example, oysters subjected to 5.0 ppb of Cr+6 for 12 weeks contained 3.1 mg Cr/kg dry weight in soft parts and retained 52% of the accumulated Cr after they were transferred to Cr-free seawater for 28 weeks (Zaroogian and Johnson 1983). Mussels (*Mytilus edulis*) subjected to the same dose-time regimen contained 4.8 mg/kg, but retained only 39% after 28 weeks of depuration. Both oysters and mussels contained higher residues after exposure to 10.0 ppb Cr+6 for 12 weeks—5.6 and 9.4 mg Cr/kg dry weight in soft parts, respectively—and both contained substantial (30-58%) residues after 28 weeks in a Cr-free environment (Zaroogian and Johnson 1983). In studies with mussels and softshell clams (*Mya arenaria*), Capuzzo and Sasner (1977) demonstrated that Cr in New Hampshire sediments (contaminated with Cr+3 from tannery wastes) was bioavailable to clams by diffusion from seawater, and that both diffusion and particulate uptake were important pathways for mussels. Accumulation was observed at sediment Cr concentrations as low as 150 ppm. Kaolinite sediments containing up to 1,200 ppm of Cr+3 produced the most pronounced adverse effects on filtration rates and ciliary activity of bivalve molluscs, leading the authors to conclude that Cr that has accumulated in areas affected by industrial wastes might have serious consequences to filter feeding bivalves.

It is emphasized that Cr+3, probably because of its very low solubility in seawater, appears to have a much lower bioavailability to most groups of marine animals than Cr+6, which is more water soluble (Carr et al. 1982). The clam *Rangia cuneata* appears to be an exception: it accumulated up to 19 mg Cr/kg in soft parts, on a dry weight basis, during exposure for 16 days to chromium-contaminated muds, and retained most of it for an extended period; the estimated biological half-time was 11 days (Carr et al. 1982). In general, benthic invertebrates rarely accumulate Cr from contaminated sediments (82-188 ppm Cr+3); only a few examples have been recorded (Neff et al. 1978).

NEMATODES

Representatives of this phylum have been used extensively as indicators of stressed environments. Population structure and species diversity of free-living nematodes inhabiting sediments in the New York Bight were moderately influenced by the heavy metal content of sands. In medium-grained sands, species diversity was inversely correlated with increased concentrations of Cr and other metals. Sands containing 3.0 to 21.5 mg

Cr/kg were also marked by high relative abundances of one or two nematode species; the tolerance of these species to Cr stress probably exceeded that of the normal nematode inhabitants of such sediments (Tietjen 1980).

CRUSTACEANS

In general, chromium seldom exceeds 0.3 mg/kg fresh weight in edible crustacean tissues (Eisler 1981). The highest value (0.6 mg Cr/kg fresh weight) reported in muscle of rock crab (*Cancer irroratus*) was from specimens collected near an ocean dump site receiving large quantities of metals. Digestive glands and gills from these crabs also contained the highest Cr residues for these tissues in crustaceans (Greig et al. 1977).

Sather (1967) observed that uptake and loss of radiochromium by the crab *Podophthalmus vigil* was independent of sex and eyestalk hormone influences. Most of the radiochromium accumulated in gills. Equilibrium was reached in gill and muscle in 2-3 days, but in midgut and hemolymph in 4-5 days. Iron interfered with chromium uptake and retention. Tennant and Forster (1969) demonstrated that Cr concentrated in setae, gills, and hepatopancreas of Dungeness crab (*Cancer magister*) and suggested that surface adsorption and physiological processes were both instrumental in Cr accumulation. Barnacles (*Balanus* sp.) incorporated Cr+6 in soft tissues up to 1,000X over ambient concentrations, reaching equilibrium in 7 days (biological half-life for some components was 120 days); however, Cr+3, which precipitates in seawater, was quickly removed by filtering activity, was not concentrated in soft tissues, and was rapidly excreted by way of the digestive system (^{51}Cr (VI) and ^{51}Cr (III) by barnacles (van Weerelt et al. 1984).

Sediment Cr concentrations of 3,200 ppm in the New Bedford (Massachusetts) Acushnet estuary, and 100 ppm in the New York Bight have been recorded (Doughtie et al. 1983). Massive cuticular lesions suggestive of shell disease characterized up to 30% of the lobsters, crabs, and shrimp collected from the New York Bight, and these lesions could also be induced in crustaceans exposed to New York Bight sediments in the laboratory. This shell disease syndrome has been induced in 41% of grass shrimp (*Palaemonetes pugio*) during exposure to 0.5 ppm Cr+6 for 28 days (Doughtie et al. 1983). It is proposed that Cr interferes with the normal functions of subcuticular epithelium, particularly cuticle formation, and subsequently causes structural weaknesses or perforations to develop in the cuticle of newly molted shrimp. Because of these Cr-induced exoskeletal deficiencies, a viaduct for pathogenic bacteria and direct Cr influx is formed that perpetuates the development of the lesion.

Of the 65,000 tons of Cr compounds used annually in exploratory oil drilling, a significant portion enters the marine environment through the discharge of used drilling muds. It has been estimated that more than 225 tons of drilling mud may be used in a single 3,000-m well (Carr et al. 1982). One of the most frequently used muds in offshore drilling operations is a chrome lignosulphonate mud containing barium sulphonate, bentonite clay, and ferrochrome or chrome lignosulphonates (Carr et al. 1982). The bioavailability of Cr to grass shrimp from used chrome lignosulphonate drilling muds is most pronounced at the mud aqueous layers. At Cr concentrations of 248 ppb in the mud aqueous fraction, grass shrimp accumulated 23.7 mg Cr/kg dry weight whole body after 7 days (Carr et al. 1982). Concentrations of drilling mud of 1% or greater in seawater were toxic to sensitive species of crustaceans (Neff et al. 1981); uptake of 4 to 5 mg/kg was reported in grass shrimp exposed to sediments containing 188 ppm Cr (Neff et al. 1978). The toxicity of Cr-contaminated drilling muds to grass shrimp may sometimes be attributable to large residuals of petroleum hydrocarbons in the sediments (Conklin et al. 1983).

ANNELIDS

Uptake and excretion studies of Cr+3 by *Hermione hystrix* (Chipman 1967) showed that Cr+3 was not readily accumulated from seawater, owing to the formation of particles and surface adsorption phenomena; furthermore, little accumulation was evident on contact with contaminated sediments. Hexavalent chromium in the medium was readily accumulated by *Hermione*; the process was slow and only small amounts were taken up in 19 days—i.e., 0.03 to 0.10 mg/kg fresh weight from media containing 3 to 10 ppb Cr+6. Higher body burdens of 0.5 to 1.8 mg Cr/kg fresh body weight were reported at 100 to 500 ppb of Cr+6, but some deaths were noted at these concentrations. Chromium accumulation by *Hermione* is a passive process and directly related to Cr+6 concentration in the medium. At least two rates of biological loss are involved—one of 8 days and another of 123 days. Chipman (1967) concluded that most of the Cr accumulated by *Hermione* from long exposure is bound in a body component having a slow turnover rate and an estimated biological half-life of

about 123 days.

Uptake of Cr+6 from seawater has been reported for *Neanthes arenaceodentata*. Whole *Neanthes* contained 30.0 mg Cr/kg dry weight after exposure for 150 days in ppb of Cr+6 (Mearns and Young 1977) and 0.5 to 1.6 mg Cr/kg fresh weight after exposure for 440 days (Oshida et al. 1976); both of these observations were similar to those of Chipman (1967), after adjustment for wet and dry weights. Concentrations as low as 12.5 ppb of Cr+6 decreased brood size in *Neanthes* (Mearns et al. 1976; Oshida et al. 1976), although no significant body residues were evident. Uptake of Cr+6 by *Neanthes* was related to dose at low ambient Cr concentrations. Worms subjected to 2.6, 4.5, 9.8, or 16.6 ppb Cr+6 for 309 days contained 0.5, 0.7, 2.2, and 2.5 mg Cr/kg whole fresh organism, respectively (Oshida and Word 1982). There was no direct relationship between tissue concentration and brood size, suggesting that Cr in *Neanthes* attaches to proteins in the body wall, gut, and parapodial regions (Oshida and Word 1982).

Neanthes arenaceodentata is the most sensitive marine organism yet tested. In worms exposed to sublethal concentrations of Cr+6, feeding was disrupted after 14 days at 79 ppb (EPA 1980), reproduction ceased after 440 days (three generations) at 100 ppb (Oshida et al. 1981), brood size was reduced after 309 to 440 days at 12.5 to 16.0 ppb (Oshida et al. 1981; Oshida and Word 1982), and abnormalities in larval development increased after 5 months at 25 ppb (Reish 1977). On the other hand, exposure for 293 days (two generations) in 50,400 ppb Cr+3 caused no adverse effects on survival, maturation time required for spawning, or brood size (Oshida et al. 1981). The polychaete *Capitella capitata* was more resistant than *Neanthes*; a decrease in brood size was noted only after exposure for 5 months to 50 and 100 ppb Cr+6 (EPA 1980).

ECHINODERMS

With the exception of two sea urchin samples collected from Puerto Rico, most Cr residues reported in echinoderms have been less than 1.0 mg/kg dry weight (Eisler 1981). The exceptions—elevated levels of 24 and 43 mg/kg fresh weight of whole organism in Puerto Rican sea urchins—were not reflected in sea cucumber muscle from the same vicinity (Fukai 1965), and thus should be viewed with caution. Echinoderms from the United Kingdom and environs were comparatively low in chromium; concentrations were less than 0.46 mg Cr/kg dry weight whole organism (Riley and Segar 1970). Embryos of a sea urchin (*Anthocidaris* sp.) developed normally in solutions containing 3.2 to 4.2 mg Cr/L, but failed to develop at 8.4-10.0 mg Cr/L (Okubo and Okubo 1962; Kobayashi 1971). Larvae of another species of sea urchin (*Hemicentrotus* sp.) were more sensitive, showing abnormal development or dying within 24 h at concentrations of less than 1.0 mg Cr/L (Okubo and Okubo 1962). Hexavalent chromium at 6.0 mg/L was associated with abnormal development in embryos of *Anthocidaris crassispina* (Kobayashi 1977).

FISH

Individual tissues of most species of finfishes contained between 0.1 and 0.6 mg Cr/kg fresh weight (Hall et al. 1978). For still unexplained reasons, chromium concentrated in the scales of some species collected in Greek waters, values ranging up to 97.0 mg Cr/kg dry weight (Papadopoulu and Kassimati 1977). Chromium concentrations also vary significantly among different species of fish collected from the same geographic area. For example, muscle Cr concentration was 1,430X greater in a porgy (*Pachymetopan qrande*) than in a goosefish (*Lophius piscatorius*) from the same collection (Van As et al. 1973).

Accumulation of chromium under controlled conditions has been documented for speckled sanddab (Mearns and Young 1977) and Atlantic croaker (Baptist et al. 1970). Sanddabs held in seawater solutions containing 3 to 5 ppm Cr+6 contained up to 100 mg Cr/kg intestine (dry weight), 10 in liver, and 3 in muscle (Mearns and Young 1977). Sanddabs accumulated significant concentrations of Cr in various tissues during long-term exposure in seawater concentrations as low as 16 ppb Cr+6 (Mearns and Young 1977). Baptist et al. (1970), who studied the retention of radiochromium-51 in croakers following a single intraperitoneal injection, wrote that retention was expressed as two exponential rate functions: 70 days for the long-lived component and 20 days for the short-lived component.

BIRDS

Male domestic chickens fed diets containing up to 100 ppm of Cr+6 for 32 days showed no adverse effects in survival, growth, or food utilization efficiency (Rosomer et al. 1961). However, teratogenic effects were documented in chicken embryos after eggs had been injected with Cr+6. Deformities included short and twisted

limbs, microphthalmia, exencephaly, everted viscera, growth stunting, and parrot beaks (Ridgeway and Karnofsky 1952; Gilani and Marano 1979). The highest incidence of teratogenic effects was observed at Cr+6 concentrations that caused some deaths, and when the administration route was through the chorioallantoic membrane as opposed to the yolk; no teratogenic effects were observed with Cr+3 salts (Ridgeway and Karnofsky 1952).

Young American black ducks (*Anas rubripes*) absorbed anionic Cr species more readily than cationic forms from the intestines, strongly indicating that ionic Cr state should be considered when avian dietary toxicity studies are being planned (Eastin et al. 1980). Adult black ducks fed diets containing 10 or 50 ppm anionic Cr+3, as Cr $K(SO_4)_2.12\ H_2O$, for 5 months were normal in survival, reproduction, and blood chemistry. However, in ducklings from treated groups that were fed Cr-contaminated diets at original parental dosages, growth patterns were altered and survival was reduced (Haseltine et al. 1985). In another study with black ducks, adults were fed diets containing 0, 20, or 100 ppm anionic Cr+3 and ducklings from these pairs were fed the same diets for 7 days; tests of avoidance responses of the ducklings to a fright stimulus showed that the Cr had no significant effect on their behavior (Heinz and Haseltine 1981).

MAMMALS

Chromium is causally associated with mutations and malignancy (Leonard and Lawerys 1980; Norseth 1981). Under appropriate conditions, Cr is a human and animal carcinogenic agent; its biological effects depend on chemical form, solubility, and valence. In general, Cr+6 compounds are hazardous to animals, whereas metallic Cr and Cr+3 are essentially nontoxic (Gale 1978); however, exposure to water solubilized Cr+3 has caused cancers and dermatitis in workers, and toxicity in rabbits (Hatherill 1981). In the chromate producing industry workers who developed respiratory cancer had been exposed to 30 to 1,100 ug/m^3 Cr in air for periods of 4 to 24 years, and workers producing chromate pigment who developed respiratory cancer had been subjected to an estimated Cr+6 exposure of 500 to 1,500 ug/m^3 for 6 to 9 years. Carcinogens released in the chromate manufacturing process have not yet been identified (Post and Campbell 1980). Levels as low as 10 ug/m^3 of Cr+6 in air produced strong irritation in nasal membranes, even after short exposures. In some persons whose lower respiratory tissues became Cr-sensitized, asthmatic attacks occurred at levels of Cr+6 as low as 2.5 ug/m^3 (Steven et al. 1976). There is no evidence of Cr sensitization in mammals other than humans. In the only animal study demonstrating a carcinogenic effect of an inhaled chromate, adenocarcinomas were reported in the bronchial tree of mice exposed throughout life to $CaCrO_4$ dust at 13 mg/m^3 (4,330 ug Cr+6/m^3) for 35 h weekly (Langard and Norseth 1979). Trivalent Cr compounds did not produce respiratory cancers (Steven et al. 1976). In rabbits, both Cr+3 and Cr+6, given 1.7 mg/kg body weight daily for 6 weeks, adversely affected blood and serum chemistry, and both produced significant morphological changes in liver (Tandon et al. 1978); similar results were observed in rats (Laj et al. 1984). Although damage effects and residue accumulations were greater in rabbits treated with Cr+6, water soluble Cr+3 compounds also may have significant biological activity (Tandon et al. 1978).

Hexavalent Cr compounds may cause skin ulceration, irritative dermatitis, ulcerations in mucous membranes, and perforations of the nasal septum. That inhalation of Cr+6 compounds may cause bronchial carcinomas has been well documented in humans (Langard and Norseth 1979). Skin lesions or ulcers were produced in guinea pigs when solutions containing 30,000 ppm of Cr+6 were applied to abraded skin or if the natural oils were removed from the skin beforehand; Cr+3 in concentrations as high as 100,000 ppm had no ulcerogenic effects (Steven et al. 1976). Allergic guinea pigs developed dermatitis when exposed to solutions of either Cr+6 or Cr+3 at concentrations as low as 10 ppb (Steven et al. 1976). In nonallergic animals, these effects were observed after repeated exposures to solutions containing 1,000 to 3,000 ppm of Cr+3 or Cr+6 salts. Local sarcomas in muscle and local carcinomas of the skin have also been demonstrated in small laboratory animals exposed to Cr+6 (Langard and Norseth 1979). Kidney and liver lesions in rats were observed when the drinking water contained 134 ppm of Cr+6 for 2 to 3 months (Steven et al. 1976).

Hexavalent Cr has established its mutagenic activity in a wide array of screening tests, whereas insoluble Cr+3 forms appear to be inactive, in analogous evaluations—perhaps because Cr+3 absorption is poor in the systems analyzed (Hatherill 1981). Studies with tissue cultures of ovary cells of the Chinese hamster showed that the addition of 52 ppb of Cr+6 not only induced sister chromatid exchanges but also inhibited cell

proliferation; there was no measurable effect at 0.52 ppb Cr+6. Trivalent Cr at 520 ppb did not measurably affect cell proliferation or chromatid exchanges (Uyeki and Nishio 1983). Genotoxic effects of Cr+6 are reversed by the addition of reducing agents or ascorbic acid (Hatherill 1981; Uyeki and Nishio 1983). Chromosomal rearrangements and aberrations were recorded in rabbit cells after exposure to Cr+6 (Hatherill 1981). Teratogenic effects induced by intravenous administration of 5 mg Cr+6/kg body weight to pregnant golden hamsters included cleft palates and defects in the ossification of the skeletal system (Gale 1978).

Accumulations of Cr in tissues and organism depend heavily on its chemical form, route of entry, and amount administered (Yamaguchi et al. 1983). Tissue accumulations were significant in dogs exposed to drinking water concentrations of 11.2 ppm Cr; but were nil at 6 ppm (Steven et al. 1976). Although both Cr+3 and +6 accumulated in brain, kidney, and myocardium of rabbits, the accumulation of Cr+6 was highest in brain and that of Cr+3 in kidney; for both valence states there was no correlation between dose and concentration of stored Cr, or extent of tissue damage (Hatherill 1981). Tissue residues in mice given 0.1 ppm Cr+6 in food and water during lifetime exposure ranged from 0.1 mg Cr/kg fresh weight in liver to 0.7 in heart; mice given 5.1 ppm for a similar period contained 0.5 to 1.8 mg Cr/kg fresh weight in tissues, the residues being highest in the heart and spleen (Schroeder et al. 1964). Trivalent Cr was poorly absorbed from the intestinal tract of rats (<1% of an oral dose), whereas absorption of Cr+6 ranged from 3 to 6% (Langard and Norseth 1979). However, both Cr+3 and Cr+6 traverse placental barriers in mice when administered intravenously (Steven et al. 1976; Langard and Norseth 1979). All chemical forms of chromium, except chromates, cleared rapidly from the blood of rats. At dose levels of 60 to 250 ug/kg body weight, Cr+6 tended to accumulate in the reticuloendothelial system, liver, spleen, and bone marrow; at the much lower doses of 10 and 1 ug/kg body weight, major accumulation sites were the bone, marrow, spleen, testes, and epididymis (Langard and Norseth 1979). Female rats given a single i.v. injection of radiochromium-51 depurated the isotope primarily by urinary clearance, and secondarily by fecal and residual clearances over an 11-day period. Retained radiochromium-51 accumulated over time in bone, kidney, spleen, and liver (Onkelinx 1977). For multicompartmental excretion patterns recorded in rats, biological half-lives of the three components were estimated to be 0.5, 5.9, and 83.4 days; in mammals, Cr is excreted primarily in urine (Langard and Norseth 1979). At least three distinct Cr+6 excretion patterns exist in rats: blood has a single component, with a biological half-life of 13.9 days; testes, brain, kidney and lung have two components; and liver has three components with half-lives of 2.4 hours, 52.8 hours, and 15.7 days (Yamaguchi et al. 1983). Excretion patterns for Cr+3 in rats were unpredictable and impossible to calculate (Yamaguchi et al. 1983). The excretion patterns for fecal Cr among 40 grazing Angus cows given 20 g dietary Cr_2O_3 (13.6 g Cr+3) daily for 72 days was diurnal; excretion was lowest at 8 p.m. and highest at 9 a.m. (Hopper et al. 1978).

FIELD INVESTIGATIONS

There is a wealth of data concerning the effects of chromium on living organisms under laboratory conditions simulating those encountered in the vicinity of high Cr discharges and accumulations typical of electroplating plants, tanneries, ocean dumping sites, and municipal waste outfalls. However, little research has been conducted under actual field conditions, except in three general fields: occupational exposures of humans in the chromate industry (discussed earlier), accidental poisoning of livestock resulting from oil-field activities, and Cr accumulations in ecosystems impacted by discharges associated with cooling waters or cooling towers.

All cases of accidental chromate poisoning in cattle have resulted from the exposure of animals to chromate compounds associated with oil field activities. Chromates are used as a corrosion inhibitor between the pipe and casing and are often added to drilling fluids (in the form of chromelignosulfonate) to improve thermal stability. One recorded case involved 20 mature cows and their 8-month-old calves, grazing in a native pasture where an oil well had just been completed. One cow and calf died and another cow and calf became uncoordinated and thin, and the feces contained bloody mucous. The calf soon died. The cow aborted, but appeared to recover completely. Liver from the dead calf had 14.8 mg Cr/kg fresh weight vs 1.8 in controls; levels of arsenic and lead were not elevated (Reagor and McDonald 1980). The cause of death was the consumption by the animals of concentrated sodium chromate found near the well site. In other cases, 2 of 80 heifers died after consuming concentrated zinc chromate, and 10 cows and one calf died after they had ingested ammonium chromate. In poisoned cows, Cr concentrations were 500 mg/kg in stomach contents, 15.8 ppm fresh weight in kidney vs. 3.0 ppm in controls, and 1.1 ppm in blood vs. 0.02 ppm for controls (Kerr and Edwards 1981).

Chromium is widely used as a corrosion inhibitor in cooling waters by the electric power industry. Its use in this capacity involves addition of a Cr+6 salt, typically sodium dichromate, which forms an oxide on metal

surfaces. Chromates are subsequently released to surface waters in high concentrations, compared with background levels of Cr in most freshwaters. In White Oak Lake (Eastern Tennessee), which received chronic inputs of chromates from cooling towers located on two tributary streams, typical Cr+6 concentrations of 3 to 10 ppm in waste effluents produced 100 to 300 ppb of Cr+6 in White Oak Lake vs. 5 ppb in a control area (Elwood et al. 1980). Concentrations of Cr in muscle of bluegills and largemouth bass from White Oak Lake did not differ significantly from those in fish from a control site—suggesting that these species either effectively regulated Cr concentration or that the elevated Cr levels in White Oak Lake (where 20 to 73% of the total chromium was Cr+6) were in a form that was unavailable for absorption into tissues. Elwood et al. (1980) suggested that Cr is an element with a determinant concentration in fish, and that accumulation is independent of environmental concentration. This concept requires validation. Noteworthy is the observation that Cr concentrations were lower in muscle and body of older freshwater teleosts—an observation consistent with the findings of Eisler (1984), who noted that liver Cr decreased with increasing age in marine teleosts.

Cooling towers of uranium enrichment facilities and gaseous diffusion plants, similar to those of 1,000-MW conventional steam electric stations, contain a chromate zinc-phosphate compound to inhibit corrosion and fouling within the cooling system. A small fraction of the cooling water, containing about 20 ppm of Cr+6, becomes entrained within the exit air flow and is deposited as drift on the landscape, together with other salts found in the recirculating water system, such as sodium pentachlorophenate, chromated copper arsenate, and acid copper chromate. Effects of the Cr component on biological systems have been under investigation in Kentucky and Tennessee for many years (Taylor and Parr 1978; Taylor 1980;Taylor et al. 1975, 1979, 1983). Analysis of vegetation along distance gradients from the cooling towers identified areas of significant drift deposition, accumulation, and magnitude of atmospheric transport over the landscape. At 13 m downwind from the point source, plant foliar concentrations of Cr were highest in winter at 1,390 ppm dry weight, decreasing to 190 in spring, and to 173 in summer as the demand for cooling—and hence the operation time of the facility—decreased. Decreased accumulations on foliage probably reflected high mobility due to leaching, and the short life span of individual leaves. In contrast, Cr concentrations in plant litter at 13 m increased from 894 ppm dry weight during winter to 1,890 ppm in summer and 2,140 ppm in autumn. Accumulation of Cr in the litter was probably related to the higher surface-to-volume ratio in the litter biomass resulting from seasonal senescence of foliage. Taylor and his coworkers emphasized that no adverse biological effects were observed in native vegetation bearing high Cr residues. Concentrations in plants and litter decreased with increasing distance from the cooling towers: concentrations in foliage at 168, 530, and 923 m downwind were 157, 10, and 1.3 ppm (dry weight), respectively; for litter, these values were 421, 24, and 5.8. Potted tobacco plants (*Nicotiana tabacum*) proved to be sensitive indicators of Cr contamination. Tobacco plants placed 15 m from the towers contained 30X background levels after 1 week and up to 237 ppm dry weight in 5 weeks; in plants placed 200 m downwind, leaf growth was reduced 75% after 7 weeks. Beetles and crickets collected near the towers contained 9 to 37 ppm Cr in gut contents (vs. 0.5 to 0.8 ppm for controls); however, assimilation rates were not measured. Cotton rats trapped in a fescue field adjacent to a large mechanical draft cooling tower contained up to 10X more Cr in hair, pelt, and bone than controls, but accumulations were negligible in viscera and other internal organs. Licking of the coat by rats appeared to be a primary route of Cr uptake—a likelihood confirmed experimentally by Langard and Nordhagen (1980). Feeding of radiochromium-51 to cotton rats demonstrated low assimilation (0.8%), and rapid initial loss of Cr+6 (99% in 1 day)—suggesting that Cr is neither essential to cotton rats nor accumulated to any great extent through ingestion of drift-contaminated vegetation or inhalation of drift-contaminated air (Taylor 1980). Biological half times of Cr assimilated by man and cotton rats were similar: 616 and 693 days, respectively. The magnitude of the half times suggests that Cr derived from a chromate has a high potential for biological interaction, but that fractional assimilation is very low—thus reducing the likelihood of toxic effects.

CURRENT RECOMMENDATIONS

As reported here, sensitive species of freshwater aquatic organisms showed reduced growth, inhibited reproduction, and increased bioaccumulation at 10.0 ug/L of Cr+6, and other adverse effects at 30.0 ug/L of Cr+3. Among marine organisms, measurable accumulations were recorded in oysters and worms at 5.0 ug/L of Cr+6, algal growth was reduced at 10.0 ug/L, and reproduction of polychaete annelid worms was inhibited at 12.5 ug/L; in all situations, Cr+3 was less damaging than Cr+6. For birds and mammals, dietary levels of 10.0 mg Cr+3/kg adversely affected young black ducks, and 5.1 mg Cr+6/kg in food and water of mice was associated with elevated tissue residues. The significance of Cr residues is unclear, but available evidence suggests that organs and tissues of fish and wildlife that contain 4.0 mg total Cr/kg dry weight should be viewed

as presumptive evidence of Cr contamination. Aerosol concentrations in excess of 10.0 ug Cr+6/m^3 are potentially harmful to human health; in the absence of supporting data, this value is recommended for protection of sensitive species of wildlife, especially migratory waterfowl.

Proposed criteria for the protection of various environmental compartments against chromium are numerous, disparate, and often contradictory (Table 6). Some of this confusion may be attributable to the general lack of confidence in analyses of chromium residues conducted some years ago, and some to the continued inability to quantify chemical species and ionic states of Cr. Uncertainties about the metabolic role of organochromium compounds, water soluble Cr+3 species, and their interactions with other components in complex and potentially toxic mixtures, further confound the issue. The essentiality of Cr to some, but not all, species of mammals is recognized, but comparable data for other groups of organisms are missing. Finally, the wide range in sensitivities and accumulation rates documented between different taxonomic groups, and even among closely related species, to Cr+3 and Cr+6 salts merits elucidation. Until these questions are resolved, the acceptance of uniform Cr criteria is debatable, and their passage to administratively legislated standards is contraindicated.

Table 6. Proposed chromium criteria for protection of selected resources.

Category and criterion (units in parentheses)	Chromium concentration	Reference[a]
Freshwater aquatic life protection (µg/L)		
USA	<0.29 Cr+6 as 24 h average; not to exceed 21 Cr+6 at any time	1
Water hardness, in mg $CaCO_3$/L		
50	<2,200 Cr+3 at any time	1
100	<4,700 Cr+3 at any time	1
200	<9,900 Cr+3 at any time	1
Colorado	<25 Cr+6; <100 Cr+3	2
Florida		
Effluent discharges	<500 Cr+6; <1,000 total Cr	2
Recovery waters	<50 total Cr	
Indiana		
Most waters	Not to exceed 0.1X 96-h LC-50 of aquatic species	2
Lake Michigan	<50 total Cr	2
Marine aquatic life protection (µg/L)		
USA	<18 Cr+6 as 24 h average; not to exceed 1,260 Cr+6 at any time	1
USA	Insufficient data base for Cr+3 at this time, but presumably less stringent than Cr+6	1
California	<2 total Cr, 6 month median; <8 total Cr, daily maximum; <20 total Cr, instantaneous mix	2
California		
Waste discharges into marine waters	<5 total Cr for 50% of measurements; <10 for 10% of measurements	3
Drinking water (µg/L)		
USA	<50 Cr+6; <170,000 Cr+3	1
California	<50 total Cr	2
Colorado	<50 Cr+6; <50 Cr+3	2
Florida	<50 total Cr	2
Brazil	<50 total Cr	4
USSR	<600 total Cr	4
Agricultural water (µg/L)		
Irrigation Colorado	<100 of Cr+6; <100 of Cr+3	2
Groundwater Florida	<50 total Cr	2
Diet		
Human health protection		
Normal dietary intake	50 to 70 g Cr+3 daily	2
"	30 to 100 µg total Cr daily	5
Food stuffs	100 to 300 g total Cr/kg fresh weight	2
Tissue residues (µg/kg fresh weight)		
Human soft tissues	<30 total Cr	2
Animal tissues	<200 total Cr	2
Air (µg/m^3)		
USA	<50 total Cr	6

Report No. 7

POLYCHLORINATED BIPHENYL HAZARDS TO FISH, WILDLIFE, AND INVERTEBRATES: A SYNOPTIC REVIEW

by
Ronald Eisler

Patuxent Wildlife Research Center
U.S. Fish and Wildlife Service
Laurel, MD 20708

SUMMARY

This account summarizes recent technical literature on the environmental chemistry of polychlorinated biphenyls (PCBs); lists PCB background concentrations in fish, wildlife, and invertebrates; documents their toxic and sublethal properties; and reviews and provides recommendations for the protection of sensitive species of aquatic organisms and wildlife.

PCBs, a group of 209 synthetic halogenated aromatic hydrocarbons, have been used extensively in the electricity generating industry as insulating or cooling agents in transformers and capacitors. Due to human activities and the chemical characteristics of the products, PCBs are now distributed worldwide, with measurable concentrations reported in aquatic organisms and wildlife from North America, Europe, the United Kingdom, and the Atlantic and Pacific oceans. PCBs elicit a variety of biologic and toxic effects including death, birth defects, reproductive failure, liver damage, tumors, and a wasting syndrome. They are known to bioaccumulate and to biomagnify within the food chain. As a result of legislation, virtually all uses of PCBs and their manufacture have been prohibited in the United States since 1979. In general, the ban has been accompanied by declines in PCB residues in fishery and wildlife resources. However, the current environmental burden of PCBs in water, sediments, disposal sites, deployed transformers, and other PCB containers is now estimated at more than 82 million kg, much of it localized, and this continues to represent a potential hazard to associated fish and wildlife.

The toxicological properties of individual PCBs are influenced primarily by two factors: the partition coefficient based on solubility in N-octanol/water (Kow); and steric factors, resulting from different patterns of chlorine substitution. In general, PCB isomers with high Kow values, and high numbers of substituted chlorines in adjacent positions, constitute the greatest environmental concern. Unfortunately, basic chemical information is lacking on many isomers. Also, biological responses to individual isomers or mixtures vary widely, even among closely related taxonomic species. The issue is further confounded by the presence of toxic impurities, such as polychlorinated dibenzofurans, which may have been formed during the PCB manufacturing process, or result from product usage. At this time, total PCB residues give a more reliable measure of environmental PCB contamination than do measurements of any Aroclor or other commercial mixtures. In view of the demonstrated differential toxicities within the array of PCB congeners, it may finally become necessary to modify existing standards and criteria based on the more toxic PCBS.

For aquatic life, water concentrations of less than 0.014 ug total PCBs/1 (ppb) appear to afford a satisfactory degree of protection, although concentrations as low as 0.006 ug/l resulted in measurable accumulation by various species of filter-feeding shellfish. Among sensitive species of teleosts, total PCB residues (in ug/kg fresh weight) in excess of 500 in diets, 400 in whole body, and 300 in eggs were demonstrably harmful, and should be considered as presumptive evidence of significant PCB contamination. Among small mammals, the mink (*Mustela vison*) is one of the most susceptible species tested; dietary levels as low as 100 ug PCBs/kg fresh weight caused death and reproductive toxicity. A tolerable daily limit for mink has been estimated at less than 1.5 ug total PCBs/kg body weight. Tolerable daily PCB levels for rhesus monkey (*Macaca mulatta*) dog (*Canis* sp.), and rat (*Rattus* spp.) were 1.0, 2. , and 5.0 ug/kg body weight, respectively. For birds, total PCB levels (in ug/kg fresh weight) in excess of 3,000 in diet, 16,000 in egg, or 54,000 in brain were frequently associated with PCB poisoning.

DISCLAIMER

Mention of trade names or commercial products does not constitute endorsement or recommendation for use by the Division of Biological Services, Research and Development, Fish and Wildlife Service, U.S. Department of the Interior.

INTRODUCTION

As a result of human activity, polychlorinated biphenyls (PCBS) are now distributed worldwide, with measurable concentrations reported in polar bears (*Ursus martinus*) from the Canadian Arctic, birds and fish from the Great Lakes, wildlife in Europe, Scandinavia, and the United Kingdom, marine organisms of the Atlantic and Pacific Oceans, and up to 91% of the adult human population in the United States. Their presence in the organisms has been shown to cause reproductive failure, birth defects, skin lesions, tumors, liver disorders, and, among sensitive species, death. PCB toxicity is further enhanced by their ability to bioaccumulate and to biomagnify within the food chain due to extremely high liposolubility. These, and other, biological effects of PCBs have been extensively reviewed by Ayer (1976), Roberts et al. (1978), NAS (1979), EPA (1980), Pal et al. (1980), D'Itri and Kamrin (1983), Fleming et al. (1983), Ernst (1984), Stickel et al. (1984), Safe (1984), Simmons (1984), and Lucier and Hook (1985a,b).

PCBs, a group of synthetic halogenated aromatic hydrocarbons, were first prepared in 1881, and since 1930 have been in general use in products that include heat transfer agents, lubricants, dielectric agents, flame retardants, plasticizers, and waterproofing materials (Roberts et al. 1978). After 1971, they were used almost exclusively as insulating or cooling agents in closed electrical systems, such as transformers and capacitors (NAS 1979). Environmental contamination resulted from industrial discharges, from leaks of supposedly closed systems, from disposal of PCB wastes to municipal sewage treatment plants, landfills, and equipment dumps, and especially through atmospheric transport of incompletely incinerated PCBS. Long-range atmospheric transport of PCBs by wind, rain, and snow is now well documented (NAS 1979). PCBs tend to bond tightly to particulate matter, notably soils and sediments of lakes, estuaries, and rivers, where they may remain available for resuspension for at least 8 to 15 years (Swain 1983). The North Atlantic Ocean seems to be the dominant sink for PCBs, accounting for 50 to 80% of the PCBs in the environment, while freshwater sediment is a major continental reservoir (NAS 1979). Other significant reservoirs of mobile PCBs still exist along with even larger, currently immobile, pools. The latter includes those materials containing PCBs that are still in service, and those deposited in landfills and dumps.

Between 1930 and 1975, more than 630 million kg of PCBs were manufactured domestically (Safe 1984). At present, PCBs are not produced in the United States. PCB legislation under the Toxic Substances Control Act, effective January 1977, required the U.S. Environmental Protection Agency (EPA) to establish labeling and disposal requirements for PCBs, and mandated an eventual ban on the manufacture and processing of PCBs (Bremer 1983). Effective July 1979, the final PCB ban rule was implemented, which prohibits the manufacture, processing, distribution in commerce, and use of PCBs except in a totally enclosed system, unless specifically exempted by EPA (Bremer 1983). Although the ban has been in effect for about 6 years, the current environmental burden of PCBs in water, sediments, disposal sites, and in deployed transformers and other containers is sufficiently large, estimated at 82 million kg (D'Itri and Kamrin 1983), to present potentially significant hazards to fish and wildlife resources.

In this account, I summarize the recent technical literature documenting environmental hazards associated with PCBs, with emphasis on aquatic organisms and wildlife, and review quality criteria recommendations for the protection of sensitive species. This account is part of a continuing series of synoptic reviews prepared in response to requests for information from environmental specialists of the U.S. Fish and Wildlife Service.

ENVIRONMENTAL CHEMISTRY

PCBs are organic compounds commercially produced by chlorination of a biphenyl (BP) with anhydrous chlorine in the presence of iron filings or ferric chloride as the catalyst. The purified product is a complex mixture of chlorobiphenyls containing 18 to 79% chlorine; the precise composition depends on the conditions under which chlorination occurred (EPA 1980). Ten possible degrees of chlorination of the biphenyl molecule give rise to ten PCB congener groups: mono-, di-, tri-, tetra-, penta-, hexa-, hepta-, octa-, nona-, and decachlorobiphenyl (Figure 1). Within any congener group, a number of positional isomers (discrete chemical compounds) are possible, depending on the number of chlorines in the molecule. For example, the tetrachloro- and pentachlorobiphenyl congener groups are composed of 30 and 46 possible isomers, respectively. Not all 209 possible isomers are likely to be formed during the manufacturing process. In general, the most common ones are those that have either an equal number of chlorine atoms on both rings, or a difference of only one

chlorine atom between rings (NAS 1979). Although chlorine substitution is favored at the ortho and para positions (Figure 1), the commercial products are complex mixtures of isomers and congeners with no apparent positional preference for halogen substitution (Safe 1984).

Recent advances in the identification and quantification of PCB isomers through mathematical and computer-assisted techniques (Dunn et al. 1984; Schwartz et al. 1984) will prove useful in data interpretation of metabolic fate studies. Unfortunately, the results of PCB analyses vary widely among cooperating laboratories. An interlaboratory comparison of spiked and unspiked samples of herring oil by 23 participating European and North American laboratories showed that calculated spike recoveries ranged from 23 to 136% (Musial and Uthe 1983). This was attributed to serious deficiencies in most steps in the analytical procedures. It seems that until these deficiencies are corrected, PCB analyses will have credibility from only a few selected laboratories.

Toxic materials as impurities in PCBs include polychlorinated dibenzofurans (PCDF) in some domestic and foreign mixtures at levels of 0.8 to 33 mg/kg. The concentrations of PCDFs in Great Lakes fish were related to the concentrations of PCBs (Stalling et al. 1983). Sometimes, PCBs used in electrical capacitors and transformers are converted under the action of heat or electrical arcing to form PCDFs including 2,3,7,8-tetrachlorobenzofuran and 2,3,4,7,8-pentachlorobenzofuran. Kanechlor 400 (Table 1), for example, with an initial PCDF content of 20 mg/kg, yielded fluid with a PCDF content of 4,975 to 11,765 mg/kg after use as a heat transfer fluid in a heat exchanger. These PCDFs were identified as the agents that poisoned more than one thousand humans in Japan in 1968 (EPA 1980; Lucier and Hook 1985a,b). Additional research is needed on PCDFs and other toxic impurities in PCBS.

PCBs are extremely stable compounds, and slow to chemically degrade under environmental conditions. Microbial degradation of PCBs depends on the degree of chlorination and the position of the chlorine atom on the biphenyl molecule; lower chlorinated BPs are readily transformed by bacteria, but not the higher chlorinated compounds (NAS 1979). Higher chlorobiphenyls, i.e., those with five or more chlorine atoms, were more persistent in the environment than those with three or less chlorine atoms; tetrachloro BPs were intermediate in persistence (EPA 1980). Passage of PCBs through activated sludge in sewage treatment plants for 48 hours resulted in 81% degradation for Aroclor 1221 (21% chlorine by weight), 26% for Aroclor 1242 (42% chlorine), and only 15% for Aroclor 1254 (54% chlorine) (NAS 1979). Because of their wide range of physical properties, their chemical stability, and their miscibility with organic compounds, PCBs have been used extensively as hydraulic fluids, plasticizers, adhesives, heat transfer fluids, wax extenders, dedusting agents, lubricants, flame retardants, and especially as dielectric fluids in capacitors and transformers. The current uses of PCBs in the United States have been severely curtailed and production was stopped during the 1970's, although significant quantities of PCBs are still used as dielectric fluids in older transformers and capacitors (Safe 1984).

Commercial PCB formulations are sold under a variety of trade names (Roberts et al. 1978; NAS 1979; EPA 1980; D'Itri and Kamrin 1983; Safe 1984). In the United States, Aroclor is the most familiar requested trademark, but PCBs have also been marketed as Chloretol, Dyknol, Inerteem, Noflamol, and Pyranol. In other countries, PCB formulations have been sold as Pyralene (France), Phenoclor (France), Kanechlor (Japan), Santotherm (Japan), Fenclor (Italy), Apirolio (Italy), Soval (USSR), Delor (Czechoslovakia), and Clophen (West Germany). Some formulations are similar; for example, Kanechlor 600, Phenoclor DP6, Clophen A60, and Aroclor 1260 all contain an average of 60% chlorine, although the former three preparations are composed of a mixture of hexachloro BPs, while Aroclor 1260 contains a variety of forms (Table 1; NAS 1979; EPA 1980).

Chlorination levels of PCB formulations differ markedly (Table 1). Among Aroclor formulations commercially produced by the Monsanto Corporation, Aroclor 1221 contained an average of 21% chlorine by weight and was a clear mobile oil. Aroclor 1254 contained 54% chlorine and was a yellow viscous liquid; 1260 contained 60% chlorine by weight and resembled a yellow sticky resin; and Aroclor 1268 was a white solid (Safe 1984). Aroclor 1254 contained less than 1% of biphenyl and monochloro BP, 0.5% dichloro BP, 1% trichloro BP, 21% tetrachloro BP, 48% pentachloro BP, 24% hexachloro BP, and 6% heptachloro BP (NAS 1979). Aroclor 1016 was similar to Aroclor 1242, with both containing an average of about 42% chlorine by weight, although 1242 contained 9% PCBs with five or more chlorines and 1016 only 5% (Roberts et al. 1978). In general, PCBs are relatively insoluble in water but freely soluble in nonpolar organic solvents and in biological lipids (EPA 1980). Monochlorobiphenyls are comparatively soluble in water (1,190-5,900 ug/1), but this decreases rapidly with increasing chlorination: dichlorobiphenyls, 80 to 1,880 ug/l; trichloro BP, about 8 ug/l; and tetrachloro BP, 3 to 170 ug/l (NAS 1979). The solubilities of various PCB isomers in water also decreased with increasing chlorine

content: 2, 4'-dichloro BP was soluble to 637 ug/l; 2,2',5-trichloro BP to 248 ug/l; 2,2',5,5'-tetrachloro BP to 26.5; 2,2',4,5,5'-pentachloro BP to 10.3; and 2,2',4,4',5,5'-hexachloro BP to 0.95 ug/l (Menzie 1978). Water solubilities of various Aroclor formulations, in ug/l, were 240 for 1242, 50 for 1248, 10 for 1254, and 3 for 1260 (NAS 1979). PCB octanol/water partition coefficients ranged between 10,000 and 20,000 for representative tri-, tetra-, and pentachlorobiphenyls. High partition coefficients with this biphasic solvent system correlate well with PCB biomagnification in fatty tissues of aquatic organisms (EPA 1980), and with incorporation into sediments (Fox et al. 1983). In fact, PCBs are strongly adsorbed on soils, sediments, and particulates in the environment, with levels usually highest in aquatic sediments containing microparticulates (EPA 1980; Duinker et al. 1983) and high organic or clay content (NAS 1979). Uptake of PCBs from contaminated marine sediments by benthic invertebrates is governed by processes that include ingestion of contaminated sediment particles, and exchange of PCBs directly from sediment particles (Larsson 1984). PCB-laden sediments of Raritan Bay, New Jersey, and lower New York Harbor were effective in producing population perturbations of benthic marine invertebrates when sediments contained high silt and clay composition; low silt and clay sediments were ineffective (Stainken 1984).

The number and position of the chlorine atoms on the biphenyl rings affects the biological properties of the compound. For example, PCBs with hydrogen atoms on two adjacent carbon atoms in one or both rings are more readily metabolized than those with hydrogen atoms adjacent only to chlorines, due to metabolic reactions involving arene oxide intermediates (EPA 1980). Furthermore, PCBs with chlorines in the 2 and 6 (ortho) positions are easily metabolized by humans while those with chlorines in the 4 and 4' (para) positions or 3, 4, or 3, 4, 5 positions on one or both rings tend to be biologically active and well-retained in tissues (EPA 1980).

In mammals, PCBs are readily absorbed through the gut, respiratory system, and skin. Initally, PCBs concentrate in liver, blood, and muscle; eventually, accumulations are highest in adipose tissue and skin. Phenolic derivatives or dihydrodiols are the major metabolites, but susceptibility of individual PCB isomers to metabolism is a function of the number of chlorine atoms present on the biphenyl rings and their arrangement. In general, most readily metabolized PCBs are also rapidly excreted in urine and bile. The highly chlorinated isomers are difficult to metabolize and accumulate almost indefinitely. PCBs can be transferred to young mammals either transplacentally or in breast milk. Retention of PCBs is highly species specific: nonhuman primates, for example, retained PCBs more efficiently than rodents (EPA 1980). PCB patterns, especially in warm-blooded animals, only vaguely resemble the mixture from which they originated (Hansen et al. 1983; Ernst 1984). Subtle differences between chlorobiphenyls are further amplified by differences among various animals to absorb, distribute, biotransform, and excrete individual PCB isomers (Hansen et al. 1983).

Biological activities of PCB isomers differ substantially. Among three symmetrical hexachlorobiphenyl (HCBP) isomers, 3,4,5,3',4',5'-HCBP was the most toxic in dietary lethal studies to domestic chickens (*Gallus* spp.), 2,4,5,21,4',5'-HCBP was least toxic, and 2,4,6,2',4',6'-HCBP intermediate in toxicity (Ayer 1976). A tetrachlorobiphenyl (3,4,3',4') was more than 1000 times more potent in producing effects in chicks than 2,4,5,2',4',5'-HCBP both as an hepatotoxin and as an inducer of cytochrome P mediated mixed function oxidases (Rifkind et al. 1984). The biological half-life of intravenously administered PCB formulations in liver of rat (*Rattus* spp.) increased with increasing chlorination: half-lives of 86 hours were determined for 4-monochlorobiphenyl, 99 hours for 4,4'-dichlorobiphenyl, 193 hours for 2,2',4,5,5'-pentachlorobiphenyl, and 1,308 hours for 2,2',4,4',5,5'-hexachlorobiphenyl (Menzie 1978).

PCBs are usually taken up by animals and stored in lipids under circumstances of increasing lipid content in organs. However, recent studies with marine fishes indicate that PCB components remain mobilizable from organs whose lipid contents increased (Boon et al. 1984). The degree of mobilization in codfish (*Gadus morhua*) and sole (*Solea solea*) appeared to be related to polar lipid components such as phospholipids and glycerols. In other aquatic species, the role of diet and tissue specific sites are important. The patterns of pentachloro BP and higher chlorinated BP (not present in seawater) were equal in marine clams, worms, and sediments, and strongly indicate that uptake was via the diet or from sediments (Duinker et al. 1983). In freshwater fishes, direct partitioning across the gill membrane of the blood:water interface controls PCB accumulation; however, dietary PCBs may significantly affect accumulation and exchange rates at the gill membrane (Rohrer et al. 1982).

Biological availability and uptake of individual PCBs from aqueous solution are influenced primarily by two factors: the partition coefficient (Kow) based on the solubilities of compounds in N-octanol/water; and steric

factors resulting from different patterns of chlorine substitution. Log Kow values for various isomers of Aroclors 1242, 1254, and 1260 are high, varying from 4.0 to 9.35, indicating high biological uptake potential. Steric effect coefficients are based on the number of chlorine atoms in the biphenyl molecule and their arrangement (Shaw and Connell 1982). For example, three chlorines in the ortho positions were assigned a steric effect coefficient of 0.3; four chlorines in the ortho postions 0.2; three or four adjacent chlorines on one ring 0.6, and on both rings 0.3; chlorines in the meta position on one ring 0.8, and on both rings 0.6. The product of log Kow and the steric effect coefficient seem to be directly related to bioaccumulation (Shaw and Connell 1982). Thus, maximum uptake was found with penta- and hexachlorobiphenyls predominant in Aroclor 1254, which have high values for log Kow and for steric effect coefficients. Comparatively less uptake was found with di-, tri-, and tetrachlorobiphenyls, typical of Aroclor 1242, which have lower values for log Kow, and with hepta- and octachlorobiphenyls, predominant in Aroclor 1260, which have lower steric effect coefficients. Structure-activity relationships, particularly for PCBS, can be applied to predictive models of contaminant cycling and biomagnification--and promises to become a fruitful research area.

Pal et al. (1980), in a review of PCBs in plant-soil systems, indicated three important research needs. First, many isomers of several PCB formulations have not been studied with respect to their biotransformation, volatilization, photodecomposition, adsorption, and transport. Second, highly chlorinated biphenyls, especially tetra-, penta-, and hexachlorobiphenyls, have not been evaluated for uptake by crops, volatilization, or distribution in soil layers. The relative build up and assimilation in soil-plant systems of hepta-, octa-, nona-, and decachlorobiphenyls have not been evaluated or studied. Finally, data are lacking on partition coefficients of PCBs between soil and water, water and atmosphere, atmosphere and plant populations, and during flow in food chains. A similar case can be made for most fish and wildlife species of current concern.

BACKGROUND CONCENTRATIONS

GENERAL

PCB concentrations have been determined for a variety of flora and fauna, and in certain nonbiological materials (Table 2). These selected data seem to represent current state-of-the-art analytical procedures for accurate and precise measurement of PCBs at detection limits of less than 0.01 ppm for most isomers. Characterization of Aroclor PCB residues in living and nonliving resources is difficult due to the chemical, physical, and metabolic transformations between product manufacture and detection in environmental samples. Schmitt et al. (1985) suggest that total PCBs in samples is a more reliable measure of environmental contamination than measurements of any commercial PCB mixtures such as Aroclor PCBS. Also, Brown et al. (1985) indicated that only a few PCB congeners (i.e., those most toxic) are appropriate for meaningful interpretation of PCB residues in biota.

There is general agreement that more samples from recent collections have detectable PCB residues, that absolute concentrations seem to be declining in some areas of known high PCB contamination, and that lower chlorinated PCBs--resembling Aroclor 1242--are disappearing. Nevertheless, many fish and wildlife species, including salmon, trout, turtles, eagles, herons, fish-eating birds, mink (*Mustela vison*), river otters (*Lutra canadensis*), and bats, all contain measurable, and in some cases potentially harmful, PCB residues, especially in adipose (fatty) tissues.

ALGAE AND TERRESTRIAL MACROPHYTES

In the Great Lakes, atmospheric deposition of PCBs is the most significant source of contamination. More than 90% of atmospheric PCBs are transported in the vapor phase and deposited by turbulent impaction. Deposition of PCBs is also associated with particulate matter, as well as direct partitioning from the vapor phase into the surface organic microlayer at the air-water interface, and these account for the remaining input (Rohrer et al. 1982). Once in the water column, the hydrophobic PCBs partition into the more apolar compartments of the ecosystem or are physically adsorbed on particulate matter. Transfer of PCBs on microparticulate materials and into phytoplankton is well documented, as is partitioning from aqueous solution into algal lipids (Rohrer et al. 1982). PCBs incorporated into phytoplankton exert inhibitory effects on photosynthesis and cell motility. In addition to direct toxic effects on algae, accumulated PCBs are readily introduced into the aquatic food chain (Rohrer et al. 1982).

Selected species of terrestrial plants collected in upstate New York showed decreases in total PCB concentrations of 42% between 1978 and 1980; however, levels in hay in 1979 varied between 0.08 and 0.10 ppm dry weight, or nearly half the Food and Drug Administration (FDA) limit of 0.2 ppm for PCBs in feeds for livestock (Buckley 1983). Plants grown on soils amended with lake sediments contaminated with Aroclors 1248, 1254, and 1260, accumulated PCBs (Sawhney and Hankin 1984). Uptake of Aroclors by beets (*Beta vulgaris*), turnips (*Brassica rapa*), and beans (*Phaseolus vulgaris*) was in the order 1248>1254>1260, indicating that lower chlorinated isomers (which are more soluble in water and more volatile) were more abundant in crop plants than higher chlorinated isomers. Based on these studies, continued monitoring of plants used as forage for livestock and wildlife appears necessary, especially in locations where soils are amended with PCB-contaminated aquatic sediments or sewage sludges.

INVERTEBRATES

Aquatic invertebrates assume an important role in the cycling of PCBs within and between ecosystems. Mysid crustaceans from Lake Michigan appear to have a low assimilation efficiency for PCBs and a high efficiency for fecal excretion of ingested PCBS; fecal pellets sink rapidly (80-170 m/day) and many probably reach the sediments intact before the onset of microbial degradation (Evans et al. 1982). By vertically migrating to the surface at night, mysids may transport PCBs into the upper regions; the PCBs will continue to recycle through the Lake Michigan ecosystem if the PCBs are excreted, egested, lost with molts, or if the mysid is consumed by fish. PCB levels of freshwater oligochaete worms from the Niagara River in New York State were positively correlated with sediment PCB levels (Fox et al. 1983). Uptake of PCBs from the sediment by chironomid (*Chironomus plumosus* - type) larvae was also directly related to the concentration of PCBs in the sediment (Larsson 1984). When larvae metamorphosed to adults, PCB compounds were concentrated and transferred from the aquatic to the terrestrial environment. In a field study near a Swedish sewage plant outfall, transport of PCBs by chironomids from the aquatic to the terrestrial environment was estimated at 20 ug of PCBs per m2 annually. Terrestrial predators that feed on emerging aquatic insects whose larval stage inhabits PCB-contaminated sediments may be exposed to PCBs (Larsson 1984).

FISH

Trace concentrations of the more persistent, more highly chlorinated PCBs are detected in fish from almost every major river in the United States (Schmitt et al. 1983, 1985). The ubiquity of PCB residues probably results from the dispersal of contaminated sediments, from atmospheric transport, and from patterns of continued use and disposal. Maximum concentrations in whole fish did not change appreciably at most locations in recent years; concentrations approaching 100 ppm fresh weight and 500 ppm in lipids were measured as recently as 1978 (Schmitt et al. 1983). Residues of PCBs in fish were more widely distributed than reported previously, but appeared to be declining in some areas of high concentration, and the less chlorinated PCBs (resembling Aroclor 1242) were disappearing. PCB concentrations in whole fish, collected Nationwide between 1976 and 1979, tended to be highest in the industrialized regions of the Northeast and the Midwest. Fish from the Hudson River, near Poughkeepsie, New York, contained 4 to 6X more PCBs than any of the other 108 stations analyzed; mean residue levels were 33.9 ppm fresh weight in 1976-1977 and 44.1 in 1978-1979 (Schmitt et al. 1983). However, data from 1982 (Brown et al. 1985) indicated a general decline in PCB content of fish from the Hudson River (although levels in some species remained substantially higher than the 5.0 ppm temporary tolerance level established by the U.S. Food and Drug Administration); this was attributed primarily to declines in the less chlorinated PCB congeners, especially Aroclor 1016. Accumulations in excess of 1.0 ppm PCBs fresh weight were reported in fish from stations in the Northeast, the Ohio River system, the Missouri River system, the Great Lakes, portions of the Mississippi River in Wisconsin, and from the Manoa Stream near Honolulu, Hawaii (Schmitt et al. 1983). In general, frequency of detectable PCB residues and total PCB residue levels in fish did not change significantly from 1974 to 1979. One exception to this pattern was the decline in residues resembling Aroclor 1242 from 14% of all samples in 1973, to 5% in 1974, to zero in 1976-1977; apparently, components most prevalent in the 1242 mixture are rapidly degraded. Furthermore, the continuing presence of residues resembling Aroclor 1248 suggest that relatively unaltered PCBs continue to enter the environment (Schmitt et al. 1983). The most recent Nationwide monitoring survey (Schmitt et al. 1985) demonstrated a significant downward trend in whole fish body burdens of PCBs in 1981-1982, with no significant increases at any station, confirming that residues were highest at stations in the industrialized regions of the Northeast, the Great Lakes, the Upper Mississippi River System, the Ohio River System, and the Cape

Fear River in North Carolina. Schmitt et al. (1985) suggested that total PCBs measure environmental PCB contamination more reliably than do measurements of any commercial mixtures such as Aroclor PCBs.

About 10% of coho salmon (*Oncorhynchus kisutch*) and 58% of chinook salmon (*0. tshawytscha*) collected in 1980 from the Great Lakes exceeded the current FDA action lever of 5.0 ppm total PCBs on a fresh weight basis. All chinook and about half the coho salmon exceeded the proposed FDA action level of 2.0 ppm total PCBs in fillets (Rohrer et al. 1982). PCBs detected in salmon from the Great Lakes in 1980 most closely resembled Aroclor 1254, although higher and lower chlorohomologues were present. PCBs resembling Aroclor 1260 were detected in only 10% of coho salmon from Lake Huron and may be the result of widespread historical use of Aroclor 1254 and more limited use of Aroclor 1260 (Rohrer et al. 1982). Marked variations in PCB content of selected tissues were evident; skinless fillets of Great Lakes salmon contained significantly lower PCB residues than skin-on fillets, with Aroclor 1254 concentrations 3.5 to 4X lower in the skinless fillets (Table 2). Also, a strong correlation was observed between the concentration of PCBs and DDE in Great Lakes salmon collected in 1980 (Rohrer et al. 1982), probably due to the chemicals' similar polarity and molecular size. The chemical interactions of PCBs with other chlorinated hydrocarbon contaminants, and their biological properties, are areas requiring additional research effort.

Although diet is a major route of PCB uptake in many species of fish, there are notable exceptions--even among closely related species. In lake trout (*Salvelinus namaycush*), for example, most (more than 99%) accumulated PCBs are from the diet and less than 1% from the medium. However, water is the major PCB uptake route in coho salmon (Rohrer et al. 1982). In the windowpane (*Scopthalmus aquosus*), a marine flounder from Long Island Sound, New York, stomach contents contained up to 0.45 ppm of PCBs fresh weight, suggesting a potentially large amount of dietary PCBs available to this species (Greig et al. 1983).

Elevated levels of PCBs (mostly Aroclor 1254) found in gonads of striped bass (*Morone saxatilis*), up to 1.4 ppm fresh weight and 2.3 on a lipid basis, may be associated with poor reproductive success of this species in Nova Scotia (Ray et al. 1984). This is similar to levels of 2.8 ppm PCBs in lipids of eggs of rainbow trout (*Salmo gairdneri*) that experienced heavy fry mortality (Rohrer et al. 1982), and to levels of 0.12 ppm PCBs on a fresh weight basis in gonads of flounder (*Platichthys flesus*) with inhibited reproduction (Ray et al. 1984). However, eggs of Atlantic salmon (*Salmo salar*) with 6.0 ppm PCBs in lipids hatched normally (Ray et al. 1984). It is clear that considerable interspecies differences exist in the responses of teleosts to PCB loadings.

Equilibrium levels of stable lipophilic contaminants in fish are directly proportional to the ambient water concentration of the chemical. Atmospheric deposition and high sediment contamination have also been implicated as major sources of PCB contamination (Rohrer et al. 1982). Lowest PCB levels in Great Lakes salmon were at stations with high flushing and high sedimentation rates (Rohrer et al. 1982). PCBs were detectable at low concentrations in brook trout (*Salvelinus fontinalis*) from remote New England lakes, tending to confirm that PCBS, and other recorded contaminants, reached the lakes by atmospheric deposition (Haines 1983).

REPTILES

Water snakes (*Nerodia* spp.) collected in Louisiana reflected PCB levels similar to those of CB residues in their prey species, primarily fresh- and brackish-water teleosts. PCBs in water snakes were detected in 95% of all fat samples and 52% of liver and muscle tissues; Aroclor 1260 accounted for most of the PCBs (Sabourin et al. 1984). Snapping turtles (*Chelydra serpentia*) are capable of storing high concentrations of PCBs in their fat without any apparent detrimental effects, and may be useful as biological indicators for lipophilic substances, including PCBs (Olafsson et al. 1983). Sea turtles contain relatively lower levels of PCBs than snapping turtles (Table 2). PCB concentrations were higher in saltwater loggerhead turtles (*Caretta caretta*), an omnivore, than green turtles (*Chelonia mydas*), which are vegetarians, again demonstrating that diet is an important route of PCB transfer (McKim and Johnson 1983).

BIRDS

In general, most bird tissues and eggs collected had measurable concentrations of PCBS, and the frequency of occurrence appears to be increasing. In 1976, 21% of European starlings (*Sturnus vulgaris*) collected Nationwide had detectable PCBS; in 1979 it was 83% (Cain and Bunck 1983). For mallards (*Anas platyrhynchos*), PCBs were detected in 39% of wing tissues in 1976-1977, and 95% In 1979-1980 (Fleming et

al. 1983). PCBs were detected in all of the eggs of six species of South African seabirds and in the majority of eggs from a seventh species in 1981-1983 (de Kock and Randall 1984); in 50 to 55% of eggs of the black-crowned night-heron (*Nycticorax nycticorax*) from Colorado, Wyoming, Washington, and Nevada taken in 1978-1980 (McEwen et al. 1984; Henny et al. 1984); in all Norwegian seabird fledglings in 1976-1977 (Fimreite and Bjerk 1983); in 77% of eggs of the black skimmer (*Rynchops nigra*) from Texas in 1981 (White et al. 1984); in 85 to 100% of all game bird tissues examined in West Germany during 1982 (Brunn et al. 1985); and in 99% of the eggs of the endangered American bald eagle (*Haliaeetus leucocephalus*), including 89% occurrence in breeding areas (Wiemeyer et al. 1984).

Populations of double-crested cormorants (*Phalacrocorax auritus*) from Lake Huron are now recovering rapidly, presumably due to a decrease in CB and other contaminant residues in eggs (Weseloh et al. 1983). In the late 1960's and early 1970's, cormorants nesting on the Great Lakes, and in particular Lake Huron, had eggs that were more highly contaminated with PCBS, DDE, and mercury, than did cormorant eggs from anywhere else in Canada. Concomitantly, egg survival, reproductive success, and colony size were either dangerously low or decreasing. In .1972, colonies were small, they showed high egg breakage and egg loss (95%), and nearly total reproductive failure (less than 0.11 young/nest). Eggshells were about 24% thinner than normal. Levels of DDE (14.5 ppm fresh weight) and PCBs (23.8) in eggs collected in 1972 were higher than other Canadian cormorant populations (Weseloh et al. 1983).

In the past, PCB residues in birds tended to be higher in areas of local contamination and heavy industrial use or discharge. But with the current stringent restrictions on PCB use, geographical distinctions are not as clear (Custer et al. 1983a; McLane et al. 1984), although residues in birds from industrialized areas still remain comparatively high (Fleming et al. 1983; White et al. 1984). For example, birds collected near the Sheboygan River, Wisconsin, contained PCB residues that would be considered harmful to some species tested in the laboratory (Table 2). The main source of PCBs at that location was a diecasting plant. Granular oil absorbent material behind the plant contained up to 120,000 ppm of PCBS; runoff and seepage from rain and floodwaters carried PCBs into the river, subsequently contaminating fish, especially carp (*Cyprinus carpio*). Whole fresh carp from the Sheboygan River contained more than 155 ppm of PCBs (as quoted in Heinz et al. 1984), suggesting that fish-eating birds may be especially at risk.

In 1981 and 1982, duck hunters in New York and New Jersey were cautioned about the consumption of wild waterfowl. At the time, waterfowl from the Hudson and Niagara rivers contained PCBs in excess of tolerances established by FDA for poultry (more than 5 ppm fresh weight), although PCB concentrations found in these waterfowl were below the levels associated with reproductive impairment or decreased survival of birds (Fleming et al. 1983).

Residues of PCBs in birds are modified by numerous biotic factors including fat content, tissue specificity, sex, and developmental stage. PCB residues in birds may also reflect levels due to aerosol transport of these compounds (Weber 1983), as well as water transport (Norheim and Kjos-Hanssen 1984). Highest PCB residues were in birds with low fat content and in poor condition on capture (Falandysz and Szefer 1984). Sexual differences in PCB content are pronounced due to the female's ability to shed a significant portion of the PCB burden into eggs (Lemmetyinen and Rantamaki 1980). Developmental stage is an important consideration when collecting bird samples for PCB analysis (Lemetyinen and Rantamaki 1980); for example, PCB level is reduced from egg to fledgling (Fimreite and Bjerk 1983). Finally, residues in brain appear to be good indicators of PCB stress in birds (Stickel et al. 1984). Concentrations greater than 300 ppm of PCBs in brain (fresh weight) were consistently recorded in dead or dying ring-billed gulls (*Larus delawarensis*) and ring-necked pheasants (*Phasianus colchicus*) poisoned by PCBs, as quoted in Heinz et al. (1984).

MAMMALS

Among mammals, the mink is especially sensitive to PCBS; only 0.64 ppm PCBs in their diets caused reproductive failure, and 1.0 ppm caused death (as quoted in Fleming et al. 1983). In western Maryland and in northern Oregon during 1978-1979 (areas with no recognized large-scale PCB pollution), levels of PCBs in livers of some wild mink were comparable to those reported for female ranch mink that failed to reproduce after eating a diet contaminated with 0.64 ppm of PCBs for 160 days (O'Shea et al. 1981; Henny et al. 1981). Some fish from the Oregon collection sites contained PCB residues (0.24-2.8 ppm fresh weight) that were equivalent to, or higher, than dietary levels fed to mink under controlled conditions (Henny et al. 1981).

PCB concentrations in river otters from the Columbia River, Oregon, during 1978 and 1979, were substantially higher than those reported in the same species from Alabama. The significance of this is not clear, but declining harvests of Columbia River otter populations (as opposed to upward trends elsewhere in Oregon) suggest that PCBs may be a contributory agent (Henny et al. 1981).

In little brown bats (*Myotis lucifugus*) and big brown bats (*Eptesicus fuscus*) from Maryland, pups found dead at birth had significantly more Aroclor than live littermates; moreover, females with elevated Aroclor 1260 residues tended to produce litters with a greater frequency of stillbirths (Clark and Lamont 1976; Clark and Krynitsky 1978).

PCBs were recently detected in 13 of 26 Florida manatees (*Trichechus manatus*), an endangered species. All individuals with detectable PCB residues were recovered from locations in the relatively urbanized areas of northeastern Florida, primarily in the lower St. Johns River and Brevard County (O'Shea et al. 1984).

In harbor seals (*Phoca vitulina*), PCB concentrations decrease with increasing blubber thickness (Van Der Zande and De Ruiter 1983). As expected, lower chlorinated PCBs were eliminated more rapidly from blubber lipids than higher chlorinated PCBS. For harbor seals in particular, blubber PCB residues contained a small fraction of lower chlorinated components when compared to PCB residues in fish that they eat (Van Der Zande and De Ruiter 1983). PCBs in adult Weddell seals (*Leptonychotes weddelli*) were predominantly penta- and hexachlorobiphenyls; a slightly higher amount of lower chlorinated biphenyls were found in newborns (Hidaka et al. 1983), suggesting that lower chlorinated biphenyls are more easily transferred from mother to pup through transplacental action than higher chlorinated biphenyls. Weddell seals contain low concentrations of PCBs in blubber compared to 10 other pinniped species and small cetaceans. This probably reflects the low PCB burdens in their diets attributed, in part, to the heavy ice and snow cover during much of the year that prevents atmospheric deposition of PCBs from entering the water and contaminating their diet (Hidaka et al. 1983).

INTEGRATED STUDIES

Biomagnification of PCBs through marine food chains in an Australian estuary became increasingly important with upper level carnivores such as gulls and pelicans, but was relatively unimportant at lower trophic levels (Shaw and Connell 1982). A similar situation was observed in Central Puget Sound in Washington in 1979 (Malins et al. 1980). PCB body burdens in marine organisms, especially benthic organisms, were directly related to the log of PCB concentration in sediments (Shaw and Connell 1982). Furthermore, PCBs were found in every tissue analyzed from fish and invertebrates in Puget Sound in 1979 (Malins et al. 1980). High PCB levels, especially in sediments, have been recorded from highly industrialized areas worldwide (Baldi et al. 1983).

PCBs used in the manufacture of electrical equipment at two facilities located on the upper Hudson River in Washington County, New York, have resulted in severe PCB contamination of the sediments--reportedly more than 100X greater than any other major river system (Sloan et al. 1983). Edible portions of fish collected from this area often exceeded the FDA tolerance level of 5.0 ppm fresh weight (Sloan et al. 1983). Carcich and Tofflemire (1982) estimated that more than 272,000 kg (perhaps as much as 603,000 kg) of PCBs were discharged into the River, and that most still resides in sediments north of Troy, New York. In the Hudson River, levels of higher chlorinated PCB components typical of Aroclor 1254 have stabilized during 1977 to 1981, suggesting that a dynamic equilibrium has been reached, and that these compounds may continue to exist at concentrations close to present levels (Sloan et al. 1983). Removal of PCB contaminated sediments by dredging from the Hudson River is now being studied, with greatest effort confined to the most highly contaminated 8% of the river bed. Disposal, by total containment and isolation of contaminated materials within a land burial facility, is one of the more preferred options (Carcich and Tofflemire 1982).

TOXICITY

AQUATIC ORGANISMS

LC-50 values of sensitive species of freshwater and marine organisms subjected to various Aroclor PCBs varied from 0.1 to 10.0 ug/l during exposure of 7 to 38 days (Table 3). In general, toxicity increased with increasing exposure, crustaceans and younger developmental stages were the most sensitive groups tested, and lower chlorinated biphenyls were more toxic than higher chlorinated biphenyls. In most toxicity tests, mortality patterns in PCB-exposed fish did not stabilize within 30 days (Johnson and Finley 1980).

BIRDS

As a group, birds were more resistant to acutely toxic effects of PCBs than mammals (Table 4). LD-50s for various species of birds varied from 604 to more than 6,000 mg Aroclor/kg diet, and for mallards more than 2,000 mg/kg body weight administered orally (Table 4). Signs of PCB poisoning among birds included morbidity, tremors (which may become continuous),. beak pointed upwards, and muscular incoordination. At necropsy, the liver frequently contained hemorrhagic areas and the gastrointestinal tract was filled with blackish fluid (Stickel et al. 1984).

For all avian species, PCB residues of 310 mg/kg fresh weight or higher in brain were associated with an increased likelihood of death from PCB poisoning. Residues in brains of starlings, red-winged blackbirds (*Agelaius phoeniceus*), common grackles (*Quiscalus quiscula*), and brown-headed cowbirds (*Molothrus ater*), that died after eating diets containing 1,500 mg Aroclor 1254/kg, varied from 349 to 763 mg/kg; surviving birds, at the 50% mortality point, contained 54 to 301 mg/kg (Stickel et al. 1984). Similar results are reported for ringed turtle-doves (*Streptopelia risoria*) after 105 days fed a 10 mg Aroclor 1254/kg diet, chickens fed Phenoclor, Clophen, and Aroclor PCBS, and finches and cormorants fed Aroclor 1254 (as quoted in Stickel et al. 1984). In the field, PCBs were the probable cause of mortality of many ring-billed gulls that died in southern Ontario in late summer and early autumn of 1969 and 1973; PCB residues in brains were 310 to 1,110 mg/kg fresh weight in 67% of the samples analyzed, and 200 to 310 in the remainder (as quoted in Stickel et al. 1984).

MAMMALS

The mink is the most sensitive wildlife species tested for which data are available (Table 4). Diets containing 6.7 to 8.6 mg Aroclor PCBs/kg fresh weight killed 50% of the mink in 9 months; single dosages administered orally produced LD-50 values of 750 to 4,000 mg/kg body weight, those administered intraperitoneally produced LD-50s between 500 and 2,250 mg/kg body weight (Table 4). Recent data (Aulerich et al. 1985) indicate that certain hexachlorobiphenyls (HCBP), such as 3,4,5,3',4',5' HCBP, are extremely toxic to mink; concentrations as low as 0.1 mg/kg fresh weight diet produced an LD-50 in 3 months, and completely inhibited reproduction in survivors. However, other HCBPS, such as 2,4,5,2',4',5' HCBP and 2,3,6,2',3',6' HCBP, were not fatal to mink under similar conditions, and did not produce adverse reproductive effects (Aulerich et al. 1985). Additional research is needed on the toxicodynamics of PCB congeners. Signs of PCB poisoning in mink included anorexia, bloody stools, fatty liver, kidney degeneration, and hemorrhagic gastric ulcers (Aulerich and Ringer 1977). The reasons for mink sensitivity to PCBs are unknown, but large variations in sensitivity to PCBs among species are common, even among those closely-related taxonomically. The European ferret (*Mustela putorius furo*), for example, is at least three times more resistant than mink to Aroclor 1242 (Table 4).

Rats fed diets containing 1,000 mg of Aroclor 1254/kg diet all died in 53 days; mortality started at day 28 (Hudson et al. 1984). These, and other feeding studies, suggest that a total intake of about 500 to 2,000 mg of Aroclor 1254 per kg body weight is the lethal level in rats for dietary exposures of 1 to 7 weeks. Prior to death, rats showed lack of muscular coordination, eyelid drooping, blanched retinas, morbidity, nasal secretions, and (with Aroclor 1268) a reddish exudate from their eyes (Hudson et al. 1984). Some rats died at 100 mg Aroclor 1254/kg body weight administered orally, or about 1/5 of the dietary LD-50 (Hudson et al. 1984).

SUBLETHAL EFFECTS

GENERAL

PCBs elicit a variety of biologic and toxic effects including skin lesions, a wasting syndrome, immunotoxicity, reproductive toxicity, genotoxic and epigenetic effects, hepatomegaly and related liver damage, and the induction of hepatic and extrahepatic drug-metabolizing enzymes. PCB accumulations from the diet and from other sources are high, and retention is lengthy in fatty tissues. Interspecies differences in sensitivity to PCBs are large, even between species that are closely related taxonomically.

TERRESTRIAL MACROPHYTES

A 5X increase in somatic mutations was observed in ostrich ferns (*Matteuccia struthiopteris*) growing near the Housatonic River in Pittsfield, Massachusetts, on sediments containing mean PCB residues of 26 mg/kg (mostly as Aroclor 1254), when compared to ostrich ferns from control areas (Klekowski 1982). No attempt was

made to duplicate these observations under controlled conditions, and no evidence of genetic damage to other plants of the PCB-contaminated area was found (Klekowski 1982).

AQUATIC ORGANISMS

Bioconcentration of Aroclor 1254 from the medium by selected species of freshwater and marine organisms varied from 60 to 340,000X (Table 5). Various species of algae also concentrate PCBs over water levels by 10,000 to 100,000X (Ernst 1984). Oysters (*Crassostrea virginica*) held for 65 days in seawater solutions containing 0.0055 to 0.06 ug/l of di-, tri-, tetra-, penta-, or hexachlorobiphenyls had bioconcentration factors of 1,200 to 4,800X; uptake was lowest for dichlorobiphenyls and became progressively higher with increasing chlorination of PCB congeners (Ernst 1984). Similar results were recorded for *Daphnia magna* exposed to five different C-14 labeled PCBs for 24 hours. BCFs varied from 473 to 11,232; formulations lowest in water solubilty (highest chlorination) were accumulated most readily (Zhang et al. 1983). For all PCBS, BCFs were generally higher with increasing exposure period, with increasing PCB concentration, and with increasing chlorination of PCB congeners (NAS 1979; Johnson and Finley 1980; EPA 1980).

Since PCBs are highly lipophilic, greatest concentrations were expected, and occurred, in fatty tissues. For example, lipid content in muscle of brown trout (*Salmo trutta*) was the best correlate of PCB concentration in muscle (Spigarelli et al. 1983). Differences in PCB content of tissue lipids were negatively correlated with phospholipid fractions in total lipid extracts; the higher the phospholipid fraction, the lower the PCB content in organ lipids. This has been verified experimentally in codfish and other species of marine teleosts (Boon et al. 1984), and probably should be explored in greater detail for other trophic levels. Other factors known to modify PCB accumulations in aquatic biota include: temperature magnitude and variation for trout (Spigarelli et al. 1983); time of incubation and age of larvae for mosquitos (Gooch and Hamdy 1983); presence of mineral oils on PCB-contaminated substrates for chironomid larvae (Meier and Rediske 1984); and diet for teleosts (Pizza and O'Connor 1983; Spigarelli et al. 1983; O'Connor and Pizza 1984). Of these, diet contributes most of the total PCB body burdens of upper level carnivores. For example, diet accounted for 90% of the total PCB body burden in brown trout (Spigarelli et al. 1983), and 51 to 83% in striped bass (Pizza and O'Connor 1983). PCB body burdens in striped bass were lower in winter during nonfeeding periods, and lower when fish migrated to a new area where dietary PCB levels were lower (O'Connor and Pizza 1984). Prey species of carnivores accumulate PCBs through contaminated sediments. PCB transfer through aquatic ecosystems has been reported in the Great Lakes using a sediment-lake trout model (Jensen 1984), and in New York Harbor from contaminated sediments to clams, shrimp, and especially nereid worms (Rubenstein et al. 1983).

Depuration of accumulated PCBs is slow, and slower yet at reduced temperatures (Zhang et al. 1983). Larvae of codfish exposed to PCBs as eggs showed no elimination after 12 days. Uptake of PCBs by yolk sac larvae was higher than in eggs; 60% of the PCBs remained after 15 days (Solbakken et al. 1984b). Larvae of chironomids (*Glyptotendipes barbipes*), held for 24 days in substrates containing 1,000 mg Aroclor 1242/kg, contained 18.0 mg Aroclor 1242/kg fresh weight; 7 days later, larvae still retained 97.8% of the total (Meier and Rediske 1984). Tissue samples of a Bermuda brain coral (*Diploria strigosa*) taken 9 months after initial exposure for 24 hours to radiolabeled 2,4,5,2',4',5'-hexachlorobiphenyl contained 84% of the original radioactivity (Solbakken et al. 1984a). Rainbow trout fed 1,150 mg Aroclor 1254/kg body weight contained high residues in various tissues 38 days posttreatment: 70 mg/kg in muscle on a fresh weight basis, 33 in liver, and 6 in gill filament (Kiessling et al. 1983). Factors affecting elimination of Aroclor 1254 by marine crustacean copepods (*Acartia tonsa*) include diet and reproductive state (McManus et al. 1983). Copepods fed during depuration eliminated PCBs more rapidly than unfed copepods. PCBs in copepod eggs were up to 4X the concentration in females producing them. Females eliminated PCBs twice as rapidly as males, indicating that egg production is an important route for PCB elimination. Fecal pellets were the most significant elimination route, but levels in fecal pellets from both sexes decreased over time suggesting a multiphasic elimination pattern. In fish, egg maturation and spawning result in a significant reduction in the body burden of persistent PCBs such as 2,5,2',5'-tetrachloro BP (Vodicnik and Peterson 1985). The percent lipid, and the percent of total lipid deposited in their eggs, markedly influences PCB transfer from fish to eggs (Niimi 1983). Mean percent PCB residue levels translocated to eggs in five species of Great Lakes fish varied from a low of 5.4 in rainbow trout to a high of 29.3 in yellow perch, and these (and intermediate) percentages reflected lipid percent levels transferred (Niimi 1983). Structural features in PCB forms and congeners cause different elimination rates between individual components in fish, resulting in differences in PCB composition between tissues and the source of uptake (Boon et al. 1984).

Decreased growth of aquatic organisms during exposure to PCBs is well documented. Concentrations as low as 0.1 ug/l of Aroclor 1254 produced growth reductions in marine diatoms and a freshwater alga (*Scenedesmus quadricauda*), and altered the population structure of phytoplankton communities (EPA 1980). Among sensitive species of freshwater algae treated with Aroclor 1242, including *S. quadricauda*, disruption of internal chloroplast membranes and failure of cytokinesis were the major changes observed (Mahanty et al. 1983). Marine algae exhibited greater-than-expected reductions in photosynthesis when stressed with mixtures of PCBs and DDE (Ernst 1984), and demonstrates the importance of toxicant evaluation of complex mixtures containing PCBs. Decreased shell growth of oysters was reported in acute tests with Aroclor 1016 at 10.1 ug/l, with Aroclor 1248 at 17.0 ug/l, with Aroclor 1254 at 14.0 ug/l, and with Aroclor 1260 at 60.0 ug/l (EPA 1980); similar results were reported for shrimp (Ernst 1984). Fry of brook trout held for 48 days at 1.5 ug Aroclor 1254/1 also showed decreased growth (Johnson and Finley 1980).

Reproductive toxicity of PCBs is reported for Baltic flounder (*Platichthys flesus*) when ovaries exceeded 0.12 mg of PCBs/kg fresh weight, and for cyprinid minnows (*Phoxinus phoxinus*) when gonads contained more than 24 mg PCBs/kg fresh weight; these are the threshold values beyond which reduced survival of developing eggs can be expected in those species Ernst 1984). Gonadal levels of 24 mg/kg in minnows were obtained with diets of 20 mg Clophen A-50/kg for 40 days, followed by 260 days on untreated diets (Ernst 1984). Rainbow trout with whole body residues of 0.4 mg Aroclor 1242/kg fresh weight produced eggs with low survival, and numerous (70%) fry deformities (EPA 1980). Rainbow trout eggs with 0.33 mg Aroclor 1254/kg fresh weight incurred 10 to 28% mortality prehatch, and numerous posthatch deformities (Niimi 1983). Eggs and fry of Atlantic salmon with PCB contents of 0.6 to 1.9 mg/kg fresh weight, or 14.4-34.0 mg/kg lipid weight, experienced 46 to 100% mortality (Niimi 1983). Embryos of sheepshead minnow (*Cyprinodon variegatus*) containing 7 mg Aroclor 1254/kg fresh weight had low survival; these values were effected through exposure of parent fish to 0.14 ug Aroclor 1254/1 for 28 days (EPA 1980). Brook trout experienced complete reproductive failure during exposure to 200 ug Aroclor 1254/1 for 71 weeks; the no effect level was 0.94 ug/l (EPA 1980). Eggs of the sea urchin, *Arbacia punctulata*, exposed for one hour to 0.5 mg Aroclor 1254/1 prior to fertilization showed reduced fertilization success and lowered survival; eggs were markedly more resistant to PCBs at the time of insemination and afterwards (Aroclor 1254) on early development and mortality in Arbacia eggs. (Adams 1983).

Mutagenic properties of Aroclor 1221 and 4-monochlorobiphenyl to bacteria were indicated by positive Ames tests, and Aroclor 1260 and Kanechlor 500 were demonstrably carcinogenic to mice and rats (NAS 1979). Unexpectedly, Aroclor 1254 prevented carcinogenesis and mutagenesis in rainbow trout. Trout fed 100 ppm dietary Aroclor 1254 for 3 months were significantly more resistant to liver carcinomas (induced by dietary aflatoxins) when PCBs were prefed prior to carcinogenic insult (Shelton et al. 1983). At the time of aflatoxin administration, trout contained 594 mg/kg PCBs in fat which declined rapidly over the next 12 months to 3.9 mg/kg. Aflatoxin-induced mutagenesis in trout liver cells was also significantly inhibited (67%) by Aroclor 1254 under similar conditions (Shelton et al. 1983).

Histopathology was reported in sensitive marine teleosts following exposure for 2 weeks to PCB concentrations of 0.5 ug/l; similar damage effects were recorded in oysters held for 24 weeks in 5 ug/l of Aroclor 1254, but not for 30 weeks in 1 ug/l (Ernst 1984).

A wide variety of biochemical perturbations were recorded among teleosts stressed by PCBS. The primary biochemical effect of PCBs is to induce hepatic mixed function oxidase systems, thus increasing the organism's capacity to biotransform or to detoxify xenobiotic chemicals and endogenous steroids (Melancon and Lech 1983; Shelton et al. 1983). Coho salmon injected intraperitoneally with 50 to 100 ug Aroclor 1254/kg body weight just prior to smoltification contained elevated levels of PCBs in liver (500 to 1,200 ppb) 2 weeks after injection when compared to controls (25 to 45 ppb), showed depressed gill Na-K ATPase and plasma thyroxin levels, and experienced great difficulty in adapting to seawater (Folmar et al. 1982). Biochemical indicators suggested that tissue accumulations of PCBs (at concentrations that clearly could be derived through a contaminated diet or from water column exposure) delayed events preparatory to, and involved in, saltwater adaptation in coho salmon. Mixtures of Aroclor 1242 and 1254 fed to rainbow trout and coho salmon at dietary concentrations of 500 ppm PCBs for 7 to 10 weeks produced inhibited growth, enlarged livers, elevated muscle water content, and lowered muscle lipid content (Leatherland and Sonstegard 1981). Salmon showed disrupted calcium and magnesium metabolism in blood, muscle, and skeleton. After about a week on PCB diets, both trout and salmon showed signs of poor muscle coordination and tetany, accompanied by lateral or ventral caudal flexion (scoliosis or lordosis). Brown trout fed diets containing 10 ppm of Clophen A-50 for 43 days were

anemic, hyperglycemic, and showed altered cholesterol metabolism (EPA 1980). Brook trout held in Aroclor 1254 solutions of more than 0.43 ug/l for 48 days had decreased concentrations of hydroxyproline in collagen isolated from the backbone (Johnson and Finley 1980). However, Aroclor 1254 did not markedly affect adrenaline response in gills of rainbow trout, or glycogen storage in muscle (Kiessling et al. 1983).

Maximum Acceptable Toxicant Concentration (MATC) values bracket the "no effect," and "measurable effect" levels, and are based on chronic exposure, and variables such as growth, reproduction, and metabolic upset. MATC values for selected species of aquatic organisms and Aroclor PCBS, with one exception, varied from 0.1 to 5.4 ug/l for the no effect level, and from 0.4 to 15.0 ug/l for measurable effects (Table 6). The exception was larvae of the sheepshead minnow (which was especially sensitive) with an MATC of 0.06 to 0.16 ug/l for Aroclor 1254 (Table 6).

BIRDS

Among sensitive avian species, PCBs disrupt normal patterns of growth, reproduction, metabolism, and behavior. In general, PCB accumulation is rapid and depuration is lengthy. Diet is an important route of PCB accumulation. Concentrations in liver (mg/kg fresh weight) were highest (900) in birds that fed on fish, followed by species that feed on small birds and mammals (50), worms and insects (0.65), and lowest (0.2) in herbivorous species (NAS 1979).

Delayed reproductive impairment was documented in ringed turtle-doves given 10 ppm of dietary Aroclor 1254 for 3 months; residues in the fat of adults was 736 ppm, and in their eggs 16 ppm fresh weight (as quoted in Heinz et al. 1984). Hatchability of ringed turtle-dove eggs from the first clutch was not reduced by consumption of Aroclor by the adults. However, 6 months later, the hatchability of the second clutch (accompanied by abnormal incubation behavior) was reduced to 10% of controls; embryos also contained chromosomal aberrations (Peakall et al. 1972). Mourning doves (*Zanaida macroura carolinensis*) given dietary Aroclor 1254 for 6 weeks at 0, 16, or ppm were observed for courtship behavior and reproductive effort during days 14 to 44 posttreatment (Tori and Peterle 1983). Doves fed 10 ppm spent twice as much time as controls in the courtship phase (billing, cooing, nest site selection), but only 50% of these pairs completed the courtship phase and progressed into nest building and incubation; of those that nested, nest initiation was significantly delayed. Doves fed 40 ppm spent the 30 days posttreatment in courtship without nesting; most of this group, especially females, did not respond normally to the presence of a mate. Tori and Peterle (1983) suggested that the disrupted reproductive behavior observed in PCB-treated doves was due to reduced estrogen and androgen levels. PCBs have been shown to degrade estrogens and androgens by increasing the activity of hepatic microsomal enzymes (as quoted in Tori and Peterle 1983). Hatchability of chicken eggs was reduced when hens were fed diets containing 20 ppm of various Aroclor PCBs (1232, 1242, 1248, or 1254). PCB residues in samples of fat from treated hens varied from 45 to 125 ppm, and in their eggs from 3 to 14 ppm (as quoted in Heinz et al. 1984). Reproductive impairment in chickens was recorded at Aroclor dietary levels as low as 5 ppm; effects at the 2 ppm level were not significant (Heinz et al. 1984). American kestrels (*Falco sparverius*) given 33 ppm of dietary Aroclor 1254 for 62 to 69 days (equivalent to 9 to 10 mg/kg body weight/daily), showed a significant decline in sperm concentration, but no compensatory increase in semen volume (Bird et al. 1983). PCB residues in treated kestrels, in ppm lipid weight, were 107 in muscle and 128 in testes; for controls, these values were 0.4 in muscle and 1.0 in testes. These results suggest that migratory flesh-eating birds feeding on a PCB-contaminated food chain might consume enough toxicant to alter their semen quality in that breeding season; when coupled with altered courtship, this could reduce the fertility of the eggs and reproductive fitness of the individual (Bird et al. 1983).

Among comparatively resistant species of birds, no significant reproductive effects were observed during long-term exposures at high Aroclor 1254 feeding levels in Japanese quail *Coturnix coturnix* (50 ppm in diets), northern bobwhites *Colinus virginianus* (50 ppm) 979), and mallards (25 ppm) (Custer and Heinz 1980). Screech owls (*Otus asio*), given 3 ppm of Aroclor 1248 in their diets for two breeding seasons, laid eggs containing 3.9 to 17.8 mg PCBs/kg fresh weight compared to control values of 0.0 to 0.6; however, reproductive variables, including eggs per clutch, hatchability, chick malformations, survival, and eggshell thickness, were not affected (McLane and Hughes 1980).

For most avian species, a reduction in eggshell thickness of 15 to 20% is suggested as a critical value beyond which population numbers will decline (Nygard 1983). Pheasants fed 50 mg of Aroclor 1254 weekly produced fewer eggs, but an effect on eggshell thinning was not apparent before other effects became obvious

(Roberts et al. 1978). However, eggshell thickness of the peregrine falcon (*Falco peregrinus*) from Norway declined 85% between 1854 and 1976; addled eggs containing dead embryos collected in 1976 had 724 ppm of PCBs in lipids, and up to 110 ppm on a fresh weight basis (Nygard 1983) Peregrine populations have declined in Norway, but the high DDT levels (which cause eggshell thinning) in tissues and eggs--together with measurable residues of dieldrin and mercury--made it difficult to ascribe thinning or population declines exclusively to PCBs (Nygard 1983). Mean PCB residues were significantly lower in eggs from successful nests of the American bald eagle than unsuccessful nests (1.3 ppm fresh weight vs. 7.2), and may be associated with eggshell thinning (Wiemeyer et al. 1984). PCB concentrations in eggs were inversely correlated with shell thickness in the bald eagle (Wiemeyer et al. 1984) as well as the black-crowned night-heron (McEwen et al. 1984; Henny et al. 1984). However, PCB content is frequently correlated positively with DDE content- (Norheim and Kjos-Hanssen 1984), which is known to interfere with avian calcium metabolism and to induce thin eggshells. The observed thickening of eggshells in black-crowned night-heron eggs between 1973 and 1979 in colonies from Rhode Island locations was associated with marked reductions in both PCBs and DDE (Custer et al. 1983a,b). At present, the evidence implicating PCBs as a major source of eggshell thinning is inconclusive.

Loss rates were followed in common grackles fed 150 ppm dietary Aroclor 1254 for 8 days, then given untreated food and killed at 1 to 32 weeks posttreatment (Stickel et al. 1984). PCB levels in bodies of grackles declined from 1,300 ppm fresh weight on the day clean food was restored, to 169 ppm 32 weeks later. The overall loss rate was estimated at 0.77% daily with a calculated biological half-life of 89 days. Similar loss rates were observed in pheasants given a single capsule dosage of Aroclor 1254 (as quoted in Stickel et al. 1984). In general, PCB residues in brain are good indicators of PCB exposure. For example, Japanese quail fed 1,000 ppm of Aroclor 1260, and that subsequently died, contained 780 ppm in brain; treated survivors contained 250 ppm (as quoted in Heinz et al. 1984). Also, various species of small birds that were killed by dietary exposure to Aroclor 1254 had PCB brain residues of 349 to 763 ppm (Heinz et al. 1984).

PCBs are associated with a variety of biochemical, histopathological, and behavioral responses in birds. PCBs affect zinc and calcium metabolism in chickens, disrupt vitamin A use in quail, and potentiate vitamin A deficiency in chickens by interfering with selenium use (Roberts et al. 1978). Body temperature, serum chemistry, and thyroid function of ringed turtle-doves was significantly altered by 3,4,3',4'-tetrachlorobiphenyl (Spear and Moon 1985). Metabolism of various respiratory pigments was disrupted by PCBs in birds and mammals (Roberts et al. 1978). PCBs are good inducers of drug-metabolizing enzymes that are vital in detoxification processes. Aroclor 1254 injected once into liver parenchymal tissue of the barn owl (*Tyto alba*), at 30 mg/kg body weight, produced increases in the levels of liver cytochrome P-450 activities (Rinzky and Perry 1983). Ringed turtle-doves fed 10 or 100 ppm of dietary Aroclor 1254 showed depressed levels of dopamine and norepinephrine; PCB residues in the brains of these doves averaged 2.8 in the 10 ppm group, and 18.3 ppm in the 100 ppm group (Heinz et al. 1984). Pelicans (Pelecanus sp.) fed 100 ppm of dietary Aroclor 1254 for 10 weeks showed increase liver histopathology (NAS 1979). Certain PCB congeners produce acute histopathologic changes in chick embryo liver, and these same congeners selectively induce cytochrome P-448 mediated mixed function oxidases; adverse effects were noted within 24 hours at concentrations as low as 146 mg of 3,4,3',4'-tetrachlorobiphenyl and 3,4,5,3',4',5'-hexachlorobiphenyl on a whole egg fresh weight basis (Rifkind et al. 1984). PCBs also have been associated with abnormal behavior in European robins (*Erithacus rubecula*), pheasants, quail, and other avian species according to Heinz et al. (1984).

MAMMALS

The mink is one of the most sensitive mammalian species to PCBs (Aulerich et al. 1985). Signs of PCB poisoning in mink include anorexia, weight loss, lethargy, and unthrifty appearance; prior to death, dark fecal stools indicative of the presence of blood from the upper gastrointestinal tract (confirmed by necropsy) was observed. Enlarged livers of mink given PCB diets were typical; a similar pattern has been associated in practically all species studied. PCB residues (10 to 15 ppm whole body fresh weight) within Great Lakes fish incorporated into the diet of mink caused reproductive problems and death in commercially ranched mink as long ago as 1965. Diets supplemented with as little as 2 ppm of Aroclor 1254 for 8 months, or 5 ppm for 4 months, resulted in near reproductive failure--with normal breeding and whelping, but a high death rate of kits; reproduction was not affected at dietary levels of 1 ppm of Aroclor 1254. Certain hexachlorobiphenyl isomers can produce death and reproductive toxicity in mink at dietary concentrations as low as 0.1 mg/kg, while other hexachlorobiphenyls are relatively innocuous (Aulerich et al. 1985). Biologically modified PCBs are more toxic to mink than corresponding technical mixtures. For example, tissues from cattle that had been dosed with

Aroclor 1254 and fed to mink at levels as low as 0.64 ppm fresh weight of diet caused severe reproductive effects, possibly because cattle tissues retained more of the highly chlorinated congeners of the PCB mixture once they have been metabolized. But Aroclors 1016 and 1221, at dietary concentrations of 2 ppm, produced no adverse reproductive effects in mink over a 9-month period, nor did Aroclor 1242 at 5 ppm during a similar period; the reasons for this are unknown but may be due to the ability of mink to metabolize selected PCB congeners. Mink, for example, easily eliminate 2,2',4,4',5,5'-hexachlorobiphenyl, but in rats, domestic pigeons (*Columba livia*), and trout, this congener remains almost indefinitely (Hornshaw et al. 1983). Placental transfer of PCBs occurs in mink, as has been demonstrated for rats, rabbits, cattle, rhesus monkeys, ferrets, and humans, and gives rise to the embryotoxicity demonstrated by these species (Ringer 1983). A significantly greater quantity of PCBs enters the growing offspring of mink from mammary transfer than from placental transfer. This PCB transfer by the lactating mink probably resulted in the high offspring mortality observed when Great Lakes fish were fed to commercial ranch mink in the late 1960's. Aroclor 1254 residues in subcutaneous fat of adult mink was up to 38X dietary levels, and some individual congeners accumulated up to 200X. The time for 50% elimination of PCBs from adipose tissues was about 98 days, and about 199 days for 100% elimination. Comparable data for other mammals indicate that PCBs are eliminated more rapidly by these species than mink, with 50% half-life times of 33 hours to 69 days for tissues of rat and dairy cows (EPA 1980; Stickel et al. 1984). In general, PCB residues in fat of mink were highest in winter when fat deposits were mobilized during cold weather and PCB residues were concentrated in remaining fat stores; this is consistent with the results obtained from pigeons subjected to low temperatures and starvation (Hornshaw et al. 1983).

The European ferret was significantly more resistant to PCBs than mink, and demonstrates that interspecies sensitivity to PCBs varies widely, even among taxonomically close species (Ringer 1983; Bleavins et al. 1984). In ferrets, total reproductive failure was documented in 9-month feeding studies of Aroclor 1242 at dietary levels of 20 ppm, but Aroclor 1016 at 20 ppm did not affect reproduction during a similar period. PCBs in maternal body fat stores of ferrets represent a reservoir that can be transferred to the developing fetus and growing neonate (Aroclor 1254) in the European ferret (Bleavins et al. 1984). Placental transfer of Aroclor 1254 to kits of the European ferret was about 0.01% per kit of the female's absorbed dietary dose when exposure occurred during the first trimester of pregnancy, and 0.04% when PCBs were administered during the third trimester. Transfer of PCBs through the dam's milk was also documented, and this route was 6 to 15X more effective than placental transfer.

The rhesus monkey (*Macaca mulatta*) is extremely sensitive to PCBs (Roberts et al. 1978; NAS 1979 EPA 1980; Safe 1984). Females fed diets containing 2.5 to 5.0 ppm of Aroclor 1248 for 6 months showed altered menstrual cycles, an increased frequency of stillbirths and abortions, a lowered birth rate, hyperpigmentation, skin eruptions, eye problems, and negatively altered behavioral patterns. Males were less sensitive than females; however, when fed diets containing 300 ppm of Aroclor 1248 for one month, both sexes showed hair loss, purulent discharges from the eyes, acneform skin eruptions, and hypertrophy of the liver and gastric mucosa. Rhesus monkeys can efficiently absorb Aroclor 1248 from the gut; 90% of a single oral dose of 1,500 or 3,000 mg/kg body weight was reported absorbed from the gastrointestinal tract. This, and the fact that rhesus monkeys were unable to efficiently eliminate or metabolize certain PCB congeners (i.e., 2,5,2',5'-tetrachlorobiphenyl) when compared to other species, may partially account for the sensitivity of this species. Infant rhesus monkeys, born to mothers exposed to 2.5 ppm of Aroclor 1248 in the diet during pregnancy and lactation, survived over 4 months; PCB levels in their fat declined over a period of 8 to 23 months.

In Japan, humans were accidentally poisoned by rice oil containing 2 to 3 mg of Kanechlor 400/kg (EPA 1980; Lucier and Hook 1985a,b). Symptoms included increased eye discharges and swelling of upper eyelids, acneform skin eruptions, skin pigmentation, hearing and vision problems, gastrointestinal disturbances, and altered blood chemistry. Infants born of Japanese women married to afflicted males were small for their age, had unusual pigmentation, premature eruption of teeth, and exophthalmia (popeyes). Three years after exposure, 50% of the patients were improving, 40% were unchanged, and 10% were worse. Even among those said to be improving, many still complained of headaches, fatigue, weakness and numbness of the limbs, and weight loss. Impurities in the Kanechlor 400 mixture included polychlorinated dibenzofurans and dioxins at levels up to 5 ppm, and these may be responsible, in part, for the observed symptoms in victims.

Mutagenic, carcinogenic, and teratogenic properties of PCBs are documented. Certain PCB congeners, such as 4-chlorobiphenyl, were highly mutagenic to *Salmonella typhimurium* in Ames tests (EPA 1980). Aroclor 1221 was less mutagenic, while Aroclors 1254 and 1268 were essentially inactive. In general, mutagenic

activity tends to decrease with increasing chlorination (EPA 1980). The carcinogenic effects of PCBs have been established in mice and rats with various Aroclor and Kanechlor PCBs and these, in turn, may enhance the carcinogenicity of other chemicals (EPA 1980). Experimental data clearly shows that commercial PCBs cause liver damage which leads to putative preneoplastic changes and hepatocellular carcinomas; however, these lesions are observed only after lengthy (11 to 21 months) exposures to relatively high doses (100 to 1,200 ppm in diets) of these chemicals (NAS 1979; Safe 1984). PCBs were also shown to inhibit the growth of experimental tumors in rats (EPA 1980); administration of Aroclor 1254 (either dietary or injected) for 5 days before or after tumor inoculation was more effective than administration between days 5 and 10. Teratogenic effects of PCBs observed in monkeys and rabbits include abnormal skull formation of fetuses exposed to high levels of Aroclor 1254 in utero, and retarded growth (EPA 1980).

Aroclor 1254 at dietary levels of 25 to 100 ppm for up to 3 weeks can significantly reduce sleeping times in animals that normally aestivate or hibernate, such as white-footed mice, *Peromyscus leucopus* (Sanders and Kirkpatrick 1977), and raccoons, *Procyon lotor* (Montz et al. 1982). The implications of this are not clear, and additional research is needed. Other systemic effects of PCBs that occur in a wide variety of animal species include hepatic disorders distinguished by altered porphyrin metabolism, increased thyroxin metabolism and ultrastructural changes in the thyroid, inhibition of ATPases, interference with oxidative phosphorylation, alterations in steroid hormone activities, immunosuppressive effects, and altered vitamin A metabolism (EPA 1980; Safe 1984).

CURRENT RECOMMENDATIONS

Effective July 1979, under Section 6e of the Toxic Substances Control Act, and unless specifically exempted by the U.S. Environmental Protection Agency, the manufacturing, processing, commercial distribution, and use of PCBs (except in a totally enclosed system) were prohibited (Bremer 1983). Similar actions had been initiated by Michigan, Wisconsin, and Minnesota in 1977 (Bremer 1983). However, PCBs remain universally distributed in the environment, and releases still include those from manufacturing, leaks from supposedly closed systems, and disposal of PCBs manufactured prior to 1971 (Ayer 1976). PCB burdens in waters, sediments, soils, disposal sites, and in deployed transformers and other containers of PCB is estimated at 82 million kg (D'Itri and Kamrin 1983). At this time, total PCB residues in organisms appear to be a more reliable measure of environmental PCB levels than measurements of any commercial mixtures (Schmitt et al. 1985). In light of the demonstrated differential toxicities within the array of PCB congeners, existing standards and criteria may need to be modified in order to reflect the more toxic PCBs (Brown et al. 1985).

PCB tolerance levels have been recommended for protection of various environmental resources and human health (Table 7). The recommended freshwater aquatic life protection criterion of 0.014 ug/l (24-hour average) is lower than 0.1 ug/l, a concentration known to adversely affect the growth of freshwater algae and fish (EPA 1980). This criterion would probably afford a satisfactory degree of protection to freshwater life if it were changed from 0.014 ug/l (24-hour average) to 0.014 ug/l (maximum). Criteria based on average daily concentrations usually indicate that high doses of toxicants may occur within a short period. Unfortunately, data bases existing for PCBs are inadequate to predict long-term effects on growth, uptake, and other variables when repeated high doses occur in short intervals.

The criterion of 0.03 ug/l (24-hour average) recommended for saltwater aquatic life protection is unsatisfactory. Concentrations of 0.1 ug/l of Aroclor 1254 are fatal to sheepshead minnows in 21 days, and concentrations as low as 0.006 ug/l result in significant uptake by oysters over a period of 65 days (Ernst 1984). Until additional data become available, the saltwater aquatic life protection criterion should not differ from the freshwater criterion (0.014 ug/l, maximum).

Fish diets containing 1.0 mg of Aroclor 1254 per kg fresh weight produced pathological changes in the kidney of rainbow trout after 11 months, and diets containing 1.2 mg Aroclor 1248/kg fresh weight produced progressive degenerative changes in the liver of lake trout after 9 months (Roberts et al. 1978). The current recommended level for PCBs in fish diets of less than 0.5 mg/kg fresh weight is based on investigations with striped bass by O'Connor and Pizza (1984). They found that food items containing less than 0.5 mg/kg fresh weight will not, in the course of one growing season, cause body burdens in striped bass to exceed 2 mg/kg fresh weight, a proposed Food and Drug Administration guideline for PCB burdens in fish. Striped bass are mobile, pelagic, and highly migratory; accordingly, dietary levels may have to be revised downwards for benthic, nonmigratory species that frequent localized areas of high PCB contamination (O'Connor and Pizza 1984).

Whole body residues of 0.4 mg PCBs/kg fresh weight are associated with reproductive toxicity in rainbow trout (EPA 1980). The large discrepancy between this value and the current recommended level of 5.0 mg/kg fresh weight in fish and shellfish (Table 7) will be discussed later. Eggs of rainbow trout containing 0.33 mg PCBs/kg fresh weight showed reduced hatch, and a significant increase in larval deformities (Niimi 1983). PCB residues of 0.12 mg/kg fresh weight in gonads of field-collected Baltic flounders may be associated with population declines of that species (Ernst 1984), but this needs to be verified experimentally.

Birds seem relatively resistant to PCBS. Among sensitive species, female screech owls fed 3.0 mg of PCBs/kg fresh weight diet laid eggs containing up to 17.8 mg/kg fresh weight; however, no other adverse effects were observed in either parents or progeny (McLane and Hughes 1980). Higher dietary exposures of 5 mg/kg in chickens, and 10 mg/kg in mourning doves resulted in reproductive impairment (Tori and Peterle 1983; as quoted in Heinz et al. 1984). Fertilized eggs of ringed turtle-doves containing 16.0 mg PCBs/kg fresh weight showed delays in growth and development (Peakall et al. 1972), and residues of this magnitude should be considered as presumptive evidence of significant PCB contamination. Residues in brain appear to be good indicators of PCB exposure in birds. Concentrations in excess of 301 mg PCBs/kg brain fresh weight is strong evidence of PCB poisoning, while concentrations in excess of 54 mg/kg fresh weight were common in brain of various avian species that survived high PCB dosages (Stickel et al. 1984).

Rats and dogs (*Canis* sp.) fed various Aroclor PCBs for 2 years showed no measurable effects at dietary levels equivalent to 0.255 (dogs) and 0.5 (rats) mg/kg body weight daily. Using a safety factor of 100, tolerable exposure limits of 2.5 (dog) and 5.0 (rat) ug PCBs/kg body weight daily were derived (Table 7). For the rhesus monkey, a comparatively sensitive species, the new temporary tolerance exposure is 1.0 ug/kg body weight daily (Grant 1983). The mink is the most sensitive animal tested to PCBs, with death and reproductive toxicity documented at 100 to 640 ug PCBs/kg fresh weight of diet (Table 7). The feeding level at which no measurable effects occur is not known with certainty. However, the calculated maximum tolerance level for mink is less than 1.54 ug PCBs/kg body weight daily. This value was derived by known growth rates of female mink between ages 7 and 31 weeks (NAS 1968)--when their body weight increased from 560 g to 1,130 g--by the percent of body weight consumed as food on a daily basis (16.4 to 27.2), and by a safety factor of 100 applied to a dietary level of 0.64 mg PCBs/kg fresh weight of diet. Since safety factors are usually applied to the no observed effect levels, a tolerable level of PCBs for mink may be less than 1.0 ug/kg body weight daily. Other species of mammalian wildlife tested were more resistant to PCBs than mink, and tolerance levels for livestock (Table 7) may also afford a reasonable degree of protection for wildlife, except mink.

Sound management of fishery and wildlife resources--including those resources that are artificially propagated and released--requires noninterference with desired uses such as health and well being of humans and other organisms at various trophic levels. Prior to the legislative restrictions on PCB use, Substantial losses to the atmosphere resulted from evaporation of plasticizers and from improper incineration, directly impacting occupational workers (EPA 1980), as well as aquatic ecosystems (Ayer 1976). In recent years, PCB levels have significantly declined in all human food items, with the possible exception of fish; most samples of fish containing more than 5.0 mg PCBs/kg fresh weight originated from the Great Lakes area (Hoeting 1983). In Michigan, all of a sample of 1,057 mothers had measurable PCBs in their breast milk at an average level of 2.3 mg/kg. Nursing infants from Michigan mothers might consume 10 to 25X the maximum daily dose rate of 1.0 ug PCBs/kg body weight that is currently recommended by the U.S. Food and Drug Administration for human adult intake (Swain 1983). The Michigan Department of Public Health has since established a Public Health Advisory related to fish consumption. They recommend that children, pregnant women, nursing mothers, and women who expect to bear children should not consume fish from the Great Lakes area (Swain 1983). Canadian PCB tolerance levels in food items for human health protection are markedly lower than those of the United States (Table 7). In one case, the current USA health tolerance level of 5.0 mg/kg fresh weight in fish and shellfish presents a distinct hazard to piscivorous teleosts and to fish-eating birds and mammals. A lowering from 5.0 to 2.0 mg PCBs/kg fresh weight in fish and shellfish has been proposed by FDA, but the tolerance level has not yet been changed; the delay appears to be based on economic reasons (Hoeting 1983). In the Great Lakes, for example, 55% of the domestic fish samples collected in 1979-1980 exceeded 2.0 mg PCBs/kg fresh weight; in 1980-1981, this was 17%; and in 1981-1982, 10% of the samples exceeded 2 mg/kg, including chinook salmon and their eggs, and lake trout (Hoeting 1983). In every collection year, measurable PCB residues were recorded in at least 28% of the Great Lakes fish samples collected (Hoeting 1983). At present, three courses of action appear warranted: continuation of the Nationwide monitoring program of fish and wildlife for PCBs and other environmental pollutants (O'Shea and Ludke 1979), additional investigations on the fate of PCBs under

conditions prevailing in the natural environment, and controlled studies on the toxicological significance of chlorinated dibenzofurans and other trace impurities found in commercial PCB mixtures and used PCB containing fluids.

Table 1. Average chlorine content, chlorine atoms per molecule, and molecular weight of selected Aroclor and Kanechlor PCB formulations (after Roberts et al. 1978).

Trade name and formulation		Percent chlorine	Mean no. chlorine atoms per molecule	Mean molecular weight
Aroclor	Kanechlor			
1221	---	20.5-21.5	1.15	192
1232	200	31.5-32.5	2.04	221
1242	300	42	3.10	261
1248	400	48	3.90	288
1254	500	54	4.96	327
1260	600	60	6.30	372
1262	---	61.5-62.5	6.80	389
1268	---	68	8.70	453

Table 2. PCB concentrations in field collections of selected species of flora and fauna. Values shown are in mg/kg (ppm) fresh weight (FW), dry weight (DW), or lipid weight (LW).

Taxonomic group, organism tissue, location and other variables	Concentration[a] (ppm)	Reference[b]

Table 6. Maximum acceptable toxicant concentration (MATC) values for Aroclor PCBs and selected species of aquatic organisms, based on exposure for life cycle, partial life cycle, or early life stage (from EPA 1980).

Ecosystem, organism, Aroclor PCB	MATC[a] (ug/l)
Freshwater	
Cladoceran, *Daphnia magna*	
1248	1.2-3.5
1254	2.5-7.5
Amphipod, *Gammarus pseudolimnaeus*	
1242	2.8-8.7
1248	2.5-5.1
Insect (midge), *Tanytarsus dissimilis*	
1254	0.5-1.2
Brook trout, *Salvelinus fontinalis*	
1254	0.7-1.5
Fathead minnow, *Pimephales promelas*	
1242	5.4-15.0
1248	0.1-0.4
1254	1.8-4.6
1260	1.3-4.0

Marine	
Sheepshead minnow, *Cyprinodon variegatus*	
Early life stage	
1016	3.4-15.0
1254	0.06-0.16

[a]Lower value in each pair indicates highest concentration tested producing no measurable effect on growth, reproduction, survival, and metabolic upset during chronic exposure; higher value indicates lowest concentration tested producing a measurable effect.

Table 7. Proposed PCB criteria for protection of various resources and human health.

Patuxent Wildlife Research Center
U.S. Fish and Wildlife Service
Laurel, MD 20708

SUMMARY

Polychlorinated dibenzo- *para*- dioxins (PCDDS) are present as trace impurities in some manufactured chemicals and industrial wastes. The chemical and environmental stability of PCDDs and their tendency to accumulate in fat have resulted in their detection within many ecosystems. In general, wherever high levels of PCDDs have been detected, the source has been a hazardous waste dump, an industrial discharge, or an application of PCDD-contaminated herbicide.

There are 75 PCDD isomers; some are extremely toxic, while others are believed to be relatively innocuous. The most toxic and most extensively studied PCDD isomer is 2,3,7,8-tetrachlorodibenzo- *para*- dioxin (2,3,7,8-TCDD). In the United States and elsewhere, accidental contamination of the environment by 2,3,7,8-TCDD has resulted in deaths in many species of wildlife and domestic animals. High residues of 2,3,7,8-TCDD in fish, i.e., more than 50 parts-per-trillion (ppt) wet weight, have resulted in closing rivers to fishing. In the most seriously affected areas, hospitalization and permanent evacuation of humans has been necessary. Laboratory studies with birds, mammals, aquatic organisms, and other species have demonstrated that exposure to 2,3,7,8-TCDD can result in acute and delayed mortality as well as carcinogenic, teratogenic, mutagenic, histopathologic, immunotoxic, and reproductive effects. These effects varied greatly among species.

No regulations governing PCDD contamination exist at present to protect sensitive species of wildlife and aquatic organisms. However, the limited data available suggest that 2,3,7,8-TCDD concentrations in water should not exceed 0.01 ppt to protect aquatic life, or 10 to 12 ppt in food items of birds and other wildlife. Additional data are needed in several areas: background levels of PCDDs in natural systems; identification of fish and wildlife populations at risk; relative importance of PCDD sources; toxicological effects of various PCDDs to aquatic biota and wildlife, especially reproductive and immunosuppressive effects; and toxic and other interaction effects of PCDDs with other groups of polychlorinated chemicals having similar structure and properties, such as biphenyls, dibenzofurans, and biphenylenes.

INTRODUCTION

Accidental contamination of the environment by polychlorinated dibenzopara- dioxins (PCDDs), especially 2,3,7,8-tetrachlorodibenzo -*para*- dioxin (2,3,7,8-TCDD), has been associated with poor reproduction of herring gulls (*Larus argentatus*) in Lake Ontario (Stolzenburg and Sullivan 1983), with the closure of selected rivers in Missouri to anglers due to high residues in fish (Powell 1984), with the destruction of fish and wildlife in Vietnam during. military defoliation operations using phenoxy herbicides (Rappe 1984), and with the death of livestock and wildlife in Missouri (Powell 1984) and Italy (Fanelli et al. 1980b). For example, in 1976, massive kills of small animals (predominantly rabbits and poultry) occurred within the first few weeks after a chemical plant explosion in Seveso, Italy, in which 2,3,7,8-TCDD was released; many humans were hospitalized (Fanelli et al. 1980b). Levels of 2,3,7,8-TCDD in milk from dairy cows and tissues of pigs, chickens, cattle, goats, and sheep from Seveso were sufficiently elevated to pose a risk to human health. Accordingly, all domestic livestock in the most seriously afflicted areas were destroyed. In eastern Missouri during 1971, waste oil contaminated with 2,3,7,8-TCDD was applied to control road dust (Powell 1984). Later, hundreds of horses kept in riding arenas became sick, and 75 died; deaths were also observed among dogs, rodents, chickens, cats, and birds near the treated areas. Soils in Times Beach, Missouri were so heavily contaminated with 2,3,7,8-TCDD that it was permanently evacuated in December 1982. The U.S. Environmental Protection Agency had earlier announced that they would buy the dioxin-contaminated city of Times Beach; once purchase is completed the city will no longer exist officially (Powell 1984). Approximately 22 kg (48.4 pounds) of 2,3,7,8-TCDD were involved in the Times Beach incident (Westing 1978).

PCDDs are present as trace impurities in some commercial herbicides and chlorophenols. They can be formed as a result of photochemical and thermal reactions in fly ash and other incineration products. Their presence in manufactured chemicals and industrial wastes is neither intentional nor desired. The chemical and environmental stability of PCDDs coupled with their potential to accumulate in fat has resulted in their detection throughout the global ecosystem. The number of chlorine atoms in PCDDs can vary between one and eight to produce up to 75 positional isomers. Some of these isomers are extremely toxic, while others are believed to be relatively innocuous. The most toxic and extensively studied PCDD isomer is 2,3,7,8-TCDD. In fact, it is the most toxic synthetic compound ever tested under laboratory conditions. This isomer is produced during the synthesis of 2,4,5-trichlorophenol, which is used in the manufacture of the herbicide 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), and other trichlorophenoxy acids, and the germicide hexachlorophene. There is general agreement that 2,3,7,8-TCDD is exceedingly stable, readily incorporated into aquatic and terrestrial ecosystems, extraordinarily persistent, and virtually impossible to destroy. PCDD-contaminated phenoxy herbicides are not the only sources of 2,3,7,8-TCDD, others include polychlorinated biphenyls and pentachlorophenols. The other 74 isomers enter the biosphere from a variety of sources (NRCC 1981). The fate and effects of PCDDs--with special reference to 2,3,7,8-TCDD and its role in poisonings of humans, aquatic organisms, wildlife, livestock, poultry, and its contamination of vegetation, soils, and sediments--have been extensively reviewed (Blair 1973; Cattebeni et al. 1978; Ramel 1978; Nicholson and Moore 1979; NRCC 1981; Hay 1982; Kociba and Schwetz 1982a,b; Choudhary et al. 1983; Josephson 1983; Long et al. 1983; Stolzenburg and Sullivan 1983; NIOSH 1984; Nriagu and Simmons 1984; Rappe 1984; Webb 1984; Kamrin and Rodgers 1985; Stalling et al. 1985a,b; Young and Cockerham 1985).

This account summarizes available data on ecological and toxicological aspects of PCDDs in the environment, with special reference to fish, wildlife, and their diets. In addition, it reviews and provides recommendations for the protection of sensitive species of wildlife and aquatic biota. This report is part of a continuing series of synoptic reviews prepared in response to requests for information from Resource Contaminant Specialists of the U.S. Fish and Wildlife Service.

ENVIRONMENTAL CHEMISTRY

The PCDDs consist of 75 isomers that differ in the number and position of attached chlorine atoms; each isomer has its own unique identity and toxicological properties. The most toxic of the chlorinated dioxin isomers is 2,3,7,8-TCDD (Figure 1). It is one of 22 possible congeners of tetrachlorodibenzo- *p*- dioxin. There is general agreement that PCDDS, including 2,3,7,8-TCDD, are (or were, until recently) found in chlorophenols, especially trichlorophenol and pentachlorophenol (Table 1), in certain phenoxy pesticides (2,4,5-T; 2,4-D; Fenoprop; Silvex; Ronnel; Erbon; Agent Orange), in hexachlorophene, and in polychlorinated biphenyls (used in electrical transformers and capacitors, and contaminated with trichlorobenzenes). PCDDs enter the environment through accidental release during chlorophenol production, through aerial application of some phenoxy herbicides, and through improper disposal of wastes into terrestrial and aquatic ecosystems (Ramel 1978; NRCC 1981; Ogilvie 1981: Choudhary et al. 1983; Josephson 1983; Stolzenburg and Sullivan 1983; NIOSH 1984; Rappe 1984;

Kamrin and Rodgers 1985). The PCDD content of technical products varies between manufacturers, between lots and grades, and between various formulations of pesticidal chemicals (NRCC 1981). More recently, PCDDs have been identified in effluents from combustion products of municipal and industrial incinerators, including fly ash and flue gas (Czuczwa and Hites 1984). These PCDDs may be associated with small particles which have long residence times in the atmosphere and can become distributed over large areas. For example, in the Great Lakes atmospheric transport of combustion products is the major source of PCDDs (mostly octa-, hepta-, and hexa-CDDs) in sediments (Czuczwa et al. 1984). High-temperature combustion of bituminous coal in an oxidized and chlorinated atmosphere (produced experimentally) yielded chlorodioxins, mostly octa-, hepta-, and hexa-CDDs and measurable quantities of tetra-CDDs (Mahle and Whiting 1980). Other potential sources of PCDDs include fossil fuel power plants, internal combustion engines, home fireplaces, and cigarette smoke (Kociba and Schwetz 1982a,b), but they require verification.

In general, PCDDs exhibit a relative inertness to acids, bases, oxidation, reduction, and heat. With increasing halogen content, they become more environmentally and chemically stabile (NRCC 1981). PCDDs are usually destroyed at temperatures greater than 1,000 C. They are resistant to biological breakdown, concentrated in fat, not readily excreted, extremely toxic to some animals, and the cumulative effects of small doses to both animals and humans are a source of increasing concern (Stolzenburg and Sullivan 1983). Most PCDDs are relatively insoluble in water, sparingly soluble in organic solvents, and will decompose on exposure to UV light, including sunlight (NIOSH 1984), or to hydroxyl compounds (Josephson 1983). The isomer 2,3,7,8-TCDD is a colorless crystalline solid at room temperature and decomposes when heated at greater than 700 C (Table 2).

Data on the bioavailability of PCDDs are scarce. It is known that PCDDs incorporated into wood as a result of chlorophenol (preservative) treatement are bioavailable. Swine and poultry using chlorophenol-treated wooden pens or litter have been found to be contaminated with PCDDs (NRCC 1981). Toxicities of individual PCDD isomers can vary by a factor of 1,000 to 10,000 for isomers as closely related as 2,3,7,8-TCDD and 1,2,3,8-TCDD or 1,2,3,7,8-penta CDD and 1,2,4,7,8-penta CDD (Rappe 1984). Isomers with the hightest biological activity and acute toxicity have 4 to 6 chlorine atoms, and all lateral (i.e., 2,3,7, and 8) positions substituted with chlorine. On this basis, the most toxic PCDD isomers are 2,3,7,8-TCDD, 1,2,3,7,8-penta CDD, 1,2,3,6,7,8-hexa CDD, 1,2,3,7,8,9-hexa CDD, and 1,2,3,4,7,8-hexa CDD (Rappe 1984).

Although PCDDs are highly persistent, volatilization and photolysis are major removal processes (NRCC 1981). In soils, 2,3,7,8-TCDD undergoes photolysis rapidly on the surface in a few hours, but more deeply buried 2,3,7,8-TCDD could have a chemical half-time greater than 10 years (NRCC 1981). Microbial degradation of 2,3,7,8-TCDD in soils is slow, with biological half-times estimated at 1.0 to 1.5 years (Ramel 1978). However 2,3,7,8-TCDD was detected in northwestern Florida from samples of soils, rodents, birds, lizards, fishes, and insects 12 years after application. This half-time in soil was estimated at 2.9 years (Westing 1978). Uptake of 2,3,7,8-TCDD from soils by vegetation is considered negligible (Blair 1973;Ramel 1978).

Other than 2,3,7,8-TCDD, identification difficulties with specific isomers make quantification difficult. To date, there has been little effort towards resolution of deficiencies in analytical methodology (NRCC 1981). A detection level of 1 pg (10^{-12}g), or lower, might be requried to find 2,3,7,8-TCDD in a one gram sample. Analyses at such low levels are complicated by interference from a multitude of other compounds, as well as by the large number of PCDD isomers and their variation in chemical properties (Rappe 1984). Although 2,3,7,8-TCDD is the most extensively studied PCDD isomer, data on its fate and persistence are generally poor, interpretations are frequently absent, and extrapolations from case to case usually impossible. The general result is a qualitative concept of this compound's behavior in environmental situations (NRCC 1981). This issue is further confounded by the presence in biological and abiotic samples of chemicals of similar structure and toxicological properties to that of 2,3,7,8-TCDD. These isosteric compounds include: 2,3,6,7-tetrachlorobiphenylene; 2,3,7,8-chlorine substituted dibenzofurans; and 3,3',4,4'-tetra-, 3,3',4,4',5-penta-, and 3,3',4,4',5,5'-hexachlorobiphenyl (Stalling et al. 1985a,b). For example, analytical results of fish, birds, and sediments indicated that every sample that was positive for 2,3,7,8-TCDD also contained 2,3,7,8-chlorine substituted dibenzofurans (Stalling et al 1985a,b).

Table 1. Levels of PCDDs in commercial chlorinated phenols, and levels of 2,3,7,8-TCDD in 2,4,5-T acid and ester formulations (Hardell 1983).

BACKGROUND CONCENTRATIONS

Data are accumulating that indicate many PCDDS, in addition to 2,3,7,8-TCDD, are present in biological and abiotic samples (NRCC 1981; O'Keefe et al. 1983; Petty et al. 1983; Stalling et al. 1983; Czuczwa et al. 1984; Lamparski et al. 1984; Kamrin-and Rodgers 1985; Stalling et al. 1985a). In general, wherever high levels of dioxins have been detected in the environment, a local application of TCDD-contaminated herbicide, hazardous waste site, or industrial discharge has usually been implicated as the source (Stolzenburg and Sullivan 1983). At Eglin Air Force Base (EAFB), located in northwestern Florida, contamination of a 208 hectare section with 2.778 kg of 2,3,7,8-TCDD (equivalent to 13 mg/ha) occurred between 1962 and 1970 as a result of repeated, massive herbicide applications (Young and Cockerham 1985). The 2,3,7,8-TCDD isomer was present as an impurity in 76,740 kg of 2,4-D and 73,010 kg of 2,4,5-T applied to this section of EAFB during the 9-year span. Ecological surveys conducted between 1970 and 1975 showed an apparently healthy and diverse wildlife fauna, although soil levels of 520 ppt of 2,3,7,8-TCDD were frequently encountered, and 2,3,7,8-TCDD residues were elevated in some species examined. The highest residues recorded in various trophic levels were 283 ppt in whole beetle grubs, up to 1,360 ppt in whole southern toads (*Bufo terrestris*), 360 ppt in viscera and 430 ppt in-carcass of a lizard, the six-lined racerunner (*Cnemidophorus sexlineatus*), 18 ppt in gonad and 85 ppt in gut contents of the spotted sunfish (*Lepomis punctatus*), 100 to 1,200 ppt in stomach contents of the southern meadowlark (*Sturnella magna argutula*), and 300 to 2,900 ppt in liver and 130 to 200 ppt in pelt of a beachmouse (*Peromyscus polionotus*) (Young and Cockerham 1985). The significance of these elevated residues will be discussed later.

In some cases, 2,3,7,8-TCDD has constituted up to 95% of the total body PCDD burden, as was true in lake trout, *Salvelinus namaycush* (O'Keefe et al. 1983), and rainbow trout, *Salmo gairdneri* (Petty et al. 1983) from Lake Ontario. Concentrations of 2,3,7,8-TCDD in whole carp (*Cyprinus carpio*), varied from 24% of total body PCDDs in Saginaw Bay, Michigan (Stalling et al. 1983), to 45 to 56% in the Niagara River (NRCC 1981). In herring gulls from Saginaw Bay, 2,3,7,8-TCDD comprised 40 to 60% of the whole body PCDD content (NRCC 1981; Petty et al. 1983), and 72 to 78% in gulls from Lakes Huron and Ontario (Stalling et al. 1983, 1985a). In 1983, Forster's tern (*Sterna forsteri*) from Green Bay, Wisconsin, contained 114 ppt of PCDDs in egg, of which 41% was 2,3,7,8-TCDD; double-crested cormorants (*Phalacrocorax auritus*) from the same area contained 25 to 214 ppt of PCDDs in whole body, of which only 10 to 31% was 2,3,7,8-TCDD (Stalling et al. 1985a). The causes of the observed variations are not known, but may be associated with localized inputs from municipal sewage treatment plants (Lamparski et al. 1984) and with atmospheric transport of incinerated domestic and industrial chemical wastes (Czuczwa et al. 1984). For example, the PCDD composition of sewage sludge from Milwaukee, Wisconsin, was relatively constant, as judged by analysis of samples from 1933, 1981, and 1982 (Lamparski et al. 1984). Total PCDD content in these samples ranged between 60,950 and 70,191 ppt, of which the great majority was in the form of octa-CDDs (82-86%), hepta-CDDs (11.0-15.4%), and hexa-CDDs (1.3-2.1%). However, the tetra-CDDs increased from 34 ppt in 1933, to 138 in 1981, and to 222 in 1981; corresponding values for the 2,3,7,8-TCDD isomer in 1933, 1981 and 1982 were 2.2, 11.0, and 16.0 ppt, respectively. Other TCDD isomers also showed increases from 6 ppt in 1933 to 22 ppt in 1982 (1,3,7,8-TCDD), and during that same period from 2.2 ppt to 140 ppt (1,2,3,7-, and 1,2,3,8-TCDD). It seems that chlorinated dibenzodioxins have been present in dried sludge from this plant for at least 50 years. Their presence in this material suggests that they may have been formed by the condensation of chlorophenols resulting from the chlorination of naturally occurring phenolic compounds (Lamparski et al. 1984). PCDDs were also found in sediments from Siskiwit Lake on Isle Royale in Lake Superior, a location which can receive only atmospheric inputs. The source of these compounds is the atmospheric transport of dioxins formed by combustion of domestic and chemical wastes. For example, particulates from a chemical waste incinerator in Midland, Michigan had 260,000,000 ppt of octa-CDDs and 170,000,000 ppt of hepta-CDDs; lower, but still elevated levels of 440,000 ppt of octa-CDDs and 310,000 ppt of hepta-CDDs were measured in municipal trash incinerator particulates (Czuczwa et al. 1984).

Data are limited on 2,3,7,8-TCDD concentrations in field collections of biological and other materials (Table 3). In the Great Lakes area, fish from the Tittabawasee and Saginaw Rivers, two tributaries of Lake Huron's Saginaw Bay, contained up to 695 ppt of 2,3,7,8-TCDD (Stolzenburg and Sullivan 1983). High 2,3,7,8-TCDD levels (87 to 162 ppt) were also recorded in fish. from the Niagara River, New York, and from parts of Lake Ontario; lower concentrations (2 to 28 ppt) were noted in fish from Lakes Erie, Huron, Michigan, and Superior (Stolzenburg and Sullivan 1983). Muscle from larger specimens of commercial fish collected from Lake Ontario in 1980 had higher levels of 2,3,7,8-TCDD than smaller fish (Ryan et al. 1984), suggesting that accumulation increases with age. The larger fish also contained high concentrations (1.2 to 4.9 parts per million, fresh weight)

of polychlorinated biphenyls (Ryan et al. 1984), demonstrating a need to elucidate TCDD interaction kinetics with other contaminants. Bottom-feeding fish, such as carp and catfish, from rivers in Michigan during 1978, contained higher 2,3,7,8-TCDD residues than surface feeders (Marless et al. 1982), indicating an association with contaminated sediments. Sediments from the Spring River, Missouri, contained 12 ppt of 2,3,7,8-TCDD immediately downstream of a now defunct hexachlorophene facility (Kleopfer and Zirschky 1983); concentrations in fish were measurable 111 km downstream from this disposal site (Table 3). Fish from the Spring River (and also the Meremac River, Missouri) contained inordinately high levels of 18 to 78 ppt of 2,3,7,8-TCDD, prompting the U.S. Food and Drug Administration to issue a health advisory in 1982 against fish consumption from these areas (Powell 1984). In Massachusetts, 6 ponds were surveyed for 2,3,7,8-TCDD in 1983 after prior treatment with phenoxy herbicides between 1958 and 1978 (Anon. 1984). Only one fish, a brown bullhead (*Ictalurus nebulosus*), age 3+ years, contained measurable (25 ppt) dioxin levels. Residues were not detectable in other species of fish sampled, including several species of ictalurid catfish, yellow perch (*Perca flavescens*), and chain pickerel (*Esox niger*). Negative results (less than 10 ppt 2,3,7,8-TCDD) were also documented in freshwater fish from Arkansas and Texas following spraying of the herbicide 2,4,5-T (Shadoff et al. 1977).

In birds, the levels of 2,3,7,8-TCDD have been decreasing, according to analysis of herring gull eggs from Lake Ontario. During the decade 1970-1980, there was a reduction of about 50% in 2,3,7,8-TCDD levels every two years (Ogilvie 1981; NRCC 1981; Nriagu and Simmons 1984). The reasons for the decline are unknown, and the relevance to higher-chlorinated PCDDs has not yet been determined. Until these questions are resolved and more substantative data are acquired on dioxin residues in birds, the current predictive trends on decline rates should be interpreted with caution.

Table 3. Concentrations of 2,3,7,8-TCDD measured in selected organisms and nonbiological materials collected from various locales. All values are in parts-per-trillion (ng/kg) fresh weight.

[b]Each reference applies to the values in the same row, and in the rows that follow for which no other reference is indicated.

Much of the information on 2,3,7,8-TCDD levels in wildlife and domestic livestock are from the vicinity of Seveso, Italy (Table 3). There, on July 10, 1976, a chemical cloud containing 2,3,7,8-TCDD was released as a result of an industrial accident. It contaminated the food (hay, grass, cut-up corn) of dairy cows (Fanelli et al. 1980a). Grossly elevated levels (7,900 ppt) were measured in milk from these herds at concentrations considered hazardous to human health, i.e., more than 7,000 ppt (Fanelli et al. 1980a). Wildlife from the most heavily-contaminated area appeared to accumulate 2,3,7,8-TCDD. Field mice (*Microtus arvalis*), for example, contained very high whole body concentrations of 2,3,7,8-TCDD (up to 49,000 ppt) almost 2 years after the critical contamination. The mechanisms for this phenomenon included ingestion of contaminated soil and licking of their dioxin-contaminated pelt (Fanelli et al. 1980c). In another study, no 2,3,7,8-TCDD was detected in livers of mountain beavers (*Aplodontia rufa*) that fed for 45 to 60 days in Oregon forests that had been sprayed with 2.2 kg of 2,4,5-T/ha (Newton and Snyder 1978). Although it was presumed that the herbicide was heavily contaminated with dioxins, no chemical analysis of the 2,4,5-T was performed.

TOXIC AND SUBLETHAL EFFECTS

GENERAL

Information is lacking or scarce on the biological properties of PCDD isomers, except 2,3,7,8-TCDD. The latter has been associated with lethal, carcinogenic, teratogenic, reproductive, mutagenic, histopathologic, and immunotoxic effects. There are substantial inter- and intraspecies differences in sensitivity and toxic responses to 2,3,7,8-TCDD. Typically, animals poisoned by 2,3,7,8-TCDD exhibit weight loss, atrophy of the thymus gland, and eventually death. The toxicological mechanisms are imperfectly understood.

TERRESTRIAL INVERTEBRATES

Reinecke and Nash (1984) reported that two species of earthworms (*Allolobophophora caliginosa, Lumbricus rubellus*) showed no adverse effects when held for 85 days in soils containing grossly elevated levels

of 5 ppm of 2,3,7,8-TCDD, but both species died at 10 ppm. In soils containing lower concentrations of 50 ppb of 2,3,7,8-TCDD, earthworms accumulated 5X soil levels in 7 days. There was no avoidance of soils contaminated with 2,3,7,8-TCDD, suggesting indifference. No surface penetration of dioxins into the body of earthworms was noted, and there was no biological breakdown of 2,3,7,8-TCDD during digestion as judged by the absence of mono-, di-, and tri-CDD's in excrement. Worm-worked soils had 2,3,7,8-TCDD retention times of 80 to 400 days, suggesting that earthworms may significantly alter half-time patterns of 2,3,7,8-TCDD in soils (Reinecke and Nash 1984).

Mutagenic responses were produced in *Escherichia coli* and certain strains of *Salmonella typhimurium* bacteria by 2,3,7,8-TCM,- but not by octa-CDD (Vos 1978). Further, chromosomal aberrations were induced in at least one species of higher plant and mammal (Ramel 1978). It must be concluded at this time that 2,3,7,8-TCDD is mutagenic or has mutagenic potential.

AQUATIC ORGANISMS

No data were available on lethal and sublethal effects of any PCDD isomer to aquatic organisms, except for 2,3,7,8-TCDD and freshwater biota (Table 4); 2,3,7,8-TCDD and liver microsomal enzyme activities in two marine species: winter flounder, *Pseudopleuronectes americanus*, and the little skate, *Raja erinacea* (Pohl et al. 1976); and 1,3,6,8-TCDD uptake and elimination by fathead minnows and rainbow trout (Corbet et al. 1983).

Sensitive species of teleosts exhibited reduced growth and fin necrosis at concentrations as low as 0.1 ppt of 2,3,7,8-TCDD after exposure for 24 to 96 hours. Concentrations of 1.0 ppt and higher were eventually fatal, and exposure to lower concentrations of 0.01 ppt for 24 hours had no measurable effect (Table 4). A typical 2.,3,7,8-TCDD poisoning sequence in guppies (*Poecilia reticulatus*) and coho salmon (*Oncorhynchus kisutch*) during a postexposure observation period included: declining interest in feeding (5-8 days postexposure); skin discoloration and fin necrosis (30 days), with caudal fin most severely affected; reduced resistance to fungal infestations; reduced swimming; and, finally, death several weeks to months after exposure (Miller et al. 1973). In general, older and larger fish die last, and smaller or younger specimens succumb first (Norris and Miller 1974).

Histopathologic and teratogenic effects were noted in fry of rainbow trout (*Salmo gairdneri*) exposed to 10 ppt of 2,3,7,8-TCDD for 96 hours as eggs, or is yolk-sac fry Helder 1981). Some fry showed extensive degeneration and necrosis of the liver, and subsequently developed edema prior to death. The remaining fry showed a high incidence of teratogenic changes, including opercular defects, and foreshortened maxillas.

Invertebrates, plants, and amphibians were comparatively resistant to 2,3,7,8-TCDD. For example, there were no adverse effects on growth, reproduction, or food consumption of algae, daphnids, and snails during immersion for 32 days in solutions containing 2.4 to 4.2 ppt of 2,3,7,8-TCDD (Yockim et al. 1978).

Accumulation of 2,3,7,8-TCDD from the aquatic environment was evident for all species examined (Table 4). The isomer 1,3,6,8-TCDD was also accumulated from the environment by freshwater teleosts, but accumulations were much lower than predicted when compared to 2,3,7,8-TCDD, and elimination was 10 to 15 times more rapid than. 2,3,7,8-TCDD (Corbet et al. 1983). In outdoor pond studies, a major portion of the added 2,3,7,8-TCDD concentrated in aquatic plants and at the sediment-water interface (Tsushimoto et al. 1982); however, most (85-99%) of the 2,3,7,8-TCDD originally added to the ecosystem remained in the sediments at the end of the study (Isensee and Jones 1975). Among teleosts, body burdens of 2,3,7,8-TCDD increased with increasing concentration in the water column and with increasing duration of exposure; on removal to uncontaminated water, less than 50% was lost in 109 days (Miller et al. 1979). The significance of 2,3,7,8-TCDD residues in aquatic organisms is not clear, and loss-rate kinetics are not fully documented; both areas merit additional research.

BIRDS

LD-50 values computed 37 days after a single oral dose of 2,3,7,8-TCDD varied from 15 ug/kg body weight in Northern bobwhite (*Colinus virginianus*), with 95% confidence limits of 9.2 and 24.5 ug/kg, to more than 810 ug/kg bodyweight for the ringed turtle-dove (*Streptopelia risoria*). Mallards (*Anas platyrhynchos*) were intermediate in sensitivity with an acute oral LD-50 value of more than 108 ug/kg body weight (Hudson et al. 1984). For all 3 species, death occurred 13 to 37 days after treatment; remission in survivors had apparently occurred by day 30 posttreatment. Gross necropsy of ringed turtle-doves that survived treatment showed enlarged livers, about twice normal size. Bobwhites showed severe emaciation, high accumulations of uric acid salts in connective tissues, and fluid accumulations in the pericardial and abdominal cavities (Hudson et al.

1984). Some birds regurgitated within a few minutes after treatment. Signs of intoxication that began 7 days after treatment included excessive drinking, loss of appetite, hypoactivity, emaciation, weakness, debility, muscular incoordination, increased reaction to stimuli, fluffed feathers, huddled position, unkempt appearance, falling, tremors, spasms, convulsions, and immobility (Hudson et al. 1984).

Table 4. Effects of 2,3,7,8-TCDD on selected species of freshwater organisms.

Taxonomic group, organism, and other variables	Dose[a]	Duration of exposure	Effects	Reference[b]
Algae and macrophytes	2.4–4.2 ppt (M)	32 days	Bioconcentration factor (BCF)	
Alga, *Odegonium cardiacum*			of 6X water at day 1; 654 to 2,083 at days 3 to 32; 500 at day 7 post-exposure (pe); 230 at day 14 pe	1
Pondweeds, *Elodea* sp. and *Ceratophyllum* sp.	53.7 ppt (M)	30 days	Residues of 7,000 ppt in 5 days; 2,500 ppt in 30 days	2
Molluscs				
Snail, *Helisoma* sp.	2.4–4.2 ppt (M)	32 days	Maximum BCF of 3,731	1
Snail, *Physa* sp.	200 ppt (M)	36 days	Reduced reproduction at day 12 pe	3
Annelids				
Worm, *Paranais* sp.	200 ppt (M)	55 days	Reduced reproduction	3

Amphibians				
Bullfrog, *Rana catesbeiana*				
Tadpole	500 µg/kg (BW)	Single dose, injected intra-peritoneally (ip)	No effect through metamorphosis	4
Adult	500 µg/kg (BW)	Single dose, injected ip	No effect at day 35 pe	4

Fish				
Northern pike, *Esox lucius*				
Eggs and fry	0.1 ppt (M)	96 h	Growth retardation	5
Rainbow trout, *Salmo gairdneri*				
Eggs	0.1 ppt (M)	96 h	Growth retardation of fry at day 72 pe	6
Juveniles	10 ppt (M)	96 h	Growth retardation, edma; 26% dead at day 72 pe	6
Immature	107 ppt (M)	2 h	Whole body residues of 1,010 ppt	7
Immature	107 ppt (M)	6 h	Some deaths beginning at day 78 pe. At day 136 pe, survivors showed reduced growth and enlarged livers; tissue residues, in ppt fresh weight, were 650 in whole trout, 260 in muscle, 3,710 in liver, and 3,880 in fat	7
Juveniles	6.3 µg/kg (BW), oral route	33 days	Fin necrosis in 14 days; some deaths at day 33	3
Juveniles	0.0063 µg/kg (BW), oral route	33 days	No effect	3
Immature	1.2 µg/kg (BW)	Single dose, injected ip	Elevated liver cytochrome P-450 content	8
Guppy, *Poecilia reticulatus*	1.1 ppt (M)	24 h	Fin disease after 42 days	9
"	1.0 ppt (M)	24 h	LC-50 at day 42 pe	9
"	0.01 ppt (M)	24 h	No effect at day 32 pe	9
"	100 ppt (M)	24 h	Fin necrosis in 10 days; all dead at day 32 pe	10
Coho salmon, *Oncorhynchus kisutch*				
Juveniles	0.56 ppt (M)	48 h	12% dead in 60 days	3
Juveniles	5.6 ppt (M)	96 h	55% dead in 60 days	3
Juveniles	56 ppt (M)	24 h	All dead in 40 days	3
Juveniles	2.05 ppt (M)	96 h	Whole body residues of 125 ppt at day 114 pe	9
Juveniles	10.53 ppt (M)	96 h	Whole body residues of 2,177 ppt at day 114 pe; reduced growth and survival	9
Mosquitofish, *Gambusia affinis*	2.4–4.2 ppt (M)	15 days	BCF of 676 at day 1; 1,482 at day 7. All dead at day 15, preceded by	

			nasal bleeding and listless swimming	1
Channel catfish, *Ictalurus punctatus*	2.4–4.2 ppt (M)	20 days	Fin necrosis, erratic swimming, hemorrhaging from anus and lower jaw, BCF of 2,181; all dead between days 15 and 20	1
Fathead minnow, *Pimephales promelas*	53.7 ppt (M)	40 days	Whole body residues of 8,500 ppt in 10 days, 2,500 ppt in 40 days	2

[a]M=concentration in ambient medium at start; BW=body weight.

[b]References: 1, Yockim et al. 1978; 2, Tsushimoto et al. 1982; 3, Miller et al. 1973; 4, Neal et al. 1979; 5, Helder 1980; 6, Helder 1981; 7, Branson et al. 1985; 8, Vodicnik et al. 1981; 9, Miller et al. 1979; 10, Norris and Miller 1974.

Domestic chickens were relatively sensitive to PCDDS, especially 2,3,7,8-TCDD, with an estimated 2,3,7,8-TCDD oral LD-50 range of 25 to 50 ug/kg body weight (Kociba and Schwetz 1982a,b). Chickens fed 1 or 10 ug of 2,3,7,8-TCDD, 1,2,3,7,8,9-hexa CDD, or hepta-CDDs per kg body weight daily for 21 days showed signs of chick edema disease, i.e., pericardial, subcutaneous, and peritoneal edema; liver enlargement and necrosis with fatty degeneration; and frequently resulted in death (NRCC 1981; Gilbertson 1983). Autopsies of poultry killed by 2,3,7,8-TCDD in Seveso, Italy, in 1976 showed signs characteristic of chick edema disease (Fanelli et al. 1980b). Pathological signs of chick edema disease were also seen in herring gull chicks on the lower Great Lakes in the early 1970's (Gilbertson 1983). Concentrations of 2,3,7,8-TCDD in eggs of the herring gull declined from about 1,000 ppt in 1971 to less than 80 ppt in 1981. This was accompanied by a decrease in the frequency of chick edema disease (Gilbertson 1983). Decreases in levels of other contaminants notably mirex were probably more important to the survival of gulls in these colonies than 2,3,7,8-TCDD (Eisler 1985); however, little data exist on the interaction of PCDDS, including 2,3,7,8-TCDD, with other contaminants appearing concomitantly in bird tissues or their diets.

Although there presently is no evidence of biomagnification of PCDDs in birds (Gilbertson 1983), it is speculated that piscivorous birds have a greater potential to accumulate PCDDs than the fish that they eat (NRCC 1981).

MAMMALS

The greater toxic potential of certain PCDD isomers involves two properties: halogen atoms occupying at least 3 of the 4 lateral ring positions (2,3,7, 8 positions) and at least one of the adjacent ring positions being nonhalogenated (Kociba and Schwetz 1982a,b). Comparative toxicity data for selected PCDD isomers to the guinea pig (*Cavia* sp.) and the mouse (*Mus* sp.) confirmed this generalization and demonstrated significant interspecies differences in sensitivity (Table 5). Other PCDD isomers tested (2,8-di CDD, octa-CDD) were relatively nontoxic to mice and guinea pigs (NRCC 1981).

Acute toxicity studies with 2.,3,7,8-TCDD have shown marked differences--up to 8,400X--between the single oral LD-50 dose for the guinea pig and the hamster (*Cricetus* sp.) (Table 6). The acute oral LD-50 value of 0.6 ug/kg body weight for guinea pigs, suggests that 2,3,7,8-TCDD may be the most toxic compound ever tested on small laboratory animals. The unusual resistance of hamsters may be associated with its enhanced rate of metabolism and excretion of 2,3,7,8-TCDD relative to other PCDD isomers examined (Olson et al. 1980b; NRCC 1981). Poisoning in mammals by 2,3,7,8-TCDD is typically characterized by loss of body weight and delayed lethality; large interspecies differences exist in lethal dosages and toxic effects (Vos 1978; Neal et al. 1979; Kociba and Schwetz 1982a,b; Josephson 1983; Matsumura 1983; Kimbrough 1984; Seefeld et al. 1984). For example, 2,3,7,8-TCDD produces prominent chloracne-type skin lesions in man and monkeys, edema formation in birds, and severe liver damage in rats, mice, and rabbits.

Table 5. Acute toxicities of selected PCDD isomers to the guinea pig and the mouse (Kociba and Schwetz 1982b).

PCDD isomer	Oral LD-50, in µg/kg body weight Guinea pig	Mouse
2,8-di CDD	>300,000	-
2,3,7-tri CDD	29,444	>3,000
2,3,7,8-TCDD	2	284
1,2,3,7,8-penta CDD	3	338
1,2,4,7,8-penta CDD	1,125	>5,000
1,2,3,4,7,8-hexa CDD	73	825
1,2,3,6,7,8-hexa CDD	70–100	1,250
1,2,3,7,8,9-hexa CDD	60–100	>1,440
1,2,3,4,6,7,8-hepta CDD	>600	-

Table 6. Acute oral toxicities of 2,3,7,8-TCDD to mammals.

[a]References: 1, Harless et al. 1982; 2, Kociba and Schwetz 1982a, b; 3, Silkworth et al. 1982; 4, Olson et al. 1980a, b.

Intraspecies differences in sensitivity to 2,3,7,8-TCDD--up to 14 fold--were recently reported among 3 strains of mice; no reasons were given to account for these differences. Oral LD-50 (30 day) values varied from 182 ug 2,3,7,8-TCDD per kg body weight in strain C57, the most sensitive strain tested, and 296 for strain BD6, to 2,570 for strain DBA (Chapman and Schiller 1985). All 3 strains of mice evidenced a 25 to 34% weight loss prior to death; however, there was no measurable decline in food consumption.

Atrophy of the thymus is a consistent finding in mammals poisoned by 2,3,7,8-TCDD, and suppression of thymus-dependent cellular immunity, particularly in young animals, may contribute to their death. Although the mechanisms of 2,3,7,8-TCDD toxicity are unclear, current research areas include the role of thyroid hormones (Rozman et al. 1984), interference with plasma membrane functions (Matsumura 1983), alterations in, ligand receptors (Vickers et al. 1985), the causes of hypophagia (reduced desire for food) and subsequent attempts to alter or reverse the pattern of weight loss (Courtney et al. 1978; Seefeld et al. 1984; Seefeld and Peterson 1984), and excretion kinetics of biotransformed metabolites (Koshakji et al. 1984).

Developing mammalian fetuses are especially sensitive to 2,3,7,8-TCDD, and maternal exposure results in increased frequencies of stillbirths. Among live births, exposure to it produces teratogenic effects such as cystic kidney, cleft palate, and spinal column deformities (Ramel 1978). Effects of 2,3,7,8-TCDD on reproduction are reported for rats (McNulty 1977; Murray et al. 1979; Kociba and Schwetz 1982a,b) and monkeys (Ramel 1978; Barsotti et al. 1979; NRCC 1981; Kociba and Schwetz 1982a,b). In a 3-generation study with rats, daily dose levels of 0.01 ug of 2,3,7,8-TCDD/kg body weight (equivalent to 120 to 290 ppt or ng/kg in the diet), produce decreased litter size at birth, increased number of stillborns, and reduced survival and growth of young in both the Fl and F2 generations. Reproduction was not affected in rats at daily dosages of 0.001 ug/kg body weight, which are equivalent to 12 to 30 ppt or ng/kg of 2,3,7,8-TCDD in the diet. Abortion and weight loss were reported in rhesus monkeys (*Macaca mulatta*) at dietary levels as low as 50 ppt 2,3,7,8-TCDD (about 0.0017 ug/kg body weight daily) after 7 to 29 months. However, comparatively high dosages (200 ppt in diets equivalent to 0.0095 ug/kg body weight daily) could be tolerated by monkeys for short periods (3X weekly for 3 weeks) with no adverse effects on reproduction. Higher dose levels for extended periods (i.e., 500 ppt in diets equivalent to about 0.011 ug/kg body weight daily for 9 months) caused death (63%) or, among survivors, abortion, chloracne, nail loss, scaly and dry skin, and progressive weakness. Most treated monkeys remained fairly alert to external stimuli until just prior to death. On removal from the 500 ppt 2,3,7,8-TCDD diet and transfer to an uncontaminated diet, a severely affected monkey became pregnant and gave birth to a well-developed infant after an uneventful gestation. This suggests that some 2,3,7,8-TCDD damage effects are not permanent.

Androgenic deficiency in male rats given a single oral dose of 15 ug 2,3,7,8-TCDD/kg BW was evident as early as 2 days posttreatment, with persistence up to 12 days. These deficiencies may account for male reproductive pathology and dysfunction in rats treated with overtly toxic doses of TCDD. Findings included depression in plasma testosterone concentrations, as well as decreased weight of seminal vesicles (by 68%), ventral prostate gland (by 48%), testes, and epididymis (Moore et al. 1985).

Accumulation of 2,3,7,8-TCDD is reported in the liver of rats during lifetime exposure to diets containing 0.022 ug 2,3,7,8-TCDD/kg (Newton and Snyder 1978), or when administered orally at 0.01 ug/kg body weight once a week for 45 weeks (Cantoni et al. 1981). Liver residues of rats fed 2,3,7,8-TCDD were 0.54 ug/kg, or about 25X dietary levels; livers of rats dosed orally contained 1.05 ug/kg, or about 2.3X the total dose received on a unit weight basis.

Unlike toxicity, elimination rates of accumulated 2,3,7,8-TCDD were within a relatively narrow range. The estimated retention times of 2,3,7,8-TCDD in small laboratory mammals (rats, mice, guinea pigs, and hamsters) extended from 10.8 to 30.2 days for 50% elimination and seemed to be little influenced by species, concentration administered, duration of dose, or route of administration (Blair 1973; Olson et al. 1980b; NRCC 1981; Koshakji et al. 1984).

Histopathological effects have been reported in rabbits and horses poisoned by 2,3,7,8-TCDD. Rabbits surviving exposure to an industrial accident in Seveso, Italy, in which 2,3,7,8-TCDD was released, had edema, hemorrhagic tracheitis, pleural hemorrhage, and dystrophic lesions of hepatic tissue (Fanelli et al. 1980b). Horses from Missouri that died after waste oil contaminated with 2,3,7,8-TCDD was applied as a dust control agent in riding arenas had liver lesions, skin hyperkeratosis, gastric ulcers, and lung and kidney lesions (Kimbrough 1984). Since 2,3,7,8-TCDD is an extremely potent porphyrogenic agent, it is probable that these animals also exhibited porphyria, a condition characterized by fragility of the skin, photosensitivity, and accumulation of porphyrins in the liver (Cantoni et al. 1981).

Teratogenic and fetotoxic effects of 2,3,7,8-TCDD are well-documented in several species of animals (Marless et al. 1982; Kociba and Schwetz 1982a,b; Kimbrough 1984; Weber et al. 1985). Cleft palate in young mice was associated with daily dosages of 1.0 ug 2,3,7,8-TCDD per kg body weight in pregnant females (no-effect level at 0.1 ug/kg), and intestinal hemorrhage was found in sensitive strains of rats given daily dosages of 0.125 ug/kg body weight (no-effect level at 0.03 ug/kg) (Kociba and Schwetz 1982a,b). The 2,3,7,8-TCDD isomer has been studied for carcinogenic potential in rats and mice. There is a good correlation between carcinogenicity in both species and long-term ingestion of higher dose levels that induce toxicity. In rats, carcinomas in liver, pharynx, skin, lung, and thyroid were documented at daily dosages of 0.01 to 0.1 ug of 2,3,7,8-TCDD/kg body weight; comparable values for mice were 0.03 to 0.07 ug/kg body weight (Kociba and Schwetz 1982a,b). No response occurred at continuous daily dose levels of 0.001 to 0.0014 ug/kg body weight in rats and 0.001 to 0.03 in mice. Carcinogenic or cocarcinogenic effects were also induced by 1,2,3,6,7,8-hexa CDD and 1,2,3,7,8,9-hexa CDD, but only at higher dose levels (Rappe 1984). It appears that 2,3,7,8-TCDD has

a greater effect on growth, survival, and reproduction of animals than on tumor formation.

Interaction effects of PCDDs with other polychlorinated compounds or mixtures are not extensively documented. For example, certain polychlorinated hexachlorobiphenyls (PCBs) have a low toxic potency to induce cleft palate deformities in mice (Birnbaum et al. 1985). However, mixtures of 2,3,7,8-TCDD and 2,3,4,5,3',4' hexachlorobiphenyl resulted in a 10-fold increase in incidence of cleft palate in mice. Thus, the toxicity of compounds such as 2,3,7,8-TCDD may be enhanced by compounds of relatively low acute toxicity such as selected PCBs. Birnbaum et al. (1985) concluded that the widespread environmental occurrence of such combinations suggests a need for further evaluation of the mechanism of this interaction.

CURRENT RECOMMENDATIONS

At present, there are no criteria or standards promulgated for any of the 75 PCDD isomers, by any regulatory agency, for the protection of sensitive species of wildlife and aquatic organisms. Data are scarce or missing on the distribution and upper limits of background levels of PCDDs in natural resources, on the identification of fish and wildlife resources potentially at risk, on the relative importance of PCDD sources, and on the comparative toxicities of various PCDDs to fish and wildlife, especially reproductive and immunosuppressive toxicities (NRCC 1981). A similar situation exists for human health protection, except for the 2,3,7,8-TCDD isomer.

For protection of human health, concentrations of 2,3,7,8-TCDD (in ppt fresh weight) in fish muscle (and presumably other food items) considered acceptable are 10 in New York State (Kleopfer and Zirschky 1983), 20 in Canada (Kleopfer and Zirschky 1983), and 25 in other States within the U.S., according to the U.S. Food and Drug Administration (Stolzenburg and Sullivan 1983). Food items containing more than 50 ppt are considered unsafe for human consumption, but fish fillets containing between 25 and 50 ppt of 2,3,7,8-TCDD may be eaten once weekly by occasional consumers of fish, and twice monthly for those who eat contaminated fish year round (Stolzenburg and Sullivan 1983). It is not known at this time whether residues of 10 to 50 ppt (or higher) of 2,3,7,8-TCDD in fish flesh represents an unacceptable risk to the growth, survival, reproduction, metabolism, or behavior of the teleost, or to its predators; clearly, this is a high priority research topic.

For protection of aquatic life, it is conservatively estimated that water levels of 2,3,7,8-TCDD should not exceed 0.01 ppt as judged by laboratory studies with freshwater teleosts. The highest 2,3,7,8-TCDD concentration tested to date which has no measurable adverse effect on freshwater fish is 0.01 ppt (Miller et al. 1979). The next highest concentration tested, 0.1 ppt, was associated with fin disease in guppies (Miller et al. 1979) and reduced growth of northern pike (Helder 1981).

Diets containing up to 10 or 12 ppt of 2,3,7,8-TCDD may prove to be nonhazardous to birds and other wildlife, as judged by the results of laboratory studies with rats, monkeys, and chickens, and by the recommendations of New York State for human health protection. Higher dietary levels of 12 to 30 ppt of 2,3,7,8-TCDD (equivalent to about 1.0 ng/kg body weight daily) are not harmful to rats, based on the results of a 3-generation study (McNulty 1977; Murray et al. 1979). However, domestic chickens are relatively sensitive, with adverse effects recorded at daily dietary levels equivalent to almost 1.0 ng/kg body weight (NRCC 1981; Gilbertson 1983). Unacceptable dietary levels of 50 ppt (equivalent to 1.7 ng/kg body weight daily) are recorded for monkeys (Ramel 1978; Barsotti et al. 1979; NRCC 1981).

In the past, the major source of 2,3,7,8-TCDD in the environment was as a contaminant in phenoxy herbicides (such as 2,4,5-T; Silvex; 2,4-D; and Agent Orange), in hexachlorophene, and in other chlorophenol-type compounds. Concentrations of 2,3,7,8-TCDD in some of these products exceeded 60,000 ppb. However, this situation has been largely corrected by new manufacturing processes and by increasingly stringent Federal regulations (NRCC 1981; Choudhary et al. 1983; Stolzenburg and Sullivan 1983; NIOSH 1984; Rappe 1984). For example, 2,3,7,8-TCDD level in 2,4,5-T has decreased from 60,000 ppb in 1957 to 2,000 ppb in 1965 as a result of new manufacturing processes, and it was limited to 500 ppb in 1970 by the Canadian Federal Government. In 1970, the U.S. Department of Defense halted the spraying of Agent Orange. In 1972, the U.S. Food and Drug Administration banned the use of hexachlorophene in nonprescription soaps and deodorants. In 1978, 7 of 14 major producers of 2,4,5-T no longer manufactured this product, and the remainder claimed that their products contained less than 100 ppb of 2,3,7,8-TCDD. In 1979, production of 2,4,5-T and Silvex ceased in the United States, although stockpiles of both are still being distributed and permitted for use on rice fields, sugarcane fields, orchards, fence rows, vacant lots, and lumber yards. In 1982, the EPA required some industries to certify that chlorophenol-type compounds were no longer used as slime control agents. On

October 18, 1983, EPA published its intent to cancel the registration of pesticide products containing 2,4,5-T and Silvex, and to prohibit the transfer, distribution, sale, or importation of any unregistered product containing 2,4,5-T, Silvex, or their derivatives (NIOSH 1984).

At present, burning or heating of commercial and purified chlorophenates, and pyrolysis of polychlorinated biphenyls contaminated with trichlorobenzenes can result in the production of 2,3,7,8-TCDD and other PCDDs (NIOSH 1984). These sources together with discharges from various municipal and industrial incinerators of chlorinated compounds probably constitute the largest source of PCDDs in the environment today. In 1983, the U.S. Environmental Protection Agency proposed to monitor 2,3,7,8-TCDD in the environment (Stolzenburg and Sullivan 1983). Specific goals of the monitoring program include: determination of 2,3,7,8-TCDD concentrations in soils and biota, with emphasis on geographic areas where PCDDs may have been manufactured, used, or stored--and where concentrations may be in excess of 1,000 ppt; monitoring of industrial and municipal incinerators for TCDD emissions; and establishment of background levels for PCDDs in areas where these compounds are not expected to occur in high levels. It seems that information is also needed on the toxicological interactions of groups of polychlorinated chemicals (such as certain biphenyls, biphenylenes, and dibenzofurans) known to be isosteric with 2,3,7,8-TCDD and which frequently coexist with 2,3,7,8-TCDD in environmental samples. Acquisition of these data should provide the basis of a risk assessment analysis for dioxin and fishery and wildlife resources.

U.S. Fish and Wildlife Service
Laurel, MD 20708

SUMMARY

Diazinon (phosphorothioic acid 0,0- diethyl 0- (6-methyl-2-(1-methylethyl)-4-pyrimidinyl) ester) is an organophosphorus compound with an anticholinesterase mode of action. It is used extensively to control flies, lice, insect pests of ornamental plants and food crops, as well as nematodes and soil insects in lawns and croplands. Diazinon degrades rapidly in the environment, with half-time persistence usually less than 14 days. But under conditions of low temperature, low moisture, high alkalinity, and lack of suitable microbial degraders, diazinon may remain biologically active in soils for 6 months or longer.

At recommended treatment levels, diazinon-related kills have been noted for songbirds, honeybees, and especially waterfowl that consume diazinon-treated grass; however, incidents involving agricultural applications may be underreported. Accidental deaths through misapplication of diazinon have also been recorded in domestic poultry, monkeys, and humans. It has been suggested, but not yet verified, that wildlife partially disabled in the field as a result of diazinon poisoning would be more likely to die of exposure, predation, starvation, or dehydration, or face behaviorial modifications, learning impairments, and reproductive declines than would similarly treated domestic or laboratory animals.

Among sensitive aquatic organisms, LC-50 (96 h) values of 1.2 to 2.0 ug/l were derived for freshwater cladocerans, and 4.1 to 5.9 ug/l for marine shrimps; freshwater teleosts were comparatively resistant, with all LC-50 (96 h) values greater than 90 ug/l. Sublethal effects were recorded at 0.3 to 3.2 ug diazinon/l and included reduced emergence of stream insects (0.3 ug/1), reduced fecundity of a marine fish (0.47 ug/1), significant accumulations in freshwater teleosts (0.55 ug/1), daphnid immobilization (1.0 ug/1), potential mutagenicity in a freshwater fish (1.6 ug/1), and spinal deformities in teleosts (3.2 ug/1). Exposure to diazinon during spawning caused temporary, but complete, inhibition of reproduction at concentrations which did not produce this effect in fish exposed continuously since hatch.

Acute oral LD-50's of about 2,500 to 3,500 ug diazinon/kg body weight were determined for goslings *(Anser* spp.), ducks *(Anas* spp.), domestic turkey (*Meleagris gallopavo)*, and the red-winged blackbird (*Agelaius phoeniceus*), the most sensitive birds tested. A dietary LD-50 of 167,000 ug diazinon/kg was determined for Japanese quail (*Corturnix japonica)*. Diazinon produced marked teratogenic effects in embryos of the domestic chicken (*Gallus gallus*) at 6.2 to 25 ug/embryo, reduced egg deposition in the ring-necked pheasant (*Phasianus colchicus*) at more than 1,050 ug/bird, and (empirically) decreased food consumption and increased weight loss in the northern bobwhite (*Colinus virginianus*) at greater than 17,500 ug diazinon/kg diet.

The rat (*Rattus rattus*) was the most sensitive mammal tested in acute oral toxicity screenings, with an LD-50 of 224,000 ug diazinon/kg body weight. Chronic oral toxicity tests with swine (*Sus scrofa*) indicated that death was probable if daily intakes were greater than 5,000 ug diazinon/kg body weight. Measurable adverse effects of diazinon have been recorded in rodents, the most sensitive mammalian group tested, at: 500 ug/kg in diets fed to rats for 5 weeks, causing blood cholinesterase inhibition; 180 ug/kg body weight administered daily to pregnant mice (*Mus musculus*) during gestation, inducing behaviorial modifications and delayed sexual maturity of progeny; and single oral doses of 1,800 and 2,300 ug/kg body weight in rats and white-footed mice (*Peromyscus leucopus*), respectively, which produced altered blood chemistry and brain cholinesterase inhibition.

For protection of sensitive aquatic organisms, diazinon concentrations in water should not exceed 0.08 ug/l; however, more data are needed on effects of fluctuating and intermittent chronic exposures of diazinon on reproduction of fish and aquatic invertebrates. Granular formulations of diazinon seem to be especially hazardous to seed-eating birds, suggesting a need to control or eliminate granular applications when these species are present. For additional protection of birds, diazinon should be used with extreme caution in areas where waterfowl feed, and in large-scale spray applications such as grasshopper control. Diazinon in combination with some agricultural chemicals produced more-than-additive adverse effects on bird growth and fecundity; accordingly, more research is needed on effects of complex mixtures of pesticides that contain diazinon. Most investigators agreed that mammals were less susceptible to diazinon than were birds, at least under controlled environmental regimens. Data are lacking on diazinon impacts to mammals under field conditions; acquisition of these data should constitute a priority research area.

INTRODUCTION

Diazinon, an organophosphorus compound with an anticholinesterase mode of action, was released for experimental evaluation in the early 1950's. Today, diazinon is used extensively by commercial and home applicators in a variety of formulations to control flies, cockroaches, lice on sheep, insect pests of ornamental plants and food crops (especially corn, rice, onions, and sweet potatoes), forage crops such as alfalfa, and nematodes and soil insects in turf, lawns, and croplands (Anon. 1972; Meier et al. 1976; Allison and Hermanutz 1977; Berg 1984; Stone and Gradoni 1985).

Waterfowl and other wildlife may acquire diazinon by drinking contaminated water, by absorbing it through legs and feet, by consuming treated grass or grain, or by ingestion of pesticide-impregnated carrier particles (Stone and Knoch 1982; Stone and Gradoni 1985). Diazinon poisonings of birds--involving 54 incidents in 17 States--have been recorded for at least 23 species, especially among waterfowl feeding on recently treated turfgrass; incidents involving agricultural applications may be less conspicuous, and thus not as well-documented (Stone and Gradoni 1985). Kills of Canada geese (*Branta canadensis*), brant (*Branta bernicla*), mallard (*Anas platyrhynchos*), American black duck (*Anas rubripes*), other species of waterfowl, and songbirds have all been associated with consumption of grass or grain shortly after diazinon application (Schobert 1974; Zinkl et al. 1978; Stone 1980; Stone and Knoch 1982). Fatal diazinon poisonings have also been recorded in humans (Soliman et al. 1982; Lox 1983), domestic chickens (*Gallus gallus*) (Sokkar et al. 1975), domestic ducklings (*Anas* spp.) and goslings (*Anser* spp.) (Egyed et al. 1974, 1976), in laboratory monkey colonies of the tamarin (*Saguinus fuscicollis*) and the common marmoset (*Callithrix jacchus*) (Brack and Rothe 1982), and the honeybee (*Apis mellifera*) (Anderson and Glowa 1984). Mammals seem to be less sensitive than birds to diazinon poisoning (Stone and Gradoni 1985). The lack of reported mammalian mortalities (only one suspected case of a pocket gopher, *Thomomys* sp., found dead in a park at Yakima, Washington, following aerial spraying of diazinon on shade trees) is consistent with the general findings of Grue et al. (1983) for organophosphorus insecticides. Sublethal effects such as reduced hatch, retarded growth, and spinal deformities in fish (Allison and Hermanutz 1977), reduced food consumption and egg production in the ring-necked pheasant (*Phasianus colchicus*) (Stromborg 1977), and behavioral modifications, reduced food intake, alterations in liver enzyme activities, reductions in vitamin concentrations, reduced body temperature, and lowered resistance to cold stress in white-footed mice (*Peromyscus leucopus*) (Montz and Kirkpatrick 1985) have been noted at diazinon concentrations markedly lower than those causing acute mortality. It has been suggested, but not proven, that wildlife partially disabled in the field as a result of diazinon poisoning would be more likely to die of exposure, predation, starvation, or dehydration, or face behaviorial abnormalities learning, impairments, and reproductive declines than would similarly treated domestic or laboratory animals, (Montz 1983; Montz and Kirkpatrick 1985).

In this account, I summarize available data on the environmental fate and effects of diazinon, with emphasis on fish and wildlife resources. Also included are recommendations for the protection of sensitive species of concern to the U.S. Fish and Wildlife Service. This report is part of a continuing series of synoptic reviews prepared in response to requests for information from Service environmental specialists.

ENVIRONMENTAL CHEMISTRY

Diazinon is a broad spectrum insecticide that is effective against a variety of orchard, vegetable, and soil pests, ectoparasites, flies, lice, and fleas. It exists as a technical grade product, a wettable powder, an emulsifiable concentrate, as granules, and in a variety of other formulations (Negherbon 1959; Anon. 1972; Eberle 1974; Berg 1984). The active ingredient in diazinon is phosphorothioic acid 0,0- diethyl 0- (6-methyl-2-1(methylethyl)-4-pyrimidinyl) ester (Figure 1). Its molecular formula and molecular weight are $C_{12}H_{2l}N_2O_3PS$, and 304.35. The technical grade is light amber to dark brown, and boils at 83 to 84 C. Diazinon is soluble in water to 40 mg/l, and dissolves readily in aliphatic and aromatic solvents, alcohols, and ketones. Diazinon may be stored on the shelf for at least 3 years with negligible degradation. Diazinon is also known as G-24480, Sarolex, Spectracide (Anon. 1972), AG-500, Alfa-tox, Basudin, Dazzel, Diazajet, Diazide, Diazol, ENT 19507, Gardentox, Neocidol, Nucidol, CAS 333-41-5 (Hudson et al. 1984), Diagran, Dianon, DiaterrFos, Diazatol, Dizinon, Dyzol, D.z.n., Fezudin, Kayazinon, Kayazol, Knox Out, and Nipsan (Berg 1984).

Some diazinon formulations contain 0.2 to 0.7% (2,000 to 7,000 mg/kg) of Sulfotep (tetraethyl dithiopyrophosphate) as a manufacturing impurity; Sulfotep is reportedly at least 100 times more toxic than diazinon to some organisms (Jarvinen and Tanner 1982). It seems that additional, research is warranted on diazinon/Sulfotep interactions.

Diazinon degrades rapidly in plants, with half-time persistence usually less than 14 days; however, persistence increases as temperatures decrease, and is longer in crops with a high oil content (Table 1). In water, diazinon breaks down to comparatively nontoxic compounds with little known hazard potential to aquatic species (Meier et al. 1976; Jarvinen and Tanner 1982), although the degradation rate is highly dependent on pH (Table 1). In soils, diazinon seldom penetrates below the top 1.3 cm (Kuhr and Tashiro 1978; Branham and Wehner 1985). But diazinon may remain biologically available in soils for 6 months or longer at low temperature, low moisture, high alkalinity, and lack of suitable microbial degraders (Anon. 1972; Bartsch 1974; Meier et al. 1976; Allison and Hermanutz 1977; Menzie 1978; Forrest et al. 1981; Branham and Wehner 1985). Bacterial enzymes, derived from *Pseudomonas* sp., can be used to hydrolyze diazinon in soil, although costs are prohibitive except in treating emergency situations involving spills of concentrated diazinon solutions. In one case, diazinon was enzymatically hydrolyzed within 24 hours in an agricultural sandy soil at concentrations as high as 10,000 mg/kg (Barik and Munnecke 1982).

[a]References: 1, Montz 1983; 2, Bartsch 1974; 3, Kuhr and Tashiro 1978; 4, Branham and Wehner 1985; 5, Jarvinen and Tanner 1982; 6, Arthur et al. 1983; 7, Meier et al. 1976; 8, Allison and Hermanutz 1977.

In almost every instance of diazinon poisoning, there has been a general reduction in cholinesterase activity levels, especially in brain and blood. Diazinon exerts its toxicity by binding to the neuronal enzyme acetylcholinesterase (AChE) for a considerable time postexposure (Montz 1983). It is emphasized that all organophosphorus pesticide compounds, in sufficient dose, inhibit AChE in vivo, and all share a common

mechanism of acute toxic action (Murphy 1975). AChE inhibition results in the accumulation of endogenous acetylcholine-in nerve tissues and effector organs, resulting in signs that mimic the muscarinic, nicotinic, and central nervous system (CNS) actions of acetylcholine. The immediate cause of death in fatal organophosphorus compound poisonings, including diazinon, is asphyxia resulting from respiratory failure. Contributing factors are the muscarinic actions of bronchoconstriction and increased bronchial secretions, nicotinic actions leading to paralysis of the respiratory muscles, and the CNS action of depression and paralysis of the respiratory center (Murphy 1975).

Diazinon is not a potent inhibitor of cholinesterase, and must be converted to its oxygen analogues (oxons), especially diazoxon (diethyl 2-isopropyl-6-methylpyrimidin-4-yl phosphate) in vivo before poisoning can occur (Wahla et al. 1976). Diazoxon is about 10,000 times more effective in reducing cholinesterase activity levels than diazinon (Fog and Asaka 1982). At least eight diazinon metabolites have been identified in vertebrates, of which four are oxons (Machin et al. 1975; Menzie 1978; Seguchi and Asaka 1981). It is generally agreed that diazinon is metabolized to diazoxon through the action of liver mixed-function oxidases and nicotinic adenine nucleotide phosphate (Menzie 1978; McLean et al. 1984). Diazinon toxicity will depend to some extent upon the relation between the rates of activation of diazinon to diazoxon, and of decomposition of the latter to harmless products (Fujii and Asaka 1982). Birds are more sensitive to diazinon than mammals, probably because mammalian blood enzymes hydrolyze diazoxon rapidly, whereas bird blood has virtually no hydrolytic activity. It seems that diazoxon stability in blood is a major factor affecting susceptibility of birds and mammals to diazinon poisoning (Machin et al. 1975).

Diazinon poisoning effects in animals can be delayed or prevented by treatment with a variety of compounds. For example, AChE in diazinon-stressed birds can be reactivated by pralidoxime (Egyed et al. 1976; Fleming and Bradbury 1981; Misawa et al. 1982). Furthermore, pretreatment of large white butterfly (*Pieris brassicae*) larvae with methylene dioxyphenyl compounds will inhibit the diazinon to diazoxon activation (Wahla et al. 1976). Added tryptophan and its metabolites may prevent teratogenic defects by maintaining nicotinic adenine nucleotide (NAD) levels in diazinon-treated chicken embryos; diazinon reportedly acts to decrease the availability of tryptophan to bird embryos, subsequently interfering with NAD metabolism and causing birth defects (Henderson and Kitos 1982). NAD metabolism in diazinon-stressed birds may also be maintained with nicotinamide (Misawa et al. 1982). In contrast to many other organophosphorus insecticides, organisms that survive diazinon-inhibited cholinesterase levels can undergo considerable spontaneous reactivation (dephosphorylation), indicating that its dephosphorylation occurs more readily than that of cholinesterase inhibited by other organophosphorus compounds (Fleming and Bradbury 1981).

ACUTE AND CHRONIC TOXICITY

GENERAL

Diazinon toxicity varies widely within and among species, and is modified by organism age, sex, and body size, climatic conditions, pesticide formulation, chemistry of the environment, and other factors (Montz 1983). Nevertheless, several trends are apparent as judged by available data. Among aquatic organisms, for example, freshwater cladocerans and marine shrimps were the most sensitive species tested, with LC-50 (96 h) values of less than 5 ug/l; freshwater teleosts were more resistant, with the lowest LC-50 (96 h) value recorded being 90 ug/l. Diazinon has considerable potential for causing acute avian poisoning episodes; sensitive species of birds, including ducks, turkey (*Meleagris gallopavo*), and red-winged blackbird (*Agelaius phoeniceus*), died at single oral doses of 2 mg of diazinon/kg body weight. Mammals are more resistant than birds to diazinon; the lowest LD-50 (acute oral) value recorded is 224 mg/kg body weight for female rats (*Rattus rattus*). Chronic oral toxicity tests with mammals suggest that daily intake exceeding 5 or 10 mg diazinon/kg body weight is probably fatal over time to swine (*Sus scrofa*) and dogs (*Canis familiaris*), respectively. Finally, 9 mg/kg of dietary diazinon fed during gestation to pregnant mice (*Mus musculus*) was associated with significant mortality of pups prior to weaning.

AQUATIC ORGANISMS

Freshwater cladocerans and marine crustaceans were the most sensitive groups tested, with LC-50(96 h) values of less than 5 ug/l for the more sensitive species (Table 2). Rainbow trout (*Salmo gairdneri*) and bluegill (*Lepomis macrochirus*) seemed to be the least resistant freshwater teleosts tested, with LC-50(96 h) values

between 90 and 120 ug/l; however, the postlarval and juvenile stages of the striped knifejaw (*Oplegnathus fasciatus*) --a marine fish cultured intensively in Japan-- were unusually sensitive (Table 2). In general, technical grade formulations of diazinon seem to be more toxic than emulsifiable concentrates, dusts, and oil solutions (Table 2). Also, large variations in acute toxicity values were evident, even among closely related species (Table 2).

Outward signs of diazinon poisoning in fish included lethargy, forward extension of pectoral fins, darkened areas on posterior part of body, hyperexcitability when startled, sudden rapid swimming in circles, and severe muscular contractions (Goodman et al. 1979). Internally, physiological mechanisms in teleosts preceding death involved the following sequence: cholinesterase inhibition, acetylcholine accumulation, disruption of nerve functions, respiratory failure, and asphyxia (Sastry and Sharma 1980).

Limited data indicated that the yellowtail (*Seriola quinqueradiata*), a marine teleost, was 84X more sensitive to diazinon than were 4 species of freshwater fishes, as judged by LC-50(48 h) values, and by its inability to biotransform diazinon to nontoxic metabolites within one hour (Fujii and Asaka 1982). Diazinon has not been detected in marine waters, but the potential exists for contamination of estuarine areas from agricultural and urban runoff (Goodman et al. 1979).

BIRDS

Diazinon adversely affects survival of developing mallard embryos when the eggshell surface is subjected for 30 seconds to concentrations 25 to 34 times higher than recommended field application rates; mortality patterns were similar for solutions applied in water or in oil (Table 3). This laboratory finding suggests that eggs of mallards, and probably other birds, are protected when diazinon is applied according to label directions. Chickens dipped in solutions containing 1,000 mg of diazinon/l, an accidentally high formulation, experienced 60% mortality within 3 days; no other deaths occurred during the next 4 months (Sokkar et al. 1975).

Results of 5-day feeding trials with 2-week-old Japanese quail (*Coturnix japonica*), followed by 3 days on untreated feed, showed an LD-50 of 167 mg diazinon/kg diet -- a concentration considered "very toxic". No deaths were observed at dietary levels of 85 mg diazinon/kg, but 53% died at 170 mg/kg, and 87% at 240 mg/kg (Hill and Camardese 1986).

Diazinon has a potential for causing acute avian poisoning episodes (Schafer et al. 1983). Ingestion of 5 granules of Diazinon 14G (14.3% diazinon) killed 80% of house sparrows (*Passer domesticus*), and all red-winged blackbirds to which they were administered (Balcomb et al. 1984). Ingestion of fewer than 5 granules of Diazinon 14G, each containing about 215 ug of diazinon, could be lethal to sparrow-sized birds (i.e., 15 to 35 g body weight), especially juveniles of seed-eaters (Hill and Camardese 1984). Acute oral LD-50's indicate that 15 mg of diazinon/kg body weight is fatal to virtually all species tested, and that 2 to 5 mg/kg is lethal to the more sensitive species (Table 4). Signs of diazinon poisoning in birds included muscular incoordination, wing spasms, wing-drop, hunched back, labored breathing, spasmodic contractions of the anal sphincter, diarrhea, salivation, lacrimation (tear production), eyelid drooping, prostration, and arching of the neck over the back (Hudson et al. 1984). Most of these signs have been observed in birds poisoned by compounds other than diazinon; these compounds also act via an anticholinesterase mode of action (Hudson et al. 1984).

Table 2. Acute toxicity of diazinon to aquatic organisms. All values shown are in micrograms of diazinon (active ingredients)/liter of medium fatal to 50% in 96 hours.

MAMMALS

Signs of diazinon poisoning in mammals included a reduction in blood and brain cholinesterase activity, diarrhea, sweating, vomiting, salivation, cyanosis, muscle twitches, convulsions, loss of reflexes, loss of sphincter control, and coma (Anon. 1972). Other compounds that produce their toxic effects by inhibiting AChE, such as organophosphorus pesticides and many carbamates, show similar effects (Murphy 1975). Two species of marmoset accidentally poisoned by diazinon exhibited, prior to death, high-pitched voices, trembling, frog-like jumping, a stiff gait, and pale oral mucous membranes; internally, bone marrow necrosis and hemorrhages in several organs were evident (Brack and Rothe 1982). Internal damage was also observed in swine and dogs that died following controlled administration of diazinon. Swine showed histopathology of liver and intestinal tract, and duodenal ulcers; dogs showed occasional rupture of the intestinal wall, and testicular atrophy (Earl et al. 1971).

Results of acute oral toxicity tests indicated that the rat was the most sensitive mammalian species tested, with an acute oral LD-50 of 224 mg diazinon/kg body weight (Table 4). It is clear that mammals are significantly more resistant to acute oral poisoning by diazinon than birds (Table 4). Diazinon was also toxic to mammals when administered dermally, through inhalation, and in the diet (Table 5). The lowest dermal LD-50 recorded was 600 mg diazinon/kg body weight for rabbits (*Lepus* sp.) using an emulsifiable (4E) formulation. The single datum for inhalation toxicity indicated that 27.2 mg of diazinon/l of air killed 50% of test rabbits after exposure for 4 hours (Table 5). Pregnant mice fed diets containing 9 mg of diazinon/kg during gestation all survived, but some pups died prior to weaning (Table 5). Results of chronic oral toxicity tests of diazinon indicated that death was probable if daily doses exceeded 5 mg/mg body weight for swine, or 10 mg/kg for dogs (Table 5).

TERRESTRIAL INVERTEBRATES

Accidental spraying of beehives in Connecticut with diazinon resulted in a complete kill of resident honeybees. Dead bees contained up to 3 mg/kg of diazinon (Anderson and Glowa 1984). Diazinon is an an effective insecticide. LD-50 values for diazinon and adult houseflies (*Musca domestica*), applied topically, were 0.4 ug/insect, or 4.6 mg/kg body weight (Negherbon 1959). LD-50 values for larvae of the large white butterfly, applied topically, were 8.8 mg/kg body weight for diazinon, and 11.0 mg/kg body weight for diazoxon (Wahla et al. 1976). Pretreatment of larvae with methylene dioxyphenyl compounds antagonized the action of diazinon by a factor of about 2, but synergized the action of diazoxon by an order of magnitude (Wahla et al. 1976).

Table 4. Acute oral toxicity of diazinon to birds and mammals. All values shown are in milligrams of diazinon/kg body weight fatal to 50% after a single oral dose.

SUBLETHAL EFFECTS

GENERAL

Among sensitive species of aquatic organisms, diazinon was associated with reduced growth and reproduction in marine and freshwater invertebrates and teleosts, spinal deformities in fish, reduced emergence in stream insects, measurable accumulations in tissues, increased numbers of stream macroinvertebrates carried downstream by currents (drift), possible mutagenicity in fish, and interference with algal-invertebrate interactions. In birds, diazinon is a known teratogen; it also is associated with reduced egg production, decreased food intake, and loss in body weight. Diazinon fed to pregnant mice resulted in offspring with brain pathology, delayed sexual maturity, and adverse behavioral modifications that became apparent late in life. For all groups tested, diazinon directly or indirectly inhibited cholinesterase activity.

AQUATIC ORGANISMS

Spinal deformities, mostly lordosis and scoliosis, were among the more insidious effects documented for diazinon. Malformations were observed in fathead minnows (*Pimephales promelas*) after 19 weeks in water containing 3.2 ug diazinon/l (Allison and Hermanutz 1977), in yearling brook trout (*Salvelinus fontinalis*) within a few weeks at 4.8 ug/l (Allison and Hermanutz 1977), and in various species of freshwater teleosts after exposure for 7 days to 50 ug diazinon/l (Kanazawa 1978).

Diazinon is a noncarcinogen and reportedly has no significant mutagenic activity in microbial systems, yeast, and mammals including humans (as quoted in Vigfusson et al. 1983). However, Vigfusson et al. (1983) have measured a significant increase in the frequency of sister chromatid exchange in central mud minnows (*Umbra limi*) that were exposed *in vivo* for 11 days to solutions containing 0.16 to 1.6 ug of diazinon/l. This finding requires verification.

Diazinon in water is bioconcentrated by brook trout at levels as low as 0.55 ug/l, but tissue residues for all aquatic organisms did not exceed 213 times that of ambient water, even after months of continuous exposure (Table 6). Diazinon and its metabolites are excreted rapidly posttreatment; the loss rate is approximately linear (Kanazawa 1978). The enzyme system responsible for diazinon metabolism in fish liver microsomes required NADPH and oxygen for the oxidative desulfuration of diazinon to diazoxon (Hogan and Knowles 1972). Fish with high fat content contained greater residues of diazinon in fatty tissues than fish with comparatively low lipid content (Seguchi and Asaka 1981), and this could account, in part, for inter-and intraspecies variations in uptake and depuration. Some organisms, such as the sheepshead minnow (*Cyprinodon variegatus*), have measurable diazinon residues during initial exposure to 6.5 ug/l, but no detectable residues after lengthy exposure (Goodman et al. 1979), suggesting that physiological adaptation resulting in rapid detoxication is possible.

Freshwater and marine alga were unaffected at water diazinon concentrations, that were fatal (i.e., 1,000 ug/l) to aquatic invertebrates (Stadnyk and Campbell 1971; Shacklock and Croft 1981). However, diazinon at 1.0 ug/l induced extensive clumping of a freshwater alga (*Chlorella pyrenoidosa*) onto the antennae of *Daphnia magna* within 24 hours (Stratton and Corke 1981). The affected daphnids were immobilized and settled to the bottom of the test containers. The causes of particulate matter adhesion are open to speculation, and additional research is merited.

Freshwater macroinvertebrates were comparatively sensitive to diazinon (Table 7). Results of large scale experimental stream studies (Arthur et al. 1983) showed that dose levels of 0.3 ug diazinon/l caused a 5 to 8-fold reduction in emergence of mayflies and caddisflies within 3 weeks; after 12 weeks, mayflies, damselflies, caddisflies, and amphipods were absent from benthic samples. Elevated (and catastrophic) drift of stream

invertebrates also was documented in diazinon-treated streams, especially for amphipods, leeches, and snails (Arthur et al. 1983).

Freshwater fish populations can be directly damaged by prolonged exposure to diazinon at concentrations up to several hundred times lower than those causing acute mortality (Sastry and Sharma 1980; Sastry and Malik 1982; Table 7). Impaired reproduction and AChE inhibition occurs concurrently in teleosts during long-term exposure to diazinon, but reproduction can be impaired for at least 3 weeks after fish are placed in uncontaminated water, even though AChE is normal and they contained no detectable diazinon residues (Goodman et al. 1979). Furthermore, diazinon exposure during spawning caused complete, but temporary, inhibition of reproduction at concentrations which did not produce this effect in fish exposed since hatch (Allison 1977). This could severely impact aquatic species with a short reproductive period (Allison 1977).

BIRDS

Diazinon produces visible Type I and II teratisms when injected into chicken embryos (Misawa et al. 1981, 1982; Henderson and Kitos 1982; Wyttenbach and Hwang 1984). Type I teratisms (related to tissue NAD depression) included abnormal beaks, abnormal feathering, and shortened limbs. Type II teratisms, which included short and wry neck, leg musculature hypoplasia, and rumplessness were associated with disruptions in the nicotinic cholinergic system. The severity of effects depended on embryo age and was dose-related. Chick embryos (age 48 hours) receiving 25 ug or more of diazinon/embryo had cervical notochord and neural tube malformations at 96 hours, and short neck at 19 days (Wyttenbach and Hwang 1984). Wry neck occurred at doses ranging from 6.2 to 100 ug/embryo, but was more frequent at higher doses. Type II teratisms were attributed to disruption of notochord sheath formation. Coinjection of 2-pyridinealdoxime methochloride (2-PAM) along with 200 ug of diazinon/embryo markedly reduced notochord and neural tube deformations (Wyttenbach and Hwang 1984). Similarly, the copresence of tryptophan--or its metabolites L-kynurenine, 3-hydroxyanthronilic acid, quinolinic acid--maintained NAD levels of diazinon-treated embryos close to, or above, normal, and significantly alleviated the symptoms of Type I teratisms (Henderson and Kitos 1982).

Reduced egg production, depressed food consumption, and loss in body weight have been observed in ring-necked pheasants at daily diazinon intakes greater than 1.05 mg/bird; a dose-related delay in recovery of egg laying was noted after termination of diazinon treatment (Stromborg 1977, 1979). Threshold levels in ring-necked pheasants of 1.05 and 2.1 mg of diazinon daily corresponded to 1/16 and 1/8 of daily ration (70 g) treated at commercial application rates. Food consumption of ring-necked pheasants was reduced significantly when only food treated with diazinon was available; pheasants avoided diazinon-treated food if suitable alternatives existed (Stromborg 1977; Bennett and Prince 1981). Dietary levels above 50 mg/kg were associated with reduced food consumption, weight loss, and reduction in egg production in northern bobwhites (Stromborg 1981). If food reduction is important, then diets containing more than 17.5 mg diazinon/kg (based on, empirical calculations) were potentially harmful to bobwhites (Stromborg 1981). The mechanisms accounting for reduction in egg deposition are not clear, but are probably related primarily to decreased food intake. They may also be associated with diazinon-induced pituitary hypofunction at the level of the hypothalamus, resulting in reduced synthesis and secretion of gonadotrophic, thyrotrophic, and adrenocorticotrophic hormones (Sokkar et al. 1975).

MAMMALS

Diazinon exerts its toxic effects by binding to the neuronal enzyme acetylcholinesterase (AChE) for long periods after exposure. Diazinon, in turn, is converted to diazoxon, which has a higher affinity for AChE (and thus greater toxicity) than the parent compound. There is a latent period in white-footed mice in reduction of

cholinesterase activities, sometimes up to 6 hours, until diazinon is converted to diazoxon (Montz 1983). Effects of multiple doses of diazinon to mammals are not clear, e.g., rats exposed to a high dose of diazinon did not respond fully to a second dose until one month later (Kikuchi et al. 1981). It is difficult to ascertain when complete recovery of diazinon-poisoned animals has occurred. It is speculated, but not verified, that wildlife recovering from diazinon poisoning may face increased predation, aberrant behavior, learning disabilities, hypothermia, and reproductive impairments (Montz 1983). Data are now lacking on recovery aspects of diazinon-poisoned native mammal populations (Montz and Kirkpatrick 1985).

Diazinon is rapidly biotransformed and excreted in mammals. Estimated half-times of diazinon persistence were 6 to 12 hours in rats (Anon. 1972) and dogs (Iverson et al. 1975). Most of the diazinon metabolites were excreted in the urine as diethyl phosphoric acid and diethyl phosphorothioic acid in dogs (Iverson et al. 1975), and as hydroxy diazinon and dehydrodiazinon in sheep (Machin et al. 1974).

Determination of AChE activity in selected tissues following diazinon exposure provided an estimate of potential toxicity, but tissue sensitivity varied widely between and among taxa. In sheep, brain cholinesterase inhibition was pronounced after diazinon insult, and metabolism of diazinon in, or close to, the brain was the most likely, source of toxicologically effective diazoxon (Machin et al. 1974, 1975). In rat, diazinon effectively reduced blood cholinesterase levels, with inhibition significantly more evident in erythrocytes than in plasma (Tomokuni and Hasegawa 1985). All mammalian bloods hydrolyze diazoxon rapidly, whereas birds have virtually no hydrolytic activity in their blood, and, as a result, were more susceptible than mammals. The stability of diazoxon in the blood appears to be a primary factor in susceptibility to diazinon poisoning (Machin et al. 1975). In species lacking blood oxonases, the liver was probably the most important site of diazinon metabolism (Machin et al. 1975). Diazinon that accumulated in rat liver was biotransformed, usually within 24 hours, by microsomal mixed-function oxidases and glutathione S-transferases; however, diazinon residues in rat kidney were almost 500 times those in liver (and 11 times brain), and were measurable in kidney but not in liver (Tomokuni and Hasegawa 1985). It now seems that diazinon residues in kidney, and cholinesterase inhibition in erythrocytes are the most useful indicators of acute diazinon poisoning in mammals.

Sublethal effects of diazinon have been recorded in rodents, the most sensitive mammal group tested. Effects were measured at 0.5 mg diazinon/kg in diets of rats for 5 weeks, at 0.18 mg/kg body weight administered daily to pregnant mice, and at single doses of 1.8 mg/kg body weight for rat and 2.3 mg/kg body weight for white-footed mice (Table 8). Many variables modify diazinon-induced responses, including the organism's sex. For example, female rats and dogs were more sensitive to diazinon than males (Earl et al. 1971; Davies and Holub 1980a, 1980b; Kikuchi et al. 1981), but male swine were more sensitive than females (Earl et al. 1971).

Table 8. Sublethal effects of diazinon to selected mammals.

Organism and dose (D = mg/kg diet; BW = mg/kg body weight daily)	Exposure period	Effect	Reference[a]
Rat, *Rattus rattus*			
0.009 (BW)	5 weeks	No effect	1
0.1 (D)	5 weeks	No effect	1
0.5 (D)	5 weeks	Depressed plasma cholinesterase	1

Sheep, *Ovis aries*			
Sprayed with 100 ppm diazinon solutions	4 min	Effective lice control for 3 weeks, partial protection for 8.6 weeks	13
450–650 (BW)	Single dose	Flesh unfit for human consumption for several weeks (high fat residues of 333–520 mg/kg)	14
Monkeys, several species			
0.5 (BW)	2.04 years	None	5
5 (BW)	2.04 years	Cholinesterase inhibition	5

[a]References: 1, Davies and Holub 1980a; 2, Kikuchi et al. 1981; 3, Davies and Holub 1980b; 4, Lox 1983; 5, Anon. 1972; 6, Spyker and Avery 1977; 7, Barnett et al. 1980; 8, Montz 1983; 9, Montz and Kirkpatrick 1985; 10, Iverson et al. 1975; 11, Earl et al. 1971; 12, Dressel et al. 1982; 13, Wilkinson 1980; 14, Machin et al. 1974.

Behavioral deficits observed in offspring of mice exposed to diazinon during gestation indicated that prenatal exposure may produce subtle dysfunctions not apparent until later in life (Spyker and Avery 1977). Pregnant mice given a daily dose of 0.18 or 9 mg diazinon per kg body weight throughout gestation gave birth to viable, overtly normal, offspring. But, pups born to mothers of the 9 mg/kg groups grew more slowly than controls and were significantly smaller at 1 month than controls (Spyker and Avery 1977). Offspring of mothers receiving 0.18 mg/kg body weight exhibited significant delays in the appearance of the contact placing reflex, and in descent of testes or vaginal opening. Mature offspring of mothers exposed to either dose level displayed impaired endurance and coordination on rod cling and inclined plane tests of neuromuscular function (Table 8). In addition, offspring of the 9 mg/kg dose had slower running speeds and less endurance in a swimming test than controls. At 101 days, forebrain neuropathology was evident in the 9 mg/kg dose, but not in the 0.18 mg/kg group. The mechanisms responsible for these effects are unknown (Spyker and Avery 1977).

Diazinon is nonmutagenic to mammals, as judged by its inability to induce sister chromatid exchanges (SCE) in Chinese hamster ovary cells (CHOC) at 80 mg/kg culture medium; most organophosphorus insecticides tested induced SCE in CHOC at this concentration (Nishio and Uyeki 1981; Chen et al. 1982). Diazoxon, an oxygen analog of diazinon, did produce SCE at 304 mg/kg, but was 3 to 10X less effective than oxygen analogs of other organophosphorus compounds screened (Nishio and Uyeki 1981).

TERRESTRIAL INVERTEBRATES

Tobacco hornworms (*Manduca sexta*) from a field sprayed with 840 mg diazinon/ha contained no detectable residues of diazoxon. Only one sample, collected about 4 hours after spraying, exceeded 1.0 mg diazinon/kg body weight. No diazinon residues in these insects were detectable after 18 days. It was concluded that the potential hazard to birds eating hornworms was minimal (Stromborg et al. 1982). In contrast, diazinon residues in molluscan slugs (*Agriolimax reticulatus*), collected from plats of spring wheat sprayed with 8,000 mg diazinon/ha, increased linearly to about 200 mg/kg at 6 weeks postapplication, then declined to background levels after 16 weeks (Edwards 1976). During this same period, soil residues decreased from about 4 mg/kg immediately after application, to about 1 mg/kg at 6 weeks, and were not detectable after 12 weeks. The high

residues observed in slugs may be due, in part, to physical adsorption of diazinon to slug mucus. Edwards (1976) concluded that slugs heavily contaminated by diazinon constituted a serious danger to birds and mammals feeding on them.

Depuration rates of diazinon differed significantly for two species of nematodes, *Panagrellus redivivus* and *Bursaphelenchus xylophilus* (Al-Attar and Knowles 1982). Both species showed maximum uptake of radiolabeled diazinon between 6 and 12 hours, and both metabolized diazinon to diazoxon and pyrimidinol. By 96 hours, 95% of the diazinon in *P. redivivus* had been metabolized, but only 26% was transformed in *B. xylophilus*, again demonstrating variability in diazinon metabolism between related species.

RECOMMENDATIONS

Certain aquatic organisms were impacted by diazinon water concentrations between 0.3 and 1.2 ug/l; effects included lowered emergence and elevated drift of stream insects (0.3 ug/l), reduced fecundity of marine minnows (0.47 ug/l), accumulations in freshwater teleosts (0.55 ug/l), and daphnid immobilization (1.0 ug/l) and death (1.2 ug/l). For protection of sensitive aquatic organisms, Arthur et al. (1983) recommended that water diazinon levels should not exceed 0.08 ug/l. This value represents a safety factor of about 4 over the lowest recorded adverse effect level of 0.3 ug/l. The safety factor may require adjustment, probably upwards, as additional data become available. Establishment of safe levels is complicated by the fact that diazinon can persist many months in neutral or basic waters, including seawater (Kanazawa 1978), but hydrolyzes rapidly in acidic waters (Allison and Hermanutz 1977). Data on chronic effects of fluctuating and intermittent exposures of fishes and invertebrates to diazinon are also needed, and these will aid in the establishment of safe concentrations for this organophosphorus pesticide (Allison and Hermanutz 1977).

Granular formulations were especially hazardous to seed-eating birds; ingestion of fewer than 5 granules of a Diazinon 14G formulation could be lethal (Hill and Camardese 1984). A reduction in diazinon content of existing granular formulations may become necessary in application areas frequented by high densities of seed-eating birds. Stone and Gradoni (1985) recommend that diazinon should not be used in areas where waterfowl feed, especially turfgrass. Suggested alternatives to diazinon for turfgrass use include Dursban (0,0- diethyl 0-(3,5,6-trichloro-2- pyridyl)-phosphorothioate), Dylox (dimethyl (2,2,2-trichloro-l-hydroxyethyl) phosphonate), Carbaryl (1-naphthyl N-methylcarbamate), and Lannate (S-methyl-N-((methylcarbamoyl) oxy)- thioacetimidate) (Stone 1980; Stone and Gradoni 1985). Diazinon should be used with caution in large-scale spray applications--such as grasshopper control--as judged by some deaths of horned larks (*Eremophila alpestris*), lark buntings (*Calamospiza melanocorys*), western meadowlarks (*Sturnella neglecta*). and chestnut-collared longspurs (*Calcarius ornatus*) when used for this purpose in Wyoming (McEwen et al. 1972). Diazinon applications to agricultural crops comprised a relatively small percentage of the reported mortality incidents, but it is likely that this category is underreported since such incidents were probably less conspicuous than those noted on lawns and golf courses (Stone and Gradoni 1985). Also, diazinon interactions with other agricultural chemicals, such as Captan (cis -N-((trichloromethyl)thio)-4-cyclohexene- 1,2-dicarboximide), may produce more-than-additive (but reversible) adverse effects on food consumption and egg production of ring-necked pheasants (Stromborg 1977). More research is needed on complex mixtures of agricultural pesticides that contain diazinon.

In female rats, the no-observable-effect level (NOEL) is 0.1 mg/kg of dietary diazinon; at 0.5 mg/kg there was a marked lowering of plasma cholinesterase activity in 5 weeks (Davies and Holub 1980a). But studies with male rats indicate that the NOEL is 2 mg/kg of dietary diazinon, or about 20X higher than female rats (Davies and Holub 1980b). Accordingly, future studies should consider sex as a variable in toxicity evaluation of diazinon. It is generally agreed that mammals are more resistant than birds to diazinon owing, in part, to their ability to rapidly metabolize diazoxon. However, data are missing on the effects of diazinon to native mammals under field conditions, and this should constitute a priority research area.

MERCURY HAZARDS TO FISH, WILDLIFE, AND INVERTEBRATES: A SYNOPTIC REVIEW

by
Ronald Eisler

U. S. Fish and Wildlife Service
Patuxent Wildlife Research Center
Laurel, MD 20708

SUMMARY

Available literature on the ecological and toxicological aspects of mercury (Hg) in the environment, with special reference to fish and wildlife resources, is reviewed and summarized. Subdivisions include sources, chemical properties, background concentrations, acute and chronic toxicity, sublethal effects, and proposed criteria to protect sensitive resources.

Mercury has been used by man for at least 2,300 years, most recently as a fungicide in agriculture, in the manufacture of chlorine and sodium hydroxide, as a slime control agent in the pulp and paper industry, in the production of plastics and electrical apparatus, and in mining and smelting operations. Mercury burdens in some environmental compartments are estimated to have increased up to 5X precultural levels, primarily as a result of man's activities. The construction of artificial reservoirs, for example, which releases Hg from flooded soils, has contributed to the observed elevation of Hg concentrations in fish tissues from these localities. Elevated levels of Hg in living organisms in Hg-contaminated areas may persist for as long as 100 years after the source of pollution has been discontinued. One major consequence of increased mercury use, coupled with careless waste disposal practices, has been a sharp increase in the number of epidemics of fatal mercury poisonings in humans, wildlife, and aquatic organisms.

Most authorities agree on six points: (1) mercury and its compounds have no known biological function, and the presence of the metal in the cells of living organisms is undesirable and potentially hazardous; (2) forms of mercury with relatively low toxicity can be transformed into forms of very high toxicity, such as methylmercury, through biological and other processes; (3) mercury can be bioconcentrated in organisms and biomagnified through food chains; (4) mercury is a mutagen, teratogen, and carcinogen, and causes embryocidal, cytochemical, and histopathological effects; (5) some species of fish and wildlife contain high concentrations of Hg that are not attributable to human activities; (6) anthropogenic use of Hg should be curtailed, as the difference between tolerable natural background levels of Hg and harmful effects in the environment is exceptionally small.

Concentrations of total Hg lethal to sensitive, representative, nonhuman species range from 0.1 to 2.0 ug/l (ppb) of medium for aquatic organisms; from 2,200 to 31,000 ug/kg body weight (acute oral) and 4,000 to 40,000 ug/kg (dietary) for birds; and from 100 to 500 ug/kg body weight (daily dose) and 1,000 to 5,000 ug/kg diet for mammals. Organomercury compounds, especially methylmercury, are always more toxic than inorganic Hg compounds. Numerous biological and abiotic factors modify the toxicity of Hg compounds--sometimes by an order of magnitude or more--but the mechanisms of action are not clear. Significant adverse sublethal effects were observed among selected aquatic species at water concentrations of 0.03 to 0.1 ug Hg/l. For some birds, adverse effects--predominantly on reproduction--have been associated with total Hg concentrations (in ug/kg fresh weight) of 5,000 in feather, 900 in egg, and 50 to 100 in diet; and with daily intakes of 640 ug/kg body weight. Sensitive nonhuman mammals showed significant adverse effects of Hg when daily intakes were 250 ug/kg body weight, when dietary levels were 1,100 ug/kg, or when tissue concentrations exceeded 1,100 ug/kg.

The most recent mercury criteria proposed by the U.S. Environmental Protection Agency for protection of freshwater aquatic life are 0.012 ug/l medium (4-day average), not to exceed 2.4 ug/l on an hourly average; however, these criteria offer only limited protection to freshwater ecosystems. The saltwater criteria of 0.025 ug Hg/l medium (4-day average), not to exceed 2.1 ug/l hourly, are unsatisfactory for the protection of marine life. For the protection of sensitive species of mammals and birds that regularly consume fish and other aquatic organisms, total Hg concentrations in these prey items should probably not exceed 100 ug/kg fresh weight for birds, and 1,100 ug/kg for small mammals. The significance of elevated Hg levels in tissues of fish and wildlife is not fully understood; some species of marine pinnipeds, for example, normally contain high concentrations of Hg in various tissues without apparent adverse effects. Usually, however, concentrations in excess of 1,100 ug/kg fresh weight of tissue (liver, kidney, blood, brain, hair) should be considered as presumptive evidence of an environmental mercury problem.

Four courses of action now seem warranted. First, toxic mercurials in agriculture and industry should be replaced by less toxic substitutes. Second, controls should be applied at the point of origin to prevent the discharge of potentially harmful Hg wastes. Third, continued periodic monitoring of Hg in fish and wildlife is needed for identification of potential problem areas., and for evaluation of ongoing mercury curtailment programs. And fourth, additional research is merited on mechanisms of mercury accumulation and detoxication in comparatively pristine ecosystems.

INTRODUCTION

The element mercury (Hg) and its compounds have no known normal metabolic function. Their presence in the cells of living organisms represents contamination from natural and anthropogenic sources; all such contamination must be regarded as undesirable and potentially hazardous (NAS 1978).

The most important ore of mercury, cinnabar (mercuric sulfide), has been mined continuously since 415 BC (Clarkson and Marsh 1982). In the period before the industrial revolution, Hg was used extensively in gold extraction and in the manufacture of felt hats and mirrors; in the 1800's, it was used in the chloralkali industry, in the manufacture of electrical instruments, and as a medical antiseptic; and since 1900, it has been used in pharmaceuticals, in agricultural fungicides, in the pulp and paper industry as a slimicide, and in the production of plastics (Clarkson and Marsh 1982). Current world use of mercury is estimated at 10,000 to 15,000 metric tons annually (Boudou and Ribeyre 1983), of which the United States accounts for about 18% (Clarkson and Marsh 1982).

The first cases of fatal mercury poisoning were reported for two men in a European chemical laboratory in 1865 (Das et al. 1982). The first documented human poisoning from an agricultural exposure to methylmercury occurred in 1940 (Das et al. 1982). As summarized by Elhassani (1983), exposure of humans to mercury compounds may result from dermal application (e.g., 1,600 infants in Argentina showed symptoms of Hg poisoning after a laundry treated their diapers with a Hg disinfectant), from diet (i.e., ingestion of Hg-contaminated fish, pork, seafoods, or grains), and from contact by respiratory routes (e.g., occupational exposure of mercury fungicide applicators in Nicaragua). Sporadic incidences of human poisonings have occurred in the United States, the Soviet Union, and Canada; and major epidemics have been reported in Japan, Pakistan, Guatemala, Ghana, Yugoslavia, and Iraq (Clarkson and Marsh 1982; Das et al. 1982; Elhassani 1983; Greener and Kochen 1983). In 1972, for example, there were 6,530 hospital admissions within 18 months (459 hospital deaths) among Iraqi farmers who ate bread made from seed wheat treated with a methylmercury fungicide. A water soluble red dye was washed off the wheat, with the assumption that the mercury would be equally soluble. Before the wheat was consumed by humans, it was fed (without apparent effect) to chickens and other :livestock for only a few days; it was not realized that a lengthy latency period was involved (Das et al. 1982; Elhassani 1983). There is no effective antidote to counteract the effects of methylmercury on the central nervous system (Elhassani 1983).

Poisoning of game birds and other wildlife in Sweden, apparently by seeds treated with organomercurials, was noticed in 1960 (Das et al 1982). Massive kills of the grey heron (*Ardea cinerea*) in the Netherlands during 1976, were attributed to a combination of low temperatures, undernourishment, and high body burdens of mercury (Van der Molen et al. 1982). Mercury contamination has resulted in the closure of pheasant and partridge hunting areas in Alberta, Canada (Mullins et al. 1977). In 1967, the Swedish medical board banned the sale of fish that contained high concentrations of organomercury salts, originating from about 40 lakes and rivers (Das et al. 1982). In 1970, after the discovery of high levels of mercury in fish from Lake St. Clair, Canada, restrictions on fishing and the sale of fish were imposed in many areas of the United States and Canada (Das et al. 1982). Since 1970, a total of 26 of the 48 States in the conterminous United States have reported mercury pollution in their waters as a direct result of human activities. These States have banned sport or commercial fishing in Hg-contaminated waters, or have issued health warnings about the consequences of eating Hg-contaminated fish or seafood from selected water courses, or have placed restrictions on fish consumption from certain streams, lakes, or rivers polluted with mercury (NAS 1978). In general, the number of Hg-contaminated fish and wildlife habitats has progressively increased--almost all as a direct result of anthropogenic activities (Boudou and Ribeyre 1983).

Most authorities on Hg ecotoxicology agree on six points. First, Hg and its compounds have no known biological function, and its presence in living organisms is undesirable and potentially hazardous. Second, forms of mercury with relatively low toxicity can be transformed into forms with very high toxicity through biological and other processes. Third, methylmercury can be bioconcentrated in organisms and biomagnified through food chains, returning mercury directly to man and other upper trophic level consumers in concentrated form. Fourth, mercury is a mutagen, teratogen, and carcinogen, and causes embryocidal, cytochemical, and histopathological effects. Fifth, high body burdens of mercury normally encountered in some species of fish and wildlife from remote locations emphasize the complexity of natural mercury cycles and human impacts on these cycles. And finally, the anthropogenic use of mercury should be curtailed, because the difference between

tolerable natural background levels of mercury and harmful effects in the environment is exceptionally small. These, and other aspects of mercury and its compounds in the environment as a result of anthropogenic or natural processes, have been the subject of many reviews, including those by Montague and Montague (1971), D'Itri (1972), Friberg and Vostal (1972), Jernelov et al. (1972, 1975), Keckes and Miettinen (1972), Buhler (1973), Holden (1973), D'Itri and D'Itri (1977), Eisler (1978, 1981), NAS (1978), Birge et al. (1979),.Magos and Webb (1979), Nriagu (1979), EPA (1980, 1985), Jenkins (1980), Clarkson and Marsh (1982), Das et al. (1982), Boudou and Ribeyre (1983), Elhassani (1983), Clarkson et al. (1984), Robinson and Touvinen (1984), and Wren (1986).

This report was prepared in response to requests for information from environmental specialists of the U.S. Fish and Wildlife Service. it is part of a continuing series of synoptic reviews on chemical contaminants and natural resources.

SOURCES OF ENVIRONMENTAL MERCURY

As a direct result of human activities, mercury levels in river sediments have increased fourfold since precultural times, and twofold to fivefold in sediment cores from lakes and estuaries (Das et al. 1982). During the past 100 years, it has been estimated that more than 500,000 metric tons of Hg entered the atmosphere, hydrosphere, and surface soils, with eventual deposition in subsurface soils and sediments (Das et al. 1982). Several activities that contribute significantly to the global input of Hg include the combustion of fossil fuels; mining and reprocessing of gold, copper, and lead; operation of chloralkali plants; and disposal of batteries and fluorescent lamps (NAS 1978; Das et al. 1982). The atmosphere plays an important role in the mobilization of Hg; 25% to 30% of the total atmospheric Hg burden is of anthropogenic origin (NAS 1978).

In the United States, mercury consumption rose from 1,305 metric tons in 1959 to 2,359 tons in 1969 (Table 1). The major use of mercury has been as a cathode in the electrolytic preparation of chlorine and caustic (Nriagu 1979). In 1968 this use accounted for about 33% of the total U.S. demand for Hg (EPA 1980). Of recent U.S. mercury consumption, electrical apparatus have accounted for about 27%; industrial and control instruments, such as switches, thermometers, and barometers, and general laboratory appliances, 14%; antifouling and mildew-proofing paints, 12%; Hg formulations to control fungal diseases of seeds, bulbs, and vegetables, 5%; and dental amalgams, pulp and paper manufacturers, pharmaceuticals, metallurgy and mining, and catalysts, 9% (EPA 1980). Mercury, however, is no longer registered for use in antifouling paints, or for the control of fungal diseases of bulbs (EPA 1980).

Mercury from natural sources enters the biosphere directly as a gas, in lava (from terrestrial and oceanic volcanic activity), in solution, or in particulate form; cinnabar (HgS), for example, is a common mineral in hot spring deposits and a major natural source of mercury (Das et al. 1982). The global cycle of Hg involves degassing of the element from the Earth's crust and evaporation from natural bodies of water, atmospheric transport (mainly in the form of Hg vapor), and deposition of Hg back onto land and water. Oceanic effluxes of Hg are tied to equatorial upwelling and phytoplankton activity and may significantly affect the global cycling of this metal. If volatilization of Hg is proportional to primary production in the world's oceans, oceanic phytoplankton activity represents about 36% of the yearly Hg flow to the atmosphere, or about 2,400 tons per year (Kim and Fitzgerald 1986). Mercury finds its way into sediments, particularly oceanic sediments, where the retention time can be lengthy (Table 2), and where it may continue to contaminate aquatic organisms (Lindsay and Dimmick 1983). Estimates of the quantities of Hg entering the atmosphere from degassing of the surface of the planet vary widely, but a commonly quoted figure is 30,000 tons annually (Clarkson et al. 1984). In aquatic ecosystems, removal of the source of anthropogenic Hg results in a slow decrease in the Hg content of sediments and biota (NAS 1978). The rate of loss depends, in part, on the initial degree of contamination, the chemical form of Hg, physical and chemical conditions of the system, and the hydraulic turnover time (NAS 1978).

Table 1. Industrial and other uses of mercury in the United States in 1959 and in 1969. All values are in metric tons (modified from Montague and Montague 1971).

	1959		1969	
Use	Tons	Percent	Tons	Percent
Chloralkali process	201	15.5	716	30.4
Electrical apparatus	308	23.6	644	27.3

Total	1,305		2,359	

Table 2. Amount of mercury in some global reservoirs (NAS 1978), and residence time (Clarkson et al. 1984).

Reservoir	Hg content (metric tons)	Residence time
Atmosphere	850	6 to 90 days
Soils	21,000,000	1,000 years
Freshwater	200	-
Freshwater biota (living)	4	-
Ocean water	4,150,000,000	2,000 years
Oceanic biota (living)	3	-
Ocean sediments	330,000,000,000	>1 million years

CHEMICAL PROPERTIES

Mercury, a silver-white metal that is liquid at room temperature and is highly volatile, can exist in three oxidation states: elemental mercury (Hg^0), mercurous ion (Hg_2^{2+}), and mercuric ion (Hg^{2+}). It can be part of both inorganic and organic compounds (EPA 1980; Clarkson et al. 1984; Table 3). All mercury compounds interfere with thiol metabolism, causing inhibition or inactivation of proteins containing thiol ligands and ultimately leading to mitotic disturbances (Das et al. 1982; Elhassani 1983). The mercuric species is the most toxic inorganic chemical form, but all three forms of inorganic Hg may have a common molecular mechanism of damage in which Hg^{2+} is the toxic species (Clarkson and Marsh 1982; Figure 1).

Chemical speciation is probably the most important variable influencing ecotoxicology of Hg, but Hg speciation is difficult, especially in natural environments (Boudou and Ribeyre 1983). Mercury compounds in an aqueous solution are chemically complex. Depending on pH, alkalinity, redox, and other variables, a wide

variety of chemical species are liable to be formed, having different electrical charges and solubilities. For example, $HgCl_2$ in solution can speciate into $Hg(OH)_2$, Hg^{2+}, $HgCl^+$, $Hg(OH)^-$, $HgCl_3^-$, and $HgCl_4^{2-}$; anionic forms predominate in saline environments (Boudou and Ribeyre 1983). In the aquatic environment, under naturally occurring conditions of pH and temperature, Hg may also become methylated by biological or chemical processes, or both (Beijer and Jernelov 1979; EPA 1980; Ramamoorthy and Blumhagen 1984; Figure 1) -- although abiological methylation is limited (Callister and Winfrey 1986). Methylmercury is the most hazardous mercury species due to its high stability, its lipid solubility, and its possession of ionic properties that lead to a high ability to penetrate membranes in living organisms (Beijer and Jernelov 1979).

All mercury discharged into rivers, bays, or estuaries as elemental (metallic) mercury, inorganic divalent mercury, phenylmercury, or alkoxyalkyl mercury can be converted into methylmercury compounds by natural processes (Jernelov 1969). The mercury methylation in ecosystems depends on mercury loadings, microbial activity, nutrient content, pH and redox condition, suspended sediment load, sedimentation rates, and other variables (NAS 1978; Compeau and Bartha 1984; Berman and Bartha 1986; Callister and Winfrey 1986; Jackson 1986). The finding that certain microorganisms are able to convert inorganic and organic forms of Hg into the highly toxic methylmercury or dimethylmercury has made it clear that any form of Hg is highly hazardous to the environment (EPA 1980, 1985). The synthesis of methylmercury by bacteria from inorganic Hg compounds present in the water or in the sediments is the major source of this molecule in aquatic environments (Boudou and Ribeyre 1983). This process can occur under both aerobic and anaerobic conditions (Beijer and Jernelov 1979; Clarkson et al. 1984), but seems to favor anaerobic conditions (Olson and Cooper 1976; Callister and Winfrey 1986). Transformation of inorganic mercury to an organic form by bacteria alters its biochemical reactivity and hence its fate (Windom and Kendall 1979; Figure 1). Methylmercury is decomposed by bacteria in two phases. First, hydrolytic enzymes cleave the C-Hg bond, releasing the methyl group. Second, a reductase enzyme converts the ionic Hg to the elemental form, which is then free to diffuse from the aquatic environment into the vapor phase. These demethylating microbes appear to be widespread in the environment; they have been isolated from water, sediments, and soils and from the gastrointestinal tract of mammals--including humans (Clarkson et. al. 1984).

Table 3. Some properties of mercury and its compounds.[a]

Property	Elemental mercury	Mercurous chloride	Mercuric chloride	Methylmercury chloride

Methylmercury is produced by methylation of inorganic mercury present in both freshwater and saltwater sediments, and accumulates in aquatic food chains in which the top-level predators usually contain the highest concentrations (Clarkson and Marsh 1982). Organomercury compounds other than methylmercury decompose rapidly in the environment, and behave much like inorganic Hg compounds (Beijer and Jernelov 1979). In organisms near the top of the food chain, such as carnivorous fishes, almost all Hg accumulated is in the methylated form, primarily as a result of the consumption of prey containing methylmercury; methylation also occurs at the organism level by way of mucous, intestinal bacteria, and enzymatic processes, but these pathways are not as important as diet (Huckabee et al. 1979; Boudou and Ribeyre 1983).

The biological cycle of Hg is delicately balanced, and small changes in input rates and the chemical form of Hg may result in increased methylation rates in sensitive systems (NAS 1978). For example, the acidification of natural bodies of freshwater is statistically associated with elevated concentrations of methylmercury in the edible tissues of predatory fishes (Clarkson et al. 1984). In chemically sensitive waterways, such as poorly buffered lakes, the combined effects of acid precipitation and increased emissions of Hg to the atmosphere (with subsequent deposition) pose a serious threat to the biota if optimal biomethylation conditions are met (NAS 1978).

Mercury binds strongly with sulfhydryl groups, and has many potential target sites during embryogenesis; phenylmercury and methylmercury compounds are among the strongest known inhibitors of cell division (Birge et al. 1979). Organomercury compounds, especially methylmercury, cross placental barriers and can enter mammals by way of the respiratory tract, gastrointestinal tract, skin, or mucous membranes (Elhassani 1983). When compared with inorganic mercury compounds, organomercurials are more completely absorbed, are more soluble in organic solvents and lipids, pass more readily through biological membranes, and are slower to be excreted (Clarkson and Marsh 1982; Elhassani 1983; Greener and Kochen 1983). Biological membranes, including those at the blood-brain interface and placenta, tend to discriminate against ionic and inorganic Hg, but allow relatively easy passage of methylmercury and dissolved Hg vapor (Greener and Kochen 1983). As judged by membrane model studies, it appears that electrically neutral mercurials are responsible for most of the diffusion transport of Hg, although this movement is modified significantly by pH and Hg speciation. It seems, however, that the liposolubility of methylmercury is not the entire reason for its toxicity and does not play a major role in its transport. This hypothesis needs to be examined further in studies with living membranes (Boudou et al. 1983).

Mercury-antagonistic drugs include 2,3-dimercaptopropanol, polythiol resins, selenium salts, vitamin E, and sulfhydral agents (in J.O. Nriagu (ed.). The biogeochemistry of mercury in the environment. Elsevier/North-Holland Biomedical Press, New York.Magos and Webb 1979; Elhassani 1983). Thiols (R-SH), which compete with Hg for protein binding sites, are the most important antagonists of inorganic mercury salts, and have been used extensively in attempts to counteract Hg poisoning in humans (Das et al. 1982). The protective action of selenium (Se) against adverse or lethal effects induced by inorganic or organic mercury salts has been reported for algae, aquatic invertebrates, fish, and mammals (Magos and Webb 1979; Heisinger 1979; Chang et al. 1981; Lawrence and Holoka 1981; Das et al. 1982; Gotsis 1982; Eisler 1985; Satoh et al. 1985). Selenite salts can release methylmercury from its linkage to proteins, and there is general agreement that a true antagonism exists between Se and Hg, although the exact mechanism is not fully established (Das et al. 1982). In marine mammals and humans, for example, Se and Hg concentrations are closely related, almost linearly in a 1:1 molar ratio, but this relation blurs in teleosts (in which Se is abundant) and fails in birds (Eisler 1985).

MERCURY IN MINAMATA, JAPAN

One of the earliest and most extensively documented cases of mercury poisoning occurred in the 1950's at Minamata Bay, in southwestern Kyushu, Japan--especially among fishermen and their families (Fujiki 1963, 1980; Irukayama 1967; Matida and Kumada 1969; Kojima and Fujita 1973; NAS 1978; Elhassani 1983; Nishimura and Kumagai 1983; Doi et al. 1984). The source of the mercury was in waste discharged from an acetaldehyde plant that used inorganic Hg as a catalyst; between 1932 and 1968, Minamata Bay received at least 260 tons of mercury, and perhaps as much as 600 tons. A severe neurological disorder was recognized in late 1953 and had reached epidemic proportions by 1956; 111 cases of poisoning were reported by the end of 1960 and 41 deaths by August 1965. By 1982, there were 1,800 verified human victims of mercury poisoning in a total regional population of 200,000; however, the total number of victims remains unconfirmed. Symptoms evidenced by human victims included sensory impairment, constriction of visual fields, hearing loss, ataxia, and

speech disturbances. Congenital cases were accompanied by disturbance of physical and mental development; about 6% of babies born in Minamata had cerebral palsy (vs. 0.5% elsewhere).

"Minamata disease" resulted from the discharge of methylmercury from chemical factories into Minamata Bay. Once diluted and diffused in the water, it was concentrated to a high level in fish and filter-feeding shellfish by several routes, including bioconcentration and food chain biomagnification. When these fish and shellfish were consumed by humans, methylmercury gradually accumulated to exceed a threshold value, causing intoxication. Spontaneously poisoned cats, dogs, rats, waterfowl, and pigs behaved erratically and died; flying crows and grebes suddenly fell into the sea and drowned; and large numbers of dead fish were seen floating on the sea surface (Doi et al. 1984). In laboratory studies, cats and rats fed shellfish from the Bay developed the same signs as those seen in animals affected spontaneously. Abnormal Hg content--i.e., more than 30 mg/kg fresh weight--was measured in fish, shellfish, and muds from the Bay, and in organs of necropsied humans and cats that had succumbed to the disease. Mercury contamination of fish and sediments was still evident in 1981, although discharges from the acetaldehyde plant ceased in 1971 (Doi et al. 1984).

There is a strong relation between the food of birds from Minamata and the Hg content in feathers; the content is highest in fish-eating seabirds and lowest in herbivorous waterfowl (Doi et al. 1984; Table 4). This same relation held in birds collected from China and Korea, although concentrations were significantly lower (Doi et al. 1984). There are close correlations between Hg contents of zooplankton and suspended particulate matter, and of sediments and fish muscle, suggesting a pathway from sediment to fish by way of suspended matter and zooplankton. The conversion from inorganic Hg to methylmercury is believed to have occurred primarily in zooplankton (Nishimura and Kumagai 1983).

Table 4. Mercury concentrations in selected biological and nonbiological materials collected from Minamata Bay, Japan and environs. Concentrations are in mg Hg/kg (ppm) fresh weight (FW), or dry weight (DW).

In aquatic environments where point sources of industrial contamination have been identified, the elimination of Hg discharges has usually improved environmental quality. Such improvement has been reported for Minamata Bay (Table 4); for sediments in Saguenay Fjord, Quebec, when chloralkali wastes were limited; for fish residues in Canada's Lake St. Clair after two chloralkali plants were closed; and in various sections of Europe and North America when industrial discharges were eliminated (Barber et al. 1984).

BACKGROUND CONCENTRATIONS

GENERAL

Mercury burdens in sediments and other nonbiological materials are estimated to have increased up to 5X prehuman levels, primarily as a result of man's activities (NAS 1978). The residence time of mercury is comparatively short (about 11 days) in the atmosphere, but is much longer (at least 1,000 years) in oceanic waters, soils, and sediments (Clarkson 1984).

An elevated concentration of mercury (i.e., >1.0 mg/kg fresh weight), usually as methylmercury, in any biological sample is often associated with proximity to human use of mercury. The elimination of Hg point-source discharges has usually been successful in improving environmental quality. However, elevated levels of mercury in biota may persist in contaminated areas long after the source of pollution has been discontinued (Rada et al. 1986). For example, Hg remains elevated today in resident biota of Lahontan Reservoir, Nevada, which received about 7,500 tons of mercury as a result of gold and silver mining operations during the period 1865 to 1895 (Cooper 1983). It is noteworthy that some groups of organisms with consistently elevated Hg residues may have acquired these concentrations as a result of natural processes, rather than from anthropogenic activities. These groups include older specimens of long-lived predatory fishes, marine mammals (especially pinnipeds), and organisms living near natural Hg-ore-cinnabar deposits.

NONBIOLOGICAL

Mercury burdens have increased 2X to 5X precultural levels in freshwater and estuarine sediments and freshwater lakes and rivers, but estimated increases in oceanic waters and terrestrial soils have been negligible (NAS 1978). Total mercury concentrations in uncontaminated natural waters (presumably unfiltered) now range from about 0.001 to 0.050 ug/l (Table 5). In sediments that were anthropogenically contaminated with Hg, concentrations were significantly elevated (usually >20.0 mg/kg) when compared with uncontaminated sediments (usually <1.0 mg/kg). The residence time of Hg in nonbiological materials is variable, and depends on a number of physicochemical conditions. Estimated half-time residence values for Hg are 11 days in the atmosphere, 1,000 years in terrestrial soils, 2,100 to 3,200 years in ocean waters, And >250 million years in oceanic sediments (NAS 1978, as quoted in Boudou and Ribeyre 1983); the estimate was 1 month to 5 years for water from the contaminated Saguenay River in Quebec (Smith and Loring 1981).

Table 5. Mercury concentrations in water and sediments.

Material (units)	Concentration	Reference[a]
Water (µg/L)		
Open ocean	0.0053 ± 0.0022	Nishimura et al. 1983

Levels of mercury in sediments may be reflected by an increased mercury content in epibenthic fauna. For example, Hg concentrations in sediments near the Hyperion sewer outfall in Los Angeles, which ranged up to 820 ug/kg and decreased with increasing distance from the outfall, were reflected in the Hg content of crabs, scallops, and whelks. Concentrations of Hg were highest in organisms collected nearest the discharge, and lowest in those collected tens of kilometers away (Klein and Goldberg 1970).

BIOLOGICAL

Information on mercury residues in field collections of living organisms is especially abundant; accordingly, only a few selected data points are shown in Table 6. Additional, more extensive, information was given by Jenkins (1980), Eisler (1981), and Wren (1986).

In general, mercury concentrations in biota were usually <1.0 mg/kg fresh weight tissue in organisms collected from locations not directly affected by man's use of the element. However, they exceed 1.0 mg/kg--and are sometimes markedly higher--in animals and vegetation from the vicinity of chloralkali plants; agricultural users of mercury; smelteries; mining operations; pulp and paper mills; factories producing Hg-containing paints, fertilizers, and insecticides; sewer outfalls; sludge disposal areas; and other anthropogenic point sources of mercury. (Several notable exceptions to this generalization are discussed later.)

Certain species of macrophytes strongly influence mercury cycling. For example, *Spartina alterniflora*--a dominant salt marsh plant in Georgia estuaries--accounted for almost half the total mercury budget in that ecosystem (Windom et al. 1976). Mangrove vegetation plays a similarly important role in mercury cycling in the Florida Everglades (Tripp and Harriss 1976). These findings suggest that more research is needed on the role of higher plants in the mercury cycle.

Mercury was detectable in the tissues of almost all freshwater fishes examined, with the majority of the Hg (>80%) present as methylmercury (Huckabee et al. 1979). Methylmercury is absorbed more efficiently than inorganic Hg from water, and probably from food, and is retained longer regardless of the uptake pathway (Huckabee et al. 1979). Reservoir construction has often been inferred to be a cause of elevated mercury concentrations in fish. It is hypothesized that increases in mercury levels observed in fish were due to bacterial methylation of naturally occurring Hg in the flooded soils (Bodaly et al. 1984). Other factors that enhance accumulation of Hg in predatory teleosts from recently created reservoirs include low pH, high humus content, and low bioproduction (Lodenius 1983; Lodenius et al. 1983). In general, mercury levels are higher in fish from younger oligotrophic reservoirs, and lower in fish from older eutrophic reservoirs; in both situations, tissue Hg levels usually decline as the reservoirs age (Abernathy and Cumbie 1977). Concentrations >0.5 mg/kg (but <1.0 mg/kg) fresh weight have been reported in trout from several wilderness lakes in northern Maine (Akielaszak and Haines 1981) and from the Adirondacks region of New York (Sloan and Schofield 1983); these values are considerably higher than might be expected for fish inhabiting remote lakes. These elevated concentrations were usually associated with lakes of low pH, low calcium, low dissolved organic carbon concentrations, and low water hardness and alkalinity.

Table 6. Mercury concentrations in field collections of selected species of flora and fauna. Values shown are in mg Hg/kg fresh weight (FW), or dry weight (DW).

[a]Concentrations are listed as mean, range, or maximum (Max.).

[b]Each reference applies to the value in the same row and in the rows that follow for which no other reference is indicated.

Nationwide monitoring of whole fish during the period 1969 to 1981 demonstrated that the highest Hg concentrations (0.33 to 1.7 mg/kg FW) were in northern squawfish (*Ptychocheilus oregonensis*) from the Columbia River basin in the Pacific Northwest (Henderson and Shanks 1973; Lowe et al. 1985). Elevated Hg concentrations in this piscivorous species were attributed primarily to the presence of major cinnabar deposits and with Hg use associated with mineral mining in the Columbia River basin. Northern squawfish may have a natural tendency to accumulate high concentrations of mercury in their flesh--as is well known for older specimens of long-lived predatory fishes such as tunas, billfishes, bluefish (*Pomatomus saltatrix*), striped bass (*Morone saxatilis*), northern pike (*Esox lucius*), and many species of sharks--but Hg uptake kinetics in squawfish requires further research (Lowe et al. 1985).

Of 159 species of finfish and sharks from the coastal waters of Alaska, Hawaii, and the conterminous United States, mercury concentrations in muscle were usually less than 0.3 mg/kg fresh weight (Hall et al. 1978). Mean Hg concentrations in excess of 0.5 mg/kg fresh weight muscle were recorded in 31 species, including 10 species of sharks and 4 species of billfishes; however, these 31 species accounted for less than 0.65% of the catch intended for human consumption (Hall et al. 1978).

In birds, it is generally acknowledged that mercury concentrations are highest in species that eat fish and other birds. Residues were highest in kidney and liver, but total Hg contents were significantly modified by food preference and availability, and by migratory patterns (NAS 1978; Delbeke et al. 1984). Also, there is an inverse relationship between total Hg and percent methylmercury in tissues of various avian species (Norheim et al. 1982; Karlog and Clausen 1983)--a pattern that seems to hold for all vertebrate organisms for which data are available. Diet and migration are the most important Hg modifiers in birds. For example, the higher levels of Hg in juvenile than in adult wood ducks (*Aix sponsa*) from Tennessee were related to dietary patterns: juveniles preferred insects, whereas adults preferred pondweed tubers; Hg residues were higher in the insects than in the pondweeds (Lindsay and Dimmick 1983). Concentrations of Hg in livers of Antarctic birds reflected Hg body burdens accumulated during migration, while the birds were overwintering near industrialized areas. Concentrations were highest in species that ate higher trophic levels of prey and were especially pronounced for skuas, *Catharacta* spp.; however, significant inherent interspecies differences were evident (Norheim et al. 1982; Norheim and Kjos-Hanssen 1984).

The significance of Hg residues in birds is not fully understood. For example, all eggs of the American bald eagle (*Haliaeetus leucocephalus*) collected Nationwide contained detectable levels of Hg, but the mean was 0.15 mg Hg/kg (fresh weight basis) in eggs from unsuccessful nests vs. 0.11 in eggs from successful nests (Wiemeyer et al. 1984). Many other contaminants--especially organochlorine compounds--were in eagle eggs, and several were present at levels that potentially interfere with eagle reproduction (Wiemeyer et al. 1984). It is not now possible to implicate Hg as a major cause of unsuccessful eagle reproduction.

Bird feathers have been used for some time as indicators of Hg loadings in terrestrial and marine environments. The keratin in bird feathers is not easily degradable, and Hg is probably associated firmly with the disulphide bonds of keratin. Consequently, it has been possible to compare Hg contents of feathers recently sampled with those from museum birds, thereby establishing a time series (Applequist et al. 1984). The most probable source of recent elevated Hg residues in feathers of the Finnish sparrowhawk (*Accipiter nisus*) was from consumption of avian granivores that had become contaminated as a result of eating seeds treated with

organomercury compounds; in 1981, 5.6 tons of methoxyethylmercury compounds were used in Finnish agriculture for protection of seeds against fungi (Solonen and Lodenius 1984). Captive Swedish eagle-owls (*Bubo bubo*), with low Hg content in feathers (<1.0 mg/kg DW), that were introduced into coastal areas quickly reflected the high (6.5 mg/kg) Hg levels in feathers of wild eagle-owls from that region. Captive birds released into inland territories, where Hg levels were near background, did not accumulate Hg in feathers (Broo and Odsjo 1981). Mercury levels in feathers of nestling Swedish gyrfalcons (*Falco rusticolus*) showed a better correlation with Hg levels in actual food items than with levels based on adult feathers. Mercury concentrations in feathers were higher in nestlings fed partly with aquatic bird species containing >0.07 mg Hg/kg in pectoral muscle than in nestlings fed willow grouse (*Lagopus lagopus*) and ptarmigan (*Lagopus mutus*), both of which contained <0.01 mg Hg/kg in pectoral muscle (Lindberg 1984). In some instances there was a substantial time lag, up to 10 years, between the introduction of a pesticide, such as alkylmercury, its subsequent banning, and measurable declines of Hg in feathers of several species of Swedish raptors; this was the case for various species of *Falco, Haliaeetus*, *Bubo, Buteo*, and *Accipiter* (Wallin 1984). Accordingly, a reduction in Hg content in feathers of free-living birds may be sufficient to establish an improved situation.

Among mammals, marine pinnipeds usually contained the highest reported concentrations of Hg in tissues (Table 6). The relatively high concentrations appeared to be a result of natural processes rather than of anthropogenic activities, however, and probably did not represent a significant risk to pinniped health. In general, Hg concentrations increased significantly with increasing age of the organism, as shown (Figure 2) in the livers of harbor seal (*Phoca groenlandica*), grey seal (*Halichoerus grypus*), California sea lion (*Zalophus californianus*), and northern fur seal (*Callorhinus ursinus*). The mechanisms to account for this phenomenon in pinnipeds are similar to those reported by Itano et al. (1984 a,b, c) for the striped dolphin (*Stenella coeruleoalba*). They showed that tissue concentrations of mercury in striped dolphins increased with increasing age of the animal, reaching a plateau in 20 to 25 years; were highest in liver, although muscle accounted for about 90% of the total body Hg burden; were present in the methylated form in fetal and suckling stages, but the proportion of methylmercury decreased over time with no absolute increase after age 10 years; were excreted slowly by all developmental stages, and slowest in older dolphins (resulting in higher accumulations); and were correlated strongly with selenium concentrations in all age groups. It is probable that inorganic Hg and selenium were complexed in a 1:1 molar ratio, in a form biologically unavailable to marine mammals (and probably other mammals), thereby significantly decreasing the risk of mercury toxicosis to individuals with grossly elevated Hg body burdens (Eisler 1984, 1985). Large colonies of pinnipeds and, to a lesser extent, marine birds along the western coast of the United States may make Hg available to mussels (*Mytilus californianus*) through fecal elimination of large amounts of Hg, resulting in abnormally high Hg levels in mussels from several west coast sites (Flegal et al. 1981).

Among furbearers in the Wisconsin River drainage system, Hg burdens were higher in fish-eating than in herbivorous species--i.e., river otter (*Lutra canadensis*) > mink (*Mustela vison*) > raccoon (*Procyon lotor*) > red fox (*Vulpes fulva*) > muskrat (*Ondatra zibethicus*) > beaver (*Castor canadensis*) (Sheffy and St. Amant 1982). In general, fur contained the highest Hg levels, followed by liver, kidney, muscle, and brain, in that order (Table 6; Sheffy and St. Amant 1982). Mercury levels in piscivorous furbearers collected from the Wisconsin River basin paralleled Hg levels in fish, crayfish, and bottom sediments from that system; levels in all compartments were highest about 30 km downstream from an area that supported 16 pulp and paper mills and a chloralkali plant (Sheffy and St. Amant 1982). Mink and river otter accumulated about 10X more Hg than did predatory fishes from the same drainage areas--suggesting that these furbearers can serve as sensitive indicators of mercury, even at very low levels of Hg contamination (Kucera 1983).

Domestic sheep (*Ovis* sp.) allowed to graze for 23 months on grass contaminated with Hg (up to 6.5 mg/kg dry weight) caused by atmospheric emissions of a nearby chloralkali site, retained about 0.1% of the total Hg taken in by ingestion and inhalation, although residues in flesh were negligible (Edwards and Pumphery 1982). It was concluded that contamination of grass as a result of atmospheric discharges of inorganic He from

chloralkali sites causes no hazard, either directly to grazing animals or indirectly to humans who might ultimately consume their flesh.

ACUTE AND CHRONIC TOXICITY

GENERAL

For all organisms tested, early developmental stages were the most sensitive, and organomercury compounds--especially methylmercury--were more toxic than inorganic forms. Numerous biological and abiotic factors modify the toxicity of Hg compounds, sometimes by an order of magnitude or more, but the mechanisms of action are not clear.

Lethal concentrations of total Hg to sensitive, representative organisms varied from 0.1 to 2.0 ug/l of medium for aquatic fauna; from 2.2 to 31.0 mg/kg body weight (acute oral) and 4.0 to 40.0 mg/kg (dietary) for birds; and from 0.1 to 0.5 mg/kg body weight (daily dose) and 1.0 to 5.0 mg/kg (dietary) for mammals.

AQUATIC ORGANISMS

Toxic concentrations of mercury salts ranged from less than 0.1 ug/l to more than 200 ug/l for representative species of marine and freshwater organisms (Table 7). The lower concentrations of <2.0 ug/l recorded were usually associated with early developmental stages, long exposures, and flowthrough tests (Table 7). Among metals tested, mercury was the most toxic to aquatic organisms, and organomercury compounds showed the greatest biocidal potential (Eisler 1981). In general, toxicity was higher at elevated temperatures (Armstrong 1979), at reduced salinities in marine organisms (McKenney and Costlow 1981), and in the presence of other metals such as zinc and lead (Parker 1979).

Signs of acute mercury poisoning in fish included flaring of gill covers, increased frequency of respiratory movements, loss of equilibrium, and sluggishness (Armstrong 1979). Signs of chronic mercury poisoning included emaciation (due to appetite loss), brain lesions, cataracts, diminished response to change in light intensity, inability to capture food, abnormal motor coordination, and various erratic behaviors (Armstrong 1979; Hawryshyn et al. 1982). Mercury residues in severely poisoned fish that died soon thereafter ranged (in mg/kg fresh weight) from 26 to 68 in liver, 16 to 20 in brain, and 5 to 7 in whole body (Armstrong 1979).

BIRDS

Signs of mercury poisoning in birds included muscular incoordination, falling, slowness, fluffed feathers, calmness, withdrawal, hyporeactivity, hypoactivity, and eyelid drooping. In acute oral exposures, signs appeared as soon as 20 minutes postadministration in mallards and 2.5 hours in pheasants. Deaths occurred between 4 and 48 hours in mallards and 2 and 6 days in pheasants; remission took up to 7 days (Hudson et al. 1984). In studies with coturnix (*Coturnix coturnix coturnix*), (Hill 1981) found that methylmercury was always more toxic than inorganic mercury, and that young birds were usually more sensitive than older birds. Furthermore, some birds poisoned by inorganic mercury recovered after treatment was withdrawn, but chicks that were fed

methylmercury and later developed toxic signs usually died, even if treated feed was removed. Coturnix subjected to inorganic mercury, regardless of route of administration, showed a violent neurological dysfunction that ended in death 2 to 6 hours posttreatment. The withdrawal syndrome in coturnix poisoned by Hg 2^+ was usually preceded by intermittent, nearly undetectable tremors, coupled with aggressiveness towards cohorts; time from onset to remission was usually 3 to 5 days, but sometimes extended to 7 days. Coturnix poisoned by methylmercury appeared normal until 2 to 5 days posttreatment; then, ataxia and low body carriage with outstretched neck were often associated with walking. In advanced stages, coturnix lost locomotor coordination and did not recover; in mild to moderate clinical signs, recovery usually took at least 1 week (Hill 1981).

Mercury toxicity to birds varies with the form of the element, dose, route of administration, species, sex, age, and physiological condition (.Fimreite 1979). For example, in northern bobwhite chicks fed diets containing methylmercury chloride, mortality was significantly lower when the solvent was acetone than when it was another carrier such as propylene glycol or corn oil (Spann et al. 1986). In addition, organomercury compounds interact with elevated temperatures and pesticides, such as DDE and parathion, to produce additive or more-than-additive toxicity, and with selenium to produce less-than-additive toxicity (*Fimreite* 1979). Acute oral toxicities of various mercury formulations ranged between 2.2 and about 31.0 mg/kg body weight for most avian species tested (Table 8). Similar data for other routes of administration were 4.0 to 40.0 mg/kg for diet and 8.0 to 15.0 mg/kg body weight for intramuscular injection (Table 8).

Residues of mercury in experimentally poisoned passerine birds usually exceeded 20 mg/kg fresh weight, and were similar to concentrations reported in wild birds that died of mercury poisoning (Finley et al. 1979). Mercury levels in tissues of poisoned wild birds were highest (45 to 126 mg/kg fresh weight) in red-winged blackbirds (*Agelaius phoeniceus*), intermediate in starlings (*Sturnus vulgaris*) and cowbirds (*Molothrus ater*), and lowest (21 to 54) in grackles (*Quiscalus quiscula*); in general, Hg residues were highest in the brain, followed by the liver, kidney, muscle, and carcass. Some avian species are more sensitive than passerines (Solonen and Lodenius 1984): liver residues (in mg Hg/kg dry weight) in birds experimentally killed by methylmercury ranged from 17 in red-tailed hawks (*Buto jamaicensis*) to 70 in jackdaws (*Corvus monedula*); and values were intermediate in ring-necked pheasants, kestrels (*Falco tinnunculus*), and magpies (*Pica pica*). Experimentally poisoned grey herons (*Ardea cinerea*) seemed to be unusually resistant to Hg; lethal doses produced residues of 415 to 752 mg Hg/kg dry weight of liver (Van der Molen et al. 1982). However, levels of this magnitude were frequently encountered in livers from grey herons collected during a massive die-off in the Netherlands during a cold spell in 1976; the interaction effects of cold stress, mercury loading, and poor physical condition of the herons are unknown ((*Ardea cinerea*) in the Netherlands. Ardea 70:173-184Van der Molen et al. 1982).

Table 9. Toxicity of organomercury compounds to selected mammalian species.

Organism	Dose, route of administration, and other variables	Effects	Reference
Dog, *Canis familiaris*	0.1 to 0.25 mg/kg body weight during entire pregnancy; oral route	High incidence of stillbirths	Khera 1979
Cat, *Felis domesticus*	0.25 mg/kg body weight daily for 90 days (total 80–90 mg Hg); dietary route	Mean survival time 78 days. Convulsions starting at day 68; all with signs by day 90. Liver residues of survivors were 40.2 and 18.1 mg/kg fresh weight for total mercury and inorganic mercury, respectively	Eaton et al. 1980
Pig, *Sus* spp.	0.5 mg/kg body weight during pregnancy; oral route	High incidence of stillbirths	Khera 1979
Rhesus monkey, *Macaca mulatta*	0.5 mg/kg body weight during days 20–30 of pregnancy	Maternally toxic, and abortient	Khera 1979
Mink, *Mustela vison*	1.0 mg/kg in diet	Fatal to 100% in about 2 months 2 months	Sheffy and St. Amant 1982
River otter,	>2.0 mg/kg in diet	Fatal	Kucera 1983

Lutra canadensis			
Mink	5.0 mg/kg in diet	All dead in 30 to 37 days. Elevated residues in kidney (37.7 mg/kg fresh weight) and liver (55.6) prior to death	Sheffy and St. Amant 1982
Humans	Various	Lethal residues in tissues, in mg/kg fresh weight, were >6.0 in brain, >10.0 in liver, and >17.0 in whole body	Khera 1979
Mule deer, *Odocoileus hemionus hemionus*	17.88 mg/kg body weight; single oral dose	LD-50	Hudson et al. 1984
Harp seal, *Pagophilus groenlandicus*	25.0 mg/kg body weight daily; oral route	Dead in 20 to 26 days. Blood Hg levels just before death were 26.8 to 30.3 mg/L	Ronald et al. 1977

MAMMALS

Methylmercury affects the central nervous system in man--especially the sensory, visual, and auditory areas concerned with coordination; the most severe effects lead to widespread brain damage, resulting in mental derangement, coma, and death (Clarkson and Marsh 1982). In mule deer (*Odocoileus hemionus hemionus*), after acute oral Hg poisoning was induced experimentally, additional signs included belching, bloody diarrhea, piloerection (hair more erect than usual), and loss of appetite (Hudson et al. 1984). The kidney is the probable critical organ in adult mammals due to the rapid degradation of phenylmercurials and methoxyethylmercurials to inorganic Hg compounds and subsequent translocation to the kidney (Suzuki 1979), whereas in the fetus the brain is the principal target (Khera 1979). Most human poisonings were associated with organomercury compounds used in agriculture as fungicides to protect cereal seed grain (Elhassani 1983); judging from anecdotal evidence, many wildlife species may have been similarly afflicted. Organomercury compounds, especially methylmercury, were the most toxic mercury species tested. Among sensitive species of mammals, death occurred at daily organomercury concentrations of 0.1 to 0.5 mg/kg body weight, or 1.0 to 5.0 mg/kg in the diet (Table 9). Larger animals such as mule deer and harp seals appear to be more resistant to Hg than smaller mammals such as mink, cats, dogs, pigs, monkeys, and river otters; the reasons for this difference are unknown, but may be related to differences in metabolism and detoxication rates. Tissue residues in fatally poisoned mammals (in mg Hg/kg fresh weight) were 6.0 in brain, 10.0 to 55.6 in liver, 17.0 in whole body, about 30.0 in blood, and 37.7 in kidney (Table 9).

OTHER GROUPS

Methylmercury compounds at concentrations of 25.0 mg Hg/kg in soil were fatal to all tiger worms (*Eisenia foetida*) in 12 weeks; at 5.0 mg/kg, however, only 21% died in a similar period (Beyer et al. 1985). Inorganic mercury compounds were also toxic to earthworms (*Octochaetus pattoni*); in 60 days, 50% died at soil Hg levels of 0.79 mg/kg, and all died at 5.0 mg/kg (Abbasi and Soni 1983).

SUBLETHAL EFFECTS

GENERAL

Mercury is a known mutagen, teratogen, and carcinogen. At comparatively low concentrations in birds and mammals, it adversely affects reproduction, growth and development, behavior, blood and serum chemistry, motor coordination, vision, hearing, histology, and metabolism. It has a high potential for bioaccumulation and biomagnification, and is slow to depurate. Organomercury compounds were more effective in producing adverse effects than were inorganic Hg compounds; however, effects were significantly enhanced or ameliorated by numerous biotic and nonbiological modifiers. For sensitive aquatic species, adverse effects were observed at water concentrations of 0.03 to 0.1 ug Hg/l. For sensitive species of birds, harmful levels were 640 ug Hg/kg body weight daily, or 50 to 500 ug Hg/kg in the diet; for sensitive mammals, these levels were 250 ug Hg/kg body weight daily, or 1,100 ug Hg/kg diet.

AQUATIC ORGANISMS

Mercury at comparatively low concentrations adversely affects the reproduction, growth, behavior, metabolism, blood chemistry, osmoregulation, and oxygen exchange of marine and freshwater organisms. In general, the accumulation of mercury by aquatic biota is rapid, and depuration is slow. It is emphasized that organomercury compounds, especially methylmercury, were significantly more effective than inorganic mercury compounds in producing adverse effects and accumulations.

Reproduction was inhibited among sensitive species of aquatic organisms at water concentrations of 0.03 to 1.6 ug Hg/l. In the planarian (Best et al. 1981); in the slipper limpet (*Crepidula fornicata*), spawning was delayed and fecundity was decreased at 0.25 ug Hg^{2+}/l (Thain 1984); in the zebrafish (*Brachydanio rerio*), hatching success was reduced at 0.1 ug Hg^{2+}/l and egg deposition was reduced at 0.8 ug/l (Armstrong 1979); fathead minnows (*Pimephales promelas*) exposed to 0.12 ug methylmercury/l for 3 months failed to reproduce (Birge et al. 1979); the leopard frog (*Rana pipiens*) did not metamorphose during exposure to 1.0 ug methylmercury/l for 4 months (EPA 1980); and in the mysid shrimp (*Mysidopsis bahia*), the abortion rate increased and population size decreased after lifetime (i.e., 28 days) exposure to 1.6 ug/l of mercury as mercuric chloride (Gentile et al. 1983). For sensitive marine invertebrates such as hydroids, protozoans, and mysid shrimp, reproduction was inhibited at concentrations between 1.1 and 2.5 ug Hg^{2+}/l; this range was 5 to 71 ug/l for more resistant species of marine invertebrates (Gentile et al. 1983).

Reduced growth of sensitive species of aquatic organisms has been recorded at water concentrations of 0.04 to 1.0 ug Hg/l. The rainbow trout (*Salmo gairdneri*) was the most sensitive species tested; growth reduction was observed after 64 days in 0.04 ug Hg/l as methylmercury, or 0.11 ug Hg/l as phenylmercury (EPA 1980). In adults of the marine mollusc *Crepidula fornicata*, growth was reduced after 16 weeks in 0.25 ug Hg^{2+}/1 (Thain 1984). Growth inhibition was recorded in freshwater algae after exposure of 24 hours to 10 days to 0.3 to 0.6 ug organomercury/l, in brook trout (*Salvelinus fontinalis*) alevins after exposure for 21 days to 0.79 ug organomercury/l (EPA 1980), and in the marine alga *Scripsiella faeroense* exposed to 1.0 ug Hg^{2+}/l for 24 hours (Kayser 1976).

Adverse effects of mercury to aquatic organisms, in addition to those listed on reproduction and growth, have been documented at water concentrations of 0.88 to 5.0 ug/l: enzyme disruption in brook trout (*Salvelinus fontinalis*) embryos immersed for 17 days in solutions containing 0.88 ug/l, as methylmercury (EPA 1980); an increased incidence of frustule abnormalities and burst thecae in two species of marine algae during exposure to 1.0 ug Hg^{2+}/l for 24 hours (Kayser 1976; Saboski 1977); arrested development of sea urchin larvae at 3.0 ug Hg^{2+}/l for 40 hours (EPA 1980); decreased rate of intestinal transport of glucose, fructose, glycine, and

tryptophan in the murrel (*Channa punctatus*) at 3.0 ug Hg^{2+}/l for 30 days (Sastry et al. 1982); altered blood chemistry in striped bass (*Morone saxatilis*) at 5.0 ug Hg^{2+}/l in 60 days (Dawson 1982); and decreased respiration in striped bass 30 days postexposure after immersion for 30 to 120 days in 5.0 ug Hg^{2+}/l (Armstrong 1979; EPA 1980). In marine molluscs exposed to water concentrations of 6 to 10 ug Hg^{2+}/l for 96 hours, the feeding of adults ceased and the swimming rate of larval stages declined (Thain 1984). At 44 ug Hg^{2+}/l for 30 days, the freshwater fish *Notopterus notopterus* showed generalized metabolic derangement (Verma and Tonk 1983). In freshwater planarians exposed to 80 to 100 ug/l as methylmercury, behavior was modified and regeneration retarded (Best et al. 1981). And at high sublethal concentrations of methylmercury, rainbow trout were listless and darkly pigmented; appetite was reduced, and digestion was poor (Rodgers and Beamish 1982).

At lower trophic levels, the efficiency of mercury transfer was low through natural aquatic food chains; however, in animals of higher trophic levels, such as predatory teleosts and fish-eating birds and mammals, the transfer was markedly amplified (Eisler 1978, 1981).

High uptake and accumulation of mercury from the medium by representative species of marine and freshwater teleosts and invertebrates have been documented (Kopfler 1974; Eisler 1978, 1981; Birge et al. 1979; Huckabee et al. 1979; EPA 1980, EPA. 1985; Stokes et al. 1981; Rodgers and Beamish 1982; Hirota et al. 1983; Clarkson et al. 1984; McClurg 1984; Niimi and Lowe-Jinde 1984; Ramamoorthy and Blumhagen 1984; Ribeyre and Boudou 1984; Thain 1984). Accumulation patterns were enhanced or significantly modified by numerous biological and abiotic factors (NAS 1978; Eisler 1978, 1981, 1984, 1985; EPA 1980, 1985; Stokes et al. 1981;Rodgers and Beamish 1982; Clarkson et al. 1984; Ramamoorthy and Blumhagen 1984; Ribeyre and Boudou 1984). In general, the accumulation of mercury was markedly enhanced at elevated water temperatures, reduced water salinity or hardness, reduced water pH, increased age of the organism, and reduced organic matter content of the medium; in the presence of zinc, cadmium, or selenium in solution; after increased duration. of exposure; and in the presence of increased nominal concentrations of protein-bound mercury. Uptake patterns were significantly modified by sex, sexual condition, prior history of exposure to Hg salts, the presence of complexing and chelating agents in solution, dietary composition, feeding niche, tissue specificity, and metabolism; however, trends were not consistent between species and it is difficult to generalize. In one example, Ribeyre and Boudou (1984) immersed rainbow trout in solutions containing 0.1 ug Hg/l, as methylmercury: after 30 days, bioconcentration factors (BCF) ranged from 28,300 for brain to 238,000 for spleen; values were intermediate for muscle (30,000), whole fish (36,000), blood (102,000), liver (110,000), kidney (137,000), and gill (163,000). The values may have been higher if exposure had extended beyond 30 days; Rodgers and Beamish (1982) showed that whole body Hg residues in rainbow trout subjected to mercury insult continued to increase for the first 66 days before stabilizing. When mercury was presented as inorganic mercuric ion at 0.1 ug/l for 30 days, BCF values were usually lower than in trout exposed to methylmercury: 2,300 for muscle; 6,800 for brain; 7,000 for whole trout; 14,300 for blood; 25,000 for liver; 53,000 for kidney; 68,600 for gill; and 521,000 for spleen (Ribeyre and Boudou 1984). The high BCF values recorded for rainbow trout were probably due to efficient uptake from water, coupled with slow depuration (Rodgers and Beamish 1982). Whole body levels up to 100 mg Hg/kg were reportedly not lethal to rainbow trout, although 20 to 30 mg/kg were associated with reduced appetite, loss of equilibrium, and hyperplasia of gill epithelium (Niimi and Lowe-Jinde 1984). However, brook trout showed toxic signs and death at whole body residues of only 5 to 7 mg/kg (Armstrong 1979). In another example, the marine copepod *Acartia clausi*, subjected to 0.05 ug/l of mercury and higher, reached equilibrium with the medium in only 24 hours. In that study (Hirota et al. 1983), BCF values for whole *Acartia* after 24-hour exposures were 14,360 for inorganic mercuric ion (0.05 ug/l) and, for methylmercury, 179,200 (0.05 ug/l) and 181,000 (0.1 ug/l).

Elimination of accumulated mercury, both organic and inorganic, from aquatic organisms is a complex multicompartmental process, but appears to be largely dependent on its rate of biological assimilation. This rate, in turn, varies widely (20% to 90%) between species, for reasons as yet unexplained (NAS 1978). For example, mercury associated with dietary components that are not assimilated is eliminated rapidly with feces. The rest is absorbed across the gut and incorporated into tissues. This assimilated fraction of mercury is depurated much more slowly, at a rate positively correlated with the organism's metabolism (NAS 1978; Rodgers and Beamish 1982). Time to eliminate 50% of biologically assimilated mercury and its compounds (Tb 1/2) is variable. Among various species of freshwater teleosts, Tb 1/2 values (in days) were 20 for guppies

Poecilia reticulatus, 23 for goldfish *Carassius auratus*, 100 for northern pike, and 1,000 each for mosquitofish *Gambusia affinis*, brook trout, and rainbow trout (Huckabee et al. 1979). similar range in. Tb 1/2 values was recorded for invertebrates and marine fishes: 297 days for the crayfish *Astacus fluviatilis*, 435 days for mussel, 481 days for the clam *Tapes decussatus* 1,030 days for the eel *Anguilla vulgaris*, and 1,200 days for the flounder *Pleuronectes flesus* (NAS 1978).

Mercury-tolerant strains of bacteria (Colwell et al. 1976), protozoa (Berk et al. 1978), crustaceans (Green et al. 1976; Weis 1976), and fish (Weis 1984) have been reported. It has been suggested that the mercury-resistant strains of bacteria that have been cultured or discovered may have application in mobilization or fixation of mercury from contaminated aquatic environments to the extent that polluted areas may become innocuous (Colwell et al. 1976). The marine protozoan *Uronemia nigricans*, after feeding on Hg-laden bacteria, acquired mercury tolerance within a single generation (Berk et al. 1978). The white shrimp (*Penaeus setiferus*), preexposed for 57 days to 1 ug Hg/l, did not differ from controls during either exposure or subsequent Hg stress experiments (Green et al. 1976); this observation suggested that nonsensitization or adaptation mechanisms are involved. The fiddler crab (*Uca pugilator*) seemed unusually resistant and showed negligible uptake or effects during exposure to 100 ug Hg/l for 2 weeks (Weis 1976). Reasons to account for Hg adaptation of the estuarine cyprinodontiform teleost *Fundulus heteroclitus* to both methylmercury and inorganic mercury are under investigation (Weis 1984).

BIRDS

Sublethal effects of mercury on birds, administered by a variety of routes, included adverse effects on growth, development, reproduction, blood and tissue chemistry, metabolism, and behavior; histopathology and bioaccumulation were also noted.

The dietary route of administration is the most extensively studied pathway of avian Hg intake. Domestic chickens fed diets containing as little as 50 ug/kg of mercury, as methylmercury, contained elevated total Hg (2.0 mg/kg fresh weight) residues in liver and kidney after 28 weeks; at 150 ug/kg, residues ranged from 1.3 to 3.7 mg/kg in heart, muscle, brain, kidney, and liver, in that general order; at 450 ug/kg in diets, residues in edible chicken tissues (3.3 to 8.2 mg/kg) were considered hazardous to human consumers, although no overt signs of mercury toxicosis were observed in the chickens (March et al. 1983). High inorganic mercury levels (500 mg/l) in drinking water of chickens decreased growth rate and food and water consumption, and elevated hemoglobin, hematocrit, and erythrocyte content within 3 days (Grissom and Thaxton 1985). The dietary concentration of 0.5 mg Hg/kg dry weight (equivalent to about 0.1 mg/kg fresh weight) in the form of methylmercury was fed to three generations of mallards (Heinz 1979). Females laid a greater percentage of their eggs outside nest boxes than did controls, and also laid fewer eggs and produced fewer ducklings. Ducklings from parents fed methylmercury were less responsive than controls to tape-recorded maternal calls, but were hyperresponsive to a fright stimulus in avoidance tests. The tissues and eggs of ducks and other species of birds collected in the wild have sometimes contained levels of mercury equal to, or far exceeding, those associated with reproductive and behavioral deficiencies in domestic mallards (e.g., 9 to 11 mg/kg in feathers; >2.0 mg/kg in other tissues); therefore, it is possible that reproduction and behavior of wild birds have been modified by methylmercury contamination (Heinz 1979). Tissue mercury residues of wild-strain mallards and game-farm mallards were not significantly different after the birds were fed diets containing 0.5 mg Hg/kg as methylmercury for extended periods--indicating that game-farm mallards are suitable substitutes for wild mallards in toxicological evaluations (Heinz 1980). Dietary concentrations of 1.1 mg total Hg/kg have been associated with kidney lesions in juvenile starlings (*Sturnus vulgaris*) and with elevated residues in the liver (6.5 mg/kg dry weight and kidney (36.3 mg/kg), after exposure for 8 >weeks (Nicholson and Osborn 1984). In American black ducks (*Anas rubripes*) fed diets containing 3.0 mg Hg/kg as methylmercury for 28 weeks, reproduction was significantly inhibited; tissue residues were elevated in kidney (16.0 mg/kg fresh weight) and liver (23.0 mg/kg); and brain lesions characteristic of mercury poisoning were present (Finley and Stendell 1978). Japanese quail (*Coturnix japonica*) fed diets containing 8 mg Hg/kg of inorganic mercury for 3 weeks had depressed gonad weights; those fed 3 mg/kg inorganic mercury or 1 mg/kg methylmercury for 9 weeks showed alterations in brain and plasma enzyme activities (Hill and Soares 1984). Grossly elevated tissue residues of 400 mg/kg in feathers and 17 to 130 mg/kg in other tissues were measured in gray partridge (*Perdix perdix*) after dietary exposure of 20 to 25 mg total Hg/kg for 4 weeks (McEwen et al. 1973).

Mercury exposure by immersion and oral administration have caused reproductive and behavorial modifications. Brief immersion of mallard eggs in solutions of methylmercury resulted in a significant incidence of skeletal embryonic aberrations at dosages of 1.0 ug Hg/egg, and higher; no increases in embryonic malformations were noted at 0.3 ug Hg/egg (Hoffman and Moore 1979). Reduced reproductive ability was noted in grey pheasants ingesting 640 ug Hg (as organomercury)/kg body weight daily for 30 days (McEwen et al. 1973); similar results were observed in ring-necked pheasants (Spann et al. 1972; Mullins et al. 1977). Behavioral alterations were noted in pigeons (*Columba livia*) given 3,000 ug inorganic Hg/kg body daily for 17 days (Leander et al. 1977) or 1,000 ug/kg body weight of methylmercury for 5 weeks (Evans et al. 1982). Observed behavioral changes in posture and motor coordination of pigeons were permanent after the brain accumulated >12,000 ug Hg/kg fresh weight, and were similar to the "spastic paralysis" observed in wild crows during the Minamata, Japan, outbreak of the 1950's, although both species survived for years with these signs (Evans et al. 1982).

Mercury residues of 790 to 2,000 ug/kg in egg, and 5,000 to 40,000 ug/kg in feathers, are linked to impaired reproduction in various bird species (Spann et al. 1972; NAS 1978; Heinz 1979; Fimreite 1979; Solonen and Lodenius 1984). Residues in eggs of 1,300 to 2,000 ug Hg/kg fresh weight were associated with reduced hatching success in white-tailed sea-eagles (*Haliaeetus albicilla*), the common loon (*Gavia immer*), and in several seed-eating species (Fimreite 1979); this range was 900 to 3,100 ug/kg for ring-necked pheasant (Spann et al. 1972), and 790 to 860 ug/kg for mallards (Heinz 1979). Residues of 5,000 to 11,000 ug Hg/kg in feathers of various species of birds have been associated with reduced hatch of eggs and with sterility (NAS 1978). Sterility was observed in the Finnish sparrow hawk (*Accipiter nisus*) at mercury concentrations of 40,000 ug/kg in feathers (Solonen and Lodenius 1984). Chicks of the common tern (*Sterna hirundo*) from a colony in Long Island, New York, with abnormal feather loss, had significantly elevated mercury levels in blood and liver (Gochfeld 1980); however, the linkage of feather loss to mercury contamination requires further examination.

Interaction effects of mercury with other contaminants, such as herbicides and pesticides, could intensify hazards to avian populations (Mullins et al. 1977). For example, a striking parallel exists between levels of Hg and of DDT and its metabolites in birds of prey, suggesting the existence of common ecotoxicological mechanisms (Delbeke et al. 1984; Wiemeyer et al. 1984); additional research is clearly needed.

MAMMALS

Mercury has no known physiological function (EPA 1985). In humans and other mammals, it causes teratogenic, mutagenic, and carcinogenic effects; the fetus is the most sensitive life stage (NAS 1978; Chang 1979; Khera 1979; EPA 1980, 1985; Elhassani 1983; Greener and Kochen 1983; Clarkson et al. 1984). Methylmercury irreversibly destroys the neurons of the central nervous system. Frequently, a substantial latent period intervenes between the cessation of exposure to Hg and the onset of signs and symptoms; this interval is usually measured in weeks or months, but sometimes in years (Clarkson et al. 1984). At high sublethal doses in man, mercury causes cerebral palsy, gross motor and mental impairment, speech disturbances, blindness, deafness, microcephaly, intestinal disturbances, tremors, and tissue pathology (Chang 1979; EPA 1980, 1985; Elhassani 1983; Clarkson et al. 1984). Pathological and other effects of Hg may vary from organ to organ, depending on factors such as the effective toxic dose in the organ, the compound involved and its metabolism within the organ, the duration of exposure, and the other contaminants to which the animal is concurrently exposed (Chang 1979). Many compounds--especially salts of selenium--protect humans and other animals against mercury toxicity, although their mode of action is not clear (NAS 1978; Chang 1979; EPA 1980, 1985; Eisler 1985).

Adverse effects of organomercury compounds to selected species of mammals have been recorded at administered doses of 0.25 mg Hg/kg body weight daily, dietary levels of 1.1 mg/kg, and blood Hg levels of 1.2 mg/l (Table 10).

Mercury transfer and biomagnification through mammalian food chains is well documented (Galster 1976; NAS 1978; Eaton et al. 1980; Eisler 1981; Huckabee et al. 1981; Sheffy and St. Amant 1982; Kucera 1983; Clarkson et al. 1984; Wren 1986), but considerable variation exists. Among terrestrial mammals, for example, herbivores such as mule deer, moose (*Alces alces*), caribou (*Rangifer tarandus*), and various species of rabbits usually contained less than 1.0 mg Hg/kg fresh weight in liver and kidney, but carnivores such as the marten (*Martes martes*), polecat (*Mustela putorius*), and red fox (*Vulpes vulpes*) frequently contained more than 30 mg/kg NAS 1978). The usually higher mercury concentrations in fish-eating furbearers than in herbivorous

species seemed to reflect the amounts of fish and other aquatic organisms in the diet. In river otter and mink from the Wisconsin River drainage system, Hg levels paralleled those recorded in fish, crayfish, and bottom sediments at that location. Highest Hg levels in all samples were recorded about 30 km downstream from an area that supported 16 pulp and paper mills and a chloralkali plant; residues were highest in the fur, followed by the liver, kidney, muscle, and brain (Sheffy and St. Amant 1982).

In marine mammals, more than 90 % of the mercury content is inorganic; however, enough methylmercury occurs in selected tissues to result in the accumulation of high tissue concentrations of methylmercury in humans and wildlife consuming such meat (Clarkson et al. 1984). The liver of the ringed seal (*Phoca hispida*) normally contains 27,000 to 187,000 ug Hg/kg fresh weight, and is a traditional and common food of the coastal Inuit people (Eaton et al. 1980). Although levels of Hg in hair (109,000 ug/kg) and blood (37 ug/l) of Inuits were grossly elevated, no symptoms of Hg poisoning were evident in the coastal Inuits. Similar high concentrations have been reported for Alaskan Eskimo mothers who, during pregnancy, ate seal oil twice a day, and seal- meat or fish from the Yukon-Kuskokwim Coast every day (Galster 1976). Despite the extremely high total Hg content of seal liver, only the small organomercury component was absorbed and appeared in the tissues. Cats fed a diet of seal liver (26,000 ug Hg/kg fresh weight) for 90 days showed no neurologic or histopathologic signs (Eaton et al. 1980). It seems that the toxic potential of seal liver in terms of accumulated tissue levels in cats (up to 862 ug total Hg/l blood, and 7,600 ug total Hg/kg hair) is better indicated by the organomercury fraction in seal liver than by the concentration of total Hg (Eaton et al. 1980).

Table 10. Sublethal effects of organomercury compounds administered to selected species of mammals.

Organism	Dose, and other variables	Effect	Reference
Rhesus monkey, *Macaca mulatta*	16 µg/kg body weight daily on days 20 to 30 of pregnancy	No measurable eff ect on reproduction	Khera 1979
Human, adult	50 µg/day	Risk of paresthesia, 0.3% (burning-prickling sensation of skin)	Clarkson et al. 1984
Human, adult	200 µg/day	Risk of paresthesia, 8%	Clarkson et al. 1984
Cat, *Felis domesticus*	250 µg/kg body weight daily on days 10 to 58 of gestation; oral route	Increased incidence of anomalous fetuses	Khera 1979
Harp seal, *Pagophilus groenlandicus*	250 µg/kg body weight daily for 90 days; dietary route	Residues of 47,200 to 82,500 µg/kg fresh weight in liver, kidney, and muscle; histopathology	Ronald et al. 1977; Ramprashad and Ronald 1977

		of middle ear	
Rat, *Rattus* sp.	500 µg/kg body weight daily; oral route	Reduced fertility	Khera 1979
Human, adult	1,000 µg/day	Risk of paresthesia, 50%	Clarkson et al. 1984
Mink, *Mustela vison*	1,100 µg/kg in diet	Residues of 7,100 to 9,300 µg/kg in brain; signs of poisoning	Kucera 1983
Rat	2,000 µg/kg in diet (as Pacific blue marlin); gestation through post-natal day 16	Adverse behavioral changes in offspring	Suzuki 1979
Rat	13,300 to 50,000 µg/kg body weight daily for 5 days; subcutaneous injection	Impaired cutaneous sensitivity and hearing up to one year post-treatment	Wu et al. 1985
Monkeys, *Macaca* spp.	Various	Visual disturbances at blood Hg levels of 1,200 to 4,000 µg/L or brain Hg levels of 6,000 to 9,000 µg/kg; tremors at blood Hg levels of 2,000 to 10,000 µg/L; kidney pathology at brain Hg levels of 1,500 µg/kg	Suzuki 1979
Human, adult	Various	Symptoms of poisoning evident at residues of 1,200 µg Hg/L blood, 2,000 to 3,000 µg/kg whole body, or 3,400 µg/kg hair	Suzuki 1979

Mice, *Mus* spp.	Various	Residues of 2,000 to 5,000 µg/kg hair or >10,000 µg/kg brain associated with motor incoordination and decreased swimming ability; no observable effect at <2,000 µg/kg hair	Suzuki 1979
Human, infant	Various	Severe effects at blood Hg levels of 3,000 µg/L	Elhassani 1983

Retention of mercury by mammalian tissues is longer for organomercury compounds (especially methylmercury) than for inorganic mercury compounds (NAS 1978; Clarkson and Marsh 1982; Elhassani 1983; Clarkson et al. 1984). Excretion of all Hg species follows a complex, variable, multicompartmental pattern; the longer-lived chemical Hg species have a biological half-life that ranges from about 1.7 days in human lung to 1.36 years in whole body of various pinnipeds.

OTHER GROUPS

Methylmercury compounds have induced abnormal sex chromosomes in the fruit fly (*Drosophila melanogaster*) (NAS 1978; Khera 1979). Earthworms (*Eisenia foetida*) exposed to soil containing methylmercury concentrations of 5.0 mg Hg/kg--typical of soil Hg levels near chloralkali plants--showed a significant reduction in the number of segments regenerated after 12 weeks, and contained 85 mg Hg/kg on a whole body fresh weight basis. Regeneration was normal at soil Hg levels of 1.0 mg/kg, although body burdens up to 27 mg/kg were recorded. It was concluded that soil contaminated with methylmercury posed a greater hazard to the predators of earthworms than to the earthworms (Beyer et al. 1985). Studies with a different species of earthworm (*Octochaetus pattoni*) and mercuric chloride, demonstrated a progressive initial increase in reproduction as soil mercury levels increased from 0.0 to the 60-day lethal level of 5.0 mg/kg (Abbasi and Soni 1983).

CURRENT RECOMMENDATIONS

Proposed mercury criteria for the protection of sensitive aquatic organisms, birds, and mammals, as well as human health, are shown in Table 11. In almost every instance, these criteria are listed as concentrations of total Hg, with most, if not all, the Hg present as an organomercury species.

In 1980, the U.S. Environmental Protection Agency's proposed mercury criteria for freshwater aquatic life protection were 0.00057 ug/l (24-hour average), not to exceed 0.0017 ug/l at any time; these criteria seemed to afford a high degree of protection to freshwater biota, as judged by survival, bioconcentration, and biomagnification. Literature documented in this paper showed that mercury concentrations in water of 0.1 to 2.0 ug/l were fatal to sensitive aquatic species and that concentrations of 0.03 to 0.1 ug/l were associated with significant sublethal effects. The 1980 proposed freshwater criteria provided safety factors for acute toxicities of 175X to 3,508X based on the 24-hour average, and 58X to 1,176X based on the maximum permissible concentration (Table 11). For protection against sublethal effects, these values were 53X to 175X based on the 24-hour mean, and 18X to 59X based on the maximum permissible concentration (Table 11). However, the most current freshwater criteria of 0.012 ug/l, not to exceed 2.4 ug/l (Table 11; EPA 1985), dramatically reduces the level of protection afforded aquatic biota: safety factors for acute toxicities are now 8X to 167X based on the 96-hour average, and only 0.04X to 0.8X based on the maximum permissible concentration. For protection against sublethal effects, these values were 2X to 8X based on the 4-day average, and only 0.01X to 0.04X based on the maximum permissible concentration, or essentially no significant protection.

The proposed saltwater criteria of EPA (1980) for mercury and marine life were unsatisfactory. Proposed saltwater values of 0.025 ug/l (24-hour average), not to exceed 3.7 ug/l at any time (Table 11), provided safety factors of 4X to 80X against acute toxicity (based on 24-hour average), but less than 0.5X based on the maximum permissible level. For protection against sublethal damage effects, the safety factors computed were 1.2X to 4X (based on 24-hour average) and less than 0.03X (based on maximum allowable concentration). The most recent saltwater criteria of 0.025 ug/l, not to exceed 2.1 ug/l (Table 11; EPA 1985), does not appear to offer a substantive increase in protection to marine life, when compared to criteria proposed 5 years earlier (EPA 1980). It seems that some downward modification is needed in the proposed Hg saltwater criteria if marine and estuarine biota are to be provided even minimal protection.

Table 11. Proposed mercury criteria for protection of various resources and human health.

Resource and criterion (units in parentheses)	Mercury concentration	Reference
Aquatic life		
Freshwater (µg/L)	Total recoverable Hg <0.00057 (24 h average), not to exceed 0.0017 at any time	EPA 1980
	<0.012, 4-day average (not to be exceeded more than once every 3 years; <2.4, one-hour average (not to be exceeded more than once every 3 years)[a]	EPA 1985
Saltwater (µg/L)	Total recoverable Hg <0.025 (24 h average), not to exceed 3.7 at any time	EPA 1980

[a]All mercury that passes through a 0.45-mm membrane filter after the sample is acidified to pH 1.5 to 2.0 with nitric acid.

The significance of elevated Hg residues in tissues of aquatic organisms is not fully understood. Concentrations >1,000 ug Hg/kg fresh weight can occur in various tissues of selected species of fish and aquatic mammals eaten by humans. But it would be incorrect to assume that aquatic food chains--especially marine food chains--incorporate Hg exclusively from anthropogenic activities (Barber et al. 1984). Some organisms, however, do contain Hg tissue residues associated with known adverse effects to the organism and its predators. Thus, whole body residues of 5,000 to 7,000 ug Hg/kg fresh weight in brook trout eventually proved fatal to that species (EPA 1980). To protect sensitive species of mammals and birds that regularly consume fish and other aquatic organisms, total mercury concentrations in these food items should probably not exceed 100 ug/kg for avian protection, or 1,100 ug/kg for small mammals (Table 11). By comparison, proposed Hg levels in fish and seafood, in ug/kg fresh weight, for human health protection should not exceed 250 for expectant mothers, and 400 to 1,000 for adults worldwide (Table 11).

Since long-lived, slow-growing, high-trophic-positon aquatic organisms usually contain the highest tissue mercury residues, some fisheries managers have proposed a legal maximum limit based on fish length or body weight, or alternatively, constraining the mean Hg concentration of the entire catch to a nominated level. In the Australian shark fishery, for example, implementation of a maximum length restriction (to a nominated level of 500 ug Hg/kg), would result in retention of less than half of the present catch of seven species (Lyle 1984).

Among sensitive avian species, adverse effects--predominantly on reproduction--have been reported at mercury concentrations (in ug/kg fresh weight) of 5,000 in feather, 900 in egg, 50 to 100 in diet, and daily administered doses of 640 on a body weight basis (Table 11). Although low Hg concentrations--e.g., 50 ug/kg in the diets of domestic chickens--sometimes produced no adverse effects on chickens, the tissue residues of Hg were sufficiently elevated to pose a hazard to human consumers (March et al. 1983). In contrast, in eggs of the American bald eagle (with 150 ug Hg/kg and low hatch), other contaminants present--especially organochlorine compounds--probably had a greater effect on hatchability than did Hg (Wiemeyer et al. 1984).

Mammals, such as the domestic cat and the harp seal, showed birth defects, histopathology, and elevated tissue residues at doses of 250 ug Hg/kg body weight daily (Table 11). The mink, at dietary levels of 1,100 ug Hg/kg, had signs of mercury poisoning; Hg residues in mink brain at this dietary level ranged from 7,100 to 9,300 ug/kg (Kucera 1983). Tissue residues in kidney, blood, brain, and hair in excess of 1,100 ug Hg/kg in other nonhuman mammals are usually considered presumptive evidence of significant Hg contamination (Table 11).

At this point, it seems that four courses of action are warranted. First, toxic mercurials in agriculture and industry should be replaced by less toxic substitutes. Second, controls should be applied at the point of origin to prevent the discharge of potentially harmful Hg wastes. Third, continued periodic monitoring of fishery and wildlife resources is important, especially in areas with potential for reservoir development, in light of the hypothesis that increased flooding increases the availability of Hg to biota. And finally, additional research is needed on mercury accumulation and detoxication in comparatively pristine ecosystems.

POLYCYCLIC AROMATIC HYDROCARBON HAZARDS TO FISH, WILDLIFE, AND INVERTEBRATES: A SYNOPTIC REVIEW

By

Ronald Eisler

U.S. Fish and Wildlife Service
Patuxent Wildlife Research Center
Laurel, MD 20708

SUMMARY

This account synthesizes available technical literature on ecological and toxicological aspects of polycyclic aromatic hydrocarbons (PAHs) in the environment, with special reference to natural resources. Subtopics include: chemical properties, sources, and fate; background concentrations in biological and nonbiological samples; toxic and sublethal effects to flora and fauna; and proposed criteria and research needs for the protection of sensitive species.

PAHs consist of hydrogen and carbon arranged in the form of two or more fused benzene rings. There are thousands of PAH compounds, each differing in the number and position of aromatic rings, and in the position of substituents on the basic ring system. Environmental concern has focused on PAHs that range in molecular weight from 128.16 (naphthalene, 2-ring structure) to 300.36 (coronene, 7-ring structure). Unsubstituted lower molecular weight PAH compounds, containing 2 or 3 rings, exhibit significant acute toxicity and other adverse effects to some organisms, but are noncarcinogenic; the higher molecular weight PAHs, containing 4 to 7 rings, are significantly less toxic, but many of the 4- to 7-ring compounds are demonstrably carcinogenic, mutagenic, or teratogenic to a wide variety of organisms, including fish and other aquatic life, amphibians, birds, and mammals. In general, PAHs show little tendency to biomagnify in food chains, despite their high lipid solubility, probably because most PAHs are rapidly metabolized. Inter- and intraspecies responses to individual PAHs are quite variable, and are significantly modified by many inorganic and organic compounds, including other PAHs. Until these interaction effects are clarified, the results of single substance laboratory tests may be extremely difficult to apply to field situations of suspected PAH contamination.

PAHs are ubiquitous in nature--as evidenced by their detection in sediments, soils, air, surface waters, and plant and animal tissues--primarily as a result of natural processes such as forest fires, microbial synthesis, and volcanic activities. Anthropogenic activities associated with significant production of PAHs--leading, in some cases, to localized areas of high contamination--include high-temperature (>700 °C) pyrolysis of organic materials typical of some processes used in the iron and steel industry, heating and power generation, and petroleum refining. Aquatic environments may receive PAHs from accidental releases of petroleum and its products, from sewage effluents, and from other sources. Sediments heavily contaminated with industrial PAH wastes have directly caused elevated PAH body burdens and increased frequency of liver neoplasia in fishes.

At present, no criteria or standards have been promulgated for PAHs by any regulatory agency for the protection of sensitive species of aquatic organisms or wildlife. This observation was not unexpected in view of the paucity of data on PAH background concentrations in wildlife and other natural resources, the absence of information on results of chronic oral feeding studies of PAH mixtures, the lack of a representative PAH mixture for test purposes, and the demonstrable--and, as yet, poorly understood--effects of biological and nonbiological modifiers on PAH toxicity and metabolism. By contrast, criteria for human health protection and total PAHs, carcinogenic PAHs, and benzo(a)pyrene have been proposed for drinking water and air, and for total PAHs and benzo(a)pyrene in food: drinking water, 0.01 to <0.2 ug total PAHs/l, <0.002 ug carcinogenic PAHs/l, and <0.0006 ug benzo(a)pyrene/l; air, <0.01 ug total PAHs/m^3, <0.002 ug carcinogenic PAHs/m^3, and <0.0005 ug benzo(a)pyrene/m^3; food, 1.6 to <16.0 ug total PAHs daily, and 0.16 to <1.6 ug benzo(a)pyrene daily. In view of the carcinogenic characteristics of many PAH compounds and their increasing concentrations in the environment, it now seems prudent to reduce or eliminate them wherever possible, pending acquisition of more definitive ecotoxicological data.

Hoffman, and Paul C. Baumann for constructively reviewing the manuscript; and Curtis H. Halvorson and James R. Zuboy for editorial services.

INTRODUCTION

Several polycyclic aromatic hydrocarbons (PAHs) are among the most potent carcinogens known to exist, producing tumors in some organisms through single exposures to microgram quantities. PAHs act at both the site of application and at organs distant to the site of absorption; their effects have been demonstrated in nearly every tissue and species tested, regardless of the route of administration (Lee and Grant 1981). The evidence implicating PAHs as an inducer of cancerous and precancerous lesions is becoming overwhelming, and this class of substances is probably a major contributor to the recent increase in cancer rates reported for industrialized nations (Cooke and Dennis 1984). PAHs were the first compounds known to be associated with carcinogenesis (Lee and Grant 1981). Occupational skin cancer was first documented in London chimney sweeps in 1775 and in German coal tar workers in the late 1800's. By the early 1900's,, soot, coal tar, and pitch were all found to be carcinogenic to humans. By 1918, it was shown that topical applications of coal tar produced skin tumors in mice and rabbits; benzo(a)pyrene, a PAH, was identified as one of the most carcinogenic compounds in coal tar (Dipple 1985). The carcinogenic activity to man of soots, tars, and oils is beyond dispute. In addition to the skin cancers noted initially, higher incidences of respiratory tract and upper gastrointestinal tract tumors were associated with occupational exposures to these carcinogens (Dipple 1985). PAH-induced cancers in laboratory animals is well documented. Benzo(a)pyrene, for example, has produced tumors in mice, rats, hamsters, guinea pigs, rabbits, ducks, and monkeys following administration by oral, dermal, and intraperitoneal routes (Pucknat 1981). Teratogenic or carcinogenic responses have been induced in sponges, planarians, echinoderm larvae, teleosts, amphibians, and plants by exposure to carcinogenic PAHs (Neff 1979, 1982b). An unusually high prevalence of oral, dermal, and hepatic neoplasms have been observed in bottom-dwelling fish from polluted sediments containing grossly-elevated PAH levels (Couch and Harshbarger 1985). PAH compounds have damaged chromosomes in cytogenetic tests, have produced mutations in mammalian cell culture systems, and have induced DNA repair synthesis in human fibroblast cultures (EPA 1980). While some PAHs are potent mutagens and carcinogens, others are less active or suspected carcinogens. Some, especially those of biological origin, are probably not carcinogens (Jackim and Lake 1978). Certain lower molecular weight, noncarcinogenic PAHs, at environmentally realistic levels, were acutely toxic to aquatic organisms, or produced deleterious sublethal responses (Neff 1985). However, few generalizations can be made about the class of PAH compounds because of the extreme variability in toxicity and physicochemical properties of PAHs and their various effects on individual species (Lee and Grant 1981).

PAHs are widely-distributed in the environment, almost ubiquitous, and have been detected in animal and plant tissues, sediments, soils, air, surface water, drinking water, industrial effluents, ambient river water, well water, and groundwater (EPA 1980). Man probably has always been exposed to PAHs from the natural background level in soils and plants (Harrison et al. 1975); avoiding exposure to nanogram quantities of these substances on a daily basis is now considered essentially impossible for all living resources (Dipple 1985). Ever since benzo(a)pyrene was recognized as a carcinogen at the beginning of this century, the presence of it and of other PAHs in the environment has received continuous attention. As one consequence, many reviews have been published on ecological and toxicological aspects of PAHs in the environment, with special reference to their carcinogenic properties. (Harrison et al. 1975; Barnett 1976; Suess 1976; Gelboin and Ts'o 1978a, 1978b, 1981; Jackim and Lake 1978; Jones and Freudenthal 1978; Lo and Sandi 1978; Jones and Leber 1979; Neff 1979, 1982a,1982b, 1985; Tsang and Griffin 1979; Bjorseth and Dennis 1980; EPA 1980; Cooke and Dennis 1981, 1983, 1984; Futoma et al. 1981; Lee and Grant 1981; Pucknat 1981; Sims and Grover 1981; Stegeman 1981; Cooke et al. 1982; Richards and Jackson 1982; Couch et al. 1983; Edwards 1983; Grimmer 1983; Quaghebeur et al. 1983; Sims and Overcash 1983; Couch and Harshbarger 1985; Harvey 1985; Johnson et al. 1985; Sugimura 1986.)

In this report, I summarize selected data on environmental aspects of PAHs, emphasizing PAH effects to aquatic and wildlife resources. This brief review is part of a continuing series prepared in response to informational requests from environmental specialists of the U. S. Fish and Wildlife Service.

ENVIRONMENTAL CHEMISTRY, SOURCES, AND FATE

PROPERTIES

Polycyclic aromatic hydrocarbons (PAHs), also known as polynuclear aromatic hydrocarbons (PNAs) and polycyclic organic matter (POM), are composed of hydrogen and carbon arranged in the form of two or more fused benzene rings in linear, angular, or cluster arrangements, which may or may not have substituted groups attached to one or more rings (Sims and Overcash 1983). In some cases, the newly defined substituted PAH has strikingly greater toxicological effects than does the parent compound (Cooke and Dennis 1984). The nomenclature of PAH compounds has been ambiguous in the past due to different peripheral numbering systems. The currently accepted nomenclature is shown in Figure 1.

Of major environmental concern are mobile PAHs that vary in molecular weight from 128.16 (naphthalene, $C_{10}H_8$) to 300.36 (coronene, $C_{24}H_{12}$). Higher molecular weight PAHs are relatively immobile because of their large molecular volumes and their extremely low volatility and solubility. Among the mobile forms are thousands of compounds that differ in the number and position of aromatic rings, and in the position of substituents on the basic ring system. The lower molecular weight unsubstituted PAH compounds, containing 2 to 3 rings, such as naphthalenes, fluorenes, phenanthrenes, and anthracenes (Figure 2), have significant acute toxicity to some organisms, whereas the higher molecular weight 4- to 7-ring aromatics do not. However, all known PAH carcinogens, cocarcinogens, and tumor producers are in the high molecular weight PAH group (Figure 3).

Physical and chemical characteristics of PAHs generally vary with molecular weight. With increasing molecular weight, aqueous solubility decreases, and melting point, boiling point, and the log Kow (octanol/water partition coefficient) increases (Table 1), suggesting increased solubility in fats, a decrease in resistance to oxidation and reduction, and a decrease in vapor pressure. Accordingly, PAHs of different molecular weight vary substantially in their behavior and distribution in the environment and in their biological effects. Additional and more comprehensive data on the physical and chemical properties of PAHs are given in Barnett (1976), Lo and Sandi (1978), Neff (1979, 1985), EPA (1980), Futoma et al. (1981), Lee and Grant (1981), Pucknat (1981), Edwards (1983), Grimmer (1983), Sims and Overcash (1983), and Whitehouse (1985).

Table 1. Some physical and chemical properties of selected PAHs.

Compound	Number of rings	Approximate molecular weight	Melting point (C)	Solubility in water (mg/l)	log Kow
Naphthalene	2	128	80	30.0	3.37
Anthracene	3	178	216	0.07	4.45
Benz(a)anthracene	4	228	158	0.014	5.61
Benzo(a)pyrene	5	252	179	0.0038	6.04
Benzo(g,h,i)perylene	6	276	222	0.00026	7.23

SOURCES

About 43,000 metric tons of PAHs are discharged into the atmosphere each year, and another 230,000 tons enter aquatic environments (Table 2). PAHs are ubiquitous in nature as a consequence of synthesis in terrestrial vegetation, microbial synthesis, and volcanic activity, but quantities formed by these natural processes are small in comparison with those produced from forest and prairie fires and anthropogenic sources (Barnett 1976; Suess 1976; Lo and Sandi 1978; Neff 1979, 1985; EPA 1980; Lee and Grant 1981; Pucknat 1981; Edwards 1983; Grimmer 1983; Sims and Overcash 1983). Anthropogenic activities associated with significant production of PAHs include: coke production in the iron and steel industry; catalytic cracking in the petroleum industry; the manufacture of carbon black, coil tar pitch, and asphalt; heating and power generation; controlled refuse incineration; open burning; and emissions from internal combustion engines used in transportation. Thus, the formation of PAHs in the environment is due to an endogenous synthesis by microorganisms, algae, and macrophytes which provide natural background, and to a second process which is connected to man-controlled high-temperature (>700 C) pyrolysis of organic materials, to open burning, and to natural volcanic activities. The discovery in fossil fuels of complex mixtures of PAHs spanning a wide range of molecular

weights has led to the conclusion that, given sufficient time (i.e., millions of years), pyrolysis of organic materials at temperatures as low as 100 to 150 °C can also lead to production of PAHs (Neff 1985).

Forest and prairie fires release much greater amounts of PAHs to the atmosphere than does fossil fuel burning. Nearly all of the airborne PAHs produced by flame pyrolysis are associated with the particulate fraction produced during combustion, and these are significantly modified by the chemical composition of the fuel, the pyrolysis temperature, the duration of exposure to elevated temperature;, and to other factors (Neff 1979; Edwards 1983). In one study, a PAH profile was established for a series of laboratory fires simulating the prescribed burning of pine needle litter (McMahon and Tsoukalas 1978). Heading fires (moving with wind) produced more total particulate matter than backing fires (moving against wind), but backing fires produced significantly higher amounts of PAHs, with the actual amounts formed dependent on fuel loading and the residence time of combustible gases in the burning zone. Emission factors for benzo(a)pyrene varied from 238 to 3,454 ug/kg in backing fires and 38 to 97 ug/kg in heading fires.

Table 2. Major sources of PAHs in atmospheric and aquatic environments (modified from Lo and Sandi 1978; Neff 1979; Edwards 1983; Sims and Overcash 1983).

Ecosystem and sources	Annual input, in metric tons
Atmosphere

Surface land runoff	2,940
Biosynthesis	2,700
Total benzo (a) pyrene	700

PAHs present in the atmosphere enter rain as a result of in-cloud and below-cloud scavenging (van Noort and Wondergem 1985). Total PAHs deposited on land and water are almost equivalent to PAH content in rainfall; significant quantities of PAHs are found in presumed pollution-free areas, indicating the importance of rain in transport and distribution of PAHs (Quaghebeur et al. 1983).

PAHs may reach aquatic environments in domestic and industrial sewage effluents, in surface runoff from land, from deposition of airborne particulates, and especially from spillage of petroleum and petroleum products into water bodies (Jackim and Lake 1978; Lake et al. 1979; Neff 1979; EPA 1980; Martens 1982; Boehm and Farrington 1984; Hoffman et al. 1984; Prahl et al. 1984). The majority of PAHs entering aquatic environments remains close to sites of deposition, suggesting that lakes, rivers, estuaries, and coastal marine environments near centers of human populations are the primary repositories of aquatic PAHs (Neff 1979). Large variations in aquatic PAH contents were evident due to localized source inputs and physicochemical conditions. For example, urban runoff from stormwater and highways to Narragansett Bay, Rhode Island, accounted for 71% of the total inputs for higher molecular weight PAHs, and 36% of the total PAHs (Hoffman et al. 1984). More than 30% of all combustion-derived PAHs in coastal sediments of Washington State is supplied by riverine transport of suspended particulate materials, while direct atmospheric input accounts for a maximum of 10% (Prahl et al. 1984). In contrast, concentrations of PAHs in sediments from the vicinity of Georges Bank, off the US northeastern coast, varied from 1 to 100 ug/kg dry weight, and were directly related to total organic carbon, silt, and clay contents in sediments; combustion-derived PAHs dominated at the higher concentrations, while lower level were often associated with a fossil fuel origin (Boehm and Farrington 1984).

Discharge water from hydrostatic testing of natural gas pipelines is a significant source of PAH loading into aquatic environments, contributing as much as 32,000 ug PAHs/1 of discharge water, mostly as naphthalenes (Eiceman et al. 1984). More than 25 PAHs, primarily anthracenes and pyrenes, were detected in pipeline residues on inner walls of natural gas pipelines at concentrations up to 2,400 ug/m^2 of inner surface; the same compounds may be reasonably expected in aqueous waste from pipeline maintenance (Eiceman et al. 1985). Release of these, or similar, discharge waters directly into aquatic environments will result in contamination similar to that caused by oil spills; however, these sites for pollution may occur in locations far distant from oil production and refinery activities (Eiceman et al. 1984). PAHs are also present in tap water at concentrations of 0.1 to 1.0 ng/l, primarily as mono- and dichlorinated derivatives of naphthalene, phenanthrene, fluorene, and fluoranthene (Shiraishi et al. 1985). The presence of PAHs and chlorinated PAHs in tap water indicates the reaction of PAHs with chlorine; however, their significance to human health and to aquatic biota is unknown.

FATE

Concern about PAHs in the environment is due to their persistence and to the fact that some are known to be potent mammalian carcinogens, although environmental effects of most noncarcinogenic PAHs are poorly understood (Neff 1985). Prior to 1900, a natural balance existed between the production and the degradation of PAHs. Synthesis of PAHs by microorganisms and volcanic activity and production by man-made high temperature pyrolytic reactions and open burning seemed to be balanced by PAH destruction via photodegradation and microbial transformation. With increased industrial development and increased emphasis of fossil fuels as energy sources, the balance has been disturbed to the extent that PAH production and introduction into the environment greatly exceeds known PAH removal processes (Suess 1976; Sims and Overcash 1983).

When released into the atmosphere, PAH compounds will become associated with particulate materials. Their residence time in the atmosphere and transport to different geographic locations are governed by particle size, meteorological conditions, and atmospheric physics. The highly reactive PAHs photodecompose readily in the atmosphere by reaction with ozone and various oxidants; degradation times range from several days to six weeks for PAHs adsorbed onto particulates <1 um in diameter (in the absence of rainfall) to <1 day to several days for those adsorbed to larger particles (Suess 1976). Smaller atmospheric particulates containing PAHs are easily inhaled (Lee and Grant 1981), and may pose special problems, as yet unevaluated, for airborne organisms such as birds, insects, and bats. Photooxidation, one of the most important processes in the removal of PAHs from the atmosphere, can also produce reaction products that are carcinogenic or mutagenic, although little is known of their persistence (Edwards 1983): One of the more common photooxidation reactions of PAHs is the formation of endoperoxides that ultimately undergo a series of reactions to form quinones (Edwards 1983). Various parameters may modify chemical and photochemical transformation of PAHs in the atmosphere,

including light intensity, concentration of gaseous pollutants (0_3, NOx, SOx), and chemicophysical characteristics of particulates or substrates into which the PAHs are adsorbed; depending on these variables, the half-life of benzo(a)pyrene in the atmosphere varies from 10 minutes to 72 days (Valerio et al. 1984). Atmospheric PAHs are transported over relatively long distances from industrial areas and from natural forest and prairie fires (Edwards 1983); however, sites nearer urban centers have much higher PAH deposition rates than more rural areas (Hites and Gschwend 1982).

Much of the PAHs released into the atmosphere eventually reaches the soil by direct deposition or by deposition on vegetation. The PAHs may be adsorbed or assimilated by plant leaves before entering the animal food chain, although some adsorbed PAHs may be washed off by rain, chemically oxidized to other products, or returned to the soil as the plants decay. PAHs assimilated by vegetation may be translocated, metabolized, and possibly photodegraded within the plant. In some plants growing in highly contaminated areas, assimilation may exceed metabolism and degradation, resulting in an accumulation in plant tissues (Edwards 1983).

In water, PAHs may either evaporate, disperse into the water column, become incorporated into bottom sediments, concentrate in aquatic biota, or experience chemical oxidation and biodegradation (Suess 1976). The most important degradative processes for PAHs in aquatic systems are photooxidation, chemical oxidation, and biological transformation by bacteria and animals (Neff 1979). Most PAHs in aquatic environments are associated with particulate materials; only about 33% are present in dissolved form (Lee and Grant 1981). PAHs dissolved in the water column will probably degrade rapidly through photooxidation (EPA 1980), and degrade most rapidly at higher concentrations, at elevated temperatures, at elevated oxygen levels, and at higher incidences of solar radiation (McGinnes and Snoeyink 1974; Suess 1976; Bauer and Capone 1985). The ultimate fate of those PAHs that accumulate in sediments is believed to be biotransformation and biodegradation by benthic organisms (EPA 1980). PAHs in aquatic sediments, however, degrade very slowly in the absence of penetrating radiation and oxygen (Suess 1976), and may persist indefinitely in oxygen poor basins or in anoxic sediments (Neff 1979). PAH degradation in aquatic environments occurs at a slower rate than that in the atmosphere (Suess 1976), and the cycling of PAHs in aquatic environments, as is true for other ecological systems, is poorly understood (Neff 1979).

Animals and microorganisms can metabolize PAHs to products that may ultimately experience complete degradation. The degradation of most PAHs is not completely understood. Those in the soil may be assimilated by plants, degraded by soil microorganisms, or accumulated to relatively high levels in the soil. High PAH concentrations in soil can lead to increased populations of microorganisms capable of degrading the compounds. Of equal importance to PAH cycling dynamics is the physical state of the PAH, i.e., whether in vapor phase or associated with particles such as flyash. Particles may increase or decrease the susceptibility of PAHs to degradation, depending on the PAH and particles involved (Edwards 1983).

PAHs can be taken into the mammalian body by inhalation, skin contact, or ingestion, although they are poorly absorbed from the gastrointestinal tract. The main routes of elimination of PAHs and their metabolites include the hepatobiliary system and the gastrointestinal tract (Sims and Overcash 1983). In mammals, an enzyme system variously known as the cytochrome P-450-dependent mixed-function oxidase, mixed-function oxidase, mixed-function oxygenase, aryl hydrocarbon hydroxylase, or drug metabolizing system, is responsible for initiating the metabolism of various lipophilic organic compounds, including PAHs. The primary function of this system is to render poorly water soluble lipophilic materials more water soluble, and therefore more available for excretion. Some PAHs are transformed to intermediates, which are highly toxic, mutagenic, or carcinogenic to the host. Oxidative metabolism of PAHs in this system proceeds via high electrophilic intermediate arene oxides, some of which bind covalently to cellular macromolecules such as DNA, RNA, and protein. Most authorities agree that metabolic activation by the mixed-function oxidase system is a necessary prerequisite for PAH-induced carcinogenesis and mutagenesis (Neff 1979). This enzyme system is known to be present in rodent tissues, and human liver, skin, placenta, fetal liver, macrophages, lymphocytes, and monocytes (Lo and Sandi 1978). Studies with rodents have shown that the mixed-function oxidase system can convert PAHs to various hydroxylated derivatives including phenols, quinones, and epoxides, and can also activate PAHs to produce carcinogenic metabolites (Lo and Sandi 1978). Fish and most crustaceans tested to date possess the enzymes necessary for activation (Statham et al. 1976; Varanasi et al. 1980; Fabacher and Baumann 1985), but some molluscs and other invertebrates are unable to efficiently metabolize PAHs (Jackim and Lake 1978; Varanasi et al. 1985). Although many aquatic organisms possess the requisite enzyme

systems for metabolic activation of PAHs, it is not certain in most cases whether these enzymes produce the same metabolites as those produced by mammalian enzymes (Neff 1979).

PAHs are metabolized by liver mixed-function oxidases to epoxides, dihydrodiols, phenols, and quinones. The intermediate metabolites have been identified as the mutagenic, carcinogenic, and teratogenic agents (Sims and Overcash 1983). The activation mechanisms occur by hydroxylation or production of unstable epoxides of PAHs which damage DNA, initiating the carcinogenic process (Jackim and Lake 1978). Metabolic formation of bay region diol epoxides represents an important pathway by which PAHs are activated to carcinogens (Figure 4). Such metabolic activation proceeds via initial formation of the dihydrodiol with the bay region double bond, followed by subsequent oxidation of the dihydrodiol to the bay region diol epoxide (Sims and Overcash 1983). Active epoxides may be converted to less toxic products by various enzymatic and other reactions (Neff 1979). In the case of benzo(a)pyrene, the "ultimate circinogen" (7 beta, 8 alpha-dihydroxy-,7,8,9,10 tetrahydrobenzo(a)pyrene- 9 alpha, 10 alpha-epoxide) reacts with the guanine of RNA and DNA, the linkage taking place between the C-10 atom of benzo(a)pyrene and the C-2 amino group of guanine (Grimmer 1983; Dipple 1985; Figure 4). Additional information on actual and theoretical mechanisms involved in the metabolic activation of PAHs are given in Cavalieri et al. (1978, 1980), Bjorseth and Dennis (1980), Herd and Greene. (1980), Cooke and Dennis (1981), Sims and Grover (1981), Grimmer (1983), Szentpaly (1984), Harvey (1985), and Yan (1985).

BACKGROUND CONCENTRATIONS

GENERAL

PAHs are ubiquitous in the environment. In nonbiological materials, concentrations are elevated in the vicinity of urban industrialized locales, and from areas of significant wood burning activities such as forest fires and residential home heating. Terrestrial vegetation and aquatic invertebrates can accumulate significant concentrations of PAHs, possibly due to inefficient or missing mixed-function oxidase systems. Fish do not appear to contain grossly elevated PAH residues; this may be related to their efficient degradation system. At present, data are lacking or unavailable on PAH background concentrations in natural populations of birds and other wildlife --although it seems unlikely that significant accumulations will occur. Some investigators have shown that aquatic invertebrates, fish, and amphibians collected from areas of high sediment PAH content show elevated frequencies of hyperplasia and neoplasia (Rose 1977; Mix 1982; Black 1983; Malins et al. 1984, 1985a, 1985b; Black et al. 1985; Baumann et al., in press), and, recently, that hepatic carcinoma has been induced in rainbow trout (*Salmo gairdneri*) by benzo(a)pyrene through dietary and intraperitoneal injection routes (Hendricks et al. 1985).

More comprehensive information on PAH background levels in various biological and nonbiological compartments is given in Lo and Sandi (1978), Neff (1979, 1985), Pucknat (1981), Edwards (1983), Grimmer (1983), and Sims and Overcash (1983).

NONBIOLOGICAL SAMPLES

Total PAH levels in air are usually much higher in winter than in summer, higher in urban communities than in rural areas (Table 3; Grimmer 1983), and appear to be related primarily to the weight of total suspended particulates in the atmosphere (Hites and Gschwend 1982; Greenberg et al. 1985; Srivastava et al. 1985; Ang et al. 1986). PAH levels in precipitation are significantly higher in winter than in summer, primarily due to emissions from household heating (Quaghebeur et al. 1983; van Noort and Wondergem 1985). Among industrial sources, the production of metallurgical coke is the single most significant source of atmospheric PAHs in Ontario, Canada. Coke production in 1977 represented about 52% of all PAH emissions from Ontario sources versus about 46% formed as a result of forest fires (Potvin et al. 1981). Beyond 2 km distant from the coke point source, PAH concentrations in air were typical of those measured in major urban nonindustrialized areas (Table 3; Potvin et al. 1981). A variety of PAHs have been detected in ambient air in the USA and elsewhere. Benzo(a)pyrene, because of its carcinogenic properties, has been monitored extensively, and has frequently been used as an indicator of PAHs (EPA 1980). In general, total PAHs in air is about 10X higher than benzo(a)pyrene levels, although this relation is extremely variable (Lee and Grant 1981). Benzo(a)pyrene levels, like total PAHs, were higher in winter than summer, probably due to residential and industrial heating; air levels in urban areas with coke ovens were 40% to 70% higher than in cities without coke ovens, but this may be related to higher industrial emissions in those cities (Lee and Grant 1981). In one case, benzo(a)pyrene

levels in air from the center of a remote mountain community in Colorado were several times higher than what is usually found in U.S. metropolitan areas, and was attributed to extensive residential wood burning (in M. Cooke, A.J. Dennis, and G.L. Fisher (eds.). Polynuclear aromatic hydrocarbons: physical and biological chemistry. Battelle Press, Columbus, Ohio.Murphy et al. 1982). Average concentrations of benzo(a)pyrene in urban air Nationwide declined from 3.2 ng/m^3 in 1966 to 0.5 ng/m^3 in 1978, an 80% decrease (Lee and Grant 1981). These decreases are believed to be due primarily to decreases in coal consumption for commercial and residential heating, improved disposal of solid wastes, and restrictions on open burning (EPA 1980).

Total PAHs	0.5–1.33	
Carcinogenic PAHs	0.18–0.56	

[a]Each reference applies to data in the same row and in the rows that immediately follow for which no reference is indicated.

A major source of PAHs in soils and soil litter is from emissions and deposition from forest fires. In a controlled burn study, Sullivan and Mix (1985) showed that lower molecular weight PAHs, such as phenanthrene and fluorene, which had been deposited in soil litter, degraded to nondetectable levels within 2 years after burning. Higher molecular weight PAHs such as benzo(k)fluorene, benzo(a)pyrene, benzo(g,h,i)perylene, perylene, and indeno(1,2,3-cd)pyrene, were more persistent in litter, decreasing after 5 years to about 20% of initial deposition. Although movement into the top 2 cm of the soil profile was initially

more pronounced for lower molecular weight PAHs, all compounds appeared to reach equilibrium between litter and soil on the basis of organic content within one year postburn. Differential persistence and fate of PAHs on slash burn sites is explained by solubility, Kow, and other physicochemical properties (Sullivan and Mix 1985). PAHs from vehicle emissions constitute a minor, but measurable, source of soil PAHs (Table 3). The majority of highway-derived PAHs appears to be deposited within 3.8 m of the road, but the influence of the highway may extend to nearly 70 m (Johnston and Harrison 1984). The use of composted municipal wastes for conditioning of agricultural soils is not recommended, as these contain at least nine identified carcinogenic PAHs (Martens 1982).

Some sediments were found to be highly contaminated with PAHs. Sediments and sediment extracts from the Buffalo River, New York, contained elevated levels of carcinogenic PAHs (1,000-16,000 ug/kg). Brown bullheads (*Ictalurus nebulosus*), in response to repeated applications of Buffalo River sediment extracts, showed epidermal hyperplasia and neoplasia when compared to controls (Black 1983). PAH concentrations in sediments from the Great Barrier Reef, Australia, were always <0.8 ug/kg dry weight, except in small areas close to sites frequently visited by power boats; in those instances, total PAH levels exceeded 13,400 ug/kg (Smith et al. 1985). Highest PAH levels measured in sediments of Cayuga Lake, New York, were found in marinas or areas of the lake receiving urban runoff, and were apparently not related to stack emissions from a nearby coal-fired power plant; Heit (1985) believed that stack emissions were either masked by other sources or were atmospherically transported and deposited elsewhere. Coastal and offshore sediments are subject to highly elevated PAH levels from a variety of sources, mostly unknown, relative to preindustrial times (Johnson et al. 1985). For example, PAH levels in sediments of Penobscot Bay, Maine, fell within the range found in sediments near industrialized regions, and were significantly higher than expected for an area previously considered to be uncontaminated (Table 3; Johnson et al. 1985).

Sewage effluents usually contained measurable levels of PAHs, although extreme variability between and among sites is common. For example, during a heavy storm, individual PAH levels in a sewage works may increase more than 100X over a dry weather period (Harrison et al. 1975). Conventional sewage treatment plant processes remove up to 90% of carcinogenic PAHs, and this may be increased to 99% using percolating filters and activated sludge processes (Harrison et al. 1975). Tiger salamanders (*Ambystoma tigrinum*), collected in 1975 from a 13 ha sewage effluent lagoon at Reese Air Force Base, Texas, showed a remarkably high incidence (53%) of neoplastic and other lesions (Rose 1977). Analysis of sludge composites showed elevated PAH levels, especially perylene; levels of organochlorine and organophosphorus pesticides, nitrosamines, and heavy metals were judged to be nonelevated (Rose 1977).

Careful disposal of used motor oils is warranted, as these contain high quantities of mutagenic and carcinogenic PAHs (Table 3; Pasquini and Monarca 1983).

All but the most heavily contaminated fresh and marine waters contain total PAH concentrations in the part-per-trillion or low part-per-billion range (Table 3; Neff 1982b). A large proportion of the PAH content in water is probably adsorbed onto suspended solids (Harrison et al. 1975). In Lake Michigan, concentrations of total PAHs in the surface microlayer varied from 0.15 to 0.45 ug/l, representing on a relative scale 106 times the concentration in air, suggesting that aerosols are a major source of these compounds and that the microlayer is a repository until the PAHs are removed by adsorption and sedimentation (Strand and Andren 1980).

BIOLOGICAL SAMPLES

Carcinogenic PAHs have been extracted from a large variety of fresh plants, including root and leaf vegetables, fruits, grains, and edible mushrooms, as well as from various marine bacteria and phytoplankton under circumstances suggesting that PAHs were present due to local biosynthesis (Suess 1976). Vegetation and soil near known PAH sources are more highly contaminated with PAHs than those collected at greater distances (Edwards 1983). PAH levels in lettuce (*Lactuca sativa*) grown in Sweden seemed to be directly related to its proximity to local recognized point sources of PAH emitters (Table 4; Larsson and Sahlberg 1982). Washing lettuce with water had little effect on phenanthrene levels, but significantly reduced other PAHs, such as benzo(a)pyrene, benz(a)anthracene, and benzo(g,h,i)perylene by 68% to 87% (Larsson and Sahlberg 1982). fruits and vegetables grown in polluted atmospheres may contain up to 100X higher levels of total PAHs than those grown in unpolluted environments (EPA 1980; Lee and Grant 1981). PAH concentrations for plants are generally greater on plant surfaces than internal tissues, greater in above ground plant parts than those below ground, and greater in plants with broad leaves (greater surface area) than those with narrow leaves (Edwards

1983). Plants can become contaminated with PAHs through environmental pollution, particularly through deposition from the atmosphere, and also through food processing. For example, the bran portion of milled wheat, as well as finished bran cereal, had a considerably higher PAH content than other fractions or finished products (Lawrence and Weber 1984b). Enrichment of PAHs in plants is associated with deposition of atmospheric particulate matter with relatively small particle sizes; thus, PAH content is usually in the order of humus > mosses > lichens (Thomas et al. 1984). Mosses appear to be good indicators of regional PAH air pollution and have been recommended for this purpose (Herrmann and Hubner 1984). Concentrations of total PAHs in soils, usually the sum of 5 to 20 PAHs, typically exceeded benzo(a)pyrene levels by at least one order of magnitude; however, concentrations of benzo(a)pyrene in vegetation were generally less than those in soil where plants were growing (Edwards 1983).

PAH accumulations in marine molluscs have been reported (Table 4); however, some of these data may be misleadingly low. For example, lengthy cold storage of 10 months can result in loss of volatile PAHs, such as anthracene, in tissues of mussels (Smith et al. 1984); accordingly, background concentrations in these organisms may be underreported. Bivalve molluscs tend to accumulate high PAH levels due to their inability to metabolize and excrete them (Lawrence and Weber 1984a), presumably due to inefficient or missing mixed-function oxidase systems (Sirota and lithe 1981). Cellular proliferative disorders, resembling neoplastic conditions in vertebrates, were found in mussels with the greatest PAH concentrations: 9.5% vs. 0.7% in control site (Mix 1982). Baseline levels of PAHs in indigenous bivalve molluscs reflected the degree of human onshore activity at the various sample sites, and presumably the level of water contamination; however, little relation was evident between accumulated levels of individual PAHs and total PAHs (Mix 1982). Elevated PAH concentrations, especially benz(a)anthracene, chrysene, fluorene, phenanthraene, and pyrene in oyster tissues and sediments were measured in samples from the vicinity of marinas, and were higher in oysters in cooler months, when lipids and glycogen were being stored preparatory to spawning (Marcus and Stokes 1985). In general, PAH concentrations in marine clams were highest in areas adjacent to industrialized bayfronts and lowest in clams inhabiting more remote areas; concentrations were lowest in autumn-winter, and highest during spring-summer (Mix and Schaffer 1983a). A similar pattern was observed in mussels, *Mytilus edulis*, with the more water soluble, lower molecular weight, PAHs bioconcentrated 10X to 100X above that of the higher molecular weight, less water soluble PAHs (Mix and Schaffer 1983b); PAH levels in mussels seemed to be independent of water salinity (Mix and Schaffer 1979). Clams contaminated with PAHs and removed to clean seawater for 24 hours showed significant depuration of unsubstituted 3- and 4-ring PAHs; in contrast, concentrations of all 5-, 6-, and 7-ring compounds, which includes most of the carcinogenic PAHs, were not significantly depurated (Mix 1982). A positive relation exists between PAH isomers in sediments, soft tissues of the mussel *Mytilus edulis*, and a seaweed (*Fucus* sp.) collected at Vancouver, British Columbia (Dunn 1980). For mussels, the general trend towards lower levels of higher molecular weight PAHs relative to levels in sediments suggests an uptake mechanism which involves the solution of PAHs in water; superimposed on this pattern is the more rapid turnover and shorter half-life of lower molecular weight PAHs in mussels (Dunn 1980).

PAH residues were higher than expected in American lobsters (*Homarus americanus*) collected offshore (mean weight 3.6 kg) when compared to smaller (0.6 kg) lobsters collected inshore (Sirota and Uthe 1981), suggesting that age or body size are important modifiers in PAH accumulation dynamics. PAH concentrations in sediments collected near a coking facility in Nova Scotia in 1980 contained up to 2,830 mg/kg dry weight, or more than 20X the levels recorded in Boston (Mass.) Harbor; concentrations in excess of 100 mg/kg dry weight sediment were recorded for phenanthrene, fluorene, pyrene, benz(a)anthracene, chrysene, benzo(e)pyrene, benzo(b)fluoranthene, and benzo(a)pyrene, and these seemed to reflect the elevated tissue levels in American lobsters collected from that locale (Sirota et al. 1983). PAH residues in digestive glands of American lobsters collected in 1979 in Nova Scotia from the vicinity of a major oil spill were higher than those from coastal control sites; however, PAH contents of edible muscle from control and oiled lobsters were similar (Sirota and Uthe 1981).

Table 4. PAH concentrations in field collections of selected biota. Values are shown in g/kg (ppb) fresh weight (FW), or dry weight (DW).

[a]Each reference applies to data in the same row and in the rows that immediately follow for which no reference is indicated.

PAH levels in fish are usually low because this group rapidly metabolizes PAHs (Lawrence and Weber 1984a); furthermore, higher molecular weight PAHs, which include the largest class of chemical carcinogens, do not seem to accumulate in fish (West et al. 1984). Raw fish from unpolluted waters usually do not contain detectable amounts of PAHs, but smoked or cooked fish contain varying levels. The concentration of benzo(a)pyrene in skin of cooked fish was much higher than in other tissues, suggesting that skin may serve as a barrier to the migration of PAHs in body tissues (EPA 1980).

Sediments and biota collected from the Hersey River, Michigan, in 1978, were heavily contaminated with phenanthrene, benz(a)anthracene, and benzo(a)pyrene when compared to a control site. Elevated PAH concentrations were recorded in sediments, whole insect larvae, crayfish muscle, and flesh of lampreys (family Petromyzontidae), brown trout (*Salmo trutta*), and white suckers. (*Catostomus commersoni*), in that general order (Black et al. 1981). The polluted collection locale was the former site of a creosote wood preservation facility between 1902 and 1949, and, at the time of the study, received Reed City wastewater treatment plant effluent, described as an oily material with a naphthalene-like odor (Black et al. 1981). In many cases, aquatic organisms from PAH-contaminated environments have a higher incidence of tumors and hyperplastic diseases than those from nonpolluted environments. Carcinogenic PAHs have not been unequivocally identified as the causative agent for an increased incidence of cancer in any natural population of aquatic organisms, according to Neff (1982b). However, a growing body of evidence, mostly circumstantial, links PAHs to cancer in feral fish populations, especially bottom dwelling fish from areas with sediments heavily contaminated with PAHs (Baumann and Lech, in press).

TOXIC AND SUBLETHAL EFFECTS

GENERAL

A wide variety of PAH-caused adverse biological effects have been reported in numerous species of organisms under laboratory conditions, including effects on survival, growth, metabolism, and especially tumor formation. Inter- and intraspecies responses to carcinogenic PAHs were quite variable, and were significantly modified by many chemicals including other PAHs that are weakly carcinogenic or noncarcinogenic. Until these interaction effects are clarified, the results of single substance laboratory tests may be extremely difficult to apply to field situations of suspected PAH contamination.

FUNGI

Fungal degradation of PAHs may be important in the detoxification and elimination of PAHs in the environment. The fungus *Cunninghamella elegans*, for example, inhibited the mutagenic: activity of benzo(a)pyrene, 3 ethyl cholanthrene, benz(a)anthracene, and 7,12-dimethylbenz(a)anthracene, as judged by results of the Ames test using *Salmonella typhimurium* (Cerniglia et al. 1985). The rate of decrease in mutagenic activity in bacterial cultures incubated with PAHs was coincident with the rate of increase in fungal metabolism. *C. elegans* metabolized PAHs to dihydrodiols, phenols, quinones, and dihydrodiol epoxides, and to sulfate,, glucuronide, and glucoside conjugates of these primary metabolites in a manner similar to that reported

for mammalian enzyme systems, suggesting that this organism (and perhaps other fungi) is important in PAH metabolism and inactivation (Cerniglia et al. 1985).

TERRESTRIAL PLANTS

Biological effects of PAHs on terrestrial vegetation have been reviewed by EPA (1980), Lee and Grant (1981), Wang and Meresz (1982), Edwards (1983), and Sims and Overcash (1983). In general, these authorities agreed on several points. First, plants and vegetables can absorb PAHs from soils through their roots, and translocate them to other plant parts such as developing shoots. Uptake rates were governed in part, by PAH concentration, PAH water solubility, soil type, and PAH physicochemical state (vapor or particulate). Lower molecular weight PAHs were absorbed by plants more readily than higher molecular weight PAHs. Under laboratory conditions, some plants concentrated selected PAHs above that of their immediate geophysical surroundings, but this has not been conclusively demonstrated in field-grown cultivated crops or other vegetation. Second, above-ground parts of vegetables, especially the outer shell or skin, contained more PAHs than underground parts, and this was attributed to airborne deposition and subsequent adsorption. Externally deposited PAHs in vegetables were difficult to remove with cold water washings; not more than 25% were removed from lettuce, kale, spinach, leeks, and tomatoes using these procedures. Third, PAH-induced phytotoxic effects were rare; however, the data base on this subject is small. Fourth, most higher plants can catabolize benzo(a)pyrene, and possibly other PAHs, but metabolic pathways have not been clearly defined. Finally, the biomagnification potential of vegetation in terrestrial and aquatic food chains needs to be measured; this work should be conducted with a variety of PAHs in both field and laboratory experiments.

Some plants contain chemicals known to protect against PAH effects. Certain green plants contain ellagic acid, a substance that can destroy the diol epoxide form of benzo(a)pyrene, inactivating its carcinogenic and mutagenic potential (Edwards 1983). PAHs synthesized by plants may act as plant growth hormones (Edwards 1983). Some vegetables, such as cabbage, brussel sprouts, and cauliflower, contain naturally occurring antineoplastic compounds including benzyl isothiocyanate and phenethyl isothiocyanate; these compounds are known to inhibit mammary cancers, stomach tumors, and pulmonary edemas induced in rats by benzo(a)pyrene and 7,12-dimethylbenz(a)anthracene (EPA 1980). Decreased activation of carcinogens has also been demonstrated in animals fed diets that were high in protein, low in carbohydrate, and containing adequate choline; the reverse was observed in diets high in carbohydrate, low in protein, or containing certain organophosphorus insecticides, piperonyl butoxide carbon tetrachloride, nickel carbonyl, or tin (EPA 1980). In cases where dietary constituents can alter the metabolism of foreign agents, such as PAHs, the anticarcinogenic effect may result from an alteration of steady state levels of activated versus detoxified metabolites (EPA 1980). The implications of these observations to herbivorous wildlife are unknown at present.

AQUATIC BIOTA

PAHs vary substantially in their toxicity to aquatic organisms (Table 5). In general, toxicity increases as molecular weight increases (although high molecular weight PAHs have low acute toxicity, perhaps due to their low solubility in water) and with increasing alkyl substitution on the aromatic ring. Toxicity is most pronounced among crustaceans and least among teleosts (Neff 1979; Table 5). In all but a few cases, PAH concentrations that are acutely toxic to aquatic organisms are several orders of magnitude higher than concentrations found in even the most heavily polluted waters (Neff 1979). Sediments from polluted regions, however, may contain PAH concentrations similar to those which are acutely toxic, but their limited bioavailability would probably render them substantially less toxic than PAHs in solution (Neff 1979).

A growing literature exists on uptake, retention, and translocation of PAHs by aquatic plants and animals. Authorities generally agree that: most species of aquatic organisms studied to date rapidly accumulate (i.e., bioconcentrate) PAHs from low concentrations in the ambient medium; uptake of PAHs is highly species specific, being higher in algae, molluscs, and other species which are incapable of matabolizing PAHs; bioconcentration factors (BCF) tend to increase as the molecular weight of the PAH increases, with increasing octanol/water partition coefficient values, with time until approaching an apparent equilibrium level (sometimes within 24 hours), and with increases in dissolved organic matter in the medium, lipid content of organism, and a variety of endogenous and exogenous factors (Jackim and Lake 1978; Southworth et al. 1978; Lee and Grant 1981; Neff 1982a). BCF values have been determined for selected PAHs and aquatic organisms (Table 6); additional BCF data for aquatic biota are available for plants (Dobroski and Epifanio 1980; Boyle et al. 1984), crustaceans (Southworth 1979; Sirota and Uthe 1981; Fox and Rao 1982; Neff 1982a; Williams et al. 1985),

tunicates (Baird et al. 1982), molluscs (Jackim and Wilson 1979; Dobroski and Epifanio 1980; Neff 1982a), and fishes (Southworth 1979; Neff 1982a; Stoker et al. 1984). Algal accumulation of benzo(a)pyrene increased linearly in a 24-hour exposure period, and correlated positively with surface area (Leversee et al. 1981), suggesting adsorption rather than absorption. Algae readily transform benzo(a)pyrene to oxides, peroxides (Kirso et al. 1983), and dihydrodiols (Warshawsky et al. 1983). Photosynthetic rates of algae, and presumably PAH accumulations, were significantly modified by light regimens. For reasons still unexplained, algae grown in "white" light (major energy in blue-green portion of the spectrum) were more sensitive to benzo(a)pyrene than were cultures grown in "gold" light (Warshawsky et al. 1983; Schoeny et al. 1984). Accumulation by oysters (*Crassostrea virginica*) and clams (*Rangia cuneata*) of naphthalene, phenanthrene, fluorene, and their methylated derivatives increased with increasing methylation and PAH molecular weight; uptake was more rapid under conditions of continuous flow than in static tests (Neff et al. 1976). When returned to PAH-free seawater, molluscs released PAHs to non- detectable levels in about 60 days, with high molecular weight PAHs depurated more slowly than low molecular weight compounds; brown shrimp (*Penaeus aztecus*) and longnose killifish (*Fundulus similis*), which can metabolize PAHs, lost PAHs more quickly than clams and oysters, which apparently lack the detoxifying enzymes (Neff et al. 1976). Pink shrimp (*Penaeus duorarum*) exposed to 1.0 ug chrysene/l for 2 days and then transferred to unpolluted seawater for an additional 28 days contained concentrations of chrysene (91 ug/kg fresh weight in abdomen, 48 ug/kg in cephalothorax) that were considered potentially hazardous to human consumers over extended periods (Miller et al. 1982). Eggs of the sand sole (*Psettichthys melanostictus*) exposed to 0.1 ug benzo(a)pyrene /1 for 5 days showed reduced and delayed hatch and, when compared to controls, produced larvae with high accumulations (2.1 mg/kg fresh weight) and gross abnormalities, such as twinning and tissue overgrowths, in 50% of the test larvae (Hose et al. 1982). Naphthalene and benzo(a)pyrene were rapidly accumulated from the medium by three species of California marine teleosts; loss was rapid, being >90% for naphthalene in 24 hours, and 20% (muscle), to 90% (gill) for benzo (a)pyrene in a similar period (Lee et al. 1972). Phenanthrene is metabolized by many species of aquatic organisms, including fish. A marine flounder *Platichthys flesus*, given a single oral dose of 0.7 mg phenanthrene/kg body weight, contained elevated phenanthrene concentrations in lipids, melanin-rich tissues (such as skin), and the eye lens; most was eliminated within 2 weeks (Solbakken et al. 1984). Different rates of accumulation and depuration of benzo(a)pyrene and naphthalene in bluegill (*Lepomis macrochirus*) and *Daphnia magna* have been documented by McCarthy and Jimenez (1985) and McCarthy et al. (1985). Benzo(a)pyrene accumulations in bluegill, for example, were 10X greater than naphthalene, but benzo(a)pyrene is extensively metabolized, whereas naphthalene is not. Consequently, postexposure accumulations of naphthalene greatly exceeded that of the parent benzo(a)pyrene. Because the more hydrophobic PAHs, such as benzo(a)pyrene, show a high affinity for binding to dissolved humic materials and have comparatively rapid biotransformation rates, these interactions may lessen or negate bioaccumulation and food chain transfer of hydrophobic PAHs (McCarthy and Jimenez 1985; McCarthy et al. 1985).

Table 5. Toxicities of selected PAHs to aquatic organisms.

PAH compound, organism, and other variables	Concentration in medium (µg/L)	Effect[a]	Reference[b]

[b]Each reference applies to data in the same row and in the rows that immediately follow for which no reference is indicated.

Time to depurate or biotransform 50% of accumulated PAHs (Tb 1/2) varied widely. Tb 1/2 values for *Daphnia pulex* and all PAH compounds studied ranged between 0.4 and 0.5 hours (Southworth et al. 1978). For marine copepods and naphthalene, a Tb 1/2 of about 36 hours was recorded (Neff 1982a). For most marine bivalve molluscs, Tb 1/2 values ranged from 2 to 16 days. Some species, such as the hardshell clam (*Mercenaria mercenaria*), showed little or no depuration, while others, such as oysters, eliminated up to 90% of accumulated PAHs in 2 weeks--although the remaining 10% was released slowly, and traces may remain indefinitely (Jackim and Lake 1978). Percent loss of various PAHs in oysters (*Crassostrea virginica*), 7 days postexposure, ranged from no loss for benzo(a)pyrene to 98% for methylnaphthalene; intermediate were benz(a)anthracene (32%), fluoranthene (66%), anthracene (79%), dimethylnaphthalene (90%), and naphthalene (97%) (Neff 1982a). Teleosts and arthropods usually had low Tb 1/2 values. In bluegill, 89% loss of benzo(a)pyrene was recorded 4 hours postexposure; for midge larvae it was 72% in 8 hours, and for daphnids it was 21% in 18 hours (Leversee et al. 1981).

The role of sediments in PAH uptake kinetics should not be discounted. Sediment-associated anthracene contributed about 77% of the steady state body burden of this compound in the amphipod *Hyalella azteca* (Landrum and Scavia 1983). For benzo(a)pyrene and the amphipod *Pontoporeia hoyi*, the sediment source (including interstitial water) accounted for 53% in amphipods collected at 60 m, but only 9% at 23 to 45 m (Landrum et al. 1984). Benthos from the Great Lakes, such as oligochaete worms (*Limnodrilus* sp., *Stylodrilus* sp.) and amphipods (*Pontoporeia hoyi*), obtain a substantial fraction of their PAH body content from the water when sediment PAH concentrations are low. However, when sediment PAH concentrations are elevated, benthos obtain a majority of their PAHs from that source through their ability to mobilize PAHs from the. sediment/pore water matrix; the high concentrations of phenanthrene, fluorene, benzo(a)pyrene, and other PAHs measured in these organisms could provide a significant source of PAHs to predator fish (Eadie et al. 1983). Great Lakes benthos appear to contain as much PAHs as the fine grain fraction of the sediment which serves as their food, although overlying water or pore water appears to contribute a larger proportion of PAHs to the organism's body burden than does sediments (Eadie et al. 1984). Marine mussels (*Mytilus edulis*) and polychaete annelid worms (*Nereis virens*) exposed for 28 days to sediments heavily contaminated with various PAH compounds accumulated significant concentrations (up to 1,000X control levels) during the first 14 days of exposure, and little thereafter; during a 5-week postexposure period, depuration was rapid, with the more water soluble PAHs excreted most rapidly; PAH levels usually remained above control values to the end of the postexposure period (Lake et al. 1985). English sole (*Parophrys vetulus*), during exposure for 11 to 51 days to PAH-contaminated sediments, showed significant accumulations of naphthalenes in liver (up to 3.1 mg/kg dry weight) after 11 days, with concentrations declining markedly thereafter; uptake of phenanthrene, chrysene, and benzo(a)pyrene was negligible during the first 7 days (Neff 1982a).

Fluorene effects in freshwater pond ecosystems have recently been evaluated (Boyle et al. 1984, 1985; Finger et al. 1985). In ponds exposed to initial fluorene concentrations of 0.12 to 2.0 mg/l, Tb 1/2 values in water ranged from 6 to 11 days. Ten weeks after fluorene introduction, little degradation had occurred in th organic bottom sediments; fluorene residues were present in fish, invertebrates, and rooted submerged macrophytes. Studies with fingerling bluegills showed that 0.062 mg fluorene/l adversely affected their ability to capture chironomid prey, 0.12 mg/l reduced growth, and 1.0 mg fluorene/l increased their vulnerability to predation by largemouth bass (*Micropterus salmoides*). The authors concluded that fluorene, at concentrations well below its solubility and at levels that could realistically occur in the environment, represents a potential hazard to aquatic organisms.

Large interspecies differences in ability to absorb and assimilate PAHs from food have been reported. For example, crustaceans (Neff 1982a) and fish (Maccubbin et al. 1985; Malins et al. 1985a, 1985b) readily assimilated PAHs from contaminated food, whereas molluscs and polychaete annelids were limited (Neff 1982a). In all cases where assimilation of ingested PAHs was demonstrated, metabolism and excretion of PAHs were rapid (Neff 1982a). Thus, little potential exists for food chain biomagnification of PAHs (Southworth 1979; Dobroski and Epifanio 1980; Neff 1982a). In laboratory aquatic ecosystem studies, Lu et al. (1977 found that benzo(a)pyrene can be accumulated to high, and potentially hazardous, levels in fish and invertebrates. In the case of mosquitofish (*Gambusia affinis*), almost all of the accumulated benzo(a)pyrene was from its diet, with negligible accumulations from the medium. However, mosquitofish degraded benzo(a)pyrene about as rapidly as it was absorbed, in contrast to organisms such as snails (*Physa* sp.) which retained most (88%) of the accumulated benzo(a)pyrene for at least 3 days postexposure, presumably due to deficiencies in their mixed function oxidase detoxication system (Lu et al. 1977). Benzo(a)pyrene, when administered to northern pike (*Esox lucius*) through the diet or the medium, followed similar pathways: entry via the gills or gastrointestinal system, metabolism in the liver, and excretion in the urine and bile (Balk et al. 1984). Benthic marine fishes exposed to naphthalene or benzo(a)pyrene, either in diet or through contaminated sediments, accumulated substantial concentrations in tissues and body fluids (Varanasi and Gmur 1981). The tendency of fish to metabolize PAHs extensively and rapidly may explain why benzo(a)pyrene, for example, is frequently undetected, or only detected in low concentrations in livers of fish from environments heavily contaminated with PAHs (Varanasi and Gmur 1980, 1981). Extensive metabolism of benzo(a)pyrene plus the presence of large proportions of polyhydroxy metabolites in liver of English sole indicates the formation of reactive intermediates such as diol epoxides and phenol epoxides of benzo:a)pyrene, both of which are implicated in mammalian mutagenesis and carcinogenesis (Varanasi and Gmur 1981).

[a]m = minutes, h = hours, d = days.

[b]Each reference applies to the values in the same row and in the rows that follow for which no other reference is indicated.

Cytotoxic, mutagenic, and carcinogenic effects of many PAHs are generally believed to be mediated through active epoxides formed by interaction with microsomal monooxygenases. These highly active arene oxides can interact with macromolecular tissue components and can further be metabolized or rearranged to phenols or various conjugates. They can also be affected by epoxide hydrolase to form dihydrodiols, which are precursors of biologically active diol epoxides--a group that has been implicated as ultimate carcinogens. Investigators generally agree that marine and freshwater fishes are as well equipped as mammals with liver PAH-metabolizing enzymes; rapidly metabolize PAHs by liver mixed-function oxidases, with little evidence of accumulation; translocate conjugated PAH metabolites to the gall bladder prior to excretion in feces and urine; and have mixed-function oxidase degradation rates that are significantly modified by sex, age, diet, water temperature, dose-time relationships, and other variables. In addition, many species of fishes can convert PAHs, benzo(a)pyrene for example, to potent mutagenic metabolites, but because detection of the 7,8-dihydrodiol, 9,10-epoxide by analytical methods is extremely difficult, most, investigators must use biological assays, such as the Ames test, to detect mutagenic agents. At present, the interaction effects of PAHs with inorganic and other organic compounds are poorly understood. Specific examples of the above listed phenomena for PAH compounds and teleosts are documented for benzo(a)pyrene (Ahokas et al. 1975; Lu et al. 1977; Gerhart and Carlson 1978; Melius et al. 1980; Varanasi et al. 1980, 1984; Stegeman et al. 1982; Couch et al. 1983; in K.L. Hoover (ed.). National Cancer Institute Monograph 65, Washington, D.C.Hendricks 1984; Melius 1984; Schoor 1984; Schoor and Srivastava 1984; Hendricks et al. 1985; Neff 1985; Fair 1986; In vitro

metabolism and in vivo binding of benzo(a)pyrene in the California killifish (Fundulus parvipinnis) and speckled sanddab (von Hofe and Puffer 1986), 3-methylcholanthrene (Gerhart and Carlson 1978; Melius et al. 1980; Melius and Elam 1983; (Schoor and Srivastava 1984; Neff 1985), benz(a)anthracene, chrysene, and pyrene (Gerhart and Carlson 1978), and 7,12-dimethylbenz(a)anthracene (Stegeman et al. 1982).

Baumann et al. (1982) summarized reports on increasing frequencies of liver tumors in wild populations of fish during the past decade, especially in brown bullhead (*Ictalurus nebulosus*) from the Fox River, Illinois (12% tumor frequency), in Atlantic hagfish (*Myxine glutinosa*) from Swedish estuaries (6%), in English sole from the Duwamish estuary, Washington (32%), and in tomcod (*Microgadus tomcod*) from the Hudson River, New York (25%). In all of these instances, significant levels of contaminants were present in the sediments, including PAHs. PAHs have been identified as genotoxic pollutants in sediments from the Black River, Ohio, where a high incidence of hepatoma and other tumors has been observed in ictalurid fishes (West et al. 1984, 1986). Reports of tumors in Great Lakes fish populations have been increasing. Tumors of thyroid, gonad, skin, and liver are reported, with tumor frequency greatest near areas contaminated by industrial effluents such as PAHs; liver tumors were common among brown bullhead populations at sites with large amounts of PAHs in sediments (Baumann 1984). A positive relationship was finally established between sediment PAH levels and prevalence of liver lesions in English sole in Puget Sound, Washington (Malins et al. 1984; Varanasi et al. 1984), and sediment levels and liver tumor frequency in brown bullheads from the Black River, Ohio (Baumann and Harshbarger 1985; Black et al. 1985). Sediment PAH levels in the Black River, Ohio, from the vicinity of a coke plant outfall, were up to 10,000 times greater than those from a control location: concentrations were greater than 100 mg/kg for pyrene, fluoranthene, and phenanthrene; between 50 and 100 mg/kg for benz(a)anthracene, chrysene, and benzofluoranthenes; and between 10 and 50 mg/kg for individual naphthalenes, benzo(e)pyrene, benzo(a)pyrene, perylene, indeno(1,2,3-cd)pyrene, benzo(g,h,i)perylene, and anthanthrene (Baumann et al. 1982). Brown bullheads from this location contained >1.0 mg/kg of acenapthalene (2.4), phenanthrene (5.7), fluoranthene (1.9), and pyrene (1.1), and lower concentrations of heavier molecular weight PAHs; bullheads also exhibited a high (33%) liver tumor frequency, which seemed to correspond to their PAH body burdens. Investigators concluded that the elevated frequency of liver neoplasia in Black River bullheads was chemically induced, and was the result of exposure to PAHs (Baumann et al. 1982; Baumann and Harshbarger 1985).

Neoplasms in several species of fishes have been produced experimentally with 3-methylcholanthrene, acetylaminofluorene, benzo(a)pyrene, and 7, 12-dimethylbenz(a)anthracene, with tumors evident 3 to 12 months postexposure (Couch and Harshbarger 1985; Hendricks et al., 1985). Under laboratory conditions, liver neoplasms were induced in two species of minnows (*Poeciliopsis* spp.) by repeated short-term exposures (6 hours once a week, for 5 weeks) to an aqueous suspension of 5 mg/l of 7, 12-dimethylbenz(a)anthracene. About 44% of the fish surviving this treatment developed hepatocellular neoplasms 6 to 9 months postexposure (Schultz and Schultz 1982). Eastern mudminnows (*Umbra pygmaea*) kept in water containing up to 700 ug PAHs/l for 11 days showed increased frequencies of chromosomal aberrations in gills: 30% vs. 8% in controls (Prein et al. 1978). High dietary benzo(a)pyrene levels of 500 mg/kg produced significant elevations in hepatic mixed-function oxidase levels in rainbow trout after 9 weeks (Hendricks et al. 1985). Rainbow trout fed diets containing 1,006 mg benzo(a)pyrene/kg for 12 months developed liver tumors (Couch et al. 1983). About 25% of rainbow trout kept on diets containing 1,000 mg benzo(a)pyrene/kg for 18 months had histologically confirmed liver neoplasms as compared to 15% after 12 months, with no evidence of neoplasia in controls (Hendricks et al. 1985). Young English sole may activate and degrade carcinogenic PAHs, such as benzo(a)pyrene, to a greater extent than adults, but additional research is needed to determine if younger fish are at greater risk than older sole to PAH-induced toxicity (Varanasi et al. 1984). In English sole, a high significant positive correlation between PAH metabolites (1-and 3-hydroxy benzo(a)pyrene, hydroxy and dehydrodiol metabolites of pyrene and fluoranthene) in bile, and idiopathic liver lesions, prevalence of neoplasms, megalocytic hepatosis, and total number of hepatic lesions (Krahn et al. 1986) suggests that selected PAH metabolites and key organs or tissues may be the most effective monitors of PAH contamination in aquatic organisms.

In addition to those effects of PAHs emphasizing survival, uptake, depuration, and carcinogenesis previously listed, a wide variety of additional effects have been documented for aquatic organisms. These include: inhibited reproduction of daphnids and delayed emergence of larval midges by fluorene (Finger et al. 1985); decreased respiration and heart rate in mussels (*Mytilus californianus*) by benzo(a)pyrene (Sabourin and Tullis 1981); increased weight of liver, kidney, gall bladder, and spleen of sea catfish (*Arius felis*) by 3-methylcholanthrene, which was (dose-related (Melius and Elam 1983); photosynthetic inhibition of algae and

macrophytes by anthracene, naphthalene, phenanthrene, pyrene (Neff 1985) and fluorene (Finger et al. 1985); immobilization of the protozoan, *Paramecium caudatum*, by anthracene, with an EC-50 (60 min) of 0.1 ug/l EPA 1980); perylene accumulation by algae (Stegeman 1981); accumulation without activation of benzo(a)pyrene and benzo(a)anthracene by a marine protozoan (*Parauronema acutum*), and biotransformation of various fluorenes by *P. acutum* to mutagenic metabolites (Lindmark 1981); interference by toluene and anthracene with benzo(a)pyrene uptake by freshwater amphipods (Landrum 1983); abnormal blood chemistry in oysters (*Crassostrea virginica*) exposed for one year to 5 ug 3-methylcholanthrene/l (Couch et al. 1983); and enlarged livers in brown bullheads from a PAH-contaminated river (Fabacher and Baumann 1985).

AMPHIBIANS AND REPTILES

Limited data were available on biological effects of benzo(a)pyrene, 3-methylcholanthrene, and perylene to reptiles and amphibians (Balls 1964; Stegeman 1981; Anderson et al. 1982; Schwen and Mannering 1982a, 1982b; Couch et al. 1983).

Implantation of 1.5 mg of benzo(a)pyrene crystals into the abdominal cavity of adult South African clawed toads (Balls 1964). Immature toads were more resistant with only 45% bearing lymphoid tumors of liver, kidney, spleen, or abdominal muscle 272 to 310 days after implantation of 1.5 mg of benzo(a)pyrene crystals in the dorsal lymph sac or abdominal cavity. Implantation of 3-methylcholanthrene crystals into *X. laevis* provokes development of lymphoid tumors similar to those occurring naturally in this species; moreover, these tumors are readily transplantable into other *Xenopus* or into the urodele species *Triturus cristatus* (Balls 1964). Intraperitoneal injection of perylene into tiger salamanders can result in hepatic tumors (Couch et al. 1983).

A critical point of interaction between PAHs and reptiles/amphibians involves the transformation of these compounds by cytochrome P-450-dependent monooxygenase systems (Stegeman 1981 ;Schwen and Mannering 1982a). Mixed-function oxidation systems can be induced in liver and skin of tiger salamanders by perylene (Couch et al. 1983) and 3-methylcholanthrene (Anderson et al. 1982), and in liver of the leopard frog (*Rana pipiens*) and garter snake (*Thamnophis* sp.) by benzo(a)pyrene and 3-methylcholanthrene (Stegeman 1981; Schwen and Mannering 1982a, 1982b). A single dose of 40 mg/kg body weight of 3-methylcholanthrene was sufficient to induce mixed-function oxidase activity for several weeks in the leopard frog (Schwen and Mannering 1982b). Amphibians, including tiger salamanders, are quite resistant to PAH carcinogenesis when compared to mammals, according to Anderson et al. (1982). This conclusion was based on studies with *Ambystoma* hepatic microsomes and their inability to produce mutagenic metabolites of benzo(a)pyrene and perylene (as measured by bacterial *Salmonella typhimurium* strains used in the Ames test); however, rat liver preparations did produce mutagenic metabolites under these procedures (Anderson et al. 1982).

BIRDS

Only two articles were available on PAHs and avian wildlife, and both concerned mallards (*Anas platyrhynchos*). In one study, Patton and Dieter (1980) fed mallards diets that contained 4,000 mg PAHs/kg (mostly as naphthalenes, naphthenes, and phenanthrene) for a period of 7 months. No mortality or visible signs of toxicity were evident during exposure; however, liver weight increased 25% and blood flow to liver increased 30%, when compared to controls. In the second study, Hoffman and Gay (1981) measured embryotoxicity of various PAHs applied externally, in a comparatively innocuous synthetic petroleum mixture, to the surface of mallard eggs. The most embryotoxic PAH tested was 7,12-dimethylbenz(a)anthracene: approximately 0.002 ug/egg (equivalent to about 0.036 ug/kg fresh weight, based on an average weight of 55 g per egg) caused 26% mortality in 18 days, and, among survivors, produced significant reduction in embryonic growth and a significant increase in the percent of anomalies, e.g., incomplete skeletal ossification, defects in eye, brain, liver, feathers, and bill. At 0.01 ug 7,12-dimethylbenz(a)anthracene/egg, only 10% survived to day 18. Similar results were obtained with 0.015 ug (and higher) chrysene/egg. For benzo(a)pyrene, 0.002 ug/egg did not affect mallard survival, but did cause embryonic growth reduction and an increased incidence of abnormal survivors. At 0.01 ug benzo(a)pyrene/egg, 60% died in 18 days; at 0.05 ug/egg, 75% were dead within 3 days of treatment. Embryos may contain microsomal enzymes that can metabolize PAHs to more highly toxic intermediates than can adults, and avian embryos may have a greater capacity to metabolize PAHs in this manner than do mammalian embryos and fetuses (as quoted in Hoffman and Gay 1981); this observation warrants additional research. Several investigators have suggested that the presence of PAHs in petroleum, including benzo(a)pyrene, chrysene, and 7,12-dimethylbenz(a)anthracene, significantly enhances the overall embryotoxicity in avian species, and that the relatively small percent of the aromatic hydrocarbons contributed

by PAHs in petroleum may confer much of the adverse biological effects reported after eggs have been exposed to microliter quantities of polluting oils (Hoffman and Gay 1981; Albers 1983).

MAMMALS

Numerous PAH compounds are distinct in their ability to produce tumors in skin and in most epithelial tissues of practically all animal species tested; malignancies were often induced by acute exposures to microgram quantities. In some cases, the latency period car be as short as 4 to 8 weeks, with the tumors resembling human carcinomas (EPA 1980). Certain carcinogenic PAHs are capable of passage across skin, lungs, and intestine, and can enter the rat fetus, for example, following intragastric or intravenous administration to pregnant dams (EPA 1980). In most cases, the process of carcinogenesis occurs over a period of many months in experimental animals, and many years in man. The tissue affected is determined by the route of administration and species under investigation. Thus, 7,12-dimethylbenz(a)anthracene is a potent carcinogen for the mammary gland of young female rats after oral or intravenous administration; dietary benzo(a)pyrene leads to leukemia, lung adenoma, and stomach tumors in mice and both PAH compounds can induce hepatomas in skin of male mice when injected shortly after birth (Dipple 1985). Acute and chronic exposure to various carcinogenic PAHs have resulted in destruction of hematopoietic and lymphoid tissues, ovotoxicity, antispermatogonic effects, adrenal necrosis, changes in the intestinal and respiratory epithelia, and other affects (Table 7; EPA 1980; Lee and Grant 1981). For the most part, however, tissue damage occurs at dose levels that would also be expected to induce carcinomas, and thus the threat of malignancy predominates in evaluating PAH toxicity. There is a scarcity of data available on the toxicological properties of PAHs which are not demonstrably carcinogenic to mammals (EPA 1980; Lee and Grant 1981).

Target organs for PAH toxic action are diverse, due partly to extensive distribution in the body and also to selective attack by these chemicals on proliferating cells (EPA 1980). Damage to the hematopoietic and lymphoid system in experimental animals is a particularly common observation (EPA 1980). In rats, the target organs for 7,12-dimethylbenz(a)anthracene are skin, small intestine, kidney, and mammary gland, whereas in fish the primary target organ is liver (Schultz and Schultz 1982). Application of carcinogenic PAHs to mouse skin leads to destruction of sebaceous glands and to hyperplasia, hyperkeratosis, and ulceration (EPA 1980). Tumors are induced in mouse skin by the repeated application of small doses of PAHs, by a single application of a large dose, or by the single application of a subcarcinogenic dose (initiation) followed by repeated application of certain noncarcinogenic agents (promotion) (Dipple 1985). Newborn mice were highly susceptible to 3-methylcholanthrene, with many mice dying from acute or chronic wasting disease following treatment; some strains of mice eventually developed thynomas, but other strains showed no evidence despite serious damage to the thymus (EPA 1980).

In general, PAH carcinogens transform cells through genetic injury involving metabolism of the parent compound to a reactive diol epoxide. This, in turn, can then form adducts with cellular molecules, such as DNA, RNA, and proteins, resulting in cell transformation (Dipple 1985; Ward et al. 1985). In the case of benzo(a)pyrene, one isomer of the 7,8-diol, 9,10-epoxide is an exceptionally potent carcinogen to newborn mice and is believed to be the ultimate carcinogenic metabolite of this PAH (Slaga et al. 1978). One of the most toxicologically significant processes involved in the response to PAH absorption is the interaction with drug metabolizing enzyme systems (Lee and Grant 1981). Increased production of mixed-function oxidase enzymes in various small mammals has been induced by halogenated naphthalenes (Campbell et al. 1983), 3-methylcholanthrene (Miranda and Chhabra 1980), and numerous other PAHs (EPA 1980). PAH metabolites produced by microsomal enzymes in mammals can be arbitrarily divided into water soluble groups, and organosoluble groups such as phenols, dihydrodiols, hydroxymethyl derivatives, quinones, and epoxides (EPA 1980). In the case of benzo(a)pyrene, the diol epoxides are usually considered as the ultimate carcinogens. Other microsomal enzymes convert epoxide metabolites to easily excretable water soluble compounds, with excretion primarily through feces and the hepatobiliary system (EPA 1980). Interspecies differences in sensitivity to PAH-induced carcinogenesis are due largely to differences in levels of fixed function oxidase activities, and these will directly affect rates at which active metabolites are converted to less active products (Neff 1979).

Investigators agree that unsubstituted aromatic PAHs with less than 4 condensed rings have not shown tumorgenic activity; that many, but not all, 4-, 5-, and 6-ring PAH compounds are carcinogenic; and that only a few unsubstituted hydrocarbons with 7 rings or greater are tumorogenic or. carcinogenic (Neff 1979; EPA 198);

Dipple 1985). Many PAH compounds containing 4 and 5 rings and some containing 6 or more rings, provoke local tumors after repeated application to the dorsal skin of mice; the tumor incidence exhibited a significant dose-response relationship (Grimmer et al. 1985). Among unsubstituted PAHs containing a nonaromatic ring, e.g., cholanthrene and acenapthanthracene, all active carcinogens retained an intact phenanthrene segment (EPA 1980). The addition of alkyl substituentss in certain positions in the ring system of a fully aromatic PAH will often confer carcinogenic activity or dramatically enhance existing carcinogenic potency. For example, monomethyl substitution of benz(a)anthracene can lead to strong carcinogenicity in mice, with potency depending on the position of substitution in the order 7 > 6 > 8 = 12 > 9; a further enhancement of carcinogenic activity is produced by appropriate dimethyl substitution, with 7,12-dimethylbenz(a)anthracene among the most potent PAH carcinogens known. Alkyl substitution of partially aromatic condensed ring systems may also add considerable carcinogenic activity as is the case with 3-methylcholanthrene. With alkyl substitutes longer than methyl, carcinogenicity levels decrease, possibly due to a decrease in transport through cell membranes (EPA 1980).

Table 7. Some effects of PAHs on selected laboratory animals.

Effect (units), organism, PAH compound	Concentration	Reference[a]

A good correlation exists between skin tumor initiating activities of various benzo(a)pyrene metabolites nd their mutagenic activity in mammalian cell mutagenesis systems (Slaga et al. 1978), although variations in chromosome number and structure may accompany tumors induced by various carcinogenic PAHs in rats, mice, and hamsters (Bayer 1978; EPA 1980). Active PAH metabolites, e.g., dihydrodiols or diol epoxides, can produce sister chromatid exchanges in Chinese hamster ovary cell (Bayer 1978; EPA 1980; Pal 1984). When exchanges were induced by the diol epoxide, a close relationship exists between the frequency of sister chromatid exchanges and the levels of deoxyribnucleoside-diol-epoxide adduct formation (Pal 1984). In general, noncarcinogenic PAHs were not mutagenic (EPA 1980).

Laboratory studies with mice have shown that many carcinogenic PAHs adversely affect the immune system, thus directly impacting an organism's general health, although noncarcinogenic analogues had no immunosuppressive effect; further, the more carcinogenic the PAH, the greater the immunosuppression (Ward et al. 1985).

Destruction of oocytes and follicles in mice ovary is documented following intraperitoneal injection of benzo(a)pyrene; 3-methylcholanthrene, and 7,12-dimethylbenz(a)anthracene; the rate of destruction was proportional to the activity of the ovarian cytochrome P-450 dependent monooxygenase, as well as the carcinogenicity of the PAH (Mattison 1980). However, no information is presently available to indicate whether PAHs present a hazard to reproductive success. In those cases where teratogenic effects are clearly evident, e.g., 7, 12-dimethylbenz(a)anthracene, the required doses were far in excess of realistic environmental exposures (Lee and Grant 1981).

Numerous studies show that unsubstituted PAHs do not accumulate in mammalian adipose tissues despite their high lipid solubility, probably because they tend to be rapidly and extensively metabolized (EPA 1980; Lee and Grant 1981).

Biological half-life (Tb 1/2) of PAHs is limited, as judged by rodent studies. In the case of benzo(a)pyrene and rat blood and liver, Tb 1/2 values of 5 to 10 minutes were recorded; the initial rapid elimination phase was followed by a slower disappearance phase lasting 6 hours or more (EPA 1980). Tb 1/2 values from the site of subcutaneous injection in mice were 1.75 weeks for benzo(a)pyrene, 3.5 weeks for 3-methylcholanthrene, and 12 weeks for dibenz(a,h)anthracene; the relative carcinogenicity of each compound was directly proportional to the time of retention at the injection site (Pucknat 1981).

Many chemicals are known to modify the action of carcinogenic PAHs in experimental animals, including other PAHs that are weakly carcinogenic or noncarcinogenic. The effects of these modifiers on PAH metabolism appear to fall into three major categories: those which alter the metabolism of the carcinogen, causing decreased activation or increased detoxification; those which scavenge active molecular species of carcinogens to prevent their reaching critical target sites in the cell; and those which exhibit competitive antagonism (DiGiovanni and Slaga 1981b). For example, benz(a)anthracene, a weak carcinogen when applied simultaneously with dibenz(a,h)anthracene, inhibited the carcinogenic action of the latter in mouse skin; a similar case is made for benzo(e)pyrene or dibenz(a,c)anthracene applied to mouse skin shortly prior to initiation with 7,12-dimethylbenz(a)anthracene, or 3-methylcholanthrene (DiGiovanni and Slaga 1981a). Benzo(a)pyrene, a known carcinogen, interacts synergistically with cyclopenta(cd)pyrene, a moderately strong carcinogen found in automobile exhausts, according to results of mouse skin carcinogenicity studies (Rogan et al. 1983). Other PAH combinations were cocarcinogenic, such as benzo(e)pyrene, pyrene, and fluoranthene

applied repeatedly with benzo(a)pyrene to the skins of mice (DiGiovanni and Slaga 1981a). Effective inhibitors of PAH-induced tumor development include selenium, vitamin E, ascorbic acid, butylated hydroxytoluene, and hydroxyanisole (EPA 1980). In addition, protective effects against PAH-induced tumor formation have been reported for various naturally occurring compounds such at flavones, retenoids, and vitamin A (EPA 1 80). Until these interaction effects are clarified, the results of single substance laboratory studies may be extremely difficult to apply to field situations of suspected PAH contamination. Additional work is also needed of PAH dose-response relationships, testing relevant environmental PAHs for carcinogenicity, and elucidating effects of PAH mixtures on tumor formation (Grimmer 1983).

RECOMMENDATIONS

At present, no criteria or standards have been promulgated for PAHs by any regulatory agency for the protection of sensitive species of aquatic organisms or wildlife. This observation is not unexpected in view of several factors: (1) the paucity of data on PAH background concentrations in wildlife and other natural resources; (2) the absence of information on results of chronic oral feeding studies of PAH mixtures and the lack of a representative PAH mixture for test purposes; and (3) the demonstrable--and as yet, poorly understood--effects of biological modifiers, such as sex, age, and diet, and interaction effects of PAHs with inorganic and other organic compounds, including other PAHs.

Nevertheless, the growing data base for aquatic life indicates a number of generalizations: (1) many PAHs are acutely toxic at concentrations between 50 and 1,000 ug/l; (2) deleterious sublethal responses are sometimes observed at concentrations in the range of 0.1 to 5.0 ug/l; (3) uptake can be substantial, but depuration is usually rapid except in some species of invertebrates; and (4) whole body burdens in excess of 300 ug benzo(a)pyrene/kg (and presumably other PAHs) in certain teleosts would be accompanied by a rise in the activity of detoxifying enzymes.

Current aquatic research has focused on PAHs because of their known relationship with carcinogenesis and mutagenesis. Many reports exist of high incidences of cancer-like growths and developmental anomalies in natural populations of aquatic animals and plants, but none conclusively demonstrate the induction of cancer by exposure of aquatic animals to environmentally realistic levels of carcinogenic PAHs in the water column, diet, or sediments (Neff 1982b, 1985). However, recent studies by Baumann, Malins, Black, Varanasi and their coworkers, among others, have now established that sediments heavily contaminated with PAHs from industrial sources were the direct cause of elevated PAH body burdens and elevated frequencies of liver neoplasia in fishes from these locales. At present, only a few sites containing high PAH concentrations in sediments have been identified (Couch and Harshbarger 1985), suggesting an urgent need to identify and to evaluate other PAH-contaminated aquatic sites. Most fishery products consumed by upper trophic levels, including man, contain PAH concentrations similar to those in green vegetables and smoked and charcoal-broiled meats, and would probably represent a minor source of PAH toxicity; however, consumption of aquatic organisms, especially filter-feeding bivalve molluscs, from regions severely contaminated with petroleum or PAH-containing industrial wastes, should be avoided (Jackim and Lake 1978; Neff 1982b). Neff (1982b) suggested that repeated consumption of PAH-contaminated shellfish may pose a cancer risk to humans. If true, this needs to be evaluated using seabirds, pinnipeds, and other wildlife groups which feed extensively on molluscs that are capable of accumulating high burdens of carcinogenic PAHs, in order to determine if similar risks exist.

For avian wildlife, data are missing on PAH background concentrations and on acute and chronic toxicity; these data should be collected posthaste. Studies with mallard embryos and PAHs applied to the egg surface showed toxic and adverse sublethal effects at concentrations between 0.036 and 0.18 ug PAH/kg whole egg (Hoffman and Gay 1981). Additional research is needed on petroleum-derived PAHs and their effects on developing embryos of seabirds and other waterfowl.

PAH criteria for human health protection (Table 8) were derived from tests with small laboratory mammals, primarily rodents. Accordingly, these proposed criteria should become interim guidelines for protection of nonhuman mammalian resources pending acquisition of more definitive data. The proposed PAH criteria are controversial. Pucknat (1981) states that there is no way at present to quantify the potential human health risks incurred by the interaction of any PAH with other PAHs or with other agents in the environment, including tumor initiators, promoters, and inhibitors. The problem arises primarily from the diversity of test systems and bioassay conditions used for determining carcinogenic potential of individual PAHs in experimental animals, and is confounded by the lack of a representative PAH mixture for test purposes, the absence of data for animal and

human chronic oral exposures to PAH mixtures, and the reliance on data derived from studies with benzo(a)pyrene to produce generalizations concerning environmental effects of PAHs--generalizations which may not be scientifically sound--according to Pucknat (1981). EPA (1980) emphasizes that only a small percentage of PAH compounds are known to be carcinogenic, and that measurements of total PAHs (i.e., the sum of all multiple fused-ring hydrocarbons having no heteroatoms) can not be equated with carcinogenic potential; furthermore, when the term "total PAHs" is used, the compounds being considered should be specified for each case. Lee and Grant (1981) state that an analysis of dose-response relationships for PAH-induced tumors in animals shows, in some cases, deviation from linearity in dose-response curves, especially at low doses, suggesting a two-stage model consistent with a linear nonthreshold pattern. Because overt tumor induction follows a dose-response relationship consistent with a multihit promotion process, the multihit component of carcinogenesis may be supplied by environmental stimuli not necessarily linked or related to PAH exposure.

The well-documented existence of carcinogenic and anticarcinogenic agents strongly suggests that a time assessment of carcinogenic risk for a particular PAH can be evaluated only through a multifactorial analysis (Lee and Grant 1981). One of the most toxicologically significant processes involved in the response to PAH absorption is the interaction with drug metabolizing enzyme systems. The induction of this enzyme activity in various body tissues by PAHs and other xenobiotics is probably critical to the generation of reactive PAH metabolites at the target site for tumor induction. At present, wide variations occur in human and animal carcinogen-metabolizing capacity. Moreover, it has not yet been possible to definitely correlate enzyme activity with susceptibility to carcinogenesis. The obligatory coupling of metabolic activation with PAH-induced neoplasia in animals indicates that the modulation of drug metabolizing enzymes is central to carcinogenesis (Lee and Grant 1981).

[b]Total of 3 PAHs: benzo (a) pyrene, benzo (j) fluoranthene, and indeno (1,2,3-cd) pyrene.

[c]Based on all carcinogenic PAHs.

[d]Assuming 1,600 g food daily, 70 kg adult, 1 to 10 g total PAHs/diet.

[e]As above, except 0.1 to 1.0 g benzo (a) pyrene/diet.

[f]Assuming average of 15 to 23 m^3 of air inhaled daily.

[g]From Wang and Meresz (1982).

PAHs from drinking water contribute only a small proportion of the average total human intake (Harrison et al. 1975). The drinking water quality criterion for carcinogenic PAH compounds is based on the assumption that each compound is as potent as benzo(a)pyrene, and that the carcinogenic effect of the compounds is proportional to the sum of their concentrations (EPA 1980). Based on an oral feeding study of benzo(a)pyrene in mice, the concentration of this compound estimated to result in additional risk of one additional case for every 100,000 individuals exposed (i.e, 10^{-5}) is 0.028 ug/l. Therefore, with this assumption, the sum of the concentrations of all carcinogenic PAH compounds should be less than 0.028 ug/l in order to keep the lifetime cancer risk below 10^{-4} (EPA 1980). The corresponding recommended criteria which may result in an incremental cancer risk of 10^{-6} and 10^{-7} over the lifetime are 0.0028 and 0.00028 ug/l, respectively (Table 8). If the above estimates are made for consumption of aquatic organisms only, the levels are 0.311 (10^{-5}), 0.031(10^{-6}), and 0.003(10^{-7}) ug/kg, respectively (EPA 1980). The use of contaminated water for irrigation can also spread PAHs into other vegetable foodstuffs (EPA 1980). When vegetables grown in a PAH-polluted area are thoroughly washed and peeled, their contribution to total PAH intake in humans is not significant (Wang and Meresz 1982). Herbivorous wildlife, however, may ingest significant quantities of various PAHs from contaminated vegetables--but no data were available on this subject.

PAHs are widely distributed in the environment as evidenced by their detection in sediments, soils, air, surface waters, and plant and animal tissues. However, the ecological impact of PAHs is uncertain. PAHs show little tendency for bioconcentration despite their high lipid solubility (Pucknat 1981), probably because most PAHs are rapidly metabolized. Sims and Overcash (1983) list a variety of research needs regarding PAHs in soil-plant systems. Specifically, research is needed to establish: the rates of PAH decomposition in soils; the soil PAH levels above which PAH constituents adversely affects the food chain and enhancement factors that increase degradation rates of PAHs, especially PAHs with more than 3 rings. Once these factors have been determined, PAH disposal into soils may become feasible at environmentally nonhazardous levels.

Diet is the major source of PAHs to humans. Authorities agree that most foods contain 1 to 10 ug total PAHs/kg fresh weight, that smoking or barbecuing fish and meats increases total PAH content up to 100X, that contaminated molluscs and crustaceans may contribute significantly to PAH intake, and that PAH carcinogenic risk to humans has existed at least since man began to cook his food (Barnett 1976; EPA 1980; Lee and Grant 1981; Lawrence and Weber 1984a). A total of 22 PAHs has been identified in foods, of which 11 have been found to be carcinogenic in experimental animals. Of these, only 5 (benzo(a)pyrene, benz(a)anthracene, 3-methylcholanthrene, dibenz(a,h)anthracene, and 7,12-dimethylbenz(a)anthracene) have been demonstrated to induce tumors following oral administration to rats and mice, and only 3 of the 11 exhibited positive dose-response relationships in chronic studies with mice (Lo and Sandi 1978). At the present time, there is no evidence that any of the 11 known carcinogenic PAHs or their combinations can cause cancer in human beings via the oral route, especially in quantities likely to be present in foods (Lo and Sandi 1978).

In view of the carcinogenic characteristics of many PAH compounds, their increasing concentrations in the environment should be considered alarming, and efforts should be made to reduce or eliminate them wherever possible (Suess 1976).

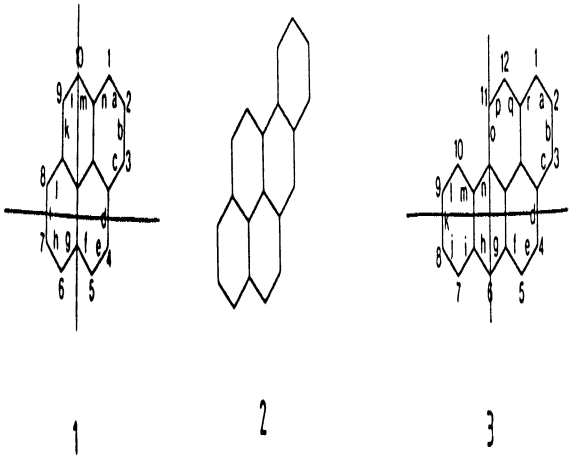

Figure 1. Nomenclature of PAHs (modified from Lee and Grant, and Grimmer 1983). The PAH formula is oriented so that the greatest number of rings are in a horizontal row and a maximum number of rings are above and to the right of the horizontal row. The first carbon atom that belongs to the uppermost ring and is not engaged in ring fusion with another ring is given the number C-1; numbering continues in a clockwise direction omitting those carbon atoms which do not carry a hydrogen atom. The bond between C-1 and C-2 is designated as side “a”; other peripheral sides continue in clockwise direction in alphabetical order. Examples are: (1) pyrene (correctly oriented, numbered, and lettered), (2) benzo(a)pyrene (not oriented correctly), (3) benzo(a)pyrene (correctly oriented, numbered, and lettered).

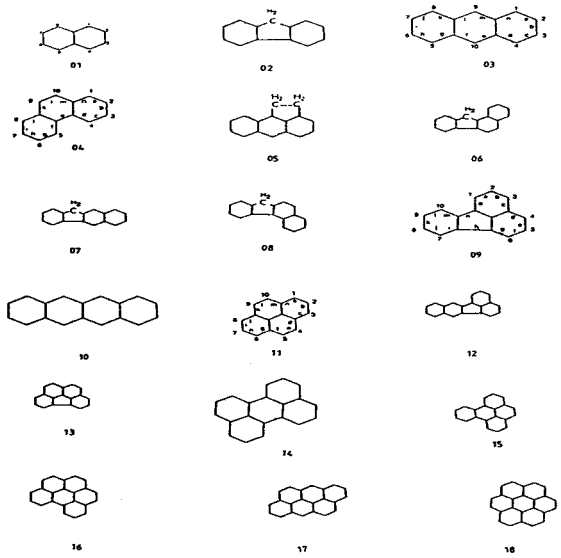

Figure 2. Ring structures of representative noncarcinogenic PAHs (modified from Lee and Grant 1981, and Neff 1985). The numbering and lettering system for several PAHs is also given. Compounds are: (1) naphthalene, (2) fluorene, (3) anthracene, (4) phenanthrene, (5) aceanthrylene, (6) benzo(a)fluorene, (7) benzo(a)fluorene, (8) benzo(a)fluorene, (9) fluoranthene, (10) napthacene, (11) pyrene, (12) benzo(a)fluoranthene, (13) benzo(g, h, i)fluoranthene, (14) perylene, (15) benzo(e)pyrene, (16) benzo(g, h, i)perylene, (17) anthanthrene, (18) coronene.

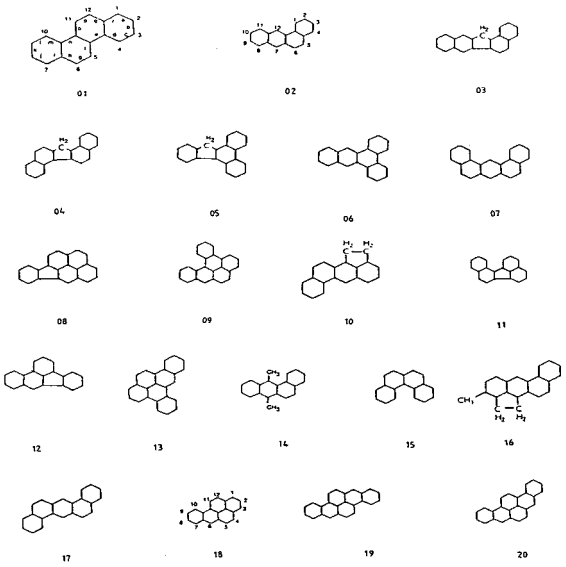

Figure 3. Ring structures of representative tumorogenic, cocarcinogenic, and carcinogenic PAHs (modified from Lee and Grant 1981). The numbering and lettering system for several PAHs is also given. Compounds are: (1) chrysene, (2) benz(a)anthracene, (3) dibenzo(a,h)fluorene, (4) dibenzo(a,g)fluorene, (5) dibenzo(a,c)fluorene, (6) dibenz(a,c)anthracene, (7) dibenz(a,j)anthracene, (8) indeno (1,2,3-cd) pyrene, (9) dibenzo(a,1)pyrene, (10) cholanthrene, (11) benzo(j)fluoranthene, (12) benzo(b)fluoranthene, (13) dibenzo(a,e)pyrene, (14) dimethylbenz(a)anthracene, (15) benzo(c)phenanthrene, (16) 3-methylcholanthrene, (17) dibenz(a,h)anthracene, (18) benzo(a)pyrene, (19) dibenzo(a,h)pyrene, (20) dibenzo(a,i)pyrene. Compounds 1 to 9 are weakly carcinogenic, cocarcinogenic, or tumorogenic; compounds 10 to 13 are carcinogenic; compounds 14 to 20 are strongly carcinogenic.

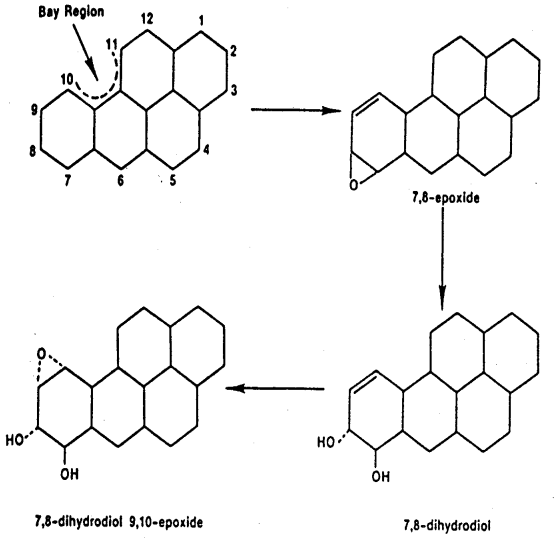

Figure 4. The bay region dihydrodiol epoxide route of benzo(a)pyrene (modified from Dipple 1985).

ARSENIC HAZARDS TO FISH, WILDLIFE, AND INVERTEBRATES: A SYNOPTIC REVIEW

by
Ronald Eisler

U.S. Fish and Wildlife Service
Patuxent Wildlife Research Center
Laurel, MD 20708

SUMMARY

Arsenic (As) is a relatively common element that occurs in air, water, soil, and all living tissues. It ranks 20th in abundance in the earth's crust, 14th in seawater, and 12th in the human body.

Arsenic is a teratogen and carcinogen that can traverse placental barriers and produce fetal death and malformations in many species of mammals. Although it is carcinogenic in humans, evidence for arsenic-induced carcinogenicity in other mammals is scarce. Paradoxically, evidence is accumulating that arsenic is nutritionally essential or beneficial. Arsenic deficiency effects, such as poor growth, reduced survival, and inhibited reproduction, have been recorded in mammals fed diets containing <0.05 mg As/kg, but not in those fed diets with 0.35 mg As/kg. At comparatively low doses, arsenic stimulates growth and development in various species of plants and animals.

Most arsenic produced domestically is used in the manufacture of agricultural products such as insecticides, herbicides, fungicides, algicides, wood preservatives, and growth stimulants for plants and animals. Living resources are exposed to arsenic by way of atmospheric emissions from smelters, coal-fired power plants, and arsenical herbicide sprays; from water contaminated by mine tailings, smelter wastes, and natural mineralization; and from diet, especially from consumption of marine biota. Arsenic concentrations are usually low (<1.0 mg/kg fresh weight) in most living organisms but are elevated in marine biota (in which arsenic occurs as arsenobetaine and poses little risk to organisms or their consumer) and in plants and animals from areas that are naturally arseniferous or are near industrial manufacturers and agricultural users of arsenicals. Arsenic is bioconcentrated by organisms, but is not biomagnified in the food chain.

Arsenic exists in four oxidation states, as inorganic or organic forms. Its bioavailability and toxic properties are significantly modified by numerous biological and abiotic factors that include the physical and chemical forms of arsenic tested, the route of administration, the dose, and the species of animal. In general, inorganic arsenic compounds are more toxic than organic compounds, and trivalent species are more toxic than pentavalent species. Arsenic may be absorbed by ingestion, inhalation, or through permeation of skin or mucous membranes; cells take up arsenic through an active transport system normally used in phosphate transport. The mechanisms of arsenic toxicity differ greatly among chemical species, although all appear to cause similar signs of poisoning. Biomethylation is the preferred detoxification mechanism for absorbed inorganic arsenicals; methylated arsenicals usually clear from tissues within a few days.

Episodes of arsenic poisoning are ether acute or subacute; chronic cases of arsenosis are seldom encountered in any species except man. Single oral doses of arsenicals fatal to 50% of sensitive species tested ranged from 17 to 48 mg/kg body weight (BW) in birds and from 2.5 to 33 mg/kg BW in mammals. Susceptible species of mammals were adversely affected at chronic doses of 1 to 10 mg As/kg BW, or 50 mg As/kg diet. Sensitive aquatic species were damaged at water concentrations of 19 to 48 ug As/l (the U.S. Environmental Protection Agency drinking water criterion for human health protection is 50 ug/l), 120 mg As/kg diet, or (in the case of freshwater fish) tissue residues >1.3 mg/kg fresh weight. Adverse effects to crops and vegetation were recorded at 3 to 28 mg of water soluble As/l (equivalent to about 25 to 85 mg total As/kg soil) and at atmospheric concentrations >3.9 ug As/m^3.

Numerous and disparate arsenic criteria have been proposed for the protection of sensitive natural resources; however, the general consensus is that many of these criteria are inadequate and that additional information is needed in at least five categories: (1) developing standardized procedures to permit correlation of biologically observable effects with suitable chemical forms of arsenic; (2) conducting studies under controlled conditions with appropriate aquatic and terrestrial indicator organisms to determine the effects of chronic exposure to low doses of inorganic and organic arsenicals on reproduction, genetic makeup, adaptation, disease resistance, growth, and other variables (3) measuring interaction effects of arsenic with other common environmental contaminants, including carcinogens, cocarcinogens, and promoting agents; (4) monitoring the incidence of cancer and other abnormalities in natural resources from areas with relatively high arsenic levels, and correlating these with the possible carcinogenicity of arsenic compounds; and (5) developing appropriate models of arsenic cycling and budgets in natural ecosystems.

White, and Laverne Cleveland for technical and scientific review; and Paul H. Eschmeyer and James R. Zuboy for editorial services.

INTRODUCTION

Anxiety over arsenic (As) is understandable, and frequently justifiable. Arsenic compounds were the preferred homicidal and suicidal agents during the Middle Ages, and arsenicals have been regarded largely in terms of their poisonous characteristics in the nonscientific literature (NAS 1977). Data collected on animals, including man, indicate that inorganic arsenic can cross the placenta and produce mutagenic, teratogenic, and carcinogenic effects in offspring (Nagymajtenyi et al. 1985). Correlations between elevated atmospheric arsenic levels and mortalities from cancer, bronchitis, and pneumonia were established in an epidemiological study in England and Wales, where deaths from respiratory cancer were increased at air concentrations >3 ug As/m^3 (NRCC 1978). Chronic arsenical poisoning, including skin cancer and a gangrenous condition of the hand and feet called Blackfoot's disease, has occurred in people from several communities in Europe, South America, and Taiwan that were exposed to elevated concentrations of arsenic in drinking water (EPA 1980). More recently, about 12,000 Japanese infants were poisoned (128 deaths) after consuming dry milk containing 15 to 24 mg inorganic As/kg, which originated from contaminated sodium phosphate used as a milk stabilizer. Fifteen years after exposure, the survivors sustained an elevated frequency of severe hearing loss and brain wave abnormalities Pershagen and Vahter 1979).

Many reviews on ecotoxicological aspects of arsenic in the environment are available; particularly useful are those by Woolson (1975), NAS (1977), NRCC (1978), Pershagen and Vahter (1979), EPA (1980, 1985), Hood (1985), and Andreas (1986). These authorities agree on six points. 1. Arsenic is a relatively common element, and is present in air, water, soil, plants, and in all living tissues. 2. Arsenicals have been used in medicine as chemotherapeutics since 400 BC, and organoarsenicals were used extensively for this purpose until about 1945, with no serious effects when judiciously administered. 3. Large quantities of arsenicals are released into the environment as a result of industrial and especially agricultural activities, and these may pose potent ecological dangers. 4. Exposure of humans and wildlife to arsenic may occur through air (emissions from smelters, coal-fired power plants, herbicide sprays), water (mine tailings runoff, smelter wastes, natural mineralization), and food (especially seafoods). 5. Chronic exposure to arsenicals by way of the air, diet, and other routes have been associated with liver, kidney, and heart damage hearing loss; brain wave abnormalities; and impaired resistance to viral infections. And 6. Exposure to arsenic has been associated with different types of human cancers such as respiratory cancers and epidermoid carcinomas of the skin, as well as precancerous dermal keratosis. Only recently (Deknudt et al. 1986) has the epidemiological evidence of human carcinogenicity been confirmed by carcinogenesis in experimental animals.

This report was prepared in response to requests for information from environmental contaminant specialists of the U. S. Fish and Wildlife Service. It is part of a continuing series of reviews on chemical pollutants and natural resources.

SOURCES, FATE, AND USES

Global production of arsenic is estimated to be 75,000 to 100,000 tons annually, of which the United States produces about 21,000 tons and uses about 44,000 tons; major quantities are imported from Sweden, the world's leading producer (NAS 1977; EPA 1980). Almost all (97%) of the arsenic made worldwide enters end-product manufacture in the form of arsenic trioxide (As_2O_3), and the rest is used as additives in producing special lead and copper alloys (NAS 1977). More than 80% of the As_2O_3 is used to manufacture products with agricultural application, such as insecticides, herbicides, fungicides, algicides, sheep dips, wood preservatives, dyestuffs, and the medicines for eradication of tapeworm in sheep and cattle (NAS 1977). The sole producer and refiner of As_2O_3 in the United States is a copper smelter in Tacoma, Washington (NAS 1977).

Arsenic naturally occurs as sulfides and as complex sulfides of iron, nickel, and cobalt (Woolson 1975). In one form or another, arsenic is present in rocks, soils, water, and living organisms at concentrations of parts per billion to parts per million (NAS 1977). Soil arsenic levels are normally elevated near arseniferous deposits, and in mineralized zones containing gold, silver, and sulfides of lead and zinc (Dudas 1984). Secondary iron oxides formed from the weathering of pyrite act as scavengers of arsenic (Dudas 1984). Pyrite is a known carrier of arsenic and may contain up to 5,600 mg/kg; for example, total arsenic is 10X above normal background levels in soils derived from pyritic shale (Dudas 1984). Natural weathering of rocks and soils adds about 40,000 tons of arsenic to the oceans yearly, accounting for <0.01 mg/l input to water on a global basis (NRCC 1978). Many species of marine plants and animals often contain naturally high concentrations of arsenic (NAS 1977), but it is

usually present in a harmless organic form (Woolson 1975). Anthropogenic input of arsenic to the environment is substantial, and exceeds that contributed by natural weathering processes by a factor of about 3X (NRCC 1978).

The most important concept with respect to arsenic cycling in the environment is constant change. Arsenic is ubiquitous in living tissue and is constantly being oxidized, reduced, or otherwise metabolized. In soils, insoluble or slightly soluble arsenic compounds are constantly being resolubilized, and the arsenic is being presented for plant uptake or reduction by organisms and chemical processes. Man reportedly has modified the arsenic cycle only by causing localized high concentrations (NAS 1977). The speciation of arsenic in the environment. is affected partly by indiscriminate biological uptake, which consumes about 20% of the dissolved arsenate pool and results in measurable concentrations of reduced and methylated arsenic species. The overall arsenic cycle is similar to the phosphate cycle; however, regeneration time for arsenic is much slower--on the order of several months (Sanders 1980). The ubiquity of arsenic in the environment is evidence of the redistribution processes that have been operating since early geologic time (Woolson 1975). A prehuman steady state solution to the global arsenic cycle (Austin and Millward 1984) indicates that major reservoirs of arsenic (in kilotons) are magma (50 billion), sediments (25 billion), oceanic deep waters (1.56 million), land (1.4 million), and ocean mixed layers (270,000); minor amounts occur in ocean particulates (100), and in continental (2.5) and marine tropospheres (0.069). Arsenic is significantly mobilized from the land to the troposphere by both natural and anthropogenic processes. Industrial emissions account for about 30% of the present day burden of arsenic in the troposphere (Austin and Millward 1984). Agronomic ecosystems, for example, may receive arsenic from agricultural sources such as organic herbicides, irrigation waters, and fertilizers, and from such nonagricultural sources as fossil fuels and industrial and municipal wastes (Woolson 1975). Arsenic is mobile and nonaccumulative in air, pant, and water phases of agronomic ecosystems; arsenicals sometimes accumulate in soils, but redistribution mechanisms usually preclude hazardous accumulations (Woolson 1975).

Arsenic compounds have been used in medicine since the time of Hippocrates, ca. 400 BC (Woolson 1975). Inorganic arsenicals have been used for centuries, and organoarsenicals for at least a century in the treatment of syphylis, yaws, amoebic dysentery, and trypanosomiasis (NAS 1977). During the period 1200 to 1650, however, arsenic was used extensively in homicides (NRCC 1978). In 1815, the first accidental death was reported from arsine (AsH_3) poisoning, and in 1900-1903 accidental poisonings from consumption of arsenic-contaminated beer were widely reported (NRCC 1978). In 1938, it was established that arsenic can counteract selenium toxicity (NRCC 1978). The introduction of arsphenamine, an organoarsenical, to control venereal disease earlier this century gave rise to intensive research by organic chemists, which resulted in the synthesis of at least 32,000 arsenic compounds. But the advent of penicillin and other newer drugs nearly eliminated the use of organic arsenicals as human therapeutic agents (EPA 1980). Arsenical drugs are still used in treating certain tropical diseases, such as African sleeping sickness and amoebic dysentery, and are used in veterinary medicine to treat parasitic diseases, including filariasis in dogs (*Canis familiaris*) and blackhead in turkeys (*Meleagris gallopavo*) and chickens, *Gallus* spp. (NAS 1977). Today, abnormal sources of arsenic that can enter the food chain from plants or animals include arsenical pesticides such as lead arsenate; arsenic acid, $HAsO_3$; sodium arsenite, $NaAsO_2$; sodium arsenate, Na_2AsO_4; and cacodylic acid, $(CH_3)_2$ As(OH) (NAS 1977).

The major uses of arsenic are in the production of herbicides, insecticides, desiccants, wood preservatives, and growth stimulants for plants and animals. Much smaller amounts are used in the manufacture of glass (nearly all of which contains 0.2% to 1.0% arsenic as an additive--primarily as a decolorizing agent) and textiles, and in medical and veterinary applications (NAS 1977; EPA 1980). Arsenic is also an ingredient in lewisite, a blistering poison gas developed (but not used) during World War I, and in various police riot control agents (NAS 1977). The availability of arsenic in certain local areas has been increased by various human activities: smelting and refining of gold, silver, copper, zinc, uranium, and lead ores; combustion of fossil fuels, such as coal and gasoline; burning of vegetation from cotton gins treated with arsenical pesticides; careless or extensive use of arsenical herbicides, pesticides, and defoliants; dumping of land wastes and sewage sludge (1.1 mg/l) in areas that allow leaching into groundwater; use of domestic detergents in wash water (2.5 to 1,000 mg As/1); manufacture of glass; and by the sinking of drinking water wells into naturally arseniferous rock (NRCC 1978; EPA 1980). There are several major anthropogenic sources of environmental arsenic contamination: industrial smelters--the effluent from a copper smelter in Tacoma, Washington, contained up to 70 tons of arsenic discharged yearly into nearby Puget Sound (NRCC 1978); coal-fired power plants, which collectively emit about

3,000 tons of arsenic annually in the United States (EPA 1980); and production and use of arsenical pesticides, coupled with careless disposal of used pesticide containers (NAS 1977). Elevated levels of arsenic have been reported in soils near smelters, in acid mine spoils, and in orchards receiving heavy applications of lead arsenate (NAS 1977; Dudas 1984). Air concentrations of arsenic are elevated near metal smelters, near sources of coal burning, and wherever arsenical pesticides are applied (NAS 1977). Atmospheric deposition of arsenic has steadily increased for at least 30 years, as judged by sedimentary evidence from lakes in upstate New York (Smith et al. 1987). Arsenic is introduced into the aquatic environment through atmospheric deposition of combustion products and through runoff from fly-ash storage areas near power plants and nonferrous smelters (Smith et al. 1987). Elevated arsenic concentrations in water were recorded near mining operations, and from mineral springs and other natural waters--usually alkaline and with high sodium and bicarbonate contents (NAS 1977). In the United States, the most widespread and frequent increases in dissolved arsenic concentrations in river waters were in the northern Midwest; all evidence suggests that increased atmospheric deposition of fossil fuel combustion products was the predominant cause of the trend (Smith et al. 1987).

Agricultural applications provide the largest anthropogenic source of arsenic in the environment (Woolson 1975). Inorganic arsenicals (arsenic trioxide; arsenic acid; arsenates of calcium, copper, lead, and sodium; and arsenites of sodium and potassium) have been used widely for centuries as insecticides, herbicides, algicides, and desiccants. Paris green (cuprous arsenite) was successfully used in 1867 to control the Colorado potato beetle (*Leptinotarsa decemlineata*) in the eastern United States. Arsenic trioxide has been applied widely as a soil sterilant. Sodium arsenite has been used for aquatic weed control, as a defoliant to kill potato vines before tuber harvest, as a weed killer along roadsides and railroad rights-of-way, and for control of crabgrass (*Digitaria sanguinalis*). Calcium arsenates have been applied to cotton and tobacco fields to protect against the boll weevil (*Anthonomus grandis*) and other insects, Lead arsenate has been used to control insect pests of fruit trees, and for many years was the only insecticide that controlled the codling moth (*Carpocapsa pomonella*) in apple orchards and the horn worm larva (Sphyngidae) on tobacco. Much smaller quantities of lead arsenate are now used in orchards because fruit growers rely primarily on carbamate and organophosphorus compounds to control insect pests; however, lead arsenate is still being used by some growers to protect orchards from certain chewing insects. The use of inorganic arsenicals has decreased in recent years due to the banning of sodium arsenite and some other arsenicals for most purposes, although they continue to be used on golf greens and fairways in certain areas to control annual bluegrass (*Poa annua*). In recent decades, inorganic arsenicals have been replaced by organoarsenicals for herbicidal application, and by carbamate and organophosphorus compounds for insect control (Woolson 1975). By the mid-1950's, organoarsenicals were used extensively as desiccants, defoliants, and herbicides (NRCC 1978). Organoarsenicals marketed in agriculture today, which are used primarily for herbicidal application, include cacodylic acid (also known as dimethylarsinic acid) and its salts--monosodium and disodium methanearsonate (Woolson 1975; NAS 1977). Organoarsenicals are used as selective herbicides for weedy grasses in turf, and around cotton and noncrop areas for weed control; at least 1.8 million ha (4.4 million acres) have been treated with more than 8,000 tons of organoarsenicals (NAS 1977). In 1945, it was discovered that one organoarsenical (3-nitro-4 hydroxyphenyl arsonic acid) controlled coccidiosis and promoted growth in domestic chicken (Woolson 1975). Since that time, other substituted phenylarsonic acids have been shown to have both therapeutic and growth promoting properties as feed additives for poultry and swine (*Sus* spp.), and are used for this purpose today under existing regulations (Woolson 1975; NAS 1977)--although the use of arsenicals in poultry food was banned in France in 1959 (NRCC 1978).

CHEMICAL AND BIOCHEMICAL PROPERTIES

Elemental arsenic is a gray, crystalline material characterized by atomic number 33, atomic weight of 74.92, density of 5.727, melting point of 817 °C, sublimation at 613 °C, and chemical properties similar to those of phosphorus (Woolson 1975; NAS 1977; NRCC 1978; EPA 1980; 1985). Arsenic has four valence states: -3, 0, +3, and +5. Arsines and methylarsines, which are characteristic of arsenic in the -3 oxidation state, are generally unstable in air. Elemental arsenic, As° is formed by the reduction of arsenic oxides. Arsenic trioxide (As+3) is a product of smelting operations and is the material used in synthesizing most arsenicals. It is oxidized catalytically or by bacteria to arsenic pentoxide (As+5) or orthoarsenic acid (H_3AsO_4). Arsenic in nature is rarely in its free state. Usually, it is a component of sulfidic ores, occurring as arsenide; and arsenates, along with arsenic trioxide, which is a weathering product of arsenides. Most arsenicals degrade or weather to form arsenate, although arsenite may form under anaerobic conditions. Biotransformations may occur, resulting in volatile arsenicals that normally are returned to the land where soil adsorption, plant uptake, erosion,

leaching, reduction to arsines, and other processes occur. This natural arsenic cycle reflects a constant shifting of arsenic between environmental compartments.

Arsenic species in flooded soils and water are subject to chemically and microbiologically mediated oxidation or reduction and methylation reactions. At high Eh values (i.e., high oxidation-reduction potential) typical of those encountered in oxygenated waters, pentavalent As+5 tends to exist as H_3AsO_4 H_2AsO_4, $HAsO_2$, and AsO_4^{-3}. At lower Eh, the corresponding trivalent arsenic species can be present, as well as AsS_2, (Thanabalasingam and Pickering 1986). In aerobic soils, the dominant arsenic, species was As+5, and small quantities of arsenite and monomethylarsonic acid were present in mineralized areas; in anaerobic soils, As+3 was the major soluble species (Haswell et al. 1985). Inorganic arsenic is more mobile than organic arsenic, and thus poses greater problems by leaching into surface waters and groundwater (NRCC 1978). The trivalent arsenic species are generally considered to be more toxic, more soluble, and more mobile than As+5 species (Thanabalasingam and Pickering 1986). Soil microorganisms metabolize arsenic into volatile arsine derivatives. Depending on conditions, 17% to 60% of the total arsenic present in soil may be volatilized (NRCC 1978) Estimates of the half-life of arsenic in soil varied from 6.5 years for arsenic trioxide to 16 years for lead arsenate (NRCC 1978).

In water, arsenic occurs in both inorganic and organic forms, and in dissolved and gaseous states (EPA 1980). The form of arsenic in water depends on Eh, pH, organic content, suspended solids, dissolved oxygen, and other variables (EPA 1985). Arsenic in water exists primarily as a dissolved ionic species; particulates account for less than 1% of the total measurable arsenic (Maher 1985a). Arsenic is rarely found in water in the elemental state (0), and is found in the -3 state only at extremely low Eh values (Lima et al. 1984). Common forms of arsenic encountered in water are arsenate, arsenite, methanearsonic acid, and dimethylarsinic acid (EPA 1985). The formation of inorganic pentavalent arsenic, the most common species in water, is favored under conditions of high dissolved oxygen, basic pH, high Eh, and reduced content of organic material; reverse conditions usually favor the formation of arsenites and arsenic sulfides (NRCC 1978; Pershagen and Vahter 1979; EPA 1980), although some arsenite is attributed to biological activity (Maher 1985a). Water temperature seems to affect arsenic species composition in the estuary of the River Beaulieu in the United Kingdom, where reduced and methylated species predominate during warmer months and inorganic As during colder months; the appearance of methylated arsenicals during the warmer months is attributed both to bacterial and abiotic release from decaying plankton and to grazing by zooplankton (Howard et al. 1984). Also contributing to higher water or mobile levels are the natural levels of polyvalent anions, especially phosphate species. Phosphate, for example, displaces arsenic held by humic acids and sorbs strongly on the hydrous oxides of arsenates (Thanabalasingam nd Pickering 1986).

Physical processes play a key role in governing arsenic bioavailability in aquatic environments. For example, arsenates are readily sorbed by colloidal humic material under conditions of high organic content, low pH, low phosphate, and low mineral content (EPA 1980; Thanabalasingam and Pickering 1986). Arsenates also coprecipitate with, or adsorb on, hydrous iron oxides and form insoluble precipitates with calcium, sulfur, aluminum, and barium compounds (EPA 1980). Removal of arsenic from seawater by iron hydroxide scavenging seems to be a predominant factor in certain estuaries. The process involves both As^{+3} and As^{+5} and results in a measurable increase in arsenic levels in particulate matter, especially at low salinities (Sloot et al. 1985). Arsenic sulfides are comparatively insoluble under conditions prevalent in anaerobic aqueous and sedimentary media containing hydrogen sulfide; accordingly, these compounds may accumulate as precipitates and thus remove arsenic from the aqueous environment. In the absence of hydrogen sulfide, these sulfides decompose within several days to form arsenic oxides, sulfur, and hydrogen sulfide (NAS 1977).

In reduced environments, such as sediments, arsenate is reduced to arsenite and methylated to methylarsinic acid or dimethylarsenic acids: these compounds may be further methylated to trimethylarsine or reduced to dimethylarsine, and may volatilize to the atmosphere where oxidation reactions result in the formation of dimethylarsinic acid (Woolson 1975). Arsenates are more strongly adsorbed to sediments than are other arsenic forms, the adsorption processes depending strongly on arsenic concentration, sediment characteristics, pH, and ionic concentration of other compounds (EPA 1980). An important mechanism of arsenic adsorption onto lake sediments involves the interaction of anionic arsenates and hydrous iron oxides. Current evidence suggests that arsenic is incorporated into sediments at the time of hydrous oxide formation, rather than by adsorption onto existing surfaces (Aggett and Roberts 1986). Arsenic concentrations in lake

sediments are also correlated with manganese; hydrous manganese oxides--positively charged for the adsorption of Mn^{+2} ions--play a significant role in arsenic adsorption onto the surface of lake sediments (Takamatsu et al. 1985). The mobility of arsenic in lake sediments and its release to the overlying water is related partly to seasonal changes. In areas that become stratified in summer, arsenic released from sediments accumulates in the hypolimnion until turnover, when it is mixed with epilimnetic waters; this mixing may result in a 10 to 20% increase in arsenic concentration (Aggett and O'Brien 1985). Microorganisms (including four species of fungi) in lake sediments oxidized inorganic As^{+3} to As^{+5} and reduced inorganic As^{+5} to As^{+3} under aerobic conditions; under anaerobic conditions, only reduction was observed (Freeman et al. 1986). Inorganic arsenic can be converted to organic alkyl arsenic acids and methylated arsines under anaerobic conditions by fungi, yeasts, and bacteria--although biomethylation may also occur under aerobic conditions (EPA 1980).

Most arsenic investigators now agree on the following points: (1) arsenic may be absorbed by ingestion, inhalation, or through permeation of the skin or mucous membranes; (2) cells accumulate arsenic by using an active transport system normally used in phosphate transport; (3) arsenicals are readily absorbed after ingestion, most being rapidly excreted in the urine during the first few days, or at most a week (the effects seen after long-term exposure are probably a result of continuous daily exposure, rather than of accumulation); (4) the toxicity of arsenicals conforms to the following order, from greatest to least toxicity: arsines > inorganic arsenites > organic trivalent compounds (arsenoxides) > inorganic arsenates > organic pentavalent compounds > arsonium compounds > elemental arsenic; (5) solubility in water and body fluids appears to be directly related to toxicity (the low toxicity of elemental arsenic is attributed to its virtual insolubility in water and body fluids, whereas the highly toxic arsenic trioxide, for example, is soluble in water to 12.0 g/l at 0 C, 21.0 g/l at 25 C, and 56.0 g/l at 75 C); and (6) the mechanisms of arsenical toxicity differ considerably among arsenic species, although signs of poisoning appear similar for all arsenicals (Woolson 1975; NRCC 1978; Pershagen aid Vahter 1979).

The primary toxicity mode of inorganic As+3 is through reaction with sulfhydryl groups of proteins and subsequent enzyme inhibition; inorganic pentavalent arsenate does not react as readily as As+3 with sulfhydryl groups, but may uncouple oxidative phosphorylation (Howard et al. 1984; EPA 1985). Inorganic As+3 interrupts oxidative metabolic pathways and sometimes causes morphological changes in liver mitochondria. Arsenite in vitro reacts with protein-SH groups to inactivate enzymes such as dihydrolipoyl dehydrogenase and thiolase, producing inhibited oxidation of pyruvate and beta-oxidation of fatty acids (Belton et al. 1985). Inorganic As+5 may also exert toxic effects by the reaction of arsenous acid (HAsO) with the sulfhydryl (SH) groups of enzymes. In the first reaction, arsenous acid is reduced to arsonous acid ($AsOH_2$), which then condenses to either monothiols or dithiols to yield dithioesters of arsonous acid. Arsonous acid may then condense with enzyme SH groups to form a binary complex (Knowles and Benson 1984a,b).

Methylation to methylarsonic acid ($(CH3)_2AsO_3H_2$) and dimethylarsinic acid ($(CH3)_2AsO_2H$) is usually the major detoxification mechanism for inorganic pentavalent arsenates and trivalent arsenites in mammals. Methylated arsenicals rapidly clear from all tissues except perhaps the thyroid (Marafante et al. 1985; Vahter and Marafante 1985; Yamauchi et al. 1986) Methylated arsenicals are probably common in nature. Methylation of arsenic (unlike methylation of mercury) greatly reduces toxicity and is a true detoxification process (Woolson 1975). Before methylation (which occurs largely in the liver), As+5 is reduced to As+3-- the kidney being an important site for this transformation (Belton et al. 1985). Arsenate reduction and, subsequent methylation is rapid: both. arsenite and dimethylarsinate were present in hamster (*Cricetus* sp.) plasma only 12 minutes postinjection of inorganic As+5 (Hanlon and Ferm 1986c). Demethylation of methylated arsenicals formed in vivo has not yet been reported (EPA 1980).

Toxic effects of organoarsenicals are exerted by initial metabolism to the trivalent arsonoxide form, and then by reaction with sulfhydryl groups of tissue proteins and enzymes to form an arylbis (organylthio) arsine (NAS 1977). This form, in turn, inhibits oxidative degradation of carbohydrates and decreases cellular ATP, the energy storage molecule of the cell (NRCC 1978). Among the organoarsenicals, those physiologically most injurious are methylarsonous acid ($CH3As(OH)_2$) and dimethylarsinous acid ($(CH3)_2AsOH$) (Knowles and Benson 1984b). The enzyme inhibitory forms of organoarsenicals (arsonous acid) are formed from arsenous acid and the corresponding arsonic acids by a wide variety of enzymes and subcellular particles (Knowles and Benson 1984a). Organoarsenicals used as growth promoters and drugs are converted to more easily excretable

(and sometimes more toxic) substances, although most organoarsenicals are eliminated without being converted to inorganic arsenic or to demethylarsinic acids (Pershagen and Vahter 1979).

ESSENTIALITY, SYNERGISM, AND ANTAGONISM

Limited data are available on the beneficial, protective, and essential properties of arsenic, and on its interactions with other chemicals.

Arsenic apparently behaves more like an environmental contaminant than as a nutritionally essential mineral (NAS 1977). Nevertheless, low doses (<2 ug/daily) of arsenic stimulated growth and metamorphosis in tadpoles, and increased viability and cocoon yield in silkworm caterpillars (NAS 1977). Arsenic deficiency has been observed in rats: signs include rough haircoat, low growth rate, decreased hematocrit, increased fragility of red cells, and enlarged spleen (NAS 1977). Similar results have been documented in goats and pigs fed diets containing less than 0.05 mg As/kg (NAS 1977). In these animals, reproductive performance was impaired, neonatal mortality was increased, birth weight was lower, and weight gains in second-generation animals were decreased; these effects were not evident in animals fed diets containing 0.35 mg As/kg (NAS 1977).

The use of phenylarsonic feed additives to promote growth in poultry and swine and to treat specific diseases does not seem to constitute a hazard to the animal or to its consumers. Animal deaths and elevated tissue arsenic residues occur only when the arsenicals are fed at excessive dosages for long periods (NAS 1977). Arsenic can be detected at low levels in tissues of animals fed organoarsenicals, but it is rapidly eliminated when the arsenicals are removed from the feed for the required 5-day period before marketing (Woolson 1975).

Selenium and arsenic are antagonists in several animal species. In rats, dogs, swine, cattle, and poultry, the arsenic protects against selenium poisoning if arsenic is administered in the drinking water and selenium through the diet (NAS 1977; NRCC 1978; Pershagen and Vahter 1979). Inorganic arsenic compounds decrease the toxicity of inorganic selenium compounds by increasing biliary excretion (NRCC 1978). However, in contrast to antagonism shown by inorganic arsenic-inorganic selenium mixtures, the toxic effects of naturally methylated selenium compounds (trimethylselenomium chloride and dimethyl selenide) are markedly enhanced by inorganic arsenicals (NRCC 1978).

Toxic effects of arsenic can be counteracted with saline purgatives, with various demulcents that coat irritated gastrointestinal mucous membranes, and by sodium thiosulfate (NAS 1977), and by mono- and dithiol-containing compounds and 2,3-dimercaptopropanol (Pershagen and Vahter 1979). Arsenic uptake in rabbit intestine is inhibited by phosphate, casein, and various metal chelating agents (EPA 1980). Mice and rabbits are significantly protected against sodium arsenite intoxication *by* N-(2,3-dimercaptopropyl)phthalamidic acid (Stine et al. 1984). Conversely, the toxic effects of arsenite are potentiated by excess dithiols, cadmium, and lead, as evidenced by reduced food efficiency and disrupted blood chemistry in rodents (Pershagen and Vahter 1979).

Arsenic effectively controls filariasis in cattle; new protective uses are under investigation. The control of parasitic nematodes (*Parafilaria bovicola*) in cattle was successful after 30 weekly treatments in plungement dips containing 1,600 mg As_2O_3/l; however, the muscle of treated cattle contained up to 1.3 mg As/kg, or 12X the amount in controls (Nevill 1985). Existing anionic organic arsenicals used to control tropical nematode infections in humans have sporadic and unacceptable lethal side effects. Cationic derivatives have been synthesized in an attempt to avoid the side effects and have been examined for effects on adult nematodes (*Brugia pahangi*) in gerbils (*Meriones unguiculatus*). All arsenicals were potent filaricides; the most effective-compounds tested killed 95% of adult *B. pahangi* after five daily subcutaneous injections of 3.1 mg As/kg body weight (Denham et al. 1986).

Animals previously exposed to sublethal levels of arsenic may develop tolerance to arsenic on reexposure. Although the mechanism of this process is not fully understood, it probably includes the efficiency of in vivo methylation processes (EPA 1980). For example, resistance to toxic doses of As+3 or As+5 increases in mouse fibroblast cells pretreated with a low As+3 concentration (Fischer et al. 1985). Also, growth is better in arsenic-conditioned mouse cells in the presence of arsenic than in previously unexposed cells, and inorganic arsenic is more efficiently methylated. In vivo biotransformation and excretion of inorganic arsenic as monomethylarsonic acid (MMA) and dimethylarsinic acid (DMA) has been demonstrated in a number of mammalian species,

including man. It seems that cells may adapt to arsenic by increasing the biotransformation rate of the element to methylated forms, such as MMA and DMA (Fischer et al. 1985). Pretreatment of ovary cells of Chinese hamster (*Cricetus* spp.) ovary cells with sodium arsenite provided partial protection against adverse effects of methyl methanesulfonate (MMS), and may even benefit the MMS-treated cells; however, posttreatment dramatically increases the cytotoxic, clastogenic, and mitotic effects induced by MMS (Lee et al. 1986b).

Although arsenic is not an essential plant nutrient, small yield increases have sometimes been observed at low soil arsenic levels, especially for tolerant crops such as potatoes, corn, rye, and wheat (Woolson 1975). Arsenic phytotoxicity of soils is reduced with increasing lime, organic matter, iron, zinc, and phosphates (NRCC 1978). In most soil systems, the chemistry of As becomes the chemistry of arsenate; the estimated half-time of arsenic in soils is about 6.5 years, although losses of 60% in 3 years and 67% in 7 years have been reported (Woolson 1975). Additional research is warranted on the role of arsenic in crop production, and in nutrition, with special reference to essentiality for aquatic and terrestrial wildlife.

BACKGROUND CONCENTRATIONS

GENERAL

In abundance of elements, arsenic ranks 20th in the earth's crust (1.5 to 2 mg/kg) 14th in seawater, and 12th in the human body (Woolson 1975). It occurs in various forms, including inorganic and organic compounds and trivalent and pentavalent states (Pershagen and Vahter 1979). In aquatic environments, higher arsenic concentrations are reported in hot springs, in groundwaters from areas of thermal activity or in areas containing rocks with high arsenic content, and in some waters with high dissolved salt content (NAS 1977). Most of the other elevated values reported in lakes, rivers, and sediments are probably due to anthropogenic sources, which include smelting and mining operations; combustion of fossil fuel; arsenical grasshopper baits; synthetic detergent and sewage sludge wastes; and arsenical defoliants, herbicides, and pesticides (NAS 1977). Most living organisms normally contain measurable concentrations of arsenic, but except for marine biota, these are usually less than 1 mg/kg fresh weight. Marine organisms, especially crustaceans, may contain more than 100 mg As/kg dry weight, usually as arsenobetaine, a water soluble organoarsenical that poses little risk to the organism or its consumer. Plants and animals collected from naturally arseniferous areas or near anthropogenic sources may contain significantly elevated tissue residues of arsenic. Additional and more detailed information on background concentrations of arsenic in abiotic and living resources was given by NAS (1977), Hall et al. (1978), NRCC (1978), EPA (1980), Jenkins (1980), and Eisler (1981).

NONBIOLOGICAL SAMPLES

Arsenic is a major constituent of at least 245 mineral species, of which arsenopyrite is the most common (NAS 1977). In general, background concentrations of arsenic are 0.2 to 15 mg/kg in the lithosphere, 0.005 to 0.1 ug/m in air, <10 ug/l in water, and <15 mg/kg in soil (NRCC 1978). The commercial use and production of arsenic compounds have raised local concentrations in the environment far above the natural background concentrations (Table 1).

Weathering of rocks and soils adds about 45,000 tons of arsenic to the oceans annually, accounting for less than 0.01 mg/l on a global basis (NRCC 1978). However, arsenic inputs to oceans increased during the past century both from natural sources and as a result of industrial use, agricultural and deforestation activities, emissions from coal and oil combustion, and loss during mining of metal ores. If present activities continue, arsenic concentrations in oceanic surface waters may increase overall by about 2% *by* the year 2000, with most of the increased burden in estuaries and coastal oceans--e.g., Puget Sound, Washington; the Tamar, England; and the Tejo, Portugal (Sanders 1985). Estimates of the residence times of arsenic are 60,000 years in the ocean and 45 years in a freshwater lake (NRCC 1978). In the hydrosphere, inorganic arsenic occurs predominantly as As+5 in surface waters, and significantly as As+3 in groundwaters containing high levels of total arsenic. The main organic species in freshwater are methylarsonic acid and dimethylarsinic acid, and these are usually present in lower concentrations than inorganic arsenites and arsenates (Pershagen and Vahter 1979). Total arsenic concentrations in both surface and groundwaters are usually < 10 ug/l; in certain areas, however, levels above 1 mg/l have been recorded (Pershagen and Vahter 1979).

In air, most arsenic particulates consist of inorganic arsenic compounds, often as As+3. Burning of coal and arsenic-treated wood, and smelting of metals are major sources of atmospheric arsenic contamination (i.e., >1

ug/m^3); in general, atmospheric arsenic levels are higher in winter, due to increased use of coal for heating (Pershagen and Vahter 1979).

The main carrier of arsenic in rocks and in most types of mineral deposits is iron pyrite (FeS_2) which may contain >2,000 mg/kg of arsenic (NRCC 1978). In localized areas, soils are contaminated by arsenic oxide fallout from smelting ores (especially sulfide ores) and combustion of arsenic-rich coal (Woolson 1975).

Arsenic in lacustrine sediment columns is subject to control by diagenetic processes and adsorption mechanisms, as well as anthropogenic influences (Farmer and Lovell 1986). For example, elevated levels of arsenic in surface or near surface sediments may be due to several causes (Farmer and Lovell 1986): natural processes (Loch Lomond, Scotland); or to human activities such as smelters (Lake Washington, Washington; Kelly Lake, Ontario, Canada), manufacture of arsenical herbicides (Brown's Lake, Wisconsin), and mining operations (Northwest Territories, Canada). Elevated levels of arsenic in sediments of the Wailoa River, Hawaii, are caused by As_2O_3 applied as an anti-termite agent between 1932 and 1963, and are mostly in anaerobic sediment regions where the chemical has been relatively undisturbed by biological activity; low levels of arsenic in the biota of that estuary suggest that arsenic is trapped in the anaerobic sediment layers (Hallacher et al. 1985).

Arsenic geochemistry in Chesapeake Bay, Maryland, depends on anthropogenic inputs and phytoplankton species composition (Sanders 1985). Inputs of anthropogenic arsenic into Chesapeake Bay are estimated at 100 kg daily, or 39 tons/year--probably from sources such as unreported industrial discharges, use of arsenical herbicides, and from wood preservatives (Sanders 1985). The chemical form of the arsenic in solution varies both seasonally and along the axis of the Bay. Arsenic is present only as arsenate in winter, but substantial quantities of reduced and methylated forms are present in summer in different areas. The forms and distribution patterns of arsenic during the summer suggest that separate formation processes exist. Arsenite, present in low salinity regions, may have been formed by chemical reduction in anoxic, subsurface waters and then mixed into the surface layer. Methylated arsenicals are highly correlated with ;landing crops of algae. One particular form, methylarsonate, is significantly correlated with the dominant alga *Chroomonas*. Since both arsenic reactivity and toxicity are altered by transformation of chemical form, the observed variations in arsenic speciation have considerable geochemical and ecological significance (Sanders 1985).

BIOLOGICAL SAMPLES

Background arsenic concentrations in living organisms are usually <1 mg/kg fresh weight in terrestrial flora and fauna, birds, and freshwater biota. These levels are higher, sometimes markedly so, in biota collected from mine waste sites, arsenic-treated areas, near smelters and mining areas, near areas with high geothermal activity, and near manufacturers of arsenical defoliants and pesticides (Table 2). Marine organisms, however, normally contain arsenic residues of several to more than 100 mg/kg dry weight (Lunde 1977); as discussed later, however, these concentrations present little hazard to the organism or to its consumers.

Shorebirds (seven species) wintering in the Corpus Christi, Texas, area contained an average of only 0.3 mg As/kg fresh weight in livers (maximum of 1.5 mg/kg), despite the presence of smelters and the heavy use of arsenical herbicides and defoliants; these values probably reflect normal background concentrations (White et al. 1980). Similar arsenic levels are reported in livers of brown pelicans (*Pelecanus occidentalis*) collected from South Carolina (Blus et al. 1977). The highest arsenic concentration recorded in seemingly unstressed coastal birds was 13.2 mg/kg fresh weight lipids (Table 2). This tends to corroborate the findings of others who demonstrated that arsenic concentrates in lipid fractions of marine plants, invertebrates, and higher organisms. An abnormal concentration of 16.7 mg As/kg fresh weight was recorded in liver of an osprey (*Pandion haliaetus*) from the Chesapeake Bay region (Wiemeyer et al. 1980). This bird was alive but weak, with serious histopathology including the absence of subcutaneous fat, and the presence of serous fluid in the pericardial sac and disorders of the lung and kidney. It died shortly after collection. Arsenic concentrations in liver from other ospreys collected in the same area usually were <1.5 mg As/kg fresh weight.

Arsenic concentrations in tissues of marine biota show a wide range of values, being highest in lipids, liver, and muscle tissues, and varying with the age of the organism, geographic locale, and proximity to anthropogenic activities (Table 2). In general, tissues with high lipid content contained high levels of arsenic. Crustacean tissues sold for human consumption and collected in U.S. coastal waters usually contained 3 to 10

mg As/kg fresh weight (Hall et al. 1978), or 1 to 100 mg/kg dry weight (Fowler and Unlu 1978), and were somewhat higher than those reported for finfish and molluscan tissues. Marine finfish tissues usually contained 2 to 5 mg As/kg fresh weight (Table 2). However, postmortem reduction of As+5 to As+3 occurs rapidly in fish tissues (Reinke et al. 1975), suggesting a need for additional research in this area. Maximum arsenic values recorded in elasmobranchs (mg/kg fresh weight) were 30 in muscle of a shark, *Mustelus antarcticus*, and 16.2 in muscle of a ray, *Raja* sp. (Eisler 1981). The highest arsenic concentration recorded in marine mammals, 2.8 mg As/kg fresh weight lipid, was from a cetacean captured by Norwegian whalers (Eisler 1981).

Arsenic appears to be elevated in marine biota because of their ability to accumulate arsenic from seawater or food sources, and not due to localized pollution (Maher 1985b). The great majority of the arsenic in marine organisms exists as water-soluble and lipid-soluble organoarsenicals that include arsenolipids, arsenosugars, arsenocholine, arsenobetaine ($(CH3)_3AsCH_2COOH$), monomethylarsonate ($CH3AsO(OH)_2$), and demethylarsinate ($(CH3)_2AsO(OH)$), as well as other forms. There is no convincing hypothesis to account for the existence of all the various forms of organoarsenicals found in marine organisms. One suggested hypothesis is that each form involves a single anabolic/catabolic pathway concerned with the synthesis and turnover of phosphatidylcholine (Phillips and Depledge 1986). Arsenosugars (arsenobetaine precursors) are the dominant arsenic species in brown kelp (*Ecklonia radiata*), giant clam (*Tridacna maxima*), shrimp (*Pandalus borealis*), and ivory shell (*Buccinum striatissimum*) (Shiomi et al. 1984a,b; Francesconi et al. 1985; Matsuto et al. 1986; Phillips and Depledge 1986). For most marine species, however, there is general agreement that arsenic exists primarily as arsenobetaine, a water soluble organoarsenical that has been identified in tissues of western rock lobster (*Panulirus cygnus*), American lobster (*Homarus americanus*), octopus (*Paroctopus* sp.), sea cucumber (*Stichopus japonicus*), blue shark (*Prionace glauca*), sole (*Limanda* sp.), squid (*Sepioteuthis australis*), prawn (*Penaeus latisulcatus*), scallop (*Pecten alba*), and many other species including teleosts, molluscs, tunicates, and crustaceans (Shiomi et al. 1984b; Francesconi et al. 1985; Hanaoka and Tagawa 1985a,b; Maher 1985b; Norin et al. 1985; Matsuto et al. 1986). The potential risks associated with consumption of seafoods containing arsenobetaine seem to be minor. The chemical was not mutagenic in the bacterial *Salmonella typhimurium* assay (Ames test), had no effect on metabolic inhibition of Chinese hamster ovary cells at 10,000 mg/l, and showed no synergism or antagonism on the action of other contaminants (Jongen et al. 1985). Arsenobetaine was not toxic to mice at oral doses of 10,000 mg/kg body weight during a 7-day observation period, and was rapidly absorbed from the gastrointestinal tract and rapidly excreted in urine without metabolism, owing to its high polar and hydrophilic characteristics (Kaise et al. 1985).

LETHAL AND SUBLETHAL EFFECTS

GENERAL

As discussed later, most authorities agree on 10 points: (1) inorganic arsenicals are more toxic than organic arsenicals, and trivalent forms are more toxic than pentavalent forms; (2) episodes of arsenic poisoning are either acute or subacute--cases of chronic arsenosis are rarely encountered, except in humans; (3) early developmental stages are the most sensitive to arsenic; (4) inorganic arsenic can traverse placental barriers--as little as 1.7 mg As+5/kg body weight at critical stages of hamster embryogenesis, for example, can produce fetal death and malformation; (5) biomethylation is the preferred detoxification mechanism for inorganic arsenicals; (6) arsenic is bioconcentrated by organisms, but not biomagnified in the food chain; (7) depressed crop yields were recorded at 3 to 28 mg of water soluble soil As/l, or about 25 to 85 mg total As/kg soil--adverse effects on vegetation were recorded at concentrations in air >3.9 ug As/m^3; (8) some aquatic species were adversely affected at water concentrations of 19 to 48 ug As/l, or 120 mg As/kg in the diet, or tissue residue of 1.3 to 5 mg As/kg fresh weight; (9) sensitive species of birds died following single oral doses of 17.4 to 47.6 mg As/kg body weight; and (10) adverse effects were noted in mammals at single oral doses of 2.5 to 33 mg As/kg body weight, at chronic oral doses of 1 to 10 mg As/kg body weight, and at feeding levels of 50 mg, sometimes only 5 mg, As/kg in the diet.

It is emphasized in the literature that arsenic metabolism and toxicity vary greatly between species, and that effects are significantly altered by numerous physical, chemical, and biological modifiers. Adverse health effects, for example, may involve respiratory, gastrointestinal, cardiovascular, and hematopoietic systems, and may range from reversible effects to cancer and death, depending partly on the physical and chemical forms of arsenic tested, the route of administration, and dose.

CARCINOGENESIS, MUTAGENESIS, AND TERATOGENESIS

Epidemiological studies show that increased risk of cancers in skin, lung, liver, lymph, and hematopoietic systems of humans is associated with exposure to inorganic arsenicals. These increased cancer risks are especially prevalent among smelter workers and in those engaged in the production and use of arsenical pesticides where atmospheric levels exceed 54.6 ug As/m^3 (NRCC 1978; Belton et al. 1985; Pershagen and Bjorklund 1985). Skin tumors, mainly of low malignancy, have been reported after consumption of arsenic-rich drinking waters; a total dose of several grams, probably as As+3 is usually required for the development of skin tumors (Pershagen and Vahter 1979). High incidences of skin cancer and hyperpigmentation were noted among several population groups, especially Taiwanese and Chileans, consuming water containing more than 0.6 mg As/l; the frequency of cancer was highest among people over age 60 who demonstrated symptoms of chronic arsenic poisoning (NRCC 1978).

Arsenic reportedly inhibits cancer formation in species having a high incidence of spontaneous cancers (NRCC 1978). In fact, arsenic may be the only chemical for which there is sufficient evidence for carcinogenicity in humans but not in other animals (Woolson 1975; Belton et al. 1985; Lee et al. 1985). In general, animal carcinogenicity tests with inorganic and organic arsenicals have been negative (Hood 1985), even when the chemicals were administered at or near the highest tolerated dosages for long periods (NAS 1977). Most studies of arsenic carcinogenesis in animals were presumably of insufficient duration to simulate conditions in long-lived species such as humans (NRCC 1978). However, mice developed leukemia and lymphoma after 20 subcutaneous injections of 0.5 mg As+5/kg body weight: 46% of the experimental group developed these signs vs. none in controls (NRCC 1978). Recently, pulmonary tumorogenicity has been demonstrated in hamsters administered calcium arsenate intratracheally (Pershagen and Bjorklund 1985). Cacodylic acid and other organoarsenicals are not carcinogenic, but may be mutagenic at very high doses (Hood 1985).

Several inorganic arsenic compounds are weak inducers of chromosomal aberrations, sister chromatid exchange, and in vitro transformation of mammalian cells; however, there is no conclusive evidence that arsenic causes point mutations in any cellular system (Pershagen and Vahter 1979; Belton et al. 1985; Lee et al. 1985; Deknudt et al. 1986). Studies with bacteria suggest that arsenite is a comutagen, or may inhibit DNA repair (Belton et al. 1985).

Arsenic is a known teratogen in several classes of vertebrates, and has been implicated as a cause of birth defects in humans. Specific developmental malformations have been produced experimentally in mammals using inorganic As+3 or As+5 either through a single dose or a continuous dose during embryogenesis (Hanlon and Ferm 1986b). Teratogenic effects are initiated no later than 4 hours postadministration of As; fetal abnormalities are primarily neural tube defects (Hanlon and Ferm 1985c), but may also include protruding eyes, incomplete development of the skull, abnormally small jaws and other skeletal anomalies (NRCC 1978). Inorganic As+3 and As+5, but not organoarsenicals, cross placental barriers in many species of mammals, and result in fetal deaths and malformations (NRCC 1978; EPA 1980). Recent studies with hamsters, for example, showed that sodium arsenite can induce chromatid breaks and chromatid exchanges in Chinese hamster ovary cells in a dose dependent manner (Lee et al. 1986b). In an earlier study (Lee et al. 1985), As+3 was about 10X more potent than As+5 in effecting transformations, The birth defects were most pronounced in golden hamsters exposed to As+5 during the 24-hour period of critical embryogenesis--i.e., day 8 of gestation (Ferm and Hanlon 1985)--when 1.7 mg As+5/kg body weight induced neural tube defects in about 90% of the fetuses. Hanlon and Ferm (1986a) showed that hamsters exposed to As+5 and heat stress (39 °C for 50 minutes) on day 8 of gestation produced a greater percentage of malformed offspring (18 to 39%) than did hamsters exposed to As+5 alone (4% to 8%).

TERRESTRIAL PLANTS AND INVERTEBRATES

In general, arsenic availability to plants is highest in coarse-textured soils having little colloidal material and little ion exchange capacity, and lowest in fine-textured soils high in clay, organic material, iron, calcium, and phosphate (NRCC 1978). To be absorbed by plants, arsenic compounds must be in a mobile form in the soil solution. Except for locations where arsenic content is high, e.g., around smelters, the accumulated arsenic is distributed throughout the plant body in nontoxic amounts (NAS 1977). For most plants, a significant depression in crop yields was evident at soil-As concentrations of 3 to 28 mg/l of water soluble arsenic and 25 to 85 mg/kg of total arsenic (NRCC 1978). Yields of peas (*Pisum sativum*), a sensitive species, were decreased at 1 mg/l of water soluble arsenic or 25 mg/kg of total soil As; rice (*Oryza sativum*) yields were decreased 75% at 50 mg/l of

disodium methylarsonate in silty loam; and soybeans (*Glycine max*) grew poorly when residues exceeded 1 mg As/kg (Table 3; NRCC 1978). Forage plants grown in soils contaminated with up to 80 mg total As/kg from arsenical orchard sprays contained up to 5.8 mg As/kg dry weight; however, these plants were considered nonhazardous to grazing ruminants (Merry et al. 1986).

Attention was focused on inorganic arsenical pesticides after accumulations of arsenic in soils eventually became toxic to several agricultural crops, especially on former orchards and cotton fields. Once toxicity is observed, it persists for several years even if no additional arsenic treatment is made (Woolson 1975). Poor crop growth was associated with bioavailability of arsenic in soils. For example, alfalfa (*Medicago sativa*) and barley (*Hordeum vulgare*) grew poorly in soils containing only 3.4 to 9.5 mg As/kg, provided the soils ware acidic, lightly textured, low in phosphorus and aluminum, high in iron and calcium, and contained excess moisture (Woolson 1975). Use of inorganic arsenical herbicides, such as calcium arsenate, to golf course turfs for control of fungal blight sometimes exacerbates the disease. The use of arsenicals on Kentucky bluegrass (*Poa pratensis*) is discouraged under conditions of high moisture and root stress induced by previous arsenical applications (Smiley et al. 1985).

Methylated arsenicals, whether herbicides or defoliants, are sprayed on plant surfaces. They can reach the soil during application or can be washed from the plants. Additional arsenic enters soils by exchange from the roots or when dead plant materials decay (Hood 1985). Cacodylic acid and sodium cacodylate are nonselective herbicides used in at least 82 products to eliminate weeds and grasses around trees and shrubs, and to eradicate vegetation from rights-of-ways and other noncrop areas (Hood 1985). Normal application rates of various organoarsenicals for crop and noncrop purposes rarely exceed 5 kg/ha (Woolson 1975). Under recommended treatment levels, organoarsenical soil residues were not toxic to crops, and those tested (soybean, beet, wheat) were more resistant to organoarsenicals than to comparable levels of inorganic arsenicals (Woolson 1975).

Air concentrations up to 3.9 ug As/m^3 near gold mining operations were associated with adverse effects on vegetation; higher concentrations of 19 to 69 ug As/m^3, near a coal fired power plant in Czechoslovakia, produced measurable contamination in soils and vegetation in a 6-km radius (NRCC 1978).

The phytotoxic actions of inorganic and organic arsenicals are different and each is significantly modified by physical processes. The primary mode of action of arsenite in plants is inhibition of light activation, probably through interference with the pentose phosphate pathway (Marques and Anderson 1986). Arsenites penetrate the plant cuticle to a greater degree than arsenates (NAS 1977). One of the first indications of plant injury by sodium arsenite is wilting caused by loss of turgor, whereas stress due to sodium arsenate does not involve rapid loss of turgor (NAS 1977). Organoarsenicals, such as cacodylic acid, enter plants mostly by absorption of sprays; uptake from the soil contributes only a minor fraction (Hood 1985). The phytotoxicity of organoarsenical herbicides is characterized by chlorosis, cessation of growth, gradual browning, dehydration, and death (NAS 1977). In general, plants cease to grow and develop after the roots have absorbed much arsenic (NRCC 1978). Plants can absorb arsenic through the roots and foliage, although translocation is species dependent. Concentrations of arsenic in plants correlate highly and consistently with water extractable soil arsenic, and usually poorly with total soil arsenic (NRCC 1978). For example, concentrations of arsenic in corn (*Zea mays*) grown in calcareous soils for 25 days were significantly correlated with the soil water extractable arsenic fraction, but not other fractions; extractable phosphorus was correlated positively to both arsenic in corn and to the water soluble arsenic fraction (Sadiq 1986). In the moss *Hylocomium splendens*, arsenate accumulation from solution was through living shoots, optimum uptake being between pH 3 and 5 (Wells and Richardson 1985). Some plants, such as beets (*Beta vulgaris*) accumulated arsenic more readily at elevated temperatures, but the addition of phosphate fertilizers markedly depressed uptake (Merry et al. 1986).

Soils amended with arsenic-contaminated plant tissues were not measurably affected in CO_2 evolution and nitrification, suggesting that the effects of adding arsenic to soils does not influence the decomposition rate of plant tissues by soil microorganisms (Wang et al. 1984). The half-life of cacodylic acid is about 20 days in untreated soils and 31 days in arsenic-amended soils (Hood 1985). Estimates of the half-life of inorganic arsenicals in soils are much longer, ranging from 6.5 years for arsenic trioxide to 16 years for lead arsenate (NRCC 1978).

Data on arsenic effects to soil biota and insects are limited. In general, soil microorganisms are capable of tolerating and metabolizing relatively high concentrations of arsenic (Wang et al. 1984). This adaptation seems usually to be due to decreased permeability of the microorganism to arsenic (NAS 1977). Tolerant soil microbiota can withstand concentrations up to 1,600 mg/kg; however, growth and metabolism were reduced in sensitive species at 375 mg As/kg and, at 150 to 165 mg As/kg, soils were devoid of earthworms and showed diminished quantities of bacteria and protozoans (NRCC 1978). Honeybees (*Apis mellifera*) that were killed accidentally by As+3 spray dusting contained 4 to 5 ug As per bee (NAS 1977)--equivalent to 21 to 31 mg/kg body weight (Table 3). Larvae of the western spruce budworm (*Choristoneura occidentalis*) continued to feed on As+3 -contaminated vegetation until a threshold level of about 2,300 to 3,300 mg As/kg dry weight whole larvae was reached; death then sometimes occurred (Table 3; Robertson and McLean 1985). Larvae that had accumulated sufficient energy reserves completed the first stage of metamorphosis, but developed into pupae of subnormal weight; larvae containing <2,600 mg As+3/kg ultimately developed into adults of less than normal weight, and some containing >2,600 mg/kg dry weight died as pupae (Robertson and McLean 1985).

AQUATIC BIOTA

Adverse effects of arsenicals on aquatic organisms have been reported at concentrations of 19 to 48 ug/l in water, 120 mg/kg in diets, and 1.3 to 5 mg/kg fresh weight in tissues (Table 4). The most sensitive aquatic species tested showing adverse effects were three species of marine algae, which showed reduced growth in the range of 19 to 22 ug As+3/l; developing embryos of the narrow-mouthed toad (*Gastrophryne carolinensis*), of which 50% were dead or malformed in 7 days at 40 ug As+3/l; and a freshwater alga (*Scenedesmus obliquus*), in which growth was inhibited 50% in 14 days at 48 ug As+5/l (Table 4). Chronic studies with mass cultures of natural phytoplankton communities exposed to low levels of arsenate (1.0 to 15.2 ug/l) showed that As+5 differentially inhibits certain plants, causing a marked change in species composition, succession, and predator-prey relations; the significance of these changes on carbon transfer between trophic levels is unknown (Sanders and Cibik 1985; Sanders 1986). Adverse biological effects have also been documented at water concentrations of 75 to 100 ug As/l. At 75 ug As+5/l, growth and biomass in freshwater and marine algae was reduced; at 85 to 88 ug/l of As+5 or various methylated arsenicals, mortality was 10% to 32% in amphipods (*Gammarus pseudolimnaeus*) in 28 days; at 95 ug As+3/l, marine red alga failed to reproduce sexually; and at 100 ug As+5/l, marine copepods died and goldfish behavior was impaired (Table 4). Rainbow trout (*Salmo gairdneri*) fed diets containing up to 90 mg As+5 kg were only slightly affected, but those given diets containing 120 mg As/kg (as As+3 or As+5), and higher, grew poorly, avoided food, and failed to metabolize food efficiently; no toxic effects were reported over 8 weeks of exposure to diets containing 1,600 mg/kg, as methylated arsenicals (Table 4). In bluegills (*Lepomis macrochirus*), tissue residues of 1.35 mg As/kg fresh weight in juveniles and 5 mg/kg in adults are considered elevated and potentially hazardous (NRCC 1978).

Toxic and other effects of arsenicals to aquatic life are significantly modified by numerous biological and abiotic factors (Woolson 1975; NAS 1977; NRCC 1978; EPA 1980, 1985; Howard et al. 1984; Michnowicz and Weaks 1984; Bryant et al. 1985; Sanders 1986). The LC-50 values, for example, are markedly affected by water temperature, pH, Eh, organic content, phosphate concentration, suspended solids, and presence of other substances and toxicants, as well as arsenic speciation, and duration of exposure. In general, inorganic arsenicals are more toxic than organoarsenicals to aquatic biota, and trivalent species are more toxic than pentavalent species. Early life stages are most sensitive, and large interspecies differences are recorded, even among those closely related taxonomically.

Arsenic is accumulated from the water by a variety of organisms; however, there is no evidence of magnification along the aquatic food chain (Woolson 1975; NAS 1977; NRCC 1978; Hallacher et al. 1985; Hood 1985). In a marine ecosystem based on the alga *Fucus vesiculosus*, arsenate (7.5 ug As+5/l) was accumulated by all biota. After 3 months, arsenic was concentrated most efficiently by *Fucus* (120 mg/kg dry weight in apical fronds) and filamentous algal species 30 mg/kg dry weight); little or no bioaccumulation occurred in invertebrates, although arsenic seemed to be retained by gastropods and mussels (Rosemarin et al. 1985). In a freshwater food chain composed of algae, daphnids, and fish, water concentrations of 0.1 mg cacodylic acid/l produced residues (mg As/kg dry weight), after 48 hours of 4.5 in algae and 3.9 in daphnids, but only 0.09 in fish (NAS 1977). Microcosms of a Delaware Cordgrass (*Spartina alterniflora*) salt marsh exposed to elevated levels of As showed that virtually all arsenic was incorporated into plant tissue or strongly sorbed to cell surfaces (Sanders and Osman 1985). Studies with radioarsenic and mussels (*Mytilus galloprovincialis*) showed that accumulation varied with nominal arsenic concentrations, tissues, age of the mussel, and temperature and

salinity of the medium (Unlu and Fowler 1979). Arsenate uptake increased with increasing arsenic concentration in the medium, but the response was not linear, accumulation being suppressed at higher external arsenic concentrations. Smaller mussels took up more arsenic than larger ones. In both size groups, arsenic was concentrated in the byssus and digestive gland. In general, arsenic uptake and loss increased at increasing temperatures. Uptake was significantly higher at 19 o/oo salinity than at 38 o/oo, but loss rate was about the same at both salinities. Radioarsenic loss followed a biphasic pattern; biological half-life was 3 and 32 days for the fast and slow compartments, respectively; secretion of the byssal thread played a key role in elimination (Unlu and Fowler 1979). Factors known to modify rates of arsenic accumulation and retention in a marine shrimp (*Lysmata seticaudata*) include water temperature and salinity, arsenic concentration, age, and especially frequency of molting (Fowler and Unlu 1978).

Bioconcentration factors (BCF) experimentally determined for arsenic in aquatic organisms are, except for algae, relatively low. The BCF values for inorganic As+3 in most aquatic invertebrates and fish exposed for 21 to 30 days did not exceed 17X; the maximum was 6X for As+5, and 9X for organoarsenicals (EPA 1980, 1985). Significantly higher BCF values were recorded in other aquatic organisms (NRCC 1978), but they were based on mean arsenic concentrations in natural waters that seemed artificially high. A BCF of 350X was reported for the American oyster (*Crassostrea virginica*) held in 5 ug As+3/l for 112 days (Zaroogian and Hoffman 1982). There was no relation between oyster body burdens of arsenic and exposure concentrations; however, diet seemed to contribute more to arsenic uptake than did seawater concentrations (Zaroogian and Hoffman 1982). An arsenic-tolerant strain of freshwater alga (*Chlorella vulgarus*) from an arsenic-polluted environment showed increasing growth up to 2,000 mg As+5/l, and could survive at 10,000 mg As+5/l (Maeda et al. 1985). Accumulations up to 50,000 mg As/kg dry weight were recorded (Maeda et al. 1985)--suggesting a need for additional research on the extent of this phenomenon and its implications on food web dynamics.

Some investigators have suggested that arsenic in the form of arsenite is preferentially utilized by marine algae and bacteria (Johnson 1972; Bottino et al. 1978; Johnson and Burke 1978). Arsenate reduction to arsenite in seawater depends on phosphorus in solution and available algal biomass (Johnson and Burke 1978). During algal growth, as phosphate is depleted and the P+5/As+5 ratio drops, the rate of As+5 reduction increases. The resultant As+3, after an initial peak, is rapidly oxidized to As+5, indicating the possibility of biological catalysis of oxidation as well as mediation of As+5 reduction. It is generally accepted that As+3 is more toxic than arsenates to higher organisms; however, As+5 had a more profound effect on growth and morphology of marine algae than did As+3. Possibly marine algae erect a barrier against the absorption of As+3, but not of As+5. Within the cell, As+5 can then be reduced to the possibly more toxic As+3. For example, the culture of two species of marine algae (*Tetraselmis chui, Hymenomonas carterae*) in media containing various concentrations of As+5 or As+3 showed that arsenic effects varied with oxidation state, ration, and light intensity. Arsenate was incorporated and later partly released by both species. Differences between rates of uptake and release suggest that As+5 undergoes chemical changes after incorporation into algal cells (Bottino et al. 1978). When bacterial cultures from the Sargasso Sea and from marine waters of Rhode Island were grown in As+3-enriched media, the bacteria reduced all available As+5 and utilized As+3 during the log growth phase--presumably as an essential trace nutrient. The arsenate reduction rate per cell was estimated to be 75×10^{-11} mg As/minute (Johnson 1972).

The ability of marine phytoplankton to accumulate high concentrations of inorganic arsenicals and transform them to methylated arsenicals that are later efficiently transferred in the food chain is well documented (Irgolic et al. 1977; Benson 1984; Matsuto et al. 1984; Freeman 1985; Froelich et al. 1985; Maeda et al. 1985; Norin et al. 1985; Sanders 1985; Yamaoka and Takimura 1986). Algae constitute an important source of organoarsenic compounds in marine food webs. In the food chain composed of the alga *Dunaliella marina*, the grazing shrimp *Artemia salina*, and the carnivorous shrimp *Lysmata seticaudata*, organic forms of arsenic were derived from in vivo synthesis by *Dunaliella* and efficiently transferred, without magnification, along the food chain (Wrench et al. 1979). Laboratory studies with five species of euryhaline algae grown in freshwater, or seawater, showed that all species synthesized fat soluble and water soluble arseno-organic compounds from inorganic As +3 and As+5. The BCF values in the five species examined ranged from 200X to about 3,000X--accumulations being highest in lipid phases (Lunde 1973). In Charlotte Harbor, Florida, a region that has become phosphate-enriched due to agricultural activity, virtually all of the arsenic taken up by phytoplankters was biomethylated and returned to the estuary, usually as monomethylarsonic and dimethylarsenic acids (Froelich et al. 1985). The ability of marine phytoplankton to methylate arsenic and release the products to a surrounding environment

varies between species and even within a particular species in relation to their possession of necessary methylating enzymes (Sanders 1985). The processes involved in detoxifying arsenate after its absorption by phytoplankton are not firmly established, but seem to be nearly identical in all plants, suggesting a similar evolutionary development. Like phosphates and sulphates, arsenate may be fixed with ADP, reduced to the arsonous level, and successfully methylated and adenosylated--ultimately producing the 5-dimethylarsenosoribosyl derivatives accumulating in algae (Benson 1984).

Sodium arsenite has been used extensively as an herbicide for control of mixed submerged aquatic vegetation in freshwater ponds and lakes; concentrations of 1.5 to 3.8 mg As+3/l have usually been effective and are considered safe for fish (NAS 1977). Recent data, however, have indicated that As+3 concentrations considered effective for aquatic weed control may be harmful to several species of freshwater teleosts, including bluegills, flagfish, fathead minnows, and rainbow trout (Table 4). Finfishes exposed to 1 to 2 mg total As/l for 2 to 3 days may show one or more of several signs: hemorrhagic spheres on gills; fatty infiltration of liver; and necrosis of heart, liver, and ovarian tissues (NRCC 1978). In green sunfish (*Lepomis cyanellus*), hepatocyte changes parallel arsenic accumulations in the liver (Sorensen et al. 1985). Organoarsenicals are usually eliminated rapidly by fish and other aquatic fauna. Rainbow trout, for example, fed a marine diet containing 15 mg organic arsenic/kg had only negligible tissue residues 6 to 10 days later, although some enrichment was noted in eyes, throat, gills, and pyloric caeca (Pershagen and Vahter 1979). Oral administration of sodium arsenate to estuary catfish (*Cnidoglanis macrocephalus*) and school whiting (*Sillago bassensis*) resulted in tissue accumulations of trimethylarsine oxide. Arsenobetaine levels, which occur naturally in these teleosts, were not affected by As+5 dosing. The toxicity of trimethylarsine oxide is unknown, but the ease with which it can be reduced to the highly toxic trimethylarsine is cause for concern (Edmonds and Francesconi 1987).

BIRDS

Signs of inorganic trivalent arsenite poisoning in birds (muscular incoordination, debility, slowness, jerkiness, falling hyperactivity, fluffed feathers, drooped eyelid, huddled position, unkempt appearance, loss of righting reflex, immobility, seizures) were similar to those induced by many other toxicants and did not seem to be specific for arsenosis. Signs occurred within 1 hour and deaths within 1 to 6 days postadministration; remission took up to 1 month (Hudson et al. 1984). Internal examination suggested that lethal effects of acute inorganic arsenic poisoning were due to the destruction of blood vessels lining the gut, which resulted in decreased blood pressure and subsequent shock (Nystrom 1984). Coturnix (*Coturnix coturnix*), for example, exposed to acute oral doses of As+3 showed hepatocyte damage, i.e., swelling of granular endoplasmic reticulum; these effects were attributed to osmotic imbalance, possibly induced by direct inhibition of the sodium pump by arsenic (Nystrom 1984)

Western grasshoppers (*Melanophus* spp.) poisoned by arsenic trioxide were fed, with essentially no deleterious effects, to nestling northern bobwhites (*Colinus virginianus*), mockingbirds (*Mimus polyglottos*), American robins, (*Turdus migratorius*), and other songbirds (NAS 977). Up to 134 poisoned grasshoppers, containing a total of about 40 mg As, were fed to individual nestlings without any apparent toxic effect. The species tested that were most sensitive to various arsenicals were brown-headed cowbird (*Molothrus ater*) with an LD-50 (11-day) value of 99.8 mg of copper acetoarsenite/kg diet; California quail (*Callipepla californica*) with an LD-50 single oral dose value of 47.6 mg of sodium arsenite/kg body weight; and chicken with 33 and turkey with 17.4 mg/kg body weight of 3-nitro-4-hydroxy phenylarsonic acid as a single oral dose (Table 5).

Chickens rapidly excrete arsenicals; only 2% of dietary sodium arsenite remained after 60 hours (NAS 1977), and arsanilic acid was excreted largely unchanged (Woolson 1975). Excretion of arsanilic acid by chickens was affected by uptake route: excretion was more rapid if administration was by intramuscular injection than if it was oral (NRCC 1978). Studies with inorganic As+5 and chickens indicated that arsenates rapidly penetrated mucosal and serosal surfaces of epithelial membranes; that As+5 intestinal absorption was essentially complete within 1 hour at 370 mg As+5/kg BW but only 50% complete at 3,700 mg/kg BW; that Vitamin D_3 was effective in enhancing duodenal As+5 absorption in rachitic chicks; and that As+5 and phosphate did not appear to share a common transport pathway in the avian duodenum (Fullmer and Wasserman 1986).

MAMMALS

Mammals are exposed to arsenic primarily by the ingestion of naturally contaminated vegetation and water, or through human activity. In addition, feed additives containing arsonic acid derivatives are often fed to domestic livestock to promote growth and retard disease. Some commercial pet foods contain up to 2.3 mg As/kg dry weight (NRCC 1978). Uptake may occur by ingestion (the most likely route), inhalation, and absorption through skin and mucous membranes. Soluble arsenicals are absorbed more rapidly and completely than are the sparingly soluble arsenicals, regardless of the route of administration (NRCC 1978).

Acute episodes of poisoning in warm-blooded organisms by inorganic and organic arsenicals are usually characterized by high mortality and morbidity over a period of 2 to 3 days (NAS 1977; Selby et al. 1977). General signs of arsenic toxicosis include intense abdominal pain, staggering gait, extreme weakness, trembling, salivation, vomiting, diarrhea, fast and feeble pulse, prostration, collapse, and death. Gross necropsy shows a reddening of gastric mucosa and intestinal mucosa, a soft yellow liver, and red edematous lungs. Histopathological findings show edema of gastrointestinal mucosa and submucosa; necrosis and sloughing of mucosal epithelium; renal tubular degeneration; hepatic fatty changes and necrosis; and capillary degeneration in gastrointestinal tract, vascular beds, skin, and other organs. In subacute episodes, where animals live for several days, signs of arsenosis include depression, anorexia, increased urination, dehydration, thirst, partial paralysis of rear limbs, trembling, stupor, coldness of extremities, and subnormal body temperatures (NAS 1977; Selby et al. 1977). In cases involving cutaneous exposure to arsenicals, a dry, cracked, leathery, and peeling skin may be a prominent feature (Selby et al. 1977). Nasal discharges and eye irritation were documented in rodents exposed to organoarsenicals in inhalation toxicity tests (Hood 1985). Subacute effects in humans and laboratory animals include peripheral nervous disturbances, melanosis, anemia, leukopenia, cardiac abnormalities, and liver changes. Most adverse signs rapidly disappeared after exposure ceased (Pershagen and Vahter 1979).

Arsenic poisoning in most animals is usually manifested by acute or subacute signs; chronic poisoning is infrequently seen (NAS 1977). The probability of chronic arsenic poisoning from continuous ingestion of small doses is rare, because detoxication and excretion are rapid (Woolson 1975). Chronic toxicity of inorganic arsenicals is associated with weakness, paralysis, conjunctivitis, dermatitis, decreased growth, and liver damage (NRCC 1978). Arsenosis, produced as a result of chronic exposure to organic arsenicals, was associated with demyelination of optic and sciatic nerves, depressed growth, and decreased resistance to infection (NRCC 1978).

The technical literature on arsenic (Table 6) shows general agreement on eight points: (1) Arsenic metabolism and effects are significantly influenced by the organism tested, the route of administration, the physical and chemical form of the arsenical, and the dose. (2) Inorganic arsenic compounds are more toxic than organic arsenic compounds and trivalent species more so than pentavalent. (3) Inorganic arsenicals can cross the placenta in most species of mammals. (4) Early developmental stages are the most sensitive, and man appears to be one of the most susceptible species. (5) Animal tissues usually contain low levels (<0.3 mg As/kg fresh weight) of arsenic; after the administration of arsenicals these levels are elevated, especially in liver, kidney, spleen, and lung; several weeks later, arsenic is translocated to ectodermal tissues (hair, nails) because of the high concentration of sulfur-containing proteins in these tissues. (6) Inorganic arsenicals are oxidized in vivo, biomethylated, and usually excreted rapidly in the urine, but organoarsenicals are usually not subject to similar transformations. (7) Acute or subacute arsenic exposure can lead to elevated tissue residues, appetite loss, reduced growth, loss of hearing, dermatitis, blindness, degenerative changes in liver and kidney, cancer, chromosomal damage, birth defects, and death. (8) Death or malformations have been documented at single oral doses of 2.5 to 33 mg As/kg body weight, at chronic doses of 1 to 10 mg As/kg body weight, and at dietary levels >5 and <50 mg As/kg diet.

Episodes of wildlife poisoning by arsenic are infrequent. White-tailed deer (*Odocoileus virginianus*) consumed, by licking, fatal amounts of sodium arsenite used to debark trees. The practice of debarking trees with arsenicals for commercial use has been almost completely replaced by mechanical debarking equipment (NAS 1977). Snowshoe hares (*Lepus* sp.) appear to be especially sensitive to methylated arsenicals; hares died after consuming plants heavily contaminated with monosodium methanearsonate as a result of careless silviculture practices (Hood 1985).

Unlike wildlife, reports of arsenosis in domestic animals are common in ovines and felines, less common in ovines and equines, and rare in porcines and poultry (NAS 1977). In practice, the most dangerous arsenic preparations are dips, herbicides, and defoliants in which the arsenical is in a highly soluble trivalent form, usually as trioxide or arsenite (Selby et al. 1977). Accidental poisoning of cattle with arsenicals, for example, is well documented. In one instance, more than 100 cattle died after accidental overdosing with arsenic trioxide applied topically to control lice. On necropsy, there were subcutaneous edematous swellings and petechial hemorrhages in the area of application, and histopathology of intestine, mucosa, kidney, and epidermis (Robertson et al. 1984). In Bangladesh, poisoned cattle showed depression, trembling, bloody diarrhea, restlessness, unsteady gait, stumbling, convulsions, groaning, shallow labored breathing, teeth grinding, and salivation (Samad and Chowdhury 1984). Cattle usually died 12 to 36 hours after the onset of signs; necropsy showed extensive submucosal hemorrhages of the gastrointestinal tract (Samad and Chowdhury 1984), and tissue residues >10 mg/kg fresh weight in liver and kidney (Thatcher et al. 1985). It sometimes appears that animals, especially cattle, develop an increased preference for weeds sprayed with an arsenic weed killer, not because of a change in the palatability of the plant, but probably because arsenic compounds are salty, and thus attractive to animals (Selby et al. 1977).

When extrapolating animal data from one species to another, the species tested must be considered. For example, the metabolism of arsenic in the rat (*Rattus* sp.) is unique, and very different from that in man and other animals. Rats store arsenic in blood hemoglobin, excreting it very slowly--unlike most mammals which rapidly excrete ingested inorganic arsenic in the urine as methylated derivatives (NAS 1977). Blood arsenic, whether given as As+3 or As+5, rapidly clears from humans, mice, rabbits, dogs, and primates, with a half-life of 6 hours for the fast phase and about 60 hours for the slow phase (EPA 1980). In rat, however, blood arsenic is mostly retained in erythrocytes, and clears slowly, with a Tb 1/2 of 60 to 90 days (EPA 1980). In rats, the excretion of arsenic into bile is 40X faster than in rabbits and up to 800X faster than in dogs (Pershagen and Vahter 1979). There is now general and widespread agreement that the rat is unsatisfactory for use in arsenic research (NAS 1977; NRCC 1978; Pershagen and Vahter 1979; EPA 1980; Webb et al. 1986).

Dimethylarsinic acid is the major metabolite of orally administered arsenic trioxide, and is excreted rapidly in the urine (Yamauchi and Yamamura 1985). The methylation process is true detoxification, since methanearsonates and cacodylates are about 200X less toxic than sodium arsenite (NAS 1977). The marmoset monkey (*Callithrix jacchus*), unlike all other animal species studied to date, was not able (for unknown reasons) to metabolize administered As+5 to demethylarsinic acid. Most was reduced to As+3. Only 20% the total dose was excreted in urine as unchanged As+5, another 20% as As+3, and the rest was bound to tissues giving distribution patterns similar to arsenite (Vahter and Marafante 1985). Accordingly, the marmoset--like the rat--may be unsuitable for research with arsenicals.

Arsenicals were ineffective in controlling certain bacterial and viral infections. Mice experimentally infected with bacteria (*Klebsiella pneumonias*) or viruses (pseudorabies, encephalitis, encephalomyocarditis) showed a significant increase in mortality when treated with large doses of arsenicals compared to nonarsenic-treated groups (NAS 1977; Aranyi et al. 1985).

It has been suggested, but not yet verified, that many small mammals avoid arsenic-treated feeds and consume other foods if given the choice (NAS 1977); also, that cacodylic acid, which has negligible effects on wildlife, reduces species diversity due to selective destruction of vegetation (Hood 1985). Both topics merit more research.

CURRENT RECOMMENDATIONS

Numerous criteria for arsenic have been proposed to protect natural resources and human health (Table 7). But many authorities recognize that these criteria are not sufficient for adequate or (in some cases) reasonable protection, and that many additional data are required if meaningful standards are to be promulgated (NAS 1977); NRCC 1978; Pershagen and Vahter 1979; EPA 1980, 1985). Specifically, data are needed on the following subjects: cancer incidence and other abnormalities in natural resources from areas with elevated arsenic levels, and the relation to potential carcinogenicity of arsenic compounds; interaction effects of arsenic with other carcinogens, cocarcinogens, promoting agents, inhibitors, and common environmental contaminants; controlled studies with aquatic and terrestrial indicator organisms on physiological and biochemical effects of long-term, low-dose exposures to inorganic and organic arsenicals--including effects on reproduction and genetic makeup; methodologies for establishing maximum permissible tissue concentrations for arsenic; effects

of arsenic in combination with infectious agents; mechanisms of arsenical growth-promoting agents; role of arsenic in nutrition; extent of animal adaptation to arsenicals, and the mechanisms of action, and physicochemical processes influencing arsenic cycling. In addition, techniques should be developed and procedures implemented in three fields: (1) development of more sophisticated measurements of chemical forms of arsenic in plant and animal tissues; (2) correlations of biologically observable effects with appropriate chemical forms of arsenic; and (3) management of arsenical wastes that will accommodate recycling, reuse, and long term storage.

Some proposed, arsenic criteria merit additional comment, such as those on aquatic life protection, levels in seafoods and drinking water, and use in food-producing animals as growth stimulants or for disease prevention and treatment.

For saltwater life protection, the current water quality criterion of 36 ug As+3/l (EPA 1985; Table 7) seems to offer a reasonable degree of safety; only a few species of algae show adverse effects at <36 ug/1--e.g., reduced growth at 19 to 22 ug/l. In 1980, this criterion was 508 ug/l (EPA 1980), or about 14X higher; the current downward modification seems to be indicative of the increasingly stringent arsenic criteria formulated by regulatory agencies. But the current criterion for freshwater life protection of 190 ug As+3/1 (EPA 1985; Table 7), which is down from 440 ug As+3/1 in 1980 (EPA 1980), is unsatisfactory. Many species of freshwater biota are adversely affected at <190 ug/l of As+3, As+5, or various organoarsenicals (Table 4). These adverse effects include death and malformations of toad embryos at 40 ug/l, growth inhibition of algae at 48 to 75 ug/l, mortality of amphipods and gastropods at 85 to 88 ug/l, and behavioral impairment of goldfish (*Carassius auratus*) at 100 ug/l. It seems that some downward adjustment in the current freshwater aquatic life protection criterion is warranted.

Current permissible concentrations of arsenic in seafood in Hong Kong destined for human consumption range from 6 to 10 mg/kg fresh weight (Table 7); however, these values are routinely exceeded in 22% of finfish, 20% of bivalve molluscs, 67% of gastropods, 29% of crabs, 21% of shrimp and prawns, and 100% of lobsters (Phillips et al. 1982). The highest arsenic recorded in Hong Kong seafood products was in gastropods (*Hemifusus* spp.), in which the concentrations of 152 to 176 mg/kg FW were among the highest recorded in any species to date (Phillips et al. 1982). Probably most of the arsenic in seafood products is present as arsenobetaine or in other comparatively harmless forms. In effect, arsenic criteria for seafoods are neither enforced nor enforceable. Most toxicologists from the U.S. Food and Drug Administration believe that the average daily intake of arsenic in the different food commodities does not pose a hazard to the consumer (Jelinek and Corneliussen 1977).

For maximum protection of human health from the potential carcinogenic effects due to exposure of arsenic through drinking water or contaminated aquatic organisms, the ambient water concentration should be zero, based on the nonthreshold assumption for arsenic. But zero level may not be attainable. Accordingly, the levels that may result in an incremental increase of cancer risk over a lifetime are estimated at 10^{-5} , or one additional case per 100,000 population. These values are estimated at 0.022 ug As/l for drinking water, and 0.175 ug As/l for water containing edible aquatic resources (EPA 1980; Table 7).

Various phenylarsonic acids--especially arsanilic acid, sodium arsanilate, and 3-nitro-4-hydroxy-phenylarsonic acid--have been used as feed additives for disease control and for improvement of weight gain in swine and poultry for almost 40 years (NAS 1977). The arsenic is present as As+5 and is rapidly excreted; present regulations require withdrawal of arsenical feed additives 5 days before slaughter for satisfactory depuration (NAS 1977). Under these conditions, total arsenic residues in edible tissues do not exceed the maximum permissible limit of 2 mg/kg fresh weight (Jelinek and Corneliussen 1977). It now seems that organoarsenicals will continue to be used as feed additives unless evidence indicates otherwise.

Table 1. Total arsenic concentrations in selected nonbiological materials.

Material and units (in parentheses)	Concentration[a]	Reference[b]
Air (ug/m^3)		
Remote areas	<0.02	1
Urban areas	(0.0-0.16)	
Near smelters		
U.S.S.R.	(0.5-1.9)	2
Texas	Max. 1.4	2
Tacoma, Washington	Max. 1.5	2
Romania	Max. 1.6	2
Germany	(0.9-1.5)	2
Coal-fired power plant, Czechoslovakia	(19 to 69)	3
Orchard spraying of Pb arsenate	Max. 260,000	3
Near U.S. cotton gin burning vegetation treated with arsenic	Max. 400	3
Drinking water (g/L)		
Nationwide, U.S.A.	2.4 (0.5-214)	4
Fairbanks, Alaska	224 (1-2,450)	4
Bakersfield, California	(6-393)	4
Nevada, 3 communities	(51-123)	4
Mexico, from plant producing As_2O_3	(4,000-6,000)	2
Japan, near factory producing arsenic sulfide	3,000	2
Ghana, near gold mine	1,400	2
Minnesota, contaminated by residual arsenical grasshopper bait	(11,800-21,000)	1
Methylated arsenicals, U.S.A.	usually <0.3 (0.01-1)	5
Dust (mg/kg)		
Tacoma, Washington		
Near smelter	1,300	1
Remote from smelter	70	1
Fossil fuels (mg/kg)		
Coal		
Canada	4 (0.3-100)	3
USA	5	2

Czechoslovakia	Max. 1,500	2
Worldwide	13 (0.0-2,000)	1
Coal ash	(<20-8,000)	3
Flyash	(2.8-200)	3
Petroleum	0.2	3
Petroleum ash	Max. 100,000	3
Automobile particulates	298	3
Groundwater (ug/L)		
Near polymetallic sulfide		
deposits	Max. 400,000	3
Near gold mining activities	>50	2
USA	Usually <10	2
USA	17.9 (0.01-800)	3
Lake water (ug/L)		
Dissolved solids		
<2,000 mg/L	(0.0-100)	6
>2,000 mg/L	(0.1-2,000)	6
Lake Superior	(0.1-1.6)	6
Japan, various	(0.2-1.9)	6
Germany, Elbe River	(20-25)	6
Searles Lake, California	(198,000-243,000)	1,4
California, other lakes	(0.0-100)	1,4
Michigan	Max. 2.4	1,4
Wisconsin	(4-117)	1,4
Florida	Max. 3.6	1,4
Lake Chatauqua, New York	(3.5-35.6)	1.4
Lake Ohakuri, New Zealand	(30-60)	7
Finfeather Lake, Texas	Max. 240,000	8
Thermal waters, worldwide	(20-3,800)	
	Max. 276,000	1,2,3,9
Rain (ug/L)		
Canada	(0.01-5)	3
Rhode Island	0.8	1
Seattle, Washington	17	1
River water (ug/L)		
Polluted, USA	Max. 6,000	4
Nonpolluted, USA	Usually <5	4
Nationwide, USA, 1974-1981		
25th percentile	<1	10
50th percentile	1	10
75th percentile	3	10
Rock (mg/kg)		
Limestones	1.7 (0.1-20)	1

Sandstones	2 (0.6-120)	1
Shales and clays	14.5 (0.3-490)	1
Phosphates	22.6 (0.4-188)	1
Igneous, various	1.5-3 (0.06-113)	1
Seawater (ug/L)		
Worldwide	2 (0.15-6)	6
Pacific Ocean	(1.4-1.8)	11
Atlantic Ocean	(1.0-1.5)	11
South Australia		
Total dissolved As	1.3 (1.1-1.6)	12
As^{+5}	1.29	12
As^{+3}	0.03	12
Particulate As	<0.0006	12
U.K., Beaulieu estuary		
Water temperature <12° C		
Inorganic arsenic	(0.4-0.9)	13
Suspended arsenic	(0.02-0.24)	13
Organoarsenicals	(0.19-0.75)	13
Water temperature >12° C		
Inorganic arsenic	(0.6-1.1)	13
Suspended arsenic	(0.2-0.6)	13
Organoarsenicals	ND	13
Sediments (mg/kg dry weight)		
Near sewer outfall	35	3
From areas contaminated by smelteries, arsenical herbicides, or mine tailings		
Surface	(198-3,500)	1,7,9,14,15
Subsurface	(12-25)	1,7,9,14,15
Upper Mississippi River	2.6 (0.6-6.2)	16
Lake Michigan	(5-30)	1
Naturally elevated	>500	1,9
Oceanic	33.7 (<0.4-455)	3
Lacustrine	(5-26.9) Max. 13,000	3
Snow (mg/kg)		
Near smelter	>1,000	3
Soil pore waters (ug/L)		
Mineralized areas		
Arsenate	(79-210)	17
Arsenite	(2-11)	17
Monomethyl arsonic acid (MMAA)	(4-22)	17
Total arsenic	(93-240)	17

Unmineralized areas		
Arsenate	(18-49)	17
Arsenite	(1-7)	17
MMAA	<1	17
Total arsenic	(13-59)	17
Soils (mg/kg dry weight)		
USA, uncontaminated	7.4	18
Worldwide, uncontaminated	7.2	18
Canada		
Near Gold mine		
Air levels 3.9 mg As/m^3	21,213	3
80 km distant	(10-25)	3
Near smelter		
Japan	Max. 2,470	2
Tacoma, Washington	Max. 380	2
Treated with arsenical pesticides		
USA	165 (1-2,554)	6
Canada	121	6
Synthetic detergents (mg/kg)		

[a]Concentrations are listed as mean, minimum-maximum (in parentheses), and maximum (Max.).

Table 2. Arsenic concentrations in field collections of selected species of flora and fauna. Values listed are in mg As/kg fresh weight (FW), or dry weight (DW).

Ecosystem, species, and other variables	Concentration in mg/kg[a]	Reference[b]
Terrestrial Plants		
Colonial bentgrass, *Agrostis tenuis*		
On mine waste site	1,480, Max. 3,470 DW	1
On low arsenic soil	(0.3-3) DW	1
Scotch heather, *Calluna vulgaris*		
On mine waste site	1,260 DW	1
On low arsenic soil	0.3 DW	1
Coontail, *Ceratophyllum demersum*		
From geothermal area, New Zealand	(20-1,060) DW	1
Cereal grains		
From arsenic treated areas	Usually <3 DW, Max. 252 DW	2
Nontreated areas	Usually <0.5 DW, Max. 5 DW	2
Grasses		
From arsenic treated areas	(0.5-60,000) DW	2
Nontreated areas	(0.1-0.9) DW	2
Apple, *Malus sylvestris*		
Fruit	<0.1 FW; <1.8 DW	1
Alfalfa, *Medicago sativa*		
USA	1.6 FW	1
Montana, smelter area	(0.4-5.7) FW	1
White spruce, *Picea alba*		
Arsenic-contaminated soil		
Branch	(2.8-14.3) DW	1
Leaf	(2.1-9.5)	1
Trunk	(0.3-55) DW	1
Root	(45-130) DW	1
Control site		
All samples	<2.4 DW	1
Pine, *Pinus silvestris*, needles		
Near U.S.S.R. metals smelter; soil levels 120.0 mg As/kg	22 FW	3
Trees		
Nontreated areas	Usually <1 DW	2
Lowbush blueberry, *Vaccinium angustifolium*		

Maine, leaf		
Arsenic-treated soil	(6.8-15) DW	1
Control	0.8 DW	1
Various species		
From uncontaminated soils	(<0.01-5) DW	2
From arsenic-impacted (80 mg/kg) soils	1.2 (<0.2-5.8) DW	4
Vegetables		
From arsenic-treated areas	Usually <3 DW, Max. 145 DW	2
Nontreated areas	Usually <1 DW, Max. 8 DW	2
Vegetation		
Near gold mine, Canada, Air levels up to 3.9 mg As/m^3	Max. 11,438 DW	5
80 km distant	(12-20) DW	5
Freshwater Flora		
Aquatic Plants		
Arsenic-treated areas	(20-1,450) DW	2
Untreated areas	(1.4-13) DW	2
Irish moss, *Chondrus crispus*		
Whole	(5-12) DW	1
Pondweeds, *Potamogeton* spp.		
Whole		
Near geothermal area	(11-436) DW	1
Control site	<6 DW	
Freshwater Fauna		
Alewife, *Alosa pseudoharengus*		
Whole, Michigan	0.02 FW	1
Muscle, Wisconsin	0 FW	1
White sucker, *Catostomus commersoni*		
Muscle	(0.03-0.13) FW	1
Whole	(0.05-0.16) FW	1
Common carp, *Cyprinus carpio*		
Upper Mississippi River, 1979		
Whole	0.4 (0.2-0.6) DW	6
Liver	0.4 (0.3-1) DW	6
Nationwide		
Whole	0.05 FW	1
Muscle	(0.0-0.2) FW	1
Northern pike, *Esox lucius*		
Muscle		
Canada	(0.05-0.09) FW	1

Great Lakes	<0.05 FW	1
Sweden	0.03 FW	1
New York	<0.1 FW	1
Wisconsin	<0.01 FW	1
Fish, various species		
Whole	Max. 1.9 FW	2
Whole	(0.04-0.2) FW	7
Netherlands, 1977-1984		
Muscle	(0.04-0.15) FW	8
Nationwide, USA		
Whole, 1976-1977	(0.05-2.9) FW	9
Near smelter (water arsenic 2.3-2.9 mg/L)		
Muscle, 3 species		
Total arsenic	0.05-0.24) FW	10
Inorganic arsenic	(0.01-0.02) FW	10
Liver, 2 species		
Total arsenic	0.15 FW	10
Inorganic arsenic	0.01 FW	10
Control location (water arsenic <0.5 mg/L)		
Muscle		
Total arsenic	(0.06-0.09) FW	10
Inorganic arsenic	<0.03 FW	10
Liver		
Total arsenic	0.09 FW	10
Inorganic arsenic	<0.01 FW	10
Channel catfish, *Ictalurus punctatus*		
Muscle		
Native	(0.0-0.3) FW	1
Cultured	(0.2-3.1) FW	1
Whole, nationwide	(<0.05-0.3) FW	1
Green sunfish, *Lepomis cyanellus*, liver		
Polluted waters (from manufacturer of arsenical defoliants and pesticides), Texas. Mean water concentration 13.5 mg As/L; sediment content of 4,700 mg/kg		
Age 1 to 2	(19.7-64.2) DW	11
Age 3	15 DW	11

Age 4	(6.1-11.5) DW	11
Bluegill, *Lepomis macrochirus*		
From pools treated with arsenic		
Muscle	1.3 FW	1
Skin and scales	2.4 FW	1
Gills and GI tract	17.6 FW	1
Liver	11.6 FW	1
Kidney	5.9 FW	1
Ovary	8.4 FW	1
Control locations		
All tissues	<0.2 FW	1
Whole		
Nationwide	(<0.05-0.15) FW	1
Upper Mississippi River, 1979	0.3 (0.2-0.4) DW	6
Smallmouth bass, *Micropterus dolomieui*		
Muscle		
Wisconsin	<0.13 FW	1
Lake Erie	0.22 FW	1
New York	(0.03-0.51) FW	1
Whole, nationwide	(<0.05-0.28) FW	1
Largemouth bass, *Micropterus salmoides*		
Whole, nationwide	(<0.05-0.22) FW	1
Muscle		
Wisconsin	(0.0-0.12) FW	1
New York	(0.03-0.16) FW	1
Striped bass, *Morone saxatilis*		
Muscle	(0.2-0.7) FW	1
Coho salmon, *Oncorhynchus kisutch*		
Muscle		
Wisconsin	<0.15 FW	1
Lake Erie	(0.07-0.17) FW	1
New York	<0.5 FW	1
USA	0.09 FW	1
Yellow perch, *Perca flavescens*		
All tissues	<0.16 FW	1
Rainbow trout, *Salmo gairdneri*		
All tissues	<0.4 FW	1
Atlantic salmon, *Salmo salar*		
Oil		

Liver	6.7 FW	1
Muscle	(0.8-3.1) FW	1
Lake trout, *Salvelinus namaycush*		
Whole, nationwide	(0.06-0.68) FW	1
Marine Flora		
Algae		
Green	(0.5-5) DW	2
Brown	Max. 30 DW	2
11 species	(2-58) DW	12
Various species	(10-100) DW	13
Seaweed, *Chondrus crispus*		
Alga, *Fucus* spp.		
Oil	(6-27) FW	2
Fatty acid	(5-6) FW	2
Brown alga, *Fucus vesiculosus*

Table 3. Toxic and sublethal effects of various arsenic compounds on selected species of terrestrial plants and invertebrates.

Ecosystem, species, and other variables	Arsenic concentration and effects	Reference[a]
Terrestrial Plants		
Crops		
Total water soluble As in soils	Depressed crop yields at 3 to 28 mg/L	1
Total soil As concentrations	Depressed crop yields at 25 to 85 mg/kg	1
Common bermudagrass, *Cynodon dactylon*		
Arsenite	Plants grown on As- amended soils (up to 90 mg As^{+3}/kg) contained up to 17 mg As/kg dry weight in stems, 20 in leaves, and 304 in roots	2
Fruit orchards		
Inorganic arsenites and arsenates	Soils contain 31 to 94 mg/kg dry weight (vs. 2.4 in untreated orchards); whole rodents contain <0.002 mg As/kg fresh weight (vs. nondetectable in untreated orchards)	3
Soybean, *Glycine max*		
Total As	Toxic signs at plant residues >1 mg total As/kg	1
Grasslands		
Cacodylic acid	Kill of 75% to 90% of all species at 17 kg/ha; recovery modest	3
Rice, *Oryza sativum*		
Disodium methylarsonate	75% decrease in yield at soil (silty loam) concentrations of 50 mg/kg	1

Scots pine, *Pinus sylvestris*		
Inorganic As^{+5}	Seedlings die when soil (sandy) concentrations exceed 250 mg/kg dry weight. Maximum BCF factors low: 0.6 for roots; 0.1 for shoots. Residues >62 mg As/kg DW in shoots are toxic, and 3,300 mg/kg DW usually fatal	4
Pea, *Pisum sativum*		
Sodium arsenite	15 mg/L inhibits light activation and photosynthetic CO_2 fixation in chloroplasts	5
Sandhill plant communities		
Cacodylic acid	No lasting effect at 2.25 kg/ha. Some species defoliated st 6.8 kg/ha. Significant effect, including 75% defoliation of oaks and death of all pine trees, at 34 kg/ha	3
Cowpea, *Vigna* sp.		
Total water soluble As in soils	Decreased yields at 1 mg/L	1
Total soil As concentrations (loamy sand)	Toxic at 25 mg/kg	1
Yeast		
Arsenate	At 75 mg/L, 60% reduction in phosphate transport and glucose metabolism in 30 min; at 375 mg/L, 100% reduction	1
Terrestrial Invertebrates		
Honeybee, *Apis mellifera*		
Inorganic arsenite	Following arsenic spray dusting, dead bees contained 20.8 to 31.2 mg/kg FW (adults) or 5 to 13 mg/kg FW (larvae)	6
Beetles		
Cacodylic acid	Dietary levels of 100 to 1,000 mg/kg fatal to certain pestiferous species	3
Western spruce budworm, *Christoneura occidentalis*, sixth instar stage		
Arsenic trioxide	Dietary levels of 99.5 mg/kg FW killed 10%, 2,250 mg/kg killed 50%, and 65,300 mg/kg was fatal to 90%. Newly molted pupae and adults of As-exposed larvae had reduced weight. Regardless of dietary levels, concentrations of As ranged up to 2,640 mg/kg DW in dead pupae, and 1,708 mg/kg DW in adults	7

Anderson 1986; 6, Jenkins 1980; 7, Robertson and McLean 1985.

Table 4. Lethal and sublethal effects of various arsenic compounds on selected species of aquatic biota.

Ecosystem, species, arsenic compound, and other variables	Arsenic concentration	Effect	Reference[b]
Freshwater Plants			
Algae, various species			
As^{+3}	1.7 mg/L	Toxic	1
As^{+3}	4 mg/L	Decomposition	1
As^{+3}	2.3 mg/L	95% to 100% kill in 2 to 4 weeks of 4 species	2,3
As^{+5}	0.075 mg/L	Decreased growth	3
Alga, *Ankistrodesmus falcatus*			
As^{+5}	0.26 mg/L	EC-50 (14 days)	3
Alga, *Scenedesmus obliquus*			
As^{+5}	0.048 mg/L	EC-50 (14 days)	3
Alga, *Selenastrum capricornutum*			
As^{+5}	0.69 mg/L	EC-50 (4 days)	3
Freshwater Invertebrates			
Cladoceran, *Bosmina longirostris*			
As^{+5}	0.85 mg/L	50% immobilization in 96 h	4
Cladoceran, *Daphnia magna*			
As^{+3}	0.63 to 1.32 mg/L	MATC[c]	3
As^{+3}	0.96 mg/L	LC-5 (28 days)	5
As^{+3}			
Starved	1.5 mg/L	50% immobilization (96 h)	6
Fed	4.3 mg/L	50% immobilization (96 h)	6
As^{+5}	0.52 mg/L	Reproductive impairment of 16% in 3 weeks	3
As^{+5}	0.93 mg/L	LC-5 (28 days); maximum bioconcentration factor (BCF) of 219X	5
As^{+5}	7.4 mg/L	LC-50 (96 h)	2

DSMA	0.83 mg/L	LC-0 (28 days)	5
SDMA	1.1 mg/L	LC-0 (28 days)	5
Total As	1 mg/L	18% decrease in body weight in 3 weeks	1
Total As	1.4 mg/L	50% reproductive impairment in 3 weeks	1
Total As	2.8 mg/L	LC-50 (21 days)	1
Total As	4.3 to 7.5 mg/L	Immobilization (21 days)	1
Cladoceran, *Daphnia pulex*			
As^{+5}	49.6 mg/L	50% immobilization (48 h)	4
As^{+3}	1.3 mg/L	LC-50 (96 h)	2,3
As^{+3}	3 mg/L	EC-50 (48 h)	7
Amphipod, *Gammarus pseudolimnaeus*			
As^{+3}	0.87 mg/L	50% immobilization (96 h)	6
As^{+3}	0.088 mg/L	LC-20 (28 days)	5
As^{+3}	0.96 mg/L	LC-100 (28 days)	5
As^{+5}	0.97 mg/L	LC-20 (28 days); no accumulations	5
DSMA	0.086 mg/L	LC-10 (28 days)	5
DSMA	0.97 mg/L	LC-40 (28 days)	5
SDMA	0.85 mg/L	LC-0 (28 days)	5
Snail, *Helisoma campanulata*			
As^{+3}	0.96 mg/L	LC-10 (28 days)	5
As^{+5}	0.97 mg/L	LC-0 (28 days); maximum BCF of 99X	5
DSMA	0.97 mg/L	LC-0 (28 days)	5
SDMA	0.085 mg/L	LC-0 (28 days)	5
SDMA	0.085 mg/L	LC-32 (28 days)	5
Stonefly, *Pteronarcys californica*			
As^{+3}	38 mg/L	LC-50 (96 h)	7
Stonefly, *Pteronarcys dorsata*			
As^{+3}	0.96 mg/L	LC-0 (28 days)	5
As^{+5}	0.97 mg/L	LC-20 (28 days); maximum BCF of 131X	5

DSMA	0.97 mg/L	LC-0 (28 days)	5
SDMA	0.85 mg/L	LC-0 (28 days)	5
Cladoceran, *Simocephalus serrulatus*			
As^{+3}	0.81 mg/L	LC-50 (96 h)	3
Zooplankton			
As^{+3}	0.4 mg/L	No effect	1
As^{+3}	1.2 mg/L	Population reduction	1
Freshwater Vertebrates			
Marbled salamander, *Ambystoma opacum*			
As^{+3}	4.5 mg/L	EC-50 (8 days) concentration producing death and malformations in developing embryos	3
Goldfish, *Carassius auratus*			
As^{+5}	0.1 mg/L	15% behavioral impairment in 24 h; 30% impairment in 48 h	1
As^{+5}	24.6 to 41.6 mg/L	LC-50 (7 days)	1
As^{+3}	0.49 mg/L	EC-50 (7 days)	3
MSMA	5 mg/L	LC-50 (96 h)	3
Narrow-mouthed toad, *Gastrophryne carolinensis*			
As^{+3}	0.04 mg/L	50% death or mal-formations noted in developing embryos in 7 days	3
Channel catfish, *Ictalurus punctatus*			
As^{+3}	25.9 mg/L	LC-50 (96 h)	8
Flagfish, *Jordanella floridae*			
As^{+3}	14.4 mg/L	LC50 (96 h)	6
As^{+3}	2.1 to 4.1 mg/L	MATC[c]	3
Bluegill, *Lepomis macrochirus*			
As^{+3}			
Juveniles	0.69 mg/L	Reduced survival 16 weeks after a single treatment	2,3
Adults	0.69 mg/L	Histopathology after 16 weekly treatments	2

As^{+3}	4 mg/L	Population reduction of 42% after several monthly applications	8
As^{+3}	30 to 35 mg/L	LC-50 (96 h)	7,8
MSMA	1.9 mg/L	LC-50 (96 h)	3
Total As	Tissue residues of 1.35 mg/kg fresh weight (juveniles) and 5 mg/kg (adults)	Threshold acute toxic value	1
Spottail shiner, *Notropis hudsonius*			
As^{+3}	45 mg/L	LC-50 (25 h)	8
As^{+3}	29 mg/L	LC-50 (48 h); survivors with fin and scale damage	8
Chum salmon, *Oncorhynchus keta*			
As^{+3}	11 mg/L	LC-50 (48 h)	8
Minnow, *Phoxinus phoxinus*			
As^{+3}	20 mg/L	Equilibrium loss in 36 h	8
As^{+5}	234 to 250 mg/L	Lethal	8
Fathead minnow, *Pimephales promelas*			
As^{+3}	14.1 mg/L	LC-50 (96 h)	6
As^{+3}	2.1 to 4.8 mg/L	MATC[c]	6
As^{+5}	25.6 mg/L	LC-50 (96 h)	3
As^{+5}	0.53 to 1.50 mg/L	MATC[c]	3
Rainbow trout, *Salmo gairdneri*			
As^{+3}	0.13 mg/L	Ec-10 (28 days)	3
As^{+3}			
Embryos	0.54 mg/L	LC-50 (28 days)	2
Adults	23 to 26.6 mg/L	LC-50 (96 h)	5
As^{+3}	0.96 mg/L	LC-50 (28 days)	7,8
As^{+3} or As^{+5}	Fed diets containing 120 to 1,600 mg As/kg for 8 weeks	Growth depression, food avoidance, and impaired feed efficiency at all levels	9
As^{+5}	Fed diets containing 10 to	No effect level at about 10 mg/kg diet.	

	90 mg As/kg for 16 weeks	Some adaptation to dietary As observed in trout fed 90 mg/kg diet, as initial negative growth gave way to slow positive growth over time	9
As^{+5}	0.97 mg/L	LC-0 (28 days); no accumulations	5
DSMA	0.97 mg/L	LC-0 (28 days)	5
SDMA	0.85 mg/L	LC-0 (28 days)	5
SC	1,000 mg/L	LC-0 (28 days)	14
DMA or ABA	Fed diet containing 120 to 1,600 mg/kg for 8 weeks	No toxic response at any level tested	9
Brook trout, *Salvelinus fontinalis*			
As^{+3}	15 mg/L	LC-50 (96 h)	3
Marine Plants			
Algae, 2 spp.			
As^{+3} or As^{+5}	1 mg/L	No effect	10
As^{+5}	1,000 mg/L	No deaths	10
Algae, 3 spp.			
As^{+3}	0.019 to 0.022 mg/L	Reduced growth	3
Red alga, *Champia parvula*			
As^{+3}	0.065 mg/L	Normal sexual reproduction	10
As^{+3}	0.095 mg/L	No sexual reproduction	10
As^{+3}	0.30 mg/L	Death	10
As^{+5}	10 mg/L	Normal growth, but no sexual reproduction	10
Phytoplankton			
As^{+5}	0.075 mg/L	Reduced biomass of populations in 4 days	3
Red alga, *Plumaria elegans*			
As^{+3}	0.58 mg/L	Arrested sporeling development 7 days posttreatment after exposure for 18 h	12

Alga, *Skeletonema costatum*			
As^{+5}	0.13 mg/L	Growth inhibition	3
Alga, *Thalassiosira aestivalis*			
As^{+5}	0.075 mg/L	Reduced chlorophyll a	3
Marine Invertebrates			
Copepod, *Acartia clausi*			
As^{+3}	0.51 mg/L	LC-50 (96 h)	3
Dungeness crab, *Cancer magister*			
As^{+3}	0.23 mg/L	LC-50 (96 h) for zoea	3
Amphipod, *Corophium volutator*			
As^{+5}			
Water temperature, °C			
5	8 mg/L	LC-50 (230 h)	11
10	8 mg/L	LC-50 (150 h)	11
15	8 mg/L	LC-50(74 h)	11
15	4 mg/L	LC-50 (140 h)	11
15	2 mg/L	LC-50 (192 h)	11
Pacific oyster, *Crassostrea gigas*			
As^{+3}	0.33 mg/L	LC-50 (96 h) for embryos	3
American oyster, *Crassostrea virginica*			
As^{+3} (eggs)	7.5 mg/L	LC-50 (48 h)	8
Copepod, *Eurytemora affinis*			
As^{+5}	0.025 mg/L	No effect	12
As^{+5}	0.1 mg/L	Reduced juvenile survival	12
As^{+5}	1 mg/L	Reduced adult survival	12
Clam, *Macoma balthica*			
As^{+5}			
Water temperature, °C			
5	220 mg/L	LC-50 (192 h)	11
10	60 mg/L	LC-50 (192 h)	11
15	15 mg/L	LC-50 (192 h)	11
Mysid, *Mysidopsis bahia*			
As^{+3}	0.63 to 1.27 mg/L	MATC[c]	3
As^{+5}	2.3 mg/L	LC-50 (96 h)	3
Blue mussel, *Mytilus edulis*			
As^{+3}	16 mg/L	Lethal in 3 to 16 days	8
Mud snail, *Nassarius obsoletus*			
As^{+3}	2 mg/L	Depressed oxygen	

		consumption in 72 h	8
Oligochaete annelid, *Tubifex costatus*			
As^{+5}			
Water temperature, °C			
5	500 mg/L	LC-50 (130 h)	11
10	500 mg/L	LC-50 (115 h)	11
15	500 mg/L	LC-50 (85 h)	11
Marine Vertebrates			
Grey mullet, *Chelon labrosus*			
As^{+3}	27.3 mg/L	LC-50 (96 h); some skin discoloration	13
Dab, *Limanda limanda*			
As^{+3}	28.5 mg/L	LC-50 (96 h); respiratory problems	13
Pink salmon, *Oncorhynchus gorbuscha*			
As^{+3}	2.5 mg/L	LC-0 (10 days)	8
As^{+3}	3.8 mg/L	LC-54 (10 days)	3
As^{+3}	7.2 mg/L	LC-100 (7 days)	3
Teleosts, 3 spp.			

---

[a]As^{+3}, inorganic trivalent arsenite; As^{+5}, inorganic pentavalent arsenate; DMA, dimethylarsinic acid; ABA, p-aminobenzenearsonic acid; DMSA, disodium methylarsenate ($CH_3AsO(ONa)_2$); SDMA, sodium dimethylarsenate ($(CH_3)_2AsO(ONa)$); MSMA, monosodium methanearsonate; SC, sodium cacodylate.

[b]References: 1, NRCC 1978; 2, EPA 1980; 3, EPA 1985; 4, Passino and Novak 1984; 5, Spehar et al. 1980; 6, Lima et al. 1984; 7, Johnson and Finley 1980; 8, NAS 1977; 9, Cockell and Hilton 1985; 10, Thursby and Steele 1984; 11, Bryant et al. 1985; 12, Sanders 1986; 13, Taylor et al. 1985; 14, Hood 1985.

[c]Maximum acceptable toxicant concentration. Lower value in each pair indicates highest concentration tested producing no measurable effect on growth, survival, reproduction, or metabolism during chronic exposure; higher value indicates lowest concentration tested producing a measurable effect.

Table 5. Lethal and sublethal effects of various arsenicals on selected species of birds.

Species and arsenic compound	Effect	Reference[a]
Chukar, *Alectoris chukar*		
Silvisar-510 (mixture of cacodylic acid and tri-ethanolamine cacodylate)	Single oral LD-50 dose of ~2,000 mg/kg body weight (BW); signs of poisoning evident within 10 min and mortalities within 1 to 2 days postadminis-tration. Remission took up to 1 month	1
Mallard, *Anas platyrhynchos*		
Sodium arsenite	323 mg/kg BW is LD-50 acute oral value	1,2,3
Sodium arsenite	500 mg/kg diet is fatal to 50% in 32 days; 1,000 mg/kg diet fatal to 50% in 6 days	2
Sodium cacodylate	1,740 to 5,000 mg/kg diet fatal to 50% in 5 days	4
Silvisar 510	Single oral LD-50 >2,400 mg/kg BW; regur-gitation and excessive drinking noted	1
Lead arsenate	5,000 mg/kg diet not fatal in 11 days	2
Copper acetoarsenite	5,000 mg/kg diet fatal to 20% in 11 days	2
California quail, *Callipepla californica*		
Sodium arsenite	LD-50 single oral dose of 47.6 mg/kg BW	1
Northern bobwhite, *Colinus virginianus*		
Copper acetoarsenite	480 mg/kg in diet fatal to 50% in 11 days	2
Sodium cacodylate	1,740 mg/kg in diet for 5 days produced no effect on behavior, no signs of intoxication, and negative necropsy	4

Monosodium methanearsonate, CH_4AsNaO_3	Single oral LD-50 dose of 3,300 mg/kg BW	4
Chicken, *Gallus gallus*		
Inorganic trivalent arsenite	Up to 34% dead embryos at dose range of 0.01-1 mg As^{+3}/embryo; threshold for malformations at dose range 0.03-0.3 mg/embryo	3
Inorganic pentavalent arsenate	Up to 8% dead at dose range 0.01-1 mg As^{+5}/embryo; threshold for malformations at dose range 0.3-3 mg/embryo	3
Disodium methyl arsenate	Teratogenic to embryos when injected at 1 to 2 mg/egg	3,4
Sodium cacodylate	Developmental abnormal-ities at embryonic injected doses of 1 to 2 mg/egg	4
Dodecylamine p-chlorophenylarsonate	At dietary levels of 23.3 mg/kg, liver residues were 2.9 mg/kg FW at 9 weeks. No ill effects noted	5
3-Nitro-4-hydroxy phenylarsonic acid	At 18.7 mg/kg diet for 9 weeks, liver residues of 2.4 mg/kg FW. Those fed diets containing 187 mg/kg for 9 weeks had no ill effects; liver content of 7.5 mg/kg FW	5
3-Nitro-4-hydroxy phenylarsonic acid	LC-50 dose of 33 mg/kg BW (single oral) or 9.7 mg/kg BW (intraperitoneal injection)	2
Arsanilic acid	Fed diets containing 45 mg/kg for 9 weeks; no effect except slightly elevated liver content of 1.2 mg/kg fresh weight. At dietary levels of 455 kg/mg, liver residues were 6.4 mg/kg FW after 9 weeks; no other effects evident	5
Cacodylic acid	Dosed orally without effect at 100 mg/kg BW daily for 10 days	4

Chickens, *Gallus* spp.		
Arsanilic acid	50% excreted in 36 to 38 h	3
Arsenate	50% excreted in 60 to 63 h	3
Turkey, *Meleagris gallopavo*		
3-Nitro-4-hydroxy phenylarsonic acid	Single oral LD-50 dose of 17.4 mg/kg BW	2
Brown-headed cowbird, *Molothrus ater*		
Copper acetoarsenite	All survived 11 mg/kg diet for 6 months; maximum whole body residue of 1.7 mg As/kg dry weight	2
Copper acetoarsenite	All survived 33 mg/kg diet for 6 months (whole body content of 6.6 mg As/kg dry weight) or 7 months (8.6 DW)	2
Copper acetoarsenite	99.8 mg/kg in diet fatal to 50% in 11 days	2
Copper acetoarsenite	100 mg/kg in diet for 3 months fatal to 100%; tissue residues of 6.1 dry weight in brain, 40.6 in liver	2
Gray partridge, *Perdix perdix*		
Lead arsenate	300 mg/kg BW fatal in 52 h	2
Ring-necked pheasant, *Phasianus colchicus*		
Sodium arsenite	Single oral dose of 386 mg/kg BW is LD-50 value	1
Copper acetoarsenite	Single oral dose of 1.403 mg/kg BW is LD-50 value	3

Table 6. Lethal and sublethal effects of various arsenicals on selected species of mammals.

Organism and arsenical	Effect	Reference[a]
Cow, *Bos bovis*		
Arsenate	Cows fed 33 mg As^{+5} daily per animal for 3 months had slightly elevated levels in muscle (0.02 mg/kg fresh weight vs. 0.05 in controls) and liver (0.03 vs. 0.012), but normal levels in milk and kidney	1
Arsenite	Cows fed 33 mg As^{+3} daily per animal for 15 to 28 months had tissue levels, in mg/kg fresh weight, of 0.002 for milk (vs. <0.001 for controls), 0.03 for muscle (vs. 0.005), 0.1 for liver (vs. 0.012), and 0.16 for kidney (vs. 0.053)	1
Cattle, *Bos* spp.		
Arsenic pentoxide (wood ashes treated with As preservative)	Several deaths after eating wood ashes (780 mg/kg dry weight); tissue residues, in mg As/kg fresh weight, of 13.9 in liver, 23.7 in kidney, and 25.8 in rumen contents (vs. normal values of <0.5)	2
Arsenic trioxide	Single oral dose of 15 to 45 grams/animal fatal	3
Arsenic trioxide	Toxic dose is 33 to 55 mg/kg body weight (BW), or 13.2 to 22 grams for a 400-kg animal. Animals accidentally poisoned topically contained up to 15 mg As/kg fresh weight liver, 23 in kidney, and 45 in urine (vs. <1 for all normal tissues)	4
Cacodylic acid, $(CH_3)_2AsO(OH)$	Calves were anorexic in 3 to 6 days when fed diets containing 4,700 mg/kg.	
	Adult oral dosages of 10 mg/kg BW daily for 3 weeks followed by 20 mg/kg BW daily for 5 to 6 weeks was lethal. Adverse effects at 25 mg/kg BW daily for 10 days	5
Methanearsonic acid,	Calves were anorexic in 3 to 6 days	

$CH_3AsO(OH)_2$	when fed diets containing 4,000 mg/kg	5
Monosodium methanearsonate	10 mg/kg BW daily for 10 days fatal	3
Sodium arsenite	Single oral dose of 1 to 4 grams fatal	3
Dog, *Canis familiaris*		
Cacodylic acid	Single oral LD-50 value of 1,000 mg/kg BW. Fed diets containing 30 mg/kg for 90 days with no ill effects	5
Methanearsonic acid	Fed diets containing 30 mg/kg for 90 days with no ill effects	5
Sodium arsenite	50 to 150 mg fatal	3
Domestic goat, *Capra* sp.		
Arsenic acid	Single oral dose of 2.5 to 7.5 mg/kg BW (50 to 150 mg) was acutely toxic	3
Guinea pig, *Cavia* sp.		
Arsenic acid	Dietary levels of 350 mg/kg resulted in blindness and optic disc atrophy in 25 to 30 days	6
Arsenic trioxide	Fed diets containing 50 mg/kg for 21 days; elevated As residues, in mg/kg fresh weight, of 4 in blood, 15 in heart (vs. <1 for all control tissues)	7
Sodium arsanilate	Subcutaneous injection of 70 mg/kg BW caused degeneration of sensory walls of inner ear; elevated As residues in cochlea	6
Sodium arsenate	Intraperitoneal injection of 0.2 mg/kg BW at age 2 months causes deafness	6
Hamster, *Cricetus* sp.		
Arsenate	Maternal dose of 5 mg As^{+5}/kg BW caused some fetal mortality, but no malformations; higher dose of 20 mg/kg BW caused 54% fetal deaths and malformations	3
Calcium arsenate	Pulmonary tumorigenicity demonstrated 70 weeks after 15 intratracheal weekly injections of 3 mg/kg BW	8
Dimethylarsinate	50% growth reduction in Chinese hamster ovary cells (CHOC) at 90 to 112 mg/L	9
Gallium arsenide	Single oral dose of 100 mg/kg BW mostly (85%) eliminated in 5 days, usually in	

	form of organoarsenicals; all tissue levels <0.25 mg/kg	10
Sodium arsenate	Dosed intravenously on day 8 of gestation: 2 mg/kg BW had no measurable effect; 8 mg/kg produced increased incidence of malformation and resorption; 16 mg/kg BW killed all embryos	6
Sodium arsenate	50% growth reduction in CHOC at 2.25 mg/L	9
Sodium arsenite	Chinese hamster ovary cells (CHOC) show 50% growth reduction at 0.3 mg/L	9
Sodium cacodylate	Single intraperitoneal injection of 900 to 1,000 mg/kg during midgestation results in some maternal deaths, and increased incidences of fetal malformations	5
Horse, *Equus caballus*		
Sodium arsenite	Daily doses of 2 to 6 mg/kg BW (1 to 3 grams) for 14 weeks is fatal	3
Cat, *Felis domesticus*		
Inorganic arsenate or arsenite	Chronic oral toxicity at 1.5 mg/kg BW	6
Human, *Homo sapiens*		
Arsenic trioxide	Fatal at 70 to 189 mg, equivalent to about 1 to 2.6 mg As/kg BW	6
Arsenic trioxide	LD-50 dose of 7 mg/kg BW	3
Cacodylic acid	LD-50 of 1,350 mg/kg BW	3
Lead arsenate	Some deaths at 7 mg/kg BW	3
Total arsenic	Accumulations of 1 mg/kg BW daily for 3 months in children, or 80 mg/kg BW daily for 3 years produced symptoms of chronic arsenic poisoning	3
Total arsenic, daily oral dose	Prolonged dosages of 3 to 4 mg daily produced clinical symptoms of chronic arsenic intoxication	3
Total arsenic in drinking and cooking water	Prolonged use produced symptoms of chronic arsenic intoxication (0.6 mg/L) or skin cancer (0.29 mg/L)	3
Total arsenic, probably as arsenate	12,000 Japanese infants poisoned (128 deaths) from consumption of dry milk contaminated with arsenic; average exposure of 3.5 mg As daily for one month. Severe hearing loss, brain wave abnormalities, and other central nervous system disturbances noted 15 years postexposure	6

Total inorganic arsenic	Daily dose of 3 mg for 2 weeks may cause severe poisoning in infants, and symptoms of toxicity in adults	6
Cynmolgus monkey, *Macaca* sp.		
Fish arsenic meal (witch flounder, *Glyptocephalus cynoglossus*) containing 77 mg total As/kg	Given a single meal at 1 mg/kg BW; tissue residues normal after 14 days	11
As above, except arsenic trioxide substituted for total As	As above	11
Mammals, many species		
Calcium arsenate	Single oral LD-50 range of 35 to 100 mg/kg BW	3
Lead arsenate	Single oral LD-50 range of 10 to 50 mg/kg BW	3
Mammals, most species		
Arsenic trioxide	3 to 250 mg/kg BW lethal	12
Sodium arsenite	1 to 25 mg/kg BW lethal	12
Mouse, *Mus* spp.		
Arsenate	Maternal dose of 10 mg As^{+5}/kg BW results in some fetal deaths and malformations	3
Arsenic trioxide	Single oral LD-50 (96 h) value of 39.4 mg/kg BW; LD-0 (96 h) of 10.4 mg/kg BW	12
Arsenic trioxide	"Adapted" group (50 mg As/L in drinking water for 3 months) had subcutaneous LD-50 value of 14 mg/kg BW vs. 11 for nonadapted group	12
Arsenic trioxide	Air concentrations of 28.5 mg/m^3 for 4 h daily on days 9 to 12 of gestation caused fetotoxic effects and chromosomal damage to liver cells by day 18; effects included reduced survival, impaired growth, retarded limb ossification, and bone abnormalities. At 2.9 mg/m^3, a 9.9% decrease in fetal weight was recorded; at 0.26 mg/m^3, a 3.1% decrease was measured	13
Cacodylic acid	Oral dosages of 400 to 600 mg/kg BW on days 7 to 16 of gestation produces fetal malformations (cleft palate), delayed	

	skeletal ossification, and fetal weight reduction	5
Sodium arsenate	Maximum tolerated doses in terms of abortion or maternal death over 24 h in 18-day pregnant mice were 20 mg As^{+5}/kg BW, intraperitoneal route, and 50 mg/kg BW when administered orally. Residue half-life was about 10 h regardless of route of administration	14
Sodium arsenite	Fed 5 mg/kg diet for three generations: reduced litter size, but outwardly normal	6
Sodium arsenite	LD-50 of 9.6 mg/kg BW, subcutaneous route; LD-90 (7 days postadministration) of 11.3 mg/kg BW, subcutaneous route	15
Sodium arsenite	LD-50 of 12 mg/kg BW intraperitoneal route. At 10 mg/kg BW, damage to bone marrow and sperm	16
Sodium cacodylate	Single intraperitoneal injection of 1,200 mg/kg BW during midgestation results in increased rates of fetal skeletal malformations	5
Mule deer, *Odocoileus hemionus hemionus*		
Silvisar-510 (mixture of cacodylic acid and tri-ethanolamine cacodylate)	Single oral LD-50 dose >320 mg/kg BW; appetite loss	17
White-tailed deer, *Odocoileus virginianus*		
Sodium arsenite (used to debark trees)	Lethal dose of 923 to 2,770 mg equivalent to about 34 mg/kg BW; liver residues of 40 mg/kg fresh weight	12
Arsenic acid (herbicide to control Johnson grass)	23 deer killed from apparent misuse. Arsenic levels, in mg/kg fresh weight, in deer found dead were 19 in liver, 18 in kidney, and 22.5 in rumen contents. Soils from area contained ~2.4 mg As/kg, and water 0.42 mg As/L	12
Domestic sheep, *Ovis aries*		
Arsanilic acid	One-year-old castrates fed diets with 273 mg As/kg for 28 days had 0.54 mg As/L in blood, 29 mg/kg dry weight in liver, 24 in kidney,	

	and 1.2 in muscle (vs. <0.01 in all control tissues). After 6 days on an As-free diet, liver residues were <5 mg/kg DW. Maximum tissue levels in sheep fed diets containing 27 mg As/kg for 28 days were 3.2 mg/kg DW kidney; for a 144 mg/kg DW diet, the maximum tissue level was 27 mg/kg DW liver	7
Sodium arsenite	Single oral dose of 5 to 12 mg/kg BW (0.2 to 0.5 grams) was acutely toxic	3
Soluble arsenic	Lambs fed supplemental arsenic for 3 months at 2 mg As/kg dry weight diet contained maximum concentrations of 2 mg/kg fresh weight brain (vs. 1 in controls), 14 in muscle (2), 24 in liver (4), and 57 in kidney (10)	18
Total arsenic	Sheep fed on diets containing lakeweed, *Lagarosiphon major* (288 mg As/kg DW) at 58 mg total As/kg diet for 3 weeks without ill effect. Tissue residues increased during feeding, but rapidly declined when lakeweed was removed from diet	7
Rat, *Rattus* spp.		
Arsanilic acid	No teratogenesis observed in 7 generations at dietary level of 17.5 mg/kg; positive effect on litter size and survival	6
Arsenate	Fed diets containing 50 mg/kg for 10 weeks with no effect on serum uric acid levels	19
Arsenic trioxide	Single oral LD-50 (96 h) value of 15.1 mg/kg BW	12
Arsenic trioxide	Single dose of 17 mg/kg BW administered intratracheally is maximally tolerated nonlethal dose; 2 weeks later, blood As elevated (36 mg/L) and lung histopathology evident	20
Arsenic trioxide	After 21 days on diet containing 50 mg/kg, tissue arsenic levels were elevated in blood (125 mg/L vs. 15 in controls), heart (43 mg/kg FW vs. 3.3), spleen (60 vs. <0.7) and kidney (25 vs. 1.5)	7

Arsenite	Oral administration of 1.2 mg/kg BW daily for 6 weeks reduced uric acid levels in plasma by 67%	19
Arsenite	Oral administration of 1.2 mg/kg BW daily for 6 weeks reduced uric acid levels in plasma by 67%	19
Cacodylic acid	Fetal and maternal deaths noted when pregnant rats dosed by gavage at 50 to 60 mg/kg BW daily during gestation days 6 to 13. Fetal abnormalities observed when dams given oral dosages of 40 to 60 mg/kg BW on days 7 to 16 of gestation	5
3-Nitro-4-hydroxy-phenylarsonic acid	Single oral LD-50 value of 44 mg/kg BW	12
Sodium arsenate	LD-75 (48 h) value of 14 to 18 mg/kg BW (intraperitoneal route)	12
Sodium arsenate	Single intraperitoneal injection of 5 to 12 mg/kg on days 7 to 12 of gestation produced eye defects, exencephaly, and faulty development of kidney and gonads	6
Sodium arsenite	LD-75 (48 h) value of 4.5 mg/kg BW (intraperitoneal injection	12
Rodents, various species		
Cacodylic acid	LD-50 (various routes) values range from 470 to 830 mg/kg BW	5
Sodium cacodylate	LD-50 (various routes) values range from 600 to 2,600 mg/kg BW	5
Pig, *Sus* sp.		
Sodium arsenite	Drinking water containing 500 mg/L lethal at 100 to 200 mg/kg BW	12
3-Nitro-4-hydroxy-phenylarsonic acid	Arsenosis documented after 2 months on diets containing 100 mg/kg, or after 3 to 10 days on diets containing 250 mg/kg	12
Rabbit, *Sylvilagus* sp.		
Cacodylic acid	Adverse effects at dermal dosages equivalent to 4 to 6 grams/kg BW	5
Calcium arsenate	Single oral dose of 23 mg/kg BW fatal in 3 days	12
Copper acetoarsenite	Single oral dose of 10.5 mg/kg BW fatal in 50 h	12
Inorganic arsenate	Single oral LD-50 value of 8 mg/kg BW	3

[a]References: 1, Vreman et al. 1986; 2, Thatcher et al. 1985; 3, NRCC 1978; 4, Robertson et al. 1884; 5, Hood 1985; 6, Pershagen and Vahter 1979; 7, Woolson 1975; 8, Pershagen and Bjorklund 1985; 9, Belton et al. 1985; 10, Yamauchi et al. 1986; 11, Charbonneau et al. 1978; 12, NAS 1977; 13, Nagymajtenyi et al. 1985; 14, Hood et al. 1987; 15, Stine et al. 1984; 16, Deknudt et al. 1986; 17, Hudson et al. 1984; 18, Veen and Vreman 1986; 19, Jauge and Del-Razo 1985; 20, Webb et al. 1986.

Table 7. Proposed arsenic criteria for protection of selected natural resources and human health.

Resource, criterion, and other variables	Criterion or effective arsenic concentration (reference)
Aquatic Life	
Freshwater biota: medium concentrations	Four-day mean water concentration not to exceed 190 ug total recoverable inorganic As^{+3}/L more than once every 3 years; 1-h mean not to exceed 360 ug inorganic As^{+3}/L more than once every 3 years. Insufficient data for criteria formulation for inorganic As^{+5}, or for any organoarsenical (EPA 1985)
Freshwater biota: tissue residues	Diminished growth and survival reported in immature bluegills (*Lepomis macrochirus*) when total arsenic residues in muscle >1.3 mg/kg fresh weight (FW) or >5 mg/kg in adults (NRCC 1978)
Saltwater biota: medium concentrations	Four-day average water concentration not to exceed 36 ug As^{+3}/L more than once every 3 years; 1-h mean not to exceed 69 ug As^{+3}/L more than once every 3 years. Insufficient data for criteria formulation for inorganic As^{+5}, or for any organoarsenical (EPA 1985)
Saltwater biota: tissue residues	Depending on chemical form of arsenic, certain marine teleosts may be unaffected at muscle total arsenic residues of 40 mg/kg FW (NRCC 1978)
Birds	
Tissue residues	Residues, in mg total As/kg FW, liver or kidney in 2 to 10 range are considered elevated; residues >10 mg/kg are indicative of arsenic poisoning (Goede 1985)
Turkey, *Meleagris gallopavo*	
Arsanilic acid in diet	Maximum dietary concentration for turkeys less than 28 days old is 300 to 400 mg/kg feed (NAS 1977)
Phenylarsonic feed additives for disease control and improvement of weight gain in domestic poultry; safe dietary levels	Maximum levels in diets, in mg/kg feed, are 50 to 100 for arsanilic acid, 25 to 188 for 3-nitro-4-hydroxy-phenylarsonic acid (for chickens and turkeys, not recommended for ducks and geese), and 180 to 370 for others (NAS 1977)
Domestic Livestock	
Prescribed limits for arsenic in feedstuffs	
Straight feedstuffs, except	<2 mg total As/kg FW (Vreman et al. 1986)

those listed below	
Meals from grass, dried	<4 mg total As/kg FW (Vreman et al. 1986)
lucerne, or dried clover	
Phosphate mealstuffs	<10 mg total As/kg FW (Vreman et al. 1986)
Fish meals	<10 mg total As/kg FW (Vreman et al. 1986)
Tissue residues	
Poisoned	
Liver, kidney	5 to >10 total As/kg FW (Thatcher et al. 1985; Vreman et al. 1986)
Normal, muscle	<0.3 mg total As/kg FW (Veen and Vreman 1986)
Vegetation	
No observable effects	<1 mg total water soluble soil As/L; <25 mg total As/kg soil; <3.9 ug As/m^3 air (NRCC 1978)
Human Health	
Diet	
Permissible levels	
Total diet	<0.5 mg As/kg dry weight diet (Sorensen et al. 1985)
Fruits, vegetables	The tolerance for arsenic residues as As_2O_3, resulting from pesticidal use of copper, magnesium, and sodium arsenates is 3.5 mg/kg (Jelinek and Corneliussen 1977)
Muscle of poultry and swine, eggs, swine edible byproducts	< 0.5 mg total As/kg FW (Jelinek and Corneliussen 1977)
Edible byproducts of chickens and turkey, liver and kidney of swine	<2 mg total As/kg FW (Jelinek and Corneliussen 1977)
Seafood products	In Hong Kong, limited to 6 mg total As/kg FW for edible tissues of finfish, and 10 mg/kg for molluscs and crustaceans (Phillips et al. 1982)
Adverse effects	
Consumption of aquatic organisms living in As-contaminated waters	
Cancer risk of	
10^{-5}	0.175 ug As/L (EPA 1980)
10^{-6}	0.0175 ug As/L (EPA 1980)
10^{-7}	0.00175 ug As/L (EPA 1980)
Drinking water	
Allowable concentrations	
Total arsenic	<10 ug/L (NAS 1977)
Total arsenic	<50 ug/L (Pershagen and Vahter 1979; EPA 1980; Norin et al. 1985)
Adverse effects	
Cancer risk of	

10^{-5}	0.022 ug As/L (EPA 1980)
10^{-6}	0.0022 ug As/L (EPA 1980)
10^{-7}	0.00022 ug As/L (EPA 1980)
Symptoms of arsenic toxicity observed	9% incidence at 50 ug As/L, 16% at 50 to 100 ug/L, and 44% at >100 ug As/L (NRCC 1978)
Harmful after prolonged consumption	
"Cancer"	In Chile, cancer rate estimated at 0.01% at 82 ug As/L, 0.17% at 600 ug As/L (NRCC 1978)
Skin cancer	0.26% frequency at 290 ug/L and 2.14% at 600 ug/L (EPA 1980)
Total intake	
No observable effect	
North America	0.007 to 0.06 mg As daily (Pershagen and Vahter 1979)
Japan	0.07 to 0.17 mg As daily (Pershagen and Vahter 1979)
USA	
1960's	0.05 to 0.1 mg As daily (Pershagen and Vahter 1979)
1974	0.015 mg As daily (Pershagen and Vahter 1979)
Canada	0.03 mg As daily (NRCC 1978)
Netherlands	
Acceptable	2 ug total inorganic As/kg body weight (BW) (about 0.14 mg daily for 70 kg adult); 0.094 mg daily through fishery products (Vos and Hovens 1986)
Adverse effects (Prolonged exposure)	
Subclinical symptoms	0.15 to 0.6 mg As daily (NRCC 1978)
Intoxication	3 to 4 mg As daily (NRCC 1978)
Blackfoot disease	Total dose of 20 grams over several years increases prevalence of disease by 3% (Pershagen and Vahter 1979)
Mild chronic poisoning	0.15 mg As daily or about 2 ug/kg BW daily (NRCC 1978)
Chronic arsenicism	Lifetime cumulative absorption of 1 gram As, or intake of 0.7 to 2.6 grams/year for several years (in medications) can produce symptoms after latent period of 4 to 24 years (NRCC 1978)
Tissue residues	
No observed effect levels	
Urine	<0.05 mg As/L (NRCC 1978)
Liver, kidney	<0.5 mg As/L (NRCC 1978)
Blood	<0.7 As/kg (NRCC 1978)
Hair	<2 mg As/kg (NRCC 1978)
Fingernail	<5 mg As/kg (NRCC 1978)

Arsenic-poisoned	
Liver, kidney	2 to 100 mg As/kg FW; confirmatory tests >10 mg As/kg FW; residues in survivors several days later 2 to 4 mg/kg FW (NAS 1977)
Whole body	In child, symptoms of chronic arsenicism evident at 1 mg As/kg BW, equivalent to intake of about 10 mg/month for 3 months; for adults, these values were 80 mg/kg BW, equivalent to about 2 grams/year for 3 years (NRCC 1978)
Air	
Allowable concentrations	
Arsine	<200 ug/m^3 for USA industrial workers; proposed mean arsine limit of <4 ug/m^3 in 8 h period and <10 ug/m^3 maximum in 15 min (NAS 1977)
Arsine	<4 ug/m^3 (NRCC 1978)
Total As	<3 ug/m^3 in USSR and Czechoslovakia, <500 µg/m^3 for USA industrial workers (NAS 1977)
Total As (threshold limit value-time weighted average: 8 h/day, 40-h work week)	Proposed limit of <50 ug/m^3, maximum of 2 µg/m^3 in 15 min, <10 ug airborne inorganic As/m^3 (EPA 1980)
Arsenic trioxide	<0.3 ug/m^3 in USSR, <0.1 ug/m^3 in USA (Nagymajtenyi et al. 1985)
Adverse effects	
Increased mortality	Associated with daily time-weighted average As exposure of >3 ug/m^3 for 1 year (NRCC 1978)
Respiratory cancer (increased risk)	Associated with chronic exposure >3 ug As/m^3, or occupational exposure (lifetime) of >54.6 ug As/m^3 (NRCC 1978)
Respiratory cancer (increased risk)	Exposure to 50 ug As/m^3 for more than 25 years associated with 3X increase (Pershagen and Vahter 1979)
Skin diseases	Associated with ambient air concentrations of 60 to 13,000 ug As/m^3 (NRCC 1978)

SUMMARY

Chlorpyrifos (phosphorothioic acid O, O,-diethyl 0-(3,5,6,-trichloro-2-pyridinyl) ester), an organophosphorus compound with an anticholinesterase mode of action, is used extensively in a variety of formulations to control a broad spectrum of agricultural and other pestiferous insects. Domestic use of chlorpyrifos in 1982 was about 3.6 million kg; the compound is used mostly in agriculture, but also to control mosquitos in wetlands (0.15 million kg applied to about 600,000 ha) and turf-destroying insects on golf courses (0.04 million kg).

Accidental or careless applications of chlorpyrifos have resulted in the death of many species of nontarget organisms such as fish, aquatic invertebrates, birds, and humans. Applications at recommended rates of 0.028 to 0.056 kg/surface ha for mosquito control have produced mortality, bioaccumulation, and deleterious sublethal effects in aquatic plants, zooplankton, insects, rotifers, crustaceans, waterfowl, and fish; adverse effects were also noted in bordering invertebrate populations.

Degradation rate of chloropyrifos in abiotic substrates varies, ranging from about 1 week in seawater (50% degradation) to more than 24 weeks in soils under conditions of dryness, low temperatures, reduced microbial activity, and low organic content; intermediate degradation rates reported have been 3.4 weeks for sediments and 7.6 weeks for distilled water. In biological samples, degradation time is comparatively short--usually less than 9 hours in fishes, and probably the same in birds and invertebrates.

Chlorpyrifos is acutely toxic to some species of aquatic invertebrates and teleosts at nominal water concentrations ranging between 0.035 and 1.1 ug/l. Acute single-dose oral LD-50 values of chlorpyrifos to susceptible avian species ranged from 5 to 13 mg/kg body weight. Mammals were comparatively tolerant of chlorpyrifos: acute oral LD-50's were reported to be 151 mg/kg body weight, and higher. Lethal dietary concentrations for sensitive species of birds ranged from 30 to 50 mg chlorpyrifos/kg food. Sublethal effects were recorded in all species of organisms examined at concentrations below those causing mortality. These effects included bioconcentration from the medium by teleosts (410X to 1,000X); cholinesterase activity reduction in brain and hematopoietic tissues; reduced growth; impaired reproduction, including sterility and developmental abnormalities; motor incoordination; convulsions; and depressed population densities of aquatic invertebrates.

Three courses of action are recommended. (1) Restrict the use of chlorpyrifos for mosquito control in wetlands, estuaries, and waterfowl breeding areas because recommended treatment levels are demonstrably harmful to nontarget resident biota. (2) Curtail agricultural use in watershed areas pending acquisition of additional data on chlorpyrifos toxicokinetics. (3) Develop suitable replacements for chlorpyrifos in mosquito control programs; specifically, pesticides with more specificity to target organisms, and lower toxicity to nontarget biota.

INTRODUCTION

Chlorpyrifos (phosphorothioic acid 0, 0-diethyl O-(3,5,6-trichloro-2-pyridinyl) ester), also known commonly as Dursban and Lorsban, was first registered as a broad spectrum insecticide in 1965, and subsequently was used widely to control a variety of pests such as fire ants, turf and ornamental plant insects, cockroaches, mosquitos, termites, hornflies, lice, and fleas (EPA 1986). In 1982, total agricultural use of chlorpyrifos was estimated at 2.2 to 3.2 million kg, and industrial uses ranged between 0.68 and 1.04 million kg (EPA 1982). In 1984, about 0.15 million kg (0.33 million pounds) of chlorpyrifos was applied to about 600,000 ha (1.48 million acres) of wetlands in the United States for mosquito control (Odenkirchen 1987). Treatment programs in which chlorpyrifos concentrations suitable for mosquito control and other insect pests were used have been shown to be detrimental to nontarget species, including aquatic organisms, waterfowl, and terrestrial organisms from surrounding ecosystems (Linn 1968; Hurlbert et al. 1970, 1972; Atkins 1972; Streu and Cruz 1972; Nelson and Evans 1973; Butcher et al. 1977; Thirugnanam and Forgash 1977; Tagatz et al. 1982;.Goodman et al. 1985a; McEwen et al. 1986; Mayer 1987; Odenkirchen 1987; Smith 1987). Domestic use of chlorpyrifos has resulted in the death of an 11-day-old infant (CDC 1980) and the poisoning of office workers (Hodgson et al. 1986). Prophylactic use of chlorpyrifos on farm animals has caused reproductive impairment of livestock (Everett 1982). Chlorpyrifos-resistant strains of insects have been detected recently; they include the German cockroach (*Blattella germanica*) in Florida and Nebraska (Milio et al. 1987) and the sawtoothed grain beetle (*Oryzaephilus surinamensis*) in Australia (Collins 1985).

This report was prepared in response to requests for information from environmental specialists of the U.S. Fish and Wildlife Service. It is part of a continuing series of brief reviews on chemical contaminants and natural resources.

ENVIRONMENTAL CHEMISTRY

Formulations of chlorpyrifos include emulsifiable concentrates, wettable powders, granules, pellets, microencapsulates and impregnated materials. Suggested diluents for concentrates include water and petroleum distillates, such as kerosene and diesel oil. Carrier compounds include synthetic clays with alkyl/aryl sulfonates as wetting agents (Table 1). Little information is available to assess the influence of various use formulations on toxicity, dispersal, decomposition, and bioavailability. Chemical and other properties of chlorpyrifos are summarized in Table 2.

The degradation half-life time (Tb 1/2) of chlorpyrifos is 7.1 days in seawater (Schimmel et al. 1983), and 53 days in distilled water (Freed et al. 1979). Degradation is usually through hydrolysis to produce 3,5,6-trichloro-2-pyridinol, and phosphorothioics acid (Brust 1966; Smith 1966, 1968; Marshall and Roberts 1978). Temperature, pH, radiation, and metal cations all significantly affect chlorpyrifos Tb 1/2 in water: half-life is decreased with increasing water pH, temperature, sunlight, and metal cation concentrations (Brust 1966; Mortland and Raman 1967; Smith 1968; Schaefer and Dupras 1969, 1970; Meikle and Youngson 1970).

In soil, Tb1/2 values for chlorpyrifos range from less than 1 week to more than 24 weeks, depending on soil moisture, microbial activity, clay and organic content, and temperature. In 411 soils studied, increasing temperature resulted in decreased Tb 1/2 values (Miles et al. 1983). Degradation was more rapid in sandy loam than in organic muck soils, more rapid in moist than in dry soils, and more rapid in clay than in other soil types (Getzin 1981; Miles et al 1983, 1984). The major routes of chlorpyrifos loss from soils are chemical hydrolysis in moist soils, clay-catalyzed hydrolysis in dry soils, and microbial degradation and volatilization (Marshall and Roberts 1978).

The half-life of chlorpyrifos in sediments is comparatively long; it was 24 days in a sediment-water slurry Schimmel et al. 1983). In a pond treated with chlorpyrifos, total waterborne residues decreased by a factor of more than 10X, while total sediment residues rose by about 3X (Hurlbert et al. 1970). Similar results were noted in an artificial lake treated with chlorpyrifos: lake water concentrations peaked 1 day after treatment at 0.9 ug/l and plateaued near 0.2 ug/l after 3 weeks (Mulla et al. 1973).

Table 1. Selected chlorpyrifos formulations and carriers (modified from Marshall and Roberts 1978).

Compound[a]	Formulation	Carrier
Dursban 2E	Emulsifiable concentrate of 0.285 kg/L (2.4 lb/gal)	Solution in aromatic distillate with anionic/ nonionic emulsifier blend and residual chlorinated solvent
Dursban M	Emulsifiable concentrate of 0.57 kg/L (4.8 lb/gal)	As above
Dursban 6	Solution of 0.855 kg/L (7.2 lb/gal)	Solution in an aromatic distillate
Dursban 2½G	Granular, 2.5%	Absorbed onto stabilized clay with release agents added
Lorsban 4C	Emulsifiable concentrate of 0.479 kg/L (4.0 lb/gal)	Solution in aromatic naphtha with emulsifiers
Lorsban 25W	Wettable powder, 25%	Dispersion on blended clays with alkyl/aryl sulfonates as wetting agents

LABORATORY INVESTIGATIONS

AQUATIC ORGANISMS

During 96-hour toxicity tests, several species of freshwater and marine invertebrates and fishes died at chlorpyrifos concentrations between 0.035 and 0.58 ug/l. LC-50 (96-hour) values, in ug chlorpyrifos/l, for sensitive species tested were 0.035 for mysid shrimp *Mysidopsis bahia*; 0.11 for amphipod, *Gammarus lacustris*; 0.13 for fathead minnow, *Pimephales promelas*; 0.38 for stonefly, *Pteronarcella badia*; and 0.58 for striped bass, *Morone saxatilis*; (Mayer and Ellersieck 1936; Table 3). Toxicity was usually greater at elevated temperatures and at increasing pH levels (Johnson and Finley 1980). In general, arthropods were the most sensitive group assayed and molluscs the most tolerant (Borthwick and Walsh 1981; Table 3). The bullfrog (*Rana catesbeiana*) also appears to be comparatively tolerant to chlorpyrifos, as judged by a single oral LD-50 value of >400 mg/kg body weight (Hudson et al. 1984).

Sublethal effects of chlorpyrifos exposure have been documented for many species of freshwater and marine fauna; they include inhibition of cholinesterase (ChE) activity levels in brain and hematopoietic organs, sluggishness, motor incoordination, delayed maturation and growth, reproductive impairment, and reduced feed intake (Rongsriyam et al. 1968; Thirugnanam and Forgash 1977; Marshall and Roberts 1978; Tagatz et al. 1982; Jarvinen et al. 1983; EPA 1985, 1986; Goodman et al. 1985b; Norberg and Mount 1985; Hansen et al. 1986). Reproductive impairment, for example, was observed in *Daphnia magna* at 0.08 ug chlorpyrifos/1 (EPA 1985). Reduction in setting rate was shown in oyster larvae after exposure to 0.1 ug/l for 8 days (Tagatz et al. 1982). In fathead minnows exposed to 0.12 ug chlorpyrifos/1 for 200 days, ChE activity was significantly reduced, fecundity was reduced, maturation delayed and, in second generation fish, growth and maturation were reduced (Jarvinen et al. 1983). Equilibrium loss was documented in 50% of brown shrimp (*Penaeus aztecus*) after exposure to 0.32 ug chlorpyrifos/1 for 24 hours (Marshall and Roberts 1978). Growth of the California grunion (*Leuresthes tenuis*) was reduced 20% in an early life stage during immersion in 0.5 ug chlorpyrifos/1 for 35 days and 26% in fry after exposure to 1.0 ug/l for 26 days (Goodman et al. 1985b). Additional and more comprehensive data on sublethal effects of chlorpyrifos to aquatic biota are listed elsewhere (EPA 1986).

Table 3. Acute toxicities of chlorpyrifos to selected species of aquatic invertebrates and fishes. Values are in µg chlorpyrifos per liter of medium fatal to 50 percent in 96 hours.

Bioconcentration of chlorpyrifos from the medium varied substantially among five species of fishes, but generally paralleled ambient levels of chlorpyrifos (Table 4). Increases in bioconcentration factors (BCF) in chlorpyrifos-exposed teleosts may be associated with three variables: increased metabolic rate, as indicated by hyperventilation, hyperactivity, and decreased growth; increased bioavailability of chlorpyrifos as a result of solvent-induced supersaturation or increased food availability; and decreased depuration rates due to possible physiological dysfunction (Goodman et al. 1985a,.b; Hansen et al. 1986). At high BCFs, adverse effects on growth and survival were observed in sheepshead minnow (*Cyprinodon variegatus)* by Cripe et al. (1986) and in Gulf toadfish (*Opsanus beta*) by Hansen et al. (1986). Chlorpyrifos is excreted rapidly from fish; the estimated Tb 1/2 is 8.7 hours, and equilibration occurs with them surrounding medium in 24 to 72 hours (Smith et al. 1966; Blau and Neely 1975; Marshall and Roberts 1978). No detectable chlorpyrifos residues were found after 12 days in 10 species of estuarine invertebrates--including oligochaete annelids, molluscs, and crustaceans--after treatment with 0.046 kg chlorpyrifos/ha (Marganian and Wall 1972).

BIRDS AND MAMMALS

Signs of chlorpyrifos intoxication, as summarized by Hudson et al. (1984), include excessive blinking, hypoactivity, hyperexcitability, excessive drinking, muscular incoordination, rapid breathing, muscular weakness, tremors, piloerection (mammals) or fluffed feathers (birds), salivation, lacrimation, diarrhea, excessive urination, prostration, loss of righting reflex, spasms, tetany, coma, and convulsions. Death usually occurs between 1 hour and 9 days after exposure, Chlorpyrifos oxon (

0,0-diethyl-0-(3,5,6-trichloro-2-pyridyl) phosphate) is the active oxygen analog of chlorpyrifos and is probably responsible for most of the anticholinesterase mode of action of chlorpyrifos; the oxon is extensively and rapidly detoxified in mammalian liver via enzymatic hydrolysis by at least two microsomal esterases (Sultatos and Murphy 1983). Significant accumulations of chlorpyrifos were not detected in domestic turkeys (*Meleagris gallopavo*) and chickens. In birds kept in pens on soil treated with 4.5 to 9.0 kg active ingredients chlorpyrifos/ha, tissue residues were 0.16 mg/kg after 1 week; these decreased thereafter, although birds remained on the treated soil (Kenaga 1974).

LD-50 values, based on a single oral dose, ranged from 5 to 157 mg chlorpyrifos/kg body weight (BW) in birds, and from 151 to 1,000 in mammals; however, 7 of 14 avian species had reported LD-50 values of <25.0 mg/kg BW (Table 5). Many species of birds that survived chlorpyrifos poisoning showed gross pathological changes (Tucker and Crabtree 1970); furthermore, the slope of the acute dose-response curve was low (Hudson et al. 1984). These findings suggested that decreasing dosage levels did not produce proportional decreases in response, and indicated a reduced safety margin for chlorpyrifos owing to mortalities that occur frequently at levels much lower than the calculated LD-50 values (Hudson et al. 1984); however, more research is needed to verify this trend.

Table 4. Chorpyrifos bioconcentration factors (BCF) by selected species of fishes (Goodman et al. 1985a, b; Hanesen et al. 1986).

[a]Bioconcentration factor: concentration in whole organism (µg/kg fresh weight) divided by concentration in medium (µg/L).

Reduction in cholinesterase activity levels of various tissues (blood, brain) is one of the earliest signs of chlorpyrifos intoxication. Cholinesterase reductions have been demonstrated in turkeys fed diets containing 50 mg chlorpyrifos/kg (estimated daily dose of 0.7 mg/kg BW) for 20 days (Schlinke et al. 1969), in chickens fed diets of 25 mg/kg (estimated daily dose of 0.94 mg/kg BW) for 20 days (Schlinke 1970), and in mallard (*Anas platyrhynchos*) ducklings fed 75 mg chlorpyrifos/kg diet for 14 days (Herin et al. 1978). Low temperatures (27.5 C Vs. 35°C) potentiated dose-related ChE depression in juvenile northern bobwhite (*Colinus virginianus)*, suggesting a need for more research on cold stress interactions between acute oral chlorpyrifos exposure (Maguire and Williams 1987).

Dietary concentrations of 30 to 100 mg chlorpyrifos/kg feed produce some deaths in birds, and 136 to about 500 mg/kg feed usually kills at least 50% (Table 6). In chickens fed diets of 100 mg chlorpyrifos/kg--equivalent to an estimated daily dose of 6.8 mg/kg BW--egg fertility was reduced by 15% and hatchability by 17% (Schom et al. 1973). Dietary levels lethal to mallard ducklings were 136 to 180 mg/kg feed, equivalent to 10 mg/kg BW fed daily for 5 days (Kenaga 1974). In adult mallards given diets containing 80 mg chlorpyrifos/kg for 60 to 84 days, body weight, food consumption, brain cholinesterase activity levels, and egg production were all reduced; moreover, egg weight and eggshell thickness were reduced, the resultant ducklings weighed less than controls, and survival was comparatively poor at age 7 days. No effect on any variable was observed at diets of 8 mg/kg (Gile and Meyers 1986; Meyers and Gile 1986).

Dermal application routes are also toxic. Some deaths were recorded in turkeys from dermal treatments of 15 to 20 mg chlorpyrifos/kg BW (Schlinke et al. 1969). Higher levels applied to feathers killed turkeys within 8 hours (Marshall and Roberts 1978). Newborn piglets (*Sus* spp.) were especially more sensitive than those 30-36 hours old to cutaneous applications of chlorpyrifos; newborns showed clinical signs consistent with organophosphorus toxicosis after a 2.5% aerosol preparation (dosage unknown) was applied to the tail and umbilicus (Long et al. 1986). Accidental poisoning of cattle (*Bos* spp.) by chlorpyrifos through dermal application to control ticks resulted in some deaths; among bulls that survived, sperm production was reduced 43% in seriously affected animals and 12% in those with no outward signs of poisoning (Everett 1982).

Chlorpyrifos is not mutagenic, as judged by mitotic recombination assays (Poole et al. 1976), and did not increase sister chromatid exchange above background in tests with chick (*Gallus* spp.) embryos and Chinese hamster (*Cricetus* spp.) ovary cells (Muscarella et al. 1984).

Table 5. Chlorpyrifos toxicity to a variety of birds and mammals via single oral dose route of administration. Values are in mg chlorpyrifos/kg body weight lethal to 50% within 14 days.

[a]References: 1, Kenaga, 1974; 2, Hill et al. 1975; 3, Hill and Camardese 1986.

Chlorpyrifos-impregnated ear tags are under development to control horn flies (*Haematobia irritans*) in U.S. cattle (Byford et al. 1986). Cattle fitted with ear tags (0.96 g chlorpyrifos per tag/365 kg animal, or about 2.6 mg chlorpyrifos/kg BW) had slightly elevated tissue residues (0.13 mg/kg fat) after 12 weeks, but residues were well within current acceptable tolerance levels of 2.0 mg chlorpyrifos/kg fresh weight cattle fat, meat, or meat by-products (Byford et al. 1986). In dogs (*Canis familiaris)*, chlorpyrifos-impregnated collars provided effective control of adult fleas (*Ctenocephalides* spp.) for up to 11 months, with no significant adverse reactions regardless of canine coat length, size, or age (Higgins and Jarvis 1986).

FIELD INVESTIGATIONS

There have been many accidental spills of chlorpyrifos, but little quantitative assessment of the environmental effects. One exception is a spill in April 1985 in England (Boreham and Birch 1987). In that instance, a truck overturned, spilling 205 liters of chlorpyrifos into an adjacent stream that drained into the Roding River. A resulting sharp decrease in the number and type of macroinvertebrate benthic organisms in affected parts of the river, compared to unaffected areas, lasted 6 months. In addition, certain chlorpyrifos-resistant benthic organisms were unusually abundant.

Chlorpyrifos controls mosquito larvae at applied dosages between 0.028 and 0.056 kg/ha, equivalent to 9 to 18 ug chlorpyrifos/1 in 152 mm (6 inches) of water (Marshall and Roberts 1977; Eaton et al. 1985); in 1984 alone, chlorpyrifos was used for this purpose on about 600,000 ha (Odenkirchen 1987). No obvious deleterious effects of chlorpyrifos have yet been noted in mammals, amphibians, or reptiles under field conditions of current use (Table 7). However, at recommended dosage application rates for control of mosquitos and other pestiferous insects (usually 0.028 to 0.056 kg/ha), adverse effects have been documented on survival, reproduction, metabolism, and species diversity of a variety of fishes, terrestrial and aquatic invertebrates, freshwater flora, waterfowl, and horned larks (*Eremophila alpestris)*, and on the marketability of various crops (Mulla et al. 1971, 1973; Hurlbert et al. 1972; Macek et al. 1972; Nelson and Evans 1973; Hoy and Shea 1981; Table 7).

We emphasize that the effectiveness of chlorpyrifos under field conditions, like that of other organophosphorus pesticides, is significantly modified by numerous variables such as formulation, route of administration, pond substrate, dose, and water temperature (Macek et al. 1969; Bailey et al. 1970; Rawn et al. 1978; Odenkirchen 1987).

Table 7. Chlorpyrifos effects on selected ecosystems.

Ecosytstem, and other information	Application rate and other variables	Effects and reference
Aquatic		
Lake	0.004 kg/ha, emulsifiable concentrate, oil diluent single application	After 24 h, aquatic insect populations reduced 14% to 40% and snails reduced 10% (Moore and Breeland 1967)
Freshwater lake	0.014 kg/ha (equivalent to about 1.2 µg/L), single application	Freshwater algae (*Ankistrodesmus* sp., *Tetraedron* sp.) reduced 30% to 90% 7 days posttreatment; reduced population growth evident one year postapplication (Brown et al. 1976)
Flooded rice field	Individual applications of 0.014 to 0.019 kg/ha, emulsifiable concentrate, oil diluent, 3 applications at 5-week intervals	Mortality after 72 h, 32% in caged bluegills (*Lepomis macrochirus*), 50% to 70% in mayfly nymphs (*Siphlonurus* sp.), and

		32% in predatory diving beetles (Washino et al. 1972)
Freshwater ponds, (8 m x 17 m x 0.3 m deep)	Individual applications of 0.011, 0.056, 0.11, or 1.11 kg/ha; 4 applications at 2-week intervals	Initial population inhibition of mosquitofish (*Gambusia* sp.), but reproduction resumed except for 1.11 kg/ha group. Fish whole body residues in 0.056 kg/ha group, in mg/kg body weight, were 2.8 at 4 h 1.7 at 24 h, and 0.1 after 2 weeks. Insect and zooplankton populations reduced >92%; little recovery was evident after third treatment. The 0.056 kg/ha treatment regimen, at 4 h, resulted in residues of 10 µg/L in water, 375 µg/kg in vegetation, and nondetectable levels in mud; at 14 days, all residues were nondetectable (Hurlbert et al. 1970)
Artificial lake	0.02 kg/ha, granular formulation, single application	Chironomid larvae population remained >90% depressed for 5 months (Mulla et al. 1971)
Salt marsh	0.028 kg/ha (0.025 lbs/acre), single aerial application, mosquito larvicide granules	No observable effects on caged blue crabs (*Callinectes sapidus*), penaeid shrimp, or fishes; some fiddler crabs (*Uca* sp.) dead (FWS 1968)
Salt marsh	Individual applications of 0.028 kg/ha, 4 applications at 2-week intervals	In killifish (*Fundulus heteroclitus*), convulsions, ChE depression, and deaths noted. ChE remained depressed for

		about 10 weeks after final application (Thirugnanam and Forgash 1977)
Artificial streams, each 520 m long, 0.14 ha of surface area, with pools 30.5 m long x 3.6 m wide x 81 cm deep	Continuous treatment stream recieved 0.22 µg chlorpyrifos/L for days 1 to 41, and 1.0 µg/L from days 41 to 100. Intermittent treatment stream received dosage 14x higher than continuous treatment stream, but dosage was confined to 24 h every 14 days. Chlorpyrifos administered as emulsifiable concentrate in petroleum derivative solvent	When compared to control stream, no effect on total abundance of benthic organisms. However, in both treated streams, species diversity decreased by equal amounts and was still decreasing at day 100. Adverse sublethal effects were noted in fathead minnow, *Pimephales promelas* (spinal deformities) and bluegills (ChE inhibition, signs of organophosphorus poisoning) only in the pulse-dosed stream. In all streams, however, fish survived, grew, and reproduced equally well (Eaton et al. 1985)
Shallow pond, mean depth 0.25 m, surface area 0.11 ha, high vegetation	Individual applications of 0.056 kg/ha technical grade, 2 applications at 34-day interval	After 63 days, 46% to 55% mortality in centrarchid populations, and 75% reduction in insect populations of caddisflies, mayflies, and midges (Macek et al. 1972)
Shallow ponds	0.056 kg/ha, emulsifiable concentrate, oil diluent single application	All caged green sunfish (*Lepomis cyanellus*) died (Linn 1968)
Woodland pools	Single application of 0.056 kg/ha, granular formulation	Increased algal growth on leaf litter observed months after treatment, attributed to reduction in grazing stress by

		mosquito larvae (Hagmann and Porteus 1972)
Woodland pools	0.056 kg/ha, granular formulation, single application	Isopod populations reduced 90% to 95% (Cooney and Pickard 1974)
Freshwater ponds	Single dose of chlorpyrifos, equivalent at 4, 10, or 1,000 µg/L	Increased algal bloom duration in treated ponds, possibly due to loss of grazing fauna (Butcher et al. 1977)
Salt marsh, 202 ha (500 acres),	0.56 kg/ha (0.5 lbs/acre), single application applied as aerial spray, to kill mosquito larvae	Killed significant numbers of fishes and crustaceans (FWS 1968)
Salt marsh, 78 ha plot	0.56 kg/ha, emulsifiable concentrate, once, aerially	After 48 h, mortality was 35% in caged fish and 84% in caged shrimp; no other adverse effects were noted during the next 27 days (Wall and Marganian 1971)
Salt marsh estuary, Bay St. Louis, Mississippi, 408 ha site (1,008 acres)	0.56 kg/ha (0.5 lbs/acre), granular, single aerial application, for mosquito control	After spraying, all caged fiddler crabs died, white shrimp (*Penaeus setiferus*) populations were reduced, and large numbers of blue crabs were found dead. No observable effects on terrestrial organisms, including insects. One month after spraying, shrimp and blue crab populations seemed normal, although fiddler crabs were absent (FWS 1967)
Freshwater pond	Single application of pelletized 10.6% chlorpyrifos to obtain theoretical water concentrations of 250 µg/L and higher	Species diversity of diatoms reduced >50% in 6 weeks, vs. 12% increase in controls (Nelson et al. ı .

Terrestrial

Temporary woodland pool	Average maximum water concentration of 1.6 µg chlorpyrifos/L	No obvious adverse effects on wildlife, i.e., 3 spp. of rodents, one sp. frog, one sp. turtle (Nelson and Evans 1973)
Freshwater ponds (8 m x 17 m x 0.3 m deep)	Individual applications of 0.011, 0.056, 0.11 and 1.11 kg/ha; 4 applications at 2-week intervals	High mortality (>42%) of mallard (*Anas platyrhynchos*) ducklings on all treated ponds, vs. none dead on control ponds (Hurlbert et al. 1970)
Salt marsh	0.025 kg/ha, single application	No gross effects on wildlife (Ludwig et al. 1968)
Rice field area	0.029 kg/ha, single application	All honeybees (*Apis* sp.) within 0.4 km downwind of spray area were dead; 95% were dead at 0.8 km and 89% at 1.2 km (Atkins 1972)
New Mexico ranchlands	Dust formulations of 0.48 and 1.97 kg/ha, to control wildlife flea populations	No observable deleterious effects in rodents and rabbits 3 to 4 weeks posttreatment (Miller et al. 1970)
Wheat fields	0.56 and kg/ha, to control pale western cutworm (*Agrotis orthogonia*)	Horned larks (*Eremophila alpestris*) had brain ChE activity levels depressed 22% at 3 days posttreatment, and 8% at 16 days. No sick or dead birds found; however, no systematic searches were made for the small lark carcasses, nor were specific observations for toxic signs conducted (McEwen et al. 1986)
Iraqi date palm (*Phoenix* sp.) orchards	Emulsifiable concentrate applied once after fruiting and infesta-	Chlrorpyrifos residues in dates decreased from 1.28 mg/kg fresh weight

	tion with high pressure ground sprayers at 0.98 kg/ha to control insect pests	at day one postapplication to 0.2 mg/kg on day 15, to 0.05 on day 29, and to nondetectable concentrations on day 71. Concentrations of the chlorpyrifos oxygen analog, however, after reaching a peak of 0.5 mg/kg on day 15, were still detectable (0.1 mg/kg) at day 85, suggesting that dates should be harvested at least 8 weeks after chlorpyrifos treatment (Mansour 1985)
Turf	1.12 kg/ha, emulsifiable concentrate, single application, to control chinch bug (*Blissus leucopterus listus*)	Most arthropods in turf killed immediately after application. Target pest populations remained depressed for one year posttreatment, but other insect populations recovered to levels greater than controls after 3.5 months (Streu and Cruz 1972)

RECOMMENDATIONS

Current water quality criteria formulated for chlorpyrifos by the U.S. Environmental Protection Agency (EPA 1986) for aquatic life protection seem to afford a reasonable degree of safety, at least during short-term exposure. Specifically, the proposed criteria for freshwater are 0.041 ug/l (4-day average concentration) and 0.083 ug/l (1-hour average concentration), neither of which should be exceeded more than once every 3 years; for saltwater, the criteria are 0.0056 ug/l and 0.011 ug/l, respectively.

The acceptable tolerance level of chlorpyrifos in meat and meat by-products destined for human consumption is 2.0 mg/kg fresh weight (Byford et al. 1986). The significance of this concentration to animal health, or to consumers other than man, is unknown. More research is needed to establish maximum tolerable chlorpyrifos limits in tissues of sensitive fish and wildlife.

Information is lacking on the effectiveness of chlorpyrifos in large-scale (>40 ha) coldwater ecosystems, typical of those found in Alaska or northern tier States; accordingly, we recommend initiation of long-term studies in these potential problem areas.

As judged by our analysis of available literature, three courses of action now seem warranted: (1) Restrict the use of chlorpyrifos for mosquito control in wetlands, estuaries, and waterfowl breeding areas because recommended treatment levels are demonstrably harmful to nontarget species, including mallard ducklings. The unsuitability of chlorpyrifos for mosquito control is further supported by the finding that certain mosquito populations in California are showing signs of chlorpyrifos resistance, and thus may require more aggressive future treatment programs (tarsalis populations (Reisen et al. 1984). (2) Curtail agricultural use of chlorpyrifos in watershed areas pending acquisition of additional data on its transport, fate, and effects, including data on chlorpyrifos flux rates from oils and sediments and its resultant bioavailability. (3) Develop suitable replacements for chlorpyrifos in mosquito control programs. These replacement compounds should exhibit a relatively long half-life in aquatic environments while avoiding the broad spectrum toxicity typical of chlorpyrifos to large numbers of nontarget organisms.

LEAD HAZARDS TO FISH, WILDLIFE, AND INVERTEBRATES: A SYNOPTIC REVIEW

by

Ronald Eisler

U.S. Fish and Wildlife Service
Patuxent Wildlife Research Center
Laurel, MD 20708

SUMMARY

Lead (Pb) and its compounds have been known to man for about 7,000 years, and Pb poisoning has been recognized for at least 2,500 years. All credible evidence indicates that Pb is neither essential nor beneficial to living organisms, and that all measured effects are adverse--including those on survival, growth, reproduction, development, behavior, learning, and metabolism.

Various living resources are at increased risk from Pb: migratory waterfowl that frequent hunted areas and ingest shot; avian predators that eat game wounded by hunters; domestic livestock near smelters, refineries, and Pb battery recycling plants; captive zoo animals and domestic livestock held in enclosures coated with Pb-based paints; wildlife that forage extensively near heavily traveled roads; aquatic life in proximity to mining activities, areas where Pb arsenate pesticides are used, metal finishing industries, organolead industries, and areas of Pb aerosol fallout; and crops and invertebrates growing or living in Pb-contaminated soils.

Adverse effects on aquatic biota reported at waterborne Pb concentrations of 1.0 to 5.1 ug/l included reduced survival, impaired reproduction, reduced growth, and high bioconcentration from the medium. Among sensitive species of birds, survival was reduced at doses of 50 to 75 mg Pb^{2+}/kg body weight (BW) or 28 mg organolead/kg BW, reproduction was impaired at dietary levels of 50 mg Pb /kg, and signs of poisoning were evident at doses as low as 2.8 mg organolead/kg BW. In general, forms of Pb other than shot (or ingestible Pb objects), or routes of administration other than ingestion, are unlikely to cause clinical signs of Pb poisoning in birds. Data for toxic and sublethal effects of Pb on mammalian wildlife are missing. For sensitive species of domestic and laboratory animals, survival was reduced at acute oral Pb doses of 5 mg/kg BW (rat), at chronic oral doses of 5 mg/kg BW (dog), and at dietary levels of 1.7 mg/kg BW (horse). Sublethal effects were documented in monkeys exposed to doses as low as 0.1 mg Pb/kg BW daily (impaired learning at 2 years postadministration) or fed diets containing 0.5 mg Pb/kg (abnormal social behavior). Signs of Pb exposure were recorded in rabbits given 0.005 mg Pb/kg BW and in mice given 0.05 mg Pb/kg BW. Tissue Pb levels were elevated in mice given doses of 0.03 mg Pb/kg BW, and in sheep given 0.05 mg Pb/kg BW. In general, organolead compounds were more toxic than inorganic Pb compounds, food chain biomagnification of Pb vas negligible, and younger organisms were most susceptible. More research seems merited on organolead toxicokinetics (including effects on behavior and learning), and on mammalian wildlife sensitivity to Pb and its compounds.

Recent legislation limiting the content of Pb in paints, reducing the Pb content in gasoline, and eliminating the use of Pb shot nationwide (Pb shot phaseout program/schedule starting in 1986, and fully implemented by 1991) in waterfowl hunting areas will substantially reduce environmental burdens of Pb and may directly benefit sensitive fishery and wildlife resources. Continued nationwide monitoring of Pb in living resources is necessary in order to correlate reduced emission sources with reduced tissue Pb concentrations.

DISCLAIMER

Mention of trade names or commercial products does not constitute endorsement or recommendation for use by the U.S. Government.

ACKNOWLEDGMENTS

I thank Nancy A. Bushby, Lynda J. Garrett, and Joyce E. Haber for technical services; Julia Armstrong and Jean Higgis for secretarial help; Louis N. Locke, Jerry R. Longcore, Keith A. Morehouse, Oliver H. Pattee, Matthew C. Perry, and Christopher J, Schmitt for reviewing the manuscript; and Paul H. Eschmeyer and James R. Zuboy for editorial services.

INTRODUCTION

Lead (Pb) has been known for centuries to be a cumulative metabolic poison; however, acute exposure is lessening. Of greater concern is the possibility that continuous exposure to low concentrations of the metal as a result of widespread environmental contamination may result in adverse health effects (Nriagu 1978b). Environmental pollution from Pb is now so high that body burdens in the general human population are closer than the burdens of any other toxic chemical to those that produce clinical poisoning (Hejtmancik et al. 1982). Further, Pb is a mutagen and teratogen when absorbed in excessive amounts, has carcinogenic or cocarcinogenic properties, impairs reproduction and liver and thyroid functions, and interferes with resistance to infectious diseases (EPA 1979).

Ecological and toxicological aspects of lead and its compounds in the environment have been extensively reviewed. (Wetmore (1919); Bellrose (1959), Aronson (1971), Barth et al. (1973), NRCC (1973), Holl and Hampp (1975), Boggess (1977), Rolfe and Reinbold (1977), Forbes and Sanderson (1978), Nriagu (1978a, 1978b), Wong et al. (1978), CEP (1979), EPA. (1979, 1980, 1985), Levander (1979), Tsuchiya (1979), Branica and Konrad (1980), Jenkins (1980) NAS (1980), Eisler (1981), Harrison and Laxen (1981), Demayo et al. (1982), Mudge (1983), De Michele (1984), Feierabend and Myers (1984), Walsh and Tilson (1984), Lumeij (1985), Feierabend and Russell (1986), FWS (1986a), Kania and Nash (1986), Lansdown and Yule (1986), McDonald (1986), Sanderson and Bellrose (1986), Pain (1987). There is agreement by all authorities on five points. First, Pb is ubiquitous and is a characteristic trace constituent in rocks, soils, water, plants, animals, and air. Second, more than 4 million metric tons of Pb are produced worldwide each year, mostly for the manufacture of storage batteries, gasoline additives, pigments, alloys, and ammunition. The widespread broadcasting of Pb through anthropogenic activities, especially during the past 40 years, has resulted in an increase in Pb residues throughout the environment--an increase that has dislocated the equilibrium of the biogeochemical cycle of Pb. Third, Pb is neither essential nor beneficial to living organisms; all existing data show that its metabolic effects are adverse. Fourth, Pb is toxic in most of its chemical forms and can be incorporated into the body by inhalation, ingestion, dermal absorption, and placental transfer to the fetus. Fifth, Pb is an accumulative metabolic poison that affects behavior, as well as the hematopoietic, vascular, nervous, renal, and reproductive systems. In humans, Pb causes stillbirths, miscarriages, inhibited development of fetuses, decreased male fertility, and abnormal sperm. Severe damage to the central nervous system from exposure to large amounts of Pb may result in stupor, convulsions, coma, and death. Children that survive Pb poisoning are often permanently retarded or have permanent neurological handicaps. At subclinical injury levels, Pb causes slight, but irreversible, damage to the brain development of growing children.

Natural resources are also affected by environmental Pb contamination, and some wildlife species numbers may be reduced as a result. For example, waterfowl deaths resulting from the ingestion of spent Pb shot pellets from shotgun shells were discovered more than 100 years ago in Italy and in the United States; since then Pb poisoning of waterfowl has occurred in 15 countries (Street 1983). In North America alone, approximately 3,000 tons of Pb shot are expended annually into lakes, marshes, and estuaries by several million waterfowl hunters (FWS 1986, 1987). Spent pellets are eaten by waterfowl and other birds, either in mistake for seeds or as pieces of grit. These pellets may be retained in the gizzard for weeks, where they are reduced chemically and mechanically, form soluble toxic salts, and cause characteristic signs of Pb intoxication--especially lethargy and emaciation (Street 1983). At least 2% of all North American waterfowl--or about 2 million ducks and geese (Lumeij 1985)--die each year as a direct result of ingestion of Pb shot (Bellrose 195!). These deaths contribute to the decline of some species, such as the canvasback, *Aythya valisineria* (Dieter 1979), pintail, *Anas acuta* (White and Stendell 1977), and black duck, *Anas rubripes* (Pain and Rattner 1988). Up to 7X more waterfowl died from Pb toxicosis as a result of ingesting spent pellets than from wounding by hunters (Zwank et al. 1985). In addition, Pb-poisoned waterfowl show delayed mortality from Pb-induced starvation, are readily captured by predators, are susceptible to disease, and reproduce poorly (Dieter 1979). Susceptibility is markedly influenced by species, by the number and size of shot ingested, and by the types of foods eaten (White and Stendell 1977). Swans are among the more vulnerable waterfowl. In England, Pb poisoning through the ingestion of discarded Pb fishing sinkers is the major cause of death in the mute swan, *Cygnus olor* (Birkhead 1983); for all species of swans in England, about half died as a direct result of Pb poisoning (Demayo et al. 1982). In Washington State, 30% of the endangered trumpeter swans (*Cygnus buccinator*) found dead had died of Pb poisoning from ingestion of Pb shot (Kendall and Driver 1982). Lead toxicosis caused by ingestion of spent shot and other Pb objects has also been reported for sandhill crane, *Grus canadensis* (Windingstad et al. 1984); Canada goose, *Branta canadensis* (Szymczak and Adrian 1978); mourning dove, *Zenaidura macroura* (Locke and Bagley

1967); and wild turkey, *Meleagris gallopavo* (Stone and Butkas 1978). Secondary poisoning has been documented in at least five species of raptors that ate food containing Pb shot (especially hunter-wounded animals): Andean condor, *Vultur gryphus* (Locke et al. 1969); bald eagle, *Haliaeetus leucocephalus* (Pattee and Hennes 1983); honey buzzard, *Pernis apivorus* (Lumeij et al. 1985); king vulture, *Sarcorhampus papa* (Decker et al 1979); and California condor *Gymnogyps californianus* (Janssen et al. 1986).

The availability of Pb-based paints, discarded oil filters, used crankcase oil, Pb storage batteries, or pastures contaminated by industrial lead operations make Pb one of the most common causes of accidental poisoning in domestic animals (Demayo et al. 1982). Cattle and horses in the vicinity of a Pb smelter in California developed signs of Pb poisoning, and many died between 1880, when the smelter opened, and 1971, when the smelter closed (Burrows 1981). Of the mules used in the early mining of Pb, all died during their first year of service (Burrows 1981). Lead toxicosis has been reported in buffalos and cattle in India after they ate green fodder near a factory that recycled Pb from old batteries (Kwatra et al. 1986). Total milk yield declined sharply, and stillbirths and abortions increased significantly in cattle that ingested Pb-contaminated hay; the field from which the hay had been cut had a history of use for clay pigeon shoots and contained an estimated 3.6 tons of Pb shot pellets (Frape and Pringle 1984). In sheep grazing in areas near Pb mines, the frequency of abortions was high, and the learning behavior of the lambs was impaired (Demayo et al. 1982). Many species of zoo animals, including monkeys, fruit-eating bats, and parrots, have been fatally poisoned from ingestion of flaking Pb-based paint on the walls and bars of their cages (NRC 1973). Ingestion of Pb-based paint chips was one cause of epizootic mortality of fledgling Laysan albatross, *Diomedea immutabilis*, at Midway Atoll in 1983 (Sileo and Fefer 1987). At present, there is no known dietary requirement for Pb in domestic animals, nor has it been shown unequivocally that Pb plays any beneficial role (NRCC 1973). On the contrary, Pb demonstrably and adversely affects weight, survival, behavior, litter size, and skeletal development (Tsuchiya 1979), and induces teratogenic and carcinogenic responses in some species of experimental animals (NRCC 1973; EPA 1980).

Lead is not essential for plants, and excessive amounts can cause growth inhibition, as well as reduced photosynthesis, mitosis, and water absorption (Demayo et al. 1982). The decline of some European spruce forests has been attributed to excessive concentrations of atmospheric Pb (Backhaus and Backhaus 1986).

Lead is toxic to all phyla of aquatic biota, though effects are modified significantly by various biological and abiotic variables (Wong et al. 1978). Wastes from Pb mining activities have severely reduced or eliminated populations of fish and aquatic invertebrates, either directly through lethal toxicity or indirectly through toxicity to prey species (Demayo et al. 1982). Health advisories warning anglers against eating Pb-contaminated fish have been posted in Missouri (Schmitt and Finger 1987). The significant increases in Pb concentration shown by marine corals between 1954 and 1980 were representative of the increases noted in other biota as a direct result of increased global Pb availability during that period (Dodge and Gilbert 1984).

In this report, I summarize available data on lead in the environment, with emphasis on fishery and wildlife resources, and review current recommendations for the protection of sensitive species. This account is part of a continuing series of brief, reviews prepared in response to requests for information from environmental specialists of the U.S. Fish and Wildlife Service.

SOURCES AND USES

Lead is a comparatively rare metal, with an average abundance in the earth's crust of 16 mg/kg (EPA 1980); it is also a major constituent of more than 200 identified minerals, of which only 3 are sufficiently abundant to form mineral deposits (EPA 1980): galena (PbS), angelesite ($PbSO_4$), and cerusite ($PbCO_3$). Galena, the primary form of Pb in the natural state, is often associated with sphalerite (ZnS), pyrite (FeS_2), chalcopyrite ($CuFeS_2$), and other sulfur salts (May and McKinney 1981). Most (88 %) of the domestic primary Pb production originates from stratabound deposits in southeastern Missouri, another 8% from Idaho's Couer D'Alene district, and the rest from deposits in Colorado and Utah. Primary Pb is smelted and refined at plants in Texas, Montana, Nebraska, Missouri, and Idaho. Scrap Pb, or secondary Pb, accounted for about half the domestic consumption in 1978; by 1980, more Pb was produced from secondary sources than from domestic ores (May and McKinney 1981).

About 4 million tons of Pb are refined annually worldwide (Table 1) Domestic Pb consumption is 1.3 million tons annually, of which about half is used in storage battery manufacture and, until recently, about 20% in the manufacture of gasoline antiknock additives such as tetramethyllead (TML) and tetraethyllead (TEL) (Table 2). Pigments and ceramics account for about 6% of consumption, and metallic Pb products, Pb-containing alloys, paint, solder, and ammunition constitute other minor use categories (EPA 1980). Lead enters the atmosphere mainly through smelter emissions, primarily as $PbSO_4$ and PbO- $PbSO_4$, and through vehicle emissions, which include unburned Pb, TEL, TML, and various Pb halides, sulfates, phosphates, and oxides (Harrison and Laxen 1981).

Lead and its compounds have been known to man for about 7,000 years, and Pb poisoning has occurred for at least 2,500 years (Barth et al. 1973). In Egypt, between 5,000 and 7,000 BC, Pb was used for glazing pottery, solder, ornaments, net sinker, anchors, caulking, coins, weights, aqueducts, piping, and cooking utensils (Nriagu 1978a). The biocidal properties of Pb were familiar to the ancient Egyptians, and Pb salts were sometimes used by them for homicidal purposes (De Michele 1984). Lead encephalopathy (inflammation of the brain) has been recognized since 400 BC among workers in the Pb trades; initial symptoms are dullness, irritability, ataxia, headaches, memory loss, and restlessness. These symptoms often progressed to delirium, mania, coma, convulsions, and sometimes death. The same general effects were described in young children and infants, among which mortality was sometimes 40% (EPA 1980). Extensive use of Pb by the Romans, circa 500, in pipes for water transport, in cosmetics, and as a wine sweetener (Harrison and Laxen 1981), is estimated to have increased environmental Pb levels to about 5X the existing background levels (Eisenreich et al. 1986). The decline of the Roman Empire may have been hastened by endemic lead poisoning--a theory supported by residue data showing high Pb concentrations in bones and remains of Roman aristocrats (Nriagu 1978a)--perhaps through ingestion of excessive amounts of wine laced with Pb (De Michele 1984). After the fall of the Romans, the use of Pb declined sharply. In the 14th century, gunpowder was introduced into Europe and was the impetus for the development of a weapon that fired a malleable metal pellet: a lead shot (EPA 1979). Otherwise, the metal's resistance to corrosion led to its use as lead sheets applied as roofing for cathedrals and as protective encasement of underground pillars. In 1721, the first Pb mine was established in the New World by English settlers at Falling Creek, Virginia, primarily to supply bullets and shot (EPA 1979). By 1750, European and British Pb smelting operations were flourishing (Nriagu 1978a). In 1763, Pb deposits in southeastern Missouri were permanently opened (EPA 1979). The 18th century's Industrial Revolution produced an estimated 10-fold increase in existing Pb background levels (Eisenreich et al. 1986). In the late 1700's, symptoms of acute Pb poisoning recorded among industrial workers were called "Mill Reek" or "Devonshire Colic" (NRCC 1973). Lead poisoning was frequently recorded among U.S. lead miners in 1870-1900, especially in Utah, Colorado, and New Mexico. By 1880, the United States had surpassed Germany and Spain in the mining and refining of Pb, and has continued as the leader in the output of refined Pb (EPA 1979). Air pollution from combustion of leaded gasoline containing TEL rose in the 1920's (NRCC 1973). In the mid-1940's, atmospheric Pb concentrations increased sharply due to massive increases in Pb emissions from automobiles; since then, increased Pb emissions to the atmosphere have matched trends in gasoline Pb content and consumption (Eisenreich et al. 1986; Smith et al. 1987). In 1957, the United States was overtaken by Australia and the USSR in domestic mine production of Pb; however, in 1967, the opening of the "New Lead Belt" in Missouri revived mining in the United States, and subsequently Pb was produced at the annual rate of 450,000 to 550,000 metric tons (EPA 1979). In 1975, the United States was again the leading Pb producer from mine sources, accounting for 16% of the world total; at that time, about 70% of the world Pb production came from the USA, the USSR, Australia, Canada, Peru, Mexico, China, Yugoslavia, and Bulgaria (Tsuchiya 1979,). In 1986, world mine production of lead was 2,352,000 tons of which USA mine production was 353,000 tons, or 15% of the world total, and production in Missouri was 308,000 tons, or 87% of the USA total (personal communication, R. L. Amistadi, Doe Run Company, St. Louis, Missouri).

Table 1. World Pb production, consumption, and principal end uses (modified from Harrison and Laxen 1981; Demayo et al. 1982).

Production consumption, and use	Metric tons, in thousands
Production, 1978	
Mined Pb	3,625

CHEMICAL PROPERTIES

Elemental Pb is a bluish-gray, soft metal of atomic weight 207.19 and atomic number 82; it melts at 327.5 C, boils at 1,749 C, and has a density of 11.34 g/cm^3 at 25^{o}C. Metallic Pb is sparingly soluble in hard, basic waters to 30 ug/l, and up to 500 ug/l in soft, acidic waters. Lead has four stable isotopes: Pb-204 (1.5%), Pb-206 (23.6%), Pb-207 (22.6%), and Pb-208 (52.3%). Of its 24 radioactive isotopes, two (Pb-210, Tb 1/2 of 22 years; Pb-212, Tb ½ of 10 hours) have been used in tracer experiments. Lead occurs in four valence states: elemental (Pb^o), monovalent (Pb^+), divalent (Pb^{2+}), and tetravalent (Pb^{4+}); all forms are environmentally important, except possibly Pb^+. In nature, lead occurs mainly as Pb^{2+}; it is oxidized to Pb^{4+} only under strong oxidizing conditions, and few simple compounds of Pb^{4+} other than PbO_2 are stable. Some Pb salts are comparatively soluble in water (lead acetate, 443 g/l; lead nitrate, 565 g/l; lead chloride, 9.9 g/1), whereas others are only sparingly soluble (lead sulfate, 42.5 mg/l; lead oxide, 17 mg/l; lead sulfide, 0.86 mg/1); solubility is greatest at elevated temperatures in the range 0 to 40° C. Of the organoleads, tetraethyllead (TEL) and tetramethyllead (TML) are the most stable and the most important because of their widespread use as antiknock fuel additives. Both are clear, colorless, volatile liquids, highly soluble in many organic solvents; however, solubility in water is only 0.18 mg/l for TEL, and 18.0 mg/l for TML. Boiling points are 199^o C for TEL and 110 C for TML; both undergo photochemical degradation in the atmosphere to elemental Pb and free organic radicals, although the fate of automotive organoleads has yet to be fully evaluated. Additional information on the general chemistry of lead and its compounds was reviewed by NRCC (1973), Boggess (1977), Nriagu (1978a), EPA (1979, 1980), Tsuchiya (1979), Harrison and Laxen (1981), and Demayo et al. (1982).

Lead chemistry is complex. In water, for example, Pb is most soluble and bioavailable under conditions of low pH, low organic content, low concentrations of suspended sediments, and low concentrations of the salts of calcium, iron, manganese, zinc, and cadmium. Accordingly, solubility of lead is low in water, except in areas of local point source discharges (Harrison and Laxen 1981; Scoullos 1986). Lead and its compounds tend to concentrate in the water surface microlayer (i.e., the upper 0.3 mm), especially when surface organic materials are present in thin films (Demayo et al. 1982). Organolead compounds are generally of anthropogenic origin and are found mostly in the aquatic environment as contaminants; however, some organolead complexes form naturally, and their rate of formation may be affected by man-made organoleads (Nriagu 1978a). In surface waters, Pb exists in three forms: dissolved labile (e.g., Pb^{2+}, $PbOH^+$, $PBCO_3$), dissolved bound (e.g., colloids or strong complexes), or as a particulate (Benes et al. 1985). The labile forms represent a significant part of the Pb input from washout of atmospheric deposits, whereas particulate and bound forms were common in urban runoff and ore-mining effluents (Benes et al. 1985). The solubility of Pb compounds in water is pH dependent, and ranges from about 10 g Pb/1 at pH 5.5, to less than 1 ug Pb/1 at pH 9.0 (EPA 1980); little detectable Pb remains in solution at pH >8.0 (Prause et al. 1985). At pH 6.5 and water alkalinity of 25 mg $CaCO_3$/1, elemental Pb is soluble to 330 ug/l; however, Pb under the same conditions is soluble to 1,000 ug/l (Demayo et al. 1982). In acidic waters, the common forms of dissolved Pb are salts of $PbSO_4$ and $PbCl_4$, ionic Pb, cationic forms of lead hydroxide, and (to a lesser extent) the ordinary hydroxide $Pb(OH)_2$. In alkaline waters, common species include the anionic forms of Pb carbonate and hydroxide, and the hydroxide species present in acidic waters (NRCC 1973). Unfortunately, the little direct information available about the speciation of Pb in natural aqueous solutions has seriously limited our understanding of Pb transport and removal mechanisms (Nriagu 1978a).

Most Pb entering natural waters is precipitated to the sediment bed as carbonates or hydroxides (May and McKinney 1981). Lead is readily precipitated by many common anions; desorption and replacement by other cations is extremely slow (Boggess 1977). In some acidic lakes, the deposition of particulate Pb was strongly correlated with the deposition of aluminum and carbon, especially during periods of increasing pH (White and Driscoll 1985). Precipitation of sparingly soluble Pb compounds is not a primary factor controlling the concentration of dissolved Pb in stream waters. Migration and speciation of Pb was strongly affected by water flow rate, increasing flow rate resulting in increased concentrations of particulate and labile Pb and a decrease in bound forms. At low stream flow, Pb was rapidly removed from the water column by sedimentation (Benes et al. 1985).

In the sediments, Pb is mobilized and released when the pH decreases suddenly or ionic composition changes (Demayo et al. 1982). However, there was no significant release of Pb from dredge spoils suspended in estuarine waters of different salinities for 4 weeks (Prause et al. 1985). Some Pb^{2+} in sediments may be transformed to tetraalkyllead compounds, including TML, through chemical and microbial processes. There is also the possibility of methylation of ionic Pb in vivo by fish and other aquatic biota, but the mechanisms are unclear (May and McKinney 1981). Methylation of Pb in sediments was positively related to increasing temperatures, reduced pH, and microbial activity, but seemed to be independent of Pb concentration (Demayo et al. 1982). In general, the concentration of tetraalkylleads in sediments is low, representing less than 10% of total Pb (Chau et al. 1980).

MODE OF ACTION

Lead modifies the function and structure of kidney, bone, the central nervous system, and the hematopoietic system and produces adverse biochemical, histopathological, neuropsychological, fetotoxic, teratogenic, and reproductive effects (Boggess 1977; Nriagu 1978b; De Michele 1984). Inorganic Pb absorbed into the mammalian body enters the bloodstream initially and attaches to the red blood cell. There is a further rapid distribution of the Pb between blood extracellular fluid and other storage sites that is so rapid that only about half the freshly absorbed Pb remains in the blood after a few minutes. The storage sites for Pb are uncertain, although they are probably in soft tissues as well as bone; the half-time residence life (Tb 1/2) of inorganic Pb is estimated to be 20 days in blood, 28 days in whole body, and 600 to 3,000 days in bone (Harrison and Laxen 1981). Inorganic Pb in the environment can be biologically methylated to produce alkyllead compounds (Walsh and Tilson 1984). Bile is an important route of excretion; ingested Pb probably proceeds sequentially from gut, to blood, to bone and soft tissue, and by way of the bile to small intestine and fecal excretion (De Michele 1984).

Tetraalkyllead mode of action differs from that of inorganic Pb. Although initial entry is still into the bloodstream, the Pb is evenly distributed between blood plasma and the red blood cells. Tetraalkylleads are lost rapidly from the bloodstream, although some reappear in 5 to 10 hours associated exclusively with the red blood cells, probably as trialkyllead, though a fraction may be converted to inorganic Pb. The organoleads concentrate in liver, and it is there that tetraalkyllead is probably converted to trialkyllead. Otherwise, the Pb is widely dispersed throughout the body with Tb 1/2 values of 200 to 350 days (Harrison and Laxen 1981). Tetraethyllead, by virtue of its liposolubility, is rapidly accumulated in nonbony tissues, particularly the brain, where the onset of signs of poisoning is rapid (Nriagu 1978b). Short-term repeated exposures of rats (*Rattus* spp.) to TEL results in a neurotoxic syndrome consisting of altered reactivity to noxious stimulation through disruption of forebrain-area function (Hong et al 1983). Several fish species metabolize tetraalkylleads to trialkyllead compounds by way of their mixed function oxidase system (Wong et al. 1981). The trialkyllead derivatives are considered responsible for the toxicity of the parent compound (Walsh and Tilson 1984). Trialkylleads and dialkylleads rapidly traverse biological membranes in bird eggs and accumulate in the yolk and developing embryo (Forsyth et al. 1985). At present, the organolead mode of action is poorly understood, but organolead compounds are known to inhibit amino acid transport, uncouple oxidative phosphorylation, and inhibit cerebral glucose metabolism (Hong et al. 1983).

Biochemically, Pb exerts deleterious effects on hematopoiesis through derangement of hemoglobin synthesis, resulting in a shortened life span of circulating erythrocytes, often resulting in anemia. Two essential enzymes in heme formation that are extremely sensitive to Pb are delta aminolevulinic acid dehydratase (ALAD), which catalyzes the dehydration of delta amino levulinic acid (ALA) to form porphobilinogen (PBG), and ferrochelatase (= heme synthetase), which catalyzes the insertion of Fe^{2+} into protoporphyrin IX (PP). This second reaction requires the presence of glutathione and ascorbic acid. Some of the intermediates in heme follow sequentially: ALA, PBG, uroporphyrinogen III, coproporphyrinogen III, protoporphyrinogen IX, and PP. It is now well established that ALAD and ferrochelatase are the most sensitive biochemical indicators of Pb exposure, the net result being lowered ALAD activity and elevated PP activity (Barth et al. 1973; Nriagu 1978b; EPA 1979, 1980; Tsuchiya 1979; Harrison and Laxen 1981; Hoffman et al. 1981; De Michele 1984; Schmitt et al. 1984; Lumeij 1985).

Inhibition of blood ALAD activity after exposure to Pb has been documented in many species of freshwater and marine teleosts (Hodson 1976; Hodson et al. 1977, 1980; Johansson-Sjobeck and Larsson 1979; Krajnovic-Ozretic and Ozretic 1980; Demayo et al. 1982; Schmitt et al. 1984; Haux et al. 1986), in the freshwater cladoceran, *Daphnia magna* (Berglind et al. 1985), in ducks, quail, doves, swallows, raptors, and songbirds

(Finley et al. 1976.; Dieter and Finley 1978; Dieter 1979; Hoffman et al. 1981; Franson and Custer 1982; Kendall et al. 1982; Kendall and Scanlon 1982; Eastin et al. 1983; Franson et al. 1983; Hoffman et al. 1985a, 1985b; Beyer et al. 1988), and in humans, sheep, mice, rats, rabbits, and calves (Barth et al. 1973; Boggess 1977; Nriagu 1978b; Tsuchiya 1979; Hejtmancik et al. 1982; Hayashi 1983; Peter and Strunc 1983; Schlick et al. 1983; Gietzen and Wooley 1984; Zmudzki et al. 1984). Lead-induced ALAD inhibition has been recorded not only in blood, but also in brain, spleen, liver, kidney, and bone marrow (Johansson-Sjobeck and Larsson 1979; Hoffman et al. 1981, 1985a, 1985b; Schlick et al. 1983; Friend 1985). Time for ALAD recovery to normal levels is dose dependent, organ specific, and usually directly correlated with blood Pb concentrations (Finley et al. 1976; Hodson et al. 1977; Dieter 1979; Hayashi 1983; Friend 1985). ALAD activity levels in Pb-stressed teleosts were normal 3 to 11.7 weeks postadministration (Hodson et al. 1977; Johansson-Sjobeck and Larsson 1979; Krajnovic-Ozretic and Ozretic 1980; Demayo et al. 1982); this range was 2 to 14 weeks in birds (Dieter and Finley 1978; Kendall et al. 1982; Kendall and Scanlon 1982; Friend 1985), and 3 to 12 weeks in mammals (Barth et al. 1973; Schlick et al. 1983). The physiological significance of depressed blood ALAD activity levels, except perhaps as an early indicator of Pb exposure, is debatable. Aside from a few instances of moderate anemia in workers at lead smelters, other abnormalities noted were not regarded as serious (Barth et al. 1973 Lead-induced depression in ALAD activity in mallard (*Anas platyrhynchos* ducklings and ring-necked pheasant (*Phasianus colchicus*) chicks was not associated with signs of overt toxicity (Eastin et a . 1983); a similar case is made for Pb-stressed domestic chickens (*Gallus* sp.) showing 98% reduction in ALAD activity (Franson and Custer 1982), and for American kestrel (*Falco sparverius*) showing an 80% reduction (Franson et al. 1983). Birds may be more sensitive than mammals to Pb-induced depressions in blood ALAD activity (Dieter et al. 1976). In ducks, for example, inhibition of ALAD would be more harmful than a comparable depression in mammals, for three reasons (Dieter et al. 1976). First, metabolic activity is greater in nucleated duck erythrocytes than in human erythrocytes. Second, ducks require porphyrin synthesis not only for hemoglobin production (as in humans), but also for production of respiratory heme-containing enzymes. Finally, the half-life of erythrocytes is shorter in ducks than in humans: 40 days vs. 120 days.

Elevated blood protoporphyrin IX activity resulting from Pb-inhibition of heme synthetase has been documented for humans and small mammals (Peter and Strunc 1983) and for many species of birds (Anders et al. 1982; Carlson and Nielsen 1985; Friend 1985; Franson et al. 1986; Beyer et al. 1988); recovery to normal levels occurs in a Pb-free environment in 2 to 7 weeks. Franson et al. (1986) endorsed the blood protoporphyrin IX technique instead of ALAD as a means of measuring Pb stress because of its comparative simplicity and lower cost.

Other chemical changes that have been observed as a result of Pb exposure include increased serum creatinine and serum alanine aminotransferase in birds, suggestive of kidney and liver alterations (Hoffman et al. 1981); changes in potassium, chloride, and glucose metabolism in rainbow trout, *Salmo gairdneri* (Haux and Larsson 1982); and a decrease in brain acetylcholinesterase activity in rats (Gietzen and Wooley 1984).

In kidney, Pb tends to accumulate in the proximal convoluted tubule cells of the renal cortex, producing morphological changes such as interstitial fibrosis, edema, and acid-fast intranuclear inclusion bodies, as well as biochemical changes (Locke et al. 1966; Boggess 1977; Nriagu 1978b; EPA 1980; De Michele 1984). Renal intranuclear inclusion bodies occurred in 83% of mallards experimentally poisoned by dietary Pb acetate or Pb shot (Beyer et al. 1988); similar results have been reported in other species of birds (Clemens et al. 1975; Anders et al. 1982) and in primates, cattle, and bats (Zook et al. 1972; Osweiler and Van Gelder 1978; Colle et al. 1980; Tachon et al. 1983).

In the cladoceran *Daphnia magna,* about 90% of the total body Pb burden is adsorbed to the exoskeleton (Berglind et al. 1985). In animals with a vertebral column, total amounts of Pb tend to increase with age; by far the most Pb is bound to the skeleton, especially in areas of active bone formation (Barth et al. 1973; Tsuchiya 1979; EPA 1980; Hejtmancik et al. 1982; Mykkanen et al. 1982; Peter and Strunc 1983; De Michele 1984; Eisler 1984; Berglind et al. 1985; Marcus 1985). The retention of Pb stored in bone pools poses a number of difficulties for the usual multicompartmental loss-rate models. Some Pb in bones of high medullary content, such as the femur and sternum, have relatively long retention times--i.e., Tb 1/2 of >20 years in humans--whereas Pb stored in bones of low medullary content have Tb 1/2 values of 20 to 200 days, similar to the values for Pb in soft tissues and blood (Tsuchiya 1979; Marcus 1985). In birds, medullary bone undergoes sequences of bone formation and destruction associated with the storage and liberation of calcium during eggshell formation, indicating that sex and physiological condition primarily influence Pb kinetics in avian bone (Finley

and Dieter 1978). Marcus (1985) endorsed the use of diffusion models based on the exchange of Pb between blood in canaliculi and the crystalline bone of the osteon to account for retention and bioavailability. More research is needed on the role of bone in Pb kinetics.

Lead damages nerve cells and ganglia, and alters cell structure and enzyme function. Axonal degenerative changes, especially in neuronal cell bodies, were recorded in Pb-poisoned freshwater snails (*Viviparous ater*), leading to altered protein synthesis (Fantin et al. 1985). Mallards dosed orally with Pb shot developed demyelinating lesions in vagal, branchial, and sciatic nerves, and showed vascular damage in the cerebellum; lesions were similar to those in Pb-intoxicated guinea pigs (*Cavia* sp.), rats, and guinea hens, *Gallus* sp. (Hunter and Wobeser 1980). Crop stasis in birds, which is characterized by paralysis of the alimentary tract, impaction of food in the gizzard and proventriculus, and regurgitation of crop fluid, has been produced by Pb shot or Pb acetate solutions. Lead induces crop dysfunction by acting either directly on the smooth muscle or on associated nerve plexuses of crop tissue, depending on the route of administration (Clemens et al. 1975; Boyer et al. 1985; Boyer and Di Stefano 1985). Mammals, including humans, undergo similar alimentary distress following intakes of lead (Boyer et al. 1985).

Effects of Pb on the nervous system are both structural and functional, involving the cerebellum, spinal cord, and motor and sensory nerves; the result may be deterioration of intellectual, sensory, neuromuscular, and psychological functions (Nraigu 1978b). The pathogenesis of Pb-induced injury to the nervous system is poorly understood, but may be mediated through vascular damage, the direct action of Pb on neurons, or alterations in porphyrin metabolism (Hunter and Wobeser 1980). Retarded brain growth in prenatal guinea pigs has been recorded at subclinical levels of Pb (i.e., at concentrations producing no elevation in blood Pb and no change in body weight), and this effect is potentiated at temperatures of 42^{o} C (Edwards and Beatson 1984). Lead may cause a transient disturbance in the blood-brain barrier during early postnatal growth of rats. This effect is associated with the presence of hemorrhagic lesions, suggesting focal damage to the vessels as an important event in the pathogenesis of Pb encephalopathy to suckling rats (Sundstrom et al. 1985). Brain histopathology has been recorded in Pb-poisoned chickens (Narbaitz et al. 1985) and cattle (Osweiler and Van Gelder 1978). Brain Pb concentrations are usually among the lowest in body organs, but the brain is one of the main sites of action. During chronic Pb poisoning, distribution of Pb in the brain is positively related to both dose and duration of exposure; preferential accumulation is in the hippocampus area of the brain. Significant amounts of Pb persisted in rat brain tissue up to 4 weeks after the withdrawal of Pb treatment (Collins et al. 1982). The role of organolead compounds in hippocampal function is largely unknown (Czech and Hoium 1984).

Absorption and retention of Pb from the gastrointestinal tract, the major pathway of intake, varies widely because of the age, sex, and diet of the organism. Diet is the major modifier of Pb absorption and of toxic effects in many species of domestic and laboratory animals, waterfowl, and aquatic organisms. In fact, the lack of certain major minerals in the diet often affected toxicity and storage of Pb in tissue more than did doubling the dosages of Pb in the diet (Levander 1979). Dietary deficiencies in calcium, zinc, iron, vitamin E, copper, thiamin, phosphorus, magnesium, fat, protein, minerals, and ascorbic acid increased Pb absorption and its toxic effects (Longcore et al. 1974b; Forbes and Sanderson 1978; Levander 1979; Sleet and Soares 1979; Colle et al. 1980; EPA 1980; Hodson et al. 1980; De Michele 1984; Stone and Fox 1984; Zmudzki et al. 1983, 1984; Carlson and Nielsen 1985; Gilmartin et al. 1985). Toxic effects of Pb-stressed fauna also were exacerbated when animals were fed diets containing excess cadmium, lactose, ethylenediaminetetraacetic acid, zinc, fat, protein, sodium citrate, ascorbate, amino acids, vitamin D, copper, mercury, fiber content, and nitrilotriacetic acid (Clemens et al. 1975; Forbes and Sanderson 1978; Nriagu 1978b; Levander 1979; EPA 1980; Krajnovic-Ozretic and Ozretic 1980; Burrows and Borchard 1982; Hamir et al. 1982; Zmudzki et al. 1983, 1984; De Michele 1984; Carlson and Nielson 1985). Protection against various toxic effects of ingested Pb was provided by measured dietary supplements of calcium, iron, zinc, ascorbic acid, and vitamin E (Krajnovic-Ozretic and Ozretic 1980; Gilmartin et al. 1985). Many other conditions affect Pb absorption, including size of Pb particle (EPA 1980; Hamir et al. 1982), type of Pb compound ingested (EPA 1980), presence of other compounds that act synergistically (Barth et al. 1973) or antagonistically (Luoma and Bryan 1978), and dosage (Finley and and Dieter 1978). For example, smaller Pb particles, <180 um in diameter, were absorbed from the intestinal tract up to 7 times more rapidly than larger particles of 180 to 250 um (EPA 1980). However, when large pieces of Pb are ingested, such as lead shot, these may lodge in the gastrointestinal tract, dissolve slowly, and cause Pb poisoning (Nriagu 1978b). Also, lead phthalates were absorbed more rapidly than carbonates, acetates,

sulfides, and naphthanates, in that sequence (EPA 1980). It is evident that all of these variables, as well as diet, need to be considered in risk assessment of Pb.

BACKGROUND CONCENTRATIONS

GENERAL

Lead concentrations were usually highest in ecosystems nearest Pb mining, smelting, and refining activities; Pb storage battery recycling plants; areas of high vehicular traffic; urban and industrialized areas; sewage and spoil disposal areas; dredging sites; and areas of heavy hunting pressure. In general, Pb does not biomagnify in food chains. Older organisms usually contain the greatest body burdens, and Pb accumulations are greatest in bony tissues. It seems that resources that are now at high risk (i.e., increased mortality, reduced growth, or impaired reproduction) from Pb include the following: migratory waterfowl that congregate at heavily-hunted areas; raptors that eat hunter-wounded game; domestic livestock near smelters, refineries, and recycling plants; wildlife that forage extensively near heavily traveled roads; aquatic life in proximity to mining activities, Pb arsenate pesticides, metal finishing industries, lead alkyl production, and Pb aerosol fallout; and crops and invertebrates growing or living in Pb-contaminated soils. Data on background concentrations in nonbiological and living resources are cited extensively in Bernhard and Zattera (1975), Nriagu (1978a,b), Wong et al. (1978), Branica and Konrad (1980), Jenkins (1980), Eisler (1981), Harrison and Laxen (1981), and Demayo et al. (1982).

NONBIOLOGICAL SAMPLES

Average Pb concentrations in nonbiological materials worldwide were much higher in sediments (47,000 ug/kg), soils (16,000), and sediment interstitial waters (36) than in atmospheric and other hydrospheric compartments (Table 3). Most of the lead discharged into surface waters is rapidly incorporated into suspended and bottom sediments, and most will ultimately be found in marine sediments (Harrison and Laxen 1981). Sediments now constitute the largest global reservoir of Pb; sediment interstitial waters and soils constitute secondary reservoirs (Table 3).

Lead concentrations were elevated in certain nonbiological materials as a result of nonhunting human activities and natural processes (Table 4). In sediments, Pb concentrations ranged from 3 mg/kg in carbonate marls off the Florida coast to more than 11,000 mg/kg at Sorfjord, Norway, the site of massive discharges of Pb-containing industrial and domestic wastes (Nriagu 1978a). Lead contaminates sediments from sources as diverse as steelworks, shipyards, crude oil refineries, cement and ceramic factories, Pb storage battery recycling plants, and heavy traffic (Scoullos 1986). Mining activities are also important. High concentrations of Pb were measured in sediments (up to 2,200 mg/kg) and detritus (up to 7,000 mg/kg) of the Big River in southeastern Missouri (Czarneski 1985). The Big River drains what was once the largest Pb-mining district in the world; commercial mining was extensive between the early 1700's and 1972. During this period more than 200 metric tons of tailings accumulated within the Big River watershed as a result of seepage from tailings ponds, from erosion of tailings piles on the banks, and through accidental discharges (Niethammer et al. 1985).

Table 3. Amounts of lead in global reservoirs (modified from Nriagu 1978a).

Reservoir	Concentration (µg/kg)	Total Pb in pool (millions of metric tons)

[a]Concentrations are shown as mean, minimum and maximum (in parentheses), and maximum (Max.).

[b]Each reference applies to data in the same row and in the rows that immediately follow for which no reference is indicated.

In soils, Pb concentrates in organic-rich surface horizons (NRCC 1973). In one instance, only 17 mg of soluble Pb/kg was found in soils 3 days after the addition of 2,784 mg of Pb (as lead nitrate)/kg (NRCC 1973). The estimated residence time of Pb in soils is about 20 years; complete turnover in topsoil is expected every few decades (Nriagu 1978a). In forest litter, however, the mean residence time of Pb is lengthy; estimates range from 220 years (Turner et al. 1985) to more than 500 years (Friedland and Johnson 1985).

Lead deposited on roadways is removed in drainage water, and later accumulated in roadside soils (Harrison et al. 1985). Amounts of Pb in roadside soils are increased as a direct result of the combustion of gasoline containing organolead additives. In general, the amounts of Pb were greatest along roads with the highest density of vehicular traffic, and amounts decreased rapidly with increasing distance from the roadway (Harrison and Dyer 1974; Boggess 1977; Chmiel and Harrison 1981; Way and Schroder 1982; Table 4). Elevated levels of Pb in soils also were recorded from the vicinity of storage battery reclamation plants, smelting activities, and mining and milling operations (Boggess 1977; Burrows 1981; Kisseberth et al. 1984). Fly ash from coal burned in homes or privately hauled from power plants, which contains 100 to 450 mg Pb/kg and is frequently used to reclaim land for the growth of forage and pasture crops and as an alkaline amendment in the reclamation of strip mined areas (Nriagu 1978a), is considered another source of soil Pb. Two additional sources of Pb in soils are municipal sewage sludge and lead-arsenate pesticides (Nriagu 1978a). Sewage sludge, which contains up to 100 mg Pb/kg and is applied as a fertilizer and soil conditioner at the rate of 50 million tons annually, may increase top soil levels by as much as 25 mg Pb/kg. Lead arsenate, a pesticide used to reduce bird hazards near airport runways by controlling earthworm abundance, and also to control pests in fruit orchards, represents another local source of lead contamination to soils.

Lead reaches the aquatic environment through industrial and municipal discharges, in atmospheric deposition, from weathering processes in areas of natural Pb mineralization, and in highway runoff (EPA 1980; Harrison and Laxen 1981; Birdsall et al. 1986). Industrial Pb input to aquatic environments is estimated at 10X that introduced by natural weathering processes (Scoullos 1986); sewage and aerosols are major sources (Harrison and Laxen 1981). Snowmobile exhausts are considered a major source of lead in some locations; concentrations up to 135 ug Pb/l have been recorded in surface waters at the time of ice breakup (Adams 1975). On the other hand, Pb content in water (and sediments) of a fly ash settling pond of a coal-fired power plant did not increase as a result of plant operations (White et al. 1986).

Anthropogenic activities leading to increased air Pb levels include primary and secondary lead smelting, the burning of gasoline containing lead antiknock agents, coal combustion, storage battery manufacture, and pigment production (NRCC 1973). It is generally agreed that combustion of leaded gasoline is the primary source of atmospheric Pb. Atmospheric Pb is usually attached to aerosols <0.2 um in diameter, is efficiently scavenged by precipitation, has a short atmospheric residence time that is usually measured in days but may range up to 14 weeks depending on meteorological conditions, and may be transported long distances (i.e., hundreds or thousands of kilometers) from emitting sources (NRCC 1973; Harrison and Laxen 1981; Harrison et al. 1985; Eisenreich et al. 1986). Along roadways, more than 90% of Pb emissions are dispersed by the atmosphere away from the immediate vicinity of the road; air Pb levels stabilize at low levels about 30 m from the road as a result of rapid settling of particles >5 um in diameter, and from the downwind traverse of particles entrained in the turbulent atmosphere (Boggess 1977; Harrison et al 1985). Since 1970, the lead content in

gasoline has decreased; profiles of Pb in dated sediment cores and Pb in atmospheric aerosols suggest that the environment is responding to decreasing use of leaded gasoline, and that atmospheric Pb concentrations and fluxes will continue to decrease susbstantially if use of Pb in gasoline is further decreased (Eisenreich et al. 1986).

FUNGI, MOSSES, LICHENS

Concentrations of Pb were highest in specimens collected near metal smelters, lead mines, industrial areas, and urban locations (Table 5). Lead concentrations were 9 to 13X greater in a lichen (*Parmelia baltimorensis*) collected in Washington, DC, in 1970 than in the same lichen collected 34 years earlier (Jenkins 1980).

TERRESTRIAL PLANTS

Elevated Pb contents were recorded in various species of plants from the vicinity of metal smelters, roadsides, soils heavily contaminated with Pb, natural ore deposits, and Pb recycling factories (Table 5). Bioavailability of Pb in soils to plants is limited, but is enhanced by reduced soil pH, reduced content of organic matter and inorganic colloids, reduced iron oxide and phosphorus content, and increased amounts of Pb in soils (NRCC 1973; Boggess 1977). Lead, when available, becomes associated with plants by way of active transport through roots and by absorption of Pb that adheres to foliage (Boggess 1977). Lead concentrations were always higher in the older parts of plants than in shoots or flowers (Bunzl and Kracke 1984; Table 5).

Table 5. Lead concentrations in field collections of selected species of flora and fauna. Values shown are in mg Pb/kg (ppm) fresh weight (FW), or dry weight (DW).

[a]Concentrations are listed as mean, (minimum-maximum), and maximum (Max.).

[b]Each reference applies to data in the same row and in the rows that immediately follow for which no reference is indicated.

Damage to plants with elevated Pb contents is usually negligible, but varies widely among species. Atmospheric Pb may have contributed to the decline of European spruce forests. The mean Pb content of needles and litter was significantly higher where tree decline was most pronounced than in areas where forests were unaffected (Backhaus and Backhaus 1986). Lead can have deleterious effects on plant growth processes at current Pb levels in urban areas and may similarly affect plants in rural areas in the future (Rolfe and Reinbold 1977). A reduction in yield of corn or soybeans is expected in low-binding capacity soils with Pb levels greater than 200 mg/kg (Rolfe and Reinbold 1977). Hay grown near roadsides may be toxic to horses and cattle (Rolfe and Reinbold 1977). In extreme cases, reforestation has been initiated in areas where forage is so heavily contaminated with Pb that it has become necessary to slaughter domestic livestock because the

amounts of Pb in their livers and kidneys became unacceptably high (Edwards and Clay 1977). Typical area reforestation includes removal of contaminated forage by cutting, bailing, and burying native grasses; burning of stubble and litter; and adding of agricultural lime at the rate of 2,244 kg/ha (2,000 pounds/acre) to all soils within 1,525 m (5,000 feet) of sites where Pb levels exceed 175 mg/kg (Edwards and Clay 1977).

TERRESTRIAL INVERTEBRATES

In earthworms, lead levels were highest in those closest to highways and in areas with high volumes of traffic (Goldsmith and Scanlon 1977; Table 5). Various species of insects and soil invertebrates from roadsides, from areas receiving sewage sludge, and from metal smelter environs also contain high amounts of Pb (Table 5). Amounts of Pb in whole body were higher in earthworms, millipedes, and woodlice collected from soil and plant litter near highways than away from highways; soil and litter seem to be major reservoirs of Pb in roadside communities (*Malacosoma americanum*) and their host plant (Beyer and Moore 1980). In contrast, Pb concentrations in the eastern tent caterpillar (*Malacosoma americanum*) were lower than those reported for roadside soil and litter invertebrates, and were about 76% of that in leaves of its host, the black cherry *Prunus serotina* (Beyer and Moore 1980).

The use of terrestrial invertebrates as sentinel organisms has been suggested for monitoring Pb. The spider *Araneus umbricatus*, for example, contained Pb body burdens that correlated with that in a lichen (*Lecanora conizaeoides*) that is currently used to monitor atmospheric Pb (Clausen 1984). Similarly, the woodlouse (*Porcellio scaber*) seems to reflect Pb concentrations in adjacent soil or leaf litter (Hopkin et al. 1986).

AQUATIC BIOTA

Freshwater algae, invertebrates, and fish had comparatively elevated Pb concentrations when collected near industrialized areas, ponds with high numbers of Pb shot, urban areas, Pb mines, and tailings ponds (Table 5). For marine biota, Pb residues were highest where Pb concentrations were high in the water--near bridges, near industrial disposal areas, near sewage and disposal areas, near dredging sites, and at mining sites (Table 5). Among aquatic biota, Pb concentrations were usually highest in algae and benthic organisms, and lowest in upper trophic level predators. No significant biomagnification of Pb occurs in aquatic food chains (Boggess 1977; Rolfe and Reinbold 1977; Branica and Konrad 1980; Demayo et al. 1982; Flegal 1985; Table 5). Lead concentrations in cartilaginous and bony fishes--and also birds and mammals--were usually highest in areas of high human and vehicular density, and near lead mines and ore concentration plants. Lead concentrations in aquatic (and terrestrial) vertebrates tend to increase with increasing age of the organism, and to localize in hard tissues such as bone and teeth (Eisler 1981, 1984).

In stream sediments, Pb was highest in urban streams and lowest in the rural streams, reflecting Pb inputs from storm runoff; species diversity was greater in the rural streams, due partly to lowered contaminant loadings, including Pb (Rolfe and Reinbold 1977).

Nationwide monitoring of freshwater fishes conducted periodically by the U.S. Fish and Wildlife Service (National Biocontaminant Monitoring Program) showed that whole body Pb burdens were highest for Atlantic coast streams, the Great Lakes drainage, the Mississippi River system, the Columbia River system, and in certain Hawaiian streams (May and McKinney 1981). Major sources of Pb in Atlantic coast streams included wastes from metal finishing industries, brass manufacturing, lead alkyl production, primary and secondary Pb smelting, coal combustion, and manufacture of lead oxide. For the Great Lakes, especially for the Lake St. Clair collection site, industrial sources and urban Pb aerosol fallout from the Detroit area were major sources. In the Mississippi River system, naturally occurring deposits of Pb ores, and effluents from zinc producers and industrial dischargers were prevalent. The Columbia River system was characterized by Pb inputs from natural geologic deposits, industrial effluents, and the mining and smelting of Pb. Hawaiian streams received most of their Pb from urban runoff, vehicle sources, and agricultural and residential use of Pb arsenate (May and McKinney 1981).

Fish collected in 1979-1981 in the Big River, Missouri, near a ruptured tailings pond dam where Pb concentrations in tailings approached 4,000 mg/kg, contained greatly elevated whole body Pb burdens of 9 to 18 mg/kg fresh weight (Schmitt et al. 1984). By comparison, the highest Pb concentration recorded to date in the National Biocontaminant Monitoring Program is 6.7 mg/kg fresh weight in whole Mozambique tilapia (*Tilapia*

mossambica) from Honolulu in 1979 (Lowe et al. 1985). Catostomids from contaminated portions of the Big River contained elevated blood Pb levels, depressed blood ALAD activity levels, and Pb concentrations in edible tissues exceeding 0.3 mg/kg fresh weight--a level considered hazardous to human health (Schmitt et al. 1984). The Missouri Department of Health later issued an advisory against eating castostomids caught in a 65-km section of the Big River (Czarneski 1985).

Whitefish, *Coregonus* spp., from Pb-contaminated Swedish lakes, showed depressed blood ALAD and blood chemistry derangement when compared to fish from a reference lake--suggesting that Pb affects natural populations of fish in a manner similar to that observed in laboratory studies (Haux et al. 1986).

The significance of organolead residues in aquatic life is unknown, and merits additional research. In Ontario, Canada, about 16% of all fish sampled contained tetraalkyllead compounds, although none were recorded in water, vegetation, or sediments from the collection sites (Chau et al. 1980). Tetramethyllead reportedly was produced from biological and chemical methylation of several inorganic and organic Pb compounds in the aquatic environment, and has been detected at low concentrations in marine mussels, lobsters, and bony fishes (Wong et al. 1981).

AMPHIBIANS AND REPTILES

Tadpoles of bullfrogs (*Rana catesbeiana*) and green frogs (*R. clamitans*) from drainages along highways with different daily average traffic volumes (4,272 to 108,800 vehicles per day) contained elevated amounts of Pb (up to 270 mg/kg dry weight), which were positively correlated with Pb in sediments and with average daily traffic volume. Lead in tadpoles living near highways may contribute to the Pb levels reported in wildlife that eat tadpoles. Diets with amounts of Pb similar to those in tadpoles collected near heavily traveled highways have caused adverse physiological and reproductive effects in some species of birds and mammals (Birdsall et al. 1986). Elevated Pb sconcentrations also were recorded in various species of amphibians and reptiles collected near Pb smelters and mines (Table 5).

BIRDS

In general, Pb concentrations were highest in birds from urban locations (perhaps reflecting greater exposure to automotive and industrial contamination) and in birds near Pb mining and smelting facilities. Lead residues also are greatest in older birds (especially in bone, because of accumulation over time), in sexually mature females, and in waterfowl that have ingested Pb shot pellets (Table 5).

Continued deposition of Pb shot by hunters into wetlands habitats exposes birds to lead. Lead shot is a substantial localized source of contamination, especially in prime waterfowl habitat (Bellrose 1951, 1959; NRCC 1973; White and Stendell 1977; Stendell et al. 1979; Wobeser 1981; Clausen et al. 1982; Longcore et al. 1982; Mudge 1983; Driver and Kendall 1984; Hall and Fisher 1985). Several million hunters are estimated to deposit more than 6,000 metric tons of Pb shot annually into lakes, marshes, and estuaries; this represents about 6,440 pellets per bird bagged. Shot densities as great as 860,000 pellets/ha (2,124,000/acre) have been estimated in some locations (Wobeser 1981), although concentrations of 34,000 to 140,000/ha are more common (Longcore et al. 1982; Driver and Kendall 1984). For example, Pb shot in bottom sediments from Merrymeeting Bay, Maine, a prime waterfowl staging area, averaged 99,932 shot/ha (274,000/acre), and ranged from 59,541 to 140,324/ha; shot were significantly more numerous in silt than in sand sediments. In general, shot sink more rapidly in soft than in firm substrates, and there is only slight carryover of shot from one season to the next in areas with silt or peat bottoms (Wobeser 1981).

Waterfowl and other birds ingest spent shot during feeding and retain them as grit in the gizzard; the pellets are eroded and soluble Pb is absorbed from the digestive tract. In many species, the ingestion of a single pellet is often fatal. Most deaths, however, go unnoticed and unrecorded. Species such as the mallard and pintail that feed in shallow water by sifting through bottom mud are more likely to encounter shot than are species that feed on submerged vegetation or at the surface (Wobeser 1981). Ingested Pb shot was recorded in 6 of 10 duck species; the frequency was 8.1% in American black ducks sampled in Maine during the hunting seasons of 1976 through 1980 (Longcore et al. 1982). In dry seasons, species that probe for food deep in the sediment are especially susceptible (Hall and Fisher 1985). In England, ingested pellets occurred in 3.2% of the total waterfowl in 16 species examined. Incidences of shot were relatively high (7.1% to 11.8%) in four species (Mudge 1983): greylag goose (*Anser anser*), gadwall (*Anas strepera*). pochard (*Aythya ferina*), and tufted duck

(*Aythya fuligula*). At least 8,000 mallards in Britain die each winter of Pb toxicosis from ingestion of spent shot (Mudge 1983). It is estimated that about 2.4 million ducks die worldwide of Pb shot poisoning each year--and this estimate does not include population losses resulting from the sublethal effects of Pb (Wobeser 1981). Among larger species of waterfowl, outbreaks of Pb poisoning have been documented in Canada geese, whistling swans (*Cygnus columbianus*), trumpeter swans, and mute swans (Eskildsen and Grandjean 1984). Lead-poisoned waterfowl tend to seek seclusion and often die in areas of heavy cover; these carcasses are rapidly removed by predators and scavengers, and may result in secondary Pb poisoning, especially among raptors such as the bald eagle (Feierabend and Myers 1984; Reichel et al. 1984). Of 293 bald eagles found dead nationwide between 1978 and 1981, 17 (5.8%) probably died of Pb poisoning after ingesting hunter-killed or hunter-crippled waterfowl containing Pb pellets (Reichel et al. 1984).

The relation between embedded shot and lead toxicosis is unclear. The incidence of embedded shot in various species of waterfowl ranged from 11% to 43% in adults, and 2% to 11% in immatures (Perry and Artmann 1979; Perry and Geissler 1980). Many birds that were struck by shotgun pellets but survived may have died prematurely or been eaten by predators. In one study, the bodies of 23% of adult Atlantic brant (*Branta bernicla hrota*) that died from starvation in New Jersey in 1977 contained embedded lead shot (Kirby et al. 1983). The effects on survival and fecundity of receiving and carrying relatively high frequencies of embedded shot might be significant, and during years of low adult numbers might have substantial population consequences (Kirby et al. 1983).

Lead in seeds and invertebrates within rights-of-way of major highways probably is not a hazard to adult ground-foraging songbirds, as judged from experiments with the European starling (*Sturnus vulgaris*). However, the effects of Pb on survival of fledglings are unknown, although Pb causes reductions in blood hemoglobin, hematocrit, ALAD activity, and brain weight (Grue et al. 1986). In another study, Pb concentrations in feather, carcass, and stomach contents of adult and nestling barn swallows (*Hirundo rustica*) were greater near a major U.S. highway than in a rural area; however, the number of eggs and nestlings, the body weight of nestlings at 17 days of age, and body weights of adults were similar in the two colonies, suggesting that contamination of roadsides with Pb from automobile emissions is not a major hazard to birds that feed on flying invertebrates (Grue et al. 1984).

Signs of Pb poisoning, i.e., depressed blood ALAD activity or elevated blood Pb levels, were reported for birds near a metal smelter (Beyer et al. 1985), in 17% of canvasbacks from Chesapeake Bay in 1974 (Dieter et al. 1976), and in three species of waders from the Dutch Wadden Sea living in an urban postnuptial moulting area (Goede and de Voogt 1985). The decline in submerged aquatic vegetation in Chesapeake Bay and the later shift in diet of some waterfowl species of Chesapeake Bay from the vegetation (Pb content 2.2 to 18.9 mg/kg dry weight), to the softshell clam *Mya arenaria* (1.3 to 7.6 mg Pb/kg dry weight), or to other bivalve molluscs (0.8 to 20.4 mg Pb/kg dry weight), probably did not increase dietary Pb burdens in these species (Di Guilio and Scanlon 1985).

The significance of trace amounts of organolead residues in birds is unknown. Trialkyllead seems to concentrate in avian kidney, but contributes less than 5% of the total amount of Pb in kidneys (Johnson et al. 1982).

MAMMALS

The highest body burdens of Pb reported in mammals were near urban areas of dense vehicular traffic, near metal mines and smelters, or near plants that reclaimed storage batteries; concentrations were higher in older organisms, especially in bone and hematopoietic tissues (Table 5; Goldsmith and Scanlon 1977; Way and Schroder 1982). A similar pattern of Pb occurrence and distribution was evident for human populations (Barth et al. 1973).

Diet provides the major pathway for Pb exposure, and amounts in bone are indicative of estimated Pb exposure and metabolism (Chmiel and Harrison 1981). Amounts of whole body Pb and feeding habits of roadside rodents were correlated: body burdens were highest in insectivores such as shrews; intermediate in herbivores, and lowest in granivores (Boggess 1977; Getz et al. 1977c). Food chain biomagnification of Pb, although uncommon in terrestrial communities, may be important for carnivorous marine mammals, such as the California sea lion (*Zalophus californianus*); accumulations were 52 highest in hard tissues, such as bone and teeth, and lowest in soft tissues, such as fat and muscle (Braham 1973). A similar pattern was observed in the

harbor seal, *Phoca vitulina* (Roberts et al. 1976).

The most sensitive index of Pb intoxication in populations of deer mice was the formation of acid-fast-staining intranuclear inclusion bodies within proximal convoluted tubule cells of kidney; secondary indicators included decreased body weight, renal edema, reticulocytosis, increased urinary ALA excretion, and decreased hematocrit (Mierau and Favara 1975). Mierau and Favara (1975) concluded that Pb pollution from automobile exhausts has had little impact on deer mice, and that severe Pb poisoning is unlikely at traffic densities below 200,000 vehicles per day. Others, however, believe that Pb emissions from automotive exhausts may pose unnecessary risks to various species of bats, rodents, and mule deer (*Odocoileus hemionus*). Estimated doses of Pb ingested by the little brown bat (*Myotis lucifugus*) and highway populations of shrews and voles equaled or exceeded dosages that have caused death or reproductive impairment in domestic animals; further, mean Pb concentrations in bats and shrews near highways exceed those reported for small rodents with Pb-induced renal abnormalities collected from abandoned Pb-mining sites (Clark 1979). Mule deer from the Rocky Mountain National Park, Colorado, that graze on (heavily contaminated) roadside forage must consume 1.4% of their daily intake from roadsides before harmful amounts of Pb (3 mg Pb/day) are obtained (Harrison and Dyer 1984); however, this value needs to be verified.

Cows (*Bos bovis*) adjacent to a Pb battery reclamation plant showed signs of Pb toxicosis, including muscle tremors, blindness, dribbling urine, and drooling. Mice trapped within 400 m of the plant had acid-fast-staining intranuclear inclusions in renal tubular epithelial cells--a useful diagnostic indicator of Pb poisoning. A faulty air pollution control system at the plant caused deposition of particulate Pb on the cornfield used for cattle forage, and was the probable source of the Pb toxicosis in the animals (Kisseberth et al. 1984). Industrial airborne Pb pollution is responsible for contamination of cattle and horses (*Equus caballus*) within 1,000 m of the source, resulting in elevated blood Pb levels in both species, stillbirths and abortions in cattle, and some deaths in horses (Edwards and Clay 1977).

Proximity to the smokestacks of metal smelters is positively associated with increased levels of Pb in the hair (manes) of horses and in tissues of small mammals, and is consistent with the results of soil and vegetation analyses (EPA 1972). Lead concentrations were comparatively high in the hair of older or chronically impaired horses (EPA 1972). However, tissues of white-tailed deer (*Odocoileus virginianus*) collected near a zinc smelter did not contain elevated levels of Pb (Sileo and Beyer 1985). Among small mammals near a metal smelter, blood ALAD activity was reduced in the white-footed mouse but normal in others, e.g., the short-tailed shrew (Beyer et al. 1985). The interaction effects of Pb components in smelter emissions with other components, such as zinc, cadmium, and arsenic, are unresolved (EPA 1972), and warrant additional research.

LETHAL AND SUBLETHAL EFFECTS

GENERAL

Lead adversely affects survival, growth, reproduction, development, and metabolism of most species under controlled conditions, but its effects are substantially modified by numerous physical, chemical, and biological variables. In general, organolead compounds are more toxic than inorganic Pb compounds, food chain biomagnification of Pb is negligible, and the younger, immature organisms are most susceptible. Uptake of Pb by terrestrial plants is limited by the low bioavailability of Pb from soils; adverse effects seem to occur only at total concentrations of several hundred mg Pb/kg soil.

In aquatic environments, waterborne Pb was the most toxic form. Adverse effects were noted on daphnid reproduction at 1.0 ug Pb^{2+} /1, on rainbow trout survival at 3.5 ug tetraethyllead/l, and on growth of marine algae at 5.1 ug Pb $^{2+}$/1. High bioconcentration factors were recorded for filter-feeding bivalve molluscs and freshwater algae at 5.0 ug Pb $^{2+}$/1.

Ingestion of spent lead shot by migratory waterfowl and other birds is a significant cause of mortality in these species, and also in raptors that eat the waterfowl killed or wounded by hunters. Forms of Pb other than shot are unlikely to cause clinical signs of Pb poisoning in birds, except for certain alkyllead compounds that bioconcentrate in aquatic food items. Among sensitive species of birds, survival was reduced at doses of 75 to 150 mg Pb^{2+} /kg BW or 28 mg alkyllead/kg BW, reproduction was impaired at dietary levels of 50 mg Pb^{2+} /kg, and signs of poisoning were evident at doses as low as 2.8 mg alkyllead/kg BW.

The veterinary medical literature on Pb toxicosis is abundant for domestic livestock and small laboratory animals, but notably lacking for feral mammals. Among sensitive species of mammals, survival was reduced at acute oral doses as low as 5 mg/kg BW in the rat, at chronic oral doses of 0.3 mg/kg BW in the dog, and at dietary levels of 1.7 mg Pb/kg BW in the horse. Sublethal effects were documented in monkeys given doses as low as 0.1 mg Pb/kg BW daily (impaired learning 2 years postadministration), or fed diets containing 0.5 mg Pb/kg (abnormal social behavior). Reduction in ALAD activity was recorded in blood of rabbits given 0.005 mg Pb/kg BW, and in mice given 0.05 mg Pb/kg BW. Tissue residues increased in mice given 0.03 mg Pb/kg BW, and in sheep given 0.05 mg Pb/kg BW.

TERRESTRIAL PLANTS AND INVERTEBRATES

Fruits and vegetables acquire Pb by surface deposition from rainfall, dust, and soil, and by biological uptake through the root system (EPA 1980). Foliar absorption of Pb and transport to the root could account for a significant portion of the Pb in root tissues; however, this transport process varies widely among species. Dollard (1986) showed that this pathway accounted for 35% of the root Pb content in the radish (*Raphanus sativus*), but for <3% in carrots (*Daucus carota*) and beans (*Phaseolus vulgaris*). Corn (*Zea mays*) contained 30 mg Pb/kg dry weight when grown in soils containing Pb concentrations of 924 mg/kg, but only 17 mg/kg when grown in soils containing 786 mg Pb/kg. Sadiq (1985) concluded that contamination of soils with up to 800 mg Pb/kg probably does not elevate concentrations of Pb in corn plants. Within any plant species, however, there are Pb-resistant and Pb-sensitive breeds; some genetically fixed resistant species grow in soils containing up to 10,000 mg Pb/kg (Holl and Hampp 1975).

Plants readily accumulate Pb from soils of low pH or low organic content; however, uptake is significantly reduced after the application of lime or phosphate, which converts Pb to hydroxides, carbonates, or phosphates of relatively low solubility (Demayo et al. 1982). Lead persists for lengthy periods in forest litter; the estimated Tb 1/2 is 220 years (Turner et al. 1985). Lead seems to be tightly bound by most soils, and substantial amounts must accumulate before it affects the growth of higher plants (Boggess 1977). Although Pb is preferentially bound in soils by organics and oxides, interaction kinetics of Pb with other metals are complex and largely unknown (Bjerre and Schierup 1985). For example, uptake of Pb from soils by oat seeds (*Avena sativa*) was inhibited by cadmium salts, and reduced in loamy or organic soils; further, Pb in soils interfered with manganese uptake, and also increased the availability of cadmium and other heavy metals (Bjerre and Schierup 1985).

Lead inhibits plant growth, reduces photosynthesis, and reduces mitosis and water absorption (Demayo et al. 1982). Inhibition of photosynthesis is attributed to the blocking of protein sulfhydryl groups and to changes in phosphate levels in living cells (Holl and Hampp 1975). For two species of roadside weeds (*Cassia* spp.), pollen germination was reduced by 90% and seed germination by 87% at Pb levels of about 500 mg/kg dry weight in soil and about 300 mg/kg dry weight in foliage (Krishnayya and Bedi 1986). Normal germination rates were recorded at Pb levels of 46 mg/kg in soil and 22 mg/kg dry weight in foliage; however, some adverse effects were evident at Pb levels of 12 to 312 mg/kg in soil, and 55 to 97 mg/kg dry weight in foliage (Krishnayya and Bedi 1986). Tetraethyllead from automobile exhaust fumes is known to react in the light to produce the highly phytotoxic triethyllead cation (Backhaus and Backhaus 1986), which can freely permeate the plasma membranes of plant cells (Stournaras et al. 1984). Growth of cultures of soybean (*Glycine max*) cells exposed to 207 ug Pb/1 (as triethyllead salts) was inhibited before the cells died (Stournaras et al. 1984). There is no 56 evidence for biomagnification of Pb in the food chain of vegetation, to cattle, to dung, to the dung beetle (Robel et al. 1981), nor is there convincing evidence that any terrestrial vegetation is important in food chain biomagnification of Pb (EPA 1980).

Concentrations of Pb in soil litter ranged from 3,200 mg/kg in locations near a zinc smelter in Palmerton, Pennsylvania, to 150 mg/kg at sites 105 km distant; relative concentrations of cadmium, zinc, and copper were similar (Beyer et al. 1984). In woodlice (*Porcellio scaber*) fed litter from these locales for 8 weeks, survival decreased as metal content in the litter increased, but the major cause of death was zinc poisoning and not Pb poisoning (Beyer et al. 1984). Woodlouse (*Oniscus asellus*) hepatopancreas that were collected 3 km downwind of a metal smelter contained large amounts of zinc, copper, cadmium and Pb. Centipedes (*Lithobius variegatus*) that ate woodlice hepatopancreas did not assimilate Pb even though the food contained concentrations that were many times greater than normally encountered (Hopkin and Martin 1984). However, survival and reproduction were reduced in woodlice (*P. scaber*) fed soil litter treated with 12,800 mg Pb/kg, as lead oxide, for 64 weeks, or two generations (Beyer and Anderson 1985). This amount of Pb is similar to the

amounts reportedly associated with reductions in natural populations of decomposers, such as fungi, earthworms, and arthropods. The poisoning of decomposers may disrupt nutrient cycling, reduce the number of invertebrates available to other wildlife for food, and contribute to food chain contamination (Beyer and Anderson 1985). The effects of Pb on soil microbial populations is unknown (Boggess 1977).

Herbivorous land snails (*Helix* spp.) are important in Pb cycling through contaminated ecosystems (Dallinger and Wieser 1984; Beeby 1985). *Helix pomatia* fed lettuce enriched with Pb (about 1,000 mg Pb/kg dry weight lettuce) for 32 days contained 1,301 mg Pb/kg dry weight in the mid-gut gland (vs. 52 in controls), and much lower amounts (<30 mg/kg) in other tissues. After the snail had fed on uncontaminated lettuce for 50 days, Pb remained elevated at 1,203 mg,/kg in the mid-gut gland, which contained more than 90% of the total body burden (Dallinger and Wieser 1984).

AQUATIC BIOTA

In general, the responses of aquatic species to Pb insult differed markedly (Table 6). Among sensitive species, however, several trends were evident: (1) dissolved waterborne Pb was more toxic than total Pb; (2) organic lead compounds were more toxic than inorganic forms; (3) adverse effects on daphnid reproduction were evident at 1.0 ug Pb^{2+} /l; (4) high bioconcentrations were measured in oysters at 1.0 ug Pb /1 and in freshwater algae at 5.0 ug Pb^{2+} /l; (5) tetramethyllead was acutely toxic to rainbow trout at 3.5 ug/l; (6) growth inhibition of a marine alga was reported at 5.1 ug Pb^{2+} /1; and (7) for all species, effects were most pronounced at elevated water temperatures and reduced pH, in comparatively soft waters, in younger life stages, and after long exposures (Table 6).

Table 6. Lethal and sublethal effects of lead[a] to selected species of aquatic organisms.

Ecosystem, taxonomic group, species, and other variables	Concentration (µg Pb/L medium)	Exposure duration	Effect[b]	Reference[c]

[a]As total Pb, unless indicated otherwise.

[b]BCF = bioconcentration factor; MATC = maximum acceptable toxicant concentration. Lower value in each MATC pair indicates highest concentration tested producing no measurable effect on growth, survival, reproduction, and metabolic upset during chronic exposure; higher value indicates lowest concentration tested producing a measurable effect.

Lead is toxic to all phyla of aquatic biota, but its toxic action is modified by species and physiological state, and by physical and chemical variables. Wong et al. (1978) stated that only soluble waterborne Pb is toxic to aquatic biota, and that free cationic forms are more toxic than complexed forms. The biocidal properties of soluble Pb are also modified significantly by water hardness: as hardness increased, Pb becomes less bioavailable because of precipitation increases (NRCC 1973). In salmonids, for example, the toxicity and fate of Pb are influenced by the calcium status of the organism, and this relation may account for the reduced effects of Pb in hard or estuarine waters. In coho salmon (*Oncorhynchus kisutch*), an increase in waterborne or dietary calcium reduced uptake and retention of Pb in skin and skeleton (Varanasi and Gmur 1978).

Organolead compounds are, in general, more toxic than inorganic Pb compounds to aquatic organisms. Ethyl derivatives were more toxic than methyl derivatives, and toxicity increased with increasing degree of alkylation, tetralkyllead being the most toxic (Chau et al. 1980). Tetraethyllead was about 10X more effective than tetramethyllead in reducing oxygen consumption by coastal marine bacteria, and was 1.5 to 4X more toxic than tetramethyllead to marine teleosts (Marchetti 1978). Tetramethyllead chloride was 20X as toxic as $Pb(NO_3)_2$ to freshwater algae, and 2X as toxic as trimethyllead acetate (Wong et al. 1978). In seawater, the release of tetraalkyllead compounds is more likely than accumulation to result in acutely toxic effects; however, alkyllead compounds degrade rapidly to trialkyllead chlorides, which are only 0.1 to 0.01 as toxic as TEL compounds (Haddock and Taylor 1980). Alkyllead compounds are accumulated more readily by freshwater teleosts than are inorganic Pb compounds. The BCF values for tetramethyllead and rainbow trout, for example, ranged from 124 in lipids after exposure for 1 day, to 934 after 7 days (Demayo et al. 1982). Depuration of tetramethyllead is rapid; the estimated Tb 1/2 values range from 30 hours for intestinal lipids to 45 hours for skin and cephalic fat deposits (Wong et al. 1981). Some microorganisms in lake sediments transform certain inorganic and organic Pb compounds into the more toxic tetramethyllead, but the pathways are not well understood (Wong et al. 1978).

Lethal solutions of Pb (as well as of many other heavy metals) cause increased mucous formation in fishes. The excess coagulates over the entire body and is particularly prominent over the gills, interfering with respiratory function and resulting in death by anoxia (Aronson 1971; NRCC 1973). Increasing waterborne concentrations of Pb over 10 ug/l are expected to provide increasingly severe long-term effects on fish and fisheries (Demayo et al. 1982). Fish that are continuously exposed to toxic concentrations of waterborne Pb show various signs of Pb poisoning: spinal curvature, usually as lordosis; anemia; darkening of the dorsal tail region, producing a black-tail effect due to selective destruction of chromatophores but not of melanophores; degeneration of the caudal fin; destruction of spinal neurons; ALAD inhibition in erythrocytes, spleen, liver, and renal tissues; reduced ability to swim against a current; destruction of the respiratory epithelium; basophilic stippling of erythrocytes; elevated Pb concentrations in blood, bone, gill, liver, and kidney; muscular atrophy; paralysis; renal pathology; growth inhibition; retardation of sexual maturity; altered blood chemistry; testicular and ovarian histopathology; and death (Aronson 1971; NRCC 1973; Adams 1975; Davies et al. 1976; Holcombe et al. 1976; Hodson et al. 1977, 1980, 1982; Johansson-Sjobeck and Larsson 1979; Reichert et al. 1979; Ozoh 1980; Demayo et al 1982; Kumar and Pant 1984; Rai and Qayyum 1984; Hodson and Spry 1985; Haux et al. 1986). The prevalence of signs is closely correlated with duration of exposure to Pb and to its uptake (Hodson et al 1982). Toxic effects of Pb uptake in fishes are increased under conditions favoring their rapid growth. Hodson et al. (1982) have shown that the rate of intoxication by Pb--as judged by uptake rates into tissues and incidence and prevalence of black tail--did not increase with fish size, but rather with growth rate.

Rooted aquatic plants, such as wild rice (*Zizania aquatica*), can accumulate up to 67 mg Pb/kg dry weight when cultured in tanks contaminated with high concentrations of powdered Pb (equivalent to 7,400 kg Pb/ha);

however, this level is not considered hazardous to waterfowl feeding on wild rice (Behan et al. 1979). Lead content in plants collected from heavily hunted areas near refuges did not differ from those collected in the protected areas (Behan et al. 1979), which suggests that Pb bioavailability to rooted aquatics is substantially lower from shot than from powdered Pb. In another study with rooted macrophytes, *Navicula* sp. and *Elodea canadensis* rapidly accumulated Pb from solutions containing 1.0 mg Pb^{2+} /l, i.e., 70 mg Pb/kg dry weight per minute; the process was overwhelmingly passive (Everard and Denny 1985). Depuration was rapid; 90% of the Pb sorbed during the first hour by shoots of *Elodea* was released within 14 days after transfer to clean water, though 10% seemed to be irreversibly bound (Everard and Denny 1985).

High accumulations of Pb from ambient seawater by marine plants is well documented; concentration factors vary from 13,000 to 82,000 for algae from Raritan Bay, New Jersey (Seeliger and Edwards 1977), and from 1,200 to 26,000 for algae from Sorfjorden, Norway (Melhuus et al. 1978). Studies on the kinetics of lead uptake and retention in two species of marine algae (*Phaeodactylum tricornutum*, *Platymonas subcordiformes*) showed that both species accumulated Pb from the medium at ambient concentrations of 20 ug/l, and higher (Schulz-Baldes and Lewin 1976). In the first phase, usually completed within minutes after addition of Pb, cells of *Phaeodactylum* became saturated when the Pb reached a remarkable 11,640 mg/kg dry weight. In the second phase, the lead content of *Platymonas* continued to rise slowly, but that of *Phaeodactylum* declined after 2 or 3 days. In both species the content of bound Pb increased with increasing exposure time, suggesting that during prolonged exposure Pb is initially adsorbed to the cell surface, then translocated into the cell wall, the plasma membrane, and eventually the cytoplasm (Schulz-Baldes and Lewin 1976).

Sediments are not only sinks for Pb but may act as a source of Pb to aquatic biota after contamination from the original source has subsided (Knowlton et al. 1983). The uptake of Pb from artificially contaminated pond sediments was recorded in roots and foliage of submersed aquatic macrophytes (*Potamogeton foliosus*, *Najus guadalupensis*) and in the exoskeleton of crayfish (*Orconectes nais*). Accumulation of Pb in crayfish primarily was through adsorption; most was lost through molting, though some internal uptake and elimination occurred without molting (Knowlton et al. 1983). Crustacean molts represent 15% of the Pb body burden and are probably more significant than fecal pellets in Pb cycling processes (Fowler 1977).

Median BCF values in aquatic biota exposed to various concentrations of Pb^{2+} for 14 to 140 days varied from about 42 in fish to 2,570 in mussels; intermediate values were 536 for oysters, 500 for insects, 725 for algae, and 1,700 for snails (EPA 1985). There are several notable exceptions to this array: significantly higher values have been reported in crustacean hepatopancreas (Heyraud and Cherry 1979), in various species of freshwater invertebrates (Spehar et al. 1978), in fish bone (Demayo et al. 1982) and liver (Haux and Larsson 1982), and in whole oysters (Zaroogian et al. 1979). In oysters, for example, BCF values varied from 3,450 to 6,600 after exposure to solutions containing 1.0 to 3.3 ug Pb^{2+} /1 for 140 days, but oysters and their progeny were apparently unaffected at whole body burdens (less shell) up to 11.4 mg Pb/kg dry weight (Zaroogian et al. 1979). Many species of aquatic biota contain Pb in amounts >1,000 mg/kg fresh weight (>10,000 mg/kg dry weight) including some marine seaweeds, freshwater macrophytes and algae, annelids, crustaceans, echinoderms, molluscs, and teleosts (Wong et al. 1978); presumably, the Pb was sorbed passively and little, if any, was incorporated biologically. Variations in Pb concentrations in aquatic biota probably reflect the ability of individual species to adsorb waterborne Pb, and may be a direct function of the ratio of surface to body weight (Demayo et al. 1982). The residence time of Pb in aquatic biota seems to be related to the route of administration: Tb 1/2 values were 9 days by waterborne routes and 40 days by diet (Vighi 1981).

Although Pb is concentrated by biota from water, there is no convincing evidence that it is transferred through food chains (Branica and Konrad 1980; Settle and Patterson 1980). Lead concentrations tended to decrease markedly with increasing trophic level in both detritus-based and grazing aquatic food chains (Wong et al. 1978). In the marine food chain of seawater (<0.08 ug Pb/1), to a brown alga (*Egregia laevigata*), to the red abalone (*Haliotis rufescens*), Pb concentrations in the alga and abalone were both <0.04 mg Pb/kg fresh weight after 6 months, indicating negligible biomagnification (Stewart and Schulz-Baldes 1976). When seawater contained 1,000 ug Pb/l, young abalones that fed on *Egregia* for 6 months contained up to 21 mg Pb/kg fresh weight, but neither growth nor activity was affected; Pb selectively accumulated in the digestive gland (38 mg/kg), and was lowest in muscle (<l mg/kg)--the part normally consumed by humans (Stewart and Schulz-Baldes 1976). In the freshwater food chain of an alga (*Selenastrum capricornutum*), to a daphnid (*Daphnia magna*), to the guppy (*Poecilia reticulata*), Pb accumulation progressively decreased from the alga to the guppy.

Thus, in organisms held for 28 days in solutions containing 5 ug Pb/l, Pb content was 460 mg/kg dry weight in the alga, 23 mg/kg in the grazing daphnids, and 4 to 16 mg/kg in the guppies that fed on the daphnids (Vighi 1981). Concentrations of Pb in the freshwater snail, *Lymnaea peregra*, collected near an abandoned Pb mine were positively correlated with the Pb content in its diet; the digestive glands contained up to 5,600 mg/kg dry weight (Everard and Denny 1984). The gut contents of eels (*Anguilla anguilla*) grazing on contaminated snails contained up to 4,350 mg Pb/kg, but the Pb was rapidly released; feces from both snails and eels return the Pb to the ecosystem as particulates and detritus (Everard and Denny 1984).

As discussed earlier, Pb clearly inhibits the formation of heme at several points, adversely affects blood chemistry, and accumulates in hematopoietic organs of aquatic organisms. In addition, Pb interferes with chlorophyll formation in plants by inhibiting the conversion of coproporphyrinogen to proporphyrinogen by competing with iron, inhibits allantoise formation in annelids, inhibits alpha-glycerophosphate dehydrogenase activity in trout, increases glutamic oxalacetate transaminase activity in *Daphnia*, affects neural and hormonal systems that control activity and metabolic rates in fish, interacts with polar sites of glycoproteins in epidermal mucous of fish, and may inhibit vitamin C and tryptophan metabolism (Wong et al. 1978).

Some populations of freshwater isopods are tolerant to Pb. Inasmuch as nontolerant isopods from an unpolluted site can be made tolerant by exposure to low levels, it is suggested that naturally occurring tolerance may be achieved by acclimatization (Fraser 1980). Research is needed on Pb transformation mechanisms, on toxic forms of Pb and interaction effects with other compounds, and on effects of Pb-contaminated sediments on benthos (Wong et al. 1978).

AMPHIBIANS AND REPTILES

Lead poisoning in adult leopard frogs (*Rana pipiens*) is indicated by a series of signs: sloughing of integument; sluggishness; decreased muscle tone; decreases in red blood cells, white blood cells, neutrophils, and monocytes; erosion of the gastric mucosa; and (before death) excitement, salivation, and muscular twitching. The 30-day LC-50 value for *R. pipiens* was 105 mg Pb/l, but some deaths and elevated liver residues were noted at water concentrations as low as 25 mg/l (Kaplan et al. 1967). In soft water (99 mg $CaCO_3$/1) some marbled salamanders (*Ambystoma opacum*) exposed to 1.4 mg Pb/1 died in 8 days (EPA 1985). At about 1.0 mg/l, Pb blocked synaptic transmission by competitive inhibition of calcium in the bullfrog, *Rana catesbeiana* (Kober and Cooper 1976). At 0.5 mg Pb/l, tadpoles of *Rana utricularia* required additional time to metamorphose; and at 1.5 mg Pb/l, thyroid histopathology was recorded and the delay in metamorphosis was more pronounced (Yeung 1978).

No data were available on toxic or sublethal effects of Pb to reptiles under controlled conditions.

BIRDS

Lead poisoning resulting from the ingestion of Pb shotgun pellets has been recognized as a cause of waterfowl deaths since the late 1800's (Wetmore 1919; Bellrose 1959). More than a million ducks--especially mallards--and geese die annually from Pb shot poisoning (Clemens et al. 1975). The principal cause is the ingestion of spent shot by migrating birds feeding in heavily hunted areas. The pellets are retrieved from the marshy bottoms of shallow and deep water by waterfowl in search of feed and grit. Shot retained in the gizzard is solubilized by a combination of the powerful muscular grinding action and the low pH (2.0 to 3.5) of gizzard contents. The released Pb is available for absorption, producing weakened birds whose reproductive abilities are reduced and that may starve or fall prey to predators (Clemens et al. 1975). Absorbed lead causes a variety of effects leading to death, including damage to the nervous system, muscular paralysis, inhibition of heme synthesis, and damage to kidneys and liver (Mudge 1983). Lead poisoning in waterfowl is a debilitating disease in which death follows exposure by an average of 2 to 3 weeks (Friend 1985). During this time, affected birds lose mobility, tend to avoid other birds, and become increasingly susceptible to predation and other causes of mortality. Accordingly, acute large-scale die-offs of Pb-poisoned waterfowl are uncommon (Friend 1985).

The relation between incidence of Pb shot in waterfowl gizzards and biological effects varies widely, and is probably a function of shot availability caused by differences in shooting intensity, size of pellets, availability of

grit, firmness of soil and sediments, and depth of surface water (Street 1983). Also, Pb accumulations and the frequency of avian Pb toxicosis following ingestion of Pb shot are modified by the age and sex of the bird, geographic location, habitat, and time of year (Finley and Dieter 1978; Mudge 1983; Srebocan and Rattner 1988).

The effect of diet on vulnerability to Pb makes interpretation of published information on experimental Pb poisoning in waterfowl extremely difficult (Chasko et al. 1984). For example, many mallards on a diet of corn die within 10 to 14 days after ingesting a single Pb shot, whereas similar birds on a balanced commercial duck ration appear outwardly normal after ingesting as many as 32 pellets of the same size (Wobeser 1981). Also, multiple nutritional deficiencies may have additional effects in potentiating the toxicity of Pb in mallards (Carlson and Nielsen 1985).

Birds of prey may ingest Pb in the form of shot from dead or crippled game animals, or as biologically incorporated Pb from Pb-poisoned waterfowl, small roadside mammals, and invertebrates (Stendell 1980; Pattee 1984). Lead poisoning in carnivorous birds has been reported in various species of eagles, condors, vultures, and falcons, and most--if not all--cases seem to result from ingestion of Pb shot in food items (Custer et al. 1984). Some raptors ingest many shot in a short time. For example, the stomach of a bald eagle suspected of dying from Pb poisoning contained 75 shot (Jacobson et al. 1977). Results of experimental Pb shot poisoning of bald eagles (Table 7) confirmed results of nationwide monitoring showing that 5.4% of all dead eagles found in 1974-1975 died of Pb poisoning, as evidenced by liver Pb levels of 23 to 38 mg/kg fresh weight (Pattee et al. 1981). Ingestion of food containing biologically incorporated Pb, although contributing to the Pb burden of carnivorous birds, is unlikely in itself to cause clinical Pb poisoning (Custer et al. 1984). A similar case is made for powdered Pb (Franson et al. 1983), and forms of Pb other than shot (Table 7); the strong indication is that the form in which Pb is ingested is crucial.

Signs of Pb poisoning in birds have been extensively documented (Bellrose 1951, 1959; Jordan and Bellrose 1951; Clemens et al. 1975; Forbes and Sanderson 1978; Hunter and Wobeser 1980; Pattee et al. 1981; Wobeser 1981; Franson and Custer 1982; Johnson et al. 1982; Eastin et al. 1983; Kendall and Scanlon 1983; Street 1983; Di Giulio and Scanlon 1984; Fimreite 1984; Gjerstad and Hanssen 1984; Hudson et al. 1984; Anderson and Havera 1985; Burger and Gochfeld 1985; Carlson and Nielsen 1985; Friend 1985; Hoffman et al. 1985a; Lumeij 1985; Beyer et al. 1988). Outwardly, Pb-poisoned birds show the following signs: loss of appetite, lethargy, weakness, emaciation, tremors, drooped wings, green liquid feces, and impaired locomotion, balance, and depth perception. Internally, Pb-poisoned birds show microscopic lesions of the proventricular epithelium, pectoral muscles, brain, proximal tubular epithelium of the kidney, and bone medullary osteocytes; an enlarged bile-filled gall bladder; anemia; elevated protoporphyrin IX levels in blood; decreased ALAD activity levels in blood, brain, and liver; reduced brain weight; abnormal skeletal development; cephalic edema; and esophageal impaction. Postmortem examination of Pb-poisoned birds may show edematous lungs; serous fluid in the pleural cavity; bile regurgitation; abnormal gizzard lining; a usually pale, emaciated, and dehydrated carcass; and elevated Pb levels in liver (>2 mg/kg fresh weight, >10 mg/kg dry weight), kidney (>6 mg/kg dry weight), and blood (> 0.2 mg/1).

Toxic and sublethal effects of Pb and its compounds on birds held under controlled conditions vary widely with species, with age and sex, and with form and dose of administered Pb (Table 7). Several generalizations are possible: decreased blood ALAD and increased protoporphyrin IX activity levels are useful early indicators of Pb exposure; Pb shot and certain organolead compounds are the most toxic forms of Pb; nestlings are more sensitive than older stages; and tissue Pb concentrations and pathology both increase in birds given multiple doses over extended periods (Table 7).

Table 7. Lethal and sublethal effects of lead to selected species of birds.

Species, route of administration, dose, and other variables	Effects	Reference[a]
Northern pintail, *Anas acuta*		
Single oral dose of 2 No. 5 pellets	No difference from control group in band recovery rate from hunter kills	1
Mallard, *Anas platyrhynchos*		
Single oral dose of 1 No. 4 shot (1.4 g)	Some deaths. Residues (mg/kg fresh weight) >3 in brain, >10 in clotted heart blood, >6 in kidney, and up to 20 in liver	2
Single oral dose		
1 No. 6 shot (1.0 g)	Mortality 9% in 20 days	3
1 No. 4 shot (1.6 g)	Mortality 19% in 20 days	3
2 No. 6 shot (2.0 g)	Mortality 23% in 20 days	3
4 No. 6 shot (4.0 g)	Mortality 36% in 20 days	3
6 No. 6 shot (6.0 g)	Mortality 50% in 20 days	3
8 No. 6 shot (8.0 g)	Mortality 100% in 20 days	3
Single oral dose of 1 No. 4 shot (205 mg), equal to 151 mg/kg body weight (BW)	Some deaths; blood ALAD activity depressed 30% after 3 months, 15% after 4 months	4
Single oral dose of 1 No. 4 Pb shot (200 mg)	Residues (mg/kg dry weight femur) 488 in laying hen, 114 in nonlaying hen, and 9 in drake	5
Single oral dose of 1 shot (200 mg)	After 30 days, residues (mg/kg fresh weight) 1.0 in blood, 2.5 in liver, and 0.5 in brain. Decrease in ALAD activity in blood and cerebellum	6
Single oral dose of shot	Dosed birds recaptured in significantly greater numbers than controls	7
Single oral dose of tetraethyllead	LD-50 of 107 mg/kg BW. Signs of intoxication included	

	excessive drinking, regurgitation, hypoactivity, muscular incoordination, fluffed feathers, eyelid drooping, tremors, and loss of appetite. Regurgitation within 7 min, other signs as soon as 20 min, and death usually between 1 and 4 days posttreatment. Remission took up to 8 days	7a
Fed diets containing 25 mg Pb/kg, as lead nitrate, for 12 weeks	No deaths; no pathology; no significant accumulations of Pb in liver, kidney, or bone; no changes in hemoglobin or hematocrit; decrease in blood ALAD activity, and increase in blood Pb levels--both returned to normal diet within 3 weeks on Pb-free diet	8
Fed diets containing 100 mg Pb^{2+}/kg	Elevated levels in bone (9.6 mg/kg fresh weight vs. 0.7 in controls) and egg (1.3 vs. 0.9 in controls)	9
Fed diets containing metallic Pb for 42 days		
100 mg/kg diet dry weight	Elevated Pb levels (mg/kg dry weight) in kidney (23), liver (7), and bone (5)	10
10 mg/kg diet	Residues (mg/kg dry weight) of 4 in kidney (vs. <0.5 in controls), 0.7 in liver (vs. <0.5 in controls), and 0.8 in bone (vs. 0.9 in controls)	10
Ducks, *Anas* spp.		
Single oral dose of 2 shot (254 mg) or 5 shot (635 mg)	Weight loss, emaciation, elevated Pb concentrations in bone, some deaths. American black duck, *Anas rubripes*, more sensitive than mallards	11
Birds		
Dietary route, 11 species,	All had inclusions in proximal	

diagnosed as Pb-poisoned	convoluted tubules of kidney; liver Pb residues ranged from 3.1 to 15 mg/kg fresh weight	12
Lethal dietary administration of lead acetate, 6 species	Before death, birds were emaciated and showed increases in blood protoporphyrin and decreases in ALAD; renal intra-nuclear inclusion bodies were present in 83% of all birds that died from Pb poisoning. Median Pb concentrations (mg/kg fresh weight) ranged in the liver from 20 in male red-winged blackbirds (*Agelaius phoeniceus*) to 111 in female northern bobwhites (*Colinus virginianus*), and in the kidney from 22 mg/kg in the blackbird to 190 in the bobwhite	13
Rock dove, *Columba livia*		
Intragastric administration of 6.25 mg Pb (as lead acetate)/kg BW daily for 64 weeks	Anemia, elevation of erythrocyte porphyrin, kidney pathology; residues (mg/kg fresh weight) of 603 in kidney, 501 in bone, 8 in liver, 2 in brain, 4.4 in blood, 0.8 in sciatic nerve, and 0.1 in crop	14
Intubation of 6.25 mg Pb (as lead acetate)/kg BW, chronic exposure	Interfered with four-step learning sequence; elevated blood Pb levels remained for 5 weeks after Pb exposure	15
Japanese quail, *Coturnix japonica*		
Single oral dose of tetraethyllead	LD-50 of 24.6 mg/kg BW	7a
Fed diets containing different forms of Pb for 5 days		
5,000 mg metallic Pb/kg	No effect on survival or food consumption	16
5,000 mg Pb (as lead nitrate)/kg	No overt signs of toxicity	16
5,000 mg Pb (as lead subacetate $C_4H_{10}O_8Pb_3$)/kg	No overt signs of toxicity	16
2,761/mg Pb (as	LD-50	16

lead arsenate)/kg		
Prairie falcon, *Falco mexicanus*		
Fed shotgun-killed pheasants and ducks	Death, preceded by vomiting, ataxia, blindness, and convulsions. Lead shot recovered from stomach; residues (mg/kg dry weight) of 57 in liver and 78 in kidney	17
American kestrel, *Falco sparverius*		
Fed mallard homogenate containing 16 to 87 (biologically incorporated) mg Pb/kg fresh weight for 60 days	Residues of 0.4 mg/kg fresh weight in liver and 7.6 mg/kg dry weight in bone	18
Oral administration of 1 No. 9 shot daily for 60 days	Residues (mg/kg fresh weight) of 0.4 in liver and 28.7 in bone	18
Fed control diet containing 0.4 mg Pb^{2+}/kg fresh weight	Residues of 0.1 mb/kg fresh weight in liver and 4.2 mg/ kg dry weight in bone	18
Fed diets containing 50 mg metallic Pb powder/kg for at least 5 months	Blood ALAD reduced 80%; liver residues of 1.3 to 2.4 mg/kg dry weight; no effects on blood chemistry	19
As above, except diet contained 10 mg/kg	No measurable effects	19
Fed diets containing metallic Pb powder for 6 months		
50 mg Pb/kg diet	No adverse effects on survival, egg laying, fertility, or egshell thickness. Elevated residues (mg/kg dry weight) in humerus (13), tibia (62), and liver (2)	20
10 mg Pb/kg diet	Elevated Pb in bone (4 to 9 mg/kg dry weight vs. <0.8 in controls) and in liver (3 vs. <0.5 in controls)	20
Nestlings dosed orally		

with metallic Pb powder daily for 10 days		
625 mg/kg BW	Mortality (40% in 6 days); reduced growth; reduced kidney and liver weight; abnormal skeletal development; ALAD depression in all tissues examined; elevated burdens (mg/kg fresh weight) in kidney (15), liver (6), and brain (3)	21
125 mg/kg BW	Reduced growth, reduced brain weight, abnormal skeletal development, ALAD depressions in hematopoietic tissues, elevated burdens (mg/kg fresh weight) in kidney (7), and liver (4)	21
25 mg/kg BW	ALAD depression in all tissues examined; burdens (mg/kg fresh weight) elevated in kidney (3) and in liver 1.4)	21
Fed 60 days with homogenized cockerels (*Gallus* sp.) containing up to 448 mg (biologically incorporated) Pb/kg dry weight	No effect on survival, growth, hemoglobin, hematocrit, and erythrocyte number. Elevated burdens in kidney, liver, femur, brain, and blood	22
Chicken, *Gallus* sp.		
Fed diets containing 1,850 mg Pb/kg, as lead acetate, for 4 weeks	No deaths or severe clinical hematological effects; growth rate suppressed 47%, blood Pb residues 3.2 to 8.3 mg/L	23
Bald eagle, *Haliaeetus leucocephalus*		
Oral administration of 10 No. 4 shot (2,000 mg)		
Eagles dying 10 to 133 days posttreatment	Residue levels (mg/kg dry weight) 0.9 in muscle, 1.4 in brain, 6 in kidney, 10 in tibia, 10.3 in humerus, 10.4 in femur, and 16.6 in liver. Loss in body weight 16% to 23%	

	at death	24
Eagle sacrificed at day 133 posttreatment (bird went blind)	Residue levels (mg/kg dry weight) <0.1 in muscle, 2.1 in brain, 3.2 in kidney, 3.4 in liver, and 12.2 to 13.8 in bone	24
Controls	Residue levels (mg/kg dry weight) <0.1 muscle, 0.1 in brain, 0.4 in liver, 0.5 in kidney, and 4.5 to 6.6 in bone	24
Willow ptarmigan, *Lagopus lagopus*		
Single oral dose		
1 No. 6 shot (100 mg)	Weight loss of 12% in 15 days; residues of 3.3 mg/kg fresh weight in liver, 56 mg/kg dry weight in tibia	25, 26
3 No. 6 shot (300 mg)	Some deaths between days 8 and 15 posttreatment, reduced food intake, weight loss, lethargy, diarrhea; residues of 7.3 mg/kg fresh weight liver, 139 dry weight tibia	25, 26
6 No. 6 shot (600 mg)	If shot retained in gizzard, death resulted; residues (mg/kg) 72 fresh weight in liver, 154 dry weight in tibia	25, 26
Controls	Residues (mg/kg) 0.1 fresh weight in liver, 5 dry weight in tibia	25, 26
Raptors, 4 spp.		
Fed rock doves (*Columba livia*) and brown hares (*Lepus europaeus*) containing Pb shot for 3 weeks to 6 months	Death preceded by weight loss, convulsions, and inability to fly. Residues (mg/kg dry weight) at death ranged from 57 to 175 in liver, and 34 to 221 in kidney	27
Common tern, *Sterna hirundo*		
Single injection of 200 mg Pb^{2+}	Adverse effects on behavior (locomotion, balance, righting response, feeding tasks, behavioral thermo-regulation); most apparent	

	within 5 days postinjection	28
Ringed turtle-dove, *Streptopelia risoria*		
Single oral dose of 2 pellets (220 mg)	Blood Pb (mg/L) 4.69 at 24 h, and 0.14 at 14 days (vs. control values of 0.004 to 0.012 mg/L); blood ALAD depressed from 24 h through 14 days	29
Single oral dose of 4 shot (440 mg)	Mortality 71% at 6 C in 7 days; nil at 21 C in 9 days--but some with seizures and kidney histopathology. No spermatozoa in seminiferous tubules. Lead residues elevated in bone, liver, and brain in both groups, but more elevated in cold-stressed group	30, 31
Single oral dose of 4 shot (440 mg)	Testicular damage in adults held at 6 C or 21 °C; mortality higher in cold-stressed group	32
Single oral dose of 4 shot (488 mg)	Some deaths. Intranuclear inclusion bodies in cells of kidney proximal convoluted tubules	12
Single oral dose of 75 mg Pb/kg BW, as lead acetate	Some deaths; kidney damage	12
Intubation with 75 mg Pb (as lead acetate)/kg BW daily for 7 days	Residues, (mg/kg dry weight) 457 in kidney, 29 in liver, and 12.4 in brain; seizures; depressed blood ALAD activity; blood Pb concentration 311 mg/L	33
Controls	Concentrations (mg/kg dry weight) 8.2 in kidney, 3.0 in brain, 1.2 in liver; blood Pb concentration 18 mg/L	33
Drinking water with 100 µg Pb^{2+}/L for 2 weeks before pairing, and throughout a breeding cycle	Reduction in testes weight and speratozoa number. No effect on egg production or fertility. Bone Pb levels higher than controls especially in females. Significantly higher Pb	

	concentrations in bone, liver, and feather in progeny of Pb-treated parents than in controls	34
European starling, *Sturnus vulgaris*		
Oral administration (capsule) of triethyllead chloride at 2,000 ug daily (28 mg/kg BW) for 11 days, or until death	Mortality 100% by day 6. Dying birds showed decreased respiration, squatting, fluffed feathers, and abnormal head posture. Average residues (mg/kg fresh weight) 6.0 in bone, 7.3 in brain 19.9 in kidney, 20.0 in muscle, and 40.2 in liver.	35
As above, but dose was 200 ug daily (2.8 mg/kg BW)	No deaths, reduced food consumption. All tissue residues <2.0 mg/kg fresh weight (vs. <0.1 in controls).	35
Oral administration (capsule) of trimethyllead chloride at 2,000 ug daily (28 mg/kg BW) for 11 days, or until death	Mortality 100% by day 6. Signs included impaired balance, tremors, fluffed feathers, uncoordinated feeding movements, weight loss, inability to fly. Residues (mg/kg fresh weight) averaged 4.3 in bone, 11.0 in muscle, 16.7 in brain, 30.2 in kidney, and 82.4 in liver	35
As above, but dose was 200 µg daily (2.8 mg/kg BW)	No deaths, survivors hyperactive. Average tissue residues (mg/kg fresh weight) 0.4 in bone, 3.1 in muscle, 3.5 in brain, 3.7 in liver, and 5.4 in kidney	35
Mourning dove, *Zenaida macroura*		
Single oral dose		
1 No. 8 shot (72 mg)	Mortality 24% in 4 weeks; normal courtship and reproductive activities, but egg hatching significantly reduced; Pb residues elevated in kidney, liver, and bone	36
2 No. 8 shot (144 mg)	Mortality 60% in 4 weeks	36

4 No. 8 shot (288 mg)	Mortality 52% in 4 weeks	36
Single oral dose of		
4 No. 8 shot		
4 days posttreatment	Residues (mg/kg dry weight)	
	345 to 639 in kidney and	
	58 to 215 in liver (vs. <12 in	
	controls)	37
8 days posttreatment	Residues (mg/kg dry weight)	
	1,279 to 1,901 in kidney and	
	179 to 267 in liver	37

Trialkyllead salts are 10 to 100X more toxic to birds than are inorganic Pb salts; they tend to accumulate in lipophilic soft tissues in the yolk and developing embryo, and have high potential as neurotoxicants (Forsyth et al. 1985); accordingly more research is needed on alkyllead toxicokinetics. Some alkyllead compounds have been implicated in bird kills. In autumn 1979, about 2,400 birds of many species were found dead or disabled on the Mersey estuary, England, an important waterfowl and marsh bird wintering area; smaller kills were observed in 1980 and 1981 (Bull et al. 1983). Affected birds contained elevated Pb concentrations in liver (>7.5 mg/kg fresh weight), mostly as organolead. Bull et al. (1983) suggested that trialkyllead compounds were discharged from a petrochemical factory producing alkylleads, into the estuary where they were accumulated (up to 1.0 mg/kg fresh weight) by clams (*Macoma balthica*) and other invertebrates on which the birds could feed. Birds dosed experimentally with trialkyllead compounds died with the same behavioral and internal signs found in Mersey casualties; tissue levels of trialkyllead were similar in the two groups of birds (Osborn et al. 1983). Sublethal effects that might influence survival in the wild were found in both sublethally dosed and apparently healthy wild birds when tissue levels of trialkyllead compounds were matched in the two groups of birds. It was concluded that trialkyllead compounds were the main cause of the observed mortalities and that many apparently healthy birds were still at risk (Osborn et al. 1983).

Nestlings of altricial species (those confined to the nest for some time after hatch) may be considerably more sensitive to Pb exposure than adults, and also more sensitive than hatchlings of many precocial species (Hoffman et al. 1985a). Hatchlings of precocial species, including chickens, Japanese quail (*Coturnix coturnix*), mallards, and pheasants, are relatively tolerant to moderate Pb exposure, i.e., there was no effect on growth at dietary levels of 500 mg Pb/kg, or survival at 2,000 mg Pb/kg (Hoffman et al. 1985a,b).

Some species of domestic birds are resistant to Pb toxicosis. for example, blood Pb levels of 3.2 to 3.8 mg/l in Pb-stressed cockerels (*Gallus* sp.) were much higher than residues considered diagnostic for Pb poisoning in most domestic mammals, except swine--which tolerated up to 143 mg Pb/1 blood (Franson and Custer 1982).

MAMMALS

Three stages of recognizable Pb poisoning, or plumbism, have been reported in humans (NRCC 1973): (1) mild or severe dysfunction of the alimentary tract as shown by loss of appetite, constipation, abdominal cramps, headaches, general weakness, and fatigue; (2) atrophy of forearm extensor muscles., or paralysis of these muscles and more striking atrophy; and (3) lead encephalopathy, which occurs frequently in Pb-poisoned infants

and young children, but only rarely in industrial workers. In general, people with hepatitis, anemia, and nervous disorders were more susceptible to Pb poisoning (Barth et al. 1973). The transfer of Pb across the human placenta and its potential threat to the fetus have been recognized for more than 100 years; women occupationally exposed to Pb showed a comparatively high abortion rate (Tachon et al. 1983). Sensitivity of the brain to the toxic effects of Pb is considerably greater in the fetus than in the infant or young child (EPA 1980). Lead is not considered carcinogenic to humans (Tsuchiya 1979). However, reports of chromosomal aberrations in human blood lymphocytes (Barth et al. 1973) suggested that Pb is a probable mutagen.

Signs of plumbism in domestic and laboratory animals (data on feral mammals are noticeably lacking), which are similar to those in humans, have been well documented (Barth et al. 1973; NRCC 1973; Mierau and Favara 1975; Davies et al. 1976; Roberts et al. 1976; Forbes and Sanderson 1978; Nriagu 1978b; Osweiler and Van Gelder 1978; Tsuchiya 1979; Ward and Brooks 1979; EPA 1980; Mahaffey et al. 1980; Hamir 1981; Harrison and Laxen 1981; Burrows and Borchard 1982; Demayo et al. 1982; Hamir et al. 1982; Mykkanen et al. 1982; Tachon et al. 1983; Gietzen and Wooley 1984; Berglind et al. 1985; Table 8). There is general agreement on several details: significant differences occur between species in response to Pb insult; effects of lead are more pronounced with organolead than inorganic lead compounds; younger developmental stages are the most sensitive; and the effects are exacerbated by elevated temperatures, and by diets deficient in minerals, fats, and proteins. Tetramethyllead, for example, is about 7X more toxic than tetraethyllead to animals, and both compounds showed toxic effects earlier than did inorganic Pb compounds. In severe cases, death is usually preceded by impairment of normal functions of the central nervous system, the gastrointestinal tract, and the muscular and hematopoietic systems. Signs include vomiting, lassitude, loss of appetite, uncoordinated body movements, convulsions, stupor, and coma. In nonfatal cases, signs may include depression, anorexia, colic, disturbed sleep patterns, diarrhea, anemia, visual impairment, blindness, susceptibility to bacterial infections, excessive salivation, eye blinking, renal malfunction, peripheral nerve diseases affecting the motor nerves of the extremities, reduced growth, reduced life span, abnormal social behavior, and learning impairment. Lead crosses the placenta and is passed in milk, producing early intoxication of the fetus during pregnancy and the newborn during lactation. High Pb doses in mammals induce abortion, reduce or terminate pregnancy, or can result in stillbirths or an increase in skeletal malformations. These signs, together with Pb levels in blood and tissues and histopathological examination, are used to diagnose Pb poisoning.

Lead adversely affected the survival of sensitive mammals tested at different concentrations (Table 8): 5 to 108 mg Pb/kg BW in rats (acute oral),0.32 mg Pb/kg BW daily in dogs (chronic oral), and 1.7 mg Pb/kg diet in horses (chronic dietary). Adverse sublethal effects (Table 8) were noted in monkeys given 0.1 mg Pb/kg BW daily (impaired learning 2 years postadministration) or fed diets containing 0.5 mg Pb/kg (abnormal social behavior); in rabbits given 0.005 mg Pb/kg BW (reduced blood ALAD activity) or 0.03 mg Pb/kg BW (elevated blood Pb levels); in mice at 0.05 mg Pb/kg BW (reduced ALAD activity); or in sheep at 0.05 mg Pb/kg BW (tissue accumulations).

Table 8. Lethal and sublethal effects of lead to selected species of mammals.

Species, dose, and other variables	Effects	Reference[a]
Cattle, cows, *Bos* spp.		
Tissue Pb (mg/kg fresh weight)	Signs of clinical Pb toxicosis	
0.81 in blood, 26.4 in liver, 50.3 in kidney, and 400 in rumen contents	observed	1
Calves given 2.7 mg Pb/kg body weight (BW), as Pb acetate, for 20 days; milk diet	Death	2
Calves given 3.0 to 3.5 mg Pb/kg BW daily for 3 months;	No effect	2

grain and hay diet		
Calves given 5 mg Pb/kg BW, as Pb acetate, for 7 days; grain and hay diet	Appeared normal	3
Calves given 5 mg Pb/kg BW, as Pb acetate, for 7 days; milk diet	Signes of Pb poisoning; some deaths	3,4
Calves given 5 mg Pb/kg BW daily for 10 to 20 days	Blindness, 16% mortality	4
Calves given forage containing 5 to 6 mg Pb/kg	Fatal in 2 months	1
Calves given 5 to 6 mg Pb/kg BW daily for 3 years	Chronic toxicity	2
Adults given 6 mg Pb/kg BW daily for 3 years	No deaths	5
Calves given 6 to 7 mg Pb/kg BW daily for 2 months	Fatal	2
Fed 6 to 7 mg Pb (as Pb acetate)/kg BW daily	Intoxication within 8 weeks; most dead at day 105	6
Consumed vegetation (17 to 20 mg Pb/kg fresh weight) near Pb battery recycling plant	Some deaths, mostly younger animals; neurological signs. Lead levels, in mg/kg fresh weight, were 13.8 to 35.8 in blood, 6.9 to 96.5 in feces, 97 in liver, and 138 in kidney. Histopathology of liver and kidney	7
Calves given 20 mg Pb/kg BW daily	Fatal in 8 to 22 days	2
Accidentally exposed for 10 days to toxic levels of Pb, as Pb shot, through corn silage. Silage storage area received shot from a nearby trap shooting range. Silage contained 32 mg Pb/kg	1.5% dead (2/70), 27% with signs of poisoning (kidney pathology, hemorrhaging). Tissue Pb concentrations of 16 mg/kg fresh weight in liver, >32 in kidney, and up to 0.8 in blood	6
Calves, single oral dose of 220 to 400 mg Pb/kg BW, as Pb acetate	LD-50	2
Total dose of 50 to 100 grams	Toxic	6
Dog, *Canis familiaris*		
Fed 0.32 mg Pb/kg BW daily	Chronic toxic level	4
Fed 3 mg Pb/kg BW daily, as	Anorexia and convulsions	

lead carbonate	at 180 days	8
Fed low calcium/phosphorus diet containing 100 mg Pb/kg, equivalent to about 3.5 mg Pb/kg BW	At 12 weeks, anemia, weight loss, and renal necrosis Tissue Pb levels (mg/kg fresh weight) 1.2 in brain, 1.7 in blood, 15.7 in spleen, 23.4 in liver, 32.2 in kidney, and 735 in bone	9
Total dose of 10 to 25 grams	Toxic	6
Goat, *Capra* sp.		
Total dose of 20 to 25 grams	Toxic	6
Guinea pig, *Cavia cobaya*		
Single intraperitoneal injection of 25 mg/kg BW, as Pb acetate	Reduced brain weight of newborn pigs. Effect synergized when dams were exposed to elevated (42 C) temperatures for 24 h: 88% with microencephaly vs. 5% in group given 25 mg/kg without hyperthermia	10
Horse, *Equus caballus*		
Tissue Pb levels, in mg/kg fresh weight, of 0.39 in blood, 18 in liver, and 16 in kidney	Signs of clinical Pb toxicosis observed	1
Ate forage containing 1.7 mg Pb/kg	Fatal in several months	1
Consumed 2.4 mg Pb/kg BW daily	Lethal	4
Fed 6.25 mg Pb/kg BW daily for 105 days, as Pb acetate	No deaths; blood Pb levels of 350 to 380 µg/L at day 105	6
Fed hay collected near Idaho smelter containing 423 mg Pb/kg, equivalent to about 7.4 mg Pb/kg BW daily	All dead in 84 to 100 days. Total Pb ingested ranged from 136 to 154 grams	11
Fed 9.8 mg Pb/kg BW daily for 105 days, as Pb acetate	No deaths; blood Pb levels of 530 to 650 µg/L at day 105	6
Fed noncontaminated hay plus 10 mg Pg/kg BW daily, as Pb acetate	All dead in 113 to 304 days. Total Pb ingested ranged from 190 to 544 grams	11
Total dose of 500 to	Toxic	6

700 grams		
Cat, *Felis domesticus*		
Fed pine voles (*Pitymys pinetorium*) from orchard sprayed with Pb arsenate. Concentrations (mg Pb/kg dry weight) were 60.3 in whole voles, 5.7 in cat diet containing voles, and 3.2 in control cat diet	After 86 days, tissue residues elevated in cat kidney (1.3 mg Pb/kg dry weight vs. 0.2 for controls), liver (0.5 vs. 0.1), and bone (5.0 vs. 0.9)	12
Rabbit, *Lepus* sp.		
Given 0.9, 0.03, 0.06, 0.15, 0.3, or 3 mg Pb/kg BW for 6 days	Blood Pb levels (µg/L) generally increased from 170 (control) to 910 (0.03), 530 (0.06), 1,430 (0.15), 1,930 (0.3), and 5,160 (3.0)	13
Exposed to 2.46 µg Pb/m^3 air for life	No effect	13
>5 µg Pg/kg BW daily	Reduced blood ALAD activity	13
Mouse, *Mus* sp.		
0.05 to 0.1 mg Pb/kg BW daily	Irreversible inhibition of ALAD activity in bone marrow and red blood cells	14
Tissue concentrations of 0.78 mg/kg femur bone marrow, 3.7 mg/L blood, 15.8 mg/kg brain, or 43 mg/kg liver	Inhibition of ALAD activity 50% within 10 min	14
1.5 mg Pb/kg BW daily, as tetraethyllead chloride	Reduction in success of implanted ova	8
2.2 mg/kg BW or 3 mg/kg BW daily, as tetraethyllead	Frequency of pregnancy reduced when dose given 3 to 5 days after mating	8
Pregnant females given single intrauterine injection of 20 mg Pb/kg BW on day 8 of gestation	Smaller litters, increased fetal deaths	15
800 mg Pb/L, as lead acetate, in drinking water for 11 weeks	Decrease in litter size, decreased survival of pups, and decrease birth weight	16
1,000 mg Pb/L in drinking water for 9 months	No effect on survival or fertility	4

Sheep, *Ovis aries*		
Lambs fed 50 µg Pb/kg daily (~ 3 mg)	Tissue accumulations	5
Lambs exposed to low levels (350 µg Pb/L blood) *in utero*	Impaired visual discrimination and learning behavior	17
1.0 mg Pb/kg BW daily, as Pb acetate, for 3 months	Of 10 ewes, 3 aborted, 6 delivered normally, and 1 died; placental transfer of Pb established	5
Pregnant ewes given 3 mg Pb/kg BW daily	No effect	4
4.2 mg Pb/kg BW in diet for 4 weeks before gestation, and throughout gestation and lactation	Lambs showed impaired learning	18
Fed 5 mg Pb/kg BW first 45 days of pregnancy	Bore normal full-term lambs	9
Given 5 mg Pb/kg BW daily for one year	No adverse effects	5
Pregnant ewes given 5.7 mg Pb/kg BW daily	Fatal	4
Nonpregnant ewes given 6 mg Pb/kg BW daily	Toxic threshold	4
8 mg Pb/kg BW daily for 220 days	Mortality	5
Fed 9 mg Pb/kg BW throughout pregnancy	Aborted and died	9
Fed diet containing 138 mg/kg dry weight for 124 days	Elevated residues in bone (22 mg/kg vs. 2.6 in controls) and kidney (8.3 vs. 1.0)	4
Lambs fed diets containing 400 mg Pb/kg, but deficient in calcium and sulphate	Dead within 5 weeks	4
Lambs fed diets containing 400 mg Pb/kg, diet adequate in minerals	Some weight loss in 10 months, but normal otherwise	4
Single oral dose of 600 mg Pb/kg BW	Fatal	9
Total dose of 20 to 25 grams	Toxic	6
Primates, various species		
Cynmolgus monkey, *Macaca iris*		
Intramuscular injection of 1.0 mg Pb/kg BW daily during pregnancy or lactation	Fetus exposed to lead through placenta or maternal milk	19

1.5 mg Pb/L in drinking water as lead acetate, for 9 months (equivalent to 0.5 mg Pb/kg BW daily), or 6 mg/L (2 mg/kg BW), or 15 mg/L (5 mg/kg BW)	Increasing blood Pb levels from third month, according to dose; kidney pathology. Effects more severe in animals on low calcium diets	20
Intramuscular administration of 5 mg Pb^{2+}/kg BW daily during pregnancy or lactation	Abortions and death in pregnant monkeys; cerebral pathology in newborns	19
Cynmolgus monkey, *Macaca fascicularis*		
Dosed orally from birth to age 200 days with 100 µg Pb (as Pb acetate)/kg BW, 5x weekly, milk substitute diet	Blood Pb concentration of 254 µg/L; declined to 131 µg/L over next 100 to 150 days. At age 3 years, impaired ability to perform motor discrimination reversal tasks	21
As above, except dose is 50 µg Pb/kg BW	Blood Pb levels of 154 µg/L (vs. 35 µg/L in controls), declining to 109 µg/L at day 150 post-administration. At age 3 years, group showed impaired color discrimination. No overt signs of toxicity, normal blood chemistry (except Pb), normal growth and development skills	21
Rhesus monkey, *Macaca mulatta*		
Infants given 0.5 mg Pg/kg diet for 4 weeks	Hyperactivity, insomnia, abnormal social behavior	18
Adults given 20 mg Pb/L in drinking water for 4 weeks	No effect	18
Baboon, *Papio anubis*		
Intratracheal injection of lead carbonate at doses of 50 to 135 mg Pb/kg BW for 29 to 362 days	73% dead (11/15) on receiving total dose of 1,250 to 7,800 mg Pb. Before death, some animals lost weight, became increasingly aggressive, had hepatic centrilobular necrosis, were uncoordinated and weak, and experienced convulsions; the blood contained up to 62 mg Pb/L	22
Single injection of 105 mg Pb/kg BW	Blood Pb concentrations rose from 117 µg/L at start to 3,100 µg/L at day 4 postadministration;	

	blood Pb remained >1,000 µg/L for at least 24 days	22
Rat, *Rattus* spp.		
Exposed to 10 µg Pb/m^3 air for one year	Elevated tissue residues in blood, soft tissues, and bone	13
Exposed to 21.5 µg Pb/m^3 air for one year	Blood Pb increased, but stabilized after 4 months; Pb levels remained elevated in bone, kidney, and liver after 6 months	13
1.5 mg Pb/L in drinking water for several days	Disturbed sleep patterns	18
Weanling females given 0.0, 0.5, 5, 25, 50, or 250 mg Pb (as Pb acetate)/L drinking water for 6 to 7 weeks, then mated and exposed continuously through gestation and lactation	At 25 mg/L and higher, growth retardation and delayed vaginal opening observed; some maternal deaths occurred and were associate with blood Pb concentrations >200 µg/L. Some pup malformations and deaths in all groups. The 5 mg/L group had elevated blood Pb levels	23
Single intravenous injection (mg Pb/kg BW in parentheses)		
Tetramethyllead (80)	LD-50	24
Tetraethyllead (10)	LD-50	24
Trimethyllead (20 to 25)	LD-50	24
Triethyllead (8)	LD-50	24
Single oral dose (mg Pb/kg BW)		
Tetramethyllead (108)	LD-50	24
Tetraethyllead (12)	LD-50	24
Single intraperitoneal injection (mg Pb/kg BW)		
Tetramethyllead (70 to 100)	LD-50	24
Tetraethyllead (10)	LD-50	24
Trimethyllead (17)	LD-50	24
Triethyllead (5)	LD-50	24
5 mg Pb/L drinking water, lifetime exposure	Lowered survival and reduced longevity	4
Single intraperitoneal injection of 7 mg Pb/kg BW, as tetraethyllead	Depressed food intake, and hyperactivity	25
Male weanlings exposed to age	At day 86: behavioral deficits;	

50 days to drinking water containing 25 mg Pg/L, as Pb acetate	blood Pb concentrations of 150 to 200 µg/L; brain Pb levels (µg/kg) 70 in treated group vs. 28 in controls	26
25 mg Pb/kg diet for 3 weeks	Increased locomotor activity	18
21-day-old rats exposed to 50, 100, or 500 mg Pb/L drinking water, as Pb acetate, for 335 days	Impaired behavior during first 4 months at 50 mg/L, but not thereafter. At 100 mg Pb/L and higher, behavior was impaired for at least 100 days postadministration. Brain and blood Pb levels reflected exposure concentration and duration	27
Neonatal rats given 50 mg Pb/kg BW intragastrically as Pb acetate, on days 6 to 18 postpartum	Impaired transfer of maze learning acquired during food deprivation	28
100 mg/kg BW daily, as lead nitrate	Some deaths of progeny in 3 weeks	8
Lead acetate in drinking water at 100, and 300 mg Pb/L from age 21 to 55 days	Impaired motor skills	29
200 mg/kg BW daily	50% of progeny dead in 3 weeks	8
4,000 mg Pb/L in drinking water for 130 days	Serum testosterone levels depressed, Leydig cell lesions; no effect at lower concentration tested (2,000 mg/L)	30
Nursing rats given diets containing zero, 2,000, 4,000, or 10,000 mg Pb/kg as metallic Pb powder	Lead-treated rats showed dose-related response to noise stimuli. Blood Pb levels (µg/L) in pups were 40 for controls, 250 for the 2,000 mg/kg group, 360 for the 4,000 mg/kg group, and 550 for the 10,000 mg/kg group	31
Swine, *Sus* sp.		
Oral doses of 64 mg Pb/kg BW, as Pb acetate, 6x weekly for 13 weeks	No deaths, reduced blood ALAD activity, blood Pb concentration (a remarkable) 143 mg/L	32
As above, except doses administered intraperitoneally	All died	32
Total dose of 10 to 25 grams	Toxic	6

Although Pb is undeniably toxic at high levels of exposure, the implications of lower levels of exposure are poorly defined (Nriagu 1978b). Behavioral effects such as hyperactivity, distractability, and decreased learning ability, as well as certain peripheral neuropathies, have been ascribed to subclinical Pb exposure (Hejtmancik et al. 1982). Impaired learning ability of Pb-stressed animals showing no obvious signs of Pb intoxication has been documented for rats (Cory-Slechta et al. 1981, 1983, 1985; Angell and Weiss 1982; Nation et al. 1982; Geist et al. 1985; Massaro et al. 1986), sheep (Nriagu 1978b; EPA 1980), and primates (Rice 1985)--although variability was great in all studies. Some learning deficits may be reversible and may not persist beyond a period of rehabilitation (Geist et al. 1985), and some may be induced only at relatively high exposure levels (Hastings et al. 1984). Abnormal social behavior (usually aggression) has been reported in baboons and monkeys (Hopkins 1970; Nriagu 1978b), although mice showed inhibited development of isolation-induced aggression (Ogilvie and Martin 1982). Altered parent-child relationships were suggested when suckling rats were used as surrogates. In that study, pregnant rats fed diets containing powdered Pb nursed for longer periods than normal, and the resultant offspring were slower to explore their environment (Barrett and Livesey 1983). Lead-exposed pups, with blood Pb levels as low as 200 ug/l (considered elevated but within the "normal" range) at weaning, showed an altered dam-pup interaction that resulted in the dam spending longer periods in the nest than usual. Retarded development of Pb-treated pups may account for the longer bouts of nesting by Pb-stressed dams, and the delay in age at which pups explore and learn. Barrett and Livesey (1983) concluded that maternal behavior was related to delays in pup development, and that the functional isolation of pups from their environment may be the antecedent to altered behavior later in maturity.

No data are currently available on effects of Pb-induced altered parent-offspring relationships, impaired learning ability, or abnormal social behavior for any population of free-ranging wildlife.

Ingestion of Pb-containing paint from bars or walls is a significant cause of death among captive wild animals--including many species of apes, monkeys, bears, ferrets, pinnipeds, foxes, panthers, bats, raccoons, and armadillos--and is probably underreported (Hopkins 1970; Zook et al. 1972; Fowler 1975; Forbes and Sanderson 1978). A similar situation exists for domestic animals--including dogs, cats, goats, horses, swine, cattle, and sheep (Dollahite et al. 1978; Forbes and Sanderson 1978; Osweiler and Van Gelder 1978; Hamir 1981). Passage of laws regulating the amount of Pb in paint has decreased the frequency of Pb poisoning, but many animals are still at risk from this source. Lead also occurs in used motor oils, gasoline, batteries, shot, putty, golf balls, linoleum, and printers ink--all of which are considered sources of Pb poisoning to domestic animals (Dollahite et al. 1978).

Although the use of lead arsenate as an insecticide in orchards is diminishing, residues of Pb still remain in the upper soil surface and will continue to remain bioavailable almost indefinitely (Gilmartin et al. 1985).

Naturally occurring radiolead-210, which has a half-life of 22 years, is a significant contributor to the natural radiation dose in man; comparatively high levels have been reported in certain grasses and lichens, and their consumers, such as reindeer, caribou, and ptarmigan, as well as in lanternfishes (Nriagu 1978b). The implications of this finding to wildlife health are unknown.

CURRENT RECOMMENDATIONS

Proposed Pb criteria for the protection of natural resources and human health are numerous and disparate (Table 9). Some of the criteria do not provide adequate protection. The most recent criteria for aquatic life protection, for example, range from 1.3 to 7.7 ug total waterborne Pb/1 (Table 9; EPA 1985); however, within this range high accumulations and adverse effects on growth and reproduction were recorded among sensitive species. Moreover, certain organolead compounds were lethal to some species of aquatic biota within this

range, but no criteria have been formulated yet for this highly toxic group of chemicals. Nor have any criteria been proposed for Pb in tissues of aquatic biota connoting elevated or hazardous levels to the organism. It is noteworthy that health effects to man through ingestion of Pb-contaminated seafood (and probably other fishery products) are considered negligible. Total Pb concentrations observed in highly polluted areas in the 1970's were usually about one-tenth those showing effects on marine organisms (Branica and Konrad 1980).

Organolead compounds are more toxic than ionic forms. Since methylation of ionic Pb in vivo or in stored tissues is possible, and since some liver enzyme systems are capable of converting tetraethyllead to the more toxic triethyllead species, it would appear that the current Canadian permissible concentration limit of 10 mg Pb/kg fresh weight in fishery products should be reevaluated downwards (Sirota and lithe 1977). Downward evaluation has also been recommended for the standard of 2 mg/kg in the UK, where new guidelines have been recommended for total Pb and for tetralkyllead compounds in fishery products (Wong et al. 1981). Increasing use of organolead compounds as wood preservatives, as biocides, and as catalysts in the manufacture of plastics, polyurethanes, and polyvinyl chlorides (Walsh and Tilson 1984) may adversely affect survival, sensory reponsiveness, and behavioral reactivity in aquatic organisms (Chau et al. 1980; Maddock and Taylor 1980; Wong et al. 1981; Demayo et al. 1982) and avian wildlife (Bull et al. 1983; Osborn et al. 1983; Forsyth et al. 1985). It seems that additional research is needed on organolead toxicokinetics, with special reference to fishery and wildlife resources.

[a]Each reference applies to the values in the same row, and in the rows that follow for which no other reference is indicated.

[b]Four-day average, not to be exceeded more than once every 3 years.

[c]One-hour average, not to be exceeded more than once every 3 years.

[d]Equals 1.8 to 2.5 g/gallon.

[e]Equals 0.5 g/gallon.

[f]Average 8-hour period.

[g]Blood Pb levels, usually expressed as µg/deciliter, have been converted to µg/L, for uniformity, in the present work.

The evidence implicating ingestion of spent lead shot as a major cause of mortality in waterfowl and other birds is overwhelming. Moreover, forms of inorganic lead--besides Pb shot or other ingestible-sized Pb objects--are not known to produce subclinical signs of Pb toxicosis in avian populations. Accordingly, in the 1986 advent of the Pb shot phaseout, steel shot nontoxic zones were established for the protection of bald eagles and waterfowl in 44 States. Possession of shotshells containing Pb shot by hunters of waterfowl in a steel shot zone is now considered a violation of Federal regulations (FWS 1986, 1986a, 1987). By 1991-1992, and thereafter, all uses of Pb shot for hunting waterfowl and coots are to be eliminated nationwide, including Alaska. The conversion to a nontoxic shot zone may be deferred until--but not beyond--the 1991-1992 hunting season in States that demonstrate, through monitoring, compliance with the following criteria: minimum of 100 birds sampled; less than 5% of birds examined having one or more Pb shot in the gizzard; and less than 5% of the birds collected having >2 mg Pb/kg fresh weight in liver, or with >0.2 mg Pb/1 in blood, or with blood protoporphyrin concentrations >0.4 mg/l. In addition, the occurrence of three or more individual specimens confirmed as lead-poisoned during the monitoring year will disqualify the area for deferral (FWS 1986, 1986a, 1987). States may elect to forego monitoring and convert to nontoxic shot zones on a countywide or statewide scheduled or accelerated basis (FWS 1986, 1987).

The level of human exposure in Pb-using industries has been reduced considerably in recent years; associated with this observation is the reduction in Pb content of gasolines, the removal of Pb-based paints for interior household use, and the reduction in Pb content of outside paints (Table 9; Boggess 1977). These actions will undoubtedly prove beneficial in reducing the elevated Pb concentrations now observed in communities of flora and fauna along heavily traveled roads, and in providing additional protection to captive zoo animals and other animals held in enclosures with Pb-painted bars and walls. The decreased use of leaded

gasoline has resulted in a significant decline in Pb concentrations in streams (Smith et al. 1987), and in whole body burdens of Pb in starlings collected nationwide, among which the decline was most pronounced in birds from urban areas (White et al. 1977). Continued nationwide monitoring of Pb in fish and wildlife is necessary to determine if this is a continuing downward trend, and also to identify areas of high or potential Pb contamination.

Data for Pb effects on mammalian wildlife are conspicuously absent. In view of the large interspecies differences in Pb responses reported for domestic livestock and laboratory populations of small animals (Table 9), more research is needed to determine if Pb criteria for these groups are applicable to sensitive species of mammalian wildlife.

One of the more insidious effects documented for Pb in warm-blooded organisms is neurobehavioral deficits (including learning impairments) at dose levels producing no overt signs of toxicity, i.e., apparently normal growth and developmental skills, and sometimes, nonelevated blood Pb levels (EPA 1980, 1985; Rice 1985). Behavioral deficits have been reported for young rats when blood Pb levels exceeded 0.1 mg/l, and in children with blood Pb concentrations of 0.4 to 0.5 mg/l (EPA 1980; Rice 1985), and in birds when Pb was administered early in development (Burger and Gochfeld 1985). Recently, behavioral impairment was recorded in 3-year-old monkeys that received 50 or 100 ug Pb/kg BW from birth to age 200 days. Blood Pb levels immediately after exposure, and at time of testing, were 0.15 to 0.25 mg/l (age 200 days), and 0.11 to 0.13 mg/l (age 3 years); this is the first report of behavioral impairment in a primate species at blood Pb concentrations that are considered to be well within the bounds of safety for children (Rice 1985). This subject appears to constitute a high priority research need for wildlife species of concern.

TIN HAZARDS TO FISH, WILDLIFE, AND INVERTEBRATES: A SYNOPTIC REVIEW

by

Ronald Eisler

Patuxent Wildlife Research Center
Laurel, MD 20708

SUMMARY

Tin (Sn) has influenced our life style for the past 5,000 years. Today we are exposed to tin on a daily basis; including tinplated baby food cans; alloys such as pewter, bronze, brass, and solder; and toothpaste containing stannous flouride. These inorganic tin compounds are not highly toxic due to their low solubility, poor absorption, low accumulation, and rapid excretion. Synthetic organotin compounds, however, first manufactured commercially in the 1960's, may present a variety of problems to animals, including impaired behavior and reduced growth, survival, and reproduction. Some triorganotins--for example, in antifouling marine paints, in molluscicides, and in agricultural pesticides--can be harmful to sensitive species of nontarget biota at recommended application protocols.

Background concentrations of organotin compounds are frequently elevated--occasionally to dangerous levels--in aquatic organisms collected near marinas and other locales where organotin-based antifouling paints are extensively used. But more information is needed on background concentrations of organotins, especially those from terrestrial ecosystems.

Tributyltin compounds are especially toxic to aquatic organisms. Adverse effects were noted at concentrations of 0.001 to 0.06 ug/l on molluscs and at 0.1 to 1.0 ug/l on algae, fish, and crustaceans. In general, bioconcentration of organotins from seawater was high, especially by algae, but degradation was sufficiently rapid to preclude food chain biomagnification. In contrast, current environmental concentrations of some organotins are not likely to be directly toxic to birds and mammals. Birds seem to be relatively resistant to organotins, although data are scarce. Preliminary studies of 75 days duration suggest that diets containing 50 mg tin as trimethyltin chloride/kg were fatal to ducklings; 5 mg/kg killed 40%, and 0.5 mg/kg was not lethal. Trimethyltin compounds were lethal to other species of birds tested at doses of 1 to 3 mg/kg body weight. Other tests with ducklings and eleven other mono-, di-, tri-, and tetraalkyltin compounds at dietary levels equivalent to about 50 mg Sn/kg showed no adverse effects on survival. Small laboratory mammals were adversely affected by trimethyltin compounds at doses as low as 0.15 mg/l in drinking water (learning deficits), 0.63 mg/kg body weight (diet aversion), and 1.25 mg/kg body weight (death); neurotoxicological effects of trimethyltins were usually not reversible. Triethyltins were also toxic to small mammals, but effects--which were similar to those of trimethyltins--were usually reversible after cessation of exposure.

All evidence to date indicates that organotin compounds are not carcinogenic.

Methodologies and data necessary for the promulgation of effective criteria and standards to protect natural resources seem to be deficient in eight key areas: (1) routine analytical chemical methodologies for extraction, separation, and identification of inorganic and organic tin compounds and their chemical speciation products in biological and other samples; (2) mechanisms of toxicity for organotin compounds; (3) rates of uptake, retention, and translocation of organotins in biota; (4) persistence and mobility rates of organotins in nonbiological materials; (5) rates of tin methylation and biotransformation in biological and abiotic samples; (6) organotin interactions with other toxic chemicals; (7) quantitative structure activity relation for use in evaluating organotin toxicity; and (8) long-term environmental monitoring studies in terrestrial and aquatic ecosystems for establishment of baseline concentrations.

ACKNOWLEDGMENTS

I thank Lynda J. Garrett, Joyce E. Haber, Christine Holden, and Nancy A. Bushby for technical services; Julia L. Armstrong for secretarial assistance; Denny R. Buckler, W. James Fleming, Roy B. Laughlin, Jr., and T. Peter Lowe for constructively reviewing the manuscript; and Nancy M. Wells and James R. Zuboy for editorial services.

INTRODUCTION

Interest in the toxicity of tin compounds dates to the early 1800's when investigators demonstrated that inorganic tin compounds produced muscular weakness, loss of pain sensation, and immobility in dogs (Reiter and Ruppert 1984; Idemudia and McMillan 1986b). In man, organotins can be assimilated by inhalation, absorption through the skin, and from food and drinking water (Zuckerman et al. 1978). The first documented case of organotin poisoning of humans was in 1880 when workers complained of headaches, general weakness, nausea, and diarrhea after exposure to triethyltin acetate vapors (Reiter and Ruppert 1984). Renewed interest in the toxicity of organotin compounds resulted from a medical tragedy in France in 1954. "Stalinon," a proprietary compound of diethyltin diiodide plus linoic acid used to treat furuncles and other skin infections, caused 217 poisonings and 111 deaths (Piver 1973; Duncan 1980; Idemudia and McMillan 1986b). The identified toxic components in Stalinon were triethyltin contaminants; victims received a total dose of 3 grams over a 6- to 8-week period. Symptoms included constant severe headache, rapid weight loss, vomiting, urine retention, vertigo, hypothermia, abdominal pain, and visual and psychic disturbances. Some of the more severely affected patients had convulsions. Death usually occurred in coma or from respiratory or cardiac failure. In survivors, headaches and diminished visual acuity remained for at least 4 years.

Recent world production of organotin compounds is about 30,000 tons, although relatively few organotin compounds, perhaps only 25, are presently produced and used to any great extent (Laughlin and Linden 1985). Diorganotins are used in the manufacture of antioxidants, whereas triorganotins are used as general biocides against microbial and invertebrate pests and in marine antifouling paints (Laughlin and Linden 1985). The first antifouling paints incorporating an organotin compound as a biocide were developed in 1961. Because of their effectiveness and availability in a variety of colors, tributyltin antifouling paints are now the most commonly used type, replacing copper-, mercury-, and lead-based paints (Stebbing 1985). Worldwide synthesis of tributyltin compounds is about 900 metric tons annually for all applications (Laughlin et al. 1986a). Tributyltins are highly toxic to aquatic plants and animals, readily accumulate in fish and molluscs from contaminated localities, and are present in some harbors where their release from antifouling paints--found usually on small boats and recreational craft--is the putative source (Walsh et al. 1985; EPA 1986; Laughlin et al. 1986a). Tributyltin is a contributory factor and probably a major cause for the reproductive failure of the European flat oyster (*Ostrea edulis*) in recent years in some locations (Thain and Waldock 1986). in fact, tributyltins are capable of causing adverse biological effects at levels far below that of any previously reported marine pollutant (Lawler and Aldrich 1987).

The widespread agricultural applications of trialkyltin biocidal agents have greatly increased the relative exposure risks to workers handling these materials (Rosenberg et al. 1985). Internationally, tin was recognized as a potential environmental contaminant at the Paris and Helsinki conventions in 1974; in later conventions, organotin compounds were moved to the "black list" (Vrijhof 1985). Due to the increasing use of organotin compounds as a class, the Canadian government, in 1979, placed organotins on Canada's Category III Contaminant List. Category III indicates that additional data are needed on the occurrence, persistence, and toxicity of organotins for preparation of informed environmental and human health risk assessments (Chau et al. 1984).

Many reviews and bibliographies are available on the environmental impacts of inorganic and organic tin compounds.[1] These authorities agree that inorganic tin compounds are comparatively harmless and that many organotin compounds are potentially very hazardous to natural resources--especially tributyltin compounds to aquatic biota. One rare exception to this generalization involved 113 cases of acute gastrointestinal illness in Washington and Oregon in 1969 associated with ingestion of canned tomato juice contaminated by inorganic tin; detinning in many cans resulted in tin levels as high as 477 mg inorganic tin per liter of juice. It seems that excessive use of nitrate fertilizer on one tomato crop was the ultimate cause of the detinning (Barker and Runte 1972).

This report summarizes selected data on ecological and toxicological aspects of organic and inorganic tin compounds, with emphasis on fishery and wildlife resources. It is part of a continuing series of reports on chemical contaminants prepared in response to informational requests from environmental specialists of the U.S. Fish and Wildlife Service.

CHEMICAL AND BIOCHEMICAL PROPERTIES

GENERAL

The chemical, physical, and biochemical properties of inorganic tin compounds differ dramatically from those of representative organotin compounds. There is general agreement that inorganic tins are not highly toxic due to their poor absorption and rapid turnover rate in tissues and to their being essential for growth in at least one species (rat). Of the 260 known organotin compounds, all but a few are manufactured, and 36 are listed as toxic (Watanabe 1980). Most authorities agree on several points regarding organotin compounds: information concerning the mechanism of toxic action is incomplete; there is no evidence of carcinogenicity; trialkyltin compounds are the most toxic; and there are large differences in resistance between and within species.

INORGANIC TIN

Elemental tin has an atomic number of 50, an atomic mass of 118.69, and exists in three allotropic forms: white tin at room temperature, nonmetallic grey tin at <13.3 C, and brittle tin at >161 C. White tin is a stable silver-white, lustrous, soft metal with a density of 7.27, a melting point of 231.9 C, and a boiling point of 2,507 C. Tin has 10 stable isotopes (Sn-112, -114, -115, -116, -117, -118, -119, -120, -122, and -124), the most for any element. Inorganic tin compounds exist in the +2 (stannous) and +4 (stannic) oxidation states. Stannous compounds are generally more polar than stannic compounds, are unstable in dilute aqueous solutions, are easily oxidized, and normally contain some Sn+4. Stannic oxide occurs naturally as the mineral cassiterite, has a melting point of 1,127 C, and has wide application in industry. Additional information on inorganic tin chemistry is listed in Zuckerman et al. (1978), WHO (1980), and Davies and Smith (1982).

Signs of inorganic tin poisoning in mammals include local effects such as vomiting, diarrhea, and eye and nose irritation; however, these vary considerably among species (WHO 1980). The major systemic effects include ataxia, twitching of limbs, weakness of limbs, paralysis, growth retardation, decreased hemoglobin levels, and--at extremely high doses--testicular degeneration, pancreatic atrophy, formation of spongy brain white matter, and kidney necrosis. In humans, symptoms of inorganic tin intoxication include nausea, vomiting, diarrhea, stomach ache, fatigue, and headache. The lowest concentration producing outbreaks was about 250 mg Sn per liter in canned orange and apple juice. Ingestion of 50 mg of tin through eating canned peaches that contained Sn concentrations of about 450 mg/kg caused acute symptoms in 2 of 7 human volunteers (WHO 1980). Inhalation of SnO_2 dust is a hazard in the deep-mining of tin; deposits in lungs are easily detectable as "stannosis" (Krigman and Silverman 1984).

Inorganic tin and its salts are not highly toxic due to their poor absorption, relative insolubility of their oxides, and rapid tissue turnover (WHO 1980; Hassett et al. 1984; Krigman and Silverman 1984; Blunden and Chapman 1986). The absorption of ingested inorganic tin is usually less than 5%, although up to 20% has been reported. Stannous compounds are more readily absorbed from the gastrointestinal tract than stannic compounds, but absorbed tin leaves the vascular system rapidly. Bone is the main site of tin deposition, followed by lung, liver, and kidney. Penetration of the blood-brain and placental barriers by inorganic tin seems to be very slight. Except for lung, inorganic tin does not accumulate in organs with increasing age. Absorbed inorganic tin is excreted mainly in the urine, although excretion through the bile may account for up to 15% of the total. Tin and its inorganic compounds do not produce significant dermatitis or allergic reactions to skin epithelium, and results of all long-term studies of carcinogenicity, teratogenicity, and mutagenicity have been negative to date (WHO 1980).

The half-time (Tb 1/2) of inorganic tins in animals was reviewed by WHO (1980). Studies with Sn+2 in mouse, rat, monkey, and dog show that in all species elimination is a four-compartment process regardless of the route of administration (i.e., intraperitoneal or intravenous). The Tb 1/2 for the longest-lived Sn component

was >3 months. In studies with rats, for example, radiotin-113 in skeleton following intramuscular administration had a Tb1/2 of 3 to 4 months, but for oral administration of Sn+2 and Sn+4 it was only 28 to 40 days in bone and 10 to 20 days in liver and kidney.

Inorganic tin can be biomethylated by microorganisms in the aquatic environment and subsequently mobilized in the ecosystem (Tugrul et al. 1983; Yemenicioglu et al. 1987). The process is slow and usually does not proceed beyond the monomethyltin stage (Zuckerman et al. 1978), although dimethyltin formation by *Pseudomonas* bacteria has been reported (Smith 1978b).

Tin is an essential nutrient for growth in the rat, and a tin-deficient diet leads to reduced growth (WHO 1980; Krigman and Silverman 1984). The mechanism of action is unclear, but involves increasing metabolic activity of liver lysosomes and liver hydrolytic enzymes during regeneration (Dwivedi et al. 1985a,b).

ORGANOTINS

Organotins are compounds with at least one tin-carbon bond. In most organotin compounds, tin is in the tetravalent oxidation state. Four series of organotin compounds are known: R_4Sn, R_3SnX, R_2SnX_2, and $RSnX_3$ wherein R is usually a butyl, octyl, or phenyl group, and X is commonly chloride, fluoride, oxide, hydroxide, carboxylate, or thiolate (CEC 1978). The possible molecular composition and structure of the R groups are virtually unlimited (Laughlin et al. 1985). At least 260 organotin compounds presently are known, of which 36 are listed as toxic chemicals (Watanabe 1980). Except for some methyltin compounds, all organotins are manufactured (Laughlin et al. 1985). Most commercially used organotins are characterized by low mobility in the environment because of low aqueous solubility, low vapor pressure, and high affinity for soils and organic sediments (Blunden and Chapman 1986). Solubility data for organotin compounds are incomplete. In general, their solubility in water is limited to about 5 to 50 mg/l, but they are very soluble in many common organic solvents (WHO 1980). The presence of chloride in seawater reduces the solubility of tributyltin and triphenyltin compounds, probably by association with the hydrated cation to form the covalent organotin chloride (Blunden et al. 1985). Organotin compounds are analyzed in aqueous media by spectrophotometric, fluorometric, and electrochemical techniques. However, if picomole per liter concentrations are required, additional techniques must be used. More work needs to be done on analytical detection methods of organotins in sediments and biota (Thompson et al. 1985).

Methylation of inorganic and methyltin compounds has been reported with the formation of mono-, di-, tri-, and tetramethyltin compounds. In addition, tributylmethyltin and dibutylmethyltin species have been found in harbor sediments, which suggests that some butyltin compounds may be methylated in aquatic systems (Guard et al. 1981; Thompson et al. 1985; Donard et al. 1987).

Abiotic and biological degradation of organotins generally occurs through sequential dealkylation or dearylation (Zuckerman et al. 1978; WHO 1980; Smith 1981b; Chau et al. 1984; Blunden et al. 1985). Organotin compounds undergo successive cleavage of tin-carbon bonds to ultimately produce inorganic tin as follows: $R_4Sn \xrightarrow{k4} R_3SnX \xrightarrow{k3} R_2SnX_2 \xrightarrow{k2} RSnX_3 \xrightarrow{k1} SnX_4$. The reaction rate, k, usually proceeds as k4 > k3 > k2 = k1. The breaking of a Sn-C bond can occur by a number of different processes, including ultraviolet irradiation (UV), biological cleavage, chemical cleavage, gamma irradiation, and thermal cleavage (WHO 1980; Blunden and Chapman 1982, 1986; Blunden et al. 1985; Thompson et al. 1985). In general, UV and biological cleavage are the most important processes. The main abiotic factors that seem to limit organotin persistence in the environment are elevated temperatures, increased intensity of sunlight, and aerobic conditions (Table 1). A probable environmental degradation scheme for tributyltin and triphenyltin compounds is shown in Figure 1.

The tendency of an organotin compound to be concentrated by an organism depends on its partition behavior between lipid and aqueous phases. In general, compounds highly soluble in octanol and only slightly soluble in water have high Kow values. Kow values of organotins increase with number and molecular weight of organic groups attached to the tin atom, with significant bioaccumulation potential for organotins with R groups of butyl and larger (Thompson et al. 1985). Kow values for tributyltins in seawater vary from 5,500 to 7,000, but can be significantly modified by salinity and speciation products (Laughlin et al. 1986b). Thus, organotins would be expected to accumulate in lipid-rich surface microlayers of natural waters (Cardwell and Sheldon 1986) and

in biota (as discussed later). However, the ability of microorganisms, algae, and higher organisms to reduce various organotins into less toxic metabolites that can be rapidly excreted seems to preclude food chain biomagnification and to lessen the potential hazards to natural resources from consumption of organisms with elevated organotin residues (Table 1; Cardwell and Sheldon 1986).

Most authorities now agree on five points: (1) information concerning the mechanism of the toxic action of organotin compounds is inadequate; (2) results of all studies with various organotins for possible carcinogenicity are negative; (3) triorganotin compounds are the most toxic group of organotins; (4) large inter- and intraspecies differences exist in resistance to organotin compounds; and (5) organotins can alter enzyme activity levels in many organs and tissues including brain, liver, and kidney (Piver 1973; Duncan 1980; WHO 1980; Davies and Smith 1982; Maguire et al. 1982; Arakawa and Wada 1984; Dwivedi et al. 1985b; Blunden and Chapman 1986).

The monoorganotin compounds, $RSnX_3$ have a generally low toxicity and do not seem to have any important biological action in mammals (Duncan 1980; Davies and Smith 1982; Krigman and Silverman 1984; Blunden and Chapman 1986).

Dialkylorganotins, R_2SnX_2, are associated with hepatotoxicity (ethyl, propyl, butyl, and pentyltins), immunotoxic effects to T-cells (butyl and octyltins), and skin and eye irritation (methyl, ethyl, propyl, butyl, and octyltins; Watanabe 1980; Krigman and Silverman 1984). The diorganotins combine with coenzymes or enzymes possessing dithiol groups and exert their toxic action by inhibiting alpha-keto acid oxidation and blocking mitochondrial respiration (Duncan 1980; WHO 1980; Davies and Smith 1982). Resistance to diorganotin toxicity varies widely among species. For example, dibutyltins and dioctyltins--unlike other organotins tested--were toxic to rat thymocytes, but did not induce similar effects on lymphoid atrophy in mice, guinea pigs, or Japanese quail (Seinen et al. 1977b). Selected dibutyltins are effective as antihelminthics and are used to kill parasitic worms in chickens and turkeys without harm to host birds (Davies and Smith 1982).

Table 1. Biological and abiotic degradation times of selected organotins.

Degradation route, organism or compartment, and tin compound	Time for 50% degradation and other variables (reference)
Biological	
Microorganisms	
Tributyltin	1 to 2 weeks in aerated medium in dark, 6 to 13 weeks in aerated medium in light, <1 year in anaerobic medium (Cardwell and Sheldon 1986)
Triphenyltin	60 to 140 days under aerobic, light conditions (Smith 1981b)
Algae, *Ankistrodesmus falcatus*	
Tributyltin	25 days (Maguire et al. 1984)
Bivalve molluscs, 3 species	
Tributyltin	10 to 14 days (Cardwell and Sheldon 1986; Laughlin et al. 1986a)
Sheepshead minnow, *Cyprinodon variegatus*	
Tributyltin	14 to 28 days (Cardwell and Sheldon 1986)
Abiotic	
Distilled water	
Tributyltin	>89 days at initial concentration of 0.7 mg Sn/L, 18 days at 2.0 to 4.0 mg Sn/L (Walsh et al. 1986a)
Freshwater	

Tributylin	3 to 89 days (Duncan 1980; Smith 1981b; Ward et al. 1981; Maguire and Tkacz 1985; Walsh et al. 1985)
Triphenyltin	8 months at 1.0 to 2.5 mg/L, 100 days at 0.5 mg/L (Duncan 1980)
Diphenyltin	2 to 3 days (Soderquist and Crosby 1980)
Seawater	
Tributyltin	6 to 19 days; most rapid at low initial concentrations under high illumination (Seligman et al. 1986)
Triphenyltin	About 140 days (Duncan 1980)
Sediments	
Trimethyltin	About 80 days at 16 C to form the more volatile $(CH_3)_4Sn$ (Guard et al. 1981)
Tributyltin	At least 10 months at 20 ºC (Maguire and Tkacz 1985)

In any member of the organotin series R_nSnX_{4-n}, progressive substitution of organic groups at tin produces a maximum biological activity for the triorganotin derivatives, R_3SnX (Davies and Smith 1982). Among triorganotin compounds, trimethyltins are highly toxic to insects, birds, and mammals; triethyltins to mammals; tripropyltins to gram-negative bacteria; tributyltins to fish, molluscs, fungi, and gram-positive bacteria; triphenyltins to fish, fungi, and molluscs; and tricyclohexyltins to mites (Duncan 1980; Davies and Smith 1982; Maguire et al. 1982; Blunden and Chapman 1986). In mammals, the lower triorganotin homologues (trimethyltins, triethyltins) are essentially neurotoxic, the intermediate trialkyltins and triphenyltins are primarily immunotoxic, and the higher homologues are only slightly toxic or not toxic (Krigman and Silverman 1984; Snoeij et al. 1985). The toxicity of triorganotin compounds is probably due to their ability to bind to proteins and to inhibit mitochondrial oxidative phosphorylation (Smith 1978b; Duncan 1980; WHO 1980; Davies and Smith 1982; Blunden and Chapman 1986). Triorganotins also interfere with phagocytosis and exocytosis and other pathways where sulfhydryl groups play a pivotal role (Elferink et al. 1986), and inhibit uptake of gamma-aminobutyric acid and Na^+-K^+-ATPase in brain (Costa 1985). Impairment of phagocytosis and related activities of polymorphonuclear leukocytes may enhance susceptibility for infection (Elferink et al. 1986).

Trimethyltins are the most toxic trialkyltins to mammals, regardless of the nature of the substituent (X group) according to Smith (1978b). They induce pathological lesions in brain and overt neurological and behavioral changes in rodents (Chang 1986). Trimethyltins are neurotoxins that damage the limbic system, cerebral cortex, and brain stem and can traverse the placenta and accumulate in the fetus (Reuhl aid Cranmer 1984). Trimethyltins (but not inorganic, monomethyl, or dimethyltins) inhibit brain protein synthesis by 47% and can cause a decrease of 4.2 °C in body temperature of mice within 1 hour postadministration of 3.0 mg/kg body weight (Costa and Sulaiman 1986). Raising the ambient temperature to 35 °C prevented hypothermia in treated mice and resulted in only a 20% inhibition in protein synthesis. More research is needed on the role of protein synthesis in organotin-induced neurotoxicity.

Triethyltins modify phosphorylation processes in subcellular fractions of rat brain proteins (Piver 1973; Neumann and Taketa 1987). Signs of triethyltin poisoning in rodents include weakness of hindlimbs, dyspnea, and peripheral vasodilation (Watanabe 1980). Internally, acute triethyltin intoxication is characterized by a transient edema of the central and peripheral nervous systems manifested by extensive intramyelinic vacuolation due to splitting of myelin lamellae; changes are reversible (Watanabe 1980; Reuhl and Cranmer 1984). Neuronal death is reported following triethyltin intoxication during the neonatal period, possibly as a result of elevated intracranial pressure (Reuhl and Cranmer 1984). In rabbit brain, triethyltins alter activity of pyruvate dehydrogenase (Neumann and Taketa 1987).

Studies on tributyltin uptake and depuration from food or water by rats, crabs, oysters, and fish showed that in all species it was accumulated and metabolized, at least partly, within 48 hours to dibutyltins, monobutyltins, and more polar metabolites; however, oysters (*Crassostrea virginica)* metabolized significantly less tributlytin than did other species tested (Lee 1985). The accumulation of tributyltin compounds in different tissues

correlated well with lipid content nd supports a partitioning mode of uptake (Laughlin et al. 1986a). The mixed function oxygenase system from hepatic tissues was able to metabolize tributyltins by forming hydroxylated metabolites (Lee 1985). Tributyltins are also potent cytotoxicants in rabbit erythrocyte and skin cultures (Gray et al. 1985).

The potential of tricyclohexyltins to modify the inducibility of cytochrome P-450 by various substances, such as 3-methylcholanthrene, is of considerable toxicological importance (Rosenberg et al. 1985). Significant metabolic interactions can result from a combination of environmental chemicals and drugs that produce alterations in heme and mixed function oxygenase activity (Rosenberg et al. 1985), suggesting that more research is needed on interaction effects of organotins with other environmental substances or contaminants.

The biological effects of the tetraorganotin compounds, R_4Sn, seem to be caused entirely by the R_3SnX derivative that is produced by their rapid in vivo dealkylation (Duncan 1980; Davies and Smith 1982; Blunden and Chapman 1986). Increasing toxicity of tetra- and triorganotins in mammals has been shown to be associated with decreasing length of their ligands, as reflected by solubility in biological fluids (Arakawa et al. 1981). It is not known if damage is produced by the metal or by its alkyl derivative, but the presence of trialkyl groups seems to enhance the toxicity of tin--probably by increasing its partition into lipids, thus aiding the absorption of the metal and speeding its distribution to the site of action (Arakawa et al. 1981).

SOURCES AND USES

Metallic tin is derived mainly from the mineral cassiterite (SnO_2) and to a lesser extent from the sulphide ore stannite Cu_2S-FeS-SnS_2, although it can be derived from rarer minerals such as malayaite, $CaSnSiO_5$. (Blunden et al. 1985). Tin is one of the earliest metals known and has influenced our life style through the ages. Tin alloy artifacts dating from about 5,000 years ago have been unearthed at Ur, the site of ancient Babylonia (Zuckerman et al. 1978). Today we are exposed to tin on a daily basis through the use of tinplated food cans; of alloys such as pewter, bronze, brass, and solder; and from toothpaste containing stannous flouride (Zuckerman et al. 1978). Inorganic tin compounds are also used in a variety of industrial processes such as the strengthening of glass, as a base for colors, as catalysts in various chemical reactions, as stabilizers in perfumes and soaps, and as dental anticariogenic agents (WHO 1980). Organotin use is increasing rapidly in antifouling marine paints, in molluscicides, and in agriculture, which often causes serious adverse effects on nontarget biota.

In 1975, the total world tin production was 236,000 tons, of which 72% was produced by China (10%), Indonesia (8%), Malaysia (35%), Thailand (7%), and 6% each by the UK and USSR (WHO 1980). The world production of recycled tin was about 20,000 tons, of which France produced about half (WHO 1980). The production and consumption of tin chemicals, especially organotins, has increased markedly in the past several decades (Table 2).

The United States is the major consumer of tin and organotin compounds, followed by Japan, the UK, Germany, and France (WHO 1980). In 1976, for example, the United States consumed 11,000 tons of organotins, or about 39% of the world organotin production (Chau et al. 1984). The projected total demand for primary tin up to the year 2000 is estimated at 7.5 million tons. Total reserves currently are about 6.5 million tons; however, it is likely that new discoveries and increases in known reserves will result in sufficient new tin to meet the demand for this period (WHO 1980).

The uses of inorganic and organotin compounds are numerous and increasing (Table 3). Industrial consumption of organotins, for example, rose from about 5,000 tons in 1965 to about 35,000 tons in 1980. At present, the uses of nontoxic organotin compounds (R_2SnX_2 and $RSnX_3$ types) account for about 67% of the total world production, although use of R_3SnX types as selective biocides has increased disproportionately in recent years (Davies and Smith 1982). Tin now has more of its organometallic derivatives in commercial use than any other element (Blunden et al. 1985).

Table 2. Annual tin production and consumption.

Chemical group and other variables	Amount, in metric tons	Reference[a]
Organotins		
Production Worldwide		
Total		
1950	<5,000	1
1955	~5,000	2
1976	24,000 to 28,000	3, 4, 5, 6

Table 3. Major uses of inorganic and organic tin compounds.

Compounds, uses, and references (in parentheses)
INORGANIC TIN COMPOUNDS: Tin plate, solder, brass, bronze, and other alloys; heat stabilizers for polyvinyl chloride manufacture; tin and tin alloy electroplating baths; catalysts for silicone and polyurethane foam production; in glass manufacture; flame retardants for woolen fabrics; in toothpastes and dentifrices; for control of parasitic worms in sheep; radiopharmaceuticals; in ceramic glazes and pigments; in fluorescent phosphors, in weighting and dying of silk; stone polishing; corrosion inhibitors; color and perfume stabilizers in soaps (WHO 1980; Blunden et al. 1985).
MONOORGANOTINS: Polyvinyl chloride stabilizers, catalysts, SnO_2 precursors (CEC 1978; WHO 1980; Chau et al. 1984; Blunden et al. 1985, Blunden and Chapman 1986).
DIORGANOTINS: Catalysts for silicones, polyurethane foams; polyvinyl chloride stabilizers; precursor for forming SnO_2 films on glass; antihelminthics for poultry; lubricating oil additives (Piver 1973; CEC 1978; WHO 1980; Chau et al. 1984; Blunden et al. 1985; Blunden and Chapman 1986).
TRIORGANOTINS: Agrochemical fungicides, herbicides, miticides, insecticides, nematocides, acaricides, antifeedants; biocide in marine paints; slimicide in paper pulp mills and cooling towers; rodent repellant; molluscicides; wood preservative fungicides; disinfectants; stone preservation; textile and leather protection (Piver 1973; Hunter 1976; Kumpulainen and Koivistoinen 1977; CEC 1978; WHO 1980; Davies and Smith 1982; Chau et al. 1984; Subramanian 1984; Wilkinson 1984; Blunden et al. 1985; Maguire and Tkacz 1985; Thompson et al. 1985; Blunden and Chapman 1986),
TETRAORGANOTINS: Used in manufacture of R_nSnX_{4-n} compounds from $SnCl_4$; catalysts for olefin polymers; stabilizers for transformer oils; corrosion inhibitor in lubricating oils (CEC 1978; WHO 1980; Davies and Smith 1982)

Biocidal applications of organotins to control marine fouling communities, agricultural pests, and as selective molluscicides merit brief additional comment. The use of antifoulants on ships is necessitated by the damage some organisms can cause to wooden structures and by the reduced fuel efficiency and speed due to drag when vessels become heavily fouled (Laughlin et al. 1984). Until recently, the most widely used antifouling paint contained a copper base that is biocidally active when copper leaches as an ion from the paint (Hall et al. 1987). However, short effective lifetimes and high costs have limited the usefulness of copper-based paints. Organocompounds of arsenic, mercury, or lead have also been used in antifouling paints, but these paints have been removed from the commercial market due to the toxicological risks during preparation and application and to their hazards to the environment (Blunden et al. 1985; Hall et al. 1987). Organotin coatings are currently promoted because of their excellent antifouling action, long lifetime (up to 4 years), and lack of corrosion (Messiha and Ikladious 1986). Oganotin coatings, especially tributyltins, present potential environmental problems to nontarget aquatic biota due to their extreme toxicity.

Use of organotin antifouling paints on recreational and commercial water craft has increased markedly in recent years. In Maryland, for example, 50% to 75% of the recreational boats used in Chesapeake Bay are covered with organotin paints (Hall et al. 198). The organotin biocide released by hydrolysis from the surface of the paint film into seawater provides the antifoulant action. In consequence, the depleted outer layer of paint film, containing hydrophilic carboxylate groups, is easily eroded by moving seawater exposing a fresh surface layer of organotin acrylate polymer. In continuing tests by the U.S. Navy, ablative organotin fouling coatings have demonstrated more than 48 months of protection (Blunden et al. 1985). As discussed later, the use of organotin compounds in antifouling paints has been severely curtailed. Several organotins have been used extensively as agricultural pesticides, especially tricyclohexyltin and triphenyltin compounds (Hunter 1976;

Kumpulainen and Koivistoinen 1977; Blunden et al. 1985). In general, these compounds showed low phytotoxicity, low toxicity to nontarget organisms, no evidence of development of resistant insect strains, and degradation to form harmless tin residues. It is probable that agricultural uses of organotins will increase. The toxicity of triorganotin compounds to aquatic invertebrates, especially slow release formulations of tributyltins, is usually high, and this property has been used advantageously to eradicate certain species of freshwater snails that are intermediate vectors of schistosomiasis, i.e., *Biomphalaria* spp., *Bulinus* spp. (Chliamovitch and Kuhn 1977; CEC 1978; Duncan 1980; Seinen et al. 1981). Unfortunately, nontarget biota, including some sensitive species of fishes, are killed at recommended application levels (EPA 1987).

Organotins enter air, soil, and water primarily as a result of routine agricultural, industrial, municipal, and biocidal operations (Table 4). Deposition rates of organotins from air into soils and water are unknown at present, but may be significant around urban and industrialized areas. Total tin concentrations--primarily inorganic tin--in the atmosphere of the northern hemisphere are significantly higher than those in the southern hemisphere and are dominated by anthropogenic sources (Table 5). The most important of these sources seems to be the incineration of municipal wastes, which accounts for most of the tin flux to the atmosphere (Byrd and Andreae 1986a). Riverine fluxes of tin to the oceans vary between 36 and 71 million kg annually, almost all of it in particulate fractions (Byrd and Andreae 1986b).

Table 4. Possible modes of entry of organotins into air, soil, and water (Blunden et al. 1985).

Environmental compartment and organotin group	Sources
Air	
R_3SnX	Agricultural spraying, volatilization from biocidal treatments, antifouling paint sprays
R_3SnX, R_2SnX_2, $RSnX_3$	Incineration of organotin-treated or -stabilized waste materials
R_2SnX_2, $RSnX_3$	Glass coating operations to produce SnO_2 films
Soil	
R_3SnX	Agricultural applications, wood preservation
R_3SnX, R_2SnX_2, $RSnX_3$	Burial of waste materials containing organotins
Water R_3SnX	Antifouling coatings, molluscicides, overspray from agricultural operations, land runoff from agricultural use, industrial processes (i.e., slimicides in paper manufacture)
R_2SnX_2, $RSnX_3$	Leaching from organotin stabilized polyvinyl chloride

Table 5. Total tin flux to the atmosphere and hydrosphere (modified from Byrd and Andreae 1986a, b).

Environmental compartment and other variables	Annual flux, in millions of kilograms

Riverine flux to oceans	
Dissolved fraction	0.09
Particulate fraction	35.6–71.2

BACKGROUND CONCENTRATIONS

GENERAL

In aquatic environments, organotin concentrations were elevated in sediments, biota, and surface water microlayers collected near marinas, aquaculture rearing pens, and other facilities where organotin-based antifouling paints were used. In some cases, organotin concentrations in the water column were sufficiently high to pose a substantial risk to sensitive species. Data are now extremely limited on background concentrations of organotins in all environmental samples, especially in terrestrial ecosystems, and this may be attributed, in part, to limitations in routine chemical analytical capabilities.

NONBIOLOGICAL

Tin concentrations in water, air, soils, sediments, and other nonbiological materials are documented but information is scarce except for aquatic systems (Table 6). In aquatic systems, several trends were evident. First, tin and organotin compounds tend to concentrate in surface microlayers by factors up to 10,000X relative to subsurface water; in the case of organotins, this may be due to partitioning into the film of petroleum hydrocarbons commonly present on water surfaces (Maguire et al. 1982; Cleary and Stebbing 1987; Hall et al. 1987). Second, organotin concentrations, especially tributyltins, were highest in the vicinity of marinas and harbors, and this is consistent with its use as an antifouling agent in some paints for boats, ships, and docks (Chau et al. 1984; Maguire et al. 1986; Randall et al. 1986; Valkirs et al. 1986). Peak tributyltin concentrations occurred in late spring and early summer in association with postwinter launching of freshly painted boats (Hall et al. 1987). Third, organotin levels throughout the water column of marinas in numerous freshwater and marine locations were sufficiently elevated to cause chronic toxic effects in sensitive organisms including algae, copepods, oysters, mussel larvae, and fish (Maguire et al. 1982, 1986; Waldock and Thain 1983; Chau et al. 1984; Maguire and Tkacz 1985; Beaumont and Newman 1986; Cardwell and Sheldon 1986; Thain and Waldock 1986; Cleary and Stebbing 1987; Hall et al. 1987; Stromgren and Bongard 1987). Fourth, methyltin species were infrequently detected. Their occurrence was positively correlated with the presence of relatively high concentrations of inorganic tin and was due primarily to biotic and abiotic methylation of both organotin and inorganic tin compounds (Chau et al. 1984; Maguire et al. 1986). Finally, butyltin species were detected in harbor sediments at concentrations that were toxicologically hazardous to benthic fauna (Waldock and Thain 1983; Chau et al. 1984; Maguire et al. 1986). Tributyltin species can be accumulated from the sediments by oligochaetes (*Tubifex tubifex, Limnodrilus hoffmeisteri*), thus making it potentially available to bottom-feeding fish; oligochaetes can also degrade tributyltins by a sequential debutylation, with Tb1/2 estimates of 5 months in water and 4 months in water-sediment mixtures (Maguire and Tkacz 1985).

BIOLOGICAL

Information on background concentrations of total tin in tissues of field populations of animals and plants was abundant, but few data were available on organotin species (Table 7).

Tin concentrations in marine algae and macrophytes varied between 0.5 and 101 mg total Sn/kg dry weight and clearly demonstrated that most species of aquatic flora bioconcentrate tin from seawater (Table 7). Marine plants are also important in the cycling of tin. Living algae are effective in immobilizing tin from seawater and regulating the formation and degradation of toxic methyltin compounds (Donard et al. 1987). Dead and decaying algae accumulate inorganic and organotin compounds, release them, and ultimately remove tin from the estuary to the atmosphere by formation of tetramethyltins (Donard et al. 1987).

Organotin content in fish tissues is quite variable, ranging from a low of 3% to 6% of the total tin body burden (Tugrul et al. 1983) to 18% for goatfish (*Upeneus moluccensis)* to 5% for *Mullus barbatus*, another species of goatfish (Salihoglu et al. 1987). By contrast, the limpet (*Patella caerulea*) contains 35% to 75% of its total tin body burden as organotin (Tugrul et al. 1983).

In January 1982, France banned organotin compounds for use in antifouling paints. By 1985, tin and organotin concentrations in seawater and Pacific oysters (*Crassostrea gigas*) were 5 to 10X lower than those found in 1982 (Alzieu et al. 1986). In Arcachon Bay, France, a decrease in the incidence and extent of anomalies in oyster calcification mechanisms was noted that seemed to be correlated with decreases in tin contamination (Alzieu et al. 1986). Crassostreid oysters can accumulate radiotin (Sn-113) to a higher degree than other species of bivalve molluscs, a characteristic that may be useful as a bioindicator in the event of contamination due to this isotope (Patel and Ganguly 1973).

Antifouling paints containing tributyltin compounds are used widely on netting panels of sea cages at fish and shellfish aquaculture units to minimize the obstruction of water exchange through the cages (Davies et al. 1987). Under these conditions, tributyltin paints were detrimental to the growth and survival of juvenile scallops and to calcium metabolism and growth of adult oysters (Paul and Davies 1986) and resulted in elevated concentrations of tributyltin in salmon tissues (Short and Thrower 1986; Davies and McKie 1987). Scallops (*Pecten maximus)* reared in sea pens for 31 weeks on nets coated with tributyltin oxide contained 2.5 mg total Sn/kg fresh weight soft parts (1.9 mg tributyltin/kg), but lost up to 40% during a 10-week depuration period. Scallop adductor muscle contained 0.53 mg tributyltin/kg, suggesting that this tissue--the one consumed by humans--is a probable tin storage site (Davies et al. 1986). Pacific oysters (*Crassostrea gigas*) reared for 31 weeks on tributyltin-exposed nets contained a maximum of 1.4 mg tributyltin/kg FW at week 16 (controls 0.12 mg/kg), but lost 90% during a 10-week depuration period (Davies et al. 1986). Atlantic salmon (*Salmo salar)* held for 3 months during summer in cages with tributyltin-treated net panels contained 0.75 to 1.5 mg tributyltin/kg fresh weight muscle vs. 0.28 mg/kg at start (Davies and McKie 1987). Based on laboratory studies, it is probable that Atlantic salmon were exposed to approximately 1.0 ug tributyltin/l during this interval (Davies and McKie 1987). Chinook salmon (*Oncorhynchus tshawytscha)*, reared in sea pens treated with tributyltin paints, contained <0.013 mg tributyltin/kg muscle fresh weight when introduced into the pens. Concentrations were 0.3 mg/kg after 3 months, 0.8 mg/kg at 13 months, and 0.9 mg/kg at 19 months. Cooking did not destroy or remove organotins from salmon muscle tissues (Short and Thrower 1986).

Table 7. Tin concentrations in field collections of living flora and fauna. Unless indicated otherwise, all values are in mg total Sn/kg fresh weight (FW) or dry weight (DW) tissue.

LETHAL AND SUBLETHAL EFFECTS

GENERAL

Inorganic tin compounds are of low toxicologic risk due largely to their low solubility, poor absorption, low accumulations in tissues, and rapid excretion. By contrast, some organotin compounds--especially trialkyltins--produce a variety of harmful effects resulting in impaired behavior and lowered growth, survival, and reproduction. Among aquatic organisms, tributyltin compounds were especially potent. Adverse effects were noted in molluscs at water concentrations of 0.001 to 0.06 ug/l and in algae, fish, and other species of invertebrates at 0.1 to 1.0 ug/l. Bioconcentration of organotins was high, but degradation was sufficiently rapid to preclude food chain biomagnification. Birds seem to be relatively resistant to organotins, although data are extremely scarce. Preliminary data suggest that diets containing 50 mg of tin as trimethyltin chloride/kg are fatal to all mallard ducklings in 75 days; however, no deaths occurred in 75 days at 50 mg/kg of eleven other mono-, di-, tri-, and tetraalkyltin compounds. Trimethyltin was lethal to other species of birds tested at doses of 1 to 3 mg/kg body weight. Trimethyltins and triethyltins were the most toxic organotin compounds tested on small laboratory mammals. Neurotoxicological effects of trimethyltins were usually not reversible, while those caused by triethyltins were reversible after exposure. Adverse effects of trimethyltins were produced at concentrations as low as 0.15 mg/l in drinking water (learning deficits), 0.625 mg/kg BW (diet aversion), and 1.25 mg/kg BW (death).

AQUATIC ORGANISMS

Results of acute toxicity tests with several organotin compounds and *Daphnia magna* indicated several distinct trends: toxicity increased with length of alkyl group from methyl to butyl; the anion substituents are relatively unimportant; and bioavailability is correlated with increasing solubility in lipids, which is a direct function of Kow, the n-octanol/water partition coefficient (Vighi and Calamari 1985). Structure-activity relations seem to have high predictive capacity in hazard assessment, and those for organotins seem particularly promising (Vighi and Calamari 1985). For example, studies on the biocidal properties of structurally distinct diorganotins (R_2SnX_2) and triorganotins (R_3SnX) to zoeae of a marine crab show, within a homologous series, that diorganotins are less toxic than the corresponding triorganotins (Table 8). It was concluded that the toxicity of organotins to crab zoeae seems to be a function of the hydrophobic characteristics conferred by the number and structure of the organic ligands (Laughlin et al. 1985).

Table 8. Toxicity of selected diorganotin and triorganotin compounds to zoeae of the marine mud crab (*Rithropanopeus harrisii*) exposed from hatching to age 14 days (modified from Laughlin et al. 1985).

Signs of tributyltin poisoning in rainbow trout and other freshwater teleosts include sluggishness; loss of appetite; altered body pigmentation; air gulping; loss of positive rheotaxis; increased rate of opercular movements; damaged gills, cornea, and epithelial cells of bile duct; and increases in blood hemoglobin, erythrocyte number, and hematocrit (Chliamovitch and Kuhn 1977; Thompson et al. 1985). These changes were consistent with the known inhibitory effects on mitochondrial and oxidative phosphorylation of triorganotin compounds. Suppression of regeneration in echinoderms, and presumably other aquatic groups, may be due

primarily to neurotoxicological action of orginotins, or secondarily by direct action on tissue at the breakage point (Walsh et al. 1986b).

Studies on lethal and sublethal effects of tin compounds to representative species of aquatic organisms demonstrate that organotin compounds are more toxic than inorganic tin compounds; triorganotin compounds are more toxic than mono-, di-, or tetraorgano forms; and tributyltin compounds are the most toxic triorganotin compounds tested (Table 9). Adverse effects of tributyltins were noted at water concentrations of 0.001 to 0.06 ug/l in marine gastropod and bivalve molluscs and at 0.1 to 1 ug/l in algae, echinoderms, fish, crustaceans and coelenterates (Table 9). In order of toxicity, tributyltins were followed by tripropyltins (harmful effects recorded at 0.001 to 10 ug/l to gastropods, fish, and algae), triphenyltins (0.6 to 1 ug/l to diatoms and annelids), triethyltins (3.8 to 10 ug/l to fish and algae), trimethyltins (20 ug/l to algae and crustaceans), and tripentyltins (50 to 100 ug/l to gastropods). Because many organotin compounds are slow-acting poisons, short-term toxicity tests seriously underestimate the toxicity of these compounds (Laughlin and Linden 1985).

Biological factors known to modify lethal and sublethal effects of organotins include age of the organism, inherent interspecies resistance, and tissue specificity. Abiotic modifiers include exposure route, and physicochemical regimen. Early developmental stages were more sensitive to organotins than later developmental stages in marine annelids (Walsh et al. 1986a), mysid shrimp (Hall and Pinkney 1985), and rainbow trout (Thompson et al. 1985). Mortality of zoeae of fiddler crabs (*Uca pugilator*) to trimethyltins was greatest at elevated temperatures and low salinities (Thompson et al. 1985). Mussels exposed through a diet of algae showed slow accumulation of organotins when compared to exposure from the medium; the reverse was observed for crabs (Evans and Laughlin 1984; Hall and Pinkney 1985; Laughlin et al. 1986a). A marine diatom (*Thalassiosira pseudonana*) showed no adaptation or resistance to triphenyltins or tributyltins (Walsh et al. 1985), but another diatom (*Amphora coffeaeformis*) was extremely resistant (Thomas and Robinson 1986, 1987). Finally, mortality was substantially higher when organisms were exposed simultaneously to organotins through water and sediments; in the case of grass shrimp (*Palaemonetes pugio*), the addition of contaminated sediments increased mortality by up to 1,000X (Clark et al. 1987).

Table 9. Lethal and sublethal effects of inorganic and organic tin compounds in ambient medium to selected species of aquatic organisms.

Compound and organism	Concentration (µg/L)	Effect	Reference[a]
Inorganic tins			
Dab (fish), *Limanda limanda*	35	No deaths in 96 h	1
Marine diatoms, 2 species	316 to 325	50% growth inhibition in 72 h	2

Marine diatom, *S. costatum*	35 to 56	50% growth inhibition in 72 h	2
Golden orfe	1,000	LC-50 (48 h)	5
Tributyltins			
Dogwhelk, *Nucella lapillus*	0.001 to 13%	Development of male 0.02 characteristics in	

		of female snails after 31 days, 27% in 91 days and 41% in 120 days. Whole body BCF values about 19,000x in 31 days, 36,000x in 91 days,78,000x in 120 days	7
Snail, *B. glabrata*	0.001	Reduction in egg deposition on continuous exposure from hatching	8
B. glabrata	0.1	Exposure for 34 days followed by 50-day recovery period produced 60% mortality, 80% reduction in egg deposition, and reduced growth	3
B. glabrata	0.4	LC-99 (30 days)	9
B. glabrata	1.0	50% reduction in egg laying after exposure for 2 to 3 weeks	3
B. glabrata	3	BCF of 48x in muscle after 120 h	3
B. glabrata	7	LC-100 (20 days)	9
B. glabrata	15	LC-100 (5 days)	9
B. glabrata	75	LC-100 (24 h)	4
Pacific oyster, *Crassostrea gigas*	0.01 to 0.02	Spat show reduced growth and hypoxia compensation after 2 weeks	10
C. gigas	0.15	Reduced growth and shell thickening after 8 weeks	11
C. gigas	0.2	BCF of ~ 6,000x in adult soft tissues in 21 days, 11,400x in whole spat in 56 days	3
C. gigas, larvae	1.0	LC-100 (12 days)	8
C. gigas, larvae	1.6	LC-100 (48 h)	12
C. gigas	1.6	No growth. BCF after 8 weeks varied from 2,300x to 3,100x	11
Copepod, *Eurytemora affinis*	0.0125	No adverse effects in 13 days	34
E. affinis	0.1	LC-74 (13 days)	34
E. affinis	0.5	Reduction in brood size in 48 h	34
E. affinis	0.6	LC-50 (72 h)	34
E. affinis	2.2	LC-50 (48 h)	34
Bay mussel, *Mytilus edulis*	0.05	Some larval deaths in 96 h	13
M. edulis, larvae	0.1	LC-50 (15 days)	14
M. edulis, larvae	0.24	Growth reduction after 45 days	12, 14
M. edulis	0.31	No shell growth in 66 days	14
M. edulis	0.4	Reduction in shell growth rate in 7days	15
M. edulis, adults	0.97	LC-50 (66 days)	14, 16
M. edulis, larvae	0.5	LC-100 (96 h)	13
European oyster, *Ostrea edulis*	0.06	Reduced growth rate in 10 days	14
O. edulis	0.24	No larval release after	

		exposure for 74 days; BCF of 875x	17
O. edulis	2.6	Reduced growth in 74 days; BCF of 397x	17
O. edulis, larvae	3.4	LC-50 (48 h)	17
Marine algae, 3 species	0.1	Reduced growth rate in 48 h	18
Brittle star, *Ophioderma brevispina*	0.1	Arm regeneration inhibited	19
Sheepshead minnow, *Cyprinodon variegatus*	0.18 to 1.0	Maximum BCF's after 167 days were 1,600x in muscle, 3,900x in viscera, 52,000x in liver; no adverse effects on growth or reproduction	20
C. variegatus	0.96	LC-50 (21 days)	8
C. variegatus	1.6	Maximum BCF's after 58 days were 1,810x in muscle, 2,120x in head, 4,580x in viscera, and 2,600x in whole fish. Loss after 28 days depuration ranged from 64% to 80%	20
C. variegatus	3.2	LC-100 (21 days)	20
C. variegatus	5 to 8	LC-50 (96 h)	3
C. variegatus	18	LC-50 (7 days)	8
Oysters, several species	0.2	LC-70 (113 days)	8
Rainbow trout, *Salmo gairdneri*	0.2 to 1.0	Exposure of yolk-sac fry for 110 days produced liver disfunction, reduced growth, and altered blood chemistry; no deaths	8, 21
S. gairdneri	5	Kidney degeneration in 12 days, some deaths	21
S. gairdneri	11. to 20	LC-50 (96 h)	5, 22
S. gairdneri	11.7	Bile duct pathology after 5 days; destruction of corneal epithelium after 7 days	3
S. gairdneri	21	LC-50 (48 h)	9
S. gairdneri	28	LC-50 (24 h)	23
Baltic amphipod, *Gammarus oceanicus,* larvae	0.3	Reduced survival after 5 weeks	24
G. oceanicus	3	LC-100 (16 days)	3
Alga, *Skeletonema costatum*	0.33 to 0.36	50% growth inhibition in 72 h	2
Copepod, *Acartia tonsa*	0.4	50% immobilization in 144 h	25
A. tonsa	0.55	LC-50 (6 days)	8
A. tonsa	1.0	LC-50 (96 h)	25
Fiddler crab, *Uca pugilator*	0.5	Limbs regenerated during	

		19 days showed a variety of deformities and retardation of regenerative growth	26, 35
U. pugilator	0.5 to 50	Non-dose dependent reduction in burrowing activity in 15 to 60 min; hyperactivity in 1 to 3 weeks	36
Mysid shrimp, *Metamysidopsis elongata,* juveniles	0.5 to 1.0	LC-50 (96 h)	3
American oyster, *Crassostrea virginica*	0.73 to 1.9	Reduced larval growth in 66 days	16
C. virginica, larvae	0.9	50% immobilization in 48 h	12
Hydroid, *Campanularia flexuosa*	1.0	100% growth inhibition in 11 days	3
Cladoceran, *D. magna*	1.0	Reduced survival and impaired reproduction in 15 days	14
D. magna	1.7	LC-50 (48 h)	12
D. magna	3	LC-50 (24 h)	23
American lobster, *Homarus americanus*	1.0	No effect on larval metamorphosis in 6 days	8
H. americanus, larvae	5	LC-100 (6 days)	25

Freshwater clam, *Anodonta anatina*	5	LC-100 (6 weeks)	29
Mud snail, *Nassarius obsoletus*	5 to 6	Induced male characteristics in females in 64 days	3
N. obsoletus	8	LC-50 (61 days)	3
Tubifex worm, *Tubifex tubifex*	6	LC-50 (48 h)	9
Amphipod, *Orchestia traskiana*	6	LC-47 (9 days)	3
O. traskiana	10	LC-80 (9 days)	3
O. traskiana	15	LC-93 (9 days)	3
Mud crab, *Rithropanopeus harrisii*	6	BCFs after 4 days were 650x in muscle,	

		4,400x in hepatopancreas, and 1,300x in gill	37
R. harrisii	15	Weight loss after 15 days	3, 37
Bluegill, *Lepomis macrochirus*	7.6	LC-50 (96 h)	12
L. macrochirus	33	LC-50 (48 h)	8
Mysid shrimp, *Mysidopsis bahia*	8	LC-50 (96 h)	30
Mummichog (fish), *Fundulus heteroclitus*	9	Avoidance	3
F. heteroclitus	24	LC-50 (96 h)	12
Crab, *Carcinus maenus*	10	LC-50 (96 h)	3
Amphioxus, *Branchiostoma caribaeum*	10	LC-100 (96 h)	30
Snail, *Neritina* sp.	10	LC-100 (6 days)	3
Snails, *Biomphalaria* spp.	10 to 30	LC-50 (24 h)	8
Channel catfish, *Ictalurus punctatus*	12	LC-50 (96 h)	8
Marine diatom, *S. costatum*	14.7	LC-50 (72 h)	2
Snail, *Lymnaea* sp.	15	LC-100 (~5 days)	3
Atlantic menhaden, *Brevoortia tyrannus*	15	Avoidance by juveniles	3
Speckled sanddab, *Citharichthys stigmaeus*	20	LC-50 (96 h)	3
Grass shrimp, *Palaemonetes pugio*	20	LC-50 (96 h)	30
Green alga, *Ankistrodesmus falcatus*	20	BCF of ~ 30,000x at day 7	23
A. falcatus	40	BCF of 8,600x at day 7	23
Guppy, *Poecilia reticulata*	21 to 30	LC-50 (96 h)	8
P. reticulata	26 to 34	LC-50 (48 h)	5
Mozambique tilapia, *Tilapia mossambica*	28	LC-50 (24 h)	8
Duckweed, *Lemna media*	30	Reduced growth in 10 days	31
Snail, *Australorbis glabratus*	30	LC-100 (5 days)	31
European frog, *Rana temporaria*, tadpole	30	LC-50 (5 days)	32
R. temporaria, tadpole	75	LC-100 (24 h)	9
Harlequin fish, *Rasbora heteromorpha*	42	LC-50 (48 h)	8
Jewelfish, *Hemichromus bimaculatus*	45	LC-70 (48 h)	8
Fathead minnow, *Pimephales promelas*	45	LC-50 (96 h)	8
Golden orfe	50	LC-50 (48 h)	5
Cladoceran, *Daphnia longispina*	60	LC-100 (72 h)	31
Bleak (fish), *Alburnus alburnus*	70 to 400	LC-50 (96 h)	5
Goldfish, *Carassius auratus*	75	LC-100 (24 h)	31
Duckweed, *Lemna media*	500	LC-100 (10 days)	31
Tetrabutyltins			
Golden orfe	10,000	LC-50 (48 h)	5

Tripentyltins			
Snail, *B. glabrata*	50 to 100	LC-50 (24 h)	4
Triphenyltins			
Marine diatoms, 2 species	0.6 to 1.1	50% growth inhibition in 72 h	2
Lugworm, *A. cristata*	0.75–1.0	Abnormal larval development	28
A. cristata, larvae	1.5 to 2.5	LC-0 (168 h)	28
A. cristata, larvae	4 to 10	LC-100 (96 h)	23
Algae, various species	2 to 20	50% growth inhibition in 4 h to 8 days	3
Marine diatom, *S. costatum*	4.3 to 13.8	LC-50 (72 h)	2
Copepod, *Nitroca spinipes*	8	LC-50 (96 h)	3
Snail, *B. glabrata*	10 to 1,000	LC-50 (24 h)	4
Rainbow trout	15	LC-50 (96 h)	30
Snail, *Biomphalaria sudanica*	17	LC-50 (24 h)	3
Cladoceran, *D. magna*	20	LC-100 (30 days)	3
Cladoceran, *D. longispina*	50	LC-100 (48 h)	33
Snail, *Australorbis glabratus*	50	LC-100 (7 days)	33
A. glabratus	200	LC-100 (72 h)	33

Aside from direct toxic effects that antifouling paint residues may have on marine life, there is no evidence of any risk from cytogenetic damage. Tributyltins, for example, were not genotoxic to larvae of the mussel (*Mytilus edulis*) based on results of sister chromatid exchange and analysis of chromosomal aberrations (Dixon and Prosser 1986). Teratogenic effects, however, were detected in larvae of the lugworm (*Arenicola cristata*) at sublethal concentrations of tributyltins (Walsh et al. 1986a), and algae (*Nitzschia liebethrutti*) exposed to 15 mg inorganic Sn/l for 14 days had frustule abnormalities (Saboski 1977).

Bioconcentration of inorganic and organic tin compounds from the medium is considerable. Bioconcentration factors (BCF's) for inorganic tin and marine algae were about 1,900X; moreover, tin-resistant bacteria contained a remarkable 3.7 to 7.7 grams Sn/kg dry weight (Maguire et al. 1984). BCF's for organotin compounds varied from about 400X to 30,000X among various species of molluscs, algae, and crustaceans and were highest when ambient tin concentrations were <1.0 ug/l, when exposure times were comparatively lengthy, and when organism lipid content was elevated (Thompson et al. 1985;Champ 1986; Laughlin et al. 1986a; Thain and Waldock 1986). Sheepshead minnows (*Cyprinodon variegatus*) were unable to reach equilibrium with a medium containing 1.61 ug tributyltin/l after 58 days of exposure and maximum BCF values recorded were 2,600X in whole fish, 1,810X in muscle, 4,580X in viscera, and 2,120X in the remainder of the carcass; however, whole body loss was 52% after depuration for 7 days and 74% after 28 days (Ward et al. 1981). Sheepshead minnows were able to metabolize tributyltins into lower alkyl moieties, which were less toxic. Thus, even though significant bioconcentration occurred, the chronic toxicity of tributyltins to sheepshead minnow was not significantly greater than its acute toxicity (Ward et al. 1981).

Benthic fauna are probably capable of transferring organotins from sediments to bottom-feeding teleosts. For example, sediments spiked with 0.98 mg Sn/kg dry weight, as tributyltin, resulted in concentrations of 4.41 mg/kg whole body dry weight in oligochaete annelid worms after 22 weeks, up from 0.38 at the start (Maguire and Tkacz 1985).

Imposex--the superimposition of male characteristics onto a functionally normal female reproductive anatomy--is a phenomenon documented in populations of marine gastropod molluscs in the vicinity of yacht basins and marinas and is a sensitive indictor of tributyltin contamination. A female with imposex displays one or more male characteristics such as a penis, a vas deferens, or convolution of the normally straight gonadal oviduct. It is measured by frequency of occurrence in the adult females and by the intensity of expression of all male characteristics in bearer females. Imposex is prevalent in mud snails (*Nassarius obsoletus*) near estuarine marinas and has been induced experimentally in that species by exposure for 60 days to three tributyltin compounds at concentrations of 4.5 to 5.5 ug/l (Smith 1981a,b). Imposex has been documented extensively in declining populations of the common dogwhelk (*Nucella lapillus*), especially in southwestern England (Bryan et al. 1986, 1987; Gibbs and Bryan 1986; Davies et al. 1987; Gibbs et al. 1987). These authorities agree on six points: (1) dogwhelk populations near centers of boating and shipping activity show the highest degrees of imposex, coinciding with the introduction and increasing use of antifouling paints containing tributyltin compounds; (2) imposex is not correlated with tissue burdens of arsenic, cadmium, copper, lead, silver, or zinc, but is correlated with increasing concentrations of tributyltin and dibutyltin fractions; (3) transplantation of dogwhelks from a locality with little boating activity to a site near a heavily used marina causes a marked increase in the degree of imposex and in tissue accumulations of tributyltins; (4) imposex can be induced in female dogwhelks by exposure to 0.02 ug Sn/l leached from a tributyltin antifouling paint; after exposure for 120 days, 41% of the females had male characters and whole body residues of 1.65 mg Sn/kg dry weight soft parts (vs. 0.1 in controls), of which almost all was tributyltin (1.64 vs. 0.08 mg/kg in controls). Concentrations as low as 0.0015 ug tributyltin/l can initiate imposex in immature females; (5) declining dogwhelk populations studied were characterized by a moderate to high degree of imposex, relatively fewer functional females, few juveniles, and a general scarcity of laid egg capsules. Many females in late imposex contained aborted capsules as a result of oviduct blockage, resulting in sterility and premature death; and (6) there was no evidence that loss of tin leads to any remission of imposex; in fact, all evidence indicates that gross morphological changes that occur in late imposex are irreversible. It is clear that additional research is needed on the imposex phenomenon in molluscs and on its implications to vertebrates and other taxonomic groups.

BIRDS

Information is scarce on the effects of tin and organotin compounds on birds. However, limited data suggest that triorganotin compounds, especially trimethyltins--and to a lesser extent triethyltins--are the most toxic (Table 10).

Dr. W. James Fleming of the Patuxent Wildlife Research Center has recently concluded a 75-day feeding study with mallard ducklings (*Anas platyrhynchos*) and 12 organotin compounds. Preliminary results indicated that trimethyltin was the most toxic compound tested. A dietary level of 50 mg of Sn as trimethyltin chloride/kg food was fatal to all ducklings; 5 mg/kg killed 40%, but all survived at 0.5 mg/kg diet. Death was preceded by mild to severe tremors, progressing to ataxia and lethargy. Large neurons of the pons, medulla oblongata, gray matter of the spinal cord, and cells of the cerebral cortex exhibited degeneration and necrosis. All ducklings survived exposure to 50 mg/kg ration of tetraethyltin, tetrabutyltin, tetraphenyltin, triethyltin chloride, tripropyltin chloride, tributyltin chloride, tributyltin oxide, triphenyltin chloride, tricyclohexyltin chloride, dimethyltin chloride, and dibutyltin chloride (Fleming, personal communication). Sublethal effects were recorded at 50 mg triethyltin chloride/kg (low body weight, vacuolization of spinal cord and brain white matter), at 50 mg tributyltin chloride/kg (enlarged liver), and at 50 mg tetrabutyltin/kg (elevated kidney weight). Residue and other analyses are now in progress.

Table 10. Lethal and sublethal effects of selected organotin compounds to birds.

Compound and organism	Effect (reference)
Dialkyltins	
Japanese quail, *Coturnix japonica*	No measurable effect at dietary levels of 150 mg/kg for 2 weeks (Seinen et al. 1977b)
Trialkyltins	
Mallard, *Anas platyrhynchos*	Ducklings fed diets containing 50 mg trimethyltin chloride/kg died within 60 days (personal communication, Dr. W. James Fleming, Patuxent Wildlife Research Center)
Pigeon, *Columba* sp.	Trimethyltin injections (3 intra-muscular injections, 2 weeks apart) at 1.0 mg/kg body weight interfered with ability to perform motor tasks; no evidence of cumulative effects (Idemudia and McMillan 1986b)
Domestic chicken, *Gallus* sp.	Single oral dose of 3 mg trimethyltin/kg body weight produced tremors, convulsions, and death within 24 h (Stoner et al. 1955)
Pigeon	Triethyltin injections (4 intramuscular injections, 2 weeks apart) at 1.75 mg/kg body weight resulted in total suppression of pecking behavior for 3 h; recovery underway by 27 h post-injection (Idemudia and McMillan 1986a)
Domestic chicken	Single oral dose of 3 mg triethyltin sulfate/kg body weight resulted in immediate collapse, salivation, convulsions, and death in a few min; at 2 mg/kg, bird was unconscious for 1 to 1.5 h postadministration, with recovery beginning in 1 day (Stoner et al. 1955)
Domestic chicken	Feeding of 160 mg triethyltin hydroxide/kg diet for 15 weeks was not fatal, but caused muscular weakness and some diet avoidance (Stoner et al.1955)
Japanese quail	Acute oral LD-50 of tricyclohexyltin hydroxide varies between 255 and 390 mg/kg body weight; dietary levels of 20 mg/kg had no measurable effect on growth, survival, or reproduction (Zuckerman et al. 1978)
Domestic chicken	Acute oral LD-50 of 654 mg of tricyclohexyltin hydroxide (Smith 978a)
Tetraalkyltins	
Domestic chicken	Daily doses >0.0001 mg tetraethyltin/ kg body weight produced Adverse effects on blood chemistry and CNS (Duncan 1980)

MAMMALS

Inorganic tin compounds and some heterocyclic organic tin compounds are of low toxicologic risk to mammals (Table 11), due largely to their low solubility, poor absorption, low tissue accumulations, and rapid tissue excretion (Hiles 1974; Kimbrough 1976). Inorganic tin compounds accumulate mostly in liver and kidney, rarely in brain, in proportion to dose and regardless of the exposure route (Hassett et al. 1984). Noncyclic organotin compounds, by contrast, have produced adverse effects on the skin, eyes, gastrointestinal tract, liver, bile duct, kidney, hematopoietic system, central nervous system, reproduction, growth, and chromosomes of small laboratory animals (Table 11). Effects of diorganotin compounds can be distinguished from those of tri- and tetraorganotin compounds. The chief toxicological difference is that some trialkyltins have a specific effect on the central nervous system resulting in cerebral edema, whereas diorganotins do not produce this effect but are potent irritants that induce inflammatory reactions. The tetraorganotins resemble triorganotins, which are usually more toxic than either mono- and diorganotins (WHO 1980; Table 11).

Diorganotin compounds cause cerebral edema and inhibit mitochondrial respiration by preventing the oxidation of keto acids, presumably through inhibition of alpha-keto oxidase activity (Piver 1973; WHO 1980). Large interspecies variability exists in the capacity of diorganotins to induce lymphoid atrophy. For example, dioctyltins and dibutyltins were selectively cytotoxic to rat thymocytes after dietary exposures of 50 to 150 mg/kg diet for 2 weeks; in contrast, no lymphoid atrophy occurred in mice, guinea pig, or Japanese quail given similar dosages and exposures (Seinen et al. 1977a,b). Route of exposure can also modify effects of diorganotins. Oral exposure to dibutyltin compounds, for example, produces inflammatory changes in bile duct of rat and necrotic changes in liver of mice and rats; dermal exposure causes bile duct injury in rats and rabbits; and intravenous administration produces pulmonary edema in rats (WHO 1980). Intratesticular administration of high doses of some dibutyltins produced marked degeneration in rat testes within 7 days, including atrophy of seminiferous tubules and complete arrest of spermatogenesis; however, similar results have been reported for cadmium, zinc, and copper salts (Saxena et al. 1985).

Table 11. Effects of tin compounds on selected species of animals.

Tin compound, organism	Dose	Effect (reference)[a]
Inorganic tins		
Rat, *Rattus* sp.	6.7 mg/kg body weight (BW)	Single intraperitoneal (ip) injection caused deficits in auditory startle habituation tests (1)
Dog, *Canis familiaris*	54 mg/kg BW	LD-100, single oral dose (2)
Rat	20 to 30 mg/kg BW, or 1.0 g/kg diet	No observed effect level after 13 weeks (3)
Rat	188 mg/kg BW	LD-50, single oral dose of tin fluoride (4)
Rat	700 mg/kg BW	LD-50, single oral dose of tin chloride (4)
Rat	2,275 mg/kg BW	LD-50, single oral dose of Sn^{+2} (3)
Rat	10 g/kg diet	Normal growth after 4 weeks (3)
Rat	>10 g/kg BW	LD-50, single oral dose of SnO (4)
Mouse, *Mus* sp.	Radiotin-113	50% clearance after 29 days following ip injection (5)
Methyltins		
Rat	120 mg/L drinking water	Impaired learning of pups when dam consumed Sn-laced water throughout 21-day gestation (6)
Rat	575 to 1,370 mg/kg BW	LD-50, single oral dose (7, 8)

Rat	600 mg/L	LC-50, aerosol dose for 1 h (7)
Ethyltins		
Rat	200 mg/kg BW	LD-50, single oral dose (7)
Butyltins		
Mouse	1,400 to >6,000 mg/kg BW	LD-50, single oral dose (3)
Rat	2,220 to 2,300 mg/kg BW	LD-50, single oral dose (7)
Octyltins		
Rat	2,400 to 3,800 mg/kg BW	LD-50, single oral dose (7)
Mouse	4,600 mg/kg BW	LD-50, single oral dose (3)
Dimethyltins		
Rat	74 to 237 mg/kg BW	LD-50, single oral dose (7)
Rat	1,070 mg/L	LC-50, aerosol dose for 1 h (7)
Diethyltins		
Rat	40 to 100 mg/kg BW	LD-50, single oral dose (9)
Dibutyltins		
Rat	0.1 and 1.0 mg/kg BW	Kidney damage after 12-month dietary exposure (3)
Mouse	1 to 10 mg/L drinking water	Reduction in tumor growth rates (10)
Rat	2 mg/kg BW daily or 40 mg/kg diet	No observable effect level after 90 days (9)
Rat, mouse	10 mg/kg BW	Dermal application daily for 10 days causes severe effect on skin and bile duct (3)
Mouse	35 to 112 mg/kg BW	LD-50, single oral exposure (9)
Rat	80 mg/kg diet	Slight reduction in growth rate and food intake; mild anemia after 90 days (9)
Rat	100 to 520 mg/kg BW	LD-50, single oral dose (8)
Dioctyltins		
Rat	50 or 150 mg/kg diet	After 6 weeks altered immune function as evidenced by inhibition of T-lymphocyte activity (11)
Guinea pig, *Cavia* sp.; mouse	50 or 150 mg/kg diet	No evidence of altered immune function (11)
Rat	945 to 7,000 mg/kg BW	LD-50, single oral exposure (7, 8, 9)
Mouse	1,140 to 4,000 mg/kg BW	LD-50, single oral exposure (9)
Trimethyltins		
Rat	0.15 to 1.0 mg/L in drinking water	Dams consuming contaminated water throughout 21-day gestation pro-

		duced pups with decreased learning ability at age 11 days (6)
Rat	0.625 mg/kg BW	3 ip doses resulted in flavor aversion (12)
Cynomolgus monkey, *Macaca fascicularis*	0.75 mg/kg BW	Single intravenous (iv) injection produced reduced appetite 7 days postexposure (13)
Cynomolgus monkey	1.1 mg/kg BW	Single iv injection resulted in tremors, hyperactivity, ataxia, stupor, unconsciousness (13)
Cynomolgus monkey	1.25 mg/kg BW	Single iv injection is fatal within 4 days (13)
Cynomolgus monkey	1.5 mg/kg BW	Single iv injection is fatal within 2 days (13)
Cynomolgus monkey	3.0 mg/kg BW	Single iv injection is fatal within 24 h (13)
Hamster, *Cricetus* sp.	About 3.0 mg/kg BW	LD-100, single oral dose (14, 15)
Rat	3.0 mg/kg BW	Loss in body weight and disrupted diurnal pattern of drinking and in rearing young after single oral dose, 2-week observation period (16)
Mouse	3.0 mg/kg BW	Single ip dose produced hypoactivity and impaired motor activity (12)
Marmoset, *Callithrix jacchus*	About 3.0 mg/kg BW	LD-50, single oral dose (14, 15)
Gerbil, *Gerbillus* sp.	About 3.0 mg/kg BW	LD-50, single oral dose (14, 15)
Man, *Homo sapiens*	About 3.0 mg/kg BW	LD-50, single oral dose (14, 15)
Rat	<4 mg/kg BW	No effect following stomach gavage route of administration (1)
Rat	5 mg/kg BW	Single oral dose produces hyperactivity (12)
Rat	6 mg/kg BW	No significant effect on behavior (17)
Rat	7 mg/kg BW	Significantly altered behavior (17)
Rat	>8 mg/kg BW	Lethal within 4 days after stomach gavage (1)
Rat	9.1 to 30 mg/kg BW	LD-50, single oral dose (9, 18)
Rat	15 mg/kg diet	Neuronal degradation in 2 weeks (19)
Rat	16 mg/kg BW	LD-50, single ip dose (2)
Rat	30 mg/kg BW	LD-100, single oral dose (7)
Triethyltins		
Rat	0.25 mg/kg BW	Impaired response to pain after 14 subcutaneous (sc) injections (12)
Rat	0.38 mg/kg BW	Flavor aversion after 2 ip doses (12)
Rat	1.0 mg/kg BW	Reduced amplitude startle response after 3 oral doses (12)
Rat	1.5 mg/kg BW	Hypoactivity, single sc injection (12)
Mouse	2.0 mg/kg BW	Hypoactivity, 27 days after single ip injection (12)
Rat	4.0 to 9.0 mg/kg BW	LD-50, single oral dose (8)

Guinea pig	5 to 10 mg/kg BW	LD-50, single oral dose (9)
Rat	5 mg/L in drinking water for 15 days followed by 10 mg/L for 15 days	Brain edema (20)
Rat	10 mg/kg BW	LD-50, single ip dose (2)
Rat	10 mg/kg BW	LD-100, single oral dose (7)
Rabbit, *Lepus* sp.	10 mg/kg BW	LD-50, single ip dose (2)
Rabbit	10 mg/kg BW	LD-50, single oral dose (8)
Rabbit, rat, guinea pig	10 mg/kg BW	LD-100, single oral dose (21)
Rat	15 mg/kg diet	Cerebral edema in 2 weeks (19)
Rat	20 mg/kg diet	After 7 days, decreased food intake; after 3 to 4 weeks, hind limb weakness and some deaths; on return to normal diet, signs of poisoning gone in 7 days with normal weight in 4 weeks (21)
Rabbit	40 mg/kg diet	Muscular weakness after chronic exposure (21)
Tripropyltins		
Rat	44 to 120 mg/kg BW	LD-50, single oral dose (4, 8)
Tributyltins		
Rabbit	0.04 mg/kg BW	After 16 weeks, central nervous system dysfunction (20)
Guinea pig	0.2 mg/L air	Ocular and nasal irritation, asphyxic convulsions, death within 1 h (20)
Mouse	0.2 mg/kg BW	Reduces mammary tumor growth rate; adversely affects thymus gland growth (22)
Rat	0.36 to 0.95 mg/kg BW	Single dermal application causes skin irritation (3)
Rat	10 mg/kg BW	LD-50, single ip dose (2)
Rabbit	12 mg/kg BW	Daily doses for 6 months were not fatal; signs of intoxication disappeared within a few weeks after withdrawal (20)
Guinea pig	20 mg/kg BW	LD-50, single oral dose (9)
Rat	32 mg/kg diet	Impaired growth after 30 days (20)
Mouse	46 to 230 mg/kg BW	LD-50, single oral dose. LD-50 values were lowest for tributyltin acetate (46 mg/kg BW) followed by benzoate

		(108), chloride (117), laurate (180), and oleate (230) (9)
Rat	50 to 380 mg/kg BW	LD-50, single oral dose (7, 8, 9)
Rabbit	60 mg/kg BW	LD-50, single oral dose (9)
Rat	150 mg/kg diet	61% reduction in thymus weight after 2 weeks (19)
Rat	320 mg/kg diet	Some deaths in 30 days (20)
Triphenyltins		
Rat	0.6 mg/kg BW daily	After 6 weeks, diminished exploratory behavior in maze and significantly more errors in maze learning (23)
Guinea pig	3.7 mg/kg BW	LD-50, single ip dose (2)
Guinea pig	10 to 24 mg/kg BW	LD-50, single oral dose (2, 9)
Guinea pig	25 to 50 mg/kg diet	At 25 mg/kg, 83% dead in 77 days; at 50 mg/kg, all dead by day 29 (7)
Rat	25 to 300 mg/kg diet	No measurable effect at 25 mg/kg in 170 days; some lesions at 50 mg/kg in 105 days; impaired growth at 200 mg/kg in 70 days; weight loss and some deaths at 300 mg/kg in 117 days (7)
Rat	34 mg/kg BW	LD-50, single ip dose (23)
Mouse	81 to 245 mg/kg BW	LD-50, single oral dose (3)
Rat	118 to 268 mg/kg BW	LD-50, single oral dose (7, 8)
Trihexyltins		
Rat	1,000 mg/kg BW	LD-50, single oral dose (8)
Tricyclohexyltins		
Dogs, rats	6 to 12 mg/kg diet	Some weight loss in 2 years, but no other toxic effects (20)
Rat	13 mg/kg BW	LD-50, single ip dose (2)
Sheep, *Ovis* sp.	15 to 150 mg/kg BW	No observed effect at injected dose of 15 mg/kg BW; adverse effects at 25 to 50 mg/kg; death at 150 mg/kg (8)
Rat	25 mg/kg BW	Gastroenteritis after 19 days (3)
Rat	235 to 650 mg/kg BW	LD-50, single oral dose (20)
Rabbit	500 to 1,000 mg/kg BW	LD-50, single oral dose (7)
White-footed mice, *Peromyscus leucopus*	710 mg/kg BW	LD-50, single oral dose (3)
Guinea pig	780 mg/kg BW	LD-50, single oral dose (7)
Dogs, monkeys, cats (*Felis domesticus*)	>800 mg/kg BW	LD-50, single oral dose (8)
Mouse	1,070 mg/kg BW	LD-50, single oral dose (3)
Trioctyltins		
Rat	29,200 mg/kg BW	LD-50, single oral dose (7)

Tetramethyltins		
Rat	195 to 331 mg/kg BW	LD-50, single oral dose (7)
Tetraethyltins		
Rabbit	7 mg/kg BW	LD-50, single oral dose (8)
Rat	9 to 16 mg/kg BW	LD-50, single oral dose (8)
Mouse	40 mg/kg BW	LD-50, single oral dose (3)
Guinea pig	40 mg/kg BW	LD-50, single oral dose (3)
Tetrabutyltins		
Rat	6,000 mg/kg BW	LD-50, single oral dose (7)

Trimethyltin, triethyltin, and tributyltin compounds are highly toxic to animals and man. Trimethyltin and triethyltin compounds are more toxic to mammals than are the higher triorganotin homologues, probably because of poorer absorption of higher trialkyltin compounds from the gastrointestinal tract (Kimbrough 1976; WHO 1980). Trimethyltin and triethyltin compounds are potent inhibitors of oxidative phosphorylation in the mitochondria for which these compounds have a high binding affinity (WHO 1980). Different triorganotin compounds cause different neuronal patterns of toxicity in adult animals (Reiter and Rupert 1984). Trimethyltins, for example, produce largely irreversible behavioral impairments, such as hyperactivity and impaired learning and performance, and these are consistent with reported neuronal cell death in limbic system structures. Triethyltins, with their direct effect on muscle--consistent with reports of myelin vacuolation and cerebral edema--produce largely reversible effects (Reiter and Ruppert 1984). Differences in chronic toxicity between triethyltins and trimethyltins have resulted in different strategies in assessment of hazard. Evaluations of triethyltin have focused on repeated testing throughout dosing, followed by a recovery period. But evaluations of trimethyltin-induced behavioral impairments have generally focused on testing weeks to months after exposure (Reiter and Rupert 1984).

Symptoms of trimethyltin intoxication in man include irritability, headache, depression, aggressiveness, disorientation, appetite loss, memory deficits, and decreased libido; changes were largely reversible following cessation of exposure (Reiter and Ruppert 1984; Reuhl et al. 1985). At high doses, trimethyltins cause death in primates and humans, preceded by seizures, anorexia, and emotional lability (Brown et al. 1984). Trimethyltin produced adverse effects in laboratory animals over an unusually narrow dose range, with differences of 10X or less between doses producing no observable effects and those producing 100% mortality in all species tested (McMillan and Wenger 1985). Trimethyltin effects in small laboratory animals are usually not reversible. Signs of trimethyltin poisoning include tremors, hyperexcitability, aggressive behavior, weight loss, neuronal destruction in hippocampus and other portions of the brain, seizures, learning and memory impairment, self-mutilation, altered sensitivity to stimuli, and disrupted patterns of drinking and eating (Aldridge et al. 1981; Brown et al. 1984; Hassett et al. 1984; Reiter and Ruppert 1984; Bushnell and Evans 1985; McMillan and Wenger 1985; Reuhl et al. 1985). Trimethyltin-induced behavioral disruptions usually peak 3 to 5 days after exposure, but effects persist for extended periods and seem to be irreversible (Reiter and Ruppert 1984; McMillan and Wenger 1985). Rats sometimes survive the trimethyltin behavior syndrome and appear outwardly normal, although later neuropathological examination shows extensive bilateral damage, including hippocampus shrinkage and cell loss (Aldridge et al. 1981).

Triethyltins were the most potent organotins tested on mammals, although other organotins produced similar signs of poisoning (Table 11). Mammals poisoned by triethyltin compounds showed muscle weakness within hours of dosing; after a short period of recovery, tremors developed, leading to convulsions and death 2 to 5 days after dosing. Although toxicity produced by triethyltins becomes more pronounced with continued exposure, reversal of behavioral deficits occurs within weeks after dosing is terminated (Reiter and Ruppert 1984). Initial reaction to triethyltin exposure in rats was fluid accumulation in white matter of the central nervous

system, which persisted for as long as the compound was administered; after administration the effects reversed (Piver 1973). There is general agreement that triethyltin-induced behavioral changes are accompanied by cerebral edema, neurodegenerative disorders, interference with oxidative phosphorylation, and disrupted metabolism of glucose and enzyme activity (Kimbrough 1976; Hassett et al. 1984; Reiter and Ruppert 1984; McMillan and Wenger 1985; Reuhl et al. 1985; Linee and Hennon 1986).

Triphenyltins are skin and eye irritants to rats and rabbits (WHO 1980). They do not accumulate in rats, dogs, and guinea pigs although some triphenyltin acetate was partly absorbed by cattle and sheep--with most excreted in 6 to 8 weeks (Duncan 1980). Thymus atrophy was associated with a lymphocyte depletion in the thymic cortex and is the predominant effect of the intermediate trialkyltins. Intermediate trialkyltin homologues caused a dose-related reduction of thymus weight in male rats after 2 weeks on diets containing 150 mg organotin/kg; decreases were 19% for triphenyltin, 47% for tripropyltin, and 61% for tributyltin (Snoeij et al. 1985). Tributyltins and other organotins induce chromosomal aberrations in mammals, although this was not observed in tests with aquatic invertebrates (Dixon and Prosser 1986).

Tetraorganotin compounds produce muscular weakness, paralysis, respiratory failure, tremors, and hyperexcitability as acute effects in mice and dogs; latent effects are similar to those seen in triorganotin poisoning (WHO 1980). Tetramethyltin, for example, produces the same toxic syndrome as trimethyltin in rats because it is rapidly dealkylated in vitro to the latter compound (Aldridge et al. 1981). Signs of triorganotin poisoning in rabbits were evident shortly after administration of tetraorganotin compounds, suggesting that triorganotins were soon distributed to the site of action in amounts sufficient to produce signs of poisoning (Arakawa et al. 1981). The dealkylation and distribution of tetraorganotins are related to alkyl chain length and to their accumulations in tissues, including brain. In 3-hour studies with rabbits, at intravenous dosage rates of 2 to 3 mg/kg BW, tetraethyltin was quickly distributed to liver, but tetrapropyltin and tetrabutyltin were slowly distributed (Arakawa et al. 1981). Tetraethyltin was more readily converted into the corresponding trialkyltin than was tetrapropyltin. About 20% of the tetraethyltin, 4% of the tetrapropyltin, and 1% of the tetrabutyltin were converted to their corresponding trialkyltins. Thus, the extent of formation of triorganotins decreased as the size and stability of the ligand increased. There was poor distribution of tetraorganotins to brain, but the amounts of triorganotin metabolites found in brain increased over time. Particularly, the transfer of triethyltin to the brain was significant and compatible with the appearance of signs of toxicity. It was concluded that the extent of the dealkylation and the toxicity of organotin compounds depends on the length of their alkyl group, which was associated with their rate of absorption and ultimate distribution (Arakawa et al. 1981).

Organotin compounds are not mutagenic, teratogenic, or carcinogenic, as judged by largely negative but incomplete evidence (Duncan 1980; WHO 1980; Cardarelli et al. 1984b). It has been suggested that some organotins retard the onset and growth of cancer in laboratory animals and that the anticarcinogenic action is mediated through the thymus gland (Cardarelli et al. 1984b). The absence of tin in tissues may also be associated with tumor development (Cardarelli et al. 1984)). In one study, mice with cancer-prone mammary glands and transplanted mammary tumors had significantly reduced tumor growth rates after oral dosing with tributyltin fluoride (Cardarelli et al. 1984b). In another study, tumor growth rates were significantly reduced in mice continuously exposed to various diorganotin compounds in drinking water at I and 10 mg/l (Cardarelli et al. 1984a). It is hypothesized that the unknown thymic organotins are antagonistic to cancers in mice and possibly man (Cardarelli et al. 1984a, b). Additional research on potential anticarcinogenic properties of organotins is clearly indicated.

TERRESTRIAL INVERTEBRATES

Resistance to organotin acaricides has been reported in several populations of spider mites. After cyhexatin and fenbutatin oxide were used for 10 to 17 years on pears and apples to control mites, populations of McDaniel spider mite (*Tetranychus mcdanieli*), two-spotted spider mite (*T. urticae*), and European red mite *Panonychus ulmi*) slowly began to develop strains that were resistant to these chemicals (Croft et al. 1987).

CURRENT RECOMMENDATIONS

Proposed organotin criteria for the protection of aquatic life, domestic animals, and human health, vary substantially (Table 12). The most stringent criteria now proposed are for triorganotins and aquatic life; these vary from 0.002 to 0.008 ug/l (Table 12). But even these comparatively low concentrations will not protect certain species of gastropod molluscs or larvae of the sheep sturgeon (*Accipenser nudiventris*) from tributyltin

impacts, as discussed earlier. No criteria are currently proposed for protection of mammals against trimethyltins and triethyltins, the most toxic organotins tested in this group. Trimethyltins, for example, produce nonreversible neurotoxicological effects to certain species of small laboratory animals at concentrations as low as 0.15 mg/l drinking water or 0.625 mg/kg BW and are fatal at 1.25 mg/kg BW.

Hazard evaluation posed by organotin compounds to natural resources is predicated partly on their chemical composition, partly on their concentration and persistence in abiotic materials and diet items, and partly on their availability from these materials to organisms. In each of these areas, key data are missing for promulgation of effective regulations. It seems that additional research is needed in eight areas to acquire these data: (1) the development of sensitive and rapid analytical schemes for the extraction and separation of inorganic tin and organic tin compounds and their chemical speciation products from water, sediments, and biological materials (WHO 1980; Reuhl and Cranmer 1984; Hall and Pinkney 1985; Laughlin and Linden 1985; Thompson et al. 1985; Blunden and Chapman 1986); (2) elucidation of mechanisms and modes of toxicity for organotin compounds, especially those involving sublethal chronic exposures and cellular and subcellular impacts (WHO 1980; Reuhl and Cranmer 1984; Hall and Pinkney 1985; Thompson et al. 1985; Vrijhof 1985); (3) acquisition of data on organotin toxicokinetics, including data on routes of exposure, uptake, retention, and translocation. Studies should emphasize whole organisms, to determine if food chain biomagnification is a potential problem; reproductive organs, in which organotin burdens may affect proliferation; and edible tissue , especially muscle and liver, which are selectively consumed by humans and various animal species (WHO 1980; Reuhl and Cranmer 1984; Wilkinson 1984; Hall and Pinkney 1985; Thompson et al. 1985); (4)determination of the persistence and mobility of organotin compounds-- especially in aquatic abiotic materials, such as sediments, sediment interstitial waters, suspended particulates, and the water column--and on the partitioning of these compounds between the surface microlayer and subsurface waters (Wilkinson 1984; Thompson et al. 1985); (5) determination of the extent of tin methylation and the biotransformation and pharmacodynamics of organotins (WHO 1980); (6) measurement of biological interaction effects of organotins with other toxic chemicals under stressful environmental conditions of temperature, oxygen, and other variables (Thompson et al. 1985); (7) development of quantitative structure activity relations for use in evaluating toxicity of organotin compounds (Hall and Pinkney 1985; Laughlin and Linden 1985; Laughlin et al. 1985; Laughlin 1987); and (8) initiation of long-term environmental monitoring studies in terrestrial and aquatic ecosystems to establish appropriate baseline concentrations and to separate these from contaminant effects (Kumpulainen and Koivistoinen 1977; WHO 1980; Hall and Pinkney 1985; Thompson et al. 1985).

Table 12. Proposed organotin criteria for protection of natural resources and human health.

Resource, organotin compound	Criterion or effective tin concentration	Reference[a]
Aquatic life		
Freshwater		
Triorganotins		
North Carolina	<0.008 µg/L	1
Triethyltins		
Max. permissible concentration	<100 µg/L	2
Tributyltins		
Acute value	<0.97 µg/L	3
Chronic value	<0.30 µg/L	3
Safe level	0.12 to <0.27 µg/L	2

Antifouling paints containing organotin compounds have been associated with a number of adverse effects to marine biota, including contamination of salmon farmed in sea cages with treated net panels (Side 1987) and reduced growth of oysters (Cleary and Stebbing 1985). The United States Navy, however, proposes to implement fleetwide use of organotin antifouling paints that contain tributyltin as a biocide. This procedure will

result in a 15% fuel consumption reduction, increase the interval between cleaning ship hulls from 2 years (with cuprous oxide-based antifouling paints) to about 7 years, and increase ship speed up to 40% as a direct result of reduced drag (USN 1984). Since naval vessels rarely remain moored for extended periods in coastal areas, hazard effects to the environment are minimal--despite the size of the vessel--when compared to boating practices at local marinas (USN 1984). Accordingly, civilian use of marine paints containing organotin compounds has been severely restricted in recent years. France banned tributyltin compounds in antifouling paints in January 1982 for use on vessels under 25 m (82 feet) length (Waldock and Thain 1983; Side 1987). The State of Virginia enacted legislation that prohibits the use of tributyltin paints on nonaluminum vessels under 25 m (Anon. 1987). Similar legislation is pending in at least 12 coastal and Great Lakes States (Anon. 1988). In April 1987, England banned the retail sale of antifouling paints containing organotin compounds at concentrations greater than 4 grams of total tin per liter (Side 1987).

Because of their hazards, use of the more toxic triorganotin biocides should be curtailed to prevent their entry into the environment (Piver 1973). Continued monitoring of tributyltin levels is highly recommended at present, especially in areas of extensive boating activity (Simmonds 1986).

BIOLOGICAL REPORT 85(1.16)
FEBRUARY 1989

Contaminant Hazard Reviews
REPORT NO. 16

INDEX TO COMMON AND SCIENTIFIC NAMES OF SPECIES LISTED IN CONTAMINANT HAZARD REVIEWS 1 THROUGH 15

by
Ronald Eisler

and

Joyce Haber Corley

U.S. Fish and Wildlife Service
Patuxent Wildlife Research Center
Laurel, MD 20708

SUMMARY

The Contaminant Hazard Review series emphasizes ecotoxicological aspects of selected chemical pollutants to fishery and wildlife resources, and includes reports on various agricultural pesticides (mirex, carbofuran, toxaphene, diazinon, chlorpyrifos), metals and metalloids (arsenic, cadmium, chromium, mercury, lead, selenium, tin), and organic industrial wastes (polycyclic aromatic hydrocarbons, dioxins, polychlorinated biphenyls). The present account is a cumulative index to the common and scientific names of all biological species listed in the first 15 reports in the Contaminant Hazard Review series, published as U.S. Fish and Wildlife Service Biological Reports 85(1.1) through 85(1.15), inclusive. Individual species were cross-referenced by contaminant and corresponding page numbers.

DISCLAIMER

Mention of trade names or commercial products does not constitute U.S. Government endorsement or recommendation for use.

ACKNOWLEDGMENTS

We thank Barbara A. Roberts and Julia L. Armstrong for secretarial assistance, Lynda J. Garrett for constructively reviewing the manuscript, and James R. Zuboy, Paul A. Opler, Paul H. Eschmeyer, and Nancy M. Wells for editorial services.

INTRODUCTION

A total of 15 Contaminant Hazard Reviews have been published since 1985 (Eisler 1985a,b,c,d; 1986a,b,c,d; 1987a,b; 1988a,b; 1989; Eisler and Jacknow 1985; Odenkirchen and Eisler 1988). These reviews briefly summarized ecological and toxicological aspects of various chemical pollutants, with particular emphasis on fishery and wildlife resources. Specifically, reviews were prepared on selected agricultural pesticides (mirex, carbofuran, diazinon, toxaphene, chlorpyrifos), metalloids (arsenic, selenium), metals (cadmium, lead, chromium, mercury, tin), and organic industrial wastes (polychlorinated biphenyls, dioxins, polycyclic aromatic hydrocarbons).

We present herein an index to the common and scientific names of all species listed in Contaminant Hazard Reviews 1 to 15. This report was prepared in response to a request from environmental specialists of the U.S. Fish and Wildlife Service. Taxonomic nomenclatures for plants, invertebrates, and vertebrates are under constant revision. Accordingly, we elected to conform as much as possible to the systems and spellings used by Swain and Swain (1948) for insects, Edwards (1974) for birds, American Fisheries Society (1980) for fishes, Johnson and Finley (1980) and Jenkins (1980) for invertebrates, Jenkins (1980) and Scott and Wasser (1980) for plants, and Nowak and Paradiso (1983) for mammals.

In this report, individual species are arranged alphabetically in the Index by scientific and common name. The scientific name is followed by an underlined number that refers to one of the Contaminant Hazard Reviews in the following list, and to the page numbers within the report.

1=Mirex (Eisler 1985a)
2=Cadmium (Eisler 1985b)
3=Carbofuran (Eisler 1985c)
4=Toxaphene (Eisler and Jacknow 1985)
5=Selenium (Eisler 1985d)
6=Chromium (Eisler 1986a)
7=Polychlorinated biphenyls (Eisler 1986b)
8=Dioxins (Eisler 1986c)
9=Diazinon (Eisler 1986d)
10=Mercury (Eisler 1987a)
11=Polycyclic aromatic hydrocarbons (Eisler 1987b)
12=Arsenic (Eisler 1988a)
13=Chlorpyrifos Odenkirchen and Eisler 1988)
14=Lead (Eisler 1988b)
15=Tin (Eisler 1989)

INDEX

Anas strepera:

Anchovy, Engraulidae

Andropogon scoparius:

Anguilla anguilla:

Anguilla rostrata:

Anguilla sp.:

Anguilla vulgaris:

Anhinga, Anhinga anhinga

Anhinga anhinga:

Ankistrodesmus falcatus:

Ankistrodesmus sp.:

Annelids, Nereis, Tubifex

Anodonta anatina:

Anser anser:

Anser spp.:

Aster, Aster, Astragalus
Aster spp.:
Aster, tansy, Machaeranthera spp.
Asterias forbesi:
Asterionella formosa:
Asteroid, Echinus esculentus
Asteromonas gracilis:
Astragalus argillosus:
Astragalus beathii:
Astragalus bisculcatus:
Astragalus confertiflorus:
Astragalus crotulariae:
Astragalus racemosus:
Astragalus spp:
Astralium rogosum:
Atherinasoma microstoma:
Atherix sp.:
Atriplex spp.:
Auks, Alcidae
Australorbus glabratus:
Avena sativa:
Avocet, American, Recurvirostra americana
Aythya affinis:
Aythya americana:
Aythya ferina:
Aythya fuligula:
Aythya spp.:
Aythya valisineria:

Baboon, Papio anubis
Bacillus spp.:
Bacillus subtilis:
Bacteria, Aeromonas, Agrobacter, Arthrobacter, Bacillus, Escherichia, Flavobacterium, Klebsiella,
Pseudomonas, Salmonella
Balaenoptera physalis:
Balanus sp.:
Barley, Hordeum vulgare
Barnacle, Balanus sp.
Barn-owl, common, Tyto alba
Bass
Black sea, Centropristis striata
Largemouth, Micropterus salmoides
Rock, Ambloplites rupestris
Smallmouth, Micropterus dolomieui
Striped, Morone saxatilis

Bullfrog, Rana catesbeiana
Bullhead
    Black, Ictalurus melas
    Brown, Ictalurus nebulosus
Bunting, lark, Calamospiza melancorys
Bursaphelenchus xylophilus:
Buteo jamaicensis:
Buteo lineatus:
Buteo sp.:
Butorides striatus:
Butorides virescens:
Butterfly, large white, Pieris brassicae
Buzzard, honey, Pernis apivorus

Cabbage, Brassica oleracea capitata
Caddisfly, Triaenodus tardus
Calamospiza melanocorys:
Calcarius ornatus:
Calidris canutus:
Callinectes sapidus:
Callipepla californica:
Callithrix jacchus:
Callorhinus ursinus:
Calluna vulgaris:
Cambarus latimanus:
Cambarus sp.:
Campanularia flexuosa:
Cancer anthonyi:
Cancer irroratus:
Cancer magister:
Canis familiaris:
Canis latrans:
Canis sp.:
Canvasback, Aythya valisineria
Capitella capitata:
Capra hircus:
Capra sp.:
Capreolus capreolus:
Carassius auratus:
Carassius carassius grandoculis:
Carcharhinus longimanus:
Carcharhinus spp.:
Carcinus maenus:
Caretta caretta:
Caribou, Rangifer tarandus
Carnation, Dianthus sp.

Carp
    Common, Cyprinus carpio
    Indian, Saccobranchus fossilis
    Round Crucian, Carassius carassius grandoculis
Carpocapsa pomonella:
Carpodacus mexicanus:
Carrot, Daucus sp.
Cassia spp.:
Castilleja spp.:
Castor canadensis:
Cat, domestic, Felis domesticus
Caterpillar
    Eastern tent, Malacosoma americanum
    Gypsy, Porthetria dispar
    Saltmarsh, Estigmene acrea, Estigmene sp.
Catfish
    Air-breathing, Clarius batrachus
    African, Mystus vittatus
    Blue, Ictalurus furcatus
    Channel, Ictalurus punctatus
    Sea, Arius felis
    Various, Cnidoglanis, Ictalurus
Catharacta skua:
Catharacta spp.:
Catostomus commersoni:
Cattle, Bos sp.
Cauliflower, Brassica oleracea botrytis
Cavia cobaya:
Cavia porcellus:
Cavia sp.:
Celery, Apium graveolans
Centipede, Lithobius variegatus
Centropristis striata:
Ceratophyllum demersum:
Ceratophyllum sp.:
Ceratopogonidae:
Cervidae:
Cervus canadensis:
Cervus sp.:
Ceryle alcyon:
Champia parvula:
Channa punctatus:
Chaoborus punctipennis:
Chaoborus sp.:
Chard, Swiss, Beta vulgaris cicla
Chelon labrosus:

Chelonia mydas:
Chelydra serpentia:
Cherry
    Black, Prunus serotina
    Red, Prunus avium
Chicken
    Attwater's greater prairie, Tympanuchus cupido attwateri
    Domestic, Gallus gallus, Gallus sp.
    Prairie, Tympanuchus cupido
Chilomonas paramecium:
Chinocetes bairdii:
Chipmunk, Eutamias townsendii
Chironomid, Chironomus, Glyptotendipes
Chironomidae:
Chironomus plumosus:
Chironomus tentans:
Chlamydomonas reinhardi:
Chlamydomonas spp.:
Chlamys ferrei nipponensis:
Chlorella pyrenoidosa:
Chlorella vulgaris:
Chlorophyte, Hydrodictyon, Oedogonium
Choerodon azurio:
Chondrus crispus:
Choristoneura occidentalis:
Chroomonas sp.:
Chrysanthemum, Chrysanthemum
Chrysanthemum sp.:
Chrysemys scripta:
Chrysopa carnea:
Chukar, Alectoris chukar
Cichlasoma facetum:
Cichlid, Cichlasoma facetum
Cipangopaludina malleata:
Citharichthys stigmaeus:
Citrus tachibana:
Claassenia sp.:
Cladoceran, Bosmina, Daphnia, Simocephalus
Cladophora sp.:
Clam
    Asiatic, Corbicula fluminea
    Bentnose, Pitar morrhuana
    Giant, Tridacna maxima
    Hardshell or Quahaug, Mercenaria mercenaria
    Softshell, Mya arenaria
    Various, Donax, Glebula, Hormomya, Macoma, Rangia, Scrobicula, Tapes

Clams:
Clarias batrachus:
Clethrionomys glareolus:
Clinocardium nuttali:
Clover, Trifolium sp.
Clupea harengus pallasi:
Cnemidophorus sexlineatus:
Cnidoglanis macrocephalus:
Cockle, Clinocardium nuttali
Cockroach, German, Blattella germanica
Cod
    Atlantic, Gadus morhua
    Tom, Microgadus tomcod
Coleoptera:
Colinus virginianus:
Collembola:
Columba livia:
Columba sp.:
Colymbus (=Gavia) arcticus (= arctica):
Comandra spp.:
Condor
    Andean, Vultur gryphus
    California, Gymnogyps californianus
Coontail, Ceratophyllum demersum
Coot, American, Fulica americana
Copepod, Acartia, Eurytemora, Nitroca, Tisbe
Coral, Diploria, Montastrea
Corals:
Corbicula fluminea:
Corbicula manilensis:
Coregonus clupeaformis:
Coregonus spp.:
Cormorant
    Double-crested, Phalacrocorax auritus
    Various, Phalacrocorax spp.
Corn, Zea mays
Corophium volutator:
Cortinarius spp.:
Corvidae
Corvus brachyrhynchos:
Corvus monedula:
Cotton, Gossypium hirsutum
Cottontail, eastern, Sylvilagus floridanus
Coturnix coturnix:
Coturnix japonica:
Coturnix risoria:

Cow, Bos bovis
Cowbird, brown-headed, Molothrus ater
Cowpea, Vigna sp.
Coyote, Canis latrans
Crab
    Alaskan king, Paralithodes camtschatika
    Alaskan snow, Chionocetes bairdii
    Blue, Callinectes sapidus
    Drift-line, Sesarma cinereum
    Dungeness, Cancer magister
    Fiddler, Uca pugilator
    Hermit, Pagurus longicarpus
    Mud, Rithropanopeus harrisii
    Rock, Cancer irroratus
    Stone, Menippe mercenaria
    Various, Carcinus, Neptunus, Podophthalmus
Crabs:
Crane
    Lesser sandhill, Grus canadensis canadensis
    Sandhill, Grus canadensis
Crangon crangon:
Crappie, white, Pomoxis annularis
Crassostrea commercialis:
Crassostrea gigas:
Crassostrea spp.:
Crassostrea virginica:
Crataegus spp.:
Crawfish, Cambarus sp.
Crayfish, Astacus, Orconectes, Pacifastacus, Procambarus
Crayfishes
Crepidula fornicata:
Cricetus spp.:
Cricket, Gryllidae
Cristigera sp.:
Croaker, Atlantic, Micropogonias undulatus
Crocodile, American, Crocodylus acutus
Crocodylus acutus:
Crocothemis erythryaea:
Crow, American, Corvus brachyrhynchos
Ctenocephalides spp.
Culex pipiens quinquefasciatus:
Culex spp.:
Cunninghamella elegans:
Cutworm, Lepidoptera
Cygnus buccinator:
Cygnus columbianus:

Cygnus olor:
Cynodon dactylon:
Cynoscion nebulosus:
Cyprinodon variegatus:
Cyprinus carpio:

Dab, Limanda limanda
Damselflies, Odonata
Daphnia galeata mendotae:
Daphnia longispina:
Daphnia magna:
Daphnia pulex:
Daphnia sp.:
Daphnids
Daucus sp.:
Deer
    Mule, Odocoileus hemionus
    Roe, Capreolus capreolus
    Various, Cervidae
    White-tailed, Odocoileus virginianus
Dendrocygna bicolor:
Dianthus sp.:
Dicranum scoparium:
Digitaria sanguinalis:
Diomeda immutabilis:
Diplopoda, Millipedes
Diplodus sargus:
Diploria strigosa:.
Dog, Canis familiaris, Canis sp.
Dogfish
    Smooth, Mustelus canis
    Spiny, Squalus acanthias
Dolphin, striped, Stenella coeruleoalba
Donax venustus:
Dorosoma cepedianum:
Dorosoma petenense:
Dove
    Mourning, Zenaida macroura
    Ringed turtle, Streptopelia risoria
    Ring-necked, Streptopelia capicola
    Rock, Columba livia
Drosophila melanogaster:
Drum, freshwater, Aplodinotus grunniens
Duck
    American black, Anas rubripes
    American wood, Aix sponsa

Fulvous whistling, Dendrocygna bicolor
Tufted, Aythya fuligula
Mottled, Anas fulvigula
Various, Anas spp.
Duckweed, Lemna media, Lemna minor
Dugesia dorotocephala:
Dunaliella marina:
Dunaliella tertiolecta:

Eagle
Bald, Haliaeetus leucocephalus
White-tailed sea-, Haliaeetus albicilla
Earthworm
Australian, Lumbricus sp.
Various, Allolobophophora, Eisenia, Eisenoides, Lumbricus, Octochaetus
Earthworms:
Echinodermata:
Echinus esculentus:
Ecklonia radiata:
Eel, American, Anguilla rostrata
Eels, Anguilla
Egret, cattte, Bubulcus ibis
Eichhornia crassipes:
Eider, common, Somateria mollissima
Eisenia foetida:
Eisenia rosea:
Eisenoides carolinensis:
Egregia laevigata:
Elasmopus pectenicrus:
Elk, Cervus canadensis (=elaphus), Cervus sp.
Elm, Ulmus americana
Elodea canadensis:
Elodea sp.:
Engraulidae:
Enhydra lutris:
Enteromorpha linzi:
Enteromorpha sp.
Entosiphon sulcatum:
Eopsetta griporjewi:
Ephemerella sp.:
Eptesicus fuscus:
Equus caballus:
Eremophila alpestris:
Erethizon dorsatum:
Erithacus rubecula:
Erolia (= Calidris) spp.:

Escherichia coli:
Esox lucius:
Esox niger:
Estigmene acrea:
Eucyclops agilis:
Euphausid, Meganyctiphanes norvegica
Eurytemora affinis:
Eutamias townsendii:
Falco columbarius:
Falco mexicanus:
Falco peregrinus:
Falco rusticolus:
Falco sp:
Falco sparverius:
Falco tinnunculus:
Falcon
    Peregrine, Falco peregrinus
    Prairie, Falco mexicanus
    Swedish gyr, Falco rusticolus
Felis domesticus
Fern, ostrich, Matteuccia struthiopteris
Ferret, European, Mustela putorius furo
Fescue, Festuca arundinacea
Festuca arundinacea:
Festuca rubra:
Finch, house, Carpodacus mexicanus
Fish, harlequin, Rasbora heteromorpha
Flagfish, Jordanella floridae
Flatworm, see Dugesia dorotocephala
Flavobacterium:
Fleas, Ctenocephalides spp., Siphonaptera
Flounder
    Baltic or European, Platichthys flesus
    Roundnose, Eopsetta grigorjewi
    Summer, Paralichthys dentatus
    Windowpane, Scopthalmus aquosus
    Winter, Pseudopleuronectes americanus
    Witch, Glyptocephalus cynoglossus
    Yellowtail, Limanda limanda
Fly
    Crane, Tipula sp
    Damsel, Ischnura
    Dragon, Crocothemis, Macromia, Pseudagrion
    Fruit, Drosophila melanogaster
    Horn, Haematobia irritans, Muscidae
    House, Musca domestica, Musca sp.

May, Hexagenia, Siphlonurus
Snipe, Atherix sp.
Stone, Claassenia, Isoperla, Pteronarcella, Pteronarcys
Formicidae
Fox, red, Vulpes vulpes
Fragaria vesca:
Fratercula spp.
Frog
Bull, Rana catesbeiana
Cricket, Acris sp.
European, Rana temporaria
Green, Rana clamitans
Leopard, Rana sphenocephala
Tree, Hyla sp.
Various, Rana, Xenopus
Frogs:
Fruitworm, Lepidoptera
Fucus distichus:
Fucus spp.
Fucus vesiculosus
Fulica americana:
Fundulus heteroclitus:
Fundulus kansae:
Fundulus similis:
Fungi:
Fungus, Cortinarius spp., Cunninghamella elegans

Gadopsis marmoratus:
Gadus morhua:
Gadwall, Anas strepera
Galleria melonella:
Gallinule, purple, Porphyrula martinica
Gallus sp.:
Gambusia affinis:
Gammarus duebeni:
Gammarus fasciatus:
Gammarus lacustris:
Gammarus oceanicus:
Gammarus pseudolimnaeus:
Gammarus spp.:
Gar, spotted, Lepisosteus oculatus
Gasterosteus aculeatus:
Gastrophryne carolinensis:
Gastropods:
Gavia arctica:
Gavia immer:

Gazelle, Antilopinae
Gerbil, Gerbillus sp., Meriones unguiculatus
Gerbillus sp.:
Girella punctata:
Glebula rotundata:
Globicephala macrorhynchus:
Glycine max:
Glyptocephalus cynoglossus:
Glyptotendipes barbipes:
Goat, domestic, Capra hircus, Capra sp.
Goatfish, Mullus, Upeneus
Goby, edible, Boleophthalmus dussumieri
Goldenrod, Solidago graminifolia
Goldfish, Carassius auratus
Goose
    Canada, Branta canadensis
    Greylag, Anser anser
    Various, Anser spp.
Goosefish, Lophius piscatorius
Gopher, pocket, Thomomys sp.
Goshawk, Accipiter gentilis
Gossypium hirsutum:
Grackle
    Common, Quiscalus quiscala
    Great-tailed, Quiscalus mexicanus
Grape, Vitis sp.
Grass
    Bahia, Paspalum notatum
    Blue, Poa annua
    Brome, Bromus inermis, Bromus spp.
    Buffalo, Bouteloua dactyloides
    Colonial bent-, Agrostis tenuis
    Common Bermuda, Cynodon dactylon
    Crab, Digitaria sanguinalis
    Marsh, Spartina sp.
    Johnson, Sorghum halepense
    Red fescue, Festuca rubra
    Saltmarsh, Spartina alterniflora
    Western wheat, Agropyron smithii
Grasshopper, western, Melanoplus spp.
Grasshoppers:
Grebe
    Eared, Podiceps nigricollis
    Great crested, Podiceps cristata
    Pied-billed, Podilymbus podiceps
Grebes, Podicipediformes

Grindelia spp.:
Grindelia squarrossa:
Groundnut, Arachis hypogea
Grouse
    Ruffed, Bonasa umbellus
    Sharp-tailed, Tympanuchus phasianellus
Grunion, California, Leuresthes tenuis
Grus canadensis:
Grus canadensis canadensis:
Gryllidae:
Gudgeon, topmouth, Pseudorasbora parva
Gull
    California, Larus californicus
    Franklin's, Larus pipixcan
    Great black-backed, Larus marinus
    Herring, Larus argentatus
    Laughing, Larus atricilla
Lesser black-blacked, Larus fuscus
Ring-belled, Larus delawarensis
Gumweed, Grindelia spp., Grindelia squarrosa
Guppy, Poecilia reticulata
Gutierrezia spp.:
Gymnogyps californianus:
Haddock, Melanogrammus aeglifinus
Haematobia irritans:
Haematopus ostralegus:
Hagfish, Atlantic, Myxine glutinosa
Hake
    Blue, Antimora rostrata
    Red, Urophycus chuss
Haliaeetus albicilla:
Haliaeetus leucocephalus
Haliaeetus sp.:
Halibut, Atlantic, Hippoglossus hippoglossus
Halichoerus grypus hippoglossus
Halichoerus grypus:
Haliotis rufescens:
Hamster
    Chinese, Cricetus spp.
    Golden, Cricetus spp.
Haplopappus spp.:
Hardy head, small-mouthed, Atherinasoma microstoma
Hare, Lepus europaeus
Hawk
    Cooper's, Accipiter cooperii
    Pigeon (= Merlin), Falco columbarius

Red-shouldered, Buteo lineatus
Red-tailed, Buteo jamaicensis
Hawthorn, Crataegus spp.
Heather, Scotch, Calluna vulgaris
Helianthus spp.:
Helisoma campanulata:
Helisoma sp.:
Helisoma trivolvis:
Helix aspersa:
Helix spp.:
Hemicentrotus sp.:
Hemichromus bimaculatus:
Hemifusus spp.
Hen, guinea Gallus sp.
Hermione hystrix:
Heron
Black-crowned night-, Nycticorax nycticorax
Gray, Ardea cinerea
Great blue, Ardea herodias
Green-backer (=Green, Striated), Butorides striatus
Little green, Butorides virescens (=striatus)
Yellow-crowned night, Nycticorax violaceus
Herring, Pacific, Clupea harengus pallasi
Hexagenia bilineata:
Hexagenia sp.:
Himantopus mexicanus:
Hinnites multirugosus:
Hippoglossus hippoglossus:
Hirundo rustica:
Hog, Sus spp.
Hogchoker, Trinectes maculatus
Holothurian, sea cucumber, Stichopus
Homarus americanus:
Homo sapiens:
Honeybee, Apis mellifera, Apis spp.
Hordeum *vulgare*:
Hormomya mutabilis:
Hornworm, tobacco, Manduca sexta
Horse, Equus caballus
Hyacinth water, Eichhornia crassipes
Hyalella azteca:
Hydra, Hydra oligactis, Hydra sp.
Hydra oligactis:
Hydra sp.:
Hydrodictyon reticulatum
Hydroid, Campanularia

Hyla sp.:
Hymenomonas carterae:
Hypnum cupressiforme:
Hypogymnia physodes:

Ibis, white-faced, Plegadis chihi
Ictalurus furcatus:
Ictalurus melas:
Ictalurus nebulosus:
Ictalurus punctatus:
Ictalurus spp.:
Indoplanorbis exustus:
Ipomoea batatas:
Ischnura sp.:
Ischnura verticalis:
Isoperla sp.:
Isopod, Asellus sp.
Isurus oxyrinchus:

Jackdaw, Corvus monedula
Jewelfish, Hemichromus bimaculatus
Jordanella floridae:

Kale, Brassica oleracea acephala
Kelletia kelletia:
Kelp
    Brown, Ecklonia radiata
    Giant, Macrocystis pyrifera
Kestrel, Falco tinnunculus
Kestrel, American, Falco sparverius
Killifish
    Diamond, Adinia xenica
    Freshwater, Fundulus kansae
    Longnose, Fundulus similis
Kingfisher, belted, Ceryle alcyon
Kittiwake, black-legged, Rissa tridactyla
Klebsiella pneumoniae:
Knifejaw, striped Oplegnathus fasciatus
Knot, red, Calidris canutus
Knotted wrack, Ascophyllum nodosum

Lacewing, common green, Chrysopa carnea
Lactuca sativa:
Lactuca spp.:
Lagarosiphon major:
Lagodon rhomboides:

Lagopus lagopus:
Lagopus mutus:
Laminaria digitata:
Laminaria hyperborea:
Lamprey, Petromyzontidae
Lanistes carinatus:
Lanternfishes, Myctophidae
Laomedea loveni:
Lark
    Horned, Eremophila alpestris
    Southern meadow, Sturnella magna argutula
    Western meadow, Sturnella neglecta
Larus argentatus:
Larus atricilla:
Larus californicus:
Larus delawarensis:
Larus fuscus:
Larus marinus:
Larus pipixcan:
Lecanora conizaeoides:
Ledum sp.:
Leeches:
Leek, Allium porrum
Leiostomus xanthurus:
Lemna media:
Lemna minor:
Lepidoptera:
Lepisosteus oculatus:
Lepomis cyanellus:
Lepomis gibbosus:
Lepomis macrochirus:
Lepomis megalotis:
Lepomis microlophus:
Lepomis punctatus:
Leptinotarsa decemlineata:
Leptonychotes weddelli:
Lepus europaeus:
Lepus sp.:
Lettuce, Lactuca sativa, Lactuca spp.
Leuciscus idus melanotus:
Leucospius delineatus:
Leuresthes tenuis:
Lichen, Hypogymnia, Lecanora, Parmelia
Lily, water, Nuphar luteum
Limanda limanda:
Limanda sp.:

Limnodrilus hoffmeisteri:
Limnodrilus sp.:
Limpet,
    Slipper, Crepidula fornicata
    Various, Acmaea, Littorina, Patella
Limpkin, Aramus guarauna
Lithobius variegatus:
Littorina littorea:
Loach, Misgurnis fossilis
Lobster
    American, Homarus americanus
    Spiny, Nephrops, Panulirus
    Western rock, Panulirus cygnus
Lobsters:
Locoweed, Astragalus spp.
Loligo vulgaris:
Lolium perenne:
Longspur, chestnut-collared, Calcarius ornatus
Loon
    Arctic, Gavia arctica
    common, Gavia immer
Lophius piscatorius:
Lophodytes cucullatus:
Louse, wood, Oniscus, Porcellio
Lugworm, Arenicola cristata
Lumbricus herculeus:
Lumbricus rubellus:
Lumbricus sp.:
Lumbricus terrestris:
Lutjanus griseus:
Lutra canadensis:
Lycopersicon esculentum:
Lygaeidae:
Lymnaea palustris:
Lymnaea peregra:
Lymnaea stagnalis:
Lymnaea sp.:
Lynx rufus:
Lysmata caudata:
Lysmata seticaudata:

Macaca fascicularis:
Macaca iris:
Macaca mulatta:
Macaca sp.:
Machaeranthera spp.:

Mergus serrator:
Mergus spp.:
Meriones unguiculatus:
Merlin, Falco columbarius
Metamysidopsis elongate:
Mice
    Deer, Peromyscus maniculatus
    White-footed, Peromyscus leucopus
Microcystis aeruginosa:
Microgadus tomcod:
Micropogonias undulatus:
Micropterus dolomieui:
Micropterus ochrogaster, see Microtus ochrogaster
Micropterus salmoides:
Microtus agrestis:
Microtus arvalis:
Microtus ochrogaster:
Microtus pennsylvanicus:
Midge, Chaoborus, Chironomus, Tanytarsus
Midge, phantom, Chaoborus punctipennis
Milkvetch, Astragalus spp.
Millipedes:
Mimus polyglottos:
Mink, Mustela vison
Minnow,
    Cyprinid, Phoxinus, Puntius
    Eastern mud, Umbra pygmaea
    Fathead, Pimephales promelas
    Mud, Umbra limi
    Sheepshead, Cyprinodon variegatus
    Various, Poeciliopsis
Misgurnis fossilis:
Mite
    European red, Panonychus ulmi
    McDaniel spider, Tetranychus mcdanieli
    Two-spotted spider, Tetranychus urticae
    Various, Arachnids
Mockingbird, northern, Mimus polyglottos
Mole, Talpa europaea
Molothrus ater:
Monkey
    Cynomolgus, Macaca spp.
    Rhesus, Macaca mulatta
    Squirrel, Saimiri spp.
Monkeys:
Montastrea annularis:

Moose, Alces alces
Morone saxatilis:
Mosquito, Aedes, Culex,
Mosquitofish, Gambusia affinis
Moss
    Irish, Chondrus crispus
    Various, Brachythecium, Hylocomium, Hypnum, Sphagnum
Moth
    Codling, Carpocapsa pomonella
    Greater wax, Galleria melonella
    Pineapple gummosis, see Lepidoptera
Mouse
    Beach, or Old field, Peromyscus polionotus
    Field, Microtus arvalis
    Domestic, Mus spp.
    Western jumping, Zapus princeps
    Wood, Apodemus sylvaticus
Moxostoma duquesnei:
Mudalia potosensis:
Mugil cephalus:
Mullet
    Gray, Chelon labrosus
    Striped, Mugil cephalus
    Yellow-eye, Aldrichetta forsteri
Mullus barbatus:
Mummichog, Fundulus heteroclitus
Murre, common, Uria aagle
Murrel, Channa punctatus
Mus spp.:
Musca domestica:
Musca sp.:
Muscidae:
Muskrat, Ondatra zibethicus
Mussel
    Common, Mytilus edulis
    Duck, Anodonta anatina
    Various, M. californianus, M. edulis planulatus, M. galloprovincialis
Mussels:
Mustela putorius furo:
Mustela vison:
Mustelus antarcticus:
Mustelus canis:
Mya arenaria:
Myctophidae:
Myotis grisescens:
Myotis lucifugus:

Myotis spp.:
Myoxocephalus scorpius:

PENTACHLOROPHENOL HAZARDS TO FISH, WILDLIFE, AND INVERTEBRATES: A SYNOPTIC REVIEW

by
Ronald Eisler

U.S. Fish and Wildlife Service
Patuxent Wildlife Research Center
Laurel, MD 20708

SUMMARY

Pentachlorophenol (PCP) is a synthetic organochlorine compound that was first manufactured commercially in 1936 and is now used primarily as a wood preservative and secondarily as a herbicide, insecticide, fungicide, molluscicide, and bactericide. Current global production of PCP is estimated to be 50 million kg annually. Widespread use of PCP has resulted in the detection of residues in air, rain, snow, groundwater, surface water, drinking water, fish, and aquatic invertebrates, as well as in human urine, blood, and milk. Pentachlorophenol may be incorporated into animal tissues through inhalation, diet, or contact; its toxic action results from its ability to interfere with the production of high energy phosphate compounds essential for cell respiration. Pentachlorophenol has caused numerous occupational illnesses and deaths, and has had significant adverse effects on domestic animals. It is fetotoxic and teratogenic, but evidence for mutagenicity and carcinogenicity is incomplete or negative. Commercial PCP preparations often contain variable amounts of toxic impurities--including chlorophenols, hexachlorobenzene, phenoxyphenols, dioxins, and dibenzofurans--that contribute to its toxicity. Pentachlorophenol is rapidly accumulated and rapidly excreted, and has little tendency to persist in living organisms; it is readily degraded in the environment by chemical, microbiological, and photochemical processes.

In sensitive aquatic species, PCP adversely affected growth, survival, and reproduction at media concentrations of 8 to 80 ug PCP/1 in algae and higher plants, at 3 to 100 ug/l in invertebrates, and <1 to 68 ug/l in fish. In birds, PCP was fatal at 380 to 580 mg/kg body weight (BW) in oral doses, >3,580 mg/kg in the diet, and >285 mg/kg in contaminated nesting materials .(i.e., wood shavings). Residues >11 mg PCP/kg fresh weight in bird tissues were associated with acute toxicosis. Adverse sublethal effects in birds were noted at dietary levels as low as 1 mg/kg ration. In small laboratory mammals and domestic livestock, acute oral LD-50's ranged from 27 to 300 mg/kg BW. Tissue residues in mammals were elevated at PCP doses as low as 0.05 mg/kg BW, and at air levels >0.l mg/m^3. Histopathology, reproductive impairment, growth retardation, and other effects were evident in sensitive mammals at PCP concentrations of 0.2 to 1.25 mg/kg BW, and at dietary levels >30 mg/kg ration.

Pentachlorophenol is an undesirable pollutant whose use patterns should be carefully regulated to avoid contamination of soil, water, and food.

Recommendations for protection of sensitive fishery and wildlife resources follow; however, it is emphasized that some of these recommendations are markedly lower than those proposed by regulatory agencies. For protection of aquatic life, it is recommended that the PCP water concentration not exceed 3.2 ug/l; but even at this level certain species of fishes and oysters accumulate enough of the toxicant to retard their growth. In birds, dietary concentrations >1.0 mg/kg feed and tissue residues >2.0 mg/kg fresh weight should be viewed as presumptive evidence of significant environmental PCP contamination. Data are scarce for PCP and mammalian wildlife; until more data are collected, PCP levels recommended for human health protection (i.e., "no adverse effects" levels) are suggested as reasonable substitutes. In humans, no adverse effects were noted at daily PCP intakes equivalent to 39 ug/kg BW in food, or at concentrations of 21 ug/l in drinking water, 0.5 mg/m^3 in air, 0.5 mg/l in blood plasma, and 1.0 mg/l in blood.

DISCLAIMER

Mention of trade names or commercial products does not constitute endorsement or recommendation for use by the U.S. Government.

TABLES

ACKNOWLEDGMENTS

I thank Nancy A. Bushby, Lynda J. Garrett, and Joyce Haber Corley for literature search and retrieval; Barbara A. Roberts for secretarial help; Donald R. Clark, Laverne Cleveland, and Mark J. Melancon for technical and scientific review; and Paul H. Eschmeyer and James R. Zuboy for editorial services.

INTRODUCTION

Pentachlorophenol (PCP) and its water soluble salt, sodium pentachlorophenate, are commercially produced organochlorine compounds used primarily as preservatives of wood and wood products, and secondarily as herbicides, insecticides, fungicides, molluscicides, and bactericides (EPA 1980; Prescott et al. 1982). Both compounds have been sold for these purposes since 1936 under a variety of trade names (Knudson et al. 1974). Because of its widespread use, animals and humans are exposed to significant amounts of PCP; detectable PCP levels are found in most people living in industrialized societies, probably as a result of food chain exposure to PCP-treated wood products (Dougherty 1978; McConnell et al. 1980; Prescott et al. 1982). In Japan, PCP has been widely used as a herbicide in rice fields, but owing to its high toxicity to fishes, its use was limited (beginning in 1971) to upland fields (Nishimura 1984; Mikesell and Boyd 1986). The use of PCP in Japan has resulted in the contamination of all surface water in that country to concentrations of 0.01 to 0.1 ug/l (Lu et al. 1978). The chemical and its degradation products bioconcentrate in fish and are among the phenolic compounds known to taint fish flesh (Boyle et al. 1980). It has been detected in marine fishes and invertebrates, in drinking water, and in human blood and urine (Schimmel et al. 1978; Klemmer et al. 1980; (Trujillo et al. 1982). All samples of human milk from nursing mothers tested in Bavaria from 1979 to 1981 contained PCP (Gebefugi and Korte 1983).

In man, illnesses and deaths have been reported after exposure to PCP through diet or by direct contact with PCP-treated products (Prescott et al. 1982). For example, 20 of 80 infants who wore, for 8 days, diapers rinsed in an antimicrobial laundry neutralizer containing sodium pentachlorophenate developed enlarged livers and spleens, had high fevers, and sweated profusely; although most recovered spontaneously, 7 died (Knudsen et al. 1974; EPA 1980). At least 24 industrial PCP fatalities have been reported. The first deaths occurred at a wood preservative plant in France in 1952. Others were recorded at a chemical factory in Japan in 1953, during herbicide spraying in Australia in 1956, at a sawmill in Indonesia in 1958, in South Africa in 1961, and in Canada and the United States in 1965 (Wood et al. 1983). The acute toxic action of PCP in man and experimental animals is caused by the uncoupling of oxidative phosphorylation mechanisms, resulting in marked increases in metabolism (Murphy 1986).

Data are scarce on PCP effects on wildlife, although it is speculated that no wildlife losses should occur under normal PCP application conditions and that chronic toxicity would not be serious because PCP is rapidly excreted (Bevenue and Beckman 1967). However, mortality was heavy in two species of bats that came into contact with PCP-treated timbers up to 14 months after treatment (Racey and Swift 1986). Furthermore, evidence accumulating on the harmful effects of PCP to domestic animals suggests that the chemical may have considerable adverse effects on other species of wildlife. In the poultry industry, for example, PCP has been implicated in the cause of musty taint in chicken meat and eggs and in increased morbidity in chickens housed on PCP-contaminated wood shavings or given PCP-contaminated food (Prescott et al. 1982). Pentachlorophenol is repellent to animals; diets containing PCP have been rejected by rats, cats, and cattle (Bevenue and Beckman 1967). In farm animals, PCP intoxication has been increasing as a result of confinement in buildings recently treated with a PCP wood preservative, and through dermal contact with PCP-treated fences and feed bunks (Osweiler et al. 1984). Dairy cattle contaminated by PCP produced less milk, grew poorly, and developed skin lesions (Firestone et al. 1979; Greichus et al. 1979; Parker et al. 1980). The issue is confounded by the presence of various amounts of toxic impurities--primarily dioxins and dibenzofurans--in technical and commercial preparations of PCP; these contaminants are mainly responsible for its observed toxicity in rabbits, rats, pigs, cattle, and chickens (Dougherty 1978; McConnell et al. 1980; Prescott et al. 1982). In one example in 1957, millions of chickens died in the southeastern United States after eating poultry feeds containing fat from hides preserved with PCP. Nine dioxins were detected in the toxic animal fat, including the potent 1,2,3,7,8,9-hexachlorodibenzo-p-dioxin isomer (Parker et al. 1980; Stedman et al. 1980; Prescott et al. 1982).

Useful reviews on the ecological and toxicological aspects of PCP have been published by Bevenue and Beckman (1967), Cote (1972), Rao (1978), EPA (1980), Williams (1982), and Choudhury et al. (1986). I here synthesize the available data on environmental aspects of PCP, with emphasis on fish and wildlife. It is part of a continuing series of reviews on chemical contaminants prepared in response to requests for information from environmental specialists of the U.S. Fish and Wildlife Service.

ENVIRONMENTAL CHEMISTRY

GENERAL

Pentachlorophenol and its water soluble salt, sodium pentachlorophenate, are used extensively in agriculture and industry. Most--about 80%--of the 50 million kg of PCP manufactured each year is used in the protection and preservation of wood products. Commercial samples of technical grade PCP are heavily contaminated with many compounds, including chlorophenols, dioxins, dibenzofurans, hexachlorobenzene, and phenoxyphenols; the relative toxicities and accumulation potentials of some of these contaminants may exceed those of PCP by several orders of magnitude. Pentachlorophenol interferes with the production of high energy phosphate compounds essential for cell respiration. In general, it readily degrades in the environment by photochemical, chemical, and microbiological processes.

SOURCES AND USES

Although PCP was first synthesized in 1841, it was not produced commercially until 1936 (Wood et al. 1983; Menzer and Nelson 1986). It has since been registered for use as an insecticide, fungicide, herbicide, algicide, and disinfectant, and as an ingredient in antifouling paint; at least 578 products contain PCP (Cote 1972; Cirelli 1978; Choudhury et al. 1986;Murphy 1986). By 1967, PCP and its sodium salt, sodium pentachlorophenate (Na-PCP), were used extensively in industry and agriculture, due in large part to the solubility of PCP in organic solvents and of Na-PCP in water (Bevenue and Beckman 1967; Cirelli 1978). The major commercial application of technical grade preparations of PCP is in wood preservation formulations, where its fungicidal and bactericidal actions inhibit the growth of wood-destroying organisms (Kinzell et al. 1981).

In the United States, about 80% of the 23 million kg of technical PCP produced annually--or about 46% of worldwide production--is used for wood preservation (Pignatello et al. 1983; Kinzell et al. 1985; Zischke et al. 1985; Choudhury et al. 1986; Mikesell and Boyd 1986). It is the third most heavily used pesticide, preceded only by the herbicides atrazine and alachlor (Kinzell et al. 1981). There are about 470 wood preservative facilities in the United States, scattered among 45 states; they are concentrated in the south, southeast, and northwest--presumably due to the availability of preferred timber species in those regions (Cirelli 1978). Livestock facilities are often constructed of wood treated with technical PCP; about 50% of all dairy farms in Michigan used PCP-treated wood in the construction of various components of livestock facilities (Kinzell et al. 1985). The chemical is usually applied to wood products after dilution to 5% with solvents such as mineral spirits, No. 2 fuel oil, or kerosene. More than 98% of all wood processed is treated with preservative under pressure; about 0.23 kg of PCP is needed to preserve one cubic foot of wood (Cirelli 1978). Lumber treated with PCP retains its natural appearance, has little or no odor, and can be painted as readily as natural wood (Wood et al. 1983).

In addition to its extensive use by the construction and lumber industries to control damage by mold, termites, powder post beetles, and wood boring insects (Bevenue and Beckman 1967), PCP has been used as a bactericide and fungicide to protect many products, such as adhesives, paper and paperboard, cable coverings, leather, paints, textiles, rope, ink, rubber, and petroleum drilling muds (Bevenue and Beckman 1967; Firestone et al. 1979; Williams 1982). It has been used to control algae and fungi in cooling towers at electric plants (Williams 1982). It has also been added to fabrics for moth proofing, though derivatives such as pentachlorphenol laurate are more widely used for this purpose because their resistance to dry cleaning and washing exceeds that of PCP, and their toxicity to mammals is lower (Bevenue and Beckman 1967). It has been applied in agriculture and around industrial sites as an herbicide and preharvest desiccant, on pastureland, and in pineapple, rice, and sugarcane fields (Bevenue and Beckaman 1967). A Japanese manufacturer has added PCP to soy sauce--in violation of the law--as a preservative (Bevenue and Beckman 1967). It has also been used as a bird repellant: PCP discourages woodpeckers when it is mixed as a pellet and plugged into holes drilled by the bird (Cirelli 1978).

In Canada, the main use of PCP is in the protection and preservation of wood, and secondarily as an herbicide and insecticide for agricultural purposes. A total of 50 wood preserving plants--mostly in British Columbia, Alberta, and Ontario--used about 2.7 million kg of PCP in 1978 (Hoos 1978). Treatment with PCP significantly increased the life of timbers, construction lumber, telephone poles, and railway ties; for example, jackpine poles treated with PCP lasted at least 35 years, compared to 7 years for untreated poles (Hoos 1978).

Sodium pentachlorophenate has been used to control schistosomiasis by eliminating snails that are intermediate hosts of human schistosomes (Bevenue and Beckman 1967). It is also used as a fungicide, bactericide, and algicide in construction materials, emulsion polymers, paints, textiles, and finished paper products; as a preservative for ammonium alginate; and at concentrations of 15 to 40 mg/l, to control microbial growth in secondary oil recovery (Bevenue and Beckman 1967; Cirelli 1978).

PROPERTIES

Pentachlorophenol is readily soluble in most organic solvents, oils, and highly aromatic and olefinic petroleum hydrocarbons--a property that makes it compatible for inclusion in many pesticide formulations (Table 1; Bevenue and Beckman 1967). Purified PCP, however, is practically insoluble in water; therefore, the readily water-soluble sodium pentachlorophenate salt is substituted in many industrial applications (Table 1; Bevenue and Beckman 1967).

The solubility of sodium and potassium pentachlorophenate in water is pH-dependent; it increases from 79 mg/l at pH 5.0 to >4 g/l at pH 8.0 (Bevenue and Beckman 1967). But differential toxicity of PCP in solution is primarily attributable to variations in uptake as a function of pH (Jayaweera et al. 1982; Kaiser and Valdmanis 1982; Fisher and Wadleigh 1986; Smith et al. 1987), and not to water solubility. At pH 4.0, for example, PCP is fully protonated and therefore highly lipophilic, and has its greatest accumulation potential. Conversely, PCP is completely ionized at pH 9.0; lipophilicity is markedly reduced as is its toxicity to the alga *Selenastrum capricornutum* (Jayaweera et al. 1982; Smith et al. 1987) and the midge, *Chironomus riparius* (Fisher and Wadleigh 1986).

In recent years it has become clear that many commercial samples of technical grade PCP are heavily contaminated with a large number of potentially toxic compounds and materials (Fig. 1, Table 2). These contaminants include, in part, various isomers of chlorophenols, dibenzofurans, dioxins, hexachlorobenzene, and phenoxyphenols (Table 2), as well as various chlorinated diphenyl ethers, dihydroxybiphenyls, anisoles, catechols, guaiacols, and other chlorinated dibenzodioxin and dibenzofuran isomers (Kaufman 1978; Nilsson et al. 1978; Firestone et al. 1979; EPA 1980; Singh et al. 1985; Menzer and Nelson 1986; Mikesell and Boyd 1986; Murphy 1986; Holsapple et al. 1987). In relative toxicity and accumulation potential, some contaminants in technical grade PCP may exceed the parent compound by several orders of magnitude (Huckins and Petty 1981). For example, some isomers of hexachlorodibenzodioxin, which are present in technical grade PCP at concentrations of 1,000 to 17,300 ug/kg (Table 2), produce LD-50 values in guinea pigs of 60 to 100 ug/kg body weight--thus ranking them as extremely toxic chemicals (Eisler 1986; Murphy 1986).

FATE

Pentachlorophenol may be absorbed into the body through inhalation, diet, or skin contact (Bevenue and Beckman 1967; Williams 1982; Gray et al. 1985). Its acute toxicity results from its ability to interfere with the production of high energy phosphate compounds essential for cell respiration. This interference, or uncoupling, causes stimulation of the cell's metabolism to the toxic stage, which is accompanied by fever and other signs of stress (Bevenue and Beckman 1967; Hodson and Blunt 1981; Williams 1982). The metabolic consequences resemble those of vigorous exercise in some species (Hodson and Blunt 1981). In addition to the proven uncoupling effects on oxidative phosphorylation, the overall inhibitory effects on a variety of enzymes, metabolism of lipids and carbohydrates, ion transport, and protein synthesis may account for the broad spectrum biocidal effects of PCP and its salts (Rao et al. 1979; Gray et al., 1985; Smith et al. 1987). Pentachlorophenol is fetotoxic and teratogenic during early gestation; however, evidence of its mutagenic or carcinogenic properties is incomplete (Williams 1982).

Table 1. Chemical and other properties of pentachlorophenol (from Bevenue and Beckman 1967; Cote 1972; Cirelli 1978; EPA 1980; Williams 1982; Hudson et al. 1984; Choudhury et al. 1986; Hill and Camardese 1986; Mayer 1987).

Variable	Datum
Chemical name	Pentachlorophenol, CAS-87-86-5
Alternate names	Chem-Penta, Chemtrol, Chlorophen, Dow Pentachlorophenol, Dowicide 7, Dowicide EC-7, Dowicide G, DP-2, Durotox, Lauxtol A, Ontrack WE-1, PCP, Penchlorol, Penta, Penta General Weed Killer, Pentacon, Penta-kil, Pentanol, Pentasol, Penwar, Permacide, Permaguard, Permasem, Permatox, Priltox, Santobrite, Santophen, Sinituho, Term-l-trol, Weed-Beads, Weedone
Primary uses	Wood preservative, preharvest defoliant, herbicide, molluscicide, insecticide, fungicide
Producers:	Dow Chemical Company, Monsanto Company, Reichold Chemical Company, Vulcan Materials Company
Empirical formula	C_6Cl_5OH
Structural formula	Physical state	White solid with needle-like crystals. Produced by chlorination of Molten phenol. Technical grade material is dark gray to brown
Molecular weight	266.35
Melting point	190 to 191 °C
Boiling point	309 to 310 °C (decomposes)
Specific gravity	1.978
Vapor pressure	
25 °C	0.0016 mm Hg
100 °C	0.02 mm Hg
211 °C	40.0 mm Hg
Solubility	
Water	
0 °C	5 mg/L

20 °C	14 mg/L
30 °C	20 mg/L
50 °C	35 mg/L
Carbon tetrachloride	20 to 30 g/L
Benzene	110 to 140 g/L
Ethanol	470 to 520 g/L
Methanol	570 to 650 g/L
Solubility of sodium salt (sodium pentachlorophenate, CAS 131-52-2) in water at 25 °C	330 g/L
Log octanol/water partition coefficient	5.01 to 5.12

[b]Total, when not indicated otherwise.

Pentachlorophenol readily degrades in the environment by chemical, microbiological, and photochemical processes (Kaufman 1978; Choudhury et al. 1986). Its suggested metabolic fates include oxidation and dechlorination to tri- and tetrachloro-p-hydroquinones, and glucuronide conjugation to PCP- and tetrachloro-p-hydroquinone conjugates (Williams 1982). In soils, reductive dehalogenation appears to be the most significant PCP degradation pathway, producing mono-, di-, tri-, and tetrachlorophenols, as well as various tetrachlorocatechols and tetrachlorohydroquinones. Further degradation results in ring cleavage, liberation of chloride, and carbon dioxide evolution; degradation is more rapid in flooded or anaerobic soils than in aerobic moist soils (Kaufman 1978). Irradiation of PCP solutions with sunlight or ultraviolet light produces photodegradation products that include chlorinated phenols, tetrachlorodihyroxyl benzenes, and nonaromatic fragments such as dichloromaleic acid (Wong and Crosby 1978; EPA 1980). Subsequent irradiation of the tetrachlorodiols produces hydroxylated trichlorobenzoquinones, trichlorodiols, dichloromaleic acid, and nonaromatic fragments (Wong and Crosby 1978; Boyle et al. 1980). Prolonged irradiation of PCP or its degradation products yielded colorless solutions containing no ether-extractable volatile materials; evaporation of the aqueous layer left no observable polymeric residue Wong and Crosby 1978). Photolytic condensation of PCP to form octachlorodioxins was observed on a wood substrate. Octachlorodioxin residues ranged from 4 mg/kg for purified PCP, to about 1,500 mg/kg for technical grade PCP (Lamparski et al. 1980).

Pentachlorophenol can be degraded by microbial flora both aerobically and anaerobically; degradation is more rapid under aerobic conditions but slows significantly at temperatures <19 C (Pignatello et al. 1985, 1986). Several strains of aerobic bacteria can metabolize and degrade PCP: *Flavobacterium* sp., a pseudomonad, a coryneform bacterium, and a strain of *Arthrobacter* (Pignatello et al. 1983; Mikesell and Boyd 1986; Steiert and Crawford 1986; Steiert et al. 1987). Microbial degradation under aerobic or anaerobic conditions was the major process by which PCP was degraded in estuarine sediments; tidal transport and photodegradation played minor roles (DeLaune et al. 1983). The biotic process requires a moderately long adaptive response by the aquatic microflora, but eventually becomes the predominant mechanism of PCP removal (Pignatello et al. 1983, 1985). Several significant observations were recorded when the degradation and transformation of PCP were documented in freshwater streams continuously dosed with PCP for 16 weeks (Pignatello et al. 1983): photolysis accounted for a 5% to 28% decline in initial PCP concentrations and was most rapid at the water surface under conditions of bright sunlight; adsorption to sediments and uptake by biota accounted for less than 5% loss in acclimated waters and probably less than 15% in unacclimatized waters; and microbial degradation of PCP became significant about 3 weeks after dosing and eventually became the primary mechanism of PCP removal, accounting for up to a 46% decline in initial PCP.

The half-life (Tb 1/2) of PCP in water ranged from 0.15 to 1.5 days; degradation was most rapid under conditions of high incident radiation, high dissolved oxygen, and elevated pH (Bevenue and Beckman 1967Wong and Crosby 1978; Boyle et al. 1980; Niimi and Cho 1983; Crossland and Wolff 1985; Smith et al. 1987). The Tb 1/2 in the water column controlled by microbial degradation alone is usually 5 to 12 hours (Pignatello et al. 1986). Technical grade PCP was initially degraded at the same rate as reagent grade PCP by anaerobic microorganisms in municipal sewage sludge, but was later degraded more slowly. Dechlorination and mineralization (to carbon dioxide and methane) of the reagent grade PCP was complete in 7 to 9 days, but only half the technical grade PCP had been transformed in 6 to 10 days (Mikesell and Boyd 1986).

In soils, PCP persisted for 15 to more than 60 days, depending on soil conditions and application rate. At initial concentrations of 100 mg PCP/kg soil, the Tb 1/2 was 10 to 40 days at 30°C under flooded conditions; however, in aerobic soils there was virtually no degradation after 2 months (Kaufman 1978). In rice paddy soils, initial concentrations of 4 mg PCP/kg fell to 2 mg/kg in 7 days (Bevenue and Beckman 1967). Pentachlorophenol was still measurable after 12 months in warm, moist soils (Cote 1972; EPA 1980). In estuarine sediments, degradation was most rapid under conditions of increased oxygen and a pH of 8.0 (DeLaune et al. 1983).

Pentachlorophenol solutions in water at the appropriate pH and dissolved oxygen content decompose in sunlight, and this makes a strong case for the likelihood of essentially total PCP destruction in aquatic environments (Wong .and Crosby 1978). The short residence time of PCP in an aquatic system before degradation further suggests that biological effects would be most pronounced in localized areas that receive PCP continuously from a point source (Niimi and Cho 1983).

BACKGROUND CONCENTRATIONS

GENERAL

Measurable PCP concentrations in field collections of living and nonliving materials over widespread geographic areas are almost certainly due to anthropogenic activities, especially to the use of the chemical as a wood preservative.

BIOLOGICAL AND NONBIOLOGICAL SAMPLES

Pentachlorophenol-contaminated air, rain, snow, surface waters, drinking waters, groundwaters, and aquatic biota are common in the United States (Table 3; Pignatello et al. 1983; Choudhury et al. 1986). Residues of PCP in food, water, and mammalian tissues may result from the direct use of PCP as a wood preservative and pesticide or as a result of use of other chemicals that form PCP as degradation products--i.e., hexachlorobenzene and lindane (EPA 1980; Choudhury et al. 1986). To confound matters, PCP was judged to be the source of dioxin and dibenzofuran contamination in chickens in Canada (Ryan et al. 1985). More than 50% of all chickens sampled contained hexachlorinated dibenzo-p-dioxins (hexs CDDS) at concentrations of 27 ng/kg fat and higher; 62% contained hepta CDDs at more than 52 ng/kg, and 46% contained octa CDDs at more than 90 ng/kg; concentrations of hexa-, and heptachlorinated dibenzofurans were similar.

Pentachlorophenol was found at high concentrations in all samples of sediments, waters, and biota collected near industrial facilities that used PCP as a wood preservative (Niimi and Cho 1983; Table 3). Fish can bioconcentrate PCP from water up to 10,000 times (Fox and Joshi 1984). However, similar concentrations were measured in blue mussel, *Mytilus edulis* (Folke and Birklund 1986), and softshell clam, *Mya arenaria* (Butte et al. 1985), from the vicinity of PCP-contaminated wastewater discharges as well as from more distant collection sites; thus PCP bioaccumulation in marine bivalve molluscs does not appear to be dose related.

Table 3. Pentachlorophenol concentrations in nonbiological and living materials.

Compartment and units	Concentration	Reference[a]
Nonbiological		
Aquatic (µg/L)		
Rivers, Southwest Japan	1 to 10	1
Willamette River, Oregon	0.1 to 0.7	1

LETHAL AND SUBLETHAL EFFECTS

GENERAL

The toxicity of commercial or technical grades of PCP significantly exceeds that of analytical or purified PCP. Some of this added toxicity is attributed to impurities such as dioxins, dibenzofurans, chlorophenols, and hexachlorobenzene. Pentachlorophenol is rapidly accumulated and rapidly excreted, and has little tendency to persist in living organisms. It acts by uncoupling oxidative phosphorylation.

Terrestrial plants and soil invertebrates were adversely affected at 0.3 mg PCP/l (root growth), and at 1 to 5 g PCP/m^2 soil (reduction in soil biota populations).

Pentachlorophenol was most toxic and most rapidly metabolized in aquatic environments at elevated temperatures and reduced pH. Adverse effects on growth, survival, and reproduction of representative sensitive species of aquatic organisms occurred at PCP concentrations of about 8 to 80 ug/l for algae and macrophytes, about 3 to 100 ug/l for invertebrates (especially molluscs), and <1 to 68 ug/l for fishes, especially salmonids.

Fatal PCP doses for birds were 380 to 504 mg/kg BW (acute oral), >3,850 mg/kg in diets, and >285 mg/kg in nesting materials. Adverse sublethal effects were noted at dietary levels as low as 1.0 mg/kg ration. Residues (mg/kg fresh weight) in birds found dead from PCP poisoning were >11 in brain, >20 in kidney, >46 in liver, and 50 to 100 in egg.

Data are scarce on the toxicity of PCP to mammalian wildlife, but studies with livestock and small laboratory animals show that the chemical is rapidly excreted. However, there is great variability between species in their ability to depurate PCP, as well as in their overall sensitivity. Acute oral LD-50's in laboratory animals were 27 to 300 mg/kg BW. Tissue residues were elevated at dietary levels as low as 0.05 mg/kg feed and at air levels >0.l mg/m^3. Histopathology, reproductive impairment, and retarded growth were evident at doses of 0.2 to 1.25 mg/kg BW, and when the diets fed contained >30 mg PCP/kg.

TERRESTRIAL PLANTS AND INVERTEBRATES

Pentachlorophenol is toxic to plant mitochondria; the mode of action is similar to that in other organisms--i.e., uncoupling of oxidative phosphorylation. At 267 ug PCP/L, 50% uncoupling was noted in isolated mitochondria of potato, *Solanum tuberosum*, and mung bean, *Phaseolus aureus* (Ravanel and Tissut 1986). Both PCP and its metabolite tetrachlorohydroquinone adversely affect cell growth and synthesis of RNA and ribosome in yeast, *Saccharomyces* sp., in a dose-related manner (Ehrlich et al. 1987).

Uptake of PCP by rice (*Oryza sativa*) grown over a 2-year period under flooded conditions was studied after a single application of radiolabeled PCP was applied to the soil at 23 kg/ha (Weiss et al. 1982). During the first year, PCP uptake was 12.9% of the application. Roots contained about 5 mg PCP/kg, distributed as follows (mg/kg): 3.95 as unextractable residues, 0.48 as polar nonhydrolyzable substances, 0.43 as free and conjugated lower chlorinated phenols, 0.14 as free PCP, 0.07 as anisoles, 0.06 as conjugated PCP, 0.03 as hydroxymonomethoxytetrachlorobenzenes, and 0.01 as dimethoxytetrachlorobenzenes. In the second year, PCP uptake was reduced to 2.5%, and soil residues corresponded to 8.4 kg/ha; the amounts of unextractable residues in plants increased, and lower chlorinated conjugated phenols were identified (Weiss et al. 1982). Root growth in rice seedlings was inhibited 50% at 0.3 mg PCP/1 (Nagasawa et al. 1981).

Pentachlorophenol applied to beech forest soils every 2 months for 2 years at the rate of 1.0 g/m^2 markedly reduced populations of soil organisms; at 5.0 g/m^2, it drastically reduced most of the soil animal species, and also the microflora (Zietz et al. 1987). Reduction of the soil metabolism by PCP retards decomposition and affects the overall nutrient balance of forest ecosystems (Zietz et al. 1987).

AQUATIC BIOTA

Pentachlorophenol affects energy metabolism by partly uncoupling oxidative phosphorylation and increasing oxygen consumption, by altering the activities of several glycolytic enzymes and the citric acid cycle enzymes, and by increasing the consumption rate of stored lipid (Johansen et al. 1985; Brown et al. 1987; McKim et al. 1987). Collectively, these events could reduce the availability of energy for maintenance and growth and thereby reduce the survival of larval fish and the ability of prey to escape from a predator (Brown et al. 1985, 1987).

The accumulation of PCP in fishes is rapid, and primarily by direct uptake from water rather than through the food chain or diet (Niimi and Cho 1983). Signs of PCP intoxication in fish include rapid swimming at the surface and increased opercular movements, followed by loss of balance, settling to the bottom, and death (Holmberg et al. 1972;Gupta 1983). The PCP is rapidly excreted by fishes after conjugates of PCP-glucuronide and PCP-sulfate are formed; half-lives in tissues are less than 24 hours (EPA 1980). Major roles were played by gall bladder and bile in PCP-glucuronide depuration kinetics, and by gill in PCP-sulfate depuration (Kobayashi 1978; Lech et al. 1978; McKim et al. 1986). It has been suggested that the efficient elimination of PCP should allow vertebrates to tolerate periodic low doses of PCP without toxic effects (McKim et al. 1986).

Many species of aquatic organisms were found dead in rice fields of Surinam, South America, after they were sprayed with PCP to control populations of snails (Vermeer et al. 1974). Residues of PCP in dead organisms (mg PCP/kg fresh body weight) were 8.1 in frogs (*Pseudis paradoxa*); 36.8 in snails (*Pomacea* spp.); and, in three species of fish, 31.2 in krobia (*Cichlasoma bimaculatum*), 41.6 in kwi kwi (*Hoplosternum littorale*), and 59.4 in srieba (*Astyanax bimaculatus*). Pentachlorophenol was also implicated in fish kills in Europe and North America, all of which were associated with the pulpwood industry (Schimmel et al. 1978). In December 1974, near Hattiesburg, Mississippi, water containing PCP in fuel oil that overflowed the banks of a holding pond of a wood-treatment waste water facility killed all fish in a 24 ha lake. Concentrations of PCP in water and fish returned to background concentrations 10 months after the spill; however, the chemical persisted in leaf litter and sediments for at least 17 months after the spill (Pierce and Victor 1978). In December 1976, another fish kill was observed near the same facility. Residues of PCP in surviving fish--including bluegills (*Lepomis macrochirus*), largemouth bass (*Micropterus salmoides*), and channel catfish (*Ictalurus punctatus*)--were greatly elevated one month later: 8 to 19 mg PCP/kg fresh weight in muscle, 42 to 48 mg/kg in gill, and 130 to 221 mg/kg in liver (Pierce and Victor 1978). Pentachlorophenol persisted in fish for 6 to 10 months before reaching background concentrations.

Studies with experimental ecosystems have indicated that the effects of PCP on community structure and activity are profound. These included a reduction in the number of individuals and species of estuarine macrobenthos after exposure to 55 to 76 ug PCP/l for 5 to 9 weeks (Tagatz et al. 1977, 1983) or 15.8 ug/l for 13 weeks (Tagatz et al. 1978); a decrease in periphyton biomass, fish growth, and larval drift, and a suppression of community metabolism at 48 ug PCP/l after 3 months exposure (Hedtke and Arthur 1985; Zischke et al. 1985; Yount and Richter 1986); elevated levels of PCP in postlarval shrimp, *Penaeus vannamei*, after chronic exposure to 10 ug PCP/1 (Seidler et al. 1986); and bioconcentration factors after exposure to radiolabeled PCP of 5X for an alga (*Oedogonium cardiacum*), 21X for a snail (*Physa* sp.), 26X for a mosquito larva (*Culex pipiens quinquefasciatus*), 132X for mosquitofish (*Gambusia affinis*), and 205X for *Daphnia magna* (^{14}C pentachlorophenol in laboratory model ecosystems. Pages 53-63 Lu et al. 1978)

In laboratory studies, increased accumulation and adverse effects on growth, survival, and reproduction were seen in sensitive species of aquatic organisms: in algae and macrophytes at water concentrations (ug PCP/1) of 7.5 to 80; in a wide variety of invertebrates, especially molluscs, at 2.5 to 100; and in fishes, especially salmonids, at <1.0 to 68 (Table 4).

Biocidal properties of PCP were significantly modified by water pH and temperature, and by the purity of PCP compounds tested. In general, PCP was most toxic and was metabolized most rapidly (Table 4) at elevated water temperatures (EPA 1980; Hodson and Blunt 1981; Niimi and Palazzo 1985; Fisher 1986) and at reduced pH (Bevenue and Beckman 1967; EPA 1980; Dave 1984; Choudhury et al. 1986; Fisher 1986; Seidler et al. 1986). Increasing pH of the water column decreases the hazard of PCP to aquatic biota: at pH above 4.8, for example, hydroxyl proton is dissociated and penetration in aquatic organisms is reduced (Fisher 1986). All authorities agree that commercial or technical grades of PCP are significantly more toxic to aquatic organisms

than is purified PCP (EPA 1980; Cleveland et al. 1982; Huckins and Petty 1983; Dominguez and Chapman 1984; Stuart and Robinson 1985; Hamilton et al. 1986; Nagler et al. 1986). The sublethal effects of low concentrations of commercial PCP to aquatic biota are due primarily to impurities composed mostly of octa- and nonachlorophenoxyphenols (Hamilton et al. 1986), and also to relatively large quantities of hexachlorobenzene, dioxins, and dibenzofurans (Cleveland et al. 1982).

BIRDS

Signs of PCP intoxication in birds include excessive drinking and regurgitation, rapid breathing, wing shivers or twitching, jerkiness, shakiness, ataxia, tremors, and spasms (Hudson et al. 1984). Signs sometimes appear within 10 minutes. Mallards usually die 2 to 24 hours posttreatment, and ring-necked pheasants 3 to 5 days posttreatment; remission in pheasants requires up to 2 weeks (Hudson et al. 1984).

Pentachlorophenol killed various species of birds at single oral doses of 380 to 504 mg/kg BW, at dietary concentrations of 3,850 mg/kg ration fed over a 5-day period, and when nesting materials contained >285 mg/kg. Residues (mg/kg fresh weight tissue) in birds found dead from PCP poisoning were 11 in brain, 20 in kidney, 46 in liver, and 50 to 100 in egg (Table 5). Sublethal effects, including liver histopathology and diarrhea, were reported in domestic chickens at dietary levels as low as 1 mg PCP/kg feed over an 8-week period; significant accumulations in tissues were measured after consumption for 14 days of diets containing 10 mg PCP/kg (Table 5). Residues in chickens fed PCP-containing diets for 8 weeks were dose-related and highest in kidney and liver and lower in other tissues; the high residues may reflect the principal routes of metabolism and excretion (Stedman et al. 1980). The loss of body fat in chickens, accomplished by feeding bile acid binding resins, hastens PCP excretion (Table 5; Polin et al. 1986).

Table 4. Lethal and sublethal effects of pentachlorphenol on selected species of aquatic organisms.

Species and other variables	Concentration, in µg PCP/L medium	Effect	Reference[a]
Algae and macrophytes			
Alga, *Chlorella pyrenoidosa*	7.5	Total chlorosis inhibition in 72 h	1
Alga, *Skeletonema costatum*	17 to 20	50% reduction in cell numbers at 96 h	1
Filamentous algae (*Chara* sp., *Enteromorpha* sp.)	50 to 100	Lethal in 30 days in outdoor ponds; Their decay was responsible for depression of dissolved oxygen and later fish deaths	2
Alga, *Scenedesmus costatum*	80	50% growth inhibition in 96 h	2
Alga, *Selenastrum capricornutum*	110 to 150	50% growth reduction in 96 h in soft water	3
S. capricornutum	290	50% growth inhibition in 96 h	2
S. capricornutum	760	50% growth reduction in 96 h in hard water	3
Alga, *Dunaliella tertiolecta*	170 to 206	50% reduction in cell numbers in 96 h	1
Alga, *Thalassiosira pseudonana*	179 to 189	50% reduction in cell numbers in 96 h	

Duckweed, *Lemna minor*	800	50% inhibition of chlorosis in 48 h	1
L. minor	1,000	Inhibition of photosynthetic oxygen production	5
L. minor	1,400	No measurable effect after exposure for 21 days	4
Invertebrates			
Eastern oyster, *Crassostrea virginica*	2.5	BCF of 78x in 28 days; 100% depuration within 4 days postexposure	6
C. virginica	25	BCF of 41x between days 4 and 28 of exposure; 100% depuration within 4 days postexposure	6
C. virginica	34	50% reduction in shell deposition in 8 days	1
C. virginica	40	50% abnormal development of larvae in 48 h	7
C. virginica	77	LC-50 (96 h)	1
Cladoceran, *Ceriodaphnia reticulata*	4.1	Reduction in number of young produced per female in lifetime exposure	4
C. reticulata	164	LC-50 (48 h)	8
Polychaete worm, *Ophryotrocha diadema*	10 to 13	No effect on reproduction in 41 days	8
O. diadema	23 to 75	50% inhibition in reproduction in 41 days	8
Clam, *Mulinia lateralis*	15.8	Populations reduced after 7 days	9
Razor clam, *Ensis minor*	15.8	Populations reduced after 7 days	9
Hydra, *Hydra littoralis*	19	Threshold for reproduction inhibition	8
Snail, *Physa gyrina*	26	Reproduction in number of egg masses produced and in egg survival during lifetime exposure	4, 10
P. gyrina	220	LC-50 (96 h) at 24 °C	4
P. gyrina	730	LC-50 (96 h) at 8.6 °C	11
P. gyrina	1,380	LC-50 (96 h) at 3.2 °C	4
Pacific oyster, *Crassostrea gigas*	55	62% of exposed embryos developed abnormally in 48 h	1
Midge, *Chironomus riparius*, 4th instar	84	LC-50 (24 h) at pH 4	12
C. riparius	465	LC-50 (24 h) at pH 6	12
C. riparius	631	50% locomotion inhibition at 35 °C	13
C. riparius	1,176	50% locomotion inhibition at 15 °C	13
C. riparius	1,948	LC-50 (24 h) at pH 9	12
Snail, *Lymnaea acuminata*	100	LC-16 (96 h)	14

L. acuminata	160	LC-50 (96 h)	14
L. acuminata	210	LC-84 (96 h)	14
Snail, *Australorbis glabratus*	100	Reduction in egg production and viability after exposure for 7 to 8 days	2
Sea urchin, *Paracentrotus lividus*, embryos	100	Reductions in various amino acid activity levels during exposure for 40 h	15
P. lividus	200	Number and size of swimming blastulae, gastrulae, and plutei reduced in 40-h exposure	15
Short-necked clam, *Tapes philippinarum*	100	Lethal in 120 h	16
Snail, *Lymnaea luteola*	112	LC-50 (96 h)	17
Flatworm, *Pugesia lugubris*	130	LC-50 (48 h)	8
Snail, *Lymnaea stagnalis*	180	LC-50 (16 days)	2
Cladoceran, *Daphnia magna*	180	No observable effect level in lifetime exposure	1
D. magna	320	Some adverse effects observed in lifetime exposure	1
D. magna	370 to 440	50% immobilization in 48 h	18
D. magna	475	LC-50 (96 h)	1
Cladoceran, *Simocephalus vetulus*	204	LC-50 (96 h) at 24 °C	4
S. vetulus	670	LC-50 (96 h) at 18 °C	11
Tubificid worm, *Tubifex tubifex*	286	LC-50 (24 h) at pH 7.5	1
T. tubifex	619	LC-50 (24 h) at pH 8.5	1
T. tubifex	1,294	LC-50 (24 h) at pH 9.5	1
Snail, *Gillia altilis*	300	LC-50 (96 h) in flow-through test	19
G. altilis	810	LC-50 (96 h) in static test	19
Mysid, *Mysidopsis bahia*	320	LC-50 (96 h)	20
Grass shrimp, *Palaemonetes pugio*	400 to 440	LC-50 (96 h) during molting	20, 21
P. pugio	473 to 637	Adversely affects initiation and progress of limb regeneration without altering duration of molt cycle	22
P. pugio	649 to 1,200	LC-50 (96 h)	1, 7
P. pugio	1,000	Histopathology of gill, hepatopancreas, and midgut epithelial cells after exposure for 12 days in shrimp that molted; normal tissues in shrimp that had not yet molted	21
P. pugio	2,500	LC-50 (96 h) during intermolt	20, 21

Polychaete worm, *Neanthes arenaceodentata*	435	LC-50 (96 h)	1
Amphipod, *Gammarus pseudolimnaeus*	770	Significant decreases in free amino acids after 5 days; in whole body glycogen, protein, and caloric content after 15 days; and in lipid content after 30 days	23
G. pseudolimnaeus	860	LC-50 (30 days)	23
G. pseudolimnaeus	1,150	LC-50 (96 h)	24
G. pseudolimnaeus	1,680	At 48 h, significant decrease in total free amino acid levels	24
Pond snail, *Vivparus bengalensis*	840	LC-50 (96 h)	25
Caddisfly, *Philarctus quaeris*	1,200	LC-50 (96 h)	11
Mayfly, *Callibaetis skokianus*	1,700	LC-50 (96 h)	11
Amphipod, *Crangonyx psedogracilis*	1,900	LC-50 (96 h)	11
Isopod, *Asellus racovitzai*	2,300	LC-50 (96 h) at 8.6 °C	11
A. racovitzai	4,320	LC-50 (96 h) at 4.2 °C	4
A. racovitzai	>7,770	LC-50 (96 h) at 3.2 °C	4
Crayfish, *Astacus fluviatilis*	9,000	LC-50 (8 days) at pH 6.5	26
A. fluviatilis	53,000	LC-50 (8 days) at pH 7.5	26
Vertebrates			
Rainbow trout, *Salmo gairdneri*	0.035	After 115 days, whole fish BCF 286x to 572x; half eliminated in 7 days	8, 57
S. gairdneri	0.7	After 115 days, BCF of 160x in whole fish; Tb1/2 elimination time of 7 days	8, 57
S. gairdneri	1.0	Whole body BCF of 221x in 18 h and 466x in 11.7 days; Tb1/2 of 65 h and 95% depuration in 12 days. Highest PCP tissue residues were bile >> liver >> blood > kidney > spleen > skin-bone-gill-gonad > muscle	27
S. gairdneri	7.4	27% inhibition of growth in 28 days	1
S. gairdneri	10 to 20	Some deaths during exposure from fertilization to yolk-sac absorption; 100% dead at 5 mg dissolved oxygen (DO)/L and 20 mg PCP/L; 100% dead at 3 mg DO/L and 10 mg PCP/L	28
S. gairdneri	11	No adverse effects observed during exposure from fertilization through day 72	29

S. gairdneri	19	Embryo mortality negligible during exposure from fertilization through day 72. Alevin mortality 3x greater than in controls. Growth in length and weight reduced. Fin erosion, mild cranial malformations, and lethargy reported	29
S. gairdneri	22	48% reduction in viable oocytes after exposure for 18 days	30
S. gairdneri	25	After 24 h, BCF of 40x in muscle, 240x in fat, 260x in blood, and 640x in liver. Tb1/2 values ranged from 7 h in muscle to 23 h in fat	31, 58
S. gairdneri	28	11% to 19% inhibition in growth in 20 to 38 days	1
S. gairdneri	34 to 121	LC-50 (96 h)	1, 29, 32, 33, 34
S. gairdneri	40	100% mortality during exposure from fertilization to yolk-sac absorption (72 days)	28
S. gairdneri	46	LC-100 (41 days)	1
S. gairdneri	49	81% reduction in oocytes available to complete oogenesis after exposure for 18 days	30
S. gairdneri	60	Eye abnormalities noted in developing embryos after exposure for 17 days; all dead at day 72 of exposure	29
S. gairdneri	10,000	LC-50 (3.5 h)	35
Sockeye salmon, *Oncorhynchus nerka*	3.2	10% growth inhibition in 6 weeks	1
O. nerka	63 to 68	LC-50 (96 h)	1, 56
Common carp, *Cyprinus carpio*	9.5	LC-50 (96 h), larvae	8
C. carpio	266	Reduction in liver glucose and glycogen release after 3 days; high accumulations in liver	36
C. carpio	1,500	LC-50 (3 h)	37
Largemouth bass, Micropterus salmoides	10	Food conversion efficiency significantly reduced in a concentration-dependent fashion at concentrations >10 µg/L	38
M. salmoides	25.2	Growth reduction after exposure for 52 days	38
M. salmoides	45	Decline in feeding activity after 8 weeks	38

M. salmoides	50	After 14 days, food conversion efficiency reduced 30%, reduction in ability to capture prey and in food consumed	39
M. salmoides	54	LC-50 (120 days)	38
M. salmoides	67	Exposure for 8 weeks produced hyperactivity and reductions in feeding rate and in prey capture	40
M. salmoides	136 to 287	LC-50 (96 h)	38, 39, 41
Rasbora, *Rasbora daniconius neilgeriensis*	10	LC-0 (96 h)	42
R.d. neilgeriensis	67	LC-16 (96 h)	42
R.d. neilgeriensis	148	LC-50 (96 h)	42
R.d. neilgeriensis	330	LC-84 (96 h)	42
Pinfish, *Lagodon rhomboides*	31 to 53	LC-50 (96 h)	1, 7, 20
Bluegill, *Lepomis macrochirus*	32 to 215	LC-50 (96 h)	1, 11, 32, 33
L. macrochirus	100	After exposure for 8 days, BCF 13x in muscle, 60x in gill, 210x in gastrointestinal tract, and 350x in liver. Rapid elimination, but some residues in muscle and liver were detectable 16 days postapplication	43
L. macrochirus	100	Liver histopathology after 32 days; degenerative changes detectable after 2 days	44
L. macrochirus	432	LC-100 (8 days)	10
Fathead minnow, *Pimephales promelas*	45	No observable effect level in lifetime exposure	1, 54
P. promelas	48	Growth and larval drift reduced after exposure for 12 weeks	10
P. promelas	50	Whole body BCF of 174x after 14 days; nondetectable residues after 14 days in clean water	45
P. promelas	73	Some adverse effects in lifetime exposure	1, 54
P. promelas	85	Growth reduction after 90 days exposure	46
P. promelas	120	LC-50 (96 h) at 16.6 °C	4
P. promelas	170	LC-50 (96 h) at 10.1 °C	4
P. promelas	200 to 350	LC-50 (96 h)	2, 11, 35
P. promelas	300	LC-50 (96 h) at 3.4 °C	4
Atlantic salmon, *Salmo salar*	46	Altered temperature preference in 24 h	1

S. salar	500	LC-50 (96 h)	35
S. salar	2,000	LC-50 (10.5 h)	35
S. salar	10,000	LC-50 (2.7 h)	35
Sheepshead minnow, *Cyprinodon variegatus*	47	No observable effect level in lifetime exposure	1
C. variegatus	88	12% mortality in lifetime exposure	47
C. variegatus	195	Life cycle exposure resulted in reduced hatch and survival of second generation fish	47
C. variegatus	223 to 392	LC-50 (96 h) for fry age 1 day to 6 weeks	7
C. variegatus	389	LC-100 (60 days)	47
C. variegatus	442	LC-50 (96 h)	1, 47
Flounder, *Pleuronectes platessa*	50	LC-50 (8 weeks), eggs	8
P. platessa	60 to 140	LC-50 (96 h), larvae	8
P. platessa	100 to 130	LC-50 (96 h), juveniles	8
Channel catfish *Ictalurus punctatus*	54 to 68	LC-50 (96 h)	8, 32, 33
Coho salmon, *Oncorhynchus kisutch*	55	LC-50 (96 h)	1
White crappie, *Pomoxis annularis*	56 to 75	LC-50 (96 h)	35
Longnose killifish, *Fundulus similis*	57 to 610	Whole body BCF of 53x after 168 h; Tb1/2 of 4. 7 days. Whole body residues up to 33 mg/kg fresh weight	48
Chinook salmon, *Oncorhynchus tshawytscha*	68 to 78	LC-50 (96 h)	1, 32, 55
White sucker, *Catostomus commersoni*	85	LC-50 (96 h)	4
Eel, *Anguilla anguilla*	100	Seawater-exposed eels, after exposure for 8 days, had 33 mg PCP/kg fresh weight in liver, 9 in muscle, and 4 in blood; after depuration for 8 days, values were 12 in liver, 4 in muscle, and 2 in blood. Eels exposed in freshwater for 4 days had 2 to 9 mg PCP/kg tissue, and <1.2 mg/kg 38 days postexposure	49
Goldfish, *Carassius auratus*	100	BCF of 1,000x after 12 h. Residues in dead fish were 82 to 116 mg PCP/kg	

		BW; no surviving fish contained more than 114 mg/kg	16, 48
C. auratus	200	Whole body residue of 116 mg/kg after exposure for 120 h	48
Tilapia, *Tilapia nilotica*	100	In 24-h tests, fish acclimatized to seawater were twice as resistant as freshwater-acclimatized fish to biocidal PCP properties, and contained lower residues	50
Mullet, *Rhinomugil corsula*	100	Metabolic rate elevated after 3 h	37
R. corsula	1,000	LC-50 (3 h)	37
Striped mullet, *Mugil cephalus*	112	LC-50 (96 h), whole body BCF of 38x	1, 6
Brook trout, *Salvelinus fontinalis*	128	LC-50 (96 h)	1
Salamander, *Ambystoma mexicanus*	130	LC-0 (48 h)	8
A. mexicanus	300	LC-50 (48 h)	8
Common shiner, *Notropis cornutus*	180	25% growth reduction after exposure for 7 days	51
N. cornutus	320	LC-100 (7 days)	51
Fish, 19 species	200 to 600	LC-50 (96 h)	35
Frog, *Xenopus laevis*	210	LC-0 (48 h)	8
X. laevis	260	LC-50 (48 h)	8
Guppy, *Poecilia reticulata*	500 to 700	Reduction in ability to escape from piscine predators	52
P. reticulata	700	LC-21 (30 days)	52
P. reticulata	1,000	LC-0 (12 days); possible acclimatization	53
P. reticulata	1,020	LC-50 (96 h)	52
Sea lamprey, *Petromyzon marinus*	924	LC-100 (4 h)	1

Table 5. Effects of pentachlorophenol on selected species of birds.

Species and other variables	Effect and reference
Mallard, *Anas platyrhynchos*	Acute oral LD-50 of 380 mg/kg body weight (BW); 95% confidence interval 205 to 704 mg/kg BW (Hudson et al. 1984)
Japanese quail, *Coturnix japonica*. Birds age 14 days were fed treated diets for 5 days, then untreated feed for 3 days	No deaths at 3,100 mg/kg diet, 35% dead at 3,850, 50% at 5,139 (4,149 to 6,365), and 69% dead at 6,000 mg PCP/kg diet (Hill and Camardese 1986)
Domestic chicken, *Gallus gallus*. Fed diets containing 1, 10, 100, or 1,000 mg PCP/kg for 8 weeks	Liver histopathology and diarrhea recorded in all treated groups vs. non in controls. The 1,000 mg/kg diet was the only ration to adversely affect the weight of all organs analyzed. After 5 weeks on PCP-free diet, residues were still measurable in adipose tissues of all treated birds (Stedman et al. 1980)
Domestic chicken. Fed dietary levels of 600, 1,200, or 2,400 mg/kg for 8 weeks	No deaths in any group. Residues (mg/kg fresh weight) in 600 mg/kg group at 8 weeks were 2 in muscle, 10 in fat, 25 in liver and 80 in kidney vs. <0.02 in controls; no significant difference from controls in growth, blood chemistry, histopathology, or immune response. In the 1,200- and 2,400-mg/kg groups body weight decreased and liver weight increased; tissue residues were dose related (Prescott et al. 1982)
Domestic chicken. Raised over wood shavings containing 134 mg PCP/kg for 9 weeks	The PCP residues (mg/kg FW) were 3.7 in liver 0.4 in muscle, and 0.3 in fat, vs. <0.08 in controls (Newsome et al. 1984)

Domestic chicken. Fed diets containing 10 mg PCP/kg for 14 days, then 21 days on PCP-free diets containing either no additives, 5% mineral oil, or 5% colestipol hydrochloride	Body burden at 14 days was 362 µg/bird or 1.1 µg/kg BW. After 21 days, body burdens were 255 µg/bird in no-additive diet and nondetectable levels of <0.7 µg/bird in mineral oil and colestipol additive diets (Polin et al. 1986)
Domestic chicken. Eggs received single injected dose	Hatching reduced 50% at a dose of 50 mg PCP/kg egg and 100% at 100 mg/kg (none hatched) (Stedman et al. 1980)
Ring-necked pheasant, *Phasianus colchicus*	Acute oral LD-50 of 504 mg/kg BW; 95% confidence interval 343 to 743 mg/kg BW (Hudson et al. 1984)
Snail kite, *Rostrhamus sociabilis.* Found dead in rice fields after spraying to control populations of snails (*Pomacea glauca, P. lineata*)--the exclusive food of snail kites. Residues in soft parts of snails found dead after spraying were about 37 mg PCP/kg fresh weight	Residues in dead snail kites, in mg PCP/kg FW, were 46 in liver, 20 in kidney, and 11 in brain vs. <0.2 in controls, and 2 to 17 in birds surviving exposure (Vermeer et al. 1974)
Canary, *Serinus canarius*. Nesting on straw containing 285 mg PCP/kg	Reduced hatch, high mortality of young during the first week posthatch, and none surviving to age 3 months. Prior to death, young showed inhibited growth and feather development. Adult birds appeared normal (Dorrestein and Zelle 1979)

Spraying of PCP to control populations of water snails in rice fields of Surinam resulted in the death of fish and birds, including snail kites (*Rostrhamus sociabilis*), certain egrets and herons, and wattled jacanas (*Jacana jacana*). Levels of PCP in these birds and their food items suggested that PCP-contaminated food probably caused the deaths (Vermeer et al. 1974; Table 5).

Pentachlorophenol is widely used as a wood preservative, which often results in residues in wood shavings used as poultry litter. A moldy smell and taste in chicken tissue has been traced to the presence of chloroanisoles formed from PCP and tetrachlorophenol in the bedding. Several dioxins, diphenyl ethers,

dibenzofurans, and 2-phenoxyphenols have also been identified (Newsome et al. 1984). For example, PCP-contaminated (134 mg/kg) commercial wood shavings used as chicken litter contained detectable levels of heptachlorinated diphenyl ethers (18 ug/kg), octachlorinated diphenyl ethers (12 ug/kg) nonachlorinated diphenyl ethers (6 ug/kg), octachlorinated 2-phenoxyphenols (299 ug/kg), nonachlorinated 2-phenoxyphenols (50 ug/kg), heptachlorinated dibenzodioxins (19 ug/kg), and octachlorinated dibenzodioxins (143 ug/kg). After 9 weeks, PCP was detectable in liver, fat, and muscle; chlorinated diphenyl ethers were detectable in fat, but not in muscle or liver; octa- and nonachlorinated 2-phenoxyphenols were found in all three tissues; and dioxins only in liver and fat (Newsome et al. 1984). Exposure of domestic chickens to litter contaminated with PCP enhanced susceptibility to common poultry pathogens, perhaps due to immunosuppression by the chemical (Prescott et al. 1982).

MAMMALS

Data are scarce on the biological effects of PCP on mammalian wildlife, although evidence continues to accumulate on this subject for man, livestock, and small laboratory animals. Available data on PCP and mammals are briefly summarized, but it is not now clear if these findings are applicable to representative species of sensitive mammalian wildlife.

Pentachlorophenol tends to accumulate in mammalian tissues unless it is efficiently conjugated into a readily excretable form (Kinzell et al. 1985). The ability to conjugate PCP varies widely among species (Braun and Sauerhoff 1976; EPA 1980). For example, both laboratory rats (*Rattus* sp.) and humans eliminate about 75% of all PCP in the urine in an unconjugated form, but rhesus monkeys (*Macaca mulatta*) are unable to excrete PCP efficiently, whereas mice were the most efficient. As one result, Tb 1/2 values were low (about 24 hours) for mice, high (up to 360 hours) for rhesus monkey, and intermediate for rats and humans (EPA 1980). In man, however, the observed elimination half-life indicates that steady-state body burdens are 10 to 20 times higher than values extrapolated from animal pharmacokinetic data (Uhl et al. 1986).

Pentachlorophenol is not a carcinogen, and the evidence for mutagenicity is mixed. No carcinomas were produced in rodents, regardless of the composition of the PCP solution tested or route of exposure (EPA 1980; Choudhury et al. 1986). Some studies suggested that PCP may be mutagenic in the bacterium *Bacillus subtilis*, the yeast *Saccharomyces cerevisiae*, and in laboratory mice (*Mus* sp.), but not in two other species of bacteria tested--*Salmonella typhimurium* and *Escherichia coli* (Choudhury et al. 1986).

The primary sources of PCP in man include direct intake by way of diet, air, or water and through contact with PCP-contaminated materials (Uhl et al. 1986). The chief routes of exposure in an industrial setting are by way of inhalation and skin contact. Percutaneous absorption is significantly enhanced when PCP is dissolved in organic solvents, such as fuel oil, or when PCP comes in contact with open cuts and scratches (Wood et al. 1983). Pentachlorophenol has resulted in death in man through suicide and occupational and accidental exposures (EPA 1980; Rozman et al. 1982; Lambert et al. 1986).

Cases of PCP poisoning, including fatalities, were characterized by high fever, renal insufficiency, profuse perspiration, rapid heart beat and breathing, abdominal pain, dizziness, nausea, spasms, and death 3 to 25 hours after onset of symptoms (Knudsen et al. 1974; EPA 1980; Wood et al. 1983). Postmortem examination showed kidney degeneration, inflamed gastric mucosa, edematous lungs, and centrilobular degeneration of liver (EPA 1980; St. Omer and Gadusek 1987). Symptoms of nonfatal PCP intoxication in man include conjunctivitis, chronic sinusitus, nasal irritation, upper respiratory complaints, sneezing, coughing, recurring headache, neurological complaints, weakness, and several types of skin lesions (Knudsen et al. 1974; EPA 1980; Rozman et al. 1982). All symptoms were related to proximity to PCP-treated wood, and sometimes to elevated PCP residues in serum and urine (Lambert et al. 1986). At the cellular level, PCP--like other halogenated phenols--uncouples oxidative phosphorylation. A possible antidote to PCP poisoning is the administration of cholestyramine, a compound that interferes with the enterohepatic cycle of PCP, and also increases its elimination directly across the intestinal wall (Rozman et al. 1982).

The exposure of livestock to PCP can result from ingestion of feeds stored or fed in PCP-treated wooden structures, licking of treated wood, cutaneous absorption by direct contact with treated wood, and inhalation of air containing preservative chemicals--particularly volatile chlorophenols (Forsell et al. 1981). Acute signs of PCP intoxication in various domestic and laboratory animals include elevated blood sugar, vomiting, elevated blood pressure, increased respiration rate, tachycardia, motor weakness, weakened eye reflex, frequent

defecation, high fever, collapse, asphyxial convulsions, and death followed by rapid rigor mortis (Knudsen et al. 1974; Nishimura 1984; St. Omer and Gadusek 1987). In domestic cattle (*Bos* sp.) PCP has also been associated with decreased milk production, skin lesions, increased mastitis, persistent infections, and reduced survival (Forsell et al. 1981).

Among sensitive species of mammals tested against PCP (Table 6), acute oral LD-50 values ranged from 27 to 300 mg/kg BW, but most values were between 55 and 150 mg/kg BW. Sublethal effects were noted at much lower concentrations than those causing death. They included elevated tissue residues at dietary intake; equivalent to 0.05 mg/kg BW, or atmospheric concentrations >0.1. mg/m^3; organ damage at 0.2 to 2.0 mg/kg BW; reproductive impairment at >1.25 mg/kg BW; and retarded growth and reproduction in animals fed rations containing >30 mg/kg (Table 6).

Many commercial lots of technical PCP are known to contain small--but possibly biologically significant--amounts of highly toxic dioxins, dibenzofurans, and hexachlorobenzene. These contaminants may be responsible for most of the toxicity of technical PCP preparations (McConnell et al. 1980; Parker et al. 1980; Wollesen et al. 1986; Holsapple et al. 1987). However, both technical and analytical grade PCP can induce hepatic mixed function oxidases in intoxicated rats and cattle. In cattle, this effect was observed in both calves and adults, and in hepatic as well as pulmonary microsomes, and seemed to be dose related (Shull et al. 1986).

Table 6. Effects of pentachlorophenol on selected animals.

Organism, dose, and other variables	Effects and reference
Domestic cattle, *Bos taurus*	
Oral dose of 0.05 or 0.5 mg/kg BW	Maximal plasma values of 1.5 and 9.6 mg/L, respectively. Calves fed grain and hay from a PCP-treated feeder for 10 days contained plasma PCP levels of 1.1 mg/L, but levels returned to normal after access to feeder was denied (Osweiler et al. 1984)
Fed equivalent of 0.2 mg/kg BW daily for 75 to 84 days, then 2.0 mg/kg BW daily for 50 to 62 days	No effect on milk production, feed intake, body weight, lymphocyte function, or histopathology of spleen, thymus, or lymph nodes. Postmortem examination showed enlarged liver, lungs, kidneys, and adrenals; significant loss of renal function (Forsell et al. 1981; Kinzell et al 1981)
Fed 0.2 mg/kg BW daily for 95 days, then given single oral dose of uniformly ring-labeled C^{14}-PCP; analyzed 4 days postadministration	Highest residues were in liver, kidney, and lungs; in milk, the fat fraction contained the greatest amount. Tb1/2 for absorption was 4.3 h, and for elimination 43 h. Most excretion was by way of urine (76%), then milk, and feces (5% each). In urine, PCP was present in the conjugated form (Kinzell et al. 1985)
Fed 20 mg technical grade PCP/kg BW daily for 10 days, then 10 mg/kg BW for an additional 60 days	No clinical effects noted during the 70-day treatment or during a 165-day posttreatment period. Contaminants in PCP--including several dioxins and hexachlorobenzene--were found in milk, fat, and blood. PCP residues in whole milk rose to 4 mg/kg, but

	declined to <0.1 mg/kg within a few days after PCP cessation (Firestone et al. 1979)
Female yearling Holsteins were fed technical or analytical grade PCP in diets at 20 mg/kg BW daily for 42 days (647 mg/kg diet), then 15 mg/kg BW daily for 118 days (491 mg/kg diet)	Technical grade PCP was related to decreased body weight and feed conversion efficiency, anemia, enlarged liver and lungs, decreased thymus weight, and lesions in urinary bladder mucosa. Holsteins exposed to analytical grade PCP were comparable to controls. The toxicity of PCP in cattle seems to be due to its contamination with toxic impurities, especially dioxins (McConnell et al. 1980; Parker et al. 1980)
140 mg/kg BW	Acute oral LD-50 (Knudsen et al. 1974)
Domestic dog, *Canis familiaris*	
150 to 200 mg/kg BW	Acute oral LD-50 (Knudsen et al. 1974)
Guinea pig, *Cavia porcellus*	
100 mg/kg BW	Acute oral LD-50 (Choudhury et al. 1986)
Hamster, *Cricetus* spp.	
1.25 to 20 mg/kg BW	Fetal deaths and resorption (EPA 1980)
Man, *Homo sapiens*	
Average concentrations of 0.0012 to 0.18 mg/m^3 air for 3 to 34 years among occupationally exposed workers	Concentrations of PCP in blood of 20 workers ranged between 0.023 and 0.775 mg/L and were below the "biological tolerance value" of 1.0 mg/L; no effect on sister chromatid exchange or chromosomal aberrations (Ziemsen et al. 1987)
<0.02 to >0.1 mg/L urine in occupationally exposed woodworkers	During a 16-day vacation and plant shutdown, urinary excretion accounted for 90% elimination in those with high initial PCP levels (i.e., >0.1 mg/L) to 67% elimination in those with initial urinary levels of 0.02 to 0.1 mg PCP/L, and to 34% reduction in workers with <0.02 mg/L; Tb1/2 was estimated at 33 h in urine and 30 h in plasma (Kalman and Horstman 1983)
Single oral dose of 0.1 mg/kg BW	In urine of four subjects, 74% was eliminated unchanged and 12% as PCP-glucuronide; 4% was eliminated in feces as PCP and PCP-glucuronide. A peak blood level of 0.25 mg/L was reached 4 h after dosing (EPA 1980)
>1.0 mg/m^3 air	Painful irritation in upper respiratory tract, sneezing, and coughing in persons newly exposed to PCP; up to 2.4 mg/m^3 can be tolerated by conditioned individuals (EPA 1980)

Total dose of 3.9 to 18.0 mg	Steady state attained in about 3 months; Tb1/2 values of 20 days in whole body and about 17 days in urine and blood (Uhl et al. 1986)
8 to 1,130 mg/kg fresh weight tissue	Residues in tissues of 33-year-old male who died after working in chemical plant for 3 weeks; job involved breaking up large blocks of PCP with jackhammer. Before death, high body temperature and coma. After death, rigor mortis was profound and immediate. Postmortem examination showed cerebral edema, fatty degeneration of viscera, and PCP levels (mg/kg) of 8 in stomach contents, 29 in urine, 52 in liver, 116 in lung, 162 in blood, 639 in kidney, and 1,130 in bile (Wood et al. 1983; Gray et al. 1985)
28 to 225 mg/kg fresh weight tissue	Residues associated with acute toxicosis and death were 28 to 123 in kidney, 50 to 176 in blood, and 62 to 225 in liver (EPA 1980)
75 to 225 mg/kg fresh weight tissue	Residues in tissues of PCP suicide victim were 75 in urine, 116 in kidney, 173 in blood, and 225 in liver (EPA 1980)
4,000 mg/L solution	Immersion of hands for 10 min produced skin irritation (EPA 1980)
Domestic cat, *Felis domesticus*	
Pine wood shavings used as litter, containing 470 mg PCP/kg	Of 14 cats in contact with litter, 3 died and 8 became ill but recovered. Maximum PCP residues (mg/kg) in the dead cats were 20 in liver, 24 in kidney, and 10 in stomach contents (Peet et al. 1977)
Rhesus monkey, *Macaca mulatta*	
10 mg/kg BW, single oral dose	Residues highest in liver and GI tract; all other tissues contributed <4% of total body burden (EPA 1980)
10 mg/kg BW, single oral dose	Tb1/2 values in blood and urine were 41 to 72 h in males and 84 to 92 h in females (Braun and Sauerhoff 1976)
50 mg/kg BW, repeated 4 weeks later	During the first day after each dose, 20% was excreted into urine 0.5% into feces, and 20% into bile. The addition of 4% cholestyramine to diets for 6 days resulted in increased fecal excretion by a factor of 18x and increased total body burden excretion by 1.4x (Rozman et al. 1982)
Mouse, *Mus musculus*	
Fed diets equivalent to 3 mg/kg BW daily for 24 months	No measurable effect in females, based on clinical chemistry, hematology, routine histopathology, and organ weight changes (EPA 1980)

Fed diets equivalent to 10 mg/kg BW daily for 22 months	No measurable effect in males, based on clinical chemistry, hematology, routine histopathology, and organ weight changes (EPA 1980)
15 to 37 mg/kg BW through intraperitoneal or subcutaneous route	Tb1/2 of about 24 h through urinary excretion (EPA 1980)
Fed diets containing 50 mg pure (99%) PCP/kg or technical grade (86%) for 10 to 12 weeks	Mice exposed to technical grade PCP had enhanced tumor susceptibility (1.9x) from transplanted tumors; mortality increased 2.4x over controls after sarcoma virus inoculation. Mice exposed to pure PCP showed no enhanced growth of reduced tumors, but developed splenic tumors; 22% vs. none in controls (Kerkvliet et al. 1982)
65 to 252 mg/kg BW	Acute oral LD-50; females more sensitive than males (Knudsen et al. 1974; Borzelleca et al. 1985; Choudhury et al. 1986)
White rabbit, *Oryctolagus cuniculus*	
1 to 3 mg/kg BW daily for 90 days administered orally	No signs of intoxication (EPA 1980)
39 mg/kg BW	Lethal cutaneous dose administered in pine oil (Cote 1972)
60 to 200 mg/kg BW	Acute dermal lethal dose (EPA 1980)
100 to 130 mg/kg BW	Acute oral LD-50 (Knudsen et al. 1974; Choudhury et al. 1986)
350 mg/kg BW	Lethal cutaneous dose administered in olive oil (Cote 1972)
Domestic sheep, *Ovis aries*	
120 mg/kg BW	Acute oral LD-50 (Knudsen et al. 1974)
Pipistrelle bat, *Pipistrellus pipestrellus*	
Females roosting in contact with timbers treated with 5% PCP solutions	All bats introduced 6 weeks postapplication died in 3 to 7 days; those introduced 8 weeks postapplication died in 1 to 2 days; bats in contact with timbers 14 months postapplication died in 5 to 23 days
Laboratory rat, *Rattus norvegicus*	
Dietary levels of 20, 100, and 500 mg/kg feed equivalent to 1.2, 6, and 30 mg/kg BW daily, respectively	No effect after exposure for 8 months to pure grade PCP at doses of 20 and 100 mg/kg. Technical grade PCP produced disruptions in liver enzyme activity in females at 20 and 100 mg/kg. At 500 mg/kg body weight gain was reduced in both sexes and by both grades of PCP (EPA 1980)

Diets containing 25, 50, or 200 mg PCP/kg, equivalent to 1.5, 3, and 12 mg/kg BW daily, respectively	After 12 weeks, no observable effect at 25 mg/kg diet; dose-related adverse effects on liver, kidney calcium deposits, and blood chemistry at higher dietary levels (Knudsen et al. 1974)
Dietary level of 50 mg/kg, equivalent to about 3 mg/kg BW daily	After 62 days, no observable effect on reproduction, neonatal growth, survival, or development. After 12 weeks, males had decreased hemoglobin and erythrocytes. After 2 years, no significant adverse effects on growth, survival, reproduction, or development (Schwetz et al. 1978; EPA 1980; McConnell et al. 1980)
5.0 to 5.8 mg/kg BW on days 6 to 15 of gestation	Delayed ossification of skull (EPA 1980)
10 mg/kg BW	After a single oral dose, 0.44% remained after 9 days; 82% of total residue was in kidney and liver, and lowest residues were in brain, spleen, and fat. A maximum residue of 45 mg/L was attained in blood plasma; the Tb1/2 in plasma was 13 to 121 h (EPA 1980)
10 or 100 mg/kg BW	After a single dose, elimination occurred by way of several routes: catabolism to tetrachlorohydroquinone; excretion of unchanged PCP and its glucuronide conjugate in urine; excretion of PCP or its metabolites into bile. More than 90% was eliminated during the rapid phase, the Tb1/2 being 13 to 17 h (Braun et al. 1977)
Dietary levels of 200 mg/kg, equivalent to about 13 mg/kg BW daily	After 181 days, reduction in crown-rump length and increase in fetal skeletal variations (Welsh et al. 1987)
15 mg/kg daily of purified PCP on days 6 to 15 of gestation	No measurable effect on development (EPA 1980)
27 to 300 mg/kg BW	Acute oral LD-50 range. Lower values in tests when PCP dissolved in fuel oil, in weanling rats, and in adult rats; higher values in tests with juveniles and when immersion vehicle is peanut oil (Knudsen et al. 1974; McConnell et al. 1980; Borzelleca et al. 1985; Choudhury et la. 1986; St. Omer and Gadusek 1987)
Dietary levels equivalent to 30 mg/kg BW daily	Decrease in neonatal survival and growth after 62 days. After 2 years, no evidence of carcinogenicity but adverse effects on adult growth and serum enzyme activity levels (Schwetz et al. 1978)

50 mg/kg BW on days 6 to 15 of gestation	100% fetal resorption (EPA 1980)
60 mg/kg BW	Single dose on day 9 or 10 of gestation produced reduction in fetal weight; no effect when given on days 11, 12, or 13 (EPA 1980)
120 mg/kg BW	Single dose results in early hepatic glycogen depletion and elevation in blood glucose (Nishimura 1984)
Domestic pig, *Sus* spp.	
5, 10, or 15 mg purified PCP/kg BW daily for 30 days	No effect on weight gain, food consumption, or kidney weight. Significanlty enlarged liver in 10 and 15 mg/kg groups. Elevated PCP residues in all groups. Residues in 5 mg/kg group vs. controls, in mg/kg fresh weight, were: 78.1 vs. 0.7 for blood, 6.7 vs. 0.2 for muscle, 22.0 vs. 0.2 for kidney, and 28.9 vs. 0.5 for liver (Greichus et al. 1979)
27 to 55 mg/kg BW	Fatal chronic dose (Schipper 1961)
30 mg/kg BW daily for 7 days	Acute toxicosis (Greichus et al. 1979)
Pregnant swine in direct contact with lumber freshly treated with PCP	Extensive mortality in newborn swine (Schipper 1961)
Eastern chipmunk, *Tamias striatus*	
138 mg/kg BW	Acute oral LD-50 (Ege 1985)
200 mg/kg BW	Acute oral LD-100 (Ege 1985)
Fed diets containing 250 or 500 mg PCP/kg for 2 weeks	No increase in metabolic activity. Some weight loss due to food avoidance; enlarged livers (Ege 1985)

CURRENT RECOMMENDATIONS

Commercial PCP preparations often contain variable amounts of chlorophenols, hexachlorobenzene, phenoxyphenols, dioxins, dibenzofurans, chlorinated diphenyl ethers, dihydroxybiphenyls, anisoles, catechols, and other chlorinated dibenzodioxin and dibenzofuran isomers. These contaminants contribute to the toxicity of PCP, sometimes significantly, although the full extent of their interactions with PCP and with each other in PCP formulations are unknown. Unless these contaminants are removed or sharply reduced in existing technical and commercial grade PCP formulations, efforts to establish sound PCP criteria for protection of natural resources may be hindered.

Proposed PCP ambient water quality criteria to protect freshwater and marine life now range from 48 to 55 ug/l for acute effects, 3.2 to 34 ug/l for chronic effects, and daily mean concentrations of 6.2 ug/l, not to exceed 140 ug/l (Table 7). Available data, however, suggest that significant adverse effects occur at much lower PCP concentrations--i.e., between 0.035 and 19 ug/l. In rainbow trout (*Salmo gairdneri*), for example, concentrations of 0.035 to 1.0 ug/l produced elevated issue residues (Choudhury et al. 1986; McKim et al. 1986), 7.4 ug/l caused growth inhibition in 28 days (EPA 1980), and 10 to 19 ug/l produced adverse effects and some deaths

(Chapman and Shumway 1978; Dominguez and Chapman 1984). Other sensitive fish species include sockeye salmon (*Oncorhynchus nerka*), showing growth inhibition after prolonged exposure to 1.8 or ug PCP/1 (EPA 1980; Choudhury et al. 1986); larvae of common carp (*Cyprinus carpio*), having an 96-hour LC-50 of 9.5 ug/l (Choudhury et al. 1986); and largemouth bass (*Micropterus salmoides*), exhibiting reduced food conversion efficiency at 10 ug/l (Johansen et al. 1987). Among sensitive species of plants and invertebrates, American oysters (*Crassostrea virginica*) have elevated tissue residues after exposure for 28 days to 2.5 ug/l (Schimmel et al. 1978); cladocerans have impaired reproduction at 4.1 ug/l (Hedtke et al. 1986); alga show chlorosis inhibition in 72 hours at 7.5 ug/l (EPA 1980); and estuarine macrobenthos populations decreased in abundance and species after exposure for 13 weeks to 15.8 ug/l (Tagatz et al. 1981). Also, an air concentration of 0.2 mg/m^3--a tolerable level to humans (Table 7)--interfered with photosynthesis in duckweed, *Lemna minor* (Huber et al. 1982).

As judged by these studies, it seems appropriate to suggest modification of certain aquatic PCP criteria. A maximum PCP concentration of 3.2 ug/l is indicated, and this level would probably protect most aquatic species, although it would not prevent accumulations and growth inhibition in salmonids or accumulations in oysters. Additional research is needed to establish sound water quality criteria for PCP, and also to interpret the significance of its residues and their metabolites in tissues of representative species.

Table 7. Proposed pentachlorophenol criteria for protection of fish, wildlife, and humans.

Resource and criterion	Concentration or dose	Reference[a]
Aquatic biota		
Freshwater life		
Acute	48 to <55 µg/L	1,2,3
Chronic	<3.2 µg/L	1
24-h mean	<6.2 µg/L	2
Maximum concentration	<140 µg/L	2
Fish		
Warmwater species	10 to <15 µg/L	4
Coldwater species	20 to <40 µg/L	4
Saltwater life		
Acute	<53 µg/L	1
Chronic	<34 µg/L	1, 5
Birds		
Tissue residues		
Contaminated	>2 mg/kg fresh weight	6
Life-threatening	>11 mg/kg fresh weight	6
Diets		
Adverse effects	>1.0 mg/kg diet	7
Fatal	>3,850 mg/kg diet	8
Wood shavings		
Litter	<134 mg/kg	9
Nesting materials	<285 mg/kg	10
Livestock and laboratory mammals		
No measurable adverse		

effects		
Rat		
Females	3 mg/kg BW daily for 24 months	1, 11
Males	10 mg/kg BW daily for 22 months	1, 11
Rabbit	3 mg/kg BW daily for 90 days	1
Adverse effects		
Elevated tissue residues, cattle		
Blood plasma	0.05 mg/kg BW, single dose	12
Internal organs	0.2 mg/kg BW for 95 days	13
Histopathology, cattle		
Internal organs	0.2 mg/kg BW daily for about 80 days, then 2.0 mg/kg BW daily for about 59 days	14, 15
Internal organs	50 mg/kg diet for 12 weeks, equivalent to 3 mg/kg BW daily	16
Reproductive impairment		
Hamster	1.25 to 20 mg/kg BW, single dose	1
Rat	5 mg/kg BW daily or 50 mg/kg diet daily, chronic	5
Rat	5 to 5.8 mg/kg BW daily	1, 17
Increased tumor frequency		
Mice	50 mg/kg diet, chronic	18
Death, various species		
Acute oral LD-50	55 to 200 mg/kg BW	5, 16, 19, 20
Acute dermal LD-50	60 to 200 mg/kg BW	1
Contaminated wood shavings, dermal contact	470 mg/kg	21
Human health		
Current exposure levels, 70 kg adult		
Food	15 µg daily, or 0.21 µg/kg BW daily	1
Water	0.12 µg daily, or 1.7 µg/kg BW daily	1
No adverse effect levels		
Food, upper safe limit, 70 kg adult	30 µg/kg BW, or 2.1 mg per person	1
Wood, in contact with food	Up to 50 mg/kg	1
Drinking water	21 µg/L[b]	1, 5, 22
Upper safe limit	1.01 mg/L	1
Air, 8 h exposure		

daily, 5 days weekly	<0.5 mg/m^3	1, 5, 23, 24
Blood	<1.0 mg/L	25
Blood plasma	<0.5 mg/L	24
Total intake	<3 µg/kg BW daily[c]	
Total intake, 70 kg adult	<30 µg/kg BW daily or	
	2.1 mg daily[d]	5
Expectant mothers	No safe level established to	
	guard against fetal toxicity	17
Adverse effect levels		
Air	>1.0 mg/m^3	1
Dermal solutions	4,000 mg/L	1
Tissue residues associated		
with acute toxicosis		
Kidney	>28 mg/kg fresh weight	1
Blood	>40 to 80 mg/L	1, 23
Liver	>62 mg/kg fresh weight	1
Tissue residues associated		
with death		
Stomach contents	8 mg/kg fresh weight	24, 26
Urine	29 to 75 mg/L	1, 24, 26
Liver	52 to 225 mg/kg fresh	
	weight	1, 24, 26
Lung	116 mg/kg fresh weight	24, 26
Blood	162 to 176 mg/L	1, 24, 26
Kidney	116 to 639 mg/kg fresh	1, 24, 26
	weight	
Bile	1,130 mg/kg fresh weight	24, 26

[b]Based on no observable adverse effect level of 3 mg/kg BW daily in rat study, uncertainty factor of 1,000x and water consumption of 2 liters daily.

[c]Based on animal data and uncertainty factor of 1,000x.

[d]Based on rat chronic oral no observable effect level of 3 mg/kg BW daily and uncertainty factor of 100.

Dietary concentrations of 1.0 mg/kg and higher produced diarrhea and liver histopathology in chickens (*Gallus* spp.) after 8 weeks (Stedman et al. 1980), and deaths occurred at relatively high dietary concentrations, i.e., 3,850 mg/kg, in Japanese quail (*Coturnix japonica*) after 5 days (Hill and Camardese 1986). Wood shavings contaminated with PCP produced elevated residues when used as litter for domestic chickens (Newsome et al. 1984), and death in canaries (*Serinus canarius*), when used as nesting materials (Dorrestein and Zelle 1979). Tissue residues >2 mg/kg fresh weight are considered to be indicative of significant

environmental PCP contamination, and those >11 mg/kg fresh weight were associated with birds that died or were recovering from PCP exposure (Table 7; Vermeer et al. 1974). No data are now available on avian wildlife and PCP contamination in their diets, residues in their tissues, or frequency of use of PCP-contaminated wood shavings for nesting materials and other purposes.

As judged by studies with domestic and small laboratory mammals, no observable adverse effects have been noted at dietary levels equivalent to 3 to 10 mg PCP/kg BW (Table 7). Variability is great among species, however, and adverse effects have been documented in some species (Table 7) at doses as low as 0.05 to 0.2 mg/kg BW (elevated tissue residues), 0.2 to 2.0 mg/kg BW or 50 mg/kg diet (histopathology, reproductive impairment, increased tumor frequency), and 55 to 60 mg/kg BW (death). Based on guidelines for carcinogen risk assessment and inadequate evidence for animal carcinogenicity or absence of human cancer data, PCP is classified as group D, meaning that it is not classified as a human carcinogen (Choudhury et al. 1986).

Data for man indicate that adverse effects occur at concentrations in air >1.0 mg PCP/m^3 and in tissues >8 mg/kg fresh weight (Table 7). No adverse effects were noted at daily intakes of 2.1 mg per 70-kg adult or 30 ug/kg BW, up to 1.01 mg/l in drinking water, <0.5 mg/m^3 in air, <0.5 mg/l in blood plasma, and <1.0 mg/l in blood (Table 7). It is noteworthy that the currently recommended PCP air concentration of 0.5 mg/m^3 results in a daily intake of 2.5 to 3.8 mg (based on 15 to 23 m^3 of air inhaled daily, 8 hour exposure), equivalent to 42 to 63 ug/kg BW for a 60 kg female. These levels are higher than the currently recommended no adverse effect level of 30 ug/kg BW daily (Table 7), and overlap or exceed the 58 to 74 ug/kg BW daily range--a level recommended by Williams (1982). Air concentrations >1.0 mg PCP/m^3 can produce respiratory irritation in unacclimatized individuals, but concentrations as high as 2.4 mg/m^3 can be tolerated by conditioned individuals (EPA 1980). The biological tolerance value of <1,000 ug PCP/1 in blood, recommended by Ziemsen et al. (1987), is based on occupational air exposure studies: exposure to maximum average air concentrations of 0.18 mg PCP/m^3 for up to 34 years produced blood PCP residues of 23 to 775 ug/l, with no measurable adverse effects. The authors concluded that PCP and its impurities in occupationally relevant concentrations below the maximum concentration in the workplace and below the biological tolerance value do not produce genotoxic damage that can be detected on the chromosomal level, either in vivo or in vitro.

The human taste threshold for PCP in drinking water is about 30 ug/l (EPA 1980), a level far below the upper safe limit of 1.01 mg/l and near the no observable effect level of 21 ug/l (Table 7). Odor detection is not as sensitive as taste: the odor threshold for PCP ranges from about 857 ug/l at 30 C, to 1,600 ug/l at 20 to 22 C, to 12,000 ug/l at 60 C (EPA 1980). It is not clear whether the determined organoleptic threshold values made the water undesirable or unfit for consumption (EPA 1980). If fish and wildlife species of concern have PCP organoleptic thresholds that are similar to those of humans, or lower, will they too avoid contaminated habitats or diets?

Data for PCP and terrestrial wildlife are incomplete and--in view of the large interspecies variations in sensitivity--need to be collected. Until they are, it seems reasonable to apply to wildlife the same levels recommended for human health protection.

ATRAZINE HAZARDS TO FISH, WILDLIFE, AND INVERTEBRATES: A SYNOPTIC REVIEW

by
Ronald Eisler

U.S. Fish and Wildlife Service
Patuxent Wildlife Research Center
Laurel, MD 20708

SUMMARY

The herbicide atrazine (2-chloro-4-ethylamino-6-isopropylamino-1,3,5-triazine) is the most heavily used agricultural pesticide in North America. In the United States alone, more than 50 million kg (110 million pounds) are applied annually to more than 25 million ha (62 million acres), primarily to control weeds in corn and sorghum. Residues have been detected at phytotoxic concentrations in groundwater, lakes, and streams as a result of runoff from treated fields. Atrazine degrades rapidly, usually by way of hydrolysis, nitrogen dealkylation, and splitting of the triazine ring to less toxic compounds not normally inhibitory to plants and animals. The half-time persistence of atrazine in soils is usually about 4 days, but may range up to 385 days in dry, sandy, alkaline soils, under conditions of low temperature and low microbial densities. Half-time persistence is about 3 days in freshwater, 30 days in marine waters, 35 days in marine sediments, and less than 72 hours in vertebrate animals.

Sensitive species of aquatic plants experience temporary, but reversible, adverse effects at concentrations in the range of 1 to 5 ug atrazine/l. However, potentially harmful phytotoxic concentrations of atrazine, i.e., >10 ug/l for extended periods, have not been documented in the environment, and are probably unrealistic under current application and degradation rates. Aquatic fauna are indirectly affected at atrazine concentrations of 20 ug/l and higher, partly through reduction of the food supply of herbivores, and partly through loss of macrophyte habitat. Direct adverse effects to aquatic invertebrates and fishes were measured at 94 ug/l and higher. Bioaccumulation of atrazine is limited, and food chain biomagnification is negligible in aquatic ecosystems. Birds are comparatively resistant to atrazine, having a low probability for uptake and retention. Known acute oral LD-50 values for birds are >2,000 mg/kg body weight, and dietary LD-50s are >5,000 mg/kg ration. However, indirect ecosystem effects of atrazine on seed- and insect-eating birds are unknown, and should be investigated. Data are lacking for atrazine toxicity to mammalian wildlife, but tests with domestic livestock and small laboratory animals indicate that this group is also comparatively resistant. Acute oral LD-50s for mammals are >1,750 mg/kg body weight; no adverse effects were measured at chronic dietary levels of 25 mg/kg (about 1.25 mg/kg body weight) and, for some species, 100 mg/kg diet.

Proposed criteria for aquatic life protection include <5 ug atrazine/1 for sensitive species of aquatic flora, and <11 ug/l for most species of aquatic plants and animals. No criteria have been promulgated for human or animal health protection, although it has been suggested that <7.5 ug/l in drinking water, and <0.0375 mg atrazine/kg body weight (<2.25 mg daily for a 60 kg adult, <1.5 mg/kg diet based on consumption of 1.5 kg food daily) would pose a negligible risk to human health. Additional data are needed on toxicity, environmental fate, and chemistry of atrazine and its metabolites in order to maintain existing registrations or to permit new registrations. In particular, more research is needed on possible synergistic or additive effects of atrazine with other agricultural chemicals in aquatic environments.

INTRODUCTION

Atrazine (2-chloro-4-ethylamino-6-isopropylamino-1,3,5-triazine) is the most heavily used agricultural pesticide in North America (DeNoyelles et al. 1982; Stratton 1984; Hamilton et al. 1987), and is currently registered for use in controlling weeds in numerous crops, including corn (*Zea mays*), sorghum (*Sorghum vulgare*), sugarcane (*Saccharum officinarum*), soybeans (*Glycine max*), wheat (*Triticum aestivum*), pineapple (*Ananas comusus*). and various range grasses (Reed 1982). Atrazine was first released for experiment station evaluations in 1957 and became commercially available in 1958 (Hull 1967; Jones et al. 1982). In 1976, 41 million kg (90 million pounds) were applied to 25 million ha (62 million acres) on farms in the United States, principally for weed control in corn, wheat, and sorghum crops; this volume represented 16% of all herbicides and 9% of all pesticides applied in the United States during that year (DeNoyelles et al. 1982; Hamala and Kollig 1985). By 1980, domestic usage had increased to 50 million kg (Reed 1982). In Canada, atrazine was the most widely used of 77 pesticides surveyed (Frank and Sirons 1979). Agricultural use of atrazine has also been reported in South Africa, Australia, New Zealand, Venezuela, and in most European countries (Reed 1982). Resistance to atrazine has developed in various strains of weeds typically present in crop fields--sometimes in less than two generations (Bettini et al. 1987; McNally et al. 1987)--suggesting that future agricultural use of atrazine may be limited.

Atrazine has been detected in lakes and streams at levels ranging from 0.1 to 30.3 ug/l; concentrations peak during spring, which coincides with the recommended time for agricultural application (Hamilton et al. 1987). In runoff waters directly adjacent to treated fields, atrazine concentrations of 27 to 69 ug/l have been reported, and may reach 1,000 ug/l (DeNoyelles et al. 1982). Some of these concentrations are demonstrably phytotoxic to sensitive species of aquatic flora (DeNoyelles et al. 1982; Herman et al. 1986; Hamilton et al. 1987). Although atrazine runoff from Maryland corn fields was suggested as a possible factor in the decline of submerged aquatic vegetation in Chesapeake Bay, which provides food and habitat for large populations of waterfowl, striped bass (*Morone saxatilis*), American oysters (*Crassostrea virginica*), and blue crabs (*Callinectes sapidus*), it was probably not a major contributor to this decline (Forney 1980; Menzer and Nelson 1986).

This report was prepared in response to requests for information from environmental specialists of the U. S. Fish and Wildlife Service. It is part of a continuing series of brief reviews on hazards of selected chemicals to natural resources.

ENVIRONMENTAL CHEMISTRY

Atrazine is a white crystalline substance that is sold under a variety of trade names for use primarily as a selective herbicide to control broadleaf and grassy weeds in corn and sorghum (Table 1). It is only slightly soluble in water (33 mg/l at 27 °C), but soluble (360 to 183,000 mg/1) in many organic solvents. Atrazine is usually applied in a water spray at concentrations of 2.2 to 4.5 kg/ha before weeds emerge. Stored atrazine is stable for several years, but degradation begins immediately after application (Table 1). The chemical is available as a technical material at 99.9% active ingredient and as a manufacturing-use product containing 80% atrazine for formulation of wettable powders, pellets, granules, flowable concentrates, emulsifiable concentrates, or tablets (EPA 1983).

There are three major atrazine degradation pathways: hydrolysis at carbon atom 2, in which the chlorine is replaced with a hydroxy group; N-dealkylation at carbon atom 4 (loss of the ethylpropyl group) or 6 (loss of the isopropyl group); and splitting of the triazine ring (Knuesli et al. 1969; Reed 1982). The major atrazine metabolite in both soil and aquatic systems is hydroxyatrazine. In soils, it accounts for 5% to 25% of the atrazine originally applied after several months compared to 2% to 10% for all dealkylated products combined, including deethylated atrazine and deisopropylated atrazine (Stratton 1984; Schiavon 1988a,b). Atrazine may be converted to nonphytotoxic hydroxyatrazine by chemical hydrolysis, which does not require a biological system (Dao 1977; Wolf and Jackson 1982). Bacterial degradation, however, proceeds primarily by N-dealkylation (Giardi et al. 1985). In animals, N-dealkylation is a generally valid biochemical degradation mechanism (Knuesli et al. 1969). In rats, rabbits, and chickens, most atrazine is excreted within 72 hours; 19 urinary metabolites--including hydroxylated, N-dealkylated, oxidized, and conjugated metabolites--were found (Reed 1982). There is general agreement that atrazine degradation products are substantially less toxic than the parent compound and not normally present in the environment at levels inhibitory to algae, bacteria, plants, or animals (DeNoyelles et al. 1982; Reed 1982; Stratton 1984).

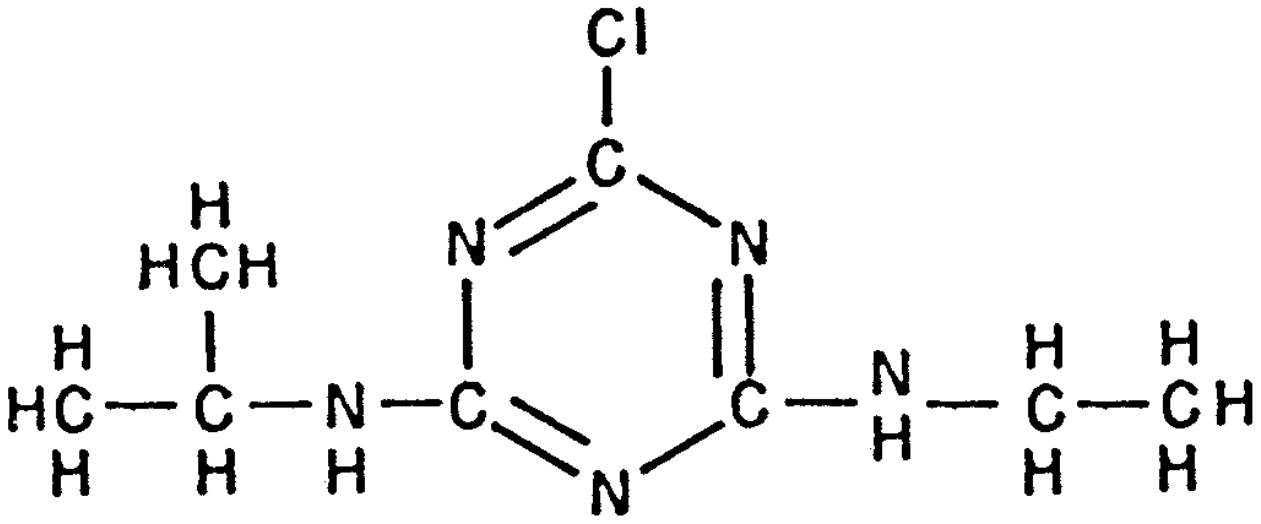
Residues of atrazine rapidly disappeared from a simulated Northern Prairie freshwater wetland microcosm during the first 4 days, primarily by way of adsorption onto organic sediments (Huckins et al. 1986). This is consistent with the findings of others who report 50% loss (Tb 1/2) from freshwater in 3.2 days (Moorhead and Kosinski 1986), 82% loss in 5 days, and 95% loss in 55 days (Lay et al. 1984), although one report presents evidence of a 300-day half-life for atrazine (Yoo and Solomon 1981). In estuarine waters and sediments, atrazine is inactivated by adsorption and metabolism: half-time persistence in waters has been estimated to range between 3 and 30 days, being shorter at elevated salinities; for sediments this range was 15 to 35 days (Stevensen et al. 1982; Glotfelty et al. 1984; Isensee 1987). The comparatively rapid degradation of atrazine to hydroxyatrazine in estuarine sediments and water column indicates a low probability for atrazine accumulation in the estuary, and a relatively reduced rate of residual phytotoxicity in the estuary for the parent compound (Jones et al. 1982).

Table 1. Chemical and other properties of atrazine

(Anon. 1963; Hull 1967; Knuesli et al. 1969; Gunther and Gunther 1970; Reed 1982; Beste 1983; Hudson et al. 1984; Huber and Hock 1986; Huckins et al. 1986; EPA 1987).

Variable	Datum
Chemical name	2-chloro-4-ethylamino-6-isopropylamino-1,3,5-triazine
Alternate names	CAS 1912-24-9, ENT 28244, G-30027, Aatrex, Aatrex 4L, Aatrex 4LC, Aatrex Nine-0, Aatrex 80W, Atranex, ATratol, Atratol 8P, Atratol 80W, Atrazine 4L, Atrazine 80W, Atred, Bicep 4.5L, Co-Op, Co-Op Atra-pril, Cristatrina, Crisazine, Farmco atrazine, Gesaprim, Griffex, Primatol A, Shell atrazine herbicide, Vectal, Vectal SC
Primary uses	Selective herbicide for control of most annual broadleaf and grassy weeds in corn, sugar cane, sorghum, macadamia orchards, rangeland, pineapple, and turf grass sod. Nonselective herbicide for weed control on railroads, storage yards, along highways, and industrial sites. Sometimes used as selective weedicide in conifer reforestation, Christmas tree plantations, and grass seed fields
Major producer	Ciba-Geigy Corporation
Application methods	Usually as water spray or in liquid fertilizers applied preemergence, but also may be applied preplant or postemergence. Rates of 2 to 4 pounds/acre (2.24 to 4.48 kg/ha) are effective for most situations; higher rates are used for nonselective weed control, and on high organic soils
Compatibility with other pesticides	Compatible with most other pesticides and fertilizers when used at recommended rates. Sold in formulation with Lasso®, Ramrod®, and Bicep®
Stability	Very stable over several years of shelf life, under normal illumination and extreme temperatures. Stable in neutral, slightly acid or basic media. Sublimes at high temperatures and when heated, especially at high temperatures in acid or basic media, hydrolyzes to hydroxyatrazine (2-hydroxy-4-ethylamino-6-isopropylamino-*s*-triazine), which

	has no herbicidal activity
Empirical formula	$C_8H_{14}ClN_5$
Structural formula	



Molecular weight	215.7
Melting point	173 ºC to 175 ºC
Vapor pressure	5.7×10^{-8} mm mercury at 10 ºC, 3.0×10^{-7} at 20 ºC, 1.4×10^{-6} at 30 ºC, and 2.3×10^{-5} at 50 ºC
Henry's Law constant	6.13×10^{-8} to 2.45×10^{-7} atm-m^3/mole
Physical state	The technical material is a white, crystalline, noncombustible, noncorrosive substance
Purity	No impurities or contaminants that resulted from the manufacturing process were detected
Solubility	
Water	22 mg/L at 0 ºC, 32 mg/L at 25 ºC, 320 mg/L at 85 ºC
N-pentane	360 mg/L at 27 ºC
Petroluem ether	12,000 mg/L at 27 ºC
Methanol	18,000 mg/L at 27 ºC
Ethyl acetate	28,000 mg/L at 27 ºC
Chloroform	52,000 mg/L at 27 ºC
Dimethyl sulfoxide	183,000 mg/L at 27 ºC
Log Kow	2.71

Atrazine is leached into the soil by rain or irrigation water. The extent of leaching is limited by the low water solubility of atrazine and by its adsorption onto certain soil constituents (Anon. 1963). Runoff loss in soils ranges from 1.2% to 18% of the total quantity of atrazine applied, but usually is less than 3% (Wolf and Jackson

1982). Surface runoff of atrazine from adjacent conventional tillage and no-tillage corn watersheds in Maryland was measured after single annual applications of 2.2 kg/ha for 4 years (Glenn and Angle 1987). Most of the atrazine in surface runoff was lost during the first rain after application. In 1979, the year of greatest precipitation, 1.6% of the atrazine applied moved from the conventional tillage compared to 1.1% from the no-tillage watershed, suggesting that no-tillage should be encouraged as an environmentally sound practice (Glenn and Angle 1987). Lateral and downward movement of atrazine was measured in cornfield soils to a depth of 30 cm when applied at 1.7 kg/ha to relatively moist soils; in lower elevation soils, atrazine accumulated by way of runoff and infiltration (Wu 1980). Downward movement of atrazine through the top 30 cm of cornfield soils indicates that carryover of atrazine to the next growing season is possible: between 5% and 13% of atrazine was available one year after application (Wu 1980; Wu and Fox 1980). Atrazine is not usually found below the upper 30 cm of soil in detectable quantities, even after years of continuous use; accordingly, groundwater contamination by atrazine is not expected at recommended application rates (Anon. 1963; Hammons 1977; Wolf and Jackson 1982; Beste 1983).

Atrazine persistence in soils is extremely variable: reported Tb 1/2 values ranged from 20 to 100 days in some soils to 330 to 385 days in others (Jones et al. 1982); intermediate values were reported by Forney (1980), Stevenson et al. (1982), and Stratton (1984). Atrazine activity and persistence in soils is governed by many physical, chemical, and biological factors. In general, atrazine loss was more rapid under some conditions than others: it was more rapid from moist soils than from dry soils, during periods of high temperatures than during periods of low temperatures, from high organic and high clay content soils than from sandy mineral soils, during summer than in winter, from soils with high microbial densities than from those with low densities, from soils of acidic pH than from those of neutral or alkaline pH, during storm runoff events than during normal flows, at shallow soil depths than at deeper depths, and under conditions of increased ultraviolet irradiation (Anon. 1963; McCormick and Hiltbold 1966; Hull 1967; Gunther and Gunther 1970; Dao 1977; Hammons 1977; Frank and Sirons 1979; Forney 1980; Stevenson et al. 1982; Wolf and Jackson 1982; Beste 1983; EPA 1987). Microbial action, usually by way of N-dealkylation and hydrolysis to hydroxyatrazine, probably accounts for the major breakdown of atrazine in the soil, although nonbiological degradation pathways of volatilization, hydroxylation, dealkylation, and photodecomposition are also important (Hull 1967; Gunther and Gunther 1970; Reed 1982; Menzer and Nelson 1986).

BACKGROUND CONCENTRATIONS

Atrazine concentrations in human foods are negligible. Monitoring of domestic and imported foods in the human diet by the U.S. Food and Drug Administration between 1978 and 1982 showed that only 3 of 4,500 samples analyzed had detectable atrazine residues. Two samples in 1980 contained 0.01 and 0.08 mg atrazine/kg and one in 1978, following a known contamination incident, contained 47 mg/kg (Reed 1982).

Atrazine and its metabolites have been observed in freshwater streams contiguous to agricultural lands; 0.1% to 3% of the atrazine applied to the fields was lost to the aquatic environment (Jones et al. 1982). Atrazine concentrations in runoff waters from treated cornfields may exceed 740 ug/l (Table 2). Elevated levels were associated with high initial treatment rates, major storms shortly after application, conventional tillage practices (vs. no tillage), and increased flow rates, increased suspended solids, and increased dissolved nitrates and nitrites. Concentrations in runoff water usually declined rapidly within a few days (Forney 1980; Setzler 1980; Stevenson et al. 1982). Groundwater contamination by way of atrazine treatment of cornfields has been unexpectedly reported in parts of Colorado, Iowa, and Nebraska. Contamination was most pronounced in areas of highly permeable soils that overlie groundwater at shallow depths (Wilson et al. 1987).

The total amount of atrazine reaching the Wye River, Maryland, estuary depended on the quantity applied in the watershed and the timing of runoff. In years of significant runoff, 2% to 3% of the atrazine moved to the estuary within 2 weeks after application and effectively ceased after 6 weeks (Glotfelty et al. 1984). In Chesapeake Bay waters, a leakage rate of 1% of atrazine from agricultural soils resulted in aqueous concentrations averaging 17 ug/1--concentrations potentially harmful to a variety of estuarine plants (Jones et al. 1982). The maximum recorded atrazine concentration in runoff water entering Chesapeake Bay was 480 ug/l (Forney 1980). However, these concentrations seldom persisted for significant intervals, and only rarely approached those producing long-term effects on submerged aquatic vegetation (Glotfelty et al. 1984).

Atmospheric transport of atrazine-contaminated aerosol particulates, dusts, and soils may contribute significantly to atrazine burdens of terrestrial and aquatic ecosystems. The annual atmospheric input of atrazine

in rainfall to the Rhode River, Maryland, as one example, was estimated at 1,016 mg/surface ha in 1977, and 97 mg/ha in 1978 (Wu 1981). A similar situation exists with fog water. When fog forms, exposed plant surfaces become saturated with liquid for the duration of the fog (Glotfelty et al. 1987).

Table 2. Atrazine concentrations in selected watersheds.

Locale and other variables	Concentration[a] In ug/1 or up/kg	Reference[b]
Atrazine-treated cornfields		
Iowa, shortly after application		
Runoff water	4,900	1
Sediments	7,350	1
Kansas, 1974		
Runoff water		
May	1,074	1

LETHAL AND SUBLETHAL EFFECTS

GENERAL

In terrestrial ecosystems, atrazine effectively inhibits photosynthesis in target weeds, and may also affect certain sensitive crop plants. Atrazine metabolites are not as phytotoxic as the parent compound. Degradation is usually rapid, although atrazine may persist in soils for more than one growing season. Soil fauna may be adversely affected shortly after initial atrazine application at recommended levels, but long-term population effects on this group are considered negligible.

As discussed later, sensitive species of aquatic flora experience temporary adverse effects at concentrations as low as 1.0 to 5.0 ug/l; however, most authorities agree that potentially harmful levels, i.e., >10 ug/l for long periods, have not been documented and are probably unrealistic under current application protocols

and degradation rates. The observed declines in submerged aquatic vegetation in the Chesapeake Bay are not now directly attributable to atrazine use. Atrazine indirectly affects aquatic fauna at concentrations of 20 ug/l and higher by reducing the food supply of herbivores and, to some extent, their macrophyte habitat. Direct adverse effects on growth and survival of aquatic fauna were evident in the range of 94 to 500 ug/l. Bioaccumulation of atrazine is limited and food chain biomagnification is negligible in aquatic ecosystems.

Birds show a low probability for atrazine uptake and accumulation. Known acute oral LD-50s and dietary LD-50s are high: >2,000 mg/kg body weight, and 5,000 mg/kg diet. Indirect ecosystem effects of atrazine on insect- and seed-eating birds are not known, and seem to merit study.

Data are lacking for mammalian wildlife, but tests with domestic livestock and small laboratory animals strongly indicate that this group is comparatively resistant to atrazine. Acute oral LD-50s are >1,750 mg/kg body weight, and no adverse effects are evident at dietary levels of 25 mg/kg food (about 1.25 mg/kg body weight) and sometimes 100 mg/kg food over extended periods.

TERRESTRIAL PLANTS AND INVERTEBRATES

Atrazine enters plants primarily by way of the roots and secondarily by way of the foliage, passively translocated in the xylem with the transpiration stream, and accumulates in the apical meristems and leaves (Hull 1967; Forney 1980; Reed 1982; Wolf and Jackson 1982). The main phytotoxic effect is the inhibition of photosynthesis by blocking the electron transport during Hill reaction of photosystem II. This blockage leads to inhibitory effects on the synthesis of carbohydrate, a reduction in the carbon pool, and a buildup of carbon dioxide within the leaf, which subsequently causes closure of the stomates, thus inhibiting transpiration (Stevenson et al. 1982; Jachetta et al. 1986; Shabana 1987).

Atrazine is readily metabolized by tolerant plants to hydroxyatrazine and amino acid conjugates. The hydroxyatrazine can be further degraded by dealkylation of the side chains and by hydrolysis of resulting amino groups on the ring and some carbon dioxide production (Hull 1967; Reed 1982; Beste 1983). Resistant plant species degrade atrazine before it interferes with photosynthesis. Corn, for example, has an enzyme (2,4-dihydroxy-7-methoxy-1, 4 [2H]-berzoxazin-3 [4H]-one) that degrades atrazine to nonphytotoxic hydroxyatrazine (Wu 1980; Stevenson et al. 1982). In sensitive plants, such as oats, cucumber, and alfalfa, which are unable to detoxify atrazine, the compound accumulates, causing chlorosis and death (Anon. 1963; Hull 1967). Corn and sorghum excrete about 50% of accumulated atrazine and metabolize the rest to insoluble residues that are indigestible to sheep (*Ovis aries*) and rats (*Rattus* sp.). These results strongly suggest that the final disposition of atrazine metabolites does not occur in either plants or animals, but ultimately through microbial breakdown (Bakke et al. 1972b).

Long-term applications of atrazine for weed control in corn result in degradation products, mainly hydroxylated analogues, that may persist in soil for at least 12 months after the final herbicide application, and may enter food crops planted in atrazine-treated soil in the years after cessation of long-term treatment (Frank and Sirons 1979; Kulshrestha et al. 1982). In one example, atrazine was applied to a corn field for 20 consecutive years at rates of 1.4 to 2.2 kg/ha (Khan and Saidak 1981). Soils collected 12 months after the last application contained atrazine (55 ug/kg dry weight), hydroxyatrazine (296 ug/kg), and various mono dealkylated hydroxy analogues (deethylatrazine at 14 ug/kg, deethylhydroxyatrazine, at 17 ug/kg, and deisopropylhydroxyatrazine at 23 ug/kg). Oat (*Avena sativa*) seedlings grown in this field contained hydroxyatrazine (64 to 73 ug/kg fresh weight) and deisopropylhydroxyatrazine (84 to 116 ug/kg); similar results were obtained with timothy, *Phleum pratense* (Khan and Saidak 1981). In areas with a relatively long growing season, a double cropping of soybeans (*Glycine max*)--planted after corn is harvested for silage or grain--is gaining acceptance. Under conditions of warm weather, relatively high rainfall, and sandy soils, soybeans can be safely planted after corn (14 to 20 weeks after atrazine application) when rates of atrazine normally recommended for annual weed control (1.12 to 4.48 kg/ha) are used (Brecke et al. 1981).

Seed germination of sensitive species of plants was reduced by 50% at soil atrazine concentrations between 0.02 and 0.11 mg/kg (Table 3). Mustard (*Brassica juncea*) was especially sensitive, and died shortly after germination. Soil atrazine residues of this magnitude were typical of those remaining at the beginning of a new growing season following corn in sandy loam under tropical conditions (Kulshrestha et al. 1982). Reduction in seed germination was also noted at soil atrazine concentrations of 0.25 to 0.46 mg/kg for the lentil *Lens esculenta*, the pea *Pisum sativum*, and the gram *Cicer arietinum* (Kulshrestha el al. 1982). Many species of

mature range grasses are tolerant of atrazine but are susceptible as seedlings; seedlings of the most sensitive three species of eight tested were adversely affected in soils containing 1.1 mg atrazine/kg (Bahler et al. 1984; Table 3).

Soil fungi and bacteria accumulated atrazine from their physicochemical environment by factors between 87X and 132X (Wolf and Jackson 1982), probably through passive adsorption mechanisms. Atrazine stimulated the growth of at least two common species of fungal saprophytes known to produce antibiotics: *Epicoccum nigrum* and *Trichoderma viride* (Richardson 1970). *Trichoderma*, for example, grew rapidly at all treatments tested (up to 80 mg/kg soil) and showed optimal growth 3 to 10 days postinoculation (Rodriguez-Kabana et al. 1968). Atrazine suppressed the growth of various species of soil fungi, including *Rhizoctonia solani*, *Sclerotium rolfsii*, and *Fusarium* spp., and stimulated the growth of other species known to be antagonistic to *Fusarium*. This selectivity is likely to induce a shift in the fungal population of atrazine-treated soil that would be either harmful or beneficial to subsequent crops, depending on whether saprophytic or pathogenic fungi attained dominance (Richardson 1970).

At 2.5 mg atrazine/kg soil, equivalent to 2 kg/ha in the top 10 cm, field and laboratory studies demonstrated that mortality in arthropod collembolids (*Onchiurus apuanicus*) was 47% in 60 days; however, fecundity was not affected at dose levels up to 5.0 mg/kg soil. It was concluded that atrazine applications at recommended treatment levels had negligible long-term population effects on sensitive species of soil fauna (Mola et al. 1987). At 5 or 8 kg atrazine/ha, all species of soil fauna tested, except some species of nematodes, were adversely affected (Popovici et al. 1977). One month postapplication, population reductions of 65% to 91% were recorded in protozoa, mites, various insect groups, and collembolids at 5 kg/ha; after 4 months, populations were still depressed by 55% to 78% (Popovici et al. 1977). At 9 kg atrazine/ha, soil faunal populations of beetles, collembolids, and earthworms remained depressed for at least 14 months after initial treatment (Mola et al. 1987).

Table 3. Atrazine effects on selected species of terrestrial plants.

Species, dose, and other variables	Effect and reference
Soil alga, *Chlorella vulgaris*	
0.1 and 0.5 ug/L soil water	Chlorophyll production stimulated (Torres and O'Flaherty 1976)
1.0 ug/L and higher	Chlorophyll production inhibited; more-than-additive toxicity observed in combination with simazine and malathion (Torres and O'Flaherty 1976)
Mustard, *Brassic juncea*	
20 ug/kg dry weight soil	Seed germination reduced 50%; death shortly thereafter (Kulshrestha et al. 1982)
Cyanobacteria, 4 species, isolated from rice-cultivated soils in Egypt	
50 ug/L soil water for 7 days	Suppressed pigment biosynthesis in *Aulosira fertilissima* and *Tolypothrix tenuis*, reduced growth in *Anabaena oryzae* and *Nostoc muscorum*, and reduced carbohydrate content in *Nostoc* and

	Tolypothrix (Shabana 1987)
100 to 500 ug/L soil water for 7 days	All variables affected in all species (Shabana 1987)
Barley, *Hordeum vulgare*	
50 ug/kg dry weight soil	Seed germination reduced 50% (Kulshrestha et al. 1982)
Oat, *Avena sativa*	
70 ug/kg dry weight soil	Seed germination reduced 50% (Kulshrestha et al. 1982)
Wheat, *Triticum aestivum*	
110 ug/kg dry weight soil	Seed germination reduced 50% (Kulshrestha et al. 1982)
0.6 kg/ha	Effectively controls weeds in wet sandy soils; some damage to crop possible in dry clay soils (Amor et al. 1987)
Range grasses, four species, seedlings	
1.1 mg/kg soil	Survival reduced, and growth reduced in surviving seedlings (Bahler et al. 1984)
Weed, *Chenopodium album*, seedlings from French garden never treated with chemicals	
0.5 kg/ha	Survival 12%; progeny of these survivors were resistant to 1 kg/ha treatment (Bettini et al. 1987)
1.0 kg/ha	Fatal to 100% (Bettini et al. 1987)
Corn, *Zea mays*	
1.25 kg/ha	No effect on growth or yield (Malan et al. 1987)
5.0 kg/ha	Severe phytotoxicity 25 to 30 days after planting; growth inhibition during early development. Recovery, with no negative effect on final yield (Malan et al. 1987)
Soybean, *Glycine max*, planted after corn, *Zea mays*	
2.24 kg/ha	No effect on yield when planted at least 8 weeks after atrazine application (Brecke et al. 1981)
4.48 kg/ha	At least 10-week interval required after atrazine application for successful germination (Brecke et al. 1981)

AQUATIC PLANTS

Since the mid-1960's, seagrasses and freshwater submersed vascular plants have declined in many aquatic systems, especially Chesapeake Bay (Forney and Davis 1981; Stevenson et al. 1982; Kemp et al. 1983; Cunningham et al. 1984). These plants provide food and habitat to diverse and abundant animal populations. In Chesapeake Bay, this decline has been associated with an overall decline in the abundance of fish and

wildlife, and has been interpreted as an indication of serious disturbance in the ecological balance of the estuary. More than 10 native species of submerged aquatic plants in Chesapeake Bay have decreased in abundance. In the upper estuary, this decline was preceded by an invasion of Eurasian watermilfoil (*Myriophyllum spicatum*), which eventually also died back (Kemp et al. 1983). Runoff of herbicides, including atrazine, from treated agricultural lands has been suggested as a possible factor involved in the disappearance of Chesapeake Bay submerged vegetation. During the past 20 years, the most widely used herbicide in the Chesapeake Bay watershed--and in the surrounding coastal plain--has been atrazine. Since its introduction into the region in the early 1960's, atrazine use has grown to about 200,000 kg annually in Maryland coastal communities alone (Kemp et al. 1983). Potentially phytotoxic concentrations of atrazine would be expected in estuaries with the following characteristics (which seem to apply in most of upper Chesapeake Bay): immediately adjacent to cornfields in the watershed; rains occur shortly after atrazine application; clay soils in fields producing more rapid runoff; soils with circumneutral pH and relatively low organic content; and large estuarine areas of low salinity and poor mixing (Stevenson et al. 1982).

At this time, most authorities agree that atrazine could induce some loss in aquatic vegetation but was not likely to have been involved in the overall decline of submerged plants in Chesapeake Bay (Forney 1980; Plumley and Davis 1980; Forney and Davis 1981; Kemp et al. 1983, 1985; Jones et al. 1986), and that nutrient enrichment and increased turbidity probably played major roles (Kemp et al. 1983, 1985). In the open waters of Chesapeake Bay, atrazine concentrations have rarely exceeded 1 ug/l; in major tributaries, such as the Choptank and Rappahanock Rivers, concentrations of 5 ug/l may occur after a major spring runoff. These runoffs sometimes generate transient, 2- to 6-hour concentrations up to about 40 ug/l in secondary tributaries (Kemp et al. 1983). In some small coves on the Chesapeake Bay, submerged plants may be exposed periodically to atrazine concentrations of 5 to 50 ug/l for brief periods during runoffs; however, dilution, adsorption, and degradation tend to reduce concentrations in the water phase to <5 ug/l within 6 to 24 hours (Jones et al. 1986). Since atrazine degrades rapidly in estuarine conditions Tb 1/2 1 to 6 weeks), concentrations of atrazine on suspended and deposited estuarine sediments were seldom >5 ug/kg, suggesting little potential for accumulation (Kemp et al. 1983). The photosynthesis of redheadgrass (*Potamogeton perfoliatus*) was significantly inhibited by atrazine concentrations of 10 to 50 ug/l; however, it returned to normal levels within 1 hour after atrazine was removed (Jones et al. 1986). Recovery of redheadgrass within several weeks has also been documented after exposure to 130 ug/l for 4 weeks (Cunningham et al. 1984). In Chesapeake Bay, potential long-term exposure of submersed aquatic plants to concentrations of atrazine in excess of 10 ug/l is doubtful; therefore, any observed reductions in photosynthesis by these plants under such conditions would be minor and reversible (Jones et al. 1986).

Some authorities, however, suggest that the effects of atrazine on aquatic plants may be substantial. For example, atrazine concentrations between 1 and 5 ug/l adversely affect phytoplankton growth and succession; this, in turn, can adversely affect higher levels of the food chain, beginning with the zooplankton (DeNoyelles et al. 1982). Also, exposure to environmentally realistic concentrations of 3.2 to 12 ug atrazine/l for about 7 weeks was demonstrably harmful to wildcelery (*Vallisneria americana*), a submersed vascular plant in Chesapeake Bay (Correll and Wu 1982 . At highest concentrations of 13 to 1,104 ug/l for 3 to 6 weeks, growth of representative submerged macrophytes in Chesapeake Bay was significantly depressed, and longer exposures were fatal to most species (Forney 1980). Atrazine concentrations of 100 ug/l reportedly cause permanent changes in algal community structure after exposure for 14 days, including decreased density and diversity, altered species composition, and reduced growth (Hamala and Kollig 1985). It seems that additional research is needed on the role of atrazine and on its interactions with other agricultural chemicals in regard to observed declines in submerged plants. It is emphasized that degradation products of atrazine did not play a role in the disappearance of the submerged vascular plants from the Chesapeake Bay. For example, 500 ug/l of deethylated atrazine was needed to produce 20% to 40% photosynthetic inhibition in four major species of submerged macrophytes in 2 hours, but only 95 ug/l of the parent atrazine caused 50% inhibition in a similar period (Jones and Winchell 1984).

Many studies have been conducted on the effects of atrazine on various species of aquatic flora under controlled conditions (Table 4). At concentrations of 1 to 5 ug/l, and exposure periods of 5 minutes to 7 weeks, documented adverse effects in sensitive species included inhibition in photosynthesis, growth, and oxygen evolution (Table 4). Higher concentrations were associated with altered species composition, reduced carbon uptake, reduced reproduction, high accumulations of atrazine, decreased chlorophyll *a* production, ultrastructural changes on chloroplasts, and death (Table 4). Phytotoxic effects were significantly increased at

elevated levels of incident illumination, elevated water temperatures, decreased water pH, decreased dissolved oxygen concentrations, decreased nutrient content, and at increasing atrazine concentrations in the water column (Forney and Davis 1981; Karlander et al. 1983; Jones and Estes 1984; Malanchuk and Kollig 1985; Mayasich et al. 1986). Phytotoxicity was not significantly influenced by atrazine concentrations in the sediments or hydrosoils, or by the salinity of the medium (Forney 1980; Forney and Davis 1981; Jones and Estes 1984; Huckins et al . 1986).

Atrazine was 4 to 10 times more effective than its degradation products in producing growth reduction, photosynthesis inhibition, and acetylene-reducing ability in two species of green algae, *Chlorella pyrenoidosa*, *Scenedesmus quadricauda*, and three species of cyanobacteria, *Anabaena* spp. (Stratton 1984). Atrazine reduced growth 50% at 0.03 to 5.0 mg/l and inhibited photosynthesis 50% at 0.1 to 0.5 mg/l. Comparable values for deethylated atrazine were 1.0 to 8.5 mg/l for growth reduction, and 0.7 to 4.8 mg/l for photosynthesis inhibition; for deisopropylated atrazine, these values were 2.5 to >10 mg/l for growth reduction and 3.6 to 9.3 mg/l for photosynthesis inhibition; hydroxyatrazine and diaminoatrazine were nontoxic to most cultures tested (Stratton 1984). Smooth cordgrass (*Spartina alterniflora*), the major emergent species in North American salt marshes, is only slightly affected by relatively high levels of atrazine, due possibly to its ability to metabolize this compound (Davis et al. 1979; Forney and Davis 1981; Stevenson et al. 1982). Studies with radiolabeled atrazine and *Spartina* roots were conducted during 2-day exposures, followed by 28 days in atrazine-free solution (Pillai et al. 1977; Weete et al. 1980). After 2 days, 90% of the atrazine had translocated to the shoots. Atrazine was readily metabolized to chloroform-soluble substances, then to water-soluble substances, and finally to insoluble substances. Atrazine in the chloroform-soluble fraction decreased from 85% to 24% by day 28; the aqueous fraction contained 15% at the start and 60% at day 28. The basis of *Spartina* resistance is due primarily to its ability to convert atrazine to N-dealkylation products, such as 2-chloro-4-amino-6-isopropylamino-s-triazine. However, at least 14 water-soluble metabolites were isolated; about half contained the fully alkylated triazine rings, and most of the others had the 4-amino-6-isopropylamino derivative. Acid hydrolysates of the metabolites contained small amounts of amino acids, suggesting that a conjugation pathway, in addition to N-deakylation, may be operative in *Spartina*.

Table 4. Atrazine effects on selected species of aquatic plants.

Species, dose, and other variables	Effect and reference
Phytoplankton communities in experimental microcosms	
0.5 to 5.0 ug/L, 39 weeks	No measurable adverse effects (Brockway et al. 1984)
1.0 to 5.0 ug/L, several days	Reduced photosynthesis in sensitive species (DeNoyelles et al. 1982)
>17.9 ug/L, 21 days	Decreased oxygen production, decreased content of calcium and magnesium (Pratt et al. 1988)
20 ug/L, 20 days	Altered species composition (DeNoyelles and Kettle 1985)
20 ug/L, 136 days	Reduced growth, altered succession; atrazine resistant species now dominant (DeNoyelles et al. 1982)
50 ug/L, 12 days	Oxygen production decreased 20% to 30% (Brockway et al. 1984)
100 ug/L, 14 days	Algal densities and biomass reduced, diversity decreased, and species composition altered. Within 16 days after removal of atrazine stress, net productivity was indistinguishable from controls, but

	community structure remained altered at day 21 (Hamala and Kollig 1985)
100 ug/L, 20 days	Carbon uptake reduced >40% (DeNoyelles and Kettle 1985)
500 ug/L, 53 days	Immediate decline in primary productivity and community metabolism; no recovery (Stay et al. 1985)
5,000 ug/L, 12 days	Death (Brockway et al. 1984)
Alga, *Cyclotella meneghiniana*	
1.0 ug/L, 5 min	Some inhibition in oxygen evolution (Millie and Hersh 1987)
99 to 243 ug/L, 5 min	Oxygen evolution reduced 50% (Millie and Hersh 1987)
500 ug/L, 5 min	Oxygen evolution 100% inhibited (Millie and Hersh 1987)
Wildcelery, *Vallisneria americana*	
1.3 ug/L, 47 days	No measurable effect (Correll and Wu 1982)
3.2 ug/L, 49 days	Some reduction in leaf area (Correll and Wu 1982)
12 ug/L, 47 days	LC-50; reduced reproduction and leaf area in survivors (Correll and Wu 1982)
75 ug/L, 12 to 28 days	Inhibited photosynthesis (Correll and Wu 1982)
100 ug/L, 6 weeks	Growth inhibited 29% (Forney and Davis 1981)
120 ug/L, 30 days	LC-100 (Correll and Wu 1982)
163 ug/L, 21 to 42 days	Growth inhibition of 50% (Forney 1980)
320 ug/L, 6 weeks	Growth inhibited 36% (Forney and Davis 1981)
Elodea, *Elodea canadensis*	
3.2 ug/L, 3 to 4 weeks	Growth inhibited 1% (Stevenson et al. 1982)
13 ug/L, 21 to 42 days	Growth inhibited 50% (Forney 1980)
32 ug/L, 3 to 4 weeks	Growth inhibited 15% to 39% (Forney and Davis 1981)
100 ug/L, 3 to 4 weeks	Growth inhibited 53% (Forney and Davis 1981)
Redheadgrass, *Potamogeton perfoliatus*	
4 ug/L, 4 weeks	Photosynthesis reduced 10% (Kemp et al. 1985)
10 ug/L, 3 weeks	Growth inhibited 15% (Forney and Davis 1981)
50 ug/L, 2 h	Equilibrium reached within 15 min, maximum residues of 3.5 mg/kg dry weight (Jones et al. 1986)
55 ug/L, 4 weeks	Photosynthesis reduced 50% (Kemp et al. 1985; Larsen et al. 1986)
80 ug/L, 2 h	Photosynthesis inhibited 50% (Jones et al. 1986)
100 ug/L, 2 h	Photosynthesis inhibition and residues of about 9.0 mg/kg dry weight; recovery rapid in atrazine-free medium but some photo-synthetic depression for up to 77 h (Jones et al. 1986)
100 ug/L, 4 weeks	Photosynthesis inhibition; water levels of 87 ug atrazine/L at 4 weeks; recovery in 2 to 3 weeks in atrazine-free medium (Kemp et al. 1985)
130 ug/L, 4 weeks	Decreased oxygen production immediately on exposure; significant recovery within 2

	weeks despite constant atrazine concentrations (Cunningham et al. 1984)
320 ug/L, 3 weeks	Growth inhibited 45% to 54% (Forney and Davis 1981)
450 to 650 ug/L, 2 h	Photosynthesis inhibited 87%; residues of about 5 mg/kg dry weight (Jones et al. 1986)
474 ug/L, 21 to 42 days	Growth reduced 50% (Forney 1980)
1,200 ug/L, 4 weeks	Pronounced phytotoxic effects; no recovery (Cunningham et al. 1984)
Eurasian watermilfoil, *Myriophyllum spicatum*	
5 ug/L, 4 weeks	Enhanced oxygen production (Kemp et al. 1985)
11 ug/L, 4 weeks	Photosynthesis reduced 1% (Kemp et al. 1985)
50 ug/L, 4 weeks	Oxygen production depressed (Kemp et al. 1985)
117 ug/L, 4 weeks	Photosynthesis reduced 50% (Kemp et al. 1985; Larsen et al. 1986)
320 ug/L, 4 weeks	Growth inhibited 22% (Forney and Davis 1981)
1,000 ug/L, 4 weeks	Growth inhibited 62% (Forney and Davis 1981)
1,000 ug/L, 4 weeks	Residues <1 ug/kg (Kemp et al. 1985)
1,104 ug/L, 21 to 42 days	Growth inhibited 50% (Forney 1980)
Common cordgrass, *Spartina alterniflora*	
10 ug/L, 3 to 4 weeks	Biomass reduction of 6% (Stevenson et al. 1982)
100 ug/L, 3 to 4 weeks	Biomass reduction of 34% (Stevenson et al.1982)
1,000 ug/L, 3 to 4 weeks	Biomass reduction of 46% (Steveneson et al. 1982)
Shoal grass, *Halodule wrightii*	
10, 40, or 120 ug/L, 22 days	Enhanced growth when compared to controls (Mitchell 1985)
420 ug/L, 22 days	Above ground biomass reduced 26% (Mitchell 1985)
1,490 ug/L, 22 days	Above ground biomass reduced 45% compared to controls (Mitchell 1985)
Marine alga, *Nannochlsoris oculata*	
15 ug/L, 7 days	Growth reduction (Mayasich et al. 1987)
50 ug/L, 72 h	Some growth inhibition; inhibition greatest under conditions of elevated temperature and illumination (Karlander et al. 1983)
Alga and macrophytes, various species	
20 ug/L, 6 weeks	Bioconcentration factors up to 32x Huckins et al. 1986)
Submerged aquatic macrophytes, 4 species: *Potamogeton* sp., *Ruppia* sp., *Myriophyllum* sp., *Zannichellia* sp.	
20 ug/L, 2 h	Photosynthesis inhibition of about 1% (Jones and Winchell 1984)
95 ug/L, 2 h	Photosynthesis inhibition 50%; atrazine significantly more effective than deethylated atrazine, seisopropylated atrazine, and hydroxyatrazine, in that order, in effecting

	inhibition (Jones and Winchell 1984)
Algae, various species	
22 ug/L, 7 days	No effect on photosynthesis rate, chlorophyll content, or cell numbers (Plumley and Davis 1980)
37 to 308 ug/L, 24 h	Carbon uptake reduced 50% (Larsen et al. 1986)
60 to 100 ug/L, 72 h	Growth inhibited 50% in seven species (Mayer 1987)
60 to 460 ug/L, 1 h	Oxygen evolution inhibited 50% in 18 species (Hollister and Walsh 1973)
77 to 102 ug/L, 24 h	Photosynthesis reduction of 50% (Larsen et al. 1986)
80 to 907 ug/L, 3 weeks	Growth inhibited 50% (Larsen et al. 1986)
100 ug/L, 2 h	Growth inhibited 50% in three species (Mayer 1987)
100 ug/L, 3 days	Reduced productivity; complete recovery by day 7 (Moorhead and Kosinski 1986)
100 to 300 ug/L, 10 days	Growth inhibited 50% in four species (Mayer 1987)
100 to 460 ug/L, 72 h	Growth inhibited 50% in eight species (Mayer 1987)
220 ug/L, 7 days	Reduced photosynthesis; no effect on chlorophyll production and cell division rate in three estuarine species (Plumley and Davis 1980)
Algae, *Chlorella* spp.	
54 ug/L, 10 days	Growth reduction of 30% (Gonzalez-Murua et al. 1985)
200 ug/L, 48 h	Photosynthesis reduced 30%, but no effect on growth (Lay et al. 1984)
250 ug/L, 7 days	Growth reduction; 90% of atrazine passively accumulated within 1 h (Veber et al. 1981)
Submersed vascular plant, *Zannichellia palustris*	
75 ug/L, 21 to 42 days	Photosynthesis inhibition (Correll and Wu 1982)
Submersed vascular plant, *Potamogeton pectinatus*	
75 ug/L, 21 to 42 days	Photosynthesis stimulation (Correll and Wu 1982)
650 ug/L, 21 to 42 days	Photosynthesis inhibition (Correll and Wu 1982)
Submersed vascular plant, *Zostera marina*	
75 ug/L, 21 to 42 days	Photosynthesis stimulation (Correll and Wu 1982)
650 ug/L, 21 to 42 days	Photosynthesis inhibition (Correll and Wu 1982)
Periphyton communities in freshwater enclosures	
80 to 1,560 ug/L, 10 months	Declines in net production, cell numbers, biomass, number of taxa, and chlorophyll activity; larger algal species (*Mougeotia, Oedogonium*, *Tolypothrix*, *Epithemia*) were the most sensitive. At higher concentrations, population shifted from a chlorophyte-dominated to a diatom-dominated community

	(Hamilton et al. 1987)
100 ug/L, 2 treatments, 6 weeks apart	After initial application, all blue green algae disappeared and organic matter significantly decreased. Within 3 weeks of second treatment, a 36% to 67% reduction in organic matter, chlorophyll, algal biomass, and rate of carbon assimilation was measured. Some species of green algae decreased in abundance, but others increased (Herman et al. 1986)
Duckweed, *Lemna minor*	
250 ug/L, 15 days	Ultrastructural changes on chloroplasts of mesophyll cells; no effect on chlorophyll and lipid distribution (Beaumont et al. 1980; Grenier et al. 1987)

Estuarine fungi contribute substantially to plant detritus due to their abundance and degradative potential. Fungi are known to accumulate soluble atrazine from seawater through sorption, and release up to *2.2%* as hydroxyatrazine and other atrazine metabolites; another 4.6% is more tightly associated and less available to the external environment. The combined processes result in atrazine accumulation, and may contribute to its transport and redistribution through the estuary (Schocken and Speedie 1982, 1984).

AQUATIC FAUNA

A marine copepod (*Acartia tonsa*) was the most sensitive aquatic animal tested against direct effects of atrazine, having a 96-hour LC-50 of 94 ug/l (Table 5). Adverse effect levels to selected species of aquatic invertebrates and fishes ranged from 120 ug/l to 500 ug/l, based on lifetime exposure studies (Table 5). The most sensitive criterion measured during long-term chronic exposure varied among species. Among freshwater invertebrates, for example, the most useful criterion was survival for *Gammarus*, the number of young produced for *Daphnia*, and developmental retardation for *Chironomus* (Macek et al. 1976).

Table 5. Lethal and sublethal effects of atrazine on selected species of aquatic fauna. Concentrations listed are in micrograms of atrazine per liter of medium.

Ecosystem, organism, and other variables	Concentration (ug/L)	Effect	Reference [a]
Freshwater Invertebrates			
Midge, *Chironomus riparius*			
Adults	20	Whole body residue of 160 ug/kg in 6 weeks	1
Larvae	20	Whole body residue of 569 ug/kg in 6 weeks	1
Cladoceran, *Daphnia magna*	20	After 6 weeks, whole body residue of 300 ug/kg	1
D. magna	200	Exposure for six generations. Number of	

		young per female in 21 days did not differ from controls in generations 1, 2, and 3, but significant reduction measured in generations 4, 5, and 6	2
D. magna	6,900 (5,200 to 8,100)	LC-50 (48 h)	3
Scud, *Gammarus fasciatus*	60 to 140	MATC[b]	3
G. fasciatus	>2,400	Some deaths in 48 h	3
G. fasciatus	5,700 (3,600 to 8,000)	LC-50 (48 h)	3
Midge, *Chironomus tentans*	110 to 230	MATC[b]	3
C. tentans	500	Some deaths in 48 h	3
C. tentans	720 (360 to 1,440)	LC-50 (48 h)	3
Leeches, two species (*Glossiphonia complanata, Helobdella stagnalis*)	<1,000	Adverse effects on growth, food intake, and egg production	11
Leeches, two species	6,300 to 9,900	LC-50 (28 days)	11
Leeches, two species	16,000	No deaths in 96 h	11
Freshwater fishes			
Brook trout, *Salvelinus fontinalis*	60 to 120	MATC[b]	3
S. fontinalis	450	Reduced incubation time of developing embryos	3
S. fontinalis	740	After 44 weeks, concentration in muscle <0.2 mg/kg fresh weight	3
S. fontinalis	6,300 (4,100 to 9,700)	LC-50 (8 days)	3
Bluegill, *Lepomis macrochirus*	90 to 500	MATC[b]	3
L. macrochirus	94	After 78 weeks, concentration in muscle <0.2 mg/kg fresh weight	3
L. macrochirus	500	At 28 days, fish were lethargic and ate poorly, and swam erratically	3
L. macrochirus	6,700 (5,400 to 8,400)	LC-50 (7 days)	3
L. macrochirus	8,000 to 42,000	LC-50 (96 h)	3, 4, 5, 6
L. macrochirus	46,000	LC-50 (24 h)	6
Fathead minnow, *Pimephales promelas*	210	After 43 weeks, concentration in	

		eviscerated carcass was <1.7 mg/kg fresh weight	3
P. promelas,	210 to 520	MATC[b]	3
P. promelas fry	520	LC-25 (96 hours)	3
P. promelas	15,000 (11,000 to 20,000)	LC-50 (8 days)	3
Rainbow trout, *Salmo gairdneri*	4,500 to 24,000	LC-50 (96 h)	4, 6
Marine invertebrates			
Mysid shrimp, *Mysidopsis bahia*	80 to 190	MATC[b]	7
M. bahia	1,000 (650 to 3,100)	LC-50 (96 h)	7
Copepod, *Acartia tonsa*	94 (52 to 167)	LC-50 (96 h)	7
Brown shrimp, *Penaeus aztecus*	1,000	50% immobilized in 48 h	8
American oyster, *Crassostrea virginica,*	1,000	No effect on survival or growth	9
C. virginica	>1,000	Growth reduced 50% in 96 h	8
C. virginica	>30,000	No effect on development in 48 h	7
"Shrimp"	1,000	LC-30 (96 h)	9
Pink shrimp, *Penaeus duorarum*	6,900	LC-50 (96 h)	7
Grass shrimp, *Palaemonetes pugio*	9,000	LC-50 (96 h)	7
Fiddler crab, *Uca pugilator*	>29,000	LC-50 (96 h)	7
Fiddler crab, *Uca pugnax*	100,000	Interfered with escape response when exposed in August; negligible effects in November; young males most sensitive	10
U. pugnax	1,000,000 to 10,000,000	Reduced survival after 10 weeks	10
Mud crab, *Neopanope texana*	750,000	No deaths in 96 h	9
N. texana	1,000,000	LC-50 (96 h)	9
Marine fishes			
Sheepshead minnow, *Cyprinodon variegatus*	1,900 to 3,400	MATC[b]	7
C. variegatus	>16,000	LC-50 (96 h)	7
Spot, *Leiostomus xanthurus*	8,500	LC-50 (96 h)	7

[b]Maximum acceptable toxicant concentration. Lower value in each pair indicates highest concentration tested producing no measurable effect on growth, survival, reproduction, or metabolism during chronic exposure; higher value indicates lowest concentration tested producing measurable effect.

Ambient concentrations as low as 20 ug atrazine/l have been associated with adverse effects on freshwater aquatic fauna, including benthic insects (Dewey 1986) and teleosts (Kettle et al. 1987), although effects were considered indirect. For example, the abundance of emerging chironomids (*Labrundinia pilosella*), and other aquatic insects declined at 20 ug atrazine/l (Dewey 1986). Richness of benthic insect species and total emergence declined significantly with atrazine addition. The effects were primarily indirect, presumably by way of reduction in food supply of nonpredatory insects, and to some extent their macrophyte habitat. Dietary habits and reproductive success were negatively affected in three species of fish after exposure for 136 days in ponds containing 20 ug atrazine/l (Kettle et al. 1987). About 70% of the original concentration applied was present in water at the end of the study. The reproduction of channel catfish (*Ictalurus punctatus*) and gizzard shad (*Dorosoma cepedianum*) failed, and that of bluegills, as measured by number of young per pond, was reduced more than 95%. Also, the number of prey items in the stomachs of bluegills were significantly higher in control ponds (25.6) than in a treated pond (3.8), and number of taxa represented were significantly greater. Macrophyte communities in treated ponds were reduced more than 60% in 2 months. The authors concluded that the effects of atrazine on bluegills were probably indirect, and that the reduction of macrophytes that had provided habitat for food items led to impoverished diets and more cannibalism by adult bluegills (Kettle et al. 1987).

Bioaccumulation of atrazine from freshwater is limited, and food chain biomagnification is negligible. In a farm pond treated once with 300 ug atrazine/l, residues at 120 days posttreatment ranged between 204 and 286 ug/kg in mud and water, and from not detectable in bullfrog (*Rana catesbeiana*) tadpoles to 290 ug/kg (all fresh weights) in whole bluegills; values were intermediate in zooplankton and clams. No residues were detectable in biological components one year posttreatment, when residues were <21 ug/kg in water and mud (Klaassen and Kadoum 1979). In a laboratory stream treated four times with 25 ug atrazine/l for 30 days, followed by depuration for 60 days, maximum accumulation factors ranged from about 4X in annelids to 480X in mayfly nymphs; however, residue concentrations declined to posttreatment levels within a few days after depuration began. Maximum atrazine concentrations recorded, in mg/kg whole organism fresh weight, were 0.2 in the clam *Strophitis rugosus*, 0.4 in the snail *Physa* sp., 0.9 in crayfish, *Orconectes* sp., 2.4 in the mottled sculpin *Cottus bairdi*, 3.0 in the amphipod *Gammarus pseudolimnaeus*, and 3.4 in mayflies, *Baetis* sp. (Lynch et al. 1982). In studies with the freshwater snail *Ancylus fluviatilis* and fry of the whitefish *Coregonus fera*, atrazine was rapidly accumulated from the medium by both species and saturation was reached within 12 to 24 hours; bioconcentration factors were 4X to 5X at ambient water concentrations of 50 to 250 ug atrazine/l (Gunkel and Streit 1980; Gunkel 1981). Elimination of atrazine was rapid: 8 to 62 minutes for *Coregonus*, and 18 minutes for *Ancylus*. No accumulation of atrazine was recorded in molluscs, leeches, cladocerans, or fish when contamination was by way of the diet (Gunkel and Streit 1980; Gunkel 1981). Atrazine accumulations in *Daphnia pulicaria* were significantly correlated with whole body protein content at low (8 °) water temperatures, and with fat content at elevated (20°C) water temperatures (Heisig-Gunkel and Gunkel 1982).

Atrazine is rapidly degraded in boxcrabs (*Sesarma cinereum*) feeding on smooth cordgrass (*Spartina alterniflora*) grown in radiolabeled atrazine solution. After 10 days, only 1.2% of the total radioactivity in the crab was unchanged atrazine, compared to 24% in the food source. The accumulation of water-soluble atrazine metabolites (86% of total radioactivity) in *Sesarma* suggested that glutathione conjugation, or a comparable pathway, was responsible for the almost complete degradation and detoxification of atrazine in crabs (Davis et al. 1979; Pillai et al. 1979). Atrazine does not appear to be a serious threat to crabs in Chesapeake Bay, where water concentrations of 2.5 ug/l have been recorded, although it could have an indirect effect on crabs by decreasing the algal population, which composes a portion of their diet (Plumley et al. 1980).

BIRDS

Atrazine is not acutely lethal to birds at realistic environmental levels, i.e., oral LD-50 values were >2,000 mg/kg BW and dietary LC-50s were >5,000 mg/kg (Table 6). Also, the probability is low for chronic effects of atrazine on wetland aquatic organisms and for biomagnification of toxic residues through waterfowl food chains (Huckins et al. 1986). However, indirect effects of atrazine on insect- and seed-eating birds have not been investigated, and this may be critical to the survival of certain species during nesting and brood-rearing. Studies are needed on the potential indirect ecosystem effects of atrazine, with special reference to seed-eating birds.

Domestic chickens (*Gallus* sp.) rapidly metabolized atrazine by way of partial N-dealkylation accompanied by hydrolysis; dealkylation occurred mainly at the ethylamino group, resulting in intermediate degradation products (Foster and Khan 1976; Khan and Foster 1976). In vitro studies with bird liver homogenates also demonstrated active transformation of atrazine and its metabolites. Chicken liver homogenates released nonextractable atrazine residues that had accumulated in corn plants, present mainly as 2-chloro mono N-dealkylated compounds, and subsequently metabolized them to 2-hydroxy analogues (Khan and Akhtar 1983). Liver homogenates in the goose (*Anser* sp.) contained enzyme systems that metabolized atrazine by partial N-dealkylation and hydrolysis; hydrolysis predominated and resulted in the formation of hydroxyatrazine, which does not undergo further degradation by dealkylation. But partly N-dealkylated metabolites, such as deethylatrazine and deisopropylatrazine, were further hydrolyzed to the corresponding hydroxy analogues (Foster et al. 1980).

MAMMALS

Data are lacking for atrazine's effects on mammalian wildlife, although there is a growing body of evidence on domestic and small laboratory mammals. Available data demonstrate that mammals are comparatively resistant to atrazine, and that the compound is not carcinogenic, mutagenic, or teratogenic (Reed 1982; Table 7). There have been no established cases of skin irritation resulting from experimental or commercial applications of atrazine, and no documented cases of poisoning in man (Anon. 1963; Hull 1967). No observable ill effects were detected in cattle, dogs, horses, or rats fed diets that included 25 mg atrazine/kg food over extended periods (Beste 1983). Most members of the triazine class of herbicides, including atrazine, have low acute oral toxicities--usually >1,000 mg/kg body weight (Murphy 1986; Table 7). But at dosages bordering on lethality, rats showed muscular weakness, hypoactivity, drooped eyelids, labored breathing, prostration (Beste 1983), altered liver morphology and renal function (Santa Maria et al. 1986, 1987), and embryotoxicity (Peters and Cook 1973).

Animals feeding-on atrazine-treated crops are at limited toxicological risk. Crop plants metabolize atrazine to hydroxyatrazine, dealkylated analogues, and cysteine-and glutathione-conjugates of atrazine; mature plants contain little unchanged atrazine. Bound atrazine residues in plants are of limited bioavailability to animals (Bakke et al. 1972a; Khan and Akhtar 1983; Khan et al. 1985). Metabolic degradation of atrazine in mammals is usually rapid and extensive; unchanged atrazine was recovered only from the feces (Anon. 1963). Liver enzyme systems in pigs, rats, and sheep metabolize atrazine by partial N-dealkylation and hydrolysis (Bakke et al. 1972a; Dauterman and Muecke 1974; Foster et al. 1980). However, atrazine is reportedly converted in vivo to N-nitrosoatrazine in mice, *Mus* sp. (Krull et al. 1980). Since N-nitrosoatrazine is carcinogenic and mutagenic to laboratory animals (Krull et al. 1980), more research is recommended on the extent of nitrosation of atrazine in the environment.

Table 6. Atrazine effects on selected species of birds.

Species, dose, and other variables	Effect and reference
Chicken, *Gallus* sp.	
Laying hens were fed diets containing 100 mg/kg for 7 days	No visible adverse physiological effects or signs of toxicity. No effect on egg production or growth. No residues of atrazine or its metabolites detected in eggs. In excreta, however, atrazine and atrazine metabolites were detected after 24 h on treated diet and remained measurable until day 11, or after 4 days on an untreated diet (Foster and Khan 1976; Reed 1982)
Adults fed diets containing 100 mg/kg for 7 days, followed by uncontaminated diet for 7 days. Residues of atrazine and its metabolites were determined in selected tissues	Residues, in mg/kg FW, were as follows: atrazine, 38.8 in abdominal fat and 0.04 in muscle; hydroxyatrazine, 16.2 in liver, 4.3 in kidney 2.5 in oviduct, 0.7 in abdominal fat, and 0.5 in gizzard; and deethylhydroxyatrazine in liver, 2.3 in kidney, 0.8 to 1.8 in muscle, and 0.3 in gizzard (Khan and Foster 1976)
Ring-necked pheasant, *Phasianus colchicus*	
Males, age 3 months, given 2,000 mg/kg body weight (BW), administered orally	Survivors showed weakness, hyperexcitability, ataxia, and tremors; remission by day 5 posttreatment (Hudson et al. 1984)
Mallard, *Anas platyrhynchos*	
Females, age 6 months, given 2,000 mg/kg BW, administered orally	Survivors showed weakness, tremors, ataxia, and weight loss. Signs of poisoning appeared within one hour posttreatment and persisted up to 11 days (Tucker and Crabtree 1970; Hudson et al. 1984)
19,650 mg/kg diet for 8 days	LD-50 (Beste 1983)
Coturnix, *Coturnix japonica*	
Chicks, age 7 days, given diets containing 5,000 mg/kg for 5 days plus 3	One of 14 birds tested died on day 3 of feeding; no other adverse effects reported (Hill and Camardese 1986)

days on untreated feed	
Northern bobwhite, *Colinus virginianus*	
5,760 mg/kg diet for 8 days.	LD-50 (Beste 1983)

Table 7. Lethal and sublethal effects of atrazine on selected species of mammals.

Species, dose, and other variables	Effect and reference
Cattle, Cow, *Bos* spp.	
30 mg atrazine/kg diet for 21 days	Tissue residues <0.1 mg/kg fresh weight (Reed 1982)
100 mg atrazine/kg diet for 21 days	No detectable atrazine (<0.04 mg/kg) or hydroxyatrazine (<0.05 mg/kg) found in milk (Reed 1982)
Domestic sheep, *Ovis aries*	
30 mg atrazine/kg diet for 28 days	Tissue residues <0.1 mg/kg fresh weight (Reed 1982)
100 mg atrazine/kg diet for 28 days	No adverse effects (Reed 1982)
Mice, *Mus* spp.	
46.4 mg/kg body weight (BW) given daily on days 6 through 14 of pregnancy	No effect on reproduction (Peters and Cook 1973)
82 mg/kg diet for 18 months	Negative oncogenicity results (Reed 1982)
1,750 to 3,900 mg/kg BW	Acute oral LD-50 value (Anon. 1963; Hull 1967; Reed 1982)
Dog, *Canis familiaris*	
150 mg/kg diet for two years, equivalent to 3.75 mg/kg BW daily	No observable effect level (Reed 1982)
1,500 mg/kg diet for two years	No oncogenic effects; decreased body weight, reduced hemoglobin and hematocrit (Reed 1982)
Rat, *Rattus* spp.	
Inhalation exposure to a dust aerosol of Atrazine 80W (80% wettable powder) for one hour to concentrations between 1.8 and 4.9 mg/L atmosphere	No deaths, or signs of toxicological or pharmacological effects (Hull 1967)

100 mg/kg diet for 2 years, equivalent to 5 mg/kg BW daily	No gross microscopic signs of toxicity (Anon. 1963; Reed 1982; Beste 1983)
100 mg/kg diet for three generations, equivalent to 5 mg/kg BW daily	No teratogenic or reproductive effects (Reed 1982)
Daily oral administration on days 6 to 15 of gestation, in mg/kg BW	
10	No adverse maternal or fetal effects (Infurna et al. 1988)
70	Increased salivation; initial reduction in feed consumption (Infurna et al. 1988)
700	Mortality 78% before necropsy; increased incidences of salivation, ptosis, bloody ulva, swollen abdomen, and fetal skeletal malformations (Infurna et al. 1988)
100, 200, 400, or 600 mg/kg BW daily, given orally for 14 days	All dose levels increased elimination of sodium, potassium, chloride, and urine protein; interference with creatinine clearance at 200 mg/kg BW and higher (Santa Maria et al. 1986)
100, 200, 400 or 600 mg/kg BW daily for 14 days	At 100 mg/kg, significant increases in serum lipids, serum alkaline phosphatase, and serum alanine aminotransferase; no liver histopathology At 200 mg/kg, a significant reduction in body weight. At 400 mg/kg, liver enlargement and loss in body weight. A dose-dependent decrease in growth and in serum glucose and a dose-related increase in total serum lipids were recorded. At 600 mg/kg, liver histopathology (Santa Maria et al. 1987)
100, 300, or 900 mg/kg diet for 3 weeks	Except for lymphoenia, which was observed at all dose levels, no other effects were measured in the 100 and 300 mg/kg groups. At 900 mg/kg, significant decreases occurred in body weight, food intake, blood lymphocytes and thymus weight, and significant increases occurred in thyroid weight, mesenteric lymph nodes, and histopathology (Vos et al. 1983)
200 mg/kg BW injected subcutaneously on days 3, 6, and 9 of gestation	No effect on number of pups per litter or on weight at weaning (Peters and Cook 1973)
800, 1,000, or 2,000 mg/kg BW injected	At 2,000 mg/kg BW, most pups born dead; at 800 and 1,000 mg/kg BW, litter size

subcutaneously on days 3, 6, and 9 of gestation	reduced 50% to 100% (Peters and Cook 1973)
1,000 mg atrazine/kg diet from first day of pregnancy throughout gestation	No effect on number of pups per litter or on weight on weaning (Peters and Cook 1973)
1,000 mg/kg diet for two years, equivalent to 50 mg/kg BW daily	No signs of oncogenicity, but reduced food intake and lower body weight (Reed 1982)
1,800 to 5,100 mg/kg BW	Acute oral LD-50 (Anon. 1963; Hull 1967; Reed 1982; Beste 1983)
White rabbit, *Oryctolagus cuniculus*	
Daily oral administration on gestational days 7 through 19, in mg/kg BW	
1	No adverse maternal or fetal affects (Infurna et al. 1988)
5	Moderate reductions in food consumption and body weight gain (Infurna et al. 1988)
75	Increased abortion rate; no death of does. Weight loss, reductions in feed consumption and fetal and embryotoxic effects, including reduced fetal weight and increased incidence in skeletal variations (Infurna et al. 1988)
9,300 mg/kg BW	Acute dermal LD-50 (Beste 1983)

CURRENT RECOMMENDATIONS

Labels on products containing atrazine are required to contain information on acceptable uses and potential hazards to groundwater and to fish and wildlife (EPA 1983). At present, atrazine is approved for use as an herbicide to control broadleaf and grassy weeds on corn, sorghum, sugarcane, pineapple, macadamia nuts, rangeland, turf grass sod, conifer reforestation areas, Christmas tree plantations, grass seed fields, noncrop land, guava, grass in orchards, millet, perennial ryegrass, and wheat. Because atrazine is expected to leach into groundwater, it was recommended (EPA 1983) that labels of atrazine products bear the following statement: "Atrazine leaches readily and accepted label rates have been found to result in contamination of water supplies by way of groundwater. Therefore users are advised to avoid use of atrazine in well drained soils, particularly in areas having high groundwater tables." Cautionary statements on potential hazards to living resources is another labeling requirement: "This pesticide is toxic to aquatic invertebrates. Do not apply to water or wetlands. Runoff and drift from treated areas may be hazardous to aquatic organisms in neighboring areas. Do not contaminate water by cleaning of equipment or disposal of wastes. Do not discharge into lakes, streams, ponds, or public water supplies unless in accordance with an [approved EPA] permit" (EPA 1983).

Current permissible tolerances for atrazine range from 0.02 mg/kg (the limit of detection of the analytical method) in meat, milk, and eggs, to 15 mg/kg in orchard grass forage, fodder, and hay (Reed 1982; EPA 1983). However, the current 15 mg/kg tolerance in forage is considered high, and a new upper limit of 4 mg/kg is proposed. This limit would be expressed in terms of atrazine and three major metabolites: 2-amino-4-chloro-6-isopropylamino-1, 3, 5-triazine; 2-amino-4-chloro-6-ethylamino-1, 3, 5-triazine; and 2-chloro-4, 6-diamino-1, 3, 5-triazine (Reed 1982; EPA 1983).

The maximum recommended safe level of atrazine to algal diatoms is 10 ug/l (Karlander et al. 1983), although temporary inhibition of chlorophyll production in sensitive algal species has been reported in the range of 1 to 5 ug/l (Torres and O'Flaherty 1976). Proposed atrazine concentrations for aquatic life protection range from about 1 to 11 ug/l: 1 to 2 ug/l for protection of estuarine productivity (Stevenson et al. 1982; Ward and Ballantine 1985); 1 to 7 ug/l for no adverse effect levels to most species of submerged aquatic vegetation (Glotfelty et al. 1984); 5 to 10 ug/l for minor reductions in photosynthesis in sensitive species of aquatic macrophytes (Glotfelty et al. 1984); 9 ug/l for sensitive aquatic invertebrates, as judged by an uncertainty factor of 10 applied to a 96-hour LC-50 (Ward and Ballantine 1985); and 11 ug/l for salt marsh algae, based on the least effect level of 110 ug/l, and an uncertainty factor of 10 (Plumley and Davis 1980). Atrazine concentrations >11 ug/l sometimes occur during periods of runoff and non-flushing (Stevenson et al. 1982), but rarely persist at levels necessary to markedly inhibit photosynthesis in aquatic plants, i.e., 60, to 70 ug/l (Glotfelty et al. 1984).

In laboratory animals, atrazine is only slightly toxic on an acute basis; no carcinogenic, mutagenic, or reproductive effects have been seen at low doses, and reduced food intake and body weight were the primary adverse effects seen at high doses in chronic studies with rats and dogs (Reed 1982). However, data are lacking on indirect ecosystem effects of atrazine application on terrestrial wildlife--especially on insectivores and granivores; studies should be initiated in this subject area.

No allowable daily intake of atrazine in the human diet has been established, although 0.0375 mg/kg body weight daily has been proposed --equivalent to 2.25 mg daily for a 60-kg adult, or 1.5 mg/kg diet based on 1.5 kg food daily (Reed 1982). In man, the theoretical maximum residue contribution (TRMC)--a worst case estimate of dietary exposure--is 0.77 mg daily, assuming 1.5 kg of food eaten daily; this is equivalent to 0.51 mg/kg diet, or 0.013 mg/kg body weight daily for a 60-kg person (EPA 1983). Another TRMC calculation is based on 0.233 mg daily per 1.5 kg diet, equivalent to 0.156 mg/kg diet, or 0.0039 mg/kg body weight daily for a 60-kg person (Reed 1982). Both TRMC estimates are substantially below the proposed limit of 0.0375 mg/kg body weight daily. Lifetime exposure to drinking water concentrations of 2.3 ug atrazine/l poses negligible risk to human health, as judged by the no adverse effect level of 7.5 ug/l when 1% of the allowable daily intake is obtained from this source (EPA 1987; Wilson et al. 1987). Higher allowable concentrations are proposed over short periods: 123 ug/l for adults and 35 ug/l for children over a 10-day period (EPA 1987).

Additional data are needed on toxicity, environmental fate, and chemistry of atrazine in order to maintain existing registrations or to permit new registrations (EPA 1983). Specifically, data are needed on mobility and degradation rates of atrazine and its metabolites in soils; accumulation studies in rotational crops, fish, and aquatic invertebrates; and chronic testing with representative flora and fauna on survival, reproduction, carcinogenesis, teratogenesis, and mutagenesis (EPA 1983). Animal metabolism studies are required if tolerances for residues in animal products are expressed in terms of atrazine and its metabolites (EPA 1983). Finally, more research on aquatic species is merited on synergistic and additive effects of atrazine in combination with other agricultural chemicals at realistic environmental levels of 1 to 50 ug/l, and on the toxic effects of dealkylated atrazine metabolites (Stevenson et al. 1982).

MOLYBDENUM HAZARDS TO FISH, WILDLIFE, AND INVERTEBRATES: A SYNOPTIC REVIEW

by
Ronald Eisler

U.S. Fish and Wildlife Service
Patuxent Wildlife Research Center
Laurel, MD 20708

SUMMARY

The element molybdenum (Mo) is found in all living organisms and is considered to be an essential or beneficial micronutrient. However, the molybdenum poisoning of ruminants has been reported in at least 15 States and 8 foreign countries.

Molybdenum is used primarily in the manufacture of steel alloys. Its residues tend to be elevated in plants and soils near Mo mining and reclamation sites, fossil-fuel power plants, and Mo disposal areas. Concentrations of Mo are usually lower in fish and wildlife than in terrestrial macrophytes.

Aquatic organisms are comparatively resistant to Mo salts: adverse effects on growth and survival usually appeared only at water concentrations >50 mg Mo/l. But in one study, 50% of newly fertilized eggs of rainbow trout (*Oncorhynchus mykiss*) died in 28 days at only 0.79 mg Mo/l. High bioconcentration of Mo by certain species of aquatic algae and invertebrates--up to 20 grams of Mo/kg dry weight--has been recorded without apparent harm to the accumulator; however, hazard potential to upper trophic organisms (such as waterfowl) that may feed on bioconcentrators is not clear. Data on Mo effects are missing for avian wildlife and are inadequate for mammalian wildlife. In domestic birds, adverse effects on growth have been reported at dietary Mo concentrations of 200 mg Mo/kg, on reproduction at 500 mg/kg, and on survival at 6,000 mg/kg.

Molybdenum chemistry is complex and inadequately known. Its toxicological properties in mammals are governed to a remarkable extent through interaction with copper and sulfur; residues of Mo alone are not sufficient to diagnose Mo poisoning. Domestic ruminants, especially cattle, are especially sensitive to Mo poisoning when copper and inorganic sulfate are deficient. Cattle are adversely affected--and die if not removed--when grazing on pastures where the ratio of copper to Mo is <3, or if they are fed low copper diets containing Mo at 2 to 20 mg/kg diet; death usually occurs when tissue residues exceed 10 mg/kg body weight. The resistance of other species of mammals tested, including domestic livestock, small laboratory animals, and wildlife, was at least 10X that of cattle. Mule deer (*Odocoileus hemionus*), for example, showed no adverse effects at dietary levels of 1,000 mg/kg.

Additional research is needed in several fields: the role of Mo on inhibition of carcinomas and dental caries; the establishment of minimum, optimal, and upper daily requirements of Mo in aquatic and wildlife species of concern; the improvement in diagnostic abilities to distinguish molybdenum poisoning from copper deficiency; and the determination of sensitivity of early developmental stages of fishes to Mo insult.

INTRODUCTION

Molybdenum (Mo) is present in all plant, human, and animal tissues, and is considered an essential micronutrient for most life forms (Schroeder et al. 1970; Underwood 1971; Goyer 1986). The first indication of an essential role for Mo in animal nutrition came in 1953 when it was discovered that a flavoprotein enzyme, xanthine oxidase, was dependent on Mo for its activity (Underwood 1971). It was later determined that Mo is essential in the diet of lambs, chicks, and turkey poults (Underwood 1971). Molybdenum compounds are now routinely added to soils, plants, and waters to achieve various enrichment or balance effects (Friberg et al. 1975; Friberg and Lener 1986).

There are certain locations where plants will not grow optimally because of a deficiency in Mo, and other places where the levels of Mo in plants are toxic to livestock grazing on the plants (Chappell and Peterson 1976). Molybdenum poisoning in cattle was first diagnosed in England in 1938; molybdenosis was shown to be associated with consumption of herbage containing large amounts of this element, and to be controllable by treatment with copper sulfate (Underwood 1971). Molybdenum poisoning of ruminants, especially cattle, has been reported in at least 15 States, and in Canada, England, Australia, New Zealand, Ireland, the Netherlands, Japan, and Hungary. Molybdenosis was most pronounced in areas where soils were alkaline, high in Mo and low in copper, or near industrial point sources such as coal, aluminum, uranium, or molybdenum mines; steel alloy mills; or oil refineries (Dollahite et al. 1972; Alloway 1973; Kubota 1975; Buck 1978; Ward 1978; Chappell et al. 1979; Kincaid 1980; King et al. 1984; Kume et al. 1984; Sas 1987). All cattle are susceptible to molybdenosis, milking cows and young stock being the most sensitive (Underwood 1971). Industrial molybdenosis in domestic cattle and sheep, which usually involved a single farm or pasture, has been widely documented: in Colorado in 1958 from contaminated river waters used in irrigation, in Alabama in 1960 from mine spoil erosion, in North Dakota in 1968 from fly ash from a lignite burning plant, in Missouri in 1970-1972 from clay pit erosion, in Pennsylvania in 1971 from aerial contamination by a molybdenum smelter, in South Dakota in 1975 from Mo-contaminated magnesium oxide, and in Texas in 1965-1972 from uranium mine waste leachate (Ward 1978). In humans, a gout-like disease in two villages in Armenia was attributed to the ingestion of local foods high in Mo and grown in high Mo soils (Friberg and Lener 1986). Esophageal cancer was prevalent in various parts of southern Africa where food was grown in low Mo soils; it was reported in China in a low frequency rate that was significantly correlated with increasing Mo concentrations in cereals and drinking water (Luo et al. 1983). Additional and more extensive data on ecological and toxicological aspects of Mo in the environment were reviewed by Schroeder et al. (1970), Underwood (1971), Friberg et al. (1975), Chappell and Peterson (1976, 1977), Ward (1978), Chappell et al. (1979), Gupta and Lipsett (1981), and Friberg and Lener (1986).

This report was prepared in response to an informational request from environmental specialists of the U. S. Fish and Wildlife Service. It is part of a continuing series of brief reviews on chemical contaminants and natural resources.

ENVIRONMENTAL CHEMISTRY

GENERAL

Molybdenum is a comparatively rare element that is used primarily in the manufacture of steel alloys for the aircraft and weapons industries. Most of the recent global production of about 100,000 tons annually comes from the United States--primarily Colorado. Anthropogenic activities that have contributed to environmental Mo contamination include combustion of fossil fuels, and smelting, mining, and milling operations for steel, copper, and uranium, as well as for molybdenum. In general, the chemistry of Mo is complex and inadequately known. Its toxicological properties are governed to a remarkable extent by interactions with copper and sulfur, although other metals and compounds may confound this interrelation.

SOURCES AND USES

Molybdenum, discovered about 200 years ago, entered the commercial market in the 1920's as a result of extensive metallurgical research into its alloying properties and to the finding at Climax, Colorado, of the largest proven reserves of Mo worldwide (King et al. 1973). Molybdenum does not occur free in nature and is found only in combination with sulfur, oxygen, tungsten, lead, uranium, iron, magnesium, cobalt, vanadium, bismuth, or calcium. The most economically important ores are molybdenite (MoS_2), jordisite (amorphous MoS_2), and

ferrimolybdate ($FeMoO_3$ - H_20); less important are wulfenite ($PbMoO_4$) powellite ($CaMoO_4$), and ilsemannite (Mo_3O_8) (Friberg et al. 1975; Chappell et al. 1979; Friberg and Lener 1986; Goyer 1986).

World Mo production has increased from about 90 metric tons in 1900--half from Australia and Norway, half from the United States--to 136 tons in 1906, 1,364 in 1932 (an order of magnitude increase in 26 years), 10,909 in 1946, and 91,000 tons in 1973. Through the years, Mo has been produced in about 30 countries; in 1973, about 60% of the worldwide production was from the United States, 15% from Canada, 15% from the USSR and China combined, and 10% from other nations--Chile, Japan, Korea, Norway, and Mexico (King et al. 1973). By 1979, the United States produced about 62% of the world production of 103,000 metric tons, and exported about half, chiefly to western Europe and Japan; other major producers in 1979 were Canada, Chile, and the USSR (Kummer 1980). In the United States, only three mines in Colorado account for almost 70% of domestic production. Other active Mo mining sites in North America are in Arizona, Nevada, New Mexico, Utah, and California; Mo reserves have also been proven in Idaho, Alaska, Pennsylvania, and British Columbia (Kummer 1980). About 65% of domestic Mo is recovered from ores rich in Mo; the rest is a by-product from ores of copper, tungsten, and uranium (Chappell et al. 1979).

As a result of various human activities, Mo enters the environment from many sources (King et al. 1973; Friberg et al. 1975; Chappell et al. 1979). Coal combustion is the largest atmospheric source of Mo, contributing about 550 metric tons annually, or 61% of all atmospheric Mo worldwide that comes from anthropogenic sources. In Sweden alone, about 2.5 tons of Mo are emitted into the atmosphere yearly from oil combustion (Friberg et al. 1975). Molybdenum mining and milling are the source of about 100 metric tons annually to aquatic systems. At the world's largest Mo mine in Climax, Colorado, where about 36,000 tons of tailings are generated daily, the operation releases up to 100 tons of Mo annually as aqueous effluent. Other sources are Mo smelting, uranium mining and milling, steel and copper milling, oil refining, shale oil production, and claypit mining.

Molybdenum is used in the manufacture of high-strength low-alloy steels and other steel alloys in the aircraft and weapons industries, and in the production of spark plugs, X-ray tubes and electrodes, catalysts, pigments, and chemical reagents (Friberg et al. 1975; Kummer 1980; Goyer 1986). The most important industrial compound is the trioxide, MoO_3, which is resistant to most acids, and is oxidized in air at >500 °C (Shamberger 1979).

CHEMICAL PROPERTIES

Molybdenum, which can function both as a metal and metalloid, is an essential component in a large number of biochemical systems--including xanthine oxidase. At least four metalloenzymes are known that are Mo-dependent, and all are molybdoflavoproteins (Schroeder et al. 1970). Molybdenum is characterized by the following physical and chemical properties: atomic number 42; atomic weight 95.94; density 10.2; melting point 2,617 C; boiling point 4,612 °C; oxidation states 0, +2, +3, +4, +5, and +6; crystalline forms as gray-black powder, or silver-white metal; mass numbers (percent contribution of naturally occurring Mo) of 92 (15.86%), 94 (9.12%), 95 (15.7%), 96 (16.5%), 97 (9.45%), 98 (23.75%), and 100 (9.62%.); and radioactive isotopes of mass number 90, 91, 93, 99 (Tb 1/2 of 67 hours, frequently used as a tracer), 101, 102, and 105 (Busev 1969; Schroeder et al. 1970; Shamberger 1979; Friberg and Lener 1986). In water at pH >7, Mo exists primarily as the molybdate ion, MoO_4^{2-};at pH <7, various polymeric compounds are formed, including the paramolybdate ion, $Mo_7O_{24}^{6-}$ (Busev 1969). In soils, molybdate was sorbed most readily to alkaline, high calcium, high chloride soils; retention was least in low pH, low sulfate soils (Smith et al. 1987). There is general agreement that molybdenum chemistry is complex and inadequately known. Additional and more extensive information on its properties were summarized in major reviews by Busev (1969), Boschke (1978), Brewer (1980), Coughlan (1980), Newton and Otsuka (1980), Parker (1983), and Mitchell and Sykes (1986).

MODE OF ACTION

Interactions among some trace metals are so pervading and so biologically influential that the results of nutritional and toxicological studies conducted with a single element can be misleading unless the dietary and body tissue levels of interacting elements are clearly defined (Underwood 1979). For molybdenum, interactions are so dominant--especially in ruminant species--that a particular level of intake in the diet can lead to Mo

deficiency or to Mo toxicity in the animal, depending on the relative intakes of copper and inorganic sulfate (Schroeder et al. 1970; Underwood 1971, 1979; Clawson et al. 1972; Suttle 1973, 1983a; Friberg et al. 1975; Buck 1978; Ward 1978; Chappell et al. 1979; Shamberger 1979; Van Ryssen and Stielau 1980; Gupta and Lipsett 1981; Ivan and Veira 1985; Friberg and Lener 1986; Goyer 1986; Kincaid et al. 1986).

The first indications of interaction between copper and Mo came more than 40 years ago from studies of grazing cattle in certain areas of England. Afflicted animals lost weight, developed severe diarrhea, and (in extreme cases) died. The disease is sometimes called teart (rhymes with heart) or molybdenosis, and is caused by eating herbage rich in Mo--i.e., 20 to 100 mg/kg dry weight diet compared to <5 mg/kg in nearby healthy pastures--and low or deficient in copper and inorganic sulfate (Underwood 1979). Molybdenosis is a copper-deficiency disease that occurs particularly in cattle and sheep and is usually caused by the depressing effect of Mo on the physiological availability of copper (Clawson et al. 1972; Dollahite et al. 1972; Alloway 1973; Erdman et al. 1978; Mills and Breamer 1980; Van Ryssen and Stielau 1980; Nederbragt 1982; Suttle 1983a; Goyer 1986). The disease was treated successfully with copper sulfate at 1 to 2 grams daily in the diet, or 200 to 300 mg daily by intravenous injection (Buck 1978; Underwood 1979; Ivan and Veira 1985). When ruminant diets contained copper at 8 to 11 mg/kg weight--a normal range--cattle were poisoned at Mo levels of 5 to 6 mg/kg and sheep at 10 to 12 mg/kg. When dietary copper was low (i.e., <8 mg/kg) or sulfate ion level was high, Mo at 1 to 2 mg/kg ration was sometimes toxic to cattle. Increasing the copper in diets to 13 to 16 mg/kg protected cattle against concentrations up to 150 mg/kg of dietary Mo (Buck 1978). Studies of Mo metabolism are of limited value unless one knows the status in the diet of inorganic sulfate, which alleviates Mo toxicity in all known species by increasing urinary Mo excretion (Underwood 1971, 1979).

Copper prevents the accumulation of Mo in the liver and may antagonize the absorption of Mo from food. The antagonism of copper to Mo depends on sulfate, which may displace molybdate (Goyer 1986). In certain sheep pastures, for example, the herbage may contain up to 15 mg copper/kg dry weight and <0.2 mg Mo/kg dry weight--conditions favoring the development of a high copper status that may lead to copper poisoning. Treatment consists of providing molybdate salt licks, which are highly effective in reducing copper levels in grazing sheep (Buck 1978; Underwood 1979).

A low copper:molybdenum ratio (i.e., <2), rather than the absolute dietary concentration of Mo, is the primary determinant of susceptibility to molybdenum poisoning; molybdenosis is not expected when this ratio is near 5 (Buck 1978; Ward 1978; Mills and Breamer 1980). Ratios of copper to molybdenum in sweet clover (*Melilotus* spp., a known Mo accumulator plant) growing in coal mine spoils in the Dakotas, Montana, and Wyoming ranged from 0.4 to 5, suggesting that molybdenosis can be expected to occur in cattle and sheep grazing in low Cu:Mo areas (Erdman et al. 1978). A similar situation existed in British Columbia, where 19% of all fodders and grains had a Cu:Mo ratio <2 (Underwood 1979).

There are several explanations for the high sensitivity of ruminants to increased dietary Mo and sulfur, the most plausible being the role of thiomolybdates (Penumarthy and Oehme 1978; Lamand et al. 1980; Nederbragt 1980, 1982; Suttle 1980, 1983b; Mills et al. 1981; Suttle and Field 1983; Weber et al. 1983; Hynes et al. 1985; Friberg and Lener 1986; Allen and Gawthorne 1987; Sas 1987; Strickland et al. 1987). Thiomolybdates are compounds formed by the progressive substitution for sulfur and oxygen in the molybdate (MoO_4^{2-}) anion when hydrogen sulfide and MoO_4^{2-} interact in vitro at neutral pH. Di-, tri-, and tetra-thiomolybdates are formed, but only the last of these effectively impairs copper absorption. When sufficient tetrathiomolybdate (MoS_4) is formed in the rumen, it and copper in the gut combine and the resultant complex is bound strongly to proteins of high molecular weight. The molybdoproteins so formed are strong chelators of copper, and may be the agents responsible for copper deficiency through formation of biologically unavailable copper complexes in gut, blood, and tissues of animals that consume diets containing high concentrations of Mo. To confound matters, the complex molybdenum-copper-sulfur interrelation can be modified, or disrupted entirely, by many compounds or mixtures. These include the salts of tungsten (Schroeder et al. 1970; Underwood 1971; Mills and Breamer 1980; Luo et al. 1983; Goyer 1986), zinc (Penumarthy and Oehme 1978; Parada 1981; Alary et al. 1983), lead and manganese (Underwood 1971), iron (Phillippo et al. 1987b), vanadium (Vaishampayan 1983), chromium (Vaishampayan 1983; Chung et al. 1985), phosphorus (Underwood 1971; Baldwin et al. 1981), cystine and methionine (Underwood 1971, 1979), fluoride (Goyer 1986), and proteins (Underwood 1971, 1979; Friberg and Lener 1986; Kincaid et al. 1986).

BACKGROUND CONCENTRATIONS

GENERAL

Molybdenum levels tend to be elevated in nonbiological materials and in terrestrial flora in the vicinity of Mo mining and reclamation activities, fossil-fuel power plants, and disposal areas for Mo-contaminated sewage sludge, fly ash, and irrigation waters. Concentrations of Mo in fish, wildlife, and invertebrates were low when compared to those in terrestrial plants, although certain aquatic invertebrates were capable of high bioconcentration. Concentrations of Mo alone, however, were not sufficient to diagnose Mo deficiency or toxicosis.

NONBIOLOGICAL SAMPLES

Elevated levels of Mo in nonbiological materials have been reported near certain mines, power plants, and oil shale deposits, as well as in various sewage sludges, fertilizers, and agricultural drainwaters (Table 1).

Molybdenum is concentrated in coal and petroleum, and the burning of these fuels contributes heavily to atmospheric Mo (King et al. 1973). Combustion of fossil fuels contributes about 5,000 metric tons of Mo annually to the atmosphere; atmospheric particulates contain about 0.001 ug Mo/m^3 air (Goyer 1986).

Natural Mo concentrations in ground and surface waters rarely exceed 20 ug/l; significantly higher concentrations are probably due to industrial contamination. Existing wastewater and water treatment facilities remove less than 20% of the Mo; accordingly, drinking water concentrations are near those of the untreated source (Chappell et al. 1979). Molybdenum concentrations in saline waters appear to be directly related to salinity (Prange and Kremling 1985; Sloot et al. 1985). In the Wadden Sea, for example, Mo concentrations were 0.08, 0.4, and 1.0 ug/l at salinities of 0.07, 1.2, and 3.3%, respectively (Sloot et al. 1985).

Table 1. Molybdenum concentrations in selected nonbiological materials.

Material, unit and location	Concentration [a]	Reference [b]
Seawater (ug/L)		
Worldwide	<1 to 10	1, 2, 3
Worldwide	4 to 12	4
Pacific Ocean, all depths	10.3 + 0.2	5

The Mo content of soil may vary by more than an order of magnitude, causing both deficient and excessive concentrations for plants and ruminants in some parts of the world (Friberg et al. 1975). Native soils may contain enough Mo to cause molybdenosis in range livestock in some areas of the United States, particularly in Oregon, Nevada, and California (Kubota et al. 1967; Erdman et al. 1978). Elevated soil Mo levels can result from both natural and industrial sources. Usually when soil Mo levels exceed 5 mg/kg dry weight, a geological anomaly or industrial contamination is the likely explanation (Chappell et al. 1979). Molybdenum is more

available biologically to herbage plants in alkaline soils than in neutral or acidic soils (Underwood 1971; Friberg et al. 1975; Shacklette et al. 1978; Wright and Hossner 1984). Liming of acidic soils or treatment with Mo-containing fertilizers can effectively raise the Mo content of herbage (Underwood 1971; Pierzynski and Jacobs 1986).

The disposal of sewage sludge, fly ash from coal combustion, and Mo-contaminated irrigation waters to agricultural fields may result in the production of Mo-rich herbage. Sewage sludges rich in Mo and applied to agricultural soils resulted in elevated Mo content in corn and soybeans in a dose-dependent pattern (Pierzynski and Jacobs 1986). Similarly, fly ash from coal combustion applied to pasture and croplands at rates sufficient to provide Mo at concentrations of 40 g/kg and higher resulted in potentially hazardous levels in vegetation to ruminant grazers. Molybdenum in fly ash applied to soils remained biologically available for extended periods, especially in calcareous soils (Elseewi and Page 1984). Irrigation has also been proposed as a possible disposal method for large quantities of water having Mo concentrations of 5 to 100 mg/l that result from mining and reclamation activities. This method of disposal is not recommended unless all animals are kept off irrigated sites and the vegetation can be harvested and destroyed until Mo levels in the plants remain below 10 mg/kg dry weight (Smith et al. 1987).

BIOLOGICAL SAMPLES

All plants contain Mo and it is essential for the growth of all terrestrial flora (Schroeder et al. 1970). Molybdenum concentrations were elevated in terrestrial plants, especially in those collected from soils amended with fly ash, liquid sludge, or Mo-contaminated irrigation waters, in naturally occurring teart pastures, and in the vicinity of Mo mining and ore processing activities, steelworks, and other metal processors; Mo concentrations greater than 20 mg/kg dry weight were frequently documented in plants from contaminated areas (Table 2). Legumes, especially trefoil clovers (*Lotus* sp.) selectively accumulated Mo; concentrations of 5 to 30 mg/kg dry weight were common in Mo-contaminated areas (Friberg et al. 1975; Shacklette et al. 1978). The Mo levels were sometimes high and potentially toxic in legumes from poorly drained acidic soils (Kubota et al. 1967; Underwood 1971). Some terrestrial grasses displayed copper:Mo ratios between 0.5 and 3.7. Since ratios greater than 2 were within the range where molybdenosis is likely, and since most of the Mo concentrations were greater than the maximum tolerable level of 6 mg/kg dry weight, hypocuprosis (molybdenosis) in cattle was expected (Schalscha et al. 1987). Major sources of Mo overload in fodder were in plants grown on high-Mo alkaline soils and from industrial contamination by coal and uranium mines and alloy mills (Sas 1987). Variations in Mo content of pasture species ranged from 0.1 to 200 mg/kg dry weight, and most variations were due to soil and species differences (Underwood 1971). Pasture plants collected from mountainous areas of southern Norway were usually deficient in copper, and low to partly deficient in Mo. As a result, the copper:Mo ratios were generally high and may explain the occurrence of chronic copper poisoning in grazing sheep in that region (Garmo et al. 1986).

Except in terrestrial plants, Mo concentrations were low in all groups examined; maximum concentrations reported from all sampling locales were about 6 mg/kg dry weight in aquatic plants, about 4 mg/kg fresh weight in aquatic invertebrates, 2 mg/kg fresh weight in fishes (except for rainbow trout liver and kidney--26 to 43 mg/kg fresh weight--from fish collected near a Mo tailings outfall), 4 mg/kg dry weight in birds, 30 mg/kg dry weight in domestic ruminant liver, 85 mg/kg dry weight in the horse, and <4 mg/kg dry weight in mammalian wildlife and man (Table 2).

There are large interspecies differences among aquatic organisms in their ability to accumulate Mo from the medium. Marine bivalve molluscs usually contained 30X to 90X more Mo than the ambient seawater; however, some species from Greek waters had bioconcentration factors up to 1,300X (Eisler 1981). Marine plankton accumulated Mo from seawater by factors up to 25X (Goyer 1986). But growth in aquatic phytoplankton populations was inhibited under conditions of low or missing Mo, nitrogen, and organic matter concentrations; the role of Mo in this process requires clarification (Paerl et al. 1987). In rainbow trout (*Oncorhynchus mykiss*), residues of Mo in tissues were affected only slightly by the concentrations in water; tissue residues ranged from 5 to 118 ug/kg fresh weight in water containing trace (<6 ug/1) concentrations, 10, to 146 ug/kg in water containing low (6 ug/1) concentrations, and from 13 to 322 ug/kg in water containing high (300 ug/1) concentrations (Ward 1973). A similar pattern was reported for kokanee salmon, *Oncorhynchus nerka* (Ward 1973). Rainbow trout held for 2 weeks in live traps 1.6 km downstream from a Mo mine tailings outfall survived, but liver and kidney had significantly elevated levels of Mo, calcium, manganese, iron, zinc, strontium, and

zirconium, and 10% less potassium; the observed mineral changes may have been due to outfalls from nonmolybdenum mines discharged into the river system (Kienholz 1977).

Molybdenum mining operations are not detrimental to mammalian wildlife, as judged by normal appearance and low Mo levels in liver and kidney of nine species--including deer, squirrel, chipmunk, badger, beaver, marmot, and pika--collected from areas of high environmental Mo levels (Kienholz 1977). I must emphasize, however, that Mo levels in animal tissues give little indication of the dietary Mo status, and are of little diagnostic value for this purpose unless the sulfate, protein, and copper status of the diet are also known. This point is discussed in greater detail later.

Table 2. Molybdenum concentration in field collections of selected species of animals and plants. Values shown are Mo in mg/kg (ppm Mo) fresh weight (FW), dry weight (DW), or ash weight (AW).

EFFECTS

GENERAL

Trace quantities of Mo are beneficial and perhaps essential for normal growth and development of plants and animals. In mammals, Mo can protect against poisoning by copper, mercury, and probably other metals, and may have anticarcinogenic properties. For all organisms, the interpretation of Mo residues depends on knowledge of Mo, copper, and inorganic sulfate concentrations in diet and in tissues.

Some Mo compounds have insecticidal properties at low concentrations and have been proposed as selective termite control agents.

Aquatic flora and fauna seem to be comparatively resistant to Mo salts; adverse effects on growth and survival were usually noted only at water concentrations of 50 mg Mo/l, and higher. However, one study with newly fertilized eggs of rainbow trout produced an LC-50 (28 day) value of 0.79 mg Mo/l compared to an LC-50 (96 hour) value of 500 mg/l for adults. Also, bioconcentration of Mo by selected species of algae and invertebrates (up to 20 g/kg dry weight) poses questions on risk to higher trophic level organisms.

In birds, adverse effects of Mo have been reported on growth at dietary concentrations of 200 to 300 mg/kg, on reproduction at 500 mg/kg, and on survival at 6,000 mg/kg.

In mammals, cattle are especially sensitive to Mo poisoning, followed by sheep, under conditions of copper and inorganic sulfate deficiency. Cattle were adversely affected when grazing pastures with a copper:Mo ratio <3, or when fed low copper diets containing 2 to 20 mg Mo/kg diet, or when total daily intake approaches 141 mg Mo; cattle usually die at doses of 10 mg Mo/kg body weight. Other mammals, including horses, pigs,

rodents, and ruminant and nonruminant wildlife are comparatively tolerant to Mo. Deer, for example, are at least 10 times more resistant than domestic ruminants to Mo; no adverse effects in deer were noted at dietary levels of 1,000 mg/kg after 8 days, slight effects at 2,500 mg/kg after 25 days, and reduction in food intake and diarrhea at 5,000 mg/kg diet after 15 days.

TERRESTRIAL PLANTS

In a major literature review, Gupta and Lipsett (1981) concluded that Mo was essential for plant growth due to its role in the fixation of nitrogen by bacteria using the enzymes nitrogenase and nitrate reductase, and that plants readily accumulated MoO_4^{2-} except under conditions of low pH, high sulfate, and low phosphate, and in some highly organic soils. Molybdenum deficiency has been recorded in a variety of crops worldwide, but there is an extremely narrow range between adequacy and deficiency. In lettuce (*Lactuca sativa*), for example, adverse effects were noted at 0.06 mg/kg (dry weight) in plants, but sufficiency was attained at 0.08 to 0.14 mg/kg; a similar case is made for *Brassica* spp., i.e., Brussels sprouts, cabbage, and cauliflower (Gupta and Lipsett 1981). In certain species, such as beets (*Beta vulgaris*) and corn (*Zea mays*), the ratio between deficiency and sufficiency may differ by more than 10X (Gupta and Lipsett 1981).

Okra (*Abelmoschus esculentus*), grown in soils supplemented with Mo at 1, 2, or 3 mg/kg, as sodium molybdate, showed increasing growth and yields when compared to nonsupplemented soils; fruiting occurred earlier and persisted longer with increasing Mo concentration (Singh and Mourya 1983). The cashew (*Anacardium occidentale*)--one of the most valuable plantation crops in India--developed yellow- leaf spots accompanied by low Mo levels and excess manganese in low pH soils; in extreme cases the tree was defoliated (Subbaiah et al. 1986). The disorder was corrected by foliar spraying of Mo salts or by liming the soil. A similar case was reported for Florida citrus in the 1950's, which was shown to be due to Mo deficiency (Subbaiah et al. 1986).

Soils amended with sewage sludge containing 12 to 39 mg Mo/kg dry weight (soil contained 2 mg Mo/kg dry weight at start and 4.8 to 6 mg/kg after treatment) were planted with corn and bromegrass (*Bromus inermis*). A lime-treated sludge increased Mo concentrations in plant tissues after several years of sludge application; maximum values recorded were 1.9 mg Mo/kg dry weight in bromegrass and 3.7 in corn (Soon and Bates 1985). No toxicity of Mo has yet been observed in field-grown crops, although forages containing 10 to 20 mg/kg dry weight are considered toxic to cattle and sheep (Soon and Bates 1985).

TERRESTRIAL INVERTEBRATES

Sodium molybdate and other molybdenum compounds in toxic baits have potential for termite control (Brill et al. 1987). Baits containing 1,000 mg Mo/kg were fatal to 99% of the termite *Reticulitermes flavipes* in 48 days. After 8 to 10 days, termites became steel-gray in color, but appeared otherwise normal; mortality began only after day 16. Termites did not avoid the poisoned bait, even at concentrations of 5,000 mg Mo/kg. Yoshimura et al. (1987) reported similar results with another species of termite; sodium molybdate killed 100% of the workers in a colony of *Coptotermes formosanus* within 24 hours after they ate filter paper treated with a 5% solution. Some other species of insects--including fire ants (*Solenopsis* sp.) and various species of beetles and cockroaches--were not -affected when exposed to baits containing 5,000 mg Mo/ kg for 48 days (Brill et al. 1987).

AQUATIC ORGANISMS

Aquatic plants are comparatively resistant to Mo; in sensitive species adverse effects were evident on growth at 50 mg/l, and on development at 108 mg/l (Table 3). Bioconcentration of Mo from the medium by certain freshwater algae can result in residues up to 20 grams/kg dry weight without apparent damage (Table 3); the implications of this phenomenon to waterfowl and to other species that consume Mo-laden algae need to be explored.

Molybdenum is considered essential for aquatic plant growth, but the concentrations required are not known with certainty and are considered lower than those for any other essential element (Schroeder et al. 1970; Henry and Tundusi 1982). Molybdenum starvation restricts nitrogen fixation in algae, thereby limiting photosynthetic production during depleted conditions. Blue-green alga (*Anabaena oscillaroides*) cultured in Mo-deficient media containing 0.004 to 0.005 ug Mo/l rapidly depleted Mo in the medium; this ability was lost at higher

concentrations of added Mo, when *Anabaena* began to accumulate the element (Steeg et al. 1986). The addition of tungstate to Mo-deficient media enhances dinitrogenase inactivation, resulting in inhibited algal growth; this process is reversed at Mo levels of 0.005 to 0.04 ug/l (Steeg et al. 1986). On the other hand, algal growth was significantly enhanced when vanadium (V) was present at 12.5 ug/l, although higher concentrations of V were growth inhibitory in 7 days (Vaishampayan 1983).

Algal uptake of Mo is rapid during the first 2 hours, and slower thereafter; the sequential biological reduction of hexavalent to pentavalent to trivalent Mo occurs intracellularly in green algae (Sakaguchi et al. 1981). Uptake is greater in freshwater than in seawater, greater at increased doses, and greater at reduced algal densities (Sakaguchi et al. 1981); it is also greater at elevated temperatures (Penot and Videau 1975).
