Molybdenum occurs naturally in seawater as molybdate ion, MoO_4^{2-}, at about 10 ug/l (Abbott 1977). Despite the high concentrations of dissolved Mo in offshore seawater, phytoplankton from offshore locales contain extremely low Mo residues, almost typical of Mo-deficient terrestrial plants (Howarth and Cole 1985). This phenomenon is attributed to the high concentrations of sulfate in seawater; sulfate inhibits molybdate assimilation by phytoplankton, making it less available in seawater than in freshwater. As one result, nitrogen fixation and nitrate assimilation--processes that require Mo--may require greater energy expenditure in marine than in fresh waters and may explain, in part, why marine ecosystems are usually nitrogen-limited and lakes are not (Howarth and Cole 1985). Experimentally increasing the ratio of sulfate to molybdate inhibits molybdate uptake by marine algae, slows nitrogen fixation rates, and slows the growth of organisms that use nitrate as a nitrogen source (Howarth and Cole 1985).

Table 3. Molybdenum effects on selected species of aquatic organisms.

Organism, Mo concentration, and other variables	Effect	Reference [a]
Aquatic plants		
Blue-green alga, *Anabaena oscillaroides*		
0.005 ug/L	Bioconcentration factor (BCF) of 3,300 in 60 min	1
0.073 ug/L	BCF of 550 in 60 min	1
25 ug/L	BCF of 7 to 24 in 60 min	1
Green alga, *Chlorella vulgaris*		
10 mg/L	Residues of about 20,000 mg/kg dry weight in 20 h. Dead (heat-killed) *Chlorella* contained 4,902 mg/kg dry weight in 1 h versus 3,264 mg/kg in live cells	2
20 mg/L	Normal growth in 96 h	2
50 mg/L	Reduced growth in 96 h	2
Euglena, *Euglena gracilis*		
5.4 mg/L	Normal growth and reproduction	3
96 mg/L	No abnormal cells in 48 h	3
108 mg/L	Abnormal development, cells forming clusters. Culture is photosensitive with blue color	3
>960 mg/L	No growth	3
Freshwater alga, *Nitella flexilis*		
0.014 ug/L	BCF of 628 in 25 days	4
3.3 mg/L	BCF of 39 in 24 days; elevated	

	residues of 130 mg/kg fresh weight	4
Blue-green alga, *Nostoc muscorum*		
17.7 ug/L	Required for growth	5
Invertebrates		
Amphipod, *Allorchestes compressa*		
60 mg/L	No deaths (=LC-0) in 96 h	6
247 mg/L	50% dead (=LC-50) in 96 h	6
450 mg/L	97% dead (=LC-97) in 96 h	6
Starfish, *Asterias rubens*		
127 mg/L	LC-50 (24 h) at pH 5.8	7
254 mg/L	LC-50 (24 h) at pH 8.2	7
Copepod, *Calanus marshallae*		
20 mg/L	Minor increase in oxygen consumption in 24 h	8
100 mg/L	Decreased oxygen consumption in 24 h	8
560 mg/L	LC-50 (19 days)	8
Green crab, *Carcinus maenus*		
1,018 mg/L	LC-50 (48 h)	7
American oyster, *Crassostrea virginica*		
1,375 mg/L	Reduction of 50% in shell growth in 96 h	9
Hermit crab, *Eupagurus bernhardus*		
100 mg/L	LC-0 (50 days)	7
222 mg/L	LC-50 (48 h)	7
Euphausiid, *Euphausia pacifica*		
560 mg/L	LC-50 (112 h)	8
Amphipod, *Gammarus* sp.		
3.3 mg/L	BCF of 4.8 in whole animal in 24 days	4
Lake periphyton		
0.014 ug/L	BCF of 3,570 in 24 days	4
Clam, *Margaretifera margaretifera*		
3.3 mg/L	Maximum BCF values in 15 to 24 days were 1.8 in shell, 0.9 in soft parts, and 0.3 in muscle	4
Mysid shrimp, *Mysidopsis bahia*		
1,205 mg/L	LC-50 (96 h)	9
Mussel, *Mytilus edulis*, larvae		
147 mg/L	Development reduced 50% in 48 h, based on survival and abnormalities	10
Crayfish, *Pacifiastacus leniusculus*		
3.3 mg/L	BCF in 24 days of 5.7 for muscle and 9.8 for carapace	4
Pink shrimp, *Penaeus duorarum*		
1,909 mg/L	LC-50 (96 h)	9
Pullet-shell (clam), *Venerupis pallustra*		
381 mg/L	LC-50 (24 h)	7

Fish		
Sheepshead minnow, *Cyprinodon variegatus*		
3,057 mg/L	LC-50 (96 h)	9
Bluegill, *Lepomis macrochirus*		
1,320 mg/L	LC-50 (96 h)	11
Fathead minnow, *Pimephales promelas*		
70 mg/L	LC-50 (96 h), soft water	11
360 mg/L	LC-50 (96 h), hard water	11
Steelhead trout, *Oncorhynchus mykiss*		
0.014 ug/L	Max. BCF of 1,143 in liver and gastrointestinal tract after chronic exposure	4
3.3 mg/L	Max. BCF in 24 days of 5.4 in spleen 4.5 in liver, 2.3 in muscle, 1.8 in gill, and 0.6 in gastrointestinal tract	4
Rainbow trout, *O. mykiss*		
Embryo and larval stages exposed for a total of 28 days starting at fertilization through 4 days posthatch		
28 ug/L	LC-1 (28 days)	12
125 ug/L	LC-10 (28 days)	12
790 (610 to 990) ug/L	LC-50 (28 days)	12
17.0 to 18.5 mg/L, exposed continuously for one year from eyed eggs to juvenile stage	No significant effect on survival, growth, or blood hematocrit	10, 11
500 mg/L	LC-25 (96 h), mean length 20 mm	11
800 mg/L	LC-50 (96 h), mean length 20 mm	11
1,320 mg/L	LC-50 (96 h), mean length 55 mm	11

[a]References: 1, Steeg et al. 1986; 2, Sakaguchi et al. 1981; 3, Colmano 1973; 4, Short et al. 1971; 5, Vaishampayan 1983; 6, Ahsanullah 1982; 7, Abbott 1977; 8, Anderson and Mackas 1986; 9, Knothe and Van Riper 1988; 10, Morgan et al. 1986; 11, McConnell 1977; 12, Birge et al. 1980.

Limited data suggested that aquatic invertebrates were very resistant to Mo; adverse effects were observed on survival at >60 mg Mo/l and on growth at >1,000 mg Mo/l (Table 3). Bioconcentration factors were low, but depending on initial dose, measured residues (mg/kg fresh weight) were as high as 16 in amphipods, and were 3 in clams, 18 in crayfish muscle, and 32 in crayfish carapace (Short et al. 1971). The host organisms seemed unaffected under these Mo burdens, but effects on upper trophic level consumers were not clear. Tailings from a pilot molybdenum mine on the North American Pacific coast were acutely lethal at concentrations of >61,000 mg tailings solids/1 seawater to larvae of the mussel *Mytilus edulis*, and to adults of the amphipod *Rhepoxynius abronius* and the euphausiid *Euphausia pacifica*; acute sublethal effects were observed at >277,000 mg/l (Mitchell et al. 1986). All species of invertebrates tested in this preliminary study were more sensitive than juvenile coho salmon, *Oncorhynchus kisutch* (Mitchell et al. 1986). In another study, zooplankton exposed to Mo mine tailings <8 um in diameter at high sublethal concentrations ingested and excreted these particles (-

Anderson and Mackas 1986). The lowest tailing concentration tested at which a deleterious effect was observed was 100 mg/l for depression of respiration in the copepod *Calanus marshallae*, and 560 mg/l for increased mortality in copepods and the euphausiid *Euphausia pacifica*; concentrations of Mo mine tailings were always <15 mg/l at 0.5 km downstream from a Mo tailings outfall (Anderson and Mackas 1986).

Freshwater and marine fishes were--with one exception--extremely resistant to Mo; LC-50 (96 hour) values ranged between 70 mg/l and <3,000 mg/l (Table 3). The exception was newly fertilized eggs of rainbow trout exposed for 28 days through day 4 posthatch; the LC-50 (28 day) value was only 0.79 mg/l (Birge et al. 1980), and suggested that additional research is needed on the sensitivity of early life stages to Mo. In general, Mo was more toxic to teleosts in fresh water than in seawater and more toxic to younger fish than to older fish; in rainbow trout it bioconcentrated up to 16 mg/kg fresh weight in liver, 18 in spleen, 7 in muscle, 6 in gill, and 2 in gastrointestinal tract (Table 3; Short et al. 1971). Environmental levels of molybdenum as molybdate measured in the Mo mining areas of Colorado were not considered harmful to rainbow trout (McConnell 1977). Molybdenum enrichment of Castle Lake, California (a high mountain lake in which Mo was determined to be the limiting micronutrient), coupled with favorable environmental conditions, led to record high yields of trout. The addition of 16 kg of sodium molybdate, or 6.4 kg Mo, to Castle Lake in July 1963 was followed by larger standing crops of zooplankton and bottom fauna, which probably promoted survival of the 1965 year class and resulted in record yields to the angler of rainbow trout and brook trout (*Salvelinus fontinalis*) in 1967 (Cordone and Nicola 1970). Enrichment of Mo-deficient waters to improve angler success merits additional research.

BIRDS

Data are missing on the effects of Mo on avian wildlife under controlled conditions. All studies conducted with birds have been restricted to domestic poultry.

Signs of Mo deficiency in domestic chickens included loss of feathers, lowered tissue Mo concentrations, reduced xanthine dehydrogenase activity in various organs, decreased uric acid excretion, disorders in ossification of long bones, and changes in joint cartilage that led to complete immobility; signs were eliminated when diets were supplemented with Mo at concentrations of 0.2 to 2.5 mg/kg (Reid et al. 1956; Friberg and Lener 1986). Efforts to produce a Mo deficiency syndrome in birds and mammals by feeding diets low in Mo have been unsuccessful (Friberg et al. 1975). Thus, it has been necessary to introduce a compound with a known property of inhibiting Mo, namely wolframate (Na_2WO_4), a tungsten compound. Wolframate increases Mo excretion, leading to Mo deficiency in rats and chickens. With this technique it has been possible to produce an assumed Mo deficiency in chicks consisting of reduced weight gain and sometimes death (Friberg et al. 1975). Dietary requirements to maintain normal growth in rats and chicks were probably less than 1 mg Mo/kg food, and thus substantially less than that of any other trace element recognized as essential (Mills and Breamer 1980). In fact, birds may require Mo at concentrations up to 6 mg/kg in their diets for optimal growth (Kienholz 1977). Dietary Mo counteracts adverse effects in chicks on growth and survival induced by hexavalent chromium. Chicks fed 900 mg chromium/kg ration for 4 weeks showed significantly depressed growth, 25% mortality, and elevated liver chromium; however, diet supplementation to 150 mg Mo/kg resulted in normal growth and liver chromium values, and no deaths (Chung et al. 1985).

Early studies with chicks and turkey poults showed that the addition of only 13 to 25 ug Mo per kg--as molybdate or molybdic acid--to basal diets containing 1.0 to 1.5 mg Mo/kg resulted in a growth advantage of 14% to 19% in 4 weeks over that in unsupplemented groups (Reid et al. 1956, 1957). Roosters given dietary supplements of 100 or 400 ug Mo per bird daily for 4 weeks to basal diets containing 0.51 mg Mo/kg had reduced serum uric acid values when compared to those of controls; the significance of this finding is not clear (Karring et al. 1981). Birds are relatively resistant to Mo. For example, day-old chicks fed diets containing 20% Mo mine tailings for 23 days were unaffected, and those fed diets containing 40% Mo mine tailings showed only a slight reduction in body weight during the same period (Kienholz 1977). Dietary levels of 200 mg Mo/kg ration results in minor growth inhibition of chicks; and at 300 mg/kg feed, the growth of turkey poults was reduced (Underwood 1971). Dietary supplements of 500 mg Mo/kg ration produced a slight decrease in growth rate of chicks after 4 weeks; hens, however, laid 15% fewer eggs than controls, and all eggs contained embryolethal concentrations of 16 to 20 mg Mo/kg (Friberg et al. 1975). At dietary supplements of 1,000 mg Mo/kg, egg production was reduced 50% in domestic chickens (Friberg et al. 1975). Dietary loadings of 2,000 mg/kg induced severe growth depression and a 100X increase in Mo content in tibia (Underwood 1971), and an 80% reduction in egg production (Friberg et al. 1975). At 4,000 mg/kg diet, severe anemia was reported in chickens

(Underwood 1971). Mortality of chicks fed 6,000 mg Mo/kg diet for 4 weeks was 33%; at 8,000 mg Mo/kg diet for 4 weeks, 61% of the chicks died and survivors weighed only 16% as much as the controls (Friberg et al. 1975). Chicks, unlike mammals, did not experience Mo reduction in tissues after sulfate administration--although sulfate markedly reduced the signs of No toxicity (Underwood 1971).

MAMMALS

Data on the effects of Mo on mammalian wildlife are scarce. Almost all studies conducted to date on Mo effects under controlled conditions have been on livestock, especially cattle and sheep.

Molybdenum is beneficial and perhaps essential to adequate mammalian nutrition; moreover, it can protect against poisoning by copper or mercury, and may be useful in controlling cancer. Evidence of functional roles for Mo in the enzymes xanthine oxidase, aldehyde oxidase, and sulphite oxidase suggests that Mo is an essential trace nutrient for animals (Underwood 1971; Earl and Vish 1979; Mills and Breamer 1980). Signs of Mo deficiency include decreased intestinal and liver xanthine oxidase activity (Mills and Breamer 1980). Molybdenum prevents damage to the liver in sheep recieving excess copper; accumulations of copper and Mo in kidney were present in a biologically unavailable form and of negligible physiological significance (Van Ryssen et al. 1982). Dietary supplements of 70 mg Mo per day for a restricted period is recommended for reduction of liver Cu in sheep, provided dietary Cu levels are simultaneously reduced (Van Ryssen et al. 1986). Molybdenum, as sodium molybdate, protects against acute inorganic mercury toxicity in rats by altering the metabolism of cysteine-containing proteins in the cytoplasm of liver and kidney, resulting in lowered mercury content in these organs (Yamane and Koizumi 1982; Koizumi and Yamane 1984). Anticarcinogenic properties of Mo in rats have been reported, although the mechanisms of action are unknown. In one study, 2 or 20 mg Mo/1 in drinking water significantly inhibited cancer of the esophagus and forestomach experimentally induced by N-nitrososarcosine ethyl ester (Luo et al. 1983). In another study with virgin female rats, 10 mg Mo/l in drinking water reduced by half the number of mammary carcinomas experimentally induced by N-nitroso-N-methylurea (Wei et al. 1985). Additional research seems warranted on the role of Mo in cancer inhibition.

Molybdenosis has been produced experimentally in many species of mammals, including cattle, sheep, rabbits, and guinea pigs (Friberg et al. 1975). Signs of Mo poisoning vary greatly among species, but generally include the following: copper deficiency, especially in serum; reduced food intake and growth rate; liver and kidney pathology; diarrhea and dark-colored feces; anemia; dull, wiry, and depigmented hair; reproductive impairment, including delayed puberty, female infertility, testicular degeneration, and abnormal or delayed oestrus cycle; decreased milk production; joint and connective tissue lesions; bone abnormalities; and loosening and loss of teeth (Underwood 1971; Dollahite et al. 1972; Friberg et al. 1975; Erdman et al. 1978; Penumarthy and Oehme 1978; Ward 1978; Chappell et al. 1979; Mills and Breamer 1980; Alary et al. 1981; Baldwin et al. 1981; Friberg and Lener 1986; Van Ryssen et al. 1986; Phillippo et al. 1987a). These authorities also agree on three additional points: first, early signs of molybdenosis are often irreversible, especially in young animals; second, the severity of the signs depends on the level of Mo intake relative to that of copper and inorganic sulfate; and third, if afflicted animals are not removed promptly from Mo-contaminated diets and given copper sulfate therapy, death may result.

Molybdenum poisoning in ruminants, or teart disease, has been known since the mid 1800's and affects only ruminants of special pastures. Degree of teartness varies from field to field and season to season, and is usually proportional to the Mo content in herbage. Molybdenum levels in typical teart pastures range from 10 to 100 mg/kg dry weight compared to normal levels of 3 to 5 mg/kg (Friberg and Lener 1986). If herbage contains more than 12 mg Mo/kg dry weight, problems should be expected in cattle, and to a lesser extent in sheep (Friberg et al. 1975). In situations where cattle are accidentally exposed to high Mo levels, the administration of copper sulphate should result in Mo excretion, up to 50% in 10 days (Penumarthy and Oehme 1978). Aside from cattle and sheep, all evidence indicates that other mammals are comparatively tolerant of high dietary intakes of Mo, including horses, pigs, small laboratory animals, and mammalian wildlife (Underwood 1971; Buck 1978; Chappell et al. 1979; Friberg and Lener 1986; Table 4). Cattle excrete Mo primarily through feces, but other (more tolerant) species such as pigs, rats, and man, rapidly excrete Mo through urine and this may account, in part, for the comparative sensitivity of cattle to Mo (Underwood 1971). Cattle normally excrete about 67% of all administered MoO_3 in feces and urine in 7 days; guinea pigs excreted 100% in urine in 8 days; and swine excreted 75% in urine in 5 days (Penumarthy and Oehme 1978). Cattle are adversely affected when they graze copper-deficient pastures containing 2 to 20 mg/kg Mo, and the copper to Mo ratio is less than 3; or when

they are fed low copper diets containing 5 mg (or more) Mo/kg dry weight; or when total daily intake approaches 141 mg Mo; or when body weight residues exceed (a fatal) 10 mg Mo/kg (Table 4). It is clear that both the form of Mo administered and the route of exposure affect Mo metabolism and survival (Table 4). By comparison, adverse effects (some deaths) were noted at 250 mg Mo/kg body weight (BW) (in guinea pigs), at 50 mg/kg BW in domestic cats (central nervous system impairment), at 10 mg/l drinking water in mice (survival), at 10 to 15 mg total daily intake in man (high incidence of gout-like disease), and at to 3 mg/m^3 air in man for 5 years (respiratory difficulties), or 6 to 19 mg/m^3 in man for 4 years (Table 4).

Table 4. Molybdenum effects on selected species of mammals.

Species, dose, and other variables	Effects (reference) [a]
Cattle, cows, *Bos* spp.	
Near steelworks, 20 kg Mo as MoO_3 emitted daily in gaseous form; fallout deposits ~2 mg/m^2 monthly, corresponding to a pasture Mo content from 2 to 20 mg Mo/kg dry weight. Pasture had slight copper deficiency of natural origin, with copper:Mo ratio in pastures <3	About 40% of 5,000 grazing cows with signs of molybdenosis. No signs of poisoning before steelworks began operations. Signs evident almost immediately in first grazing season; most pronounced in younger animals closest to source. Remedial actions included copper glycine administration to cattle, and installation of additional emission filters at the steelworks (1)
Low dietary Mo (<5 mg Mo/kg), adequate copper	Growth normal; fertilization rate 100% liver copper >70 mg/kg dry weight; 63% of embryos developed normally (2)
Fed diets containing 5 mg Mo/kg dry weight and 4 mg copper/kg dry weight for 84 weeks	Decreased food intake, reduced efficiency of food use, altered iron metabolism, clinical signs of copper deficiency. Onset of puberty delayed 10 weeks, decreased conception rate (fertility 12% to 33% vs. 57% to 80% in controls), disrupted oestrus cycle (67% were anoestrus vs. 7% in controls), and other signs consistent with decreased releases of luteinizing hormones associated with altered ovarian secretion (3, 4)
High dietary Mo (15 to 20 mg Mo/kg), copper-deficient	Growth and fertilization normal; liver copper 10 mg/kg dry weight; only 16% of embryos developed normally (2)

Fed diets of normal copper, and high Mo (30 mg/kg feed)	Blood Mo level of 0.6 to 0.8 mg/L (5)
Diets containing 40 mg Mo/kg and 6 mg copper/kg fed to lactating cows for 9 weeks	Reduction of 30% in milk yield; rapid decline in plasma copper; milk Mo levels of 1.6 mg/L; growth reduction in nursing calves (6)
Fed diets of 60 mg Mo/kg dry weight	Low liver copper, intestinal disturbances, brittle bones prone to fracture (7)
Dairy herd fed pelleted feed containing 140 mg Mo/kg fresh weight and up to 10 mg copper/kg fresh weight	Molybdenosis. Contaminated magnesium oxide (12,200 mg Mo/kg) added to ration at 1% was the source of the excess Mo (8)
Drinking water with Mo as ammonium molybdate. Basal diet with 13 mg copper/kg and 2,900 mg sulfur/kg	
1 or 10 mg Mo/L in drinking water for 21 days	In 5-week-old calves, there was no effect on liver or plasma copper levels (9)
50 mg Mo/L in drinking water for 21 days	Copper liver concentration reduced to 201 mg/kg dry weight vs. 346 in controls; copper in plasma elevated to 1,100 ug/L vs. 690 in controls. No effect on growth, or food and water consumption (9)
Total daily intake of 100 mg Mo	Normal milk Mo level of 0.06 mg/L (5)
Total daily intake of 141 mg Mo	Anorexia, darrhea, and weight loss in Swiss beef cattle (10)
Total daily intake of 500 mg Mo	Milk Mo level of 0.37 mg/L (5)
Total daily intake of 1,360 mg Mo daily as soluble molybdate	Signs of molybdenum poisoning (7)
10 mg Mo/kg body weight	Lethal dose (11)
Guinea pig, *Cavia* sp.	
Chronic exposure, daily dose in mg Mo/animal	

25, as MoO_3	75% mortality (12)
200, as calcium molybdate	25% mortality (12)
Air concentrations of 28 to 285 mg Mo/m^3	Hexavalent Mo compounds absorbed appreciably, but not disulfide compounds (10, 13)
Dose, in mg Mo/kg body weight, various administration routes	
80	LD-0 (12)
250	Some deaths (11)
400	LD-75 (4 days) (12)
800	LD-100 (4 months) (12)
Domestic ruminants	
Pastures containing 10 to 20 mg Mo/kg dry weight	"Risk" zone for molybdenosis (12)
Pastures containing 20 to 100 mg Mo/kg dry weight	"Teart" disease characterized by anemia, poor growth, diarrhea; prolonged exposure resulted in joint deformities, and death (13)
Horses, ponies, *Equus* sp.	
Feeding on teart pastures with elevated Mo content	No effect (5)
Given single oral dose of radio Mo-99, as molybdate, or about 20 to 28 mg	Mo appeared rapidly in plasma as Mo-99 molybdate, but quickly cleared with Tb 1/2 of 7 to 10 h (14)
Fed diets containing 20 mg Mo/kg dry weight for 4.5 months; diet supplemented with sulfur for one month at 1.2 g/kg feed	Animals remained healthy. No decline in total plasma copper or increase in plasma insoluble copper (14)
Fed diets containing up to 107 mg Mo/kg for 14 days	Increasing dietary Mo resulted in decreasing copper retention due to increasing excretion of copper in feces; up to 1.45 g Mo/kg body weight absorbed and retained with no obvious adverse effects (15)
Cat, *Felis domesticus*	
Intravenous injection, in mg Mo/kg body weight	
25	Increased arterial blood pressure (12)
50	Central nervous system impairment (12)

Man, *Homo sapiens*	
Drinking water, in ug/L	
50	No effect (11)
200	Increased urinary excretion, normal serum Mo levels, no change in copper metabolism (11)
Total intake, in mg Mo daily	
0.18	Average intake in United States (11)
0.5 to 1	Increased urinary copper excretion (11)
10	Increase in blood and urine Mo levels, increases in serum ceruloplasmin, increased xanthine oxidase activity (11)
10 to 15	Increased uric acid, decreased copper excretion, high incidence of gout-like disease (11)
Atmospheric concentrations, in mg Mo/m^3 air	
1 to 3; 5-year exposure	Respiratory difficulties (12)
6 to 19; 4-year exposure	Respiratory difficulties (12)
Mouse, *Mus* spp.	
10 mg Mo/L in drinking water of breeding mice	Decrease in survival of F_2 and F_3 generations (16)
Sheep, *Ovis* spp.	
Mo deficient diets of 0.03 mg/kg	High incidence of renal xanthine calculi (5)
Mo adequate diet of 0.4 mg/kg, due to resowing of pasture and lime treatment	Zero incidence of renal calculi (5)
Mo content of pasture 0.4 to 1.5 mg/kg dry weight	Mo concentrations, in mg/kg fresh weight, were 0.0 to 0.03 in plasma, 2.0 to 2.4 in liver, and 0.4 to 0.5 in kidney. No lameness or connective tissue lesions (17)

2.4 mg Mo/kg diet in lambs	Significantly enhanced growth when compared to sheep fed 0.36 mg Mo/kg diet; growth associated with increased cellulose digestibility by rumen biota (5)
Grazing pastures treated 3x with 420 g Mo/ha: at start, week 45 and week 72. Mo content of pasture usually 5.5 to 12.5 mg/kg dry weight	Mo concentrations, in mg/kg fresh weight, were 1.7 to 2.4 in plasma, 6.0 to 6.4 in liver, and 6.9 to 8.1 in kidney. Lameness and connective tissue lesions in most sheep (17)
Given diets of high copper (82 mg/kg) and sulfur (3.8 g/kg), and Mo at 20, 40, or 60 mg/kg for 193 days	Liver damage due to copper at low Mo (20 mg/kg) diets; at 40 and 60 mg Mo/kg, both metals accumulated in kidney cortex but no evidence of liver histopathology or kidney damage (18)
Breeding ewes fed diets of normal copper, high Mo (30 mg/kg feed)	Blood Mo level of 2.4 to 3.4 mg/L (5)
Diets of 50 mg Mo/kg	Avoidance by lambs; may be learned olfactory recognition (19)
Lambs grazing on soils where copper:Mo ratio is <0.4	Swayback observed in 15% to 39% (10)
Ram lambs fed diets of adequate sulfate and copper (7.7 mg/kg dry weight). Copper to Mo ratios of 5.5, 5.3, 1.1, or 0.7 for 105 days	No significant measurable effects at ratios of 5.5 and 5.3. Secondary copper deficiency (molybdenosis) at 1.1 ratio evident in blood and plasma, and in liver at 0.7 (20)
Lambs fed daily intake of 8 mg Mo, 36.3 mg copper, and 3.7 g sulfur for 125 days	No effect on growth of food intake; significant increases in levels of kidney cortex copper, liver Mo, and plasma copper; major differences in responses among breeds tested (21)
Total intake raised from 0.4 daily mg daily to 96 mg daily	Blood Mo level of 4.95 mg/L (5)
Fed 75 mg copper daily for 50 days,	Molybdenosis within 8 days (22)

followed by 140 mg Mo and 4 g sulfur daily for 13 days with no added copper	
As above, but 70 mg Mo daily at day 13 for 34 days	40% reduction in liver copper (22)
White rabbit, *Oryctolagus* sp.	
Dietary Mo concentrations, in mg Mo/kg ration	
100; lifetime exposure	Reduced growth, hair loss, dermatosis, anemia, skeletal and joint deformities, decreased thyroxin (11)
500; 12 weeks	No obvious effects (12)
1,000; 12 weeks	Some growth retardation (12)
2,000 to 4,000	Many deaths of weanlings in about 37 days, and of adults in 53 days. Survivors were anorexic, diarrhetic, anemic, and had front-leg abnormalities; successful recovery after copper therapy (12)
5,000	Thyroid dysfunction (11)
Rat, *Rattus* spp.	
Drinking water, in mg Mo/L	
10; chronic exposure of 3 years	Disrupted calcium metabolism (29). Increased sensitivity to cold stress, elevated tissue residues of 50 to 60 mg Mo/kg dry weight (23, 24)
20; 30 weeks exposure	No effect on growth or organ histology (25)
50; lifetime exposure	Some growth retardation (11)
1,000; lifetime exposure	No severe signs observed in breeding adults. Resultant pups, however, maintained on this regimen were stunted, rough haired, sterile (males), and hyperactive (11)
Dose, in mg Mo per animal daily for up to 232 days	
10	LD-25 to LD-50 for hexavalent Mo compounds (12)

100	LD-50 for calcium molybdate (12)
125	LD-50 for MoO_3 (12)
333	LD-50 for ammonium molybdate (12)
Atmospheric concentrations, in mg Mo/m^3	
64; 2 h	Outwardly normal, some microscopic damage due to MoO_3 exposure (12)
Up to 5,000 ammonium paramolybdate, 12,000 molybdenum dioxide, 15,000 molybdenum trioxide, or 30,000 metallic Mo; one-hour exposure	Four weeks postexposure, there were no adverse effects except for some irritation of upper respiratory passage (12)
Feeding levels, in mg Mo/kg diet	
50	Diet avoidance (19). In low sulfate diets and 5 weeks exposure, rats had reduced growth and mandibular exostoses (10)
80; copper-deficient	Inhibited growth and reduced survival (5, 26)
80; 35 mg $CuSO_4$/kg	No measurable effects (5, 26)
100; lifetime exposure	Appetite loss, weight loss, reduced growth, anemia, mandibular exostoses, bone deformities, liver and kidney histopathology, increased liver copper residues, male sterility (11)
400	After 5 weeks, growth depression, anemia, mandibular exostoses; some deaths at lifetime exposures (12)
500 or 800	No deaths in 6 weeks; growth retardation and anemia (12)
500 or 1,000; 77 mg copper/kg	Poor growth (5, 26)
500 or 1,000;	Normal growth (5, 26)
5,000	Lethal in 2 weeks (11, 12)
Dose, in mg Mo/kg body weight	

0.00002 to 0.001	50% excretion (Tb 1/2) in 60 h to 113 h for kidney, liver, spleen, small intestine, and skin (10)
0.003	Tb 1/2 in 47 h (10)
>0.003	Tb 1/2 in 3 h when administered subcutaneously, 6 h for intragastric application (10)
4.5, intravenous injection	Biliary excretion of Mo^{+6} compounds was more rapid than Mo^{+5} compounds (27)
100	When inhaled as MoO_3, irritating to eyes and mucous membranes and eventually lethal. Repeated oral administration leads to histopathology of liver and kidney (13)
100 to 150	Lethal (11)
114	All recovered after intraperitoneal injection of sodium molybdate (12)
117	All dead within a few hours after intraperitoneal injection of sodium molybdate (12)
500; daily	Tolerated when given as disulfide (13)
500; 28 days	Reduced growth, disrupted blood and enzyme chemistry, histopathology of liver and kidney; partly reversed by 20% protein diet (28)
Domestic pig, *Sus* sp.	
Fed diets containing 1,000 mg Mo/kg for 3 months	No effect (5)

In newborn lambs from ewes that consumed high-Mo diets during pregnancy, demyelinization of the central nervous system was severe, accompanied by low copper contents in the liver (Earl and Vish 1979). Sheep are

more tolerant than cattle to Mo poisoning due, in part, to a lower turnover of ceruloplasmin, a copper-transporting enzyme that is inhibited by Mo; however, this characteristic makes sheep more sensitive than cattle to copper poisoning (Ward 1978). For example, chronic copper poisoning in sheep in several districts in Norway is probably due to Mo-deficient forages rather than to excess copper intake (Froslie et al. 1983). Swayback is a spastic paralysis in lambs born of ewes that were copper deficient during pregnancy Todd 1976). In northern Ireland, where cases have been reported, pastures were not copper deficient and swayback was due to an imbalance of copper, Mo, and sulfur. Very severely affected lambs were paralyzed in all limbs and died shortly after birth because they were unable to stand and suckle. Lambs less severely affected developed signs in about 2 weeks, but usually only the hind limbs were affected. Brain and spinal cord lesions were present, resulting in demyelination of spinal cord and cavitation of brain tissues; lesions were irreversible, but death might have been avoided with adequate copper therapy (Todd 1976).

Horses are generally considered to be tolerant of dietary copper deficiencies and of copper and Mo excesses that affected ruminants. Yet Mo accumulated in equine liver and has been implicated as a possible contributory factor in bone disorders in foals and yearlings grazing pastures containing 5 to 25 mg Mo/kg (Cymbaluk et al. 1981; Strickland et al. 1987). Cattle and horses are highly susceptible to pyrrolizidine alkaloids, an ingredient in certain poisonous plants such as tansy ragwort (*Senecio jacobaea*). Signs of poisoning included elevated copper levels in liver followed by fatal hemolytic crisis. Sheep are more resistant to alkaloids than equines or bovines, and sheep grazing has been recommended as a means of controlling tansy ragwort. However, dietary supplements of 10 mg Mo/kg increased the susceptibility of sheep to tansy ragwort intoxication, despite the observed increase in copper excretion (White et al. 1984).

In rodents, Mo is neither teratogenic nor embryocidal to golden hamsters at doses up to 100 mg/kg body weight, and has no measurable effect on fertility or gestation of female rats given similar high doses (Earl and Vish 1979). Voluntary rejection of high-Mo diets by rats results in anorexia. This phenomenon implies sensory, probably olfactory, recognition of molybdate in combination with other dietary constituents to form compounds with a characteristic odor detectable by rats (Underwood 1971). The ability to reject high-Mo diets requires a learning or conditioning period because it is lacking or weak with freshly prepared diets and extends to a discrimination between a toxic (high Mo) and nontoxic (high Mo plus sulfate) diet. Rats may associate a gastrointestinal disturbance with a sensory attribute of diets containing toxic levels of Mo (Underwood 1971).

Data on Mo effects to mammalian wildlife are scarce, although those available strongly suggest that domestic livestock are at far greater risk (Table 4). Studies with mule deer (*Odocoileus hemionus*) showed that this species was at least an order of magnitude more tolerant to high levels of dietary Mo than were domestic ruminants, and at least as resistant as swine, horses, and rabbits (Ward and Nagy 1976; Ward 1978; Chappell et al. 1979). Female mule deer showed no visible effects after 33 days on diets containing up to 200 mg Mo/kg feed, or after 8 days at 1,000 mg/kg. Only slight effects--some reduction in food intake and some animals with diarrhea--were observed at diets of 2,500 mg/kg for 25 days. At feeding levels of 5,000 and 7,000 mg/kg for periods of 3 to 15 days, signs were more pronounced; however, recovery began almost immediately after transfer to uncontaminated feed. Signs of copper deficiency and of molybdenosis are very similar, and careful diagnosis is necessary to ensure use of the correct remedial action. For example, some populations of Alaskan moose (*Alces alces gigas*) showed faulty hoof keratinization and decreased reproductive rates, but this was attributed to copper-deficient browse growing on low copper soils, and not to increased Mo levels in herbage (Flynn et al. 1977). In another case, a high proportion of white-tailed deer (*Odocoileus virginianus*) feeding near uranium-mine spoil deposits in several Texas counties--areas in which extreme molybdenosis has been documented in grazing cattle--had antlers that were stunted, twisted, and broadened or knobby at the tips (King et al. 1984). However, the copper levels in liver of these deer were similar to those of deer in a control area--16.7 mg/kg fresh weight vs. 18.0--and only 1 of 19 deer examined from the mining district had a detectable Mo concentration in liver (0.7 mg/kg fresh weight) vs. none in any control sample. On the basis of low contents of copper in soils and vegetation, it was concluded that white-tailed deer examined were experiencing copper deficiency (hypocuprosis), with signs similar to molybdenosis (King et al. 1984).

In humans, Mo is low at birth, increases until age 20 years, and declines thereafter (Goyer 1986). Although conclusive evidence that Mo is required by humans is lacking, there is general agreement that it should be considered as one of the essential trace elements. The absence of any documented deficiencies in man indicates that the required level is much less than the average daily intake of 180 ug Mo in the United States (Chappell et al. 1979). Human discomfort has been reported in workers from copper-Mo mines, and in those

eating food products containing 10 to 15 mg Mo/kg and <10 mg copper/kg and grown on soils containing elevated Mo of 77 mg/kg and 39 mg copper/kg. Symptoms included general weakness, fatigue, headache, irritability, lack of appetite, epigastric pain, pain in joints and muscles, weight loss, red and moist skin, tremors of the hands, sweating, dizziness (Friberg et al. 1975), renal xanthine calculi, uric acid disturbances (Schroeder et al. 1970), and increased serum ceruloplasmin (Friberg and Lener 1986). The typical human adult contains only 9 mg of Mo, primarily in liver, kidney, adrenal, and omentum (Goyer 1986). Most of the ingested Mo is easily absorbed from the GI tract and excreted within hours or days in urine, mostly as molybdate; excesses may be excreted also by the bile, particularly as hexavalent Mo (Friberg et al. 1975; Goyer 1986; Friberg and Lener 1986). At high dietary levels Mo reportedly prevents dental caries (Schroeder et al. 1970), but this requires verification.

RECOMMENDATIONS

Although Mo is generally recognized as an essential trace metal for plants and animals, and may reduce the incidence and severity of carcinomas in rats (Luo et al. 1983; Wei et al. 1985) and dental caries in humans (Shamberger 1979), there is no direct evidence of Mo deficiency being detrimental to animal health. The minimum daily Mo requirements in diets are not yet established due to problems in preparing Mo-free rations (Chappell et al. 1979). As a consequence, no regulatory agency recognizes Mo as safe and necessary, and Mo can not be legally incorporated into animal feeds (Penumarthy and Oehme 1978).

The richest natural sources of Mo (i.e., 1.1 to 4.7 mg Mo/kg fresh weight) are plants unusually high in purines such as legumes and whole grains (Schroeder et al. 1970), followed by leafy vegetables, liver, and kidney (Shamberger 1979); the poorest sources are fruits, sugars, oils, and fat (Schroeder et al. 1970).

The greatest economic importance of molybdenosis is associated with subclinical manifestations of copper deficiency resulting from forages containing a low copper:Mo ratio. Unfortunately, these conditions are often difficult to diagnose accurately, and animal response to copper may be difficult to demonstrate (Ward 1978). One recommended treatment for afflicted cattle is 2 grams daily of copper sulfate to cows and 1 gram daily to young stock, or intravenous injection of 200 to 300 mg of copper sulfate daily for several days (Underwood 1971).

The animals most sensitive to Mo insult are domestic ruminants, especially cattle. Diets containing >15 mg Mo/kg dry weight and with a low copper to Mo ratio, or drinking water levels >10 mg Mo/l were frequently associated with molybdenosis in cattle (Table 5). By contrast, adverse effects were documented in birds at dietary levels >200 mg Mo/kg ration, in ruminant wildlife at dietary levels >2,500 mg Mo/kg, and in aquatic organisms--with one exception--at >50 mg Mo/l (Table 5). The exception was newly fertilized eggs of rainbow trout, which were about 21X more sensitive to Mo than were zygotes about 1/3 through embryonic development, and about 90X more sensitive than adult fish (Table 5).

Table 5. Proposed Mo criteria for the protection of living resources and human health.

Resource, criterion, and other variables	Concentration	Reference [a]
Terrestrial plants		
Okra, *Abelmoschus esculentus*		
Increased growth	3 mg/kg soil	1
Lettuce, *Lactuca sativa*		
Mo deficiency	~0.06 mg/kg dry weight (DW) plant	2
Mo sufficiency	>0.08 mg/kg DW	2
Corn, *Zea mays*		

No adverse effect	3.7 mg/kg DW plant	3
Terrestrial invertebrates		
Toxic baits		
Termites	~1,000 mg/kg	4
Other insect species	>5,000 mg/kg	4
Aquatic life		
Algae		
Deficiency levels	<0.005 to 17.7 ug/L	5, 6
High bioconcentration	>0.014 ug/L	7
Growth reduction	>50 mg/L	8
Invertebrates		
Reduced survival	>60 mg/L	9
Fish		
Adults		
High bioconcentration	>0.014 ug/L	7
Reduced survival	>70 mg/L	10
Eggs		
Newly fertilized		
Reduced survival	>0.79 mg/L	11
No adverse effects	<28 ug/L	11
Eyed		
Adverse effects	>17.0 mg/L	10, 12
Birds		
Mo deficiency	13 to 200 ug/kg diet	13, 14, 15
Normal growth	~1.0 mg/kg diet	16
Optimal growth	6.0 mg/kg diet	17
Growth reduction	200 to 300 mg/kg diet	18
Reproductive impairment	500 mg/kg diet	19
Reduced survival	6,000 mg/kg diet	19
Mammals		
Cattle, Cows (*Bos* spp.)		
Forage		
Healthy pasture	3 to 5 mg/kg DW	18
Possibility of molybdenosis	10 to 20 mg/kg DW	19
Probability of molybdenosis	20 to 100 mg/kg DW	18, 19
Toxic	15 to 30 mg/kg DW	20
Maximum tolerable level	6 mg/kg DW	20, 21
Recommended	0.1 to 0.5 mg/kg DW	22
Ratio of Copper to Mo in diet		
Mo in diet		
Molybdenosis probable	<0.4	23

Critical	<2.0	20
Critical	>20.0	22
Optimal for growth and reproduction	6.1 to 10.1	22, 23
Drinking Water		
Safe level	<10 mg/L	24
Minimum toxic concentration for calves	10 to 50 mg/L	24
Guinea pig, *Cavia* sp.		
No effect on survival	80 mg/kg body weight	19
Cat, *Felis domesticus*		
Adverse nonlethal effects	25 to 50 mg/kg body weight	19
Mule deer, *Odocoileus hemionus*		
No effect	200 to 1,000 mg/kg diet	25, 26, 27, 28
Reduction in food intake	2,500 mg/kg diet	25, 26, 27, 28
Nonlethal adverse effects	5,000 to 7,000 mg/kg diet	25, 26, 27, 28
Sheep, *Ovis* sp.		
Forage, recommended	<0.5 mg/kg dry weight	22
Rat, *Rattus* sp.		
Minimum daily need	0.5 ug	29
Disrupted calcium metabolism, elevated tissue residues	10 mg/L drinking water	30, 31, 32
Cancer inhibition	2 to 20 mg/L drinking water	33, 34
Food avoidance	50 mg/kg diet	35
Human health		
Total daily intake, 70 kg adult		
Minimal need	120 ug	29
Average range	100 to 500 ug	18, 19, 28, 29, 36, 37
Maximum	10 to 15 mg	28
In Mo mining areas	>1 mg	19
From food		
USA	170 ug	28
USA	335 (210 to 460) ug	19
USSR		
Children	159 ug	19
Adults	353 ug	19
UK	128 (110 to 1,000) ug	19
From drinking water	<5 ug	28
No effect level	<500 ug	28
Adverse effects		
Biochemical	0.5 to 10 mg	28
Clinical	10 to 15 mg	28

Drinking water		
Safe level	<50 ug/L	28
Irrigation water		
Safe level	<10 ug/L	28
Air		
Maximum permissible concentration		
USSR	6 mg/m^3	3
USA, 8 h daily, 5 days weekly	9.5 to 10 mg/m^3	15, 36
Blood		
"Normal"	14.7 ug/L

Proposed criteria for human health protection include drinking water concentrations <50 ug Mo/l, and daily dietary intakes <7 ug Mo/kg food--based on a 70 kg adult (Table 5). Molybdenum concentrations in blood of "healthy" people averaged 14.7 ug Mo/l, distributed between the plasma and erythrocytes. Anemic people had significantly lower blood Mo levels; in leukemia patients Mo levels increased significantly in whole blood and erythrocytes but not in plasma (Shamberger 1979). Additional work is recommended on the use of blood in fish and wildlife as an indicator of Mo stress and metabolism.

Increasing problems associated with marginal mineral deficiencies and unfavorable mineral interaction--as has been the case in the older agricultural areas of northern Europe--can be anticipated as pasture and forage production becomes more intensive (Ward 1978). Research has been recommended in areas having a high Mo content in soils and vegetation, and also in non-contaminated areas where consumption habits favor a high Mo intake and an imbalance in relation to other dietary constituents of importance, such as copper (Friberg et al. 1975). In some parts of the world where Mo has been substituted for lime, the soils have become more acidic, thus making them difficult to farm. Liming under these conditions may elevate soil Mo from levels, previously considered safe to levels potentially hazardous to grazing animals through high Mo herbage (Gupta and Lipsett 1981). The addition of Mo fertilizers to sheep pastures resulted in small increments in Mo content with negligible risk of induced copper deficiency. But it would be unwise to apply Mo fertilizers to temperate grasslands grazed by animals of low initial copper status, as judged by growth retardation of lambs from pastures supplemented with Mo (Suttle 1983a).

Boron Hazards to Fish, Wildlife, and Invertebrates: A Synoptic Review

by
Ronald Eisler

U.S. Fish and Wildlife Service
Patuxent Wildlife Research Center
Laurel, Maryland 20709

ABSTRACT. Ecological and toxicological aspects of boron (B) in the environment are reviewed, with emphasis on natural resources. Subtopics covered include environmental chemistry, background concentrations, effects, and current recommendations for the protection of living resources.

The United States is the major producer of boron compounds and supplies about 70% of the annual global demand. Although boron is ubiquitous in the environment, human activities such as mining, coal burning, drainwater disposal, and use of borax laundry detergents have resulted in elevated boron loadings in the atmosphere and in irrigation waters. The chemistry of boron is complex and rivals that of carbon in its diversity. However, most boron compounds enter or degrade in the environment to B-0 compounds (borates)such as borax and boric acid--and these are considered to be the most significant ecologically.

Boron is an essential trace element for the growth of terrestrial crop plants and for some species of fungi, bacteria, and algae, but excess boron is phytotoxic. Representative species of aquatic organisms, including plants, invertebrates, fishes, and amphibians, usually tolerated up to 10 mg B/L of medium for extended periods without harm. In waterfowl, growth was adversely affected at dietary levels of 30 to 100 mg B/kg fresh weight, tissue boron concentrations were elevated at 100 to 300 mg B/kg diet, and survival was reduced at dietary levels of 1,000 mg B/kg; all of these dietary levels currently exist near agricultural drainwater disposal sites in the western United States. Boron is not now considered essential in mammalian nutrition, although low dietary levels protect against fluorosis and bone demineralization. Excessive consumption (i.e., > 1,000 mg B/kg diet, > 15 mg B/kg body weight daily, > 1.0 mg B/L drinking water, or > 210 mg B/kg body weight in a single dose) adversely affects growth, survival, or reproduction in sensitive mammals. Boron and its compounds are potent teratogens when applied directly to the mammalian embryo, but there is no evidence of mutagenicity or carcinogenicity. Boron's unique affinity for cancerous tissues has been exploited in neutron capture radiation therapy of malignant human brain tumors.

Current boron criteria recommended for the protection of sensitive species include < 0.3 mg B/L in crop irrigation waters, < 1.0 mg B/L for aquatic life, < 5.0 mg B/L in livestock drinking waters, < 30 mg B/kg in waterfowl diets, and < 100 mg B/kg in livestock diets.

TABLES

Introduction

Borax ($Na_2B_40_7$ .10 H_20) was the first of the boron (B) minerals to be traded by the Babylonians more than 4,000 years ago for use in the working and welding of gold (Greenwood and Thomas 1973). Borax has been known as a cleaning agent since the days of the ancient Greek and Roman empires and was used as a food preservative in Europe and America, although its use for the latter purpose has been discontinued (Weir and Fisher 1972). Boron and its compounds were used in Egyptian and Roman eras to prepare borosilicate glass. Borax glazes were known from about the year 200; by 1556, borax was widely used throughout Europe as a flux (Greenwood and Thomas 1973). Boric acid (H_3BO_3) was first synthesized in 1707 (Greenwood and Thomas 1973). Boric acid and borates are the main boron compounds of ecological significance; other boron compounds usually degrade or are transformed to borates or boric acid (Sprague 1972).

Boron is an essential trace element for the growth and development of higher plants, although the range between insufficiency and excess is generally narrow, varying with the plant; boron is not required in fungi and animals (Sprague 1972; Weir and Fisher 1972; Birge and Black 1977; Goldbach and Amberger 1986). In the southwestern United States, naturally elevated boron concentrations in surface waters used for irrigation may be sufficiently high to cause toxicity to plants of commercial importance (Benson et al. 1984). Another major source of boron entering ground and surface waters results from the use of borax-containing laundry products coupled with ineffective removal of boron by conventional sewage processes (Benson et al. 1984). Agricultural drainwaters contaminated with boron are considered potentially hazardous to waterfowl and other wildlife populations throughout areas of the western United States (Smith and Anders 1989).

Medical and household uses of boric acid solutions as antiseptics have led to numerous accidental poisonings by ingestion or absorption through abraded skin, particularly in infants (Environmental Protection Agency 1975; Dixon et al. 1976; Landolph 1985; Siegel and Wason 1986). Poisonings have been reported in English children consuming milk containing 0.7 g boric acid/L, and in burn patients treated topically with saturated boric acid solutions (National Academy of Sciences 1980). In the 1940's, topical preparations of boric acid became a popular remedy for diaper rash in England. By 1953, at least 60 fatal cases of boric acid poisoning had been reported in English infants (O'Sullivan and Taylor 1983). Inhalation of boranes, especially diborane (B_2H_6), pentaborane (B_5H_9), and decaborane ($B_{IO}H_{14}$)--which is used as a rocket propellant--is toxic to exposed workers (Dixon et al. 1976; NAS 1980). Boron compounds, especially boric acid, can also accumulate in animal tissues and produce a reduction in fertility, an increase in developmental abnormalities--especially those involving the skeletal system--stillbirth, and death (Weir and Fisher 1972; Lee et al. 1978; Landolph 1985). At present, there seems to be a reasonable margin between a toxic dose in humans and other vertebrates and in boron levels that may occur as incidental residues from the use of borax and boric acid in agriculture and industry (Weir and Fisher 1972). Additional information on ecological and toxicological aspects of boron in the environment is presented in reviews by Sprague (1972), Environmental Protection Agency (EPA; 1975), National Academy of Sciences (NAS; 1980), Anonymous (1983), Klasing and Pilch (1988), and Butterwick et al. (1989).

In this report, I summarize available data on boron in the environment, with emphasis on fishery and wildlife resources. It is part of a continuing series of brief reviews on chemical contaminants and natural resources that are prepared in response to informational requests from environmental specialists of the U.S. Fish and Wildlife Service.

Environmental Chemistry

General

The United States supplies about 70% of the global boron demand, and Turkey supplies 18%. Of the total annual United States production of about 500,000 tons, 45% is used in the manufacture of glass and glassware, 15% in laundry products, 10% in enamels and glazes, and 8% in agricultural chemicals. It is estimated that boron compounds enter the North American environment at a rate of 32,000 tons annually as a result of human activities, primarily from laundry products, irrigation drainwater, agricultural chemicals, coal combustion, and mining and processing (Table 1). Boron compounds tend to accumulate in aquatic ecosystems because of the relatively high water solubility of these compounds (EPA 1975).

The chemistry of boron is exceedingly complex and rivals that of carbon in its diversity. Most boron compounds, however, enter or degrade in the environment to borates (B-0 compounds), such as borax and boric acid, and these are considered to be the most significant ecologically.

Toxicosis in animals has resulted from ingestion of boric acid or borax solutions, from topical applications of boric acid solutions to damaged skin, and from inhalation of boranes; the exact mechanisms of action are not understood. Boron and its compounds are potent teratogens when applied directly to the embryo, but there is no evidence of mutagenicity or carcinogenicity. Boron's unique affinity for cancerous tissues has been exploited in neutron capture radiation therapy of malignant human brain tumors.

Sources and Uses

Boron is a dark brown element that is widespread in the environment but occurs naturally only in combined form, usually as borax, colemanite ($Ca_2B_60_{11} \cdot 5H_20$), boronatrocalcite ($CaB_40_7NaBO_2 \cdot 8H_20$), and boracite ($Mg_7Cl_2B_{16}O_{30}$; EPA 1975; NAS 1980). In the United States, boron deposits in the form of borax are concentrated in the desert areas of southern California, especially near Boron, California (EPA 1975). Proven deposits of sodium tetraborates--from which borax is prepared and from which boron can be isolated--also exist in Nevada, Oregon, Turkey, Russia, and China (Sprague 1972; NAS 1980). The United States supplies about 70% of the world boron demand, and Turkey supplies 18%; the most common commercial compounds are boric acid and borax (Sprague 1972; Butterwick et al. 1989).

The majority of the 555,000 tons of boron produced annually in the United States--of which half is usually exported--is in the form of sodium tetraborate compounds. Of the total production, about 42% occurs as anhydrous borax ($Na_2B_40_7$), 29% as borax pentahydrate ($Na_2B_40_7 \cdot 5H_20$), 10% as borax decahydrate or borax, and 16% as boric acid or boric oxide (B_20_3; Sprague 1972; EPA 1975). Boron and its compounds are used in the manufacture of glassware (40 to 45%); soaps and cleansers (15%); enamels, frits, and glazes (10%); fertilizers (5%); and herbicides (2 to 3%); 22 to 28% goes for other uses (Sprague 1972; EPA 1975; NAS 1980). Borates have some toxicity to insects and, in relatively high concentrations, can control cockroaches, woodboring insects, gypsy moths, and larvae of flies in manure piles and in dog runs (Sprague 1972; EPA 1975). Some organoboron compounds are used to sterilize fuel distribution and storage systems against fungi and bacteria (Sprague 1972). Radioboron-10 is widely used in radiation therapy against brain tumors, especially in Japan (Hatanaka 1986). Various boron compounds are also used widely as thermal protection materials in space probes, in fireproofing of fabrics and wood, in leather manufacture, in numerous pharmaceuticals and hygienic products, in steel hardening, in deoxidation of bronze, as a high-energy fuel, as neutron-absorbing shielding near atomic reactors, and as water softeners, pH adjusters, emulsifiers, neutralizers, stabilizers, buffers, and viscosifiers (NAS 1980; Parry and Kodama 1980; Schillinger et al. 1982; Siegel and Wason 1986).

Most boron ends up in the aquatic environment because of the relatively high water solubility of all boron compounds, especially B-containing laundry products and sewage (EPA 1975). Conventional sewage treatment removes little or no boron (EPA 1975). Of the total boron in coal, as much as 71% may be lost to the atmosphere upon combustion; more than 50% of the boron found in coal ash is readily water soluble (Pagenkopf and Connolly 1982). The release of boron from coal fly ash to leachate water is dependent on the ash to water ratio: at 1 g ash/L up to 90% of the boron is soluble; at 50 g/L only 40% is released; at 100 g/L less than 30% is released. Coating of coal ash with aluminum solution reduces boron solubility by about 90% because of the formation of an insoluble aluminum-borate complex (Pagenkopf and Connolly 1982).

Table 1. Environmental sources of domestic boron (EPA 1975).

Source	Metric tons, annually
Laundry products	14,000
Agricultural chemicals and fertilizers	7,000
Coal combustion	4,000
Mining and processing	3,000
Glass and ceramics	1,500
Miscellaneous	2,500
Total	32,000

Boron compounds listed in the "Commodity List of Explosives and Other Dangerous Articles" are boron trichloride ($BC1_3$), boron trifluoride (BF_3), decaborane ($B_{10}H_{14}$), and pentaborane (B_5H_9; EPA 1975). Boron trichloride is a corrosive liquid; the maximum quantity allowed in containers by rail is 1 L, and by air only one container is permitted per aircraft. Boron trifluoride is a nonflammable gas restricted to 140 kg in one outside container by rail, and to 140 kg in cargo planes only. Decaborane is a flammable solid, and transport by rail or air is limited to 12 kg. Pentaborane is a flammable liquid and is prohibited for transport by air or rail. Diborane (B_2H_6) and higher boranes are unstable and are classified as dangerous articles in transport; no more than 0.1 kg can be shipped in a cylinder (EPA 1975). Organic boron-oxygen compounds readily hydrolyze and should be stored and transferred in an inert atmosphere; usually, glass containers are used for shipping small quantities, and steel containers or tank cars are used for bulk items. Hazardous atmospheric conditions resulting from high concentrations of boron compounds are localized and are not considered a serious environmental problem (EPA 1975).

Chemical Properties

The element boron has an atomic number of 5, a molecular weight of 10.811, an oxidation state of 3 for simple compounds (but other oxidation states for carboranes and other polyhedral cage boron compounds), a specific gravity of 2.34, a melting point of 2,300 °C, sublimation at 2,550 °C, and is almost insoluble in water. Boron exists as B-10 (19.78%) and B-11 (80.22%) isotopes, and it contributes about 0.001% to the Earth's crust, although it does not occur free in nature (EPA 1975; Smith 1985). The chemistry of boron is exceedingly complex and rivals that of carbon in diversity. Reviews on boron's chemistry are especially abundant and include those by Steinberg and McCloskey (1964), Brotherton and Steinberg (1970a, b), Greenwood and Thomas (1973), Grimes (1982), Evans and Sparks (1983), Smith (1985), Emin et al. (1986), Heller (1986), Niedenzu and Trofimenko (1986), and Hermanek (1987).

Most boron compounds degrade in the environment to B-0 (borate) compounds, and these are the boron compounds of ecological significance-especially borax and boric acid (Sprague 1972; Antia and Cheng 1975; Thompson et al. 1976). Sodium tetraborate decahydrate (borax) has a melting point of 75°C, a boiling point of 320°C, and is soluble in water to 20 g/L at O°C and to 1,700 g/L at 100°C (EPA 1975). Boric acid has a melting point of 169°C, a boiling point of 300°C and, like borax, is exceedingly soluble in water: 63.5 g/L at 30°C and 276 g/L at 100°C (EPA 1975).

Boron exists in several forms in the soil (EPA 1975), and in soil solution it exists largely as the undissociated weak monobasic acid that accepts hydroxyl groups (Gupta and Macleod 1982). Most plant-available boron in soils is associated with soil organic matter (Gupta and Macleod 1982), with the hot-water soluble boron fraction (Hingston 1986), and with soil solution pH ranges of 5.5 to 8.5 and 10 to 11.5 (Goldberg and Glaubig 1986). It is assumed that boron adsorbs to soil particles and aluminum and iron oxide minerals (Goldberg and Glaubig 1986).

The predominant boron species in seawater is boric acid (Thompson et al. 1976); concentrations are higher at higher salinities and in proximity to industrial waste discharges (Liddicoat et al. 1983; Narvekar et al. 1983). In seawater, borate or boric acid occurs naturally at 4.5 to 5.5 mg/L. About 76% of the total inorganic boron in seawater occurs as undissociated boric acid [$B(OH)_3$], and the remainder is identified as the borate ion

$[B(OH)_4^-]$. Of the total borate ion, 44% seems to be complexed with sodium, magnesium, and calcium (Antia and Cheng 1975). Other evidence suggests additional complexation of borate with ferric ions and polyhydroxylated organic compounds (Antia and Cheng 1975).

Mode of Action

The complexing ability of the boron atom is considered to be the key explanation of why it is essential to higher plants (EPA 1975), although the exact mechanism of action is still unknown. Boron's complexing ability is thought to beneficially influence transport of sugars and other organic compounds, production of plant growth regulators, biosynthesis of nucleic acids and phenolic acid, carbohydrate metabolism, respiration, and pollen germination (EPA 1975; Nielson 1986).

Boron poisoning in animals is primarily an experimental phenomenon, although livestock in certain regions may be exposed to high concentrations in drinking water--up to 80 mg B/L--that have not been shown to be toxic (NAS 1980). Toxicosis in humans has resulted from ingestion of boric acid or borax solutions, topical applications of boric acid solutions to burn-damaged skin, and inhalation of boranes (NAS 1980). In mammals, boron is thought to regulate parathyroid function through metabolism of phosphorus, magnesium, and especially calcium. Boron has a close relation with calcium metabolism, most likely at the cell membrane level (Nielsen 1986).

Dietary boron at nontoxic concentrations, as sodium borate or boric acid, is rapidly and almost completely absorbed from the gastrointestinal tract, doesn't seem to accumulate in healthy tissues, and is excreted largely in urine, usually within hours; similar patterns are evident for humans, dogs, cows, rabbits, and guinea pigs (NAS 1980; Benson et al. 1984; Nielsen 1986; Siegel and Wason 1986). Boric acid poisoning in animals, regardless of route of administration, is characterized by the following signs: generalized erythema (boiled lobster appearance) starting in the axillary, inguinal, and facial regions, eventually covering the entire body with conjunctival redness, followed by massive desquamation 2 to 3 days later; acute gastroenteritis, including nausea and vomiting; diarrhea; anorexia; cardiac weakness; excessive urinary excretion of riboflavin; decreased oxygen uptake by the brain; hypoacidity; altered enzyme activity levels; impaired growth and reproduction; and death from circulatory collapse and shock, usually within 5 days (Dani et al. 1971; Sprague 1972; EPA 1975; NAS 1980; Schillinger et al. 1982; Settimi et al. 1982; Siegel and Wason 1986).

Boron hydrides or boranes, such as B_2H_6, B_4H_{10}, and B_5H_9, from chemical processes produce acute central nervous system pulmonary damage and lung disease through inhalation (NAS 1980; Klaassen et al. 1986). Boranes produce toxic effects by creating embolisms of hydrogen gas as they react with tissue, and by depleting biogenic amines of the central nervous system and inhibiting aminotransferases and other pyridoxol-dependent enzymes (Korty and Scott 1970; EPA 1975). Boranes produce similar effects in humans and animals, and these are generally ascribable to central nervous system depression and excitation (Naeger and Leibman 1972; Smith 1985). Symptoms of borane intoxication include pulmonary irritation, headache, chills, fatigue, muscular weakness and pain, cramps, dizziness, chest tightness, and pneumonia (NAS 1980). Boranes may adversely affect male reproductive capacity (Klaassen et al. 1986), but this requires verification. Decaborane ($B_{l0}H_{14}$), as one example, is a highly lipid-soluble compound that can enter the body through inhalation, ingestion, or the skin. In water, decaborane is rapidly transformed into intermediate products that are eventually degraded to boric acid. The intermediate products, but not decaborane or boric acid, reduce phosphomolybdic acid and inhibit glutamic-oxaloacetic transaminase; treatment of intermediates with pyridoxol phosphase tends to reverse the inhibitory activity (Naeger and Leibman 1972). Low decaborane doses cause behavioral effects such as depression, catatonia, and convulsions (EPA 1975).

Inorganic borates are quite toxic, seemingly complexing hydroxy compounds and interfering with protein synthesis (EPA 1975). Organoborate compounds exert physiological effects on the central nervous system and peripheral nervous system, acting as spasmolytics, sedatives, and convulsants, depending on their structure (EPA 1975). Boron trihalides, such as BBr_3, $BC1_3$, and BF_3, are corrosive to the eyes, skin, and mucous membranes, and will cause burns on the skin seemingly because of the hydrolysis of the trihalides to their halogen acids, and not to boron (EPA 1975; Smith 1985).

Boron is a potent teratogen when applied directly to the embryo. Boric acid injected into chicken and amphibian embryos produced abnormal development of the neural tube, notochord, tail, and limbs, perhaps through complexing polyhydroxy compounds and interfering with riboflavin metabolism (Landauer 1952, 1953a, 1953b, 1953c; Landauer and Clark 1964; EPA 1975; Settimi et al. 1982). Boron and its compounds, however, are neither mutagenic nor carcinogenic (Landolph 1985). Nonmutagenicity is based on results of the *Salmonella typhimurium*-mammalian microsome mutagenicity assay; boron neither enhances nor inhibits the activity of benzo(a)pyrene, a known mutagen (Anonymous 1983; Benson et al. 1984). There is no evidence that boron is a possible carcinogen, although long-term, selective uptake of boron by tumors has been reported (EPA 1975).

Boron seems to have an affinity for cancerous tumors, and this property has been exploited in radiation therapy (Hamada et al. 1983; Hatanaka 1986). Boron-10 has been used in neutron capture therapy to cure malignant sarcomas implanted in the hind legs of mice, as well as spontaneous malignant melanomas in pigs (Slatkin et al. 1986). The sulfhydral borane monomer $(B_{12}H_{11}SH)^{2-}$ is used as a B-10 carrier in neutron therapy of malignant human brain tumors and seems to be most effective at 30 µ*g* B-10/kg tissue (Hatanaka 1986). Polyhedral boranes attached to monoclonal antibodies that are tumor-specific may become useful in tumor therapy by neutron irradiation (Parry and Kodama 1980). It is possible, however, that uptake of boron may be a nonspecific attribute of tumors and of a variety of normal tissues that lack a blood-brain barrier. Thus, the potential usefulness of selected B-10 carriers for treating extracranial neoplasms seems questionable (Slatkin et al. 1986).

Background Concentrations

General

Terrestrial plants are normally rich sources of boron. Levels in meat and fish are usually low. These generalizations, however, are based on extremely limited data. Boron is ubiquitous in the environment, although human activities such as mining, coal burning, and use of borax laundry detergents have resulted in elevated boron loadings in the atmosphere and in irrigation waters. Comparatively high levels of boron were recorded in fish, insects, and aquatic plants at Kesterson National Wildlife Refuge, which was contaminated by agricultural drainwater; the significance of the contamination is under investigation.

Nonbiological

Boron is distributed widely in the environment (Ahl and Jonsson 1972; EPA 1975). Naturally elevated boron levels are usually associated with marine sediments, thermal springs, large deposits of boron minerals, seawater, and certain groundwaters (Table 2). Human activities, however, have resulted in elevated boron concentrations near coal-fired plants, in mine drainage waters, in municipal wastes, and in agricultural drainage waters. In one instance, agricultural drainwater practices in western California produced boron concentrations in local rivers, groundwaters, and surface waters that exceeded the established limits for the protection of crops and aquatic life (Table 2; Schuler 1987; Klasing and Pilch 1988).

Coal-fired power plants are major sources of atmospheric boron contamination; at least 30% of boron in coal is lost in this manner (Cox et al. 1978; Gladney et al. 1978). The seemingly large amounts of boron lost to the environment through stack emissions may be directly related to the organic content of coal (Table 2; Gladney et al. 1978). Also, disposal of B-laden drainage waters from boron mines is a major problem in certain geographic areas. In Turkey, for example, which possesses about 60% of the world's boron reserves--localized in a rectangular area about 100 x 200 km near the Simav River--drainage waters discharged from the mines as a result of borate production have elevated boron concentrations in the Simav River to levels unsuitable for crop irrigation. About 68,000 ha of agricultural land irrigated by the Simav River are now threatened by boron pollution (Okay et al. 1985). In the United States, laundry detergents originating from household use may contribute as much as 50% of the boron loadings in effluents discharged into aquatic environments; lesser amounts are contributed by soil minerals, rainfall, and industry and sewage effluents (EPA 1975).

Biological

Boron occurred at high concentrations in plants, insects, and fish at Kesterson National Wildlife Refuge in California--the recipient of contaminated agricultural drainwater--when compared to a nearby control area (Table 3; Ohlendorf et al. 1986; Schuler 1987). These authors indicated that little is known about the effect of boron ingestion on bird reproduction, although both boric acid and borax produced mortality and teratogenic development when injected into eggs. Recent studies on effects of boron on waterfowl growth, physiology (Hoffman et al. 1990), and reproduction (Smith and Anders 1989) are discussed later.

Table 3. Boron concentrations in field collections of selected species of plants and animals. Concentrations are in mgB/kg fresh weight (FW), dry weight (DW), or ash weight (AW).

[a]1, NAS 1980; 2, Nielsen 1986; 3, Ohlendorf et al. 1986; 4, Boyd and Walley 1972; 5, Ahl and Jonsson 1972; 6, Eisler 1981; 7, Thompson et al. 1976; 8, Jenkins 1980; 9, Schuler 1987; 10, Klasing and Pilch 1988.

Terrestrial plants, especially nuts, some fruits, and vegetables, are rich sources of boron (Table 3). Honey is another good source of boron, and concentrations up to 7.2 mg/kg dry weight (DW) have been reported (Nielsen 1986). Boron concentrations are also elevated in marine plants, zooplankton, and corals, but are low in fish and certain marine invertebrates (Table 3). No data are available on boron levels in terrestrial mammalian wildlife. Data for humans and domestic animals indicate that boron levels are elevated in bony tissues, but are always less than 0.6 mg B/kg fresh weight (FW) or 1.5 mg/ kg DW in other tissues examined (Table 3).

Effects

General

Boron is essential for the growth of higher plants and has been applied to B-deficient soils for at least 50 years to improve yields of many crops. Phytotoxic levels of B occur usually as a result of human activities, such as B-contaminated irrigation waters and excess applications of B-rich fertilizers, sewage sludges, and fly ashes. Boron compounds at comparatively high concentrations are used to control pestiferous insects through direct biocidal action, through enhancement of disease sensitivity, or through use as a chemosterilant.

Representative species of aquatic plants, invertebrates, fishes, and amphibians can usually tolerate up to 10 mg B/L medium for extended periods without adverse effects, although it has been suggested that concentrations >0.l mg B/L may ultimately affect reproduction in rainbow trout (*Oncorhynchus mykiss*), and >0.2 mg/L may impair survival of other fish species.

In waterfowl, diets that contain 30 or 100 mg B/kg FW adversely affect growth rate. Elevated tissue residues were recorded in ducks fed diets containing between 100 and 300 mg B/kg, and reduced survival occurred at dietary levels of 1,000 mg B/kg. Boron is a potent avian teratogen when injected directly into embryos during the first 96 h of development.

In mammals, the lethal dose of boron, as boric acid, varies according to species, and usually ranges between 210 and 603 mg B/kg body weight (BW); early developmental stages are especially sensitive. Excessive boron consumption adversely affects growth and reproduction in sensitive species of mammals (i.e., > 1,000 mg B/kg diet, > 15 mg B/kg BW daily, >1.0 mg B/L drinking water, or >3 g B/kg BW single dose on the first day of pregnancy). Boron is not considered essential for mammalian growth, but does protect against fluorosis and bone demineralization.

Terrestrial Plants

The role of boron in nutrition and toxicity of terrestrial crops has been reviewed extensively by Eaton (1944), EPA (1975), Gupta (1979, 1983), Gupta and Macleod (1982), Pilbeam and Kirkby (1983), and Gupta et al. (1985). It is generally agreed that boron is essential for the growth of higher plants and some species of fungi, bacteria, and algae, and that excess B is phytotoxic. It is also agreed that plants vary greatly in their sensitivity to B toxicity (Boyd and Walley 1972; EPA 1975; Birge and Black 1977; Goldberg and Glaubig 1986; Dear and Lipsett 1987). The exact mode of action of boron is unknown; however, its complexing ability facilitates the movement of sugars and other materials, and it is involved in cell wall bonding, conversion of glucose-l-phosphate to starch, and metabolism of nucleic acids (Sprague 1972; Gupta et al. 1985; Goldbach and Amberger 1986). Boron level in plants depends on the content and availability of soil boron, season, disease

state, inherent species or variety differences, and interactions with other substances (EPA 1975; Gestring and Soltanpour 1987). Most of the plant-available boron comes from the decomposition of soil organic matter and from boron adsorbed and precipitated onto soil surface particles; however, soil solution boron is the most important form, and plants take it up directly from this source (Gupta et al. 1985). Boron availability to plants is strongly associated with the hot-water-soluble fraction. This usually ranges from 0.4 to 4.7% of the total boron; the highest percentage occurs in fine-textured soils, and the lowest occurs in coarse-textured soils (Gupta and Macleod 1982). Uptake of boron by plants is about x 4 higher at pH 4 than at pH 9, highest in the temperature range 10 to 30°C, and higher with increased light intensity (Sprague 1972).

For the past 50 years, boron has been applied to B-deficient soils to improve crop yields of grains, fruits, vegetables, legumes, pine trees, tobacco, cotton, sunflowers, and peanuts (EPA 1975; Gupta 1979; Lipsett et al. 1979; Shorrocks and Nicholson 1980; Hopmans and Flinn 1984; Gupta and Cutcliffe 1985; Willett et al. 1985; Combrink and Davies 1987; Dear and Lipsett 1987; Mozafar 1987; Nuttall et al. 1987; Rerkasem et al. 1988). Boron is unique among the essential micronutrients because it is the only element normally present in soil solution as a nonionized molecule over the pH range suitable for plant growth (Gupta 1979). Boron deficiency in plants is widespread and has been reported in one or more crops in at least 43 States, almost all Canadian Provinces, and many countries (Gupta 1979). Boron deficiency in crops is more widespread than that of any other micronutrient (Gupta et al. 1985). It is more likely to occur in light-textured acid soils in humid regions because of boron's tendency to leach; however, deficiency may also occur in heavy-textured soils with high pH because boron is readily adsorbed under these conditions (Gupta et al. 1985). Deficiency signs include browning and spotting of leaves, chlorosis, abnormal thickening of cell walls, increased production of indoleacetic acid, accumulation of polyphenolic compounds, changes in membrane permeability, necrosis, and finally death (EPA 1975; Gupta 1979). Visible signs of deficiency in corn are accentuated by calcium deficiency, and are least evident when calcium is added to excess. Under conditions of boron and calcium deficiency combined, yields are low, and starch phosphorylase activity in corn leaves increases markedly, as does that of ribonuclease and polyphenol oxidase (Chatterjee et al. 1987). Interaction effects were also measured between B and potassium in alfalfa (Walker et al. 1987). Boron deficiency is usually corrected by application of 0.5 to 3 kg B/ha, depending on crop and formulation (Gupta 1979). Adding boron promotes the translocation rate of photosynthetic products and increases $C0_2$ incorporation into free amino acids (Gupta 1979).

Boron toxicity has been reported in many species of grasses, fruits, vegetables, grains, trees, and other terrestrial plants (Table 4; Gupta and Macleod 1982; Dye et al. 1983; Glaubig and Bingham 1985; Francois 1986; Nicholaichuk et al. 1988). Toxic levels generally do not occur on agricultural lands unless boron compounds have been added in excessive quantities, such as with fertilizer materials, irrigation water sewage sludge, or coal ash (Gupta and Macleod 1982; Gestring and Soltanpour 1987). Boron-contaminated irrigation water is one of the main causes of boron toxicity to plants. The continued use and concentration of boron in the soil due to evapotranspiration is the reason for eventual toxicity problems (Gupta et al. 1985). Borates have also been used as herbicides for complete kill of vegetation at application rates of 2,244 kg/ha (equivalent to 2,000 pounds/acre; Sprague 1972). Borates are frequently applied at elevated concentrations (i.e., >2 g/kg soil) in combination with organic pesticides to produce bacteriostatic effects; the resultant B-produced reduction in microbial degradation of the pesticide effectively extends the pesticide's biocidal properties (Sprague 1972). In some instances, cooling tower drift from geothermal steam containing boron may cause foliar boron toxicity near generating units (Glaubig and Bingham 1985; Sage et al. 1989).

Boron poisoning in plants is characterized by stunted growth, leaf malformation, browning and yellowing, chlorosis, necrosis, increased sensitivity to mildew, wilting, and inhibition of pollen germination and pollen tube growth (EPA 1975; Glaubig and Bingham 1985; Mitchell et al. 1987). In barley (*Hordeum vulgare*), for example, excess boron caused decreased growth and grain yield, elevated residues in leaves, and increased rate of leaf senescence (Table 4; Riley 1987). Barley grown on zinc-deficient soils tended to accumulate boron up to x 2.5 within 7 days; a similar pattern was evident for excess phosphorus (Graham et al. 1987). Thus, under conditions of marginally high boron in the rooting zone, low zinc, and high phosphorus, boron may accumulate to toxic levels in plants (Graham et al. 1987). Toxic effects in plants—including leaf injury—were observed in 26% of plants at or below substrate concentrations that resulted in greatest growth, indicating considerable overlap between injurious and beneficial effects of boron in plants (Eaton 1944). In general, deficiency effects in plants were evident when boron concentrations in soil solution were <2 mg/L; optimal growth occurred at 2 to 5 mg/L; and toxic effects were evident at 5 to 12 mg B/L (Gupta et al. 1985). However, considerable variation

exists in resistance to boron between species (Table 5). Sensitive species are known to include citrus, stone fruits, and nut trees; semitolerant species include cotton, tubers, cereals, grains, and olives; tolerant species usually include most vegetables (Gupta et al. 1985).

Table 4. Boron toxicity to some terrestrial plants.

Species, dose, and other variables	Effect	Reference[a]
Bigleaf maple, *Acer macrophyllum*		
0.9–5.4 mg B/L in saturated soil extracts	Reduced growth; >25% foliar damage; leaf residues of 76–324 mg B/kg ash weight (AW)	1
Madrone, *Arbutus menziesii*		
2.2–5.4 mg B/L in saturated soil extracts	Growth inhibition; >25% foliar damage; leaf residues of 216–540 mg B/kg AW	1
Beet, *Beta vulgaris*		
Soil B solutions		
5 mg/L	Optimal growth	2
15 mg/L	Injury evident	2
Broccoli, *Brassica oleracea italica*		
Grown in nutrient solutions containing		
0.08 mg B/L	Chlorophyll levels and net photosynthetic rates were significantly lower than those for plants grown in 0.41–0.81 mg B/L solutions	3
4.1 and 8.1 mg B/L	Leaf damage evident; lower chlorophyll levels and lower net photosynthetic rate than 0.4 and 0.8 mg B/L groups	3
Rhodes grass, *Chloris gayana*		
Grown in fly ash containing 3 mg hot-water-soluble B/L	Toxic. Residues >149 mg/kg dry weight (DW)	4
Lemon, *Citrus limonia osbeck*		
Soil B concentrations		
0.03–0.04 mg/L	Optimal growth	2
1 mg/L	Injury evident	2
Soybean, *Glycine max*		
Grown in soils amended with scrubber sludge residues (4.1 g B/kg) from coal-fired power plant for 2–3 years	Higher sludge B levels of 2 mg B/kg soil surface at year 1, and 1.2 mg B/kg at year 2 produced signs of B toxicity, including decreased growth and elevated residues in leaf (>83 mg/kg DW) and in seeds (>47 mg/kg DW)	5
Sunflower, *Helianthus annuus*		
50 mg B/L growth medium	Adversely affects phospholipid composition and synthesis in roots and microsomes from seedlings by inhibition of choline phosphotransferasse	6
10 mg B/L growth medium	Tolerated level	6

Barley, *Hordeum vulgare*		
Residues, in mg B/kg DW		
0.5–1.0 in soil	Residues of 46–100 mg/kg DW in leaves	7
30 in shoots	Damage to older leaves	8
50–70 in shoots	Reduction of 10% in DW of shoots	7
60–80 in leaf	Toxicity evident	8
80–120 in shoots	Toxic signs, but no yield reductions	8
120–130 in shoots	Grain yield reduced 10%	8
Alfalfa, *Madicago sativa*		
850–975 mg B/kg DW plant	Reduced yield	9
Rice, *Oryza sativa*		
Whole plant B residues		
38 mg/kg DW	No signs of toxicity	10
43–55 mg/kg DW	Signs of toxicity evident	10
Soil waters		
2.5–5 mg B/L	Toxic	10
French bean, *Phaseolus vulgaris*		
Grown in fly ash containing 3 mg hot-water-soluble B/L	Toxic. Residues >209 mg/kg DW	4
Residues in whole plant, in mg B/kg DW		
9–12	Slow flowering and pod formation; general yellowing of tips	11
>125	Reduced growth; burned older leaves dark brown	11
Digger pine, *Pinus sabiniana*, seedlings	Growth reduction; foliar damage >25%; needle	
13–17 mg B/L in saturated soil extracts	residues 1,242–1,512 mg B/kg AW	1
Pear, *Pyrus communis*		
82–164 kg B/ha applied to soil around pear trees in a nonirrigated orchard over a 6-year period	Toxicity observed during application and during 4 years postapplication. Toxicity was associated with residues, in mg B/kg DW, of 90–115 in blossom clusters and 45–55 in fruit. Within 5 years postapplication, soil B levels were <2 mg/kg, and all visible signs of toxicity had disappeared	12
Vegetation, various species		
2,244 kg borates/ha (2,000 lbs/acre)	Total kill of most species	2
Soil B concentrations		
1 mg/L	Optimal growth	2
5 mg/L	Injury evident	2
Plant residues		
>98 mg B/kg DW	Marginal burning and dark brown tips of older leaves	11

[a]1, Glaubig and Bingham 1985; 2, Sprague 1972, 3, Petracek and Sams 1987; 4, Aitken and Bell 1985; 5, Ransome and Dowdy 1987; 6, Belver and Donaire 1987; 7, Riley 1987; 8, Kluge and Podlesak 1985; 9, Gestring and Soltanpour 198; 10, Cayton 1985; 11, Gupta 1983; 12, Crandall et al. 1981.

Table 5. Boron concentrations in soil water associated with optimal growth and plant injury (from Sprague 1972).

Plant category	Boron concentration in soil water (mg/L) — Optimal growth	Boron concentration in soil water (mg/L) — Plant injury (usually)
Sensitive species	Trace to 1	1–5
Semitolerant species	Usually 1–5	5–15
Tolerant species	Usually 5–10	5–25

Table 6. Lethal and sublethal effects of boron on terrestrial invertebrates.

Organism, dose, and other variables	Effect	Reference[a]
Fruit fly, *Anastrepha ludens*		
Baits containing cottonseed hydrolysate and borax	Reduced infestation in oranges by 68%, and in mangoes by 98%	1
Honey bee, *Apis mellifera*		
8.7 mg B/L syrup (50 mg boric acid/L)	No effect on survival	2
17.5 mg B/L syrup (100 mg boric acid/L)	Fatal to about 50%	2
German cockroach, *Blattella germanica*		
Baits containing 25% boric acid plus honey	Population reduction of 50% in about 5 days, 80% in 4 weeks, and 98% in 6 to 9 months	3
Sugar diet containing		
11% boric acid	44% dead in 72 h	1
25% boric acid	79% dead in 72 h	1
50% boric acid	80% dead in 72 h	1
100% boric acid	91% dead in 72 h	1
Baits containing 20% boric acid	88% population reduction in 2 weeks; 92 to 95% reduction in 4 to 12 weeks	4
Gypsy moth, *Lymantria dispar*, larvae		
0.25% boric acid solution (436 mg B/L)	No effect on gypsy moth nucleopolyhedrosis virus (NPV)	5
0.5% boric acid	Enhanced NPV activity by x2	5
1% boric acid	Enhanced NPV activity by x11	5
Houseflies, *Musca domestica*		
250–5,000 mg B/kg diet, as boric acid	Inhibits reproduction	2
Isobornyl thiocyanoacetate		
27.3 µg/fly	LD50	1
Aerosols, >2%	50% knockdown in 6 min	1
American cockroach, *Periplaneta americana*		
Baits containing 1.5% boric acid	All dead in 6 days	6

Woodboring insects		
Common houseborer		
430 mg boric acid/m^3 wood	Adequate wood protection	2
Termites, 3 species		
>10,000 mg boric acid/m^3 wood	Required for wood protection	2

[a]1, EPA 1975; 2, Sprague 1972; 3, Gupta and Parrish 1984; 4, Wright and Dupree 1982; 5, Shapiro and Bell 1982; 6, Lizzio 1986.

Terrestrial Invertebrates

Relatively high concentrations of boron compounds are used to control fruit flies, cockroaches, gypsy moth larvae, houseflies, and woodboring insects (Table 6; Sprague 1972; EPA 1975). Boric acid is an effective stomach poison for several insect species (including German cockroaches [*Blattella germanica*], which are unable to detect the presence of boric acid (EPA 1975). Insect infestation of wood and other substrates can be prevented by pretreatment with boric acid or borax at doses of 0.25 to 0.55 kg/m^3 of wood (EPA 1975). Boric acid and other boron compounds are effective chemosterilants of the cotton boll weevil (*Anthonomus grandis*) and houseflies (EPA 1975).

Aquatic Organisms

Boron effects on aquatic plants are highly species-specific (Rao 1981; Table 7). Borate, like silicate, is an essential micronutrient for the growth of aquatic plants, such as diatoms, and it seems that a chemical combination of both nutrients in the form of silicoborate may be required by certain diatoms (Antia and Cheng 1975). In aquatic plants, boron affects nucleic acid metabolism, carbohydrate biosynthesis and transport, membrane integrity, and it interacts with growth substances (Frick 1985). Diatoms (*Cylindrotheca fusiformis*) cultured under B-deficient conditions stop dividing and swell in size despite increased photosynthetic rates. Boron-deficient diatoms accumulate rubidium, phenolic compounds, nitrates, and phosphates, and they show increased activity of various enzymes, especially glucose-6-phosphate dehydrogenase; however, respiratory adjustment is negligible until nutrient stress becomes irreversible in about 48 h (Smyth and Dugger 1980, 1981). Boron, under conditions of excess, alleviates nutrient deficiency in some phytoplankters and may cause temporal variations of phytoplankton composition in coastal waters (Rao 1981). Phytoplankton can tolerate up to 10 mg inorganic B/L in the absence of stress from pH adversity and nutrient deficiency, although higher borate concentrations up to 100 mg/L are expected to cause species redistribution by favoring the growth of some species and suppressing that of others (Table 7; Antia and Cheng 1975).

Data are limited for aquatic invertebrates and boron, although those data available suggest that the no-observable-effect levels were 13.6 mg B/L for freshwater organisms and 37 mg B/L for marine biota (Table 7). Juvenile Pacific oysters (*Crassostrea gigas*) accumulated boron in relation to availability, but showed no prolonged retention following cessation of exposure (Thompson et al. 1976). At current industrial discharge levels of about 1.0 mg B/L, no hazard is clear to oysters and aquatic vertebrates (Thompson et al. 1976).

The most sensitive aquatic vertebrates tested for which data are available were coho salmon (*Oncorhynchus kisutch*), with an LC50 (16-day) value of 12 mg B/L in seawater, and sockeye salmon (*O. nerka*), showing elevated tissue residues after exposure for 3 weeks in seawater containing 10 mg B/L (Table 7). Boron concentrations between 0.001 and 0.1 mg/L had little effect on survival of rainbow trout embryos after exposure for 28 days (Table 7). These low levels may represent a reduction in reproductive potential of rainbow trout, and >0.2 mg B/L may impair survival of other fish species, according to Birge and Black (1977); however, additional data are needed to verify these speculations. Birge and Black (1977) reported that concentrations of 100 to 300 mg B/L killed all species of aquatic vertebrates tested, that embryonic mortality and teratogenesis were greater in hard water than in soft water, but that larval mortality of fish and amphibians was higher in soft water than in hard water, and that boron compounds were more toxic to embryos and larvae than to adults. Moreover, they found no measurable effect of boron toxicity to aquatic vertebrates in water temperature in the range of 13 to 29°C, dissolved oxygen between 6.4 and 10.3 mg/L, and pH between 7.5 and 8.5.

Table 7. Lethal and sublethal effects of boron on aquatic organisms.

Taxonomic group, organism, compound, dose, and other variables	Effect	Reference[a]
Aquatic plants		
Blue green alga, *Anacystis nidulans*, boric acid, H_3BO_3		
0.01–4.0 mg B/L	Grows well in B-deficient media; growth neither stimulated nor inhibited at higher levels	1, 15
50 mg B/L	No effect on growth or organic constituents	2
75–100 mg B/L	Growth and chlorophyll content reduced; at 72 h, photosynthetic pigments depleted	2
100 mg B/L	Decrease in protein content causing inhibition in nitrate uptake and nitrate reductase activity. Decreased chlorophyll content and photosynthesis inhibition within 72 h	2, 15
Green alga, *Chlorella pyrenoidosa*, boric acid		
10 mg B/L	No effect on growth or cell composition. Bioconcentration factor (BCF) of x4 after 7 days	3
50 mg B/L	BCF of x5 after 7 days	3
50–100 mg B/L	Altered cell division and amino acid activity after 72 h; reversible photosynthesis inhibition. Giant cells formed with increased nitrate and protein	4
100 mg B/L	BCF of x4.8 after 7 days	3
>100 mg B/L	Totally inhibitory for cell division and biomass synthesis in 72 h	4
Duckweed, *Lemna minor*, boric acid		
Control media, 10–20 mg B/L, pH 5.0	Normal growth	5
100 mg B/L, pH 5.0	Growth inhibited; recovery on transfer to control media	5
20 mg B/L, pH 4.0	Residues of 93 mg B/kg fresh weight (FW) v. 63 in controls	5
20 mg B/L, pH 7.0	Growth inhibited. Residues of 257 mg/kg FW v. 49 in controls	5
Marine algae, 19 species, boric acid		
5–10 mg B/L	No inhibitory effect on growth rate in 60 days; stimulatory to some species	6
10–50 mg B/L	Prolonged survival of peak populations of certain diatoms after growth cessation: *Bellerochea polymorpha* at 10 mg B/L, *Skeletonema costatum* at 50 mg B/L	6
50 mg B/L	Growth inhibition in 26% of species tested; adaptation and recovery by most species	6
100 mg B/L	Growth inhibition in 12 of 19 species tested; 8 species did not recover and died	6
Marine phytoplankton		
30 mg B/L, high nitrates, phosphates, silicates, and low temperatures	Increased primary production and carbon assimilation	7
30 mg B/L, low nutrients, high temperatures	Photosynthesis inhibited up to 62%	7

30 mg B/L, unialgal cultures, 5-days-old	Photosynthesis inhibition	7
As above, 14-days-old	Enhanced photosynthesis in certain species	7
Invertebrates		
Sea urchin, *Anthocidaris crassispina*, embryos, boric acid		
37 mg B/L	Normal development	8
75 mg B/L	Fatal	8
Cladoceran, *Daphnia magna*, boric acid		
6.4 mg B/L	Highest concentration tested in 21-day exposure producing no measurable effect	9, 10
13.6 mg B/L	Lowest concentration tested in 21-day exposure causing reduction in number of broods, total young produced, mean brood size, and mean size	9, 10
27 mg B/L	LC14 (21 days)	10
53 mg B/L	LC50 (21 days)	10
54–200 mg B/L	No deaths (48 h)	9, 10
106 mg B/L	LC100 (21 days)	10
115–246 mg B/L	LC50 (48 h)	9, 10
420 mg B/L	LC100 (48 h)	9
Mosquito larvae, 3 species, boric acid, mg/L		
250 (43.7 mg B/L)	LC97-LC99 through hatching	11
4,000 (700 mg B/L)	LC100 (48 h), freshly hatched	11
3,000 (524 mg B/L)	LC100 (48 h), second instar	11
10,000 (1,748 mg B/L)	LC100 (48 h), third instar	11
16,000 (2,797 mg B/L)	LC100 (48 h), pupae	11
Vertebrates		
Fowler's toad, *Bufo fowleri*, embryos, through day 4 posthatch		
Boric acid		
Soft water, 50 mg $CaCO_3$/L		
25 mg B/L	LC1 (7.5 days)	12
145 mg B/L	LC50 (7.5 days)	12
Hard water, 200 mg $CaCO_3$/L		
5 mg B/L	LC1 (7.5 days)	12
123 mg B/L	LC50 (7.5 days)	12
Toad, *Bufo vulgaris*, embryos		
874 mg B/L, as boric acid. Exposure for 24 h from 2-cell stage to tailbud stage	Malformations included edema, microcephalia, short tail, and suppressed forebrain development	11
Goldfish, *Carassius auratus*, embryos, through day 4 posthatch		
Boric acid		
Soft water		
0.6 mg B/L	LC1 (7 days)	12
46 mg B/L	LC50 (7 days)	12
Hard water		
0.2 mg B/L	LC1 (7 days)	12
75 mg B/L	LC50 (7 days)	12
Borax, $Na_2B_4O_7 \cdot 10H_2O$		
Soft water		
0.5 mg B/L	LC1 (7 days)	12

65 mg B/L	LC50 (7 days)	12
Hard water		
0.9 mg B/L	LC1 (7 days)	12
59 mg B/L	LC50 (7 days)	12
Mosquitofish, *Gambusia affinis*, adults		
Boric acid		
5,600 mg/L (979 mg B/L)	LC50 (96 h)	12
Sodium borate		
3,600 mg/L	LC50 (96 h)	12
Channel catfish, *Ictalurus punctatus*, embryos, through day 4 posthatch		
Boric acid		
Soft water		
0.5 mg B/L	LC1 (9 days)	12
155 mg B/L	LC50 (9 days)	12
Hard water		
0.2 mg B/L	LC1 (9 days)	12
22 mg B/L	LC50 (9 days)	12
Borax		
Soft water		
5.5 mg B/L	LC1 (9 days)	12
155 mg B/L	LC50 (9 days)	12
Hard water		
1.7 mg B/L	LC1 (9 days)	12
71 mg B/L	LC50 (9 days)	12
Bluegill, *Lepomis macrochirus*		
Boron trifluoride, BF_3		
15,000 mg B/L	LC50 (24 h)	12
Dab, *Limnada limnada*		
74.0 mg B/L	LC50 (96 h)	13
88.3 mg B/L	LC50 (24 h)	13
Coho salmon, *Oncorhynchus kisutch*, underyearlings		
12 mg B/L	LC50 (283–384 h), seawater	14
113 mg B/L	LC50 (283–552 h), fresh water	14
Rainbow trout, *Oncorhynchus mykiss*, embryos, through day 4 posthatch		
Boric acid		
Soft water		
0.1 mg B/L	LC1 (28 days)	12
100 mg B/L	LC50 (28 days)	12
Hard water		
0.001 mg B/L	LC1 (28 days)	12
79 mg B/L	LC50 (28 days)	12
Borax		
Soft water		
0.07 mg B/L	LC1 (28 days)	12
27 mg B/L	LC50 (28 days)	12
Hard water		
0.07 mg B/L	LC1 (28 days)	12
54 mg B/L	LC50 (28 days)	12
Adults		
339 mg B/L	LC50 (48 h)	10, 12, 16
350 mg B/L	No effect in 30 min	16
3,500 mg B/L	All alive after 30 min, but in obvious distress	16
14,000 mg B/L	After exposure for 30 min, all recovered if	16

	placed in flowing B-free water	
Sockeye salmon, *Oncorhynchus nerka*		
10 mg B/L, exposure in seawater for 3 weeks	Maximum residues, in mg/kg FW, were 17 in bone, 12 in kidney, 10 in gill, 9 in liver, and 8 in muscle. Maximum control values were always <1.0, except bone, which was 4.4 mg/kg FW	14
Leopard frog, *Rana pipiens*, embryos, through day 4 posthatch		
Boric acid		
Soft water		
13 mg B/L	LC1 (7.5 days)	12
130 mg B/L	LC50 (7.5 days)	12
Hard water		
22 mg B/L	LC1 (7.5 days)	12
135 mg B/L	LC50 (7.5 days)	12
Borax		
Soft water		
5 mg B/L	LC1 (7.5 days)	12
47 mg B/L	LC50 (7.5 days)	12
Hard water		
3 mg B/L	LC1 (7.5 days)	12
54 mg B/L	LC50 (7.5 days)	12

Birds

Boron is a potent teratogen to domestic chicken embryos when injected into eggs. Injection of boron into the yolk sac of chicken embryos during the first 96 h of development with 1.0 to 2.5 mg of boric acid--equivalent to 3.2 to 8.0 mg B/kg FW egg (55 g egg)--produced a wide range of developmental abnormalities (Table 8). Several compounds are known to counteract B-induced avian developmental abnormalities, or to reduce the frequency of malformations, although the mode of action is unclear. These compounds include sodium pyruvate, to counteract rumplessness (Landauer 1952); nicotinamide, to decrease frequency of facial defects (Landauer 1952) and melanin formation (Landauer 1953c); and riboflavin, which greatly reduced the teratogenic effects of boric acid (Landauer 1952, 1953a, 1953b; Landauer and Clark 1964). Other polyhydroxy compounds, such as D-ribose, pyridoxine hydrochloride, and D-sorbitol hydrate, also reduced or abolished boric acid-induced teratogencity in chick embryos (Landauer 1953b).

High concentrations of boron have been found in the San Joaquin Valley of California in irrigation drainwater and in aquatic plants consumed by waterfowl. Measured boron concentrations in that locale exceeded 20 mg/L in subsurface agricultural drainage waters, 400 mg/kg DW in widgeongrass (*Ruppia maritime*) and algae, 150 mg/kg DW in aquatic insects, 1,860 mg/kg DW in some aquatic plants, and up to 3,390 mg/kg DW in seeds consumed by waterfowl (Schuler 1987; Klasing and Pilch 1988; Smith and Anders 1989; Hoffman et al. 1990). At present, only selenium has been implicated as the cause of abnormal development among waterfowl in western areas affected by irrigation drainwaters (Ohlendorf et al. 1986; Hoffman et al. 1988, 1990). However, recent studies by Smith and Anders (1989) and Hoffman et al. (1990) with mallards demonstrate that dietary boron concentrations well below levels that can occur in the environment represent a toxicological hazard that has not been considered in the management of agricultural drainwater. For example, dietary concentrations of 300 to 400 mg B/kg of feed FW--substantially lower than boron levels reported near some western wildlife refuges contaminated by agricultural drainwater--adversely affect mallard growth, behavior, and brain biochemistry and are often associated with elevated tissue boron levels (Table 8). Dietary levels of 100 mg B/kg FW resulted in reduced growth of female mallard ducklings (Hoffman et al. 1990), and diets containing as little

as 30 mg B/kg FW fed to mallard adults adversely affected growth rate of their ducklings (Smith and Anders 1989). Resource managers must now consider boron, as well as selenium, and their possible interactions, as a toxic hazard to wildlife populations throughout areas of the western United States (Smith and Anders 1989).

Table 8. Lethal and sublethal effects of boron on birds.

Species, dose, and other variables	Effect	Reference[a]
Domestic chicken, *Gallus domesticus*		
Embryo, yolk injection		
Boric acid		
0.01 mg B/kg body weight (BW)	LD1	1
1.0 mg B/kg BW	LD50	1
1.0 mg at 28 h of development	Developmental abnormalities	2
2.0 mg at 28 h of development	Malformations of nervous system, eyes, and spinal cord	3
2.5 mg at 24 h of development	Rumplessness	7
2.5 mg at 84 h of development	Skeletal deformities, cleft palate, missing toes, eye deformities	4, 5, 6
15.8 mg B/kg egg at 96 h of development	LD50 (96 h). Most (70 to 85%) of the survivors at age 18 days had edema, inhibited feather growth, pale body coloration, and reduced BW	10
Borax		
0.01 mg B/kg BW	LD1	1
0.5 mg B/kg BW	LD50	1
Adult		
875 mg B/kg diet, as boric acid, for 6 days	Egg production ceased; production normal 14 days after B withdrawn	1
Mallard, *Anas platyrhynchos*		
Adults fed diets containing various concentrations of B, as boric acid, for 3 weeks, then mated. Resultant ducklings continued on same diets for 21 days. Data collected on reproduction, survival, residues, and histopathology when ducklings were age 21 days		
8 mg B/kg diet fresh weight (FW) (controls). Diets contained about 10% moisture	Boron residues in egg, liver, and brain of adults and ducklings were always <3 mg B/kg dry weight (DW)	8
30 mg B/kg diet FW	Duckling weight gain reduced compared to controls. Residues in egg and duckling liver and brain about 3–4 mg B/kg DW; residues <3 in adult liver and brain	8
300 mg B/kg FW	Duckling BW at hatch significantly lower than controls; duckling weight gain reduced. Mean residues, in mg B/kg DW, were 13 in egg, 15 in adult liver (Max. 24), 17 in duckling liver (Max. 36), 14 in adult brain (Max. 24), and 19 in duckling brain (Max. 44)	8
1,000 mg B/kg diet FW	No observable effect on adults. No effect on egg fertility or shell thickness. Significantly reduced hatching success; duckling mortality through age 7 days significantly greater than controls; body weight lower. Total number of 21-day-old	8

	ducklings produced per female, and brain to BW ratios were significantly higher than controls. Mean B residues, in mg/kg DW, were 49 in egg, 33 in adult liver (Max. 74), 51 in duckling liver (Max. 89), 41 in adult brain (Max. 89), and 66 in duckling brain (Max. 110). No histopathology evident in liver, brain, kidney, or heart	
Ducklings, age 1 day, 2-week dietary exposure		
1,000 mg B/kg FW diet, as boric acid	Adverse effects on growth	9
5,000 mg B/kg diet, as boric acid	Some deaths	9
Ducklings, age 1 day, 10-week dietary exposure to boric acid		
Controls, 13 mg B/kg FW diet. Diets contained 12–14% moisture	Brain B concentration of 2 mg/kg DW	9
100 mg B/kg FW diet	Delayed growth of females, plasma triglyceride levels evaluated, abnormal liver metabolism, brain residue of 4 mg/kg DW	
400 mg B/kg FW diet	Delayed growth of females, plasma triglyceride elevated, brain B residue of 5 mg/kg DW, decrease in brain ATP, altered duckling behavior in bathing and resting	9
1,600 mg B/kg FW diet	Some deaths (10%), delayed growth, decreased food consumption, plasma triglyceride elevated, brain B residue of 51 mg/kg DW (Max. 99), decrease in brain calcium and ATP, reduction in time spent bathing and standing, increase in time spent resting, increased serum calcium, lower hematocrit and hemoglobin; no histopathology of brain, liver, or kidney	9

[a]1, Birge and Black 1977; 2, Schowing and Cuevas 1975; 3, Schowing et al. 1976; 4, Landauer 1953a; 5, Landauer 1953b; 6, Landauer 1953c; 7, Landauer 1952; 8, Smith and Anders 1989; 9, Hoffman et al. 1990; 10, Ridgeway and Karnofsky 1952.

Mammals

Epidemics and sporadic cases of oral intoxication in humans are often due to inadvertent addition of boric acid to infant formulas (Siegel and Wason 1986). Pacifiers and some other products containing boron compounds have been sold in Ireland despite a recommendation from the Pharmaceutical Society of Great Britain that these products should not be sold because of hazards to infants (O'Sullivan and Taylor 1983). Fatal cases of boron poisoning have involved misuse of boron compounds in hospitals, either from accidental substitution of boric acid solution for water in infant formula or from accidental use of boric acid as a diapering powder (EPA 1975). In an adult fatality, the victim died after inundation by borax solution (EPA 1975). In one case, a 12-month-old girl developed violent vomiting, coughing, irritability, tremors, seizures, and a delirious reaction after accidentally swallowing a mixture containing 3 g of boric acid and 300 mg of cinchocaine chloride prescribed for a painful dental protrusion (Egfjord et al. 1988). Her plasma boric acid level 6 h later was 26 mg/L; the half-time persistence (Tb l/2) for boric acid in plasma is about 7 h (Egfjord et al. 1988). The lethal dose of boric acid varies according to the species. In mammals it ranges from 210 to 603 mg B/kg BW, and death is due to central nervous system paralysis and gastrointestinal irritation (Table 9; NAS 1980). Human newborns are especially sensitive, and accidental deaths have been recorded at doses between 50 and 140 mg B/kg BW (Table 9).

Table 9. Lethal and sublethal effects of boron on mammals.

Organism, route of administration, dose, and other variables	Effect	Reference[a]
Cattle, *Bos* spp.		
Drinking water		
Supplemented with 15, 30, 60, or 120 mg B/L for 10 days	Boron levels in plasma rose from 2.7 mg/L in controls to 4.4 (15 mg/L group), 5.3 (30 mg/L group), 8.3 (60 mg/L group), and 13.4 mg/L in the 120 mg B/L drinking water supplement	5
29 mg B/L, and higher	When given a choice, cattle preferred tap water to drinking water supplemented with B compounds	1
120 mg B/L, as borax, for 10 days	No effect on feed or water consumption; no overt signs of toxicosis	2
150 mg B/L, as borax, for 30 days equivalent to 15.3 mg B/kg body weight (BW) daily	Decreased feed consumption, weight loss, edema, inflammation of legs, daily elevated plasma B levels of 1.2 mg/L v. 0.5 in controls, abnormal blood chemistry	1, 2, 3, 4, 5
Diet		
Consumed feed containing 157 mg B/kg, as borax, for 42 days	No adverse effects	3
Fed 2 to 2.5 g of boron daily as borax, for 40 days	No observable adverse effects; all B excreted, mostly in urine	6
Fed 20 g of borax daily	Milk B residues increased from <1.0 mg/L to >3 mg/L	5
Ingested total dose of 100–300 g of boron equivalent to 200–600 mg B/kg BW	Toxic dose	7
Found dead after consuming 1 kg of borax, or about 250 g of B	Residues in mg B/kg fresh weight (FW) were 1,300 in ruminal fluids, 1,900 in abomasal fluids, 24 in liver, 19 in rumen, and 21 in abomasums	7
Dog, *Canis familiaris*		
Diet		
350 mg B/kg feed, 2 years	Tolerated	8
1,540 mg borax/kg or 3,000 mg boric acid/kg, chronic study (174–524 mg B/kg diet)	No adverse effects	6, 9
1,170 mg B/kg, 38 weeks	Testicular degeneration, spermatogenesis cessation	5, 8
Inhalation		
92 mg pentaborane/m^3 for 15 min	LC50	9
Guinea pig, *Cavia* sp.		
Inhalation		
0.018 mg decaborane/m^3, 6 h daily, 5–6 exposures	Eye inflammation, listlessness, emaciation, convulsions	3
Human, *Homo sapiens*		
Dermal		
7-month-old infant treated for dermatitis with 3% boric acid powder	Fatal. Boron concentrations elevated in bile, intestinal contents, and spleen	9

Adult administered about 645 g of boric acid dermally	Toxicosis observed	
Inhalation		
Borax dust, 1.1–14.4 mg/m^3, occupational exposure for at least 5 years	At 14.4 mg/m^3, 33% of workers noted dryness of mouth, nose, or throat; 28% had eye irritation problems; 15% had nosebleeds and cough; 13% had sore throat or shortness of breath and ches tightness. At 4.0 and 1.1 mg/m^3, no symptoms except eye irritation were noted by more than 5 and 3% of exposed participants	11
Boranes, various	Pulmonary irritation, headache, nausea, fatigue, muscular weakness, liver and kidney pathology	3
Oral		
3 mg B daily for 119 days in diet containing 0.25 mg B	Reduction in urinary excretion of calcium and magnesium by postmenopausal women	12
20 mg B daily	Normal adult intake	6
Solutions >88 mg B/L or >500 mg boric acid/L	Fatal to infants	13
1–3 g boric acid, or 0.3–0.8 g/kg BW	Lethal to newborns	14
2–4.5 g boric acid or 0.5–1.2 g/kg BW	Nonfatal to infants, but serum levels elevated from 20–150 mg borate/L	14
>3.5 g boric acid daily	Probably harmful or lethal to infants and newborns	10
4 g boric acid or borates daily	No toxicosis in adults	6, 9
4.5–15 g of boric acid, equivalent to 1.25–4.2 g/kg BW, in accidentally contaminated formula in newborn nursery	Death preceded by severe symptomology; serum levels of 400–1,000 mg borate/L	13, 14
5–6 of borates, or 0.7 g/kg BW	Fatal to infants	14, 15
15–20 g of boric acid, equivalent to 0.25–0.3 g/kg BW	Fatal to adults	9, 14, 15
Infants, age 6–16 weeks		
Given pacifiers dipped in a proprietary borax (107 g/L) and honey compound. Dose during 1-month-exposure period estimated at 3–9 g borax	Some developed seizure disorders characterized by vomiting, loose stools, irritability, diarrhea; elevated blood B values of 2.6–8.5 mg B/L v. <0.6 in controls. When preparation witheld, seizures stopped and children remained well for at least 5 years	13
Injections, intravenous		
Adult males, age 22–28 years, given single infusion of 562–611 mg boric acid equivalent to 8.0–8.7 mg B/kg BW	Boric acid half-time persistence was 21 h. Most was excreted in urine 24 h, 94% in 96 h, and ~99% in 120 h; plasma boric acid concentration after infusion was about 16 mg/L v. 0.5 at start; no discomfort during or after infusion	16
Adults given dose of 20 g boric acid	No permanent adverse effects	9
Monkey, *Macaca* sp.		
Inhalation		
Pentaborane, 640 mg/m^3, 2 min	LC50	9
Intraperitoneal injection		
Decaborane, 1 mg/kg BW daily, multiple	Altered brain wave activity	9

injections		
Decaborane, 6 mg/kg BW, single injection	LC50	9
Mice, *Mus* sp.		
Drinking water		
5 mg B/L, lifetime exposure	No effect on growth, longevity, or tumor incidence	2, 5
Ingestion		
3 g B/kg BW, first day of pregnancy	94% of embryos failed to develop past blastocyst stage v. 9% in controls	9
Diet		
1,500 mg boric acid/kg (262 mg B/kg)	All dead within 10 days	17
Injection, intravenous		
1.32 g sodium borate/kg BW, single dose	LD50	18
Injection, intraperitoneal		
25.2 mg decaborane/kg BW, single dose	LD50	9
44.7 mg decaborane/kg BW, single dose, prior treatment for 8 days at 250 mg/kg BW with pyridoxine hydrochloride	LD50	9
2,817 mg sodium borate/kg BW, single dose	LD50	18
Inhalation		
Pentaborane		
0.011 mg/m^3 for 4 h	LC50	3
50 mg/m^3, 15 min	LC50	9
342 mg/m^3, 2 min	LC50	9
1,034 mg/m^3, 30 s	LC50	9
Rabbit, *Oryctolagus* sp.		
Diet		
Equivalent to 800–1,000 mg borates/kg BW daily for 4 days	Growth retardation	18
Intragastric route		
Daily dose of 100 mg calcium borate 4 months	Altered serum chemistry	9
Intravenous injection		
Single dose of 800–900 mg boric acid/kg BW	LD50	18
Intraperitoneal injection		
30 mg decaborane/kg BW	Death within 24 h	3
Dermal		
25–200 mg boric acid/kg BW daily	Nonirritative and nontoxic when applied to intact skin	18
Sodium borate solutions of 50,000 or 100,000 mg borates/L applied to skin	Mildly or moderately irritating	18
Boron oxide dust	Application to skin produced erythema that lasted 2–3 days; instillation in eyes produced immediate conjunctivitis as a result of exothermic hydration of boron oxide to boric acid	19
Inhalation		
120–150 mg calcium borate/m^3, 2 h daily, 10-week exposure	Respiratory tract pathology, growth inhibition, enlarged liver	9
Rat, *Rattus* sp.		

Drinking water		
Free access for 90 days to drinking water containing 0.3, 1.0, or 6.0 mg B/L	Rats refused to drink water at 1.0 or 6.0 mg/L	15
0.3 mg boric acid/L for 6 months	No effect on gonadotoxicity	20
1.0 mg boric acid/L for 6 months, equivalent to 0.05 mg B/kg BW daily	Decreased spermatozoid count, reduction in spermatozoid activity	20
6 mg B/L, 90 days	No toxic effect on male reproductive system, blood chemistry, or growth	5, 15
6 mg B/L for 6 months, equivalent to 0.3 mg B/kg BW daily	Gonadotoxicity in male rats; altered enzyme activity levels in blood and liver	20, 21
75 mg B/L, as borax, for 45 days	No effect on growth or reproduction	3
100 mg B/L for 21 days	Tissue B levels in kidney, liver, brain, and blood increased for first 9 days but returned to normal by day 21 except for blood, which continued to rise	
150 mg/L for 70 days, or 170 mg B/L for 25 days	Slight reduction in growth rate	
>150 mg B/L for extended periods	Adverse effects probable	5
300 mg B/L for 49–70 days	Growth rate reduced 21% but no change in food consumption; coarse coat; atrophied scrotal sacs	4
440 mg B/L for 25 days	Growth inhibition	4
3 g sodium tetraborate/L for 10–14 weeks	Increase in activity of cerebral succinic dehydrogenase, brain acid proteinase, and in brain RNA concentration; decrease in liver cytochrome P-450 activity	22
Diet		
0.09–1.71 mg boric acid/kg BW daily for 6 months (0.015–0.3 mg B/kg BW daily)	Adverse changes in testes	18
350 or 525 mg B/kg diet, as borax or boric acid, for 2 years	No observable adverse effects on fertility, lactation, litter size, weight, or appearance	6
500, 1,000, or 2,000 mg B/kg diet, as borax, for 30–60 days, equivalent to 12, 25, or 50 mg B ingested daily	No adverse effects at 500 mg B/kg diet for 60 days. At 1,000 and 2,000 mg B/kg, adverse effects measured on male reproductive capacity, including germinal aplasia and infertility; effects persisted for at least 8 months following B exposure at highest dose	23
525 mg B/kg diet for 90 days	Tolerated	8
1,000 mg boric acid or borax/kg BW daily	Weight loss after 1 week on borax diet or 2 weeks on boric acid diet; toxic signs after 3 weeks on both diets	24
1,050 mg B/kg diet, as borax or boric acid, for 2 years	Testicular degeneration	6
1,060 mg B/kg diet, as sodium borate, chronic exposure	Growth retardation and testicular atrophy	18
1,170 mg B/kg diet, 2 months	Coarse coat, scaly tails, hunched position, bloody discharge from eyes, depressed hemoglobin and hematocrit	5
1,170 mg B/kg diet, as borax or boric acid 2 years	Sterility in males and females	6, 8
1,750 mg B/kg diet, 25 days	Reduction of 50% in growth rate	4
1,750 mg B/kg diet, as sodium borate, chronic	Severe testicular atrophy	18

Oral, single dose		
450 mg B/kg BW	No effect on male fertility	15
510–690 mg B/kg BW, as borax	LD50	8, 9, 24
550–710 mg B/kg BW, as boric acid	LD50	8, 9, 24
600 mg B/kg BW	LD50	2
3.45–5.14 g sodium borate/kg BW	LD50	18
5.1 g boric acid/kg BW	LD50	6
6.1 g borax/kg BW	LD50	6
Injection subcutaneous		
1.4 g boric acid/kg BW	LD50	18
Injection, intravenous		
5–75 mg boric acid/kg BW	Slight reduction in arterial blood pressure	21
Injection, intraperitoneal		
42 mg sodium borate/kg BW, single injection	Tissue residues after 30 min, in mg B/kg FW, were 25 in blood, 30 in liver, and 50 in kidney v. <5 in all control tissues. After 3 months, residues were 20 mg B/kg FW in brain, 45 in heart, 60 in liver, and 75 in kidney	21
Inhalation, boron trifluoride		
2, 6, or 17 mg BF_3/m^3, 6 h daily, 5 days weekly, 13 weeks	At 17 mg/m^3, altered proximal tubluar epithelium of kidney and abnormal serum chemistry. At 6 mg/m^3, elevated fluoride levels in urine, serum, and bone, but no toxic response. No difference from controls at 2 mg/m^3	26
24 or 66 mg/m^3, 6 h daily, 9 days	Clinical signs of respiratory irritation, nasal discharge, weight loss, increased lung weight, depressed liver weight, kidney pathology at 66 but not 24 mg/m^3	26
55 mg/m^3, 4–7 h daily, 5 days weekly, 6 weeks	Some deaths in rats and other rodent species tested, but no deaths in nonrodent species	26
180 mg/m^3, 6 h daily, consecutive days	All dead prior to sixth exposure	26
259 mg/m^3, 4–7 h daily, 2 days	All dead. Mortality was lower for guinea pigs, dogs, rabbits, mice, and cats. Lung and kidney damage in all species	26
1,210 mg/m^3, 4 h	50% dead	26
Inhalation, boron oxide		
470 mg/m^3, 10 weeks	Reddish exudates from nose, but no deaths or signs of lung damage	19
470 mg/m^3, 24 weeks	No signs of toxicosis	9
Inhalation, decaborane		
20 mg/m^3, 6 h daily, 5 days weekly	Tremors, convulsions, nervousness, restlessness, weight loss, belligerency	3
36 mg/m^3, 4 h	LC50	3
Inhalation, pentaborane		
3 mg/m^3, 6 h daily, 5 days weekly	Extreme belligerency, tremors, weight loss	3
18 mg/m^3, 4 h	LC50	3

Table 10. Proposed boron criteria for the protection of natural resources and human health.

Resource and other variables	Criterion	Reference[a]
Crops		
Irrigation waters		
Sensitive crops	0.3–1.25 mg B/L	1, 2, 3
Semitolerant crops	0.67–2.5 mg B/L	1, 2, 3
Tolerant crops	1–4 mg B/L	1, 2, 3
Maximum safe concentration	4 mg B/L	2
Residues in crops		
Boron deficiency	<15 mg B/kg dry weight (DW) plant	4, 5
Toxicosis	>200 mg B/kg DW plant	4, 5
Aquatic organisms		
Nonhazardous levels in water		
Fish, oysters	1 mg B/L	6
Aquatic plants	4 mg B/L	2
Fish	5 mg B/L	2
"Safe" levels in water		
Largemouth bass, *Micropterus salmoides*	<30 mg B/L	1
Bluegill, *Lepomis macrochirus*	<33 mg B/L	1, 7
Adverse effects, sensitive species	10–12 mg/L	6
Waterfowl		
Diet		
No observed adverse effect	<13 mg/kg fresh weight (FW)	17
Adverse effects	30–100 mg/kg FW	17, 18
Fatal	1,000 mg/kg FW	18
Livestock		
Diet		
Boron deficiency	<0.4 mg B/kg DW	5
Toxic signs probable	>100 mg B/kg DW	5
Maximum tolerable level, as borax	150 mg B/kg DW	4, 5
Total dose, toxic	100–300 g of B (equivalent to 200–600 mg B/kg body weight)	9
Drinking water		
Maximum allowable	5 mg B/L	4, 8, 10, 11
Maximum tolerated	40 mg B/L	10
"Safe"	40–150 mg B/L	11
Adverse effects	>150 mg B/L	5
Pesticide applications		
Boric acid, 99% powder	Effective for control of household cockroaches, ants, and fleas	2
Boric acid, 8% solution	Fungicide for vegetables, fruits, and trees	12
Human health		
Daily intake		
Worldwide	Range 0.3–41 mg B, means usually 10–20 mg B	4, 5, 13
Finland	1.7 mg B	5
England	2.8 mg B	5
United States	3 mg B	4

No effect level	4 g boric acid	14
Adverse effect level		
Chronic intoxication	4–5 g boric acid	14
Lethal to infants and small children	5–6 g boric acid	14
Lethal to adults	18–20 g boric acid, single dose	14
Drinking water		
Recommended	<0.3 mg B/L	15
USSR	<0.5 mg B/L	10
United States	<1.0 mg B/L	4, 11
"Safe"	<20 mg B/L	2, 10
No toxic effects	20–30 mg B/L	2
Dermal, ocular		
Sodium borate and boric acid	Safe as cosmetic ingredients at <5% concentrations; not recommended on infant skin or injured skin	12, 16
Air, Threshold Limit Value (8 h daily, 5 days weekly)		
Pentaborane	0.01 mg/L	4
Dioborane	0.1 mg/L	4
Decaborane	0.5 mg/L	4
Sodium borate	1–5 mg/m^3	16, 17
Boron trifluoride	3 mg/m^3	3
Calcium borate	4–6 mg/m^3	3
Boron tribromide	10 mg/m^3	3
Boron oxide	10 mg/m^3	3

[a]1, Sprague 1972; 2, Papchristou et al. 1987; 3, EPA 1975; 4, NAS 1980; 5, Nielsen 1986; 6, Thompson et al. 1976; 7, Birge and Black 1977; 8, Weeth et al. 1981; 9, Brockman et al. 1985; 10, Seal and Weeth 1980; 11, Green and Weeth 1977; 12, Siegel and Wason 1986; 13, Benson et al. 1984; 14, Schillinger et al. 1982; 15, Krasovskii et al. 1976; 16, Anonymous 1983; 17, Hoffman et al. 1989; 18, Smith and Anders 1989.

In mammals, excessive boron consumption results in a reduced growth rate and sometimes loss in body weight; these may not be entirely due to reduced feed and water consumption (Table 9; Seal and Weeth 1980). Growth retardation has been reported in cattle Even 150 mg B/L drinking water (about 15 mg B/kg BW daily), in dogs consuming diets containing 1,760 mg B/kg, in rabbits eating rations equivalent to > 140 mg B/kg BW daily, and in rats given 150 mg B/L drinking water or 1,060 mg B/kg diet (Table 9). In some instances, animals will avoid B-contaminated drinking water if given a choice. Rats, for example, will reject drinking water containing as little as 1.0 mg B/L (Dixon et al. 1976), and cattle will avoid water containing > 29 mg B/L (Green and Weeth 1977).

Male workers engaged in boric acid production showed weakened sexual activity, decreased seminal volume, low sperm count and motility, and increased seminal fructose (EPA 1975). Adverse effects on reproduction of laboratory animals have been reported in sensitive species fed diets containing more than 1,000 mg B/kg, given drinking water containing 1.0 mg B/L (equivalent to about 0.3 mg B/kg BW daily), or given a single oral dose of 3,000 mg B/kg BW on the first day of pregnancy (Table 9).

Volatile boron compounds, especially boranes, are usually more toxic than boric acid or soluble borates (Table 9; NAS 1980). However, there is little commercial production of synthetic boranes, except for sodium borohydride—one of the least toxic boranes (Sprague 1972). Boron trifluoride is a gas used as a catalyst in several industrial systems, but on exposure to moisture in air it reacts to form a stable dihydride (Busch et al. 1086). For boric oxide dusts, occupational exposures to 4.1 mg/m^3 (range 1.2 to 8.5), are associated with eye irritation; dryness of mouth, nose and throat; sore throat; and cough (Garabrant et al. 1984).

No requirement for boron in mammals is known. Boron may accumulate in tissues because of slow excretion rates, although the significance of elevated residues is largely unknown (EPA 1975). Boron dietary

supplements to postmenopausal women age 48 to 82 years induced changes consistent with the prevention of calcium loss and bone demineralization (Nielson et al. 1987). In cattle, increases in boron ingestion were associated with elevated boron levels in plasma and urine, increased boron excretion, decreased plasma phosphate concentrations, and increased renal and urinary clearance of phosphates (Weeth et al. 1981). Boron accumulations in rat testes were associated with progressive germ cell depletion that persisted long after toxic exposure to boron had occurred (Lee et al. 1978).

Boron effectively counteracts symptoms of fluoride intoxication in humans (Zhou et al. 1987) and in experimentally poisoned rabbits (Elsair et al. 1980a, 1980b, 1981). Men suffering from skeletal fluorosis experienced 50 to 80% improvement after drinking solutions containing 300 to 1,100 mg of borax/L daily, 3 weeks a month for 3 months (Zhou et al. 1987). Boron enhances sequestration of fluoride from bone and excretion through kidneys and possibly the intestinal tract (Elair et al. 1980a, 1981).

Recommendations

Many boron criteria have been proposed for the protection of crops, aquatic life, waterfowl, livestock, and human health (Table 10).

Boron concentrations in contaminated industrial effluents seldom exceed 1.0 mg B/L, a level considered nonhazardous to aquatic life (Table 10; Thompson et al. 1976). However, future accumulations of boron in groundwaters through wider uses of B-containing cleansing agents may adversely affect aquatic organisms and other species of plants and animals, as now occurs in areas where natural boron deposits exist (EPA 1975). Long-term monitoring of groundwaters and surface waters for boron levels seems warranted.

Results of chronic feeding studies using mallards demonstrate that diets containing 13 mg B/kg FW produce no adverse effects, but those containing 30 or 100 mg B/kg FW are associated with elevated tissue boron residues and growth reduction, and diets containing 1,000 mg B/kg are fatal (Table 10). More research is needed on the fate and effects of boron on waterfowl and raptors, especially in those areas where high dietary boron loadings are encountered as a result of agricultural drainwater disposal practices.

Minimum concentrations of dietary boron needed to maintain animal health are not known with certainty. However, diets containing < 0.4 mg B/kg FW may adversely affect metabolism of rats and chicks; accordingly, animal diets should contain >0.3 mg B/kg FW until necessary feeding data become available (Nielsen 1986). Also, the defensible boron maximum for livestock drinking water may be considerably higher than 5 mg/L (Table 10) because several “safe” water sources in Nevada exceeded this upper maximum and approached 80 mg B/L (Green and Weeth 1977). Data are unavailable on boron effects on terrestrial wildlife. Until these data become available, it seems reasonable to apply the same criteria proposed for livestock protection (Table 10) to mammalian wildlife; that is, diets should contain more than 0.4 mg B/kg DW but less than 100 mg/kg, and drinking water < 5 mg/L.

Medicinal use of boric acid and borax for babies has resulted in anorexia, nausea, vomiting, diarrhea, marked cardiac weakness, a red eruption over the entire body, and (rarely) death (NAS 1980). The medical community has abandoned the use of boric acid solutions as irritants and antiseptics (Siegel and Wason 1486), abandoned all medical uses in Denmark (Egfjord et al. 1988), and severely limited availability (prescription only) in Ireland (O'Sullivan and Taylor 1983). Increased use of boric acid as a household pesticide should be viewed with concern, especially in households where children have access to nonsafety-capped boric acid containers (Siegel and Wason 1986).

The fact that boron is essential to plants is firmly established (NAS 1980). However, when boron concentrations in irrigation waters exceed 2 mg/L, extensive plant toxicity should be expected (Pagenkopf and Connolly 1982). High boron concentrations in some potential irrigation waters in the western United States (at levels capable of causing crop damage) have prompted implementation of boron criteria for irrigation waters (Table 10), although no legally enforceable boron standards have been promulgated (EPA 1975). Information is needed on crop plants in the following subjects: interaction of boron with other elements in the soil and its effects on boron availability to plants, the role of boron on pollination as it affects seed yield and sugar content of crops, and distinguishing signs of boron deficiency in plants from similar signs of molybdenum deficiency (Gupta and Macleod 1982).

Acknowledgments

I thank N. A. Bushby, L. J. Garrett, and J. Haber Corley for technical services; B. A. Roberts for secretarial help; N. C. Coon, D. J. Hoffman, A. D. Lemly, and G. J. Smith for technical review of the manuscript; and J. R. Zuboy for editorial services.

Abstract

ABSTRACT.-Technical chlordane is an organochlorine compound first introduced into the United States in 1947 in a variety of formulations for use as a broad-spectrum pesticide. By 1974, about 9.5 million kilograms of chlordane were produced annually. Concern over the potential carcinogenicity of chlordane has led to sharply curtailed production. Since 1983, chlordane use in the United States has been prohibited, except for control of underground termites.

Technical chlordane consists of about 45 components, primarily *cis*-chlordane (19%), *trans*-chlordane (24%), heptachlor (10%), *cis*- and *trans*-nonachlor (7%), and various chlordane isomers (22%). Chemical analysis of technical chlordane is difficult because of analytical interferences from other organochlorine compounds, nonstandardization of analytical techniques, variations in the number and relative composition of components in weathered chlordane, and, uncertainty of structural formulas and other properties of several compounds present.

Past chlordane use, coupled with atmospheric transport as the major route of dissemination, produced global contamination of fish and wildlife resources and human populations. The chemical and its metabolites were frequently detected in all species examined, but usually at low concentrations. Residues in fish muscle sometimes exceeded the U.S. Food and Drug Administration action level of 0.3 mg/kg fresh weight recommended for human health protection. In general, chlordane in animals is highest near areas where the chemical has been applied to control termites; concentrations are highest in fat and liver, especially in predatory species.

The half-life of chlordane in water is comparatively short; *cis*-chlordane, for example, usually persists less than 18 h in solution. In soils, however, some chlordane isomers persist for 3 to 14 years because of low solubility in water, high solubility in lipids, and relatively low vapor pressure. There seems to be little accumulation of chlordane in crops grown in contaminated soils.

Chlordane is readily absorbed by warm-blooded animals through skin, diet, and inhalation, and distributed throughout the body. In general, residues of chlordane and its metabolites are not measurable in tissues 4 to 8 weeks after exposure, although metabolism rates varied significantly between species. Food chain biomagnification is usually low, except in some marine mammals. In most mammals, the metabolite oxychlordane has proven much more toxic and persistent than the parent chemical.

Many species of aquatic organisms are adversely affected at concentrations in water between 0.2 and 3.0 µg/L technical chlordane. Sensitive bird species had reduced survival on diets containing 1.5 mg chlordane per kilogram in their diet, or after a single oral dose as low as 14.1 mg chlordane per kilogram body weight. Chlordane has produced liver cancer in laboratory strains of domestic mice, but carcinogenicity has not been established in other mammals.

Chlordane criteria for protection of marine life (0.004 µg/L, 24-h mean; not to exceed 0.09 µg/L) seem satisfactory. Proposed criteria for freshwater life protection (0.0043 µg/L, 24-h mean; not to exceed 2.4 µg/L) however, overlap the range of 0.2 to 3.0 µg/L shown to adversely affect certain fish and aquatic invertebrates, suggesting that some downward modification in the maximum permissible level is needed. Chlordane criteria for protection of birds and mammals are inadequate because the data base is incomplete. Until these data become available, a reasonable substitute is the criteria proposed for human health protection, namely, daily intake not to exceed 0.001 mg chlordane per kilogram body weight, and diet not to exceed 0.3 mg chlordane per kilogram fresh weight.

Most authorities agree that more studies are needed in several areas: monitoring of oxychlordane concentrations in wildlife; interpretation of the biological significance of residue levels found in wildlife; standardization of analytical extraction and other techniques for quantitation of chlordane and its metabolites; reexamination of aquatic toxicity data where test concentrations exceeded the solubility of chlordane in water (6 to 9 µg/L); interaction effects with other agricultural chemicals; reevaluation of the cancer risk of chlordane on representative organisms at realistic environmental levels; effects of depleted soil fertility from chlordane-induced earthworm suppression; and continuance of epidemiological studies on exposed workers.

Technical chlordane is a mixture of chlorinated hydrocarbons that has been used as an insecticide since its introduction in 1947. Chlordane was the first cyclodiene insecticide to be used in agriculture and was the second most important organochlorine insecticide in the United States in 1976-77, behind toxaphene, with an estimated annual production of 9 million kilograms (Nomeir and Hajjar 1987). Chlordane is now the leading insecticide in controlling termites, with about 1.2 million homes in the United States alone treated annually for this purpose (Nomeir and Hajjar 1987).

Chlordane has been detected in human milk in Canada, Hawaii, Japan, Mexico, Mississippi, and Spain (World Health Organization [WHO] 1984; Ohno et al. 1986). Chlordane compounds have been detected in oysters from the South Atlantic Ocean and Gulf of Mexico, in fish from the Great Lakes and major river basins of the United States, in the blubber of cetaceans from the coastal waters of North America, and the Antarctic atmosphere (Kawano et al. 1988). In fact, all available evidence suggests that chlordane is ubiquitous in the environment. Air and water transport of technical chlordane has resulted in the detection of chlordane and its metabolites in rainwater, drinking water, air, surface waters, soils, sediments, plankton, earthworms, fish, shellfish, birds and their eggs, aquatic invertebrates, cats, dogs, livestock, and humans (Zitko 1978; Environmental Protection Agency 1980; Sudershan and Khan 1980; Kerkhoff and Boer 1982; Wickstrom et al. 1983; Johnson et al. 1986; Nomeir and Hajjar 1987; Suzaki et al. 1988). Despite its widespread use, persistence, and tendency to accumulate in fat, there was no firm evidence of direct lethal or sublethal effects on terrestrial vertebrate wildlife until Blus et al. (1983) recorded several chlordane-related mortalities. A North Dakota marsh treated with chlordane had decreased reproductive success and some deaths of young of several bird species but this was attributed to depletion of invertebrate prey and not to acute poisoning (Hanson 1952). More recently, chlordane was implicated as the principal toxicant in 30 pesticide poisoning cases of hawks, owls, herons, and other birds in New York between 1982 and 1986 (Stone and Okoniewski 1988).

The U.S. Environmental Protection Agency (EPA) considers chlordane as a probable human carcinogen (defined as inadequate evidence from human studies and sufficient evidence from animal studies), as judged by chlordane-induced cancer of the liver in domestic mice (Arruda et al. 1987). In 1978, EPA restricted chlordane use to subterranean termite control, nonfood plants, and root dip. Limited agricultural use was permitted until 1980. In 1987, EPA registered chlordane again, limiting its sale and use to licensed applicators for subterranean termite control (Arruda et al. 1987). However, it seems that significant home and garden use exists, especially for control of termites and undesirable lawn insects (Wood et al. 1986). Reviews on ecological and toxicological aspects of chlordane in the environment are available; particularly useful are those by Ingle (1965), Menzie (1974), National Research Council of Canada [NRCC] (1975), International Agency for Research on Cancer [IARC] (1979), EPA (1980, 1988), WHO (1984), Klaassen et al. (1986), and Nomeir and Hajjar (1987).

This report was prepared in response to requests for information on chlordane from regional environmental contaminant specialists of the U.S. Fish and Wildlife Service. It is part of a continuing series of brief reviews on chemicals in the environment, with emphasis on fishery and wildlife resources.

Chemical and Biochemical Properties

Technical chlordane (64 to 67 % chlorine) is produced by the condensation of cyclopentadiene and hexachlorocyclopentadiene to yield chlordene (Figure). Addition of chlorine across the 2-3 olefinic bond of chlordene forms *cis*-chlordane and *trans*-chlordane; substitution of chlorine into position 1 of chlordene forms heptachlor, and further addition of chlorine across the 2-3 olefinic bond forms *cis*-nonachlor and *trans*-nonachlor (Ribick and Zajicek 1983). Technical chlordane includes about 45 components. Its approximate composition is 19% *cis*-chlordane ($C_{10}H_6Cl_8$), 24% *trans*-chlordane ($C_{10}H_6Cl_8$), 21.5% chlordene isomers ($C_{10}H_6Cl_6$), 10% heptachlor ($C_{10}H_5Cl_7$), *7% cis*- and *trans*-nonachlor ($C_{10}H_5Cl_9$), 2% Diels-Alder adduct of cyclopentadiene and pentachlorocyclopentadiene, 1 % hexachlocycloropentadiene, 1 % octachlorocyclopentene, and 15.5% miscellaneous constituents (NRCC 1975; IARC 1979; EPA 1980; WHO 1984). Oxychlordane and heptachlor epoxide are toxicologically significant degradation products (Figure; Perttila et al. 1986).

Chlordane produced before 1951 contained a significant quantity of hexachlorocyclopentadiene--a toxic irritant to warm-blooded animals; chlordane produced after 1951 contains little or none of this compound (Ingle 1965). A high-purity chlordane formulation containing about 74% *cis*-chlordane and 24% *trans*-chlordane is also available (Nomeir and Hajjar 1987).

Chemical analysis of technical chlordane is difficult because of frequent variations in both the number and relative composition of components in weathered chlordane (Ribick and Zajicek 1983). Other difficulties are encountered from analytical interferences from various organochlorine compounds; furthermore, the exact structure has not been determined for a number of compounds in technical chlordane, and the majority of compounds have not been isolated or synthesized for use as comparative standards (Ribick and Zajicek 1983).

Cis-chlordane (CAS number 5103-71-9) and *trans*-chlordane (CAS number 5103-74-2) are characterized by the following properties: molecular weight of 409.76; chemical formula of ($C_{10}H_6Cl_8$); viscous, amber-colored liquid; boiling point between 104 and 105° C for *trans*-chlordane, and between 106 and 107° C for *cis*-chlordane; density of 1.59 to 1.63 at 25° C; soluble in most organic solvents, but only sparingly soluble in water, that is, 9µg/L at 25° C; vapor pressure of 0.00001 mm mercury at 25° C; and a log Kow (octanol/water partition coefficient) of 5.16 (Ingle 1965; NRCC 1975; IARC 1979; EPA 1980, 1988; WHO 1984). Pesticides containing chlordane or technical chlordane have been sold under a variety of names including 1068, Aspon, Belt, CD-68, Chlor-dan, Chlordan, Chlorindan, Chlor-kil, Chlorodane, Chlortox, Cortilanneu, Corodane, Dichlorochlordene, Dichlorodene, Dowchlor, ENT 9932, HCS 3260, Kypclor, M 140, M 410, Niran, Niran 5% granular bait, Octachlor, Octa-klor, Octaterr, Ortho-klor, Synklor, Tat Chlor 4, Topiclor 20, Toxichlor, and Velsicol 1068 (IARC 1979; Johnson and Finley 1980; Hudson et al. 1984; WHO 1984; Hill and Camardese 1986; Mayer 1987; EPA 1988).

Technical chlordane is stable under ultraviolet (UV) light, although some components, such as chlordane, heptachlor, *cis*-chlordane, and *trans*-chlordane, will form photoisomers under high intensity UV in the presence of sensitizers, such as ketones (NRCC 1975; Menzie 1978). Several compounds were measured in alfalfa grown on soils treated with chlordane, including 1,2-dichlorochlordene, oxychlordane, and photo-*cis*-chlordane, as well as the parent chlordane compounds (WHO 1984). The half-life (Tb 1/2) of *cis*-chlordane in water is comparatively short, between 1.1 and 17.5 h (Feroz and Khan 1979a). In soils, technical chlordane has a half-life ranging from 0.5 to 1.0 years for some samples, and 4 to 10 years for other samples. The lower Tb 1/2 values refer to the initial rapid disappearance of chlordane from the soil; if studies continue over several years, the remaining chlordane is relatively persistent, with a Tb 1/2 of 5 to 7 years (NRCC 1975). Measurable residues of chlordanes in soil were present more than 14 years after application (EPA 1988). Chlordane persists in soils because of its low solubility in water, relatively low vapor pressure, and high tendency to adsorb to soil particles; accordingly, soil-bound chlordanes are not likely to become serious contaminants of the lower soil strata or deep water sources (WHO 1984). Transport into the hydrosphere from contaminated soils will occur through erosion of soil particles or sediments, not by desorption and dissolution (Klaassen et al. 1986).

Chlordane is a nerve stimulant; at low chronic doses it produces hyperexcitability and lack of coordination in animals, and at high acute doses causes tremors and convulsions (Ingle 1965; Klaassen et al. 1986). Chlordane induces hepatic microsomal drug-metabolizing enzymes, resulting in enhanced biotransformation at low doses, although high doses may result in liver hypertrophy (Klaassen et al. 1986). The physiological target sites are in nerve and muscle membranes, presumably on proteins and phospholipids; the ultimate effect is axonic with membrane disruption, resulting in spasmic muscle twitching and death (Greenhalgh 1986).

Chlordane is readily absorbed by warm-blooded animals through skin, diet, and inhalation. It is quickly distributed in the body and tends to concentrate in liver and fat (WHO 1984). Up to 75% of a single oral dose of chlordane administered to rats and mice was absorbed in the gut, and up to 76% of an aerosol dose was absorbed in the respiratory tract (Nomeir and Hajjar 1987); rabbits absorbed 33% in the gut following oral administration (EPA 1988). Chlordane residues in mammals were usually not measurable 4 to 8 weeks after cessation of exposure (Ingle 1965). Chlordane persistence in human serum and whole body was estimated at 88 days and 21 days, respectively; this compares to a Tb 1/2 of about 23 days in rats fed chlordane for 56 days (EPA 1980).

Excretion kinetics of chlordane are complex, and different isomers exit through different pathways (EPA 1980, 1988). In rats, chlordane elimination was almost complete 7 days after receiving single oral doses up to 1 mg/kg body weight (BW); 24 h after treatment, 70% of the *cis*-chlordane and 60% of the *trans*-chlordane had been excreted (WHO 1984). In rodents, chlordane and its metabolites were usually excreted in feces, regardless of the administration route; the *cis*-isomer was excreted slightly faster than the *trans*-isomer, although identical metabolites seemed to be formed (EPA 1980; Menzie 1969, 1980; WHO 1984; Nomeir and

Hajjar 1987). In rabbits, however, up to 47 % of the administered dose was voided in the urine, and *cis*- and *trans*-chlordane were excreted at the same rate (Nomeir and Hajjar 1987).

Microorganisms such as *Nocardiopsis* sp., an actinomycete, can metabolize *cis*- and *trans*-chlordane to at least eight solvent-soluble substances, including dichlorochlordene, oxychlordane, heptachlor, heptachlor *endo*-epoxide, chlordene chlorohydrin, and 3-hydroxy-*trans*-chlordane (Beeman and Matsumura 1981). Based on studies of chlordane metabolism in animals, four metabolic pathways arc proposed: (1) hydroxylation to form 3-hydroxychlordane, which on dehydration forms 1,2-dichlorochlordene, with subsequent epoxidation to oxychlordane (*trans*-chlordane is converted to oxychlordane 7 times faster than is *cis*-chlordane); (2) dehydrochlorination to form heptachlor, from which heptachlor epoxide and other hydroxylation products may be formed; (3) dechlorination to monochlorodihydrochlordene; and (4) the replacement of chlorine by hydroxyl groups resulting in the formation of hydroxy metabolites, which are excreted or further transformed by conjugation with glucuronic acid (Feroz and Khan 1979a; WHO 1984; Nomeir and Hajjar 1987; EPA 1988). Metabolism of chlordanes and nonachlors to oxychlordane is orders of magnitude greater in fish-eating and carnivorous birds than in marine mammals (Kawano et al. 1988). The reasons for this are unclear and merit further research.

Trans-nonachlor, a major component of technical chlordane, was frequently found as the major chlordane residue in humans, whereas oxychlordane was the major component in rats fed technical chlordane (Nomeir and Hajjar 1987). *Trans*-nonachlor is converted efficiently by rat liver microsomes to *trans*-chlordane, but this ability is lacking in humans, resulting in the accumulation of *trans*-nonachlor in humans (Nomeir and Hajjar 1987).

Although technical chlordane is a mixture of compounds, two metabolites--heptachlor epoxide and oxychlordane--can kill birds when administered through the diet (Blus et al. 1983). These two metabolites originate from biological and physical breakdown of chlordanes in the environment, or from metabolism after ingestion. Heptachlor can result from breakdown of *cis*- and *trans*-chlordane, eventually oxidizing to heptachlor epoxide; oxychlordane can result from the breakdown of heptachlor, *cis*-chlordane, *trans*-chlordane, or *trans*-nonachlor (Blus et al. 1983). Heptachlor epoxide has been identified in soil, crops, and aquatic biota, but its presence is usually associated with the use of heptachlor, not technical chlordane--which also contains some heptachlor (NRCC 1975). Various components in technical chlordane may inhibit the formation of heptachlor epoxide or accelerate the decomposition of the epoxide, but the actual mechanisms are unclear (NRCC 1975).

In mammals, oxychlordane ($C_{10}H_4Cl_8O$) is a metabolite *of cis*- and *trans*-chlordanes and *trans*-nonachlor (Miyazaki et al. 1980), and has proven much more toxic and persistent than the parent chemicals (WHO 1984; Kawano et al. 1988). Oxychlordane has been measured in the fat of rats, dogs, and pigs fed either isomer, and in milk and cheese from cows fed alfalfa treated with technical chlordane (WHO 1984; Nomeir and Hajjar 1987; EPA 1988). Oxychlordane was isolated and identified from adipose tissues of pigs fed diets (for 90 days) containing 300 mg/kg of *cis*-chlordane or *trans*-chlordane (Schwemmer et al. 1970). Sharply elevated oxychlordane levels were detected in milk from cows fed chlordane for 60 days; when chlordane was removed from their diet, oxychlordane residues in milk dropped rapidly during the week following termination, and stabilized after 2 weeks (EPA 1980). The Tb 1/2 for oxychlordane in beef cattle grazing in heptachlor-contaminated pastures for 4 weeks was about 92 days (Petterson et al. 1988). Rats and rabbits given chlordane orally or through the diet retained the highest levels in adipose tissue, followed by liver, kidney, brain, and muscle; oxychlordane was the most persistent residue after chlordane was removed from the diet (WHO 1984; EPA 1988).

Uses

Chlordane was first produced commercially in the United States in 1947 and became available in five basic formulations, including 5% granules, oil solutions containing 2 to 200 g/L, and emulsifiable concentrates containing chlordane at 400 to 800 g/L (WHO 1984). Production of chlordane in the United States in 1971 was estimated at 11.3 million kg (Glooschenko and Lott 1977). By 1974, about 9.5 million kilograms of chlordane were used domestically to control commercial pests (35%); in homes, lawns, and gardens (30%); on corn (20%); turf (6%); potatoes (5%); tomatoes (2%); and other uses (IARC 1979). On 6 March 1978, the EPA issued a cancellation proceeding on chlordane, allowing limited use on certain crops and pests until 1 July 1983, but no use thereafter except for underground termite control (IARC 1979; EPA 1988). A similar situation exists

in Japan, where the only permitted use of chlordane is for control of termites and powder post beetles (Miyazaki et al. 1980). Use in Japan is estimated at 500,000 kg a year (Yamagishi et al. 1981 b).

In Canada, chlordane had been used in soils (usually at 0.45 to 4.5 kg/ha) against corn rootworms, strawberry root weevils, wireworms, white grubs, and subterranean cutworms infesting a wide range of crops (Glooschenko and Lott 1977). In the past, at least 75 different formulations containing chlordane as the active insecticidal ingredient had been registered for sale in Canada; the most widely sold formulation, accounting for about 60% of chlordane in soils, was the 25% granular type that was used extensively for corn rootworm control (NRCC 1975). Sales of chlordane in Canada increased about tenfold between 1969 and 1971 because of restrictions on DDT and other organochlorines; however, chlordane use was restricted in Canada in 1978 (Elliott et al. 1988).

Background Concentrations

General

Chlordanes and their metabolites are ubiquitous in the environment at low concentrations, but at a high occurrence in samples analyzed. Atmospheric transport is considered to be the major route of global dissemination. Some chlordane isomers persist in soils for 3 to 15 years, although there seems to be little accumulation of chlordanes by crop plants grown in these soils. Lengthy persistence of various chlordane isomers, especially *cis*-chlordane and *trans*-nonachlor, has been reported in certain organisms, but this has varied greatly between species and tissues.

In living organisms, chlordane concentrations are usually highest in samples collected near areas where chlordane was applied to control termites or other pests, in predatory species, and in tissues with high lipid content. Food chain biomagnification is usually low except in certain marine mammals. In some fishes, chlordane levels in muscle have been sufficient to endanger fish health (100 µg/kg fresh weight) or human consumers of fish (300 µg/kg fresh weight).

Nonbiological Samples

Air and water transport of technical chlordane has resulted in the detection of chlordane and its metabolites in nonbiological samples worldwide (Table 1). Chlordane enters the atmosphere mainly through aerial applications of dust and spray formulations, soil erosion by wind, and volatilization from soil and water (WHO 1984). In aquatic systems, chlordane enters by way of surface runoff and rainfall; chlordane is rapidly adsorbed onto bottom sediments, where it persists (WHO 1984). Atmospheric transport of chlordanes is considered the major route of global dissemination (Pyysalo et al. 1981; Wickstrom et al. 1981). Levels of chlordane compounds in the marine atmosphere of the Southern Hemisphere are nearly the same as those of DDT and its metabolites; this strongly suggests that chlordane compounds are globally distributed and dispersed (Kawano et al. 1985). The yearly input of *cis*-chlordane to the Arctic Ocean from atmospheric sources is estimated at 3,000 kg; if *cis*-chlordane constitutes 19% of technical chlordane, then more than 600,000 kg of technical chlordane has entered the Arctic Ocean since 1948 (Hoff and Chan 1986). Chlordane is frequently measured in the air of buildings where the compound has been used for insect control (WHO 1984). Chlordane has been found in household dust in the homes of farmers and pesticide formulators at exceedingly high mean levels: 5.8 to 23.1 mg/kg air-dried dust (WHO 1984).

Chlordane has been detected in both groundwater and surface water at low levels of 0.001 to 0.01 µg/L (EPA 1988). A high frequency of chlordane was detected in seawater samples collected from a Hawaiian marina: up to 90% of all samples contained *cis*-chlordane, and 68 % contained *trans*-chlordane (IARC 1979). Because of chlordane's use as a soil-injected insecticide, and its persistence, it has the potential to contaminate groundwater, particularly when it is applied near existing wells (EPA 1988).

In soils, chlordane is comparatively immobile and persistent and has only a limited capacity for translocation into edible portions of food crops (NRCC 1975). Total chlordane content in cropland soils nationwide in 1971-72 averaged 0.05 to 0.06 mg/kg dry weight, and ranged between 0.01 and 7.9 mg/kg dry weight (Table 1); maximum values, in excess of 3.0 mg/kg, were recorded in soils from Illinois (7.0), Ohio (5.0), Indiana (4.1), and Iowa (Carey et al. 1978, 1979). The half-life of chlordane in soil when used at agricultural rates is about 1 year (IARC 1979), but residues may be measurable much longer, depending on soil type (NRCC 1975). For example, 10 years after application of 8.5 kg technical chlordane per hectare, up to 20% of the active

ingredients were still measurable; in another study, 15 % of the active ingredients remained in turf soils after 15 years (WHO 1984). *Cis*- and *trans*-chlordanes were less persistent in mineral soils than in organic mucky soils (WHO 1984). Chlordanes were usually detected in surface soils of basins receiving urban runoff water at a maximum concentration of 2.7 mg/kg; this decreased with soil depth to <0.03 mg/kg at depths below 24 cm (Nightingale 1987). Chlordane levels in soils near Air Force bases in the United States in 1975-76 were similar to those found in nonmilitary urban environments (Lang et al. 1979).

Chlordanes in sediments usually were highest in those sediments with the highest organic content, especially downstream from the center of anthropogenic activities (Smith et al. 1987). Sediments from a lake in which the overlying water column initially was treated to contain 10 µg technical chlordane per liter contained measurable residues 2.8 years after application: total chlordanes--consisting of *cis*-chlordane, *trans*-chlordane, and *trans*-nonachlor--averaged 20 µg/kg and ranged up to 46 µg/kg (Albright et al. 1980). The yearly flux of chlordanes from sediments to the overlying water column has been estimated at 0.02 $\mu g/m^2$, based on measurements made in the Sargasso Sea and deep North Atlantic Ocean between 1978 and 1980 (Knap et al. 1986).

Terrestrial Crops

Maximum total chlordane concentrations in corn (*Zea mays*) and sorghum (*Sorghum halepense*) samples collected nationwide in 1971, in µ/kg dry weight, were 480 in corn kernel, 1,260 in cornstalk, and 420 in sorghum (Carey et al. 1978); these values were somewhat lower in 1972: 150 in kernels, 410 in stalks, and 150 in sorghum (Carey et al. 1979). Concentrations in various crops grown in soils treated with 15 kg technical chlordane per hectare were always <260 µg/kg dry weight when clay content was 12 %, and < 150 µg/kg when clay content was 28% (WHO 1984).

Aquatic Invertebrates

Extremely high levels of chlordanes (e.g., 1,746 to 7,643 µg/kg FW) were measured in several species of south Florida corals collected in 1985 (Table 2). Researchers speculate that the elevated levels were because of the illegal disposal of chlordanes off Key Largo, Florida, in 1982 (Glynn et al. 1989).

Maximum concentrations of chlordanes in American oysters (*Crassostrea virginica*) taken in the Gulf of Mexico in 1976 were near 0.1 µg/kg dry weight (Table 2). Chlordane concentrations were substantially lower than concentrations of other organochlorines measured in oysters, such as DDT (28 µ/kg) and polychlorinated biphenyls (90 µg/kg), suggesting a need for additional studies on interaction effects of chlordane residues with those of other environmental chemicals (Rosales et al. 1979).

Marine clams and worms tended to underrepresent chlordane concentrations in the ambient sediments; concentration factors were less than 0.2 for clams and 0.6 for worms (Ray et al. 1983). Similarly, chlordane concentrations in clams from the Shatt al-Arab River in Iraq closely reflected chlordane concentrations in water particulates when compared to levels in water columns or in sediments (DouAbul et al. 1988).

Table 2. Chlordane concentrations in field collections of selected animals. Values shown are in micrograms per kg (parts per billion) fresh weight (FW), dry weight (DW), or lipid weight (LW).

oxychlordane	1 (0.2–1.8) LW	4
Amphibians		
Frogs, *Rana* spp., Louisiana, 1978–79, chlordanes, muscle, whole body	ND	10
California newt, *Taricha torosa*, liver, from lake sprayed with 10 µg technical chlordane per liter		
Total chlordanes		
Time, after application		
14 days	Max. 34, 094 LW	26
9.3 months	Max. 10,094 LW	26
1.24 years	Max. 4,882 LW	26
2.84 years	Max. 601 LW	26
Reptiles		

American crocodile, *Crocodylus acutus*, infertile eggs		
cis-chlordane	Max. 10 FW	29
cis-nonachlor	Max. 30 FW	29
trans-nonachlor	Max. 40 FW	29
oxychlordane	Max. 70 FW	29
Northern water snake, *Nerodia sipedon*, Lake Michigan, 1978, chlordanes		
All tissues, stomach contents	ND	30
Common garter snake, *Thamnophis sirtalis*, Lake Michigan, 1978, *trans*-nonachlor		
Carcass	(100–250) FW	30
Stomach contents	ND	30
Other chlordane isomers	ND	30
Birds		
Mallard, *Anas platyrhynchos*, wing, nationwide		
1976–77		
Chlordane isomers		
Atlantic Flyway	(10–60) FW	31
Mississippi Flyway	(10–20) FW	31
Central Flyway	(10–20) FW	31
Pacific Flyway	(10–20) FW	31
1981–82		
cis-chlordane	Max. 20 FW	32
trans-nonachlor	Max. 50 FW	32
American black duck, *Anas rubripes*, chlordane isomers		
Atlantic Flyway, 1978, egg		
Maryland	50 FW	33
Massachusetts	80 FW	33
Maine	120 FW	33
New Hampshire	(130–160) FW	33
Atlantic Flyway, 1976–77, wing	10–50 FW	31
Great blue heron, *Ardea herodias*, northwestern United States, 1977–82		
Egg		
oxychlordane	Max. 570 FW	78
heptachlor epoxide	Max. 460 FW	78
cis-chlordane	Max. 1,360 FW	78
cis-nonachlor	Max. 690 FW	78
trans-nonachlor	Max. 2,250 FW	78
Whole body, oxychlordane	Max. 470 FW	78
Brain, oxychlordane	Max. 230 FW	78
Canvasback, *Aythya valisineria*		
Egg, breeding areas, 1972–73		

cis-chlordane	<1,000 FW	34
cis-nonachlor	ND	34
oxychlordane	<1,000 FW	34
Carcass (less GI tract, skin, feet, beak) Chesapeake Bay, Maryland, winter		
cis-chlordane		
1973	ND	35
1975	9,000 FW	35
trans-nonachlor		
1973	ND	35
1975	11,000 FW	35
oxychlordane		
1973	ND	35
1975	5,000 FW	35
Birds, 4 species, eastern and southern United States, 1972–74, egg, total chlordanes	<100 FW	36
Birds, New York State, 1982–86, found dead or debilitated, brain tissue, chlordane implicated as primary cause of distress		
Cooper's hawk, *Accipiter cooperii*		
oxychlordane	Max. 5,800 FW	79
heptachlor epoxide	Max. 4,300 FW	79
trans-nonachlor	Max. 1,300 FW	79
Sharp-shinned hawk, *Accipiter striatus*		
oxychlordane	Max. 4,300 FW	79
heptachlor epoxide	Max. 3,500 FW	79
trans-nonachlor	Max. 1,000 FW	79
Great blue heron		
oxychlordane	Max. 2,400 FW	79
heptachlor epoxide	Max. 600 FW	79
Great horned owl, *Bubo virginianus*		
oxychlordane	Max. 8,700 FW	79
heptachlor epoxide	Max. 7,700 FW	79
trans-nonachlor	Max. 2,300 FW	79
Blue jay, *Cyanocitta cristata*		
oxychlordane	Max. 5,000 FW	79
heptachlor epoxide	Max. 3,700 FW	79
trans-nonachlor	Max. 2,000 FW	79
Eastern screech owl, *Otus asio*		
oxychlordane	Max. 2,600 FW	79
heptachlor epoxide	Max. 1,800 FW	79
trans-nonachlor	Max. 1,800 FW	79
Common grackle, *Quiscalus quiscula*		

oxychlordane	Max. 10,800 FW	79
heptachlor epoxide	Max. 9,100 FW	79
Eastern bluebird, *Sialia sialis*		
oxychlordane	Max. 3,000 FW	79
heptachlor epoxide	Max. 2,200 FW	79
European starling, *Sturnus vulgaris*		
oxychlordane	Max. 7,700 FW	79
heptachlor epoxide	Max. 5,000 FW	79
trans-nonachlor	Max. 500 FW	79
American robin, *Turdus migratorius*		
oxychlordane	Max. 1,300 FW	79
heptachlor epoxide	Max. 2,700 FW	79
trans-nonachlor	Max. 1,900 FW	79
Cackling Canada goose, *Branta canadensis minima*, 1973–74, carcass, breeding areas, total chlordanes		
Uncontaminated	<1 FW	37
Contaminated (Oregon, California)		
Immature male	<0.2 FW	37
Adult male	1.7 FW	37
Adult female	2.0 FW	37
Common goldeneye, *Bucephala clangula*, fat, oxychlordane		
On arrival at wintering grounds, New York		
Juveniles	40 (10–300) LW	38
Adults	220 (120–370) LW	38
Just before to spring migration		
Adults	250 (190–320) LW	38
Dunlin, *Calidris alpina*, Washington State, 1980, whole		
Total chlordanes	Max. 60 FW	39
Peregrine, *Falco peregrinus*, Alaska, 1979–84, egg		
trans-nonachlor	Max. 290 FW	40
oxychlordane	130 FW; Max. 960 FW	40
Atlantic puffin, *Fratercula arctica*, Hornoy, Norway, 1982–83, oxychlordane plus *trans*-nonachlor		
Adults		
Uropygial gland	1,429 (48–2,815) LW	41
Liver	93 (262–1,531) LW	41
Chicks		
Brain	833 (445–1,289) LW	41
Chicken, *Gallus* sp., contaminated through use of former chlordane container to hold cage disinfectants, Australia		
Egg	300 DW	42
Pullets, fat		
30 weeks old	920 DW	42

80 weeks old	670 DW	42
Nationwide, egg		
cis-chlordane	1 FW	9
trans-chlordane	2 FW	9
Gull-billed tern, *Sterna nilotica*, South Carolina, 1972–75		
Egg		
Oxychlordane	Max. 290 FW	80
trans-nonachlor	ND	80
Bald eagle, *Haliaeetus leucocephalus*		
Egg, total chlordanes		
Maryland, Virginia, 1980–84	1,100 FW	82
Maine, 1980–84	500 FW	82
Ohio, 1981–84	840 FW	82
Oregon, 1980–83	220 FW	82
Arizona, 1982–84	160 FW	82
Wisconsin, 1980–83	330 FW	82
Nationwide, found dead or moribund		
1971–74		
Brain		
cis-chlordane plus *trans*-chlordane	270 FW	43
cis-nonachlor	290 FW	43
oxychlordane	150 FW	43
Carcass (less skin, beak, feet, GI tract, liver)		
cis-chlordane plus *trans*-chlordane	27,000 LW	43
cis-nonachlor	30,000 LW	43
oxychlordane	15,000 LW	43
1975–77		
Brain		
cis-chlordane	90–190 FW; Max. 6,400 FW	44
cis-nonachlor	130–170 FW; Max. 750 FW	44
trans-nonachlor	200–330 FW; Max. 7,400 FW	44
oxychlordane	180–290 FW; Max. 2,600 FW	44
Carcass (less skin, viscera)		
cis-chlordane	220–320 FW; Max. 4,500 FW	44
cis-nonachlor	100–150 FW; Max. 1,700 FW	44
trans-nonachlor	280–380 FW; Max. 6,000 FW	44
oxychlordane	130–180 FW; Max. 2,300 FW	44
1978–81		
Brain		
cis-chlordane	90–190 FW; Max. 2,300 FW	45
cis-nonachlor	100–230 FW; Max. 1,600 FW	45
trans-nonachlor	180–410 FW; Max. 4,100 FW	45
oxychlordane	120–260 FW; Max. 2,700 FW	45

Carcass (less skin, viscera)		
cis-chlordane	120–290 FW; Max. 2,200 FW	45
cis-nonachlor	120–190 FW; Max. 1,200 FW	45
trans-nonachlor	230–370 FW; Max. 4,100 FW	45
oxychlordane	90–130 FW; Max. 1,450 FW	45
Herring gull, *Larus argentatus*		
Egg, Canada, 1973		
cis- and *trans*-chlordanes	220 LW	6
cis-nonachlor	20 LW	6
trans-nonachlor	520 LW	6
Egg, Maine, 1977		
trans-nonachlor	50 (ND to 500) FW	46
Egg, Virginia, 1977		
trans-nonachlor	40 (ND to 440) FW	46
oxychlordane	20 (ND to 180) FW	46
Chicks, age 21 days		
Liver, oxychlordane	6 (2–13) FW	47
Muscle, oxychlordane	4–140 FW	47
Glaucous-winged gull, *Larus glaucescens*, Alaska, 1973–76		
Egg		
cis-chlordane	Max. 75 FW	48
cis-nonachlor	Max. 26 FW	48
oxychlordane	Max. 250 FW	48
Great black-backed bull, *Larus marinus,* Maine, 1977		
Egg		
cis-chlordane	40 (ND to 500) FW	46
oxychlordane	220 (ND to 430) FW	46
Red breasted merganser, *Mergus serrator*, Lake Michigan, United States, 1978, carcass		
trans-nonachlor	Max. 480 FW	30
Long-billed curlew, *Numenius americanus*, Oregon, 1981–83, convulsions noted, brain		
cis-chlordane	(110–300) FW	49
trans-chlordane	(ND to 50) FW	49
cis-nonachlor	(ND to 470) FW	49
trans-nonachlor	(140 –4,100) FW	49
oxychlordane	(2,500–4,400) FW	49
heptachlor epoxide	(1,000–4,800) FW	49
Yellow-crowned night-heron, *Nycticorax violaceus*, Louisiana, 1978–79, whole body		
Total chlordanes	ND	10
Osprey, *Pandion haliaetus*		
Eastern United States, 1975–82, dead or moribund, carcass		

(less skin, feet, and back)		
cis-chlordane	Max. 680 FW	50
cis-nonachlor	Max. 480 FW	50
trans-nonachlor	Max. 280 FW	50
oxychlordane	Max. 350 FW	50
Eagle Lake, California, 1973–84, egg		
cis-chlordane	Max. 10 FW	51
trans-nonachlor	Max. 6 FW	51
oxychlordane	Max. 6 FW	51
Fourteen states, United States, 1970–79, egg		
cis-chlordane	Usually <100; Max. 1,100	52
cis-nonachlor	Usually <100; Max. 400	52
trans-nonachlor	Usually <100; Max. 500	52
oxychlordane	Usually <100; Max. 400	52
Passeriformes, 38 species, western United States, 1980, carcass (less beak, feet, GI tract, feathers)		
oxychlordane	Usually <50 FW; Max. 290 FW	53
Brown pelican, *Pelecanus occidentalis*, South Carolina, 1974–75, egg		
oxychlordane	Max. 530 FW	81
heptachlor epoxide	Max. 500 FW	81
cis-chlordane	Max. 960 FW	81
trans-nonachlor	Max. 980 FW	81
cis-nonachlor	Max. 630 FW	81
Adelie penguin, *Pygoscelis adeliae*, Antarctic Ocean, 1980–82, subcutaneous fat		
cis-chlordane	0.9 LW	4
trans-chlordane	<0.05 LW	4
cis-nonachlor	1.7 LW	4
trans-nonachlor	15 LW	4
oxychlordane	16 LW	4
Black skimmer, *Rynchops niger*, South Carolina, 1972–75		
Egg		
oxychlordane	Max. 520 FW	80
trans-nonachlor	Max. 520 FW	80
Adults, found dead		
oxychlordane		
Brain	Max. 880 FW	80
Carcass	Max. 560 FW	80
cis-chlordane		
Brain	Max. 540 FW	80
Carcass	Max. 150 FW	80

Shorebirds, 7 species, Corpus Christi, Texas, winter 1976–77, skinned carcasses		
Total chlordanes	Usually <1,000 FW; Max. 1,700 FW	54
Forster's tern, *Sterna forsteri*, egg, Lake Michigan, 1983		
cis-chlordane	(<10–60) FW	77
trans-chlordane	(<10–20) FW	77
trans-nonachlor	(<10–170) FW	77
oxychlordane plus heptachlor epoxide	(10–230) FW	77
heptachlor	(10–300) FW	77
European starling, *Sturnus vulgaris*, whole (less beak, wing tip, feet, skin), nationwide		
1972		
oxychlordane	Max. 100 FW	55
1979		
total chlordanes	Max. 290 FW	56
1982		
cis-chlordane	Max. 30 FW	57
cis-noncachlor	Max. 70 FW	57
trans-nonachlor	Max. 40 FW	57
oxychlordane	Max. 140 FW	57
Northern gannet, *Sula bassanus*, eastern Canada, 1969–84		
Egg		
cis-chlordane		
1969	Max. 550 FW	58
1970	Max. 520 FW	58
1984	Max. 150 FW	58
cis-nonachlor		
1969	Max. 380 FW	58
1970	Max. 370 FW	58
1984	Max. 150 FW	58
oxychlordane		
1969	Max. 208 FW	58
1970	Max. 202 FW	58
1984	Max. <100 FW	58
Tree swallow, *Tachycineta bicolor*, Alberta, Canada, 1978–79		
Eggs and nestlings		
cis-chlordane	<30 FW	59
oxychlordane	<30 FW	59
Thick-billed murre, *Uria lomvia*, northern Pacific Ocean, 1980–82, subcutaneous fat		
cis-chlordane	3 (1.4–3.9) LW	4
trans-chlordane	<0.05 LW	4

cis-nonachlor	10 (3–15) LW	4
trans-nonachlor	3 (1.7–4.5) LW	4
oxychlordane	82 (63–130) LW	4
total chlordanes	98 (63–150) LW	4
Waterbirds, 3 species, Galveston Bay, Texas, 1980–82, total chlordanes		
Carcass (less skin, feet, bill, GI tract)	Max. 1,200 FW	60
Egg	Max. 900 FW	60
Mammals		
Bats, 3 species, Maryland and West Virginia, 1973, near high chlordane use area, oxychlordane		
Carcass	Max. 3,000 FW	61
Guano	Max. 100 FW	61
Cow, *Bos bovis*, milk, total chlordanes		
Nationwide	20–60 FW	9
Illinois, 1971–73	50 FW	62
Cattle, *Bos* sp., grazing heptachlor-contaminated pastures for 4 weeks (some deaths), oxychlordane, subcutaneous fat		
End of grazing	5,700 FW	63
48 days later	180 FW	63
Dog, *Canis familiaris*, Tokyo, 1979, adipose tissue		
trans-nonachlor	17 FW	11
oxychlordane	71 FW	11
total chlordanes	88 FW	11
Cat, *Felis domesticus*, Tokyo, 1979, adipose tissue		
cis-nonachlor	60 FW	11
trans-nonachlor	51 FW	11
oxychlordane	50 FW	11
total chlordanes	160 FW	11
Long-finned pilot whale, *Globicephala melaena*, Newfoundland, 1980, blubber		
Total chlordanes		
Males	1,600 (1,000–3,200) FW	64
Females	700 (200–1,900) FW	64
Grey seal, *Halichoerus grypus*, Gulf of Finland, 1976–82		
Blubber		
cis-chlordane	50 FW	65

Fishes

Health advisories have been issued near Lawrence Kansas, based on chlordane levels in edible fish tissues. In fish from the Kansas River, Kansas, in 1986, chlordanes were detected more frequently and at higher levels than other contaminants measured (Arruda et al. 1987). More than 80% of the sites sampled in Kansas had detectable chlordanes in fish; at more than 50% of these sites, levels exceeded 0.1 mg/kg fresh weight--a guideline for the protection of predatory fish. At three urban sites in Kansas, concentrations of chlordanes in fish have approached or exceeded the Food and Drug Administration action level of 0.3 mg chlordane per kilogram of fresh weight for protection of human health. The most likely source of chlordane in fish from the Kansas River is urban and suburban use of chlordane as a termite control agent (Arruda et al. 1987). Other health advisories based on chlordane contamination have been issued. In 1985, people were warned not to eat shovelnose sturgeon (*Scaphirhynchus platyrynchus*) from the Missouri and Mississippi rivers. In 1987, advisories warned against the consumption of sturgeon from the Missouri River between Kansas City and St. Louis, and against bullhead catfishes, suckers, carps, sturgeons, and sturgeon eggs from the Mississippi River near St. Louis (Bush and Grace 1989).

Chlordane residues were detected in 36% of all fish samples collected in major domestic watersheds in 1976 (Veith et al. 1979). In the Great Lakes region in 1979, chlordane residues in fish tissues exceeded 100 µ/kg on a fresh weight basis in about 40% of the samples measured; residues were highest in samples collected near Alton, Illinois, and Fairborn, Ohio (Kuehl et al. 1983).

The two most abundant components of technical chlordane found in fish tissues from Tokyo Bay, Japan, were *trans*-nonachlor and *cis*-chlordane (Yamagishi et al. 1981 b; Table 2). However, this may vary between locales. For example, *cis*-chlordane and *trans*-chlordane were the most abundant components in fish samples collected throughout Japan during the past 20 years, followed, in order, by *cis*-nonachlor, *trans*-nonachlor, and oxychlordane (Loganathan et al. 1989). Of the total chlordanes measured in muscle of northern pike *(Esox lucius)* from the Baltic Sea, 37% was *cis*-chlordane, 34% *trans*-chlordane, and 15% each *trans*-nonachlor and oxychlordane (*(Esox lucius)* and Baltic herring (Moilanen et al. 1982). For liver tissue of northern pike, 35 % was oxychlordane, 28% *trans*-chlordane, 22% *cis*-chlordane, and 14% *trans-non*achlor (*(Esox lucius)* and Baltic herring *(*Moilanen et al. 1982). In the United States, only chlordanes and nonachlors have been detected as significant residues in fish collected nationwide. The most abundant component was *cis*-chlordane, followed by *trans*-nonachlor, *trans*-chlordane, and *cis*-nonachlor (Ribick and Zajicek 1983). The two most abundant components were detected in about 93 % of all fish samples collected in 1978 and 1979; residues were usually highest in Hawaii, the Great Lakes, and the Corn Belt (Ribick and Zajicek 1983). Fish from Manoa Stream in Hawaii had high residues because of heavy use of technical chlordane in pineapple culture and termite control (Ribick and Zajicek 1983). Nationwide monitoring of freshwater fishes showed that chlordane concentrations in

whole fish did not change from 1980 to 1994, following a period of decline; however, *trans*-nonachlor replaced *cis*-chlordane as the most abundant component, suggesting a lower influx of chlordane to the aquatic environment from terminated use of chlordane in agriculture in the mid- 1970's (Schmitt et al. 1990; Table 2). Residues of *cis*-chlordane and *trans*-nonachlor--the most abundant and persistent of the chlordane components measured --were present at 85 and 89% of the stations sampled in 1984 (Schmitt et al. 1990). Maximum chlordane levels in fish in 1984 occurred in the Great Lakes, Hawaii, watersheds of the Ohio, Missouri, and Mississippi rivers, and in the Delaware and Raritan rivers in the Northeast (Schmitt et al. 1990).

Atmospheric transport may be the main source of chlordane in Finland --a country that prohibits chlordane use— because chlordanes are distributed evenly in the Finnish environment (Pyysalo et al. 1983). No chlordane compounds were detected in rainbow trout (*Oncorhynchus mykiss*) taken from lakes in eastern Finland, although measurable residues were detected in other fish species. This phenomenon is attributed to the superior ability of rainbow trout to metabolize chlordanes to oxychlordane (Pyysalo et al. 1981).

Amphibians and Reptiles

Chlordane residue data for amphibians and reptiles are extremely limited. Maximum concentrations of chlordane isomers did not exceed 70 µg/kg FW of oxychlordane in eggs of the American crocodile, *Crocodylus acutus,* or 250 µg/kg FW in carcass of the common garter snake, *Thamnophis sirtalis* (Table 2). However, California newts, *Taricha torosa*, taken near a lake treated with 10 µg/L technical chlordane had greatly elevated chlordane residues in liver and comparatively low concentrations in carcass, stomach, and stomach contents. After 14 days, livers contained about 34 mg/kg total chlordanes lipid weight--about 19% chlordanes, 9% nonachlors, and 6% chlordanes (Albright et al. 1980). After 2.8 years, 98% of the total chlordanes was lost. *Trans*-nonachlor was the most persistent component in newt liver, accounting for up to 55% of the total chlordanes in specimens collected 2.8 years after application (Albright et al. 1980; Table 2).

Birds

Technical chlordane components and their metabolites--especially oxychlordane--are comparatively elevated in tissues with high lipid content, in older birds, and in raptors (Table 2).

Chlordane isomers occur frequently in birds collected nationwide. In 1976, for example, 41 % of European starlings (Cain and Bunck 1983). In 1982, oxychlordane was detected in 45 % of all starlings analyzed, *trans*-nonachlor in 40%, *cis*-nonachlor in 9%, and *cis*- and *trans*-chlordanes in fewer than 2% (Bunck et al. 1987). Chlordane isomers were detected at frequencies exceeding 50% in wings of American black ducks *(Anas rubripes)* and mallards *(Anas platyrhynchos)* from the Atlantic Flyway in 1976-77 (White 1979), in eggs of 19 species of Alaskan seabirds in 1973-76 (Ohlendorf et al. 1982), and in carcasses of ospreys (Pand*ion haliaetus)* found dead in the eastern United States between 1975 and 1982 (Wiemeyer et al. 1987). Frequency of detection for chlordane isomers ranging between 14 and 40% has been reported in wings of American black ducks and mallards from flyways other than the Atlantic Flyway (White 1979), in 19 species of passeriformes from the western United States in 1980 (DeWeese et al. 1976), and in 7 species of Texas shorebirds in 1976-77--although residues in shorebirds were below levels known to adversely affect reproduction or survival (White et al. 1980).

Carcasses of bald eagles (*Haliaeetus leucocephalus*) collected between 1978 and 1981 usually contained oxychlordane at 45 to 56% frequency, *trans*-nonachlor at 62 to 74%, *cis*-chlordane at 38 to 45%, and *cis*-nonachlor at 38 to 47%. Frequency of occurrence in the brain was lower, ranging between 19 and 55% for individual isomers (Reichel et al. 1984). However, a positive correlation was established in bald eagles between concentration of chlordanes in brain on a fresh weight basis and in carcass on a lipid weight basis; this relation seems to extend to other birds as well (Barbehenn and Reichel 1981). Bald eagles also contained appreciable quantities of other organochlorine compounds, and a few--for example, dieldrin--were sometimes present at concentrations considered life-threatening (Reichel et al. 1984). A similar situation exists in other species of raptors (Ambrose et al. 1988).

Some chlordane isomers tend to persist in avian tissues for lengthy periods. In northern gannets (*Sula bassanus*), the half-time persistence of *cis*-chlordane, *cis*-nonachlor, and oxychlordane was estimated at 11.2, 19.4, and 35.4 years (Elliott et al. 1988). Oxychlordane residues in the thick-billed murre *(Uria lomvia)* tend to be high because of rapid excretion through uropygial gland secretions of *cis*- and *trans*-chlordanes and

nonachlors, and to biotransformation of these and other chlordane components to oxychlordane (Kawano et al. 1988). This observation is alarming because the metabolite oxychlordane has proven much more toxic and persistent than the parent chemicals (Kawano et al. 1988). Secondary poisonings of raptors after consumption of poisoned bait or prey that had accumulated a large quantity of chlordane were documented for the red-shouldered hawk *(Buteo lineatus)* and the great horned owl (*Bubo virginianus*); concentrations of oxychlordane and heptachlor epoxide found in brain and carcass of both species (Blus et al. 1983) were within the lethal range reported in experimental studies (Stickel et al. 1979).

Chlordane-induced mortality of the long-billed curlew *(Numenius americanus)* has been documented at least four times since 1978, despite restriction of technical chlordane use since 1980 to subterranean applications for termite control (Blus et al. 1985). Death of these curlews was probably due to over-winter accumulations of oxychlordane of 1.5 to 5.0 mg/kg brain FW and of heptachlor epoxide at 3.4 to 8.3 mg/kg--joint lethal ranges for oxychlordane and heptachlor epoxide in experimental birds— compared with 6 mg/kg brain for oxychlordane alone, and 9 mg/kg for heptachlor epoxide alone (Blus et al. 1985). Additional research is needed on toxic interactions of chlordane components with each other and with other chemicals in the same environment.

Mammals

Chlordane levels in mammals were usually highest in lipids, in animals collected near areas of high chlordane use, and in aquatic mammals, especially marine species (Table 2). Biomagnification of total chlordane through the food chain was strongly evident in marine mammals; chlordanes were concentrated gradually from zooplankton, through squid and fish, to porpoises and dolphins (Kawano et al. 1986; Muir et al. 1988; Table 2). Chlordane residues in marine mammals were positively related to lipid content and not to the age of the animal (Perttila et al. 1986).

A high death rate over a 2-year period was evident in the little brown bat (*Myotis lucifugus*) following application of chlordane; young bats were most affected in the first year after application and adults in the second year (Kunz et al. 1977). Residues were greatly elevated in the brain and carcass of another bat, the gray bat (*Myotis grisescens*)-an endangered species--found dead near areas of high chlordane use (Table 2).

Chlordane levels in human blood were comparatively elevated among individuals living in residences treated with chlordane during the past 5 years, and in termite control operators; oxychlordane levels were usually significantly higher than *trans*-nonachlor except among those who consumed large quantities of fish (Wariishi et al. 1986; Wariishi and Nishiyama 1989).

Lethal and Sublethal Effects

General

Chlordane has been applied extensively to control pestiferous soil invertebrates, usually at rates between 0.6 and 2.24 kg/ha; within this range sensitive nontarget species, especially earthworms, were adversely affected.

Nominal water concentrations between 0.2 and 3.0 µg/L were harmful to various species of fish and aquatic invertebrates. Effects included a reduction in survival, immobilization, impaired reproduction, histopathology, and elevated chlordane accumulations. *Cis*-chlordane, when compared with *trans*-chlordane, was more toxic, preferentially stored, and concentrated to a greater degree. In aquatic organisms, *cis*-chlordane photoisomers were frequently more toxic than the parent form. Oxychlordane was not a major metabolite in aquatic fauna.

Sensitive bird species had reduced survival after consumption of diets as low as 1.5 mg chlordane per kilogram of ration, or after a single oral dose as low as 14.1 mg/kg BW; accumulations were documented in tissues following consumption of diets containing 0. 1 to 0.3 mg chlordane per kilogram of feed. Oxychlordane was the most persistent metabolite in avian brain tissue.

Concern for the continued widespread use of chlordane centers on its ability to cause liver cancer in domestic mice. Other adverse effects in mammals, such as elevated tissue residues and growth inhibition, were frequently associated with diets containing between 0.76 and 5.0 mg chlordane per kilogram of feed. Metabolism of technical chlordane by mammals results primarily in oxychlordane, a metabolite that is about 20 times more toxic than the parent compound and the most persistent metabolite stored in adipose tissues.

Chlordane interactions with other agricultural chemicals produced significant biological effects in warm-blooded organisms, indicating a need for additional research on this subject.

Terrestrial Invertebrates

Chlordane has been used extensively to control grubs, ants, snails, and terrestrial invertebrates. Chlordane applied to wheat crops in India at 0.6 kg/ha and higher controlled infestation by two species of termites *(Odontotermes obesus, Microtermes obesi)* and increased grain yield; chlordane applications of 0.4 kg/ha and lower were ineffective (Khan and Singh 1985). Chlordane has been used to control the imported fire ant *(Solenopsis invicta),* although registration for this purpose by EPA has now been withdrawn (Williams and Lofgren 1983). Application of 4.5 g of chlordane per ant mound, applied as an emulsifiable concentrate, resulted in 83 to 94% control 4 to 5 weeks after treatment (Williams and Lofgren 1983). Cricket (*Acheta pennsylvanicus*) nymphs died within one minute of contact with technical chlordane; dead crickets showed cellular disruption of the caecal lining, the malpighian tubules, and the digestive tract (Greenhalgh 1986).

Chlordane, at 1. 12 to 2.24 kg/ha, was lethal to fly and beetle larvae and also caused reductions in populations of various species of soil invertebrates (WHO 1984). Among nontarget soil species, earthworms were especially sensitive. Significant reductions in earthworm populations were recorded following application of 2.2 kg/ha; metabolism was adversely affected in 2 weeks at 13 kg/ha and remained depressed for at least 5 years; at 80 kg/ha, 46% died in 4 days (NRCC 1975). In soil, chlordane effects decreased with increasing soil temperature and organic content; the heptachlor component in technical chlordane had the greatest biological activity to soil fauna (NRCC 1975).

Aquatic Organisms

Signs of chlordane poisoning in fish included hyperexcitability, increased respiration rate, erratic swimming, loss of equilibrium and convulsions; death frequently occurred within 12 h of exposure (NRCC 1975). Chlordane adversely affected sensitive species of fish and aquatic invertebrates at nominal water concentrations between 0.2 and 3.0 µg/L (Table 3). Specifically, reduced survival was measured in shrimp and crabs at water concentrations of 0.2 to 2.0 µg/L, and in freshwater and marine fishes between 1.7 and 3.0 µg/L; immobilization, impaired reproduction, and histopathology were recorded in shrimp, fish, and planarians between 0.8 and 3.0 µg/L; and high accumulations were evident in fish, shrimp, and oysters between 0.2 and 4.2 µg/L. Growth stimulation and high residues were measured in resistant species of algae, such as *Scenedesmus quadricauda,* at media concentrations up to 100 µg chlordane per liter; in sensitive algal species, however, growth was inhibited at water concentrations as low as 10 µg/L (Table 3).

Large intraspecfic and interspecific differences in sensitivity to chlordane were evident (Table 3). Some of this variability was attributed to variations in water temperature, salinity, and sediment loadings; some to the age, condition, and nutritional history of the test organism; and some to the chlordane formulation and isomer tested (NRCC 1975; EPA 1980; and Finley 1980; McLeese and Metcalf 1980; Mayer and Ellersieck 1986). In general, granular chlordane formulations were most toxic, organisms at a young developmental stage and organisms with reduced lipid content were most sensitive, and adverse effects were most pronounced under conditions of elevated water temperatures, reduced salinities, decreased sediment loadings, and increased duration of exposure. Reduced bioavailability and lessened toxicity of chlordane to daphnids was associated with increasing concentrations (up to 200 mg/L) of suspended solids and their associated carbon content (Hall et al. 1986). Sediment loadings of 5.8 mg chlordane per kilogram were fatal to 50% of sandworms *(*McLeese et al. 1982). Resistance or adaptation to chlordane has been reported in mosquitofish *(Gambusia affinis)* collected from ditches near treated cotton fields; these fish were up to 20 times more resistant than newly exposed fish (NRCC 1975).

Residues of *cis*-chlordane were preferentially stored and magnified over *trans*-chlordane by freshwater fish and invertebrates in ponds treated with technical chlordane at concentrations up to 1.14 µg/L; the *cis* isomer, with an estimated Tb 1/2 of 46 days, persisted longer than did the *trans*- isomer (Johnson and Finley 1980). Tissue concentrations of 106,000 µg total chlordenes per kilogram, on a lipid weight basis, were associated with reduced survival of estuarine invertebrates (Zitko 1978). Moribund amphipods *(Hyallela azteca),* for example, contained 137,000 to 2,180,000 µg/kg lipid of various chlordanes, heptachlors, and chlordenes (Zitko 1978). In fish, chlordane concentrations of 300,000 to 4,000,000 µg/kg lipid weight in tissues were lethal (Zitko 1978).

Cis-chlordane was 8 times more toxic to bluegill *(Lepomis macrochirus)* than was *trans*-chlordane (Johnson and Finley 1980). *Cis*-chlordane was also more toxic to goldfish *(Carassius auratus)* than was *trans*-chlordane because of its comparatively rapid uptake from the medium and lengthy storage in body tissues, estimated at 99 % after 25 days (Feroz and Khan 1979b). The elimination rate of *cis*-chlordane from a cichlid (*Cichlasoma* sp.) was estimated at 2.9% weekly over a 20-week period, with a Tb 1/2 of about 17 weeks; metabolites accounted for 12.5% (dichlorochlordene, oxychlordane, chlordene chlorohydrin, dihydroxyheptachlor, dihydroxydihydrochlordene, plus four unidentified compounds) and unchanged *cis*-chlordane for 87.5 % (Feroz and Khan 1979a).

Table 3. Chlordane effects on selected aquatic organisms. Compound tested was technical chlordane, unless indicated otherwise.

Organism and concentration in medium in ug/L	Effect	Reference[b]
Algae		
Blue-green alga, *Chlamydomonas* sp.		
0.1–50	Stimulatory to growth	1
>100	Inhibitory to growth	1
Estuarine phytoplankton, mixed species		
5	No effect on growth in 5 days	2
10	Daily additions of 10 µg/L for 8 days reduced algal growth rate and carbon uptake. Inhibition persisted for 2–48 h and did not affect community composition	2
Marine dinoflagellate, *Exuviella baltica*		
50	Exposure for 7 days resulted in disintegration of many cells, reduced cell density and reduced carbon fixation. Particle size distribution altered, and this could affect availability of food for particle feeding herbivores	3
Green alga, *Scenedesmus quadricauda*		
0.1–100	Stimulatory to respiration and growth; bioconcentration factor (BCF) ranged from x6,000 to x15,000 in 24 h for all doses, and from x6,700 to x103,000 in 5 days	1, 4
>1,000	Growth inhibition	4
Invertebrates		
Blue crab, *Callinectes sapidus*		
260	50% immobilization in 48 h	5
Dungeness crab, *Cancer magister*		
0.015	No effect on survival or molting	6
0.15	LC50 (37 days), molting inhibited	6
1.3	LC50 (96 h), zoeae	6
220	LC50 (96 h), adults	6
Sand shrimp, *Crangon septemspinosa*		

2	LC50 (96 h)	7
American oyster, *Crassostrea virginica*		
4.2	8% reduction in shell growth in 96 h, BCF of x2,619 in soft parts	8
6.2–10	50% reduction in shell growth in 96 h, BCFof x3,200–x8,300	5, 6, 8
100	BCF of x7,300 after exposure for 10 days	9
Daphnid, *Daphnia magna*		
12.1 and 21.6	Maximum acceptable toxicant concentration (MATC)[a]	6
28	50% immobilization in 96 h	10
97	LC50 (48 h) for chlorinated chlordane	11
152	LC50 (48 h) for chlorinated emulsifiable concentrate	11
270	LC50 (48 h)	12
813	LC50 (48 h) for dechlorinated chlordane	11
1,174	LC50 (48 h) for dechlorinated emulsifiable concentrate	11
Daphnid, *Daphnia pulex*		
2.3	50% immobilization in 48 h for *trans*-nonachlor	13
24	LC50 (48 h)	14, 15
57	LC50 (96 h) for *cis*-chlordane	16
269	LC50 (96 h) for *trans*-chlordane	16
550	LC50 (96 h) for *cis*-photochlordane	16
930	LC50 (96 h) for oxychlordane	16
Planarian, *Dugesia dorotocephala*		
0.2	No deaths in 5 days	17
>1.0	Impaired reproduction after 10-day exposure	17
~3.0	LC50 (5 days)	17
10.0	LC100 (10 days)	17
Amphipod, *Gammarus fasciatus*		
40	LC50 (96 h), 95% confidence interval of 21–60 µg/L	14, 15
Amphipod, *Hyallela azteca*		
97	50% immobilization in 168 h	10
Freshwater bivalve mollusk, *Lamellidens marginalis*, exposed to 0.12 mg technical chlordane/L for up to 30 days		
2 days	Residues, in mg/kg FW, were 5.0 in gill, 3.6 in foot, 3.1 in muscle, and 2.2 in intestine	26
8 days	Residues, in mg/kg FW, ranged between 2.4 in gill and 1.1 in muscle	26

30 days	Residues, in mg/kg FW, were 1.0 in gill, 1.0 in foot, 0.4 in intestine, and 0.1 in muscle	26
Sandworm, *Nereis virens*		
220	LC50 (12 days), but no deaths in 96 h. At 96 h, signs of stress included everted proboscis, loss of equilibrium, emergence from sediments, and failure to burrow	18
Crayfish, *Orconectes nais*		
31.6	LC50 (35 days)	14
50	LC50 (96 h)	14
Korean shrimp, *Palaemon macrodactylus*		
11	LC50 (96 h)	15
Grass shrimp, *Palaemonetes pugio*		
4.2	LC15 (19 h), BCF about x1,070	8
4.8	LC50 (96 h), BCF of x1,900–x2,300	8
Brown shrimp, *Penaeus aztecus*		
2.4	50% immobilization in 48 h	5
Pink shrimp, *Penaeus duorarum*		
0.24	LC10 (96 h), whole body BCF of x2,960 in survivors	8
0.4	BCF of x4,000–x6,000 in 96 h	8
4.4	LC50 (48 h)	8
Stonefly, *Pteronarcy californica*		
15	LC50 (96 h), 95% confidence interval of 9–24 µg/L	14, 15
Daphnid, *Simocephalus serrulatus*		
20	LC50 (48 h)	14, 15
Fish		
Goldfish, *Carassius auratus*		
13	LC50 (96 h) for *cis*-photochlordane	16
15	LC50 (96 h) for oxychlordane	16
26	Exposed for 24 h to *cis*-chlordane. Whole body BCF at 10 and 25 days after exposure were x2,280 and x1,820, respectively	19
27	LC50 (96 h) for *cis*-chlordane	16
82	LC50 (96 h)	6
440	LC50 (96 h) for *trans*-chlordane	16
Sheepshead minnow, *Cyprinodon variegatus*		
0.5 and 0.8	MATC[a]	20
0.8	Reduced hatch during continuous exposure	20
1.7	Some deaths in second-generation fish during	20

	continuous exposure	
2.8	Some deaths in adult fish during exposure for 189 days	20
3.3	No deaths in 28 days, whole body BCF of x3,333	8
7.1	Equilibrium loss in fry after exposure for 10 days	8
12.5–24.5	LC50 (96 h)	8, 20
15	LC25 (96 h), BCF up to x18,700 in survivors	8
36	No effect on fertilization success or embryo survival after adults exposed for 28 days	8
Common carp, *Cyprinus carpio*		
3.0	LC50 (96 h)	6
Threespine stickleback, *Gasterosteus aculeatus*		
90–160	LC50 (96 h)	6, 15
Freshwater catfish, *Heteropneustes fossilis*		
150	No deaths in 96 h	21
247	Muscle glycogenolysis and hyperglycemia in 2–12 h	21
275	LC50 (96 h)	21
3,500	LC100 (96 h)	21
Channel catfish, *Ictalurus punctatus*		
7–46	LC50 (96 h)	14
Pinfish, *Lagodon rhomboides*		
5.4	LC30 (94 h), whole body BCF of x3,070	8
6.4	LC50 (96 h), BCF up to x7,500	8
Bluegill, *Lepomis macrochirus*		
1.2 and 2.2	MATC[a]	10
7.1–17	LC50 (96 h) for *cis*-chlordane	14, 16
9.2	LC50 (96 h) for oxychlordane	16
12	LC50 (48 and 96 h) for *cis*-photochlordane	16, 22
19–85	LC50 (96 h)	6, 10, 14, 15
41	LC50 (96 h) for chlorinated technical chlordane	11
50.5–140	LC50 (96 h) for *trans*-chlordane	14, 16
62	LC50 (96 h) for chlorinated emulsifiable concentrate	11
582	LC50 (96 h) for dechlorinated technical chlordane	11
800	LC50 (96 h) for dechlorinated emulsifiable concentrate	11

Largemouth bass, *Micropterus salmoides*		
3.0	LC50 (96 h)	14
Striped bass, *Morone saxatilis*		
11.8	LC50 (96 h)	6
Striped mullet, *Mugil cephalus*		
3.2	LC50 (48 h)	5
Cutthroat trout, *Oncorhynchus clarki*		
27	LC50 (96 h)	14
Coho salmon, *Oncorhynchus kisutch*		
14–56	LC50 (96 h)	6, 14, 15
Rainbow trout, *Oncorhynchus mykiss*		
8–47	LC50 (96 h)	6, 14, 15, 24
Chinook salmon, *Oncorhynchus tshawytscha*		
57	LC50 (96 h)	15
Sea lamprey, *Petromyzon marinus*		
1,000	LC100 (14 h)	9
Fathead minnow, *Pimephales promelas*		
25–115	LC50 (96 h)	10, 14, 15
Indian carp, *Saccobranchus fossilis*		
420	LC50 (96 h)	23
Brown trout, *Salmo trutta*		
11	LC50 (96 h)	14
Brook trout, *Salvelinus fontinalis*		
0.32	Adverse effects during chronic exposure	10
22	No deaths in 96 h	25
30-47	LC50 (96 h)	6, 10, 25

[a] MATC = maximum acceptable toxicant concentration. Lower value in each MATC pair indicates highest concentration tested producing no measurable effect on growth, survival, reproduction, and metabolism during chronic exposure; higher value indicates lowest concentration tested producing a measurable effect.

[b] 1. Glooschenko et al. 1979; 2. Biggs et al. 1978; 3. Magnani et al. 1978; 4. Glooschenko and Lott 1977; 5. Mayer 1987; 6. EPA 1980; 7. McLeese and Metcalfe 1980; 8. Parrish et al. 1976; 9. NRCC 1975; 10. Cardwell et al. 1977; 11. Randall et al. 1979; 12. Hall et al. 1986; 13. Passino and Smith 1987; 14. Johnson and Finley 1980; 15. EPA 1973; 16. Podowski et al. 1979; 17. Best et al.; 1981; 18. McLeese et al. 1982; 19. Feroz and Khan 1979b; 20. Parrish et al. 1978; 21. Mirsha and Srivastava 1984; 22. Sudershan and Khan 1980; 23. Verma et al. 1982; 24. Mayer and Ellersieck 1986; 25. Zitko 1979; 26. Agrawal 1986.

Photoisomers seem to be more toxic than the parent form. For example, *cis*-photochlordane was about twice as lethal to bluegills and goldfish than was *cis*-chlordane (Sudershan and Khan 1980). Bluegills exposed to 5 µg/L of radiolabeled *cis*-photochlordane or *cis*-chlordane for 48 h accumulated *cis*-chlordane from the medium by a factor of x78, and *cis*-photochlordane by a factor of x 140 (Sudershan and Khan 1980). During the next 6 weeks, 20% of the cis-chlordane was eliminated in a linear pattern, and about 50% was eliminated in 46 days. Elimination of *cis*-photochlordane followed a biphasic pattern and was most rapid during the first 3 weeks; 40% was eliminated in the fast 6 weeks, and 50% was eliminated in 15 weeks. Less than 7% of the radioactivity retained in *cis*-chlordane-treated bluegills was in the form of two conjugates, compared with 16% in the form of 14 metabolites for *cis*-photochlordane. No oxychlordane was found in bluegill tissues after treatment; this

compound is one of the predominant metabolites found in chlordane-treated rodents and cockroaches. Thus, absence of epoxidation and presence of a mechanism of hydroxylation followed by conjugation seems to be the most active mode of chlordane metabolism in bluegill (Sudershan and Khan 1980).

Cis-photochlordane was about one-tenth as toxic to *Daphnia pulex* than was *cis*-chlordane (Podowski et al. 1979). This is in sharp contrast to the pattern shown in bluegill and goldfish (Sudershan and Khan 1980); further, *cis*-photochlordane and *cis*-chlordane toxicity to mice and houseflies was about the same (Podowski et al. 1979), which demonstrates the difficulty in generalizing about the comparative toxicity of chlordane isomers.

Amphibians and Reptiles

Shortly after chlordane was applied to wooden huts in Australia for termite control, large numbers of dead skinks *(Morethia boulengeri, Lerista puctorittata)* and frogs *(Litoria caerulea, L. peronii)* were discovered, presumably killed by the chlordane (Henle 1988). Toad *(Bufo arenarum)* embryos survived 0.5 mg technical chlordane per liter for 8 days but died by day 20; all embryos held in 15 mg/L were dead by day 15 (Juarez and Guzman 1984). For tadpoles of the common toad *(Bufo bufo)* a 48-h LC50 of 2 mg/L was reported (WHO 1984).

Birds

Signs of chlordane intoxication in birds include sluggishness, drooped eyelids, fluffed feathers, low crouching on perch, reduced food intake, and weight loss. Later, afflicted animals rested on their breasts, wings spread, quivering and panting rapidly, back arched, neck arched over the back, and convulsing (Stickel et al. 1983). Signs of intoxication appeared within 5 min, and death usually occurred in the first 8 days of exposure; remission took up to 4 weeks in some birds (Hudson et al. 1984).

The most sensitive birds tested against technical chlordane were California quail *(Callipepla californica),* with an acute oral LD50 of 14.1 mg/kg BW; ring-necked pheasant (*Phasianus colchicus*), with an acute oral LD50 of 24 to 72 mg/kg BW; and European starlings (*Sturnus vulgaris*) fed diets containing 1.5 mg/kg ration for 57 days or 6.25 mg/kg for 24 days (Table 4). Accumulations of various chlordane isomers and metabolites were evident in chickens (*Gallus* sp.) fed diets containing as little as 0.1 mg technical chlordane per kilogram of feed for 6 weeks or 0.3 mg/kg for 4 weeks (NRCC 1975). Vapor toxicity of chlordane is persistant. In one instance, a room used for housing rock doves was sprayed with a chlordane solution; walls and floors were then scrubbed and the room left unoccupied for 2 months. When rock doves were returned to the room, enough chlordane remained to be lethal to all birds (Ingle 1965). Similar cases are reported for mice, presumably after use of very concentrated chlordane solutions (Ingle 1965).

Table 4. Chlordane effects on selected birds.

Organism and other variables	Effect	Reference
Red-winged blackbird, *Agelaius phoeniceus*, fed diets containing		
10 mg/kg for 84 days	Residue of 1.8 mg *cis*-chlordane per kilogram body weight (BW), fresh weight (FW)	Stickel et al. 1983
50 mg/kg for 42 days	Whole body *cis*-chlordane content of 9.2 mg/kg FW	Stickel et al. 1983
100 mg/kg for 21 days	Whole body *cis*-chlordane content of 14.8 mg/kg FW	Stickel et al. 1983
Plus 3 or 7 days off dosage	Whole body *cis*-chlordane content of 5.4 and 2.6 mg/kg FW, respectively	Stickel et al. 1983
200 mg/kg diet	LD50 within 9 days	Stickel et al. 1983
Mallard, *Anas platyrhynchos*		
Single oral dose, age 4–5 months, 1,200 mg/kg BW	LD50	Hudson et al. 1984

858 mg/kg diet for 5 days followed by 3 days of clean diet, ducklings age 10 days	LD50	Hill et al. 1975
709 mg/kg diet	LD50	NRCC 1975
Birds, 4 species, from marsh treated with 1.12 kg chlordane per hectare	No reproduction in blue-winged teal (*Anas discors*) and northern shovelers (*Anas clypeata*); reproduction inhibited by 60% in coots (*Fulica americana*) and red-winged blackbirds (*Agelaius phoeniceus*); disruption of food cycles in marsh was probable cause	NRCC 1975
Birds, 4 species, fed diets containing 71% cis-chlordane and 23% *trans*-chlordane at 50–500 mg/kg diet	Oxychlordane concentrations in brain of dead birds ranged from 9.4–22.1 mg/kg FW in brown-headed cowbirds (*Molothrus ater*), common grackles (*Quiscalus quiscula*), and red-winged blackbirds. In European starlings (*Sturnus vulgaris*), oxychlordane ranged from 5.0 to 19.1 mg/kg FW in birds that died, and from 1.4 to 10.5 mg/kg FW in sacrificed birds	Stickel et al. 1983
Birds, 3 species, fed diets containing 150 mg technical chlordane per kilogram	LD50 reached in 6–7 days for starlings, cowbirds, and red-winged blackbirds	Stickel et al. 1979
California quail, *Callipepla californica*		
Single oral dose of 14.1 mg/kg BW	LD50	Hudson et al. 1984
Northern bobwhite, *Colinus virginianus*		
10–120 mg/kg diet for 14 weeks	LD50	NRCC 1975; WHO 1984
250 mg/kg diet for 10 days, juveniles	LD50	WHO 1984
250 mg/kg diet for 100 days, adults	LD50	WHO 1984
Japanese quail, *Coturnix japonica*		
25 mg/kg diet, 4 weeks	No effect on survival, weight gain, or activity	NRCC 1975
200 mg/kg diet, 7 days	LD100	NRCC 1975
14-day-old chicks fed treated diets for 5 days, then untreated diets for 3 days		
203 mg/kg diet	No effect on survival or food consumption	Hill and Camardese 1986
308 mg/kg diet	LD50	Hill and Camardese 1986
370 mg/kg diet	LD73, reduced food consumption	Hill and Camardese 1986
500 mg/kg diet	LD93, reduced food consumption	Hill and Camardese 1986
Chicken, *Gallus* sp.		
Fed diet containing 0.1 mg/kg for 6 weeks	Egg chlordane residue about 0.2 mg/kg FW, and fat residue about 0.33 mg/kg FW	NRCC 1975
Adults fed diet containing 0.3 mg/kg for 4 weeks	No adverse effects on growth, egg hatchability, or chick growth	NRCC 1975
Fed diet containing 10 mg/kg for 5 days	Egg chlordane residue about 4 mg/kg FW	NRCC 1975
220–230 mg/kg BW	Acute oral LD50	NRCC 1975
Ring-necked pheasant, *Phasianus colchicus*		
Single oral dose of 24–72 mg/kg BW	LD50	Hudson et al. 1984
50 mg/kg diet for 100 days, juveniles	LD50	WHO 1984
318 mg/kg diet	LD50	NRCC 1975
430 mg/kg diet for 5 days, then clean diet	LD50	Hill et al. 1975

for 3 days, juveniles		
European starling, *Sturnus vulgaris*		
Fed diet containing 1.5, 6.25, 25 or 100 mg chlordane per kilogram	Time for 50% mortality was 57 days for 1.5 mg/kg diet, 24 days for 6.25 mg/kg diet, 6.5 days for the 25 mg/kg diet, and 3.25 days for the 100 mg/kg diet	Stickel et al. 1979
Fed diet containing 100 mg nonachlor per kilogram for 35 days	8% dead	Stickel et al. 1983
200 mg chlordane per kilogram diet	LD50 usually within 14 days	Stickel et al. 1983
500 mg chlordane per kilogram diet	LD50 in 5 days	Stickel et al. 1983
Common barn owl, *Tyto alba*, adults		
Fed diets containing 75 mg/kg until 50% died; survivors sacrificed and residues measured	Mortality reached 50% on day 40. Maximum residues in brains of birds dying during exposure (or sacrificed), in mg/kg FW, were 6.5 (9.0) for *cis*-chlordane, 4.5 (9.0) for trans-nonachlor, 3.2 (9.0) for trans-chlordane, and 1.0 (2.0) for cis-nonachlor	O. H. Pattee, Patuxent Wildlife Research Center, personal communication
Fed diets containing 150 mg/kg until 50% died; survivors sacrificed and residues measured	Mortality reached 50% on day 17. Maximum residues in brains of owls dying during exposure (or sacrificed), in mg/kg FW, were 5.1 (1.8) for *cis*-chlordane, 3.6 (1.8) for *trans*-chlordane, 3.2 (2.1) for *trans*-nonachlor, and 0.9 (0.4) for *cis*-nonachlor	O. H. Pattee, Patuxent Wildlife Research Center, personal communication

Reproductive impairment was reported in several species of waterfowl from a marsh treated with 1.12 kg technical chlordane per hectare (Table 4). Recent studies by Lundholm (1988) with two species of ducks *(Anas* spp.) and the domestic chicken (*Gallus* sp.) demonstrated that various organochlorine compounds, including chlordane, interfered (in a dose-dependent manner) with reproduction by reducing the binding of progesterone to its cytoplasmic receptor in the shell gland mucosa of birds, especially ducks.

The lethal effect of technical chlordane in birds is attributed primarily to chlordane metabolites, especially oxychlordane, and to a lesser extent heptachlor epoxide (Stickel et al. 1983). Oxychlordane was the most persistent chlordane component in avian brain tissues. The half-time persistence of oxychlordane in brain was 63 days, and 95% loss was estimated in 280 days; the Tb 1/2 for heptachlor epoxide was 29 days, and for *trans*-nonachlor it was 19 days (Stickel et al. 1979). Oxychlordane residues in brain tissue approaching 5 mg/kg FW were considered within the lethal hazard zone to birds (Stickel et al. 1979).

Technical heptachlor contains about 15 % *cis*-chlordane and 2.5% *trans*-chlordane. Diets containing 50 mg technical heptachlor per kilogram fed to brown-headed cowbirds *(Molothrus ater),* red-winged blackbirds *(Agelaius phoeniceus),* common grackles *(Quiscalus quiscula),* and European starlings produced 50% mortality in 9 to 24 days; birds that died contained 9.2 to 27 mg oxychlordane per kilogram of FW brain and survivors contained 2.7 to 7.8 mg/kg (Stickel et al. 1979). Red-winged blackbirds were fed diets containing 10 mg technical chlordane per kilogram for 84 days, 50 mg/kg for 42 days, or 100 mg/kg for 21 days; all contained about 17% of the total diet fed as *cis*-chlordane, with whole body residues in mg/kg FW of 1.8, 9.2, and 14.8; accumulations of *trans*-chlordane were negligible (Sticker et al. 1983).

Chlordane interactions with other agricultural chemicals are significant and merit additional research. In one study, male Japanese quail *(Coturnix japonica)* pretreated for 8 weeks with 10 mg chlordane per kilogram of diet had increased resistance to parathion, but not to paraoxon, as judged by cholinesterase activity (Ludke 1977). In another study, northern bobwhites *(Colinus virginianus)* treated with 10 mg chlordane per kilogram of diet for 10 weeks, followed by endrin stress, had greater accumulations of chlordane in the brain than did birds treated only with chlordane (Ludke 1976).

Mammals

Concern for the continued widespread use of chlordane is centered around its carcinogenicity in mice, *Mus* sp. (Ewing et al. 1985). Chlordane produced liver cancer in both sexes of two different strains of domestic mice (EPA 1980; WHO 1984; Tojo et al. 1986; Table 5). A dose-dependent incidence of hepatocellular carcinoma was evident in mice fed chlordane in their diets; frequency of liver carcinomas was not significantly different from controls at dietary levels of 5 mg/kg and lower but were greatly elevated (i.e., 70% frequency) at dietary levels of 50 mg/kg and higher (EPA 1980). In contrast to mice, chlordane was not a hepatic carcinogen in rats at dietary levels up to 64 mg/kg ration (WHO 1984; EPA 1988); however, a dose-related increase in follicular cell thyroid neoplasms and malignant fibrous histocytomas was recorded in chlordane-exposed rats Ohno et al. 1986). In humans, no increased evidence of cancer was proven among employees in chlordane manufacturing facilities, although there was a statistically significant increase in death rate from cerebrovascular disease in that group (Klaassen et al. 1986).

Human toxicity data for chlordane usually are obtained after accidental exposure through spillage onto clothing or ingestion (Ingle 1965; NRCC 1975; EPA 1980). In one case, a 15-month-old girl accidentally swallowed a mouthful of chlordane suspension and within 3 h displayed tremors and incoordination. Repeated seizures developed and she was treated with ethyl chloride, amobarbitol, and gastric lavage with magnesium sulfate; ataxia and excitability disappeared in about 3 weeks. At age 26, she was in excellent health and seemed not to have experienced latent effects from the childhood incident (WHO 1984). Other cases of accidental chlordane poisoning in children are documented, and all seem to have recovered completely after treatment (WHO 1984).

Symptoms of acute chlordane poisoning in humans include irritability, salivation, labored respiration, muscle tremors, brain wave abnormalities, incoordination, convulsions, deep depression, and sometimes death (IARC 1979; EPA 1980, 1988). Signs of acute chlordane intoxication in other mammal species are similar to those in humans and may also include aplastic anemia and acute leukemia; cyanosis; pathology of gastrointestinal tract, liver, kidney, lung, and heart; pulmonary congestion; degenerative changes in the central nervous system; impaired uptake and utilization of glucose; interference with immunocompetence response; diarrhea; avoidance of food and water; enhanced estrone metabolism; increased production of hepatic mixed function oxidase enzymes; altered enzyme activity in brain and in kidney cortex; enlarged liver; hair loss; abdominal distention; hunched appearance; inhibited oxidative phosphorylation in liver mitochondria; and thyroid carcinoma (Saxena and Karel 1976; IARC 1979; Reuber and Ward 1979; WHO 1984; Barnett et al. 1985; Johnson et al. 1986, 1987; Klaassen et al. 1986; EPA 1988; Suzaki et al. 1988). Acute oral LD50 values for technical chlordane and sensitive mammals usually ranged between 25 and 50 mg/kg BW (Table 5). Chlordane-related compounds (i.e., *cis*-chlordane, *trans*-chlordane, heptachlor, heptachlor epoxide) stimulate superoxide (O_2^-) generation in guinea pig leucocytes, alter membrane potential, and increase intracellular calcium concentration; toxicity of individual compounds seems to be related to superoxide generation (Suzaki et al. 1988). Metabolism of chlordane isomers results in oxychlordane, a metabolite that is about 20 times more toxic to rats than is the parent compound and is the most persistent metabolite stored in rat adipose tissue (Menzie 1978; EPA 1980). Oxychlordane accounted for 53% in females and 63% in males of all chlordane isomers in fat of rats killed 24 h after a single oral dose of 1.0 mg/kg BW technical chlordane (Nomeir and Hajjar 1987). Acute oral LD50 values in the rat, in mg/kg BW, were 19.1 for oxychlordane; 89 to 392 for *cis*-chlordane; 200 to 590 for technical chlordane; 327 for *trans*-chlordane; >4,600 for chlordane, 3-chlordene, 1-hydroxychlordene, chlordene epoxide, 1-hydroxy, and 2,3-epoxy chlordane; and >10,000 for 2-chlorochlordene (Table 5).

Chlordane adversely affects growth and fertility of laboratory animals (Talamantes and Jang 1977; IARC 1979; Klaassen et al. 1986; EPA 1988; Table 5). Neonatal exposure of mice to chlordane retards growth, as judged by lowered body weights during the first 12 weeks (Talamantes and Jang 1977). No fetotoxic or teratogenic effects were observed in rats born to dams fed chlordane in their diets for 2 years at levels up to 300

mg/kg diet; however, pups nursed by dams consuming chlordane at 150 or 300 mg/kg diet developed signs of toxicity (EPA 1988). In uterine mucosa of the rabbit, chlordane isomers (as well as isomers of DDE and polychlorinated biphenyls) reduced the binding of progesterone to its cytoplasmic receptor in a dose-dependent manner, which suggests a pathway to account for chlordane-induced reproductive impairment (Lundholm 1988).

Table 5. Chlordane effects on selected mammals.

Organism, dose, and other variables	Effects	Reference
Cow, *Bos bovis*		
Oral doses equivalent to 1, 10, or 100 mg/kg diet for 60 days, then no dose for 30 days	At 1 mg/kg diet equivalent, total chlordane in fat increased from 0.24 mg/kg at day 30 to 0.47 at day 60; 30 days later, residues remained elevated at 0.45 mg/kg. The same pattern was seen at higher dose levels but residues were higher at 1.2–1.5 mg/kg in the 10 mg/kg diet group, and 2.6–4.0 in the 100 mg/kg group	Nomeir and Hajjar 1987
Fed diets containing 10 mg/kg for 10 days	Milk contained less than 50 µg/L	NRCC 1975
Fed diets containing 20 mg/kg for 150 days	Milk contained less than 200 µg/L	NRCC 1975
25–90 mg/kg body weight (BW)	Acute oral LD50	WHO 1984
Dog, *Canis familiaris*		
Fed diets containing 0.3, 3, 15, or 30 mg chlordane per kilogram of food for 2 years	Liver abnormalities in 15 and 30 mg/kg groups; no adverse effects at lower doses on behavior, appearance, survival, weight gain, or blood chemistry. In the 3 mg/kg group, equivalent to 0.075 mg/kg BW daily, maximum residue in fat was 3.6 mg/kg	NRCC 1975; WHO 1984; EPA 1988
Daily oral dose ranging between 5 and 200 mg/kg BW	Dose-dependent mortality. All died between 25 days and 93 weeks	WHO 1984
Single oral dose of 200–700 mg/kg BW	No deaths	WHO 1984
Goat, *Capra* sp.		
180 mg/kg BW	Acute oral LD50	WHO 1984
Guinea pig, *Cavia* spp.		
Males exposed daily for 90 days to 67 mg/kg BW through dermal painting	Mild degenerative changes in skin and testes	WHO 1984
Hamster, *Cricetus* spp.		
1,720 mg/kg BW	Acute oral LD50	EPA 1980; WHO 1984
Human, *Homo sapiens*		
100 µg/L	Reduced growth and altered cell morphology in human cell cultures	EPA 1980
25–50 mg/kg BW	Acute lethal oral dose	WHO 1984
100 mg/kg BW	Fatal	IARC 1979
Female swallowed 6g of chlordane, equivalent to 104 mg/kg BW	Death in 9 days	WHO 1984
Contamination of water supply in Chattanooga, Tennessee, by up to 1.2 g	Gastrointestinal and neurological symptoms in 13 reported cases	WHO 1984

chlordane per liter		
Cynomolgus monkey, *Macaca* spp.		
Inhalation for 90 days of air containing 10 µg technical chlordane per liter	No measurable effect	Khasawinah et al. 1989
Indian desert gerbil, *Meriones hurrianae*		
Males dosed intramuscularly at 2.5 mg/kg BW every 3 days for 45 days	Hyperproteinemia, hyperglycemia, and enhanced serum alkaline and acid phosphatase activities	WHO 1984
Single intramuscular injection of 25, 50, or 75 mg/kg BW	Dose-dependent hyperglycemia, due to increased production of liver glucose in blood of treated animals, reaching a maximum glucose level about 1 h after injection, persisting for up to 3 days, and approaching control levels within 1 week	Saxena and Karel 1976
Mouse, *Mus* spp.		
On days 2, 3, and 4 of life, each received 0.075 or 0.15 mg of either *cis*-chlordane or *trans*-chlordane	Depressed growth and delayed development in eye and vaginal opening during first 12 weeks; all normal at necropsy after 15 weeks	Talamantes and Jang 1977
Oral doses of 0.08 or 0.25 mg daily for 30 days, equivalent to 100 and 300 mg/kg BW	Significant dose-related reduction in size of seminiferous tubules and in percentage of damaged tubules. High dose group experienced 24–58% reduction in spermatogenesis (and high death rate), low dose group 11–21% reduction, and controls 0.5–6.1% reduction	Balash et al. 1987
0.09 mg/kg BW daily for 2 years, equivalent to 0.76 mg/kg diet	Increased liver to BW ratios in both sexes. At higher dietary concentrations equivalent to 0.43 and 1.1 mg/kg BW daily, liver necrosis was observed in males	EPA 1988
Daily oral doses for 14 days of 0.1, 4, or 8 mg *trans*-chlordane per kilogram BW	Significant dose-related increase in liver weight and leukocytes; no effect on immunocompetence	Johnson et al. 1986
Pregnant females treated with 0.16 or 8 mg/kg BW throughout gestation	Decreased immune competence in offspring of high-dose group challenged with oxazolone at age 101 days	WHO 1984
Single oral dose of *cis*-chlordane of 1.0 mg/kg BW	Peak tissue concentrations reached, in µg/kg FW, were 1,180 in liver, 880 in fat, 349 in kidney, 248 in lungs, 164 in muscle, 92 in testes, and 68 in brain. Peak concentration in blood of 113 µg/L reached in 8 h; 34% of total dose excreted in feces by 12 h after treatment. After 14 days, measurable residues detected in gonad, muscle, fat, and kidney	Ewing et al. 1985
Offspring from parents given 1.0 or 2.5 mg/kg BW for 7 consecutive days	Impaired conditioned avoidance response behavior, and hyperactivity	WHO 1984

Fed diets containing 5, 25, or 50 mg technical chlordane per kilogram ration for 18 months	Dose-related incidence of hepatic nodular hyperplasias in the 25 and 50 mg/kg diets and an increased incidence of hepatomas in the male 5 and 25 mg/kg groups. Controls experienced a high incidence of premature deaths	Epstein 1976
Females injected intraperitoneally with 25 mg/kg BW once weekly for 3 weeks	Fertility reduced by about 50%	EPA 1988
Fed diets containing 25 to 100 mg chlordane per kilogram food for six generations	At 100 mg/kg, decreased viability in first and second generations and no offspring in third generation. At 50 mg/kg, viability was reduced in fourth and fifth generations. No significant effects in the 25 mg/kg group, even after six generations	WHO 1984
Males fed diets containing 29.9 or 56.2 mg technical chlordane per kilogram for 80 weeks	Frequency of liver tumors was 88% in high-dose group, 33% in low-dose group, and 19% in controls	EPA 1980
Females fed diets containing 30 or 64 mg technical chlordane per kilogram for 80 weeks	Frequency of liver tumors was 70% in high-dose group, 6% in low-dose group, and 4% in controls	EPA 1980
Males given single dose of 50 or 100 mg/kg BW, then mated with untreated females	No dominant lethal changes produced	EPA 1980
390–430 mg/kg BW	Acute oral LD50	IARC 1979; EPA 1980
Rabbit, *Oryctolagus* sp.		
Oral doses of 1, 5, or 15 mg/kg BW daily on days 6–18 of gestation	Some miscarriages in 1 and 15 mg/kg groups; no changes in behavior, appearance, or body weight; no teratogenic effects observed	WHO 1984
Dosed orally with 14.3 mg of radiolabeled *trans*-chlordane daily for 10 weeks and killed 2 weeks after the last dose	Residues were highest in abdominal and subcutaneous fat (235 mg/kg FW), followed by heart and spleen (75–91 mg/kg), then liver, brain, and blood (25–44 mg/kg)	Nomeir and Hajjar 1987
20 mg/kg BW, single intravenous injection	LD74	Ingle 1965
Dermal exposure for 90 days, equivalent to 20–40 mg/kg BW	LD50	WHO 1984
Dosed orally with *cis*-chlordane at 67 mg/kg BW, or *trans*-chlordane at 30 mg/kg BW every 4 days for a total of 4 doses, then killed 5 days after the last dose	Residues in the *trans*-chlordane group were higher (17–77 mg/kg) than in the *cis*-chlordane group (8–67 mg/kg) although *trans*-chlordane was administered at a much lower dose. Fat and kidney usually contained the highest concentrations, and brain the lowest. Oxychlordane was measured in all tissues at 0.1 mg/kg in brains, 11 mg/kg in fat, and 0.5 to 2 mg/kg in liver, muscle, and kidney	Nomeir and Hajjar 1987
100–500 mg/kg BW	Acute oral LD50	Ingle 1965; EPA 1980
780–1,200 mg/kg BW	Acute dermal LD50; death preceded by skin	WHO 1984

	irritation, tremors, and convulsions	
Sheep, *Ovis aries*		
Single oral dose of 500 mg/kg BW	Incoordination and partial blindness; full recovery in 5–6 days	WHO 1984
Single oral dose of 1,000 mg/kg BW	Severe respiratory and nervous signs in 16 h, and death in 48 h	WHO 1984
Baboon, *Papio anubis*		
Fed diets containing chlordane, equivalent to 0.1–1.0 mg/kg BW daily, for 2 years	At 1.0 mg/kg BW, cytochrome P-450 activity was significantly increased, but no other significant effects were recorded on general health or on any major organ system	WHO 1984
Rat, *Rattus* spp.		
Inhalation of air for various intervals containing technical chlordane		
0.1 µg/L, 90 days	Adverse biological response	Khasawinah et al. 1989
5.8 or 28.2 µg/L, 28 days	No measurable difference from controls at low dose; impaired liver function at high dose	Khasawinah et al. 1989
154 µg/L, 5 days	Death	Khasawinah et al. 1989
413 µg/L, 2 days	Death	Khasawinah et al. 1989
Fed technical chlordane at dietary levels of 1, 5, or 25 mg/kg, equivalent to daily doses of 0.045, 0.229, and 1.175 mg/kg BW respectively, for 130 weeks (2.5 years)	No significant effects on hematology, clinical chemistry, body weight, or survival rate. Dose-dependent hepatocellular necrosis (34% in high-dose group); liver adenomas in males and hepatocellular swelling in females from the high-dose group	EPA 1988
0.05 mg radiolabeled *trans*-chlordane per kilogram BW, single oral dose, residues measured over 96 h after exposure	Maximum resides, in mg/kg FW, and time after administration were: liver, 0.1, 2 h; adipose tissue, 0.09, 96 h; kidney, 0.07, 4 h; skin, 0.03, 8 h; brain, 0.01, 4 h; muscle, 0.008 4 h; and blood 0.003, 4 h. Half-time persistence was 6.5–13 h for the rapidly decreasing phase and 4.8–8.9 days for the slowly decreasing phase	Ohno et al. 1986
Daily intraperitoneal injections of technical chlordane at 0.15, 1.75, or 25 mg/kg daily for 42 days	Dose-dependent alterations of brain potentials without behavioral signs of chronic toxicity	EPA 1980
Single oral dose of 0.2 mg/kg BW of *cis*-chlordane, *trans*-chlordane, or oxychlordane	Maximum residues in fat after 24 h, in mg/kg FW, were 0.3 for *cis*-chlordane, 0.7 for *trans*-chlordane, and 0.5 for oxychlordane	Nomeir and Hajjar 1987
Single oral dose of 0.2 or 1.0 mg/kg BW technical chlordane	Maximum residues in fat at 24 h, in mg/kg FW, were 0.5 for the low-dose group, and 3.7 for the high-dose group	Nomeir and Hajjar 1987
Fed diets containing 0.3, 3, 15, 30, or 60 mg technical chlordane per kilogram diet for 3 generations	Levels up to and including 30 mg/kg diet had no measurable effect on fertility, number of young produced, growth, or mortality rate; no gross or microscopic differences between the	NRCC 1975; WHO 1984

	groups. At 60 mg/kg, the second F_3 generation litters had elevated mortality (11%) during the latter part of the nursing period; these animals also showed gross and microscopic pathology	
Single oral dose of 1.0 mg *cis*-chlordane per kilogram BW	Peak tissue concentration, in mg/kg FW, were noted within 4 h after treatment: liver, 1.9; fat, 1.2; kidney, 0.7; lung, 0.3; brain 0.2; testes, 0.1; muscle, 0.1; and blood, 0.08. After 12 h, 7% was excreted, and after 3 days, 83% was voided	Ewing et al. 1985
Single oral dose of 1.0 mg/kg BW	About 50% excreted in feces after 1 day and 90% in 7 days; only 2–3% of the dose was detected in the urine	Nomeir and Hajjar 1987
Fed oxychlordane in diets for 90 days at rate equivalent to 2.0 mg/kg BW daily	No gross pathology or histological lesions	NRCC 1975; WHO 1984
Fed 2.5, 25, or 75 mg technical chlordane per kilogram of diet for 2 years	Severe toxic signs at 25 and 75 mg/kg; liver damage at 2.5 mg/kg diet	WHO 1984
Long-term feeding studies at dietary concentrations between 5 and 320 mg technical chlordane per kilogram	Reduced survival and growth at dietary levels >150 mg/kg; liver enlargement and micropathology at >20 mg/kg; no effect on reproduction at 150 mg/kg diet; no adverse effects at 5 mg/kg diet	Ingle 1965
Fed *cis*-chlordane at dietary levels of 0.5, 15, 25, or 35 mg/kg	Increased mortality and growth retardation in 4–5 months at 35 mg/kg diet; growth normal in other groups; some liver damage in 25 and 35 mg/kg groups	WHO 1984
Daily oral dose of 6.5–25 mg technical chlordane per kilogram BW, for 15 days	No tremors or convulsions; however, dose-related liver pathology was noted	WHO 1984
Single oral dose of 10 mg radiolabeled *trans*-chlordane per kilogram BW	Maximum residues, in mg/kg FW and time after administration were: liver, 21, 4 h; kidney, 18, 4h; adipose tissue, 11, 16 h; skin, 5, 8 h; brain, 3.4, 4 h; muscle 1.4, 4 h; and blood, 0.6, 4 h; half-life of 5–12 h for the fast component, and 4.3–7.3 days for the slow component	Ohno et al. 1986
Fed diets containing 15 or 25 mg/kg of *cis*-chlordane for 78 weeks	No adverse effects on liver at 15 mg/kg diet; some effects at 25 mg/kg	NRCC 1975
Fed *trans*-chlordane at dietary levels of 15, 25, 35, or 75 mg/kg diet	Decreased survival, liver damage, and growth retardation of males in 8 months at 75 mg/kg diet; growth normal at other doses	WHO 1984
19.1 mg oxychlordane per kilogram BW	Acute oral LD50	WHO 1984
20 mg technical chlordane per kilogram diet for 350 days	Residues in mg/kg FW, were about 20 for adipose tissue, 0.8 for liver, and 0.2 for heart	NRCC 1975
Daily oral doses of 25 mg/kg BW for 15 days	No toxic signs	EPA 1980

Fed diets containing 35 mg/kg *trans*-chlordane for 78 weeks	No adverse effects on liver	NRCC 1974
Daily oral dose of 50 mg technical chlordane per kilogram BW for 15 days	2 of 5 rats died; toxic signs in survivors	WHO 1984
83–392 mg/kg BW	Acute oral LD50 for *cis*-chlordane	EPA 1980, 1988
Fed diets containing 100 or 200 mg/kg ration of *cis*-chlordane or *trans*-chlordane for 11–15 days	Maximum residues, in mg/kg lipid, in females fed 100 mg/kg *cis*-chlordane were 23 for *cis*-chlordane and 100 for oxychlordane; for the 200 *cis*-chlordane group, levels were 48 for *cis*-chlordane and 182 for oxychlordane. Females fed 100 mg/kg *trans*-chlordane had 10 mg/kg lipid of *trans*-chlordane and 201 of oxychlordane; for the 200 mg/kg group, residues were 23 mg/kg lipid of *trans* chlordane and 470 of oxychlordane; for all groups, residues in males were x6–21 lower than in females	Nomeir and Hajjar 1987
Fed diets averaging 121 and 241 mg/kg feed (females) and 203 and 407 mg technical chlordane per kilogram diet (males) for 80 weeks	Increased mortality, tremors, growth reduction; elevated incidence of thyroid neoplasms and malignancies in all treated animals, but no hepatocellular carcinomas	IARC 1979; EPA 1988
137 mg/kg BW	Acute oral LD50 for rats fed a low protein diet	EPA 1980
200–590 mg technical chlordane per kilogram BW	Acute oral LD50	NRCC 1975; EPA 1980; WHO 1984
205 mg technical chlordane per kilogram BW	Acute dermal LD50 for females	WHO 1984
Fed diets containing 300, 500, or 1,000 mg technical chlordane per kilogram	75% dead at 300 mg/kg diet after 100 days; all dead in 70 days at 500 mg/kg, or in 10 days at 1,000 mg/kg	WHO 1984
311 mg/kg BW	Acute oral LD50 for rats fed a normal protein diet	EPA 1980
Fed diets containing 320 mg technical chlordane per kilogram from weaning	Reduced sexual activity, reduction in number of viable litters, increase rate of death of progeny before weaning	WHO 1984
327 mg *trans*-chlordane per kilogram BW	Acute oral LD50	EPA 1980; WHO 1984
335 mg/kg BW	Acute oral LD50 for males	IARC 1979
343 mg/kg BW	Acute intraperitoneal (IP) LD50 for adults	EPA 1980
350 mg/kg BW	IP injection produced mild tremors and disorientation within a few minutes, and death within 60 min	EPA 1980
530–690 mg/kg BW	Acute dermal LD50 for females	EPA 1980; WHO 1984
539 mg/kg BW	Acute IP LD50 for newborns pretreated with 40 mg/kg BW phenobarbitol	EPA 1980
840 mg/kg BW	Acute dermal LD50 for males	EPA 1980
1,121 mg/kg BW	Acute IP LD50 for newborns	EPA 1980
Oral administration, in mg/kg BW, of 4,600	Less than 50% dead	WHO 1984

chlordene, 4,600 3-chlorochlordene, 4,600 1-hydroxychlordene, 4,600 chlordene epoxide, 4,600 1-hydroxy, 2, 3-epoxy chlordene, or 10,200 2-chlorochlordene		
Pig, *Sus* spp.		
Fed diet containing 300 mg/kg of *cis*-chlordane or *trans*-chlordane for 60–90 days	Residues of total chlordanes in fat ranged from 9 mg/kg to 72 mg/kg; values were highest for *trans*-chlordane and lowest for *cis*-chlordane	NRCC 1975

Chlordane tends to accumulate in adipose tissues and, to a lesser extent, in liver (Table 5). In general, animals given a single oral dose of chlordane eliminated 80 to 90% of the dose within 7 days, usually by way of the feces; the *cis* isomer is eliminated more rapidly than the *trans* isomer and results in preferential accumulations of *trans*-chlordane (Nomeir and Hajjar 1987). In rats, *trans*-chlordane is rapidly absorbed and distributed to liver and kidney at single oral dosages as low as 0.05 mg/kg BW Ohno et al. 1986). Rabbits fed *trans*-chlordane for 10 weeks excreted 70% of accumulated chlordane during the following 2 weeks on a chlordane-free diet (Menzie 1974). Treatment with *trans*-chlordane resulted in a greater percentage of oxychlordane in fat than did treatment with *cis*-chlordane. When chlordane was removed from the diet of treated animals, levels in fat declined 60% at a relatively steady rate over 4 weeks, but then only slightly thereafter; accumulations in liver, kidney, brain, and muscle were much lower than in fat, but excretion kinetics were similar (Nomeir and Hajjar 1987).

Results of chronic feeding studies show that dietary concentrations of chlordane between 0.76 and 5 mg/kg ration did not affect survival but did produce adverse effects on various species of laboratory animals and livestock (Table 5). Dietary concentrations of 0.76 mg/kg (equivalent to 0.09 mg/kg BW daily) were associated with enlarged livers in mice, 1.0 mg/kg produced elevated residues in cow's milk, 2.5 mg/kg resulted in liver pathology in rats, 3 mg/kg (equivalent to 0.075 mg/kg BW daily) produced high residues in fat of dogs, and 5 mg/kg caused liver pathology in mice (Table 5).

Negative results for mutagenicity of *cis*-chlordane and *trans*-chlordane were reported in various strains of bacteria and in hepatocyte cultures of small mammals. But technical chlordane proved mutagenic to selected strains *of Salmonella typhimurium* and induced gene conversions in certain strains of the yeast *Saccharomyces cervisiae* (IARC 1979; EPA 1980, 1988; WHO 1984).

Chlordane interacts with other chemicals to produce additive or more than additive toxicity. For example, chlordane increased hepatotoxic effects of carbon tetrachloride in the rat (EPA 1980; WHO 1984), and in combination with dimethylnitrosamine acts more than additively in producing liver neoplasms in mice (Williams and Numoto 1984). Chlordane in combination with endrin, methoxychlor, or aldrin is additive or more-than-additive in toxicity to mice (Klaassen et al. 1986). Protein deficiency doubles the acute toxicity of chlordane to rats (WHO 1984). In contrast, chlordane exerts a protective effect against several organophosphorus and carbamate insecticides (WHO 1984) protects mouse embryos against influenza virus infection and mouse newborns against oxazolone delayed hypersensitivity response (Barnett et al. 1985). More research seems warranted on interactions of chlordane with other agricultural chemicals.

Recommendations

All use of chlordane was banned in Norway in 1967 (Ingebrigtsen et al. 1984). In August 1975, EPA issued its intent to suspend registrations and prohibit production of all pesticides containing heptachlor or chlordane, based on evidence of carcinogenicity (Glooschenko and Lott 1977). On 1 July 1983, chlordane use was prohibited in the United States for any purpose except to control underground termites; a similar situation exists in Japan (Ohno et al. 1986; Tojo et al. 1986).

The continued use of chlordane, coupled with its general persistence in the environment, suggests that extreme caution be taken in all stages of its manufacture, transport, storage, and application (Greenhalgh 1986).

In particular, chlordane use near marine environments is not recommended because of chlordane's high toxicity to marine life (EPA 1988). At elevated risk of chlordane toxicity in the human population are children, as a result of the milk they consume; fisherman and their families, because of high consumption of fish and shellfish; people living downwind from fields treated with chlordane; and individuals residing in houses treated with chlordane-containing pesticides (EPA 1980).

The proposed criterion for marine life protection of 0.004 µg/L as a 24-hour mean, not to exceed 0.09 µg/L at any time (Table 6), seems to offer a reasonable degree of protection. But the proposed freshwater criterion of 0.0043 µg/L 24-hour average, not to exceed 2.4 µg/L at any time (Table 6), overlaps the range of 0.2 to 3.0 µg/L, shown earlier to be harmful to sensitive species of fish and aquatic invertebrates; accordingly, the maximum permissible freshwater value should be adjusted downward. "Safe" residues in tissues of aquatic biota require clarification, and probably additional research effort. Criteria on chlordane for protection of mammalian wildlife are missing, and those formulated for birds are incomplete and require data on no-observable-effect levels from lifetime exposures (Table 6). Until this information becomes available, it seems prudent to use criteria developed for human health protection as temporary guidelines for the protection of vertebrate wildlife. Specifically, daily intake should not exceed 0.001 mg total chlordane, including chlordane, *trans*-chlordane, and oxychlordane per kilogram BW; and food items should not exceed 0.3 mg/kg FW (Table 6).

Table 6. Proposed chlordane criteria for protection of natural resources of human health.

Resource	Criterion or effective chlordane concentration	Reference[a]
Aquatic life		
Water concentration, safe level		
Fresh water	<0.0043 ug/L, 24-h average; not to exceed 2.4 ug/L at any time	1
Salt water	<0.004 µg/L, 24-h average; not to exceed 0.09 ug/L at any time	1
Tissue concentrations		
Fish		
Reduced survival	>300 mg/kg tissue, lipid weight (LW) basis	2
No observed adverse effect level (NOEL)	<0.1 mg/kg fresh weight (FW) tissue	3
Estuarine invertebrates, lethal	>106 mg/kg tissue LW	2
Birds		
Concentration in brain		
Joint lethal range	1.1–5.5 mg/kg FW for oxychlordane and 3.4–8.3 mg/kg FW for heptachlor epoxide	4, 12
Single lethal range	6 mg/kg FW for oxychlordane or 9 mg/kg FW for heptachlor epoxide	4, 12
Diet, acceptable range, but producing slight elevation in tissue concentrations	0.1–0.3 mg/kg diet	6
Mammals		
Dog, *Canis familiaris*, NOEL	<3 mg/kg diet, equivalent to <0.075 mg/kg body weight (BW) daily	5, 6
Rat, *Rattus* sp., NOEL	<5 mg/kg diet, equivalent to 0.25 mg/kg BW daily	5
Livestock water use, United States	<3 ug/L	

Human health		
Drinking water		
Worldwide	<0.3 ug/L	5
Canada, United States	<3.0 ug/L	1, 7
Chronic, child, United States	<0.5 ug/L	7
Maximum 1-day exposure, adult, USA	63.0 ug/L	7
Increased lifetime risk of cancer, 70-kg adult, 2 L daily[b]		
10^{-4}	2.7 ug/L	7
10^{-5}	0.27 ug/L	7
10^{-6}	0.027 ug/L	7
Acceptable daily intake[e] 70-g adult	<70 ug, equivalent to <0.001 mg/kg BW	1, 3, 5, 6, 8
Diet		
U.S. Food and Drug Administration "action level"	0.3 mg/kg FW	3, 8, 9, 10
Australia	<0.05 mg/kg FW in meats, including oxychlordane	11
Worldwide	Usually <0.3 mg/kg FW, but residue tolerances vary between 0.02 and 0.5 mg/kg FW, based on the sum of *cis*-chlordane, *trans*-chlordane, and oxychlordane	5, 8
Air		
USSR	Maximum allowable concentration of 0.01 mg/m^3	5
Romania	<0.3 mg/m^3, maximum allowed is 0.6 mg/m^3	5
Belgium, Finland, United States, Japan, the Netherlands	<0.5 mg/m^3	1, 5, 7, 8
15-min exposure limit, United States	<2 mg/ m^3	1

[a] 1. EPA 1980; 2. Zitko 1978; 4. Blus et al. 1983; 5. WHO 1984; 6. NRCC 1975; 7. EPA 1988; 8. IARC 1979; 9. 1965; 10. Wood et al. 1986; 11. Petterson et al. 1988; 12. Stickel et al. 1979.

[b] One excess cancer per million (10^{-6}) is associated with lifetime exposure to chlordane in drinking water at concentrations as low as 0.027 µg/L, the most conservative estimate. A lifetime health advisory computation was not possible because chlordane is a probable human carcinogen (EPA 1988).

[c] Consumed fish are considered to be the only source of chlordane; up to 98% of chlordane exposure results from aquatic organisms with high top (up to 14,100 times) bioconcentration potential (EPA 1980). Urban residents should not consume more than 8 ounces (227 g) of dish daily containing 0.03 mg total chordanes per kilogram FW, and nonurban residents up to 1, 135 mg of fish daily containing 0.03 mg/kg FW (Arruda et al. 1987). The value of 0.001 mg/kg BW is based on the no-observed-effect level of 5 mg/kg in the diet of the rat, equivalent to 0.25 mg/kg BW, and 3 mg/kg in the diet of the dog, equivalent to 0.075 mg/kg BW (WHO 1984).

Additional research on chlordane is recommended in nine general areas: (1) monitoring of background concentrations of oxychlordane in wildlife, since this metabolite is more toxic and persistent than the parent chemical (Kawano et al. 1988); (2) interpretation of the biological significance of residue levels found in wildlife; (3) adoption of improved uniform methods of quantitation so that residue levels can be compared, and so that a time estimate of their environmental significance can be made (NRCC 1975; EPA 1988); (4) reexamination of aquatic toxicity data where concentrations tested exceeded the solubility of chlordane in water of 6 to 9 µg/L (WHO 1984); (5) evaluation of interaction of chlordane with other agricultural chemicals, including heptachlor, to clearly delineate any additive, synergistic, or antagonistic effects (WHO 1984); (6) reevaluation of the cancer risk of chlordane to experimental animals (WHO 1984); (7) measurement of chronic exposures of fish and wildlife to realistic environmental levels (WHO 1984); (8) measurement of effects of depleted soil fertility from chlordane-induced earthworm suppression on migratory birds and other wildlife (NRCC 1975; WHO 1984); and (9) continuance of epidemiological studies on workers who have been exposed to chlordane (WHO 1984).

Paraquat Hazards to Fish, Wildlife, and Invertebrates:
A Synoptic Review

by

Laurel, Maryland 20708

Abstract

Paraquat (1,1' -dimethyl-4,4'-bipyridinium) and its dichloride salt (1,1', dimethyl-4, 4'-bipyridinium dichloride) are broad-spectrum contact plant killers and herbage desiccants that were introduced commercially during the past 25 years. Today, they rank among the most widely used herbicides globally and are frequently used in combination with other herbicides. The recommended paraquat field application rates for terrestrial weed control usually range between 0.28 and 1.12 kg/ha (0.25 and 1.0 lb/acre), and for aquatic weed control the range is 0.1 - 2.0 mg/L. Target plant species are unable to metabolize paraquat and tend to contain elevated residues; paraquat-resistant strains of terrestrial flora, whose numbers are increasing, require greater concentrations for control and may contain proportionately greater residues. Paraquat from decayed flora is usually adsorbed to soils and sediments. Paraquat in surface soils generally photodecomposes in several weeks, but paraquat in subsurface soils and sediments may remain bound--and biologically unavailable--for many years without significant degradation.

Paraquat is not significantly accumulated by earthworms and other species of soil invertebrates and is usually excreted rapidly by higher animals; however, delayed toxic effects--including death of birds and mammals--are common. At concentrations below the recommended application rate, paraquat is embryotoxic to developing eggs of migratory waterfowl (0.056 kg/ha) and adversely affects sensitive species of freshwater algae and macrophytes (250 µg/L), larvae of crustaceans (0.9-5.0 µg/L), and frog tadpoles and carp (500 µg/L). Sensitive species of birds are negatively affected at daily dose rates of 10 mg/kg body weight or when fed diets containing 20 mg/kg ration or drinking water containing 40 mg/L. Adverse effects in sensitive mammals were observed at dietary levels of 85 - 100 mg/kg ration and higher or 100 mg/L in drinking water. Acute oral LD50 values for sensitive species of birds were near 200 mg/kg body weight and, for mammals, 22 - 35 mg/kg body weight. Humans are among the more sensitive species, and numerous human poisonings have resulted from accidental or intentional ingestion of a concentrated paraquat formulation.

The biochemical mechanism of paraquat toxicity is due to the cyclic oxidation and reduction in tissues, leading to production of superoxide anion and other free radicals and eventually the highly destructive hydrogen peroxide. The lung is the organ most severely affected in paraquat poisoning, due largely to the preferential accumulation of paraquat in lung alveolar cells. Although many organs are affected by paraquat, death is usually due to progressive pulmonary fibrosis. At present, there is no completely successful treatment for paraquat-induced lung toxicity.

More information is needed in several areas in order to establish effective criteria for the protection of sensitive species of fish and wildlife against paraquat. These include: flux rates of paraquat from soil into terrestrial food chains; biomagnification potential of paraquat in aquatic food chains, with special reference to plants, plant detritus, amphibians, and reptiles, toxicokinetics of mixtures of paraquat and other herbicides applied concomitantly; and the implications of the high sensitivities of crustacean larvae and waterfowl embryos to paraquat. (Eisler, R. 1990. Paraquat hazards to fish, wildlife, and invertebrates: a synoptic review. U.S. Fish and Wildlife Service Biological Report 85 (1.22). 28 pp.

Paraquat (1,1'-dimethyl-4,4'-bipyridinium) is one of the most widely used herbicidal chemicals in the world and is now available in more than 130 countries (Kimbrough 1974; Calderbank 1975; Dasta 1978; Haley 1979; Hughes 1988; L. Smith 1988). Its chemical structure was first described in 1882, its oxidizing and reducing properties in 1933, and its herbicidal properties in 1955. Paraquat was marketed commercially in the United Kingdom in 1962 and registered for use in the United States in 1964. As the dichloride salt, it has found wide use as a nonselective contact herbicide at application rates of 1.12 kg/ha (1 lb/acre) and lower. Useful reviews on ecological and toxicological aspects of paraquat include those by Kimbrough (1974), Smith and Heath (1976), Autor (1977), Dasta (1978), Haley (1979), Summers (1980), Bauer (1983), Onyeama and Oehme (1984), L. Smith (1985, 1988), and J. Smith (1988).

Paraquat kills plants by affecting the green parts, not the woody stems, and is usually completely and rapidly inactivated by contact with clay in the soil. In its bound form, paraquat is biologically inert and innocuous to plants and animals (Fletcher 1974).

Numerous human injuries and deaths have resulted from intentional ingestion of the concentrated commercial product (Fletcher 1974; Dasta 1978; Haley 1979; Crome 1986; J. Smith 1988; L. Smith 1988). For example, in the first 10 years following paraquat commercial use, 232 human deaths from paraquat poisoning were reported (about half were suicides), and almost all were due to the drinking of concentrated material. Most poisonings resulted from the ingestion of the 21 % cation concentrate, which had been decanted and stored in empty beer, soft drink, or lemonade bottles; paraquat is a reddish-brown liquid that resembles root beer or cola drinks. One individual sprinkled paraquat on French fried potatoes, thinking it was vinegar. He died 25 days later. Another died after applying the concentrated solution to his beard and scalp to treat a lice infestation. In Japan, more than 1,000 persons each year are reportedly poisoned by paraquat. Initially, paraquat may produce multiorgan toxicity of kidneys, liver, heart, central nervous system adrenal glands, skeletal muscle, and spleen, but the ultimate target organ is the lung, in which progressive irreversible pulmonary fibrosis develops. This effect has been described in humans, rats, mice, guinea pigs, and dogs (Kimbrough 1974; Giri et al. 1979; Hampson and Pond 1988; O'Sullivan 1989). There is no known specific antidote for paraquat poisoning.

In 1977, the discovery by narcotics authorities that some marijuana imported from Mexico had been treated with paraquat as a control agent generated much interest in the media (Dasta 1978; Haley 1979). Up to 70% of the paraquat in paraquat-treated marijuana is converted, on smoking, to bypyridine, a respiratory irritant. Frequent consumption of heavily contaminated marijuana may result in cyanosis and possibly death. The use of paraquat for this purpose has been largely discontinued.

In normal use as a spray, minor reversible injuries are reported to abraded skin, eyes, nose, and fingernails; it is not absorbed through intact skin (Kimbrough 1974; J. Smith 1988). Paraquat is fetotoxic, as judged by deliberate ingestion of concentrated solutions by nine pregnant Taiwanese women. Paraquat crosses the placenta and concentrates there to levels 4 - 6 times that of maternal blood. All fetuses died whether or not an emergency cesarean section was performed (Talbot and Fu 1988). Recent research has focused on the tendency of paraquat to accumulate in neuromelanin of mammals and amphibians and to cause lesions in the pigmented nerve cells, leading to effects very similar those of Parkinson’s disease (De Gori et al. 1988; Lindquist et al. 1988).

This report is part of a series of brief reviews on hazards of selected chemicals to fishery and wildlife resources. It was prepared in response to requests for information on paraquat from environmental specialists of the U.S. Fish and Wildlife Service.

Uses

Paraquat is a broad-spectrum contact weed killer and herbage desiccant that is used widely in agriculture and horticulture. Paraquat was formulated in 1882, but its herbicidal properties were not discovered until 1955. Since its introduction in the early 1960's, paraquat has been used extensively in about 130 countries--including Canada, the United Kingdom, and the United States--on a wide variety of agricultural crops (Fletcher 1974; Haley 1979; Kelly et al. 1979; Anonymous 1988).

Primary uses of paraquat include weed control in orchards, plantation crops, and forests; weed control before sowing or before crop emergence; pasture renovation; preharvest desiccation; and aquatic weed control, although use as an aquatic herbicide in the United States is not permitted (Anonymous 1963, 1974; Summers

1980; Dial and Bauer 1984). Paraquat is registered for preplant or preemergence use for cotton, barley, corn, lettuce, melons, peppers, potatoes, sallower, soybeans, sorghum, sugar beets, tomatoes, and wheat. It is also registered for use on noncrop areas, such as roadsides, highway margins, rights-of-way, and around commercial buildings, power plants, storage yards, fence lines, and parkways (Anonymous 1963, 1974). In Switzerland, it is used to control voles *(Arvicola terrestris)* in fruit orchards (Summers 1980).

Paraquat is available as the dichloride or dimethylsulfate salt; both compounds are extremely soluble in water (Kimbrough 1974). In the United States, paraquat dichloride is available as a 29% liquid concentrate containing 240 g/L (2 lb/gal) of paraquat cation, or as a 42 % liquid concentrate. Elsewhere, it is sold as Gramoxone liquid, containing 20-24% of paraquat dichloride (Fletcher 1974; Bauer 1983; Dial and Dial 1987a). Paraquat dichloride concentrates usually contain various wetting agents (condensation products of ethylene oxide and alkyl phenols), spreaders, humectants to promote moisture retention (calcium chloride, glycerol, polyethylene glycol), plant adhesion materials (carboxymethylcellulose, polymethacrylates), and antifoaming agents (Summers 1980).

The recommended field application rates for terrestrial weed control usually range between 0.28 and 1. 12 kg paraquat cation per hectare (0.25 and 1.0 lb/acre), or 0.56 and 2.24 kg paraquat dichloride per hectare (0.5 and 2.0 lb/acre)--both applied as an aerosol--and 0.1 and 2.0 mg/L for aquatic weed control, although sensitive aquatic plants may be affected between 0.019 and 0.372 mg/L (Ross et al. 1979; Summers 1980; Bauer 1983; Dial and Bauer 1984).

Paraquat is frequently used in combination with other herbicides (Fletcher 1974; Summers 1980). Water solutions of the dichloride salt, which usually contain 240 g/L, have been successfully mixed with 2,4-D, substituted ureas, dalapon, amitol, and various triazines (Anonymous 1963, 1974).

Background Concentrations

Data are scarce on ecosystems treated with paraquat. It is clear, however, that both terrestrial and aquatic plants accumulate paraquat, and that the compound disappears rapidly from the water column and tends to concentrate in surface muds (Table 1).

Table 1. Paraquat concentrations in field collections of selected organisms and nonbiological materials.

Sample, and other variables	Concentration (mg/kg dry weight)	Reference[a]
Treated fields		
Alfalfa, *Medicago sativa*	Up to 30	1
Grasses, various species	Up to 60	1
Mud, surface; from British lake treated with 0.5 mg/L		
Days after treatment		
1	1.2	2
2	2.4	2
8	6.7	2
32	11.2	2
197	17.7	2
364	8.0	2
Colorado farm pond treated with 1.0 mg/L		
3 h after treatment		
Water	0.6	3
Mud	1.1	3
Submerged plant, *Chara* sp.	320	3
Algae, *Spirogyra* sp.	320	3
4 days after treatment		
Water	0.2	3

Mud	0.8	3
Chara sp.	840	3

Environmental Chemistry

General

Paraquat is a nonvolatile, ionic compound that is almost completely insoluble in organic solvents, which is typical of the bipyridyl group of chemicals. As discussed later, the biochemical mechanism of paraquat toxicity is due to the cyclic oxidation and reduction that occurs in various tissues, especially lung, leading to production of superoxide anion and other free radicals; these chemical species react with polyunsaturated free radicals, eventually forming the highly destructive hydrogen peroxide. Excretion of paraquat is rapid in living organisms, but delayed toxic effects, including death, are not unusual. No treatment or chemical has proven completely successful in protecting against paraquat-induced lung toxicity.

Paraquat is strongly adsorbed to soils and sediments and is biologically unavailable in that form; however, it is not degraded significantly for many years, except in surface soils. In surface soils, paraquat loss through photodecomposition approaches 50% in 3 weeks. In freshwater ecosystems, loss from the water column is rapid: about 50% in 36 h and 100% in 4 weeks. In marine ecosystems, 50-70% loss of paraquat from seawater was usually recorded within 24 h.

Chemical Properties

Paraquat is a nonvolatile, ionic compound that is almost completely insoluble in fat, and therefore not likely to be accumulated in food chains (Calderbank 1975). The compound belongs to the bipyridyl group of chemicals and is typical of the many hundreds that have been synthesized, variation usually being the result of introducing different quaternizing groups on the nitrogen atoms, which also shift (Fletcher 1974; Table 2). Paraquat dichloride is produced from pyridine in the presence of sodium in anhydrous ammonia by quaternizing the 4,4'-dipyridyl with methyl chloride (Haley 1979). The common paraquat salts are all fully ionized, and experiments have shown that the anions (e.g., chloride, sulfate, methyl sulfate) do not affect the toxicity of paraquat (Fletcher 1974). Chemical and other properties of paraquat are briefly summarized in Fig. 1 and Table 2.

Mode of Action

Paraquat is absorbed systematically in mammals, following different routes of exposure; absorption is greatest for the pulmonary route, followed by intragastric and dermal routes (Chui et al. 1988). Administration of paraquat by every route of entry tested frequently results in irreversible changes in the lung (Boudreau and Nadeau 1987). In the intestinal tract, where some microbial degradation occurs, most paraquat (95 - 100%) is usually excreted unchanged in feces and urine within 2 days (Summers 1980). Absorption in the gastrointestinal tract ranges from 0.26% in cows to 5% in humans, 8% in guinea pigs, 16% in cats, and up to 20% in rats; the half-time persistence (Tb 1/2) of paraquat in certain tissues is 20 - 30 min, but up to 4 days in muscle and 2 days in plasma (Bauer 1983). Delayed toxic effects of paraquat occurring after the excretion of virtually all of the material have caused it to be classified as a 'hit and run" compound--that is, a compound causing immediate damage, the consequences of which are not readily apparent (Conning et al. 1969).

Table 2. Chemical and other properties of paraquat (Anonymous 1963, 1974, 1988; Haley 1979; Kelly et al. 1979; Johnson and Finley 1980; Hudson et al. 1984; Hill and Camardese 1986; Mayer 1987).

Variable	Datum
Chemical name	
Paraquat (cation)	1,1'-dimethyl-4,4'-bipyridinium
Paraquat dichloride (salt)	1,1'-diemthyl-4,4'-bipyridinium dichloride
Molecular weight	186.2 (cation); 257.2 (salt)
CAS number	4685-14-17 (cation); $C_{12}H_4Cl_2N_2$ (salt)
Alternate names	Cekuquat, Crisquat, Dextrone, Dextrone X, Dexuron, Dual Paraquat, Esgram, Gramonol, Gramoxone, Gramuron, Herbaxon, Herboxone, Methyl Viologen, Ortho Paraquat, Orvar, Paracol, Paraquat CL, Pathclear, Pillarquat, Pillarxone, Preeglone, PP 148, PP 910, Sweep, Tenaklene Totacol, Toxer Total, Weedol
Solubility at 20º C	
Water	561 g/L
Methanol	144 g/L
Ethanol	1.7 g/L
Acetone	200 mg/L
Most organic solvents	Insoluble or sparingly soluble
Physical state	Solid; white (pure), yellow (technical)
Main uses	Herbicide, desiccant
Specific gravity	1.24–1.26
Melting point	175 C to 180 C, decomposes at 345º C
Stability	Stable on exposure to hot acids; unstable in alkalis at pH >10
Flash point	Nonexplosive, nonflammable
Volatility	Nonvolatile

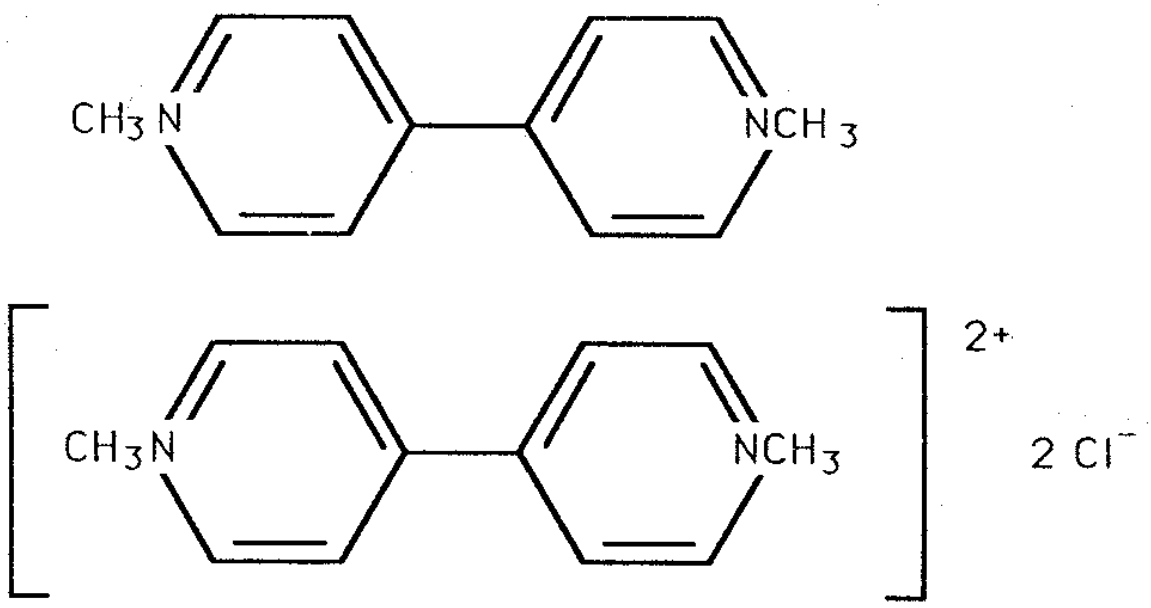

Fig. 1. Structural formula of paraquat cation (*upper*) and of paraquat dichloride salt (*lower*).

Most authorities agree that free radical pathology is the most likely mechanism by which paraquat is cytotoxic (Bus et al. 1976; Frank et al. 1982; Patterson and Rhodes 1982; Combs and Peterson 1983; Onyeama and Oehme 1984; Gabryelak and Klekot 1985; Smith 1985; Wong and Stevens 1986; Seto and Shinohara 1987; Suleiman and Stevens 1987; Darr et al. 1988; Dunbar et al. 1988a; Wegener et al. 1988; Wenning et al. 1988). The biochemical mechanism of paraquat toxicity is related to the cyclic oxidation and reduction of paraquat that occurs in lung cells, which leads to continued production of high levels of superoxide anion (0_2^-) and other cytotoxic oxygen free radicals. Superoxide anion and other oxygen free radicals initiate the peroxidation of membrane lipids, causing tissue damage and death. Paraquat oxidation is coupled with the reduction of molecular oxygen, forming superoxide anion, singlet oxygen, and hydroxyl radicals. These molecular species react with polyunsaturated fatty acid free radicals and, on further oxidation, with lipid hydroperoxide radicals. The hydroperoxide radicals then maintain the formation of new fatty acid radicals while being converted to lipid peroxides in a chain reaction. Various enzymes in the cells catabolize the superoxide radical and reduce the lipid hydroperoxides to less-toxic lipid alcohols. The superoxide anions are converted to hydrogen peroxide and oxygen; hydrogen peroxide is further inactivated to water and oxygen by catalases and peroxidases. In the presence of reduced nicotinamide adenine dinucleotide phosphate (NADPH), paraquat is reduced by microsomal NADPH-cytochrome reductase. The reduction of lipid peroxides by glutathione peroxidase requires reduced glutathione. Because the reduction of oxidized glutathione is coupled with NADPH oxidation by way of glutathione reductase, it seems that the availability of NADPH is essential for paraquat detoxification, and that the critical depletion of NADPH may render the cell more susceptible to lipid peroxidation.

The lung is the organ most severely affected in paraquat poisoning (Campbell 1968; Conning et al. 1969; Haley 1979; Aldrich et al. 1983; Bauer 1983; Combs and Peterson 1983; Christian et al. 1985; Smith 1985; Wong and Stevens 1986; Boudreau and Nadeau 1987; Baud et al. 1988; Dunbar et al. 1988a; Wegener et al. 1988). Pulmonary injury is due largely to the preferential accumulation of paraquat in the lung--mediated by an energy dependent system for uptake of endogenous polyamines--and to the continuous exposure of the lung to atmospheric oxygen. Characteristic signs of poisoning include severe anoxia, marked and widespread fibroblastic proliferation in the alveolar walls around the terminal bronchi and blood vessels, and frequently death. The specific toxicity to the lung can be explained by the accumulation of paraquat in the alveolar Type H cells. These cells are responsible for the synthesis of pulmonary surfactant, the surface-active material lining the alveolar epithelium. The pulmonary surfactant is secreted after storage in cytoplasmic organelles known as lamellar bodies. Therefore, any damage to the alveolar epithelium could alter synthesis and secretion of the pulmonary surfactant. The pulmonary effects of paraquat are probably related to the conversion of paraquat to a free radical followed by conversion to a long-lived dihydroderivative, which causes transformation of normal alveolar epithelial cells to fibroblasts. The increase in toxicity of paraquat by oxygen supports the hydroperoxide theory, in which the reversible action of the free radical's oxidation-reduction gives rise to hydrogen peroxide. Paraquat also depletes NADPH in the isolated lung to the extent of mixed function oxidation impairment. Depletion of NADPH would impair fatty acid and lipoprotein synthesis and inhibit various detoxification and biosynthetic functions.

Other organs and systems affected by paraquat include the kidney (pathology of proximal tubules), liver (hepatocellular necrosis), spleen and thymus (pathology), circulatory system (irregular and feeble heart beat, myocardial congestion, increase in erythrocytes and leucocytes, external pericarditis, myocardium edema), brain (neuronal depletion, myelin destruction), gastrointestinal tract (esophagitis; ulceration of buccal cavity, pharynx, gastric mucosa; mucosal erosion), skin (erythema, hyperkeratosis), reproductive system (degeneration), nervous system (hyperexcitability, irritability, incoordination, convulsions), various enzyme systems, and the eye (Giri et al. 1979, 1982, 1983; Summers 1980; Bauer 1983; Seto and Shinohara 1987, 1988; Hughes 1988; Takegoshi et al. 1988).

Several early indicators of paraquat-induced stress have been proposed, including alkaline phosphatase activity, fibronectin levels, and intracellular calcium uptake. Alkaline phosphatase activity is associated with the lamellar body, and changes in this variable are suggested as indicative of toxicity to Type II alveolar epithelium cells (Boudreau and Nadeau 1987). Levels of fibronectin, an extracellular matrix glycoprotein, were elevated in patients with fibrotic lung diseases and in monkeys given multiple injections of paraquat (Dubaybo et al. 1987). Lung intracellular calcium uptake was significantly disrupted, even at doses that normally produce significant increases in lung water content (Agarwal and Coleman 1988). These subjects seem to merit additional research, as does the role of polyamines in mediating fibrotic changes in the lung (Dunbar et al. 1988b);

paraquat-altered synthesis of proteins, DNA, collagen, and pentose phosphate metabolism (Simon et al. 1983); and hyperoxia--that is, increased oxygen-free radical generation (Frank et al. 1982).

Certain treatments or chemicals provide varying degrees of protection against paraquat-induced lung toxicity and lethality, although no treatment or chemical has proven completely successful. Present treatment of paraquat-poisoned animals and humans is directed to elimination of the material from the body using repeated doses of adsorbents such as Fuller's earth or bentonite; cathartics to reduce paraquat absorption; and hemodialysis, forced diuresis, and hemofiltration to enhance excretion (Fletcher 1974; Autor 1977; Haley 1979; Pond et al. 1987; Kitakouji et al. 1989). The use of 100% oxygen is contraindicated, as mortality is greatly increased (Fletcher 1974; Autor 1977; Wong and Stevens 1986). Toxicity mediated by free radicals can be moderated by several cellular defense mechanisms, including superoxide dismutase, catalase, glutathione peroxidase, vitamin E, and reduced glutathione (Gabryelak and Klekot 1985; Wenning et al. 1988). Recently, a low molecular weight superoxide dismutase mimic, based on manganese, was found to protect mammalian cells against the cytotoxic effects of the superoxide radical produced by paraquat (Darr et al. 1988). Under carefully controlled conditions of administration, certain chemicals reportedly provide limited protection to small laboratory animals: nicotinic acid (Shibata and Iwai 1988); niacin (Heitkamp and Brown 1982); cysteine (Szabo et al. 1986); N-acetylcysteine (Wegener et al. 1988); metallothionein--a metal-binding low molecular weight protein rich in cysteine (Sato et al. 1989); d-penicillamine (Szabo et al. 1986); clofibrate (Frank et al. 1982); lipid-soluble antioxidants (Kohen and Chevion 1988; Wegener et al. 1988); various amino acids (Heitkamp and Brown 1982); phenobarbitol (Bus et al. 1976; Summers 1980); methyl predinsolone (Kitazawa et al. 1988); and certain anti-inflammatory drugs (Autor 1977). In plants, the pea *(Pisum sativum)* is protected by cerium chloride--in part, through counteracting peroxide formation (Vaughn and Duke 1983).

Paraquat toxicity is increased and its effects otherwise exacerbated in organisms fed diets deficient in selenium or vitamin E, although high levels of these substances in diets did not provide protection (Autor 1977; Haley 1979; Summers 1980); by methyl prostaglandins (Williams et al. 1988) or diethyl maleate (Summers 1980); and by increased iron and copper (Kohen and Chevion 1988; Ogino and Awai 1988). Dietary changes that do not result in nutrient deficiency or toxicity may affect the biocidal properties of paraquat and other compounds. In studies with rodents subjected to paraquat insult, survival was higher in those fed cereal-based diets versus purified diets, aid higher in egg-white (protein) purified diet versus a casein diet (Tanaka et al. 1981; Evers et al. 1982), suggesting a need to use strictly defined diets in the study of paraquat toxicity to control for any paraquat- diet interactions.

Paraquat adhering to the plant surface is usually degraded photochemically (Haley 1979; Summers 1980). Paraquat is phytotoxic through inhibition of processes involving photosynthesis and respiration (Haley 1979; Christian et al. 1985; Anonymous 1988). Its mode of action in plants is similar to that in animals--that is, lipid peroxidation of membranes due to formation of the superoxide radical and related species (Summers 1980). Photosynthetic tissues reduce paraquat to stable free radicals that, on reoxidation, produce hydrogen peroxide. Unsaturated lipids in the cells are oxidized by the peroxide, and damage is dependent largely on production of hydrogen peroxide (Haley 1979; Vaughn and Duke 1983). The reaction is light- and oxygen-dependent (Conning et al. 1969; Kelly et al. 1979).

In bacteria *(Escherichia coli),* paraquat is concentrated, reduced to the monocation radical, and combined with molecular oxygen to produce the superoxide radical within the cell. Copper and iron are essential mediators in bacteriocidal effects; the cytoplasmic membrane is the target organelle in paraquat toxicity to *E. coli*, and extent of damage correlates positively with levels of these metals (Kohen and Chevion 1988).

Fate in Soils and Water

In contact with soil, paraquat is rapidly adsorbed usually in the clay mineral lattice sheets-and inactivated by base exchange; the process is facilitated by the flat and highly polarizable nature of the paraquat ion (Anonymous 1963; Conning et al. 1969; Calderbank 1975; Summers 1980; Kearney et al. 1985). The strong binding of paraquat to soil constituents reduces the mobility of the herbicide due to leaching, although paraquat is displaced from binding sites by low concentrations of ions of ammonium, potassium sodium, and calcium (Smith and Mayfield 1978). Paraquat adsorption is not significantly affected by soil pH, but is modified by soil porosity, moisture content, residence time, and adsorption capacity (Smith and Mayfield 1978; Summers 1980). Paraquat applied to a sandy loam soil at field application rates between 0.56 and 2.24 kg/ha was adsorbed by organic matter and clays, usually in the top centimeter of soil (Smith and Mayfield 1978). Typical soils contain

paraquat at about 300 mg/kg after treatment at recommended applications; however, adsorption capacity varies among soils. Clay minerals, such as kaolinite, can adsorb 2,500 - 3,500 mg/kg, whereas others, such as montmorillonite, adsorb up to 85,000 mg/kg after paraquat treatment (Summers 1980).

Paraquat is not degraded significantly in soil by chemical or microbiological vectors during incubation periods up to 16 months at 250 °C (Smith and Mayfield 1978). For example, paraquat dichloride, applied once annually at 4.48 kg/ha or 4 times annually at 1. 12 kg/ha, remained essentially undegraded in the soil for 6 years (Fryer et al. 1975; Moyer and Lindwall 1985). Massive applications to soils of 3,000 kg/ha can persist for at least 6 months without significant degradation (Moyer and Lindwall 1985). Bacterial degradation--which occurs only slowly in soils--consists of demethylation, followed by ring cleavage to eventually form the carboxylated 1-methylpyridinium ion (Fig. 2). Photochemical decomposition of paraquat is the predominant mechanism of paraquat degradation in soils (Smith and Mayfield 1978). In surface soils, paraquat loss through photodecomposition was 20-50% in 3 weeks (Christian et al. 1985). Photochemical degradation products of paraquat include 4-carboxy-1-methylpyridium ion and methylamine hydrochloride (Fig. 2). Laboratory studies have demonstrated that paraquat in soils slated for disposal can be degraded by ultraviolet (UV) irradiation in the presence of oxygen or ozone. Reaction products identified were 4-carboxy-1-methylpyridium ion, 4-picolinic acid, hydroxy-4-picolinic acid, succinic acid, N-formylglycine, malic acid and oxalic acid (as trimethylsilicon derivatives), and 4,4'-bipyridyl (Kearney et al. 1985).

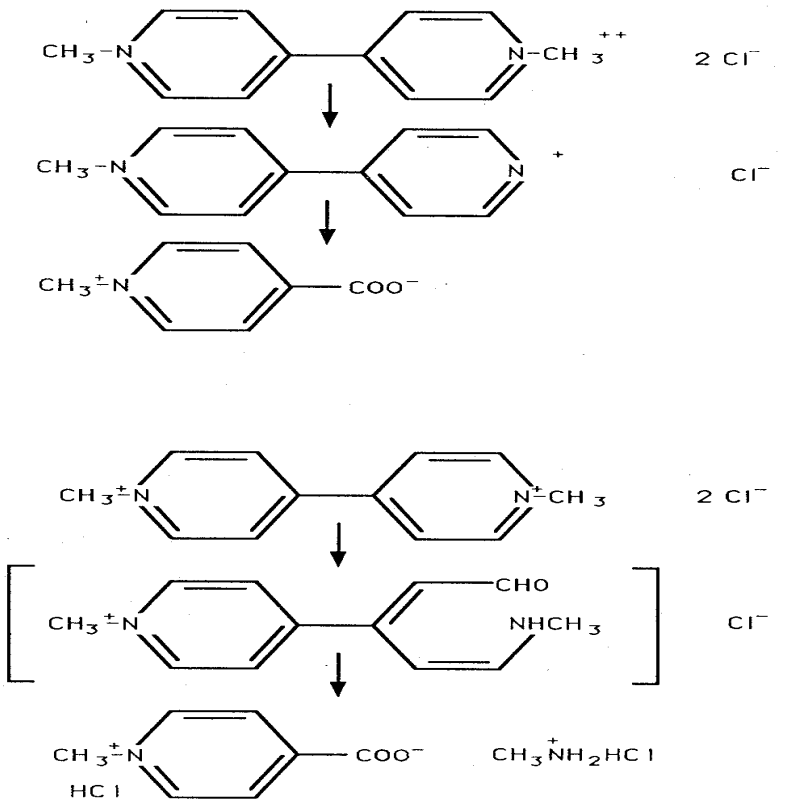

Fig. 2. Proposed pathway of paraquat degradation by a bacterial isolate (*upper*) and by ultraviolet irradiation (*lower*). Modified from Funderburk and Bozarth (1967).

Paraquat is used to control aquatic weeds. It also passes into aquatic environments through rain, where it is rapidly accumulated by aquatic organisms, especially fish (Gabryelak and Klekot 1985). Paraquat applied to control aquatic weeds is accumulated by aquatic macrophytes and algae, and it is adsorbed to sediments and suspended materials. Initial applications of 1 - 5 mg/L in the water column are usually not detectable under field conditions after 8 to 27 days (Summers 1980). The half-time persistence of paraquat in the water column at normal doses for weed control (i.e., 0.5 - 1.0 mg/L) was 36 h; less than 0.01 mg/L was detectable in 2 weeks (Calderbank 1975). In solution, paraquat was subject to photodecomposition and microbial metabolism,

degrading to methylamine and 4-carboxy-1 -methylpyridium ion (Kearney et al. 1985). In fresh water, without sediment or plants, 100% of the initial paraquat concentration of 0.5 mg/L was degraded in 35 weeks. When sediments were present, 100% loss from the water column occurred in 6-8 weeks, and when both sediment and aquatic plants were present, paraquat was not detectable in the water column in 3 - 4 weeks (Summers 1980). Mud cores taken from a paraquat-treated lake had elevated paraquat residues but showed no phytotoxic effects on barley seedlings germinated on them (Calderbank 1975).

Paraquat loss from seawater in 24 h was 70% at an initial concentration of 1 mg/L, 68% at 5 mg/L, and 76% at 10 mg/L; most of the loss occurred within the first 60 min (Fytizas 1980).

Lethal and Sublethal Effects

General

Adverse effects of paraquat (death, inhibited germination of seeds, reduced growth) in sensitive species of terrestrial plants and soil microflora have been documented at application rates of 0.28 - 0.6 kg/ha, at soil concentrations of 10 - 25 mg/kg (growth inhibition), and at soil-water concentrations as low as 1.6 mg/L (reduced growth, inhibited synthesis of protein and RNA). Among terrestrial invertebrates, certain species of mites were sensitive to paraquat at recommended rates of application, and the sensitive honeybee *(Apis mellifera)* died when its diet contained 100 mg/kg. However, paraquat in soils was not accumulated by earthworms *(Lumbricus terrestris)* and other species of soil invertebrates after applications up to 112 kg/ha. These points, and others listed in this section, are discussed in greater detail later.

Freshwater algae and macrophytes usually die at paraquat concentrations between 0.25 and 0.5 mg/L; marine algae, however, are relatively resistant and usually require 5 mg/L or higher for significant inhibition in growth to occur in 10 days. Aquatic invertebrates, especially crustaceans, seem to be the most sensitive group, with effects most pronounced at elevated temperatures in early developmental stages. Adverse effects were noted in crab larvae at nominal water concentrations between 0.9 and 5.0 µg/L, although 1,000 µg/L and higher were needed to produce similar effects in other species of aquatic invertebrates. Amphibians and fishes were usually unaffected at concentrations below 3,000 µg/L, although sensitive species such as frog tadpoles and common carp *(Cyprinus carpio)* were affected at 500 µg/L. There was little accumulation of paraquat from the medium by aquatic fauna.

Paraquat is embryotoxic to sensitive species of birds. Concentrations equivalent to 0.056 kg/ha applied in oil solution to the surface of mallard (*Anas platrhynchos*) eggs inhibited development; when applied in aqueous solution, paraquat was toxic at a dose equivalent to 0.56 kg/ha. In each case, adverse effects occurred below the recommended field application rate of about 1.0 kg/ha. The lowest doses of paraquat that produced harmful effects in sensitive birds were 10 mg/kg body weight (BW) in nestlings of the American kestrel (*Falco sparverius*), 20 mg/kg in the diet of northern bobwhite (*Colinus virginanus*), 40 mg/L in the drinking water of domestic chickens (*Gallus* sp.), and 199 mg/kg BW in mallard (acute oral LD50).

Sensitivity of mammals to paraquat was variable, due to inherent differences in interspecies resistance. Representative mammals were measurably affected at aerosol concentrations of 0.4 - 6.0 µg/L, acute oral doses of 22-35 mg/kg BW, dietary concentrations of 85 - 100 mg/kg and drinking water levels of 100 mg/L.

Terrestrial Plants and Invertebrates

In terrestrial plants, paraquat's action is at the point of local absorption (Anonymous 1963). Characteristic damage signs to susceptible species include wilting and general collapse in herbaceous plants. Regrowth may occur in some perennial plants, but in resistant species temporary scorch may be the most marked effect (Anonymous 1963). In sugarcane (*Saccharum officinarum*), paraquat application severely desiccated the plant within 72 h and disrupted activity of leaf amylase and sucrose (Haley 1979). Paraquat, once absorbed in plants, is likely to persist (Bauer 1983). The addition of cationic or nonionic surface active agents increases the phytocidal effectiveness of paraquat (Anonymous 1963), but in combination with various herbicides, paraquat was markedly less phytotoxic to certain cereal grains (O'Donovan and O'Sullivan 1986).

Paraquat adsorbed to soils is usually unavailable to crops. In wheat (*Triticum aestivum*), effects from

contaminated soils were negligible until soil residues surpassed 600- 1,000 kg/ha, causing growth reduction of 10%, or 1,650 kg/ha, causing elevated residues in leaves but not in grain (Moyer and Lindwall 1985).

Three species of grains (barley, *Hordeum vulgare;*wheat; oat, *Avena sativa)* died (>95% kill) following paraquat application of 0.28 kg/ha (O'Donovan and O'Sullivan 1986). At 0.6 kg/ha, paraquat inhibited germination and growth in seeds of six species of grasses (Kentucky bluegrass, *Poa pratensis;* perennial ryegrass, *Lolium perenne;* bentgrass, *Agrostis tenuis;* tall fescue, *Festuca arundinacea;* red fescue, *Festuca rubra;* orchard grass, *Dactylus glomerata*), but two species of legumes (alfalfa, *Medicago sativa*; red clover, *Trifolium pratense*) were comparatively resistant (Salazar and Appleby 1982). Paraquat was phytotoxic to several species of terrestrial plants (rape, *Brassica napus;* ryegrass; white clover, *Trifolium repens)* for several days following application of 1.1 - 2.2 kg/ha (Summers 1980). Transpiration rate of soybean (*Glycine max*) was lowered at 1 mg/kg (Haley 1979). Paraquat is not considered to be carcinogenic or teratogenic, but is weakly mutagenic to some plants (e.g., 4.1 % chromosomal aberrations in seeds of wheat at 9.3 mg/kg; Haley 1979). Spray solutions containing 0.6 g paraquat per liter applied to crowns of eastern redcedar (*Juniperus virginiana*) killed up to 90% of small trees and up to 30% of large trees; at 0.3 g/L, up to 60% of small trees were affected (Engle et al. 1988). Seedlings of corn (*Zea mays*) sprayed with 0.2% paraquat ion solution for 6 h had decreased rates of total protein synthesis and some polysome dissociation (Wu et al. 1988), suggesting that additional research is needed on mutagenicity of paraquat in plants.

Paraquat resistance has been documented in several genera of weeds. For example, paraquat-resistant strains of barley grass *(Hordeum glaucum)* were first noted in 1982 in Australia; resistant strains (based on chromosome counts and resistance to paraquat) were confined to a small number of alfalfa fields where paraquat had been used consistently for at least 10 years. However, the potential exists for this biotype to be transferred and established in other areas by the movement of livestock, machinery, hay, and seeds (Islam and Powles 1988; Tucker and Powles 1988). Paraquat-resistant strains of weeds have been reported in Australia, Egypt, England, and Japan (Polos et al. 1988). Paraquat-resistant strains of bacteria, ferns, and other species of flora have been documented (Carroll et al. 1988). Paraquat-tolerant ferns (*Ceratopteris richardii*) were 10 to 20 times more resistant than sensitive wild-type strains (Carroll et al. 1988). Paraquat-resistant strains of perennial rye were up to 10 times more resistant than normal susceptible strains (Faulkner and Harvey 1981). In the case of barley grass, survival was reduced 50% at 0.025 kg/ha in normal susceptible biotypes, but in resistant biotypes, 3.2 kg/ha was required (Islam and Powles 1988; Tucker and Powles 1988). Paraquat-tolerant plants may enjoy certain advantages over nonresistant plants, including resistance to various air pollutants. For example, paraquat-tolerant tobacco plants (*Nicotiana tabacum*), which had higher superoxide dismutase activity than controls, were tolerant to aerosol sprays of 2 mg SO_2/L, while controls experienced severe damage (Tanaka et al. 1988).

In every case of resistance, paraquat had been applied 2 or 3 times annually during the preceding 5 - 11 years; in some cases, a cross-resistance to atrazine was also reported (Polos et al. 1988). Paraquat-resistance mechanisms in plants include increased epicuticular wax (preventing penetration), binding of paraquat to cell walls, restricted movement into chlorplasts, and altered redox potential (Polos et al. 1988). For example, sequestration of paraquat within the apoplast of the leaf seems to be inheritable and controlled by a single nuclear gene with incomplete dominance (Islam and Powles 1988). Studies with paraquat-tolerant strains of various plants, including perennial rye and tobacco, suggest that tolerance is related to their general ability to rapidly detoxify the generated oxygen species through increased levels of superoxide dismutase, glutathione reductase, and other antioxidants (Shaaltiel et al. 1988).

At recommended field concentrations paraquat had negligible effect on soil microflora or soil fertility, although it did cause a temporary suspension of soil nitrification (Haley 1979). A concentration as low as 1.0 mg/L completely inhibited ammonium and nitrite oxidation for 40 days in a mixed culture of nitrifying bacteria isolated from soil (Gadkari 1988). Paraquat at 1.6 mg/L adversely affected *Escherichia coli* in 6 h as judged by diminished growth rate and inhibited synthesis of RNA and protein; at a higher concentration of 18.6 mg/L, interference with metabolism of glucose and DNA synthesis was observed (Davison and Papirmeister 1971). Four species of soil bacteria had 50% growth inhibition at paraquat concentrations between 93 and 18,600 mg/kg soil; moreover, the mode of action in some species of microorganisms may differ from the generally accepted mechanisms for paraquat toxicity in mammals (Carr et al. 1986). Sensitive species of soil fungi experienced marked growth inhibition between 10 and 25 mg paraquat per kilogram of soil. (Summers 1980). In

various genera of soil fungi *(Rhizopus, Ophiobolus, Helminthosporium,Fusarium, Eurotium),* paraquat concentrations up to 100 mg/L could be tolerated; at higher concentrations, spore germination was suppressed, mycelial growth was inhibited, and spore development was abnormal (Haley 1979).

Terrestrial invertebrates show varying degrees of sensitivity to paraquat. In honeybees, paraquat concentrations of 100 mg/kg syrup (diet) produced toxic signs, 4.4 kg/ha applied as a spray killed 90% in 3 days, and 1,000 mg/L in drinking water killed most in a few days and 100% within 5 weeks (Summers 1980). In soils, adsorbed paraquat may be ingested by soil invertebrates, such as earthworms, but it was not absorbed from the gut into tissues and was rapidly lost when the earthworms were transferred to clean soil (Calderbank 1975). For example, earthworms fed soil treated with 112 kg/ha had 111 mg/kg in gut contents, but <0.3 mg/kg in the carcass without gut (Summers 1980). Two species of springtails (Collembola; *Folsomia candida*, *Tullbergia granulata*) were fed diets containing 600 mg/kg for 22 weeks; they survived without measurable adverse effects. However, higher dietary levels of 1,000 and 5,000 mg/kg were associated with decreased survival, lengthier instar development, decreased egg production, and decreased egg viability (*Folsomia candida* and Tullbergia granulate (Subagja and Snider 1981). Adults and larvae of the German cockroach (*Blattella germanica*) died after consuming diets containing 1,000 mg/kg (Summers 1980). Also, paraquat was lethal to two species of mites (*Tetranychus urticae*, *Typhlodromus* sp.) at concentrations below recommended field application rates (Summers 1980).

Aquatic Organisms

In general, paraquat is more toxic to aquatic fauna in soft water than in hard water, more toxic to early developmental stages than to juveniles or adults, and more toxic in formulations containing wetting agents than in formulations without them (Summers 1980). In water, paraquat is taken up rapidly by plants or adsorbed to particulate matter in the water column; however, paraquat is not bioconcentrated by aquatic fauna (Calderbank 1975; Summers 1980). Paraquat effects on aquatic biota are summarized in Table 3, and these data suggest several trends. Early developmental stages of certain species of crustaceans are extremely sensitive, and significant adverse effects occur in the range of 0.9-100 µg/L, although most species of crustaceans and all other species of invertebrates tested were relatively unaffected at concentrations below 1,000 µg/L. Freshwater algae and macrophytes are eliminated after treatment with 250 - 500 µg/L, but marine algae are relatively resistant and require 5,000 µg/L or higher to produce significant growth inhibition. Usually, aquatic vertebrates are not adversely affected and show little accumulation at 1,000 µg/L or lower, but at 500 µg/L, frog tadpoles have low survival and a high frequency of developmental abnormalities, and carp experience biochemical upset.

Paraquat controlled *Typha* and *Phragmites* in Egyptian irrigation canals, drains, and marshes without apparent harm to fishes (Haley 1979). Paraquat residues in decomposed plants become available for adsorption to sediments and bottom muds and are not readily available for microbial degradation (Summers 1980). Indirect fish kills may occur from anoxia due, in part, to consumption of dissolved oxygen by decaying weeds (Bauer 1983). Paradoxically, it has been suggested that paraquat may be helpful in improving the oxygen status of aquatic environments at a concentration of 1 mg/L by restricting nitrate production due to inhibition of bacterial nitrification (Chan and Leung 1986; Gadkari 1988). At effective herbicidal concentrations, paraquat was also toxic to eggs-but not adults-of three species of snail vectors of bilharzias (*Bulinus truncatas, Biomphalaria alexandrina, Lymnaea calliaudi*); newly hatched snails were the most sensitive (Haley 1979).

Changes in fauna of a reservoir following use of paraquat for weed control are likely to be indirect effects caused by decomposition of angiosperms (Brooker and Edwards 1974). Planktonic invertebrates closely associated with aquatic macrophytes were either eliminated by paraquat or survived at lower densities for at least a year following treatment; analysis of content of fish stomachs showed dietary changes following weed control and reflected availability of many invertebrate species associated with aquatic plants (Brooker and Edwards 1974).

Paraquat can induce activities of antioxidant enzymes such as superoxide dismutase, glutathione peroxidase, and catalase in many species of plants, invertebrates, and vertebrates. Results of studies with ribbed mussels (*Geukensia demissa*) support the hypothesis that these bivalve mollusks can activate redox cycling compounds and demonstrate responses typical of oxidative stress observed in other species (Wenning et al. 1988). Paraquat also disrupts glucose metabolism and acetylcholinesterase activity and accumulates in melanin. Disrupted glucose metabolism in paraquat-stressed carp was attributed to a high level of circulating epinephrine (Simon et al. 1983). Paraquat-induced acetylcholinesterase inhibition in erythrocytes and electric

organs of the electric eel (*Electrophorus electricus*) was reversible (Seto and Shinohara 1987, 1988). Paraquat tended to concentrate in melanin, as judged by accumulation in neuromelanin of frogs (*Rana temporaria*) after intraperitoneal injection (Lindquist et al. 1988), with important implications for research on Parkinson's disease. It seems that paraquat has a structural similarity to a metabolite of 1-methyl -4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), which may induce a Parkinson-like condition; like paraquat, MPTP and its metabolites have melanin affinity (Lindquist et al. 1988).

Birds

Signs of oral paraquat intoxication in birds include excessive drinking and regurgitation, usually within 10 min of exposure. Other signs appeared after 3 h: diarrhea, ruffled feathers, muscular incoordination, imbalance, wing drop, hyporeactivity, slowness, weakness, running and falling, constriction of the pupil, and terminal convulsions. Additional signs reported after dermal exposure include blistering and cracking of skin, lacrimation, wing spread, and wing shivers. Death usually occurred between 3 and 20 h postexposure; remission took up to 12 days (Smalley 1973; Haley 1979; Summers 1980; Hudson et al. 1984). The blood chemistry pattern of paraquat-intoxicated Japanese quail (*Coturnix japonica*) suggested adrenal gland impairment, although recovery from hematologic effects was rapid (Clark et al. 1988). Paraquat causes pseudofeminization of male chicken and quail embryos; testes showed intersexual phenomena and Mullerian duct abnormalities; both sexes had a reduction in gonocyte number (Haley 1979; Bauer 1983).

Table 3. Effect of paraquat on selected species of aquatic plants and animals. Concentrations are milligrams of paraquat cation per liter of medium.

Taxonomic group, organism, and other variables	Concentration (ppm)	Effects	Reference[a]
Algae and macrophytes			
Lesser duckweed, *Lemna minor*	0.00074	Herbicidal	1
Submerged weeds			
4 species	0.25–0.5	Herbicidal	2
3 species	0.5–2.5	Herbicidal	2
Chara sp., *Polygonum* sp.	0.5	No adverse effects in 32 days	3
Freshwater algae			
3 species	0.25–1.0	Herbicidal	2
2 species	>5.0	Herbicidal	2
Rooted emergents			
2 species	0.25–0.5	Herbicidal	2
2 species	2.0–3.0	Herbicidal	2
1 species	>5.0	Herbicidal	2
Floating weeds			
Water weed, *Elodea canadensis*	0.5	Eradicated from British lakes in 32 days for at least 2 years	3
4 species	0.5	Herbicidal	2
Pondweed, *Potamogeton pusillus*	0.5	Residues of 36 mg/kg dry weight (DW) in 14 days	4, 5
Eurasian watermilfoil, *Myriophyllum spicatum*	1.0	Residues up to 112 mg/kg DW in 14 days	4, 5
Cattail, *Typha latifolia*	0.5	Shoreline colonies severely affected after 32-day exposure	3
Duckweed, *Spirodella oligorrhiza*	0.5	Inhibits chlorosis in 48 h	3
Marine algae			
Isochrysis galbana	5	50% growth inhibition in 10 days	6
Phaeodactylum tricornutum	10	50% growth inhibition in 10 days	6
Dunaliella tertiolecta	20	50% growth inhibition in 10 days	6
Chlorococcum sp.	50	50% growth inhibition in 10 days	6
4 species	2,500–>5,000	Respiration reduced 50% in 2 h	6
Invertebrates			
Mud crab, *Rithropanopeus harrisii*, larvae	0.00086	LC50 (19 days)	4
Rithropanopeus harrisii, larvae	0.001–0.005	50% mortality before zoeal stage	4
Isopod, *Asellus meridianus*			
15 C	0.1	LC50 (14 days)	7
15 C	0.58	LC50 (8 days)	7
5 C	0.62	LC50 (14 days)	7
5 C	6.3	LC50 (8 days)	7
Freshwater invertebrates, 3 species (*Asellus, Lymnaea, Sialis*)	0.5	No deaths in 4 days following spray application to British lake	3
Gastropod, *Murex brandaris*	1	LC50 (18 days)	8
Murex brandaris	10	LC50 (24 h)	8
Murex brandaris	1–10	Residues (in mg/kg fresh weight [FW] soft parts), after 3-day exposure ranged between 1.5 and 2.8; were dose dependent	8

Hermit crab, *Pagurus* sp.	1	LC50 (10 days)	8
Pagurus sp.	10	LC50 (36 h)	8
Pagurus sp.	1–5	Residues, in mg/kg whole body FW, after 3-day exposure ranged between 3.2 and 15; were dose dependent	8
Brown shrimp, *Penaeus aztecus*	>1	50% immobilization in 48 h	6
American oyster, *Crassostrea virginica*	>1	50% growth reduction in 96 h	6
Louisiana red crayfish, *Procambarus clarkii*			
Juvenile	1.4	LC50 (96 h)	9
Juvenile	2.4	LC50 (72 h)	9
Adult	17	LC50 (72 h)	9
All stages	Sublethal	Dose-dependent increase in hyperactivity and oxygen consumption	9
Daphnid, *Daphnia hyalina*	2.5	LC50 (14 days)	7
Daphnid, *Daphnia pulex*	2.7	50% immobilization in 48 h	10
Daphnia pulex	4	LC50 (48 h)	11
Cladoceran, *Simocephalus serrulatus*	2.8	50% immobilization in 48 h	10
Simocephalus serrulatus	3.7	LC50 (48 h)	11
Liver fluke, *Fasciola hepatica*			
Egg through miracidium	5	LC50 (20 days); effects counteracted by dinoseb	12
Egg	6	Delayed embryonic development; delayed hatch of miracidia	12
Egg	8	26% hatch	12
Egg	10	9% hatch	12
Egg	15	No hatch	12
Freshwater copepods, 2 species (*Eucyclops, Diaptomus*)	5	LC50 (48 h)	13
Freshwater copepods, 2 species	10	LC50 (24 h); effects counteracted by metribuzin, another herbicide	13
Aquatic insects, nymphs			
Corixid, *Sigara* sp.	5	LC50 (14 days)	7
Baetid, *Cloeon dipterum*	29	LC50 (14 days)	7
Daphnid, *Daphnia magna*	6	24% immobilized in 26 h; all mobile daphnids transferred to paraquat-free medium died within 24 h	14
Amphipod, *Gammarus fasciatus*	11	LC50 (96 h)	10, 11
Ribbed mussel, *Geukensia demissa*	93	Elevated catalase activity, lipid peroxidation rate, and total superoxide dismutase levels in 12–36 h	15
Geukensia demissa	744	No deaths in 7 days	15
Geukensia demissa	1,190	LC100 (7 days)	15
Chironomid, *Psectrocladius* sp., 4th instar larvae	>100	LC50 (14 days)	7
Stonefly, *Pteronarcys californica*	>100	LC50 (96 h)	10, 11
Mosquito larvae, 2 species	275–>1,000	LC50	4
Fish			
Common carp, *Cyprinus carpio*	0.5	After 6 days, 300% increase in phosphorylase and 200% increase in glucose-6-phosphatase activities in liver; increase in sugar level and serum lactic dehydrogenase activity	18
Cyprinus carpio	5	Increase in activities of various liver enzymes, and in blood sugar levels	19

		during 6-day exposure; effects enhanced by the herbicide methidathion	
Cyprinus carpio	10	During 96-h exposure, significant alterations were recorded in lipid peroxidation rate, hemoglobin concentration, and erythrocyte antioxidant enzymes--that is, catalase, superoxide dismutase, and glutathione peroxidase activities	20
Cyprinus carpio	13–214	Acetylcholinesterase activity reduced 50% after 2-h exposure in serum (13 mg/L), heart (39 mg/L), muscle (102 mg/L), and brain (214 mg/L)	21
Freshwater fish			
4 species	1	Maximum residues, in mg/kg whole body FW, during 16-day exposure, ranged between 0.6 in green sunfish (*Lepomis cyanellus*) and 1.6 in bluegill (*Lepomis macrochirus*); intermediate values recorded for rainbow trout (*Oncorhynchus mykiss*) and channel catfish (*Ictalurus punctatus*)	22
3 species	10	In 96-h exposures, paraquat caused exposure-dependent increase in lipid peroxidation rate and in activity enhancement of peroxide metabolism enzymes in erythrocytes	23
Smallmouth bass, *Micropterus dolomieui*	1	Adverse sublethal effects	22
Striped mullet, *Mugil cephalus*	1	LC50 (16 days); survivors had pronounced gill histopathology and residues (in mg/kg FW) of 0.2 in muscle, 0.2 in ovary, 4.7 in skin, and 6.1 in digestive tract	8
Mugil cephalus	10	LC50 (60 min)	8
Thai silverbarb, *Puntius gonionotus*	1	No tissue histopathology after 12-day exposure	24
Puntius gonionotus	1	No tissue histopathology after 12-day exposure; gills normal during 5-day exposure	24
Longnose killifish, *Fundulus similis*	>1	LC50 (48 h)	6
Mosquitofish, *Gambusia affinis*	3	Adverse effects	22
Gambusia affinis	604	LC50 (96 h)	5
Zebra danio, *Brachydanio rerio*	7.5–48.5	LC50 (96 h)	4
Shortfin molly, *Poecilia mexicana*	12	LC50 (24 h)	5
Medaka, *Oryzias latipes*			
Egg	12	Normal development	5
Egg	23	Abnormal development	5
Embryo	>50	100% lethal	5
Bluegill, *Lepomis macrochirus*	13	LC50 (96 h)	10, 11
Guppy, *Poecilia reticulata*	15–22	LC50 (96 h)	4
Rainbow trout, *Oncorhynchus mykiss*	15–32	LC50 (96 h)	5, 10, 11
Oncorhynchus mykiss	>100	LC50 (24 h)	10

Brown trout, *Salmo trutta*	25	LC50 (96 h)	5
Channel catfish, *Ictalurus punctatus*	>100	LC50 (96 h)	5, 10, 11
Amphibians			
Northern leopard frog, *Rana pipiens*			
Early gastrula stage	0.1	Normal growth, survival, development, and swimming behavior after 7-day exposure	16
Early gastrula stage	0.5	High mortality, high number of tail abnormalities, reduced growth rate in survivors, abnormal swimming behavior after 7-day (3 days posthatch) exposure to 0.5 mg/L and higher	16
15-day-old tadpoles	0.5	33% dead after exposure for 16 days	17
15-day-old tadpoles	2	95% dead after exposure for 16 days; growth retardation and increase in developmental abnormalities such as tail malformations and cranial defects	17
Fowler's toad, *Bufo woodhousei fowleri*, tadpole	15	LC50 (96 h)	10
Bufo woodhousei fowleri	56	LC50 (24 h)	10
Western chorus frog, *Pseudacris triseriata*, tadpole	28	LC50 (96 h)	10
Pseudacris triseriata	43	LC50 (24 h)	10
Frog, *Limondynastes peronii*, adult	100	LC50 (96 h)	5
Frog, *Adelotus brevis*, adult	262	LC50 (96 h)	5

[a]1, Ross et al. 1979; 2, Anonymous 1963; 3, Way et al. 1971; 4, Summers 1980; 5, Bauer 1983; 6, Mayer 1987; 7, Brooker and Edwards 1974; 8, Fytizas 1980; 9, Leung et al. 1980; 10, Mayer and Ellersieck 1986; 11, Johnson and Finley 1980; 12, Christian et al. 1985; 13, Naqvi et al. 1981; 14, Crosby and Tucker 1966; 15, Wenning et al. 1988; 16, Dial and Bauer 1984; 17, Dial and Dial 1987b; 18, Simon et al. 1983; 19, Asztalos et al. 1988; 20, Matkovics et al. 1987; 21, Nemcsok et al. 1984; 22, Earnest 1971; 23, Gabryelak and Klekot 1985; 24, Sinhaseni and Tesprateep 1987.

The lowest doses of paraquat causing measurable adverse effects in sensitive species of birds (Table 4) were 0.2 mg/kg BW administered by single intravenous injection to Japanese quail, causing anemia; 0.25 mg/kg applied in oil solution to the surface of mallard eggs, producing reduced survival, reduced growth, and increased frequency of developmental abnormalities; 10 mg/kg BW administered orally for 10 days to nestlings of the American kestrel, causing reduced growth; 20 mg/kg in diet of the northern bobwhite, producing a reduction in egg deposition; 40 mg/L in drinking water of the domestic chicken, causing elevated tissue residues and an increase in the number of abnormal eggs produced; and 199 mg/kg BW in mallards, producing an acute oral LD50.

Paraquat is highly toxic to avian embryos but less toxic to adult birds (Bunck et al. 1986). It is toxic by several routes of administration, including injection and topical application (Hoffman et al. 1985). Of 42 herbicides and insecticides tested, paraquat was the most toxic to mallard eggs. Paraquat applied to eggshell surfaces in nontoxic oil vehicles was significantly more embryotoxic than were aqueous paraquat solutions, presumably due to greater penetration of oil past the shell and membranes (Hoffman and Eastin 1982; Hoffman and Albers 1984; Table 4). The LC50 values for paraquat and mallard eggs were 1.68 kg/ha (1.5 lb/acre) in aqueous emulsion and 0.11 kg/ha (0.1 lb/acre) in an oil vehicle (Hoffman and Eastin 1982). The computed LC50 aqueous value was about 1.5 times that of the recommended field application rate of about 1.0 kg/ha; however, Paraquat in aqueous solution caused some deaths at only half the field level of application, and survivors showed impaired growth and some developmental abnormalities (Hoffman and Eastin 1982; Table 4).

Table 4. Effects of paraquat on selected species of birds.

Species, dose, and other variables	Effects	Reference
Mallard, *Anas platyrhynchos*		
Fertilized eggs exposed on day 3 of incubation for 0.5 min at room temperature		
Oil solutions		
0.25 mg/kg/egg, equivalent to 0.56 kg/ha or 0.05 lb/acre	17% dead, reduced growth, 16% abnormal development	Hoffman and Eastin 1982
0.5 mg/kg/egg	50% dead, some abnormal survivors	Hoffman and Albers 1984
2.5 mg/kg/egg	83% dead, 60% abnormal	Hoffman and Eastin 1982
Aqueous solutions		
2.5 mg/kg/egg, equivalent to 0.56 kg/ha or 0.5 lb/acre	23% dead, survivors stunted, 9% abnormal	Hoffman and Eastin 1982
8.3 mg/kg/egg	50% dead; computed LC50 concentration about 1.5 times the recommended field application rate; at 1.5–3.0 times the field level, paraquat produced abnormal development, including edema, stunting, and brain malformations	Hoffman and
27.7 mg/kg/egg	73% dead, 63% of survivors abnormal	Hoffman and Eastin 1982
Adults and juveniles		
199 mg/kg body weight (BW)	Acute oral LD50; deaths usually occurred 3–20 h after treatment; remission took up to 12 days	Hudson et al. 1984
600 mg/kg BW	Percutaneous LD50 for 10- to 11-month-old drakes after a 24-h dermal foot exposure; deaths occurred 6–22 h after treatment; remission took up to 5 days	Hudson et al. 1984
4,048 mg/kg diet	Fatal to 50% after 5 days on treated diet plus 3 days on untreated ration	Heath et al. 1972
Northern bobwhite, *Colinus virginianus*		
Parent generation (P_1) fed diets containing 20, 60, 180, or 360 mg/kg ration for 6 weeks; in next generation (F_1), none was administered	360 mg/kg P_1 group had reduced fertility and hatchability, significant body weight loss, reduction in ovary and oviduct weight; no histopathology or increase in chick abnormalities; the 180 mg/kg P_1 group laid significantly fewer eggs during treatment; all F_1 hens from the 20, 60, and 180 mg/kg groups started laying 1 week later than controls and produced fewer eggs; F_1 males experienced delay in maturation; F_1 chicks from the	Bauer 1983, 1985

	20 mg/kg group were significantly heavier than all other groups	
Fed diets containing 25 or 100 mg/kg food for 60 days	No signs of toxicity or impaired learning	Bunck et al. 1986
981 mg/kg diet, 2- to 3-week-old birds	Fatal to 50% after 5 days on treated diet plus 3 days on untreated diet	Heath et al. 1972; Anonymous
Japanese quail, *Coturnix japonica*		
Juveniles received a single intravenous injection of 0.2, 2, or 20 mg/kg BW	Some deaths in 20 mg/kg group; all survivors from all groups showed hemolytic anemia within 24 h postinjection, recovery beginning within 72 h; the 0.2 mg/kg birds also showed reductions in erythrocyte number, hematocrit, and hemoglobin within 24 h	Clark et al. 1988
14-day-old chicks fed treated diets for 5 days followed by 3 days of untreated food		
500 mg/kg diet	Fatal to 20%	Hill and Camardese 1986
948–970 mg/kg diet	Dietary LD50	Heath et al. 1972; Hill and Camardese 1986
1,516 mg/kg diet	Fatal to 90%	Hill and Camardese 1986
Eggs dusted with 0.4–0.8% paraquat powder	58–79% hatching rate	Bauer 1983
100 mg/L in drinking water	Lethal within 7 days	Summers 1980
American kestrel, *Falco sparverius*		
Nestlings		
Daily oral doses, for 10 days, of 10, 25, or 60 mg/kg BW	Compared to controls, all groups exhibited reduced growth rate and elevated total sulfhydryl and protein-bound sulfhydryl levels in lung; the 25 mg/kg group had reduced skeletal growth of humerus and femur; in the 60 mg/kg group, 44% died in 4 days, survivors showed abnormal blood chemistry, liver histopathology, kidney damage, reduced skeletal growth of humerus, femur, radius-ulna and tibiotarsus	Hoffman et al. 1985, 1987
Domestic chicken, *Gallus* sp.		
Egg		
>0.1 mg/kg	Hatching rate reduced after injection	Fletcher 1967; Bauer 1983
0.5 mg	Injected eggs did not hatch	Haley 1979
0.4–0.8% paraquat powder	46–77% hatching rate for eggs dusted with powder	Bauer 1983
Adult		
Single intravenous injection of 25 mg paraquat dichloride/kg BW	60% reduction in urine flow within 50 min	Prashad et al. 1981
40 mg/L drinking water for 14 days, followed by 14 days of paraquat-free water	No effect on egg production or hatchability, but 7% increase in number of abnormal eggs produced; residues in eggs rose to about	Fletcher 1967

	0.1 mg/kg, but declined to below detection limits 6 days after treatment ended; no effect on food and water consumption of hens or on number and type of abnormalities in chicks	
131 mg/kg BW	Acute oral LD50, diet deficient in vitamin E and selenium	Combs and Peterson 1983
148 mg/kg BW	Acute oral LD50, diet deficient in selenium	Combs and Peterson 1983
419 mg/kg BW	Acute oral LD50, diet deficient in vitamin E	Combs and Peterson 1983
Chicks, 8 days old, 200–380 mg/kg BW	Acute oral LD50	Haley 1979; Summers 1980; Bauer 1983
Turkey, *Meleagris gallopavo*		
20 mg/kg BW	Lethal dose, intravenous injection route	Smalley 1973
100 mg/kg BW	Lethal dose, intraperitoneal injection route	Smalley 1973
290 mg/kg BW	Lethal dose, oral administration route	Smalley 1973
500 mg/kg BW	Lethal dose, dermal route	Smalley 1973
Ring-necked pheasant, *Phasianus colchicus*		
1,468 mg/kg diet	Fatal to 50% after 5-day treated diet plus 3-day untreated diet	Heath et al. 1972

Nestlings of altricial species, such as the American kestrel, were more sensitive to paraquat exposure than were young or adults of precocial species (Hoffman et al. 1985). Several food items of kestrels (e.g., grasshoppers, small rodents, passerine birds) are readily contaminated by paraquat through direct contact during agricultural spraying or by ingestion of contaminated vegetation (Hoffman et al. 1985). From a comparative viewpoint, however, lungs of nestling kestrels were less sensitive to paraquat than were mammalian lungs (Hoffman et al. 1987).

Northern bobwhite hens immediately exposed to simulated field application rates of paraquat took longer to lay a clutch of eggs once laying had commenced; the completed clutch appeared 10 days later in the season than birds free from paraquat exposure. It is uncertain whether the paraquat-induced delay in sexual maturation produced experimentally will also be reflected in nonlaboratory situations (Bauer 1983, 1985). Turkeys (*Meleagris gallopavo*), for example, held in field plats sprayed 24 h earlier with paraquat at 100 times the recommended agricultural application rate (i.e., up to 14 kg/ha or 200 oz cation per acre) showed no signs of toxicity 30 days after spraying (Smalley 1973).

Acute toxicity of paraquat in the domestic chicken was highly responsive to nutritional selenium status and not to vitamin E status; as little as 0.01 mg Se/kg of ration protected 8-day-old chicks against acute paraquat poisoning (Combs and Peterson 1983). Paraquat administered to chickens by way of diet was less toxic than the same amount administered in drinking water (Fletcher 1967).

Mammals

Resistance to paraquat among mammals varied substantially because of inherent differences in sensitivity between species, route of administration, and reproductive state (Table 5). The lowest recorded doses of paraquat causing measurable adverse effects on growth, survival, or reproduction were aerosol concentrations of 0.4-6.0 µg/L (rat, guinea pig); 0.05 mg administered directly in the lung (rat); intravenous injection of 1-12 mg/kg BW (sheep, dog, rat); subcutaneous injection of 2.4-28 mg/kg BW (rat, mouse, monkey); intraperitoneal injection of 3-10 mg/kg BW (mouse, guinea pig, goat); acute oral dose of 22-35 mg/kg BW (dog, cat, hare, guinea pig); oral application of 70 to 90 mg/kg BW (rat); dietary levels of 85-100 mg/kg of ration (dog, mouse, rat); and drinking water concentration of 100 mg/L (mouse).

In general, intraperitoneal and intravenous injection were the most sensitive administration routes (Bauer 1983). LD50 dermal values, however, are often not true percutaneous values because of oral contamination from normal grooming (Summers 1980). Aerosol exposure to paraquat produced a concentration-dependent rapid, shallow breathing pattern in guinea pigs (*Cavia* sp.) 18 h after exposure (Burleigh-Flayer and Alarie 1988). Aerosol LC50 values in paraquat toxicity tests with mammals were directly related to the duration of exposure, paraquat concentration in spray, and particle size; particles of 3 µm (diameter) seemed most effective (Haley 1979).

Following accidental ingestion, paraquat produces rapidly progressive, fatal, interstitial inflammation and fibrosis of the lung in humans, and this has been produced experimentally in several species of laboratory animals (Butler and Kleinerman 1971; Murray and Gibson 1972). Initial symptoms of paraquat poisoning include burning of the mouth and throat followed by nausea and vomiting. After a latent period of up to several days, increasing respiratory distress develops; death is usually the result of a progressive fibrosis and epithelial proliferation that occurs in the lungs (Kirnbrough 1974). Paraquat poisoning in humans has a mortality of 30-70%, depending largely on the dose ingested. It causes multiorgan failure, including the heart, lungs, kidney, liver, and brain. Although recovery may follow mild involvement of any of these organs, many patients die from progressive untreatable pulmonary fibrosis. This illness usually succeeds renal failure and relates in part to active pulmonary uptake of paraquat (D.W. Webb 1983). In one case, a 15-year-old boy accidentally ingested a mouthful of paraquat and developed severe respiratory distress, necessitating transplantation of one lung; paraquat-induced rejection of the graft resulted in death 2 weeks after the operation (Matthew et al. 1968). Paraquat cannot be absorbed significantly through intact human skin, but in the event of broken or abraded skin brief exposure to a paraquat concentration of 5 g/L may result in death (J. Smith 1988).

Table 5. Effects of paraquat on selected species of mammals.

Species, dose, and other variables	Effect	Reference
Cow, cattle, *Bos* sp.		
Calves administered 5 mg/kg BW, intravenous injection	No effect on pulmonary function or blood gases after 7 days	Kiorpes et al. 1982
20 mg/L in drinking water for 1 month	No measurable effect	Calderbank 1975
35–75 mg/kg BW	Acute oral LD50	Fletcher 1974; Haley 1979; Summers 1980; Heitkamp and Brown 1982
200–400 mg/kg diet for 30 days	No observable effect; no measurable residues in meat or milk	Calderbank 1975
Dog, *Canis familiaris*		
25 ug/L air, 60-min exposure	No ill effects	Haley 1979
Fed diets containing 7, 34, 85, or 170 mg/kg ration for 27 months	No significant abnormalities at 7 or 34 mg/kg; toxic effects noted at 85 and 170 mg/kg diet	Anonymous 1974
12 mg/kg BW, single intravenous injection	Extensive lung damage after 7 days	Hampson and Pond 1988
25 mg/kg BW, single intravenous injection	All dead within 36 h; before death, plasma levels of glucose, cortisol, and catecholamines increased and glucose levels decreased; increases in activity of plasma lactic dehydrogenase, creatinine phosphokinase, glutamic oxaloacetic transaminase, creatinine, and rennin; residues in dead dogs (in ug/kg fresh weight [FW]) were highest in bile (41), kidney (8), lung (5), liver (5), spleen (4), heart (3), adrenal (3), pancreas (1), thymus (1), and muscle (1)	Giri et al. 1982, 1983
25–50 mg/kg BW	Acute oral LD50	Heitkamp and Brown 1982; Anonymous 1988

36 mg/kg diet for 2 years	No measurable effect	Haley 1979
Goat, *Capra* sp.		
10 mg/kg BW, intraperitoneal injection	Mild paraquat-related lung tissue changes, but toxicosis was not clinically significant after 10 days	Kiorpes et al. 1982
Guinea pig, *Cavia* sp.		
Aerosol exposure (in mg/m^3)		
0.1, 0.4, or 0.8, 6 h daily, 5 days weekly, 3-week exposure	Rapid shallow dose-dependent breathing pattern, with return to control values during first 7 days' exposure, suggesting adaptation	Burleigh-Flayer and Alarie 1988
0.7, 4-h exposure, 2-week observation	Decrease in lung volume and increase in respiratory frequency; maximum effects measured several days postexposure with return to control values	Burleigh-Flayer
0.83–2.07, 4-h exposure, flow rate 21 L/min, particles usually <0.65 u diameter	Concentration-related decrease in lung volume and twofold increase in respiratory frequency 18 days postexposure	Burleigh-Flayer and Alarie 1987
3 mg/kg BW	Acute intraperitoneal LD50	Haley 1979; Manzo et al. 1979
22–80 mg/kg BW	Acute oral LD50 in 7 days	Murray and Gibson 1972; Haley 1979; Summers 1980; Heitkamp and Brown 1982; Bauer 1983
Chinese hamster, *Cricetus* spp.		
Cultured cells subjected to 0.8 mg/L for 3 h, recovery for 21 days	50% frequency of chromosomal aberrations; higher frequency by pretreatment with diethyldithiocarbamate (an inhibitor of superoxide dismutase), or dimethyl maleate (a glutathion scavenger), or at high oxygen concentrations	Sofuni and Ishidate
Cat, *Felis domesticus*		
26–50 mg/kg BW	Acute oral LD50	Fletcher 1974; Haley 1979; Summers 1980; Heitkamp and Brown 1982; Bauer 1983
26–50 mg/kg BW	Peak concentration in blood of 13 mg/L	Conning et al. 1969
Human, *Homo sapiens*		
26–50 mg/kg BW		
Child, 6-year-old, accidentally swallowed unknown amount of Gramoxone W	Residue in urine 6 days after exposure was 3.6 mg/L; death 7 days after onset of symptoms; autopsy showed ulceration of buccal mucosa, emphysema, severe lung damage, jaundice, renal failure	Campbell 1968
Adult male, died 30 h after swallowing paraquat solution	Histopathology of lung and adrenal gland; residues (in mg/kg FW), highest in kidney (17), followed by lung (6), muscle (4.4), liver (3.8), blood (1.4), skin (0.9), and brain (0.4)	Spector et al. 1978
Ingestion--but not necessarily swallowing--of about 15 mL ("mouthful") of a 20% solution	Fatal dose	Kimbrough 1974; Spector et al. 1978
4–>40 mg/kg BW	Acute oral LD50	Manzo et al. 1979; Summers 1980
Ingestion of 30 mg/kg BW	Associated with hepatic, cardiac, or renal failure sometimes death	Dasta 1978
Total ingested dose of 3–6 g	Fatal dose	Haley 1979

Hare, *Lepus* sp.		
35 mg/kg BW	Acute oral LD50	Fletcher 1974
Japanese monkey, *Macaca fuscata*		
Adults <3.5 years old, 2 mg/kg BW every 2 days for 8 to 10 days, subcutaneous injection	After 4 injections (8 days), 63% died; after 5 injections, 75% died; all deaths occurred between days 11 and 35; at day 66, survivors had elevated lung collagen and increased ceruloplasmin	Masaoka et al. 1987
Monkey, *Macaca* sp.		
50–75 mg/kg BW	Acute oral LD50 in 7 days	Fletcher 1974; Smith and Heath 1976; Heitkamp and Brown 1982; Bauer 1983
>63 mg/kg BW, oral route	All dead within 2 days; death preceded by convulsions	Murray and Gibson 1972
Mouse, *Mus musculus*		
Fed diets containing 45, 90, or 125 mg/kg ration for two generations	At 45 mg/kg and 90 mg/kg, no significant difference from controls in reproductive organ development, fertility, mating behavior, emryotoxicity, or developmental abnormalities; at 125 mg/kg diet, survival was significantly lower, fewer pairs reproduced, females mature later; second-generation mice were more resistant than first generation	Dial and Dial 1987a
Domestic mouse, *Mus* spp.		
1.65 or 3.35 mg/kg BW intraperitoneal injection, or 20 mg/kg BW orally, daily on days 8–16 of gestation	No significant teratogenic effects; low accumulations in embryos	Bus et al. 1975
Fed diets containing 2, 10, 30, or 100 mg/kg ration for 2 years	Maximum no-effect level was 30 mg/kg diet, equivalent to 3.92 mg/kg BW daily for males and 3.82 mg/kg BW daily for females	Anonymous 1988
Single intraperitoneal injection of 8 mg/kg BW on day 9 of pregnancy, or 2 mg/kg BW on day 9, 10, 11, and 12 of pregnancy	No measurable effect on survival, reproduction, birth weight, or chromosomal aberrations; no evidence of mutagenicity to mice liver cells	Selypes et al. 1980
16–30 mg ion/kg BW	LD50, intraperitoneal injection	Manzo et al. 1979; Selypes et al. 1980; Anonymous 1988
28 mg ion/kg BW	LD50, subcutaneous injection	Anonymous 1988
38–120 mg/kg BW	Acute oral LD50	Fletcher 1974; Haley 1979
50 or 100 mg/L in drinking water	Low dose had no effect on growth or survival; high dose group showed increased postnatal moratlity after 2 generations	Bauer 1983
Rabbit, *Oryctolagus* sp.		
Single intravenous injection of 0.05 mg/kg BW	Plasma concentrations (in mg/L), 0.6 within 2 h, 0.01 at 8 h, and <0.002 at 24 h; estimated half-life (Tb 1/2) of 24.5 h	Yonemitsu 1986
Single intravenous injection of 5 mg/kg BW	Plasma concentrations (in mg/L), about 30 in 2 h, 1 in 8 h, 0.1 in 24 h, and <0.01 in 48 h; estimated Tb 1/2 of 12.8 h; kidney histopathology evident 7 days after injection but lung damage negligible	Yonemitsu 1986
Daily oral administration of 11 mg/kg BW for 30 days	No significant toxic signs	Dikshith et al. 1979

5 intraperitoneal injected doses totaling 2–100 mg/kg BW	At doses of 25 mg/kg BW and higher, rabbits usually died within 4 days posttreatment; no delayed pulmonary changes in rabbits typical of those induced in man and other animals observed in survivors up to 1 month after treatment	Butler and Kleinerman 1971
20 mg/kg BW, intravenous injection	Tended to concentrate in lung; lung histopathology and biochemical upset	Ilett et al. 1974
24 mg/kg BW, 20 dermal applications	No effect	Anonymous 1974
49–150 mg/kg BW	Acute oral LD50	Fletcher 1974; Haley 1979
Total 60-min aerosol dose of 250 mg	Significantly increased levels in serum of phospholipids, cholesterol, and triglycerides; reduced growth rate; no evidence of liver or lung damage	Seidenfeld et al. 1984
346–480 mg/kg BW	Acute dermal LD50	Anonymous 1974; Haley 1979
Sheep, *Ovis aries*		
Single intravenous injection of 1, 2, 4, or 8 mg/kg BW	Nephrotoxic, producing glemerular and tubular defects in a dose-dependent manner, including inhibited glomerular filtration rates and inhibited paraquat secretion; LD50 (6 weeks), about 1 mg/kg BW; serum levels 60 min postexposure (in mg/L), 0.07 for the 1 mg/kg group, 0.25 for the 2 mg/kg group, 1.23 for the 4 mg/kg group, 2.05 for the 8 mg/kg group	D. B. Webb 1983; D. W. Wegg 1983
50–75 mg/kg BW	Acute oral LD50	Fletcher 1974; Summers 1980; Heitkamp and Brown 1982
Rat, *Rattus* sp.		
0.000116 or 0.000232 ug/kg BW hourly for 7 days, intravenous infusion, equivalent of total dose of 0.0465 mg (low dose) or 0.093 mg (high dose)	No adverse effects evident at low dose; at high dose, survivors showed weight loss, histopathology, increased lung glutathione and glucose-6-phosphate dehydrogenase activity--reflecting paraquat-induced oxidant stress and increased demand on lung NADPH	Dunbar et al. 1988a
0.0001 or 0.0004 mg/L air, daily 6-h exposure for 3 weeks	No effect at 0.0001 mg/L; pulmonary irritation at 0.0004 mg/L	Haley 1979
0.001–1.0 mg/kg BW, entire dose in right lung	Dose-dependent lung injury and fibrosis; tissue fibronectin levels remained elevated 14 days after administration	Dubaybo et al. 1987
0.006 mg/L air, 60-min exposure	LC50; 3 um-size particle most effective	Haley 1979
0.01 or 0.05 mg, injected into brain	Intense pattern of behavioral stimulation, including increased locomotor activity, especially circling, and convulsions; abnormal brain wave patterns	De Gori et al. 1988
0.0116 mg/kg BW, single dose, various routes	Dose administered by intravenous and intragastric routes cleared rapidly; urine and feces major excretion routes; Tb 1/2 in blood	Chui et al. 1988

	about 68 min; dermal- and pulmonary-route doses tended to remain at site of injection	
0.05 mg/kg BW, entire dose in lung	Pulmonary lesions, lung congestion and collapse, edema, hemorrhage, degenerate changes, proliferative fibrosis in lung tissue	Kimbrough and Gaines 1970; Summers 1980
0.09–9.00 mg/kg BW, single subcutaneous injection	Dose-dependent avoidance of foods at >0.5 mg/kg BW; the ED50 for conditioned taste aversion was 2.4 mg/kg BW (minimum effective dose was 0.78 mg/kg BW); none of these doses produce overt clinical or histological signs of toxicity	Dey et al. 1987
0.125 or 0.25 mg/kg BW hourly, continuous intravenous infusion	After 7 days, lungs of high-dose group had elevated putrescine, spermicine, and ornithine decarboxylase activity, reflecting changes in polyamine metabolism; no measurable effects in low-dose group	Dunbar et al. 1988b
Pregnant dams given 1.5, 4.5, or 13.5 mg/kg BW daily from day 7 to day 17 of gestation	No fetal toxicity or teratogenicity in any group, although maternal survival was low in the 13.5 mg/kg group	Anonymous 1988
6 mg/kg BW, intravenous injection Fed diets containing 10, 30, 100, or 300 mg/kg for 2 years	Lung fibrosis No adverse effects in males at 30 mg/kg diet (1.06 mg/kg BW daily) and lower, or in females at 100 mg/kg diet (4.3 mg/kg BW daily) and lower; lung histopathology observed in males at 100 mg/kg diet and both sexes at 300 mg/kg; at growth, reduced food and water intake, abnormal blood chemistry, and increased frequency of cataracts; no conclusive evidence of carcinogenicity	Summers 1980 Anonymous 1988
10 or 30 mg/kg BW, intraperitoneal injection	At both doses there was a decrease in calcium uptake by lung microsomes for 3–4 days postinjection, followed by recovery during next 4 days	Agarwal and Coleman 1988
14–34 mg/kg BW, intraperitoneal injection	LD50	Haley 1979; Manzo et al. 1979; Anonymous 1988
16–18 mg/kg BW, intravenous injection	LD50	Sharp et al. 1972
18 mg/kg BW, single intraperitoneal injection	Significant increases in enzymes and compounds responsible for protecting against lipid peroxidation, including catalase, glucose-6 phosphate dehydrogenase, and nonprotein sulfhydryl	Omaye and Reddy 1980
19–26 mg/kg BW, subcutaneous injection	LD50	Haley 1979; Lock 1979; Anonymous 1988
20 mg/kg BW, intravenous injection		
Postinjection time		
5 min	Residues (in mg/kg), 90 in kidney, 30 in plasma 10–20 in lung, liver, and muscle	Summers 1980
4 h	Residues (in mg/kg), 8 in lung, 6 in kidney, 2 in liver, 0.8 in muscle, 0.3 in plasma	Summers 1980

3 days	Lung contained 3 mg/kg, kidney 0.7, muscle 0.5, liver 0.3, plasma 0.04	Summers 1980
10 days	In survivors, muscle contained 0.25 mg/kg, lung 0.1, kidney 0.06, liver 0.03, plasma 0.01	Summers 1980
Fed diets containing 20, 100, or 200 mg/kg ration for two generations	Maternal and fetal toxicity in 200 mg/kg diet	Anonymous 1988
21 mg/kg BW	90-dose oral LD50 in females	Kimbrough and Gaines 1970
27 mg/kg BW, single intravenous injection	Lung surfactant decreased 32% within 24 h, suggesting loss in alveolar stability	Haley 1979
Adult males, 30 mg/kg BW, intraperitoneal injection	No deaths 72 h after single injection; marked reduction of acid alkaline phosphatase activity in alveolar epithelium of lung	Boudreau and Nadeau 1987
45 mg/kg BW, intraperitoneal injection	After 48 h, marked increase in blood glucose, depressed plasma insulin level, marked depletion of liver glycogen, significant increase in plasma creatinine phosphokinase and glutamic oxaloacetic transaminase activity	Giri et al. 1979
Fed 8-week diets containing 50, 120, or 250 mg/kg ration	No progressive accumulations in tissues; no pulmonary lesions at 50 or 120 mg/kg diet--however, 100% of 250 mg/kg group had pulmonary lesions	Summers 1980
Fed 2-year diet containing 70 mg/kg ration	No significant toxicity	Anonymous 1974
70–90 mg/kg BW, dermal exposure	LD50	Kimbrough and Gaines 1970; Kimbrough 1974; Haley 1979; Anonymous 1988
95–174 mg/kg BW	Acute oral LD50	Kimbrough and Gaines 1970; Murray and Gibson 1972; Anonymous 1974, 1988; Kimbrough 1974; Manzo et al. 1979; Heitkamp and Brown 1982; Bauer 1983
125 mg/kg BW, oral dose	Survivors had decreased kidney glomerular filtration rate within 24 h	Lock 1979
170 mg/kg diet for 2 years	No measurable effect	Haley 1979

Paraquat tends to rapidly localize in selected tissues of injected mice, including melanin, alveolar-type cells of the lung, choroid plexus, muscle, liver, gallbladder, intestinal contents, and proximal tubules of the kidney (Waddell and Marlowe 1980). Half-time persistence of paraquat in rat tissues ranged from 20 - 30 min in plasma to about 5 days in muscle (Sharp et al. 1972).

Acute effects of paraquat poisoning in livestock and small laboratory animals are similar to those in humans (Conning et al. 1969; Murray and Gibson 1972; Rose et al. 1976; Smith and Heath 1976; Haley 1979; Kelly et al. 1979; Manzo et al. 1979; Summers 1980; Table 5). Signs of acute paraquat toxicosis included hyperexcitability leading to convulsions or incoordination, inflammation of the mouth and throat, vomiting, reluctance to eat or drink, diarrhea, tachycardia, eye irritation of the conjunctiva, corneal lesions, skin reddening, skin ulceration, skin necrosis, histopathology of liver and kidney, and respiratory failure. Paraquat was selectively accumulated in lungs of canines, primates, and rodents, regardless of route of administration. Lung pathology included congestion, hemorrhage, edema, and collapse; this was associated with degeneration of alveolar and bronchial cells. Death may occur within 10 days of acute exposure.

Chronic administration of small doses or repeated injections usually produces no clinical signs for several weeks. Generally, signs develop suddenly and include weight loss, anorexia, and death--usually within 10 days of onset of signs (Smith and Heath 1976). Decreased food consumption and consequent loss of body weight are common in paraquat-poisoned rats and dogs. The *area postrema* of the hindbrain is an important neural site for detection of blood-borne chemicals and is speculated to control paraquat-induced taste aversion formation and weight loss (Dey et al. 1987).

Rabbits are comparatively resistant to paraquat-induced lung damage, regardless of the route of administration (Dikshith et al. 1979; Summers 1980; Bauer 1983). However, the closely related hare (*Lepus europaeus*) is comparatively sensitive to paraquat. Hares--placed on alfalfa plats within a few hours after the fields were treated with paraquat at 0.6 kg/ha--experienced 50% mortality in 120 h; survivors that were killed 2 weeks later showed lung damage and ulceration of the lingual mucous membrane. Plant residues were about 30 mg/kg fresh weight for alfalfa and 60 mg/kg for weeds; residues were negligible in tissues of the hare (Lavaur et al. 1973). In a similar incident in Italy, Stracciari et al. (1980) found that only 1 of 56 hares found dead had lung damage, although all had elevated urine paraquat levels of 0.5 mg/L. It was concluded that paraquat alone was not the causative agent of death, and that paraquat interactions with other chemicals applied at the same time on other crops in the same area may have been responsible.

Paraquat applications to spruce plantations for grass control had no effect on the movement or density of field mice (*Microtus arvalis*) and voles (*Microtus agrestis*), but shrews (*Sorex* sp.) migrated from treated areas to untreated ones (Summers 1980).

Paraquat is poorly absorbed from the gut and readily excreted. Typical gut absorption rates (%) and peak concentrations in blood (mg/L) were 15-20% and 3- 4 mg/L in rats, 5- 10% and 1 mg/L in guinea pigs, 16% and 13 mg/L in cats, 0.26% in cows, and 1-5% in humans (Conning et al. 1969). Paraquat is actively secreted by a renal mechanism that is vulnerable to paraquat toxicity; poisoning of the secretory component removed a large part of the excretory capacity for paraquat (D. W. Webb 1983). In rats, a single oral LD50 dose produced a reduction in renal function within 24 h. This effect is probably secondary to a decrease in plasma volume with a consequent reduction in renal blood flow (Lock 1979). Paraquat caused mild renal tubular damage in rats; within 24 h of injection of 20 mg/kg BW, there was marked diuresis, sugar and albumin in the urine, and increased plasma urea concentrations (Lock and Ishmael 1979). Paraquat-poisoned mice showed a decreased ability to excrete organic acids and bases, probably reflecting interference with proximal tubule function because no change in glomerular filtration rate was observed (Ecker et al. 1975).

Paraquat was not mutagenic, as judged by noninterference with DNA metabolism, and had no reverse mutation-inducing capability (Anonymous 1988). Paraquat had little or no teratogenicity to mammals (Bus et al. 1975). No teratogenic effects were observed in rats fed diets containing paraquat concentrations of 400 mg/kg for 3 generations (Anonymous 1988). The most common malformations in paraquat-stressed rats were those involving costal cartilage (Bauer 1983). Recent studies demonstrated transplacental transfer of paraquat in pregnant rats and guinea pigs. High concentrations of radiolabeled paraquat were found in the placenta and throughout the fetuses within 30 min of intravenous administration; concentrations in placenta, maternal blood, and fetal blood were in the ratio of 16:4:1 (Ingebrigtsen et al. 1984), suggesting that additional research is needed on paraquat embryotoxicity.

Recommendations

Criteria have not yet been promulgated by regulatory agencies for the protection of sensitive species of fish and wildlife against paraquat.

Degradation rate of paraquat in certain soils can be slow, and the compound can persist for years--reportedly in a form that is biologically unavailable. However, data are missing or incomplete on flux rates of paraquat from soil into food webs and on interaction dynamics of paraquat with other herbicides frequently applied at the same time. It seems prudent to keep close watch on the residues of paraquat in soils in situations where repeated applications have been made over long periods (Summers 1980).

Aquatic invertebrates, especially early developmental stages of crustaceans, are unusually sensitive to paraquat; adverse effects are documented in the range of 1.0- 100 µg/L (Table 6). For this reason, paraquat should be used with caution in estuarine and marshy areas (Summers 1980). Fish seem to be "safe" against aquatic weed control concentrations of < 1.0 mg paraquat per liter (Summers 1980), but aquatic plants tend to accumulate paraquat from the medium; accordingly, more research is needed on the effects of ingestion of contaminated plants and plant detritus by amphibians, reptiles, and other aquatic fauna (Dial and Dial 1987b).

Eggs of migratory waterfowl seem to be especially sensitive to paraquat at recommended application rates in an oil vehicle, but they were significantly more resistant to the same dose applied in water (Table 6). Application of paraquat in oil solution seems contraindicated in areas containing nesting waterfowl.

Among mammals, humans are among the most sensitive to paraquat, and permissible residues in our diet are low when compared to no-observed-effect levels in other warm-blooded species (Table 6). An air concentration of 0.4 mg/m^3 may exceed a safe level for certain mammals, particularly if the size of the aerosol particle is submicroscopic and capable of penetrating the lung (Burleigh-Flayer and Alarie 1988). Accordingly, the present paraquat aerosol standard--set at 0.5 mg/m^3—may have to be lowered. Misuse of paraquat has raised the question of cancellation of its registration, cancellation of its use in homes and recreational areas, or changing its packaging to prevent people from drinking it (Haley 1979). In almost all cases of fatal human poisonings, death was due to the ingestion of a concentrated (20%) solution. More dilute formulations (5 % paraquat) are usually not fatal if swallowed accidentally, suggesting that a dilute form of paraquat should be the only formulation permitted commercially (Kimbrough 1974).

Table 6. Proposed paraquat criteria for the protection of natural resources and human health.

Resource, proposed criterion, and other variables	Concentration	Reference[a]
Aquatic organisms		
Adverse effects level, in mg/L		
Algae and macrophytes		
Freshwater	0.25	1
Marine	5.0	2
Invertebrates

Biological Report
This publication series of the Fish and Wildlife Service comprises reports on the results of research, developments in technology, and ecological surveys and inventories of effects of land-use changes on fishery and wildlife resources. They may include proceedings of workshops, technical conferences, or symposia; and interpretive bibliographies. ISSN 0895-1926

Copies of this publication may be purchased from the National Technical Information Service (NTIS), 5285 Port Royal Road, Springfield, VA 22161.

Abstract. Cyanides are used widely and extensively in the manufacture of synthetic fabrics and plastics, in electroplating baths and metal mining operations, as pesticidal agents and intermediates in agricultural chemical production, and in predator control devices. Elevated cyanide levels are normally encountered in more than 1,000 species of food plants and forage crops, and this probably represents the greatest source of cyanide exposure and toxicosis to man and to range animals. Anthropogenic sources of cyanide in the environment include certain industrial processes, laboratories, fumigation operations, cyanogenic drugs, fires, cigarette smoking, and chemical warfare. Although cyanide is ubiquitous in the environment, levels tend to be elevated in the vicinity of metal processing operations, electroplaters, gold-mining facilities, oil refineries, power plants, and solid waste combustion.

Many chemical forms of cyanide are present in the environment, including free cyanide, metallocyanide complexes, and synthetic organocyanides, also known as nitriles. But only free cyanide (i.e., the sum of molecular hydrogen cyanide, HCN, and the cyanide anion, CN^-) is the primary toxic agent, regardless of origin.

Cyanides are readily absorbed through inhalation, ingestion, or skin contact and are readily distributed throughout the body via blood. Cyanide is a potent and rapid-acting asphyxiant; it induces tissue anoxia through inactivation of cytochrome oxidase, causing cytotoxic hypoxia in the presence of normal hemoglobin oxygenation. Diagnosis of acute lethal cyanide poisoning is difficult because signs and symptoms are nonspecific, and numerous factors modify its biocidal properties, such as dietary deficiencies in vitamin B_{12}, iodine, and sulfur amino acids. Among the more consistent changes measured in acute cyanide poisoning are inhibition of brain cytochrome oxidase activity, and changes in electrical activity in heart and brain. At sublethal doses, cyanide reacts with thiosulfate in the presence of rhodanese to produce the comparatively nontoxic thiocyanate, most of which is excreted in the urine. Rapid detoxification enables animals to ingest high sublethal doses of cyanide over extended periods without harm. Antidotes in current use to counteract cyanide poisoning include a combination of sodium nitrite and sodium thiosulphate (United States), cobalt edetate (United Kingdom, Scandinavia, France), or a mixture of 4-dimethylaminophenol and sodium thiosulphate (Germany).

All available evidence suggests that cyanides are neither mutagenic, teratogenic, nor carcinogenic. Moreover, there are no reports of cyanide biomagnification or cycling in living organisms, probably owing to its rapid detoxification. Cyanide seldom persists in surface waters and soils owing to complexation or sedimentation, microbial metabolism, and loss from volatilization. More data are needed on cyanide distribution and transformation in the atmosphere.

Analytical methods for the determination of free and bound cyanides and cyanogenic compounds in biological materials are under constant revision. Further, unless tissue samples are obtained promptly after cyanide exposure and analyzed immediately, erroneous analytical values will result.

Higher plants are adversely affected by cyanide through cytochrome oxidase inhibition; the rate of production and release of cyanide by plants to the environment through death and decomposition is unknown. Nonacclimatized soil bacteria are adversely affected at 0.3 mg HCN/kg; acclimatized populations, however, can degrade wastes containing up to 60 mg total cyanide per kilogram. In some cases, soil bacteria and fungi produce cyanides as secondary metabolites, with adverse effects on certain plants. Several species of arthropods normally contain elevated whole-body cyanide concentrations, and these confer protection against predators and allow consumption of cyanogenic plants.

Fish were the most sensitive aquatic organisms tested. Adverse effects on swimming and reproduction were observed between 5 and 7.2 µg free cyanide per liter; lethal effects usually occurred between 20 and 76 µg/L. Biocidal properties of cyanide in aquatic environments were significantly modified by water pH, temperature, and oxygen content; life stage, condition, and species assayed; previous exposure to cyanides; presence of other chemicals; and initial dose tested.

Birds that feed predominantly on flesh were more sensitive to cyanide than were herbivores. Free cyanide levels associated with high avian death rates include 0.12 mg/L in air, 2.1-4.6 mg/kg body weight (BW) via acute oral exposure, and 1.3 mg/kg BW administered intravenously. Dietary levels of 135 mg total cyanide per kilogram ration resulted in growth reduction of chicks, but 103 mg total cyanide per kilogram ration had no measurable effect on domestic chickens.

Cyanogenic plants represent a problem for various range animals and wildlife, primarily among species that eat rapidly. Intakes of 4 mg HCN/kg BW are lethal to these species if it is consumed quickly. Cassava (*Manihot esculenta*) is a cyanogenic plant that accounts for up to 70% of human caloric intake in some areas, and this is associated with serious, long-term toxic effects including ataxia, optic nerve lesions, altered thyroid function, demyelination, and increases in tissue thiocyanate levels. Acute oral LD50 values for representative species of mammals ranged between 2 and 3.6 mg HCN/kg BW. Despite the high lethality of large single exposures, repeated sublethal doses--especially in diets--can be tolerated by many species for extended periods, perhaps indefinitely. Mammalian deaths were also recorded at air concentrations of 140 mg HCN/m^3 (exposure for 60 min) and 4,400 mg HCN/m^3 (exposure for 1 min), and at dermal applications between 2.3 mg HCN/kg BW for abraded skin and 100 mg HCN/kg BW for intact skin. Adverse nonlethal effects were noted at drinking water concentrations >150 mg HCN/L and at dietary concentrations >720 mg HCN/kg ration.

Free cyanide criteria currently proposed for natural resource protection include <3 µg/L medium for aquatic life, and <100 mg/kg diet for birds and livestock. For human health protection, free cyanide values are <10 µg/L drinking water, <50 mg/kg diet, and <5 mg/m^3 air.

Key words: Cyanide, toxic effects, wildlife, cyanogenic plants, aquatic organisms, criteria.

The origin of terrestrial life probably depended on the presence and reactivity of hydrogen cyanide and its derivatives; paradoxically, hydrogen cyanide is toxic to the majority of living matter (Marrs and Ballantyne 1987). Cyanide is a general respiratory poison--although uptake can also occur through ingestion or dermal absorption--producing reactions within seconds, and death within minutes (Towill et al. 1978; Environmental Protection Agency [EPA] 1980). The toxic mechanism of cyanide primarily involves the inhibition of cytochrome oxidase, the terminal oxidative enzyme of the mitochondrial electron transport chain, producing blockage of aerobic ATP synthesis (Egekeze and Oehme 1979; Younes and Strubelt 1988). Because of their highly effective lethal potency, cyanides were used for genocidal programs in Germany in World War II, in mass suicides by members of the People's Temple religious sect in Guyana, and in the substitution of medication in Tylenol capsules in drugstores in various cities in the United States. In fact, cyanides are responsible for more human deaths than any other chemicals known, owing to their deliberate use in suicide, murder, chemical warfare, genocide, and judicial execution (Way 1981, 1984; Ballantyne and Marrs 1987a; Gee 1987; Marrs and Ballantyne 1987; Yamamoto 1989). High sublethal doses of cyanide are rapidly detoxified, and accidental acute cyanide poisonings in humans are uncommon (Towill et al. 1978).

Cyanide compounds are useful to society in terms of their key role in synthetic and industrial processes, for certain fumigation and agricultural uses, and for some therapeutic applications (Ballantyne and Marrs 1987a). Cyanides are present in effluents from iron and steel processing plants, petroleum refineries, and metal-plating plants, and constitute a hazard to aquatic ecosystems in certain waste-receiving waters (Smith et al. 1979), and to livestock (EPA 1980;Towill et al. 1978). Cyanide serves no useful purpose in the human body, yet it is present in our food, air, and water (Becker 1985).

Natural sources of cyanide include various species of bacteria, algae, fungi, and higher plants that form and excrete cyanide (Way 1984). The most widely distributed major food crop with a high content of cyanogenic glycosides is cassava (*Manihot esculenta*), also known as manioc. Cassava is a staple food in human diets in over 80 countries, and it is sometimes added to animal feeds as a substitute for more expensive cereal grains (Gomez et al. 1988). In humans, chronic cyanide intoxication caused by consumption of cassava is the main etiological factor in the debilitating tropical ataxic neuropathy (Egekeze and Oehme 1980). Other plants having comparatively elevated cyanide content include fruit pits, sweet potatoes (*Ipomoea batatas*), corn (*Zea mays*), bamboo shoots (*Bambusa* spp.), linseed, (*Linum* sp.), lima beans (*Phaseolus lunatus*), and millet (*Panicum miliaceum*; Way 1984). In higher plants that contain cyanogenic glycosides, at least 20 of these compounds have been identified (EPA 1980). Amygdalin--one of the more intensively studied cyanogenic glycosides--is found in seeds of the cherry (*Prunus* spp.), plum (*Prunus* spp.), peach (*Prunus persica*), apricot (*Prunus armenaica*), apple (*Malus domestica*), pear (*Pyrus communis*), and many parts of the cherry laurel (*Prunus laurocerasus;* EPA 1980). Apricot seeds and peach kernels are food delicacies in Turkey, and have caused at least nine poisonings (two fatal) in children from that country (Gee 1987). Acute cyanide poisoning has occurred in the United States from the ingestion of almond-flavored milkshakes prepared from apricot kernels (Way 1984). Amygdalin is also the chief ingredient in laetrile, a medication prescribed by some physicians to control tumors. Both laetrile and amygdalin-containing fruit pits have been implicated as the causes of acute cyanide poisoning in humans (EPA 1980). Another naturally occurring group of organic cyanides (nitriles) is the highly toxic pseudocyanogenic glycosides, especially cycasin, and these have been implicated in a variety of tropical diseases of the nervous system, and partial or total blindness (EPA 1980). Other nitriles found in plants include the lathyrogenic compounds, glucosinolates, and the cyanopyridine alkaloids (EPA 1980).

That certain plants, such as bitter almonds *(Prunus dulcis),* cherry laurel leaves, and cassava, are poisonous if consumed in sufficient quantities has been known for at least 2,000 years. But it was not until the 1700's that cyanide was recognized as the basis for their lethal toxicity. The first account of an experimental administration of extract of bitter almonds and other poisons to dogs (*Canis familiaris*) dates from 1679, as reviewed by Sykes (1981) and Ballantyne (1987a). In 1731, two fatal cases of human poisoning in Ireland were caused by drinking cherry laurel water, in this instance used as a flavoring agent in cooking and to dilute brandy. In that same year it was shown that cherry laurel water administered to dogs by various routes proved rapidly fatal. By 1781, it was well established that mammals, birds, reptiles, amphibians, fish, and insects could all be killed with small doses of laurel water, and that death was more rapid than that produced by other poisons tested. It was also at this time that cyanide was first implicated as a homicidal agent in England. In 1782, hydrocyanic acid was isolated from Prussian blue (a dye) by the Swedish chemist Scheele. In 1786, Scheele accidentally broke a vial of the material and died from vapor poisoning. In 1787, it was determined that hydrocyanic acid contained hydrogen, carbon, and nitrogen, but did not contain oxygen, formerly believed to be an essential component of all acids. Between 1802 and 1815, hydrocyanic acid was found to be lethal in small quantities to birds and dogs, and to act rapidly when given orally, intravenously, or applied to the eye surface. By 1803, it was known that cyanide occurred naturally and could be extracted from apricots or almonds. In 1815, hydrocyanic acid was prepared in a semipure form. Between 1817 and 1948, cyanide, in appropriate doses, was used therapeutically in England for the treatment of pulmonary diseases and tuberculosis, and as a sedative. By 1830, cyanogenic glycosides containing HCN were isolated from cassava; today, more than 800 species of cyanogenic plants have been identified. In 1876, it was first demonstrated that cyanide inhibited tissue oxidation. In 1894, cobalt compounds were suggested as antidotes due to their marked cyanide-binding capacity. Studies on cyanide detoxification conducted between 1877 and 1894 showed that thiosulphate administration caused the formation of thiocyanate--a relatively harmless metabolite. By the late 1800's, cyanide was regarded as a common plant metabolite rather than as an unusual poison. In 1929, it was conclusively demonstrated that cyanide combines with the trivalent iron atom in cytochrome oxidase, a respiratory enzyme that links the tricarboxylic acid cycle and formation of metabolic water. Many reviews have been published on cyanide in the environment; particularly useful are those by Doudoroff (1976), Towill et al. (1978), Smith et al. (1979), Egekeze and Oehme (1980), EPA (1980, 1989), Vennesland et al. (1981a), Leduc et al. (1982), Leduc (1984), Way (1984), Ballantyne and Marrs (1987a), and Evered and Harnett (1988).

Cyanide hazards to fish, wildlife, and livestock are well documented. Massive kills of freshwater fish by accidental discharges of cyanide wastes are fairly common (Holden and Marsden 1964; Leduc 1978; Towill et al. 1978; EPA 1980). In one case, cyanide-containing mine effluents from a Canadian tailings pond released into a nearby creek killed more than 20,000 steelhead (Oncor*hynchus mykis;* Leduc et al. 1982). Many species

of birds were found dead near burrows of the blacktailed prairie dog (*Cynomys ludovicianus*) after the burrows had been treated with calcium cyanide to control prairie dog populations; dead birds included the burrowing owl (*Athene cunicularia*), the bald eagle (*Haliaeetus leucocephalus*), and the golden eagle (*Aquila chrysaetos;* Wiemeyer et al. 1986). An endangered California condor (*Gymnogyps californianus*) found dead in Kern County, California, in November 1983 had particles of a yellow fluorescent tracer in its mouth; these particles were similar to those mixed with sodium cyanide in M-44 spring-loaded ejector mechanism devices used in a U.S. Fish and Wildlife Service Animal Damage Control Program in that vicinity, suggesting that cyanide was a possible cause of death (Krynitsky et al. 1986). M-44 devices are known to have caused the death of magpies (*Pica* sp.), ravens and crows *(Corvus* spp.), wild turkeys *(Meleagris gallopavo),* and various unidentified species of hawks and vultures (Wiemeyer et al. 1986). Between 1980 and 1989, 519 mammals--mostly rodents (35%) and bats (34%)--were found dead at cyanide-extraction, gold-mine leach ponds in California, Nevada, and Arizona; the list included coyote *(Canis latrans),* foxes, skunks, badger *(Taxidea taxus),* weasels, rabbits, deer, and beavers (Clark and Hothem 1991). Also found dead at these same leach ponds were 38 reptiles, 55 amphibians, and 6,997 birds (Clark and Hothem 1991), including many species of waterfowl and songbirds (Allen 1990). The influence of cyanide-extraction gold-mining operations on wildlife is currently under investigation by scientists at the Patuxent Wildlife Research Center.

The major threat of cyanide poisoning to livestock and terrestrial mammalian wildlife is through ingestion of plants containing high levels of cyanogenic glycosides (Towill et al. 1978; Marrs and Ballantyne 1987). Plants implicated in cyanide poisoning of animals include the sorghums (Johnson grass, *Sorghum halepense;* Sudan grass, *Sorghum sudanense*), arrowgrass (*Triglochin* spp.), elderberry (*Sambucus* spp.), wild cherry (*Prunus* spp.), and the pits of several common fruits, such as apple, peach, and apricot; these plants and fruit pits have the potential of releasing cyanide upon ingestion (Egekeze and Oehme 1980). Domestic goats (*Capra* spp.) died of cyanide poisoning after eating leaves and fruit of the crab apple *(Malus sylvestris);* the crab apple contains cyanogenic glycosides in its leaves and fruit (Shaw 1986). Cyanide poisoning of cattle (*Bos* spp.) by forage sorghums and various hybrid cultivars has been reported in India (Bapat and Abhyankar 1984) and elsewhere (Cade and Rubira 1982; Biehl 1984). Cattle appear to be more vulnerable to cyanide poisoning than are sheep (*Ovis aries*), horses (*Equus caballus*), and pigs (*Sus* spp.; Cade and Rubira 1982). *Equine sorghum cystitis ataxia* is a condition observed in horses grazing on Sorghum or hybrid Sudan grass pastures; it is characterized by urinary incontinence, posterior incoordination, and degenerative central nervous system lesions (Egekeze and Oehme 1980). Grazing cyanogenic plants can induce sulfur deficiency in sheep, presumably because sulfur detoxifies the released cyanide (Towill et al. 1978). The increasing use of cassava and other cyanogenic plants in animal feeding portends a greater exposure to dietary cyanides (Davis 1981).

This report briefly reviews the technical literature on ecological and toxicological aspects of cyanide, with emphasis on fishery and wildlife resources, and provides recommendations for the protection of sensitive species of concern to the U.S. Fish and Wildlife Service. This account is part of a continuing series of synoptic reviews prepared in response to informational requests from Service environmental specialists.

Chemical Properties

The chemical speciation of cyanides varies according to their source. Specific terms used to describe cyanide include free cyanide, cyanide ion, simple cyanides, complex cyanides, nitriles, cyanogens, and total cyanide. The most common forms of cyanide in the environment are free cyanide, metallocyanide complexes, and synthetic nitriles. A brief description of each cyanide species follows (Smith et al. 1978, 1979; Towill et al. 1978; Egekeze and Oehme 1980; EPA 1980, 1989; Davis 1981; Leduc 1981, 1984; Leduc et al. 1982; Simovic and Snodgrass 1985; Ballantyne 1987a; Homan 1987; Marrs and Ballantyne 1987).

Free cyanide is the primary toxic agent in the aquatic environment. Free cyanide refers to the sum of molecular HCN and the cyanide anion (CN^-), regardless of origin. In aqueous solution with pH 9.2 and lower, the majority of the free cyanide is in the form of molecular HCN. The chemical names for HCN include hydrogen cyanide, hydrocyanic acid, cyanohydric acid, and prussic acid. Hydrogen cyanide (Table 1) is a colorless, flammable liquid or gas that boils at 25.7° C and freezes at -13.2° C. The gas rarely occurs in nature, is lighter than air, and diffuses rapidly; it is usually prepared commercially from ammonia and methane at elevated temperatures with a platinum catalyst. It is miscible with water and alcohol, but is only slightly soluble in ether. In water, HCN is a weak acid with the ratio of HCN to CN^- about 100 at pH 7.2, 10 at pH 8.2, and 1 at

pH 9.2. HCN can dissociate into H and CN^-. Cyanide ion, or free cyanide ion, refers to the anion CN^- derived from hydrocyanic acid in solution, in equilibrium with simple or complexed cyanide molecules. Cyanide ions resemble halide ions in several ways and are sometimes referred to as "pseudohaline" ions. For example, silver cyanide is almost insoluble in water, as are silver halides. Cyanide ions also form stable complexes with many metals.

Simple cyanides typically refer to alkali water-soluble salts, such as NaCN, KCN, $Ca(CN)_2$, and $Hg(CN)_2$, but also include several cyanide salts of alkali, alkaline earth, or heavy metals, that is, $Zn(CN)_2$, $Cd(CN)_2$, $Ni(CN)_2$, and AgCN, of varying degrees of solubility. In water, NaCN and KCN will completely dissociate to give free cyanide. All simple cyanides ionize in water to release cyanide ion which, depending on pH, will form hydrocyanic acid. For sodium cyanide, the reaction proceeds as follows:

(1) $NaCN \quad Na^+ + CN^-$

(2) $CN^- + HOH \quad HCN + OH^-$

Increased pH will maintain a larger fraction of the cyanide as CN^-, and acidification will cause the reverse. At pH 7, about 99% of the free cyanide is in the form of HCN, whereas at pH 9.3 HCN composes 50%. Since HCN is extremely water soluble and is also one of the most toxic cyanide species, it is noteworthy that the toxicity of simple cyanides will not be affected measurably below pH 8.3. Acidification of dilute (milligrams per liter) cyanide solutions will not initiate any greater release of HCN, but acidification of concentrated (grams per liter) solutions promotes HCN formation and release.

Table 1. Some properties of potassium cyanide, hydrogen cyanide, and sodium cyanide (from EPA 1989).

Property	Potassium cyanide	Hydrogen cyanide	Sodium cyanide
CAS number	151-50-8	74-90-8	143-33-9
Chemical formula	KCN	HCN	NaCN
Molecular weight	65.12	27.03	49.01
Physical state	Solid	Gas or liquid	Solid
Boiling point (º C)	--	25.7	1,496
Melting point (º C)	634.5	–13.21	563.7
Specific gravity	1.5	0.7 (liquid)	1.6
Solubility in water (g/L)	716 at 20º C	Miscible	480 at 10º C

Complex cyanides are compounds in which the cyanide anion is incorporated into a complex or complexes; these compounds are different in chemical and toxicologic properties from simple cyanides. In solution, the stability of the cyanide complex varies with the type of cation and the complex that it forms. Some of these are dissociable in weak acids to give free cyanide and a cation, while other complexes require much stronger acidic conditions for dissociation. The least-stable complex metallocyanides include $Zn(CN)_4^{2-}$, $Cd(CN)_3^-$, and $Cd(CN)_4^{2-}$; moderately stable complexes include $Cu(CN)_2^-$, $Cu(CN)_3^{2-}$, $Ni(CN)_4^{2-}$, and $Ag(CN)^{2-}$; and the most stable complexes include $Fe(CN)_6^{4-}$and $Co(CN)_6^{4-}$**.** The toxicity of complex cyanides is usually related to their ability to release cyanide ions in solution, which then enter into an equilibrium with HCN; relatively small fluctuations in pH significantly affect their biocidal properties.

Cyanogen [$(CN)_2$] is the simplest compound containing the cyanide group. Cyanogen is an extremely toxic, flammable gas that reacts slowly with water to form HCN, cyanic acid, and other compounds; it is rapidly

degraded in the environment. Cyanogen and its halide derivations are comparable in toxicity to hydrogen cyanide.

Nitriles are defined as organic compounds (RCN) containing the cyanide group. Cyanide bound to carbon as nitriles (other than as cyanogenic glycosides) are comparatively innocuous in the environment, and are low in chemical reactivity and are biodegradable. For simple mononitriles there is a clear progression, with more cyanide being released as chain length increases. A similar pattern exists in dinitriles, but corresponding compounds require a longer carbon chain than mononitriles before free cyanide is produced. Based on studies with chicken liver homogenates (Davis 1981), mononitriles were more toxic than dinitriles, and within each group the order of toxicity was $CH_3 > C_2H_5 > C_3H_7 > C_4H_9 > C_5H_{11} > C_7H_{15}$. Cyanohydrins [$R_2C(OH)CN$] and cyanogenic glycosides [$R_1R_2C(OR_3)CN$] are special classes of nitriles, in that under appropriate conditions they will decompose to HCN and cyanide ions. Cyanogens (not to be confused with cyanogen), such as acrylonitrile, propionitrile, and succinonitrile, are nitrile-containing materials of varying complexity and lability, and can liberate free and toxicologically available amounts of cyanide. But the nonnitrile portion of the cyanogen molecule may exert an independent or interactive toxicity, causing a complex response.

Cyanates contain the OCN group. Inorganic cyanates that are formed industrially by the oxidation of cyanide salts hydrolyze in water to form ammonia and bicarbonate ion. Alkyl cyanates are insoluble in water and form cyanurates. Alkyl isocyanates contain the OCN radical, are formed from cyanates, and, like cyanates, are readily hydrolyzed. Thiocyanates (SCN group) are formed from cyanides and sulfur-containing materials and are relatively stable.

Total cyanides refers to all cyanide-containing compounds, including simple and complex cyanides, cyanoglycosides, and free cyanide. Total cyanides is a chemical measurement of free cyanide present in solution or released by acidification or digestion. Only free cyanide is considered to be a biologically meaningful expression of cyanide toxicity. Under most circumstances, the concentration of total cyanide will exceed that of HCN. In some waters, however, the total cyanide concentration may consist almost entirely of free cyanide, or it may contain cyanides that readily photodecompose or dissociate to yield HCN. The relation between total cyanide and free cyanide in natural waters varies with receiving-water conditions, type of cyanide compounds present, degree of exposure to daylight, and presence of other chemical compounds.

Hydrogen cyanide has frequently been associated with the odor of bitter almonds (Ballantyne 1983; Gee 1987). The threshold odor for olfactory detection of atmospheric HCN is 1 mg/L, but the odor may not be detected for various reasons, including the presence of other odors and the fact that only 20% to 40% of those tested could detect a cyanide odor.

Analytical methods for determining free and bound cyanide and cyanogenic compounds in biological materials are under revision. Current methods include chromatography; enzymic postcolumn cleavage; electrochemical detection; and ultraviolet, infrared, proton, and carbon-13 nuclear magnetic resonance spectroscopies (Brimer 1988). Proposed newer analytical methodologies include chemiluminescence (Wu et al. 1989); deproteinization techniques (Krynitsky et al. 1986); thin film dissociation coupled with preferential ultraviolet irradiation (Kelada 1989); differential pulse polarography (Westley 1988); and modified spectrophotometric (Blago 1989; Ohno 1989), colorometric (Lundquist and Sorbo 1989), and ion chromatographic determinations (Nonomura and Hobo 1989). Analysis of cyanide and cytochrome oxidase is usually conducted with samples of whole blood, serum, plasma, brain, or ventricular myocardium tissues. Samples should be obtained as soon as possible after cyanide exposure and analyzed immediately, otherwise erroneous analytical values will result (Towill et al. 1978; Ballantyne 1983). Brain and liver are recommended for cyanide analysis if removed and analyzed within a week (Ballantyne et al. 1974). Cyanide measurements are further confounded by the presence of various antidotal agents (Ballantyne 1983); by various tissue preservatives, such as formaldoxime (Knocke 1981) and sodium fluoride (Curry et al. 1967); and by the spontaneous postmortem production of cyanide in various tissues (e.g., sterile blood, brain, liver, kidney, uterus, intestines) over time in cases of noncyanide death (Curry et al. 1967; Ballantyne et al. 1974).

Mode of Action

Cyanide is a potent and rapid-acting asphyxiant. At lethal doses, inhalation or ingestion of cyanide produces reactions within seconds and death within minutes. Cyanide's toxic effect is due to its affinity for the ferric heme form of cytochrome a_3, also known as cytochrome c oxidase, the terminal oxidase of the mitochondrial respiratory chain (Towill et al. 1978; Egekeze and Oehme 1980; Solomonson 1981; Way 1981, 1984; Leduc et al. 1982; Biehl 1984; Ballantyne 1987a; Marrs and Ballantyne 1987; Yamamoto 1989). Inhibition of the enzyme cytochrome c oxidase is thought to involve a two-step reaction--initial penetration of cyanide into a protein crevice followed by binding to heme iron. Formation of a stable cytochrome c oxidase-CN complex in the mitochondria produces a blockage of electron transfer from cytochrome oxidase to molecular oxygen and cessation of cellular respiration, causing cytotoxic hypoxia in the presence of normal hemoglobin oxygenation. Tissue anoxia induced by the activation of cytochrome oxidase causes a shift from aerobic to anaerobic metabolism, resulting in the depletion of energy-rich compounds such as glycogen, phosphocreatine, and adenosine triphosphate, and the accumulation of lactate with decreased blood pH. The combination of cytotoxic hypoxia with lactate acidosis depresses the central nervous system--the most sensitive site of anoxia--resulting in respiratory arrest and death. If the absorption rate is significantly greater than the detoxification rate, there will be a rapid accumulation of free cyanide in tissues and body fluids, resulting in the prompt onset of signs of acute cyanide poisoning. Acute cyanide poisoning is frequently encountered as a relatively massive overdose, where the amount of cyanide greatly exceeds the minimal concentration necessary to inhibit cytochrome c oxidase. In such cases, many enzymes and biological systems are disrupted, including various metalloenzymes, nitrate reductase, nitrite reductase, myoglobin, various peroxidases, catalase, and ribulose diphosphate carboxylase, resulting in severe signs of toxicity and rapid death.

The great majority of the absorbed cyanide reacts with thiosulfate in the presence of enzymes to produce thiocyanate, which is excreted in the urine over a period of several days. Owing to this rapid detoxification, animals can ingest high sublethal doses of cyanide over extended periods without harm (Towill et al. 1978; Egekeze and Oehme 1980; EPA 1980; Davis 1981; Solomonson 1981; Leduc 1984; Ballantyne 1987a; Oh et al. 1987; Marrs and Ballantyne 1987; Westley 1988; Mengel et al. 1989). Authorities are also in general agreement on several points: thiosulfate is usually low in the body, and higher levels can significantly protect against cyanide toxicity; species vary considerably in both the extent to which thiocyanate is formed and the rate at which it is eliminated from the body; thiocyanate metabolites resulting from the transulfuration process are about 120 times less toxic than the parent cyanide compound; thiocyanate may accumulate in tissues and has been associated with developmental abnormalities and other adverse effects; the two enzyme systems responsible for the transulfuration process are thiosulfate-cyanide sulfurtransferase--also known as rhodanese--and beta-mercaptopyruvate cyanide sulfurtransferase. Rhodanese is widely distributed in the body, but activity levels in mammals are highest in the mitochondrial fraction of liver. Rhodanese activity levels in catalyzing the transformation of thiosulfate to thiocyanate are limited by the availability of sulfur.

Minor detoxification pathways for cyanide include exhalation in breath as HCN and as $C0_2$ from oxidative metabolism of formic acid; conjugation with cystine to form 2-iminothiazolidene- 4-carboxylic acid or 2-aminothiazoline-4-carboxylic acid; combining with hydroxocobalamin (B_{12}) to form cyanocobalamin, which is excreted in urine and bile; and binding by methemoglobin in the blood (Towill et al. 1978; EPA 1980; Ballantyne 1987a; Marrs and Ballantyne 1987).

Absorption of hydrogen cyanide liquid or gas readily occurs through inhalation, ingestion, or skin contact (Towill et al. 1978; Egekeze and Oehme 1980; EPA 1980; Homan 1987). Inhalation and skin absorption are the primary hazardous routes in cyanide toxicity in occupational exposure. Skin absorption is most rapid when the skin is cut, abraded, or moist. Inhalation of cyanide salts is also potentially hazardous because the cyanide dissolves on contact with moist mucous membranes. Regardless of route of exposure, cyanide is readily absorbed into the bloodstream and distributed throughout the body. Cyanide concentrates in erythrocytes through binding to methemoglobin (Towill et al. 1978; EPA 1980), and free cyanide concentrations in plasma are now considered one of the better indicators of cytotoxicity (Ballantyne 1987a). Because of the affinity of cyanide for the mammalian erythrocyte, the spleen may contain elevated cyanide concentrations when compared to blood; accordingly, spleen should always be taken for analysis in cases of suspected cyanide poisoning (Ballantyne 1975). Cyanide also accumulates in various body cells through binding to metalloproteins or enzymes such as catalase and cytochrome c oxidase (EPA 1980). The brain is probably the major target organ

of cytotoxic hypoxia, and brain cytochrome oxidase may be the most active site of lethal cyanide action, as judged by distribution of cyanide, thiosulfate, and rhodanese (Solomonson 1981; Ballantyne 1987a). Significant positive correlations exist between cyanide concentrations in plasma, cerebrospinal fluid, and brain (Ballantyne 1987a); these correlations need further exploration.

Hydrogen cyanide formation may contribute to the toxicity of snake venom, owing to the high levels of L-amino acid oxidase in some snake venoms (Vennesland et al. 1981b). This enzyme is harmless on injection, but the tissue destruction caused by other venom components probably provides the required substrate and cofactor for HCN production.

Cyanide inhibits ion transport mechanisms in amphibian skin, gall bladder, and proximal renal tubules (Bello-Reuss et al. 1981). Measurable changes in cell membrane potentials of isolated gall bladder epithelium cells, for example, were induced by NaCN in a salamander (Bello-Reuss et al. 1981). Cyanide-induced hyperpolarization was caused primarily by an increase in permeability of the cell membrane to potassium, which, in turn, was mediated by an elevation of intracellular calcium ion activity, attributable to release from mitochondrial sources.

The binding rate of CN to hemeproteins, specifically hemoglobin components Ill and IV, is 370 times to 2,300 times slower in a marine polychaete annelid (*Glycera dibranchiata*), when compared to guinea pig (*Cavia* spp.), soybean (*Glycine* max), and sperm whale (*Physeter macrocephalus*); the significance of this observation is unclear but warrants further exploration (Mintorovitch et al. 1989).

Clinical Features

Accidental exposure to cyanides or cyanogens through inhalation, skin exposure, and swallowing occurs in agricultural fumigation, laboratories, industrial operations, domestic abuse, and products of combustion (Ballantyne and Marrs 1987b). Intentional exposure is reported from homicides, suicides (usually uncommon), judicial executions, chemical warfare, and covert activities (Ballantyne and Marrs 1987b).

Diagnosis of lethal cyanide poisoning is difficult because of the absence of gross pathology or histology, nonspecific congestion of viscera, and cerebral or pulmonary edema. Sometimes the blood is bright red, and sometimes the odor of bitter almonds is detected, but neither is sufficiently consistent for diagnostic purposes (Ballantyne and Marrs 1987b).

At low lethal doses of cyanide, the effects are principally on cytochrome oxidase in the central nervous system. At higher doses, cardiovascular signs and changes in electrical activity of the brain are among the most consistent changes measured (Way 1981, 1984). Acute and subacute toxic effects of poisoning with cyanide can vary from convulsions, screaming, vomiting, and bloody frothing to less dramatic events, such as a slow, quiet onset to coma and subsequent death (Way 1981). In the first stage of cyanide poisoning, victims exhibit headache, vertigo, weak and rapid pulse, nausea, and vomiting. In the second stage, there are convulsions, falling, dilated pupils, clammy skin, and a weaker and more rapid pulse. In the final stage, heartbeat becomes irregular and slow; body temperature falls; there is cyanosis of lips, face, and extremities, coma, frothy bloody saliva flow from mouth, and death (Way 1981). If acute exposure is to a sublethal dose of cyanide, this may lead to signs of toxicity, but as detoxification proceeds these signs will become less obvious and eventually vanish, and cyanide will be excreted as thiocyanate without accumulating (Ballantyne 1987a).

Chronic cyanide poisoning may develop in individuals who ingest significant quantities of cyanide or cyanide precursors in their diets; effects are exacerbated by dietary deficiencies in vitamin B_{12}, iodine, and sulfur amino acids, as well as by low levels and insufficient distribution of detoxifying enzymes such as rhodanese (Solomonson 1981). Cyanide toxicity of dietary origin has been implicated in acute animal deaths and as a major etiologic factor in toxic ataxic neuropathy in humans, and as a cause of blindness in humans suffering from tobacco amblyopia and Leber's hereditary optic atrophy (Egekeze and Oehme 1980). An increase in blood plasma cyanide is observed in healthy individuals who smoke cigarettes (Cailleux et al. 1988). An increase in blood plasma thiocyanate is also seen in smokers and in hemodialysis patients just before dialysis (Cailleux et al. 1988). Continuous intake of cyanide causes high levels of plasma thiocyanate and goiters in mammals; the antithyroid action (goiters) results from cyanide interference with iodine transport and thyroxine synthesis (Solomonson 1981; Leduc 1981, 1984). Signs of chronic cyanide poisoning include demyelination, lesions of the optic nerve, decrease in sulfur-containing amino acids, increase in thiocyanate, goiter, ataxia, hypertonia,

and depressed thyroid function (Solomonson 1981). These effects are common in areas that depend on cyanogenic plants--such as cassava--as a major dietary component (Solomonson 1981).

Biochemically, cyanide affects the citric acid cycle; strongly inhibits catalases and proteinases; induces glycolysis in protozoans, fish, and mammals; produces vitamin B_{12} deficiency; and modifies the phosphorylation mechanism of respiratory mitochondrial enzymes, causing arrested respiration due to inability to use oxygen (Leduc 1984).

Cyanide biomagnification or cycling has not been reported, probably because of cyanide's high chemical reactivity and rapid biotransformation (Towill et al. 1978; Marrs and Ballantyne 1987).

There is no evidence that chronic exposure to cyanide results in teratogenic, mutagenic, or carcinogenic effects (EPA 1980). Cyanide possibly has antineoplastic activity, as judged by a low therapeutic success against rat sarcomas (EPA 1980), but this requires additional documentation.

Confirmatory evidence of cyanide poisoning includes elevated blood thiocyanate levels--except, perhaps, when death was rapid--and reduced cytochrome oxidase activity in brain and myocardium, provided that all tissues were taken within a day or so of death, frozen quickly, and analyzed shortly thereafter (Biehl 1984; Marrs and Ballantyne 1987). Evaluation of cyanide poisoning and metabolism includes signs of toxicity, LD50 values, measurement of cyanide and thiocyanate concentrations, cytochrome c oxidase activity, metabolic modification of in vivo cyanogenesis, rate of cyanide liberation in vitro, and influence of modifying factors such as the animal species, dose, rate and frequency of administration, route of exposure, differential distribution of cyanide, detoxification rates, circadian rhythm interactions, age of the organism, and presence of antidotes (Ballantyne 1987a). For example, the concentration of cyanide measured in body fluids and tissues in humans and other animals following lethal administration of cyanide depends on several factors: route of exposure, with oral route yielding highest residues and inhalation route the lowest; amount and duration of exposure; nature of the material, with HCN and CN^- being most toxic; time to death; antidotes used; time to autopsy, with marked loss documented from simple evaporation, thiocyanate formation, hydrolysis, and polymerization; and time from autopsy to sample analysis, wherein cyanide concentrations may increase due to microbial action (Ballantyne and Marrs 1987b).

Antidotes

The antagonism of cyanide intoxication has been under investigation for at least 150 years. In 1840, cyanide lethality was reported to be antagonized by artificial respiration. In 1888, amyl nitrite was reported effective in antagonizing lethal effects of cyanide in dogs. In 1894, cobalt was shown to form a stable metal complex with cyanide and was used to antagonize cyanide. In 1933, the use of sodium thiosulfate as the sulfur donor was described (Way 1984). Many compounds are used today as cyanide antidotes including cobalt salts, rhodanese, sulfur donors, methemoglobin producers, carbohydrates, drugs used to treat acidosis, oxygen, methylene blue, 4-dimethylaminophenol, various aromatic amino- and nitro-compounds (such as aniline, p-aminopropiophenone, nitrobenzene), carbonyl compounds, and sodium pyruvate (Egekeze and Oehme 1980; EPA 1980; Solomonson 1981; Way 1981, 1984; Biehl 1984; Becker 1985; Ballantyne 1987b; Marrs 1987; Marrs and Ballantyne 1987; Way et al. 1988). Different antidotes are preferred in different countries: in the United States, a mixture of sodium nitrite and sodium thiosulfate; in France and the United Kingdom, cobalt edetate, also known as Kelocyanor; and in Germany, a mixture of 4-dimethylaminophenol and sodium thiosulfate.

The classic nitrite-thiosulfate treatment of cyanide poisoning, developed almost 60 years ago, is one of the antidotal combinations still employed (Way 1981). Excess oxygen improves this antidotal combination by potentiating the effectiveness of the nitrite-thiosulfate combination, as confirmed by studies in sheep and rats (Way 1984), even though, theoretically, oxygen should serve no useful purpose (Way et al. 1988). This therapeutic regimen protected rats against 20 LD50 doses of cyanide (Towill et al. 1978). Nitrite converts hemoglobin to methemoglobin, which has a high affinity for cyanide. The methemoglobin-HCN complex then slowly releases cyanide, which is converted to thiocyanate by way of rhodanese (Solomonson 1981). Sodium nitrite, administered intravenously, is now considered one of the more rapid therapeutic methods (Way 1984). The injection of sodium thiosulfate provides sulfur for the enzyme rhodanese to mediate the biotransformation of cyanide to the much less toxic thiocyanate (Egekeze and Oehme 1980). Multiple injections of sodium thiosulfate protected mice against death by organic cyanides and were more effective than sodium nitrite

(Willhite and Smith 1981). The nitrite-thiosulfate antidotal combination is one of the most effective treatments of cyanide poisoning, even though the specific mechanism of action of these two compounds is now being questioned, and concerns have been raised because of the toxicity of nitrite (Way 1981, 1984). One accepted therapy is an intravenous combination of sodium nitrite (1 mL of 20% solution) and sodium thiosulfate (3 mL of 20% solution), giving 4 mL of this mixture per 45 kg of body weight (Egekeze and Oehme 1980). For maximal effectiveness in treating cyanide intoxication in sheep, large doses of sodium thiosulfate (660 mg/kg BW) are given in combination with conventional doses of sodium nitrite (6.6 mg/kg BW; Egekeze and Oehme 1980). Livestock treatment in cases of suspected cyanide intoxication consists of intravenous administration of sodium nitrite at 10-20 mg/kg BW followed by sodium thiosulfate at 30-40 mg/kg BW; however, a sodium thiosulfate dose of 500 mg/kg BW, or more, may be more efficacious (Biehl 1984). Once clinical signs have abated, 1 g of activated charcoal per kilogram BW may be administered as a drench by way of a stomach tube (Biehl 1984). A 30-kg female goat *(Capra* sp.) was successfully treated after eating the leaves and fruit of the crab apple *(Malus sylvestris),* a plant that contains high levels of cyanogenic glycosides in leaves and fruits (Shaw 1986). Treatment consisted of four hourly treatments of 100 g of animal charcoal and bismuth subnitrate in water as a drench, followed by 300 mg sodium nitrite as a 1% aqueous solution, then 25 g of sodium thiosulfate. Another goat died despite identical treatment (Shaw 1986).

Cobalt compounds, such as hydroxocobalamin and its derivatives (i.e., cobalt histidine, cobalt chloride, dicobalt ethylenediamine tetracetic acid) have been used to treat cyanide poisoning for more than 100 years. Their efficacy was confirmed in pigeons (*Columba* sp.) and rabbits (*Oryctolagus sp*.), but cobalt compounds did not receive wide support as cyanide antagonists because of the inherent toxicity of cobalt ion (Way 1981, 1984). Nevertheless, proponents of the use of cobalt compounds (i.e., the United Kingdom, Scandinavia, much of Europe) stress the rapidity of action in forming a stable metal complex with cyanide, thereby preventing its toxic effect (Towill et al. 1978; Way 1984). One of the more frequently used cobalt compounds in cyanide treatment is hydroxocobalamin, which reverses cyanide toxicity by combining with cyanide to form cyanocobalamin (EPA 1980; Solomonson 1981). Hydroxocobalamin has been used in guinea pigs and baboons *(Papio anubis)* to lower blood cyanide levels, and in humans after inhalation or ingestion of cyanide compounds (Egekeze and Oehme 1980).

Dimethylaminophenol (DMAP) forms methemoglobin by setting up a catalytic cycle inside the erythrocyte, in which oxygen oxidizes the DMAP to N-N-dimethylquinoneimine, the latter oxidizing the hemoglobin to methemoglobin (Marrs 1987). Dogs poisoned with KCN and given DMAP intravenously had restored respiration and decreased plasma cyanide levels. The 4-dimethylamino-phenol induced ferrihemoglobin production, which combined with the cyanide in the red cells to form ferrihemoglobin cyanide (Christel et al. 1977).

No usable cyanide prophylactic therapy now exists for humans, although sodium thiosulfate, hydroxocobalamin, and other compounds have been used to protect against cyanide toxicity in laboratory animals (Mengel et al. 1989). For example, pyridoxal 5-phosphate, the active form of vitamin B_6, readily forms complexes with cyanides, and was effective in providing significant protection to rats (Keniston et al. 1987). Fructose fed prior to insult lessens cyanide-induced hepatotoxicity in rats (Younes and Strubelt 1988). L-ascorbic acid and dehydroascorbic acid probably act as protectants against cyanide toxicity by way of nontoxic cyanohydrin formation (Sprince et al. 1982). Carbon tetrachloride pretreatment was effective in protecting mice against death from most nitriles (Willhite and Smith 1981), and pretreatment with p-aminopropiophenone serves to protect against cyanide toxicity (D'Mello 1987).

Sources and Uses

Production of cyanides in the United States increased from about 136 million kg in 1963 to 318 million kg in 1976 (Towill et al. 1978; Way 1981; Marrs and Ballantyne 1987). Cyanide consumption in North America was 64 million kg in 1988 and 98 million kg in 1989; about 80% of these amounts was used in gold mining (Knudson 1990).

About 84% of domestic HCN production is used to produce organic cyanides, also known as nitriles, including acrylonitriles, methyl methacrylate, and adiponitrile (Towill et al. 1978). Nitriles tend to polymerize, which is the basis for their use in the manufacture of synthetic fibers, resins, plastics, dyestuffs, vitamins, solvents, elastomers, agricultural insecticides, and high pressure lubricants (Willhite and Smith 1981). The widespread usefulness of HCN is related to its strong tendency and that of its inorganic salts to form complexes

with metals. For example, sodium cyanide is used in metallurgy for the extraction of gold and silver from ores and in electroplating baths because it forms stable soluble complexes. Similar behavior makes alkali cyanide solutions excellent for cleaning silverware and other precious metals and is responsible for their general use in industry as metal cleaners (Towill et al. 1978). In Canada, more than 90% of the gold mined is extracted from ores with the cyanidation process. This process consists of leaching gold from the ore as a gold-cyanide complex, and gold being precipitated with the addition of zinc dust. A variety of cyanide compounds are produced during gold cyanidation (Simovic and Snodgrass 1985). In addition to their primary use in the metals and electroplating industries, and in the manufacture of synthetic fibers and plastics, various cyanide compounds have been used directly or as an intermediate to produce synthetic rubber, fumigants, rodenticides, insecticides, predator control agents, rocket fuels, paints and paint finishes, paper, nylon, pharmaceuticals, photographic chemicals, mirrors, cement, perfume, bleaches, soaps and detergents, riot control agents, fertilizers, and herbicides (Towill et al. 1978; Way 1981; Willhite and Smith 1981; Leduc 1984; Homan 1987).

Hydrogen cyanide vapor, because of its high and rapid acute lethal toxicity and ready diffusion, has been used widely to fumigate buildings, ships, and warehouses; to exterminate rabbits, rodents, and large predators; and in horticultural practice, to control insect pests that have developed resistance to other pesticides (Homan 1987; Ballantyne 1988). Typically, fumigation powders containing either calcium cyanide, $Ca(CN)_2$, or sodium cyanide, NaCN, are blown into burrows or scattered over the floor in greenhouses. On coming into contact with water, such powders liberate HCN vapor (Ballantyne 1988). Hydrogen cyanide released from $Ca(CN)_2$ is registered for use on almonds, dried beans, citrus, cocoa beans, grains, nuts, and spices (Towill et al. 1978). Cyanide-containing compounds are used for a variety of agricultural and pesticidal agents. These compounds include cyanogen (NCCN), as an intermediate in the production of some commercial fertilizers; cyanogen chloride (CNCl), in the manufacture of triazine herbicides; cyanogen bromide (CNBr), as a pesticidal fumigant; hydrogen cyanide, in the synthesis of methionine for animal feeds; ammonium thiocyanate (NH_4SCN), as a cotton defoliant; sodium thiocyanate (NaSCN), as a weedkiller; and calcium cyanamide (CaNCN), as a plant fertilizer, herbicide, pesticide, and defoliant of cotton and tomatoes (Homan 1987). Cyanide compounds have also been used as preservatives for raw vegetables (Towill et al. 1978).

Sodium cyanide has been used for about 50 years by the U.S. Fish and Wildlife Service against coyote in attempts to protect livestock, especially sheep. The Service has made extensive use of two NaCN ejector devices: "the coyote getter," from the late 1930's to 1970; and the M-44, from about 1968 to the present, except for the period 1972-74, when all uses of NaCN for predator control were canceled (EPA 1976a; Connolly and Simmons 1984). Although both ejectors dispense toxicant when pulled, they differ in the way ejection is achieved. In the coyote getter, the toxicant is in a 0.38-caliber cartridge case and is expelled by the explosive force of the primer plus a small powder charge. The M-44 uses a spring-driven plunger to push out its toxic contents. M-44 capsules weigh about 0.94 g, and consist of about 89% NaCN, 6% Celatom MP-78 (mostly diatomaceous silica), 5% potassium chloride, and 0.25% FP Tracerite yellow--used as a fluorescent marker (Connolly and Simmons 1984). Coyote getters and M-44's are set into the ground with only their tops protruding. Fetid scent or lure stimulates a coyote to bite and pull, whereupon a lethal dose of NaCN is ejected into its mouth; coma and death follow in 30 to 60 s. Although coyote getters were about 99% effective against coyotes, compared with 73% for M-44's, the Service decided that spring-driven plungers were less hazardous to operators than were explosive-driven plungers (Connolly and Simmons 1984). The coyote getter was generally much more selective than the trap for the capture of coyotes. It was less destructive than traps to small mammals, birds of prey, ground-nesting birds, deer, antelope, and domestic sheep, but more destructive to dogs, bears, and cattle (Robinson 1943). In a 1-year test period (1940-41) in Colorado, Wyoming, and New Mexico, the following numbers of animals were killed by the coyote getter: 1,107 coyotes, 2 bobcats (*Lynx rufus*), 24 dogs, 14 black-billed magpies (*Pica pica*), 7 foxes (*Vulpes* sp.), 8 unidentified skunks, 2 badgers, 2 unidentified eagles, 2 bears (*Ursus* sp.), and 1 each of hawk (unidentified), pika (*Ochotona* sp.), and cow (Robinson 1943).

Cyanide compounds have been used to collect various species of freshwater fish. In England and Scotland, cyanides are used legally to control rabbits, and illegally to obtain Atlantic salmon (*Salmo salar*) and brown trout (*Salmo trutta*) from rivers, leaving no visible evidence of damage to the fish (Holden and Marsden 1964). Sodium cyanide has been applied to streams in Wyoming and Utah to collect fish through anesthesia; mountain whitefish (*Prosopium williamsoni*) were sensitive to cyanide and died at concentrations that were tolerable to salmon and trout (Wiley 1984). Sodium cyanide was also used as a fish control agent in Illinois, Nebraska,

South Dakota, Missouri, and in the lower Mississippi River valley, but was never registered for this use because of human safety concerns (Lennon et al. 1970).

Cyanide compounds have been prescribed by physicians for treatment of hypertension and cancer (Sprince et al. 1982). Sodium nitroprusside ($Na_2Fe(CN)_5NO\text{-}2H_2O$) was widely used for more than 30 years to treat severe hypertension and to minimize bleeding during surgery (Solomonson 1981; Vesey 1987). Laetrile, an extract of ground apricot kernels, has been used for cancer chemotherapy and, in deliberate high intakes, as an attempted suicide vehicle (Gee 1987).

Road salt in some areas may contribute to elevated cyanide levels in adjacent surface waters (Ohno 1989). In climates with significant snowfall, road salt is applied as a deicing agent. Road salts are commonly treated with anticaking agents to ensure uniform spreading. One anticaking agent, sodium hexacyanoferrate, decomposes in sunlight to yield the highly toxic free cyanide that contaminates surface waters by runoff (Ohno 1989). Another anticaking agent, yellow prussiate of soda (sodium ferrocyanide), has been implicated in fish kills when inadvertently used by fish culturists (Barney 1989).

The military uses of HCN were first realized by Napoleon III, but it was not until World War I (WW I) that this application received widespread consideration. About 3.6 million kg of hydrogen cyanide were manufactured by France as a chemical weapon and used in WWI in various mixtures called Manganite and Bincennite, although its use was not highly successful because of limitations in projectile size and other factors. During WW II, the Japanese were armed with 50-kg HCN bombs, and the United States had 500-kg bombs. More than 500,000 kg of HCN chemical weapons were produced during WWII by Japan, the United States, and the Soviet Union, but it is not known to what extent these weapons were used in that conflict (Way 1981).

Cyanides are widely distributed among common plants in the form of cyanogenic glycosides (Egekeze and Oehme 1980; Solomonson 1981; Way 1981; Biehl 1984; Homan 1987; Marrs and Ballantyne 1987). Their toxicity following ingestion is primarily related to the hydrolytic release of HCN. Ingestion of cyanogenic plants probably has accounted for most instances of cyanide exposure and toxicosis in man and range animals. Of chief agricultural importance among plants that accumulate large quantities of cyanogenic glycosides are the sorghums, Johnson grass, Sudan grass, corn, lima beans, flax, pits of stone fruits (cherry, apricot, peach), vetch, linseed, sweet potatoes, bamboo shoots, southern mock orange, millet, almonds, and cassava. Factors favoring cyanide build-up in cyanogenic plants include high nitrogen and low phosphorus in soils (Biehl 1984); the potential for high glycoside levels is greatest in immature and rapidly growing plants (Egekeze and Oehme 1980). At present, more than 28 different cyanoglycosides have been measured in about 1,000 species of higher plants (Leduc 1984). In cassava, for example, more than 90% of the cyanide is present as linamurin, a cyanogenic glycoside, and the remainder occurs as free (nonglycoside) cyanide (Gomez et al. 1983). Laetrile, a preparation made from apricot kernels, contains high levels of amygdalin, a cyanogenic glycoside that can be degraded in the gut to cyanide and benzaldehyde. Several cases of cyanide poisoning in humans have been reported from intake of laetrile, either orally or anally (Solomonson 1981; Homan 1987). Cyanide formation in higher plants and microorganisms can also occur with compounds other than cyanogenic glycosides, such as glycine, glyoxylate plus hydroxylamine, or histidine (Solomonson 1981; Vennesland et al. 1981b). In some cases, plants may contain cyanide residues resulting from fumigation with HCN (Way 1981).

Many species of plants, including some fungi, bacteria, algae, and higher plants, produce cyanide as a metabolic product (Leduc et al. 1982; Leduc 1984). Some species of soil bacteria suppress plant diseases caused by soilborne pathogens by producing metabolites with antibiotic activity. Certain strains of *Pseudomonas fluorescens,* a soil bacterium, suppress black root rot of tobacco caused by the fungus *Thielaviopsis basicola* by excreting several metabolites, including HCN (Voisard et al. 1989). A wide variety of bacteria and fungi can degrade cyanide compounds, and may be useful in the treatment of cyanide wastes (Towill et al. 1978). For example, several species of fungi known to be pathogens of cyanogenic plants can degrade cyanide by hydration to formamide; dried mycelia of these species are now sold commercially to detoxify cyanide in industrial wastes (Knowles 1988).

Anthropogenic sources of cyanide in the environment include industrial processes, laboratories, fumigation operations, cyanogenic drugs, fires, cigarette smoking, and chemical warfare operations (Marrs and Ballantyne 1987). Cyanides are present in many industrial wastewaters, especially those of electroplaters; manufacturers of paint, aluminum, and plastics; metal finishers; metallurgists; coal gasification processes; certain mine

operations; and petroleum refiners (Towill et al. 1978; Egekeze and Oehme 1980; Way 1981, 1984). Electroplaters are a major source. In the United States alone, electroplaters discharge about 9.7 million kg of cyanide wastes annually into the environment from 2,600 electroplating plants (Marrs and Ballantyne 1987). Paint residues annually contribute an additional 141,300 kg of cyanide wastes into the environment, and paint sludges 20,400 kg (Way 1981; Marrs and Ballantyne 1987). Cyanide can also originate from natural processes, such as cyanide production by bacteria, algae, and fungi, and from many terrestrial plants that release free HCN when their cellular structure is disrupted (Leduc 1981). Hospital wastewaters usually contain no detectable cyanide, but concentrations up to 64 µg CN^-/L have been measured after alkali chlorination treatment (Tatsumoto and Hattori 1988). It seems that various compounds common in hospital wastewaters will produce 15-25 µg CN^-/L after alkali chlorination; these compounds include hydantoin (an antiepilepsy agent) and related nitrogenous compounds, such as hydantonic acid, 5,5-diphenyl hydantoin, imidazole, and 2-imidazolidinone (Tatsumoto and Hattori 1988).

Free hydrogen cyanide occurs only rarely in nature because of its high reactivity. The gas is sometimes found in the atmosphere, however, as a result of emissions from the petrochemical industry, malfunctioning catalytic converters on automobiles, fumigation of ships and warehouses, incomplete combustion of nitrogen-containing materials, and from tobacco smoke (Towill et al. 1978; Way 1981, 1984). Hydrogen cyanide is known to be produced in fires involving nitrogen-containing polymers and is probably the most important narcotic fire product other than carbon monoxide (Purser et al. 1984). Cyanide-related fire deaths and injuries, as judged by elevated blood cyanide and thiocyanate concentrations, have been documented in airplanes, jails, and high-rises (Becker 1985; Ballantyne 1987b; Lundquist and Sorbo 1989). In a study of fire victims in Scotland, elevated blood cyanide levels were found in 78% of fatalities, and 31% had blood levels considered to be toxic (Purser et al. 1984). Major factors that influence HCN release include the chemical nature of the material, temperature, oxygen availability, and burning time (Ballantyne 1987b). Substantial quantities of free HCN and organic cyanides are known to be produced in fire settings involving horsehair, tobacco, wool, silk, and many synthetic polymers, such as polyurethane and polyacrylonitriles (Egekeze and Oehme 1980; Purser et al. 1984; Becker 1985; Ballantyne 1987b). Polyacrylonitrile, for example, is used in fabrics, upholstery covers, paddings, and clothing; about 50% of the mass of the polymer is theoretically available as HCN under thermal decomposition (Purser et al. 1984; Homan 1987).

Background Concentrations

The reactivity of HCN, and its ability to condense with itself and other compounds, was probably responsible for the prebiotic formation of the majority of biochemical compounds required for life (Marrs and Ballantyne 1987). Cyanide is now known to be present in a number of foodstuff and forage plants, as a metabolite of certain drugs, and in various industrial pollutants; it also may be formed by the combustion of cyanide-releasing substances, such as plastics in airplane fires and tobacco in smoking (Robinson et al. 1985). Hydrogen cyanide production may occur in hepatopancreas of mussels, *Mytilus edulis* (Vennesland et al. 1981b), in rat liver (Solomonson 1981), and in green and blue-green algae during nitrate metabolism (Leduc et al. 1982). Except for certain naturally occurring organic cyanide compounds in plants, it is uncommon to find cyanide in foods consumed in the United States (EPA 1980).

The cyanide anion is found in a variety of naturally occurring plant compounds as cyanogenic glycosides, glycosides, lathyrogenic compounds, indoleacetonitrile, and cyanopyridine alkaloids. Plants that contain cyanogenic glycosides are potentially poisonous because bruising or incomplete cooking can result in glycoside hydrolysis and release of HCN (Towill et al. 1978). Cyanide concentrations in cyanogenic plants are usually highest in leaves of young plants; levels drop rapidly after pollination (Biehl 1984). There are about 20 major cyanogenic glycosides, of which usually only one or two occur in any plant. They are synthesized from amino acids and sugars and are found in many economically important plants, such as sorghum, flax, lima bean, cassava, and many of the stone fruits (Table 2; Towill et al. 1978; Shaw 1986). Cassava contains linamurin and lotaustralin, whereas the main cyanogenic glycoside in cereals is dhurrin; consumption of foods containing toxic cyanogens (primarily cassava) has been associated with death or morbidity--on an acute basis--or goiter and tropical ataxic neuropathy on a chronic consumption basis (Okolie and Ugochukwu 1989). Cassava is a perennial shrub, native to the neotropics, grown for its tuberous starchy roots, and a traditional dietary staple of many indigenous populations in Amazonia, especially the Tukanoan Indians in northwestern Amazonia (Dufour 1988). Cassava is one of the few food plants in which the cyanide content may create toxic problems. All

varieties of cassava contain cyanogenic glycosides capable of liberating HCN, but amounts vary greatly depending on variety and environmental conditions. Bitter cultivars of cassava provide over 70% of the Tukanoan's food energy, appearing in the diet as bread, meal, a starch drink, and boiled cassava juice. The greatly elevated total cyanide content in bitter varieties (Table 2) may contain 5.1-13.4% of the total as the toxic free cyanide (Dufour 1988).

The production of HCN by animals is almost exclusively restricted to various arthropods: 7 of about 3,000 species of centipedes; 46 of 2,500 species of polydesmid millipedes; and 10 of 750,000 species of insects, including 3 species of beetles, 4 moths, and 3 butterflies (Duffey 1981). Millipedes--which are eaten frequently by toads and starlings--secrete cyanide for defensive purposes in repelling predators; in zygaenid moths, cyanide seems to be localized in eggs (Table 2; Duffey 1981).

Cyanide concentrations in fish from streams that were deliberately poisoned with cyanide ranged between 10 and 100 µg total cyanide per kilogram whole body fresh weight (FW; Wiley 1984). Total cyanide concentrations in gill tissues of salmonids under widely varying conditions of temperature, nominal water concentrations, and duration of exposure ranged from about 30 µg/kg FW to >7,000 µg/kg (Holden and Marsden 1964). Unpoisoned fish usually contained < 1 µg/kg FW in gills, although values up to 50 µg/kg occurred occasionally. Lowest cyanide concentrations in gills occurred at elevated (summer) water temperatures; at lower temperatures, survival was greater and residues were higher (Holden and Marsden 1964). Fish retrieved from cyanide-poisoned environments, dead or alive, can probably be consumed by humans because muscle cyanide residues were considered to be low (i.e., <1,000 mg/kg FW; Leduc 1984).

Cyanide pollution is likely to occur in many places, ranging from industrialized urban areas to gold mines in the western United States and Northwest Territories of Canada (Table 2). Cyanides are ubiquitous in industrial effluents, and their increasing generation from power plants and from the combustion of solid wastes is expected to result in elevated cyanide levels in air and water (Leduc 1984). However, data are scarce on background concentrations of cyanides in various nonbiological materials. In soils, for example, high concentrations are unusual and are nearly always the result of improper waste disposal (Towill et al. 1978). Cyanides in soils are not absorbed or retained; under aerobic conditions, microbial metabolism rapidly degrades cyanides to carbon dioxide and ammonia; under anaerobic conditions, cyanides are converted by bacteria to gaseous nitrogen compounds that escape to the atmosphere (Towill et al. 1978). Heat treatment wastes from metal processing operations may contain up to 200 g CN/kg, mostly as NaCN, and are frequently hauled to landfills for disposal (Lagas et al. 1982). The presence of cyanide in landfill waste is potentially hazardous because of the possibility that cyanide may leach to soil and groundwater, release HCN, and disturb natural microbiological degradation of organic materials. Measurements at landfills in England and the Netherlands showed total cyanide levels up to 560 g/kg in soil and 12 µg/L in groundwater (Lagas et al. 1982). However, 7-month-long experimental studies of cyanide in heat treatment wastes in landfills showed that between 72 and 82% of the cyanide was converted, mostly to ammonium and organic nitrogen compounds; between 4 and 22% of the cyanide leached as free or complex cyanide; and up to 11% remained in the landfill (Lagas et al. 1982).

Table 2. Background concentrations of cyanide in selected living resources and nonbiological materials. Values are in milligrams total cyanide per kilogram fresh weight or milligrams per liter.

[a]Concentrations are shown as means, range (in parentheses), and maximum (Max.).

[b]1, Towill et al. 1978; 2, Shaw 1986; 3, Gomez et al. 1983; 4, Casadei et al. 1984; 5, Ukhun and Dibie 1989; 6, Dufour 1988; 7, Okolie and Ugochukwu 1989; 8, Duffey 1981; 9, Berninger et al. 1989; 10, Egekeze and Oehme 1980; 11, Leduc 1981; 12, Leduc 1984; 13, EPA 190; 14, Leduc et al. 1982; 15, Kelada 1989; 16, Nonomura and Hobo 1989; 17, Vennesland et al. 1981a; 18, Beyer 1990; 19, Clark and Hothem 1991.

[c]Concentration is in milligrams per kilogram dry weight.

Hydrogen cyanide (HCN) is a common industrial pollutant and frequently occurs in water at concentrations between 0.1 and several milligrams per liter of free HCN (Leduc 1978; Leduc et al. 1982). Total cyanides is the most often cited measurement in aqueous solutions, owing to limitations in analytical methodologies (Leduc et al. 1982). Cyanides have been identified in fresh waters of rural and wilderness areas in Canada and Germany. Concentrations ranging between 30 and 60 µg total cyanides per liter seem related to runoff, with cyanide peaks more frequent in fall and winter during periods of minimal runoff (Leduc et al. 1982). In larger rivers, cyanide was low in winter owing to dilution by high runoff, but peaked in summer because of cyanide production by plants (Leduc 1984). Cyanides do not seem to persist in aquatic environments. In small, cold oligotrophic lakes treated with 1 mg NaCN/L, acute toxicity was negligible within 40 days. In warm shallow ponds, toxicity disappeared within 4 days after application of 1 mg NaCN/L. In rivers and streams, toxicity rapidly disappeared on dilution (Leduc 1984). Cyanide was not detectable in water and sediments of Yellowknife Bay, Canada, between 1974 and 1976, although the bay receives liquid effluents containing cyanides from an operating gold mine. Nondetection was attributed to rapid oxidation (Moore 1981). Several factors contribute to the rapid disappearance of cyanide from water. Bacteria and protozoans may degrade cyanide by converting it to carbon dioxide and ammonia. Chlorination of water supplies can result in conversion to cyanate (EPA 1980). An alkaline pH favors oxidation by chlorine, and an acidic pH favors volatilization of HCN into the atmosphere (EPA 1980).

Persistence in Water, Soil, and Air

In water, cyanides occur as free hydrocyanic acid, simple cyanides, easily degradable complex cyanides such as $Zn(CN)_2$, and sparingly decomposable complex cyanides of iron and cobalt; complex nickel and copper cyanides are intermediate between the easily decomposable and sparingly degradable compounds (Towill et al. 1978). Cyanide has relatively low persistence in surface waters under normal conditions but may persist for extended periods in groundwater (Way 1981). Volatilization is the dominant mechanism for removal of free cyanide from concentrated solutions and is most effective under conditions of high temperatures, high dissolved oxygen levels, and at increased concentrations of atmospheric carbon dioxide (Leduc et al. 1982; Simovic and Snodgrass 1985). Loss of simple cyanides from the water column is primarily through sedimentation, microbial degradation, and volatilization (Leduc et al. 1982; Marrs and Ballantyne 1987). Water-soluble strong complexes, such as ferricyanides and ferrocyanides, do not release free cyanide unless exposed to ultraviolet light. Thus, sunlight may lead to cyanide formation in wastes containing iron-cyanide complexes (Towill et al. 1978; Leduc et al. 1982; Simovic and Snodgrass 1985; Marrs and Ballantyne 1987).

Alkaline chlorination of wastewaters is one of the most widely used methods of treating cyanide wastes. In this process, cyanogen chloride, (CNCl) is formed, which at alkaline pH is hydrolyzed to the cyanate ion (CNO^-). If free chlorine is present, CNO^- can be further oxidized (Way 1981; Leduc et al. 1982; Simovic and Snodgrass 1985; Marrs and Ballantyne 1987). Other methods used in cyanide waste management include lagooning for natural degradation, evaporation, exposure to ultraviolet radiation, aldehyde treatment, ozonization, acidification-volatilization-reneutralization, ion exchange, activated carbon absorption, electrolytic

decomposition, catalytic oxidation, and biological treatment with cyanide-metabolizing bacteria (Towill et al. 1978; EPA 1980; Way 1981; Marrs and Ballantyne 1987). In the case of Canadian gold-mining operations, the primary treatment for cyanide removal is to retain gold mill wastewaters in impoundments for several days to months; removal occurs through volatilization, photodegradation, chemical oxidation, and, to a lesser extent, microbial oxidation. Microbial oxidation of cyanide is not significant in mine tailing ponds, which typically have pH >10, a low number of microorganisms, low nutrient levels, large quiescent zones, and cyanide concentrations >10 mg/L (Simovic and Snodgrass 1985).

Cyanide seldom remains biologically available in soils because it is either complexed by trace metals, metabolized by various microorganisms, or lost through volatilization (Towill et al. 1978; Marrs and Ballantyne 1987). Cyanide ions are not strongly adsorbed or retained on soils, and leaching into the surrounding ground water will probably occur. Under aerobic conditions, cyanide salts in the soil are microbially degraded to nitrites or form complexes with trace metals. Under anaerobic conditions, cyanides denitrify to gaseous nitrogen compounds that enter the atmosphere.

Volatile cyanides occur only occasionally in the atmosphere, due largely to emissions from plating plants, fumigation, and other special operations (Towill et al. 1978). Under normal conditions cyanide has relatively low persistence in air, usually between 30 days and 1 year (Way 1981), although some atmospheric HCN may persist for up to 11 years (Marrs and Ballantyne 1987). Data are lacking on the distribution and transformation of cyanide in the atmosphere (Towill et al. 1978) and should be acquired.

Lethal and Sublethal Effects

Terrestrial Flora and Invertebrates

Bacteria exposed to cyanide may exhibit decreased growth, altered cell morphology, decreased motility, mutagenicity, and altered respiration (Towill et al. 1978). Mixed microbial populations capable of metabolizing cyanide and not previously exposed to cyanide were adversely affected at 0.3 mg HCN/kg; however, these populations can become acclimatized to cyanide and can then degrade wastes with higher cyanide concentrations (Towill et al. 1978). Acclimatized populations in activated sewage sludge can often completely convert nitriles to ammonia, sometimes at concentrations as high as 60 mg total cyanides per kilogram (Towill et al. 1978). Cyanide can be degraded by various pathways to yield a variety of products, including carbon dioxide, ammonia, beta-cyanoalanine, and formamide (Knowles 1988). Several species of fungi can accumulate and metabolize cyanide, but the products of cyanide metabolism vary. For example, carbon dioxide and ammonia are formed as end products by *Fusarium solani*, whereas alpha-amino butyronitrile is a major cyanide metabolite of *Rhizoctonia solani*(Towill et al. 1978). Significant amounts of cyanide are formed as secondary metabolites by many species of fungi and some bacteria by decarboxylation of glycine (Knowles 1988). Rhizobacteria may suppress plant growth in soil through cyanide production. In one case volatile metabolites--including cyanide--from fluorescent pseudomonad soil bacteria prevented root growth in seedlings of lettuce, *Lactuca sativa* (Alstrom and Burns 1989). Not all cyanogenic isolates inhibited plant growth. Some strains promoted growth in lettuce and beans by 41-64% in 4 weeks versus 49-53% growth reduction by inhibitory strains (Alstrom and Burns 1989).

In higher plants, elevated cyanide concentrations inhibited respiration (through iron complexation in cytochrome oxidase) and ATP production and other processes dependent on ATP, such as ion uptake and phloem translocation, eventually leading to death (Towill et al. 1978). Cyanide produces chromosomal aberrations in some plants, but the mode of action is unknown (Towill et al. 1978). At lower concentrations, effects include inhibition of germination and growth, but cyanide sometimes enhances seed germination by stimulating the pentose phosphate pathway and inhibiting catalase (Towill et al. 1978; Solomonson 1981). The detoxification mechanism of cyanide is mediated by rhodanese. This enzyme is widely distributed in plants (Solomonson 1981; Leduc 1984). The rate of production and release of cyanide by plants to the environment through death and decomposition is unknown (Towill et al. 1978).

Free cyanide is not found in intact plant cells. Many species of plants, such as cassava, sorghum, flax, cherries, almonds, and beans, contain cyanogenic glycosides that release HCN when hydrolyzed (Towill et al. 1978). Cyanide poisoning of livestock by forage sorghums, such as Sudan grass and various hybrid cultivars, is well known (Cade and Rubira 1982) and has led to the development of several variations of sorghums that have a reduced capability of producing cyanide poisoning (Egekeze and Oehme 1980). Cyanogenesis has an

important role in plant defense against predatory herbivores. This herbivore-plant interaction is not simple; the degree of selectivity by herbivores varies among individuals and by differences in hunger and previous diet (Jones 1988).

Cyanide metabolism in higher plants involves amino acids, N-hydroxyamino acids, aldoximes, nitriles, and cyanohydrins (Halkier et al. 1988). Cyanide is a coproduct of ethylene synthesis in higher plants. The increase in ethylene production that occurs during the senescence of certain flowers and the ripening of fruits is accompanied by a rise in beta-cyanoalanine activity; activity of this enzyme correlates closely with that of ACC (1-aminocyclopropane-l-carboxylic acid) oxidase, the last enzyme in the ethylene pathway. Manning (1988) suggested that ACC oxidase reacts with various amino acids to liberate cyanide. Cyanide added to isolated castorbean (*Ricinus communis*) mitochondria significantly enhanced the rate and amount of protein synthesis. Cyanide stimulated mitochondrial protein synthesis in a dose-dependent manner, with an optimal stimulation of over 2 times at 26 µg/L, but at this concentration mitochondrial respiration was inhibited by 90% (Kaderbhai et al. 1989). Cyanide is a weak competitive inhibitor of green bean *(Phaseolus vul*garis) lipoxygenase, an enzyme that catalyzes the formation of hydroperoxides from polyunsaturated fatty acids (Adams 1989). Because degradation of hydroperoxides causes unacceptable changes in bean flavor and color, compounds that inhibit lipoxygenase may enjoy wide application in the frozen vegetable industry (Adams 1989). Corn seedlings from cold-resistant cultivars were more resistant to 65 mg KCN/L at low temperatures (13°C) than were seedlings from cold-susceptible cultivars (25°C), as judged by respiratory activity of mitochondria (Van De Venter 1985). Results suggest that cyanide-resistant respiration may play a role in cold resistance in maize seedlings, although more evidence is needed to demonstrate that cold-resistant plants actually use their greater potential for alternative respiration at low temperatures (Van De Venter 1985).

The cyanogenic system comprising cyanogenic glycosides, cyanohydrins, betaglucosidases, and nitrile lyases is widespread in plants, but also occurs in several species of arthropods, including the tiger beetle (*Megacephala virginica*), leaf beetle (*Paropsis atomaria*), zygaenid moths, and certain butterflies (Nahrstedt 1988). In *Zygaena trifolii*, cyanide compounds seem to function as protection against predators (Nahrstedt 1988). Defensive secretions of cyanide have also been reported in polydesmid millipedes, and these organisms seem to be more tolerant than other species when placed in killing jars containing HCN (Towill et al. 1978). In a millipede (*Apheloria* sp.), cyanide is generated in a two-compartment organ by hydrolysis of mandelonitrile; cyanide generation occurs outside the gland when the components of the two compartments are mixed during ejection (Towill et al. 1978).

Highly toxic substances, such as cyanides, are sometimes feeding cues and stimulants for specialized insects. For example, instar larvae of the southern armyworm (*Spodoptera eridania*) strongly prefer cyanogenic foods, such as foliage of the lima bean, a plant with comparatively elevated cyanide content--up to 31 mg/kg in some varieties--in the form of linamurin (Brattsten et al. 1983). Feeding was stimulated in southern armyworms at dietary levels up to 508 mg KCN/kg (208 mg HCN/kg) for first to fourth instar larval stages, and between 1,000 and 10,000 mg KCN/kg diet for fifth and sixth instar larvae (Brattsten et al. 1983). Sixth instar larvae preexposed to diets containing 5,000 mg KCN/kg showed no adverse affects at dietary levels of 10,000 mg KCN/kg; however, previously unexposed larvae showed reversible signs of poisoning at 10,000 mg/kg diet, including complete inhibition of oviposition and 83% reduction in adult emergence (Brattsten et al. 1983). Experimental studies with southern armyworm larvae and thiocyanate--one of the in vivo cyanide metabolites--showed that 5,000 mg thiocyanate per kilogram diet reduced pupation by 77%, completely inhibited oviposition, and reduced adult emergence by 80% (Brattsten et al. 1983), strongly suggesting that thiocyanate poisoning is the primary effect of high dietary cyanide levels in southern armyworms.

Resistant species, such as southern armyworms, require injected doses up to 800 mg KCN/kg BW (332 mg HCN/kg BW) or diets of 3,600 mg KCN/kg for 50% mortality (Brattsten et al. 1983), but data are scarce for other terrestrial invertebrates. Exposure to 8 mg HCN/L air inhibits respiration in the granary weevil (*Sitophilus granarius*) within 15 min and kills 50% in 4 h; some weevils recover after cessation of 4-h exposure (Towill et al. 1978).

Aquatic Organisms

Numerous accidental spills of sodium cyanide or potassium cyanide into rivers and streams have resulted in massive kills of fishes, amphibians, aquatic insects, and aquatic vegetation; sources of poisonings were storage reservoirs of concentrated solutions, overturned rail tank cars, or discharge of substances generating free HCN

in the water from hydrolysis or decomposition (Leduc 1984). Data on the recovery of poisoned ecosystems are scarce. In one case, a large amount of cyanide-containing slag entered a stream from the reservoir of a Japanese gold mine as a result of an earthquake (Yasuno et al. 1981). The slag covered the streambed for about 10 km from the point of rupture, killing all stream biota; cyanide was detected in the water column for only 3 days after the spill. Within 1 month flora was established on the silt covering the above-water stones, but there was little underwater growth. After 6-7 months, populations of fish, algae, and invertebrates had recovered, although species composition of algae was altered (Yasuno et al. 1981).

Fish were the most sensitive aquatic organisms tested under controlled conditions. Significant adverse nonlethal effects, including reduced swimming performance and inhibited reproduction, were observed in the range of 5.0-7.2 µg free cyanide per liter; deaths were recorded for most species between 20 and 76 µg/L (Table 3). Among invertebrates, adverse nonlethal effects were documented between 18 and 43 µg/L, and lethal effects between 30 and 100 µg/L--although some deaths were recorded in the range 3-7 µg/L for the amphipod *Gammarus pulex* (Table 3). Algae and macrophytes were comparatively tolerant; adverse effects were reported at >160 µg free cyanide per liter (Table 3).

Table 3. Cyanide effects on selected species of aquatic organisms. All concentrations are shown as micrograms of hydrogen cyanide per liter (ppb) of medium at start unless indicated otherwise.

Species, concentration, and other variables	Effects	Reference[a]
Algae and macrophytes		
Alga, *Chlorella* sp.		
7,300	Inhibition of photosynthesis	3
30,000	Enzyme inhibition	2
Water hyacinth, *Eichhornia crassipes*		
300,000	Nonphytotoxic in 72 h; plants contained total cyanide of 6.7 g/kg dry weight (DW), equivalent to bioconcentration factor (BCF) of x22	5
Freshwater aquatic plants, nine species, 65,000, 30-min exposure	No effect on respiratory oxygen uptake in six species of angiosperms (*Myriophyllum* sp., *Potamogeton* spp., *Elodea* sp., *Ruppia* sp., *Cabomba* sp.); some effect on two species of bryophytes (*Rhynchostegium riparioides*, *Fontinalis antipyretica*) and one species of alga (*Cladophora glomerata*)	4
Alga, *Microcystis aeruginosa*		
7,990	90% kill	2
Alga, *Prototheca zopfi*		
3,000	Inhibition of respiration	2
Alga, *Scenedesmus quadricauda*		
160, as CN^-	Toxic	1
Invertebrates

Daphnid, *Daphnia pulex*		
83	LC50 (96 h)	2
Amphipod, *Gammarus pseudolimnaeus*		
16–21	MATC[b]	8
58	LC50 (96 h) at 20º C	8
184	LC50 (96 h) at 5.2º C	8
Amphipod, *Gammarus pulex*		
3	LC50 (15 h); 50% dead in 14 days after exposure for 5 h	6
7.5	LC50 (9h); exposure for 66 min results in 50% mortality 14 days after exposure	6
15	LC50 (6 h); exposure for 45 min causes 50% mortality 14 days after exposure	6
75	LC50 (3 h); exposure for 18 min results in 50% kill 14 days after exposure	6
Mussel, *Mytilus edulis*		
18	After exposure for 14 days growth was reduced and uptake of glycine was inhibited	9
100	LC20 (14 days)	9
Mysid shrimp, *Mysidopsis bahia*		
11, 20, 43, or 70	Life-cycle (29 days) exposure produced adverse effects on survival at 70 µg/L, and on reproduction at 43 µg/L; no measurable effects at lower doses of 11 and 20 µg/L	7
93–113	LC50 (96 h)	2, 7
Snail, *Physa heterostropha*		
432	LC50 (96 h)	3, 10
Fiddler crab, *Uca tangeri*		
Isolated perfused gills subjected to 26,000 CN^-/L, as KCN	Inhibited sodium chloride absorption across gill epithelium; effect reversible if exposure <5 min and nonreversible if >30 min. Salt absorption effect regulated by $(Na^+ + K^+)$ ATPase	11
Fish		
Brown bullhead, *Ictalurus nebulosus*		
Subjected to steadily increasing concentration of waterborne cyanide over a 9-h period: 200 at 1 h, 600 at 3 h, 1,000 at 5 h, and 1,800 at 9 h	Increased heart beat rate at lower concentrations and decreased rate at higher concentrations; hyperventilation in first 3 h followed by decrease in ventilation rate; oxygen consumption paralleled changes in heart and ventilatory rates. Death in 9 h	21
Longnose gar, *Lepisosteus osseus*		
12 µg CN^-/kg BW, as sodium cyanide, equivalent to 10.7 µg CN or 20 µg NaCN, single injection	Hypoxic response and bradycardia; effects appear earlier when administered into the ventral aorta or conus than into the dorsal aorta	27
Bluegill, *Lepomis macrochirus*		
5.0	Inhibited spawning following chronic exposure	22
5.2	Complete inhibition of spawning after exposure for 57–289 days	2, 8
9.3–19.8	MATC[b]	2

19.4	Reduced survival of fry in 57-day exposure which began with eggs	8
50	Tolerated concentration at higher temperatures, but no reproduction	8
56–227	LC50 (96 h) for juveniles	8, 22
109–218	LC50 (96 h) for fry	8
232–365	LC50 (96 h) for eggs	22
535–690	LC50 (96 h) for eggs at hatching	8
Largemouth bass, *Micropterus salmoides*		
101	LC50 (96 h) for juveniles	8
Cutthroat trout, *Oncorhynchus clarki*		
1,000 for 20 min	All fish recovered within 12 min and fed and grew normally during the next 6 months	31
Coho salmon, *Oncorhynchus kisutch*		
7.0	Reduction of 50% in swimming performance during 8-day exposure	13
10	Swimming speed reduced after exposure for 2 h	2
Rainbow trout, *Oncorhynchus mykiss*		
0.1 or 1.0	No effect on sperm motility or on fertilization rate at lower dose; some effect on sperm motility at higher dose	12
5.0	Reduction of 50% in swimming performance in 20-day exposure	13
10	No effect on growth during 20-day exposure at 6º C	13
10	Increased respiration rate in 4 days, growth reduction and liver damage in 9 days, abnormal oocyte development and reduced spermatogonia production in 18–20 days	2
10, 20, or 30 for 7 days, sexually mature females	Exposure to 10 or 20 µg/L caused a reduction in serum calcium to levels insufficient for the production of exogenous yolk; this was not observed in the 30 µg/L group	14
10, 20, or 30 for 18 days, juveniles	Degenerative necrosis of liver hepatocytes at all concentrations in a dose-dependent pattern. Severe initial growth repression at all concentrations followed by a significant increase, but growth remained depressed 40% and 95% in the 20 and 30 µg/L groups, respectively, at 18 days	15
10 or 20, exposure for 20 days during midsummer, sexually maturing females	Both concentrations resulted in abnormal oocytes, delayed development, and significantly reduced the number of eggs for spawning	16
15	No effect on growth during 20-day exposure at 12º C	13
18	No deaths in 96 h at 6º C	13
20	65% reduction in weight gain after 21 days	2
28	LC50 (96 h) at 6º C	10, 13, 17
30	No effect on growth during 20-day exposure at 18º C	13
32	No deaths in 96 h at 12º C	13
42	LC50 (96 h) at 12º C	13
43	LC50 (96 h) for nonexercised juveniles	18

	during winter	
46–75	LC50 (96 h) for juveniles	8, 19
52	LC50 (96 h) for exercised juveniles during winter	18
60	No deaths in 96 h at 18º C	13
68	LC50 (96 h) at 18º C	10, 13, 17
96	LC50 (144 h)	20
Subjected to steadily increasing concentrations of waterborne cyanide: 0 at start, 200 at 1 h, 600 at 3 h, 1,000 at 5 h, and 1,800 at 9 h	Reduction in heart rate, hyperventilation, increased oxygen consumption, death in 9 h	21
Chinook salmon, *Oncorhynchus tshawytscha*		
10	After 64 days, increased growth rate and production when compared to controls	13
20	Growth reduced 27% after exposure for 64 days	2
Yellow perch, *Perca flavescens*		
76–108	LC50 (96 h) for juveniles	8, 22
288–>389	LC50 (96 h) for eggs and fry	8, 22
Fathead minnow, *Pimephales promelas*		
12.9–19.6	MATC[b]	8, 22
18–58	Reduction in RNA content in larva in 96 h at 18–36 µg HCN/L, and in DNA and protein at 18–58 µg/L	28
19	Egg reduction of 59% after exposure for 265 days at 25º C	13
35	Reduction in growth rate during chronic exposure	5
44	Hatching reduced 83% after chronic exposure	13
47	Growth reduction in 30 days	28
58	Toxicosis occurred in yolk-sac larvae within 24 h as judged by significant reductions in content of RNA and protein; however, effects were not measurable in 96 h suggesting development of partial tolerance	29
>61	Adverse effects on growth and survival during lifetime exposure	13
82–113	LC50 (96 h) for fry at 25º C	8
83–137	LC50 (96 h) for juveniles	8, 22
99	LC50 (96 h) for fry at 20º C	8
107	Reduced survival in 96 h	28
121–202	LC50 (96 h) for eggs at 25º C	8
121–352	LC50 (96 h) for eggs; more toxic at low dissolved oxygen	22
122	LC50 (96 h) for fry at 15º C	8
Mixture of NaCN plus $CdSO_4$, equivalent to 170 µg CN/L	LC50 (96 h) for adults	30
Mixture of NaCN plus $ZnSO_4$, equivalent to 180 µg CN/L	LC50 (96 h) for adults	30
230, as NaCN	LC50 (96 h) for adults	30
273	LC50 (96 h) for eggs at 20º C	8
352	LC50 (96 h) for eggs at 15º C	8
Mixture of NaCN plus $NiSO_4$, equivalent to 650 µg CN/L	LC50 (96 h) for adults	8
Black crappie, *Pomoxis nigromaculatus*		
60	Some deaths in <24 h	3

101	LC50 (96 h) for juveniles	8
Plainfin midshipman, *Porichthys notatus*		
Isolated photophores exposed to 2,600, as KCN	Maximal luminescence induced by KCN; effect inhibited by d-glucose, d-glyceraldehyde 3-phosphate, and 3-phosphoglycerate	32
Atlantic salmon, *Salmo salar*		
5.0 for 12 days, adult females	Decline in plasma and gonad vitellogenin levels	23
10	Abnormal embryonic development after 58-day exposure	2
10, 80, or 100; newly fertilized eggs continually exposed for 5 months to end of sac-fry stage	Hatching delayed 6–9 days at 80 and 100 µg/L. Hatching success reduced 15% to 40% at all test concentrations, but no measurable effects on growth or survival after hatching. Abnormalities (mostly defects of eye, mouth, vertebral column) were 6% at 10 µg/L, and 19% at 100 µg/L	24
24	LC50 (24 h) at dissolved oxygen of 3.5 mg/L	25
73	LC50 (24 h) at dissolved oxygen of 10 mg/L	25
5,000, 10,000, 25,000, 50,000, or 125,000 for 30 min	Total cyanide residues in gills ranged from 1.0 to 6.6 mg/kg fresh weight (FW) in a dose dependent manner	26
50,000 for 10, 15, 20, 25, or 30 min	Residues in gills, in mg total CN/kg FW, ranged from 1.3 (10 and 15 min) to 1.9 (15 and 20 min) to 4.5 (30 min)	26
Brown trout, *Salmo trutta*		
90	LC50 (96 h)	10
5,000, 10,000, 25,000, 50,000, 75,000, or 100,000, as CN- for 30 min	Residues in gills ranged in a dose-dependent manner from 0.6 mg CN/kg FW in the 5 mg/L group to 3.4 mg/kg FW in the 100 mg/L group	26
50,000 for 10, 15, 20, or 25 min	Residues in tissues, in mg/kg FW, ranged from 0.7 to 1.8 in gill, 0.6 to 2.3 in brain, and 1.3 to 2.5 in liver; concentrations were directly related to length of exposure	26
Brook trout, *Salvelinus fontinalis*		
5.0	Reduction of 50% in swimming performance in 29-day exposure	13
5.7–11.2	MATC[b]	8, 22
10	75% reduction in swimming endurance after exposure for 26 min	2
10–50	Swimming ability reduced 98% after exposure for 29 days	20
11	Continuous exposure of mature females for 144 days before spawning resulted in 50% reduction in number of eggs produced and 15% reduction in egg viability; however, 90 days after hatch trout were 18% heavier and 10% longer than controls	13
25	Inhibited oxygen intake after 5 h	2
33	Adverse effects on juvenile growth rate during exposure for 90 days	2, 8
56–112	LC50 (96 h) range for swimup fry and juveniles	8, 22
108–518	LC50 (96 h) for sac-fry	8, 22
>212	LC50 (96 h) for eggs	8, 22

[a]1, Towill et al. 1978; 2, EPA 1980; 3, EPA 1973; 4, Azcon-Bieto et al. 1987; 5, Low and Lee 1981; 6, Abel and Garner 1986; 7, Lussier et al. 1985; 8, Smith et al. 1979; 9, Thompson 1984; 10, Leduc et al. 1982; 11, Drews and Graszynski 1987; 12, Billard and Roubaud 1985; 13, Leduc 1984; 14, Da Costa and Ruby 1984; 15, Dixon and Leduc 1981; 16, Lesniak and Ruby 1982; 17, Kovacs and Leduc 1982b; 18, McGeachy and Leduc 1988; 19, Marking et al. 1984; 20, Ballantyne 1987a; 21, Sawyer and Heath 1988; 22, Smith et al. 1978; 23, Ruby et al. 1987; 24, Leduc 1978; 25, Alabaster et al. 1983; 26, Holden and Marsden 1964; 27, Smatresk et al. 1986; 28, Barron and Adelman 1984; 29, Barron and Adelman 1985; 30, Doudoroff 1956; 31, Wiley 1984; 32, Rees and Baguet 1989.

[b]Maximum acceptable toxicant concentration. Lower value in each pair indicates highest concentration tested producing no measurable effect on growth, survival, reproduction, or metabolism during chronic exposure; higher value indicates lowest concentration tested producing a measurable effect.

Adverse effects of cyanide on aquatic plants are unlikely at concentrations that cause acute effects to most species of freshwater and marine fishes and invertebrates (EPA 1980). Water hyacinth *(Eichhornia crassipes)* can survive for at least 72 h in nutrient solution containing up to 300 mg CN/L and can accumulate up to 6.7 g/kg dry weight (DW) plant material. On this basis, 1 ha of water hyacinths has the potential to absorb 56.8 kg of cyanide in 72 h, and this property may be useful in reducing the level of CN in untreated wastewater from various electroplating factories, where concentrations generally exceed 200 mg CN/L (Low and Lee 1981). Cyanide may also affect plant community structure. Some algae, for example, metabolized CN at water concentrations <1 mg/L, but at concentrations of 1-10 mg/L, algal activity was inhibited, leaving a biota dominated by *Actinomycetes*--a filamentous bacterium (Knocke 1981).

Cyanide adversely affects fish reproduction by reducing the number of eggs spawned, and the viability of the eggs by delaying the process of secondary yolk deposition in the ovary (Lesniak and Ruby 1982; Ruby et al. 1986). Vitellogenin, a glycolipophosphoprotein present in plasma of fish during the process of yolk formation, is synthesized in liver under stimulation of estrogen and subsequently sequestered in the ovary; it is essential for normal egg development. Exposure of naturally reproducing female rainbow trout to as little as 10 µg HCN/L for 12 days during the onset of the reproductive cycle caused a reduction in plasma vitellogenin levels and a reduction in ovary weight. The loss of vitellogenin in the plasma would remove a major source of yolk (Ruby et al. 1986). Reproductive impairment in adult bluegills (*Lepomis macrochirus*) has been reported following exposure to 5.2 µg CN/L for 289 days (EPA 1980). Fertilized fish eggs are usually resistant to cyanide prior to blastula formation, but delayed effects occur at 60 to 100 µg HCN/L, including birth defects and reduced survival of embryos and newly hatched larvae (Leduc et al. 1982). Concentrations as low as 10 µg HCN/L caused developmental abnormalities in embryos of Atlantic salmon after extended exposure (Leduc 1978). These abnormalities, which were absent in controls, included yolk sac dropsy and malformations of eyes, mouth, and vertebral column (Leduc 1984).

Other adverse effects of cyanide on fish include delayed mortality, pathology, impaired swimming ability and relative performance, susceptibility to predation, disrupted respiration, osmoregulatory disturbances, and altered growth patterns. Free cyanide concentrations between 50 and 200 µg/L were fatal to the more-sensitive fish species over time, and concentrations >200 µg/L were rapidly lethal to most species of fish (EPA 1980). Cyanide- induced pathology in fish includes subcutaneous hemorrhaging, liver necrosis, and hepatic damage. Exposure of fish for 9 days to 10 µg HCN/L was sufficient to induce extensive necrosis in the liver, although gill tissue showed no damage. Intensification of liver histopathology was evident at dosages of 20 and 30 µg HCN/L and exposure periods up to 18 days (Leduc 1984). Cyanide has a strong, immediate, and long-lasting inhibitory effect on the swimming ability of fish (Leduc 1984). Free cyanide concentrations as low as 10 µg/L can rapidly and irreversibly impair the swimming ability of salmoneds in well-aerated water (Doudoroff 1976). Osmoregulatory disturbances recorded at 10 µg HCN/L may affect migratory patterns, feeding, and predator avoidance (Leduc et al. 1982; Leduc 1984). In general, fish experience a significant reduction in relative performance (based on osmoregulation, growth, swimming, and spermatogenesis) at 10 µg HCN/L, and although fish can survive indefinitely at 30 µg HCN/L in the laboratory, the different physiological requirements necessary to survive in nature could not be met (Leduc 1978, 1981; Leduc et al. 1982; Figure). Increased predation by green sunfish (*Lepomis cyanellus*) on fathead minnows *(Pimephales promelas)* was noted at sublethal concentrations of HCN, but it was uncertain if fatheads became easier prey or if green sunfish had greater appetites (Smith et al. 1979).

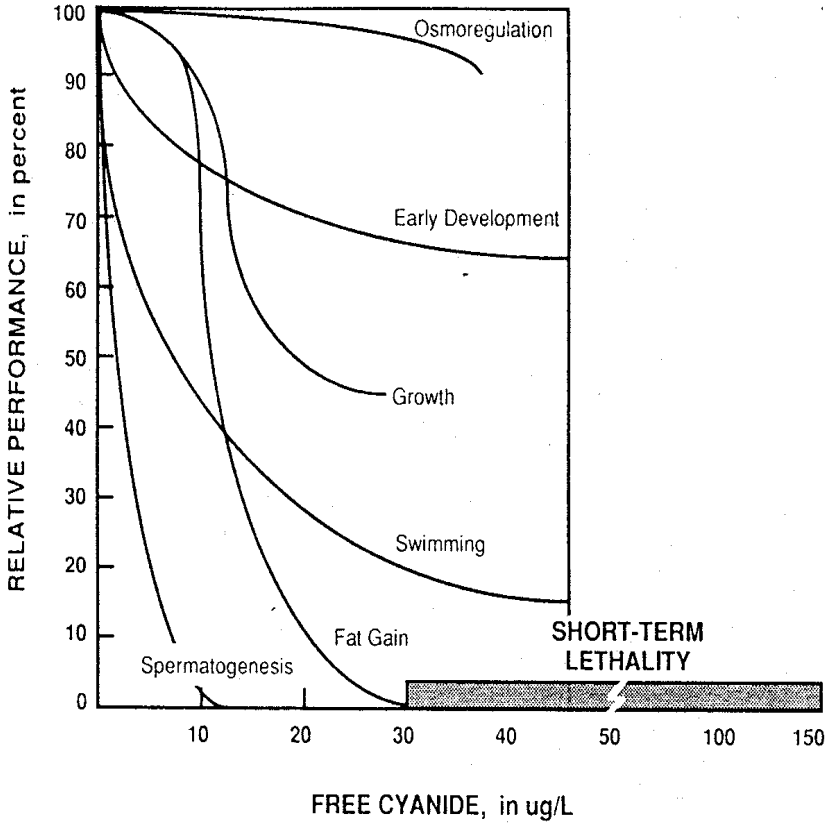

Figure. Summary of lethal and sublethal effects of free cyanide on freshwater fish. Modified from Leduc et al. (1982).

Sodium cyanide has stimulatory effects on oxygen-sensitive receptors in lungfish, amphibians, reptiles, birds, and mammals (Smatresk 1986). Facultative and aquatic air breathers appear to rely on air breathing when external chemoreceptors are stimulated, whereas obligate air-breathing fish are more responsive to internal stimuli (Smatresk 1986). Gill ventilation frequency of longnose gar (*Lepisosteus osseus*), for example, was little affected by external cyanide application, but responded strongly when cyanide was administered internally by injection (Smatresk 1986). Cyanide, like many other chemicals, can stimulate growth of fish during exposure to low sublethal levels. This phenomenon, referred to as hormesis, is little understood and warrants additional research (Leduc 1984).

The observed toxicity to aquatic life of simple and complex cyanides was attributed almost entirely to molecular (undissociated) HCN derived from ionization, dissociation, and photodecomposition of cyanide-containing compounds. The toxicity of the cyanide ion, CN^-, which is a minor component of free cyanide (HCN + CN^-) in waters that are not exceptionally alkaline is of little importance (Doudoroff 1976; Towill et al. 1978; Smith et al. 1979; EPA 1980). The acute toxicity of stable silver cyanide and cuprocyanide complex anions is much less than that of molecular HCN, but is nevertheless important; these ions can be the principal toxicants, even in some very dilute solutions. The much lower toxicities of the ferrocyanide and ferricyanide complexions--which are of high stability but subject to extensive and rapid photolysis, yielding free cyanide on direct exposure to sunlight--and the nickelocyanide ion complex are not likely to be of practical importance (Doudoroff 1976). Toxicity to aquatic organisms of organic cyanide compounds, such as lactonitrile, is similar to that of inorganic cyanides because they usually undergo rapid hydrolysis in water to free cyanide (Towill et al. 1978). There is general agreement that total cyanide concentrations in water in most cases will overestimate the actual cyanide toxicity to aquatic organisms, and that the analytically determined HCN concentration in cyanide-polluted waters

is considered to be the most reliable index of toxicity (Doudoroff 1976; Smith et al. 1979; EPA 1980; Abel and Garner 1986).

Cyanide acts rapidly in aquatic environments, does not persist for extended periods, and is highly species selective; organisms usually recover quickly on removal to clean water. The critical sites for cyanide toxicity in freshwater organisms include the gills, egg capsules, and other sites where gaseous exchange and osmoregulatory processes occur. On passing through a semipermeable membrane, the HCN molecules are usually distributed by way of the circulatory system to various receptor sites where toxic action or detoxification occurs (Leduc 1984). Once in the general circulation, cyanide rapidly inhibits the electron transport chain of vital organs. Signs of distress include increased ventilation, gulping for air at the surface, erratic swimming movements, muscular incoordination, convulsions, tremors, sinking to the bottom, and death with widely extended gill covers (Leduc 1981, 1984). The acute mode of action of HCN is limited to binding those porphyrins that contain Fe^{+3}, such as cytochrome oxidase, hydroperoxidases, and methemoglobin. At lethal levels, cyanide is primarily a respiratory poison and one of the most rapidly effective toxicants known (Leduc et al. 1982). The detoxification mechanism of cyanide is mediated by thiosulfate sulfur transferase, also known as rhodanese. This enzyme is widely distributed in animals, including fish liver, gills, and kidney. Rhodanese plays a key role in sulfur metabolism, and catalyzes the transfer of a sulfane-sulfur group to a thiophilic group (Leduc 1984). Thiosulfate administered in the water with cyanide reduced the toxicity of cyanide to fish, presumably by increasing the detoxification rate of cyanide to thiocyanate (Towill et al. 1978).

Additive or more-than-additive toxicity of free cyanide to aquatic fauna has been reported in combination with ammonia (Smith et al. 1979; Leduc et al. 1982; Alabaster et al. 1983; Leduc 1984) or arsenic (Leduc 1984). However, conflicting reports on the toxicity of mixtures of HCN with zinc or chromium (Towill et al. 1978; Smith et al. 1979; Leduc et al. 1982; Leduc 1984) require clarification. Formation of the nickelocyanide complex markedly reduces the toxicity of both cyanide and nickel at high concentrations in alkaline pH. At lower concentrations and acidic pH, solutions increase in toxicity by more than 1,000 times, owing to dissociation of the metallocyanide complex to form hydrogen cyanide (Towill et al. 1978). Mixtures of cyanide and ammonia may interfere with seaward migration of Atlantic salmon smolts under conditions of low dissolved oxygen (Alabaster et al. 1983). The 96-h toxicity of mixtures of sodium cyanide and nickel sulfate to fathead minnows is influenced by water alkalinity and pH. Toxicity decreased with increasing alkalinity and pH from 0.42 mg CN/L at 5 mg $CaCO_3$/L and pH 6.5; to 1.4 mg CN/L at 70 mg $CaCO_3$/L and pH 7.5; to 730 mg CN/L at 192 mg $CaCO_3$/L and pH 8.0 (Doudoroff 1956).

Numerous biological and abiotic factors are known to modify the biocidal properties of free cyanide, including water pH, temperature, and oxygen content; life stage, condition, and species assayed; previous exposure to cyanide compounds; presence of other chemicals; and initial dose tested. There is general agreement that cyanide is more toxic to freshwater fish under conditions of low dissolved oxygen (Doudoroff 1976; Towill et al. 1978; Smith et al. 1979; EPA 1980; Leduc 1984); that pH levels within the range 6.8-8.3 had little effect on cyanide toxicity but enhanced toxicity at acidic pH (Smith et al. 1979; EPA 1980; Leduc et al. 1982; Leduc 1984); that juveniles and adults were the most sensitive life stages tested and embryos and sac fry the most resistant (Smith et al. 1978, 1979; EPA 1980; Leduc 1984); and that substantial interspecies variability exists in sensitivity to free cyanide (Smith et al. 1979; EPA 1980). Initial dose and water temperature both modify the biocidal properties of HCN to freshwater teleosts. At slowly lethal concentrations (i.e., < 10 µg HCN/L), cyanide was more toxic at lower temperatures; at high, rapidly lethal HCN concentrations, cyanide was more toxic at elevated temperatures (Kovacs and Leduc 1982a, 1982b; Leduc et al. 1982; Leduc 1984). By contrast, aquatic invertebrates were most sensitive to HCN at elevated water temperatures, regardless of dose (Smith et al. 1979). Season and exercise modify the lethality of HCN to juvenile rainbow trout (McGeachy and Leduc 1988); higher resistance to cyanide correlated with higher activity induced by exercise and higher temperatures, suggesting a faster detoxification rate or higher oxidative and anaerobic metabolisms. Low levels of cyanide that were harmful when applied constantly may be harmless under seasonal or other variations that allow the organism to recover and detoxify (Leduc 1981). Acclimatization by fish to low sublethal levels of cyanide through continuous exposure might enhance their resistance to potentially lethal concentrations (Leduc 1981, 1984), but studies with Atlantic salmon and rainbow trout indicate otherwise. Prior acclimatization of Atlantic salmon smolts to cyanide increased their resistance only slightly to lethal concentrations (Alabaster et al. 1983). Juvenile rainbow trout previously exposed to low sublethal concentrations showed a marked reduction in fat synthesis and swimming performance when challenged with higher cyanide doses; effects were

most pronounced at low water temperatures (Kovacs and Leduc 1982a). Experimental evidence is lacking on exposure to lethal concentrations after prior exposure to high sublethal concentrations; some investigators predict decreased resistance (Leduc 1984), and others increased survival (Towill et al. 1978).

Birds

First signs of cyanide toxicosis in sensitive birds appeared between 0.5 and 5 min after exposure, and included panting, eye blinking, salivation, and lethargy (Wiemeyer et al. 1986). In more-resistant species, such as domestic chickens, signs of toxicosis began 10 min after exposure. At higher doses, breathing in all species tested became increasingly deep and labored, followed by gasping and shallow intermittent breathing. Death usually followed in 15-30 min, although birds alive at 60 min frequently recovered (Wiemeyer et al. 1986). The rapid recovery of some birds exposed to cyanide may be due to the rapid metabolism of cyanide to thiocyanate and its subsequent excretion. Species sensitivity to cyanide was not related to body size but seemed to be associated with diet (Wiemeyer et al. 1986). Birds that feed predominantly on flesh, such as vultures, kestrels, and owls, were more sensitive to cyanide than were species that feed mainly on plant material--with the possible exception of mallard (Anas *platyrhynchos*)--as judged by acute oral LD50 values (Table 4).

Table 4. Cyanide effects on selected species of birds.

Species, dose, and other variables	Effects	Reference[a]
Mallard, *Anas platyrhynchos*		
Single oral dose of NaCN		
0.53 mg CN/kg body weight (BW), equivalent to 1 mg NaCN/kg BW	No deaths	7
1.1 mg CN/kg BW (2.0 mg NaCN/kg BW)	About 6% dead	7
1.27 mg CN/kg BW (2.4 mg NaCN/kg BW)	About 33% dead	7
1.43 mg mg CN/kg BW (2.7 mg NaCN/kg BW)	LD50; 95% confidence interval (C.I.) of 2.2 and 3.2 mg NaCN/kg bW	7
Turkey vulture, *Cathartes aura*		
Single oral dose of 19.1 mg CN/kg BW, equivalent to 36 mg NaCN/kg BW	Up to 80% of the cyanide in blood was present as free cyanide and the remainder as bound cyanide	1
Single oral dose of 19.1 mg CN/kg BW, equivalent to 36 mg NaCN/kg BW	Average time to death was about 19 min and ranged between 8 and 41 min; cyanide residues postmortem, in mg CN/kg fresh weight (FW), were 6.7 in blood (Max. 21) and 0.6 in liver (Max. 2.8)	2
Rock dove, *Columba livia*		
0.12 mg CN/L air, as HCN	All dead in 10 min	2
1.6 mg CN/kg BW, equivalent to 4.0 mg KCN/kg BW	Minimum lethal dose when administered intravenously or intramuscularly	2
Black vulture, *Coragyps atratus*		
Single oral dose, as NaCN		
1.6 mg CN/kg BW	No deaths in 60 min. Mean and maximum blood CN concentrations, in mg/kg FW, were 0.7 and 0.9, respectively	2
2.4 lmg CN/kg BW	Some deaths within 30 min. Mean blood CN residues in	2

	mg/kg FW, were 0.7 in dead birds vs. 1.2 in those surviving 60 min	
2.54 mg CN/kg BW	Acute oral LD50; 95% C.I. of 2.3 and 2.8 mg CN/kg BW (4.4–5.3 mg NaCN/kg BW)	2
3.7 and 19.1 mg CN/kg BW	All dead within 16 min; maximum blood CN levels postmortem were 2.1 mg/kg FW in the low dose group and 4.2 in the high dose group	2
Japanese quail, *Coturnix japonica*		
Single oral dose, as NaCN		
4.5 mg CN/kg BW	Acute oral LD50 for adult females; 95% C.I. of 3.1 and 6.5 mg CN/kg BW	2
5.5 mg CN/kg BW	Acute oral LD50 for adult males; 95% C.I. of 4.0 and 7.5 mg CN/kg BW	2
American kestrel, *Falco sparverius*		
2.12 mg CN/kg BW, as NaCN	Acute oral LD50; 95% C.I. of 1.6 and 2.8 mg CN/kg BW	2
Domestic chicken, *Gallus domesticus*		
Intravenous route		
0.01 µg/kg BW	Most of dose recovered in urine as thiocyanate in 6 h; excretion limited by availability of transferable sulfur	3
0.6 mg CN/kg BW, equivalent to 1.5 mg KCN/kg BW	Lethal	2
0.78 mg CN/kg BW, as KCN	Sublethal; thiocyanate excretion increased 10 times after 10 min and returned to normal levels after 3.5 h; the total thiocyanate collected was equivalent to 85% of the administered dose	4
1.3 mg CN/kg BW, as KCN	Lethal	4
Inhalation route		
0.12 mg HCN/L air	All survived for at least 60 min	2
Single oral dose, as NaCN		
3.2 mg CN/kg BW, equivalent to 6.0 mg NaCN/kg BW	No deaths in 30 min; maximum CN levels, in mg/kg FW, were 1.1 in blood and 0.06 in liver	2
6.4 mg CN/kg BW	Some deaths in 30 min; maximum CN levels, in mg/kg FW were 1.6 in blood and 0.12 in liver	2
11.1 mg CN/kg BW	Acute oral LD50; 95% C.I. of 6.4 and 19.1 mg CN/kg BW	2
25.4 mg CN/kg BW	Advanced signs of acute poisoning; death probable within 30 min; maximum CN levels, in mg/kg FW, were 1.5 in blood and 0.6 in liver	2
Dietary route		
Fed cassava diets containing 4, 37, 70,	At all dietary levels, there	5

or 103 mg total cyanide per kilogram ration to day-old chicks for 8 weeks	was no significant effect on survival, growth, histology, hemoglobin, hematocrit, or lymphocyte number; however, serum thiocyanate levels increased in a dose-dependent manner	
Fed diets containing 135 mg HCN/kg Chicks, 20-day exposure	Growth and food intake significantly depressed; plasma thiocyanate concentration increased	6
Adults, 14-day exposure	Urinary excretion of thiocyanate increased 5 times in laying hens	6
California condor, *Gymnogyps californianus*		
Juvenile (8.4 kg), found dead, presumably of cyanide poisoning	No evidence of injuries or disease; yellow fluorescent particles found in mouth appeared like those placed in NaCN ejector mechanisms used in predator control. However, blood cyanide concentration was similar to that found in nonexposed vultures, including two captive California condors	2
Eastern screech-owl, *Otus asio*		
4.6 mg CN/kg BW, equivalent to 8.6 mg NaCN/kg BW	Acute oral LD50; 95% C.I. of 3.8 and 5.4 mg CN/kg BW	2
Canary, *Serinus canarius*		
0.12 mg HCN/L air	All dead in 3 min	2
European starling, *Sturnus vulgaris*		
9.0 mg CN/kg BW, as NaCN	Acute oral LD50; 95% C.I. of 4.8 and 17 mg CN/kg BW	2
Andean condor, *Vultur gryphus*		
Single oral dose of 19.1 mg CN/kg BW (36 mg NaCN/kg BW)	Blood sampled immediately after death contained 1.2 mg free CN per liter and 0.5 mg bound CN per liter	1

[a]1, Krynitsky et al. 1986; 2, Wiemeyer et al. 1986; 3, Oh et al. 1987; 4, Davis 1981; 5, Gomez et al. 1988; 6, Elzubeir and Davis 1988b; 7, Personal communication, E. F. Hill, Patuxent Wildlife Research Center.

Many species of migratory birds were found dead in the immediate vicinity of gold-mine heap-leach extraction facilities and tailings ponds, presumably as a result of drinking the cyanide-contaminated (>200 mg total cyanide per liter) waters (Clark and Hothem 1991). Migratory bird mortality from cyanide toxicosis may be eliminated at these facilities by screening birds from toxic solutions (Hallock 1990) or lowering the cyanide concentrations with hydrogen peroxide to <50 mg total cyanide per liter (Allen 1990), although the latter procedure requires verification (Clark and Hothem 1991).

Some birds may not die immediately after drinking lethal cyanide solutions. In Arizona, a red-breasted merganser *(Mergus serrator)* was found dead 20 km from the nearest known source of cyanide, and its pectoral muscle tissue tested positive for cyanide (Clark and Hothem 1991). A proposed mechanism to account for this phenomenon involves weak-acid dissociable (WAD) cyanide compounds. Cyanide bound to certain metals, usually copper, is dissociable in weak acids such as stomach acids. Clark and Hothem (1991) suggested that drinking of lethal cyanide solutions by animals may not result in immediate death if the cyanide level is

sufficiently low; these animals may die later when additional cyanide is liberated by stomach acid. More research is needed on WAD cyanide compounds.

Elevated cyanide concentrations were found in blood of chickens that died of cyanide poisoning; however, these concentrations overlapped those in survivors. Despite this variability, blood is considered more reliable than liver as an indicator of cyanide residues in exposed birds (Wiemeyer et al. 1986). No gross pathological changes in birds related to cyanide dosing were observed at necropsy (Wiemeyer et al. 1986), similar to other taxonomic groups tested.

Cyanide-nutrient interactions are reported for alanine, which appears to exacerbate cyanide toxicity, and for cystine, which seems to alleviate toxicity (Davis et al. 1988). Dietary cyanide--at levels that do not cause growth depression--alleviates selenium toxicity in chickens, but not the reverse (Davis et al. 1988; Elzubeir and Davis 1988a). For example, dietary selenium, as selenite, at 10 mg/kg for 24 days, reduced growth, food intake, and food utilization efficiency, and produced increased liver size and elevated selenium residues; the addition of 45 mg CN/kg diet (100 mg sodium nitroprusside per kilogram) eliminated all effects except elevated selenium residues in liver. The mechanism of alleviation is unknown and may involve a reduction of tissue selenium through selenocyanate formation, or increased elimination of excess selenium by increasing the amount of dimethyl selenide exhaled (Elzubeir and Davis 1988a). At dietary levels of 135 mg CN/kg plus 10 mg selenium per kilogram, chick growth was significantly decreased (Elzubeir and Davis 1988a). This interaction can be lost if there is a deficiency of certain micronutrients or an excess of vitamin K (Davis et al. 1988).

Mammals

Much of the toxicological interest in cyanide relating to mammals has focused on its rapid lethal action; however, its most widely distributed toxicologic problems are due to its toxicity from dietary, industrial, and environmental factors (Way 1981, 1984; Gee 1987; Marrs and Ballantyne 1987). Chronic exposure to cyanide is correlated with specific human diseases: Nigerian nutritional neuropathy, Leber's optical atrophy, retrobulbar neuritis, pernicious anemia, tobacco amblyopia, cretinism, and ataxic tropical neuropathy (Towill et al. 1978; Way 1981; Sprince et al. 1982; Berninger et al. 1989; Ukhun and Dibie 1989). The effects of chronic cyanide intoxication are confounded by various nutritional factors, such as dietary deficiencies of sulfur-containing amino acids, proteins, and water-soluble vitamins (Way 1981).

Most authorities now agree on five points: (1) cyanide has low persistence in the environment and is not accumulated or stored in any mammal studied; (2) cyanide biomagnification in food webs has not been reported, possibly due to rapid detoxification of sublethal doses by most species, and death at higher doses; (3) cyanide has an unusually low chronic toxicity, but chronic intoxication exists and, in some cases, can be incapacitating; (4) despite the high lethality of large single doses or acute respiratory exposures to high vapor concentrations of cyanide, repeated sublethal doses seldom result in cumulative adverse effects; and (5) cyanide, in substantial but sublethal intermittent doses can be tolerated by many species for long periods, perhaps indefinitely (Towill et al. 1978; EPA 1980; Way 1984; Ballantyne and Marrs 1987a; Table 5).

The toxicity of cyanogenic plants is a problem for both domestic and wild ungulates. Poisoning of herbivorous ungulates is more prevalent under drought conditions, when these mammals become less selective in their choice of forage; dry growing conditions also enhance cyanogenic glycoside accumulations in certain plants (Towill et al. 1978). Animals that eat rapidly are at greatest risk, and intakes of 4 mg HCN/kg BW can be lethal if consumed quickly (Egekeze and Oehme 1980). In general, cattle are most vulnerable to cyanogenic plants; sheep, horses, and pigs--in that order--are more resistant than cattle (Cade and Rubira 1982). Deer *(Odocoileus* sp.) and elk *(Cervus* sp.) have been observed to graze on forages that contain a high content of cyanogenic glycosides; however, cyanide poisoning has not been reported in these species (Towill et al. 1978).

Ruminant and nonruminant ungulate mammals that consume forage with high cyanogenic glycoside content, such as sorghums, Sudan grasses, and corn, may experience toxic signs due to microbes in the gut that hydrolyze the glycosides, releasing free hydrogen cyanide (Towill et al. 1978). Signs of acute cyanide poisoning in livestock usually occur within 10 min and include initial excitability with muscle tremors, salivation, lacrimation, defecation, urination, and labored breathing, followed by muscular incoordination, gasping, and convulsions; death can occur quickly, depending on the dose administered (Towill et al. 1978; Cade and Rubira 1982). Thyroid dysfunction has been reported in sheep grazing on stargrass *(Cynodon plectostachyus),* a plant with high cyanogenic glycoside and low iodine content. Sheep developed enlarged thyroids and gave birth to

lambs that were stillborn or died shortly after birth (Towill et al. 1978). Cyanogenic foods can exacerbate selenium deficiency, as judged by the increased incidence of nutritional myopathy in lambs on low-selenium diets (Elzubeir and Davis 1988a). A secondary effect from ingesting cyanogenic glycosides from forage is sulfur deficiency as a result of sulfur mobilization to detoxify the cyanide to thiocyanate (Towill et al. 1978).

Cyanide poisonings of livestock by forage sorghums and other cyanogenic plants are well documented (Cade and Rubira 1982). Horses in the southwestern United States grazing on Sudan grass and sorghums developed posterior muscle incoordination, urinary incontinence, and spinal cord histopathology; offspring of mares that had eaten Sudan grass during early pregnancy developed musculoskeletal deformities (Towill et al. 1978). Salt licks containing sulfur (8.5%) have been used to treat sheep after they failed to gain weight when grazing on sorghum with high HCN content (Towill et al. 1978). Sugar gum (*Eucalyptus cladocalyx*) and manna gum (*Eucalyptus viminalis*) contain high levels of cyanogenic glycosides, and both have been implicated as the source of fatal HCN poisoning in domestic sheep and goats that had eaten leaves from branches felled for drought feeding, or after grazing sucker shoots on lopped stumps (Webber et al. 1984). In one case, 10 goats died and 10 others were in distress within 2 h after eating leaves from a felled sugar gum. Dead goats had bright red blood that failed to clot and subepicardial petechial hemorrhages. Rumens of dead goats contained leaves of *Eucalyptus* spp. and smelled of bitter almonds. The 10 survivors were treated intravenously with 3 mL of a 1-L solution made to contain 20 g of sodium nitrite and 50 g of sodium thiosulphate; four recovered and six died. Of 50 afflicted goats, 24 died within 24 h and the remainder recovered (Webber et al. 1984). In rare instances HCN poisoning occurs when animals are exposed to chemicals used for fumigation or as a fertilizer (Webber et al. 1984), but there is general agreement that ingestion of plants containing high levels of cyanogenic glycosides is the most frequent cause of cyanide poisoning in livestock.

Cassava, also known as maniac, tapioca, yuca, or guacamate, is one of the very few--and, by far, the most important--food crops in which the cyanide content creates toxic problems (Cooke and Coursey 1981). Cassava is a major energy source for people and livestock in many parts of the world; it accounts for an average of 40% of the human caloric intake in Africa (Casadei et al. 1984), to more than 70% in some African diets (Way 1984). In comparison to other tropical crops it produces the highest yield per hectare (Okeke et al. 1985). Cassava is native to tropical America from southern Mexico to northern Argentina and probably has been under cultivation there for 4,000-5,000 years. It has been introduced to east Africa, Indian Ocean islands, southern India, and the Far East (Cooke and Coursey 1981). The global production of cassava roots was estimated at 50 million tons in 1950, and 100 million tons in 1980; about 44.2 million tons are grown annually in Africa, 32.7 million tons in tropical America, and 32.9 million tons in Asia (Cooke and Coursey 1981). Linamurin is the principal cyanogenic glycoside in cassava; its toxicity is due to hydrolysis by intestinal microflora releasing free cyanide (Padmaja and Panikkar 1989). Rabbits *(Oryctolagus cuniculus)* fed 1.43 mg linamurin per kilogram BW daily (10 mg/kg BW weekly) for 24 weeks showed effects similar to those of rabbits fed 0.3 mg KCN/kg BW weekly. Specific effects produced by linamurin and KCN included elevated lactic acid in heart, brain, and liver; reduced glycogen in liver and brain; and marked depletion in brain phospholipids (Padmaja and Panikkar 1989).

The use of cassava in animal feed presents two major problems: the presence of cyanogenic glycosides in the tuber, and the remarkably low protein levels in fresh and dried cassava. Pigs fed low-protein cassava diets for 8 weeks had reduced food consumption and lowered liver weight; addition of protein supplement to the diet reversed these trends (Tewe 1982b). Removal of cyanogenic glycosides from cassava tubers, mash, peels, and root meal is accomplished with several techniques. Usually, the cassava root is dried in the sun for several weeks, and this process removes most of the cyanogenic glycosides; however, under conditions of famine or food shortage, this process cannot be carried out properly (Cliff et al. 1984). Long fermentation periods, especially under conditions of high moisture content, may be effective in substantial detoxification of cassava mash (Ukhun and Dibie 1989). Cassava peels containing as much as 1,061 mg HCN/kg FW can be rendered suitable for feeding to livestock (4-625 mg/kg) by boiling for 7 min, roasting for 30 min, soaking for 15 h, or drying in the sun for 7.6 days (Okeke et al. 1985). Cassava root meal (up to 40% of cassava meal) is satisfactory as a diet supplement for domestic pigs, provided cyanide content is <100 mg/kg ration (Gomez et al. 1983).

Neuropathies associated with cassava ingestion (i.e., cyanide intoxication) can develop into a syndrome in humans and domestic animals, characterized by nerve deafness, optic atrophy, and an involvement of the sensory spinal nerve that produces ataxia. Other symptoms include stomatitis, glossitis, and scrotal dermatitis (Way 1981). Potentially more serious are long-term effects such as ataxic neuropathy, goiter, and cretinism,

which have been attributed to high cassava content in diets. Thiocyanate--one of the detoxification products--inhibits iodine absorption and promotes goiter, a common ailment in tropical countries (Cooke and Coursey 1981). At high dietary cyanide intakes there is an association with diabetes and cancer (Cliff et al. 1984), but this requires verification. The first case of cassava toxicity occurred almost 400 years ago (Cooke and Coursey 1981). The toxic principle was later identified as a cyanogenic glycoside, shown to be identical with flax linamurin (2-(beta-D-glucopyranosyloxy)-isobutyronitrile). All parts of the plant, except possibly the seeds, contain the glycoside together with the enzyme linamarase. This enzyme effects hydrolysis of the nitrile to free HCN when the tissue cellular structure is damaged (Cooke and Coursey 1981). Mantakassa disease is related to chronic cyanide intoxication associated with a diet consisting almost exclusively of cassava; in times of famine and sulfur-poor diets, Mantakassa effects were more pronounced (Casadei et al. 1984). Symptoms of Mantakassa disease include the sudden onset of difficulty in walking, increased knee and ankle reflexes, elevated serum thiocyanate levels, fever, pain, headache, slurred speech, dizziness, and vomiting. Women of reproductive age and children were the most seriously affected. Symptoms persisted for up to 4 months after treatment with hydroxycobalamin, vitamin supplements, and a high protein, energy-rich diet (Cliff et al. 1984). Mantakassa was reported in 1,102 victims in Mozambique in 1981 from a drought-stricken cassava staple area; from Zaire in 1928, 1932, 1937, and again in 1978-81; in Nigeria; and in the United Republic of Tanzania. The mean serum thiocyanate level in patients with Mantakassa is 2.6 times higher than in non-Mantakassa patients in Nigeria, and 3.5 times higher than in Tanzanian patients. Pesticides, infection, viruses, and consumption of food other than cassava were eliminated as possible causative agents in Mantakassa disease. Still unresolved is whether the disease is triggered when a threshold level of thiocyanate is reached, or when a critical combination of cyanide intoxication plus nutritional deficiency occurs (Cliff et al. 1984).

Routes of administration other than dietary ingestion should not be discounted. Livestock found dead near a cyanide disposal site had been drinking surface water runoff from the area that contained up to 365 mg HCN/L (EPA 1980). The use of cyanide fumigant powder formulations may be hazardous by contact of the powder with moist or abraded skin, contact with the eye, swallowing, and inhalation of evolved HCN (Ballantyne 1988). In rabbits, lethal systemic toxicity was produced by contamination of the eye, moist skin, or abraded skin (but not dry skin) with cyanide powder formulations (40% NaCN plus 60% kaolin) administered at 1-5 g powder per cubic meter (Ballantyne 1988). Hydrogen cyanide in the liquid state can readily penetrate the skin, and skin ulceration has been reported from splash contact with cyanides among workers in the electroplating and gold extraction industries--although effects in those instances were more likely due to the alkalinity of the aqueous solutions (Homan 1987). In one case, liquid HCN ran over the bare hand of a worker wearing a fresh air respirator; he collapsed into unconsciousness in 5 min, but ultimately recovered (EPA 1980).

Use of poisons in livestock collars is both specific and selective for animals causing depredations, as is the case for cyanide collars to protect sheep against coyotes (Sterner 1979; Table 5). These collars contain a 33% NaCN solution and are usually effective against coyotes. However, field results indicate that some coyotes kill by means other than neck attack, and some exhibit great wariness in attacking collared sheep (Savarie and Sterner 1979).

Calcium cyanide in flake form was used in the 1920's to kill black-tailed prairie dogs and pocket gophers *(Geomys bursarius)* in Kansas, and various other species of rodents in Nova Scotia (Wade 1924). For prairie dog control, the usual practice was to place 43-56 g of calcium cyanide 0.3-0.7 m below the rim of the burrow and to close the entrances. The moisture in the air liberated HCN gas, which remained in the burrow for several hours, producing 100% kill. A lower dose of 28 g per burrow was about 90% effective (Wade 1924). Control of prairie dogs with cyanide sometimes resulted in the death of burrowing owls that lived in the prairie dog burrows (Wade 1924).

Clinical signs of acute cyanide poisoning in mammals last only a few minutes after ingestion and include rapid and labored breathing, ataxia, cardiac irregularities, dilated pupils, convulsions, coma, respiratory failure, and rapid death (Egekeze and Oehme 1980; Ballantyne 1983). Cyanide poisoning causes cardiovascular changes as well as its better known effects on cellular respiration. Cyanide increases cerebral blood flow in rabbits and cats, and disrupts systemic arterial pressure in dogs (Robinson et al. 1985). Cyanide affects mammalian behavior, mostly motor functions, although these effects have not been quantified. Cyanide-induced motor alterations observed in rats and guinea pigs include muscular incoordination, increased whole-body locomotion, disrupted swimming performance, and altered conditioned avoidance responses (D'Mello 1987). As a consequence of the cytotoxic hypoxia in acute cyanide poisoning, there is a shift from aerobic to

anaerobic metabolism, and the development of lactate acidosis. A combination of rapid breathing, convulsions, and lactate acidosis is strongly suggestive of acute cyanide poisoning (Ballantyne 1983). As with other chemical asphyxiants, the critical organs that are most sensitive to oxygen depletion are the brain and heart (Egekeze and Oehme 1980). The only consistent postmortem changes found in animals poisoned by cyanide are those relating to oxygenation of the blood. Because oxygen cannot be utilized, venous blood has a bright-red color and is slow to clot (Egekeze and Oehme 1980). Bright-red venous blood is not a reliable indicator of cause of death, however, because it is also associated with chemicals other than cyanide (Ballantyne 1983).

Cyanide poisoning is associated with changes in various physiological and biochemical parameters. The earliest effect of cyanide intoxication in mice seems to be inhibition of hepatic rhodanese activity, due to either blockage by excess binding to the active site or to depletion of the sulfane-sulfur pool. These changes do not seem to occur in blood, where rhodanese functions at its maximal rate, thus preventing cyanide from reaching the target tissues and causing death (Buzaleh et al. 1989). Cyanide causes dose- and species-dependent responses on vascular smooth muscle; studies with isolated aortic strips indicate that rabbits are 80 times more sensitive than dogs or ferrets (*Mustela putorius*; Robinson et al. 1985). Rabbits killed with HCN had higher concentrations of cyanide in blood and other tissues and lower tissue cytochrome oxidase activities than did those killed with KCN (Ballantyne et al. 1972). Cyanide promotes dose- and calcium-dependent release of dopamine tissues in the domestic cat, and reductions in adenosine triphosphate (ATP) content of the carotid body (Obeso et al. 1989). Cyanide-induced hypoxia is believed to decrease ATP content of Type I glomus cells. The decrease in the phosphate transfer potential is a crucial step in the overall transduction process, that is, the activation of the transmitter release from Type I cells, with resultant release and activation of sensory nerve endings (Obeso et al. 1989). Studies with isolated heart of the domestic ferret demonstrate that cyanide affects intracellular ionic exchange of H^+, Na^+, and calcium (Fry et al. 1987); inhibits cardiac action potential (Elliott et al. 1989); and inhibits oxidative phosphorylation accompanied by an intracellular acidosis, a decrease in phosphocreatinine, and a rise in inorganic phosphate (Eisner et al. 1987). When oxidative phosphorylation is inhibited in cardiac muscle, there is a rapid decrease of developed force or pressure; most of the decrease of developed pressure produced by cyanide in ferret heart is not produced by intracellular acidosis, and may result from increased inorganic phosphate (Eisner et al. 1987). Observed changes in rat cerebral oxidative responses to cyanide may be due to redistribution of intracellular oxygen supply to mitochondria respiring in an oxygen-dependent manner or by branching effects within brain mitochondria (Lee et al. 1988). Hyperammonemia and the increase of neutral and aromatic amino acids may also be important in loss of consciousness induced by cyanide (Yamamoto 1989).

Table 5. Cyanide effects on selected species of mammals.

Species, dose, and other variables	Effects	Reference[a]
Cattle, *Bos* sp.		
Fed hybrid sorghum Sudan grass cross 988 at 15–20 kg per animal daily for 3–8 days	Of 180 cows, 21 were affected and 13 died; toxic cyanide levels were measured in fodder and in liver and ruminal contents of dead cows	44
Dog, *Canis familiaris*		
Administered doses up to 2 mg NaCN/kg body weight (BW), once or twice daily for 15 months	Acute toxic signs evident after each administration, but complete recovery within 30 min; no measurable adverse effects after 15 months	1
5.4 mg NaCN/kg BW, single subcutaneous injection	LD50	2
24 mg CN/kg BW, single oral or slow intravenous injection	Lethal; at time of respiratory arrest, blood plasma	3

route	concentration was 1 mg total CN per liter or about 0.4 mg free cyanide per liter	
Fed diets containing 150 mg NaCN/kg for 30 days	No measurable effect on food consumption, blood chemistry, behavior, or organ histology	1
Coyote, *Canis latrans*		
Single forced oral dose of NaCN, in mg/kg BW		
4	Immobilized in 13 min, but all survived for at least 30 days; some sacrificed after 30 min: NaCN residues in mg/kg fresh weight (FW) were 0.03 in blood and 0.9 in stomach	2
4.1 (2.1–8.3)	LD50	2
8	Immobilization in 9 min, death within 41 min	2
16, 32, or 64	All immobilized in less than 1 min and all died in less than 8 min. Maximum NaCN residues were 0.14 mg/L in blood and 13.0 mg/L FW in stomach	2
"Toxic" collars attached to neck of sheep and camouflaged with wool; each collar contained 50 mL of a 33% NaCN solution; toxic action commences when coyote attacks sheep and punctures collar; all coyotes tested were known to attack sheep in laboratory pens	Of three coyotes tested, one was immobilized in 1 min and died within 18 min; the other two coyotes recovered; the dead coyote had mouthed the collar for about 2 s; residues in mg NaCN/kg, were 0.26 in blood and <0.1 in stomach; the other two coyotes had mouthed the collar for 3–15 s and had NaCN levels, in mg/kg FW, of 0.014 and 0.029 in blood, and 0.6 and <0.1 in stomach	2
Toxic collar, as above; each coyote tested was known to have fatally attacked at least three domestic sheep within a 30-day period	Of the 12 coyotes that attacked the neck region of the sheep and punctured the collar, nine received lethal doses and became immobilized in 1–3 min and died 3–25 min later; the mean time to death was 11.6 min; one of the three sublethally dosed coyotes survived at last three successful attacks in which the collar was punctured, and two survived two attacks; in all cases, contact with NaCN	4

	produced shaking of the head, pawing at the mouth, rubbing the snout on the ground, and ataxia	
African giant rat, *Cricetomys gambianus*		
Weanlings fed diets for 16 weeks containing 0 mg HCN/kg (maize), 110 mg HCN/kg (cassava pulp), 150 mg HCN/kg (cassava tuber), or 597 mg HCN/kg (cassava peel)	Food consumption was similar in all diets; no pathology was observed in any organ of animals on all treatments; rats on maize and cassava pulp diets had significantly increased growth rate, feed efficiency, and protein efficiency; rats on cassava peel and tuber diets had significantly increased thiocyanate levels in serum, organs, and urine	5
Juveniles, age 10–14 weeks, fed cassava peel diets for 2 weeks containing 720 mg HCN/kg	Adverse effects on growth when cassava peel exceeds 7.8% of the ration	6
Weanlings fed 1,000 mg CN/kg diet, as KCN, for 12 weeks	Reduction in feed intake, reduced body weight, elevated thiocyante concentrations in serum (37.4 mg/L vs. 12.6), urine (341 mg/L vs. 25), liver (1.7 g/kg FW vs. 0.4), kidney (2.4 g/kg FW vs. 0.4), and spleen (2.1 g/kg FW vs. 0.3)	7
Humans, *Homo sapiens*		
Intentional oral ingestion of unknown amount of NaCN or KCN, three cases	Death between 5 and 30 min; stomach cyanide concentrations ranged between 100 and 164 mg; tissue residues postmortem in mg/kg FW, were 0.3–1.1 in blood, 0.3–1.0 in liver, and 0.2–0.3 in brain	8
Found dead, four cases, time to death unknown	Maximum cyanide concentration in stomach was 230 mg; maximum tissue residues, in mg/kg FW were 3.5 in blood, 6.3 in liver, and 0.5 in brain	8
Attempted suicide by 39-year-old-male, unknown amount of NaCN	Severe tremors and progressive loss of muscle tone--representing the first case of cyanide intoxication with delayed onset of symptoms	9
Inhalation of HCN gas, in mg/m^3, for various time intervals		

140 for 60 min	Calculated LC50	10
220 for 30 min	Calculated LC50	10
504 for 10 min	Calculated LC50	10
680 for 5 min	Calculated LC50	10
1,500 for 3 min	Calculated LC50	10
4,400 for 1 min	Calculated LC50	10
Inhalation of 2,000 mg HCN/L	First breath results in deep, rapid breathing, with collapse, convulsions, and death within 1 min	11
Inhalation of cyanogen chloride, in mg/L, for various time intervals		
1, 10 min	Irritant	1
48, 30 min	Fatal	1
159, 10 min	Fatal	1
Inhalation of cyanogen bromide, in mg/L, for various time intervals		
1.4, no time given	Irritant to eyes and nose	1
92, 10 min	Fatal	1
Single oral dose		
0.5–3.5 mg HCN/kg BW	Lethal	12, 41
0.7–3.5 mg KCN/kg BW, equivalent to 50 to 250 mg KCN/adult	Fatal	10
2 mg HCN/kg BW, or total of about 150 mg HCN	Acute LD50 for adults	13
1–5 g of NaCN or KCN, equivalent to 0.2 g/adult or 3 mg/kg BW	Minimum lethal dose	14
Tissue residues		
Whole blood, 1–2 mg free cyanide per liter	Usually lethal	42
Whole blood, 2.6–3.1 mg total CN per liter	Minimum cyanide concentration associated with death in an otherwise healthy individual	13
Whole blood, 2.6–3.1 mg total CN per liter	Minimum cyanide concentration associated with death in an otherwise healthy individual	13
Whole blood, 4–45 mg total CN per liter	Levels measured in known suicides	13
Whole body, 7 mg HCN/kg BW	Residue associated with minimum lethal dose	11
Daily dietary intake of 15–31.5 mg hydrogen cyanide from cassava	Mantakassa disease--see text for discussion	15
100 mg HCN/kg BW applied to skin surface	LD50	11
Clothing inundated with 10% NaCN solution, pH 11.4	Clinical signs of toxicity within 25 min and death in about 60 min	13
Livestock		
>200 mg HCN/kg plant materials in diet	Potentially dangerous	13

Cynomolgus monkeys, *Macaca* spp.		
Given multiple sublethal doses of KCN (5–18 mg) for 23 days	Brain histoapathology	3
Exposed to HCN gas produced from combustion of polyacrylonitrile materials at various temperatures		
300º C, 87–170 mg HCN/L air	Incapacitated in 16–30 min; blood cyanide of 4.3 mg/L	16
600º C, 120–174 mg HCN/L air	Incapacitated between 6 and 24 min, blood cyanide of 2.96 mg/L	16
900º C, 166–196 mg HCN/L air	Incapacitated between 2 and 13 min; blood cyanide concentration of 3.1 mg/L	16
Exposed to HCN gas at air concentrations of 60, 80, or 150 mg HCN/L for 30 min	At 60 mg/L, HCN had only a slight depressive effect on the central nervous system; at 80 and 150 mg/L, severe CNS depression and incapacitation occurred	17
Exposed to HCN gas at air concentrations of 100, 1092, 123, 147, or 156 mg HCN/L air	Incapacitated in 8 min at higher doses to 19 min at lowest dose tested; blood cyanide after 30 min exposure ranged between 1.7 mg/L at 100 mg HCN/L and 3.2 mg/L at 156 mg HCN/L; after recovery for 60 min, blood CN ranged between 2.0 and 2.9 mg/L	16
Domestic mouse, *Mus* spp.		
Single intraperitoneal injection		
HCN, 2.8 mg/kg BW	LD50	10
NaCN, 4.6–5.9 mg/kg BW	LD50	10
KCN, 5.3–6.7 mg/kg BW	LD50	10
Acetone cyanohydrin, $(CH_3)_2C(OH)CN$, 8.7 mg/kg BW	LD50 (7 days); first death in 5 min	18
Malonitrile, $NCCH_2CN$, 18 mg/kg BW	LD50 (7 days); first death in 4.8 h	18
Propionitrile, CH_3CH_2CN, 28 mg/kg BW	LD50 (7 days); first death in 21 h	18
N-butyronitrile, 38 mg/kg BW	LD50 (7 days); first death in 2.2 h	18
Acrylonitrile, CH_2CHCN, 46 mg/kg BW	LD50 (7 days); first death in 2.3 h	18
Succinonitrile, $NCCH_2CH_2CN$, 62 mg/kg BW	LD50 (7 days); first death in 5.1 h	18
Acetonitrile, CH_3CN, 175 mg/kg BW	LD50 (7 days); first death in 7.1 h	18
Single subcutaneous injection		
HCN, 7.8–12.0 mg/kg BW	LD50	10
KCN, 10 mg/kg BW	Loss of consciousness in 100%; blood ammonia levels increased 2.5 times; brain amino acid levels (i.e., leucine,	19

	isoleucine, tyrosine, phenylalanine) increased by 1.5–3.0 times; alpha ketoglutarate, at 500 mg/kg BW by intraperitoneal injection, completely blocked the development of cyanide-induced loss of consciousness and hyperammonemia	
Single oral dose		
8.5 mg KCN/kg BW, equivalent to 3.4 mg CN^-/kg BW	LD50	10, 20
Drinking water, 1,000 mg KCN/L, exposure for 40 days	Marked inhibition of cytochrome oxidase activity in liver, brain, and blood; increased cyanide concentrations in all tissues; inhibition of rhodanese activity; diminished labile sulfur tissue levels	43
Rabbit, *Oryctolagus* spp.		
Isolated aorta strips, 0.00014 µg NaCN/L–140 µg/L	Small contractions measured at lowest dose tested, ED50 at 70 µg/L, and maximum response at 140 µg/L; higher doses up to 14 mg/L produced relaxation	21
Single intramuscular injection, in mg/kg BW		
0.5–1.5	LD50 for HCN	10
1.6	LD50 for NaCN	10
3.1–3.3	LD50 for KCN	10
8.0		
Killed with KCN	Cyanide concentrations, in mg/kg FW, were 1.6 in serum, 5.3 in blood, and <0.4 in other tissues sampled	22
Killed with HCN	Cyanide concentrations, in mg/kg FW, were 9.3 in blood, 2.1 in brain, 2.0 in serum, 0.5 in myocardium, and <0.4 in other tissues	22
Single intravenous injection, in mg/kg BW		
0.6	LD50 for HCN	10
1.2	LD50 for NaCN	10
1.9	LD50 for KCN	10
Single dose administered to eye surface, in mg/kg BW		
1.0	LD50 for HCN	10
4.5–5.1	LD50 for NaCN	10
7.9	LD50 for KCN	10
11.2	Signs of NaCN poisoning in 3 min, death in 7 min	23
Single intraperitoneal injection, in mg/kg BW		
1.7–2.0	LD50 for HCN	10
2.8–2.9	LD50 for NaCN	10

3.6–4.0	LD50 for KCN	10
Administered as solution to skin, in mg/kg BW		
2.3	LD50 for HCN and abraded skin	10
6.9	LD50 for HCN and intact skin	10
14.3	LD50 for KCN and abraded skin	10
19.3	Abraded skin; signs of NaCN poisoning evident in 25 min, death in 41 min	23
22.3	LD50 for KCN and intact skin	10
29.5	Moist skin; signs of NaCN poisoning evident in 79 min, death in 117 min	23
>110	Dry skin; no signs of NaCN poisoning, no deaths	23
Single oral dose, in mg/kg BW		
2.5	LD50 for HCN	10
5.1	LD50 for NaCN	10
5.8	LD50 for KCN	10
12.8	Signs of NaCN poisoning in 4 min, death in 22 min	23
Single oral dose, NaCN, 10–15 mg/kg BW	All dead in 14–30 min; blood cyanide ranged between 3.7 and 5.4 mg/L	24
Inhalation of HCN from combustion of 20 g of polyacrylonitrile	All dead in 12–16 min; blood cyanide ranged between 1.6 and 3.1 mg/L	24
Interval between death and removal of tissues for analysis in rabbits killed by KCN		
Brain	Concentrations dropped from 1.6 mg/kg FW immediately after death to 1.2 in 1 day, 0.92 in 3 days, and 0.04 in 7 days	25
Blood	Residues, in mg/kg FW were 5.7 immediately after death and 2.3 after 21 days	25
Lung	Cyanide concentrations dropped from 2 mg/kg FW just after death, to 0.8 in 7 days	25
Domestic sheep, *Ovis aries*		
Intravenous or intraarterial injection, fetal lambs 80% through gestation (120 days), NaCN, 50–400 µg	Slowing of fetal heart rate, disruption of respiratory movements, significant but inconsistent changes in arterial blood pressure	26
Single intramuscular injection of 10 mg KCN/kg BW	All dead within 17 min; cyanide concentrations postmortem, in mg/kg FW, were 3.3 in blood, 1.5 in plasma, 1.6 in serum, 1.4 in cerebrospinal fluid, 0.9 in brain grey matter, and 1.0 in brain white matter	3, 10, 27
Laboratory white rat, *Rattus* spp.		
Single intraperitoneal injection		

0.1–10 mg CN/kg BW	LD50	28
5 mg NaCN or KCN/kg BW	50% decrease in brain cytochrome oxidase activity within 5–10 min	14
5 mg KCN/kg BW	Reversible intracellular metabolic changes including acidosis and increased lactate levels--typical of cellular anoxia	29
Intravenous injection, constant infusion of 0.15–0.20 mg CN/kg BW per min	LD50 in about 20 min. Rapid progressive reduction in cerebrocortical cytochrome oxidase (cytochrome aa_3) concomitant with increases up to 200% in cerebral blood flow	30
Single intracartoid artery injection of KCN		
1–2 mg/kg BW	Modest acute clinical dysfunction and incomplete suppression of brain electroencephalographic (EEG) activity	31
2.5 mg/kg BW	Some deaths; survivors showed rapid abolition of brain EEG activity, 52% reduction in brain cytochrome oxidase activity, 600% increase in lactate, 85% decrease in glycogen, 32% reduction in ATP, and 73% increase in ADP; all values returned to normal in 6–24 h, and remained normal for balance of 7-day observation period	31
3.5–5 mg/kg BW	High incidence of cardiovascular collapse and death within minutes	31
Tissue residues 2.6–2.9 mg HCN/L	Minimum lethal concentrations in rats poisoned orally with KCN	13
Inhalation exposure route, HCN vapor, in mg/m^3, for various periods		
3,778 for 10 s	LC50	10
1,128 for 1 min	LC50	10
493 for 5 min	LC50	10
151–173 for 30–60 min	LC50	10
Single oral dose		
3.4 mg KCN/kg BW	LD25	32
3.6–4.2 mg HCN/kg BW	LD50	10
5.1–5.7 mg NaCN/kg BW	LD50	10
5.7 mg KCN/kg BW	LD50	32
6, 10, or 14 mg KCN/kg BW	Some deaths in all groups; all dead at higher doses within 60 min; those killed 10 min postadministration had	13

	higer blood CN concentrations than those killed near death or at survival at 60 min	
6.4 mg NaCN/kg BW	LD50	13
7.5–10 mg KCN/kg BW	LD50	10, 13
8.6 mg KCN/kg BW	LD98	32
10 mg KCN/kg BW, equivalent to 4 mg HCN/kg BW	LD50	20
13.2 mg NaCN/kg BW or 7 mg HCN/kg BW	Dead in 10.3 min; tissue cyanide levels, in mg/kg FW, were 8.9 in liver, 5.9 in lung, 4.9 in blood, 2.1 in spleen, and 1.5 in brain	33
40 mg NaCN/kg BW, equivalent to 21 mg HCN/kg BW	Dead in 3.3 min	33
Drinking water exposure		
Equivalent to 8 mg CN/kg BW daily for 21 days	Liver normal	20
Equivalent to 21 mg CN/kg BW daily for 21 days	Significantly increased liver weight	20
200 mg CN/L for 4 weeks	Reduced growth	34
Drinking water of adults contained 150 mg CN/L, as KCN, for 2 weeks, followed by injection with radioselenium-75 and observed for 15 days	Cyanide-treated rats excreted significantly more radioselenium in urine than did controls; half-time persistence of radioselenium in treated group was 28 days vs. 38 days in controls	35
Drinking water of weanling males contained 150 mg CN/L for 9 weeks	Significant reduction in glutathion activity, and in selenium concentrations in blood kidney, liver, and muscle	35
Dietary exposure		
Fed 12 mg CN/kg BW daily for 2 years, equivalent to 300 mg HCN/kg ration	No measurable adverse effects on blood chemistry, growth, survival, or histology; elevated thiocyanate levels in liver and kidneys	1
Fed 500 mg HCN/kg ration to pregnant rats through gestation and lactation	No effect on reproduction	20
Weanlings fed diets of raw lima beans containing 727 mg CN/kg for 3 weeks, or 727 mg CN/kg diet as KCN for 3 weeks	Lima bean diet alone increased hepatic glutamate dehydrogenase (GLDH) and decreased isocitrate dehydrogenase (ICDH) activities; KCN diet had no effect on GLDH and increased ICDH activity, emphasizing the importance of dietary components when evaluating CN-containing diets	36
750 mg CN/kg diet (1,875 mg KCN/kg diet) for 8 weeks,	No measurable effect on food consumption or growth rate;	37

adequate protein	significantly increased serum and urinary thiocyanate concentrations	
As above, protein deficient diet	Reduction in body weight gain, reduction in serum thiocyanate concentration	37
Weanling males fed diets containing 1,500 mg KCN/kg, or 2,240 mg potassium thiocyanate (KSCN)/kg for 50 weeks	No deaths or clinical signs of toxicity; both groups had decreased thyroid gland activity; cyanide, but not thiocyanate, caused reduction in growth rate	38
Isolated liver segments from starved rats exposed to 100 mg KCN/L	Oxygen consumption reduced 80%, and evidence of hepatotoxicity as judged by enzyme release, glutathione depletion, and calcium accumulation in liver; hepatotoxicity prevented by feeding rats fructose	39
Domestic pig, *Sus* spp.		
Fed diet containing 96 mg CN/kg ration, as cassava peel for 72 days	No effect on food consumption or protein metabolism	40

Organic cyanide compounds, or nitriles, have been implicated in numerous human fatalities and signs of poisoning—specially acetonitrile, acrylonitrile, acetone cyanohydrin, malonitrile, and succinonitrile. Nitriles hydrolyze to carboxylic acid and ammonia in either basic or acidic solutions. Mice *(Mus* sp.) given lethal doses of various nitriles had elevated cyanide concentrations in liver and brain; the major acute toxicity of nitriles is CN release by liver processes (Willhite and Smith 1981). In general, alkylnitriles release CN much less readily than aryl alkylnitriles, and this may account for their comparatively low toxicity (Davis 1981).

No human cases of illness or death due to cyanide in water supplies are known (EPA 1980). Accidental acute cyanide poisonings in humans are uncommon (Towill et al. 1978); however, a man accidentally splashed with molten sodium cyanide died about 10 h later (Curry 1963). Human cyanide deaths usually involve suicides, where relatively large amounts of sodium cyanide or potassium cyanide are ingested and the victims die rapidly in obvious circumstances. Recovery after oral ingestion is rare. In one case, a spouse emptied capsules containing medicine and repacked them with 40% solid NaCN. The victim took one capsule and ingested about 0.05 g, but vomited and recovered completely (Curry 1963). Human deaths are increasing from gas or smoke inhalation from urban fires, possibly owing to the increased toxicity of fire atmospheres caused by the use of organocyanide plastics in modern construction and furnishings (Egekeze and Oehme 1980). Hydrogen cyanide may be important in some fires in producing rapid incapacitation, causing the victims to remain in the fire and die from carbon monoxide or other factors, although HCN concentrations of 60 mg/L air and lower had minimal effects (Purser 1984). Exposure to the mixture of HCN and carbon monoxide, with accompanying changes in cerebral blood flow during attempts to escape from fires, may be a cause of collapse and subsequent death

(Purser 1984). For example, cynomolgus monkeys (*Macaca* spp.) exposed to pyrolysis products of polyacrylonitrile (PAN) and to low-level HCN gas had similar physiological effects in both atmospheres, specifically: hyperventilation, followed by loss of consciousness after 1-5 min; and brachycardia, with arrhythmias and T-wave abnormalities. Recovery was rapid following cessation of exposure (Purser et al. 1984). Because HCN is the major toxic product formed by the pyrolysis of PAN, Purser et al. (1984) suggested that HCN may produce rapid incapacitation at low blood levels of cyanide in fires, while death may occur later due to carbon monoxide poisoning or other factors.

Finally, cyanide does not appear to be mutagenic, teratogenic, or carcinogenic in mammals (EPA 1980; Ballantyne 1987a). In fact, there has been a long-standing hypothesis for an anticancer effect of the cyanogenic glycoside amygdalin (also called laetrile). The hypothesis is based on amygdalin's selective hydrolysis by a beta glucosidase, liberating cyanide and benzaldehyde at the neoplastic site. The cyanide then selectively attacks the cancer cell, which is presumed to be low in rhodanese, whereas normal cells are assumed to possess sufficient rhodanese and sulfur to detoxify the cyanide (Way 1981). However, many tumors are neither selectively enriched in beta glucosidase nor low in rhodanese (Way 1981).

Recommendations

Proposed free cyanide criteria suggest that sensitive species of aquatic organisms are protected at <3 µg/L, birds and livestock at <100 mg/ kg diet, and human health at concentrations of <10 µg/L drinking water, <50 mg/kg diet, and <5 mg/m^3 air (Table 6).

Analytical methodologies need to be developed that differentiate between free cyanide (HCN and CN^-) and other forms of cyanide, and that are simple, sensitive (i.e., in the µg/L range), and accurate (Smith et al. 1979; Leduc et al. 1982). Procedures need to be standardized that ensure prompt refrigeration and analysis of all samples for cyanide determination because some stored samples generate cyanide while others show decreases (Gee 1987).

Periodic monitoring of cyanide in waterways is unsatisfactory for assessing potential hazards because of cyanide's rapid action, high toxicity, and low environmental persistence. A similar case is made for cyanide in the atmosphere. Development of a continuous monitoring system of cyanides in waterways and air is recommended, with emphasis on point source dischargers, such as industrial and municipal facilities (Towill et al. 1978; Egekeze and Oehme 1980; Leduc et al. 1982). Information is needed on the fate of cyanide compounds in natural waters, relative contributions of natural and anthropogenic sources, and critical exposure routes for aquatic organisms (Leduc et al. 1982). Additional research is needed on the origin of cyanide in wilderness and rural watershed areas, specifically the roles of organic wastes and their associated bacterial flora, aquatic vegetation induced by nutrient enrichment, and terrestrial plant cover in the watershed (Leduc 1984).

Table 6. Proposed free cyanide criteria for the protection of living resources and human health.

Resource criterion, and other variables	Concentration	Reference[a]
Freshwater organisms		
Effect levels, in µg/L medium		
Minimal impairment, most species of fish	3–5	1, 2, 3, 4, 5, 6
Reduced survival, amphipods	>3–34	1, 7
Safe, most fish species	3.5 (24-h average, not to exceed 52 at any time)	7
Significant impairment, most species of fish	8–16, exposure for at least 20 days	6, 7
Hazardous		
Most fish species	>11	1, 4
Microorganisms	>300	8

Reduced survival, chronic exposure		
Bivalve molluscs, larvae	>14	1
Fish, many species	30–150	1, 5
Impaired reproduction, sensitive species of fish	>25	2
Impaired swimming ability, growth, development, and behavior	>100	3, 6
Lethal to rapidly lethal, acute exposure	300–1,000	5
Marine organisms		
Effect levels, in µg/L seawater		
Adverse effects, chronic exposure	>2	7
Minimal risk	<5	1
Hazardous	>10	1
Lethal	>30	7
Sediments, Great Lakes		
Effect level, in mg total cyanide/kg dry weight (DW)		
Nonpolluted	<0.10	20
Moderately polluted	0.1–0.25	20
Heavily polluted	>0.25	20
Birds		
Domestic chickens		
Diet, safe level, in mg total cyanide/kg ration fresh weight (FW)	90–<100	9, 10
Waterfowl		
Drinking water, safe	<50	21, 22
Livestock		
level in mg/L total cyanide		
Diet, safe level, in mg/kg FW		
Free cyanide	<100	9
Total cyanide	<625	11
Forage, hazardous level, in mg/kg FW	>200	8
Laboratory white rat		
Diet, safe level, in mg/kg ration FW	<1,000	19
Blood, in mg/L		
Normal	0.25–0.45	12
Minimum lethal concentration	2.6–2.9	12
Liver		
Minimum lethal concentration, in mg/kg FW	0.5–6.1	12
Human health		
Drinking water, in µg/L		
Recommended	<5–<10	1, 6, 8, 13
United States nationwide survey	Max. 8	7
Safe	<10	1
Goal, United States	<10	7, 14
Maximum allowable limit, United States	10	13
Goal, Canada	<20	7
Lifetime health advisory, United States and Canada	<154	14

Acceptable	<200	7
Mandatory limit	200	13
Rejected	>200	1, 8
10-day health advisory		
Child	<220	14
Adult	<770	14
Diet		
Acceptable daily intake		
Water	1.5 mg, equivalent to 0.02 mg/kg body weight (BW) daily for 70-kg adult	15
Food, in mg/kg BW	8.4	7
Food, in mg/kg FW	<50	15
Food, in mg total cyanide/kg FW	<415	11
Cassava, *Manihot esculenta*, roots, total cyanide, in mg/kg FW		
Safe	<50	16
Moderately toxic	50–100	16
Very poisonous	>100	16
Food items, in mg/kg		
Cocoa	<20 DW	13
Beans, nuts	<25 DW	1
Cereals, grains	<25 DW	13
Citrus fruits	<50 FW	1
Uncooked pork	<50 FW	13
Grains	<75 FW	1
Cereals flours	<125 DW	13
Spices	<250 FW	1, 13
Frozen meat	<950 FW	1, 13
Bakery products, yeast	<1,500 DW	13

[a]1, Towill et al. 1978; 2, Smith et al. 1979; 3, Doudoroff 1976; 4, Leduc 1981; 5, Leduc 1984; 6, Leduc et al. 1982; 7, EPA 1980; 8, Egekeze and Oehme 1980; 9, Gomez et al. 1983; 10, Gomez et al. 1988; 11, Okeke et al. 1985; 12, Egekeze and Oehme 1979; 13, EPA 1973; 14, EPA 1989; 15, Marrs and Ballantyne 1987; 16, Dufour 1988; 17, Gee 1987; 18, Shaw 1986; 19, Tewe 1982; 20, Beyer 1990; 21, Allen 1990; 22, Clark and Hothem 1991.

In aquatic systems research is needed in several areas: (1) long-term effects of cyanide on life cycles, growth, survival, metabolism, and behavior of a variety of aquatic organisms and microorganisms in addition to fish (Towill et al. 1978; Leduc et al. 1982); (2) effects of seasonal pulses of cyanide on aquatic organisms in rural and wilderness areas (Leduc 1984); (3) influence of various environmental parameters (e.g., oxygen, pH, temperature), if any, on adaptive resistance to cyanide (Leduc 1981, 1984); and (4) usefulness of various biochemical indicators of cyanide poisoning, such as cytochrome oxidase inhibition (Gee 1987) and vitellogenin levels in fish plasma (*gairdneri*) (Ruby et al. 1986).

The use of M-44 sodium cyanide capsules for predator control was suspended and cancelled by the U.S. Environmental Protection Agency on 9 March 1972. M-44 use was again permitted by the U.S. Environmental Protection Agency beginning on 4 February 1976, provided that "each authorized or licensed applicator shall carry an antidote kit on his person when placing or inspecting M-44 devices. The kit shall contain at least 6 pearls of amylnitrite and instructions on their use. Each authorized or licensed applicator shall also carry on his person instructions for obtaining medical assistance in the event of accidental exposure to sodium cyanide" (EPA 1976a, 1976b).

Farmers need to be aware of factors that influence the cyanogenic potential of forage crops and to conduct regular inspections of grazing fields for cyanogenic plants. Moreover, hay and silage should be properly cured in order to minimize cyanide content before feeding to livestock (Egekeze and Oehme 1980). Selective breeding of plants with low cyanide content will help reduce livestock poisoning, but the most advisable prevention method at present is to prohibit grazing on fields where cyanogenic plants are present (Egekeze and Oehme 1980). More research seems needed on (1) effects of drought and other factors that may increase the concentration of cyanogenic glycosides in livestock forage plants, (2) mechanisms of cyanide liberation by plants, and (3) effects of cyanide on wildlife and range animals that graze on foliage with high cyanogenic glycoside content (Towill et al. 1978).

Research is needed on low-level, long-term cyanide intoxication in mammals by oral and inhalation routes in the vicinities of high cyanide concentrations, especially on the incidence of skin dermatitis, nasal lesions, and thyroid dysfunction, and on urinary thiocyanate concentrations. These types of studies may provide a more valid rationale in establishing standards and threshold limit values for HCN and inorganic cyanide (Towill et al. 1978; Egekeze and Oehme 1980).

Data are scarce on the carcinogenic, teratogenic, and mutagenic properties of cyanide, and on the distribution and transformation of cyanides in air, land, or water. Additional analysis of available information and more research in these areas is recommended. Finally, more research is needed on cyanide toxicokinetics because cyanide is a very reactive nucleophile that distributes widely through the body, is permeable to cell membranes, and may accumulate in the fetus (Towill et al. 1978).

Acknowledgments

I thank L. Garrett, N. Hestbeck, and W. Manning for literature search and retrieval services; M. Holmes and B. Roberts for secretarial assistance; D. R. Clark, Jr., C. J. Henny, J. B. Hunn, and G. C. Miller for technical review of the manuscript; and J. R. Zuboy for editorial services.

Abstract

Synthetic pyrethroids are the newest major class of broad-spectrum organic insecticides used in agricultural, domestic, and veterinary applications, and now account for more than 30% of global insecticide use. Fenvalerate [(RS) α-cyano-3-phenoxybenzyl (RS) 2-(4-chlorophenyl)-3-methylbutyrate] is one of the newer synthetic pyrethroid insecticides and the one most widely used. Technical fenvalerate is a mixture of four optical isomers, each occurring in equal amounts, but with different efficacies against insect pests. Insecticidal properties are largely associated with the 2S, αS isomer and, to a minor extent, with the 2S, αR isomer. Isomers with a 2R configuration have negligible biocidal properties; however, tumorlike growths in rodent liver are associated with the comparatively innocuous 2R, αS isomer. Pyrethroid insecticides are potent neurotoxicants that interfere with nerve membrane function by interaction with the sodium channel. Fenvalerate is among the most effective pyrethroid neurotoxicants tested, and the 2S, αS isomer is as much as 15 times more potent than other fenvalerate isomers.

Fenvalerate persists for < 10 weeks in the environment and does not accumulate readily in the biosphere. Time for 50% loss (Tb ½) in fenvalerate-exposed amphibians, birds, and mammals is 6-14 h; for reptiles, terrestrial insects, aquatic snails, and fish it is usually > 14 h-<2 days, and for crop plants it is 2-28 days. In nonbiological compartments, Tb ½ is as long as 6 days in fresh water, 34 days in seawater, 6 weeks in estuarine sediments, and 9 weeks in soils.

At recommended application rates to control pestiferous crop insects, fenvalerate and other synthetic pyrethroids are relatively harmless to birds, mammals, and terrestrial plants; however, certain nontarget species, including bees, crustaceans, and fish, are at considerable risk, especially at low temperatures. Target insect species are usually killed at fenvalerate concentrations of 0.015 µg/insect, 0.11 kg/ha by way of aerial application, 5.4 mg/kg in soil, or 50 mg/kg in diet. Fenvalerate is especially toxic to aquatic organisms (e.g., crustaceans died at 0.003-0.03 µg/L and fish and amphibians at 0.09-1.1 µg/L), and its use in or near aquatic environments now seems contraindicated. Birds and mammals are significantly more resistant than fish and invertebrates. Adverse effects on birds occur at acute oral doses >500 mg/kg body weight (BW), and 750 mg/kg ration; <50 mg fenvalerate per kilogram of feed produced no appreciable residues in eggs and meat of exposed birds. Among sensitive mammals, adverse effects on survival occur at acute oral doses of 50—450 mg/kg BW, dietary loadings of 50-1,000 mg/kg feed, and dermal applications of 1,800 mg/kg BW.

Criteria have not yet been formulated by regulatory agencies for protection of sensitive fish and wildlife resources against fenvalerate. Current guidelines for protection of poultry, livestock, and human health include <50 mg/kg in poultry diets, <5 mg/kg in livestock diets, <3 mg/kg in human diets, and <0. 125 mg/kg BW daily in humans.

Key words: Fenvalerate, insecticide, pyrethroid, crops, aquatic life, birds, wildlife, livestock, invertebrates, ecotoxicology, criteria.

Synthetic pyrethroids, including fenvalerate [(RS) α-cyano-3-phenoxybenzyl (RS) 2-(4-chlorophenyl)-3methylbutyrate]αS isomer (A. Stavola, U.S. Environmental Protectin Agency, personal communication, 28 January 1991.[1], are now broadly recognized as a major class of synthetic organic insecticides (Gray and Soderlund 1985). Introduced commercially less than 20 years ago, synthetic pyrethroids now account for more than 30% of insecticide use worldwide (Flannigan et al. 1985; Gilbert et al. 1989) in household, agricultural, and veterinary applications (Haya 1989; Williamson et al. 1989). More than 1,000 pyrethroids have been synthesized since 1973 (Flannigan et al. 1985); they include compounds containing nitrogen, sulphur, fluorine, chlorine, and bromine, in addition to carbon, hydrogen, and oxygen (Glickman and Casida 1982). The most potent synthetic pyrethroid insecticides are the cyanophenoxybenzyl pyrethroids (Casida and Lawrence 1985); fenvalerate is the most widely used compound in this group (Clark et al. 1985).

Pyrethroid insecticides are synthetic analogs of natural pyrethrins. Natural pyrethrins were widely used in Europe during the 19th century, when few effective insecticides were available (Elliott and Janes 1978). Natural pyrethrins, which contain six insecticidally active components extracted from the dried flower heads of the pyrethrum flower (*Chrysanthemum cinariaefolium*), have high insecticidal properties and low mammalian toxicity; however, they are expensive to produce and have low photostability and high biodegradability (Wouters and Bercken 1978; Gray and Soderlund 1985; Haya 1989; Williamson et al. 1989). Modern synthetic pyrethroids have been designed to provide enhanced residual activity through greater photostability and greater resistance to chemical and biological degradation, greater insecticidal activity, diminished mammalian toxicity, and greater cost effectiveness (Elliott and Janes 1978; Vijverberg and Bercken 1982; Gray and Soderlund 1985; Smith and Stratton 1986; Coats et al. 1989; Haya 1989). The first synthetic pyrethroids, allethrin and cyclethrin, were produced around 1950 but lacked adequate photostability and were not as effective insecticidally as the natural pyrethrins. Tetramethrin was introduced in 1964, but it had inferior insecticidal activity. The first synthetic pyrethroids with greater insecticidal activity than natural pyrethrins were resmethrin and cismethrin, produced in 1968. Photostable pyrethroids were produced in the mid 1970's and included deltamethrin, cypremethrin, fenpropathrion, and fenvalerate (Smith and Stratton 1986).

Pyrethroid insecticides are generally recognized as potent neurotoxicants that interfere with nerve membrane function by interaction with the sodium channel (Elliott and Janes 1978; Vijverberg et al. 1982; Gilbert et al. 1989; Haya 1989). Synthetic pyrethroids are more toxic against insect pests, up to 10 times more potent, in some instances, than other insecticides now in general use (Bradbury and Coats 1989a). However, the stereochemical structure of pyrethroid insecticides greatly influences their toxicity to insects and mammals, and this phenomenon is especially pronounced for fenvalerate (Bradbury et al. 1987b).

As broad-spectrum insecticides, the synthetic pyrethroids are necessarily toxic to a wide range of arthropods. Most insect orders are extremely susceptible, including many types of beneficial predator and parasite species (Bradbury and Coats 1989a). Synthetic pyrethroids are also toxic to fish and nontarget aquatic insects and crustaceans (Muir et al. 1985). Fenvalerate, for example, enters freshwater aquatic environments in runoff from food crop use, in drift from forest-spray procedures, and by direct spraying of water bodies (Haya 1989). Estuarine organisms may be exposed to fenvalerate and other pyrethroids after applications to corn (*Zea mays*), cotton (*Gossypium hirsutum*), rice (*Oryza sativa*), and vegetables in coastal areas or by discharges from pyrethroid manufacturers or formulating and distribution centers (Clark et al. 1989). Fenvalerate has been implicated in kills of coastal organisms in South Carolina, primarily from agricultural runoff into estuarine tidal creeks (Scott et al. 1987).

This report was prepared in response to information requests from environmental contaminant specialists of the U.S. Fish and Wildlife Service. It is part of a continuing series of brief reviews on hazards of chemicals to fish and wildlife resources. Detailed information on ecological and toxicological aspects of fenvalerate and other synthetic pyrethroid insecticides is provided in reviews by Elliott (1977), Elliott and Janes (1978), Wouters and Bercken (1978), Glickman and Casida (1982), Vijverberg and Bercken (1982), Gray and Soderlund (1985), Leahey (1985), Smith and Stratton (1986), Coats et al. (1989), and Bradbury and Coats (1989a).

[1]The technical fenvalerate formation is no longer being manufactured by the Dupont Company, although existing stocks may be used until exhausted. The new fenvalerate formulation will be sold as Asana or Esfenvalerate, and contains only the 2*S*, α*S* isomer (A. Stavola, U. S. Environmental Protection Agency, personal communication, 28 January 1991).

Environmental Chemistry

General

Synthetic pyrethroids now account for at least 30% of the world insecticide market and are rapidly replacing other agricultural chemicals for control of insect pests. Fenvalerate is one of the more recently developed and widely used synthetic pyrethroid insecticides. It is derived from a combination of α-cyano-3-phenoxybenzyl alcohol and α-isopropyl phenylacetate ester. Technical fenvalerate is a mixture of four optical isomers, each occurring in equal amounts but with different efficacies against insect pests. Fenvalerate does not usually persist in the environment for > 10 weeks, and it does not accumulate readily in the biosphere. Time for 50% loss (Tb ½) in fenvalerate-exposed amphibians, birds, and mammals was 6-14 h; for reptiles, terrestrial insects, aquatic snails, and fish it was > 14 h-<2 days; and for various species of crop plants it was 2-28 days. Fenvalerate degradation in water is due primarily to photoactivity and, in soils, to microbial activity. Half-time persistence in nonbiological materials is variable but may last as long as 6 days in fresh water, 34 days in seawater, 6 weeks in estuarine sediments, and 9 weeks in soils.

Chemical Properties

Synthetic pyrethroid insecticides are photostable analogs of the natural pyrethrins of botanical origin; they consist of a series of related esters derived from alcohols and acids that maintain critical isosteric relations with the natural product prototype (Glickman and Casida 1982; Bradbury and Coats 1989a). Small changes in substituents and stereochemistry are sufficient to produce compounds differing in their insecticidal potency, spectrum of activity, and mammalian toxicology (Gray and Soderlund 1985). Halogenated, lipophilic, photostable compounds are exceptionally active against many species of insects; although these compounds are relatively safe to birds and mammals, they are usually extremely toxic to certain freshwater and marine groups, including fish (Leahey 1985; Coats et al. 1989).

The first significant success in creating a photostabilized pyrethroid with high insecticidal activity was achieved through use of the 3-phenoxybenzyl alcohol moiety. A further step was the finding that 2-aryl-3methylbutyric acid esters of pyrethroid alcohols were both photostable and insecticidal (Gray and Soderlund 1985).

Fenvalerate is one of the more recently developed and widely used synthetic pyrethroid insecticides, and it is a highly active phenyl acetate ester of known pyrethroid alcohols—specifically, a combination of isopropyl phenyl acetate ester and α-cyano-3-phenoxybenzyl alcohol (Wouters and Bercken 1978). The phenoxybenzyl group and the halogenated phenyl ring increase the photostability of the molecule. The cyano group, substituted on the benzylic carbon, stabilizes the ester bond against hydrolysis (Coats et al. 1989).

Fenvalerate, like most other synthetic pyrethroids, is a halogenated, lipophilic, stable compound with low solubility in water and high solubility in organic solvents (Table 1). Technical fenvalerate is a racemic mixture of four isomers, composed of equal amounts of dextrorotary and levorotary forms; however, the four optical isomers (Figure) have very different efficacies against pest species. In general, fenvalerate stereoisomers with S configurations in both the acid and alcohol moieties are more active pharmacologically and toxicologically than those with R configurations (Wouters and Bercken 1978).

Uses

Pyrethroids are used primarily for the control of household and agricultural insect pests and secondarily in industrial, stored product, and veterinary applications. They are especially advantageous for use in northern climates because their toxicity is enhanced at low temperatures (Smith and Stratton 1986). Synthetic pyrethroid insecticides, including fenvalerate, are used as alternatives to organochlorine, organophosphorus, carbamate, and natural pyrethrum insecticides because they are highly toxic to insect pests, low to intermediate in persistence, and low in toxicity to warm-blooded organisms, although extremely toxic to many aquatic organisms (Hansen et al. 1983; Coats et al. 1989). By 1982, more than 30% of the world market for insecticides consisted of synthetic pyrethroids, and this percentage is increasing (Smith and Stratton 1986).

Outside of the United States, fenvalerate is used on cotton in Australia, Greece, and South Africa and on apples (*Malus* sp.), pears (*Pyrus* sp.), and potatoes (*Solanum* sp., *Ipomoea* sp.) in Canada (Reed 1981); uses in other countries, including Mexico, are anticipated (Reed 1981), as is increased use against agricultural, poultry, dairy, and household pests (Mumtaz and Menzer 1986). In agricultural use, recommended application rates of

fenvalerate range between 0.055 and 0.224 kg/ha for control of a broad spectrum of pestiferous insects (Bennett et al. 1983).

Domestically, about 6,500 kg of fenvalerate was used in 1979; all of this amount was imported (Reed 1981). In 1980, in addition to registered use, the U.S. Environmental Protection Agency allowed an additional 80,000 kg for crisis and experimental use (Reed 1981). By 1981, fenvalerate had been registered for domestic use on apples, cotton, peanuts (*Arachis* sp.), pears, and potatoes. Additional uses were allowed under various experimental or crisis exemptions on beans (*Phaseolus* spp.); black and white pepper (*Piper* spp.); broccoli, cabbage, and cauliflower (*Brassica* spp.); celery (*Apium* sp.); corn; cucumbers (*Cucumis* sp.); eggplant (*Solanum melongena*); grapes (*Vitis* spp.); lettuce (*Lactuca* sp.); peas (*Pisum* sp.); squash (*Cucurbita* spp.); and tomatoes (*Lycopersicon esculentum*; Reed 1981). By 1989, this list was expanded to include tobacco (*Nicotiana tabacum*); soybeans (*Glycine max*); sugarcane (*Saccharum officinarum*); a wide variety of nuts, fruits, and vegetables; pine seed orchards, forest tree nurseries, mosquitos, biting insects, insect vectors of disease, mite control in poultry, and fly and tick control in cattle (Spehar et al. 1982; Akhtar 1983; Bennett et al. 1983; Hansen et al. 1983; Sine 1988; Clark et al. 1989; Smith et al. 1989).

Table 1. Chemical and other properties of fenvalerate.[a]

Variable	Datum
Chemical name	(RS)-α-cyano-3-phenoxybenzyl (RS)-2-(4-chlorophenyl)-3-methylbutyrate; cyano (3-phenoxyphenyl) methyl 4-chloro-α-(1-methylethyl) benzeneacetate; α-cyano-3-phenoxybenzyl 2-(4-chlorophenyl)-3-methylbutyrate; 4-chloro-α-(l-methyl ethyl) benzeneacetic acid cyano(3-phenoxyphenyl) methyl ester; α-cyano-3-phenoxybenzyl α-(4-chlorophenyl) isovalerate
Alternate names	Agmatrin, Belmark, Ectrin, Fenkill, Phenvalerate, Pydrin, S-5602, Sanmarton, SD 43775, Sumicidin, Sumifly, Sumipower, Sumitox, WL 43775
CAS number	51630-58-1
Chemical formula	$C_{25}H_{22}ClNO_3$
Molecular weight	419.92
Physical state	Clear yellow, viscous, liquid at 23° C
Purity	Technical grade compound is 92% pure; nature and extent of impurities unknown
Vapor pressure at 25° C	1.1×10^{-8} mm mercury
Density at 23° C	1.17 g/mL
Stability	Stable in most solvents except alcohols at ambient temperature. Unstable in alkaline media. No significant breakdown after 100 h at 75° C; gradual degradation occurred in range 150-300° C
Degradation	Cleavage of the ester linkage is the primary route
Formulations	Emulsifiable concentrate, dust, granules, wettable powder
Log octanol-water partition coefficient	6.2
Solubility at 20° C	
Acetone	>450 g/L
Chloroform	>450 g/L
Methanol	>450 g/L
Hexane	77 g/L
Water	2-85 µg/L
Seawater	24 µg/L

[a] References: Elliott 1977; Coats and O' Donnell-Jefferey 1979; Reed 1981; Tagatz and Ivey 1981; Akhtar 1983; Schimmel et al. 1983; Windholz et al. 1983; Clark et al. 1987, 1989; Crofton and Reiter 1988; Sine 1988.

The delivery vehicle of fenvalerate-containing insecticide may account for wide variations in toxic action. For example, fenvalerate microcapsules used to control caterpillar pests (*Plutella xylostella*, *Spodoptera litura*) were most effective with thin-walled capsules and small particles; however, significant protection to nontarget organisms, such as fish, occurred with thicker-walled capsules and larger particles (Ohtsubo et al. 1989). The popularity of commercial synthetic pyrethroids and their widespread replacement of older, more toxic compounds in various settings mandates a thorough understanding of the formulation used and of the active and inert components (Williamson et al. 1989).

Persistence

In nonbiological samples, half-time persistence of fenvalerate was variable but frequently ranged between 2 and 6 days in fresh water, 27 and 34 days in seawater, 3 and 9 weeks in soils, and up to 6 weeks in estuarine sediments (Table 2). Persistence was longer at higher initial application rates and under conditions of reduced light, low microbial activity, and high organic content (Table 2). Fenvalerate is not readily transported from upland field application sites into the aquatic environment. Fenvalerate that directly enters the aquatic environment by way of runoff has limited bioavailability to aquatic organisms owing to rapid adsorption onto soil particles, organic matter, or plants and to chemical hydrolysis and photodecomposition (Ohkawa et al. 1980). Under acidic conditions, fenvalerate in water is stable to hydrolysis for 100 h at 75° C; Tb ½ at elevated recommended application rates is about 21 days, primarily as a result of photodegradation (Reed 1981).

Fenvalerate is one of the more persistent synthetic pyrethroids in soils (Klaassen et al. 1986). In agricultural soils, fenvalerate is tightly adsorbed to soil particles, does not easily move laterally or to lower soil layers with groundwater, and almost always localizes in the application site because of its extremely low solubility in water (Ohkawa et al. 1980; Hill 1981; Miyamoto 1988). Fenvalerate degradation rates from mineral soil surfaces are dependent on soil type, moisture, temperature, and microbial activity. Half-time persistence in soils usually ranged between 2 and 18 days, but 3 months has also been recorded (Harris et al. 1981; Reed 1981; Bennett et al. 1986). Although fenvalerate is susceptible to chemical degradation by hydrolysis and oxidation, most authorities agree that degradation in soils is due primarily to microbial activity, that microbial degradation is most rapid under aerobic conditions, and that transformed products do not persist longer than the parent compound (Ohkawa et al. 1980; Chapman et al. 1981; Bennett et al. 1986).

In biological samples, fenvalerate neither persists for lengthy periods nor is readily accumulated (Smith and Stratton 1986). In general, fenvalerate is rapidly (i.e., Tb ½ of 6-14 h) excreted by amphibians, birds, and mammals; has low persistence in various reptiles, terrestrial insects, aquatic snails, and fish; and has moderate (i.e., Tb ½ of 2-28 days) persistence in various species of target plants (Table 3; Reed 1981; Mumtaz and Menzer 1986; Bradbury and Coats 1989a, 1989b). Animals collected after 5 days from a cotton field sprayed with 0.112 kg/ha, or from the immediate vicinity, had very low fenvalerate residues (Table 3; Bennett et al. 1983). In that study fenvalerate was detected in one of nine bird species sampled, in one of four mammals, in the western ribbon snake (*Thamnophis proximos*), in one of four amphibian species, and in fish and insects. The bird was a male dickcissel (*Spiza americana*) that had established a breeding territory within the sprayed cotton field. Carnivorous ground beetles, found moribund on the ground, contained the highest mean fenvalerate residue of 0.55 mg/kg fresh weight (FW) whole body; large numbers of dead insects were found in the fields during collection. The highest residues (0.32-0.55 mg/kg) in fish and invertebrates were in those collected from a small pool in a drainage ditch, which compares with 0.92 mg/kg found in common carp (*Cyprinus carpio*) after exposure in the laboratory for 7 days to 0.8 µg fenvalerate per liter (Bennett et al.1983).

Fenvalerate is not significantly absorbed or translocated in plants. Cotton, apples, and lettuce treated with fenvalerate contained surface residues of parent fenvalerate 8 weeks after treatment (Reed 1981). In addition to the parent compound, which accounted for 80% of all residues, identified metabolites included 3-phenoxybenzaldehyde, 3-phenoxybenzyl methylbutyric acid, and conjugates of these compounds. Half-time persistence of fenvalerate on plant surfaces is between 2 and 4 weeks, and degradation is primarily a result of weathering (Reed 1981).

Various plants sprayed with 0.25 kg fenvalerate per hectare had measurable residues 7 days after application and nondetectable residues 15-30 days after treatment (Jain et al. 1979). Washing plants in cold water to remove the pesticide was effective only on the initial day of application, removing 30-50%. Afterwards, only 3-13% could be removed by washing. Cooking removed 71-88% of the fenvalerate residues on the initial

day of treatment, but in later samplings, removal was 68-70% in spinach (*Spinacea oleracea*) and tomatoes and 38-40% in okra (*Abelmoschus esculentus*) and cauliflower (*Brassica oleracea botrytis*; Jain et al. 1979).

Adsorption and persistence in plants can be modified by other chemicals or by selected carriers, although mechanisms to account for these phenomena are unclear. The application mixture influences adsorption and persistence of fenvalerate. For example, interception and persistence in sugarcane were increased when fenvalerate was applied in a 25% water to 75% soybean oil mixture versus water or soybean oil alone (Smith et al. 1989). Also, biocidal properties of fenvalerate residues on cotton foliage were increased up to 100% due to enhanced persistence of fenvalerate in the presence of toxaphene (Brown et al. 1982).

Table 2. Fenvalerate persistence in water, sediments, and soils.

Sample and other variables	Persistence	Reference[a]
Fresh water		
Various concentrations	Half-time persistence (Tb ½) of 3.2 days (range 1.9-5.8 days); longer for higher initial doses	1
0.1 µg/L	Tb ½ of 4.1 days; 90% loss in 13.5 days	11
3.9 µg/L	Maximum concentration was 2.3 µg/L 48 h after application; at 168 h it was 0.6 µg/L	1
8.3 µg/L	Concentration declined from 5.3 µg/L at 24 h to 1.8 µg/L at 168 h	1
16.5 µg/L	Concentration declined from 17.6 µg/L at 24 h to 9.1 µg/L at 168 h	1
30.6 µg/L	Concentration declined from 54.4 µg/L at 24 h to 21.2 µg/L at 168 h	1
Seawater	Tb ½ of 8 days in light, >14 days in dark; 27-34 days under alternating light and dark	2,3
Estuarine sediments		
Sterilized	No degradation in 28 days	2
"Low" concentrations	Tb ½ of 4.5-9 days	1,3
"Various" concentrations	Tb ½ of 24-42 days	2,4,5,6
0.1-10 mg/kg dry weight (DW)	73% loss in 8 weeks at initial nominal concentration of 0.1 mg/kg DW, 78% at 1.0 mg/kg, and 96% loss in 8 weeks at 10 mg/kg DW	4
Soils		
Initial concentration of 1.0 mg/kg DW soil		
Natural mineral, pH 8.0-8.1	12% remaining after 8 weeks, about 5% after 16 weeks	7
Sterilized mineral, pH 7.7-8.1	91% remaining after 8 weeks, 87% after 16 weeks	7
Natural organic, pH 7.1-7.2	58% remaining at 8 weeks, about 32% after 16 weeks	7
Sterilized organic, pH 6.5-6.9	100% remaining after 16 weeks	7
Various (clay, silt, sand), dose unknown	Tb ½ of 22-40 h	8
Mineral soils, dose unknown	Tb ½ of 6 weeks	9
Moist sand, dose unknown	Tb ½ of 9 weeks, 88% loss in 48 weeks	9
Lethbridge surface soil, agricultural, British Columbia		

Field conditions, initial application of 150 g/ha	Tb ½ of 6 weeks, 89% loss in 45 weeks	10
Laboratory study, 70 g/ha equivalent	Tb ½ of 5.2 weeks	10

Table 3. Fenvalerate persistence in plants and animals under field conditions.

Sample and othervariables	Persistence	Reference[a]
Alfalfa, *Medicago sativa*	Half-time persistence (Tb ½) of 9 11 days	1
Cotton *(Gossypium hirsutum)* treated with 0.224 kg/ha, residues on foliage 12 days later		
In combination with 2.24 kg/ha toxaphene	Fenvalerate residues were 11.6 mg/kg	2
Fenvalerate alone	Residues were 5.9 mg/kg	2
Cotton, foliage	Tb ½ of 2 days, 96% lost in 17 days	3,7
Cotton field sprayed with 0.112 kg/ha (0.1 pound per acre), Garland, Arkansas, July 1979. Animals collected from field 5 days later		
Mammals		
Deer mouse, *Peromyscus maniculatus*; white-footed mouse, *P. leucopus;* cotton rat, *Sigmodon hispidus*	<0.01 mg/kg whole body fresh weight (FW), less skin and GI tract	3
House mouse, *Mus musculus*	0.01 mg/kg whole body FW, less skin and GI tract	3
Birds		
Cardinal, *Richmondena cardinalis*; red-winged blackbird, *Agelaius phoeniceus*; eastern meadowlark, *Sturnella magna*; brown-headed cowbird, *Molothrus ater*; purple martin, *Progne subis subis*; horned lark, *Eremophila alpestris*; little blue heron, *Florida coerulea*; green-backed heron, *Butorides virescens virescens*	<0.01 mg/kg whole body FW, less skin and GI tract	3
Dickcissel, *Spiza americana*	0.02 mg/kg whole body FW, less skin and GI tract	3
Reptiles		
Western ribbon snake, *Thamnophis proximus*	0.12 mg/kg whole body FW, less skin and GI tract	3
Animals collected from location near cotton field 5 days later		

Insects		
Cicada, Cicadidae	<0.01 mg/kg FW whole body	3
Short-horned Acrididae	0.18-0.24 mg/kg FW whole body	3
Ground beetle, *Calosoma* sp.	0.55 mg/kg FW whole body	3
Molluscs		
Aquatic snail, unidentified	0.53 mg/kg FW soft parts	3
Fish		
Mosquitofish, *Gambusia affinis*	0.3 mg/kg FW whole body	3
Golden shiner, *Notemigonus crysoleucas*	0.47 mg/kg FW whole body	3
Amphibians		
Southern leopard frog, *Rana utricularia*; green frog, *Rana clamitans*; green treefrog, *Hyla cinerea*	<0.01 mg/kg FW whole body, less skin and GI tract	3
Fowler's toad *Bufo fowleri*	0.02 mg/kg FW whole body, less skin and GI tract	3
Old field site, Iowa, O. 112 kg/ha (0.1 pound per acre) applied on 9 June 1980, and again on 5 August 1980, 10 June 1981, and 21 July 1981		
Vegetation	Maximum immediately after each application was 12.1 mg/kg FW; residues after 24 days were always <1 mg/kg FW	1
Short-horned grasshopper, whole		
Applied 9 June 1980	Residues were 0.03 mg/kg FW after 36 days, and nondetectable (ND) in 49 days	1
Applied 5 August 1980	Residues were 0.33 mg/kg FW after 7 days, 0.19 after 14 days, and 0.12 after 21 days	1
Ground beetles, Carabidae, whole		
Applied June 1980	After 10 days, beetles contained 0.12 mg/kg FW; after 17 days residues were ND	1
Applied 5 August 1980	After 6 days, residues were O. 14 mg/kg FW and ND in 17 days	I
Applied 21 July 1981	Maximum residue after 24 days was 0.15 mg/kg FW	1
Deer mice, *Peromyscus maniculatus*, whole		
Applied 21 July 1988	Residues were 0.1 mg/kg FW after 2 days, and 0.01 after 21 days	1
Meadow vole, *Microtus pennsylvanicus*, whole		
Applied 21 July 1988	Residues were variable: 0.07 mg/kg FW after 2 days, O. 12 after 4 days, 0.46 after 8 days, and 0.04 after 21 days	1
Plants, 4 species, sprayed with 0.05% emulsifiable concentrate equivalent to 0.25 kg/ha		
Okra, *Abelmoschus esculentus*, initial	After 5 days residue was 1.6 mg/kg FW, after 7 days it was 0.8, and after 15 days it was ND	4

concentration of 4 mg/kg FW		
Cauliflower, *Brassica oleracea botrytis*, initial deposit of 0.86 mg/kg FW	Initial deposit degraded to 0.3 mg/kg in 7 days and was ND in 15 days	4
Tomato, *Lycopersicon esculentum*, initial residue of 0.85 mg/kg FW	Initial residue degraded to 0.67 mg/kg in 5 days, 0.3 in 15 days, and was ND in 30 days	4
Spinach, *Spinacea oleracea*, initial residue of 9.5 mg/kg FW	Initial residue degraded to 2.8 mg/kg in 15 days and was ND in 30 days	4
Plants, various, foliage	Mean Tb ½ of 8.2 days, range 2.8-14 days	6
Bean, *Phaseolus* sp.	Tb ½ of 14 days, essentially no translocation from leaf surface	1
Sugarcane, *Saccharum officinarum*, initial residue immediately after application was 18.8-28.2 mg/kg dry weight leaf	Residues after 7 days were 2.1-5.4 mg/kg DW; Tb ½ of 2.2-2.4 days	5

[a] 1. Bennett et al. 1986; 2. Brown et al. 1982; 3. Bennett et al. 1983; 4. Jain et al. 1979; 5. Smith et al. 1989; 6. Willis and McDowell 1987; 7. Buck et al. 1980.

Fenvalerate photoproducts merit consideration, as some may be comparatively toxic. Decarboxyfenvalerate is a major degradation product of fenvalerate that is formed by photochemical reactions in water and on plant foliage (Mikami et al. 1985). This photoproduct composes up to 10% of the total residues in forage crops that have been exposed to prolonged sunlight and drying. Decarboxyfenvalerate did not persist in tissues of hens, rats, and cows when consumed with feed for extended periods; its residue levels in ova, milk, and meat were negligible (Mikami et al. 1985).

Photolysis of fenvalerate in various solvents by sunlight yields products resulting from ester cleavage, primarily decarboxyfenvalerate, but also 15 other products. All sunlight photoproducts were relatively harmless to mice; LD50 values were >500 mg/kg body weight (BW; Holmstead et al. 1978). When photolysis was by way of ultraviolet light, however, two of the photoproducts formed (3-phenoxybenzoyl cyanide, 3-phenoxybenzyl cyanide) were considerably more toxic than fenvalerate; LD50 values for intraperitoneal injection in mice were >500 mg/kg BW for fenvalerate, 2 mg/kg BW for 3-phenoxybenzoyl cyanide, and 105 mg/kg BW for 3-phenoxybenzyl cyanide (Holmstead et al. 1978). This finding strongly suggests a need for additional research on fenvalerate photoproduct persistence and toxicity.

Mode of Action

General

Two types of synthetic pyrethroids have been identified, as judged by different behavioral, neurophysiological, chemical, and biochemical profiles: Type I, those pyrethroids lacking the α-cyano group, and Type II, those possessing the α-cyano group (i.e., fenvalerate). Induction of repetitive activity in the nervous system is the principal effect of pyrethroids. Repetitive activity originates from a prolongation of the transient increase in sodium permeability of the nerve membrane associated with excitation. All pyrethroids affect sodium channel gating in a similar manner, although Type II pyrethroids are significantly more neurotoxic than Type I pyrethroids.

Metabolism of fenvalerate proceeds by way of oxidation and hydrolysis to produce metabolites considered pharmacologically inactive or inferior to the parent compound. Insects and fish are extremely susceptible to fenvalerate when compared to mammals and birds; interspecies differences are associated with rates of metabolism, excretion, absorption, esterase activity, and neurosensitivity.

Fenvalerate is neither mutagenic nor teratogenic. Tumorlike growths in rodent tissues, however, were associated with the 2R, αS isomer (heretofore believed innocuous)--specifically, with its cholesterol conjugate.

Types of Pyrethroids

Two distinct types of synthetic pyrethroids have been identified, as judged by different behavioral, neurophysiological, chemical, and biochemical profiles in rodents: Type I, also known as Class 1 or T for tremor; and Type II, also known as Class 2 or CS for choreoathetosis-salivation (Wouters and Bercken 1978; Verschoyle and Aldridge 1980; Glickman and Casida 1982; Gray 1985; Gray and Soderlund 1985; Klaassen et al. 1986; Crofton and Reiter 1988; Bradbury and Coats 1989a; Gilbert et al. 1989; Williamson et al. 1989). In general, these authorities agree that pyrethroids containing both a halogenated acid esterified with the α-cyano-3-phenoxybenzyl alcohol--such as fenvalerate, deltamethrin, and cypermethrin--produce the Type II poisoning syndrome and that pyrethroids lacking either or both of these moieties (i.e., permethrin, resmethrin, cismethrin, allethrin, bromphenothrin, phenothrin, kadethrin, tetramethrin) tend to produce the Type I syndrome. Type I is characterized by sparring, aggressive behavior (in rats, but not mice), rapid onset of tremor in the extremities, increased body temperatures, and whole-body tremors. As toxicity progresses, mice show hyperactivity, whereas rats become prostrate and die with immediate onset of rigor mortis; in mice, death is often associated with spasmodic seizures. The Type I syndrome is very similar to that produced by p,p'-DDT. Type II is characterized by pawing and burrowing behavior, profuse salivation, a decrease in body temperature of rats (due partially to evaporation of saliva), tremors progressing to choreoathetosis (i.e., a sinuous, writhing movement), muscular contractions and seizures, and death. With repeated high doses sufficient to kill some rats, degenerative changes in sciatic and posterial tibial nerves were observed. The same two types of pyrethroid actions are also evident among insects.

Regardless of route of administration, signs of fenvalerate poisoning in rodents were similar. Doses administered by intercerebroventricular injection of comparatively low concentrations were more toxic than higher doses given orally or by intravenous or intraperitoneal injection, suggesting greater central nervous system involvement in Type II than in Type I poisoning. In fact, pyrethroids that produce the Type II syndrome--including fenvalerate--are 5 to 10 times more potent neurotoxicants than Type I pyrethroids, which suggests different sites of action in the central nervous system.

Sodium Gating Kinetics

Pyrethroids have an action at or near the sodium channel in the nerve, resulting in greatly altered ionic currents and disrupted nerve function through membrane depolarization. Based on studies with insects, crustaceans, frogs, and small mammals, there is general agreement that the sodium channel in the nerve membrane is the major target site for all synthetic pyrethroid insecticides (and many other neurotoxicants); that synthetic pyrethroids prolong the transient increase in sodium permeability of the nerve membrane during excitation, resulting in spontaneous depolarization and repetitive discharges; that persistent repetitive discharges lead to muscular fasciculations, acetylcholine depletion, and muscular weakness; that effects are enhanced at lower temperatures; and that α-cyano (Type II) pyrethroids are more potent neurotoxicants than noncyano (Type I) pyrethroids, differences in neurotoxic effects being attributed solely to the α-cyano substituent (Wouters and Bercken 1978; Gammon et al. 1981; Vijverberg and Bercken 1982; Vijverberg et al. 1982; Parker et al. 1984b; Flannigan et al. 1985; Gray and Soderlund 1985; Ruigt and Bercken 1986; Eells and Dubocovich 1988; Flodstrom et al. 1988; Clark and Brooks 1989; Gilbert et al. 1989; Holloway et al. 1989; Salgado et al. 1989). Most of these authorities agree that fenvalerate was the most effective pyrethroid tested for inducing pronounced repetitive activity in nerve fibers and that the 2S, αS isomer was up to 15 times more potent than other fenvalerate isomers. Pyrethroids induce the sodium channels to close more slowly than normal, resulting in a gradually decaying inward sodium current (called a tail current) after termination of membrane depolarization. Type I pyrethroids induce tail currents with time constants of decay in milliseconds, but Type II pyrethroids result in time constants of decay that are orders of magnitude longer and contain thousands of impulses, inducing a quickly reversible, frequency-dependent suppression of the action potential. Depolarization of axons by synthetic pyrethroids was most effective at low temperatures; the negative temperature dependence of the steady state current seems to be due to the stabilizing effect of low temperature on the open-modified channel.

Myelinated nerves of vertebrates are thought to sequester the pyrethroid molecules, known to be soluble in the myelin sheath, thereby preventing a portion of their chemical effect on the nerve axon (Flannigan et al. 1985). Fenvalerate, unlike other α-cyano pyrethroids, had little effect on the electrophysiological function of single myelinated nerve fibers in the frog (*Rana esculenta*), suggesting that additional research is needed on mechanisms other than membrane sodium transport (Tippe 1987).

The role of calcium in pyrethroid interaction with nerve tissue is under active investigation. Fenvalerate affects calcium-ATPase enzyme and calmodulin-activated enzyme activities, such as phosphodiesterase (Flodstrom et al. 1988). Fenvalerate inhibits calcium uptake by nerve cord of crayfish (*Procambarus clarki*) and axon of spiny lobster (*Panulirus japonicus*), an action that seems to be related to its lipophilic properties (Doherty et al. 1986). Fenvalerate enhances the calcium-dependent potassium-stimulated release of norepinephrine from rat brain and could lead to an overall depletion of brain stores of this neurotransmitter, producing a convulsive state typical of Type II pyrethroid poisoning (Brooks and Clark 1987; Clark and Brooks 1989). Fenvalerate evoked a calcium-dependent release of dopamine and acetylcholine from rabbit (*Oryctolagus* sp.) brain that was concentration related and specific for the 2S, αS isomer; release of dopamine and acetylcholine was antagonized completely by tetrodotoxin, a sodium channel blocker (Eells and Dubocovich 1988). The relatively low potency of fenvalerate and other Type II pyrethroids on potassiumstimulated calcium uptake in rat brain and other responses suggests that neither the sodium-calcium exchanger nor the voltage-dependent calcium channels are primary targets for pyrethroid toxicity (Ramadan et al. 1988).

Toxic isomers of Type II pyrethroids usually antagonize -aminobutyric acid (GABA) by interacting with the t-butyl bicyclophosphorothionate-picrotoxin binding site in brain; antagonism of GABA leads to a reduction in inhibition (Casida and Lawrence 1985). Fenvalerate seems to increase inhibition, however, and this may be explained by a differential effect on sodium channel kinetics (Gilbert et al. 1989). Fenvalerate also inhibits perhydrohistrionicotonin binding with electric organ membrane of the electric ray (*Torpedo* sp.; Abbassy et al. 1983) and interacts with binding sites for dihydropicrotoxinin and kainic acid in the brain (Gammon et al. 1982), but the significance of these observations is unclear.

Metabolism

The most important metabolic degradation pathways for synthetic pyrethroids are oxidation on the phenoxy ring, hydrolysis of the ester linkage, and conjugation of metabolites; rates and pathways differ among taxonomic animal groupings resulting in large differences in sensitivity (Holmstead et al. 1978; Kaneko et al. 1981; Akhtar 1983; Miyamoto 1988; Bradbury and Coats 1989a).

All metabolic degradation products of fenvalerate are pharmacologically inactive or inferior to the parent compound, implying that metabolic modifications lead to detoxication (Miyamoto 1988). Fenvalerate and other α-cyano pyrethroids, however, are consistently more resistant to oxidative attack than their noncyano analogs (Gray and Soderlund 1985). Liver is the predominant site of fenvalerate metabolism through hydrolysis by one or more hepatic microsomal esterases; inhibition of these enzymes results in enhanced toxicity (Ghiasuddin and Soderlund 1984). Hydrolysis has also been demonstrated in plasma, kidney, stomach, and brain tissues. Except for brain, however, these tissues were relatively unimportant in the detoxification process (Ghiasuddin and Soderlund 1984; Gray and Soderlund 1985).

Metabolism of the 2S isomers proceeds sequentially: hydroxylation at the phenoxy group, hydrolysis of the cyano group, and cleavage of the ester linkage (Coats et al. 1989). Fenvalerate and the 2S isomers yield two ester metabolites in feces from hydroxylation at the 4' and 2' phenoxy positions. Other significant metabolites were 3-phenoxybenzoic acid and its hydroxy derivatives from the alcohol moiety, 3-(4-chlorophenyl) isovaleric acid and its hydroxy derivatives from the acid moiety, and thiocyanate and carbon dioxide from the cyano moiety (Ohkawa et al. 1979). A slow elimination rate characterizes fenvalerate and other α-cyano pyrethroids when compared with noncyano pyrethroids; it seems to be due to the release of the cyano group during ester cleavage, which is then incorporated into the body thiocyanate pool and retained in the skin and stomach (Gray and Soderlund 1985). Decarboxyfenvalerate, a photolysis product of fenvalerate, is present in water and on plant surfaces, but it is extensively hydroxylated in mammals and excreted rapidly and completely into feces with no apparent toxic effects (Miyamoto 1988).

Signs of fenvalerate intoxication are similar in birds, fish, mammals, and insects, but insects and fish are extremely sensitive when compared with warm-blooded organisms, frequently by one to three orders of magnitude (Bradbury and Coats 1989a, 1989b). Increased resistance to fenvalerate and other synthetic pyrethroid insecticides in mammals and birds, when compared with aquatic organisms and terrestrial insects, is attributed to their higher metabolism, more rapid excretion, lower absorption from diet or the surrounding envirosphere, higher esterase activity, higher fat content, and lower neurosensitivity (Wouters and Bercken 1978; Ohkawa et al. 1979; Glickman and Casida 1982; Flannigan et al. 1985; Gray and Soderlund 1985; Klaassen et al. 1986; Bradbury and Coats 1989a, 1989b; Coats et al. 1989). For example, rainbow trout

(*Oncorhynchus mykiss*)—one of the more sensitive aquatic species—have significantly lower rates of metabolism and elimination of fenvalerate than those reported for birds and mammals (Bradbury et al. 1986; Bradbury and Coats 1989a, 1989b); show little or no esterase activity towards pyrethroids and substantially lower oxidative activity than warm-blooded animals (Bradbury and Coats 1989a, 1989b); efficiently accumulate fenvalerate from the medium (Gray and Soderlund 1985); and show greater intrinsic sensitivity of the central nervous system when compared with birds and mammals (Gray and Soderlund 1985; Bradbury and Coats 1989a).

Fenvalerate effects are antagonized or synergized by various compounds or chemicals. Dermal exposure to fenvalerate in mammals may produce a skin sensory response, most frequently on the face, characterized by itching and tingling. Administration of vitamin E up to 29 h before fenvalerate exposure partially reduced the fenvalerate-mediated skin sensation in guinea pigs (*Cavia* sp.; Malley et al. 1985). The effectiveness of vitamin E may be associated with its membrane stabilizing property, although the exact mode of action is unknown. Fenvalerate skin sensations were also reduced by piperonyl butoxide when applied directly to the skin or in conjunction with fenvalerate (Malley et al. 1985). Delayed toxic effects in rodents and insects were produced with various muscle relaxants, including propranolol and diazepam, perhaps through depolarization of nerve terminals (Gammon et al. 1982; Gray 1985; Gray and Soderlund 1985). Mice given profenofos, an esterase inhibitor, were up to 27 times more susceptible than were nontreated animals (Glickman and Casida 1982).

Mutagenicity, Teratogenicity, Carcinogenicity

Fenvalerate and other synthetic pyrethroids caused no oncogenic, reproductive, mutagenic, or teratogenic effects, as judged by results of 2-year feeding studies with rodents at 250-300 mg/kg diet, three-generation rodent reproduction studies at 250 mg/kg diet, various mutagenicity assays, bone marrow cytogenicity up to 150 mg/kg BW, the dominant lethal bioassay at 100 mg/kg, and a host-mediated bioassay in mice at 50 mg/kg BW (Reed 1981; Pluijmen et al. 1984; Flannigan et al. 1985; Gray and Soderlund 1985). Some chromosomal aberrations and alterations in the mitotic index were noted, however, in bone marrow and testis cells of rats given fenvalerate at 100 mg/kg BW orally, a dose that killed 71% of the rats (Gray and Soderlund 1985). A similar pattern was noted in mice (Flodstrom et al. 1988; Pati and Bhunya 1989), indicating that additional research is needed to establish mutagenicity of fenvalerate.

The carcinogenic potential of fenvalerate is based on negative or inconclusive evidence and centers on its ability to produce microgranulomas in various tissues, especially liver, in dogs (*Canis familiaris*) and rodents. Beagles exposed to fenvalerate at 250, 500, or 1,000 mg/kg diet for 6 months showed treatment-related microscopic effects, including histiocytic cell infiltrates in mesenteric lymph nodes and multifocal microgranulomas in liver (Parker et al. 1984b). Female rats fed a diet containing fenvalerate at 1,000 mg/kg ration for 2 years showed a statistically significant increase in the incidence of mammary tumors; however, this was judged by the authors (Parker et al. 1984a) to be of unlikely biological significance. Their unusual conclusion was based on four points: (1) none of the mammary tumor incidences exceeded those expected or reported on aged female rats of this strain, (2) time and appearance of tumors in control and treated groups were unchanged by treatment, (3) the benign-malignant ratio of mammary tumors was the same in control and treated groups, and (4) the tumors were common in this strain of rat and did not seem to be related to treatment.

Fenvalerate inhibits intercellular communication between fibroblast cells and enhances the development of hepatocyte loci in rat liver at nonheptatotoxic dose levels. Chemicals that possess these properties are likely to be tumor promoters (Flodstrom et al. 1988). Fenvalerate alone induced no hepatoxic effects in rat liver, as judged by transaminase activities and histology. However, some rats that were partially hepatectomized and insulted with nitrosodiethylamine—a carcinogen and tumor initiator—had significantly elevated numbers of liver foci after administrations of fenvalerate. This response suggested that fenvalerate is a potential tumor promoter (Flodstrom et al. 1988).

Linkage of the tumorlike formations in rodents with a specific fenvalerate stereoisomer was an important breakthrough (Kaneko et al. 1986; Okuno et al. 1986; Miyamoto et al. 1986; Miyamoto 1988). Granulatomous cells in spleen, lymph node, and liver of fenvalerate-stressed rats and mice tended to fuse, forming large multinucleated cells called giant cells. Researchers convincingly demonstrated that the 2R, αS isomer, heretofore believed innocuous, was solely responsible for the observed microgranulomas. The residual metabolite in this instance is the cholesterol conjugate [cholesterol (2R)-2-(4- chlorophenol) isovalerate] known as CPIA-cholesterol ester. This lipophilic conjugate forms rapidly, usually peaking within 60 min, and tends to

persist in tissues, especially in adrenal, spleen, liver, and mesenteric lymph node. Of the four fenvalerate isomers, only the 2R, αS isomer yielded CPIA-cholesterol ester in tissue homogenates of mice, rats, dogs, and monkeys. Mouse tissues showed relatively higher activities than those of other animals. Kidney, brain, and spleen of mice showed relatively higher capacities to form CPIA-cholesterol ester when compared with other mouse tissues; in all cases, enzyme activity localized mainly in microsomal fractions.

Researchers concluded that stereoselective formation of the CPIA-cholesterol ester resulted from the stereoselective formation of the CPIA-carboxyesterase complex only from the 2R, αS isomer, which subsequently undergoes cleavage by cholesterol to yield the CPIA-cholesterol ester that produced giant cells in mice (Kaneko et al. 1986; Miyamoto et al. 1986; Okuno et al. 1986; Miyamoto 1988). These findings strongly support the need for more research on carcinogenic potential of fenvalerate stereoisomers.

Effects

General

Fenvalerate is extremely toxic to representative nontarget aquatic organisms and to some beneficial terrestrial arthropods at concentrations substantially lower than those recommended to control pestiferous insects. Toxic effects are associated primarily with the 2S, αS isomer and are exacerbated at low temperatures. Birds, mammals, and terrestrial plants are normally tolerant.

Target insect species are usually killed at fenvalerate concentrations of 0.015 µg whole body, 0.11 kg/ha by way of aerial application, 5.4 mg/kg in the soil, or 50 mg/kg in the diet. Adverse effects on survival of sensitive aquatic organisms occur at 0.003-0.03 µg/L for crustaceans and 0.09-1.1 µg/L for fish and amphibians. Younger stages of sensitive birds had reduced survival at acute oral doses >500 mg/kg BW and reduced growth at diets containing >750 mg/kg ration; poultry diets containing fenvalerate at <50 mg/kg feed produced no appreciable residues in eggs and meat of exposed birds. Among sensitive mammals, adverse effects on survival were noted at acute oral doses of 50-450 mg/kg BW, dietary concentrations of 50-1,000 mg/kg, and dermal applications of 1,800 mg/kg BW.

Terrestrial Plants and Invertebrates

Terrestrial plants are relatively unaffected by fenvalerate at recommended application rates, as judged by negligible uptake of fenvalerate from treated soils, formation of numerous fenvalerate conjugates that are pharmacologically inactive, and metabolism of the liberated cyano group into amino acids and eventually carbohydrate and protein (Miyamoto 1988).

Adverse effects of fenvalerate on survival of terrestrial arthropods were observed at 0.002-0.015 µg whole body topical application, 0.11 kg/ha aerial application, 5.4 mg/kg in the soil, 50 mg/kg in the diet, and 1.4 g per ant mound (Table 4). Synthetic pyrethroids are more effective in biological systems at low temperatures. The relative sensitivity of insects when compared with mammals is attributed in part to this negative temperature coefficient; thus, warm-blooded animals are less affected than insects and other poikilotherms (Klaassen et al. 1986). Fenvalerate, for example, showed a negative correlation between temperature and toxicity to crickets (*Acheta pennsylvanicus*), being up to 1.9 times as toxic at 15° than at 32° C (Harris et al. 1981). A similar case is made for honeybees (Mayer et al. 1987) and for many species of aquatic invertebrates and fish (Mayer 1987).

Signs of lethal pyrethroid poisoning in insects and other arthropods generally include hyperexcitation, tremors, and convulsions, culminating in paralysis and death (Wouters and Bercken 1978). At sublethal doses equivalent to about 10% of a lethal dose, signs of poisoning in sensitive insects include cessation of feeding, wandering, hyperactivity, restlessness, and flushing out of hiding (Bradbury and Coats 1989a). The American cockroach (*Periplaneta americana*) exposed to topical lethal concentrations of fenvalerate had uncoordinated rapid movements followed by inactivity, appearance of water drops under wings and abdomen, and blackening of the abdomen (Yellamma and Reddy 1987). Signs appeared in < 1 h at lethal concentrations and < 3 h at sublethal concentrations. Roaches exposed to sublethal doses began recovery 6 h after exposure, attaining full recovery at 24 h (Yellamma and Reddy 1987).

Field application rates of fenvalerate at 0.05-0.2 kg/ha are recommended for insect control on many food crops. Under these conditions, fenvalerate remained completely effective for 5 days against adults and nymphs of aphids (*Lipaphis erysimi*), jassids (*Amrasca biguttula biguttula*), and white fly (*Bemisia tabaci*; Jain et al.

1979). Fenvalerate, applied as a drench to mounds, shows promise as an effective control agent of the fire ant, *Solenopsis invicta* (Phillips et al. 1984). Foliar applications of fenvalerate sprays at 135 mg/L effectively controlled various pests in pear orchards of northern California, including pear psylla (*Psylla pyricola*), codling moth (*Laspeyresia pomonella*), and pear rust mite (*Epitrimerus pyri*); populations of spider mites increased, especially the two-spotted spider mite, *Tetranychus urticae* (Riedl and Hoying 1980).

A concentration of 2 mg fenvalerate per liter is frequently applied to soils to control insect pests (Schreiber and Brink 1989). However, several species of soil protozoans (*Blepharisma undulans*, *Colpoda cucullus*, *Oikomonas termo*) have LC10 (9 h) values in the range of 0.1-0.18 mg/L, suggesting that some damage occurs to this group under recommended application protocols (Schreiber and Brink 1989). In fact, all fenvalerate treatments applied to control insect pests of crops also reduced populations of beneficial nontarget organisms, including spiders, ground beetles (*Calosoma* sp.), and crickets (Smith et al. 1989). For example, spiders (*Chiracanthium mildei*) exposed for 48 h to grapefruit leaves that had been dipped 1 h previously for 5 s in aqueous emulsions of fenvalerate at field-recommended application rates all died within 2 days postexposure (Mansour 1987).

Fenvalerate-tolerant strains of arthropods include insect vectors of disease, flies and cockroaches, arthropods of veterinary importance, and agricultural pests (Sawicki 1985). But serious control problems are restricted to only a few areas, such as Central America and Thailand, where insecticidal usage is often excessive (Sawicki 1985). The exact mechanisms of resistance are unknown, although tolerance to fenvalerate in the diamondback moth (*Plutella xylostella*), a worldwide pest of cabbage-type crops, is about 20% genetic, involving several genes and multiple loci (Tabashnik and Cushing 1989). Estimates of heritability in tolerance of insects to all biocides ranges between 14 and 47% (Tabashnik and Cushing 1989). Tolerant insect species, such as larvae of the common green lacewing (*Chrysopa carnea*), and resistant strains of houseflies and lepidopterous larvae may hydrolyze fenvalerate faster than sensitive species or susceptible strains (Glickman and Casida 1982). Fenvalerate-resistant strains of domestic houseflies (*Musca domestica*), for example, when compared with susceptible strains, absorbed up to one-third the fenvalerate, had a metabolic rate up to 8 times faster, began excretion of metabolites 5 times faster, and were twice as resistant to piperonyl butoxide, a synergist applied with fenvalerate (Golenda and Forgash 1989).

The alfalfa leaf cutter bee (*Megachile rotundata*) is the most important insect pollinator of alfalfa grown for seed production in France. Alfalfa is parasitized by many insects, including the flower midge (*Contarina medicaginis*). Fenvalerate, at 0.05 kg/ha, controls the flower midge without harm to alfalfa leaf cutter bees (Tasei and Debray 1985). In general, fenvalerate-treated plants were usually nontoxic to bees after 24 h (Mayer et al. 1987). Fenvalerate does not poison bees when they are in contact with contaminated (100 mg/kg) wax in combs (Stoner et al. 1985). Fenvalerate does not pose a serious threat to honeybees except when dietary levels exceed 50 mg fenvalerate per kilogram (Stoner et al. 1984). Field application of fenvalerate at 0.22 kg/ha on blooming alfalfa, pollen-shedding corn, and blooming red raspberry (*Rubus strigosus*) resulted in reduced honeybee visitation and low to moderate adult bee mortality (Mayer et al. 1987). Caged honeybees exposed to an equivalent dose of fenvalerate at 0.11 kg/ha experienced >50% mortality within 24 h (Table 4). However, field studies showed that 0.11 kg/ha caused no observable adverse effects to bee colonies located adjacent to a treated alfalfa field; researchers concluded that fenvalerate temporarily repelled bees, as judged by a 70% reduction in bee visits to the alfalfa field in the afternoon after application when compared with periods 24 h before and after application (Moffett et al. 1982). Impaired response to scent stimuli, in addition to repellency, may account for a reduction in bee visits. Recent studies by Taylor et al. (1987) suggested that bees surviving LD50 doses of fenvalerate were unable to distinguish odor-mediated learned responses for up to 6 days after treatment. This finding indicates that more research is needed on fenvalerate-associated olfactory inhibition.

Table 4. Lethal and sublethal effects of fenvalerate on terrestrial invertebrates.

Organism, dose and other variables	Effect	Reference[a]
Cricket, *Acheta pennsylvanicus*		
5.4 mg/kg mucky soil	LD50 (18 h)	1
6.5 mg/kg moist sand	LD50 (18 h)	1
Mosquito, *Anopheles stephensi*		
0.002 µg whole body	LD50	12
Indian hive bee, *Apis cerana indica*		
0.128-0.14 µg/bee	LD50, topical application	2
Honeybee, *Apis mellifera*		
0.11 kg/ha, caged bees	57% dead in 24 h	3
Bees caged with alfalfa treated previously with 0.22 kg/ha, and held under various photo-thermal regimens for 24 h	Bees held at 10° C in the dark experienced 96% mortality; bees held at 29° C in the dark had 58% dead; those held at 18-35° C with normal photo-period had 40% dead	3
0.22 kg/ha	Repelled bees for 10 h	4
0.4 kg/ha	Increased mortality for 3 days after exposure	4
0.43 kg/ha, caged bees	All dead in 24 h	3
0.9 kg/ha	Hazardous for 2 h after application	5
Fed sucrose syrup for 7-8.5 weeks containing fenvalerate at 0.1, 1, 10, 50, or 100 mg/kg	At 100 mg/kg, survival was lower and honey production declined. At 50 mg/kg diet, bees consumed less syrup, suggesting repellency. No measurable effect at 10 mg/kg diet and lower. Queens were not affected at any dose level	5
Colonies exposed for several weeks to 1, 10, 100, or 1,000 mg/kg incorporated into beeswax foundation	Adverse effects noted only at 1,000 mg/kg, namely, lower egg hatch and survival. Fenvalerate degradation in beeswax was 11% in 15 days, 21% in 75 days, and 81% in 130 days	6
Mite, *Chorioptes bovis*		
0.05% dip (500 mg/L) for 1 min	Kills all mites and their eggs on Angora goats (*Capra* sp.) within 7 days	7
Alfalfa leaf cutting bee, *Megachile rotundata*		
0.05 kg/ha	No effect on survival or reproduction	8
0.11 kg/ha	82% dead in 24 h	3
0.22 kg/ha	92% dead in 24 h	3
0.43 kg/ha	All dead within 24 h	3
Housefly, *Musca domestica*		
Susceptible strain		
0.013-0.015 µg per fly	LD5, topical dose	12,13
0.028 µg per fly	LD30, topical dose	13
Resistant strain		
0.150 µg per fly	LD5, topical dose	13
Alkali bee, *Nomia melanderi*		
0.11 kg/ha	64% dead in 24 h	3
0.43 kg/ha	All dead in 24 h	3
American cockroach, *Periplaneta americana*		
3.5 µg per roach	Nonlethal	9
10.5 µg per roach	LD50, topical	9
100 µg/kg BW	LD50, topical	12
200 µg/kg BW	LD95, topical. Diazepam delayed onset of action	10

Fire ant, *Solenopsis invicta*		
0.73-1.4 g per mound, applied as drench	All mounds viable after 4 weeks; 70-100% of mounds nonviable after 8 weeks	11
112 or 224 g/ha, aerial application	Ineffective control. After 4 weeks, population levels were 29-35% of controls	11

Aquatic Organisms

"Supertoxic" compounds are those with LC50 (96 h) values < 10 µg/L (Scott et al. 1987). Fenvalerate is considered supertoxic, as judged by LC50 (96 h) values of < 1.0 µg/L for sensitive aquatic organisms, and < 10 µg/L for representative aquatic species (Table 5).

Table 5. Lethal and sublethal effects of fenvalerate on aquatic organisms.

Taxonomic group, organism, dose or concentration, and other variables	Effect	Reference[a]
Algae		
Alga, *Chlamydomonas reinhardii*		
0.109-5.17 µg/L	Up to 93% of all fenvalerate was adsorbed by algae in 48 h in a biomass-dependent manner when cells increased from 100/mL to 2 million/mL. In absence of alga, up to 33% of fenvalerate added to glass containers was adsorbed to container walls in 48 h	1
Marine algae, 4 species: *Isochrysis galbana, Skeletonema costatum, Thalassiosira pseudonana, Nitzschia angularis*		
1,000 µg/L	Insufficient to produce 50% growth inhibition in 96 h	2
Invertebrates		
Mosquito, *Aedes nigromaculis*		
Multiresistant strain, 4th stage larvae		
5.6 g/ha (0.005 pounds per acre)	58% reduction 6 h after treatment	3
11.2 g/ha (0.01 pounds per acre)	81% reduction 6 h after treatment	3
28.0 g/ha (0.025 pounds per acre)	88% reduction 6 h after treatment	3
Mosquito, *Aedes* spp.		
0.9-10.0 µg/L	LC50-LC90 range for 4th stage larvae	4
1.5-4.0 µg/L	LC50-LC90 range for 24 h stage pupae	4
Rhagionid fly, *Atherix* sp.		
0.021 µg/L	LC30 (28 days)	5
0.029 µg/L	LC50 (28 days)	5
0.032 µg/L	LC50 (96 h)	5
Cladoceran, *Ceriodaphnia lacustris*		
0.01 µg/L	Filtration rate of alga *(Chlamydomonas reinhardii)* significantly decreased after 24-h exposure	6
0.05 µg/L	Decreased food assimilation rate, 24-h exposure	6

0.21 µg/L	50% immobilization of adults in 48 h	6
Chironomids		
4.2-18.0 µg/L	LC50 (24 h), 3 species	7
4.2-80.0 g/L	LC50 (24 h), 8 species	7
Midge, *Chironomus tentans,* fourth-instar larvae		
0.015-0.93 µg/L	Normal burrowing behavior	8
Exposed for 24 h in different sediment types containing initial fenvalerate concentration of 50 µg/kg fresh weight (FW) or 48 h in water above sediment; depuration for 96 h in each case		
Sand (water column and sediment interstitial water concentrations after 24 h were 1.02 and 4.82 µg/L, respectively)	Bioconcentration factor (BCF) of x69 for those held in water column and x 102 for those held in sand	8
Silt (water column 0.17 µg/L, interstitial water 0.15 µg/L)	BCF of x74 for water column, x 116 for silt	8
Clay (water column 0.3 µg/L, interstitial water 0.34 µg/L)	BCF of x32 for water column, x 152 for clay	8
Snail, *Cipangopaludina japonica*		
0.4-0.7 µg/L	BCF of x617 in 30 days	9
Sand shrimp, *Crangon septemspinosa*		
0.04 µg/L	LC50 (96 h)	10,11
American oyster, *Crassostrea virginica*		
1.0 µg/L	BCF of x4,700 in 28 days; depuration to non-detectable levels in <7 days	12
> 1,000 µg/L	Abnormal shell growth in 50% of larvae surviving exposure for 48 h	2, 11
Mosquito, 3 species of *Culex*		
1.2-30.0 µg/L	LC50-LC90 range for 24-h stage pupae	4
4.0-10.0 µg/L	LC50-LC90 range for fourth stage larvae	4
Mosquito, *Culex pipiens pipiens*, larvae		
0.45 µg/L	LC50 (24 h), technical grade	13
30.0 µg/L	LC50 (24 h), emulsifiable formulation	13
11.0 mg/kg diet	LC50 (24 h)	13
Mosquito, *Culex quinquefasciatus*		
7-8 µg/L	LC50-LC90 range for 4th stage larvae	3
Daphnid, *Daphnia galeata mendotae*		
0.005 µg/L	Life cycle (28-day) exposure produced increased longevity but decreased production of young	1
0.01 µg/L, and higher	Decreased survival, reproduction, and generation time in lifetime exposure	1
0.042-0.084 µg/L	Whole body fenvalerate residues in presence of alga (*Chlamydomonas reinhardii*) ranged from 0.51 to 1.08 mg/kg FW after 48-h exposure	14
0.05 µg/L	Decreased filtering rate and assimilation rate of algae after exposure for 24 h; decrease in population numbers in 28-day exposure	1,6

0.051-0. 109 µg/L	In absence of algae, whole body residues ranged from 1.46 to 2.66 mg/kg FW after 48 h	14
0.16 µg/L	50% of immatures immobilized in 48 h	6, 15
0.29 µg/L	50% of adults immobilized in 48 h	6, 15
Daphnid, *Daphnia magna*		
0.25 µg/L	No measurable effect after exposure for 21 days	16, 17
0.5 µg/L	After 21 days, reduced survival and inhibited reproduction	16
0.83 µg/L	50% immobilization of immatures in 48 h	6
2.1-2.5 µg/L	50% immobilization of adults in 48 h	6,18
Daphnid, *Daphnia pulex*		
0.4-0.7 µg/L	BCF of x683 in 30 days	19
Copepod, *Diaptomus oregonensis*		
0.05 µg/L	Decreased filtration rate and food assimilation rate after 48-h exposure	6
0.12 µg/L	50% of adults immobilized in 48 h	6
Mayfly, *Ephemerella* sp.		
0.022 µg/L	LC80 (14 days)	5
0.07 µg/L	50% reduction in swimming ability in 96 h	20
0.08 µg/L	LC50 (96 h)	20
0.93 µg/L	LC50 (24 h)	5,20
Amphipod, *Gammarus pseudolimnaeus*		
0.022 µg/L	LC65 (6 days)	5
0.03 µg/L	LC50 (96 h), adults	5
0.05 µg/L	LC50 (96 h), juveniles	5
0.93 µg/L	All dead or immobilized within 5 h	5
Snail, *Helisoma trivolvis*		
0.021 µg/L	BCF of x1,167 in 28 days	5,7
0.054 µg/L	BCF of x592 in 28 days	5,7
0.79 µg/L	BCF of x386 in 28 days; no adverse effects on survival or behavior	5,7
American lobster, *Homarus americanus*		
0.14 µg/L	LC50 (96 h)	10, 11
Mosquito, 4 species, larvae		
0.9-28.0 µg/L	LC50 (24 h)	7,21
Mysid shrimp, *Mysidopsis bahia*		
0.008-0.021 µg/L	LC50 (96 h)	2,11,12,18,22
97-190 µg/kg sediment, equivalent to 0.03 µg/L water column	58% dead in 4 days, 70% dead in 10 days	23
1,200-1,600 µg/kg sediment, equivalent to 0.06-0.17 µg/L water column	All dead in 4 days	23
Copepod, *Nitocra spinipes*		
0.38 µg/L	LC50 (96 h)	23
Rusty crayfish, *Orconectes rusticus*		
20 µg/L	LC100 (96 h)	24
Grass shrimp, *Palaemonetes pugio*		
0.0016 µg/L	No deaths of larvae in 20 days; larval development prolonged by 2 days	25
0.003-0.013 µg/L	LC50 (96 h)	18,26

0.0032 µg/L	Larvae exposed for 20 days had reduced survival and inhibited metamorphosis	25
0.007 µg/L	LC50 (96 h), emulsifiable concentrate, zoeae, 10 ‰ salinity	27
0.02 µg/L	LC50 (96 h), emulsifiable concentrate, zoeae, 20 ‰ salinity	27
0.040 µg/L	LC50 (96 h), adults, emulsifiable concentrate	27
0.044 µg/L	LC50 (96 h), adults, technical grade	27
0.046 µg/L	Maximum tolerated dose in 6-h exposure, adults	27
0.1-0.15 µg/L	LC50, 90 h after 6-h exposure, adults	27
88-200 µg/kg sediment	LC50(96 h)	18,23
1,000-1,200 µg/kg sediment	LC100 (96 h)	18,23
Pink shrimp, *Penaeus duorarum*		
0.84 µg/L	LC50 (96 h)	12,22
1,200-1,600 µg/kg sediment, equivalent to 0.06-0.17 µg/L	None dead in 10 days	23
10,000-13,000 µg/kg sediment equivalent to 0.2-1.9 µg/L water column	All dead in 4 days	23
Red crayfish, *Procambarus clarkii*		
0.37 µg/L	LC50 (24 h), juveniles	28
Mosquito, *Psorophora columbiae*		
28-50 µg/L	LC50--LC90 range for fourth stage larvae	4
53-82 µg/L	LC50-LC90 range for 24-h stage pupae	4
Stonefly, *Pteronarcys dorsata*		
0.11 µg/L	38% immobilized in 72 h	5
0.13 µg/L	50% immobilized in 72 h	5
0.44 µg/L	38% immobilized in 24 h; 25% dead in 72 h	5
1.02 µg/L	All immobilized in <4 h; most dead in 72 h	
Chordates		
Amphioxus, *Branchiostoma caribaeum*		
760 µg/L	LC10 (10 days)	18
1,000 µg/L	No deaths in 96 h	18
1,600 µg/L	LC50 (96 h)	18
2,500 µg/L	LC100 (96 h)	18,23
100-1,000 µg/kg sand	Effectively colonized in 8 weeks	29
10,000 µg/kg sediments	No deaths in 10 days	18
10,000 µg/kg sand	Unable to effectively colonize during 8-week study	29
Vertebrates		
Bleak, *Alburnus alburnus*		
0.3 µg/L	LC50 (96 h)	23
Desert pupfish, *Cyprinodon macularis*		
25 µg/L	LC50 (48 h)	20
Sheepshead minnow, *Cyprinodon variegatus*		
0.3-5.0 µg/L	Whole body BCF values in fish surviving 28-day exposure were x460 (0.31 µg/L), x360 (0.62 µg/L), x500 (1.2 µg/L), x700 (2.5 µg/L), and x820 (5.0 µg/L)	22
0.56 µg/L	No effect on hatchability, survival or growth in 28-day exposure	17,22
2.2 µg/L	Growth reduction in 28-day exposure	22
4.4-5.0 µg/L	LC50 (96 h), flowthrough assay	2, 12,22,30

120 µg/L	LC50 (96 h), static assay	2
Common carp, *Cyprinus carpio*		
0.4-0.7 g/L	BCF of x69-x 117 in 30-day exposure	19
0.8 µg/L	After exposure for 7 days, 50% excreted 5 days after exposure and 87% in 25 days	19
0.9 µg/L	No deaths in 48 h	31
3.8 µg/L	LC10 (48 h)	31,32
10 µg/L	At 48 h, hypoproteinemia and altered enzyme activity in gills	31,32
21-30 µg/L	LC50 (48 h)	31,32
117 µg/L	LC90 (48 h)	31
Mummichog, *Fundulus heteroclitus*		
1.2-1.8 µg/L	LC50 (96 h)	23,26
Mosquitofish, *Gambusia affinis*		
15.0 µg/L	LC50 (48 h)	20
Channel catfish, *Ictalurus punctatus*		
1.8-1.9 µg/L	LC50 (24 h)	19,28
16.5 µg/L, equivalent to 112 g/ha	Muscle residues in dead fish ranged up to 70 µg/kg FW	28
30.6 µg/L, equivalent to 224 g/ha	Muscle residues in dead fish collected 24 h after treatment ranged up to 160 µg/kg FW	28
Bluegill, *Lepomis macrochirus*		
0.3-1.1 µg/L	LC50 (96 h)	19
0.7 µg/L	Elevated whole body calcium content after 48 h	34
0.9-1.9 µg/L	LC50 (48 h) range for water hardnesses between 6 and 309 mg $CaCO_3$/L, or between 4.2 and 13.6 ‰ salinity	35
10 µg/L	LC100 (96 h)	24
Intraperitoneal injection, in mg/kg body weight (BW)		
0.12	LD50 (48 h), 2S, αS isomer	17,36,37
0.67	LD50 (48 h), technical fenvalerate--mixture of all isomers	13,17,36,37
11.5	LD50 (48 h), 2S, αR isomer	17,36,37
216	No deaths in 48 h, 2R, αS isomer	17,36,37
264	No deaths in 48 h, 2R, αR isomer	17,36,37
California grunion, *Leuresthes* tenuis		
0.06 µg/L	No observable effect concentration in 28-day early life history exposure	23
0.3-0.6 µg/L	LC50 (96 h)	2,30
Inland silverside, *Menidia beryllina*		
1.0 µg/L	LC50 (96 h)	30
Atlantic silverside, *Menidia menidia*		
0.062 µg/L	No observable effect concentration in 28-day early life history exposure	23
0.31-0.69 µg/L	LC50 (96 h)	12, 17, 22
Tidewater silverside, *Menidia peninsulae*		
0.083 µg/L	No observable effect concentration in 28-day early life history exposure	23
1.0 µg/L	LC50 (96 h)	30

Striped mullet, *Mugil cephalus*		
0.58 µg/L	LC50 (96 h)	2, 12,22
African catfish, *Mystus vittatus*		
0.13 µg/L	Safe concentration	38
6.3 µg/L	LC50 (96 h)	38
Rainbow trout, *Oncorhynchus mykiss*		
0.00028 µg/L, exposure for 48 h followed by depuration for 48 h	Tissue residues, in µg/kg FW, were 7.06 in bile; 0.2 in fat; 0.02-0.05 in blood, brain, carcass, gill, kidney, liver, muscle, ovary, erythrocytes, and spleen; and <0.02 in heart, plasma, and testes	39
0.23-2.1 µg/L	LC50 (96 h)	17,18,19, 20,41,50
3.6 µg/L	Hyperactivity in 48 h	41
4.7-76 µg/L	LC50 (24 h)	20,42
300 µg/L	All dead in 10 h. At death, brain residues of 150-160 µg/kg FW. Similar brain residues reported through lethal intraperitoneal and intravenous injection routes	13,39,43
412 µg/L	All dead in 11 h. Before death, trout displayed elevated cough rate, tremors, seizures, elevated urine Na and K, and abnormal blood chemistry. At death, gill histopathology evident, and residues, in µg/kg FW, were 160 in brain, 250 in carcass, and 3,620 in liver	40
Steelhead trout, *Oncorhynchus mykiss*		
Steelhead embryos and larvae exposed intermittently (4.5 h daily) or continuously for 70 days after fertilization to nominal concentrations of 0.018, 0.04, 0.08, 0.135, or 0.505 µg/L		
0.018 µg/L	No deaths. Whole body BCF values at 70 days were X 400 for intermittent exposure and x4,100 for continuous exposure	40
0.04 µ g/L, tested at intermittent exposure only	No deaths; BCF of x3,200	40
0.08 µg/L	For continuous exposure, no effect on survival or growth; BCF of x3,000. For intermittent exposure 32% dead, 50% reduction in growth, BCF of x 10,700	40
0.135 µg/L, continuous exposure only	More than 90% dead, with most dying after 56 days; BCF of x 11,800	40
0.505 µg/L, continuous exposure	All dead. Most died after 49 days	40
Steelhead juveniles exposed intermittently (4.5 h daily) or continuously		
0.088 µg/L	LC50 (96 h), intermittent exposure	40
0.172 µg/L	LC50 (96 h), continuous exposure	17,40
Gulf toadfish, *Opsanus tau*		
1.2 µg/L	No observable effect concentration in 28-day	23

	early life history exposure	
2.4-5.4 µg/L	LC50 (96 h)	2,12,23
Fathead minnow, *Pimephales promelas*		
0.14-0.19 µg/L	Whole body residues of larvae in 28-day exposure ranged from 230 to 880 µg/kg FW. BCF values ranged from x 1,643 to x4,631, in a dose dependent manner	21
0.19 µg/L	No effect on larval survival or growth in 30-day exposure	45
0.33 µg/L	50% of larvae exposed for 96 h developed abnormally	45
0.34 µg/L	LC50 (48 h), adults, mixture of 2S, αS and 2S, αR isomers	36,37
0.36-0.43 µg/L	Exposure of eggs and resultant larvae for 30 days had no effect on hatchability, but adversely affected larval growth, survival, and swimming ability	21,45
0.37 µg/L	Whole body residues of survivors at 96 h contained 598 µg/kg FW, equivalent to BCF of x 1,616	46
0.49 µg/L	After 96 h, survivors contained 911 µg/kg whole body, or BCF of x 1,859	46
0.75 µg/L	After 96 h, survivors contained 1,680 µg/kg BW, or BCF of x2,240	46
0.85 µg/L	LC50 (96 h), larvae	45
1.69 µg/L	LC50 (48 h), adults, technical fenvalerate	37
2.5 µg/L	Schooling behavior absent after 48 h exposure, adults	41
2.85 µg/L	Exposure of larvae for 5 h resulted in 50% deformities 96 h later	45
3.6 µg/L	Hyperactivity after 48 h, adults	41
5.4 µg/L	LC50 (96 h), adults	17
>140 µg/L	LC50 (48 h), adults, mixture of 2R, αS and 2R, αR isomers	36,37
1.0 mg/kg FW whole body	Residue at death of fenvalerate-poisoned fish	13
Northern leopard frog, *Rana pipiens pipiens*		
3 µg/L	All dead in 72 h at 4° C	47
9 µg/L	None dead in 72 h at 20° C	47
130 µg/kg BW	LD50 (24 h), subcutaneous (sc) injection	47
1,800 µg/kg BW	LD50 (24 h). Initially pretreated with sc dose of 10 mg diazepam per kilogram BW followed by sc injection dose of fenvalerate	47
Atlantic salmon, *Salmo salar*		
0.8 µg/L	Some deaths during 96-h exposure; BCF of x200	10
1.2 µg/L	LC50 (96 h)	10
2.0-4.1 µg/L	Some deaths during 54-h exposure; BCF about x 125	10
9.3 µg/L	Some deaths during 16-h exposure; BCF of x40	10
Mozambique tilapia, *Tilapia mossambica*		
9 µg/L	No deaths in 20 days, but significant decreases in activity of catalase superoxide dismutase in liver, gill, and muscle, and significant increases in activity (and presumably metabolism) of	48,49

		fructose-1, 6-diphosphate aldolase in liver, gill, kidney, and brain	
45 µg/L		LC50 (48 h)	48,49

Signs of fenvalerate poisoning in fish include loss of schooling behavior, swimming near the water surface, hyperactivity, erratic swimming, seizures, loss of buoyancy, elevated cough rate, increased gill mucus secretions, flaring of the gill arches, head shaking, and listlessness before death (Bradbury and Coats 1989a, 1989b). Fenvalerate mainly affects the teleost nervous system, as discussed earlier. It also produces osmoregulatory imbalance, as judged by altered calcium uptake (Symonik et al. 1989), abnormal sodium and potassium excretion rates, and elevated urine osmolality (Bradbury et al. 1987a; Bradbury and Coats 1989a, 1989b). Histological damage to gill surfaces by fenvalerate is attributed to high accumulations in gills, irritation due to elevated mucus secretion, increased ventilation volume, and decreased gill-oxygen uptake efficiency (Bradbury et al. 1986, 1987a; Bradbury and Coats 1989a, 1989b). In fish, as in mammals, fenvalerate toxicity is primarily dependent on the 2S, αS component of the technical mixture. Studies with individual isomers and various freshwater fishes indicate that the 2S, αS isomer is 96 times as toxic as the 2S, αR isomer, and at least 1,766 times as toxic as the 2R, αS or 2R, αR isomers (Table 5).

Laboratory studies with fenvalerate and aquatic organisms indicate marked differences in sensitivity among taxonomic groups (Table 5). Crustaceans were the most sensitive group: reduced survival was evident between 0.0032 and 0.03 µg/L, and impaired feeding and reproduction was evident between 0.0016 and 0.01 µg/L. Fish and amphibians were more tolerant to fenvalerate than were crustaceans: increased mortality was evident between 0.088 and 1.1 µg/L, and no adverse effects were demonstrated in several species between 0.062 and 0.083 µg/L, although certain salmonids showed high uptake at concentrations as low as 0.0003 µg/L. Algae, molluscs, and chordates were comparatively resistant to fenvalerate (Table 5). Survival patterns of fenvalerate-stressed aquatic organisms are significantly altered, sometimes by an order of magnitude or greater, by selected biological, chemical, and physical variables. In general, increased mortality was associated with the following: reduced metabolism and excretion (Bradbury et al. 1986; Bradbury and Coats 1989a; Coats et al. 1989; Haya 1989); depleted glycogen stores due to starvation (Haya 1989); larval and juvenile stages of development (Spehar et al. 1982; Bradbury and Coats 1989a; Haya 1989); low concentrations of humic acid and other dissolved materials (Coats et al. 1989); low particulate loadings (Coulon 1982; Coats et al. 1989); increased water hardness (Dyer et al. 1989; Coats et al. 1989); increased exposure time and bioavailability (Spehar et al. 1982; Curtis et al. 1985); emulsifiable formulations (Trim 1987; Haya 1989); low temperatures (Cole and Casida 1983; Bradbury and Coats 1989a; Coats et al. 1989); and the 2S, αS component (Ohkawa et al. 1980; Bradbury and Coats 1989a; Coats et al. 1989; Haya 1989). Fenvalerate-protective agents include diazepam and endosulfan. Diazepam provides up to 14-fold protection to frogs against toxic doses of fenvalerate (Cole and Casida 1983); endosulfan provides limited protection to estuarine fish and shrimp (Scott et al. 1987; Trim 1987).

Bioaccumulation factors for fenvalerate by representative freshwater and estuarine organisms during exposure for 28-30 days to various sublethal doses ranged from 40 to 570 times for fish, 356 to 4,700 times for invertebrates, and 477 to 933 times for algae (Smith and Stratton 1986). Because of its unusually high lipophilicity, fenvalerate is accumulated at only 30% efficiency by aquatic fauna, and uptake is not dose

dependent (Coats et al. 1989). Contamination of algal food of daphnids with fenvalerate does not seem to contribute to an increase in whole body burdens, although reduced filtration rates due to toxicity could also account for a reduced intake of fenvalerate adsorbed to algae (Table 5; Day and Kaushik 1987b, 1987c).

Fenvalerate applications of 0.055-0.220 kg/ha are recommended for control of pestiferous crop insects, but these levels are rapidly fatal to nontarget organisms if introduced accidentally into aquatic environments (Day et al. 1987). In one study, large earthen ponds containing red crayfish (*Procambarus clarki*) were treated with fenvalerate at concentrations equivalent to 28, 56, 112, or 224 g/ha. All crayfish died within 24 h at all concentrations tested (Coulon 1982). After 3 days, ponds dosed with 112 g/ha and lower were not lethal to crayfish exposed for 24 h. The 224 g/ha pond remained toxic to crayfish after 72 h (71% dead) and 120 h (32% dead); mortality was negligible (<10%) after 168 h (Coulon 1982). Fenvalerate applications of 28-112 g/ha (0.025—0.1 pounds per acre) usually control 90-100% of floodwater mosquitos and stagnant water mosquitos. But at 2 -11 g/ha equivalent, the following effects are reported: mayfly naiads are eliminated; populations of diving beetles, cladocerans, and dragonfly naiads are suppressed for up to 3 weeks; zooplankton filtration rates are reduced; colonization processes are altered; and algal and rotifer populations increase due to lack of cladoceran grazing and competition (Mulla et al. 1978, 1980; Tagatz and Ivey 1981; Anderson 1982; Spehar et al. 1982; Hansen et al. 1983; Smith and Stratton 1986; Day et al. 1987; Bradbury and Coats 1989a; Day 1989).

Sediment—water interactions are important to the understanding of fenvalerate toxicokinetics. Addition of soil to fenvalerate-treated waters reduced toxicity to channel catfish (*Ictalurus punctatus*) through adsorption of fenvalerate to clay and organic components of soil; however, crayfish were not protected (Coulon 1982). Chironomid larvae held in water on sand initially spiked with 50 µg fenvalerate per kilogram accumulated up to 15 times as much fenvalerate than did larvae held in water above spiked silt or clay; a similar pattern was evident at an initial concentration of 5 µg/kg (Muir et al. 1985). This phenomenon is attributed to the greater bioavailability of fenvalerate in sand, as judged by elevated sediment interstitial water concentrations in sand when compared with those of silt or clay (Table 5; Muir et al. 1985). Mortality was observed in systems where fenvalerate concentrations in sediments were sufficient to establish lethal concentrations in the overlying water through sediment-water partitioning; lethal effects at nominal sediment concentrations of 0.1 mg fenvalerate per kilogram were observed for mysids (*Mysidopsis bahia*) and grass shrimp (*Palaemonetes pugio*) and at 10 mg/kg for pink shrimp (*Penaeus duorarum*; Clark et al. 1989). Because fenvalerate readily sorbs and binds to organic and inorganic particulate matter, it is difficult to predict its toxic effects on aquatic biota after runoff from agricultural areas or from discharges into particulate-laden habitats (Clark et al. 1989).

Birds

Birds that died of fenvalerate poisoning contained residues of 0.1 to 1.26 mg/kg brain fresh weight (FW) and 0.74 mg/kg liver FW, based on acute oral doses of 500 to 4,000 mg/kg BW (Table 6); juveniles were more sensitive than adults (Bradbury and Coats 1989a). When compared to other synthetic pyrethroids tested in laying hens, fenvalerate provided higher, more persistent residues in tissues (Saleh et al. 1986a). Birds given single oral doses of fenvalerate as low as 250 mg/kg BW experienced significant weight loss (adults) or a reduction in the rate of weight gain (immatures); similar signs were noted at dietary levels of 15,000 mg/kg ration but not at 7,500 mg/kg feed (Bradbury and Coats 1982). Poultry diets that contain fenvalerate at <50 mg/kg feed do not produce an appreciable concentration of residues in eggs or meat of exposed birds (Akhtar et al. 1989).

Adult Japanese quail (*Coturnix japonica*) given a single oral dose of 4,000 mg/kg BW started feeding normally (Mumtaz and Menzer 1986), but in about 90 min they became hyperactive. Hyperactivity increased until 2 h postdosing, at which time feeding ceased. At 4 h, they had convulsions, irregular movements, jerking, and twitching; they became progressively ataxic and uncoordinated. One quail died at 4 h, another at 8 h. By 24 h, most of the survivors had resumed feeding, but they had an odd standing posture: head held high above the body, legs extended as far straight as possible, and wings held in an upright position close to the body. By 48 h the survivors seemed to be feeding and drinking regularly; growth was normal 14 days after exposure (Mumtaz and Menzer 1986). Signs of intoxication in fenvalerate-poisoned northern bobwhites (*Colinus virginianus*) usually appeared within 2 h and included hyperactivity, irregular locomotion, ataxia, and spastic muscle contractions (Bradbury and Coats 1982, 1989a). Bobwhites use croplands for feeding, and insects are an important dietary item of chicks and adults in summer months. Little potential exists for adverse effects of fenvalerate on bobwhite and other gallinaceous bird populations from dietary exposures, however, because

insects from sprayed fields had maximum whole body residues of only 0.5 mg/kg—a level far below that associated with adverse effects (Table 6; Bradbury and Coats 1982).

Table 6. Lethal and sublethal effects of fenvalerate on birds.

Organism, dose, and other variables	Effect	Reference[a]
Northern bobwhite, *Colinus virginianus*		
0.1-1.26 mg/kg fresh weight (FW), brain	Residues in dead birds following single oral exposure; residues increased in dose-dependent manner in dose range of 500-4,000 mg/kg body weight (BW)	1
0.74 mg/kg FW, liver	Mean residue in dead birds following single oral exposure; residue seemingly independent of dose	1
250 mg/kg BW, single oral dose, immatures, age 5 weeks	No deaths in 14 days	1
500 mg/kg BW, single oral dose, immatures	20% dead within 25 h	1
1,785 mg/kg BW, single oral dose, immatures	LD50. All deaths occurred 3 to 25 after dosing	
4,000 mg/kg BW, single oral dose, immatures	70% dead within 24 h; remainder survived at least 14 days	1
4,000 mg/kg BW, single oral dose, adults. age 19 weeks	No deaths in 14 days; all appeared normal 24 h after dosing	1
15,000 mg/kg diet, 5 days of exposure plus 3 days of clean feed	Insufficient to kill 50% of 2-week-old chicks	1
Japanese quail, *Coturnix japonica*		
4 daily treatments of 100 mg/kg BW, oral route	Maximum tissue residues 72 h after the last dose, in mg/kg FW, were 3.1 in fat, 0.9 in skin, 0.7 in liver, 0.2 in heart and kidney, 0.1 in lung, and 0.02 in brain	2
2,000 mg/kg diet, 6-week-old females, 7-day feeding	Increased liver aldrin epoxidase, intestinal cytochrome P-450, and intestinal erthoxyresorufin dealkylase	3
4.000 mg/kg BW, single oral dose. 14-day observation	75% excreted in <6 h, 90% within 24 h. Tissue residues were highest at 3 h in liver (9 mg/kg FW) and gradually declined, while in blood it peaked within 2 h and fell quickly to an equilibrium level of 1.5 mg/L	2
American kestrel, *Falco sparverius*		
Oral dose of 1,000, 2,500, or 4,000 mg/kg BW; maintained at 22° C or -5° C for 10 h after dosing	No deaths. Mild intoxication and elevated plasma alanine amino-transferase activity; holding temperature did not affect toxicity	8
Domestic chicken, *Gallus* sp.		
0.03 mg/kg diet for 32 days	No detectable residues in tissue or eggs	6
5 mg/kg BW, single	Up to 85% of administered dose eliminated	4

oral dose, residues measured in egg albumin and yolk, and various tissues during observation period of 144 h	in 24 h, 88% in 72 h. Maximum residues, in mg/kg FW, were 0.5 in kidney (24 h), 0.48 in yolk (96 h), 0.46 in liver (24 h), 0.25 in plasma (24 h), 0.19 in abdominal fat (96 h), 0.18 in albumin (24 h), 0.14 in blood cells (24 h), 0.07 in both leg muscle and heart at 144 h, and not detectable in subcutaneous fat and breast muscle	
10 mg/kg BW, single oral dose, laying hens, residues measured over 14 days	Maximum residues, in mg/kg FW, were 4.7 in blood (24 h), 4.0 in brain (7 days), 1.0 in kidney (48 h), 1.0 in heart (3 days), 0.3 in egg yolk (5 days), 0.25 in kidney (14 days), 0.23 in egg white (5 days), 0.2 in skin (5 days), 0.18 in liver (48 h), and <0.15 in fat and ovary	5
Oral doses of 1,000 mg/kg BW for 5 days, and again at 21 days	No neurotoxic effects observed in hens	6
1,500 mg/kg BW	Acute oral LD50	7

[a] 1. Bradbury and Coats 1982; 2. Mumtaz and Menzer 1986; 3. Riviere et al. 1983; 4. Akhtar et al. 1989; 5. Saleh et al. 1986a; 6. Reed 1981; 7. Smith and Stratton 1986; 8. Rattner and Franson 1984.

Birds rapidly and efficiently metabolize fenvalerate by hydrolytic cleavage of the ester bond followed by extensive hydroxylation of the acid moiety at the carbon adjacent to the carboxyl group, the methyl group, or both. Major metabolites identified in liver preparations were 2-(4-chlorophenyl)-3-methylbutyric acid, 4-hydroxyfenvalerate, 3-phenoxybenzaldehyde, and 3-phenoxybenzoic acid (Akhtar 1983; Mumtaz and Menzer 1986; Akhtar et al. 1989; Bradbury and Coats 1989a). Liver microsomal drug-metabolizing enzymes usually play an important role in pesticide metabolism; however, fenvalerate and other synthetic pyrethroids are very weak inducers of avian microsomal enzymes (Riviere et al. 1983). Birds are more resistant to fenvalerate than are mammals, as judged by studies with Japanese quail and rats. Quail excreted fenvalerate more rapidly, had lower absorption, and faster metabolism; the oral LD50 for quail was >4,000 mg/kg BW versus 450 mg/kg BW for rat, almost an order of magnitude higher (Mumtaz and Menzer 1986).

Mammals

In general, fenvalerate administered to mammals was rapidly eliminated and had little tendency to accumulate in tissues (Table 7). Fenvalerate killed sensitive species of mammals at a brain injection concentration of 1.0 mg/kg FW brain (equivalent to 14 µg/kg BW), an intraperitoneal injection concentration of 3.9 mg/kg BW, acute oral doses of 50 to 450 mg/kg BW, dietary levels of 50 to 1,000 mg/kg feed, and an acute dermal concentration of 1,800 mg/kg BW; in all cases the 2S, αS isomer was the most toxic (Table 7). Measurable residues of fenvalerate were detected in tissues of sensitive mammals at 0.15 mg/kg diet, 0.15 mg/kg BW applied dermally six times over a 3-week period, and at 2.5 mg/kg BW given orally; in all cases the 2R, αS isomer was taken up 9-16 times over other isomers (Table 7). Behavioral alterations (e. g., change in drinking water preference) occurred in mice after a single oral dose of 0.3 mg/kg BW (Table 7). No significant adverse effects were observed in dogs on diets equivalent to 12.5 mg/kg BW daily for 90 days or in rats on diets containing fenvalerate at 250 mg/kg (equivalent to 12.5 mg/kg BW) for 2 years (Table 7).

At sublethal doses in rodents (i.e., 100 mg/kg BW), fenvalerate produces neurological toxicity but no histological damage; at higher doses, pathological alterations in peripheral nerves occur (Bradbury and Coats 1989a). Rats given acutely toxic doses of fenvalerate showed histopathological changes such as axonal swelling and degeneration and myelin fragmentation of the sciatic nerve; the significance of these findings is unclear (Gray and Soderlund 1985).

Route of administration may account for wide variations in the toxic action of fenvalerate. Most authorities agree that fenvalerate is most toxic to rodents when administered by intercerebroventricular injection relative to other routes—indicating the importance of the brain in the Type II poisoning syndrome; fenvalerate was

decreasingly toxic when administered intravenously, intraperitoneally, orally, and dermally (Lawrence and Casida 1982; Flannigan et al. 1985; Grissom et al. 1985; Bradbury and Coats 1989a; Williamson et al. 1989).

Differences in fenvalerate metabolism occur, even among closely related species such as rats and mice (Kaneko et al. 1981). In both species, regardless of sex, dose level, or chiral isomer, fenvalerate is metabolized primarily by oxidation at the 2'-, 4'-phenoxy positions of the alcohol moiety and at the C-2 and C-3 positions of the acid moiety, by cleavage of the ester linkage, by conversion of the CN group to SCN^- and CO_2, and by conjugation of the resultant carboxylic acids and phenols with glucuronic acid, sulfuric acid, and amino acids. However, the taurine conjugate of 3-phenoxybenzoic acid was found in mice but not in rats; 4'-hydroxylation of the alcohol moiety and the sulfate conjugate of 3-(4'hydroxyphenoxy) benzoic acid occurred to a greater extent in rats than in mice; and more thiocyanate was excreted in mice than in rats (Kaneko et al. 1981). Dogs are remarkably different from rodents in their ability to metabolize fenvalerate (Kaneko et al. 1984). Four major differences have been observed: (1) Rats and mice show hydroxylation of the 2' position of the alcohol moiety, whereas dogs do not; (2) dogs produce 3-phenoxybenzyl alcohol and 3-(4'-hydroxyphenoxy) benzyl alcohol, whereas rodents do not; (3) the predominant conjugate of the alcohol moiety in dogs is 3-phenoxybenzoyl glycine, but this is only a minor conjugate in rodents; and (4) dogs produced more glucuronides of acid moiety and their hydroxy derivatives than did rats and mice. The proposed fenvalerate metabolic pathways in dogs (Kaneko et al. 1984) suggest that species differences and pathways are important and require more research.

Table 7. Lethal and sublethal effects of fenvalerate on mammals.

Organism, route of administration, dose, and other variables	Effect	Reference[a]
Cattle, *Bos* spp.		
Diet		
Fed 0.15 mg/kg feed for 21 days	Residues ranged up to 0.002 mg/L in milk, 0.022 mg/L in cream, 0.014 mg/kg fresh weight (FW) in fat, 0.006 mg/kg FW in liver, and <0.01 mg/kg FW in bone, brain, muscle, kidney, or lung	1
Dairy cows fed 5 or 15 mg/kg ration daily for 4 days; milk and feces collected during exposure and 6 days after exposure	Maximum concentrations of fenvalerate in milk during exposure were 48 µg/L (377 µg/kg dry weight [DW]) in the 5 mg/kg group and 250 µg/L (1,950 µg/kg DW) in the 15 mg/kg group; fenvalerate was not detectable 2 days after exposure in the low dose group and 6 days after exposure in the high dose group. In feces, the maximum concentrations ranged between 34.9 and 50.4 mg/kg DW during exposure; detectable concentrations in both groups were evident 6 days after exposure	2
Fed 10.9 mg/kg feed for 28 days	Maximum residues, in mg/kg FW, were 0.13 in whole milk, 1.0 in cream, 0.8 in fat, and 0.06 in muscle	1
Dermal		
Dairy cows of mean weight 671 kg given 0.1 g topically (0.1 mg/kg body weight [BW]) in six consecutive treatments at intervals of 3 or	After last application, no detectable fenvalerate residues were found in milk after 6 h; maximum residues in milk were 1.14 µg/L after 3 days, 0.42 in 4 days, and not detectable after 7 days	3

4 days (total 0.6 g)		
Dairy cows given three consecutive topical treatments of 0.5 g (0.5 mg/kg BW; total 1.5 g) at 2-week intervals	Maximum residues in milk, in µg/L, after last treatment were 6.8 after 6 h, 2.9 after 3 days, 2.5 at 7 days, 1.3 at 14 days, and <0.2 at 3 weeks. About 0.05% of the applied fenvalerate appears in the milk as the intact insecticide over the 59-day study	3
Dog, *Canis familiaris*		
Oral		
Male beagles, 7 months old, 1.7 mg/kg, single dose	About 84% eliminated from body within 3 days through urine and feces. Half-time persistence of 2 h in blood, and 0.7-1.0 day in whole body	4
Diet		
Fed up to 12.5 mg/kg BW equivalent for 90 days	No evidence of toxicity at any level	1
Groups of 12 beagles (6 males, 6 females 5 months old, fed fenvalerate at 250, 500, or 1,000 mg/kg feed for 6 months	For all groups, dose-dependent increase in emesis, head shaking, biting of the extremities, blood chemistry alterations, ataxia, tremors, and hepatic multifocal microgranulomas. Some males in the 1,000 mg/kg group were killed after 2 weeks while in coma. Sex-related differences were noted: increased cholesterol and alkaline phosphatase in males; poor growth and enlarged adrenals, ovaries, liver, and kidneys in females. Lymph node histopathology was observed in female 500 and 1,000 mg/kg group and in the male 1,000 mg/kg group	5
Hamster, *Cricetus* sp.		
In vitro		
5-40 mg/L	Nontoxic to isolated cells	6
Oral		
12.5 or 25 mg/kg BW for 2 days	No chromosomal aberrations in bone marrow	1
Domestic cat, *Felis domesticus*		
Dermal		
Topical aerosol treatment of fenvalerate plus Deet (N-N-diethyl-m toluamide) to control fleas and ticks	Kitten, 3 months old, died in 6 h following hypersalivation, ataxia, depression, and seizures. No histopathology at necropsy; brain AChE activity normal. Fenvalerate residues, in µg/kg, were 345,000 in skin, 230 in kidney, 150 in liver, 10 in brain. Adult (4 years old) showed signs of toxicosis 4 h after topical application; by 30 h, animal had lowered body temperature, bradycardia, and other signs of fenvalerate poisoning. At death, shortly thereafter, fenvalerate residues were 1,000 µg/kg in skin and 20 µg/kg in liver	7
Domestic mouse, *Mus* spp.		
Intercerebroventricular injection		
0.2 mg/kg BW	95% dead; 50% show signs of poisoning	8

	within 6 min of brain injection	
1.0 mg/kg FW brain, equivalent to 14 µg/kg BW	LD50; 2S, αS isomer	9
Oral, single dose		
0.3, 3, or 30 mg/kg	No deaths in any group. The 30 mg/kg group were hyperactive for 4 h after dosing. All mice preferred 0.3% saccharin solution to water	10
2.5 mg/kg BW of each of the 4 chiral isomers; tissue residues measured 6 days after administration	Residues of the 2R, αS isomer were 9-16 times as high in adrenal as that of the other 3 isomers (2S, αS; 2S, αR; 2R, αR), at least 20 times as high in heart, 6-14 times as high in kidney, 17-28 times as high in liver, at least 15 times in lung, 3-6 times in mesenteric lymph node, and >30 times as high in spleen	11
7 mg/kg BW, residues measured 6 days later	Maximum concentrations, in mg/kg FW, were 7.3 in hair, 0.9 in fat, 0.5 in skin, 0.3 in blood, and 0.08 in liver	12
8.4 mg/kg BW, residues measured 7 days later	Maximum concentrations, in mg/kg FW, were 2.3 in hair, 0.8 in fat, 0.3 in stomach contents, 0.1 in skin, and 0.05 in blood	12
50 mg/kg BW	LD50; 2S, αS isomer	13
72-845 mg/kg BW, various laboratory strains	LD50	1,13,14, 15,16
200 mg/kg BW	Slight increase in frequency of chromosome aberrations in bone marrow cells	17
>600 mg/kg BW	LD50; 2S, αR isomer	13
>5,000 mg/kg BW	LD50; 2R, αR isomer	13
Dermal		
I mg/kg BW, single application	Penetration through skin was 1.9% at 60 min, 2.2% at 6 h, and 9.1% at 24 h. Of penetrated dose, maximum percent distribution was 83% in carcass at 60 min, 1.3% in blood at 6 h, 11.5% in liver at 6 h, 2.2% in kidney at 6 h, 0.7% in fat at 6 h, and 73% in feces at 24 h	18,19
60, 600, or 1,800 mg/kg BW, single application	At 1,800 mg/kg BW, 20% died in 96 h; no deaths in other groups. Survivors in 600 and 1,800 mg/kg groups were hyperactive. All survivors preferred 0.3% saccharin solution to water	10
Intraperitoneal injection		
3.9 mg/kg BW	LD50; 2S, αS isomer	9
62 mg/kg BW	LD50	14
89 mg/kg BW	LD99	14
Diet		
Fed 5, 15, or 50 mg/kg on days 6-15 of gestation	Maternal toxicity at 50 mg/kg BW, but no effect on embryonic development	1
Fed 10, 50, 250, or 1,250 mg/kg feed for 2 years	Increased mortality, reduced growth, disrupted enzyme activity at 1,250 mg/kg. Nonneoplastic microgranulomas in lymph, liver, and spleen of 250 and 1,250 mg/kg male mice; less severe microgranu-	34

	latomous changes in mesenteric lymph node of 50 and 250 mg/kg groups; no observable effect at 10 mg/kg diet	
Fed 50, 250, or 1,250 mg/kg feed for 2 years	Nonneoplastic pathological changes diagnosed as multifocal microganulomas in lymph nodes, liver, and spleen of males at all dose levels, and in females at the 250 and 1,250 mg/kg diet level	20
Fed 100, 300, 1,000, or 3,000 mg/kg feed for 78 weeks	No evidence of carcinogenicity at any does tested. No-observable-effect-level (NOEL) was 100 mg/kg diet (equivalent to 15 mg/kg BW); dose-related effects noted in liver at 300 mg/kg diet and higher	1
125 mg/kg diet, 8 weeks, 2R, αS isomer	No deaths; 70% incidence of microgranulomas in liver	20
Fed 500 mg/kg diet of three isomers (2S, αS; 2R, αS; 2R, αR) for 2 weeks	Residues, in µg/kg FW, of the 2R, αS isomer were significantly higher than that of other isomers tested in adrenal (173 versus 10-21), heart (15 versus 2), kidney (22 versus 9-10), liver (105 versus 13), lung (31 versus 2-5), mesenteric lymph nodes (86 versus 8-12), and spleen (21 versus 1)	11
500 mg/kg diet, 13 weeks	No deaths; 100% incidence of microgranulomas or giant cell infiltration	20
500 mg/kg diet, 52 weeks, 2S, αS isomer	No microgranulomas or giant cell infiltration in liver, spleen, or lymph nodes	20
500 or 1,000 mg/kg diet, 52 weeks, 2S, αR isomer	No deaths; no microgranulomas	20
1,000 mg/kg diet, 2 weeks, 2S, αS isomer	Severe hyperexcitability and tremors and 100% kill. No microgranulomas present	20
1,000 mg/kg diet, 4 weeks, 2R, αS isomer	No deaths; 100% incidence of microgranulomas	20
1,000 mg/kg diet, 13 weeks, 2R, αR isomer	No deaths; no microgranulomas or giant cell infiltration	20
2,000 mg/kg diet, 2 weeks, 2S, αR isomer	All dead; no microgranulomas	20
Intraperitoneal (ip) injection		
40 mg/kg BW, five daily doses (total of 100 mg/kg BW)	Significant increase in frequency of chromosome aberrations induced in bone marrow cells—but frequency lower than single dose ip injection of 200 mg/kg BW	17
Subcutaneous injection		
Given five daily doses totaling 100, 150, or 200 mg/kg BW	After 35 days, incidence of sperm abnormalities was significantly increased over controls: 3.3% abnormal sperm in 100 mg/kg group, 5.9% in 150 mg/kg group, and 6.3% in 200 mg/kg group versus 2.3% in controls	17

Rabbit, *Oryctolagus* sp.		
Dermal		
0.13 mg/cm^2 skin, applied 5 days weekly for 16 weeks	Minor increases in cutaneous blood flow, skin reddening, and skin thickening	22
In vitro		
0.2-10 mg/L, liver and muscle tissues	Synthesis of protein and RNA inhibited in muscle in a dose-dependent manner; maximum inhibition was 0.2 mg/L for RNA synthesis and 10 mg/L for protein. The reverse was observed in liver; maximum stimulation was at 2 mg/L	23
Domestic sheep, *Ovis aries*		
Diet		
3-month-old lambs fed 45 mg/kg feed for 10 days, equivalent to 20 mg daily	Tissue residues, in mg/kg DW, were 3.6-4.4 in renal fat, 0.2 in leg muscle, and 0.1 in liver	24
Laboratory white rat, *Rattus* spp.		
Diet		
Fed 1, 5, 25, or 250 mg/kg ration for up to 2 years	No measurable effect on body weight, food consumption, hematology, clinical chemistry, or organ weights of any diet	25
Fed diets containing 1, 5, 25, or 250 mg/kg feed for three generations	No teratogenic or fetotoxic effects. Females in third generation fed highest dose had reduced growth	1
Fed 1, 5, 25,250, or 500 mg/kg ration for 2 years	NOEL at 250 mg/kg, equivalent to 12.5 mg/kg BW; growth suppression at 500 mg/kg diet	1
Fed 50, 150, 500, or 1,500 mg/kg feed for 15 months	NOEL at 50 mg/kg, equivalent to 2.5 mg/kg BW. Higher doses had adverse effects on growth, food consumption, and behavior	1
Fed 1,000 mg/kg ration for 2 years	Growth inhibited; organ-BW ratios increased in brain, liver, spleen, kidney, heart (females), and testes. Mammary and pituitary tumors commonly observed in treated and in control groups. No statistically significant difference in number or type of neoplasms, except for mammary tumors	25
Oral		
1.7 mg/kg BW daily for 5 consecutive days, or single dose of 8.4 mg/kg BW. Technical fenvalerate and 2S, αS isomer tested separately	No apparent differences in the nature and amount of metabolites and in the pattern of excretion and tissue residues between the racemic mixture and the 2S, αS isomer	26
Single dose, 2.5 mg/kg BW; residues, in µg/kg FW, in tissues measured 6 days after exposure		
2R, αS isomer	Residues in tissues were usually	11

	much higher than those of other isomers tested: adrenal, 371; fat, 304; heart, 40; kidney, 25; liver, 72; lung, 25; mesenteric node, 318; and spleen, 62	
2S, αS isomer	Residues were 511 in fat, 45 in mesenteric lymph node, and <22 in other tissues	11
2S, αR isomer	Fat contained 326, mesenteric lymph node 68, and other tissues <20	11
2R, αR isomer	Fat contained 756, mesenteric lymph node 94, and other tissues <23	11
Single dose of 3 mg/kg BW, individual isomers tested, fat analyzed periodically during 21 -day observation	Half-time persistence of all four isomers in fat ranged between 7 and 10 days; mean residues at 24 h and 21 days after exposure were 0.64 and 0.08 mg/kg FW, respectively	27
Decarboxyfenvalerate, single dose. 4 mg/kg BW	Almost completely eliminated in a few days, mainly by way of the feces; little translocation from GI contents and liver to other tissues; Tb ½ of 10 h in pancreas and <7 h in all other tissues	28
Single dose, 7 mg/kg BW, residues measured 6 days later	Residues, in µg/kg FW, were about 1,250 in blood, 1,200 in fat, 2,300 in hair of females, 37,000 in hair of males, 370 in liver, and 5,800 in skin	12
Single doses between 15 and 200 mg/kg BW	At 90 rain, rats showed a dosage-dependent decrease in locomotor activity and operant response rates	29
Adults given 25 or 75 mg/kg BW, 5 days a week for 10 weeks	At low dose, no signs of neurotoxicity or significant hepatotoxicity. At high dose, neurotoxicity evident only during first week; liver contained significantly elevated number of foci/cm3 and a larger percentage of liver tissue occupied by foci when compared to controls	30
450-3,000 mg/kg BW	LD50; variability due to solvent	1
451 mg/kg B W	LD50	15,21,31
Single dose of 850 mg/kg BW, observed for 7 days	Signs of toxicosis appeared in 2 h; if untreated, 80% died. Intraperitoneal injection of 400 mg/kg BW of methocarbamol followed by repeated doses of 200 mg/kg BW at every onset of signs eliminated signs of poisoning within 17 h and prevented mortality	32
Dermal		
31,155, or 310 mg/kg BW, 5 days weekly for 2 weeks; observed for 2 weeks after last treatment	No deaths. Altered blood chemistry that returned to normal during observation period, except for elevated serum alkaline phosphatase activity	33
Intravenous injection		
50-100 mg/kg BW	LD50	21

Cattle (*Bos* spp.) protected against various insect pests by fenvalerate-impregnated ear tags grow better than unprotected cattle. Beef cattle were protected against horn flies (*Haematobia irritans*) and other blood-sucking dipterans by fenvalerate-impregnated ear tags; during a 115-day grazing period, protected cattle had greater weight gain than unprotected cattle (Haufe 1982). This technique may have application in protecting fly-infested threatened or endangered species of mammals. Dairy cows tagged with 8% fenvalerate ear tags showed a 99.9% reduction in horn flies over a 16-week trial (Block and Lewis 1986). But other species of flies (housefly; stable fly, *Stomoxys calcitrans*; face fly, *Musca autumnalis*) were not controlled to the same extent, and they increased as horn fly populations decreased. Protected cows produced 117 kg more milk in 16 weeks than did unprotected cows; fat and protein percentages in milk were the same for both groups. The higher milk production in the fenvalerate-tagged group was attributed to more uninterrupted forage time, greater forage consumption, and more efficient energy utilization because less energy was expended on avoiding or removing flies (Block and Lewis 1986). Similar results were reported in dairy cows in a 12-week study (Harris et al. 1987). Fenvalerate was adequately distributed over the entire body and persisted for at least 80 days on the hair of cattle with one ear tag containing 10.5 g active ingredients (Yeung et al. 1989). Residues in hair were highest at 14 days (18.4 mg/kg FW) and lowest at 80 days (1.3-3.0 mg/kg FW). All four stereoisomers were present on cattle hair, and no stereoselective degradation occurred. Hair contained 14.8 mg/kg FW fenvalerate after 30 days with two ear tags (Yeung et al. 1989).

Cows fed fenvalerate in grain at 10 mg/kg diet for 4 days excreted most of the fenvalerate, essentially unchanged, in urine (Wszolek et al. 1981b). A secondary excretion route is feces, accounting for about 25% of the ingested dose; milk accounted for 0.44-0.64% of the total excreted (Wszolek et al. 1980). Half-time persistence of fenvalerate in milk of treated cows is about 6.4 days (Frank et al. 1984). Effects of low concentrations (1.14-6.8 µg/L) of fenvalerate in milk of treated cows on newborn suckling calves are unknown and merit additional research (Frank et al. 1984).

Fenvalerate toxicity is antagonized by atropine sulfate or methocarbamol, which may be effective in treating severe cases of poisoning (Hiromori et al. 1986). Conversely, some compounds exacerbate the toxicity of fenvalerate and interfere with a desired use. Domestic cats (*Felis domesticus*) treated with Fendeet (an aerosol mixture of fenvalerate and N-N-diethyl-*m*-toluamide) to control fleas and ticks sometimes show signs of toxicosis, such as tremors, hypersalivation, ataxia, vomiting, depression, and seizures. Signs usually appeared within hours of topical application, and females and juveniles seem to be the most sensitive group. The demonstrated ability of N-N-diethyl-*m*-toluamide to enhance the dermal absorption of fenvalerate is the probable cause of toxicosis (Dorman et al. 1990).

In occupational settings, fenvalerate produces temporary irritation and itching (Bradbury and Coats 1989a). Among human fenvalerate applicators, sensitive individuals complain of a burning and tingling skin sensation after using the insecticide, and sometimes they substitute an insecticide more toxic to nontarget species in order to avoid this uncomfortable sensation (Flannigan et al. 1985). This practice, if widespread, may compromise existing or proposed natural resource management practices.

Recommendations

Fenvalerate is listed under the Class IV Surveillance Index Classification, indicating a low hazard potential to humans from toxicological and exposure standpoints. This classification requires only nominal monitoring (Reed 1981). Monitoring efforts of regulatory agencies to the present, however, have been limited and of marginal worth in evaluating background concentrations of fenvalerate. Additional monitoring is recommended to measure fenvalerate residues in tissues of birds and mammals of U.S. Fish and Wildlife Service concern.

Products that contain fenvalerate and are registered for use on corn, wheat, soybeans, sorghum, oats, barley, rye, or cotton are subject to the provisions of the Endangered Species Act (Sine 1988). The Endangered Species Act requires that actions of federal agencies not jeopardize threatened or endangered species or their habitats. Specifically, the U.S. Environmental Protection Agency, in consultation with the U.S. Fish and Wildlife Service, determines whether use of fenvalerate poses a threat to listed species of animals and plants in various locations (Sine 1988). Clearly, fenvalerate and other synthetic pyrethroid insecticides should be used with extreme caution in habitats of endangered species.

No regulations exist for protection of sensitive natural resources against fenvalerate, although current application rates to control pestiferous crop insects are lethal to many species of nontarget organisms, including bees, fish, and crustaceans (Table 8). Current fenvalerate guidelines for protection of livestock, poultry, and human health are as follows: <5 mg/kg in diets of livestock, <50 mg/kg in diets of poultry, <3 mg/kg in human diets (< 1 mg/kg for vegetables, <0.5 mg/kg for meat, <0.25 mg/kg for milkfat), and <0.125 mg/kg BW for acceptable daily intake in humans (Table 8).

Despite the high toxicity of fenvalerate and other pyrethroids to aquatic organisms, few environmental problems have been documented, presumably due to the very low application levels needed to control insects, adsorption onto soil and organic matter, and comparatively rapid degradation (Gray and Soderlund 1985). Nevertheless, fenvalerate is extremely toxic to aquatic organisms (Table 8), has high bioaccumulation, and is persistent in sediments; these patterns are most pronounced in estuaries and other wetland environments. Fenvalerate use in areas adjacent to estuarine systems poses unacceptable risks to those ecosystems at concentrations not currently detectable by analytical methods (Schimmel et al. 1983). It seems reasonable to prohibit all uses of fenvalerate directly into aquatic environments and to severely restrict usage in areas adjacent to drainage systems.

Additional research is needed on sublethal effects of fenvalerate in the following areas: (1) impaired response to scent stimuli as demonstrated in bees (Taylor et al. 1987); (2) genotoxic potency as shown in positive genotoxic effects on mice bone marrow (Pati and Bhunya 1989); (3)photoproduct formation—especially those formed through ultraviolet irradiation--wherein at least two photoproducts were more toxic than the parent chemical (Holmstead et al. 1978); (4) enhanced tumor formation in rodent liver (Flodstrom et al. 1988); (5) development of analytical procedures to detect minute and short-lived reactive metabolites (Miyamoto 1988); (6) development of simplified and reliable laboratory test systems more representative of total natural ecosystems (Miyamoto 1988); and (7) interaction effects of fenvalerate degradation products with other chemicals (Smith and Stratton 1986). More research is also needed on indirect effects on wildlife due to reductions in nontarget insects and on bioavailability of fenvalerate to aquatic organisms from sediments and the sediment-water interface.

Table 8. Proposed fenvalerate criteria for the protection of natural resources and human health.

Resource and other variables	Criterion	Reference[a]
Bees (*Apis mellifera, Megachile* sp.)		
Adverse effects		
Whole body	>0.1 µg/bee	1
Diet	> 10 mg/kg fresh weight (FW)	2
Aerial application	0.05 >0.11 kg/ha	3,4
Aquatic organisms		
Crustaceans, decreased survival		
Water column	0.003-0.022 µg/L	5,6,7, 8,9,10, 11,12
Sediments	97-190 µg/kg FW	13
Fish		
Water column		
Persistent residues	>0.00028 µg/L	14
No adverse effects on growth survival, or reproduction	0.062-0.083 µg/L	13

Lethal	0.088-0.31 µg/L	5,10, 11, 13,15,16, 17,18,19,20
Brain residues at death	>0.16 mg/kg FW	20
Birds		
Acute oral exposure, single dose		
No deaths	<250 mg/kg body weight (BW)	21
Some deaths	>500 mg/kg BW	21
Persistent residues	>5 mg/kg BW	22
Tissue residues at death		
Brain	0.1-1.26 mg/kg FW	21
Liver	0.74 mg/kg FW	2 I
Dietary exposure		
Sublethal		
No residues in eggs or meat	<50 mg/kg diet	22
Biochemical upset	>2,000 mg/kg diet	24
Lethal	> 15,000 mg/kg diet	2 I
Mammals		
Dietary exposure		
Sublethal		
Persistent residues	0.15-15 mg/kg feed	23,25
Temporary tolerance level, livestock, dried apple pomace	5 mg/kg feed	23
No significant effects	12.5-15 mg/kg BW daily, 100-250 mg/kg diet	23,26
Significant adverse effects	250-1,000 mg/kg diet	27
Lethal	>50 mg/kg BW, >1,250 mg/kg diet	23,28
Single oral exposure		
Sublethal		
Behavioral changes	0.3-30 mg/kg BW	29
Persistent residues	>2.5 mg/kg BW	30
Lethal	50-450 mg/kg BW	20,23,31
Dermal exposure		
Sublethal		
Persistent residues	0.15-1.0 mg/kg BW	32,33,34
No deaths	310 mg/kg BW daily for 2 weeks	35
Lethal	1,800 mg/kg BW, single application	29
Human health		
Permanent tolerance level		
Meat and milk fat	<0.02 mg/kg FW	23
Temporary tolerance level		
Milk fat	<0.25 mg/kg FW	23
Meat	<0.5 mg/kg FW	23
Total diet	<3 mg/kg FW	23
Vegetables, "safe" level	<1 mg/kg FW	36
Acceptable daily intake (ADI), 60 kg person, 1.5 kg food daily	0.125 mg/kg BW	23
Theoretical daily exposure from diet		
Minimum	0.015 mg, 0.00025 mg/kg BW, 0.2% of AD1	23
Maximum	0.334 mg, 0.0056 mg/kg BW, 4.5% of ADI	23

Figure. Fenvalerate and its isomers (Ohkawa et al. 1979; Hill 1981; Kaneko et al. 1981, 1986; Vijverberg and Bercken 1982; Miyamoto et al. 1986; Bradbury et al. 1987b; Bradbury and Coats 1989a, 1989b; Coats et al. 1989).

A. Chemical structure of fenvalerate denoting two asymmetric carbon atoms (*): the 2C position of the acid moiety, and the αC position of the α-cyano-3-phenoxybenzyl alcohol moiety. These two chiral centers, at the 2C and αC positions, yield a mixture of four stereoisomers, in approximately equal amounts but with greatly different biological properties.

B. (2*S*)-α-cyano-3-phenoxybenzyl (α*S*)-2-(4-chlorophenyl)-3-methylbutyrate. The 2*S*, α*S* isomer is extremely toxic to insects and is the most active form of fenvalerate.

C. (2*S*)-α-cyano-3-phenoxybenzyl (α*R*)-2-(4-chlorophenyl)-3-methylbutyrate. The 2*S*, α*R* isomer has markedly reduced insecticidal activity when compared with the 2*S*, α*S* isomer but is greatly elevated in this respect when compared with fenvalerate stereoisomers with an *R* configuration in the acid moiety, that is, the 2*R*, α*S* and the 2*R*, α*R* isomers.

D. The 2*R*, α*S* isomer is the only fenvalerate isomer that caused granulatomous changes in liver, spleen, and mesenteric lymph node in rodents.

E. The 2*R*, α*R* isomer has greatly reduced biological and toxicological properties when compared with other fenvalerate isomers. Isomers with an *R* configuration in the acid moiety degraded slightly faster than the insecticidally active 2*S*, α*S* and 2*S*, α*R* isomers.

Abstract. Diflubenzuron (1 -(4-chlorophenyl)-3-(2,6-difluorobenzoyl)urea), also known as dimilin, is a potent broad-spectrum insect growth regulator that interferes with chitin synthesis at time of molting and is effective in controlling immature stages of insects. Diflubenzuron was approved for domestic use in 1976 to control gypsy moth (*Lymantria dispar*), and in 1979 against the cotton boll weevil (*Anthonomus grandis*). By 1989 this compound was also registered for domestic use against mosquitos, forest Lepidoptera, mushroom flies, and leaf-eating insect pests of citrus, woody ornamentals, vegetables, and fruit.

Diflubenzuron seldom persists for more than a few days in soil and water. When used properly in forest management, it is unlikely to be leached into ground water from the application site. Degradation in water and soil is most rapid when small particle formulations are applied; microorganisms are abundant; and at elevated pH, temperature, and organic loading. Chemical and biological processes initially yield 2,6-difluorobenzoic acid and 4-chlorophenylurea. Soil degradation processes and plant and animal metabolism involve further conversion of these compounds to 2,6-difluorobenzamide and 4-chloroaniline. Ultimately, the end products are either conjugated into mostly water soluble products or biologically methylated.

Diflubenzuron applied to foliage of terrestrial plants tends to remain adsorbed for several weeks with little or no absorption or translocation from plant surfaces; loss occurs mainly from wind abrasion, rain washing, or shedding of senescent leaves. Among terrestrial insects, there is great variability in sensitivity to diflubenzuron. Sensitive pestiferous species of insects die at topical applications of 0.003-0.034 µg per larvae or after consuming diets containing 0.1 mg/kg. Some beneficial insects, such as the honey bee (*Apis mellifera*), are adversely affected at 1 mg/kg fresh weight (FW) of diet.

Diflubenzuron application rates between 28 and 56 g/ha (0.025-0.05 pounds per acre) or 2.5 to 16 µg/L are highly effective against pestiferous aquatic dipterans, including representative chaoborids, chironomids, and culicids. These same dosages temporarily suppress nontarget populations of cladocerans, copepods, mayfly nymphs, corixids, and springtails; population recovery is usually complete within 80 days. In general, crustaceans were the most sensitive nontarget aquatic organisms tested. Adverse effects on crustacean growth, survival, reproduction, and behavior occur between 0.062 and 2 µg/L. Next in sensitivity are mayflies, chironomids, caddisflies, and midges; concentrations between 0.1 and 1.9 µg/L produce low emergence and survival. Moderately resistant to diflubenzuron are larvae of diving beetles, dragonfly adults and naiads, ostracods, spiders, backswimmers, and water boatmen. Relatively tolerant of diflubenzuron (i . e., no observable adverse effects at 45 µg/L) are the algae, molluscs, fishes, and amphibians. High accumulations occur on some aquatic plants during exposure to 100 µg/L and in fish during exposure to 1 to 13 µg/L, but all species in these groups seem unaffected by elevated body burdens and grow and metabolize normally.

Birds seem comparatively resistant to diflubenzuron: acute oral LD50 doses exceed 2,000 mg/kg body weight (BW); dietary concentrations <4,640 mg/kg FW are tolerated for at least 8 days; and forest birds seem unharmed by recommended diflubenzuron application procedures to control pestiferous insects. Intraspecies differences in ability to metabolize diflubenzuron are probably large; different strains of domestic chickens show significant differences in ability to accumulate and retain this compound.

No data were found on diflubenzuron effects on mammalian wildlife. However, studies on small laboratory animals and domestic livestock indicate no observable effects in cows (*Bos bovis*) given 0.25 mg/kg BW daily for 4 months, in rabbits (*Oryctolagus cuniculus*) given 4 mg/kg BW daily on days 6 to 18 of gestation, in dogs

(*Canis familiaris*) fed diets containing 40 mg/kg for 13 weeks (equivalent to 1.6 mg/kg BW daily), in rats (*Rattus* spp.) fed diets containing 160 mg/kg for 2 years, and in rabbits and rodents given single oral or dermal doses <2,000 mg/kg BW. All experimental studies conducted with laboratory animals indicate that diflubenzuron is nonmutagenic, nonteratogenic, and noncarcinogenic. Adverse effects occur in dogs fed diets containing 160 mg/kg (6.2 mg/kg BW daily) for 13 weeks (abnormal blood chemistry), in mice (*Mus* spp.) given 125 mg/kg BW daily for 30 days (hepatocellular changes), in rabbits fed diets of 640 mg/kg for 3 weeks (abnormal hemoglobin), and in rats given 5,000 mg/kg BW daily for 13 weeks (abnormal hemoglobin). Elevated tissue residues--but no other measurable effects---occur in cows given 0.05 to 0.5 mg/kg ration for 28 days or 1 to 16 mg/kg BW for 4 months, in pigs (*Sus* spp.) given a single oral dose of 5 mg/kg BW, and in sheep (*Ovis aries*) given a single oral dose of 10 mg/kg BW.

Criteria now recommended for protection of various species include the following: dietary loadings, in mg/kg FW ration, of <0.05 for human health, <0.05 for livestock, < 1 for honey bees, and <5 for poultry; seawater concentrations <0.1 µg/L for estuarine crustacean larvae; and, for all aquatic life, restricted or prohibited use of diflubenzuron in salt-marsh mosquito breeding areas and on agricultural lands less than 5 km from coastal areas. No criteria are available or proposed for protection of avian and mammalian wildlife against diflubenzuron, probably because of an incomplete toxicological data base. (Eisler, R. 1992. Diflubenzuron hazards to fish, wildlife, and invertebrates: a synoptic review. U. S. Fish and Wildlife Service Biological Report 4. 36 pp.).

Key words: Diflubenzuron, dimilin, benzoylphenyl urea, insecticide, ovicide, wildlife, aquatic organisms, ecotoxicology, criteria.

Compounds collectively known as insect growth regulators have been recognized, in recent years, as important new insecticides. These compounds include juvenile hormone mimics, antijuvenile hormone analogs, and chitin synthesis inhibitors. The most widely studied chitin synthesis inhibitor, and the only one currently registered for use against selected insect pests in the United States, is diflubenzuron (1-(4-chlorophenyl)-3-(2,6-difluorobenzoyl)urea), also known as dimilin (Christiansen 1986; Touart and Rao 1987). Chitin is a major component of the tough outer covering, or cuticle, of insects. As insects develop from immature larvae to adults, they undergo several molts, during which new cuticles are formed and old ones shed.

Diflubenzuron prevents successful development by inhibiting chitin synthetase, the final enzyme in the pathway by which chitin is synthesized from glucose (Marx 1977; Ivie 1978).

Diflubenzuron is highly effective against larval stages of many species of nuisance insects. It is used extensively to control mosquitos, midges, gnats, weevils (including the cotton boll weevil, *Anthonomus grandis*), various beetles, caterpillars of moths and butterflies (especially the gypsy moth, *Lymantria dispar*), flies, and rust mites (Marx 1977; Ivie 1978; Veech 1978; Schaefer et al. 1980; Opdycke et al. 1982a; Muzzarelli .1986). In Maryland, for example, more than 30,000 ha are sprayed annually to control gypsy moths (Swift et al. 1988a). In general, less than 140 g/ha (2 ounces per acre) of diflubenzuron is sufficient to control susceptible species, although affected larvae do not die until they molt (Marx 1977).

Most authorities agree that diflubenzuron has low mammalian toxicity, is not highly concentrated through vertebrate food chains or by absorption from water, remains stable on foliage, and seldom persists for extended periods in soil and water (Marx 1977; Ivie 1978; Schaefer et al. 1980). Chitin synthesis inhibitors, however, are not specific to insect pests. Beneficial insects also produce chitin, as do all arthropods, including spiders, crabs, crayfish, lobsters, shrimp, daphnids, mayflies, stoneflies, barnacles, copepods, and horseshoe crabs. All of these groups are adversely affected by diflubenzuron, including effects on survival, reproduction, development, limb regeneration, and population growth (Farlow 1976; Marx 1977; Christiansen 1986; Cunningham 1986; Muzzarelli 1986; Touart and Rao 1987; Weis et al. 1987).

This report was prepared in response to requests for information on diflubenzuron from environmental contaminant specialists of the U.S. Fish and Wildlife Service. It is part of a continuing series of brief reviews on chemicals in the environment, with emphasis on fishery and wildlife resources.

Environmental Chemistry

General

Diflubenzuron breakdown by hydrolysis, soil degradation, or plant and animal metabolism initially yields 2,6-difluorobenzoic acid and 4-chlorophenylurea. Ultimately, the end products are either conjugated into mostly water soluble products or are biologically acylated and methylated. At extremely low doses, diflubenzuron selectively inhibits the ability of arthropods to synthesize chitin at the time of molting, producing death of the organism from rupture of the cuticle or starvation. Other organisms that contain chitin (i.e., some species of fungi and marine diatoms), or polysaccharides similar to chitin (i.e., birds and mammals), seem unaffected.

Mobility and leachability of diflubenzuron in soils is low, and residues are usually not detectable after 7 days. Degradation is most rapid when small-particle (2-5 um) formulations are applied and soil bacteria are abundant. In water, diflubenzuron usually persists for only a few days; degradation is most rapid under conditions of high organic and sediment loadings, and elevated water pH and temperature.

Chemical and Biochemical Properties

Selected Chemical and Biochemical Properties of diflubenzuron are listed in Table 1.

Diflubenzuron degradative pathways are almost entirely through cleavage between the carbonyl and amide groups of the urea bridge. Ultimately, the end products are either conjugated into predominantly water soluble products or are acylated and methylated biologically (Metcalf et al. 1975). Hydrolysis, soil degradation, and plant and animal metabolism of diflubenzuron yield the same initial products: 2,6-difluorobenzoic acid and 4-chlorophenylurea. Soil degradation and plant and animal metabolism involve further conversion of these compounds to 2,6-difluorobenzamide and 4-chloroaniline (Schaefer et al. 1980; Gartrell 1981; Figure).

Table 1. Chemical and other properties of diflubenzuron.[a]

Variable	Data
Chemical names	1-(4-chlorophenyl)-3-(2,6-difluorobenzoyl)urea; N-[[(4-chlorophenyl)amino] carbonyl]-2,6-difluorobenzamide); l-(2,6-difluorobenzoyl)-3-(4-chlorophenyl) urea
Alternate names	Deflubenzon, Diflubenuron, Dimilin, DU 112307, Duphar BV, ENT-29054, Largon, Micromite, OMS 1804, PDD 6040-I, PH 60-40, TH 6040
Action	Insecticide, larvicide, ovicide; insect growth regulator acting by interference with deposition of insect chitin
CAS number	35367-38-5
Empirical formula	$C_{14}H_9ClF_2N_2O_2$
Molecular weight	310.68
Formulations	Granular, oil-dispersable concentrate; wettable powder
Manufacturing process and impurities	Produced by reaction of 2,6-difluorobenzamide with 4-chlorophenyl isocyanate. The technical product is 95% pure. Impurities are of low toxicological concern in terminal residues

Stability	Stable under sunlight and in neutral or mildly acidic solutions; unstable in strong basic solutions.
Physical state	White crystalline solid
Melting point	210—230°C (technical); 230-232°C (pure)
Solubility	
Water	0.1-0.2 mg/L at 20°C; 1.0 mg/L at 25°C
Polar organic solvents	Moderate to good
Octanol/water partition coefficient	3,500

[a] Metcalf et al. 1975; Farlow 1976; Johnson and Finley 1980; Gartrell 1981; Hudson et al. 1984; Mayer 1987; Poplyk 1989.

Interspecies variations in ability to metabolize difluobenzuron are common, as judged by metabolic patterns in rat, cow, and sheep. In all three species hydroxylation of either aromatic ring and scission of the ureido bridge constituted the main metabolic pathways. In cow and rat the prevailing route was ring hydroxylation; in sheep it was the scission reaction. In cow and sheep about half the 2,6-difluorobenzoyl moiety excreted in urine was conjugated to glycine, but in rat the acid was excreted largely unchanged. In sheep, where cleavage splitting of the diflubenzuron molecule was the primary metabolic route, there was no evidence of 4-chlorophenylurea or 4-chloroaniline in urine (Willems et al. 1980). More information on degradation and metabolic pathways of diflubenzuron is given in Metcalf et al. (1975), Schooley and Quistad (1979), Ivie et al. (1980), Willems et al. (1980), Franklin and Knowles (1981), and Jenkins et al. (1986).

Table 2. Diflubenzuron persistence in soil and water.

Sample, initial concentration, and other variables	Persistence	Reference[a]
Soil		
0.08 g/ha, aerial spray, single application	Values always <0.05 mg/kg up to 14 days after spraying	1
22.4 g/ha (0.02 pounds per acre) applied four times, one month between treatments	Residues, in mg/kg, after first treatment were 0.2 at 1 day and 0.016 at 7 days. Residues at time of fourth treatment were nondetectable (ND) at start, 0.01 at 1 h, 0.02 at 1 day, and ND between days 3 and 56	2
44.9 g/ha (0.04 pounds per acre) applied four times, 2 weeks between treatments	Maximum residues, in mg/kg, after first treatment were 0.07 at 1 day and 0.05 at 7 days. After fourth treatment, residues were 0.04 at start, 0.09 at 3 days, and ND between days 7 and 56	2
70, 210, or 630 g/ha applied once to sandy loam forest soil or clay loam forest soil, plus water equivalent to	Mobility of diflubenzuron was low and did not increase with dosage. No residues detected below 10 cm or in leachates in either soil type at all dosage levels. At 70 g/ha, all residues	3

50.8 cm of precipitation	were found in the top 2.5 cm; at 630 g/ha, 4-9% moved below 2.5 cm in sandy loam (mobility was lower in clay loam)	
Distilled water		
100 µg/L, 37°C	No degradation at pH 4 in 8 weeks; Tb 1/2 was about 7 days at pH 6 and <3 days at pH 10. Major degradation products were 4-chloro-phenylurea and 2,6-difluorobenzoic acid; small amounts of 2,6-difluorobenzamide and a quinazolinedione product were also formed	4
Pasture water		
22-45 g/ha (0.02-0.04 pounds per acre), single application	Maximum concentrations, in µg/L, were 8.8 in 1 h, 7.1 in 24 h, 3.9 in 48 h, and 2.6 in 72 h; most treatments produced ND (< 1 µg/L) residues in 24 h	5
45 g/ha (0.04 pounds per acre), single application	Concentrations, in µg/L, were 4 at start, 36 at 1 h, 9 at 24 h, and 6 at 14 days	1
45 g/ha, applied four times at 2-week intervals	Maximum concentrations, in µg/L, were 7.4 at 1 h after first treatment, 1.3 at 1 h after second application, 2.9 at 1 h after third treatment, and 6.4 at 1 h and 0.9 at 1 day after last treatment	1
80 g/ha, single application	Concentrations, in µ,g/L, of diflubenzuron declined from 20.3 at 1 h to 2.4 at 4 days; 4-chlorophenylurea increased slightly from 5.6 to 7.2 during this interval; 4-chloroaniline increased from 0.7 at 1 h to 2.6 at 4 days	6
Pond water		
2.5 µg/L	Concentration after treatment was 1.9 µg/L; after 2 weeks it was 0.5 µg/L	7
5 µg/L	Concentration immediately after treatment was 4.6 µg/L; after 2 weeks it was 0.3 µg/L	7
10 µg/L	Initial concentration in medium declined from 9.8 µg/L to 0.2 µg/L after 2 weeks	7
Seawater		
10 µg/L, sediments present	Tb 1/2 of 5.3 days; <0.7 µg/L in 19 days; <0.5 µg/L in 22 days	8
10 µg/L, sediments absent	Tb 1/2 of 17.8 days	8

100 µg/L	Tb 1/2 of 7.9 days at 38°C, and 35 days at 24°C	9
45 g/ha	Tb 1/2 of 10 days	9

[a] 1, Booth and Ferrell 1977; 2, Schaefer and Dupras 1977; 3, Sundaram and Nott 1989; 4, Ivie et al. 1980; 5, Schaefer and Dupras 1976; 6, Schaefer et al. 1980; 7, Apperson et al. 1978; 8, Cunningham et al. 1987; 9, Cunningham and Myers 1986.

The benzoylphenylureas--including diflubenzuron--control target insect populations at extremely low doses by selectively inhibiting their ability to synthesize chitin-bearing parts. Ingested diflubenzuron has no apparent adverse effects until the molting process is under way.

Diflubenzuron caused increases in cuticle chitinase and cuticle phenoloxidase activity, producing a softened endocuticle through reduction of its chitin content and a hardened exocuticle as a result of increased phenoloxidase activity (Farlow 1976). Diflubenzuron inhibits serine protease, thus blocking the conversion of chitin synthetase zymogen into. an active enzyme (Cunningham 1986; Muzzarelli 1986). Insect larvae treated with diflubenzuron develop cuticles that are unable to withstand the increased turgor occurring during ecdysis and that fail to provide sufficient muscular support during molting. These larvae are unable to cast their exuviae, resulting in death from starvation or rupture of the new, delicate, malformed cuticle (Farlow 1976). In addition to terrestrial insects, diflubenzuron is toxic to a wide variety of aquatic insects and crustaceans (Swift et al. 1988a, 1988b), but it doesn't seem to affect other organisms that contain chitin, including fungi (Muzzarelli 1986) and marine diatoms (Montgomery et al. 1990).

Chitin is a polymer of N-acetylglucosamine (AGA), and it rivals cellulose as the most abundant biopolymer in nature. Measured chitin concentrations in marine waters range between 4 and 21 µg/L, and planktonic crustaceans are the most significant source of chitin in the sea (Montgomery et al. 1990). Insect chitin is synthesized during phosphorylation by uridine disphospho N-acetyl glucosamine (UDPAGA)--the immediate precursor of chitin (Crookshank et al. 1978). Diflubenzuron inhibits the incorporation of chitin precursors into chitin, with a resultant accumulation of UDPAGA (Crookshank et al. 1978). Chitin is not found in vertebrates, although several important polysaccharides similar to chitin are found, including hyaluronic acid (HA). Hyaluronic acid is found in skin: synovial fluid, connective tissue, vitreous humor, and the covering of the ovum. Hyaluronic acid is a polysaccharide compound of alternating groups of glucuronic acid and AGA; the immediate precursor for glucuronic acid is uridine diphospho-glucuronic acid and that for AGA is UDPAGA. Because UDPAGA is used in the synthesis of chitin by insects and of HA by vertebrates, and because diflubenzuron interferes with the incorporation of UDPAGA into chitin by insects, diflubenzuron may interfere with the formation of HA in birds (Crookshank et al. 1978).

Persistence in Soil and Water

Mobility and leachability of diflubenzuron in soils is low, and residues are usually not detectable after 7 days. In water, half-time persistence (Tb 1/2) is usually less than 8 days and lowest at elevated temperatures, alkaline pH, and high sediment loadings (Table 2). Increased concentrations of diflubenzuron in soils and waters are associated with increased application frequency, flooding of treated supratidal areas, wind drift, and excessive rainfall (Cunningham 1986).

Diflubenzuron is persistent in postharvest soils during winter and spring months, especially if associated with plant litter; concentrations decline rapidly with the onset of high summer temperatures to <0.3 mg/kg DW soil in summer (Bull and Ivie 1978; Bull 1980).

Diflubenzuron particle size and soil flora may be important in the soil degradation process. Diflubenzuron adsorbed to smaller particles of 2 µm diameter had a short Tb 1/2 of 3-7 days; diflubenzuron adsorbed to larger particles (10 µm diameter) persisted for 8-16 weeks. Diflubenzuron adsorbed to particles of 2 µm diameter had a low rate of degradation in sterile soils (<6% in 4 weeks), but in nonsterile soils 98% degraded in the same period, suggesting that soil bacteria are important in the degradation process (Cunningham 1986). In Canada, data on mobility of a pesticidal chemical in forest soil must be collected before it can be registered for use under the Canadian Pest Control Products Act in order to assess its potential for groundwater contamination (Sundaram and Nott 1989). Diflubenzuron used properly in forest management is unlikely to be leached into ground water from a site of application (Sundaram and Nott 1989).

Water concentrations of diflubenzuron in treated ponds are significantly higher in surface and middle samples than in bottom samples during the first 5 h after treatment; however, after 24 h, distribution is about the same for all depths (Colwell and Schaefer 1980). Diflubenzuron persists for only a few days in pasture waters at 22-45 g/ha applied to control pasture mosquitos (*Aedes nigromaculis*, *A. melanimon*); hydrolysis and adsorption onto organic matter limit persistence in water (Schaefer and Dupras 1977). Water temperature and pH significantly affect persistence of diflubenzuron, though not always in a linear fashion. Degradation is most rapid at elevated temperatures and alkaline pH values. Half-time persistence of diflubenzuron at pH 7.7 and various thermal regimes is 8 days at 38° C, 35 days at 24°, and 29 days at 10°; at pH 10, Tb 1/2 values are 2 days at 38°, 14 days at 24°, and 32 days at 10°; degradation is negligible at pH 4, and at low temperatures regardless of pH (Cunningham 1986). In water, as in soil, small-particle (2-5 µm diameter) diflubenzuron formulations, such as WP-25%, degrade rapidly, usually in 2-8 days (Cunningham 1986). Larger-particle sand-granule formulations, developed for use in mosquito control programs wherein the compound needs to penetrate thick vegetation to reach the water, reduce drift during application, and also provide slower release of diflubenzuron into aquatic habitats (Cunningham 1986).

The presence of sediments in diflubenzuron marine microcosms results in rapid removal from seawater and ultimately a reduction in mortality of larval crustaceans (Table 2; Cunningham et al. 1987). But marine sediments that exceed 200 g diflubenzuron/kg--levels normally encountered at application rates for control of saltmarsh mosquitos--could be detrimental to juvenile and adult crustaceans that consume detritus and organic matter on the surface of the marsh or at the water-sediment interface (Cunningham and Myers 1986; Cunningham et al. 1987).

Uses

Diflubenzuron effectively inhibits molting in many species of insect pests, especially among the Lepidoptera, Coleoptera, and Diptera. In the United States diflubenzuron was approved for use by the U.S. Environmental Protection Agency (EPA) against the gypsy moth in 1976, the cotton boll weevil in 1979, and foliar feeders on soybeans in 1982. By 1989 diflubenzuron was also registered for domestic use against mosquitos, forest Lepidoptera, mushroom flies, and certain leaf-eating insect pests of citrus, woody ornamentals, vegetables, and fruits (Bull 1980; Nimmo et al. 1980; Gartrell 1981; Cunningham 1986; Muzzarelli 1986; Webb and Wildey 1986; Wilson and Costlow 1987; Martinat et al. 1988; Poplyk 1989).

In Europe and elsewhere diflubenzuron is used in a variety of ways not presently permitted in the United States. For example, diflubenzuron and other insect growth regulators are fed as admixtures to rations of chickens, cattle, and swine in order to control fly larvae breeding in their manures, and also as a spray directly on manures prior to disposal (Opdycke et al. 1982b; Opdycke and Menzer 1984; Giga 1987). Diflubenzuron has been administered orally as a bolus to beef cattle for control of face flies (*Musca autumnalis*) and horn flies (*Haematobia irritans*), two serious pests of cattle in North America; immature insects develop in fresh manure on open pasture. A single bolus released diflubenzuron into feces that killed horn and face fly larvae for 8 weeks and remained partially effective for 16 weeks (Scott et al. 1986).

Three diflubenzuron formulations are now in general use: an oil dispersable concentrate, a wettable powder (WP), and granules (Bull 1980; Cunningham 1986; Poplyk 1989). Granular formulations are produced by applying diflubenzuron to sand granules. Since technical diflubenzuron (99.5% pure) is a crystalline material that is almost insoluble in water (i.e., 0.1 mg/L at 20° C), it is usually dispersed in an organic solvent carrier. Wettable powders (25% active ingredients), however, are dispersed in water for use in many commercial applications; diflubenzuron particle size in WP-25 formulations usually ranges between 2 and 5 microns.

Lethal and Sublethal Effects

General

Diflubenzuron applied to foliage of terrestrial plants tends to remain adsorbed for several weeks with little or no absorption or translocation from plant surfaces; loss is mainly by wind abrasion, rain washing, or shedding of senescent leaves. Among insect species, there is great variability in sensitivity to diflubenzuron. In general, diflubenzuron is toxic to early life stages of insects at concentrations as low as 0.1 mg/kg diet and at topical applications between 0.003 and 0.034 µg per larvae. Among aquatic organisms, early developmental stages of crustaceans and insects are the most sensitive groups tested; adverse effects on growth, survival, reproduction, and behavior occur between 0.062 and 2.0 µg/L. Groups highly resistant to diflubenzuron include the algae,

gastropods, fishes, and amphibians. Birds are comparatively resistant: acute oral LD50 values exceed 2,000 mg diflubenzuron per kg body weight (BW), and dietary levels of 4,640 mg/kg ration are tolerated for 8 days. Also, forest birds seem unharmed by recommended diflubenzuron application procedures to control pestiferous insects. No data are available on mammalian wildlife. However, studies with small laboratory animals and domestic livestock suggest a high degree of resistance. No observable adverse effects occur in cows given 0.25 mg/kg BW daily for 4 months, in rabbits given 4 mg/kg BW daily on days 6 to 18 of gestation, in dogs fed diets containing 40 mg/kg for 13 weeks (equivalent to 1.6 mg/kg BW daily), in rats fed diets containing 160 mg/kg for 2 years, and in rabbits and rodents given single oral or dermal doses <2,000 mg/kg BW. All of these points are discussed later.

Terrestrial Plants

There is little to no absorption and translocation of diflubenzuron residues from plant surfaces (Gartrell 1981). Due to its stability and low volatility, diflubenzuron residues adhering to plant surfaces are removed primarily through physical effects such as wind abrasion, rain washing, or the loss of dead leaves (Bull 1980). A greenhouse study with corn (*Zea mays*), soybeans (*Glycine max*), cabbage (*Brassica oleracea capitata*), and apples (*Malus* sp.) showed no significant degradation of diflubenzuron residues in leaves for up to 16 weeks after treatment (Gartrell 1981). In a study with radiolabeled diflubenzuron a single dose applied to a cotton (*Gossypium hirsutum*) leaf showed <5% photodegradation in 4 weeks, <7% absorption in 7 weeks, <50% loss to weathering or volatilization in 4 weeks in samples not exposed to rain, and 77% loss in 3 weeks after a heavy rainfall (Bull and Ivie 1978; Bull 1980). Edible portions of rotational crops treated repeatedly with diflubenzuron at recommended application level shad low, but detectable, residues. Maximum concentrations, in mg/kg DW, were always <0.01 in wheat (*Triticum* spp.), <0.02 in cotton, <0.09 in collards (*Brassica* spp.), and <0.16 in radish (*Raphanus* spp.; Bull and Ivie 1978; Bull 1980).

Foliage of cotton that initially contained 100 mg/kg DW contained about 60 mg/kg after 7 weeks; leaf residues consisted entirely of the parent diflubenzuron (Gartrell 1981).

Diflubenzuron applied topically to lima bean (*Phaseolus lunatus*) foliage was not absorbed by the plant, as expected. Injected diflubenzuron, however, was metabolized, and certain of the metabolites were similar to those isolated from mites (Franklin and Knowles 1981).

Diflubenzuron mixed into compost layers of the cultivated mushroom (*Agaricus bisporus*) at 30 mg/kg compost to control dipteran pests of mushroom resulted in increased yield and size; however, at higher concentrations of 180 mg/kg and 1,080 mg/kg, mushroom yield and number were reduced, and this became more severe over time (White 1986). Frequent applications of diflubenzuron to agricultural soils are not detrimental to nitrogen-fixing bacteria (i. e., *Azotobacter vinelandii*), and high concentrations could stimulate nitrogenase activity in soils. This conclusion is based on a study by Martinez-Toledo et al. (1988) using nonsterile agricultural soils and sterilized soils inoculated with *A. vinelandii*. At diflubenzuron loadings between 100 and 500 mg/kg, all concentrations tested had a stimulatory effect on nitrogen fixation in both soils.

Terrestrial Invertebrates

Diflubenzuron is most toxic to early life stages of some insects at 0.1 mg/kg diet, 0.034 µg per larvae (about 3.1 mg/kg BW), or in combination with various chemicals (Table 3). Some beneficial insects, such as the honey bee (*Apis mellifera*), are adversely affected at dietary concentrations of 1 mg/kg for 12 weeks, 10 mg/kg for 10 weeks, or 59 mg/kg for 10 days (Table 3). At 28 to 56 g/ha (0.025 to 0.05 pounds per acre), diflubenzuron effectively controls mosquitos for 8-15 days (Booth and Ferrell 1977; Schaefer and Dupras 1977), especially organophosphorus insecticide-resistant strains of saltmarsh mosquitos in California (Lee and Scott 1989). Diflubenzuron was also effective in controlling strains of house fly (*Musca domestica*) that were resistant to organochlorine, organophosphorus, carbamate, and pyrethroid insecticides on a United Kingdom pig farm; 416 mg/m^2 to slurry pots of pig weaning rooms gave effective control 2-4 weeks after application (Webb and Wildey 1986).

Table 3. Diflubenzuron effects on selected terrestrial invertebrates.

Organism, dose, and other variables	Effect	Reference[a]
Nematode, *Acrobeloides* sp.		
Fed diet containing 100 mg/kg for 10 days	Population reduction of 97%	1
Boll weevil, *Anthonomus grandis*		
1 µg per female weevil, applied topically	After 8 days, about 62% was not absorbed, 3% was absorbed, and 35% was metabolized and excreted	2
113.4 g/ha, applied five times during winter	Reduced heavy infestations by >70% in upper Gulf coast area of Texas	3
Honey bee, *Apis mellifera*		
Fed sucrose syrup/sugar cake diets containing 0.01, 0.1, 1 or 10 mg/kg for 12 weeks	Adult colony survival reduced at 10 mg/kg; inhibited reproduction at 1 and 10 mg/kg; no measurable effect on survival or reproduction at 0.01 or 0.1 mg/kg	4
Fed diet containing 10 mg/kg for 10 weeks	No reduction in consumption of pollen or in quantity of brood reared, but >50% reduction in amount of sucrose syrup stored	5
Fed sucrose syrup containing 59 mg/kg for 10 days	Inhibited reproduction	6
Fed sucrose syrup containing 60 mg/L and drinking water containing 100 mg/L for 40 days	Treated bees consumed significantly less water and pollen and produced significantly less comb, brood, and new workers	7
German cockroach, *Blattella germanica*		
Nymphs fed diets containing 4, 20, 100, or 500 mg/kg for 4 weeks	None dead at 4 mg/kg, 15% at 20 mg/kg, 88% at 100 mg/kg, and all dead at 500 mg/kg	8
Common green lacewing *Chrysopa carnea*		
0.5 g/L spray	Reduced incubation period, reduced hatch, and reduced survival	9
2.0 g/L spray	No hatch	9
Termite, *Coptotermes heimi*		
Nymphs fed diets containing 100, 500, or 1,000 mg/kg	All dead in 24 days at 100 mg/kg, 20 days at mg/kg, or 16 days at 1,000 mg/kg. Some nymphs developed blister-like swellings on the abdomen and failed to molt into the next instar	10
Mosquito, *Culex pipiens quinquefasciatus*		

Adults fed 500 or 1,000 mg/kg diet for 2 days	At both doses, 40% of eggs failed to hatch or hatched abnormally; at the high dose, ovarian histopathology recorded	11
Cat flea, *Ctenocephalides felis*		
Larvae, held in rearing medium for 5-6 weeks		
90 µg/kg	LC 50, 1.5-day-old larvae	12
2,220 µg/kg	LC 50, 2.5-day-old larvae	12
> 100 mg/kg	LC 50, 3.5-day-old larvae	12
Termite, *Heterotermes indicola*		
Nymphs fed diets containing 100, 500, or 1,000 mg/kg feed	All dead in 14-16 days at 100-1,000 mg/kg diet	10
Gypsy moth, *Lymantria dispar*		
100 µg/kg diet	100% lethal to larvae	13
Cabbage moth, *Mamestra brassicae*		
2.2 mg/L spray	LC90, third instar larvae	14
Nematodes, various species		
Fed diet containing 1 mg/kg for 10 days	No effect on reproduction	1
Fed diet containing 10 mg/kg for 10 days	53% population reduction in *Panagrellus redvirus*, and 95% reduction in *Pelodera* sp.	1
American cockroach, *Periplaneta americana*		
Nymphs fed diets containing 100 or 800 mg/kg for 4 weeks	17% dead at low dose and 52% dead at high dose	8
Large white butterfly, *Pieris brassicae*		
0.39 mg/L spray	LC50, third instar larvae	14
Cotton leafworm, *Spodoptera littoralis*, fourth instar larvae, topical application		
3, 10, 30, or 100 ng per larva	Incorporation of N-acetyl glucosamine into chitin was inhibited by 23% at 3 ng per larva, 75% at 10 ng, 90% at 30 ng, and 98% at 100 ng	14
34 ng per larva, equivalent to 3.1 mg/kg BW	LD50, applied in combination with profenofos	15
468 ng per larva, equivalent to 42.5 mg/kg BW	LD50	15
4.3 mg/L, spray	LC90, third instar larvae	14
Termites		
Nymphs, 3 species, given 100-1,000 mg/kg diet	All dead in 14-24 days	10

Adults, 2 species, given 1,000 mg/kg diet	Fecundity reduced and eggs failed to develop	10

[a] 1, Veech 1978; 2, Bull 1980; 3, Cole 1980; 4, Stoner and Wilson 1982; 5, Nation et al. 1986; 6, Muzzarelli 1986; 7, Barker and Waller 1978; 8, Tsuji and Taneike 1988; 9, Zaki and Gesraha 1987; 10, Ahmad et al. 1986; 11, Mittal and Kohli 1988; 12, El-Gazzar et al. 1988; 13, Martinat et al. 1988; 14, Grosscurt et al. 1988; 15, El Saidy et al. 1989.

Chemical control of larvae of gypsy moth and other forest-insect defoliators may cause indiscriminate reduction of nontarget arthropods, which, in turn, may affect food resources of forest birds and small mammals. This problem is of special concern in West Virginia, where two species of endangered bats (Indiana bat, *Myotis sodalis*; eastern big-eared bat, *Plecotus phyllotis*) occur in areas threatened by gypsy moth defoliation (Martinat et al. 1988). Diflubenzuron applications, usually at 70 g/ha on 2 consecutive days, controlled gypsy moth larvae and also significantly reduced populations of canopy macrolepidoptera and nonlepidopteran mandibulate herbivores. Sucking herbivorous insects, microlepidoptera, and predaceous arthropods, however, were relatively unaffected, which suggests that although diflubenzuron can potentially affect food supply of forest birds and small mammals, these effects are probably minimal (Martinat et al. 1988).

Researchers generally agree that diflubenzuron causes incomplete ecdysis by interfering with chitin synthesis. However, diflubenzuron at lethal concentrations causes an effect in chironomid larvae (*Chironomus decorus*, *Tanypus grodhausi*) other than inhibition of chitin synthetase, as judged by histopathology of the alimentary canal--especially the ventriculus. Dysfunction of the ventriculus, an organ that normally lacks chitin, results in a general breakdown of the digestive apparatus of exposed chironomid larvae (Pelsue 1985).

Exposure of nematodes and of adults of several insect species, including boll weevil, housefly, and stable fly (*Stomoxys calcitrans*), to diflubenzuron results in deposition of eggs that appear normal but fail to hatch. This effect seems to be due to an ovicidal action and not to sterility of the treated adults, since the larvae appear to undergo normal development within the egg. Secretion of unmetabolized diflubenzuron into the eggs apparently accounts for observed ovicidal effects (Ivie and Wright 1978; Veech 1978; Ivie et al. 1980). Treated female boll weevils began to lay viable eggs 12 days after treatment and became as productive as controls in 24 days; additional treatment is required to maintain a significant suppression of egg hatch (Bull 1980).

Diflubenzuron is the most investigated benzoylphenylurea and has shown excellent potency for controlling mosquitos and certain lepidopterous and coleopterous pests. Some insect species, however, cannot be controlled efficiently by diflubenzuron. For example, the cotton leafworm (*Spodoptera littoralis*) is comparatively resistant because of reduced penetration through the exoskeleton, rapid elimination of unchanged diflubenzuron, and rapid metabolism, which occurs mainly through hydrolysis (El Saidy et al. 1989). To combat Spodoptera and other resistant pests, new benzoylphenylurea compounds have been developed, including chlorfluzuaron, teflubenzuron, and hexafluron (El Saidy et al. 1989).

Beneficial insects associated with fruit orchards show different responses to diflubenzuron treatment (Broadbent and Pree 1984). Lacewings (*Chrysopa oculata*) in contact with leaves containing 300 mg/kg DW had reduced survival and inhibited molting of first instar larvae, but the assassin bug (*Acholla multispinosa*) was not affected by contact with treated leaves. Lacewings and other beneficial predator insects fed diflubenzuron-treated twospotted spider mites (*Tetranychus urticae*) for 3 days showed no adverse effects after 14 days (Broadbent and Pree 1984). Spraying of diflubenzuron at 28 g/ha to control gypsy moth did not affect *Cotesia melanoscela*, a hymenopteran predator of the gypsy moth; however, another natural enemy, a virus, was adversely affected (Webb et al. 1989). Certain arthropod predators were unaffected by diflubenzuron at 70 mg/ha applied four times in 3 weeks to control the boll weevil; these include the convergent lady beetle (*Hippodamia convergens*), the bigeyed bug (*Geocoris punctipes*),and various species of *Coleomegilla*, *Orius*, *Nabis*, and *Chrysopa* (Deakle and Bradley 1982).

Diflubenzuron can be either hydrolyzed at the urea bridge or oxidized by ring hydroxylation followed by conjugation. Hydrolytic cleavage seems to be a major route for diflubenzuron metabolism in many insect species (El Saidy et al. 1989). Two-spotted spider mites showed <10% absorption in 96 h of topically applied diflubenzuron. Of the amount absorbed about 27% was metabolized in 96 h to 4-chlorophenyl urea, 2,6-

difluorobenzoic acid, 4'-chloroformanilide, 2,6-difluorobenzamide, and other metabolites (Franklin and Knowles 1981). Effects of diflubenzuron were synergized by profenofos (El Saidy et al. 1989) in cotton leafworm 4th instar larvae, and they were antagonized by 20-hydroxyecdysone (Soltani et al. 1987) in yellow mealworm beetle (*Tenebrio molitor*) pupae. More information is needed on interaction effects of diflubenzuron with other chemicals.

Aquatic Organisms

Laboratory Studies

Studies with diflubenzuron and representative aquatic organisms under controlled conditions (Table 4) show several trends:

1. Crustaceans are the most sensitive group of nontarget organisms tested--adverse effects on growth, survival, reproduction, and behavior of copepods, shrimp, daphnids, amphipods, and crabs occur between 0.062 and 2.0, µg/L medium, and early developmental stages were the most vulnerable;

2. Next in sensitivity are aquatic insects, including mayflies, chironomids, caddisflies, and midges--diflubenzuron concentrations between 0.1 and 1.9 µg/L medium produce low emergence and survival;

3. Other groups tested are comparatively resistant, that is, adverse effects occur at <45 µg/L -- in fish, for example, death occurred at >33,000 µg/L; and

4. Elevated accumulations occur in aquatic plants during exposure to 100 µg/L and in fish during exposure between 1 and 13 µg/L. All species in these groups, however, seemed unaffected by elevated body burdens, as judged by normal growth and metabolism.

Table 4. Diflubenzuron effects on selected aquatic organisms: laboratory studies.

Taxonomic group, organism, and concentration in medium in µg/L (ppb)	Effect	Reference[a]
Algae and macrophytes		
Diatom, *Cyclotella cryptica*		
5,000	No effect on photosynthesis during 14-day exposure	1
Bluegreen alga, *Plectonema boryanum*		
100	Residues, in µg/kg dry weight, during exposure for 4 days were 144,700 at 1 h, 85,700 at 1 day, 56,900 at 2 days, 11,700 at 3 days, and 8,300 at 4 days; *Plectonema* growth rate was unaffected	2
Alga, *Selenastrum capricornutum*		
45	No effect on growth during exposure for 120 h	3
Diatoms, 3 species (*Skeletonema costatum*, *Thalassiosira nordenskioldi*, *T. weissflogii*)		
1,000	No effect on photosynthesis during exposure for 11-14 days	1

5,000	Photosynthesis inhibited 70-80% in 11- to 14-day exposure	1
Coelenterata		
Hydra, *Hydra oligactis*		
0.1-0.12 (estimated)	After 24-h exposure, asexual budding rate significantly increased over controls during 20-day posttreatment period; some histopathology. Second generation hydras not significantly different from controls	4
Platyhelminthes		
Planarian, *Dugesia dorotocephala*		
5	No effect on survival, behavior, or asexual reproductive capacity after 24-h exposure	23
Aquatic insects		
Mosquito, *Aedes aegypti*, fourth instar larvae		
20 (equivalent to 0.056 kg/ha)	Fatal to 100% within 24 h, about 50% after 4 days, and <20% after 8 days	5
Mosquito, *Aedes albopictus*		
0.00025	LC30 (24 h), second instar larvae	6
0.0028	Adult emergence inhibited when second instar larvae exposed for 24 h	6
0.025	LC67 (24 h), second instar larvae	6
0.125	Histopathology of cuticle and anal gills in fourth instar larvae after 24-h exposure of third instar larvae	6
0.21	Adult emergence inhibited when third instar larvae exposed for 24 h	6
0.25	LC67 (24 h), third instar larvae	6
12.5	No histopathology of fourth instar larvae after 24-h exposure	6
25	LC 16 (24 h), fourth instar larvae	6
39.6	Adult emergence inhibited when fourth instar larvae exposed for 24 h	6
Mosquito, *Aedes nigromaculis*		
0.5	LC50 (48 h), larvae	7
Aquatic beetles *Hydrophilus triangularis*		
100	LC50 (48 h), larvae	7
Laccophilus spp.		
250	No deaths of adults in 216 h	7
Thermonectus basillaris		

250	No deaths of adults in 168 h	7
Tropisternus lateralis		
250	No deaths of adults in 48 h	7
Mayfly, Callibaetis sp.		
10	LC90 (168 h), nymphs	7
Chironomid, *Chironomus decorus*, fourth instar		
1.9	LC50	8
6.0	LC90	8
Midge, *Chironomus plumosus*		
560	50% of larvae immobilized in 48 h	9, 10
Caddisfly, *Clistoronia magnifica*		
0.1	Adult emergence inhibited during 4-week exposure	11
Midge, *Cricotopus* spp.		
1.6	No adult emergence in 96-h exposure	11
4.9	Molting and survival adversely affected during exposure for 96 h	11
Mosquito, *Culex pipiens* exposed as fourth instar larvae for 24 h		
8	50% reduction in adult emergence	12
100	74% reduction in adult emergence	12
1,000	No adult emergence	12
Mosquito, *Culex pipiens quinquefasciatus*		
1.0	Fourth instar larval dip had no effect on adult sterility	13
Chironomid, *Glyptotendipes paripes*, fourth instar		
1.8	LC50	8
4.1	LC90	8
Midge, *Goeldichironomus holoprasinus*		
10	LC90 (168 h), larvae	7
Dragonflies, *Orthemis* spp., *Pantala* sp.		
50	LC50 (168 h)	7
Blackfly, *Simulium vittatum*, larvae		
80 for 30 min at various water		

temperatures		
10°C	50% dead in 21 days	14
20°C	53% dead in 13 days	14
25°C	92% dead in 3 days	14
500 for 15 min	98% dead in 18 days at 10.5°C	14
1,000 for 30 min	All dead in 10 days at 15°C	14
Stonefly, *Skwala* sp.		
57,500	LC50 (96 h)	15
Midge, *Tanytarsus dissimilis*		
1.0	LC50, period between second and third instar larvae	3
4.9	Molting and survival adversely affected during 5-day exposure	11
Arachnoids		
Horseshoe crab, *Limulus polyphemus*		
5	Larvae exposed for 24 days showed slight delay in molting at 14 days; survival as in controls	6
50	Larvae exposed for 24 days showed molt rate as in controls, but high mortality immediately after ecdysis; reduced growth of survivors	16
Molluscs		
Clam, *Anodonta cygnea*		
200,000	After exposure for 3 months, all clams survived and appeared healthy. But normal calcification process disrupted on lamellar layer of the shell, producing fragile shell	17
Snail, *Juga plicifera*		
36—45	No effect on survival, growth, or reproduction during 3-week exposure	3,11
Snails, *Physa* spp.		
45	No measurable effect on growth, survival, or reproduction during 3-week exposure	3,11
Crustaceans		
Copepod, *Acartia tonsa*		
Adults exposed following terminal molt		
1	Hatch of viable nauplii reduced by 50% after 12-h exposure; no hatch after 36-h exposure. Effect not reversible for at least 30 h after exposure	18
10	Hatch of nauplii reduced by >95% after exposure for 24 h and 100% after 36 h. Effect not reversible for at least 26 h after exposure	18
100	No effect on egg production during 14-day	18

	exposure	
1,000	No adverse effect on survival during exposure for 5 days	18
Brine shrimp, *Artemia salina*		
Adults exposed to 1, 2, 5, or 10	During exposure for 80 days, there was a significant reduction in reproductive lifespan at 2, 5, and 10 µg/L. Nauplii produced viviparously by mated pairs were comparable to controls--except for the 10 µg/L group, which produced fewer nauplii. Cysts produced oviparously by treated pairs, however, had lower mean hatch-ability	19
Nauplii exposed to 1, 10, or 100	All dead within 30 days in the 100 µg/L group; survival same as controls in 12 days for the 1 and 10 µg/L groups	19
Barnacle, *Balanus eburneus*		
50	Some deaths when exposure exceeds 10 days	20
50-100	Significant acceleration of intermolt cycle at low dose, and among survivors at high dose	21
100	No deaths of adults in 28 days	21
750 or 1,000	High mortality during 10-day exposure; prolonged premolt; histopathology of cuticle-secreting epidermal cells	20
1,000 for 48 h plus clean seawater for 26 days	No deaths of adults	21
1,000 for 72 h plus clean seawater for 25 days	High mortality of adults, especially on days 7-14 postexposure	21
Copepods, 2 species		
100	Negligible mortality in 144 h	7
Blue crab, *Callinectes sapidus*		
1	High survival of megalops	22
3	Low survival of megalops	22
Ostracods, *Cypicerus* sp., *Cypridopsis* sp.		
500	Negligible mortality in 72 h	7
Daphnid, *Daphnia magna*		
0.062	Survival and reproduction adversely affected in full life cycle (21-day exposure)	3
2	All dead within 6 days	11
4.4-15	50% immobilized or dead in 48 h	3,9,10,15
Daphnids, 2 spp.		

1.5	LC50 (48 h)	7
Clam shrimp, *Eulimnadia* spp.		
0.15	LC50 (48 h)	7
Copepod, *Eurytemora affinis*		
0.75-1.00	MATC[b]	49
2.2	LC50 (48 h) for nauplii	49
Scud (amphipod), *Gammarus pseudolimnaeus*		
25-45	LC50 (96 h)	9,10,15
1,000	After exposure for 30 min, 22% dead in 55 days at 15°C	14
1,000	After 30-min exposure, 91% dead in 9 days at 25°C	14
Amphipod, *Hyalella azteca*		
1.8	LC50 (96 h)	3
2	LC60 (96 h)	11
1,000	After 30-min exposure, 3-7% dead in 19-21 days at 15°C	14
1,000	After 30-min exposure, 62-99% dead in 7-12 days at 25°C	14
Stone crab, *Menippe mercenaria*		
0.5	LC50 (48 h), larvae	22,24
Copepod, *Mesocyclops thermocyclopoides*		
1-15	Impaired fertility of ovigerous females	25
2-1,000	Prolongation of copepodite stage for 3-4 days followed by death without molting, in most cases. At 125 µg/L and higher, partial molting occurred but all died	25
500	No larval deaths in 48 h	25
1,000	LC50 (48 h) for copepodites. No effect on mating behavior of adults but abnormal ovisac development and decreased fecundity in some females	25
Mysid shrimp, *Mysidopis bahia*		
0.075	Reduction in number of young per female after exposure for 21 days	26
0.075	Reduced survival and reproductive success after exposure for 28 days	24
1.2	LC50 (21 days)	26
1.9	Exposure for 24 h resulted in 65% mortality 3 days after treatment; progeny produced before death had a significantly lower reproduction rate than	27

	controls, as did those in the next generation at nanogram/L (ppt) concentrations	
2.0-2.1	LC50 (96 h)	24,26,27,28
Grass shrimp, *Palaemonetes pugio*		
0.1-0.5	No effect on duration of molt cycle, but dose-related inhibition of regenerative limb growth noted (EC50 = 0.11 µg/L for left 5th periopod)	29
0.3-0.5	MATC[b]	30
0.3-0.5	Loss of positive phototaxis in embryos exposed for 96 h	31
0.3-1.0	Dose-dependent increase in swimming speed in light-adapted larvae	30
0.65	LC50 (7-14 days) intermolt-molt stage; deaths noted during or immediately after molting	29
<1.0	Almost all larvae that survived to day 15 eventually metamorphosed successfully to postlarvae	32
1.0 (initial), medium aged for 71 days, with or without sediments	No deaths of larvae in 22 days when sediments present; all larvae died within 22 days when sediments absent	34
1.0	Limited vertical migration of larvae	30
1.1	LC50 (96 h), early premolt stage	29
1.4	LC50 (96 h) larvae, 95% confidence interval (CI) 1.27-1.54, for wettable powder (WP-25) in water	32
1.6	LC50 (96 h), postlarvae	33
1.8	LC50 (96 h), larvae, 95% CI for technical grade in acetone is 1.64-2.08	32
2.5	All dead by day 15 regardless of formulation tested	32
2.5-5	Morphological abnormalities, both positive and negative phototaxis suppressed	29
3.4	LC50 (24-h exposure, held until molting complete in 24-48 h)	29
202	LC50 (96 h), adult males and nonovigerous females	33
2,000	Negligible mortality of late premolt stage during exposure for 96 h	29
6,985	LC50 (96 h), adult ovigerous females	33
Crab, *Rithropanopeus harrisii*		
0.05	No effect on positive phototaxis response of stage IV larvae	35
0.1	Reduced positive phototaxis of stage IV larvae	35
0.3-0.5	Increased swimming speed of stage I, II, and III larvae	35

0.5	No adverse effects on larval survival during exposure for 20 days	36
1.0	Decreased larval survival during 20-day exposure	36
10	All larvae died during 32-day exposure in containers without sediments; containers with sediments were no longer toxic after 19 days	34
Crab, *Sesarma reticulatum*		
1	No adverse effects on larval survival during 40-day exposure	36
3	Decreased larval survival during 40-day exposure	36
10	All larvae died during 40-day exposure	36
Copepod, *Tigriopus californicus*		
0.1-100	During 72-day exposure, no adverse effects were noted on adult survival and juvenile development at 0.1 µg/L. Reproduction was inhibited at 1 and 5 µg/L. Copepods exposed to 10 or 100 µg/L did not reproduce, were moribund, and had decreased survival.	1
Tadpole shrimp, *Triops longicaudatus*		
0.75	LC40 (24 h)	7
Fiddler crab, *Uca pugilator* Juveniles exposed for 24 h once a week for 10 weeks, then held in clean seawater for an additional 14 weeks		
0.2	No adverse effects on survival or ability to escape from test containers	37
2	No effect on survival, but reduced ability to escape from container	37
20	All died in 23 weeks; reduced mobility prior to death	37
200	All dead in 8 weeks; most deaths occurred in first 4 weeks	37
Adults exposed to 0.5, 5, or 50 after multiple autotomy of one chela and 5 walking legs	Continuous exposure for 18 days produced a dose-dependent retardation of regeneration and deaths during molt at 5 and 50 µg/L. The presence of sediment in test containers lessened effects, but did not eliminate them	38
Adults exposed for 13 weeks		
0.5-50	Some reduction in number of burrows dug at 15 and 60 min after exposure	39
Unknown	Burrowing activity normal on sediments	39

	containing 1 mg/kg	
Fish		
Mummichog, Fundulus *heteroclitus*		
29,800	No deaths in 96 h	40
33,000-255,000	LC50 (96 h)	5,40
Mosquitofish, *Gambusia affinis*		
Unknown	Fish exposed to radiolabeled diflubenzuron for 33 days contained about 6% of the parent diflubenzuron vs. 54% for alga (*Oedogonium cardiacum*), 82% for snail (*Physa* sp.), and 94% for larvae of mosquito (*Culex pipiens quinquefasciatus*)	42
200 for 8 days followed by 300 until day 14	Fish were 2.5 x more hyperactive than controls within 2 days, four times more during days 4-8, and no different from controls at day 14	43
1,000	No deaths in 10 days	7
Brown bullhead, *Ictalurus nebulosus*		
13.2 in pond surface layer 1 h after treatment, <0.2 after 14 days	Maximum concentrations, in µg/kg whole body fresh weight (FW), were 387 at day 1,190 at day 2, 42 at day 4, and ND at day 7	44
Channel catfish, *Ictalurus punctatus*		
Unknown	Runoff from soil containing 0.55 mg diflubenzuron/kg at start produced maximum residues during 28 days, in µg/kg FW, of 4 in muscle and 10 in viscera	2
>100,000	LC50 (96 h)	10,15
370,000	LC50 (96 h)	9
Bluegill, *Lepomis macrochirus*		
1-10	Bioconcentration factor of 13-20 times after 24-h exposure	45
10	After exposure for 24 h, residues 24 and 48 h later were 848 and 8 µg/kg FW whole fish (less tail and viscera)	45
200 (initial); diflubenzuron concentrations ranged from 1.3 to 5.1 between 3 h and 19 days; for 4-chlorophenylurea they were 0.6-3.1, and for 4-chloroaniline they were <0.1-0.4	Maximum concentrations in µg/kg whole fish FW, for diflubenzuron were 119 at 3 h, 812 at 1 day, 55 at 5 days, 196 at 12 days, and 86 at 19 days. For the metabolite 4-chlorophenylurea, these values were 1.6 at 3 h, 8 at 1 day, 40 at 50 days, and 33 at 19 days; and for 4-chloroaniline, 0.8 at 3 h, 2.1 at 1 day, and 1.1-1.3 for days 5-19	46
135,000-660,000	LC50 (96 h)	5,9
Cutthroat trout, *Oncorhynchus clarki*		
57,000-75,000	LC50 (96 h)	10,15

Coho salmon, *Oncorhynchus kisutch*		
150,000	No deaths in 96 h	47
1,000,000	No deaths in 96 h after 15-min exposure	47
Rainbow trout, *Oncorhynchus mykiss*		
29-300	No adverse effects on eyed eggs or fingerlings in 30-day flowthrough exposure	10
625-10,000	Dose-dependent decrease in serum glutamate oxalacetate transaminase (GOT) activity in 96 h, but values overlapped normal GOT range from this hatchery	50
150,000	No deaths in 96 h	47
240,000 (95% CI 201,000-286,000)	LC50 (96 h)	9, 10
1,000,000	No deaths in 96 h after 15-min exposure	47
Yellow perch, *Perca flavescens*		
>>50,000	LC50 (96 h)	15
Fathead minnow, *Pimephales promelas*		
36-45	Embryo-larval exposure for 30 days had no effect on survival, egg hatch, or growth	3,11
>100,000	LC50 (96 h)	10,15
430,000	LC50 (96 h)	9
White crappie, *Pomoxis annularis*		
5 (nominal), 3.3 (measured), 0.4 after 5 weeks	Whole body residues, in µg/kg FW, were 133 at 1 day, 355 at 4 days, 197 at 14 days, and 62 at 21 days	48
10	Fish exposed for 24 h in uncontaminated media contained 822 µg/kg FW whole fish less tail and viscera. Exposure for 48 or 72 h plus 24 h in uncontaminated media produced residues of 533 and 630 µg/kg FW	45
Atlantic salmon, *Salmo salar*		
10	Avoided medium when given choice in 10-min trials	41
>50,000	LC50 (96 h)	15
Brook trout, *Salvelinus fontinalis*		
>50,000	LC50 (96 h)	15

[b] Maximum acceptable toxicant concentration. Lower value in each pair indicates highest concentration tested producing no measurable effect on growth, survival, reproduction, or metabolism during chronic exposure; higher value indicates lowest concentration tested producing a measurable effect.

The major degradation products of diflubenzuron in water are 4-chlorophenylurea and 2,6-difluorobenzoic acid (Metcalf et al. 1975; Ivie et al. 1980); these compounds are less toxic to aquatic organisms than the parent chemical (Julin and Sanders 1978; Schaefer et al. 1979, 1980; Gattavecchia et al. 1981). A minor metabolite, 4-chloroaniline, which is classified as a mutagen by the National Cancer Institute and the Cancer Assessment group of the U.S. Environmental Protection Agency (Schaefer et al. 1980), is significantly more toxic to fish and *Euglena gracilis* than is diflubenzuron. For example, LC50 (96 h) values for 4-chloroaniline and four species of freshwater teleosts are 16 to 56 times lower than comparable data for diflubenzuron, but 4-chloroaniline is 76 times less toxic to *Chironomus* midge larvae in 48 h than diflubenzuron (Julin and Sanders 1978). There is a dose-dependent effect of 4-chloroaniline on *Euglena* growth inhibition and glycine metabolism in the range of 1-200 mg/L during exposure for 30 h (Gattavecchia et al. 1981). The most sensitive organism to 4-chloroaniline is bluegill (*Lepomis macrochirus*) with an LC50 (96 h) value of 2.3 mg/L (Julin and Sanders 1978). It is unlikely, however, that this concentration will be encountered under current diflubenzuron application practices.

Diflubenzuron inhibits several enzyme systems in crab and insect larvae, resulting in disrupted glucose metabolism, reduced N-acetylglucosamine incorporation into cuticle, and ultrastructural deformities of chitinous components of the cuticle (Christiansen and Costlow 1982; Christiansen et al. 1984; Christiansen 1986). Specifically, diflubenzuron inhibits chitin synthetase, a magnesium-requiring enzyme that catalyzes the transfer of N-acetyl-D-glucosamine to chitin; the final result is relatively large accumulations of N-acetylglucosamines (Horst 1981; Machado et al. 1990).

Diflubenzuron acts specifically on insects and crustaceans as a larvicide by interfering with chitin deposition into cuticles during juvenile development through ecdysis (Horst 1981; Antia et al. 1985; Cunningham 1986; Machado et al. 1990). The biosynthesis of chitin in arthropods is under hormonal control. Arthropods increase in size by resorbing a portion of the shell and initiating the secretion of a new exoskeleton under the old cuticle. At this time, chitin synthesis is maximal. After completion of about half the new shell, molting occurs, the old shell is discarded, and the new shell is synthesized. Diflubenzuron exposure produces disturbances in the cuticular structure, weakening the cuticle so that it fails mechanically during ecdysis of insects and crustaceans. In general, treated larvae appear healthy during the entire intermolt period until molting commences, at which time many larvae are unable to cast their molts completely and die within a few hours. Several genera of diatoms, including *Thalassiosira* and *Skeletonema*, produce up to 33% of their biomass as chitin. These diatoms synthesize chitin strands that extend outside their frustules to increase buoyancy (Montgomery et al. 1990). Chitin-producing diatoms, as well as nonchitanaceous diatoms, seem unaffected at elevated concentrations of 1 mg/L for periods up to 14 days (Antia et al. 1985). Some species of algae, especially *Plectonema boryanum*, are reported to efficiently degrade diflubenzuron (Schooley and Quistad 1979), but this requires verification.

Studies with laboratory stream communities dosed for 5 months confirm that insects and crustaceans are the most severely affected groups; adverse effects occur in the range 1.0-1.1 µg diflubenzuron per L. Fish and molluscs, however, show no adverse effects at 45 µg/L (Hansen and Garton 1982). Freshwater clams (*Anodonta cygnea*) exposed to high concentrations of diflubenzuron for lengthy periods may experience blocked polycondensation reactions to chitin chains in the outer mantle epithelium secretory cells, producing unstabilized chitin and increasing shell fragility. On this basis the comparatively resistant burrowing bivalve molluscs may be at risk if exposed over several calcification periods (Machado et al. 1990).

Fish accumulated diflubenzuron from water up to 160 times water levels, but tissue concentrations during exposure declined steadily over time (Schaefer et al. 1980).

Exposure of *Aedes albopictus*, a mosquito vector of dengue and encephalitis in Taiwan, for 24 h to 0.00025 to 25 µg/L diflubenzuron resulted in dose-dependent aberrations in larvae, pupae, and adults (Ho et al. 1987; Table 4). In general, most treated second and third instar *Aedes* larvae died during molting, while most fourth instar larvae developed abnormally (Ho et al. 1987). Unfortunately, levels of diflubenzuron used to control saltwater mosquitos and other insects are also toxic to zoeal stages of crustaceans (Costlow 1979) and adversely affect growth and reproduction of adults (Muzzarelli 1986). Treated larvae of estuarine crustaceans are characterized by the following: histological alterations in the cuticular layers of the exoskeleton at concentrations as low as 1 µg/L, higher mortality associated with molting and gross morphological deformities at concentrations as low as 0.5 µg/L, and behavioral modifications at concentrations as low as 0.1 µg/L (Cunningham 1986; Table 4). Behavioral effects in fiddler crabs (*Uca pugilator*) were the most sensitive indicator of diflubenzuron stress, and these effects may influence the ability of juvenile crabs to avoid predation, construct burrows, or feed adequately in nature (Cunningham and Myers 1987). Behavioral effects on cladocerans that may result in latent mortality include reduced filter feeding rates, reduced body movements, and inability to exhibit positive phototaxis, a characteristic of untreated individuals (Cunningham 1986; Table 4). Shrimp larvae exposed to 2.5 µg/L will not undergo daily vertical migration, and those exposed to 1 µg/L undergo only limited migration, which could affect horizontal transport and dispersal of populations and reduce recruitment to benthopelagic adult populations (Wilson et al. 1987). In addition to its inhibitory effect on cuticle synthesis diflubenzuron affects hormone balance by delaying or arresting the molt cycle, and it inhibits limb regeneration by inhibiting mitosis and differentiation (Touart and Rao 1987). Regenrated limbs of diflubenzuron-stressed crabs that survived ecdysis had lesions in the form of black areas in which the cuticle was improperly developed (Weis et al. 1987). Also, diflubenzuron caused a reduction in metabolism of betaecdysone in larval insects, leading to an excess of this molting hormone in the tissues. Treatment of decapod crustaceans with ecdysones frequently causes high mortality and molt acceleration (Gulka et al. 1982).

Toxicity and persistence of diflubenzuron in aquatic environments depend on formulation, frequency of application, quantity of organic matter, sediment type, and water pH and temperature. Biological variables are more important than physical variables in assessing diflubenzuron toxicity, especially the age of the test organism and frequency and synchrony of molting during the exposure period (Cunningham 1986). Crustaceans and other organisms that molt do not demonstrate a typical survival dose-response curve against diflubenzuron because death occurs only when molting is blocked (Nebeker et al. 1983; Cunningham 1986; Cunningham and Myers 1987; Wilson and Costlow 1987). In general, the most sensitive species had comparatively short larval or nymphal periods, and the organism molted frequently (Rodrigues and Kaushik 1986). Susceptible species include mayflies (*Leptophlebia* sp., *Baetis pygmaeus*), while more-resistant species include the stonefly (*Paragnetina media*) and caddisfly (*Hydropsyche bettani*). Amphipods were especially sensitive at 25° C, but not at 10°, 15°, or 20° C (Rodrigues and Kaushik 1986).

Mortality patterns of megalops larvae of blue crab (*Callinectes sapidus*) were elevated at higher temperatures but were seemingly unaffected by water salinity (Costlow 1979). In studies on larvae of black fly (*Simulium vittatum*), diflubenzuron was more effective against earlier larval instar stages than later ones; against rapidly growing larvae than starved, slow-growing larvae; and at 25° than at 20° C (Rodrigues and Kaushik 1986). Among diflubenzuron-stressed barnacles (*Balanus eburneus*), mortality was higher in fed groups than in starved groups, perhaps due to an increased uptake from contaminated food or to an increased molting rate due to feeding (Gulka et al. 1980). Increased fragility of cast exuviae from diflubenzuron-treated barnacles suggests mechanical weakening of the cuticle due to a decrease in chitin content (Gulka et al. 1982).

Field Studies

Field use of diflubenzuron in aquatic habitats for control of pestiferous insects also affects other species (Table 5). Diflubenzuron applications in marshes, ponds, streams, lakes, and rice fields routinely cause population reductions--sometimes irreversible--in many species of nontarget organisms, especially crustaceans and aquatic insects. Taxonomic groups that seem comparatively tolerant to diflubenzuron include algae, turbellarians, rotifers, aquatic beetles, molluscs, annelid worms, ostracods, and fish (Table 5). Following multiple applications to lake and pond ecosystems, diflubenzuron was not measurable in water, sediment, and aquatic

vegetation after several days (Booth and Ferrell 1977). Algae (*Plectonema boryanum*) reportedly degrade 80% of absorbed diflubenzuron in 1 h, primarily to 4-chlorophenylurea and 4-chloroaniline (Booth and Ferrell 1977).

Most authorities agree on four points:

1. Rates as low as 28 to 56 g diflubenzuron per surface ha (0.025 to 0.05 pounds per surface acre), or 2.5 to 16 µg/L, are highly effective against pestiferous dipterans, including many species of chaoborids, chironomids, and culicids (Mulla et al. 1975; Julin and Sanders 1978; Ali and Lord 1980a, 1980b; Cunningham 1986; Ali et al. 1988);

2. These same dosages suppress nontarget populations of cladocerans, copepods, mayfly nymphs, corixids, and springtails (Miura and Takahashi 1975; Mulla et al. 1975; Booth and Ferrell 1977; Julin and Sanders 1978; Ali and Lord 1980a; Cunningham 1986; Ali et al. 1988);

3. Moderately resistant to diflubenzuron are larvae of diving beetles, dragonfly adults and naiads, ostracods (*Cypericercus*, *Cyprinotus*), backswimmers, and water boatmen; highly resistant species include mosquitofish (*Gambusia affinis*), frogs and toads, snails, and algae (Miura and Takahashi 1974; Mulla et al. 1975; Nimmo et al. 1980); and

4. All populations of survivors begin to recover within days or weeks, and recovery is usually complete within 80 days after the last treatment (Mulla et al. 1975; Booth and Ferrell 1977; Ali and Lord 1980a; Nimmo et al. 1980; Cunningham 1986).

Unlike laboratory studies, diflubenzuron does not bioaccumulate markedly in fish or biomagnify through food chains, although altered feeding habits may occur. Under field conditions, marsh or pond sediments usually contain <50 µg/kg FW. This concentration presents negligible risk to channel catfish (*Ictalurus punctatus*) over a 28-day period, suggesting little hazard to catfish during multiple mosquito control applications of diflubenzuron (Booth and Ferrell 1977). Bioaccumulation of diflubenzuron from marsh applications are minimal, as judged by results of uptake studies using marsh sediments containing 550 µg/kg; maximum residues in fish tissues after 3 days were 4 µg/kg FW in muscle and 10 µg/kg DW in viscera (Schooley and Quistad 1979). Diflubenzuron residues are moderately persistent in algae, snails, saltmarsh caterpillars (*Estigmene acrea*), and mosquito larvae but are not biomagnified in food chains ending in fish (Schooley and Quistad 1979).

Maximum diflubenzuron concentrations range from 50 to 720 µg/kg FW in whole body of three species of freshwater teleosts exposed to water treated as many as eight times with 135 g/ha (Gartrell 1981). Feeding habits of freshwater fishes change in ponds showing marked reductions (94-99%) in copepod and cladoceran populations after diflubenzuron treatment (Colwell and Schaefer 1980), perhaps due to availability of various food items. In one study, black crappie (*Pomoxis nigromaculatus*) and brown bullhead (*Ictalurus nebulosus*) altered their diets for 1 month after treatment, eating about three times more insects and ostracods, and almost no cladocerans and copepods -- usually major items -- than before treatment (Colwell and Schaefer 1980).

Table 5. Diflubenzuron effects on selected aquatic organisms: field studies.

Ecosystem, dose, and other variables	Effect	Reference[a]
Coastal marsh, Louisiana		
6 applications, each of 28 g/ha, over 18-month period	Severe reduction in populations of amphipods, dragonfly naiads, corixid nymphs, and some adult beetles. Increased populations of snails, aquatic insect adults, and two species of fish. No change in 27 taxa. Results confounded by severe drought in experimental and control areas	1,2

Farm pond		
2.5, 5, or 10 µg/L; single application	Inhibited adult emergence by 95-100% of a gnat (*Chaoborus astictopus*), 2 to 7 days after treatment. Crustacean zooplankton suppressed at all treatment levels, especially cladocerans and copepods. Rotifers and algae were not affected. Bluegills that fed predominantly on cladocerans and copepods switched to chironomid midges and terrestrial insects after treatment, with no adverse effects.	3
Laboratory stream communities		
0.1, 1, 10, or 50 µg/L for 5 months	Aquatic insect populations were the most sensitive group, especially mayflies, stoneflies, and dipterans. These, and other invertebrates, showed rapid and permanent reductions in biomass and diversity at 1.0 µg/L and higher. Diversity showed an apparent dose-response relation, with no effect at 0.1 µg/L, intermediate reductions at 1 µg/L, and maximal reductions at 10 and 50 µg/L	4
Lake		
110 g/ha (3.7 µg/L), or 220 g/ha (7.4 µg/L); single application	At low dose, amphipods (*Hyalella azteca*) had 97% population reduction that remained depressed; temporary reduction in cladoceran and copepod populations. At high dose, marked population reductions in cladocerans, copepods, and ostracods (*Cyrinofus* sp.). Oligochaete worms were tolerant to both doses	5
110-280 g/ha	Effectively suppressed adult emergence of nuisance midges (*Tanytarsus*, *Procladius*) for up to 2 weeks; ineffective against a more pestiferous midge species (*Chironomus decorus*)	6
156 g/ha to lake surface, equivalent to 12 µg/L on April 26 and again on August 24	After first treatment, reduction within 1 week of three species of cladocerans (*Daphnia laevis*, *Ceriodaphnia* sp., *Bosmina longirostris*), and two species of copepods (*Cyclops* sp., *Diaptomus* sp.). No recovery of *Daphnia* and *Ceriodaphnia* for 6 months, but *Bosmina* reappeared 11 weeks later. *Diaptomus* was depleted for 4 months, but *Cyclops* recovered in 6-7 weeks. The amphipod	7

	Hyallela azteca was eliminated within 4 weeks, and no recolonization was evident after 6 months. No adverse effects on oligochaetes, snails (*Physa* sp.), or ostracods (*Cyprodopsis* sp.). After second treatment, temporary reduction in *Cyclops* and *Bosmina*, and no significant effects on ostracods, snails, or worms	
Pasture pond		
280 g/ha, single application	Controlled pasture mosquitos, *Aedes nigromaculis* and *A. melanimon*, and caused temporary reductions of cladoceran and mayfly nymph populations. Many cladocerans and mayflies died during the posttreatment ecdysis, characteristically with signs of incomplete cleavage of the middorsal ecdysial suture. More-tolerant groups included corixid and notonectid nymphs, and adult aquatic beetles. No effects on the most tolerant groups: turbellarians (*Mesotoma*, *Bothromestoma*), rotifers (*Asplanchna*), ostracods, algae, and spiders (*Pardosa* spp., *Lycosa* spp.)	8
Pond		
13.2 µg/L in pond surface layer 1 h after treatment; <0.2 µg/L after 14 days	Residues, in µg/kg whole body FW, in black crappie (*Pomoxis nigromaculatus*) were 426 at day 1,194 at day 2, 56 at day 4, and not detectable at day 7	9
16 µg/L (estimated from application of 56 g/ha)	Caused declines in third and fourth instar larvae *Culex tarsalis* mosquito 2-8 days after treatment, but not at 11 days	10
80 µg/L (estimated from application of 280 g/ha)	Adult *C. tarsalis* emergence from treated larvae almost completely inhibited for at least 11 days posttreatment	10
Rice field, flooded		
1.1-28 g/ha	100% control of massive rice field populations of fourth instar larvae of the mosquito *Psorophora columbiae* 3-5 days after treatment. Significant reductions in certain nontarget aquatic insect populations	11
About 1,000 µg/L (as judged by 280 g/ha in	Significant reductions in immature populations of the rice water weevil (*Lissorhopterus*	12

rice field water 10 cm deep)	*oryzophilus*) 4-5 days after rice emergence in a continuously flooded field	
About 1,500 µg/L (420 g/ha)	*Lissorhopterus* population reduced 75% when applied 7 days after rice emergence	12
River		
1,250 µg/L added for 1 h to control simuliid flies	After initial depression, target Diptera (flies), including Simuliidae, increased 4 to 40 times over pretreatment levels after 3-4 weeks, suggesting that one-time applications are useless. No adverse effects on adults and fry 3-4 weeks after exposure of dace (*Phoxinus lagowski*) and minnow (*Leuciscus hakonensis*)	13

[a] 1, Farlow 1976; 2, Farlow et al. 1978; 3, Apperson et al. 1978; 4, Hansen and Garton 1982; 5, Ali and Mulla 1978a; 6, Johnson and Mulla 1981; 7, Ali and Mulla 1978; 8, Miura and Takahashi 1975; 9, Colwell and Schaefer 1980; 10, Mulla et al. 1975; 11, Steelman et al. 1975; 12, Smith et al. 1988; 13, Satake and Yasuno 1987.

Although diflubenzuron is not sprayed directly on fresh waters in gypsy moth control, aerial spraying of large forest tracts may result in exposure of streams by way of leaf litter (Swift et al. 1988a). Residual diflubenzuron was present for at least 4 months on leaves submerged in flowing water, and it was toxic to various invertebrates. For example, treated leaves of the tulip poplar (*Liriodendron tulipifera*) that contain 10 mg diflubenzuron per m^2 after 4 months of submersion produce adverse effects on survival and growth when fed to craneflies (*Tipula abdominalis*, *Platycentropus radiatus*; Swift et al. 1988b). The effects of diflubenzuron on leaflitter processing rates in streams is unresolved and merits additional research (Swift et al. 1988a, 1988b).

Birds

Birds are comparatively resistant to diflubenzuron, as judged by the ability of the mallard (*Anas platyrhynchos*) to tolerate single oral doses up to 2,000 mg/kg BW or dietary loadings up to 4,640 mg/kg ration for 8 days (Table 6). Poisoning of insectivorous birds by diflubenzuron, after spraying in orchards as recommended, is highly improbable (Muzzarelli 1986). This conclusion is based on the maximum possible daily intake of insects by wild nestlings (15 mg/kg BW in Great tit, *Parus major*; 10 mg/kg BW in tree sparrow, *Passer montanus*), on a maximum whole body loading of 0.5 mg diflubenzuron per kg FW in insect prey, and on observations of normal growth and subsequent breeding of nestlings in orchards sprayed with diflubenzuron (Muzzarelli 1986).

Despite the apparent absence of direct effects in forest birds, the widespread use of diflubenzuron in the suppression of forest insect defoliators may lead to potentially harmful effects by reducing populations of immature lepidoptera and other mandibulate herbivorous insects upon which they feed. All field evidence collected to date, however, is either inconclusive or negative. In one study, 70.75 g diflubenzuron per ha was applied to an oak forest (*Quercus rubra*, *Q. velutina*, *Q. prinus*) in west Virginia to control first and second instars of gypsy moths (Martinat et al. 1987; Table 6). The maximum diflubenzuron residue recorded in a wide variety of canopy forager birds (blue-gray gnatcatcher, *Polioptila caerulea*; great crested flycatcher, *Myiarchus crinitus*; eastern wood-pewee, *Contopus virens*; black-capped chickadee, *Parus atricapillus*; tufted titmouse, *Parus biocolor*; red-eyed vireo, *Vireo olivaceous*; warblers, *Dendroica* spp.; scarlet tanager, *Piranga olivacea*) was 0.21 mg/kg whole body FW. A similar value, 0.20 mg/kg whole body FW, was recorded in ground or low foragers, including wood thrush (*Hylocichla mustelina*); ovenbird (*Seiurus aurocapillus*); rufous-sided towhee (*Pipilo erythrophthalmus*); indigo bunting (*Passerina cyanea*); song sparrow (*Melospiza melodia*), and chipping sparrow (*Spizella passerina*; Martinat et al. 1987).

In another study as much as 280 mg diflubenzuron per ha applied to control the Douglas-fir tussock moth (*Orgyia pseudotsugata*), an important defoliator of true firs spp.) and Douglas-fir (*Pseudotsuga menziesii*) in western North America, had no adverse effects on forest birds, as judged by population censuses, nesting studies, and bird behavior (Richmond et al. 1979; Table 6).

Domestic chickens (*Gallus* spp.) metabolize diflubenzuron to a greater extent than insects, but less than rodents and ruminants. The main pathway of diflubenzuron degradation in chickens is through cleavage of the urea bridge, whereas rats and cows tend to hydroxylate and conjugate the parent molecule (Opdycke and Menzer 1984). Metabolism studies in chickens showed that major residues in tissues and eggs were unchanged diflubenzuron and 4-chlorophenylurea; also present were 2,6-difluorobenzoic acid and 4-chloroaniline (Gartrell 1981). Metabolites in chicken excreta included 4-chlorophenylurea, 4-chloroaniline, 2,6-difluorobenzamide, 2,6-difluorobenzoic acid, and several unidentified compounds (Opdycke and Menzer 1984). At high dietary loadings of 50-500 mg/kg ration, diflubenzuron accumulates in fat, egg, and muscle tissues of chickens; however, excretion is rapid, and residues are usually negligible after 5 weeks on a clean diet (Table 6). Diflubenzuron fed at levels up to 250 mg/kg ration to male broiler chickens for 98 days had no effect on hyaluronic acid (HA) concentration in the combs and wattles (Crookshank et al. 1978). Both chitin and HA are polysaccharides and have a common biochemical precursor, uridine diphospho N-acetylglucosamine (UDPAGA; Crookshank et al. 1978), which is used in the synthesis of chitin by insects and in the production of HA by vertebrates. Since diflubenzuron interferes with the incorporation of UDPAGA into chitin by insects but not with HA production, it would seem that diflubenzuron is relatively harmless to birds; however, more research is needed for verification.

Intraspecies differences in diflubenzuron metabolism are reported for domestic chickens. The White Leghorn breed, for example, produced eggs with significantly higher residues than other breeds tested after 3 weeks on a diet containing 50 mg diflubenzuron per kg, and it had elevated concentrations in fat tissues after 15 weeks on a 10 mg/kg diet (Opdycke et al. 1982b; Opdycke and Menzer 1984). In chickens, diflubenzuron is usually eliminated more rapidly in feces than in eggs, but in the White Leghorn breed the major route of elimination is via egg production. The White Leghorn breed also differed significantly from the Rhode Island Red/Barred Plymouth Rock (RIR/BPR) breed in ability to metabolize diflubenzuron administered orally or intravenously (Table 6). White Leghorn chickens accumulated diflubenzuron to a greater extent than RIR/BPR chickens, and they retained residues for longer periods. Also, White Leghorn chickens produced a higher percentage and greater number of diflubenzuron metabolites in thir excreta than other breeds tested (Opdycke et al. 1982b).

Table 6. Diflubenzuron effects on selected birds.

Species, route of administration, dose, and other variables	Effect	Reference[a]
Mallard, *Anas platyrhynchos*		
Oral, single dose, 2,000 mg/kg body weight (BW)	Insufficient to kill 50%; anorexia observed on day after treatment	1
Dietary, 4,640 mg/kg Ration	Insufficient to kill 50% in 8 days	2
Forest birds		
From oaks (*Quercus* spp.) forest sprayed aerially with 70.75 g diflubenzuron/ha to control gypsy moth instars; samples collected 3 days prior to spraying, and up	Maximum concentrations, in mg/kg fresh weight (FW) whole body, were 0.21 in canopy birds 3 days postspray (0.09 at day 21); 0.20 in understory birds 1 day postspray, and non-detectable (ND) at day 21; 0.45 in foliage 1 day postspray (0.18 at day 21); 0.49 in foliage	3

to 21 days after spraying	arthropods at day 3, and 0.1 at day 21; ND in litter at all times; 0.11 in litter arthropods at day 10 and 0.03 at day 21. Controls, in all cases, contained <0.03, except litter arthropods, which contained 0.06 mg/kg	
Fir and Douglas-fir (*Abies* sp., *Pseudotsuga menziesii*) forest sprayed aerially with 140 or 280 mg/ha to control Douglas-fir tussock moth; effects evaluated in year of spraying and 1 year later	No significant changes in species diversity, brain cholinesterase activity, survival, morbidity, or behavior at either dose. Significant increases in total breeding pairs noted 1 year later in Townsend's warbler (*Dendroica townsendi*), MaGillivray's warbler (*Oporornis tolmiei*), and mountain chickadee (*Parus gambeli*). Some reductions in populations of warbling vireo (*Vireo gilvus*), golden-crowned kinglet (*Regulus satrapa*), and lazuli bunting (*Passerina amoena*), but all differences were attributed to biological variability rather than to insecticide effects	4
Domestic chicken, *Gallus* spp.		
Intravenous injection		
1 mg/kg BW, white leghorn breed, single dose	Half-time (Tb 1/2) persistence in blood of 14.7 h; 12% of dose excreted in 24 h	5
1 mg/kg BW, Rhode Island Red/Barred Plymouth Rock breed (RIR/BPR), single dose	Tb 1/2 of 8.4 h in blood; 29% of dose excreted in 24 h	5
Oral route		
5 mg/kg BW, white leghorn breed, single dose	Maximum residues after dosing, in mg/kg FW, were 0.25 in egg, 0.4 in eggshell, 0.19 in kidney, and 0.16 in ovary. Excretion of 50% in 8-12 h	5,6
5 mg/kg BW, RIR/BPR breed, single dose	Maximum residues after dosing were 0.14 mg/kg FW in eggs and ND in eggshell, kidney, and ovary. Excretion of 51% in 30-36 h and 82-91% in 13 days	5,6
White leghorn and RIR/BPR strains given 5 mg/kg BW daily for 11 days; residues measured in egg during dosing and for 10 days after dosing	Residues, in mg/kg FW egg, for white leghorn strain were highest at days 9 (3.5) and 11 (2.6). Values were 0.04 at day 20, and ND at day 21. Residues in RIR/BPR were lower: 1.7 at day 9, 1.1 at day 11, 0.02 at day 20, and ND at day 21. Tb 1/2 for egg residues ranged between 34 and	5

	38 h	
Dietary route		
0.05 mg/kg for 28 days	Fat contained 0.018 mg/kg FW at 28 days and <0.0006 mg/kg 7 days after withdrawal	7
0.5 mg/kg for 28 days	Fat contained 0.033 mg/kg FW at 28 days and less than 0.005 mg/kg 7 days after withdrawal	7
1.6 mg/kg for 3 weeks	Minor effects on larvae of house fly (*Musca domestica*) in manure; egg residue of 0.05 mg/kg FW	8
3.1 mg/kg for 3 weeks	Killed 85% of fly larvae in manure; egg residue of 0.25 mg/kg FW	8
5 mg/kg for 28 days	Fat contained 1.16 mg/kg FW at 28 days and <0.032 mg/kg 7-14 days after withdrawal	7
6.2 mg/kg for 3 weeks	Complete inhibition of fly larvae in manure; egg residue of 0.55 mg/kg FW	8
12.5, 25, or 50 mg/kg for 3 weeks	All diets completely inhibited fly larval development in manure; white egg residues, in mg/kg FW, were 1.0 for 12.5 mg/kg diet, 2.1 for 25 group, and 2.9 for the 50 mg/kg group; residues in brown eggs were half those of white eggs	8
Mature white leghorn hens fed diets containing 10, 50, !00, or 500 mg diflubenzuron/kg for 8 weeks	No adverse effects of any diet on feed consumption, growth, egg production, egg weight, eggshell thickness, fertility, hatchability, or progeny performance. Maximum concentrations in tissues after 8 weeks, in mg/kg FW, in the 500 mg/kg diet group, were 53 in fat, 10 in egg, 9 in liver, and 0.9 in muscle; for the 100 mg/kg group, these values were 21 in fat, 10 in liver, 3 in egg, and 0.5 in muscle; for the 50 mg/kg group, residues were 1.5 in fat, 1 in egg, 0.8 in liver, and 0.2 in muscle. Five weeks after withdrawal from all diets, diflubenzuron was <0.05 mg/kg FW in all tissues	9
Male broiler and layer breed chickens fed 205	No significant effect on body weight, food consumption, or weight of testes, liver, comb,	10

mg/kg ration for 98 days beginning at age 1 day	and feet	
Male and female layer-breed chickens were fed diets containing up to 250 mg/kg for 58 weeks, including a 26-week laying cycle. Progeny were reared to age 2 weeks.	No significant effect of any dose level on survival, egg production, egg weight, eggshell weight, fertility, hatchability or hatch weight and body weight of progeny. No gross abnormalities in progeny; growth and feathering as in controls	1 1

[a] 1, Hudson et at. 1984; 2, Farlow 1976; 3, Martinat et al. 1987; 4, Richmond et al. 1979; 5, Opdycke and Menzer 1984; 6, Opdycke et al. 1982b; 7, Gartrell 1981; 8, Miller et al. 1975; 9, Cecil et al. 1981; 10, Kubena 1981; 11, Kubena 1982.

Differences in ability to metabolize diflubenzuron between different strains of domestic chickens may be due to differences in lipid metabolism associated with egg production (Opdycke and Menzer 1984). No comparable data base exists for avian wildlife, and one should be developed through research.

Mammals

No data are available on effects of diflubenzuron on mammalian wildlife. However, results of studies on small laboratory animals and domestic livestock are available (Table 7), and these indicate several trends. Adverse effects levels occurred in dogs fed diets containing 160 mg/kg (6.2 mg/kg BW daily) for 13 weeks (abnormal blood chemistry), in mice given 125 mg/kg BW daily for 30 days (hepatocellular changes), in rabbits fed diets containing 640 mg/kg for 3 weeks (abnormal hemoglobin), and in rats given 5,000 mg/kg BW daily for 13 weeks (abnormal hemoglobin). Accumulations of diflubenzuron occurred in several species. Elevated tissue residues--but no other measurable effects---occurred in cows given 0.05-0.5 mg/kg ration for 28 days or 1-16 mg/kg BW for 4 months, in pigs given a single oral dose of 5 mg/kg BW, and in sheep given a single oral dose of 10 mg/kg BW (Table 7). No observable adverse effect levels occurred in cows given 0.25 mg/kg BW daily for 4 months, in rabbits given 4 mg/kg BW daily on dys 6 to 18 of gestation, in dogs fed diets containing 40 mg/kg for 13 weeks (equivalent to 1.6 mg/kg BW daily), in rats fed diets containing 160 mg/kg for 2 years, and in rabbits and rodents given single oral or dermal doses <2,000 mg/kg BW (Table 7).

All available data indicate that diflubenzuron is not a mutagen, teratogen, or carcinogen. Diflubenzuron is not mutagenic, as judged by the results of

1. The mouse lymphoma forward mutation test at the thymidine kinase locus (detects mutations to a nonfunctional thymidine kinase in a line of culture mouse lymphoma cells),

2. The Ames *Salmonella typhimurium* microsome reverse mutation test (ability to produce point gene mutations of a base pair),

3. The mouse micronucleus test (which detects chromosome breakage or chromosome loss from mitotic abnormalities in bone marrow erythrocytes; Mac Gregor et al. 1979), and

4. A DNA damage study with yeast, *Saccharomyces cerevisiae* (Gartrell 1981).

No teratogenicity or reproductive effects were associated with elevated doses of diflubenzuron in all species of mammals tested (Gartrell 1981). Diflubenzuron suppresses melanogenesis and uptake of nucleosides in mouse melanoma cells (Jenkins et al. 1986), and it inhibits growth of experimental tumors in mice, either alone or in combination with $CoC1_2$ (Table 7). Mixed function oxidase, induced by 3-methylcholanthrene, enhances the antitumor properties of diflubenzuron, suggesting that aromatic hydroxylation may be required for tumor growth regulation (Jenkins et al. 1986). The most likely diflubenzuron metabolite that affects tumor growth regulation is the form oxidized at the 2 carbon of the phenyl ring; other metabolites tested (i.e., 4-

chlorophenylurea, 3-OH-diflubenzuron) are only marginally effective (Jenkins et al. 1986). Diflubenzuron did not produce tumors in fetal cells of hamsters (*Cricetus* spp.) at whole body doses of 500 mg/kg, and this also suggests a relatively low oncogenic potential (Quarles et al. 1980). Diflubenzuron is not cytotoxic and does not inhibit the synthesis of complex carbohydrates in animal cells, as judged by results of studies with cultured rat glial cells, wherein diflubenzuron was not metabolized to any measurable extent, and more than 98% could be recovered from particulate fractions of whole cells (Bishai and Stoolmiller 1979).

Intestinal absorption of diflubenzuron in laboratory rats, measured as the sum of urinary and biliary excretion, decreases with increasing dose: from 50% at a single oral dose of 4 mg/kg BW to 4% at 900 mg/kg BW. Excretion is almost complete after 75 h; at that time up to 4% of the administered dose is recovered from skinned carcasses (Willems et al. 1980). About 80% of diflubenzuron metabolites excreted by rats seem to have the basic diflubenzuron structure intact. Three metabolites are largely excreted as conjugates in the bile. One metabolite, 2,6-difluorobenzoic acid, is excreted largely in urine. Its counterpart, 4-chlorophenylurea, was not present in urine or bile in appreciable quantity, nor was 4-chloroaniline detected (Willems et al. 1980). Lifetime feeding studies of 4-chloroaniline, a relatively common diflubenzuron metabolite, showed no compound-related effects in laboratory mice and rats (Gartrell 1981).

Oral treatment of sheep and cattle (*Bos* spp.) with diflubenzuron is followed by absorption of the compound through the gastrointestinal tract, metabolism, and elimination of residues through the urine, feces, and, to a limited extent, milk. Intact diflubenzuron is eliminated in the feces of orally dosed cattle and sheep (Ivie 1978). Major metabolites of diflubenzuron excreted by cattle and sheep result from hydroxylation on the difluorobenzoyl and chlorophenyl rings, and by cleavage between the carbonyl and amide groups to produce metabolites that are excreted free or as conjugates (Ivie 19.78). Cattle dosed repeatedly with diflubenzuron had detectable residues only in liver and milk. The parent compound, 4-chlorophenylurea, 2,6-difluorobenzoic acid, and 4-chloroaniline compose only 15% of the total residue in liver; the bulk of the residue is not extractable (Gartrell 1981). Dietary levels of 5 mg/kg ration produce low (13 µg/L), but detectable, diflubenzuron concentrations in milk of cattle (Gartrell 1981).

Table 7. Diflubenzuron effects on selected mammals.

Species, mode of administration, dose, and other variables	Effect	Reference[a]
Cattle, *Bos* sp.		
Dermal		
0.125 mg/cm^2 hide, single application, 1% solution to 400 cm^2 skin surface	No absorption through skin; rapid dis-appearance. Maximum residues in hair, in mg/kg fresh weight (FW), were 128 after 1 week, 19 after 2 weeks, and 4 after 4 weeks. For skin, these values were 0.4, 0.1, and <0.1	1
Diet		
0.05 mg/kg ration for 28 days	No detectable residues in milk and tissues, except liver (0.01 mg/kg FW); liver residues remained detectable after a 7-day withdrawal period	2
0.5 mg/kg ration for 28 days	No detectable residues in milk and tissues, except liver (0.08 mg/kg FW); liver residues remained detectable after a 7-day withdrawal period	2
5 mg/kg ration for 28 days	Liver residue of 0.54 mg/kg FW remained elevated after a 7-day withdrawal period; residues in milk reached 0.013 mg/L within the first few	2

	days of feeding and declined to nondetectable (ND) levels after a 4-day withdrawal period	
Fed diets equivalent to 0.25 mg/kg body weight (BW) daily for 4 months, single animal	No detectable residues in any tissue. Tb 1/2 of 4—5 days in manure; manure gave >95% control of larvae of the face fly, *Musca autumnalis*	3
Fed diet equivalent to 1 mg/kg BW daily for 4 months, single animal	No detectable residues in any tissue except omental fat (0.1 mg/kg FW). No houseflies (*Musca domestica*) or face flies developed in manure	3
Fed diet that increased from 1 mg/kg BW daily to 8 mg/kg BW over a 2-month period, then 16 mg/kg BW daily for 3 months	No detectable diflubenzuron residues in heart, muscle, or kidney; 130 µg/kg FW in liver; about 250 µg/kg FW in subcutaneous fat	3
Holstein bull calves fed diet equivalent to 2.8 mg/kg BW daily for first 7 months, then 1 mg/kg BW daily for 6-12 months	No effect on weight gain, serum testosterone at age 11 months, libido, sperm mobility, semen volume, or sperm concentration. No histo-pathology of liver, lung, kidney, or spleen. No tissue residues---except for one bull slaughtered at age 5 months: <20 µg/kg FW in muscle, 20 in liver and kidney, 40 in subcutaneous fat, and 80 in renal and omental fat	4
Fed diet equivalent to 8 mg/kg BW daily for 4-5 months, single animal	No detectable residues in milk	3
Fed diet equivalent to 16 mg/kg BW daily for 4-5 months, single animal	Maximum concentrations recorded were 20 µg/L in milk and 250 µg/kg FW in body fat. No obvious adverse effects on feeding behavior	3
Oral		
10 mg/kg BW, single-dose to a lactating cow	Extensively metabolized in 4 days; almost all totally excreted in 7 days: about 85% in feces, 15% in urine, 0.2% in milk. At 7 days, liver contained 2.9 mg/kg FW, skin 0.4, and	1

	all other tissues <0.4	
Dog, *Canis familiaris*		
Fed diets containing 10, 20, 40, or 160 mg/kg (equivalent to to 0.42, 0.84, 1.64, or 6.24 mg/kg BW daily) for 13 weeks	Abnormal hemoglobin levels in 160-mg/kg group after 6 weeks; no other abnormal findings or histopathology observed in any group at 13 weeks	2
Angora goat, *Capra* sp.		
30 mL of 2% diflubenzuron solution applied dermally 6 weeks after shearing, 25-kg females	Protected against Angora goat biting lice (*Bovicola limbatus*) for up to 18 weeks	5
Domestic mouse *Mus* sp.		
Diet		
4, 8, 16, or 50 mg/kg ration for 80 weeks	Increase in tumors in females at the 16-mg/kg level	2
Intraperitoneal injection		
3 daily injections of 1.2 mg, equivalent to 144 mg/kg BW, tumor-bearing strain	Tumors conditioned with COC12 then treated with diflubenzuron showed a 75% reduction in rate of tumor increase	6
5 daily injections of 20 mg (total of 100 mg, equivalent to 4,000 mg/kg BW), C57BL/6 strain with B 16 melanomas	Initial antitumor activity, as judged by 11-20% decrease in tumor volume, and a 2-3 day increase in tumor doubling time. But at midtreatment, tumors regained control rate of volume increase	6
2,150 mg/kg BW	Insufficient to kill 50%	7
Oral		
Adult males given 125, 500, or 2,000 mg/kg BW daily for 30 days	Hepatocellular changes at all dose levels, including histopathology and altered activities of glutathione S-transferase enzymes	8
>4,640 mg/kg BW	Acute oral LD50	2,7,8
Rabbit, *Oryctolagus* sp.		
Dermal		
2,000 mg/kg BW	Insufficient to kill 50%	7

Diet		
Males given 640 mg/kg feed for 18-21 days	Abnormal hemoglobin	2
In vitro studies		
Up to 5 mg/L	Protein and RNA synthesis rates were significantly stimulated in liver, and inhibited in muscle in a dose-dependent manner. Maximum effect in both tissues occurred at 5 mg/L for protein synthesis and 0.2 mg/L for RNA synthesis	9
Oral		
Females given 1, 2, or 4 mg/kg BW daily on days 6-18 of gestation	No compound-related maternal toxicity or birth defects	2
Sheep, *Ovis aries*		
Dermal		
Merrino sheep exposed to mass-released gravid females of the sheep blowfly (*Lucilia cuprina*)—a severe ectoparasite in Australia that may kill—in a fly-proof animal house after dermal application of 1,000, 1,500, or 2,500 mg diflubenzuron/L; sheep thoroughly wetted twice during 4 days	1,000 mg/L protected against fly strike for at least 110 days; 1,500 mg/L protected until end of trial at 170 days; 2,500 mg/L provided excellent protection against severe infestation. No resistance to diflubenzuron was acquired by blowflies	10
Oral		
Single dose of 10 mg/kg BW	Residues after 7 days, in mg/kg FW, were about 3 in liver, 0.4 in kidney, and <0.2 in all other tissues	1
Single dose of 500 mg/kg BW	In 4 days, bile accounted for 36% of diflubenzuron metabolites excreted, feces 32%, and urine 24%; in 7 days, feces were the major pathway	1
Laboratory white rat, *Rattus* sp.		
Diet		

Fed 10, 20, 40, or 160 mg/kg ration for three generations	No effect on fetotoxicity or teratogenicity	2
Fed 10, 20, 40, or 160 mg/kg ration for 2 years	No compound-related effects	2
Oral		
Females given 1, 2, or 4 mg/kg BW daily on days 6-15 of gestation	No compound-related maternal toxicity or birth defects	2
4 mg/kg BW, single dose	Intestinal absorption of 50%	11
5 mg/kg BW, single dose	72-93% excreted in 6 days, mostly in feces	11
900 mg/kg BW, single dose	Intestinal absorption of 4%	11
>4,640 mg/kg BW	Acute oral LD50	2,7
Males given 5,000 mg/kg BW daily for 13 weeks	Abnormal hemoglobin on days 1-4, and on day 8	2
Swine, *Sus* sp.		
Adult female pig given single oral dose of 5 mg/kg BW and observed for 11 days	By 11 days, 82% of dose was excreted unchanged in feces, and 5% in urine as metabolites (4-chlorophenylurea, 2, 6-difluorobenzoic acid, 4-chloroaniline, and 2,6-difluorobenzamide). Tissue residues, in mg/kg FW, ranged from ND in bone to 0.04-0.09 in stomach wall, brain, pancreas, small intestine, blood, heart, muscle, and ovary; from 0.11-0.2 for large intestine, subcutaneous fat, lymph, lung, and kidney; and from 0.23 to 0.4 in liver, omental fat, and gall bladder	12

[a] 1, Ivie 1978; 2, Gartrell 1981; 3, Miller et al. 1976; 4, Miller et al. 1979; 5, Miller et al. 1985; 6, Jenkins et al. 1986; 7, Poplyk 1989; 8, Young et al. 1986; 9, E1-Sebae et al. 1988; 10, Hughes and Levot 1987; 11, Willems et al. 1980; 12, Opdycke et al. 1982a.

The major hydroxylated diflubenzuron metabolite in cow milk (N-[[(4-chlorophenyl) amino] carbonyl] -2,6-difluoro-3-hydroxybenzamide) when fed to white rats is rapidly excreted with little biotransformation (Ivie 1978).

Metabolism of diflubenzuron by mammals and birds probably occurs by way of hydroxylation, conjugation, and cleavage of the urea moiety (Opdycke et al. 1982a); however, interspecies differences are considerable. In cows, for example, the major identified metabolic transformation is hydroxylation at the 3 position of the 2,6-difluorobenzoyl ring. In sheep, however, major metabolites arise through cleavage of the amide bond at the benzoyl carbon to produce 2,6-difluorobenzoic acid, which is excreted in the urine either free or conjugated with

glycine (Ivie 1978). The major diflubenzuron metabolite in cow urine is 2,6-difluoro-3-hydroxydiflubenzuron, accounting for 45%, and in feces 18%; unchanged diflubenzuron accounts for 43% of the administered dose in cow feces. In sheep urine, 2,6-difluorobenzoic acid and 2,6-difluorohippuric acid account for 57%; in sheep feces, unchanged diflubenzuron is 97% (Ivie 1978). In swine, the majority of the administered dose is eliminated in feces unchanged; the urine contains mostly metabolites, indicating that most of the absorbed diflubenzuron is metabolized (Opdycke et al. 1982a).

Recommendations

Since diflubenzuron toxicity seems to be similar in both insects and crustaceans, extreme care must be taken when this compound and other chitin synthesis inhibitors are used for insect control in areas where aquatic crustaceans occur. Otherwise, ecological instability may result, with consequences for feeding, metabolism, growth, reproduction, and survival of numerous nontarget organisms (Christiansen 1986). Specifically, diflubenzuron use in saltmarsh mosquito breeding areas or on agricultural lands less than 5 km from coastal areas is not recommended because of concerns that runoff may reach the adjacent estuaries, which are the primary hatcheries for many economically important species of crustaceans (Costlow 1979; Cunningham 1986; Cunningham and Myers 1986). Also, diflubenzuron concentrations in seawater should not exceed 0.1 µg/L, the minimum concentration known to produce measurable behavioral changes in estuarine crustacean larvae (Cunningham and Myers 1986).

If diflubenzuron and other insect growth regulators continue to be used near productive aquatic habitats, then food chain transfer studies are recommended. High accumulations of diflubenzuron by aquatic algae -- up to 4.5 mg/kg DW in some cases (Booth and Ferrell 1977)-- strongly implicate food chain transfer as a potential mechanism of contaminant transfer in aquatic invertebrate food webs. To protect certain fishes, diflubenzuron use to control copepod vectors of human disease--including various species of *Cyclops*--is not recommended in areas where these fishes breed or feed on *Cyclops* (Rao and Paul 1988).

For control of cotton pests, including the boll weevil, a maximum recommended treatment schedule is 421 g diflubenzuron per ha, applied six times, usually weekly, during the growing season (Bull 1980). Honey bees (*Apis mellifera*) in heavily sprayed areas, however, may experience adverse effects if their diets exceed 1 mg diflubenzuron per kg FW (Stoner and Wilson 1982). Diflubenzuron inhibits house fly development in poultry manure. A recommended cost-effective fly control program in poultry houses involves the feed-through method

(5 mg diflubenzuron per kg FW poultry diet) during hot, wet summers for 3-4 months, coupled with good sanitation and good manure management (Giga 1987).

For protection of domestic cattle, feeds should contain <0.05 mg diflubenzuron per kg FW; cottonseed may be added to cattle diets provided that diflubenzuron concentrations in the seed do not exceed 0.2 mg/kg FW and that cottonseed composes < 17% of the total diet bulk (Gartrell 1981).

Diflubenzuron causes biochemical upset, as judged by lowered testosterone levels in chickens and rats (EPA 1979), altered glutathione S-transferase activity in mouse liver (which adversely affects the ability to detoxify foreign substances by way of conjugation; Young et al. 1986), and disrupted hydroxylamine activity in human infants (EPA 1979). Additional research seems needed on biochemical alterations induced by diflubenzuron.

No diflubenzuron criteria are currently recommended for protection of avian and mammalian wildlife. All data available suggest that wildlife species are about as tolerant to diflubenzuron as are domestic poultry and livestock; however, the wildlife data base seems inadequate for practicable criteria formulation.

Anti-cancer properties of diflubenzuron require elucidation. The indication that one or more hydroxylated forms of diflubenzuron can regulate growth of mouse tumor cells provides a basis for further studies to identify and isolate the most active analog of this compound, and it suggests that other benzoylphenyl ureas may have similar properties (Jenkins et al. 1986).

Diflubenzuron has a Surveillance Index Classification of Class IV, indicating a sufficiently low hazard potential to human health from toxicological and exposure standpoints to justify only minimal monitoring efforts (Gartrell 1981). Human cancer risk of lifetime dietary exposure to diflubenzuron in a worst case scenario is

considered slight (EPA 1979). Diflubenzuron has little potential for human dietary exposure because of its limited use on cotton and the low residues measured on cottonseed, meat, milk, poultry, and eggs (Gartrell 1981). For protection of human health, tolerances of <0.05 mg/kg FW have been set for fat, meat, meat byproducts, poultry, milk, dairy products, and eggs, and <0.2 mg/kg FW for cottonseed (EPA 1979). These foods compose about 45% of the average human diet. If all of these foods bore residues at the tolerance level, they would contribute 0.035 mg daily on the basis of 1.5 kg food eaten daily. For a 60-kg adult, the theoretical maximum residue concentration would be 0.6 µg/kg BW daily. Tolerances would be approached only when maximum quantities of cottonseed fraction (i.e., hulls, meal, soapstock), all bearing tolerance-level residues, are incorporated into livestock diets. At present, however, no acceptable daily intake level in humans has been established (Gartrell 1981).

Acknowledgments

Abstract. Ecological and toxicological aspects of zinc in the environment are reviewed with emphasis on natural resources. Subtopics include sources and uses; chemical and biochemical properties; carcinogenicity, mutagenicity, teratogenicity; background concentrations in biological and nonbiological compartments; effects of zinc deficiency; toxic and sublethal effects on terrestrial plants and invertebrates, aquatic organisms, birds, and mammals; and recommendations for the protection of sensitive resources.

The estimated world production of zinc is 7.1 million metric tons; the United States produces about 4% of the total and consumes 14%. Zinc is used primarily in the production of brass, noncorrosive alloys, and white pigments; in galvanization of iron and steel products; in agriculture as a fungicide and as a protective agent against soil zinc deficiency; and therapeutically in human medicine. Major sources of anthropogenic zinc in the environment include electroplaters, smelting and ore processors, mine drainage domestic and industrial sewage, combustion of solid wastes and fossil fuels, road surface runoff corrosion of zinc alloys and galvanized surfaces, and erosion of agricultural soils.

Zinc has its primary effect on zinc-dependent enzymes that regulate RNA and DNA. The pancreas and bone are primary targets in birds and mammals; the gill epithelium is a primary target site in fish. Dietary zinc absorption is highly variable in animals; in general, it increases with low body weight (BW) and low zinc status and decreases with excess calcium or phytate and by deficiency of pyridoxine or tryptophan. Low molecular weight proteins called metallothioneins play an important role in zinc homeostasis and in protection against zinc poisoning; zinc is a potent inducer of metallothioneins. Zinc interacts with many chemicals to produce altered patterns of accumulation, metabolism, and toxicity; some interactions are beneficial to the organism and others are not depending on the organism, its nutritional status, and other variables. Knowledge of these interactions is essential to the understanding of zinc toxicokinetics.

In natural waters, dissolved zinc speciates into the toxic aquo ion $[Zn(H_2O)_6]^{2+}$, other dissolved chemical species, and various inorganic and organic complexes zinc complexes are readily transported. Aquo ions and other toxic species are most harmful to aquatic life under conditions of low pH, low alkalinity, low dissolved oxygen, and elevated temperatures. Most of the zinc introduced into aquatic environments is eventually partitioned into the sediments. Zinc bioavailability from sediments is enhanced under conditions of high dissolved oxygen, low salinity low pH, and high levels of inorganic oxides and humic substances.

Zinc and its compounds induce testicular sarcomas in birds and rodents when injected directly into the testes; however zinc is not carcinogenic by any other route. Growth of animal tumors is stimulated by zinc and retarded by zinc deficiency. Under some conditions, excess zinc can suppress carcinoma growth, although the mechanisms are imperfectly understood. Organozinc compounds are effective mutagens when presented to susceptible cell populations in an appropriate form; the evidence for the mutagenic potential of inorganic zinc compounds is incomplete. Zinc deficiency can lead to chromosomal aberrations, but excess zinc was not mutagenic in the majority of tests. Excess zinc is teratogenic to frog and fish embryos, but conclusive evidence of teratogenicity in higher vertebrates is lacking. In mammals, excess zinc may protect against some teratogens. Zinc deficiency may exacerbate the teratogenic effects of known teratogens, especially in diabetic animals.

Background concentrations of zinc seldom exceed 40 µg/L in water 200 mg/kg in soils and sediment, or 0.5 $\mu g/m^3$ in air. Environments heavily contaminated by anthropogenic activities may contain up to 99 mg Zn/L in

water, 118 g/kg in sediments, 5 g/kg in soft, and 0.84 µg/m^3 in air. Zinc concentrations in field collections of plants and animals are extremely variable and difficult to interpret. Most authorities agree on six points: (1) elevated concentrations (i.e., >2 g Zn/kg fresh weight [FW]) are normally encountered in some species of oysters, scallops, barnacles, red and brown algae, and terrestrial arthropods; (2) concentrations are usually <700 mg Zn/kg dry weight (DW) tissue in fish, <210 mg Zn/kg DW tissue in birds, and <210 mg Zn/kg DW tissue in mammals; (3) concentrations are higher in animals and plants collected near zinc-contaminated sites than in the same species collected from more distant sites; (4) zinc content in tissue is not proportionate to that of the organism's immediate surroundings; (5) for individual species, zinc concentration varies with age, sex, season, tissue or organ, and other variables; and (6) many species contain zinc loadings far in excess of immediate needs, suggesting active zinc regulation.

The balance between excess and insufficient zinc is important. Zinc deficiency occurs in many species of plants and animals and has severe adverse effects on all stages of growth, development, reproduction, and survival. In humans, zinc deficiency is associated with delayed sexual maturation in adolescent males; poor growth in children; impaired growth of hair, skin, and bones; disrupted vitamin A metabolism; and abnormal taste acuity, hormone metabolism, and immune function. Severe zinc deficiency effects in mammals are usually prevented by diets containing >30 mg Zn/kg DW ration. Zinc deficiency effects are reported in aquatic organism at nominal concentrations between 0.65 and 6.5 µg Zn/L of medium and in piscine diets at <15 mg Zn/kg FW ration. Avian diets should contain >25 mg Zn/kg DW ration for prevention of zinc deficiency effects and <178 mg kg DW for prevention of marginal sublethal effects.

Sensitive terrestrial plants die when soil zinc levels exceed 100 mg/kg (oak and maple seedlings), and photosynthesis is inhibited in lichens at >178 mg Zn/kg DW whole plant. Sensitive terrestrial invertebrates have reduced survival when soil levels exceeded 470 mg Zn/kg (earthworms), reduced growth at >300 mg Zn/kg diet (slugs), and inhibited reproduction at >1,600 mg Zn/kg soil (woodlouse). The most sensitive aquatic species were adversely affected at nominal water concentrations between 10 and 25 µg/L, including representative species of plants, protozoans, sponges, molluscs, crustaceans, echinoderms, fish, and amphibians. Acute LC50 (96 h) values were between 32 and 40,930 µg/L for freshwater invertebrates, 66 and 40,900 µg/L for freshwater teleosts, 195 and >320,000 µg/L for marine invertebrates, and 191 and 38,000 µg/L for marine teleosts. Acute toxicity values were markedly affected by the age and nutrient status of the organism, by changes in the physicochemical regimen, and by interactions with other chemicals, especially copper salts. Pancreatic degeneration occurred in ducks fed diets containing 2,500 mg Zn/kg ration. Ducks died when fed diets containing 3,000 mg Zn/kg feed or when given single oral doses >742 mg Zn/kg BW. Domestic poultry are routinely fed extremely high dietary levels of 20 g Zn/kg ration as a commercial management technique to force the molting of laying hens and the subsequent improvement of long-term egg production that molting produces. However, poultry chicks died at 8 g Zn/kg diet, had reduced growth at 2-3 g Zn/kg diet, and experienced pancreas histopathology when fed selenium-deficient but zinc-adequate (100 mg Zn/kg) diets. Mammals are comparatively resistant to zinc, as judged by their tolerance of extended periods on diets containing >100 times the minimum daily zinc requirement. But excessive zinc through inhalation or ingestation harms mammalian survival, metabolism, and well-being. The most sensitive species of mammals were adversely affected at dietary concentrations of 90 to 300 mg Zn/kg, drinking water concentrations >300 mg Zn/L, daily intakes >9 mg Zn/kg BW, single oral doses >350 mg Zn/kg BW, and air concentrations >0.8 mg Zn/m^3. Humans are comparatively sensitive to excess zinc. Adverse effects occur in humans at >80 mg Zn/kg diet or at daily intakes >2.3 mg/kg BW.

Proposed criteria for protection of aquatic life include mean zinc concentrations of <47 to <59 µg/L in freshwater and <58 to <86 µg Zn/L in seawater. Results of recent studies, however, show significant adverse effects on a growing number of freshwater organisms in the range of 5 to 51 µg Zn/L and on saltwater biota between 9 and 50 µg Zn/L, suggesting that some downward modification in the proposed criteria is necessary.

Although tissue residues are not yet reliable indicators of zinc contamination, zinc poisoning usually occurs in birds when the liver or kidney contains >2.1 g Zn/kg DW and in mammals when concentrations exceed 274 mg Zn/kg DW in kidney, 465 mg Zn/kg DW in liver, or 752 mg Zn/kg DW in pancreas. The proposed air quality criterion for human heath protection is <5 mg Zn/m^3, but guinea pigs were more sensitive and adverse effects were evident at >0.8-4.0 mg/m^3.

Current research needs include the development of protocols to (1) separate, quantitate, and verify the different chemical species of zinc (2) identify natural from anthropogenic sources of zinc; (3) establish toxicity thresholds based on accumulation; (4) evaluate the significance of tissue concentrations in target organs as indicators of zinc stress; and (5) measure the long-term consequences of zinc interactions with other nutrients in animals of various age and nutrient status. (Eisler, R. 1993. Zinc hazards to fish, wildlife, and invertebrates: a synoptic review. U. S. Fish and Wildlife Service Biological Report 10. 106 pp.).

Key words: Zinc, metals, toxicity, deficiency, criteria, residues, agriculture, nutrition, metallothionein, fish, invertebrates, birds, wildlife, livestock.

Zinc is an essential trace element for all living organisms. As a constituent of more than 200 metalloenzymes and other metabolic compounds, zinc assures stability of biological molecules such as DNA and of biological structures such as membranes and ribosomes (Vallee 1959; National Academy of Sciences [NAS] 1979; Casey and Hambidge 1980; Mason et al. 1988; Llobet et al. 1988b; Leonard and Gerber 1989). Plants do not grow well in zinc-depleted soils, and deficiency has resulted in large losses of citrus in California and pecans in Texas (Vallee 1959). Clinical manifestations of zinc deficiency in animals include growth retardation, testicular atrophy, skin changes, and poor appetite (Prasad 1979). The ubiquity of zinc in the environment would seem to make human deficiencies unlikely; however, reports of zinc-associated dwarfism and hypogonadism in adolescent males are now confirmed (Casey and Hambidge 1980) and reflect the fact that much of their dietary zinc is not bioavailable. Zinc deficiency was a major factor in the syndrome of nutritional dwarfism in adolescent males from rural areas of Iran and Egypt in 1961--about 3% of the population in these areas was affected--and a similar syndrome was found in Turkey, Tunisia, Morocco, Portugal, and Panama (Casey and Hambidge 1980). The use of unleavened bread as a major staple food contributed to severe zinc deficiency in the Middle East. Unleavened bread may contain adequate amounts of zinc for nutrition, and intakes may exceed recommended allowances by a wide margin; however, zinc is largely unavailable for absorption because of the high levels of fiber and phytic acid esters in unleavened bread (Casey and Hambidge 1980). Marginal deficiency of zinc in hums is probably widespread and common throughout the world, including the United States (Prasad 1979). Dietary zinc replacement usually reverses the pathologic events of zinc depletion in humans and animals (NAS 1979). But zinc repletion seems to be of little value in rat offspring with congenital malfunctions or behavioral abnormalities associated with zinc depletion (NAS 1979).

Zinc poisoning has been documented in dogs, cats, ferrets, birds, cattle, sheep, and horses, usually as a result of ingesting galvanized metal objects, certain paints and fertilizers, zinc-containing coins, and skin and sunblock preparations containing zinc oxide (Wentink et al. 1985; Ogden et al. 1988; Lu and Combs 1988a; Binnerts 1989; Robinette 1990). Signs of acute poisoning include anorexia, depression, enteritis, diarrhea, decreased milk yield, excessive eating and drinking and, in severe cases, convulsions and death (Ogden et al. 1988). Emissions from zinc smelters at Palmerton, Pennsylvania, destroyed wildlife habitat; reduced prey abundance; poisoned deer, songbirds, and shrews; and eliminated terrestrial amphibians from the mountainside at Lehigh Gap (Beyer et al. 1985; Sileo and Beyer 1985; Beyer 1988). Aquatic populations are frequently decimated in zinc-polluted waters (Solbe and Flook 1975; Everall et al. 1989b). Zinc in the aquatic environment is of particular importance because the gills of fish are physically damaged by high concentrations of zinc (NAS 1979).

Zinc toxicosis in humans is not a common medical problem, although it may appear in some metal workers and others under special conditions (NAS 1979). Industrial processes such as welding, smelting, or fabrication of molten metals can produce ultrafine metal oxides at harmful concentrations. Inhalation of these metal oxides, including oxides of zinc, causes the industrial malady known as metal fume fever (Lain et al. 1985; Lu and Combs 1988a; Llobet et al. 1988b). Symptoms occur several hours after exposure and include fever, chills, perspiration, tachycardia, dyspnea, and chest pains. Recovery is normally complete within 24 h, but susceptible workers can have persistant pulmonary impairment for several days after exposure (Lain et al. 1985). Most reports of human zinc intoxication have been in response to food poisoning from lengthy storage of acidic foods or beverages in galvanized containers (Llobet et al. 1988b; Fosmire 1990).

Historically zinc has been used by humans for industrial, ornamental, or utilitarian purposes for nearly 2,000 years and may have been used as an ointment to treat skin lesions by the ancient Egyptians and other Mediterraneans (NAS 1979). In biblical times, the Romans were known to have produced brass by mixing copper with a zinc ore (Elinder 1986). In its isolated form, zinc was not recognized until the 15th century when smelting occurred accidentally (NAS 1979). The Chinese probably were the first to extract zinc metal, although its first description in 1597 by an occidental traveler, Liborius, related that the process was observed in India (Vallee 1959). Commercial smelting began in the 18th century when it was realized that zinc could be obtained from the calamine ore used to make brass; no reports of zinc toxicosis in any form were recorded from these early accounts (NAS 1979). The first documented use of orally administered zinc was in 1826 to treat discharges from various body orifices (NAS 1979). Zinc was recognized as an essential nutrient for plants and animals in 1869. Its occurrence in biological matter, for example, human liver, was first described in 1877 (Vallee 1959). In 1934, zinc was conclusively demonstrated to be essential to normal growth and development in animals (Prasad 1979).

Zinc composes 0.004% of the earth's crust and is 25th in order of abundance of the elements (Vallee 1959). Uses of zinc include the production of noncorrosive alloys, galvanizing steel and iron products, and the therapeutic treatment of zinc deficiency (Elinder 1986). Zinc is found in coal and many manufactured products such as motor oils, lubricants, tires, and fuel oils (NAS 1979).

Ecological and toxicological aspects of zinc in the environment have been reviewed by many authorities, including Vallee (1959), Skidmore (1964), NAS (1979), Prasad (1979, 1980), U.S. Environmental Protection Agency [EPA] (1980, 1987), Nriagu (1980), Weatherley et al. (1980), Eisler (1981), Spear (1981), Apgar (1985), Elinder (1986), Vymazal (1986), Greger (1989), U.S. Public Health Service [PHS] (1989), and Sorensen (1991).

This report is part of a series of synoptic reviews on hazards of selected chemicals to plants and animals with emphasis on fishery and wildlife resources. It was prepared in response to requests for information on zinc from environmental specialists of the U.S. Fish and Wildlife Service.

Sources and Uses

World production of zinc increased from 0.5 million metric tens in 1900 to 6.1 million metric tons in 1978 (Elinder 1986) and 7.1 million metric tons in 1987 (PHS 1989). The principal ores of zinc are sulfides, such as sphalerite and wurtzite (Elinder 1986). The major world producers include Canada, the former Soviet Union, and Japan--which collectively account for about half the production--and, secondly, the United States, Australasia, Mexico, and Peru (Weatherley et al. 1980; Elinder 1986). Zinc is now available as ingots, lumps, sheets, wire, shot, strips, granules, and powder (PHS 1989). The United States produced 240,000 metric tons of zinc in 1987--mostly from Tennessee, Mississippi, and New York but also from 16 other states--and imported an additional 774,000 metric tons, thus consuming 14% of the world zinc production while producing 3.4% (PHS 1989).

Zinc is mainly used in the production of noncorrosive alloys and brass and in galvanizing steel and iron products. Zinc undergoes oxidation on the surface, thus protecting the underlying metal from degradation. Galvanized products are widely used in construction materials, automobile parts, and household appliances (Elinder 1986). Zinc oxide is used to form white pigments in rubber processing and to coat photocopy paper (EPA 1987; PHS 1989). Zinc sulfate is used as a cooperative agent in fungicides and as a protective agent against zinc deficiency in soils. When incorporated with copper compounds or arsenic-lead wettable powders and applied by spraying, it can minimize the toxic effects of these metals on fruits such as plums, apples, and peaches; in Japan alone, about 250 metric tons of zinc sulfate is sprayed in fields each year (Maita et al. 1981). Zinc is used therapeutically in human medicine in the treatment of zinc deficiency, various skin diseases, wound healing, and to reduce pain in sickle cell anemia patients (Prasad 1979; Spear 1981; EPA 1987; Warner et al. 1988).

Zinc is discharged into the global environment at an estimated yearly rate of 8.8 million metric tons; 96% of the total is a result of human activities (Leonard and Gerber 1989). Major sources of anthropogenic zinc discharges to the environment include electroplaters, smelting and ore processors, drainage from active and inactive mining operations, domestic and industrial sewage, combustion of fossil fuels and solid wastes, road surface runoff, corrosion of zinc alloys and galvanized surfaces, and erosion of agricultural soils (Weatherley et al. 1980; Spear 1981; Mirenda 1986; Llobet et al. 1988a; Buhl and Hamilton 1990). During smelting, large amounts of zinc are emitted into the atmosphere. In the United States alone during 1969, about 50,000 metric

tons of zinc were discharged into the atmosphere during smelting operations (Elinder 1986). Another 20,000 metric tons are discharged annually into U.S. estuaries (Table 1). Zinc is also dispersed from corroded galvanized electrical transmission towers for at least 10 km by runoff and by wind-driven spray and water droplets from the towers (Jones and Burgess 1984). Discharges from placer mining activities usually contain 75-165 µg Zn/L, sometimes up to 882 µg Zn/L in active mines, and these concentrations may represent acute hazards to salmonids in areas downstream of placer mine effluents (Buhl and Hamilton 1990). In Maine, galvanized culverts significantly increased zinc concentrations in stream waters, particularly in newer culverts. Zinc concentrations in culverts were highest during elevated temperatures and low flow; levels of zinc sometimes exceeded the avoidance threshold (0.05 mg/L) of Atlantic salmon (*Salmo salar*); invertebrates seemed unaffected, except for a freshwater sponge, *Spongilla* sp. (Gregory and Trial 1975). Zinc sources implicated in livestock poisonings include galvanized iron wire and troughs and zinc-containing fertilizers and fungicides (Allen et al. 1983; Reece et al. 1986). Zinc toxicosis in humans has been reported from consumption of milk stored in galvanized vessels and from food contaminated with particles of zinc from a zinc pigment plant (Zee et al. 1985). Zinc toxicity is discussed later in greater detail.

Table 1. Estimated annual zinc inputs to U.S. coastal marine ecosystems; study area comprised 116,000 km^2 (Young et al 1980).

Source	Metric tons per year
Rivers	5,950
Atmosphere	4,300
Barged wastes	3,490
Storm channels	3,060
Municipal wastewater	2,500
Direct industrial discharges	710
Vessel protection	360
Dredging release	10
Thermal discharges	2
Groundwater	1
Total	20,383

Chemical and Biochemical Properties

General

Most of the zinc introduced into aquatic environments eventually is partitioned into the sediments. Zinc release from sediments is enhanced under conditions of high dissolved oxygen, low salinity and low pH. Dissolved zinc usually consists of the toxic aquo ion ($Zn(H_2O)_6^{2+}$) and various organic and inorganic complexes. Aquo ions and other toxic species have their greatest effects on aquatic organisms under conditions of comparatively low pH, low alkalinity, low dissolved oxygen, and elevated temperatures.

Zinc has its primary metabolic effect on zinc-dependent enzymes that regulate RNA and DNA. Low molecular weight proteins, metallothioneins, play an important role in zinc homeostasis and in protection against zinc poisoning in animals; zinc is a potent inducer of metallothioneins. The pancreas and bone seem to be primary targets of zinc intoxication in birds and mammals; gill epithelium is the primary target site in fish.

Effects of excess zinc on natural resources are modified by numerous variables, especially by interactions with other chemicals. Interactions frequently produce radically altered patterns of accumulation, metabolism, and toxicity some of which are beneficial to the organism whereas others are harmful.

Chemical Properties

Zinc is a bluish-white metal that dissolves readfly in strong acids. In nature, it occurs as a sulfide, oxide, or carbonate. In solution, it is divalent and can form hydrated Zn^{2+} cations in acids, and zincated anions--probably $Zn(OH)_4^{-2}$-- in strong bases (EPA 1980, 1987). Zinc dust and powder are sold commercially under a variety of trade names: Asarco, Blue powder, CI 77949, CI pigment metal 6, Emanay zinc dust, granular zinc, JASAD Merrillite, L15, and PASCO (PHS 1989). Selected physical and chemical properties of zinc, zinc chloride, and zinc sulfate are listed in Table 2.

Because zinc ligands are soluble in neutral and acidic solutions, zinc is readily transported in most natural waters (EPA 1980, 1987). But zinc oxide, the compound most commonly used in industry, has a low solubility in most solvents (Elinder 1986). Zinc mobility in aquatic ecosystems is a function of the composition of suspended and bed sediments, dissolved and particulate iron and manganese concentrations, pH, salinity, concentrations of complexing ligands, and the concentration of zinc (EPA 1980). In freshwater, zinc is most soluble at low pH and low alkalinity: 10 mg Zn/L of solution at pH 6 that declines to 6.5 mg Zn/L at pH 7, 0.65 mg Zn/L at pH 8, and 0.01 mg/L at pH 9 (Spear 1981). Dissolved zinc rarely exceeds 40 µg/L in Canadian rivers and lakes; higher concentrations are usually associated with zinc-enriched ore deposits and anthropogenic activities. Marine waters usually contain <10 µg Zn/L, most adhering to suspended solids; however, saturated seawater may contain 1.2 - 2.5 mg Zn/L (Spear 1981).

In water the free zinc ion is thought to coordinate with six water molecules to form the octahedral aquo ion $(Zn(H_2O)_6)^{2+}$ in the absence of other complexing or adsorbing agents (Spear 1981). In freshwater zinc exists almost exclusively as the aquo ion at pH >4 and <7 (Campbell and Stokes 1985). In freshwater at pH 6, the dominant forms of dissolved zinc are the free ion (98%) and zinc sulfate (2%); at pH 9 the dominant forms are the monohydroxide ion (78%), zinc carbonate (16%), and the free ion (6%; EPA 1987). In typical river waters, 90% of the zinc is present as aquo ion and the remainder consists of $ZnHCO_3^+$, $ZnCO_3$, and $ZnSO_4$ (Spear 1981).

Table 2. Some properties of zinc, zinc chloride, and zinc sulfate (PHS 1989).

Property	Zinc	Zinc chloride	Zinc sulfate
Formula	Zn	$ZnC1_2$	$ZnSO_4$
CAS number	7440-66-6	7646-85-7	7733-02-0
Molecular weight	65.38	136.29	161.44
Melting point, ° C	419.5	290	Decomposes at 600
Boiling point, °C	908	732	
Density	7.14	2.907	3.54
Physical state	Bluish-white lustrous solid	Solid white granules	Colorless solid
Solubility	Insoluble in water, soluble in acetic acid and alkali	61.4 g/L water, 769 g/L alcohol, 500 g/L glycerol	Soluble in water, slightly soluble in alcohol

Zinc bioavailability and toxicity to aquatic organisms are highest under conditions of low pH, low alkalinity, low dissolved oxygen, and elevated temperatures (Weatherley et al. 1980). Soluble chemical species of zinc are the most bioavailable and most toxic (Spear 1981). The aquo ion predominates over other dissolved species and is suspected of being most toxic; however, aquo ion concentrations decrease under conditions of high

alkalinity, at pH >7.5, and increasing salinity (Spear 1981). Under conditions of high alkalinity and pH 6.5, the most abundant species are $ZnHCO_3^+$, Zn^{2+}, and $ZnCO_3$; at low alkalinity and an elevated pH 8.0, the descending order of abundance was Zn^{2+}, $ZnCO_3$, zinc humic acid, $ZnOH^+$, and $ZnHCO_3^+$ (Spear 1981). Water hardness is the principal modifier of acute zinc toxicity. Increased alkalinity or water hardness decreases toxicity to freshwater organism when all zinc is dissolved; this effect is associated with decreased concentration of aquo ions and is heightened by increased pH. Increased water hardness at pH <8.5 when zinc is in suspension increases toxicity associated with increased suspended $ZnCO_3$. Increased water hardness at pH >8.5 when zinc is in suspension decreases toxicity and increases suspended $Zn(OH)_2$. Suspended zinc carbonate may also be toxic, although its toxicity decreases under conditions suitable to zinc hydroxide formations; suspended $Zn(OH)_2$ is relatively nontoxic. Thus, $ZnCO_3$ composes <1% of the dissolved zinc at low pH and low alkalinity but is the predominant chemical species at high pH and high alkalinity. Organozinc complexes are not stable and under reducing conditions may dissociate, liberating Zn^{2+} (Spear 1981).

In seawater zinc exists in a dissolved state, as a solid precipitate, or adsorbed to particle surfaces. Soluable zinc in seawater exists as uncomplexed free (hydrated) ions, as inorganic complexes (the primary form in the open sea), or as organic complexes (Young et al. 1980). In seawater at pH 8.1, the dominant species of soluble zinc are zinc hydroxide (62%), the free ion (17%), the monochloride ion (6.4%), and zinc carbonate (5.8%). At pH 7, the percentage of dissolved zinc present as the free ion increases to 50% (EPA 1987). In the presence of dissolved organic materials, most of the dissolved zinc is present as organozinc complexes (EPA 1987). In estuaries and other marine environments, the relative abundance of zinc species changes with increasing salinity. At low salinities, $ZnSO_4$ and $ZnC1^+$ predominate; at higher salinities, the aquo ion predominates (Spear 1981). But as salinity decreases, the concentration of free zinc ion increases and the concentration of zinc-chloro complexes decreases, resulting in increased bioavailability of the free metal ion and increased bioconcentration by resident organisms (Nugegoda and Rainbow 1989b).

In solution, zinc is adsorbed by organic agents such as humic materials and biogenic structures (i.e., cell walls of plankton) and by inorganic adsorbing agents such as mineral particles, clays, and hydrous oxides of manganese, iron, and silicon (Spear 1981). Particulate materials in the medium may contain as little as 2% and as much as 100% of the total zinc (Sprague 1986). Formation of zinc-ligand complexes increases the solubility of zinc and probably increases the tendency for zinc to be adsorbed (EPA 1980). Sorption to particulates was lower at higher salinities because of displacement of sorbed zinc ions by alkali and alkaline earth cations (EPA 1987). Increased pH increases zinc sorption to particulates and seems to be independent of water salinity or hardhess (EPA 1987).

Most of the zinc introduced into aquatic environments is sorbed onto hydrous iron and manganese oxides, clay minerals, and organic materials and eventually is partitioned into the sediments (EPA 1987). Zinc is present in sediments as precipitated zinc hydroxide, ferric and manganic oxyhydroxide precipitates, insoluble organic complexes, insoluble sulfides, and other forms. As the sediments change from a reduced to an oxidized state, soluble zinc is mobilized and released however, the bioavailability of different forms of sediment zinc varies substantially and the mechanisms of transfer are poorly understood (EPA 1987). Sorption to sediments was complete at pH >7, but was negligible at pH <6 (EPA 1987). Zinc is dissolved from sediments at low salinities because of displacement of adsorbed zinc ions by alkali and alkaline earth cations that are abundant in brackish waters (EPA 1980). Sulfide precipitation in sediments is an important control of zinc mobility in reducing environment; precipitation of the hydroxide, carbonate, or sulfate may occur when zinc is present in high concentrations (EPA 1980).

Extractable concentrations of sediment-bound zinc positively correlated with zinc concentrations in deposit feeding clams (Luoma and Bryan 1979). Availability of sediment zinc to bivalve molluscs was higher at increased sediment concentrations of amorphous inorganic oxides or humic substances and lower at increased concentrations of organic carbon and ammonium acetatemanganese. Zinc uptake by euryhaline organisms was enhanced at low water salinity (Luoma and Bryan 1979).

Metabolism

Zinc is ubiquitous in the tissues of plants and animals (Rosser and George 1986) and is essential for normal growth, reproduction, and wound healing (Prasad 1979; Stahl et al. 1989a). More than 200 different enzymes require zinc for maximum catalytic activity, including carbonic anhydrase, alkaline phosphatase, alcohol dehydrogenase, acid phosphatase, lactic dehydrogenase, carboxypeptidase, and superoxide dismutase (Prasad 1979, 1980; Casey and Hambidge 1980; Rosser and George 1986; Blesbois and Mauger 1989; Thompson et al. 1989). Zinc has its primary effect on zinc-dependent enzymes that regulate the biosynthesis and catabolic rate of RNA and DNA (Prasad 1979; Casey and Hambidge 1980; Gipouloux et al. 1986; Sternlieb 1988). Zinc exerts a protective effect on liver by inhibiting lipid peroxidation and stabilizing lysosomal membranes (Sternlieb 1988); aids neurotransmission in the brain of fish, birds, reptiles, and mammals (Smeets et al. 1989); prolongs muscular contractions; increases oxygen affinity of myoglobin; is necessary for the growth and differentiation of muscle fiber types (Rosser and George 1986); increases numbers and birthweights of lambs of zinc-supplemented ewes; is essential for wound healing in most studied organisms (Ireland 1986); and is used therapeutically in treating patients with skin diseases, zinc deficiency and other symptoms (Mooradian et al. 1988; Sternlieb 1988).

Zinc enters the gastrointestinal tract as a component of low molecular weight proteins secreted by the salivary glands, intestinal mucosa, pancreas, and liver (Goyer 1986). Usually, only dissolved zinc is sorbed or bound. But zinc dissolution probably occurs in the alimentary tract of animals after ingestion of particulates containing undissolved zinc (EPA 1987). After ingestion, zinc is absorbed across several physiologically active membranes: gut mucosa, alveocapillary membranes, and tissue and organ membranes. The exact transport mechanism are unknown but may be associated with formation of a tetrahedral quadredentate ligand with a small organic molecule (NAS 1979). Some of the zinc taken up by the intestinal epithelial cells is rapidly transferred to the portal plasma where it associates with albumin, 2 macroglobulin, and amino acids; about 67% of the zinc in plasma is bound to albumin and about 3% is stored in the liver (Sternlieb 1988). Soluble organozinc complexes are passively absorbed across the plasma membrane of the mucosa of the intestinal villi; the soluble, nondiffusable complexes are transported in the intestinal products and excreted in feces (NAS 1979). Zinc loss from urine and sweat is usually small (Casey and Hambidge 1980). In a normal human adult about 2 g zinc is filtered by the kidneys daily and about 0.3-0.6 mg is actually excreted each day (Goyer 1986). Zinc homeostasis in rats, unlike in most mammals, is maintained by zinc secretion from the intestines rather than by regulation of zinc absorption (Elinder 1986). Initial uptake of zinc from the rat gastrointestinal tract involves binding to albumin and transport of the zinc-albumin complex from the intestines to the liver (Hoadley and Cousins 1988).

Foods rich in zinc include red meat, milk, gelatin, egg yolks, shellfish, liver, whole grain cereals, lentils, peas, beans, and rice (Sternlieb 1988). About 20-30% of zinc in the diet is absorbed, but this is highly variable and ranges from <10% to >90% (Prasad 1979; Casey and Hambidge 1980; Elinder 1986). Increased zinc absorption, for example, was associated with low body weight (BW), poor zinc status, and various prostaglandins; decreased absorption was caused by excess dietary calcium or phytate and by a deficiency of pyridoxine or tryptophan (Elinder 1986; Goyer 1986). The half-time persistence of zinc in most mammalian tissues is between 100 and 500 days; it is longer in bone and muscle and shorter in the liver (Elinder 1986).

Metallothioneins play an important role in metal homeostasis and in protection against heavy metal toxicity in vertebrates and invertebrates (Engel 1987; Overnell et al. 1987a; Andersen et al. 1989; Olsson et al. 1989; Richards 1989b; Eriksen et al. 1990). Metallothioneins are cysteine-rich (>20%), low (about 6,000) molecular weight proteins with a high affinity for copper, silver, gold, zinc, copper, and mercury. These heat-stable, metal-binding proteins are in all vertebrate tissues and are readily inducible by a variety of agents to which they bind through thiolate linkages. Zinc is a potent inducer of metallothioneins, and a redistribution of zinc from enzymes to metallothioneins is one way to maintain low intracellular zinc concentrations. Metallothioneins also serve as temporary storage proteins for zinc and other metals during early development and may function by maintaining the pool of available zinc at an appropriate concentration. Metallothioneins are quite similar among organisms, that is, all metallothioneins are small proteins of molecular weight 6,000-10,000, rich in sulfur and cysteine, and lack aromatic amino acids (Sprague 1986). Metallothioneins isolated from cattle, sheep, horses, pigs, and other livestock contain 61 amino acids; thioneine, the metal-free protein, is a single chain polypeptide with a molecular weight of about 6,000 (Richards 1989b). Chicken thioneine consists of 63 amino acids, including histidine, an

amino acid not present in mammalian metallothioneins. The unusually high cysteine content enables metallothioneins to selectively bind up to 7 zinc and 12 copper atoms per mole of protein (Richards 1989a).

Metallothioneins are involved in zinc homeostasis in the chick, rat, and calf. When zinc is present at high dietary concentrations, a temporary zinc storage protein aids in counteracting zinc toxicity (Oh et al. 1979). Zinc absorption in mice is directly proportional to intestinal metallothionein levels and implies a significant role of metallothionein in zinc absorption (Starcher et al. 1980). Chick embryo hepatic metallothionein is highly responsive to exogenous zinc introduced into the yolk and increases in a dose-dependent manner; a similar pattern is evident in turkey development (Fleet and McCormick 1988). Zinc protects against subsequent exposure to zinc insult, and protection is believed to be mediated by metallothioneins (Woodall et al. 1988). For example, preexposure of South African clawed frog (*Xenopus laevis*) tadpoles to 5 mg $ZnSO_4$ ($7H_2O$)/L for 96 h resulted in no deaths during subsequent exposure to 15 mg Zn/L for 90 h but in 45% deaths in the nontreated group; at 20 mg Zn/L, 15% died in the pretreated group versus 50% in the nontreated group (Woodall et al. 1988). Metallothioneins are an important factor in zinc regulation during the period of exogenous vitellogenesis in rainbow trout (*Oncorhynchus mykiss*). In female rainbow trout, for example, metallothioneins maintain homeostasis of hepatic zinc during egg formation (Olsson et al. 1989). In plaice (*Pleuronectes platessa*), a marine fish, intraperitoneal injection of zinc raised hepatic metallothionein-ike species by a factor of 15; metallothionein levels remained elevated for the next 4 weeks (Overnell et al. 1987a).

In marine molluscs and crustaceans, excess zinc is usually sequestered by metal-binding proteins and subsequently transported to storage or detoxification sites; soluble proteins and amino acids may contain 20-70% zinc (Sprague 1986). Metallothioneins are actively involved in zinc regulation during normal growth processes in the blue crab (*Callinectes sapidus*), as judged by a decrease in zinc content in the hemolymph and the digestive gland during molting (Engel 1987).

Elevated metallothionein levels are not necessarily indicative of heavy metal insult. Starcher et al. (1980) show that liver metallothionein levels in mice are elevated after acute stress or starvation and that this effect is blocked by actinomycin D, a protein synthesis inhibitor. It is further emphasized that not all zinc-binding proteins are metallothioneins (Webb et al. 1985; Andersen et al. 1989; Richards 1989a; Eriksen et al. 1990). Low molecular weight metal-binding proteins---not metallothioneins--were induced in snails and polychaete annelids in metals-contaminated environments (Andersen et al. 1989). A high molecular weight protein fraction was detected in the plasma of laying turkey (*Meleagris gallopavo*) hens that bound significant amounts of zinc and that coeluted with vitellogenin; vitellogenin, a metalloprotein, from laying hens contained 0.54 mg Zn/kg protein (Richards 1989a). In rock oysters (*Saccostrea cucullata*) collected near an iron-ore shipping terminal, some of the tissue zinc was bound to a high molecular weight (around 550,000), iron-binding protein called ferritin (Webb et al. 1985). Ferritin accounts for about 40% of the protein-bound zinc in rock oysters and most probably in other bivalves containing elevated tissue levels of zinc (Webb et al. 1985); however, this requires verification. In four species of sediment-feeding marine polychaete annelids, zinc was mainly associated with high molecular weight proteins, suggesting that metallothionein-like proteins may not be satisfactory for monitoring purposes and that other cytosolic components should be studied (Eriksen et al. 1990).

High zinc levels induce copper deficiency in rats and interfere with metabolism of calcium and iron (Goyer 1986). Excess zinc interferes with normal metabolism of the pancreas, bone, gall bladder and kidney in mammals and gill in fish. The pancreas is a target organ for zinc toxicity in birds and mammals. Pancreatic alterations are documented from experimentally produced zinc toxicosis in cats, sheep, dogs, calves, chickens, and ducklings and naturally in sheep and calves. Pancreatic changes were limited to acinar cells, specifically cytoplasmic vacuolation, cellular atrophy, and eventually cell death (Lu and Combs 1988a; Kazacos and Van Vleet 1989). Excess zinc may cause stimulation of bone resorption and inhibition of bone formation in chicks, dogs, monkeys, and rats (Kaji et al. 1988). By preferentially accumulating in bone, zinc induces osteomalacia--a softening of the bone caused by deficiency of calcium, phosphorus, and other minerals (Kaji et al. 1988). Zinc plays a role in bone metabolism of aging rats (Yamaguchi et al. 1989b). Normally, the femoral zinc diaphysis content in rats increases from 50 to 150 mg/kg fresh weight (FW) during the first 3 weeks of life and remains constant thereafter. Oral administration of zinc (5-20 mg/kg BW daily for 3-day-old to 28-week-old rats) increased alkaline phosphatase activity and calcium content in the femur and delayed bone deterioration in aging rats (Yamaguchi et al. 1989b). Its high affinity for electrons causes zinc to bind covalently to proteins, mostly at imidazole and cysteine residues. In the mud puppy (*Necturus maculosus*), zinc blocks apical membrane anion exchange in gallbladder epithelium and blocks chloride channels in nerve and muscle cells.

The slow onset and reversal of the effects suggest a covalent modification of the exchanger or an effect requiring Zn^{2+} transport to the cell interior (Kitchens et al. 1990).

Zinc toxicity to aquatic organisms is dependent on the physical and chemical forms of zinc, the toxicity of each form, and the degree of interconversion among the various forms. Aquatic plants and fish are relatively unaffected by suspended zinc, but many aquatic invertebrates and some fish may be adversely affected from ingesting enough zinc-containing particulates (EPA 1987). Zinc toxicosis affects freshwater fish by destruction of gill epithelium and consequent tissue hypoxia. Signs of acute zinc toxicosis in freshwater fish includes osmoregulatory failure, acidosis and low oxygen tensions in arterial blood, and disrupted gas exchange at the gill surface and at internal tissue sites (Spear 1981). Zinc exerts a critical influence on mammalian and piscine immune systems (Ghanmi et al. 1989). Lymphocytes from the pronephros of common carp (*Cyprinus carpio*) were transformed by various mitogenetic agents; zinc added to lymphocyte cultures enhanced thymidine incorporation and inhibited the response of the mitogenetic agents--although Zn^{2+} itself was toxic at these concentrations (650 µgZn^{2+}/L; Ghanmi et al. 1989).

Interactions

Zinc interacts with numerous chemicals. The patterns of accumulation, metabolism, and toxicity from these interactions sometimes greatly differ from those produced by zinc alone. Recognition of these interactions is essential to the understanding of zinc kinetics in the environment.

Cadmium

Calcium-zinc interactions are typical because sometimes they act to the organism's advantage and sometimes not, depending on the organism, its nutritional status, and other variables.

Dietary cadmium accentuates signs of zinc deficiency in turkeys, chicks, rodents, and pigs (NAS 1979). Chicks on a zinc-deficient diet showed an increased frequency of muscle and feather abnormalities when 40 mg Cd/kg diet was added; however, supplementation of the diet with 200 mg Zn/kg for 14-15 days lessened or reversed the adverse effects of cadmium (Supplee 1963). But cadmium promotes the growth of zinc-limited phytoplankton (Price and Morel 1990). Substitution of trace metals or metalloenzymes could be a common strategy for phytoplankton in trace-metal impoverished environments such as the ocean and could result in an effective colimitation of phytoplankton growth by several bioactive elements (Price and Morel 1990). Zinc-deficient marine diatoms (*Thalassiosira weissflogii*), for example, can grow at 90% of their maximum rate when supplied with cadmium (which substitutes for zinc in certain macromolecules); cobalt can also substitute for zinc, although less efficiently than cadmium (Price and Morel 1990).

Zinc diminishes or negates the toxic effects of cadmium. Specifically, zinc protected embryos of the toad (*Bufo arenarum*) and other amphibian embryos against cadmium-induced developmental malformations (Herkovits et al. 1989; Herkovits and Perez-Coll 1990; Rivera et al. 1990). Zinc counteracted adverse effects of cadmium on limb regeneration and on the growth of the fiddler crab (*Uca pugilator*; Weis 1980). Preexposure of a freshwater amphipod (*Gammarus pulex*) to 10 µg Zn/L for 2 weeks increased whole body zinc content from 74 to 142 mg/kg dry weight (DW) and protected against the toxic effects of subsequent cadmium exposure of 500 µg Cd/L for 96 h (Howell 1985). In crickets (*Acheta domesticus*), excess zinc in diets of larvae protected against cadmium toxicity (Migula et al. 1989). Zinc protected rats (*Rattus* sp.) against the toxic effects of cadmium such as testicular lesions, reduced sperm counts, hepatotoxicity, and lung damage (Sato and Nagai 1989; Saxena et al. 1989a). Zinc protected mouse (*Mus* sp.) embryos against cadmium toxicity (Yu and Chan 1988. An effective protection ratio of cadmium to zinc was 1:1 for mouse embryos, but for free living embryos of the toads, this ratio of cadmium to zinc was 1:8 (Belmonte et al. 1989). Zinc reversed the toxic action of cadmium on natural killer cells of mice: 500 mg Zn/L drinking water negated the toxic action of 50 mg Cd/L (Chowdhury and Chandra 1989). The mechanisms of zinc protection against cadmium were variously attributed to metallothionein induction (Sato and Nagai 1989), enhanced detoxification rates of cadmium (Rivera et al. 1990), and competition with cadmium for the same metalloenzyme sites (Yu and Chan 1988; Rivera et al. 1990).

Waterborne solutions of zinc-cadmium mixhires were usually additive in toxicity to aquatic organisms, including freshwater fish (Skidmore 1964) and amphipods (de March B. G. E. 1988), and to marine fish (Eisler and Gardner 1973), copepods (Verriopoulos and Dimas 1988), and amphipods (Ahsanullah et al. 1988).

However, mixtures of zinc and cadmium were less toxic than expected to *Daphnia magna*, as judged by acute lethality studies (Attar and Maly 1982).

Zinc exerted antagonistic effects on uptake of cadmium by gills of the freshwater clam (*Anodonta cygea*) but accelerated cadmium transport from gills towards internal organs (Hemelraad et al. 1987). Cadmium uptake in tissues of *Anodonta* was reduced by about 50% during exposure for 16 weeks to water containing 25 µg Cd/L and 2.5 mg Zn/L (Hemelraad et al. 1987). In a marine prawn (*Pandalus montagui*), cadmium exposure had no effect on tissue zinc levels, but zinc enhanced cadmium uptake in hepatopancreas at the expense of the carcass (Ray et al. 1980). In marine fish, cadmium was taken up more rapidly at elevated seawater zinc levels; however, zinc concentrations in fish tissues decreased with increasing tissue cadmium burdens, suggesting competition between these two metals for the same physiologically active site (Eisler 1981). Zinc concentrations in larval shrimp (*Palaemon serratus*) within its threshold regulation range of 75-525 µg Zn/L were not affected by the addition of 100 µg Cd/L (Devineau and Amiard Triquet 1985). In zebrafish (*Brachydanio rerio*), zinc did not affect cadmium uptake by the whole body or gills but inhibited intestinal uptake and tended to increase gill cadmium elimination rates (Wicklund et al. 1988). Among marine vertebrates, cadmium is selectively accumulated over zinc (Eisler 1984). In ducks, zinc selectively competes with cadmium on high and low molecular weight protein pools in the kidney and liver. Once the high molecular weight protein pool is zinc-saturated excess zinc is stored on metal binding proteins with serious implications for waterfowl stressed simultaneously with cadmium and zinc (Brown et al. 1977). On the other hand, a cadmium-induced disease in bone collagen of chicks was prevented by zinc because of preferential accumulation of zinc (Kaji et al. 1988).

Copper

Mixtures of zinc and copper are generally acknowledged to be more-than-additive in toxicity to a wide variety of aquatic organisms, including oyster larvae (Sprague 1986), marine fish (Eisler and Gardner 1973; Eisler 1984), freshwater fish (Skidmore 1964; Hilmy et al. 1987a) and amphipods (de March 1988), and marine copepods (Sunda et al. 1987; Verriopoulos and Dimas 1988). But zinc-copper mixtures were less-than-additive in toxicity to marine amphipods (*Allorchestes compressa*; Ahsanullah et al. 1988).

Zinc added to the ambient water depressed copper accumulations in tissues of juvenile catfish (*Clarias lazera*), but copper added to the medium depressed zinc uptake Hilmy et al. 1987a). A similar situation was reported in barnacles (*Elminius modestus*); however, simultaneous exposure to copper and zinc resulted in enhanced uptake of both metals (Elliott et al. 1985).

In higher organisms, zinc is a copper antagonist and potentiates the effects of nutritional copper deficiency in rats and chicks. This effect only occurs at extremely high zinc to copper dietary ratios. The addition of copper to the diet of chicks or rats in physiological amounts counteracted all observed signs of zinc intoxication (Tom et al. 1977). No antagonism was evident between dietary copper and zinc fed to channel catfish (*Ictalurus punctatus*) fingerlings; therefore, the high levels of supplemental zinc required in practical feeds should not impair copper status if normal dietary copper levels are present (Gatlin et al. 1989).

High levels of administered zinc limit copper uptake in humans and certain animals (Samman and Roberts 1988) and provides protection against toxicosis produced by copper in pigs and sheep (Allen et al. 1983). Excessive zinc in humans interferes with copper absorption from the intestine, resulting in copper deficiency and eventually in cardiovascular diseases; high zinc intakes also decrease iron bioavailability, leading to a reduction of erythrocyte life span by 67% (Saxena et al. 1989b). Copper deficiency induced by excess dietary zinc is associated with lameness in horses, donkeys, and mules (NAS 1979; Bridges 1990; Ostrowski et al. 1990).

Lead

Lead-zinc mixtures were more-than-additive in toxicity to marine copepods (Verriopoulos and Dimas 1988) and significantly delayed development of mud crab (*Rithropanopeus harrisii*) larvae (EPA 1987). Lead is accumulated up to 10 times more rapidly by marine fish at elevated zinc concentrations in seawater (Eisler 1981).

Among terrestrial animals, zinc protects against lead toxicosis. Dietary zinc reduced the toxic effects of dietary lead to larvae of the house cricket (Migula et al. 1989). Zinc at 100-200 µg/egg (1 mg Zn/kg egg) significantly protected developing white leghorn chicks against lead-induced 50 µg/egg) deformities and death

when injected into the yolk sac on day 7 of incubation (Anwer et al. 1988). Zinc also protects against lead toxicity in horses (Anwer et al. 1988) and against testicular injury induced by lead in rats (Saxena et al. 1989a).

Nickel

Nickel-zinc mixtures were additive in toxicity to marine copepods (Verriopoulos and Dimas 1988) and to the three-spined stickleback (Skidmore 1964).

Oral nickel toxicity in chicks was prevented by increased dietary zinc (Warner et al. 1988). Nickel is a leading cause of allergic contact dermatitis in many industrial nations; about 6% of the general public and about 11% of dermatology clinic patients are sensitive to nickel (Warner et al. 1988). Zinc prevents nickel sulfate-induced allergic contact dermatitis in guinea pigs (*Cavia* spp.) through addition of 100-200 mg Zn/L drinking water for 4 weeks before nickel insult (Warner et al. 1988). Nickel and other metals that cause allergic contact dermatitis penetrate the skin, complex with selected ligands, and stimulate a delayed hypersensitivity. Zinc is thought to block the sites where nickel complexes to the protein (Warner et al. 1988).

Other Chemicals

Zinc interacts with a wide variety of inorganic, organic, and biological agents, but in most cases the available information is fragmentary and the mechanisms of action are unknown. Mice pretreated with zinc at 6.5 mg Zn/kg BW for 9 days showed increased resistance to arsenic toxicosis during a 30-day observation period (Kreppel et al. 1988). Oral zinc therapy was effective in treating biological agents such as infectious pododermatitis in cattle; ovine foot rot in sheep; sporidesmin in sheep, cattle, and rodents; and the toxins of the fungus *Phomopsis leptostromiformis* in sheep (Allen et al. 1983). Calcium modifies zinc toxicity to freshwater aquatic organisms, and increased calcium is associated with decreased acute toxicity (Everall et al. 1989b; Handy et al. 1989). Zinc absorption in the rat gut is decreased after ingestion of phosphorus as polyphosphate or as orthophosphate and high levels of calcium (Greger 1989). Zinc cytotoxicity is blocked by increased calcium or iron but not by magnesium (Borovansky and Riley 1989). Zinc reportedly protects rats against carbon tetrachloride poisoning (Allen et al. 1983).

Various cheating agents, including disodium ethylene diamine tetraacetic acid (EDTA), disodium calcium cyclohexanediamine tetraacetate, D-penicillamine, 2,3-dimercapto-l-propane sulfonic acid, and 2,3-dimercaptosuccinic acid protect mice against zinc acetate poisoning (Llobet et al. 1988b). Zinc protects toad embryos against agents known to produce malformations, including excess Vitamin A, acetazolamide, calcium-EDTA, and acetaminophen (Herkovits et al. 1989). Venom of the jararaca (*Bothrops jararaca*), a venomous Brazilian serpent, contains a zinc metalloprotease called J protease; the proteolytic activity of J protease is inactivated by EDTA and other sequestering agents (Tanizaki et al. 1989).

Chromium-zinc mixtures were more than additive in toxicity to *Tisbe holothuriae*, a marine copepod. Zinc in combination with chromium was more toxic to copepods than mixtures of zinc with copper, lead, nickel, or cadmium (Verriopoulos and Dimas 1988).

Renal tubular absorption of zinc in mice was impaired by certain diuretics and was further influenced by dietary proteins (Goyer 1986).

Zinc absorption in rats was depressed after consumption of high levels of inorganic iron; absorption was normal with organoirons (Greger 1989).

Mercury-zinc mixtures were more-than-additive in toxicity to oyster larvae (Sprague 1986). Preexposure of common mussels (*Mytilus edulis*) to 50 µg Zn/L for 28 days conferred increased tolerance to 75 µg Hg/L (Roesijadi and Fellingham 1987). Zinc inhibited the accumulation of mercury in marine snails and crustaceans (Andersen et al. 1989).

Zinc deficiency places an increased demand on selenium pools in daphnids. As little as 5 µg Se/L in zinc-free water eliminated overt cuticle damage and substantially increased reproduction but did not alter the shortened life span. Cladocerans at the threshold of selenium deficiency become overly selenium-deficient when zinc supplies are lacking (Keating and Caffrey 1989). Insufficient copper introduces cuticle problems in daphnids similar to those introduced by insufficient zinc or selenium, increasing the likelihood of a proposed

relation between glutathione peroxidase (which contains selenium) and copper-zinc superoxide dismutase (Keating and Caffrey 1989).

High levels of dietary tin increased zinc loss from rats (Greger 1989). Zinc prevented toxic effects of vanadium (10 mg/kg BW) on bone metabolism of weanling rats (Yamaguchi et al. 1989a).

Carcinogenicity, Mutagenicity, Teratogenicity

General

When injected directly into the testes, zinc can induce testicular sarcomas in birds and rats but has not been shown to be tumorogenic by any other route. Zinc promotes tumor growth after conditions of zinc deficiency but excess zinc may suppress or inhibit tumor proliferation, although the mechanisms of the action are imperfectly understood. Chromosomal aberrations were observed under conditions of zinc deficiency, but excess zinc was not mutagenic in most tests. Organozinc compounds are effective mutagens when presented to susceptible cell populations in an appropriate form, but the evidence for inorganic zinc is incomplete. Zinc is teratogenic to frog and fish embryos, but conclusive evidence of teratogenicity in mammals is lacking. Zinc may protect against the effects of some mammalian teratogens. Under conditions of mild zinc deficiency, however, diabetes and effects of various teratogens are exacerbated.

Carcinogenicity

Carbamate esters of zinc, zineb, and ziram are carcinogenic and teratogenic in animals, which is, however, attributed to the action of the carbamate esters and not to zinc (Elinder 1986). Results of studies with small mammals showed zinc to be cocarcinogenic with 4-nitroquinoline-N-oxide on oral cancer and with N-ethyl-N-nitrosourea on brain cancer (Leonard and Gerber 1989).

There is conclusive evidence that repeated intratesticular injections of zinc salts can induce testicular sarcomas in birds and rats (NAS 1979; Elinder 1986; Goyer 1986; PHS 1989). Testicular teratomas in roosters were first produced experimentally in 1926 when zinc salts were injected into the testes as a method of practical castration; tumors could be induced only by intratesticular injection during the spring period of gonadal growth (Guthrie 1971). Teratomas of the testes were observed in fowl given testicular injections of 2 mL of 10% $ZnSO_4$ solution (PHS 1989). Teratomas were induced in Japanese quails (*Coturnix coturnix japonica*) by intratesticular injections of 3% zinc chloride solutions during a period of testicular growth stimulated by increased photoperiod; tumors were similar to those of domestic fowl and have histological features in common with spontaneous testicular teratomas in humans (Guthrie 1971). Testicular tumors in rats were produced by direct intratesticular injection of zinc; no other carcinogenic effects were produced by any other route regardless of dose (Goyer 1986). It is emphasized that zinc and zinc compounds are not conclusively carcinogenic except when injected directly into the testes; no field or experimental evidence exists showing zinc to be tumorogenic through any other route (NAS 1979; Phillips and Kindred 1980; Elinder 1986; Leonard and Gerber 1989; PHS 1989).

Zinc is essential for the growth of rapidly proliferating cells such as tumors. The high zinc requirements of these cells in tumor disease can result in latent zinc deficiency. Accordingly, growth of animal tumors is stimulated by zinc and retarded by zinc deficiency (Prasad 1979; Leonard and Gerber 1989). In mouse fibrosarcoma cells, zinc inhibits endonucleases, subsequently blocking DNA fragmentation and tumor cell lysis, allowing tumors to grow (Flieger et al. 1989). There is no evidence that zinc deficiency causes cancer (NAS 1979), although deficiency was associated with decreasing tumor growth (Prasad 1979; Phillips and Kindred 1980). Malignant human tissues, for example, frequently contained less zinc than normal tissue, that is, 78 mg/kg FW in a normal liver versus 18 mg/kg FW in a cancerous liver (Phillips and Kindred 1980).

Zinc can also inhibit tumor growth (NAS 1979), although the mechanisms of zinc suppression of carcinomas are imperfectly understood (Phillips and Kindred 1980). Zinc inhibits the growth of mouse melanoma cells at concentrations between 8.2 and 9.9 mg Zn/L culture medium (Borovansky and Riley 1989). The addition of 100 mg $ZnSO_4$/L to drinking water of hamsters inhibited formation of dimethylbenzanthracene-induced carcinomas (Phillips and Kindred 1980). High zinc diets of 500 mg/kg ration reduced growth of a chemically induced hepatoma in rats (Phillips and Kindred 1980). Intramuscular injections of zinc oxide or zinc acetate administered together with nickel sulfide--a potent muscle carcinogen--delayed but did not prevent 100% tumor incidence in rats during a 66-week observation period (Kasprzak et al. 1988). Administration of zinc slows the carcinogenic

process induced by nickel from the production of water-soluble and water-insoluble zinc compounds, despite markedly different retention times in muscle of zinc compounds (Tb½ ZnO = 24 days, zinc acetate = 2.5 days, Ni_3S_2 = 21 days). Zinc in either form exerted no measurable influence on nickel retention at the injection site or early local cellular reactions to nickel (Kasprzak et al. 1988). Testicular tumors in rats caused by injection of cadmium were suppressed by zinc injection (Leonard and Gerber 1989) when the zinc to cadmium molar ratio was about 100:1 (Phillips and Kindred 1980). Inhibition of cadmium carcinogenesis by zinc is a complex phenomenon, depending on dose, route, and target site (Waalkes et al. 1989). For example, the number of cadmium-induced testicular tumors in rats was reduced by 50% during a 2-year period after three subcutaneous injections of 65.4 mg Zn/kg BW given within 18 h of the initial cadmium insult, although unlike controls, this group had a marked elevation in prostatic tumors; tumor number was reduced by 92% when rats were given 100 mg Zn/L in drinking water (Waalkes et al. 1989).

Mutagenicity

Results of mutagenicity studies with whole organisms were usually negative because homeostatic controls of absorption and protein binding preclude the likelihood of zinc being genotoxic under standard feeding conditions (Thompson et al. 1989). However, zinc is an effective mutagen and clastogen when presented to a susceptible cell population in an appropriate form (Thompson et al. 1989). Zinc acetate produced dose-related positive responses in the mouse lymphoma assay and also in a cytogenetic assay with Chinese hamster ovary cells; however, results of mutagenicity assays with inorganic zinc were negative in the *Salmonella* mutation assay and in unscheduled DNA synthesis on primary cultures of rat hepatocytes (Thompson et al. 1989). Organozinc compounds have mutagenic potential, as judged by the positive responses with zinc 2,4-pentanedione and *Salmonella* (Thompson et al. 1989).

Structural chromosome aberrations, particularly chromatid gaps and increased frequency of fragment exchange, were observed in rat bone marrow cells after 14 days of exposure to 240 mg Zn/L drinking water (Kowalska-Wochna et al. 1988). Chromosomal aberrations were observed in bone marrow cells of mice fed diets equivalent to 650 mg Zn/kg BW daily in mice exposed to zinc oxide by inhalation, and in mice maintained on a low calcium diet (PHS 1989). Aberrations in bone marrow of mice given 5,000 mg Zn/kg diet may be associated with calcium deficiency (Leonard and Gerber 1989). Calcium is displaced by zinc in calcium-depleted conditions, leading to chromosomal breaks and interference in the repair process (PHS 1989).

Zinc chloride induces chromosomal aberrations in human lymphocytes in vitro (Elinder 1986). A higher incidence of chromosome anomalies in leukocytes occurs among workers exposed to zinc (Elinder 1986), but these aberrations are probably due to other (unspecified) mutagenic factors in the work environment (Leonard and Gerber 1989).

Zinc inhibits the mutagenic action of some carcinogens because it is a constituent of mutagen detoxifying enzymes or because it acts directly on the microsomal monooxygenases forming the ultimate carcinogen (Leonard and Gerber 1989). Zinc significantly reduced a genotoxic effect of lead in rat bone marrow cells (500 mg Pb/L drinking water followed by 240 mg Zn/L for 2 weeks) and also protected against lead accumulations in erythrocytes and lead-induced inhibition of delta-amino levulinic acid dehydratase (Kowalska-Wochna et al. 1988). Zinc deficiency can lead to chromosomal aberrations, but excess zinc was not mutagenic in the majority of tests for DNA damage--except for zinc-containing fungicides wherein the organic dithiocarbamate constituents were the mutagenic agents and for zinc chromate wherein the chromate ion was the active agent (Leonard and Gerber 1989). Frequencies of sister chromatid exchanges in calves with hereditary zinc deficiency, also known as Lethal Trait A46, are lower than in healthy normal cows, suggesting a fundamental association between disturbed zinc metabolism and the low incidence of sister chromatid exchanges in A46 cattle (Bosma et al. 1988).

Teratogenicity

Excess zinc is teratogenic to frog and fish embryos, possibly by inhibition of DNA synthesis (Dawson et al. 1988; Fort et al. 1989). Zinc at 150 mg/kg in rat diets was associated with inhibited fetal implantation but this needs confirmation (Elinder 1986). No conclusive evidence now exists demonstrating that excessive zinc produces any teratogenic effect in mammals (NAS 1979; Dawson et al. 1988; Leonard and Gerber 1989).

Excess zinc may protect against some teratogens, such as calcium EDTA (Leonard and Gerber 1989). Also, teratogenic effects of cadmium salts in golden hamsters was reduced by simultaneous administration of zinc salts (NAS 1979).

Zinc deficiency is clearly teratogenic in mammals (Dawson et al. 1988; Leonard and Gerber 1989). Severe maternal zinc deficiency is known to be teratogenic in rats. Fetal malformations--especially calcification defects--from maternal zinc deficiency affect almost every tissue (Ferreira et al. 1989). Skeletal malformations are most common, possibly because of a reduction in cellular proliferation and in activity of bone alkaline phosphatase (Leonard and Gerber 1989). Human zinc deficiency may act teratogenically, either directly or indirectly through other toxic agents (Jameson 1980). Zinc deficiency may exacerbate effects of several teratogenic agents such as thalidomide; there is also the possibility that zinc deficiency may increase the incidence of spina bifida and anencephaly, but this needs verification (Leonard and Gerber 1989). Diabetes during pregnancy can amplify the effects of a mild maternal zinc deficiency. In one study, diabetic and nondiabetic rat strains were fed a low zinc diet (4.5 mg Zn/kg diet), an adequate zinc diet (24.5 mg/kg), or a high zinc diet (500 mg/kg) throughout gestation. Fetuses from diabetic dams were smaller, weighed less, and had less calcified skeletons and more malformations than fetuses from control dams. In controls, maternal dietary zinc had a minor effect on fetal malformation frequency. In diabetic strains, however, the low zinc diet had a strong teratogenic effect (Uriu-Hare et al. 1989).

Background Concentrations

General

Total zinc concentrations in nonbiological samples seldom exceed 40 µg/L in water, 200 mg/kg in soils and sediments, or 0.5 µg/m^3 in air. Environments heavily contaminated by anthropogenic activities may contain up to 99 mg Zn/L in water 118 g/kg in sediments, 5 g/kg in soil, and 0.84 µg/m^3 in the atmosphere. Zinc was detectable in all samples of plants and animals measured. Grossly-elevated (i.e., >4 g/kg DW) concentrations were normally encountered in selected tissues of marine bivalve molluscs, barnacles, and polychaete annelids. In general, zinc concentrations were elevated in organisms collected near anthropogenic point sources of zinc contamination but were modified substantially by the organism's diet, age, reproductive state, and zinc-specific sites of accumulation as well as by inherent interspecies differences.

Nonbiological

Zinc concentrations in freshwater, seawater, groundwater, sewage sludge, sediments, and soils are listed in Table 3. These data are considered reliable, although newer clean laboratory techniques suggest that dissolved zinc concentrations in nonpolluted rivers may be 10 to 100 times lower than previously reported (Shiller and Boyle 1985).

Zinc concentrations in water seldom exceed 40 µg/L except near mining, electroplating and similar activities--where concentrations between 260 and 954 µg/L were frequently recorded. Drinking water usually contains <10 µg Zn/L, although concentrations >2 mg/L may occur after passage through galvanized pipes (Goyer 1986). Zinc-contaminated streams in the Platte River Basin sometimes contain up to 99 mg Zn/L and in Arkansas up to 79 mg/L (Mirenda 1986). Zinc concentrations in water downstream of placer mining activities in Alaska sometimes exceed the concentrations that are toxic to the Arctic grayling, *Thymallus arcticus* (Buhl and Hamilton 1990). The disappearance of the stone loach (*Noemacheilus barbatulus*) in the United Kingdom from streams receiving industrial wastes was attributed directly to zinc concentrations in the stream rising from 1 mg/L to a lethal 5 mg/L (Solbe and Flook 1975).

Table 3. Zinc concentrations (milligrams of zinc per kilogram fresh weight [FW] or dry weight [DW] in representative nonbiological materials.

[a]Concentrations are shown as means, range (in parentheses), and maximum (Max.).

[b] 1. Spear 1981; 2. Mann et al. 1989; 3. Buhl and Hamilton 1990; 4. EPA 1987; 5. Mann and Fyfe 1988; 6. Sprague 1986; 7. Nugegoda and Rainbow 1988b; 8. Young et al. 1980; 9. Eisler et al. 1977; 10. Beyer 1990; 11. Elinder 1986.

Concentrations of zinc in sediments and soils usually do not exceed 200 mg/kg but can range between 3 and 118 g/kg as a result of human activities (Table 3). Atmospheric zinc levels were almost always <1 µg/m^3, although they tended to be higher over industrialized areas (Goyer 1986). Average zinc concentrations were <0.001 µg/m^3 atmosphere at the South Pole, 0.01-0.02 µg,/m^3 atmosphere in rural areas of the United States, <0.01-0.84 µg/m^3 atmosphere in U.S. cities, and 0.06-0.35 µg/m^3 atmosphere at various locations in the United Kingdom (Elinder 1986).

Biological

Zinc measurements in field collections of plants and animals (Table 4) show several trends. (1) Zinc is present in all tissues of all organisms measured. (2) Concentrations are elevated in organisms near anthropogenic point sources of zinc contamination. (3) Concentrations are normally grossly elevated (>4 g/kg FW soft parts) in bivalve molluscs and barnacles. (4) Zinc-specific sites of accumulation include the frond in algae; the kidney in molluscs; the hepatopancreas in crustaceans; the jaws in polychaete annelids; the viscera, gonad, and brain in fish; the liver, kidney, and bone in birds; and the serum, pancreas, feces, liver, kidney, and bone in mammals. (5) Interspecies variations in zinc content are considerable, even among taxonomically closely-related species. (6) Intraspecies differences in zinc content vary with age, size, sex, season, and other modifiers. (7) Many species regulate zinc within a threshold range of concentrations.

Additional information on background concentrations of zinc is given in Vallee (1959), NAS (1979), Young et al. (1980), and Eisler (1980, 1981).

Terrestrial Plants and Invertebrates

Zinc concentrations in forest plants vary considerably. Some species of oaks (*Quercus* spp.), for example, are accumulators whereas others may be termed discriminators. In descending order of concentration zinc is in the roots, foliage, branches, and trunk of individual species (Van Hook et al. 1980). Small lateral roots accumulate zinc to much greater levels than other vegetation components and are probably most sensitive to changes in zinc inputs. Half-time persistence of zinc in forest ecosystems varies from about 3 years in organic matter components to >200 years in large soil pools (Van Hook et al. 1980).

Table 4. Effects of zinc on representative terrestrial plants and invertebrates.

Taxonomic group, organism, and other variables	Concentration[a] (mg/kg)	Reference[b]
Aquatic plants		
Euglena sp., from acidic mine tailings waste discharges (0.9 mg Zn/L, Max. 3.3 mg/L)	143 DW; Max. 410 DW	1

150 km	80 DW	35
Grass shrimp, *Palaemonetes pugio*		
From sediments containing 627 mg Zn/kg DW		
Exoskeleton	58 FW	36
Muscle	55 FW	36
From sediments containing 8 mg Zn/kg DW		
Exoskeleton	18 FW	36
Muscle	30 FW	36
Prawn, *Pandalus montagui*		
Cuticle	57 DW	37
Eye	70 DW	37
Gill	106 DW	37
Hepatopancreas	30 DW	37
Muscle	57 DW	37
Whole	58 DW	37
Pink shrimp, *Penaeus brasiliensis*, adults, whole	(47-75) DW; (181-290) FW	38
Insects, marine, whole	110-197 DW	13
Chaetognaths, whole	76-90 DW	13
Annelids, aquatic		
Annelids, marine		
Jaws		
Total	5,000-24,000 DW	13
Basal section	1,790 DW	13
Distal section	34,950 DW	13
Whole body	22-1,564 DW	13
Lugworm, *Arenicola*, *marina*, whole	1.8 FW	14
Freshwater leech, *Erpobdella octoculata*, adults, whole body	Upstream (18 µg Zn/L) from zinc-polluted mine waste discharge, whole body content of 1,439-1,559 DW; reproduction normal. Downstream (180 µg Zn/L), concentration after 19-month exposure was 1,932-2,432 DW; reproduction impaired	116
Sandworm, *Nereis diversicolor*		

Head	843-995 DW	39
Parapodia	216-418 DW	39
Trunk	158-218 DW	39
Echinoderms, various species, **whole**	Usually 100 DW or lower, frequently >100 DW; Max. 245 FW, 1,500 DW	3,13
Tunicates, whole	200 DW; Max. 64 FW, 370 DW	3, 13
Fish		
Catostomids, 3 species, Missouri, blood		
Site contaminated with mine tailings	10.9-13.4 FW, 94-119 DW	40
Uncontaminated site	8.7-11.2 FW, 76-86 DW	40
White sucker, *Catostomus commersoni*		
From metals-contaminated lake (400 µg Zn/L)		
Eggs	83-158 DW	41
Larvae	511 DW	41
Ovaries		
Prespawning	114 DW	41
Postspawning	290 DW	41
Testes, postspawning	89 DW	41
From control lake (2.7 µg Zn/L)		
Eggs	69-108 DW	41
Larvae	163 DW	41
Ovaries		
Prespawning	84 DW	41
Postspawning	317 DW	41
Testes, postspawning	163 DW	41
New Brunswick, whole	92-93 DW	42
Nova Scotia, whole	98-122 DW	42
African sharptooth catfish, *Clarias gariepinus*, age 4-8 years, South Africa, 1988-89, lake sediments contained 1,104 mg Zn/kg DW (595-2,189)		
Brain	335 DW	43
Fat	5O DW	43
Gill	177 DW	43
Gonad	126 DW	43
Heart	196 DW	43
Intestine	143 DW	43
Kidney	143 DW	43
Liver	143 DW	43
Muscle	59 DW	43
Spleen	163 DW	43

Vertebrae	75 DW	43
Baltic herring, *Clupea harengus*, liver	23 FW	14
Freshwater fish, various species		
Great Lakes		
Whole, less intestines, 4 species	12-20 FW	19
Liver, 10 species	11-48 FW	19
Greece, 1987-88, muscle, 11 species	7 (3-37) FW	44
United States, nationwide, whole		
1978-79	25 (8-168) FW	45
1980-81	24 (9-109) FW	45
1984		
Geometric mean	21.7 FW	121
85th percentile	34.2 FW	121
Maximum	118.4 FW	121
From metals-contaminated (636 µg dissolved Zn/L) lake, Indiana, whole		
Bowfin, *Amia calva*	93 DW	46
White sucker, *Catostomus commersoni*	102 DW; Max. 152 DW	46
Brown bullhead, *Ictalurus nebulosus*	127 DW; Max. 139 DW	46
Warmouth, *Lepomis gulosus*	140 DW; Max. 166 DW	46
Orangespot sunfish, *Lepomis humilis*	248 DW	46
Redear sunfish, *Lepomis microlophus*	477 DW; Max. 820 DW	46
Largemouth bass, *Micropterus salmoides*	119 DW; Max. 207 DW	46
Golden shiner, *Notemigonus crysoleucas*	160 DW; Max. 171 DW	46
Yellow perch, *Perca flavescens*	160 DW; Max. 171 DW	46
Black crappie, *Pomoxis nigromaculatus*	123 DW	46
From metals-contaminated stream, Missouri, muscle, 5 species	3.1-24 FW	47,115
Shortfin mako, *Isurus oxyrinchus*, vertebrae	36 (5-127) DW	48
Marine fish, various species		
Muscle		
54 species	0-5 FW	19
32 species	5.1-10 FW	19
7 species	10.1-15 FW	19
4 species	15.1-20 FW	19

2 species	20.1-25 FW	19
Whole	80 DW	3
Red Sea, 1980-82		
Triggerfish, *Balistoides viridiscens*		
Muscle	66 DW	49
Liver	154 (81-227) DW	49
Ovaries	291 (287-792) DW	49
Surgeonfish, *Ctenochaetus strigosus*, muscle	29 (11-43) DW	49
Halfbeak, *Hemiramphus marginatus*, muscle	32 DW	49
Labrids, 3 species, muscle	33 (19-51) DW	49
Lethrinids *Lethrinus* spp.		
Muscle	33 (13-112) DW	49
Liver	95 (43-146) DW	49
Ovaries	146 (72-259) DW	49

Terrestrial plants growing beneath corroded galvanized fencing have been poisoned by zinc (Jones and Burgess 1984). Vegetables are relatively low in zinc, but growing plants can accumulate zinc applied to soils (Geyer 1986). High soil level of zinc is the primary cause of vegetation damage near zinc smelters (Buchauer 1971; Leonard and Gerber 1989). Elevated zinc concentrations in soils near zinc smelters inhibit seedling root elongation and probably prevent establishment of invader species in denuded areas (Buchauer 1971). Lichen species richness and abundance were reduced by about 90% in lichen communities near a Pennsylvania zinc smelter; elevated zinc concentrations were the probable cause of the impoverished lichen flora (Nash 1975). Soils and vegetation surrounding zinc smelters in Palmerton, Pennsylvania were grossly contaminated with zinc, cadmium, and lead. Zinc was primarily responsible for the destruction of trees and subsequent erosion of the soil, reductions in moss and lichen flora, reductions in litter arthropod populations, and reductions in species diversity of soil fungi and bacteria; zinc residues were elevated in slugs and millipedes (Sileo and Beyer 1985; Beyer 1988). Soil litter invertebrates were rare or absent 2 km downwind of the smelter; unlike soil litter invertebrates from more distant sites, invertebrates collected up to 10 km upwind of the smelters had significantly elevated zinc concentrations (Beyer et al. 1985).

The maximum zinc concentration in earthworms collected from a contaminated site was 1,600 mg/kg DW whole animal; for uncontaminated sites it was 650 mg/kg (Beyer and Cromartie 1987). Whole body zinc concentrations in earthworms (*Dendrodrilus rubidus*, *Lumbricus rubellus*) tended to reflect zinc concentrations in

soil, although zinc accumulations in both species seem to be physiologically regulated when soil zinc values exceeded 1,000 mg/kg DW (Morgan and Morgan 1988).

Whole body zinc content of terrestrial isopods seems to reflect soil zinc levels and may be a useful indicator of soil contamination (Hopkin et al. 1989). *Porcellio scaber*, a terrestrial isopod known as a woodlouse, is recommended as a biological indicator of zinc contamination because of the positive correlation between zinc content in soil or leaf litter and woodlouse hepatopancreas. Zinc content in *Porcellio*, litter, and soil near a zinc smelter was >1,000 mg/kg DW in whole isopod, >9,000 mg/kg DW in hepatopancreas, > 10,000 mg/kg DW in litter, and >50,000 mg/kg DW in soil (Hopkin et al. 1986).

Interspecies variability in zinc content of terrestrial invertebrates is large and governed by numerous modifiers. For example, whole body zinc content in closely-related species of terrestrial gastropods collected from a single contaminated site was between 600 and 1,200 mg/kg DW (Greville and Morgan 1989a). In grey field slugs (*Deroceras reticulatum*), zinc was highest in late spring and lowest in summer and positively correlated with tissue cadmium concentrations; starvation for 16 days had no effect on body zinc concentrations (Greville and Morgan 1989b). Zinc tends to concentrate in mechanical structures of various invertebrates, such as mandibular teeth. High concentrations of zinc are reported in jaws of polychaete worms, cutting edges of the mandibles of herbivorous insects, mandibles of various species of beetles, copepod mandibles, chaetognath teeth and spines, mandibular teeth of ants, and fangs of spiders (Schofield and Lefevre 1989). Honey bees (*Apis mellifera*) collected near a lead smelting complex at East Helena, Montana, had depressed whole body zinc concentrations despite increased ambient air zinc values; however, whole body burdens of arsenic, cadmium, copper, and lead were significantly elevated and may have influenced zinc kinetics (Bromenshenk et al. 1988). Also, pollen was usually the most indicative source of zinc and other heavy metals in bees (Veleminsky et al. 1990).

Aquatic Organisms

Concentrations of zinc in tissues of aquatic organisms are usually far in excess of that required for normal metabolism. Much of the excess zinc is bound to macromolecules or present as insoluble metal inclusions in tissues (Eisler 1981, 1984; EPA 1987). Diet is the most significant source of zinc to aquatic organisms and is substantially more important than uptake from seawater (Eisler 1981, 1984). In general, zinc concentrations in sediments and tissues of aquatic organisms are elevated in the vicinity of smelters and other point sources of zinc and decrease with increasing distance (Ward et al. 1986; Table 4).

Freshwater algae in Canadian mine tailing environments heavily concentrate zinc and other metals and may retard metal dispersion through the water column (Mann and Fyfe 1988). Zinc levels in field collections of marine algae and macrophytes are usually at least several orders of magnitude higher than zinc concentrations in the surrounding seawater (Eisler 1981). In general, concentrations in marine aquatic flora were high when seawater zinc concentrations were elevated, although the relation was not linear. Marine flora, especially red and brown algae, are among the most effective marine zinc accumulators. Increasing accumulations of zinc in marine algae were associated with decreasing light intensity, decreasing pH, increasing temperature, decreasing levels of DDT, and increasing oxygen. Ionic zinc was accumulated more rapidly than other forms of zinc (Eisler 1981). Many species of marine algae had zinc concentrations >1 g/kg DW (Eisler 1980). These grossly elevated levels were usually associated with nearby industrial or domestic outfalls containing substantial amounts of zinc (Eisler 1981). In eelgrass (*Zostera marina*), zinc concentrations increased with age of leaf (Brix and Lyngby 1982).

In the Fal estuary, England, long-term metal pollution during the past 120 years resulted in zinc sediment levels between 679 and 1,780 mg/kg DW, producing benthic communities that favor zinc-tolerant organisms, such as oysters and nereid polychaetes, and a general impoverishment of mussels, cockles, non-nereid polychaetes, and gastropods (Bryan et al. 1987).

Zinc in molluscs is usually associated with high molecular weight proteins, with diet (as opposed to ambient water zinc concentrations), from collection locales with elevated sediment zinc burdens, and with particulate matter from dredging and storm perturbations (Eisler 1981). Zinc levels in molluscs were highest in animals collected near anthropogenic point sources of zinc. Excess zinc accumulations do not seem to affect normal molluscan life processes, and zinc is frequently accumulated far in excess of the organism's immediate needs (Eisler 1981). American oysters (*Crassostrea virginica*), for example, may naturally contain up to 4 g Zn/kg FW

soft parts; this is comparable to accumulations observed in oysters exposed to 0.2 mg Zn/L for 20 weeks (NAS 1979). Zinc tends to accumulate in the molluscan digestive gland and stomach as excretory granules and in the kidney as concretions (Eisler 1981; Sprague 1986; Sullivan et al. 1988). The preferred storage site in mussels and scallops is the kidney and in oysters, the digestive gland (Sprague 1986). In oysters, granules may contain up to 60% of the total body zinc, explaining, in part, how some shellfish can exist with such high body burdens (Sprague 1986).

Zinc in molluscan tissues is usually elevated under conditions of increasing water temperature and pH and decreasing salinity (Eisler 1981); however, zinc accumulation kinetics in molluscs vary considerably among species (Chu et al. 1990). Variations in zinc content of clam tissues were associated with seasonal changes in tissue weights (Cain and Luoma 1986). Unlike conspecifics collected at more distant sites, gastropods nearest a ferronickel smelter had elevated zinc concentrations in the hepatopancreas; however, there were no consistent seasonal variations (Nicolaidu and Nott 1990). Fluctuations in zinc content of common mussels (*Mytilus edulis*) related to size or season of collection were sufficient to conceal low chronic or short-term pollution (Amiard et al. 1986). Diet, which is the primary route of zinc accumulation in most molluscs, had no significant effect on whole body zinc content of certain predatory marine gastropods. Whole body zinc concentrations of gastropod oyster drills (*Ocenebra erinacea*) were between 1,451 and 2,169 mg/kg DW and remained unchanged after feeding for 6 weeks on Pacific oysters (*Crassostrea gigas*) containing 1,577 mg Zn/kg DW or common mussels (*Mytilus edulis*) containing 63 mg Zn/kg DW (Amiard-Triquet et al. 1988).

High zinc concentrations in crustaceans are usually associated with industrial contamination. In barnacles (*Balanus* spp.), high (>3.3 g/kg DW soft parts) levels are attributed to inorganic granules that contain up to 38% zinc and that accumulate in tissue surrounding the midgut (Eisler 1980, 1981). In descending order of chemical abundance, the granules consist of phosphorus, zinc, potassium, sulfur, and chlorine (Thomas and Ritz 1986). These insoluble, membrane-limited spheres form in response to high zinc levels in the ambient seawater within 12 days of exposure and concentrate in specified cells around the gut: the stratum perintestinale (Walker et al. 1975; Sprague 1986; Thomas and Ritz 1986). Zinc granules in barnacles represent a detoxification mechanism for surplus zinc (Thomas and Ritz 1986). Older barnacles have greater whole body zinc accumulations than younger stages, and accumulations change seasonally (Anil and Wagh 1988). Zinc concentrations in marine crustacean tissues are usually <75 mg/kg FW or <100 mg/kg DW; exceptions include hepatopancreas, molts, eggs, fecal pellets, and barnacles (Table 4). In crustaceans, zinc is slightly elevated in hepatopancreas but in most tissues only 2 to 3 times higher than in muscle (Sprague 1986). For marine crustaceans, the highest concentration recorded in muscle was 57 mg Zn/kg FW in the king crab, *Paralithodes camtschatika* (NAS 1979), and was associated with two metal binding proteins of molecular weight 11,500 and 27,000 (Eisler 1981). In crustacean tissues, zinc levels were higher in summer at lower salinities and in young animals (Eisler 1981), although young amphipods had higher zinc residues than older stages (Rainbow 1989). Seasonal accumulations of whole body zinc in the shrimp (*Palaemon serratus*) during spring and summer and loss in winter seem to reflect water zinc concentrations in the range of 0.0 to 9.0 µg/L (Alliot and Frenet-Piron 1990). Zinc is present in crustacean serum at concentrations >1,000 times greater than in ambient seawater in serum, it serves primarily as a cofactor of carbonic anhydrase--the principal enzyme involved in calcification. Serum zinc concentrations in crustaceans seem to be independent of season and water temperature or salinity (Sprague 1986).

Molting results in a 33-50% loss of total zinc in marine crustaceans; molts, together with fecal pellets, constitute an important vehicle of zinc transfer in marine ecosystems (Eisler 1981). The freshwater opossum shrimp (*Mysis relicta*) can transport zinc from sediments into the water column and in the reverse during their migratory cycle. *Mysis relicta* and other benthic invertebrates play an important role in determining the concentration of zinc and other metals in lake sediments (Van Duyn-Henderson and Lasenby 1986). Unlike decapod crustaceans, marine amphipods do not regulate body zinc concentrations; amphipod body burdens of zinc may reflect sediment total zinc levels and suggest that certain groups may be suitable bioindicators (Rainbow et al. 1989). Molting had no effect on body zinc concentration in four species of adult marine amphipods (Weeks and Moore 1991), and this forces a reexamination of the role of cast exuviae in zinc transport.

In annelids, zinc content was highest in nonselective deposit feeders, omnivores, and carnivores and from animals collected from sediments with elevated zinc levels (Eisler 1981). Freshwater tubificid worms have the potential to increase zinc concentrations in the water column, particularly during short episodes of high

burrowing activity (Krantzberg and Stokes 1985). A high zinc content seems to be a structural characteristic of jaws of marine nereid worms (Table 4). In the marine polychaete worm *Nereis diversicolor*, zinc is localized in the gut wall, epidermis, nephridia, and blood vessels; most of the body zinc is present in wandering amoebocytic cells of excretory organs. Zinc in *Nereis* may be present as insoluble granules in membrane bound vesicles; excretion is through exocytosis with the aid of amoebocytes (Fernandez and Jones 1989). Unlike the insoluble zinc phosphate granules of molluscs and crustaceans, zinc granules in *Nereis* were very soluble and retained only by sulfide precipitation (Pirie et al. 1985).

Marine vertebrates, including fish and elasmobranchs, have lower zinc concentrations in tisues (6-400 mg/kg DW) than marine plants and invertebrates (Eisler 1980, 1981, 1984). Highest concentrations in muscle of marine fish (20.1-25.0 mg/kg FW) were recorded in the northern anchovy (*Engraulis mordax*) and the Atlantic menhaden (*Brevoortia tyrannus*; NAS 1979). The highest zinc concentrations measured in whole freshwater fish in the conterminous United States in 1978-79 were in common carp (*Cyprinus carpio*) from Utah; concentrations in carp from Utah were between 70 and 168 mg Zn/kg FW versus an average of 63 mg Zn/kg FW for this species collected elsewhere (Lowe et al. 1985). Zinc concentrations in fish tend to be higher near urban areas (Peterson et al. 1989); highest in eggs, viscera and liver (Eisler and LaRoche 1972; Eisler 1981); lowest in muscle (Eisler 1981); positively correlated with metallothionein concentrations (Overnell et al. 1987b); lower in all tissues with increasing age and growth (Eisler and LaRoche 1972; Eisler 1981, 1984; Grady et al. 1989); and relatively unaffected by water salinity, temperature, or copper concentrations (Eisler and LaRoche 1972; Eisler 1981). Zinc residue data from marine fish that were dead on collection are of limited worth because dead fish accumulate zinc from seawater at a substantially higher rate than living teleosts (Eisler 1981).

Zinc concentrations in fish and other aquatic vertebrates are modified by diet, age of the organism, reproductive state, and other variables. In fish, diet is the major route of zinc uptake and juveniles accumulate zinc from the medium more rapidly than embryos or larvae (Cutshall et al. 1977; Eisler 1981). Because the diet of many teleost carnivores changes drastically with age and because upper trophic level vertebrates are frequently used as indicators of water quality, more research into zinc burdens in prey organisms is needed (Eisler 1984). A reduction in serum zinc during egg formation in a flatfish (*Pleuronectes platessa*) may represent a transfer of zinc to eggs (Overnell et al. 1987b). High (>35 mg/kg FW) zinc concentrations in eggs of Atlantic salmon are sometimes associated with increasing mortality, although low (14 mg/kg FW) concentrations seem to have no adverse effect on survival (Craik and Harvey 1988). Zinc concentrations in Atlantic salmon milt ranged from 0.5 to 5.5 mg Zn/kg and was linearly proportional to spermatozoan abundance (Poston and Ketola 1989). In lakes containing 1,150 mg Zn/kg sediment and 209-253 µg Zn/L water column, white sucker (*Catostomus commersoni*) females did not grow after sexual maturity and had increased incidences of spawning failure. Alterations in growth and reproduction were related, in part, to nutritional deficiencies as a result of chronic effects of elevated sediment zinc on the food base of the sucker, that is, invertebrate fauna were absent in the uppermost 7 m (Munkittrick and Dixon 1988). Eggs of the white sucker incubated at a metals-contaminated site (400 µg Zn/L), but not eggs of conspecifics, at a noncontaminated (2.7 µg Zn/L) site, produced larvae with a decreased tolerance to copper and with elevated zinc body burdens; larval size and fertilization rate were the same at both sites (Munkittrick and Dixon 1989).

Birds

Zinc residues were elevated in birds collected near zinc smelters (Beyer 1988). In general, the highest concentrations of zinc in birds are in the liver and kidney and the lowest in muscle (Eisler 1981, 1984). In giant Canada geese (*Branta canadensis maxima*), more zinc is contained in red muscle than in white muscle and more in slow contracting muscle than in fast muscle (Rosser and George 1986). Zinc concentrations in marine birds normally are between 12 mg/kg FW in eggs and 88 mg/kg FW in the liver. The highest recorded concentration of zinc in a marine bird was 541 mg/kg DW in the liver of a booby (*Sula* sp.) that died from polychlorinated biphenyl poisoning. Elevated zinc levels in these birds may have been a manifestation of toxicant-induced stress (i.e., breakdown in osmoregulatory processes), as in other taxonomic groups (Eisler 1981). Seabirds with high zinc concentrations in the liver and kidney tend to have high cadmium levels in these tissues (Muirhead and Furness 1988). In flamingos, zinc in the liver positively correlated with copper levels in the liver and kidney and with metallothionein levels in the kidney (Cosson 1989). In egrets, zinc positively correlated with metallothionein protein levels in the liver (Cosson 1989). In blue-winged teals (*Anas discors*), zinc concentrations were higher in the liver than in muscle, higher in males than in females, and higher in

autumn than in spring (Warren et al. 1990). Zinc concentrations in the liver of black-crowned night-herons (*Nycticorax nycticorax*) were usually higher in younger birds, although weight and sex had no direct effect on zinc content (Custer and Mulhern 1983). Zinc concentrations in tissues and feathers of dead California condors (*Gymnogyps californianus*) that had died from a variety of causes (Table 4) were similar to those in turkey vultures (*Cathartes aura*), common ravens (*Corvus corax*), and ospreys (*Pandion haliaetus*) and are considered normal (Wiemeyer et al. 1988). The highest recorded concentration in condor liver of 250 mg/kg FW approaches those in livers of mallards (*Anas platyrhynchos*) that died from high dietary loadings of zinc (Wiemeyer et al. 1988). Zinc concentrations in the liver of ospreys were similar between age groups and sexes (Wiemeyer et al. 1987). With the onset of egg production in turkeys (*Meleagris gallopavo*), serum zinc in hens increased from 1.6 to 6.9 mg/L and remained significant elevated throughout egg laying; during this same period, zinc concentration in the liver declined from 75 to 39 mg/kg DW, although total zinc in the liver increased because of an increase in liver weight (Richards 1989a).

Zinc concentrations in the sediments of the Rhine River increased about 6 times between 1900 and 1950 and have remained stable since then. But migratory waterfowl from this collection locale do not have elevated zinc concentrations in their primary feathers (Goede 1985). Zinc content in feathers of the hoopoe (*Upupa epops*) increased from 200 mg/kg DW at age 7 days to 1,000 mg/kg DW at age 35 days (Kaur 1989). Hoopoe populations are declining in India and this decline is said to be associated with increasing zinc concentrations in feathers (Kaur 1989). Feathers of the greater flamingo (*Phoenicopterus ruber*) are proposed indicators of atmospheric zinc contamination: the average zinc content was 53% more in outer barbs of the black primary feathers exposed to air pollution than in inner barbs (Cosson et al. 1988a). More research into the use of feathers as indicators of zinc contamination is needed.

Zinc concentrations in seminal plasma are about 100 times lower in domestic chickens (*Gallus* sp.) than in humans and most other mammals, except sheep. Concentrations of zinc in fowl seminal plasma after in vivo storage of spermatozoa for 24 h at 4°C were near the threshold values toxic to spermatozoa (Blesbois and Mauger 1989), suggesting that poultry spermatozoa normally function near their lower lethal zinc threshold.

Mammals

White-tailed deer (*Odocoileus virginianus*) collected near a zinc smelter, but not conspecifics from more distant sites, had elevated tissue zinc concentrations. Deer with zinc concentrations of 150 mg/kg FW (750 mg/kg DW) in the renal cortex potion of the kidney had swollen joints, lameness, and joint lesions similar to those of zinc-posioned horses from the same area (Sileo and Beyer 1985). Zinc was elevated in the kidney cortex of red deer (*Cervus elaphus*) and older deer tended to have higher concentrations (as high as 184 mg/kg DW) than younger deer (as low as 20 mg/kg FW); in older deer, zinc was associated with the metallothionein fraction (Holterman et al. 1984). Zinc residues were usually elevated in rodents near smelters (Beyer et al. 1988). Rodents from metals-contaminated forests had zinc loadings in tissues similar to those from control locations, although lead and cadmium were significantly elevated in the contaminated zone (Sawicka-Kapusta et al. 1987). Elevated zinc concentrations in mine tailings reportedly do not represent a notable contamination hazard to the invading mammalian fauna, although zinc concentrations in invertebrates, especially earthworms, and vegetation were elevated (Andrews et al. 1989; Table 4).

Otters (*Lutra lutra*) were found only on a single unpolluted tributary of a river system contaminated by zinc mine drainage waste, suggesting that a contaminated food supply may be responsible for the avoidance by otters of otherwise suitable habitat (Mason and Macdonald 1988).

Marine mammals collected near heavily urbanized or industrialized areas or near zinc pollution point sources, but not individuals of the same species and of similar age from relatively pristine environments, usually had elevated zinc concentrations (Eisler 1984). Zinc concentrations in tissues of the ringed seal (*Phoca hispida*) were essentially the same in animals near a lead-zinc mine and in animals in a distant reference site, although lead and selenium burdens were elevated in the vicinity of the mine site (Wagemann 1989). Concentrations of zinc in tissues of the Northern sea lion (*Eumetopias jubata*) were highest in the liver and pancreas and next highest in descending order in the kidney, muscle, heart, spleen, and lung; this rank order is comparable to that in human tissues (Hamanaka et al. 1982). There is considerable variation among species in tissue zinc concentrations; threefold differences are not uncommon for the same tissue in different species of marine mammals (Muir et al. 1988). Marine mammals contained the lowest zinc concentrations (2-505 mg/kg DW, elevated in the liver) of all groups of marine organisms examined. Because zinc is usually available in sufficient

quantity in the marine environment and is usually accumulated in excess of the organism's immediate needs, it remains unclear why zinc is comparatively depressed in tissues of marine mammals (Eisler 1981).

Zinc toxicosis in horses near a zinc smelter was characterized by lameness, swollen joints, and unkempt appearance, particularly in foals. Zinc concentrations in afflicted foals, but not in foals at more distant sites, were elevated in the pancreas, liver, kidney, and serum (Gunson et al. 1982). Foals born near the smelter had joint swellings that were attributable to generalized osteochondrosis; lesions were similar to those induced experimentally in animals fed high zinc diets and may have been the result of a zinc-induced abnormal copper metabolism (Gunson et al. 1982). Concentration of zinc in tissues of horses from farms near the Palmerton smelter were extremely high and approaching lethal thresholds in some cases; zinc poisoning was a cause of debility and death of foals (Sileo and Beyer 1985). Grazing mares managed with standard husbandry had significant monthly variations in plasma zinc because, in part, of dietary factors such as nutritional supplementation and seasonal variations in the quality of grazing pasture (Auer et al. 1988b). Peak plasma zinc levels in horses positively relate to age (in weanlings age 22-52 weeks) and to summer diets (Cymbaluk and Christison 1989).

Dairy cattle near a lead and zinc ore processing facility did not have elevated blood or hair zinc levels, although daily zinc intake was 5.6 mg/kg BW versus 1.2 mg/kg BW daily by cattle in a control area (Milhaud and Mehannaoui 1988). In cattle, proximity to zinc refineries did not result in significant elevation of zinc concentrations in the liver and kidney (Spierenburg et al. 1988). However, cows living within 6 km of a power plant in Czechoslovakia, but not a herd at a 26-km distance, had elevated zinc loadings in hair and poor reproduction (Pisa and Cibulka 1989). In adult bovines, zinc reserves are usually small and located primarily in the skeleton and muscle, although appreciable hepatic accumulations can occur in the fetus. At 270 days of gestation, for example, 30% of zinc in fetal cattle is in the liver; zinc concentration is about 4 times higher in the fetal than in the maternal liver (Gooneratne and Christensen 1989). Liver concentrations >120 mg Zn/kg DW in cattle are frequently associated with elevated dietary zinc loadings (Binnerts 1989). Concentrations of zinc in milk of cows and goats varied significantly between breeds and with zinc level in diet and declined markedly after parturition (Park and Chukwu 1989).

A normal 70-kg human male contains 1.5-2.0 g zinc or about 21-29 mg Zn/kg BW; normal zinc uptake is 12-15 mg daily, equivalent to 0.17-0.21 mg/kg BW (Prasad 1979). Foods rich in zinc are seafoods, meats, grains, dairy products, nuts, and legumes (Goyer 1986). About 90% of the total body zinc is in the musculoskeletal system (Rosser and George 1986). Highest zinc concentrations of 100-200 mg/kg occur in the prostate, eye, brain, hair, bone, and reproductive organs; intermediate concentrations of 40-50 mg/kg occur in the liver, kidney, and muscle (NAS 1979; Casey and Hambidge 1980). In blood, about 80% of the total zinc is in red cells where it is associated with carbonic anhydrase. The mean plasma zinc level is about 0.9 mg/L; about half is in a freely-exchangeable form loosely bound to albumin; most of the remainder is tightly bound to macroglobulins and amino acids, especially histidine and cysteine (Casey and Hambidge 1980; Goyer 1986). The greatest zinc concentration in the human body is in the prostate and may be related to the elevated levels of acid phosphatase, a zinc-containing enzyme in that organ (Goyer 1986). The prostate gland contributes zinc to spermatozoa in dogs--a necessary process for canine fertility and fecundity; in rats, however, the prostate does not contribute to zinc in spermatozoa, and its function is not essential for reproduction in rats (Saito et al. 1967).

Zinc Deficiency Effects

General

Zinc is important in the metabolism of proteins and nucleic acids and is essential for the synthesis of DNA and RNA. Zinc deficiency has been reported in humans and a wide variety of plants and animals--with severe effects on all stages of reproduction, growth, and tissue proliferation in the young. In early gestation, zinc deficiency may cause severe congenital abnormalities. Later in gestation, deficiency can cause growth inhibition and brain growth impairment, leading to altered behavioral development after birth. Feeding a low zinc diet to lactating dams produces signs of zinc deficiency in suckling pups. In humans, zinc deficiency is associated with delayed sexual maturation in adolescent males; poor growth in young children; impaired growth of hair, skin, and bone; disrupted Vitamin A metabolism; and abnormal taste acuity, hormone metabolism, and immune function.

Terrestrial Plants

Zinc deficiencies in citrus groves in California, pecan trees in Texas, and various crops in Australia resulted in large crop losses (Vallee 1959). Applications of zinc salts were effective under acidic soil conditions. But neutral or alkaline soils rendered zinc salts insoluble and zinc therapy ineffective. Zinc salts sprayed on leaves or injected into tree trunks overcame the problems of soil solubility and have generally been successful (Vallee 1959). Zinc is usually bound strongly in plants, particularly in grains, markedly decreasing its availability to animal consumers. Binding is attributed mainly to high content of phytate and also to high levels of fiber hemicelluloses, and amino acid-carbohydrate complexes (Casey and Hambidge 1980). Whole-grain cereals and legumes are considered rich sources of zinc (Casey and Hambidge 1980).

Aquatic Organisms

Nutritional zinc deficiency is rare in aquatic organisms (Spear 1981), although reports are available of experimentally-induced zinc deficiency in algae, sponges, daphnids, echinoderms, fish, and amphibians.

Experimental zinc deficiency in euglenoids (*Euglena gracilis*) was associated with arrested growth and abnormal cell differentiation and development, leading to extensive teratological abnormalities. Zinc-deprived *Euglena* survived for extended periods through decreased metabolism (Falchuk et al. 1985; Falchuk 1988). Marine algae stopped growing when ambient zinc concentrations fell below 0.7 µg/L, and zinc-deficient cultures of freshwater algae were unable to metabolize silicon (Vymazal 1986).

A freshwater sponge (*Ephydatia fluviatilis*) grew normally at a concentration of 0.65 µg Zn/L, but growth was reduced at lower concentrations (Francis and Harrison 1988).

Daphnids (*Daphnia pulex*, *Daphnia magna*) reared for six brood cycles in zinc-free water showed reduced survival, inhibited reproduction, and cuticle damage (Keating and Caffrey 1989).

Zinc is important in pH regulation of sperm of marine invertebrates. Zinc reduction in semen to <6.5 µg/L adversely affected sperm pH and motility in sea urchins (*Strongylocentrotus purpuratus*, *Lytechnicus pictus*), horseshoe crab (*Limulus polyphemus*), and starfish (Clapper et al. 1985a, 1985b).

Rainbow trout fry fed diets containing 1-4 mg Zn/kg ration had poor growth, increased morality, cataracts, and fin erosion; supplementing the diet to 15-30 mg Zn/kg alleviate these signs (Spry et al. 1988). Spry et al. (1988) also fed rainbow trout fry diets containing 1, 90, or 590 mg Zn/kg ration and simultaneously exposed them to a range of waterborne zinc concentrations of 7, 39, 148, or 529 µg Zn/L. After 16 weeks, the 7 µg Zn/L plus 1 mg/kg diet group showed clear signs of deficiency including a significantly reduced plasma zinc concentration (which was evident as early as the first week of exposure), reduced growth (with no growth after week 12), decreased hematocrit, and reduced plasma protein and whole body zinc concentration. Elevating waterbone zinc to 39 or 148 µg Zn/L partially corrected the deficiency but did not restore plasma or whole body zinc to initial levels or in fish raised for 16 weeks on a zinc-adequate diet of 90 mg Zn/kg ration. There were no toxic effects at any other dietary-waterborne zinc mixture. It was concluded that zinc uptake from water was independent of uptake from diet because at any dietary zinc level, an increase in the waterborne zinc resulted in an increase in whole body zinc. In freshwater, where waterborne concentrations of <10 µg Zn/L are most commonly encountered, waterborne zinc contributions to whole body zinc loadings are probably insignificant. When dietary zinc was adequate (i.e., 90 mg Zn/kg ration), the contribution of waterborne zinc was significant in the case of rainbow trout (Spry et al. 1988). In marine teleosts, diet is the major zinc source when seawater contained <15 µg Zn/L; at higher ambient concentrations of 600 µg Zn/L, waterborne zinc contributed up to 50% of the total body zinc burden (Spry et al. 1988).

Experimentally-produced zinc deficiency in toad embryos resulted in adults with abnormal ovarian development, altered meiotic and ovulation processes, and embryos with a high incidence of congenital malformations (Herkovits et al. 1989).

Birds

Zinc deficiency in the chicken, turkey, and Japanese quail is characterized by low survival, reduced growth rate and food intake, poor feathering, shortening and thickening of long bones of legs and wings, reduced egg production and hatchability, skeletal deformities in embryos, an uncoordinated gait, reduced bone alkaline

phosphatase activity, and increased susceptibility to infection (Blamberg et al. 1960; NAS 1979; Prasad 1979; Apgar 1985; O'Dell et al. 1989); Stahl et al. 1989a).

Laying hens (*Gallus* sp.) had low egg hatchability on diets that contained 6 mg Zn/kg and produced chicks that were weak and poorly feathered; these chicks usually died within a few days on 8-9-mg Zn/kg diets (Blamberg et al. 1960). Zinc-deficient chicks (13-16 mg Zn/kg DW diet for 4 weeks) had pathological defects in epiphyseal cartilage; no interference with calcification was noted in controls fed diets containing 93-96 mg Zn/kg feed (Westmoreland and Hoekstra 1969). Pullets fed diets containing 28 mg Zn/kg for 4 months and then 4 mg Zn/kg ration for 4.5 months produced few hatchable eggs after 4 months; prevalent malformations included faulty trunk and limb development, missing vertebrae, missing limbs and toes, abnormal brain morphology, small eyes, and skeletal malformations (Blamberg et al. 1960). Most zinc deficiency effects were reversed by increasing dietary zinc concentrations to 96-120 mg/kg (Blamberg et al. 1960).

Chicks of the Japanese quail fed an excess of zinc (25-30 mg Zn/kg diet) during their first week of life were protected during a subsequent period of zinc deprivation (1 mg Zn/kg diet for 1 week). Birds that received an initial intake of zinc in excess of requirements grew significantly better than birds on a minimal amount of zinc. Japanese quails may store excess zinc in bones; this zinc store may become available during a subsequent period of zinc deprivation, especially during a period of rapid bone growth (Harland et al. 1975); but this requires verification.

Egg production constitutes a major loss of zinc and other trace metals by the laying hen. Vitellogenin mediates the transfer of zinc from the liver to the maturing oocyte, ultimately resulting in deposition into yolk of the newly formed egg (Richards 1989a). More research into the role of zinc in avian reproduction seems needed.

Mammals

Compared with zinc toxicity, zinc deficiency is a much more frequent risk to mammals (Leonard and Gerber 1989). Zinc is required in all stages of the cell cycle, and deficiency adversely affects metabolism of DNA, RNA, proteins, and activity of carbonic anhydrase, lactic dehydrogenase, mannosidase, and other enzymes (NAS 1979; Prasad 1979, 1980; Apgar and Everett 1988). In zinc deficiency, the activity of various zinc-dependent enzymes are reduced in testes, bone, esophagus, and kidney of rats, and alkaline phosphatase activity is reduced in bone and plasma of zinc-deficient rats, pigs, and cows (Prasad 1979; Vergnes et al. 1990). Deficiency leads to loss of appetite and taste, skin disturbances, slow wound healing, impaired brain development, deficient immune system, and disrupted water metabolism (Binnerts 1989). Zinc deficiency adversely affected testicular function in humans and animals and seems to be essential for spermatogenesis and testosterone metabolism (Prasad 1980). Zinc deficiency in young men with very low zinc intakes resulted in testicular lesions and reduced accessory gland weights, primarily from reduced food intake and growth (Apgar 1985). Zinc deficiency during pregnancy produced low birth weight, malformations, and poor survival in rats, lambs, and pigs; the role of zinc in human reproductive problems is still unclear (Apgar 1985). Zinc-deficient diets for ruminants and small laboratory animals usually contain <1 mg Zn/kg ration, although rats show deficiency at <12 mg Zn/kg ration (Elinder 1986). Zinc deficiency has been documented in humans, small laboratory animals, domestic livestock, minks, and monkeys; signs of severe zinc deficiency in mammals include decreased food intake, growth cessation, fetal malformations, testicular atrophy, swelling of feet, excessive salivation, dermal lesions, parakeratosis of the esophagus, impaired reproduction, hair loss; unkempt appearance, stiffness, abnormal gait, skin and organ histopathology, and hypersensitivity to touch (NAS 1979; Jameson 1980; Elinder 1986; Gupta et al. 1988; O'Dell et al. 1989). Selected examples of zinc deficiency in various species follow.

Zinc deficiency in humans is rare and usually associated with severe malabsorption, parenteral alimentation lacking zinc, or geophagia (Sternlieb 1988). Symptoms of zinc deficiency depend in part on age, acuteness of onset, duration and severity of the zinc depletion, and the circumstances in which deficiency occurs. Many of the features of zinc deficiency observed in humans are similar to those in zinc-deficient animals (Casey and Hambidge 1980). Simple nutritional deficiency from marginal zinc intake may be common even in the United States (Casey and Hambidge 1980). Factors of zinc deficiency include inadequate dietary intake (protein-calorie malnutrition), decreased availability (high fiber-phytate diets), decreased absorption, excessive losses (increased sweating, burns), increased requirements (rapid growth, pregnancy, lactation), as well as old age, alcoholism, and possible genetic defects (Casey and Hambidge 1980). Zinc deficiency may also occur as a

result of liver or kidney disease, gastrointestinal disorders, skin disorders, parasitic infections, diabetes, and genetic disorders, such as sickle cell disease (Prasad 1979). Clinical disorders aggravated by zinc deficiency include ulcerative colitis, chronic renal disease, and hemolytic anemia (Goyer 1986). In the 40 years since human zinc deficiency was demonstrated, it has been observed in a wide variety of geographic areas and economic circumstances. Severe zinc deficiency occurs in some areas of the Middle East and North Africa and is frequently associated with the consumption of unrefined cereals as a major part of the diet (Casey and Hambidge 1980). Chronic zinc deficiency in humans is associated with dwarfism, infantile testes, delayed sexual maturity, birth defects, poor appetite, mental lethargy, immunodeficiency, skin disorders, night blindness, impotence, spleen and liver enlargement, defective mobilization of vitamin A, delayed wound healing, impaired taste acuity, abnormal glucose tolerance, impaired secretion of luteinizing hormone, and iron and folate deficiency (Prasad 1979, 1980; Casey and Hambidge 1980; Elinder 1986; Goyer 1986; Sternlieb 1988; Mackay-Sim and Dreosti 1989). A deficiency of zinc in the growing age period results in growth retardation; a severe zinc deficiency may be fatal if untreated (Prasad 1980). Zinc-deficient humans excrete <100 µg zinc daily in urine rather than a normal daily >300 µg zinc (Goyer 1986). Zinc deficiency may exacerbate impaired copper nutrition; interactions with cadmium and lead may modify the toxicity of these metals (Goyer 1986). Acrodermatitis enterohepatica is a disease characterized by skin eruptions, gastrointestinal disorders, and low serum zinc levels. One causative factor is poor intestinal absorption of zinc; a complete cure was accomplished by oral administration of 135 mg zinc daily as 600 mg zinc sulfate (Elinder 1986). Using radiozinc-65, it was shown that afflicted individuals had a greater turnover of plasma zinc, a smaller pool of exchangeable zinc, and a reduced excretion of zinc in stool and urine (Prasad 1979). Zinc deficiency in humans is usually treated by oral administration of 1 mg Zn/kg BW daily (Casey and Hambidge 1980). However, zinc-deficient humans given daily intravenous injections of 23 mg zinc experienced profuse sweating blurred vision, and hypothermia (Saxena et al. 1989b). An endemic zinc deficiency syndrome among young men has been reported from Iran and Egypt and is characterized by retarded growth, infantile testes, delayed sexual maturation, mental lethargy, anemia, reduced concentration of zinc in plasma and red cells, enlarged liver and spleen, and hyperpigmentation; oral supplementation of 30 mg zinc daily had a prompt beneficial effect (Prasad 1979; Elder 1986). A zinc deficiency syndrome during human pregnancy includes increased maternal morbidity, abnormal taste sensations, prolonged gestation, inefficient labor, atonic bleeding, and increased risks to the fetus (Jameson 1980). Pregnant women with initially low and subsequently decreasing serum zinc levels had a high frequency of complications at delivery, including congenital malformations in infants. (Jameson 1980). Multiple severe skeletal abnormalities and organ malformations in human fetuses have been attributed to zinc deficiency (Casey and Hambidge 1980). In newborns, zinc deficiency is manifested by growth retardation, dermatitis, hair loss, impaired healing, susceptibility to infections, and neuropsychologic abnormalities (Casey and Hambidge 1980; Goyer 1986).

Hereditary zinc deficiency occurs in certain strains of cattle (*Bos* spp.) and affects the skin and mucous membranes of the gastrointestinal tract. The disease, Lethal Trait A46, is caused by failure of a single autosomal recessive gene regulating zinc absorption from the intestine. Affected animals die within a few months from secondary bacterial infections unless treated daily with high oral doses of zinc compounds (Bosma et al. 1988). Certain imported breeds of cattle in the western Sudan with low zinc serum levels (i.e., <0.6 mg/L) showed signs of zinc deficiency, including stunted growth, weakness, skin lesions, and loss of hair pigment (Damir et al. 1988). Cows fed a low (25 mg/kg ration) but adequate zinc diet had liver zinc concentrations below the expected 125 mg Zn/kg DW; increasing the total zinc dietary loading to 45 or 50 mg/kg DW is recommended for counteracting reduced zinc absorption in diets with soybean products (Binnerts 1989). Cows and calves fed low zinc diets of 25 mg Zn/kg ration showed a decrease in plasma zinc from 1.02 mg/L at start to 0.66 mg/L at day 90; cows fed 65 mg Zn/kg diet had a significantly elevated (1.5 mg Zn/L) plasma zinc level and increased blood urea and plasma proteins (Ramachandra and Prasad 1989). Biomarkers to identify zinc deficiency in bovines include zinc concentrations in plasma, unsaturated zinc-binding capacity, ratio of copper to zinc in plasma, and zinc concentrations in other blood factors; indirect biomarkers include enzyme activities, red cell uptake, and metallothionein content in the plasma and liver (Binnerts 1989).

Domestic goats (*Capra* sp.) fed a zinc-deficient diet (15 mg Zn/kg developed skin histopathology and alopecia (hair loss) after 177 days; zinc-deficient diets lacking vitamin A hastened the process, and signs were evident between 46 and 68 days (Chhabra and Arora 1989). No signs were evident in goats fed vitamin A-adequate diets containing 80 mg Zn/kg ration (Chhabra and Arora 1989).

Guinea pigs (*Cavia* spp.) fed a zinc-deficient diet (1.25 mg Zn/kg FW) for 60 days had significant reductions in zinc concentration in the serum (0.5 mg/L), kidney (10 mg/kg FW), testes (9.5 mg/kg FW), and liver (9.4 mg/kg FW). Guinea pigs fed 1.25 mg Zn/kg FW diet for 45 days followed by a zinc-replete diet of 100 mg/kg FW for 15 days had normal concentrations of zinc in serum (1.6-2.0 mg/kg FW), kidney (18-20 mg/kg FW), testes (19-27 mg/kg FW), and liver (15-17 mg/kg FW; Gupta et al. 1988). Zinc-deficient guinea pigs (<3 mg Zn/kg diet, 1 mg Zn/L drinking water), but not zinc-adequate animals (<3 mg Zn/kg diet, 15 mg Zn/L), exposed from day 30 of gestation to term on day 68 produced young with a low birth weight and severe skin lesions, were sensitive to handing and slow in recovering balance when turned on side, and had a peculiar stance; fetal zinc concentrations were depressed 15-33% in the liver and placenta (Apgar and Everett 1988). Disrupted immunocompetence responses and disordered protein metabolism were found in guinea pigs fed a zinc-deficient diet of 1.25 mg/kg FW ration for 45 days; marked, although incomplete, restoration occurred when this group was switched to 100 mg Zn/kg ration for 15 days (Verma et al. 1988). Neuromuscular pathology was evident in weanling guinea pigs fed a zinc-deficient diet (<1 mg Zn/kg) for 4 weeks, as judged by abnormal posture, skin lesions, and disrupted vocalizations; signs became severe after 5-6 weeks, but a single intraperitoneal injection of 1.3 mg Zn/kg BW (as $ZnSO_4$) caused remission within 7 days (O'Dell et al. 1989). Acute experimental allergic encephalomyelitis was induced in guinea pigs maintained on low (6 mg/kg), normal (20 mg/kg), and high (200 mg/kg) levels of zinc in the diet. Acute experimental allergic encephalomyelitis is usually a fatal disease of the central nervous system induced by inoculation with protein found in myelin of the central nervous system. Those on the zinc-deficient diet exhibited the expected signs of zinc deficiency but, unlike other groups, did not develop neurological signs of acute experimental allergic encephalomyelitis (Scelsi et al. 1989). Experimental allergic encephalomyelitis suppression in the zinc-deficient guinea pigs is ascribed to the influence of zinc deficiency of the T-cell function. A model of autoimmune central nervous system disease such as experimental allergic encephalomyelitis that requires a prominent T-lymphocyte sensitization can be altered or suppressed when the immunoregulatory mechanisms are impaired by zinc deficiency (Scelsi et al. 1989).

Unlike conspecifics on diets containing 100 mg Zn/kg, rhesus monkeys (*Macaca mulatta*) fed a marginally deficient zinc diet (4 mg Zn/kg diet) between age 5.5 and 30.0 months had lower plasma zinc levels, delayed onset of accelerated weight gain and linear growth, and no loss of subcutaneous fat--typical of early adolescence (Golub et al. 1988). Marginal dietary zinc deprivation also depressed immune function in rhesus monkeys by about 30% and impaired both learning and reversal of a visual discrimination task by 33-66% (Golub et al. 1988). When pregnant rhesus monkeys are fed a diet marginally deficient in zinc (4 mg/kg), perturbations in the mother's immune system can occur. Their infants, but not controls (100 mg Zn/kg diet), had reduced immune responsiveness despite the absence of marked differences in plasma or soft tissue zinc concentrations (Keen et al. 1989). Infant rhesus monkeys from zinc-deprived (4 mg Zn/kg ration) pregnant dams and subsequently fed the same low zinc diet showed delayed skeletal maturation during their first year. The condition was most severe at age 6 months but began to return to normal despite continuation of the marginally zinc-deficient diet (Leek et al. 1988).

Mice (*Mus* sp.) fed a zinc-deficient diet of 0.7 mg Zn/kg ration for 40 days, unlike mice fed a zinc-adequate diet of 36.5 mg Zn/kg, had a reduced growth rate, impaired phagocytic function, increased susceptibility to lead poisoning, and reduced zinc content in the blood (0.7 mg/L vs. 1.0-1.1 mg/L) and liver (12 mg Zn/kg FW vs. 17-19 mg Zn/kg FW; Tone et al. 1988). Zinc deficiency during early development affects neural tube development through arrested cell growth (Mackay-Sim and Dreosti 1989). Zinc deficiency in mice may disrupt olfactory function through interference with zinc-containing neurons in higher olfactory centers. Adult mice fed a zinc-deficient diet of 5 mg Zn/kg ration for 42 days, unlike mice given 100 mg Zn/kg diet, could not distinguish odors, although olfactory epithelia seemed normal (Mackay-Sim and Dreosti 1989).

Mink (*Mustela vison*) kits fed a zinc-deficient diet of 4.1 mg Zn/kg FW ration for 4 days retained 0.49 mg Zn/kit and lost weight. Kits fed a zinc-adequate diet (35-45 mg Zn/kg FW, 100-150 mg/kg DW) retained 2.5 mg Zn/kit, and those fed 83 mg Zn/kg FW diet retained 7.8 mg Zn/kit. Kits on low doses ate less than other groups. The most important excretory route was urine in the zinc-deficient group and feces in higher dose groups (Mejborn 1989).

Domestic sheep (*Ovis aries*) fed a low zinc diet (2.2 mg Zn/kg DW diet) for 50 days, unlike sheep fed a zinc-adequate diet (33 mg Zn/kg DW diet), excreted less zinc (<4 mg daily vs. 23-25 mg), consumed less food (409 g daily vs. 898 g), and had lower plasma zinc concentrations (0.18 mg/L vs. 0.53-0.58 mg/L); a reduction in

plasma alkaline phosphatase activity and an increase in plasma zinc binding capacity were also noted (Khandaker and Telfer 1990). Sensitive indicators of zinc deficiency in lambs include significant reductions in plasma alkaline phosphatase activity and plasma zinc concentrations; signs were clearly evident in lambs fed 10.8 mg Zn/kg DW diet for 50 to 180 days (Vergnes et al. 1990). A normal diet for lambs contains 124-130 mg Zn/kg DW ration and 33 for adults (Vergnes et al. 1990). One recommended treatment for zinc-deficient sheep is ruminal insertion of zinc-containing boluses every 40 days; bolus zinc release is about 107 mg daily (Khandaker and Telfer 1990).

Zinc-deficient pregnant laboratory white rats (*Rattus* sp.) have reduced litter size, a high frequency of fetal deformities, low birth weight, and a prolonged parturition; dams are inactive and seem indifferent toward young (Harland et al. 1975). Fetal skeletal defects are prominent in rats fed zinc-deficient diets of 10 mg/kg ration during a 21-day gestation period. About 91% of zinc-deficient fetuses had multiple skeletal malformations, but controls fed 76 mg Zn/kg diet had none (Ferreira et al. 1989). Zinc-deficient (1.5 mg Zn/kg diet) pregnant rats also had increased iron levels in the liver, kidney, and spleen; depleted liver glycogen: and reduced levels of zinc in the pancreas and duodenum (Mamba et al. 1989). Zinc deficiency causes testicular atrophy and hypogonadism in rats; the effects include spermatic arrest, histopathology of seminiferous tubules and interstitial cells, reduced serum testicular testosterone levels, and reduced testicular zinc concentrations (Hafiez et al. 1990). Zinc is required in Leydig cells for normal testosterone activity. Calcitonin inhibits transmembrane influx of zinc in the isolated rat Leydig cell, but these effects usually take >2 days and are critical only in states of borderline zinc deficiency (Chausmer et al. 1989). Zinc deficiency during pubertal development of rats depresses the activity of dipeptidyl carboxypeptidase in the testes and epididymis; this enzyme is required for maturation and development of sperm cells and reduced activity may cause suppression of sexual maturity (Reeves 1990). Laboratory white rats fed zinc-deficient diets for 20 days show an aversion to the zinc-deficient diet. They readily consumed a familiar zinc-adequate diet for 15 days, but the previously deficient animals continued to avoid zinc-deficient diets when given a choice (Cannon et al. 1988). Zinc deficiency in rats (<1 mg Zn/kg diet for 26 days) significantly reduced blood pressure and this correlated positively with serum angiotensin converting enzyme activity; increasing the dietary intake of calcium had no effect on these responses (Reeves and O'Dell 1988). During zinc deficiency, zinc is mobilized from bone in young immature animals and may be available for metabolic processes including growth (Calhoun et al. 1978). Diabetic rats are at risk of developing zinc deficiency because of zinc's role in modulating immune system dysfunction in diabetes mellitus (Mooradian et al. 1988). Cadmium toxicity is related to the zinc status of the body. Zinc-deficient rats (<1 mg Zn/kg diet) and zinc-adequate rats (40 mg/kg) were both challenged with cadmium. The zinc-deficient group had accelerated zinc loss from the kidneys; enlarged liver, kidneys, spleen and lungs; and increased distribution of cadmium in tissues (Sato and Nagai 1989). Other signs in zinc-deficient laboratory white rats included decreased food intake and loss of body weight (Vallee 1959; Cannon et al. 1988; Reeves and O'Dell 1988; Dib et al. 1989; Ferreira et al. 1989; Mamba et al. 1989; Mansour et al. 1989; Sato and Nagai 1989); reduced serum zinc (Calhoun et al. 1978; Reeves and O'Dell 1988); altered cholesterol metabolism (Samman and Roberts 1988); increased serum magnesium (Reeves and O'Dell 1988); lowered bone (femur) zinc concentrations (Calhoun et al. 1978); degenerated olfactory epithelium (Mackay-Sim and Dreosti 1989); reduced serum total proteins (Mansour et al. 1989); decreased activity of glutamate, glycine, methionine, arginine, lysine, and proline (Bettger 1989); and increased dental caries (Goldberg et al. 1990).

Zinc deficiency in domestic pigs (*Sus* sp.) is associated with a condition known as porcine parakeratosis, characterized by dermatitis, diarrhea, vomiting, anorexia, severe weight loss, and eventually death; the condition is exacerbated by high calcium levels (Vallee 1959).

Lethal and Sublethal Effects

General

Significant adverse effects on growth, reproduction, and survival are documented for sensitive marine and freshwater species of aquatic plants, invertebrates, and vertebrates at nominal water concentrations between 10 and 25 µg Zn/L. Sensitive terrestrial plants died when soil zinc concentrations were >100 mg/kg and showed decreased photosynthesis when total plant contained >178 mg Zn/kg DW. Representative soil invertebrates showed reduced growth at 300-1,000 mg Zn/kg diet and reduced survival at 470-6,400 mg Zn/kg soil. Domestic poultry and avian wildlife had reduced growth at >2,000 mg Zn/kg diet, and reduced survival at >3,000 mg Zn/kg diet or at a single oral dose >742 mg Zn/kg BW; younger stages (i.e., chicks, ducklings) were least resistant.

Sensitive species of livestock and small laboratory animals were adversely affected at >0.8 mg Zn/m^3 air, 90-300 mg Zn/kg diet, >90 mg Zn/kg BW daily, >300 mg Zn/L drinking water, and >350 mg Zn/kg BW single oral dose.

Terrestrial Plants and Invertebrates

Sensitive terrestrial plants die when soil zinc levels exceed 100 mg/kg or when plant zinc content exceeds 178 mg/kg DW (Table 5). The phytotoxic zinc level for barley (*Hordeum vulgare*) is not known, but zinc content of barley leaf rarely exceeds 100 mg/kg DW (Chang et al. 1983). Uptake of zinc from soils by plants is dependent on soil type; for example, uptake is lower in coarse loamy soils than in fine loamy soils (Chang et al. 1983). Zinc uptake by barley leaf is greater with increasing rate of sludge application, but the relation is not proportional (Table 5).

Among terrestrial invertebrates, adverse effects on earthworm survival were documented at 470-662 mg/kg soil, slugs had reduced food consumption at 300 mg Zn/kg diet and reduced growth at 1,000 mg Zn/kg diet, and woodlice had impaired reproduction at 1,600 mg Zn/kg soil and reduced survival at 5,000 mg Zn/kg diet or 6,400 mg Zn/kg soil (Table 5).

High zinc concentrations in soils are responsible for reductions in populations of soil invertebrates near brass mills and zinc smelters (Beyer 1990). Soils in the vicinity of zinc smelters contained up to 35 g Zn/kg and had decreased populations of arthropods; experimentally, 20 g of total zinc per kilogram of soil could account for the decreased survival (Beyer et al. 1984). Zinc concentrations exceeding 1,600 mg/kg soil litter are associated with reduced natural populations of decomposer organisms in contaminated forest soil litter, and this has been verified experimentally (Beyer and Anderson 1985). Poisoning of decomposer organisms, such as the woodlouse (*Porcellio scaber*), may disrupt nutrient cycling and reduce the number of invertebrates available as wildlife food (Beyer and Anderson 1985). The woodlouse contains higher concentrations of zinc than other terrestrial invertebrates: up to 152 mg Zn/kg DW whole organism (Hopkin and Martin 1985). It is speculated that the large zinc stores in *P. scaber* repels predators that find zinc distasteful (Hopkin and Martin 1985).

Table 5. Effects of zinc on representative terrestrial plants and invertebrates.

Organism, dose, and other variables	Effect	Reference[a]
Plants		
Fir, *Abies pindrow,* wooden stakes coated with 10% zinc oxide	Protects wood against termite damage for 5 years compared with 4 years for copper sulfate, 2 years for calcium carbonate, and <6 months for untreated wood	1
Red maple, *Acer rubrum*, 100 mg Zn/kg culture medium	Lethal to seedlings	2
Lichen, *Cladonia uncialis*, whole plant zinc content	Depressed photosynthesis when whole lichen burden is >178 mg Zn/kg DW; decreased respiration at >3,550 mg Zn/kg DW	3
Barley, *Hordeum vulgare*, leaf, from soil treated with sludge for 3 years		
No sludge	21-25 mg/kg DW	4
80 kg Zn/ha/year	26-47 mg/kg DW	4
160 kg Zn/ha/year	29-56 mg/kg DW	4
320 kg Zn/ha/year	41-57 mg/kg DW	4

Lichen, *Lasallia papulosa*, whole plant zinc content	Significant depression in photosynthesis at >308 mg Zn/kg DW and in respiration at >3,300 mg Zn/kg DW	3
Oak, *Quercus rubra*, culture medium contained 100 mg Zn/kg	Lethal to seedlings	2
Corn, *Zea mays*, grown on sludge amended loam plots; soil contains a maximum of 460 mg Zn/kg DW	Leaf contains a maximum of 293 mg Zn/kg DW (60 mg Zn/kg for controls); grain contains a maximum of 65 mg Zn/kg DW (32 mg Zn/kg for controls)	5
Invertebrates		
Earthworm, *Aporrectodea tuberculata*; concentrations of zinc in soil ranged from 28 mg/kg DW to 470 mg/kg DW versus concentrations in whole worms (less gut contents)	At soil zinc concentration of 28 mg/kg DW (control), worms contained 320 mg Zn/kg DW. At soil zinc levels of 97, 110, 190, and 320 mg/kg DW, whole worms contained 810, 1,300, 1,100, and 650 mg Zn/kg DW, respectively. No worms were found at soil zinc levels of 470 mg/kg DW	6
Slug, *Arion ater*, fed diets containing 10, 25, 50, 100, 300, or 1,000 mg Zn/kg ration for 27 days	No deaths in any group. Significantly reduced food consumption in 300 and 1,000 mg/kg diets. All groups weighed less than controls at day 27, but growth was statistically impaired only in the 1,000 mg/kg group	7
Slug, *Arion ater*, fed diets containing up to 1,000 mg/kg feed for 30 days	No adverse effects except for glycogen depression at 1,000 mg/kg diet	8,9
Spider, *Dysdera crocata*, fed woodlice (*Porcellio scaber*) at rate of one every 3 days for 36 days		
Woodlice from uncontaminated site (87 mg Zn/kg DW whole organism)	Whole spider contains 182 mg Zn/kg DW	10
Woodlice from contaminated site (152 mg Zn/kg DW whole organism)	Whole spider contains 118 mg Zn/kg DW (116 mg Zn/kg DW in starved spiders)	10
Earthworm, *Eisenia foetida*		
10-12 µg Zn/cm^2 applied to epidermis	LC50 (48 h)	11
662 mg Zn/kg artificial soil (95% C.I. 574-674)	LC50 (2 weeks)	11
Woodlice, *Porcellio scaber*, fed soil litter containing up to 12,800 mg Zn/kg for 64 weeks	Soil litter containing ≥1,600 mg Zn/kg had adverse effects on reproduction; adult survival was reduced at >6,400 mg Zn/kg litter	12

Woodlice, *Porcellio scaber*, fed diets containing up to 20,000 mg Zn/kg feed for 8 weeks		Decreased survival at ≥5,000 mg/kg	13

[a] 1. Roomi et al. 1990; 2. Buchauer 1971; 3. Nash 1975; 4. Chang et al. 1983; 5. Hinesly et al. 1977; 6. Beyer et al. 1987; 7. Marigomez et al. 1986; 8. Recio et al. 1988a; 9. Recio et al. 1988b; 10. Hopkin and Martin 1985; 11. Neuhauser et al. 1985; 12. Beyer and Anderson 1985; 13. Beyer et al. 1984.

Slugs (*Arion ater*) are resistant to high dietary zinc intakes (1,000 mg/kg feed) for 30 days, although zinc accumulations occur in excretory and calcium cells of the digestive gland (Recio et al. 1988a, 1988b). Histochemical detection of zinc in digestive glands of *Arion* is an indication of high levels of zinc in the environment (Recio et al. 1988a). Zinc elimination in *Arion* occurs directly from lipofuscin material of excretory cells and from spherules of calcium cells; excretion of lipofuscin material through feces is the major excretory route (Recio et al. 1988a).

Zinc normally aids wound healing in terrestrial invertebrates. Wounding of the optic tentacle, foot tissue, and partial shell removal in *Helix aspersa*, a terrestrial gastropod, resulted in deposition of zinc in the wound area after 2 to 5 days. Increased zinc in *Helix* wound areas may be necessary to promote protein synthesis, collagen, formation, and mitotic cell division (Ireland 1986).

Aquatic Organisms

Significant adverse effects of zinc on growth, survival, and reproduction occur in representative sensitive species of aquatic plants, protozoans, sponges, molluscs, crustaceans, echinoderms, fish, and amphibians at nominal water concentrations between 10 and 25 µg Zn/L (Table 6).

Table 6. Effects of zinc on representative aquatic plants and animals. Concentrations are in micrograms of zinc per liter of medium.

Taxonomic group, organism, and other variables	Concentration (ppb)	Effects	Reference[a]
Plants			
Alga, *Amphidinium carteri*	400	Growth inhibition	1
Aquatic plants, various	30->200,000	Adverse effects	2
Brown alga, *Ascophyllum nodosum*	100	No effect on growth in 10 days	2
Ascophyllum nodosum	250	Decreased growth in 10 days	2
Coccolithophorid, *Cricosphaera carterae*	77	Growth reduced 50% in 4 days	2
Freshwater algae, 11 species	140-800	Growth inhibition	3
Freshwater algae, most species	>1,000	Growth inhibition	1
Brown macroalgae, *Fucus serratus*	9.5	Bioconcentration Factor (BCF) of x10,770 in 140 days	2
Fucus serratus	8.8	Altered lipid metabolism	2
Marine macroalgae, *Fucus vesiculosus*	3,500	No adverse effects	2
Fucus *vesiculosus*	7,000	Growth retardation	2
Dinoflagellate, *Glenodinium halli*	20	Chlorophyll reduced 65% in 2 days	2
Dinoflagellate, *Gymnodinium*	110-392	Chlorophyll reduced about 65%	2

splendens		in 2 days in temperature range 16-30° C	
Gymnodinium *splendens*	100	Growth inhibition in 38 days	3
Alga, *Isochrysis galbana*	74	Chlorophyll reduced 65% in 48 h at 16 ppt salinity, 20° C	2
I. galbana	430	Chlorophyll reduced 65% in 48 h at 16° C, 16 ppt salinity	2
Kelp, *Laminaria digitata*	100	Growth inhibition in 24 days	1
Brown macroalga, *Laminaria hyperborea*	250 8-10 days	Reduced growth of sperophytes in	2
Marine algae, 4 species	50-500	Decrease in cell numbers	1
Marine algae, 5 species	100	Growth inhibited in 48 h	2
Marine macroalgae, 4 species	100	No adverse effects	2
Marine macroalgae, 4 species	1,400	Growth reduction	2
Diatom, *Nitzschia closterium*	271-300	50% growth inhibition in 4 days	2
Diatom, *Nitzschia longissima*	100	Growth stimulated during exposure for 1-5 days	2
Dinoflagellate, *Procentrum micans*	319	50% growth inhibition in 4 days	2
Diatom, *Phaeodactylum tricornutum*	250	BCF of x1,800 in 3 days	2
P. tricornutum	4,800	6.7% increase in growth during 12-day exposure	2
Phytoplankton	15	Primary productivity reduced in 14 days	2
Marine alga, *Rhizosolenia* sp.	15-25	Photosynthesis reduction	3
Alga, *Scenedesmus quadricauda*	2	Adverse effects	4
S. quadricauda	64	Growth inhibition in 14 days	2
S. quadricauda	300	Lethal	4
Diatom, *Schroederella schroederi*	19	Growth inhibited 50% in 48-96 h	2
Freshwater alga, *Selenastrum capricornutum*	30	Some growth inhibition in 7 days	1
S. cupricornutum	40-68	95% growth inhibition in 14 days	1
S. capricornutum	100	100% growth inhibition in 7 days	1
Diatom, *Skeletonema costatum*	19.6	Adverse effects	4
S. costatum	50-100	Growth reduced 20-23% in 10-15 days	2
S. costatum	200	Growth stimulated in 1-5 days	2
S. costatum	265	Metabolic disruption in 3 days	2
Diatom, *Thalassiosira pseudonana*	65	Adverse effects	4
T. pseudonana	500	Growth reduced 41% in 11-15 days	2
T. pseudonana	823	Growth reduced 50% in 72 h	2
Green macroalga, *Ulva lactuca*	65	BCF of x255 in 6 days	2
Protists			
Protozoan, *Cristigera* sp.	50-125	Growth reduced in 5-h exposure	1,2
Bacterium, *Escherichia coli*	650-1,400	Growth inhibition	3
Microorganisms, various	650-1,100	Growth inhibition, usually	3

Paramecium, *Paramecium multi-micronucleatum*	560-10,000	LC50 (3 h)	3
Bacterium, *Pseudomonas* sp.	1,000-10,000	Growth inhibition	3
Protozoan, *Vorticella convallaria*	50	LC50 (48 h)	3
Porifera			
Freshwater sponge, *Ephydatia fluviatilis*			
Adults	6.5	No effect on growth; no tolerance developed with long-term exposure	5
Adults	26	After exposure for 10 days, tissue deterioration and death during 3-week postexposure period	5
Rotifers			
Rotifer, *Philodena acutiformis*			
Adults	500	LC50 (48 h), 25° C	
Adults	1,550	LC50 (48 h), 5° C	2
Molluscs			
Freshwater snail, *Ancylus fluviatilis*			
Juvenile	80	LC50 (100 days), shell length <2 mm	6
Adult	100	No adverse effect on reproduction in 100 days	6
Juvenile	130	LC50 (100 days), shell length >3 mm	6
Adult	180	Reproduction reduced in 100 days	6
Bay scallop, *Argopecten irradians*			
Larvae	50	Growth rate reduced 22% in 9 days	7
Larvae	109	Growth reduced 50% in 9 days	7
Larvae	120	LC50 (9 days), increased shell deformities	7
Larvae	150-200	All dead at metamorphosis	7
Juvenile	2,250	LC50 (96 h)	8
Freshwater snail, *Biomphalaria glabrata*	500	By day 33 of exposure, embryo survival was reduced 50% and adult growth and reproduction inhibited	9
Asiatic clam, *Corbicula fluminea*	<20	Residues were 169 mg/kg dry weight (DW) parts after feeding on periphyton containing 393-1,327 mg/kg DW for 30 days	11
C. fluminea	25	Normal growth during exposure for 30 days	10
C. fluminea	34	Residues were 433 mg/kg DW soil parts in 30 days after feeding on periphyton containing 956-4,369 mg Zn/kg DW;	11

		growth reduced; cellulase enzyme activity reduced	
C. fluminea	50-500	Growth inhibited between days 20 and 30 of exposure	10
C. fluminea	218	BCF of x126 in 28 days	2
C. fluminea	1,000	After exposure for 30 days, about 30% died. Survivors had osmoregulatory impairment and residues of 2,000 mg Zn/kg DW soft parts (200 mg Zn/kg DW soft parts in controls). Depuration complete by day 17 postexposure, and growth rate returns to normal	10
Pacific oyster, *Crassostrea gigas*			
Larvae	10-20	Reduced larval settlement in 20 days	1
Larvae	30-35	Reduced larval settlement in 6 days	2
Larvae	50	Normal growth and development in 5 days	12
Larvae	70	Abnormal shell development in 48 h	1
Larvae	75	No deaths in 48 h	1
Larvae	80-95	Growth reduced 50% in 4 days	2
Larvae	119-310	LC50 (48 h)	1,13
Larvae	125	Substrate attachment inhibited in 5 days	1,2
Larvae	200	No growth in 5 days	12
Embryo	233	LC50 (96 h)	2
Larvae	250	Increasing incidence of abnormal development and mortality	12
Sperm	444	Fertilization success reduced 50% in 60 min	2
Larvae	500	All died in 48 h	1
American oyster, *Crassostrea virginica*			
Adult	100	Whole body concentration of 2,560-2,708 mg Zn/kg fresh weight (FW) soil parts after 20-week exposure (1,036-1,708 mg Zn/kg FW soil parts in controls)	14
Adult	200	After exposure for 20 weeks, residues were 3,185-3,813 mg Zn/kg FW soft parts	14
Embryo	230	LC50 (96 h)	2
Larvae	340	LC50 (48 h)	13
Red abalone, *Haliotis rufescens*			

Larvae	19	No adverse affects after 9-day exposure	13
Larvae	41	Normal development during 48-h	13
Larvae	50	50% abnormal development during exposure for 9 days	13
Larvae	68	50% abnormal development in 48-h exposure	13
Marine gastropod, *Littorina littorea*			
Adult	0.2 (controls)	Zinc concentrations in all tissues were <185 mg/kg DW, except kidney, which was 372 mg/kg DW	15
Adult	10	After exposure for 42 days, tissue zinc residues were: head-foot 120 mg/kg DW, gills 255 mg/kg DW, whole soft parts 605 mg/kg DW, viscera 1,322 mg/kg DW, stomach 1,918 mg/kg DW, and kidney 2,153 mg/kg DW	15
Freshwater pond snail, *Lymnaea luteola*, adult	1,680	LC50 (96h)	85
Hard shell clam, *Mercenaria mercenaria*			
Larvae	50	5% died in 12 days	1
Larvae	168	50% dead or abnormal in 48 h	1
Embryo	195	LC50 (96 h)	2
Larvae	195-341	LC50 (10-12 days)	1
Larvae	279	All died in 48 h	1
Softshell clam, *Mya arenaria*			
Adult	10	Soft parts contained 9.5 mg Zn/kg FW after 16 weeks at 0-10° C, and 11 mg/kg after 2 weeks at 16-22° C	14
Adult	200	BCF of x85-135 in 50 days	2
Adult	500	Soft parts contained 31-48 mg Zn/kg FW after exposure for 6-16 weeks at 0-10° C, and 59-82 mg/kg after 1-2 weeks exposure at 16-22° C	14
Adult	900	No deaths in 7 days at 22° C	16
Adult	1,550	LC50 (7 days) at 22° C	16
Adult	25,000	All dead after 70-day exposure at 0-10° C; at exposure temperature of 16-22° C, all dead by day 14	17
Common mussel, *Mytilus edulis*			
Adult	25	Maximum kidney zinc residue after 18 days was 14.1 g/kg DW (4.9 g/kg in controls)	18

Adult	60	Shell growth rate reduced 50% in 2-6 days of exposure	2
Embryo	96-314	Development inhibited 50% in 72 h	2
Adult	100	No accumulations in tissues after 4-day exposure	19
Adult	230-860	In 7-h exposure, pumping rate decreased with increasing zinc, and was completely stopped at >470 µg/L; recovery on return to background levels	20
Adult	1,000	After exposure for 24 h, zinc concentration in soil parts rose from 150 mg/kg DW to 252 mg/kg DW and remained elevated for at least 6 weeks postexposure	21
Larvae	1,752	LC50 (48 h)	13
Adult	1,800	Reduced byssal thread production	2
Adult	5,000	LC50 (7 days)	2
Adult	5,000	LC100 (16 days)	19
Adult	20,800	LC50 (24-h exposure plus 6 weeks postexposure); none dead during exposure	22
Sperm	65,400	Respiration inhibited 50% in 20 min	23
Mud snail, *Nassarius obsoletus*			
Adult	200	Decreased oxygen consumption in 72 h	1
Egg	650	Abnormal veliger development	24
Adult	5,000	No deaths in 168 h	25
Green-lipped mussel, *Perna virdis*			
Adult	<178-362	Maintains constant body concentration over 21-day exposure period	26
Adult	>362	Accumulation in tissue	26
Adult	6,090	LC50 (96 h)	26
Freshwater snail, *Physa heterostropha*, juvenile	241	LC50 (96 h)	2
Surf clam, *Spisula solidissima*, juvenile	2,950	LC50 (96 h)	8
Bryozoans			
Bryozoan, *Bugula neritina*, larvae	200	LC50 (5 h)	3
Bryozoan, *Watersipora cucullata*, larvae	650	LC50 (5 h)	3
Crustaceans			

Copepod, *Acartia tonsa*	290	50% immobilized in 48 h	
A. tonsa	294	LC50 (96 h)	2
Amphipod, *Allorchestes compressa*	580-2,000	LC50 (96 h)	3,27
Brine shrimp, *Artemia* sp.	14-1,360	Egg hatching significantly reduced in dose-dependent manner; no effect on survival of prenauplii larvae	28
Cladoceran, *Ceriodaphnia reticulata*	51	LC50 (96 h)	2
Hermit crab, *Clibanarius olivaceous*			
Larvae	1-90	Molting delayed in dose-dependent manner	29
Larvae	100	LC50 (96 h)	29
Larvae	125	LC100 (96 h)	29
Daphnid, *Daphnia galeata mendotae*	15	BCF of x9,400 in 2 weeks	2
D. g. mendotae	30	BCF of x5,833 in 2 weeks	2
D. g. mendotae	60	BCF of x6,333 in 2 weeks	2
Daphnid, *Daphnia magna*	5-14	LC50 (72 h) at 30° C	2
D. magna	25	No effect in soft water (50 mg $CaCO_3$/L) in 50 days	30
D. magna	42-52	MATC [b]; water contains 104-211 mg $CaCO_3$/L	1,2
D. magna	68-655	LC50 (96 h)	31
D. magna	70	Reproduction reduced 16% in 21 days	2
D. magna	100	LC50 (48 h), starved	84
D. magna	250	Nonlethal in 6 weeks when sediments present in test container. Final sediment value of 13,400 mg/kg DW (600 mg/kg DW in controls). Organisms had whole body residues of 450 mg/kg DW	32
	"		
D. magna	280	LC50 (48 h), fed	3
D. magna	560	LC50 (24 h) at 25° C	84
D. magna	560	50% immobilized in 48 h	33
D. magna	2,300	LC50 (24 h) at 5° C	3
Daphnid, *Daphnia pulex*	253	LC50 (96 h)	2
D. pulex	280	LC50 (48 h)	
D. pulex	500	LC50 (24 h) at 25° C	3
D. pulex	1,550	LC50 (24 h) at 5° C	3
Copepod, *Eudiaptomus padanus*	500	LC50 (48 h)	
Amphipod, *Gammarus duebeni*			
Natural population	>100	Survival reduced in 7 days	34
Natural population	1,000	All dead in 7 days at 10 ppt	

		salinity, 84% dead at 30 ppt	34
Zinc-tolerant population	1,000	50% dead in 14 days at 10 ppt salinity, 33% dead at 30 ppt	34
American Lobster, *Homarus americanus*			
Larvae	130	LC50 (17 days)	3
Larvae	381	LC50 (96 h)	2
Adult	13,000	LC50 (11 days)	3
Mysid, *Mysidopis bahia*	120-230	MATC[b]	1,2
M. bahia	499	LC50 (96 h)	2,13
Crayfish, *Orcenectes virilis*	130,000	No deaths in 10 days	35
Hermit crab, *Pagurus longicarpus*			
Adult	200	LC50 (168 h)	25
Adult	400	LC50 (96 h)	1,2
Prawn, *Palaemon elegans*	562	LC67 (21 days)	36
Shrimp, *Pandalus montagui*	65	BCF of x 3.7 in 14 days	2
Mysid, *Praunus flexuosus*	2,000	LC50 (192 h), 5^{o}C, 4.5 ppt salinity	37
Mudcrab, *Rithropanopeus harrisii*, larvae	50	Delayed development in 16-days exposure	1
Copepod, *Tisbe holothuriae*			
Life Cycle	7	No effect on population size after exposure for 4 generations	38
Life Cycle	10	Some deaths in fourth generation	38
Life Cycle	70	All dead by end of first generation	38
Copepodid	421	LC50 (48 h)	39
Adults	620-700	LC50 (48 h)	38,40
Females with egg sacs	713	LC50 (48 h)	39
Copepod, *Tropocyclops praisinus mexicanus*, Quebec lakes, uncontaminated	52-26	LC50 (48 h) in soft water	41
T.P. mexicanus, Quebec lakes, contaminated	2,934	LC50 (48 h) in hard water lake; metal preexposure protective effect hypothesized	41
Aquatic insects			
Mayfly, *Epeorus latifolium*			
Larvae	30	Gradual decrease in growth rate in 4-week exposure; some deaths before emergence	42
Larvae	100-300	Growth inhibited after 2 weeks; all dead before emergence	42
Midge, *Tanytarsus dissimilis*, embryo through third instar	37	LC50 (10 days)	1,2

Annelids			
Polychaete worm, *Capitella capitata*			
Larvae	50-100	Abnormal development during 16 day exposure	2
Adult	1,250	LC50 (28 days)	2
Adult	10,700	LC50 (48 days)	13
Leech, *Erpobdella octoculata*			
Juveniles	60	LC50 (70 days)	43
Adults	100	LC50(70 days)	43
Adults	180	High frequency of abnormal eggs produced in 60-day exposure	43
Adults	320	Inhibited reproduction in 60-day exposure	43
Juveniles	390	LC50 (40 days)	43
Juveniles	2,100	LC50 (96 h)	43
Adults	4,800	LC50 (40 days)	43
Adults	8,800	LC50 (96 h)	43
Polychaete, *Neanthes arenaceodentata*, juveniles	900	LC50 (28 days)	3
Sandworm, *Nereis diversicolor*			
Adults	1,500	No deaths in 168 h	25
Adults	2,600	LC50 (168 h)	25
Adults	10,000	Whole body zinc concentration in survivors after exposure for 34 days was 2,500 mg/kg DW (180 mg/kg DW in controls)	14
Adults	10,000	After 96-h exposure at; 6° C, zinc residues were 1,031 mg/kg DW in head (843 mg/kg DW in controls), 366 mg/kg DW in trunk (158 mg/kg DW in controls), and 455 mg/kg DW in parapodia (275 mg/kg DW in controls); uptake was higher at 12° and 20° C	44
Adults	20,000	No death in 96 h	44
Adults	40,000	LC50 (47 h) for nontolerant strains; LC50 (70 h) for zinc-tolerant strains	45
Worm, *Spirorbis lamellora*, larvae	350	LC50 (3 h)	3
Echinoderms			
Sea urchin, *Anthocidarius crassispina*			
Egg	65	No effect on fertilization membrane formation or development in eggs transferred 1 min after insemination	46
Egg	326	Irreversible inhibition of	

		fertilization membrane formation in eggs transferred 10 s after insemination	46
Starfish, *Asterias rubens*			
Adult females	240	Increased steroid metabolism in pyloric caeca after 21 days	47
Adults	1,000	No deaths in 168 h	25
Adults	2,300	LC50 (168 h)	25
Sand dollar, *Dendraster excentricus*, sperm	28	Fertilization success reduced 50% in 60 min	2
Echinoderms, 3 species, embryos	60-200	Embryonic development inhibited	46
Red sea urchin, *Strongylocentrotus franciscanus*, sperm	313	Fertilization success reduced 50%	2
Purple sea urchin, *Strongylocentrotus purpuratus*, embryos	23	Development inhibited 50% in 5 days	2
Fish			
Longfin dace, *Agosia chrysogaster*,	228	LC50 (96 h)	2
Murrel, *Channa punctatus*, fingerlings, 31-day exposure	12,000	Growth rate reduced by day 19; liver RNA and proteins decreased by day 20; muscle RNA and proteins reduced by day 30	49,50
Texas cichlid, *Cichlasoma cyanoguttatum*, adults, exposure for 4 weeks	40 (control), 65, or 90	Residues were 0.8, 28, and 34 mg Zn/kg FW in muscle; 6, 56, and 25 mg Zn/kg FW in viscera; 6, 59, and 98 mg Zn/kg FW in gills; and 12, 66, and 92 mg Zn/kg FW in bone	51
Air-breathing catfish, *Clarias lazera*, juveniles	26,000-52,000	LC50 (96 h) at 25.1° C (26,000) through 9.3° C (52,000); at 88,000 µg/L and 18.5° C, 50% died and survivors had BCF of x544 in gill, x425 in liver, and x250 in muscle	52
Baltic herring, *Clupea harengus*, eggs exposed from fertiliza-tion through hatching	500, 2,000, 6,000, or 12,000	Histopathology of epidermis and kidney in larvae at >6,000 µg/L; no measurable effects at < 2,000 µg/L	53,54
Atlantic herring, *Clupea harengus harengus*, embryos and larvae	50	Significant increase in incidence of jaw and branchial abnormalities	2
Freshwater fish, 4 species, adults	4,600-17,300	LC50 (5 days)	55
Mummichog, *Fundulus heteroclitus*			
Adults	810	BCF of x16 in whole fish after 56 days	2
Adults	10,000	Zinc concentration in scale, rose from 229 mg/kg DW at start to 746 mg/kg DW	56

		after 45 days and to 1,608 mg/kg DW after 94 days	
Adults	10,000	Zinc content in scale after 45 days exposure and 21 to 49 days in uncontaminated water fell from 746 mg/kg DW to 422-498 mg/kg DW	56
Adults	43,000	No deaths in 8 days; no significant increase in tissue zinc levels	57
Adults	52,000-66,000	LC50 (8 days)	25,57
Adults	71,000-153,000	LC50 (48 h)	58
Mosquitofish, *Gambusia affinis*, adults, muscle	18,000	After 24 h, zinc increased from 82 to 134 µg/kg FW; significant increases in glycogen, total lipids, phospholipids, and cholesterol; decreases in RNA and proteins	59
Flagfish, *Jordanella floridae*			
Life cycle	26-51	MATC [b]	2
Larvae	85	LC80 (30 days)	3
Adults	139	BCF of x417 in whole fish in 100 days	2
Cypriniform freshwater fish, *Labeo rohita*			
Juveniles and adults	20,000	No deaths in 96 h	60
Juveniles	65,000	LC50 (96 h); liver glycogen reduced; BCF of x22 in whole fish	60
Adults	77,000	LC50 (96 h); survivors had disrupted respiration and decreased liver glycogen	60
Spangled perch, *Leiopotherapon unicolor*, adults, exposed for 2 h	5,000, 10,000, or 20,000	Temporary decrease in ventilation rate at 5 mg/L; significant increase in ventilation rate at 10 and 20 mg/L; bradycardia at 20 mg/L	61
Spot, *Leiostomus xanthurus*	38,000	LC50 (96 h)	62
Bluegill, *Lepomis macrochirus*			
Adults	76-235	Reproduction inhibition	3
Adults	100	Hyperactivity	3
Fry	235	Lethal in 3 days	1,2
Adults, exposed for 7 days, then placed in a lethal NaC1 salinity (1.46%) for 60 h	2,350	Exposed fish all dead in 60 h (8 h for controls); plasma chloride declined in zinc-exposed fish, suggesting that zinc reduces permeability of gills to chloride	63
Adults	5,400	LC50 (96 h) at 20 mg $CaCO_3$/L	3
Adults	40,900	LC50 (96 h) at 360 mg $CaCO_3$/L	3

Marine fish, most species	>1,000	LC50 (96 h)	1
Tidewater silverside, *Menidia peninsulae*	5,600	LC50 (96 h)	62
Striped bass, *Morone saxatilis*			
Larvae	100-119	LC50 (96 h)	1,2
Fry	430-1,180	LC50 (96 h)	1,2
Adults	6,700	LC50 (96 h)	1
Stone loach, *Noemacheilus barbatulus*, adults	1,900-2,000	LC50 (25 days)	3,55
N. barbatulus	3,500	LC50 (96 h)	55
Loach, *Noemacheilus* sp.	25,000	LC50 (96 h)	64
Cutthroat trout, *Oncorhynchus clarki*	61-600	LC50 (96 h)	1,65
O. clarki	360	None dead in 14 days	66
O. clarki	670	LC50 (14 days)	3,66
Coho salmon, *Oncorhynchus kisutch*			
Water hardness <50 mg $CaCO_3$/L	280	LC50 (96 h)	3
Juveniles	500-10,700	Decreased white blood cell count in 24h	3
0.5-0.9 g BW	820-1,810	LC50 (96 h)	67
Rainbow trout, *Oncorhynchus mykiss*			
Immatures	5.6	Avoidance, 10- to 20-rain tests	1,2
Larvae and alevins	10	LC54 (28 days)	3
Immatures	47	94% avoidance, 40-rain tests	2
Early life stages	70-140	LC50 (25 days)	3
Juveniles	81	Hyperglycemia in 24 h	3
Fry	90-93	LC50 (96 h)	1,2
Life cycle	140-547	MATC [b]	1,2
Weight 0.6 g	169	LC50 (96 h)	67
Juveniles	210-1,120	Increased blood glucose in 7-63 days	3
Parr	240-830	LC50 (96 h) at 30 mg CaCO3/L	1
Juveniles	310	LC20 (14 days)	66
Immatures	352	Hyperglycemia in 9 days	2
Larvae and alevins	400-2,800	LC50 (120 h)	3
Juveniles	410	LC50 (14 days)	66
Juveniles	430	LC59 (96 h) at 26 mg CaCO3/L	3
Juveniles	520	LC50 (96 h) at 47 mg CaCO3/L	3
Fry	689	LC50 (96 h)	2
Juveniles	690	Increased respiration in 24 h	3
Immatures	1,030	LC50 (96 h) value for group acclimatized to 80 µg Zn/L for 28 days (469 µg Zn/L in nonacclimatized group)	68

Adults	1,120	Reduced growth in 85 days	3
Parr	1,190-4,520	LC50 (96 h) at 350 mg CaCO3/L	1
Juveniles	2,960	LC50 (96 h) at 179 mg CaCO3/L	3
Parr	4,700	LC50 (96 h) at 500 mg CaCO3/L	1
Juveniles	4,800-7,200	LC50 (96 h) at 333-504 mg CaCO3/L	3
Fry	10,000	16°/o dead in 90 h versus none dead in group pretreated with 5 mg Zn/L for 96 h	69
Fry	15,000	79% dead in 90 h versus 20% dead in group pretreated with 5 mg Zn/L for 96 h	69
Sockeye salmon, *Oncorhynchus nerka*			
Embryo through smolt	242	No measurable effects in 18-month exposure	1
Immatures	447	LC50 (115 h)	1
Immatures	750	LC50 (96 h)	3
Chinook salmon, *Oncorhynchus tshawytscha*			
Swim up	97	LC50 (96 h)	1
Chronic exposure	270-510	MATC [b]	1,2
Smolts	446	LC50 (96 h)	2
Minnow, *Phoxinus phoxinus*			
Yearlings	50-130	Reduced growth during exposure for 150 days; no deaths	70
Larvae	60	Decreased swimming ability after exposure for 108 days	3
Larvae	80	LC37 (40 days)	3
Adults	130	Reduced growth during 150-day exposure; some deaths	70
Juveniles	160	Decreased swimming ability after 109 days	3
Adults	200	Decreased swimming ability after 100 days	3
Adults	200	Reduced growth during 30-day exposure; some deaths	70
Adults	250	LC50 (150 days)	3
Fathead minnow, *Pimephales promelas*			
Life cycle	78-145	MATC [b]	1,2
Juveniles	125	Reduced growth in 7 days	2
Larvae	152-294	LC84 (8 weeks)	3
Adults	180	65 to 83% reduction in fecundity in 10-month exposure	1,2
Adults	480	Reduced growth in 30 days	3

Embryo-larvae	500-1,400	50% developmental malformations in 96h	71
Larvae	600	LC50 (96 h)	3
Adults	600	Preexposure for 14 days increased resistance 28% over controls in 96-h zinc toxicity assays	72
Adults	800	LC50 (30 days)	3
Adults	870	LC50 (96 h) at 20 mg $CaCO_3$/L,	3
Adults	1,800	Exposure for 7 days decreased tolerance 63% in 96-h zinc toxicity assays; tolerance decreased 74% after exposure for 14 days	72
Adults	2,800	LC15 (10 months), no eggs deposited	73
Embryo-larvae	3,600	LC50 (6 days)	71
Adults	4,700-6,100	LC50 (96 h) at 50 mg $CaCO_3$/L	3
Adults	6,400-10,900	LC50 (96 h) at 100 mg $CaCO_3$/L	3
Adults	7,100	LC50 (96 h) at 166 mg $CaCO_3$/L	3
Adults	8,200-21,000	LC50 (96 h) at 200 mg $CaCO_3$/L	3
Adults	33,400	LC50 (96 h) at 360 mg $CaCO_3$/L	3
Guppy, *Poecilia reticulata*			
Age 5 days	128	After 134 days, whole body zinc content of 0.6 mg/kg DW (0.3 mg/kg DW in controls); growth reduced	74
Adults	173	Whole body BCF of x466-965 in 30 days	2
Age 5 days	250	Delayed sexual maturation after 134 days	74
Age 5 days	500	Reproduction inhibited	74
Age 5 days	1,350-1,500	LC50 (96 h)	74
Adult males	4,400-5,700	LC50 (96 h)	74
Adult females	5,600-7,300	LC50 (96 h)	74
Atlantic salmon, *Salmo salar*			
Parr	50	50% avoidance in 4 h	2
Parr	100	Avoidance within 20 rain	3
Immatures, Water hardness	100-500	LC50 (21 days)	1
14 mg $CaCO_3$/L	420	LC50 (96 h)	1
20 mg $CaCO_3$/L	600	LC50 (96 h)	1
Brown trout, *Salmo trutta*			
Yolk-sac fry	4.9	40% with noncalcified vertebrae center; all dead in 18 days at pH 4.5 and soft water	75

Yolk-sac fry	9.8-19.6	60% to 75% dead in 20-30 days; 6% to 21% with abnormal vertebrae in pH 4.5 and soft water	75
Yearlings	<140	LC50 (96 h) at pH 8, 10 mg CaCO3/L	76
Adults	570	LC17 (14 days)	66
Adults	640	LC50 (14 days)	66
Yearlings	3,200	LC50 (96 h) at pH 5, 204 mg CaCO3/L	76
Brook trout, *Salvelinus fontinalis*			
Chronic exposure	534-1,360	MATC [b]	1,2
Adults	630	LC17 (14 days)	
Adults	960	LC50 (14 days)	3,66
Cabezon, *Scorpaenichthys marmoratus*, larvae	192	LC50 (96 h)	2
Dogfish, *Scyliorhinus* sp., exposure for 25 days	15,000	No significant accumulations in kidney and muscle, but elevated levels, as judged by BCF values in gill filament (x1.6), spleen (x1.7), pancreas (x2.7), and liver (x5.2)	77,78
Arctic grayling, *Thymallus arcticus*			
BW 0.2-1.8 g	112-168	LC50 (96 h)	67
Fry	315	LC50 (96 h)	67
Alevins	1,580-2,920	LC50 (96 h)	67
Tilapia, *Tilapia sparrmanii*, adults, exposure for 72 h	98,000	Decreased oxygen consumption, mucous precipitation on gills, histopathology of gill epithelium	79
Bolti, *Tilapia zilli*			
Adults	13,000	LC50 (96 h) at 25° C	52
Adults	21,000	LC50 (96 h) at 21° C; residues in survivors were 38,000 mg/kg DW in gill (70 mg/kg DW in controls); 23,000 mg/kg DW in liver (50 mg/kg DW controls); and 2,000 mg/kg DW in muscle, blood, serum, and liver chemistry (10 mg/kg DW in controls)	58,80
Adults	27,000	LC50 (96 h) at 15.3° C	52
Adults	33,000	LC50 (96 h) at 9.3° C	52
Amphibians			
Marbled salamander, *Ambystoma opacum*, embryos	2,380	50% dead or deformed in 8 days	2
Narrow-mouthed toad, *Gastrophryne*	10	50% dead or deformed in 7 days	2

carolinensis, embryos			
Leapfrog; *Rana dalmutina*, larvae, exposed during formation of gonadal structures	9,000	Toxic effect on larval gonad, especially on germ cells of ovarian structure	S1
Newt, *Triturus cristatus*, adults, held in tank with a zinc-plated base	200 to 3,000 over a 7-day period	Zinc-poisoned newts were lethargic, ate poorly, and has skin darkening before death. Zinc residues were elevated in kidney, brain, liver, and intestine, when compared to controls. The hippocampus region of the brain of poisoned newts contained zinc-rich cells	82
South African clawed frog, *Xenopus laevis*			
Embryos	>1,500	At 96 h, some midgut malformations and pericardial edema	83
Embryos	2,700	50% malformations in 96 h	83
Embryos	3,600	50% developmental malformations in 6 days	71
Embryos	>4,000	Severe edema of the pericardium and eye, gut miscoiling, and head and mouth malformations. At high sub-lethal concentrations, severe skeletal kinking, micropthalamia, and microencephaly	83
Tadpoles, pretreated with 5 mg Zn/L for 96 h	15,000-20,000	At 15 mg/L, none died in pretreated group versus 45% dead in controls at 90 h; at 20 mg/L, 15% died in pretreated group versus 50% in untreated controls	69
Embryos	34,500	LC50 (96 h)	71,83

[b]MATC = maximum acceptable toxicant concentration. Lower value in each MATC pair indicates highest concentration tested producing no measurable effect on growth, survival, reproduction, and metabolism during chronic exposure; higher value indicates lowest concentration tested producing a measurable effect.

Acute LC50 (96 h) values for freshwater invertebrates were between 32 and 40,930 µg Zn/L; in fish, this range was 66 to 40,900 µg/L (EPA 1987). For marine invertebrates the LC50 (96 h) range was 195 µg/L for embryos of the hard-shelled clam (*Mercenaria mercenaria*) to >320 mg/L for adults of the Baltic clam (*Macoma balthica*). For marine telcosts LC50 (96 h) values were between 191 µg/L for larvae of the cabezon (*Scorpaenichthys marmoratus*) to 38 mg/L for juvenile spot, (*Leiostomus xanthurus*; EPA 1987). Many factors are known to modify the biocidal properties of zinc in aquatic environment. In general, zinc was more toxic to embryos and juveniles than to adult, to starved animals, at elevated temperatures, in the presence of cadmium and mercury, in the absence of chelating agent, at reduced salinities, under conditions of marked oscillations in ambient zinc concentrations, at decreased water hardness and alkalinity, and at low dissolved oxygen concentrations (Skidmore 1964; Weatherley et al. 1980; Spear 1981; EPA 1987; Paulauskis and Winner 1988; Table 6).

Bioconcentration factors (BCF) for zinc accumulation from the medium varied widely between and within species of aquatic organisms. For representative freshwater organisms, BCF values ranged from 107 to 1,130 for insects and from 51 to 432 for fish (EPA 1980). In marine environments, the most effective zinc accumulators included red and brown algae, ostreid and crassostreid oysters, and scallops. The ranges of BCF values for representative marine groups were 370 to 64,000 for algae, 85 to 1,500,000 for crustaceans, 15 to 500 for echinoderms, as much as 4 million for scallop kidneys, and 1,900 to 6,900 for fish (Eisler 1980). Significant zinc accumulations were reported after death in algae and fish, suggesting that residue data from these and other organisms found dead on collection are of limited worth (Eisler 1980). Maximum net daily accumulation rates by various whole marine organisms were 1.3 mg Zn/kg FW for the alga *Ascophyllum nodosum*, 7.7 mg Zn/kg FW for the common mussel *Mytilus edulis*, 19.8 mg Zn/kg FW for the oyster *Crassostrea virginica*, 32 mg Zn/k FW for the killifish *Fundulus heteroclitus*, 32 mg Zn/kg FW for the softshell clam *Mya arenaria*, and 223 mg Zn/kg FW for the sandworm *Nereis diversicolor*; in general, accumulation rates and total accumulations were higher at elevated water temperatures and at higher ambient zinc water concentrations (Eisler 1980).

Algae and Macrophytes

Blue green algae are among the most zinc-resistant aquatic plants (Vymazal 1986). Algae are classified by Vymazal (1986) as very resistant (>10 mg Zn/L), resistant (2-10 mg/L), moderately resistant (0.5-2 mg/L), low resistant (0.1-0.5 mg/L; *Navicula*, *Synedra*), and very low resistant (<0.1 mg Zn/L; *Diatoma*, *Tabellaria*, *Microspora*, *Ulothrix*).

The most sensitive aquatic plant was *Schroederella schroederi*, a diatom; 19 µg Zn/L was sufficient to inhibit growth by 50% in 48 h (EPA 1987). Freshwater aquatic plants are usually absent from areas containing >2.0 mg Zn/L; in hard waters of artificial streams containing 170 mg $CaCO_3$/L, a water concentration of 1.1 mg Zn/L caused a 50% decrease in the number of algal species (Spear 1981). Most freshwater diatom populations decreased in the range of 175-380 µg Zn/L; this sensitivity may be useful as an indicator of zinc contamination (Spear 1981). Zinc and cadmium are strongly synergistic in their toxic action to plants. Any level of cadmium >10 µg/L should be suspected of producing a significant increase in the toxicity of available zinc to freshwater plants (Whitton 1980).

In heavily-contaminated zinc environments (130-6,500 µg Zn/L), zinc-tolerant species are dominant (Spear 1981). Highly-tolerant strains of algae require 1.5-1.65 mg Zn/L for normal growth; at least three species of

some tolerant strains can live in water containing 3 g Zn/L (Vymazal 1986). Highly tolerant mutant strains of *Anacystis nidulans* required 1.5-16.5 mg Zn/L. In France, at least 17 species of freshwater algae seemed to be flourishing at 42.5 mg Zn/L and pH 4.2 (Vymazal 1986). Zinc-tolerant strains of aquatic algae tolerate high zinc concentrations with little bioconcentration. A zinc-tolerant strain of *Euglena gracilis*, for example, tolerates >700 mg Zn/L but contains <500 mg Zn/kg DW whole organism versus 50 mg Zn/L and 5,000 mg/kg DW for nontolerant strains (Fukami et al. 1988a). Another zinc-tolerant strain of *Euglena* had normal growth at 300 mg Zn/L and residues of about 7,000 mg Zn/kg DW versus the population decline of nontolerant strains at 300 mg Zn/L (Fukami et al. 1988b).

Algae are effective accumulators of zinc. Three species of marine algae had a mean BCF of 1,530 in 12 days, 4,680 in 34 days, and 16,600 in 140 days (EPA 1980). Bioconcentration factors for zinc and various species of algae are quite variable and usually range from 76 to 163,750 (Vymazal 1986; EPA 1987). Many species of aquatic plants contain ≥150 mg Zn/kg DW. In one case, algae (*Mougeotia* spp.) from northern England in zinc-contaminated waters contained a spectacular 219 g Zn/kg DW (Vymazal 1986); it is probable that most of the zinc in *Mougeotia* was not biologically incorporated. Algal accumulations of zinc are modified significantly by physiochemical variables. Zinc concentrations in algae were higher under conditions of decreasing light intensity, water pH, DDT levels, copper, cadmium, phosphate, suspended sediments, organic chelators and other complexing agents, calcium, and magnesium and under conditions of increasing water temperature, dissolved oxygen, duration of exposure, and ambient zinc concentrations (Eisler 1980; Whitton 1980; Vymazal 1986).

Unlike algae, submerged aquatic macrophytes play a minor role in cycling of zinc (Lyngby et al. 1982). Rooted aquatic macrophytes may participate in heavy metal cycling in the aquatic environment either as a source or as a sink. But studies with eelgrass (*Zostera marina*) show that zinc exchange between the sediment and the water is insignificant (Lyngby et al. 1982).

Molluscs

Zinc was most toxic to representative molluscs at elevated temperatures (Eisler 1977a; Sprague 1986; Khangarot and Ray 1987), in comparatively soft water or to marine molluscs in low salinity (Sprague 1986; Khangarot and Ray 1987), at earlier developmental stages (Munzinger and Guarducci 1988), at low dissolved oxygen concentrations (Khangarot and Ray 1987), and with increasing exposure to high zinc concentrations (Amiard-Triquet et al. 1986).

High zinc accumulations in molluscs are usually linked to high levels of calcium in tissues, low ambient concentrations of iron or cobalt, exposure to organochlorine or organophosphorus insecticides, low salinity, elevated temperatures, increased particulate loadings in medium, increasing length of exposure to higher doses of zinc, increasing age of the organism, and especially to proximity of heavily carbonized and industrialized areas (Eisler 1980). Radiozinc-65 was rapidly accumulated in southern quahogs (*Mercenaria campechiensis*) during a 10-day period; accumulation in the kidney was linear over time and enhanced at elevated phosphate loadings in the medium (Miller et al. 1985).

Large variations in daily zinc accumulation rates by marine bivalve molluscs are typical. For example, softshell clams (*Mya arenaria*) immersed in 500 µg Zn/L at 16-22° C had daily accumulation rates of 2 mg/kg FW soft parts on day 1 of exposure, 7.7 mg Zn/kg FW soft parts between days 1 and 7, and 3.3 mg Zn/kg FW soft parts between days 7 and 14. At a lower temperature regimen of 0-10° C, immersion in 500 µg/L produced daily accumulation rates of 9.9 mg/kg FW soft parts for the first 42 days, but clams lost zinc at a rate of 0.24 mg/kg daily between days 42 and 112 (Eisler 1981). At 2,500 µg/L and 16-22° C, daily accumulation rates in surviving *Mya* were 32.0 mg Zn/kg FW soft parts on day 1 of exposure and 11.7 between days 1 and 7. Changes in accumulation rates of zinc by *Mya* reflect, at least partially, complex interactions between water temperature, ambient zinc concentrations, duration and season of exposure, and physiological saturation and detoxification mechanisms (Eisler 1977a, 1977b).

The half-time persistence (Tb½) of zinc in whole molluscs is extremely variable and reported to range from 4 days in the common mussel (*Mytilus edulis*) to 650 days in the duck mussel (*Anodonta nutalliana*); intermediate values were 23-40 days in the limpet (*Littorina irroratea*), 76 days in the California mussel (*Mytilus californianus*), and 300 days in the Pacific oyster (NAS 1979). Zinc persistence in selected organs also shows considerable variability and may be significantly different from Tb½ values in the whole animal. For example, the

Tb½ of zinc in the *Mytilus edulis* kidney was estimated at 2 to 3 months (Lobel and Marshall 1988) versus 4 days for whole animal (NAS 1979).

Mytilus edulis has been used extensively as a model for molluscan zinc kinetics. Results of selected studies follow. In mussels, zinc is taken up by the digestive gland, gills, and mantle and rapidly transported by hemolymph to the kidney where it is stored in insoluble granules (Lobel and Marshall 1988). There is a high degree of variability in soft tissues of *M. edulis* that is due entirely to an unusually high degree of variability in zinc of 97 to 7,864 mg/kg DW in the kidney (Lobel 1987). This variability in zinc content of the kidney is due largely to a low molecular weight zinc complex (700-1,300) that showed a high degree of variability and a positive correlation with zinc concentration in the kidney (Lobel and Marshall 1988). But at low ambient concentrations of 50 µg Zn/L, the most sensitive bioindicators of zinc exposure were gills and labial palps (Amiard-Triquet et al. 1986). Food composition had little effect on tissue distribution of radiozinc-65 in mussels as judged by 5-day feeding studies of radiolabeled diatoms (*Thalassiosira pseudonana*), green alga (*Dunaliella tertiolecta*), glass beads, and egg albumin particles (Fisher and Teyssie 1986). Soft part BCF values ranged from 12 to 35 times and was probably due to a rapid desorption of radiozinc from the food particles into the acidic gut, followed by binding to specific ligands or molecules. The Tb½ in mussel soft parts ranged from 42 to 80 days for all food items--including glass beads--and about 20 days in shell (Fisher and Teyssie 1986). Elevated temperatures in the range 10° to 25° C were associated with increased uptake rates of zinc from seawater by mussels (Watkins and Simkiss 1988). If the temperature is oscillated through this range during a 6-h period, there is a further enhancement of zinc uptake. This effect parallels decreases in zinc content of cytosol fractions and increases in granular fractions (Watkins and Simkiss 1988). Mussels were more sensitive to zinc than other tested bivalve molluscs. The pumping rate of mussels completely stopped for as long as 7 h on exposure to 470 to 860 µg Zn/L; however, other tested bivalves showed only a 50% reduction in filtration rates in the range of 750 to 2,000 µg Zn/L (Redpath and Davenport 1988). *Mytilus edulis* accumulates zinc under natural conditions but does not depurate under some conditions (Luten et al. 1986). This conclusion was based on results of a study of mussels that were transferred from a pristine environment in the Netherlands to a polluted estuary for 70 days and then returned for 77 days. At the start, zinc concentration was 106 mg/kg DW soft parts. By day 70, it had risen to 265 mg/kg DW at a linear daily uptake of 0.47 mg/kg. But mussels contained 248 mg/kg DW on day 147, indicating that elimination was negligible (Luten et al. 1986). In another study, zinc depressed sperm motility through respiratory inhibition at 6.5 mg/L, a concentration much higher than that normally found environmentally (Earnshaw et al. 1986). In mussel spermatozoa, zinc caused reductions of bound calcium and phosphorus in both acrosomes and mitochondria, suggesting increased permeability of organelle membranes to both elements (Earnshaw et al. 1986).

Arthropods

Arthropods were the most zinc-sensitive group of tested invertebrates (Table 6). Toxicity was usually greatest to marine crustaceans (Eisler 1981), to larvae (Eisler 1980), at elevated temperatures (Spear 1981; Sprague 1986; McLusky and Hagerman 1987), during extended exposures (EPA 1980, 1987), in soft water (Winner and Gauss 1986; Paulauskis and Winner 1988), under condition of starvation (NAS 1979; Verriopoulos and Moraitou-Apostolopoulou 1989), at salinity extremes above and below the isosmotic point (McLusky and Hagerman 1987), in summer (Eisler 1980), at low concentrations of humic acid (Winner and Gauss 1986; Paulauskis and Winner 1988), in proximity to anthropogenic discharges (Eisler 1980), and at low sediment particulate loadings (Memmert 1987). Acquired zinc tolerance is reported in amphipods collected from zinc-contaminated sewage wastes (Johnson and Jones 1989) and in fiddler crabs (*Uca* spp.) from a metals-contaminated area. *Uca* from zinc-contaminated areas were more resistant to zinc than crabs from pristine areas, as judged by increased survival and lower tissue zinc concentrations (Devi 1987; Devi and Rao 1989a, 1989b). More research into acquired zinc tolerance seems warranted.

Adverse effects of zinc insult to crustaceans include gill histopathology in prawns, *Macrobrachium hendersodyanum* (Patel and Kaliwal 1989); increased tissue total proteins, decreased glycogen, and decreased acid phosphatase activity in crabs, *Portunus pelagicus* (Hilmy et al. 1988); retardation of limb regeneration of fiddler crabs, *Uca pugilator* (Weis 1980); Waiwood et al. 1987). For example, tissue zinc residues in Homarus americanus exposed for 4 days to 25 mg Zn/L were especially high in gills (2,570 mg Zn/kg DW vs. 126 mg Zn/kg DW at start), hepatopancreas (734 mg Zn/kg DW vs. 135 mg Zn/kg DW), and green gland (1,032 mg Zn/kg DW vs. 148 mg Zn/kg DW). After 7 days in uncontaminated media tissue zinc residues remained elevated in gills (675 mg Zn/kg DW), hepatopancreas (603 mg Zn/kg DW), green gland (286 mg Zn/kg DW), and other

tissues (Waiwood et al. 1987). Zinc concentrations in crustacean soft tissues usually are between 50 and 208 mg/kg DW and exceed soft tissue zinc enzymatic requirements by factors of 1.4 to 6.0 (Depledge 1989).

Half-time persistence of zinc is about 17 days in the prawn (*Palaemon elegans*; Nugegoda and Rainbow 1988b) and between 30 and 270 days in five other crustacean species (NAS 1979). Differences in half-time persistence are linked to differences in excretion rates of ionic zinc and complexed zinc. In general, crustaceans excrete ionic zinc first and complexed zinc next; surface-adsorbed zinc is turned over faster than internally-adsorbed zinc; molting accounts for a 33-50% loss of the total body burden in crabs (Eisler 1981).

Crustaceans can accumulate zinc from both water and food (EPA 1987). In uncontaminated waters, the diet is probably the major source of zinc. Absorption from the stomach is efficient and occurs in part through the hepatopancreas. When a large pulse of zinc reaches the blood from the stomach, some is excreted, but much is resorbed and stored in the hepatopancreas in a relatively nonlabile form. Ultimately, stored zinc is also excreted, although removal through the gut is unimportant (Bryan et al. 1986). Zinc absorption is initially at the gill surface, is followed by transport on a saturable carrier in the cell wall, and is most efficient at low dissolved ambient zinc concentrations. Urinary excretion is an important body removal pathway, especially at high dissolved ambient concentrations when it can account for 70-80% of the total zinc excretion (Bryan et al. 1986).

Barnacles (*Elminius modestus*) usually accumulate zinc to high body concentrations without significant excretion. Barnacle detoxification mechanisms of the stored zinc includes production of metabolically inert zinc phosphate granules (Rainbow and White 1989). However, *Elminius modestus* transplanted from an area of high ambient zinc (101 µg/L) to an environment of low ambient zinc (4 µg/L) lost zinc slowly (0.3% body burden daily) during an 11-week period. Whole body zinc burdens declined from 1,554 to 125 mg/kg DW or at about 4.1 mg/kg DW daily (Thomas and Ritz 1986). In the case of *Balanus balanoides*, another barnacle, high BCF values were attributed to inorganic granules that contained as much as 38% zinc and accumulated in tissues surrounding the midgut (Eisler 1980).

Crustaceans--and other groups--can regulate body concentration of zinc against fluctuations in intake, although the ways in which regulation is achieved vary among species (Bryan et al. 1986). Regulation of whole body zinc to a constant level is reported for many crustaceans, including intertidal prawns (*Palaemon* spp.), sublittoral prawns (*Pandalus montagui*), green crabs (*Carcinus maenus*), lobsters (*Homarus gammarus*), amphipods (*Gammarus duebeni*), isopods (*Asellus communis*), and crayfish (*Austropotamobius pallipes*; Devineau and Amiard-Triquet 1985; Bryan et al. 1986; Lewis and McIntosh 1986; Nugegoda and Rainbow 1988b; Johnson and Jones 1989; Rainbow and White 1989). The body zinc concentration at which zinc is regulated in crustaceans usually increases with increasing temperature, salinity, molting frequency, bioavailability of the uncomplexed free metal ions, and chelators in the medium (Nugegoda and Rainbow 1987, 1988a, 1989a, 1989b). Lobsters (*Homarus gammarus*) are able to equilibrate over a 30-day period in seawater containing between 2 and 505 µg/L. In response to a 100-fold rise in seawater concentrations (from 5 to 500 µg/L), zinc levels in whole body, blood, hepatopancreas, excretory organs, and gills almost doubled but changed little in muscle. Zinc concentrations in shells increased about 12 times, largely through adsorption (Bryan et al. 1986). Regulation of zinc in lobster blood is achieved by balancing uptake through the gills against urinary excretion and loss over the body surface including the gills (Bryan et al. 1986). The sublittoral prawn (*Pandalus montagui*) can regulate total body zinc concentration to a constant level (75 mg/kg DW) in dissolved zinc concentrations up to 22 µg/L, beyond which there is net accumulation of body zinc. This threshold of zinc regulation breakdown is lower than that in *Palaemon elegans* (93 µg Zn/L) and *Palaemonetes varians* (190 µg Zn/L) under the same physiochemical conditions (Nugegoda and Rainbow 1987, 1988a, 1988b, 1989a, 1989b, 1989c; Rainbow and White 1989). The authors conclude that regulation of body zinc concentration is most efficient in decapods adapted to the fluctuating environments of littoral habitats, possibly, as a result of changes in permeability of uptake surfaces in combination with improved zinc excretion systems.

Freshwater crayfish (*Orconectes virilis*) are among the more resistant crustaceans (LC50 value of 84 mg Zn/L in 2 weeks) and can easily tolerate the recommended water quality criteria of 50-180 µg/L; nevertheless, some streams in Arkansas and Colorado contain 79-99 mg Zn/L (Mirenda 1986). *Orconectes virilis* exposed to extremely high sublethal ambient zinc concentrations of 63 mg/L for 2 weeks show whole body BCF values of only 2; a similar pattern was observed at other concentrations. In all cases, zinc tended to concentrate in gills and hepatopancreas at the expense of muscle, carapace, and intestine (Mirenda 1986). In freshwater crayfish (*Procambarus acutus acutus*), the major uptake route was the ambient medium and not diet, although retention

time of dietary zinc was greater (Giesy et al. 1980). When dietary zinc was the only zinc source, crayfish rapidly reached a steady state; when water was the only zinc source, crayfish did not reach a steady state (Giesy et al. 1980). Freshwater mysidaceans and their particulate wastes may play an important role in zinc cycling. The freshwater opossum shrimp (*Mysis relicta*) feeding on sediments ingested 2 to 4 times more zinc than mysids feeding on zooplankton. However, sediment-feeding mysids excreted 3 to 5 times more zinc than zooplankton consumers; zinc concentrations were up to 24 times higher in fecal pellets of sediment feeders than in food (Van Duyn-Henderson and Lasenby 1986). In the freshwater crayfish *Austropotamobius pallipes*, fecal excretion is a major zinc removal pathway; a similar case is made for the green crab (*Carcinus maenus*; Bryan et al. 1986).

Marine copepods (*Anomalocera*, *Acartia*, *Temora*) excreted 52% of the ingested zinc in fecal pellets that subsequently leached all zinc to seawater within 24 h (Fisher et al. 1991).

Freshwater insects, including many species of mayflies, damselflies, stoneflies, and caddisflies, are relatively tolerant to zinc, with LC50 values usually >1.33 mg/L--although some species were adversely affected at concentrations between 30 and 37 µg Zn/L (EPA 1987; Table 6). Mayfly (*Epeorus latifolium*) larvae were adversely affected at ambient water concentrations of 30 µg Zn/L but could tolerate dietary loadings of 600 mg Zn/kg DW ration without measurable effects on growth or emergence (Hatakeyama 1989). Chironomid insect populations were reduced or missing immediately downstream from coal mine drainage containing 5-10 mg Zn/L; populations further downstream recovered numerically but in comparison with upstream communities, their diversity was reduced (Wilson 1988).

Annelids

Populations of freshwater oligochaetes and leeches were reduced in numbers of individuals and number of taxa in mine tailing effluents containing 146-213 µg Zn/L or sediments containing >20 g Zn/kg DW (Willis 1985b). Leeches (*Erpobdella octoculata*) experienced a reduction in density and reproductive capacity in streams containing 25 to 310 µg Zn/L from mine wastes and did not avoid these harmful concentrations (Willis 1989).

The highest rate of net zinc absorption reported for any group of invertebrates was 2,230 mg Zn/kg BW daily in sandworms (*Nereis diversicolor*) from sediments with low zinc levels during exposure for 34 days in 250 mg Zn/L. At 10 mg Zn/L, the rate decreased to 55 mg Zn/kg BW daily (Eisler 1981). Zinc uptake in *Nereis* increased with increasing sediment zinc levels, at lower salinities (Eisler 1980), and at elevated temperatures (Fernandez and Jones 1987, 1989). Zinc had no significant effect on burrowing behavior of *Nereis*, even at acutely lethal concentrations (Fernandez and Jones 1987). Sandworms from zinc-contaminated sediments were more resistant to waterborne zinc insult by 10-100 times than sandworms from clean sediments (EPA 1987). Tolerance to zinc in sandworms may be a result of acclimatization or genetic adaption. In either event, the degree of metal tolerance decreases rapidly as the level of zinc contamination declines, suggesting that some zinc-tolerant worms may be competitively inferior to normal individuals in clean environments (Grant et al. 1989). More research on zinc-tolerant populations seems merited.

Unlike other major groups of marine benthic organisms, the polychaete *Neanthes arenaceodentata* has a limited capacity to regulate zinc (Mason et al. 1988). Uptake in *Neanthes* occurs from the free ionic pool of zinc whereas EDTA complexes and EDTA-zinc complexes are largely excluded. Zinc accumulates linearly over time (350 h) and the rate decreases with increasing temperature in the range 4-21° C. Mason et al. (1988) concluded that uptake and accumulation of zinc is passive in *Neanthes* and does not require metabolic energy. Zinc transfer across the plasma membrane is by way of diffusion. Inside the cell, zinc binds to a variety of existing ligands that maintain an inwardly directed diffusion gradient, preventing zinc efflux. Accumulation rats is determined by the number and binding characteristics of the available ligands and their accessibility to zinc. After 50 h of exposure, worms selectively accumulate zinc over cadmium from the medium by a process requiring metabolic energy, and this is attributed to a change in the turnover rate and to the size and nature of the pool of zinc-binding ligands (Mason et al. 1988).

Echinoderms

In echinoderms, zinc concentrations are usually higher in detrital feeders than in carnivores, higher in surface feeders than in sediment feeders, and higher in specimens collected inshore than those collected offshore in deeper waters (Eisler 1980). Sea cucumbers (*Stichopus tremulus*) accumulate radiozinc-65 from

seawater by a factor of 1,400; however, radiozinc accumulation data should be viewed with caution because addition of stable zinc can reduce radiozinc-65 accumulations in echinoderm viscera up to 10-fold (Eisler 1981). Zinc inhibits the formation of the fertilization membrane in sea urchin eggs, possibly by interfering with cortical granule-derived proteases and proteins (Nakamura et al. 1989).

Fish

Several trends are evident (Table 6): (1) freshwater fish are more sensitive to zinc than marine species; (2) embryos and larvae are the most sensitive developmental stages; (3) effects are lethal or sublethal for most species in the range 50-235 µg Zn/L and at 4.9-9.8 µg Zn/L for the brown trout (*Salmo trutta*); and (4) behavioral modifications, such as avoidance, occur at concentrations as low as 5.6 µg Zn/L. Signs of zinc poisoning in fish included hyperactivity followed by sluggishness before death, fish swam at the surface, were lethargic and uncoordinated, showed hemorrhaging at gills and base of fins, shed scales, and had extensive body and gill mucous (Bengeri and Patil 1986). Zinc is most toxic to yearlings of brown trout in soft water at pH 4-6 and pH 8-9; toxicity at alkaline pH is attributed to the formation of ZnOH+, $Zn(OH)_2$, and $ZnCO_3$ in both hard and soft water--suggesting increased entrapment of metal precipitates within mucous and epithelial layers of the gill (Everall et al. 1989a). Acute zinc poisoning in fish is generally attributed to blockade of gas exchange across the gills, causing hypoxia at the tissue level. Tissue hypoxia in fish is a major physiological change before death once the gas exchange process at the gills is no longer sufficient to meet its oxygen requirements (Burton et al. 1972; NAS 1979; Everall et al. 1989a; Grobler et al. 1989). Cardiorespiratory responses to zinc in the spangled perch (*Leiopotherapon unicolor*) are similar to those induced by hypoxia; zinc-poisoned perch had damaged gill epithelia, resulting in impaired gas exchange and lowered oxygen tension in arterial blood (Gehrke 1988). Acute exposures to high lethal concentrations of zinc also caused histopathology of epithelia lining the oral capacity (Eisler and Gardner 1973).

Many factors modify the lethal properties of zinc to fish. Zinc is more toxic under conditions of comparatively low dissolved oxygen concentrations, high sodium concentrations, decreased loadings of organic complexing agents (Spear 1981), and low pH (NAS 1979). In guppies (*Poecilia reticulata*), females were more resistant than males to acute zinc insult; adults of both sexes were more resistant than 5-day-old fry (Pierson 1981). Dominant bluegills (*Lepomis macrochirus*) survived exposure to 32 mg Zn/L longer than submissive fish (NAS 1979). Water temperature is also an important modifier and it is generally agreed that zinc is more toxic at elevated temperatures (NAS 1979; Spear 1981; Hilmy et al. 1987c) when acclimatization temperature is considered. For example, cold-acclimatized (3° C) Atlantic salmon survived longer than warm-acclimatized (19° C) salmon when exposed to lethal concentrations of zinc at their respective acclimatization temperatures. However, at test temperatures lower than their former acclimatization temperatures, salmon were less tolerant of zinc (Hodson and Sprague 1975).

Fish surviving high sublethal concentrations of zinc had significant alterations in blood and serum chemistry, liver enzyme activity (Hilmy et al. 1987b), muscle glycogen, total lipids, phospholipids, cholesterol, RNA, and proteins (Taneja et al. 1988).

Reproductive impairment seems to be one of the more sensitive indicators of zinc stress in freshwater teleosts, and effects are evident in the 50-340 µg Zn/L range (Spear 1981). In some cases, reproduction was almost totally inhibited at zinc concentrations that had no effect on survival, growth, or maturation of these same fish (Brungs 1969). Zinc-induced developmental abnormalities were documented in marine teleosts, but concentrations were grossly elevated. Eggs of the Baltic herring (*Clupea harengus*), for example, exposed to >6 mg Zn/L had an altered rate of development and produced deformed larvae with cellular disruptions in the brain, muscle, and epidermis (Somasundaram 1985; Somasundaram et al. 1985).

Avoidance tests with fathead minnows (*Pimephales promelas*) showed that almost all except males with established territories avoid 284 µg Zn/L when given a choice; avoidance thresholds were 6.4 times higher for established males (Korver and Sprague 1989).

Limited tolerance to zinc was observed in freshwater fish preexposed to sublethal levels of zinc (Spear 1981; Heath 1987; Woodall et al. 1988; Anadu et al. 1989; Hobson and Birge 1989). In one case, rainbow trout acclimatized to 50 µg Zn/L for 21 days were as much as 5 times more tolerant to subsequent zinc exposures than nonacclimatized trout; this was not evident at 100 µg Zn/L; also, acclimatization to zinc produced tolerances to copper and cadmium in trout (Anadu et al. 1989). The mechanisms to account for this

phenomenon are unknown, but several theories are proposed: increased metallothionein synthesis (Woodall et al. 1988), although this is disputed by Hobson and Birge (1989); high mortality during preexposure may have caused the selection of more zinc-tolerant individuals (Spear 1981); and tolerance may be limited to strains capable of increased zinc excretion, although no evidence now exists linking genetic mechanisms to zinc resistance (Spear 1981).

The estimated half-time persistence (Tb½) of zinc in whole mosquitofish (*Gambusia affinis*) was 215 days (Newman and Mitz 1988). The half-time persistence of zinc in whole marine fish ranged from 35 to 75 days in the mummichog (*Fundulus heteroclitus*) to 295-313 days in a flatfish (*Pleuronectes platessa*); Tb½ in mummichogs was shortest at 30° C, longest at 10° C, and intermediate at 20° C (NAS 1979).

Fish can accumulate zinc from both the surrounding medium and from their diet (EPA 1987). The freshwater zebra danio (*Brachydanio rerio*) accumulated zinc from the medium, but there was no additional zinc enrichment from a *Daphnia* diet (Memmert 1987). In marine fish, however, diet was considered the major route of zinc intake and significantly more important than water zinc levels (Eisler 1980).

In freshwater fish, BCF values for whole individuals were between 51 and 500 times (EPA 1987) but are strongly influenced by dose, duration of exposure, water chemistry, and other variables. In mosquitofish, uptake rate from water and zinc elimination rate decreased with increasing age of the fish (Newman and Mitz 1988). In the three-spined stickleback (*Gasterosteus aculeatus*), uptake was greater in hard water than in soft water and greater in larger fish, suggesting a surface adsorption mechanism (Matthiessen and Brafield 1977). In brown trout, however, uptake was lower and excretion greater in hard water of 220 mg $CaCO_3$/L than in soft water of 9 mg $CaCO_3$/L, thereby reducing tissue burdens (Everall et al. 1989a). Starved rainbow trout accumulated zinc more rapidly than fed fish because of an increased contribution of waterborne zinc to total body zinc levels (Handy and Eddy 1990). Rapidly growing chinook salmon (*Oncorhynchus tshawytscha*) fingerlings removed radiozinc-65 from the medium and retained nearly all of it for 63 days after transfer to uncontaminated media. Most of the radiozinc-65 was translocated to vertebral column, head, and visceral mass (Joyner and Eisler 1961). The outer surface of the bone seems to be an ion-exchange medium capable of taking up large quantities of metal ions whether natural or foreign to the system. Metals thus exchanged from serum proteins may be prevented from undergoing further exchange by the overlayering action of growing bone (Joyner and Eisler 1961). Channel catfish (*Ictalurus punctatus*) fingerlings fed diets containing up to 200 mg Zn/kg FW ration for 12 weeks had elevated bone zinc levels (359 mg/kg DW vs. 254 mg/kg DW in controls) and reduced hematocrit, but survival and feed conversion efficiency was the same as by controls (Gatlin et al. 1989). Plasma zinc levels in four species of freshwater fish on diets containing 100-200 mg Zn/kg ration ranged between 9.3 and 15.1 mg Zn/L FW; in rainbow trout, zinc tended to concentrate in the erythrocyte membrane (Bettger et al. 1987).

In marine fish, zinc residues were usually higher in dead than in live or moribund animals, higher in smaller fish, higher in liver and viscera, and higher with decreasing water cadmium levels (Eisler 1980). Uptake from the medium by adult mummichogs was inversely related to zinc concentration in the water (EPA 1987). In mummichogs, zinc accumulates in scales during exposure to 10 mg Zn/L, significantly elevating the zinc to calcium ratio; ratios remained elevated for at least 4 months after transfer to low zinc media, and this phenomenon may have application for environmental monitoring (Sauer and Watabe 1989a).

Scale osteoblasts of zinc-exposed mummichogs showed an increase in the number of lysosome-like structures contained by cytoplasm and suggests that osteoblast lysosomes are involved in zinc accumulation in fish scales by enzymatic degradation of metallothioneins or other metal-binding proteins (Sauer and Watabe 1989). Dietary zinc is not well assimilated in marine flatfish. Turbot (*Scopthalmus maximus*) fed diets containing 100 (control) or 1,000 mg Zn/kg DW for 200 days were not different in renal and hepatic metallothionein levels or in zinc concentrations in the liver, kidney, muscle, skin, or bone; a similar case is made for other marine flatfish (Overnell et al. 1988). However, intraperitoneally injected (2 mg Zn/kg BW) turbots had an 18-fold increase in liver metallothionein constant and a 3-fold increase in liver zinc, confirming the ability of this species to synthesize metallothionein rapidly to a high concentration (Overnell et al. 1988).

Amphibians

Amphibian embryos are more sensitive to zinc than older stages; developmental abnormalities were evident in most species at concentrations >1.5 mg Zn/L (Table 6). Embryos of the narrowmouthed toad (*Gastrophryne carolinensis*) seem to be especially sensitive; adverse effects were reported at 10 µg Zn/L (EPA 1987), but this requires verification. Amphibians and other taxonomic groups were rare or absent in the vicinity of zinc smelters but not in more distant sites (Beyer et al. 1985).

In tests with isolated skin of frogs (*Rana* spp.), Zn^{2+} stimulates sodium transport and inhibits chloride-related tissue conductance; however, the skin of toads is relatively insensitive to zinc (Nagel et al. 1988). In early stages of embryonic development, Zn^{2+} stimulates multiplication of germ cells, but long-term treatment with $ZnSO_4$ has a toxic effect on the larval gonad and especially on the germ cells of the ovarian structure that is developed in frog larvae (Gipouloux et al. 1986).

Birds

Ducks (*Anas* spp.) had reduced survival when fed diets containing 2,500-3,000 mg Zn/kg ration or when force-fed zinc metal shot equivalent to 742 mg Zn/kg BW (Table 7). Domestic chickens (*Gallus* sp.) were more resistant: 8,000 mg Zn/kg ration was fatal to chicks, although higher doses were routinely fed to laying hens to induce molting; 2,000-3,000 mg Zn/kg ration inhibited chick growth; 178 mg Zn/kg feed caused immunosuppression in chicks; and dietary concentrations as low as 100 mg Zn/kg caused pancreas histopathology in chicks under conditions of selenium deficiency (Table 7). Excessive zinc (2,000 mg/kg diet for 21 days) fed to chicks (*Gallus* sp.) caused zinc accumulations in tissues, reduced tissue turnover of zinc, reduced liver turnover of iron, and reduced copper content of the liver and pancreas and iron in the tibia (Stahl et al. 1989b). However, hens were less sensitive and, when fed diets containing 2,000 mg Zn/kg for 44 weeks, produced chicks that had no apparent alteration in tissue zinc, copper, or iron metabolism (Stahl et al. 1990).

Table 7. Effects of zinc on representative birds.

Species, dose, and other variables	Effects	Reference[a]
Mallard, *Anas platyrhynchos*		
Fed diets containing 3,000 mg Zn/kg feed, and higher, for 30 days	At 3,000 mg/kg ration, ducks had leg paralysis and decreased food consumption; at >3,000 mg/kg diet, many deaths occurred	1
Age 7 weeks. Fed diets containing 3,000, 6,000, 9,000, or 12,000 mg Zn/kg dry weight (DW) diet for 60 days; zinc in form of zinc carbonate	Food intake reduced for all groups; the 9,000 and 12,000 mg/kg groups had almost zero intake. High mortality after 30 days in all groups; only 17% of 3,000 mg/kg group alive at day 60. Zinc residues at time of death or at day 60 for the 3,000 mg/kg group were 89 mg/kg fresh weight (FW) in pancreas (1,252 mg/kg FW in controls); 401 mg/kg FW in liver (54 mg/kg FW); 88 mg/kg FW in adrenals (45 mg/kg FW); 413 mg/kg FW in kidney (27 mg/kg FW); 32 mg/kg FW in muscle (14 mg/kg FW); 78 mg/kg FW in testes (17 mg/kg FW); and 71 mg/kg FW in ovary (31 mg/kg FW)	2
Age 1 year. Single oral dose of five number 6 zinc shot in gelatin capsules,	All shot retained in gizzard after 14 days; no adverse effects after 28 days. Residues at	3

equivalent to 0.40 g zinc or 495 mg Zn/kg body weight (BW)	28 days were 217 mg/kg DW in liver, 79 mg/kg DW in kidney, and 126 mg/kg DW in feather	
Drakes, 18 months old, force-fed eight number 6 zinc shot pellets	By day 30 posttreatment, 20% had died. The mean weight loss was 33% in dead birds and 22% in survivors. About 83% of survivors developed signs of zinc poisoning	4
Age 1 year. Single oral dose of ten number 6 zinc shot in gelatin capsules, equivalent to 0.80 g zinc or 990 mg Zn/kg BW	Two to 4 shot voided in first 48 h, but no further loss for 28 days. Residues at 28 days were 211 mg Zn/kg DW in liver (171 mg Zn/kg DW in control birds), 72 mg Zn/kg DW in kidney (61 mg Zn/kg DW), 143 mg Zn/kg DW in feather (128 mg Zn/kg DW)	3
Pekin duck, *Anas platyrhynchos*		
3-day-old male white ducklings fed diet containing 2,500 mg Zn/kg, as $ZnSO_4.H_2O$, for 56 days	Progressive ultrastructural degeneration of pancreatic acinar cells evident as early as day 5	5
Japanese quail, *Coturnix coturnix japonica*		
Intratesticular injection of 3% zinc chloride equivalent to 1 mg Zn/kg testes or 0.02 mg/kg BW	Testicular teratomas produced during a period of testicular growth stimulated by increased photoperiod	6
Hens fed diet containing 15,000 mg Zn/kg ration, as zinc oxide, for 7 days	Significant reduction in body weight, egg production approached zero at day 3, eggshell breaking strength reduced, molting induced	7
14-day-old quail fed diets containing various concentrations of zinc, as zinc phosphide (a rodenticide) for 5 days followed by 3 days of untreated feed	At 600 mg Zn/kg ration, 7% died and all had reduced food intake. At 990 mg Zn/kg diet, 53% died; at 1,634 mg/kg died, 93% died	8
Domestic chicken, *Gallus* sp.		
Developing embryos, 1 day old, with 0.76 mg Zn/yolk at start, supplemented with 0.2, 0.4, or 0.6 mg zinc	Hepatic metallothionein levels increased by factors of 3.9 (0.2 mg), 4.7 (0.4 mg), and 7.1 (0.6 mg)	9
Femurs from 9-day-old chick embryos cultivated for 6 days at 3.26 mg Zn/L	Inhibited calcium accumulations in bone and increased alkaline phosphatase activity of medium	10
As above, 6.5 mg Zn/L	Decrease in calcified tissues	10
Domestic breeding hens fed diets containing 28, 38, 48, 68, 94, or 178 mg Zn/kg ration for up to 9 months	Progeny growth after 3 weeks was not affected by maternal zinc feeding levels. A minimum of 38 mg Zn/kg diet was considered necessary for minimal feather fraying and maximal immune response in chicks. Diets containing 178 mg Zn/kg may be excessive and cause	11

	immunosuppression of young progeny without affecting growth	
Fed 28 (control), 48, 228, or 2,028 mg Zn/kg diets for 12 or 44 weeks. Hens were 56 weeks old at start of short-term study and 24 weeks old at start of long-tern study	Zinc treatments had no effect on overall egg production, feed conversion, feed consumption, hatchability, or progeny growth to age 3 weeks. Zinc was elevated in eggs from hens fed the 2,028 mg/kg diet, but chick performance and tissue zinc content were unaffected by maternal zinc nutritional status	12
Chicks fed diets containing 37 (control), 100, or 2,000 mg Zn/kg feed for 21 days	No accumulations in 100 mg/kg group; zinc excretion rate about x2 controls. No deaths in 2,000 mg/kg group, but growth rate was decreased, anemia evident, tissue copper and iron decreased, and tissue zinc increased	13
Day-old chicks fed selenium-deficient diets plus 100 mg Zn/kg FW, as zinc oxide, purified ration for 9 days	Elevated zinc concentrations in pancreas, and pancreas histopathology	14
Hens fed diets containing 218, 257, 1,762, or 1,861 mg Zn/kg diet for up to 40 weeks	Eggs from hens fed 218 or 257 mg Zn/kg diet contained a maximum of 14 mg/kg FW, equivalent to about 25% more zinc than eggs produced by control hens. Eggs from the two higher-dose diets had a maximum of 19 mg/kg FW or 57-90% more zinc than eggs produced by hens fed a control diet of 26-28 mg Zn/kg.	15
9-day-old chicks fed purified diet containing 500 mg Zn/kg ration for 2 weeks	Plasma alpha-tocopherol reduced 64%; plasma and pancreas zinc concentrations elevated	16
Day-old chicks fed selenium-adequate diet plus 2,000 mg Zn/kg FW, as zinc oxide, nonpurified ration for 9 days	Negligible effects on pancreas zinc concentration and on pancreas exocrine function	14
9-day-old chicks fed nonpurified diet containing 2,000 mg Zn/kg ration for 80 days.	No effect on plasma alpha-tocopherol or plasma and pancreas zinc content	16
Chicks fed diets containing 2,000 or 3,000 mg Zn/kg ration for 30 clays	Slight reduction in growth at 2,000 mg/kg; significant growth reduction at 3,000 mg/kg	1
Day-old chicks fed diets containing up to 4,000 mg Zn/kg ration for 4 weeks	No effect on growth, survival, or feed conversion. Zinc accumulated in tissue metallothioneins, especially in liver and kidney; levels normal after 5 days on zinc-deficient diet	17
Day-old chicks fed diets containing 4,000, 8,000, or 16,000 mg Zn/kg for 5 weeks	All dead at 16,000 mg/kg diet. The 8,000 mg/kg group had 80% mortality; survivors had signifi-cantly reduced growth and feed conversion. At 4,000 mg/kg, no significant effect on growth or	17

	survival; zinc concentrations elevated in kidney, liver, intestinal mucosa, and pancreas--but values normal after 10 days on basal diet	
Age 71 weeks, laying hens. Fed diet containing 10,000 mg Zn/kg feed for 2 days, then 5,000 mg/kg diet for 4 days	Hens started to molt and ceased laying. Feed intake decreased about 90%. Zinc concentrations increased in pancreas 7 times, in liver 6 times, in kidney 3 times, and were elevated in shell gland and yolk. High zinc levels in kidney reflect high zinc excretion rates; high pancreatic zinc (410 mg Zn/kg FW) may suppress the release of insulin by calmodulin inhibition, and could account for the rapid cessation of lay	18
White leghorns and brown layers were fed diets containing 10,000, 20,000, or 30,000 mg Zn/kg feed, as zinc oxide, for up to 3 weeks to induce molting	Cessation of egg laying in all treatments. On resumption of egg production, zinc levels in albumin or eggshell were not affected by the treatment or strain; zinc levels in yolk increased and depended on feed intake rather than dose. No increase in zinc content in eggs laid after egg production resumed, regardless of dose or duration of zinc treatment	19
White leghorn laying pullets and hens fed diet containing 20,000 mg Zn/kg feed for 5 days	Reduced body weight on day 5, and significantly lowered egg production for 4 weeks. Eggs collected 14-28 days after the 5-day study period had reduced fertility and hatchability. Normal growth, egg production, fertility, and hatch-ability during weeks 4-12 posttreatment	20
Laying hens fed diet containing 20,000 mg Zn/kg, as zinc oxide, for 4 days followed by 18 days on basal (35 mg Zn/kg) diet	At day 4, liver zinc concentrations increased 10 times, kidney 3 times, egg yolk 3 times, and pancreas 25 times; liver and kidney values returned to normal by day 22, but pancreas concentration (1,673 mg/kg DW) remained elevated when compared to controls (88 mg/kg DW). At day 10, reduced weight of ovary and oviduct	21
Turkey, *Meleagris gallopavo*		
Zinc concentration of sperm storage medium increased from 25 to 90 mg/L.	Fertilizing ability of stored sperm significantly reduced	22

Fleet and McCormick 1988; 10. Kaji et al, 1988; 11. Stahl et al. 1989a; 12. Stahl et al. 1990; 13. Stahl et al. 1989b; 14. Lu and Combs 1988a; 15. Stahl et al. 1988; 16. Lu and Combs 1988b; 17. Oh et al 1979; 18. Veheyen et al. 1990; 19. Decuypere et al. 1988; 20. Palafox and Ho-A 1988; 21. Williams et al. 1989;p 22. Blesbois and Mauger 1989.

Zinc-poisoned mallards (*Anas platyrhynchos*) force fed zinc shot pellets developed ataxia, paresis, and total loss of muscular control of legs, including the ability to swim (Wobeser 1981). The muscular, weakness associated with zinc intoxication would probably make ducks highly susceptible to predation and argues against the use of zinc shot as a substitute for lead shot (Grandy et al. 1968). Mallards fed 3,000 mg Zn/kg DW ration for 60 days had diarrhea after 15 days; leg paralysis in 20 days; high mortality after 30 days; and zinc residues that were 14 times higher in pancreas than in controls, 7 times higher in liver, 15 times higher in kidney; and 2 to 4 times higher in the adrenals, muscle, testes, and ovary at day 60 (Gasaway and Buss 1972).

In Australia, almost all aviary birds are held in cages of galvanized wire mesh, resulting in sporadic cases of "new wire disease" caused by the ingestion of galvanized metal. In one case, peachfaced lovebirds (*Agapornis roseicollis*) died within 5 weeks of placement in a newly erected wire cage; dead birds had elevated liver zinc concentrations of 75-156 mg/kg DW versus normal values of 21-33 mg/kg DW (Reece et al. 1986). Zinc poisoning in a captive Nicobar pigeon (*Caloenas nicobarica*) was attributed to plated zinc metal fragments found in the gizzard--presumably ingested from the galvanized cage bars. In addition to elevated tissue zinc concentrations, this pigeon had a swollen liver and kidneys and extensive kidney histopathology (Zee et al. 1985). A zinc-poisoned blue and gold macaw (*Ara ararauna*) showed weakness, ataxia, extreme thirst, diarrhea, cyanosis, and a plasma zinc concentration of 15.5 mg/L after ingesting galvanized hardware cloth that was 24% zinc by weight and 0.2% lead. The bird was treated with 35 mg/kg BW calcium versanate intramuscularly and 30 mg thiamine hydrochloride per kilogram of BW; recovery following chelation therapy took 2 months, at which time plasma zinc was 0.6-0.8 mg/L versus 1.3-2.0 mg/L for normal birds (Morris et al. 1986). New galvanized wire used in aviary construction should weather for 1 to 2 months and then be scrubbed with a mild acidic solution such as vinegar and rinsed; flakes of galvanized metal--which contain up to 2.4 g Zn/kg--should be removed before birds are put in cages (Reece et al. 1986).

Zinc toxicosis was diagnosed in a gray-headed chachalaca (*Ortalis cinereiceps*) after it ingested a copper-plated zinc penny; necropsy showed pancreas histopathology and severe gizzard erosion; liver contained 1,910 mg Zn/kg FW (Droual et al. 1991).

Large amounts of zinc are crucial for new feather growth. Zinc deficiency during this period results in stunted, frayed, easily-broken feathers. Studies with the giant Canada goose (*Branta canadensis maxima*) showed that zinc was released from the pectoralis muscle during molt-induced atrophy and used for growth of feathers and leg muscles during this period (Rosser and George 1986).

Zinc phosphide--a rodenticide--is relatively toxic in comparison with elemental zinc or zinc oxide; most of the biocidal action is attributed to the phosphide fraction. Acute oral LD50 values for zinc phosphide were between 16 and 47 mg/kg BW in the ring-necked pheasant (*Phasianus colchicus*), golden eagle (*Aquila chrysaetos*), mallard, and horned lark (*Eremophila alpestris*; Hudson et al. 1984). Signs of zinc phosphide poisoning include excessive drinking, regurgitation, muscular incoordination, appetite loss, sluggishness, rapid breathing, and eyelid droop. Signs appeared as soon as 15 min after dosing, and death usually occurred between 2 and 21 h; remission took up to 1 month (Hudson et al. 1984).

High dietary levels of zinc are frequently fed to poultry to force molting and reduce egg deposition (Decuypere et al. 1988; Hussein et al. 1988). Extremely high dietary levels of 20 g Zn/kg ration have been used as a commercial management technique to force the molting of laying hens .and the subsequent improvement of long-term egg production that molting produces (Lu and Combs 1988a). Laying hens given high zinc diets increased their zinc uptakes 5-40 times in a dose-dependent pattern despite the decreased food intake associated with high zinc dietary levels. Zinc preferentially accumulated in chicken kidney, liver, pancreas, and gizzard; significant increases in egg zinc occurred at dietary levels of 10 and 20 g Zn/kg (Verheyen et al. 1990). Unlike adults, high dietary levels of zinc adversely affected pancreatic exocrine function in the chick; effects were exacerbated under conditions of selenium deficiency and feeding of purified diets (Lu and Combs 1988a). Impaired enteric absorption and transport of vitamin E as a consequence of zinc-induced pancreatic insufficiency is a major cause of reduced tissue concentrations of alpha-tocopherol produced in chicks by excess dietary zinc; these effects were magnified by diets low in corn, soybean meals, and other materials known to chelate zinc and thus reduce its biological availability (Lu and Combs 1988b). Excess dietary zinc causes pancreatic damage in the chick, including reduced activities of major digestive enzymes, elevated plasma amylase activities, reduced digestibility of starch, and reduced vitamin A activity; these changes were associated directly with elevated tissue zinc concentrations, especially in the pancreas (Lu et al. 1990).

Mammals

Livestock and small laboratory animals are comparatively resistant to zinc, as judged by their tolerance for extended periods to dietary loadings >100 times the minimum recommended daily zinc requirement (Table 8). Nevertheless, excessive zinc intake through inhalation or oral exposure can have drastic effects on survival, metabolism, and well being. Sensitive species mammals were affected at 90-300 mg Zn/kg diet, >300 mg Zn/L drinking water, > 90 mg/kg BW daily, > 350 mg Zn/kg BW as a single oral dose, and > 0.8 mg Zn/m^3 air (Table 8).

Zinc is relatively nontoxic in mammals. A wide margin of safety exists between normal intakes and those producing deleterious effects. In most cases, dietary levels up to 100 times the daily requirement for extended periods show no discernable effects (NAS 1979; Wentink et al. 1985; Goyer 1986; Leonard and Gerber 1989). The possibility of oral zinc intoxification in adult humans is unusually low, as judged by the low (40%) bioavailability of zinc from the gastrointestinal tract and the high tolerances to zinc reported in domestic livestock and small laboratory animals (Llobet et al. 1988a, 1988b). Humans ingesting up to 12 g of elemental zinc, equivalent to 33 mg/kg BW for a 60-kg adult, during a 2-day period show no evidence of hematologic, hepatic, or renal toxicity (Goyer 1986).

Excessive zinc intake adversely affects survival of all tested mammals --including humans--and produces a wide variety of neurological, hematological, immunological, hepatic renal, cardiovascular, developmental, and genotoxic effects (PHS 1989). The most sensitive species of mammals showed adverse effects at dietary levels of 80-90 mg Zn/kg in humans, 300 mg Zn/kg ration in domestic cats, and 500 mg Zn/kg feed in rats; drinking water concentrations of 300 mg/L in domestic mice and 800 mg Zn/L in laboratory white rats; daily whole body intakes >90 mg Zn/kg in horses; acute oral LD50 doses of 350-800 mg Zn/kg BW in rats; intraperitoneal injections of 13 mg Zn/kg BW in mice; and 0.8 mg Zn/m^3 air in guinea pigs (Table 8).

Metal fume fever is commonly encountered by industrial workers exposed to zinc fumes and is characterized by pulmonary irritation, fever, chills, and gastroenteritis (Saxena et al. 1989b). Attacks begin 4-8 h after exposure and recovery, in 24-48 h. The pathogenesis of metal fume fever is unknown but may be associated with endogenous pyrogens released by cell lysis (Goyer 1986). Rabbits, rats, and cats exposed to zinc oxide fumes for 3.5 h at concentrations of 110-600 mg/m^3 reacted with a transient fall in body temperature followed by leucocytosis; heavily-exposed animals had signs of bronchopneumonia (Elinder 1986). The current atmospheric threshold limit value for zinc is 5 mg/m^3; however, results of studies with guinea pigs suggest that the current threshold limit value for zinc oxide should be lowered (Lam et al. 1985; Table 8).

Excessive zinc uptake is associated with lameness, unthrifty appearance, and osteochondrosis in foals and pigs, nephrosis in ferrets, and pancreatic fibrosis in sheep (Gunson et al. 1982). Zinc-poisoned mammals are usually characterized by a decreased growth rate, subcutaneous hematomas, ulcerative gastritis, hemorrhagic enteritis, lesions of major limb joints, renal lesions, elevated serum and tissue zinc concentrations, acute diarrhea, copper deficiency, impaired reproduction, and decreased activity of cardiac and hepatic cytochrome oxidase (Saxena et al. 1989b). In severe cases, histopathological changes in the liver and especially in the pancreas, and degenerative changes in the kidney and gastrointestinal tract are evident and are followed by life-threatening hemolytic anemia (Straube et al. 1980; Allen et al. 1983; Robinette 1990). The pancreas is the key to the diagnosis of zinc toxicity and in estimation of the period of exposure; in sheep, it takes about 4 weeks of continued ingestion of toxic amounts of zinc before the pancreas is affected (Allen et al. 1983). More research into the role of the pancreas in zinc toxicokinetics is needed.

Zinc is important to the normal functioning of the central nervous system. At low concentrations, zinc protects mammalian brain neurons by blocking N-methyl-D-aspartate receptor-mediated toxicity. At high concentrations, zinc is a potent, rapidly acting neurotoxicant in the mammalian brain, as judged by zinc-induced neuronal injury of in vitro mature cortical cell cultures (Choi et al. 1988). Increased brain levels of zinc are associated with Pick's disease in certain strains of rodents with inherited epileptic seizures. Intravenous injection of zinc in rats with genetically inherited epilepsy produces seizures; a similar response occurs with intracranial injection of zinc in rabbits with inherited audiogenic seizures (Choi et al. 1988).

Table 8. Effects of zinc on representative mammals.

Organism, route of administration, dose, and other variables	Effects	Reference[a]
Cows, cattle, *Bos* spp.		
Dairy cows fed control diet (310 mg Zn/kg dry weight [DW] feed) or control diet supplemented with 1,000 or 2,000 mg Zn/kg DW ration (as $ZnSO_4 \cdot H_2O$)	The 1,000 mg/kg supplement has no adverse effects on milk production, feed intake, body weight, general health, or reproduction; there was a moderate increase in zinc content of plasma and milk. Cows fed the 2,000 mg Zn/kg diet, however, had decreased milk yield and feed intake after several weeks; calf weights were lower; adverse effects reversed when excess zinc was removed from diet	1
Calves fed diets containing 600 mg Zn/kg for 21 days	Appeared normal, although zinc levels were elevated in pancreas, liver, and kidney	2
Lactating dairy cows fed diets containing 700 or 1,000 mg Zn/kg feed for 6 weeks	No change in general health or milk production; no increase in milk zinc content	2
Lactating cows fed diets containing up to 1,386 mg Zn/kg feed for 5 weeks	No significant change in food intake, weight gain, milk production or in zinc concentrations in plasma (1.15-1.3 mg/kg fresh weight [FW]) or milk (3.7-4.3 mg/kg FW)	3
Calves and young female cattle fed roughage harvested in vicinity of a factory galvanizing steel tubes, and containing 3,000-7,300 mg Zn/kg DW roughage	Signs of chronic zinc poisoning evident after 12-14 months. Signs included reduced appetite, emaciation, submandibular edema, diarrhea, moderate anemia, elevated serum zinc (4.3-6.0 mg/L versus normal 1.8-2.1 mg/L), liver zinc (420-1,600 mg/kg DW versus normal 72-248 mg/kg DW), kidney zinc (910-1,680 mg/kg DW versus normal 40-114 mg/kg DW), and low serum calcium and magnesium	4

Dog, *Canis familiaris*		
Fed diets containing up to 1,000 mg Zn/kg ration for up to 1 year	No measurable signs of damage	2
Pomeranian, 2.2 kg, 4 months old, ingested four copper-clad zinc pennies	Hemolytic anemia, vomiting, salivation, serum zinc dropped from 29 mg/L to 4.4 mg/L 15 days after coins were surgically removed (normal dog serum zinc values range between 0.6 and 2.0 mg/L)	5
Zinc-poisoned oral route, (lethal) dose unspecified	Tissue zinc concentrations (in mg/L or mg/kg FW) were 32 in serum, 16-32 in plasma, 20-25 in urine, 369 in liver, and 295 in kidney. Normal values were 0.7-1.1 in serum, 0.6-1.0 in plasma, 1.3-2.0 in urine, 17-32 in liver, and 9-23 in kidney	6 ..
Died from ingestion of 34 copper-clad zinc pennies	Elevated zinc levels in serum, liver, and kidney; jaundice, anoxeria, anemia, vomitation, dark red urine	7
Guinea pig, *Cavia* sp.		
Inhalation of 0.8 mg Zn/m^3 for 1 h	Difficulty in breathing	8
Inhalation of 4 mg Zn/m^3, 3 h daily for 6 days	Temporary lung damage	8
Inhalation of 5 mg Zn/m^3, as ultrafine zinc oxide, 3 h daily for 6 days	Decrease in lung capacity, alveolar volume, and diffusing capacity for carbon monoxide; values remained depressed for at least 72 h after last exposure. Persistent inflammation of proximal portion of alveolar ducts and adjacent alveoli	9, 10
Horse, *Equus caballus*		
Weanling foals, age 3 months, fed diets containing 7.7 mg Cu/kg plus 29, 250, 1,000, or 2,000 mg Zn/kg ration for 15 weeks. At start, serum zinc level was 0.6 mg/L and serum copper level 1.4 mg/L	Foals fed 29 or 250 mg Zn/kg diets had normal serum copper and zinc concentrations. Those fed 1,000 or 2,000 mg kg diet became hypocupremic in 5 to 6 weeks and developed lameness owing to cartilaginous disease similar to osteochondritis dessicous. Foals fed high zinc diets became lame when serum copper fell to 0.3 mg/L for >1 week; at end of study, arthritic foals had <0.2 mg Cu/L serum. Serum zinc	11

	concentrations rose to >2 mg/L within 2 weeks at 1,000 or 2,000 mg Zn/kg diet; liver zinc was <333 mg/kg DW at diets of 250 mg Zn/kg, 2,728-3,511 mg/kg DW at 1,000 mg Zn/kg diet, and 4,364-4,524 mg/kg DW at the highest dietary loading of 2,000 Zn/kg in 15 weeks	
Adults, vicinity of lead-zinc smelter, ingesting >90 mg Zn/kg body weight (BW) daily	Decreased growth, lameness, bone deformities, death.	2
Cat, *Felis domesticus*		
Fed diet containing 300 mg Zn/kg ration for 16 weeks	Weight loss and pancreas histopathology	2
Fed diets containing >600 mg Zn/kg ration	Diets rejected	2
Fed diet containing 9,000 mg Zn/kg ration for 3-53 weeks	Pancreas histopathology	8
Human, *Homo sapiens*		
Dietary route		
80 mg/kg ration for 6 weeks	Digestive problems	8
90 mg Zn/kg ration for 5 weeks	Decreased serum cholesterol levels	8
153 mg Zn/kg ration for 6 weeks	Altered immune system	8
<150 mg zinc daily	No effect on male plasma cholesterol; females have decreased cholesterol	12
160 mg zinc daily	Increased plasma cholesterol level in both sexes; increased risk of heart disease in males	12
Inhalation route, 600 mg Zn/m^3 for 10 min	Metal fume fever, that is, difficulty in breathing, flu-like symptoms	8
Oral route		
15-year-old girl who consumed 220 mg zinc sulfate twice daily "for some time"	Acute gastrointestinal bleeding ulcers	13
Boy who consumed 12 g of elemental zinc	Headache and lethargy	13
Single oral dose of 45 g zinc as $ZnS0_4$ (normal is 15-20 mg daily)	Death, preceded by dehydration, electrolyte imbalance, abdominal pain, nausea, vomiting, dizziness, muscular incoordination, and acute renal failure	14
Domestic mouse, *Mus* sp.		
Dietary route		
68, 682, or 6,820 mg Zn/kg ration for 13 weeks (fed as 300, 3,000, or	No observed effects at 682 mg/kg diet (and lower), equivalent to 104-109 mg Zn/kg BW daily. At	15

30,000 mg $ZnSO_4 \cdot 7H_2O$/kg ration)	6,820 mg Zn/kg ration, however, adverse effects were documented on survival, growth, food and water intake, and blood chemistry; lesions noted in pancreas, stomach, intestine, spleen, and kidney	
500 mg/kg for 3 months	Anemia	8
30,000 mg/kg ration for 13 weeks	Some deaths, liver and kidney histopathology	8
Drinking water, 300 mg/L, for 5-14 months	Pancreas histopathology	8
Intraperitoneal injection, four injections over 9-day period totaling 13 mg Zn/kg BW	Toxic. Severe weight loss and some deaths	23
European ferret, *Mustela putorius furo*		
Fed basal diet (27 mg Zn/kg feed) or basal diet plus 500, 1,500, or 3,000 mg Zn/kg ration for up to 197 days; four animals per group	Ferrets fed 500 mg/kg all survived with no significant histopathology; zinc concentrations were 148 mg/kg DW in liver (115 mg/kg DW in controls) and 383 mg/kg DW in kidney (180 mg/kg DW). At 1,500 mg/kg, all four ferrets were in extremis or dead by day 21. At death, liver zinc was 859 mg/kg DW and kidney zinc 1,000 mg/kg DW; ferrets had 40-50% loss in body weight; food intake had decreased 80%; and erythrocyte number, hemoglobin, and hematocrit had significantly decreased. Ferrets fed the 3,000 mg/kg diet died between days 9 and 13, lost up to 40% of initial BW, and food intake decreased 77%; postmortem examination showed blood in intestine, orange-colored liver, and kidney histopathology. Elevated zinc content in liver of 1,273 mg/kg DW and in kidney of 1,138 mg/kg DW	8,16,17
Rabbit, *Oryctolagus* sp.		
Single oral dose of 65 mg Zn/kg BW, as $ZnSO_4$	Half-time persistence of 713 min	8
Intravenous injection of 0.325 mg Zn/kg BW, as $ZnSO_4$	Half-time persistence of 268 min	8
Intraperitoneal injection of 3.4 mg zinc daily	Associated with lowered plasma cholesterol levels	12
Domestic sheep, *Ovis aries*		
Domestic ewe, age 5 years, found moribund, suspected zinc poisoning	Elevated zinc levels were 650 mg/kg DW in liver (144 mg/kg DW in controls) and 760 mg/kg DW in kidney (84 mg/kg DW); muscle residues same	18

	as controls, that is, 154 mg/kg DW (158 mg/kg DW); generalized jaundice; liver degeneration and blockage of bile ducts	
Found dead, zinc-poisoned naturally	Zinc concentrations were 463 mg/kg DW in liver (165 mg/kg DW in controls), 274 mg/kg DW in kidney (150 mg/kg DW), and 752 mg/kg DW in pancreas (88 mg/kg DW)	19
Zinc-poisoned experimentally, oral route	Zinc concentrations were 1,125-1,671 mg/kg DW in liver, 2,130-2,442 mg/kg DW in kidney, 1,440-1,932 mg/kg DW in pancreas, and 4,900 mg/kg DW in feces (158 mg/kg DW feces in controls)	19
Lambs fed diets containing 1,000 mg Zn/kg	Food intake reduced; approaching toxic level	2,7
Laboratory white rat, *Rattus* sp.		
Dietary route		
Adult males given 500 mg Zn/kg ration, as $ZnSO_4$, for 6 weeks	After 3 weeks, spermatogenesis was arrested at the primary spermatocyte stage. After 4 weeks, food consumption declined, forelimb lameness, and swelling in cervical lymph nodes. At 6 weeks, testes showed enlarged lumen and abnormal germinal epithelium	20
682 mg Zn/kg ration, as $ZnSO_4.7H_2O$, for 13 weeks	No observable effect level, equivalent to 53-55 mg Zn/kg BW daily	15
2,000 mg Zn/kg ration, chronic exposure	Tolerated	2
4,000-5,000 Zn/kg ration for 18 days	Fetotoxic dose, poor reproduction	2,8
5,000-10,000 mg Zn/kg ration	Reduced growth, anemia, poor reproduction, disrupted liver catalase and cytochrome oxidase activity, copper deficiency	14
6,820 mg Zn/kg ration for 13 weeks	Retarded growth, low food intake, abnormal blood chemistry, regressive changes in pancreas	15
Drinking water route		
Doses equivalent to 0, 160, 320, and 640 mg Zn/kg BW daily for 3 months	No significant effect of any dose on organ weight, hematocrit, hemoglobin, glucose, and enzyme activity. Effects noted only at 640 mg kg BW daily: some deaths, less drinking water ingested, decreased volume of urine, significant increase in urea, and	21

	decrease in creatinine. Tissue residues were significantly elevated over controls in high dose group at 3 months: 60 mg Zn/kg FW in liver (20 mg Zn/kg FW in controls), 38 mg Zn/kg FW in kidney (16 mg Zn/kg FW), 330 mg Zn/kg FW in bone (92 mg Zn/kg FW), 21 mg Zn/kg FW in blood (3 mg Zn/kg FW), and 36 mg Zn/kg FW in spleen (16 mg Zn/kg FW). Residues were the same as controls in brain, lung, and muscle	
800 mg Zn/L for 30 days	Liver alterations	8
Intragastric administration		
180 g adults given single dose of 500 mg, equivalent to 2,777 mg/kg BW	Serum zinc reached a maximum of 3.5 mg Zn/L after 60 min and returned to normal (1.6 mg/L) within 24 h	22
165 g adults given 500 mg daily for up to 30 days, equivalent to 3,030 mg Zn/kg BW daily	Serum zinc after 7, 14, or 80 days was 1.9, 2.2, and 2.1 mg/L, respectively; 10 days after last dose, serum zinc was normal	22
Single oral dose, 350-800 mg Zn/kg BW	Acute oral LD50	2,21
Domestic pig, *Sus* sp.		
Weanlings fed diet containing 1,000 mg Zn/kg feed for 30 days	Decreased growth rate and food intake, arthritis, lameness, and inflammation of the gastrointestinal tract	13

[a] 1. Miller et al. 1989; 2. NAS 1979; 3. Gaynor et al. 1988; 4. Wentink et al. 1985; 5. Latimer et al. 1989; 6. Robinette 1990; 7. Ogden et al. 1988; 8. PHS 1989; 9. Lain et al. 1985; 10. Goyer 1986; 11. Bridges 1990; 12. Sammon and Roberts 1988; 13. Elinder 1986; 14. Prasad 1979; 15. Malta et al. 1981; 16. Straube et al. 1980; 17. Reece et al. 1986; 18. Schlosberg 1976; 19. Allen et al. 1983; 20. Saxena et al. 1989b; 21. Llobet et al. 1988a; 22. Castellano et al. 1988; 23. Kreppel et al. 1988.

Zinc fed to adult male rats at 500 mg/kg diet for 3 weeks or longer harms the testes and other male accessory organs; effects are a direct result of zinc cytotoxicity from transfer across the blood-testes barrier (Saxena et al. 1989a). Elevated dietary zinc also depresses bone calcium levels and increases fecal calcium loss in rats (Greger 1989). Increases in serum zinc levels of rats after acute zinc overload is due mainly to increases in the zinc bound to the albumin fraction and secondarily to that bound to the globulin fraction (Castellano et al. 1988). Albumin may play a new physiological role by fitting its binding capacity to serum zinc levels, essentially binding all excess zinc that arrives in the blood (Castellano et al. 1988).

Zinc toxicosis has been observed in humans and livestock after ingestion of acidic foods or drink prepared and stored in galvanized containers (Latimer et al. 1989). Symptoms occur within 24 h and include nausea, vomiting, diarrhea and abdominal cramps. The emetic dose for zinc in humans was estimated at 225-450 mg (3.2-6.4 mg Zn/kg BW), equivalent to 1-2 g zinc sulfate (Elinder 1986). Zinc poisoning in dogs is well documented as a result of ingestion of galvanized metal objects, calamine lotion, skin and sunblock preparations containing zinc oxide, staples, nails, fertilizers, some paints, products containing zinc undecylenate, metallic hardware items with a high zinc content, nuts on certain types of animal transport cages, and pennies (Latimer et al. 1989; Robinette 1990). The propensity of some individuals to throw pennies (U.S. coinage) into animal cages while visiting zoos and animal parks should be considered a potential source of zinc poisoning in captive animals. Pennies minted before 1982 contain 95% copper and 5% zinc; however, copper-clad pennies minted after 1981 contain 97.6% zinc and 2.4% copper (Ogden et al. 1988).

Humans given zinc supplements should be aware of possible complications attendant to their use (Fosmire 1990). Low intakes of 100-300 mg zinc daily in excess of the recommended dietary allowance of 15 mg zinc daily may produce induced copper deficiency, impaired immune function, and disrupted blood lipid profiles. Patients treated with zinc supplements (150 mg daily) to control sickle cell anemia and nonresponsive celiac disease developed a severe copper deficiency in 13 to 23 months; normal copper status was restored by cessation of zinc supplements and increased dietary copper (Fosmire 1990).

Because of false positives, zinc may confound interpretation of the paralytic shellfish poisoning mouse bioassay, one of the routine tests used to measure shellfish safety for human consumption. For example, mice injected intraperitoneally with extracts of healthy oyster tissues showed extreme weakness, a drop in body temperature, cyanosis, and some deaths (McCulloch et al. 1989). The threshold for a toxic paralytic shellfish poisoning response corresponds to a drained tissue zinc level >900 mg/kg FW, and this overlaps the zinc concentration range of 230-1,650 mg/kg FW (1,900-9,400 mg/kg DW) recorded in healthy oyster soft tissues (McCulloch et al. 1989).

Recommendations

For growing agricultural crops: (1) sewage sludge may be applied to soils if total zinc content does not exceed 150 to 560 kg/ surface hectare (Table 9); (2) a maximum permissible extractable soil zinc concentration of 23 mg/kg DW is recommended, according to Soviet agronomists (Beyer 1990); and (3) seedlings of oak (*Quercus* spp.) and red maple (*Acer rubrum*) will eventually die in culture medium containing >100 mg Zn/kg (Buchauer 1971), although total zinc concentrations for global crop production routinely exceed 100 mg/kg DW soil (Table 9). Research is needed in standardized methodology for measurement of bioavailable (i.e., extractable) soil zinc and on its relation to other soil measurements such as total zinc and depth of cultivation in the case of surface application.

Table 9. Proposed zinc criteria for the protection of natural resources and human health.

Resource, criterion, and other variables	Effective zinc concentration	Reference[a]
Crop plants		
Sewage sludge applied to agricultural soils		
Europe, acceptable	150-<300 kg/ha at pH 6.0-7.0	1
Florida		
Maximum permissible	205 kg/ha	1
Unacceptable	>10,000 mg/kg dry weight (DW)	1
Oregon[b], Wisconsin[b], acceptable	250 - < 1,000 kg/ha	1
Vermont[b], acceptable	280 - < 1,120 kg/ha	1
Maryland[b], Massachusetts[b], acceptable	280-<560 kg/hg	1
Minnesota[b], Missouri[b], acceptable	280-<1,120 kg/ha	1
Illinois, maximum	560 kg/ha	1
Soils		
Soviet Union, maximum permissible	23 mg/kg DW, extractable by ammonium acetate buffer at pH 4.8	1
Alberta, Canada, for growing livestock forage	<100 mg/kg DW	1
Quebec, Canada		

Background	200 mg/kg DW	1
Marginal	500 mg/kg DW	1
Unacceptable	>3,000 mg/kg DW	1
Netherlands		
Background	200 mg/kg DW	1
Marginal	500 mg/kg DW	1
Unacceptable	>3,000 mg/kg DW	1
Ontario, Canada, acceptable	<220 mg/kg DW	1
Germany, acceptable	<300 mg/kg DW	2
New Jersey, goal	<350 mg/kg BW	1
New York, acceptable		
Agricultural soils	168-<250 kg/ha DW	1
Forest soils	<560 kg/ha DW	1
Terrestrial Invertebrates		
Earthworms		
High accumulations, but otherwise safe	97 mg/kg DW soil	3
Adverse effects	>400 mg/kg DW soil	3
Slugs, diet, adverse effects	>300 mg/kg DW	4
Freshwater aquatic life		
Water		
Total recoverable zinc		
60 mg $CaCO_3$/L	47 µg/L, 24 h average; not to exceed 180 µg/L at any time	5
100 mg $CaCO_3$/L	47 µg/L, 24 h average; not to exceed 320 µg/L at any time	5
200 mg $CaCO_3$/L	47 µg/L, 24 h average; not to exceed 570 µg/L at any time	5
Acid-soluble zinc[c]	4-day average concentration not to exceed the numerical value e ((0.8473 [ln] hardness)+ 0.7614) more than once every 3 years on average; 1-h concentration not to exceed e((0.8473 [ln] hardness)+ 0.8604) more than once every 3 years on average. See below for examples	6
50 mg $CaCO_3$/L	4-day average not to exceed 59 µg/L; 1-h average not to exceed 65 µg/L	6
100 mg $CaCO_3$/L	4-day average not to exceed 110 µg/L; 1-h average not to exceed 120 µg/L	6
200 mg $CaCO_3$/L	4-day average not to exceed 190 µg/L; 1-h average not to exceed 210 µg/L	6
Adverse effects, most sensitive species		
Brown trout, *Salmo trutta*, embryos and fry	4.9-19.6 µg/L	7

Daphnid, *Daphnia magna*	5-14 µg/L	6
Rainbow trout, *Oncorhynchus mykiss*	5.6-10 µg/L	5,6,8
Narrow-mouthed toad, *Gastrophryne carolinensis*, embryos	10 µg/L	6
Daphnid, *Daphnia galeata mendotae*	15-30 µg/L	6
Freshwater sponge, *Ephydatia fluviatilis*	26 µg/L	9
Mayfly, *Epeorus latifolium*	30 µg/L	10
Midge, *Tanytarsus dissimilis*	37 µg/L	5,6
Atlantic salmon, *Salmo salar*	50 µg/L	6
Cladoceran, *Ceriodaphnia reticulata*	51 µg/L	6
Flagfish, *Jordanella floridae*	51 µg/L	6
Diet		
Channel catfish, *Ictalurus punctatus*		
Minimum	20 mg/kg DW	11
Recommended	150-200 mg/kg DW	11
Rainbow trout, *Oncorhynchus mykiss*		
Minimum	10-30 mg/kg DW; 15-30 mg/kg fresh weight (FW)	12,13
Adequate	90 mg/kg FW	13
Sediments		
Great Lakes		
Safe	<90 mg/kg DW	1
Marginal	90-200 mg/kg DW	1
Unacceptable	>200 mg/kg DW	1
Wisconsin and Ontario, for Great Lakes sediments dredged from harbors and for disposal in water	<100 mg/kg DW	1
Marine aquatic life		
Seawater		
Total recoverable zinc	58 µg/L, 24-h average; not to exceed 170 µg/L at any time	5
Acid-soluble zinc[c] (20)	4-day average concentration does not exceed 86 µg/L more than once every 3 years on average; 1-h average concentration does not exceed 95 µg/L more than once every 3 years on average	6
No adverse effect, most species		
Algae	<1,400 µg/L	14
Molluscs	<54 µg/L	15
Crustaceans	<230 µg/L	15
Adverse effects, most sensitive species		
Brown algae, *Fucus serratus*	8.8-9.5 µg/L	6

Copepod, *Tisbe holothuriae*	10 µg/L	16
Pacific oyster, *Crassostrea gigas*, larvae	10-20 µg/L	6

Plasma	0.6-1.0 versus 16-32 mg/L	37
Urine	1.3-2.0 versus 20-25 mg/L	37
Liver	17-32 versus 369 mg/kg FW	37
Kidney	9-23 versus 295 mg/kg FW	37
Guinea pig, *Cavia* spp.		
Air, adverse effects	0.8-4.0 mg Zn/m^3	38
Diet		
Deficient	3 mg/kg DW plus 1 mg/L drinking water	39
Adequate	3 mg/kg DW plus 15 mg/L drinking water	40
Normal	20 mg/kg DW	41

Adequate	100 mg/kg FW	39
High	200 mg/kg DW	41
Tissue concentrations, zinc deficient versus normal		
Serum	0.5 versus 1.6-2.0 mg/L	39
Liver	9.4 versus 15-17 mg/kg FW	39
Testes	9.5 versus 19-27 mg/kg FW	39
Kidney	10 versus 16-20 mg/kg FW	39
Domestic goat, *Capra* sp., diet		
Soluble zinc, recommended		
Adults	>4 mg/kg DW	20
Kids	>7 mg/kg DW	20
Total zinc		
Deficient	<15 mg/kg DW	42
Recommended	80 mg/kg DW	42
Bank vole, *Clethrionomys glareolus*, diet, recommended	30 mg/kg DW	43
Horse, *Equus caballus*		
Diet		
No adverse effects	250 mg/kg DW	44
Adverse effects	1,000 mg/kg DW	44
Daily intake, adverse effects	>90 mg/kg BW	20
Domestic cat, *Felis domesticus*, diet, adverse effects	300 mg/kg DW	20
Humans, *Homo sapiens*		
Air		
Safe levels		
Zinc chloride, fumes	<1 mg/m^3	20,38
Zinc oxide, fumes	<5 mg/m^3	28,38,45,46
Zinc and zinc oxides	5-10 mg/m^3	38
Zinc oxide, total dust	10 mg/m^3	38
Zinc oxide, fume and dust, ceiling limit	15 mg/m^3	38
Adverse effects, zinc oxides	600 mg/m^3 for 10 min	38
Daily intake		
Recommended dietary intake, assuming availability of 20%		
Children		
To age 1 year	3-6 mg	48
1-10 years	8-10 mg	48
No age specified	10 mg	2,20,26,47,49,50
Males		

Age 11-17	14-15 mg	48
Age 18+	11-15 mg	48
No age specified	15 mg	2,20,26, 47,49,50
Females		
Age 10-13	13-15 mg	48
Age 14+	11-15 mg	48
No age specified	12 mg	48
Pregnant	15-20 mg	48
Lactating	25-27 mg	47,48
Maximum safe total, adults		
Not zinc deficient	0.3-1.0 mg/kg BW	2
Zinc deficient	1 mg Zn/kg BW, oral administration	48
Adverse effects level	>160 mg (>2.3 mg/kg BW)	51
Diet		
Seafoods, safe level, Australia,	<40 mg/kg FW	14
Adverse effects		
Gastrointestinal disorders	>80 mg/kg DW diet for 6 weeks	38
Severe copper deficiency	150 mg zinc daily for 13-23 months	49
Vomiting	Single dose of 225-450 mg zinc or 1-2 g of $ZnSO_4$	49
Drinking water		
Safe level	5 mg/L	2,20,38
Adverse effects, acute GI distress	>280 mg/L	20
Intravenous injection, adverse effects	23 mg/kg BW daily	52
Soils, Canada, nonhazardous to human health		
Ontario, residential, parkland, commercial, industrial	<800 mg/kg DW	1
Alberta, noncrop uses	<700 mg/kg DW	1
Tissue residues		
Serum		
Normal	0.5-1.29 mg/L	38
No toxic effects	1.92 mg/L	38
Plasma		
Zinc-deficient	0.4-0.6 mg/L	45
Normal	0.7-1.1 mg/L	48
GI disturbances	1.51 mg/L	38
Rhesus monkey, *Macaca mulatta,* diet		
Deficient	4 mg/kg DW	52
Adequate	100 mg/kg DW	53
Mouse, *Mus* spp.		

Diet		
Zinc-deficient	<5 mg/kg DW	54
Zinc-adequate	36.5 mg/kg DW	54
Tolerated	100 mg/kg DW	54
Tolerated	682 mg/kg DW for 13 weeks (107 mg/kg BW)	55
Harmful	500 mg/kg DW for 3 months	38
Harmful	6,820 mg/kg DW	55
Fatal	30,000 mg/kg DW for 13 weeks	38
Drinking water, adverse effects	300 mg/L	38
Tissue residues		
Blood		
Deficient	0.7 mg/L	56
Normal	1.0-1.1 mg/L	56
Liver		
Deficient	12 mg/kg FW	56

[b] Higher values permissible for soils with higher cation exchange capacity (Beyer 1990).

[c] Zinc that passes through a 0.45 µm membrane filter after acidification to pH 1.5-2.0 with nitric acid (EPA 1987).

[d] Higher concentrations recommended to compensate for reduced bioavailability caused by excess calcium and phytate in diet (Gatlin et al. 1989).

Data on zinc hazards to terrestrial invertebrates are limited; however, sensitive species are adversely affected at dietary concentrations >300 mg Zn/kg or at soil concentrations >400 mg/kg (Table 9).

Water quality criteria protection of aquatic life should include both total recoverable zinc and acid-soluble zinc (EPA 1980, 1987). For example, if total recoverable zinc is substantially above the proposed criteria and acid-soluble zinc is below the limit, there is cause for concern (EPA 1987). To protect about 95% of freshwater animal genera, EPA recommends water concentrations that average <47 µg total recoverable zinc per liter, not to exceed 180 µg/L at any time in soft water (i.e., <50 mg $CaCO_3$/L), or a mean concentration of 59 µg acid soluable zinc per liter, not to exceed 65 µg/L at any time in soft water (Table 9). These criteria are unsatisfactory because lower ambient zinc concentrations between 5 and 51 µg/L clearly have significant negative effects on growth, survival, and reproduction of important species of freshwater fish, amphibians, insects, sponges, and crustaceans (Table 9). Some downward modification seems necessary in the current proposed zinc criteria for freshwater aquatic life protection.

To protect important species of marine animals, EPA recommends that total recoverable zinc in seawater should average <58 µg/L and never exceed 170 µg/L; for acid-soluble zinc, these values are <86 and 95 µg/L (Table 9). As was the case for freshwater biota, there is a growing body of evidence (Table 9) demonstrating that many species of marine plants, crustaceans, molluscs, echinoderms, and fish are adversely affected at ambient zinc concentrations between 9 and 50 µg/L or significantly below the current proposed criteria for marine life protection.

Effects of zinc deficiency were produced experimentally in freshwater sponges at <0.65 µg Zn/L (Francis and Harrison 1988), in rainbow trout fed diets containing <15 mg Zn/kg FW (Spry et al. 1988), in certain species of marine algae at <0.7 µg Zn/L (Vymazal 1986), and in certain species of marine invertebrates at <6.5 µg Zn/L (Clapper et al. 1985a, 1985b) or <34 mg Zn/kg DW whole organism (White and Rainbow 1985). Zinc deficiency in natural aquatic ecosystems has not yet been credibly documented.

In aquatic environments, Spear (1981) spotlights three research needs: (1) development of analytical procedures for measurement of individual dissolved zinc species, notably the aquo ion and zinc chloride, and for nondissolved species that occur in natural waters; (2) separation of natural from anthropogenic influences of sediment-water interactions on flux rates with an emphasis on anoxic conditions, the role of microorganisms, and the stability of organozinc complexes; and (3) establishment of toxicity thresholds for aquatic organisms based on bioaccumulation and survival to determine the critical dose and the critical dose rate with an emphasis on aquatic communities inhabiting locales where zinc is deposited in sediments. These research needs are still valid.

Bird diets should contain 25-38 mg Zn/kg DW feed to prevent zinc deficiency effects, 93-120 mg Zn/kg DW feed for adequate to optimal growth, <178 mg Zn/kg DW feed to prevent marginal sublethal effects, and <2,000 mg Zn/kg DW feed to prevent the death of chicks and ducklings (Table 9). Extremely high dietary levels of 20 g Zn/kg ration are fed routinely to laying hens by poultry managers to force molting and to improve long-term egg preduction (Lu and Combs 1988a); in these cases, zinc preferentially accumulates in the kidney, liver, pancreas, and eggs (Verheyen et al. 1990). Much additional work now seems warranted on the role of zinc in avian nutrition and on the significance of tissue concentrations as an indicator of zinc stress.

The normal daily intake for all human age groups ranges between 8 and 14 mg (Casey and Hambidge 1980), but pregnant women require an additional 350-375 mg zinc during their pregnancy (Jameson 1980). Zinc used therapeutically in humans at >160 mg daily may have deleterious effects on copper status (Samman and Roberts 1988). Lower levels--close to the recommended daily allowance of 15 mg--are reported to interfere with iron metabolism and with high density lipoprotein cholesterol concentrations (Fosmire 1990) but this requires verification. The proposed air quality criterion for human health protection is 5 mg Zn/m^3, although this is demonstrably harmful to guinea pigs (Table 9). It is not yet known whether guinea pigs are more sensitive than humans to atmospheric zinc or if some downward modification is needed in the current zinc air quality criterion for protection of human health and presumably wildlife.

Single oral doses >350 mg Zn/kg BW were fatal to rats, although doses of 320 mg/kg BW were tolerated (Table 9), suggesting a rapid breakdown in ability to regulate zinc in a relatively narrow critical threshold range. More research into zinc regulation of massive doses seems needed.

Data that link zinc concentrations in tissues with environmental zinc perturbations in mammals are rare. For example, elevated zinc concentrations were >120 mg Zn/kg DW tissue in cattle liver, >180 mg Zn/kg DW tissue in sheep kidney, and >250 mg Zn/kg DW tissue in sheep liver (Table 9). The significance of zinc residues in animal tissues is unclear. No international regulations or guidelines applicable to zinc are available (PHS 1989). No U.S. Food and Drug Administration action level or other maximum acceptable concentration exists for zinc, and therefore no Final Residue Value can be calculated (EPA 1987). This seems to be a research need of high priority.

Eating seafoods that contain high concentrations of zinc does not seem to present a threat to human health. However, oysters from Tasmania allegedly caused nausea and vomiting in some people who ate them; these oysters contained about 20 g Zn/kg FW soft parts or about 500 times more than the Australian food regulation of 40 mg/kg FW (Eisler 1981).

In mammals, large differences are evident between and within species in resistance to zinc poisoning and in sensitivity to zinc nutritional needs (Table 9). Adverse effects of excess dietary zinc occurred in sensitive species at 80 mg Zn/kg DW (in humans) and 300 mg Zn/kg DW (in cats); other tested species were significantly more resistant. Daily intake rates considered harmful over long periods ranged from about 2.3 mg/kg BW in humans to >90 mg/kg BW in horses. Dietary loadings that optimally prevented zinc deficiency were 30 mg Zn/kg DW diet for bank voles, 33 mg Zn/kg DW diet for adult sheep (124-130 mg Zn/kg DW diet for lambs), 37 mg Zn/kg DW diet for mice, 45-60 mg Zn/kg DW diet for cattle, 76 mg Zn/kg DW diet for rats, 80 mg Zn/kg DW diet for goats, 100 mg Zn/kg DW diet for monkeys, and 150 mg Zn/kg DW diet for minks; recommended daily intake ranged from about 0.2 mg/kg BW in humans to 110-140 mg/kg BW in cattle (Table 9). More research with animals of various age and nutrient status is needed to determine the interaction effects of zinc with proteins, calcium, chloride, and other trace elements and on the long-term consequences of nutrient interactions (Gregor 1989).

Abstract

Famphur (phosphorothioic acid, O-[(dimethylamino)sulfonyl], phenyl] O, O-dimethyl ester), also known as Warbex, is a systemic organophosphorus insecticide used almost exclusively as a veterinary chemical to control parasites in livestock. Only famphur and its oxygen analog, famoxon, were of toxicological significance; other famphur metabolites were 31 to 237 times less toxic, as judged by acute oral-toxicity tests in the mouse (*Mus* sp.). Famphur is administered to livestock by intramuscular or subcutaneous injection, through the diet, as a dermal pour-on, or as an oral bolus. In mammals, famphur induced mortality at concentrations as low as 11.6 mg/kg body weight (BW) in intraperitoneal injection (mouse), 27 mg/ kg BW in a single oral exposure (mouse), greater than 33.3 mg/kg BW in an intramuscular injection (Brahman cattle, Bos *indicus*), and 400 mg/ kg BW in a dermal application (rat, *Rattus* sp.). Latent effects of famphur exposure were reported in reindeer (*Rangifer tarandus*) hinds one year posttreatment (altered blood chemistry). Famphur is rapidly metabolized by mammals, the half-time persistence of famphur and famoxon in subcutaneous fat of cattle after a single pour-on application is 0.9 days. Famphur has been used illegally by U.S. farmers to kill feral birds--including migratory waterfowl--thought to be depredating crops. Pour-on applications of famphur to cattle at recommended doses are sometimes associated with bird die-offs, especially the black-billed magpie (*Pica pica*). Magpie mortality was probably associated with the lengthy persistence (>90 days) of famphur on cattle hair and the ingestion of cattle hair by magpies. Cattle hair composed as much as 12% of gizzard contents of dead magpies, and hair in the gizzards of dead magpies averaged 4,600 mg famphur and famoxon / kg. Secondary poisoning of eagles and hawks foraging on famphur-killed vertebrates and tertiary poisoning of a great horned owl (*Bubo virginianus*) feeding on a famphur-poisoned hawk are documented. In the laboratory, sensitive species of birds died after single oral doses of 1.8-3.0 mg famphur/kg BW or when fed diets containing 35-49 mg famphur/kg ration. Depressed cholinesterase activity in the brain and in plasma occurred in nestlings at daily oral concentrations as low as 0.3 mg famphur/kg BW. No published data were available on the fate or effects of famphur in aquatic ecosystems. In the absence of aquatic toxicity data on famphur, it is recommended that famphur and famoxon concentrations do not exceed the analytical detection limits of these compounds in water (0.005 mg/ L) or in tissues of aquatic organisms (<0.01 mg/kg fresh weight). Current recommendations include the discontinuance of topical applications of famphur to cattle because of its association with primary and secondary poisoning of birds, and more research on famphur in the three areas of latent effects on treated livestock, fate and effects in aquatic ecosystems, and carcinogenicity evaluation.

Key words: Famphur, Warbex, organophosphorus insecticide, livestock, fish, wildlife, invertebrates, ecotoxicology.

Famphur (phosphorothioic acid, O,-[4-[(dimethylamino)sulfonyl], phenyl] O, O-dimethyl ester), also known as Warbex, is a systemic organophosphorus insecticide found effective against lice, grubs, flies, and gastrointestinal nematodes of ruminants. Introduced commercially in 1961, the compound is especially effective against cattle grubs (*Hypoderma* spp.) when fed in the diet, injected subcutaneously or intramuscularly, or applied as a pour-on and oral drench treatment (Gatterdam et al. 1967; Kaemmerer and Buntenkotter 1973; Black et al. 1979; Felton et al. 1981; Gallo and Lawryk 1991).

Many dead birds, including robins, hawks, and magpies were found after cattle were treated with pour-on applications of famphur (Henny et al. 1985; Smith 1987). The black-billed magpie (*Pica pica*) was especially sensitive; ranchers reported observations of magpies dying after famphur use on cattle as early as 1973 (Henny et al. 1985). Dead magpies usually had famphur in the gizzard contents and severely depressed brain cholinesterase activity--a characteristic of organophosphorus poisoning. Populations of the black-billed magpie in western states declined between 1968 and 1979, which coincides with widespread use of famphur in that region; however, factors other than famphur may have caused the decline (Henny et al. 1985).

This report was prepared in response to requests for information on famphur from environmental contaminant specialists of the U.S. Fish and Wildlife Service. It is part of a continuing series of brief reviews of chemicals in the environment with emphasis on fishery and wildlife resources.

Uses

The cholinesterase-inhibiting and intoxicating properties of organophosphorus compounds have been known since these products were first synthesized about 60 years ago (Randell and Bradley 1980). During World War II, the more toxic organophosphorus compounds--such as soman, tabun, and sarin--were stockpiled for use as potential chemical warfare agents. More than 50,000 organophosphorus compounds have been synthesized and screened for possible insecticidal and antihelminthic activity and several dozen, including famphur, are now available commercially (Randell and Bradley 1980). During the 1970's, most organochlorine insecticides were removed from common use in North America, Europe, and most developed countries, and the removal increased reliance on carbamate and organophosphorus compounds, the two major classes of cholinesterase-inhibiting pesticides (Mineau 1991). The relative lack of target specificity of these compounds and their high acute toxicity to many nontarget organisms were ignored in favor of their short-term environmental persistence and lack of accumulation in organisms. The anticholinesterase insecticides now account for the majority of globally registered insecticides (Mineau 1991).

Famphur is not now applied to forests or crops but is used almost exclusively as a veterinary chemical (Smith 1987). A single treatment controls cattle grubs and reduces cattle lice infestations (American Cyanamid Company 1984). Famphur is especially effective against maggots of the botfly and warble fly (*Hypoderma* spp.) and of other oestrid flies (Seel 1985). Eggs from this group of insects are laid on the feet and legs of cattle and other mammals and licked off by the host and hatch in the mouth or esophagus. The resultant larvae burrow through the tissues to the skin of the animal's back where they live until ready to pupate and cause warbles or swellings (Seel 1985; Tarry 1986). When applied carelessly, famphur and other systemic insecticides are highly toxic and frequently produce acute poisonings in ruminants (Ballantyne and Marrs 1992). Famphur is not now registered or regulated by the U.S. Environmental Protection Agency.

Cholinesterase-inhibiting agents such as famphur vary widely in their effectiveness of controlling target pests and depend on the route of administration, dose rate, formulation, and timing and frequency of applications (Mineau 1991). Famphur can be administered to livestock by intramuscular injection, orally in the diet, as a dermal pour-on, or as a bolus. Intramuscular injections of 35% famphur concentrate are usually given in the gluteal muscle (Loomis and Schock 1978). When fed in the diet, famphur is formulated as a 33.3% liquid feed premix (Pasarela et al. 1967; Smith 1987). The topical use of famphur as a systemic insecticide was recommended in 1970. At dosages between 15 and 35 mg/kg body weight (BW), 12.5-13.2% w/v famphur as a pour-on over part of the backline of cattle in fall controls warbles before they develop into grubs the following year (Henny et al. 1985) and controls various species of lice (Annand et al. 1976). When used as a pour-on for cattle-tick control, famphur may be transferred from treated cattle to untreated animals (Annand et al. 1976), presumably through body contact. The solvent used in preparing dermal formulations of famphur significantly affects absorption hazards. In the case of the laboratory white rat (*Rattus* sp.), corn oil proved to be the least hazardous solvent and acetone the most hazardous; benzene was intermediate (Durham 1967). Famphur can also be administered in a rumen bolus as a systemic insecticide against ticks in cattle. Boluses have been

designed to release 200 mg famphur/bolus daily over a 65-75 day post-ingestion period; actual release rates range from 207 to 308 mg daily (Hair et al. 1979).

Technical information by the American Cyanamid Company (1984) lists five precautions and warnings for the use of famphur: 1. Famphur is "Toxic to fish, birds, and other wildlife. Keep out of lakes, ponds, and streams. Do not apply to areas where run-off occurs. Do not contaminate water by cleaning of equipment or disposal of wastes." 2. After use, all containers should be drained and rinsed several times with a solution of water, detergent, and lye ("bury rinse solution deeply in an isolated location with 18 inches [7 cm] of cover"); the empty container should be punctured and crushed to prevent reuse. 3. Famphur should not be used in combination with any compound having cholinesterase-inhibiting activity either simultaneously or within a few days before or after treatment. 4. Famphur use on livestock is contraindicated for less than 3-months old calves; animals stressed from castration, dehorning, or overexcitement; and sick or convalescent animals. Brahman and Brahman crossbreeds are less tolerant of cholinesterase-inhibiting insecticides than other breeds, and Brahman bulls are especially sensitive and should not be treated with famphur. Cattle should not be slaughtered for at least 35 days after treatment with famphur. 5. For humans, famphur is considered harmful or fatal if swallowed or absorbed through the skin, especially by children. If poisoning should occur, physicians are advised that atropine is antidotal and that pralidoxime chloride may be effective as an adjunct to atropine. Pour-on formulations are flammable, and users should keep them away from heat, sparks, and open flames including hot branding irons and cautery dehorning devices (American Cyanamid Company 1984).

Chemistry and Metabolism

Some physical and chemical properties of famphur are listed in Table 1. Gas chromatography is used to measure famphur and its oxygen analog famoxon in bovine milk, blood, and edible tissues; detection limits are 0.005 mg/L milk and <0.01 mg/kg tissue (Pasarela et al. 1967; Annand et al. 1976). The main degradation routes of famphur in mammals occur through hydrolysis of the P-O phenyl, P-O methyl, and N-methyl bonds; oxidative desulfuration and N-demethylation take place to a small extent (Figure; Kaemmerer and Buntenkotter 1973; Eto 1974). In the metabolic scheme for famphur in mammals (Figure), only famphur and its oxygen analog, famoxon, were of toxicological significance, as judged by acute oral toxicity in mice (Gatterdam et al. 1967). In studies with mice, acute oral LD50 values in mg/kg BW were 27 for famphur; 18 for famoxon; 2,270 for O-desmethylfamphur; 860 for O, N-bisdesmethylfamphur; 2,290 for p-(N, N-dimethylsulfamoyl)phenol; 2,500 for p-(N-methylsulfamoyl)phenol; 6,400 for p-hydroxybenzenesulfonic acid; and greater than 5,000 for p(N,N-dimethylsulfamoyl)phenyl glucuronide.

Famphur residues of 1 to 3 mg/kg fresh weight (FW) are common in cattle tissues after normal pour-on applications of the chemical (Annand et al. 1976). The half-time persistence of famphur in subcutaneous fat of cattle after a single pour-on application was 0.9 days and was independent of dose within the range of 25 to 150 mg/kg BW or initial tissue residues between 1.8 and 12.3 mg/kg FW; fat residues were less than 0.08 mg/kg FW 5 days after treatment and less than 0.01 mg/ kg FW after 11 days. These observations suggest that famphur tissue residues are near or below detection levels within 1 week after treatment, even with gross misuse of the chemical (Annand et al. 1976). However, famphur at concentrations greater than 1,000 mg/ kg persists on cattle hair for greater than 90 days, and this persistence has serious implications for local bird populations (Henny et al. 1985).

Famphur and other organophosphorus compounds are metabolized and excreted with greater efficiency by mammals than by the target pests before these compounds can bind to and ultimately inhibit the cholinesterase enzyme (Randell and Bradley 1980). Mice, for example, degrade famphur rapidly. Less than 1 h after an intraperitoneal injection of 1 mg famphur / kg BW, only 8.34% of the original administered dose remained in the mouse: 8.11% as the parent famphur, 0.22% as famoxon, and 0.01% as desmethylfamphur (Kaemmerer and Buntenkotter 1973). Famphur's biocidal properties are associated with its ability to inhibit cholinesterase activity, blocking synapses at the neuromuscular junction. Useful and recent reviews of ecological and toxicological properties of cholinesterase inhibiting agents in the environment--including organophosphorus insecticides--are given by Gallo and Lawryk (199 1), Mineau (1991), and Ballantyne and Marrs (1992). Brain cholinesterase inhibition is often used to diagnose death of wildlife after exposure to famphur and other organophosphorus insecticides (Mineau 1991). It is emphasized that the type and number of cholinesterase compounds and cholinesterase activities vary widely between species and tissues, and activities are further modified by

metabolic factors, age, genotype, circadian rhythms, sex, reproductive status, nutritional status, ambient temperature, and disease (Mineau 1991).

Table 1. Chemical and other properties of famphur.[a]

Variable	Datum
Chemical names	Phosphorothioic acid 0-[4- [(dimethylamino) sulfonyl], phenyl] O, O-dimethyl ester; Phosphorothioic acid, O, O-dimethyl-, O-ester with p hydroxy-N, N-dimethylbenzene sulfonamide; Phosphorothioic acid, O, O-dimethyl O-p-(dimethylsulfamoyl) phenyl ester; 0 0-Dimethyl hydrogen phosphorothioate, O-ester with p-hydroxy-N, N-dimethylbenzenesulfonamide; 0-[4-1 (Dimethylamino) sulfonyl] phenyl phosphorothioic acid O, O-dimethyl ester; O, O-Dimethyl O, p-(N, N-dimethylsulfamoyl) phenyl phosphorothioate; O, p-(Dimethylsulfamoyl) phenyl O, O-dimethyl phosphorothioate; p-(Dimethylsulfamoyl)phenyl dimethyl phosphorothioate; O, O-dimethyl O-[p-(dimethylsulfamoyl)-phenyl] phosphorothioate; Dimethyl p-(dimethylsulfamoyl) phenyl phosphorothionate; O, O-dimethyl-O, p-(dimethylsulfamoyl) phenyl phosphorothionate
Alternate names	AC 38023, American Cyanamid 38023, Bo-Ana, CL 38023, Cyflee, Dovip, ENT 25644, Famaphos, Famfos, Famophos, Famphos, Fanfos, Warbex, 38023
Primary use	Systemic livestock insecticide
CAS number	52-85-7
Empirical formula	$C_{10}H_{16}NO_5PS_2$
Molelcular weight	325.36
Melting point, crystals vs. powder	52.5-53.5° C vs. 55° C
Solubility	
Chlorinated hydrocarbons	Highly soluble
Water	-100 mg/L
Polar solvents	Slightly soluble
Aliphatic hydrocarbons	Insoluble

[a] O'Brien et al. 1965; Gatterdam et al. 1967; Pasarela et al. 1967; Tucker and Crabtree 1970; Schafer 1972; Kaemmerer and Buntenkotter 1973; Eto 1974; Black et al. 1979; Ryan and McLeod 1979; Hudson et al. 1984; Hill and Camardese 1986; Smith 1987; Gallo and Lawryk 1991.

Lethal and Sublethal Effects

General

Famphur controls many species of pestiferous insects that afflict poultry and livestock. The LD50 values for target insects ranged from 2.4-4.1 mg/kg BW from a dermal route and 8.0-11.8 mg/kg BW from abdominal injection. Toxicity of famphur is often associated with differential degradation and cholinesterase sensitivity among various species of target pests. Famoxon is more effective than famphur in producing cholinesterase inhibition and death, and this confirms the generalization that the corresponding oxons are the more potent anticholinesterase agents.

No published data were available on famphur toxicity to aquatic life. Other data, however, suggest that acute famphur toxicity to fishes may be comparable to that of other phosphorothioate insecticides. Among birds, sensitive species had reduced survival after single oral doses of 1.8 to 3.0 mg famphur/kg BW or when fed diets containing 35-49 mg famphur/kg ration. Daily oral doses as low as 0.3 mg famphur/kg BW caused depressed cholinesterase activity in the brain and in plasma. Secondary poisoning of eagles and hawks foraging on famphur-killed vertebrates and tertiary poisoning of a great horned owl (*Bubo virginianus*) feeding on a famphur-poisoned hawk are documented. Famphur has also been used illegally to kill feral birds--including migratory waterfowl and other federally protected species--thought to be depredating crops. Famphur-induced mortality in mammals was documented at concentrations as low as 11.6 mg/ kg BW in intraperitoneal injection (mouse), 27 mg/kg BW in oral exposure (mouse), >33.3 mg/kg BW in intramuscular injection (Brahman cattle), and 400 mg/kg BW in dermal application (rat). In reindeer, altered blood chemistry was evident one year after famphur exposure. Famphur is metabolized rapidly by mammals; residues in animal tissues and milk--regardless of mode of administration, length of exposure, or dose--were usually not detectable within 4 days of final exposure.

Terrestrial Invertebrates

Famphur controls many species of pestiferous insects that afflict poultry and livestock, especially warble flies (*Hypoderma* spp.). Famphur is one of the most toxic compounds for the control of adults and late instars of the lesser mealworm (*Alphitobius diaperinus*), the most abundant beetle inhabiting poultry litter and manure (Vaughan and Turner 1984). *Alphitobius diaperinus* can transmit several diseases to poultry, including avian leukosis--one of the most costly diseases for the poultry industry. By tunnelling, *A. diaperinus* can destroy polyurethane and polystyrene panels adjacent to manure. Famphur also controls the lesser mealworm in nests of birds and in bat roosts (Vaughan and Turner 1984). The northern fowl mites (*Ornithonyssus sylviarum*) is the most important ectoparasite of commercial breeders and laying hens in the United States. However, attempts to control northern fowl mites with famphur were ineffective regardless of tested mode of administration (De Vaney and Ivie 1980).

Cattle lice (*Haematopinus* spp.)were controlled when the equivalent of 2.5 mg famphur/kg BW in diets was fed to cattle for at least 30 days (Ivey et al. 1976) or 40.5 mg/kg BW were applied as a topical pour-on (Randell and Bradley 1980). Famphur was used in 1971 to control cattle lice with pour-on applications equivalent to 15-35 mg/kg BW (Annand et al. 1976). Pour-on treatments of Australian yearling heifers were especially effective in controlling the long-nosed sucking louse (*Linognathus vituli*) and the short-nosed sucking louse (*Haematopinus eurysternus*); untreated heifers grew more slowly than famphur-treated heifers (Bailey et al. 1984). Larvae of the hornfly (*Haematobia irritans*) were controlled in manure of cattle fed famphur at 2.5-5.0 mg/kg BW daily (Ivey et al. 1976). Manure of treated cows contained low concentrations of famphur (as much as 0.14 mg/kg FW) 1 day after diet cessation, but residues were nondetectable thereafter (Henny et al. 1985).

In Alaska, reindeer (*Rangifer tarandus*) infested with reindeer warble flies (*Oedemagena tarandi*) produced hides of little value and low quality meat. Reindeer warble flies were not controlled by pour-on applications of famphur because the product was unable to penetrate the hair coat of reindeer; however, intramuscular injections were effective (Ivey et al. 1976). In Norway, Sweden, and Finland, famphur was the most promising control agent against reindeer warble flies and reindeer nostril flies (*Cephenomyis trompe*)--two parasites that together caused a 15 to 20% annual loss of total yield in reindeer husbandry (Nieminen et al. 1980).

Famphur was not very effective in the control of ticks. The tropical horse tick (*Anocentor nitens*) is a species of serious concern to horse breeders in Florida mainly because it transmits *Babesia caballi*, the causative agent of equine piroplasmosis. A secondary concern is that heavy tick infestations may cause injury to the ears of the

horse (Gladney et al. 1972). Data were unavailable on famphur control of ticks in horses; however, famphur was 99.9-100% effective in controlling *A. nitens* in Hereford steers and heifers when fed in the diet at 5 mg/kg BW for 14 to 21 days. Famphur at 2.5 mg/kg BW in cattle diets for 7 days was only partially effective (39-87.5%) in controlling horse ticks (Gladney et al. 1972). Famphur--despite multiple treatments--was not effective in controlling cattle ticks (*Haemaphysalis longicornis*) when used as a pour-on at recommended application rates in weaned Hereford calves (Heath et al. 1980).

Results of selected studies of famphur and insects indicate several trends: males are more sensitive than females; the oxygen analog, famoxon, is more toxic than the parent chemical; dermal LD50 values range from 2.4 to 4.1 mg/kg BW; abdominal injection LD50's range from 8.0 to 11.8 mg/kg BW; and metabolic degradation rates vary widely among species (Table 2). Famoxon is about 100 times more effective than famphur in controlling house flies (*Musca domestica*), which confirms the generalization that the corresponding oxons are the most effective anticholinesterase agents and are, in fact, the actual toxicants (O'Brien et al. 1965).

Differences in toxicity of organophosphorus compounds among species is often associated with differential degradation rates, pathways, and metabolites. Although injections of famphur were equally toxic to mice (*Mus* sp.), the American cockroach (*Periplaneta americana*), and the milkweed bug (*Oncopeltus fasciatus*), famphur was rapidly degraded by mice (91.7% degraded within 1 h after injection) and the cockroach (81.5% in 1 h); however, the milkweed bug degraded only 15.4% during a similar period (O'Brien et al. 1965). The variations in degradation rate among mice and cockroaches were relatively small, about 1.9 times. Despite the great similarity in famphur toxicity to mice and cockroaches, net famoxon production-like famphur persistence--was very low in the mouse but 10 times higher in the milkweed bug. The cholinesterase activity in the milkweed bug was 32 times more resistant to inhibition by famoxon than either mouse or cockroach cholinesterase, and this could account for the comparatively slow breakdown of famphur by the milkweed bug (O'Brien et al. 1965).

There is a correlation among cholinesterase-activity depression in rabbit blood, depression of cholinesterase activity in ectoparasites feeding on the blood of the host, and mortality of ectoparasites (Smith and Goulding 1970). In one case, rabbits (*Oryctolagus* sp.) parasitized by the yellow fever mosquito (*Aedes aegypti*)and Rocky mountain wood tick (*Dermacentor andersoni*) were treated with 5 to 50 mg of famphur/kg BW administered orally, subcutaneously, or intravenously. Regardless of dose or route of administration, tick and mosquito mortality was related to cholinesterase activity levels in rabbit plasma and erythrocytes. Some ectoparasite deaths were noted when cholinesterase levels in rabbits were depressed 32%; ectoparasite mortality increased to 90% at 33% depression and to 100% at 68% cholinesterase inhibition. In general, wood ticks and mosquitos reflected cholinesterase-activity levels of the host rabbit. Surviving female ticks that fed on dosed hosts laid no eggs during a 32-day post-removal observation period. Mosquitos that had fed on famphur-dosed hosts were more susceptible to cold than those that fed on control hosts (Smith and Goulding 1970).

Table 2. Famphur effects on selected terrestrial invertebrates.

Organism, dose, and other variables	Effect	Reference[a]
Lesser mealworm, *Alphitobius diaperinus*, topically applied		
3.44 mg/kg body weight (BW), 95% confidence interval (CI) 2.4-3.8 mg/kg BW	LD50 (24 h), adults	1
3.61 (95% CI of 3.32-4.08) mg/kg BW	LD50 (24 h), late instars	1
Milkweed bug, *Oncopeltus fasciatus*		
Abdominal injection, various doses		
Famoxon, 3.0 mg/kg BW	LD50	2

Famphur, 8.0 mg/kg BW	LD50	2
Single abdominal injection of 1 mg famphur/kg BW; whole body residues of famphur, famoxon, and N-desmethyl famphur measured 1 h after injection	Of total amount injected, 84.6% remained after 1 h: 79.4% famphur, 2.2% famoxon, and 3.1% N-desmethyl-famphur	2
American cockroach, *Periplaneta americana*		
Abdominal injection, various doses		
Famoxon, 4.6 (males) or 8.6 (females) mg/kg BW	LD50	2
Famphur, 9.0 (males) or 11.8 (females) mg/kg BW	LD50	2
Single abdominal injection of i mg famphur/kg BW; whole body residues of famphur, famoxon, and N-desmethylfamphur measured 1 h after injection	Of total amount injected, 18.5% remained after 1 h: 16.8% famphur, 0.5% famoxon, and 1.2% N-desmethyl-famphur	2

[a] 1, Vaughan and Turner 1984; 2, O'Brien et al. 1965.

Aquatic Organisms

An extensive literature search revealed no published data on famphur toxicity to aquatic animals. Unpublished studies of acute lethality were, however, conducted with bluegills (*Lepomis macrochirus*) and rainbow trout (*Oncorhynchus mykiss*). In those studies, the range in LC50 values at 96 h was 18 to 21 mg/L in bluegills and 4.9 to 5.3 mg/L in rainbow trout; the no-observable-effect concentration at 96 h ranged from 14 to 18 mg/ L in bluegills and was 2.1 mg/L in rainbow trout (U.S. Environmental Protection Agency, OPPTS/OPP / EFED / EEB, personal communication, 30 June 1993).

Although no data were available on effects of famphur in aquatic ecosystems, there is a substantial data base on other organophosphorus insecticides. For example, methyl parathion (O, O-dimethyl O-[p-nitrophenyl] phosphorothioate), another phosphorothioate organophosphorus insecticide, had LC50 (96 h) values for the bluegill (5.7 mg/L) and the rainbow trout (2.7 mg/L) that were similar to those of famphur (Khan 1977). But exposure for 96 h is not sufficient to satisfactorily evaluate the aquatic toxicity of organophosphorus insecticides. The mortality of adult northern puffers (*Sphoeroides maculatus*) continuously exposed to 20.2 mg/L of methyl parathion was less than 5% in 96 h but 100% in 40 days. Puffers refused to eat during exposure, and survivors between days 10 and 40 showed complete inhibition of serum esterase activity, zinc-depleted liver and gills, and altered blood chemistry (Eisler 1967, 1972). In another study, male guppies (*Poecilia reticulata*) held in sublethal concentrations (0.01-1.0 mg/L) of methyl parathion for 40 days or longer showed a dose-dependent decrease in spermatogenesis (Billard and de Kinkelin 1970). Pesticide-induced mortality patterns of representative organophophorus compounds are also modified by water temperature, pH, and salinity. The mummichog (*Fundulus heteroclitus*), an estuarine cyprinodontiform teleost, was most sensitive to organophosphorus compounds at elevated temperatures, reduced salinities, and low pH (Eisler 1970b). Duration of exposure to organophosphorus compounds also affects mummichog survival: fishes exposed to high (LC75, 24-h) concentrations of representative insecticides for more than 30 min died by day 21 postexposure; some insecticides were as much as 8.3 times more toxic after exposure for 240 h than 96 h, as judged by LC50 values (Eisler 1970b). In general, crustaceans were more sensitive than teleosts--sometimes by several orders of magnitude--to organophosphorus insecticides in 96-h tests; assayed grass shrimp (*Palaemonetes vulgaris*) and

fishes were most sensitive to organophosphorus insecticides at high salinities in the 1.2-3.6% test range and high temperatures in the 10-30° C test range (Eisler 1969; 1970c, 1972). Marine clams and gastropods were comparatively resistant to organophosphorus insecticides; none died in 96-h exposure to 25 mg/L of five organophosphorus insecticides, including methyl parathion. But during a postexposure of 133 days, some bivalves and gastropods died (Eisler 1970a), and these deaths are similar to the delayed mortality of some species of mammals and invertebrates after exposure to certain organophosphorus insecticides (Negherbon 1959).

The expected continued use of famphur in the environment and its vehicular transport along roads that border navigable waters suggest a need for aquatic toxicity data. Famphur data--like those on other organophosphorus insecticides-should reflect the influence of dose, exposure duration, formulation, and other biological and abiotic variables on growth, survival, and metabolism of representative species of aquatic organisms.

Birds

The avian acute oral LD50 of famphur is usually between 1 and 9.5 mg/kg BW (Schafer 1972; Hill and Mendenhall 1980). Laboratory studies with sensitive species of birds revealed reduced survival after a 5-day consumption of diets containing 35 to 49 mg famphur/kg ration (Hill et al. 1975; Table 3). Depressed cholinesterase activity in the brain and in plasma of European starling (*Sturnus vulgaris*) nestlings occurred after 15 daily oral exposures of concentrations as low as 0.3 mg famphur/kg BW (Powell and Gray 1980; Table 3). Signs suggesting famphur poisoning in mallards (Anas *platyrhynchos*) included regurgitation, goose-stepping, ataxia, wing drop, tremors, and tonic seizures (Tucker and Crabtree 1970; Hudson et al. 1984).

Famphur is considered a Class-II-toxic compound to the Japanese quail (*Coturnix japonica*) according to the classification of Hill and Camardese (1986). Class-II compounds (very toxic) kill 50% of the test organisms on diets containing 40 to 200 mg chemical/kg ration for 5 days. By comparison, the 50% kill in other classes (in mg/kg diet) is less than 40 in Class I (highly toxic), greater than 200-1,000 in Class III (moderately toxic), greater than 1,000-less than 5,000 in Class IV (slightly toxic), and greater than 5,000 in Class V (practically nontoxic; Hill and Camardese 1986). Smith (1987) rates famphur as a Class-I-toxic compound, as judged by results of dietary tests with mallards.

Birds killed by organophosphorus compounds in the wild consistently show 80 to 95% depression of brain-cholinesterase activity (Hill 1992). Depression of brain-cholinesterase activity by greater than 20% in birds has been used as a conservative criterion to indicate significant exposure to organophosphorus chemicals. Depression of brain-cholinesterase activity by greater than 50% and confirmation of suspected organophosphorus chemical residues in tissues or ingesta are criteria for cause-effect diagnosis of death in birds exposed to cholinesterase-inhibiting chemicals (Henny et al. 1985; Hill 1992). Death occurs in many avian species when brain-cholinesterase inhibition is 60 to 90%; however, no common barn-owls (*Tyto alba*) died or showed signs of intoxication after consuming famphur-poisoned Japanese quail, although 70% of the owls had brain-cholinesterase inhibition within these lethal bounds (Hill and Mendenhall 1980). Common barn-owls fed famphur-poisoned quail, the digestive tracts of which had been removed, showed significant but lesser brain-cholinesterase-activity inhibition than barn-owls fed intact poisoned quail, indicating that famphur or cholinesterase-inhibiting metabolites were most heavily concentrated in digestive tracts (Table 3).

The black-billed magpie seems unusually sensitive to famphur. Dead famphur-poisoned magpies contained as much as 290 mg famphur/kg liver FW, 4,770 mg/kg gizzard FW, and less than 0.2 mg/kg muscle or fat (Hill and Mendenhall 1980). There is a growing body of literature on adverse effects on magpies from pour-on (13.2% famphur) applications along the backline of cattle to control cattle warbles at the recommended rate of 0.326 mL/kg BW, not to exceed 118 mL/animal--equivalent to 43 mg/kg BW, not to exceed 15.6 g/animal (Felton et al. 1981; Henny et al. 1985; Seel 1985; Smith 1987). Felton et al. (1981) documented three occasions when dead birds were found after pour-on-famphur treatment of cattle against warble flies: (1) 12 black-billed magpies in a nearby field 2 to 3 days after cattle were treated; (2) 6 magpies during a 14-day period (although other species of corvids were present, only magpies were affected); and (3) 8 European robins (*Erithacus rubecula*) and a single dunnock (*Prunella modularis*) near a cattle crush a few days after famphur treatment. The dead birds had no measurable brain cholinesterase activity, and famphur was detected in the gizzards of birds in all 3 incidents (Felton et al. 1981). Partially paralyzed magpies containing as many as 3,500 mg famphur/kg gizzard contents were found in the vicinity of cattle recently treated with a pour-on formulation of famphur to control an

infestation by warble-flies; another 20 to 30 dead magpies were found in the immediate area (Seel 1985). Magpies and one red-tailed hawk (*Buteo jamaicensis*) were the only dead species found where cattle had been topically treated with famphur, although several other species including killdeers (*Charadrius vociferus*) and European starlings (Henny et al. 1985) were common in these pastures. Famphur residues were detected in all dead magpies and hawks, and brain-cholinesterase-activity depression ranged from 70 to 92%. Based on residue concentrations in the gizzards, dead magpies contained 5.2-6.1 mg famphur/kg whole body; these values were above the acute oral LD50 values for several species of birds (Henny et al. 1985; Table 3). The most probable explanation for the sensitivity of magpies to famphur is associated with the contents of the poisoned magpies that consisted of as much as 12% cattle hair (Henny et al. 1985). Although most organophosphorus compounds degrade rapidly, famphur persists for greater than 90 days on hair of Hereford bulls and steers and Angus yearlings. Famphur concentration in hair of a Hereford bull averaged 38,000 mg/kg FW one week after a single pour-on treatment and a maximum of 12,000 mg/kg FW 60 days posttreatment. High concentrations of famphur in the gizzards of magpies indicated that the material was ingested and not from dermal contact or inhalation. Tissue residues in mg famphur/kg FW in famphur-poisoned magpies were as much as 550 in the upper GI tract, 4.3 in the lower GI tract, and 3 in the whole body. Cow hair from gizzards of dead magpies averaged 4,600 mg famphur and famoxon/kg FW; other animal matter in the gizzard contained 620 mg famphur and famoxon/kg FW and plant matter 340 mg famphur and famoxon/kg FW. A potentially lethal dose to magpies would be 8-19 mg of treated hair at day 7 and 26-60 mg of treated hair after 60 days. Coincidentally, magpie mortality persisted for more than 3 months; most deaths occurred 5 to 13 days after cattle were treated (Henny et al. 1985). The manure-insect-bird pathway of famphur translocation is untenable because of extremely low (<0.14 mg/ kg FW) concentrations of famphur in cow manure (Henny et al. 1985).

Table 3. Famphur effects on birds.

Route of administration, organism, dose, and other variables	Effect	Reference[a]
Dietary exposure		
Treated feed for 5 days, then untreated feed for 3 days Mallard, *Anas platyrhynchos* 35 mg/kg diet	About 50% survived; ducklings age 10 days	1
Japanese quail, *Coturnix japonica*; 69 mg/kg diet, 95% confidence interval (CI) of 49-97 mg/kg diet	50% dead; 14-day-old quail	2
Ring-necked pheasant, *Phasianus colchicus*; 49 mg/kg diet, 95% CI of 40-61 mg/kg diet	50% dead; 10-day-old chicks	1
Domestic chicken, *Gallus* sp. Fed 50 mg/kg ration for 10 days (in attempt to control northern fowl mite, *Ornithonyssus sylviarum*) Common barn-owl, *Tyto alba*, adults, 475 g body weight (BW)	Ineffective in controlling mites. Feed consumption, body weight, and egg production significantly decreased	3

Barn-owls were fed whole famphur-poisoned Japanese quail. Quail received multiple doses of famphur (a total of 1 mg over a 3-day period). One poisoned *Coturnix* was fed daily for 10 days. If no famphur was lost or metabolized by *Coturnix* prior to death, then barn-owls received a maximum of 21 mg/kg BW for the 10-day period or 2.1 mg famphur/kg	Barn-owls did not avoid famphur-poisoned *Coturnix*, fed normally, and did not lose weight. By the tenth day, plasma-cholinesterase activities in barn-owls were depressed 45-81%, and brain-cholinesterase activities were depressed 32-73%	4
As above, except digestive tract was removed from famphur-poisoned Coturnix before presentation to barn-owls	Barn owls had brain-cholinesterase activity values intermediate between controls and those fed poisoned whole *Coturnix*	4
Multiple oral doses		
Japanese quail; dosing by gavage over 3 days: 300 µg on days 1 and 2 and 400 µg on day 3; mean weight of 120 g	Some deaths; cumulative dose received at day 3 = 8.33 mg/kg BW	4
Domestic chicken; 2.5 mg/kg BW once daily for 8 days; observed for 10 days posttreatment	Egg production, body weight, and feed consumption decreased significantly; ineffective in controlling northern fowl mite	3
European starling, *Sturnus vulgaris*, free-living nestlings, age 4 days. Dosed perorally with famphur dissolved in corn oil at 0.3, 1.0, or 3.0 mg famphur/kg BW daily for 15 days, then killed at age 19 days	At 0.3 mg/kg BW, 1 nestling died after the second dose (age 6 days) and another after the fifth dose vs. no deaths in controls; at day 19, brain-cholinesterase activity was depressed 51% and plasma activity 49%. At 1.0 mg/kg BW, 1 died after the third dose; at day 19, brain-cholinesterase activity level was depressed 75% and plasma cholinesterase 25%. At 3.0 mg/kg BW, 9 of 11 tested nestlings died within 8 h of the first dose, another within 8 h of the second dose, and the last was killed by a predator after the second dose. The 2 nestlings that survived a single dose were moribund and their brain-cholinesterase activity was depressed 85%	5

Single oral dose		
Red-winged blackbird, *Agelaius phoeniceus;* 1.8 mg/kg BW, 95% CI of 1.0-3.2 mg/kg BW	LD50	6, 9
Mallard; 9.87 mg/kg BW, 95% CI of 5.88-16.6 mg/kg BW	LD50 for 3-4 months old hens	7, 8
Domestic chicken; 10 mg/kg BW in gelatin capsule to control northern fowl mite; observed for 10 days posttreatment	Ineffective in controlling mites. On day 2 posttreatment, 1 of 12 chickens had died and 9 others showed muscular incoordination, especially in the legs. By day 3 posttreatment, most of the 9 were again standing and feeding and feces had reverted from a greenish diarrheic discharge to the normal consistency. By day 10 posttreatment, body weight and egg production was significantly decreased, although egg weight was unaffected	3
European starling; 4.2 mg/kg BW, 95% CI of 1.99-9.50 mg/kg BW	LD50	6, 9

[a] 1, Hill et al. 1975; 2, ill and Camardese 1986; 3, DeVaney and Ivie 1980; 4, Hill and Mendenhall 1980; 5, Powell and Gray 1980; 6, Smith 1987; 7, Tucker and Crabtree 1970; 8, Hudson et al. 1984; 9, Schafer 1972.

Secondary poisoning of flesh-eating birds foraging on famphur-killed vertebrates is well-documented; the degree of hazard to the predator related to the amount and type of consumed tissues and famphur concentrations in the prey tissues (Heinz et al. 1979; Hill and Mendenhall 1980; Henny et al. 1985, 1987; Hill 1992). Secondary poisoning of raptors killed by famphur that was topically applied to livestock include the bald eagle (*Haliaeetus leucocephalus*)--after eating cattle that died within 100 days of famphur treatment or famphur-poisoned brown-headed cowbirds (*Molothrus ater*) and European starlings-and a red-tailed hawk after eating famphur-poisoned black-billed magpies or European starlings (Henny et al. 1987). In one case, an adult-female bald eagle that was unable to fly near Lewes, Delaware, was brought to a national wildlife refuge where it died after a few days (Franson et al. 1985). Stomach contents included one lead shot and remains of brown-headed cowbirds and European starlings. A necropsy revealed no signs of lead poisoning. Clinical signs, physical examination, and presence of a full crop suggested acute poisoning. Crop and stomach contents were analyzed for a variety of pesticides, metals, and herbicides, but only famphur was elevated at 1.9 mg/ kg FW. As judged by famphur residues in the GI tract and by brain-cholinesterase-activity inhibition of 85%, the authors concluded that famphur was the probable cause of death (Franson et al. 1985). There is also a case of tertiary poisoning in which a great horned owl (*Bubo virginianus*) died after consuming a dead famphur-poisoned red-tailed hawk. In all of these cases brain-cholinesterase activity of poisoned birds was depressed greater than 50% and undigested remains contained famphur (Henny et al. 1987).

Famphur has also been used to intentionally kill birds, including migratory waterfowl and other protected species, and should be added to the list of other toxic organophosphorus insecticides such as monocrotophos, dicrotophos, and parathion that have been used for this purpose (White et al. 1989). In 1988, for example, famphur was used illegally by farmers in Georgia and West Virginia to kill birds thought to be depredating crops. Corn and grain at the mortality sites contained between 4,240 and 8,500 mg famphur/kg. Dead birds at these locations included Canada geese (*Branta canadensis*), mallards, American black ducks (*Anas rubripes*), American crows (*Corvus brachyrhynchos),* common grackles (*Quiscalus quiscula*), red-winged blackbirds (*Agelaius phoeniceus*), sandhill cranes (*Grus canadensis*), and a single red-tailed hawk. Most of the poisoned waterfowl, cranes, raptors, corvids, and songbirds from the 5 sites had severely depressed brain-cholinesterase activity (i.e., >50%), poisoned bait in the gizzards, and famphur concentrations in the gastrointestinal tracts ranging from 5 mg/kg FW in the red-tailed hawk to 1,480 mg/ kg FW in Canada geese. It was concluded that all birds died from direct ingestion of the poisoned bait, except the red-tailed hawk that had eaten one or more famphur-poisoned crows (White et al. 1989).

Mammals

Famphur is a group-D compound that is not classifiable as a human carcinogen (Sine 1991). However, a study of leukemia risk among males in Iowa and Minnesota indicated a slight but significant elevation in risk--especially chronic lymphocyte leukemias--for farmers but not for nonfarmers. Moreover, a significantly elevated leukemia risk was seen from exposure to specific animal insecticides including famphur (Brown et al. 1990). It is clear that more research is needed on the potential carcinogenicity of famphur.

Signs of famphur toxicosis in cattle include ataxia, muscular fasciculations, general weakness, lacrimation, salivation, and diarrhea (Randell and Bradley 1980). In comparison with European breeds of cattle (*Bos taurus*), the Brahman (*Bos indicus*) and European X Brahman hybrids are more sensitive to famphur, and Brahman bulls are more sensitive than cows (Johnson et al. 1972; Randell and Bradley 1980; Table 4). At a comparatively low dose of 16.6 mg famphur/kg BW, both *B. taurus* and *B. indicus* are tolerant of intramuscular injectable famphur; however, *B. indicus* is more sensitive and bulls sometimes died when treatment levels exceeded 33.3 mg/kg BW (Randell and Bradley 1980; Table 4). In addition to cattle, famphur-induced mortality in other species of mammals was documented (Table 4). Single exposures of famphur in mg/ kg BW killed rabbits (*Oryctolagus* sp.) at 2,730 in dermal exposure; mice (*Mus* sp.) at 27 in oral dose or 11.6 by intraperitoneal injection; domestic sheep (*Ovis aries*) at 400 in oral dose; and laboratory white rats (*Rattus* sp.) at 400 dermal exposure or greater than 28 in oral dose (Table 4). Mice receiving fatal or near-fatal intraperitoneal injections of famphur or famoxon began to convulse 10-20 min postinjection; death came within 45 min postinjection, usually from respiratory failure. Mice remaining alive at 60 min postinjection usually recovered (O'Brien et al. 1965).

Table 4. Famphur effects on mammals.

Organism, route of administration, dose, and other variables	Effect	Reference[a]
Cattle, *Bos* spp.		
Bolus		
Given to 180-kg calves 12 days before infestation by 30-60 day-old larvae of ticks. Sustained release equivalent to 3, 5, or 6.8-10.1 mg famphur/kg body weight (BW) daily	Ineffective at 3 mg/kg BW against fever ticks (*Boophilus annulatus*, *B. microlopus*) and the American dog tick (*Dermacentor variabilis*). At 5 mg/kg BW, famphur was effective (87-97%) against fever ticks but ineffective against the dog tick. At the highest daily release rate, famphur was 100% effective against fever ticks between	1

	days 12 and 41 but remained ineffective against the dog tick	
7 mg/kg BW daily (range 4.5-11.5 mg/kg BW daily)	Bolus was 99-100% effective against Gulf Coast tick (*Amblyomma maculatum*) and 60-86% effective against the lone star tick (*A. americanum*). Heifers showed no signs of organophosphorus insecticide poisoning but had slight reduction in erythrocyte-cholinesterase activity	2
Diet		
Lactating cows fed diets equivalent to 3.3 mg famphur/kg BW for 90 days	Concentrations in milk on day of withdrawal were 0.025 mg famphur/L and 0.023 mg famoxon / L. During the next four milkings (i.e., through day 8 posttreatment), famphur and famoxon residues in milk were always <0.005 mg/L	3
Calves fed rations equivalent to 3.3 or 9.9 mg famphur/kg BW for 90 days	Within 2 days of cessation of the low-dose-contaminated diet all calf tissues were free of famphur and famoxon; this value was 4 days for the 9.9 mg/kg BW group. Concentrations of famphur (famoxon) in mg/kg FW in the high-dose group at the end of the 90-day feeding study were 0.31 (0.03) in muscle, 1.6 (0.23) in fat, 5.6 (0.5) in liver, and 0.49 (0.19) in kidney	3
Adult rations contained equivalent of 5 mg famphur/kg BW daily	99.5-100% effective in control of Gulf Coast tick and lone star tick; ineffective against the American dog tick	1
Adults given equivalent of 5 mg famphur/kg BW daily	Effective against tropical horse tick (*Anocentor nitens)* but not completely effective against 3 other species of ticks	2
Adults given equivalent of 5 mg/kg BW daily for 10 days,	>90% control of cattle grubs (*Hypoderma* spp.). Manure from treated cattle	4

administered as a 33%-feed premix	controlled larvae of horn fly (*Haematobia irritans*) but was ineffective against larvae of the house fly (*Musca domestica*)	
Intramuscular injection		
15 mg/kg BW; Hereford steers	97% grub reduction in calves, 93% in cows, and calves, Angus cows; to 94% in steers control cattle grubs (*Hypoderma lineatum, H. bovis*)	5
16.6, 33.3, or 49.9 mg/kg BW, single injection; Brahman bulls, steers, and heifers 6-8 months old, 169-200 kg BW. Observed for 28 days posttreatment	All doses inhibited erythrocyte-cholinesterase levels by 45-95%. All groups tolerated 16.6 mg/kg BW. Severe toxicosis in the two high-dose groups (9 of 20) in bulls but not in heifers and steers; 7 of the 9 bulls died or had to be euthanized; necropsy showed severe pulmonary edema	6
18 mg/kg BW, single injection	Residues <0.7 mg/L in blood 2 h postinjection	7
36 mg/kg BW, single injection	Residues in blood >0.7 mg/L 2 h postinjection, but <0.7 mg/ L after 4 h	7
54 mg/kg BW, single injection	Residues in blood >0.7 mg/L 1-2 h postinjection, but <0.7 mg/L after 4 h	7
60.7 mg/kg BW, single injection of radiolabeled famphur	Blood plasma levels in mg/kg fresh weight (FW) were 0.4 after 4 h and 0.18 after 72 h; for famoxon, these values were not detectable at 4 h and 0.05 at 72 h. Plasma and urine radioactivity levels reached maxima after 24 h	7, 8
83.2 mg/kg BW; Brahman bulls and Angus bulls, 7-9 months old, 174-184 kg BW	5 of 6 injected Brahman bulls showed severe signs of toxicosis and 4 died within 48 h; recovery of the 5th bull took 10 days. Only 1 of 5 Angus bulls showed clinical signs of toxicosis, but it recovered	6
Oral		
9.9 mg/kg BW; single application, residues measured 24 h posttreatment; control values always <0.05 mg / kg FW of famphur and famoxon		
Fat; famphur vs. famoxon (mg / kg FW)	0.14 vs. <0.05	3

Kidney; famphur vs. famoxon (mg / kg FW)	<0.05 vs. <0.05	3
Liver; famphur vs. famoxon (mg / kg FW)	0.08 vs. 0.05	3
Muscle; famphur vs. famoxon (mg/kg FW)	<0.05 vs. <0.05	7
18 mg/kg BW	Residues in blood >0.7 mg/L 18-24 h after ingestion	7
20, 30, or 40 mg/kg BW, each with 8 mg levamisole / kg BW; administered as a paste to cattle yearlings in California, Nebraska, and Kentucky	As much as 85% reduction in cattle grubs and nematode gastrointestinal worms at 20 mg / kg BW + levamisole; as much as 98.2% reduction in 30 or 40 mg/kg BW groups	9
36 mg/kg BW, single dose	Residues in blood >0.7 mg/L 6-72 h after intake, but <0.7 mg/L after 96 h	7
Pour-on		
15 to 35 mg/kg BW, cows	Controls cattle-biting lice (*Damalina bovis*), long-nosed cattle lice (*Linognathus vituli*), and short-nosed cattle lice (*Haematopinus eurysternus*)	10
20.25, 40.5, or 60.75 mg/kg BW; Holstein Friesian calves; blood-cholinesterase-activity levels measured up to 49 days posttreatment	At the 2 lowest doses, significant depression from day 2 through day 14; blood cholinesterase normal at day 21. At 60.75 mg/kg, blood cholinesterase decreased for entire 49-day posttreatment. No outward signs of organophosphate intoxication and normal food intake and demeanor	11
23 mg/kg BW, cows	At 24 h whole milk had 0.24 mg famphur/L of which 76% was in the butterfat fraction; after 72 h residues in milk were <0.008 mg/L	10
25 mg/kg BW, cows	After 24 h, mean residue of famphur in subcutaneous fat was 1.8 mg/kg FW, maximum was 2.46 mg/kg FW	10
40 mg/kg BW; Hereford	87% effective in controlling cattle	5

steers and calves, Angus cows	grubs in calves; 100% effective in cows and steers	
40 mg/kg BW, cattle yearlings	100% effective in controlling cattle grubs and nematode gastrointestinal worms	9
40 or 50 mg/kg BW; yearling steers; Canada, late autumn; single treatment	Although not completely satisfactory for control of *Hypoderma* spp. (52-68% reduction in grubs)--possibly because of low absorption associated with low ambient temperatures at time of treatment--and some inhibition in blood-cholinesterase activity (maximum inhibition of 31-38% reached 15 days after treatment), both groups of treated steers gained significantly more weight than a control group during the posttreatment of 181 days and were otherwise normal	12
40, 80, or 209 mg/kg BW; Brahman bulls, steers, and heifers; mean weight of 117 kg		
40 mg / kg BW	Erythrocyte cholinesterase depression after 24 h was 43% in bulls and 33-34% in steers and heifers	13
80 mg/kg BW	After 5 h, 1 of 13 bulls was anorexic and salivating	13
209 mg/kg BW	After 48 h, erythrocyte-cholinesterase depression was 56% in bulls, 55% in steers, and 51% in heifers.	13
40.5 mg/kg BW, Brahman bull calves	2 of 3 famphur-treated calves died	11
45 mg/kg BW, cows	Famphur concentrations in mg/kg FW after 24 h were <0.05 in liver and kidney, 1.25 in fat, and 1.41 in muscle. After 7 days, these values were 0.53 in fat and 0.71 in muscle. By day 14, maximum values were 0.11 mg / kg FW in fat and <0.02 in other tissues	10
50 mg/kg BW, cows	After 24 h, mean residue of famphur in subcutaneous fat was 2.08 mg/kg	10

	FW, maximum was 3.00 mg/kg FW	
150 mg/kg BW, cows	After 24 h, famphur concentrations in subcutaneous fat ranged from 6.3 to 12.3 mg/kg FW	10
Angora goat, *Capra* sp.; pour-on, 4.1-4.8 mg/kg BW; nannies 27-41 kg; single application	100% effective in 14-day control of Angora goat biting louse (*Bovicola limbatus*) and hairy goat louse (*B. crassipes*); significant protection after 45 days	14
Laboratory mouse, *Mus* sp.		
Dermal; mice infected nasally or orally with rodent botfly (*Cuterebra* sp.) were dipped 48 h post-infestation for 30 sec in 25% emulsifiable famphur solutions (0.001-10%) and examined 1 week later. Entire body was submersed except head	50% kill of larvae after immersion in 0.0072% solution (18 mg famphur / L); 90% control in 0.051% solution (127.5 mg/L)	16
Oral		
Male mice, 8-12 weeks old, orally and nasally infected with 1st-stage larvae of rodent botfly. Two days after infection, mice were given single doses of 1.46 or 3.38 mg famphur / kg BW	Low dose killed 50% of larvae; high dose killed 90%	17
As above, except that mice were given 1.5 mg famphur/kg BW at 1, 2, or 3 days after infestation	Most effective control (71% dead larvae) when administered at 3 days	17
18 mg/kg BW	Acute LD50, famoxon	7
27-30 mg/kg BW	Acute LD50, famphur	7, 15
Intraperitoneal injection		
Single injection of 1 mg famphur/kg BW; residues of famphur, famoxon, and N-desmethylfamphur measured 1 h post-injection	Only 8.3% of the injected dose was measurable 1 h post-injection: 8.1% as the parent famphur, 0.2% as famoxon, and 0.01% as N-desmethylfamphur	18
5.8 mg famoxon/kg BW	LD50	18
11.6 mg famphur/kg BW	LD50	18
Rabbit, *Oryctolagus* sp.		
50 mg/kg BW; oral, subcutaneous, or	No effect on reproduction	25

intravenous route		
2,730 mg/kg BW, dermal route	LD50	15
Domestic sheep, *Ovis aries*		
Bolus; sustained release of 7 mg famphur/kg BW daily	Completely effective against Gulf Coast tick, partial control of lone star tick,	2
Intravenous injection	ineffective against American dog tick	
Single injection of radiolabeled famphur equivalent to 22.3 mg famphur/kg BW. Sheep killed at 96 h and tissues analyzed for residual radioactivity	More than 50% of the administered dose was excreted within 6 h and 98% within 48 h. About 97% was excreted in urine and <3% in feces. Residues, in mg/kg FW, were 1.4 in blood; 0.3 to 0.6 in kidney, liver, spleen, lung, and cerebrospinal fluid; and <0.1 in bile, fat, brain, and muscle	7, 8
Single injection, 22.3 mg/kg BW	Famphur (famoxon) residues in blood plasma, in mg/kg FW, were 0.6 (5.6) at 2 h, and nondetectable (0.01) at 24 h	7
Intravenous or intramuscular injection; urine collected over 24-h period after single application of radiolabeled famphur	Urinary radioactivity was due to the unchanged O-desmethyl compound (13-24%); N, N-dimethyl sulfamoylphenyl glucuronide (32-33%); O, N-bisdesmethylfamphur 31-34%); and N-methyl sulfamoylphenyl glucuronide (8-15%)	8
Intramuscular injection		
Single injection of radiolabeled famphur, equivalent to 55.1 mg/kg BW. Sheep killed at 72 h and tissues analyzed for residual radioactivity	About 64% of the administered dose was recovered in excreta after 72 h. Residues in mg/kg FW were 15 at the muscle injection site; 5-8 in kidney, bile, and fat; 1.6-2.3 in liver, spleen, lung, and blood; and 0.7-0.9 in brain, muscle, and cerebrospinal fluid	7, 8
Single injection, 55.1 mg/kg BW	Famphur (famoxon) residues in blood plasma, in mg/kg FW, were 0.9 (0.1)	7, 8
Oral, single dose; 400 mg/kg BW	LD50	15, 19, 20
Rumen infusion; peroral administration by cannulation for 72 h of ewes given doses equivalent to 5 or 7 mg	At 5 mg/kg BW, famphur caused a significant increase in mortality and decrease in percent egg hatch of adult Gulf Coast ticks and complete control	21

famphur/kg BW daily. After infusion for 72 h sheep were challenged by various blood-sucking arthropods	of the bedbug (*Cimex lectularius*) At 7 mg/kg BW daily, Gulf Coast ticks were completely controlled, but dose was ineffective against the lone star tick and the American dog tick	
Reindeer, *Rangifer tarandus*; intramuscular injection		
15 mg/kg BW, single injection	At 24 h residues were highest (8.1-9.1 mg/kg FW) in fatty tissues; at muscle injection site, residues ranged up to 635 mg/kg vs. 0.6 mg/kg FW in normal muscle. At 7 days post-treatment, residues in mg/kg FW, were 0.03-0.19 in fat, 0.03 in injection-site muscle, and 0.03 in liver. At 5 weeks, famphur was detectable only in fat; by 7 weeks, no famphur was detectable in any tissue. Famoxon was not found in any tissue at any time	22
30 mg/kg BW, single injection	Residues at 24 h in mg/kg FW were as high as 38 in fat, 8 in muscle, 5 in liver and 2.5 in kidney	22
30 mg/kg BW, single injection	90-95% reduction in larvae of warble fly (*Oedemagena tarandi*) and nostril fly *(Cephenomyia trompe*)	23
Accidental overdose (usually double-dosed), 60 mg/kg BW	Atropine sulfate is recommended antidote	23
Laboratory white rat, *Rattus* sp.		
Dermal, single application, mg/kg BW		
400	LD50, adult males	19
533	LD50, adult females	19
Diet containing 1, 3, or 25 mg famphur/kg for as many as 90 days	At 90 days all groups had depressed plasma cholinesterase, although growth and appetite seemed normal. Whole blood cholinesterase was depressed in the 3 and 25 mg/kg group; brain cholinesterase was significantly reduced in the 25 mg/kg group	24
Diet containing 25 mg famphur/kg for 90 days,	Blood chemistry and histology normal at necropsy on day 132. Rats avoided diets	24

then famphur-free diet for 42 days	during famphur-free phase	
Oral, single dose, in mg/kg BW		
28	LD50, adult males	19
35	LD50	7, 20
36-62	LD50	15
51	LD50, adult females	19
73	LD50, weanling males	19
Subcutaneous injection; urine collected during 24 h period after single application of radiolabeled famphur	Urinary radioactivity was due to the unchanged O-desmethyl compound (>50%); N,N-dimethyl sulfamoylphenyl glucoronide (30%); O,N-bisdesmethylfamphur (12%), and N-methyl sulfamoylphenyl glucuronide (7%)	8

Latent effects of famphur exposure in reindeer hinds (Nieminen et al. 1980) strongly indicated a need for additional studies in this subject area. Intramuscular injections of reindeer hinds and their 4-week-old calves controlled warble-fly infection in treated animals. Treated calves did not differ significantly from controls during the following year in body weight, body temperature, or blood chemistry. Treated hinds, however, had significantly lower erythrocyte sedimentation rates and serum-gamma-globulin concentrations and significantly higher hemoglobin, serum calcium, serum inorganic phosphorus, and serum magnesium than untreated hinds 1 year after treatment (Nieminen et al. 1980).

Reduced brain-cholinesterase activity in avian and mammalian wildlife is associated with adverse effects on metabolism, reproduction, sensory behavior, motor activity, food and water intake, learning, and memory (Mineau 1991). Cholinesterase activity in mammals regenerates rapidly after a cessation from treatment with famphur (Kaemmerer and Buntenkotter 1973). In humans, typical symptoms of organophosphorus-induced cholinesterase inhibition include headache, giddiness, nervousness, blurred vision, weakness, nausea, cramps, diarrhea, chest discomfort, sweating, salivation, vomiting, and tremors (Gallo and Lawryk 1991). In severe cases, victims show muscular weakness, convulsions, coma, loss of reflexes, loss of sphincter control, and eventually death. Effects of cholinesterase-inhibiting agents in humans are usually counteracted with repeated intravenous injections of atropine sulfate (2-4 mg), intravenous injections of pralidoxime chloride (1 g), and oxygen (Gallo and Lawryk 1991). Rats had depressed plasma-cholinesterase activity when fed diets containing as little as 1 mg famphur / kg for as many as 90 days, although growth and appetite seemed normal (Black et al. 1979). Brahman bulls had maximum erythrocyte-cholinesterase inhibition 14 days after intramuscular injection of famphur; cholinesterase-activity levels recovered towards normal during the next 14 days, and recovery correlated with the formation of new erythrocytes (Randell and Bradley 1980). Except for cholinesterase-activity inhibition, there were no signs of organophosphate intoxication in Brahman heifers and steers given single dermal doses of 20 to 61 mg famphur/kg BW. Cholinesterase activity was inhibited for as many as 14 days posttreatment at the lower (20-41 mg/kg BW) doses and for at least 7 weeks at 61 mg/ kg BW (Table 4).

Famphur is metabolized rapidly in mammals. In cattle, famphur controlled target insect pests when administered as a bolus, in the diet, as an oral paste, by intramuscular injection, or by pour-on. Regardless of mode of administration, length of exposure, or dose, famphur residues in tissues and milk were usually nondetectable within 4 days of final exposure. A similar pattern was evident in other species of mammals (Table

4). Rats and sheep metabolize famphur differently. During the first 24-h postdosing period, urine of rats contained as much as 2 times more of the unchanged O-desmethyl compound than urine of sheep, about the same amount of dimethylsulfamoylphenyl glucoronide, about 0.3 times as much O, N-bisdesmethylfamphur, and about 0.5 times less methylsulfamoylphenyl glucoronide (Gatterdam et al. 1967). With the exception of the oxon, metabolites of famphur were considerably less toxic to mammals than the parent chemical. In general, famoxon was 100 times more effective than famphur in depressing erythrocyte-cholinesterase activity (Kaemmerer and Buntenkotter 1973).

Famphur in pour-on applications penetrates skin at different rates depending on the solvent. In rat skin, penetration was most rapid when the solvent was acetone and least rapid in corn oil and benzene; the percent of remaining famphur in rat skin 3 h after a single dermal application was 38% from the acetone mixture and 67% from both benzene and corn oil solvents (O'Brien and Dannelley 1965). The penetrability of famphur pour-on formulations used in lice control on Angora goats was enhanced when applied in combination with a liquid-detergent wetting agent (Fuchs and Shelton 1985). Laboratory screening tests in which small mammals are treated with chemicals and parasitized by insects are now used to predict the effectiveness of systemic insecticides. Tests with mice and rodent botfly (*Cuterebra* sp.) were useful in predicting the effectiveness of famphur against larvae of the common cattle grub (*Hypoderma lineatum*) in cattle (Gingrich et al. 1972; Table 4), and show promise for screening additional chemicals.

Recommendations

The four primary areas of concern about famphur use are (1) mortality of birds associated with topical applications to cattle; (2) latent effects on domestic livestock; (3) the absence of aquatic toxicity data; and (4) potential carcinogenicity.

Because of its high toxicity to birds and field and experimental evidence of primary and secondary poisoning of birds, famphur is considered hazardous to feral birds--especially magpies-where cattle are topically treated with this insecticide (Felton et al. 1981; Henny et al. 1985, 1987). The pour-on application for cattle is now preferred to systematic dipping or intramuscular injection; dipping is reportedly labor intensive and costly (Hair et al. 1979). Intramuscular injection is more labor intensive, causes greater tissue damage and higher famphur absorption at the injection site, and produces a greater depression in blood-cholinesterase levels and a lower rate of weight gain in cattle than pour-on application (Loomis and Schock 1978). Nevertheless, famphur-induced mortality of magpies and other birds can be significantly reduced or eliminated by changing the insecticide application from the present pour-on method to other, now available modes of administration such as by diet, bolus, and intramuscular injection (Henny et al. 1985, 1987). Furthermore, a warning should be added to famphur labels stating that livestock dying within 3 months of famphur treatment should be removed from the range or farmland; this would offer partial protection to carrion-eating raptors such as eagles and vultures (Henny et al. 1987).

Reindeer are considered safe for human consumption 6 to 7 weeks after famphur treatment by intramuscular injection (dermal applications of famphur seldom penetrate the thick hair coat of reindeer). Treated reindeer had no detectable residues in liver, kidney, and muscle after 3 weeks (Ivey et al. 1976) and none in fat and other tissues after 6 to 7 weeks (Nordkvist 1975; Ivey et al. 1976). However, treated hinds during the following year had a significantly greater altered blood-chemistry profile than untreated hinds (Nieminen et al. 1980), suggesting a need for additional research on latent effects of famphur exposure. A safe dosage for cattle (*Bos* spp.) is 7 to 25 mg/kg BW by intramuscular injection or 40-55 mg/ kg BW by pour-on (Loomis and Schock 1978). The maximum concentration of famphur and famoxon allowed in cattle meat, fat, and meat by-products in the United States is 0.1 mg/ kg (Kaemmerer and Buntenkotter 1973; Ryan and McLeod 1979). In Australia, the maximum value is 0.05 mg/kg FW (Annand et al. 1976). The recommended minimum time between famphur treatment and slaughter of Australian cattle is 14 days. The half-time persistence of famphur in cattle tissues is 0.9 days, implying that even with gross misuse of the chemical, residues fall to low levels within a week (Annand et al. 1976). At present, no published studies were available on latent effects of famphur to cattle. Evidence of latent effects of famphur in reindeer (Nieminen et al. 1980) strongly suggest initiation of research into this subject area with cattle and other treated livestock.

No published data were available on effects and fate of famphur in aquatic ecosystems. This seems to be a high-priority research need in view of the increasing and illegal use of famphur to kill migratory waterfowl (White et al. 1989). In the absence of these data, it is recommended that concentrations of famphur and famoxon in

water and in tissues of aquatic organisms not exceed current analytical detection limits of 0.005 mg/L in water or 0.01 mg/kg FW tissue.

The carcinogenicity of famphur has not been satisfactorily resolved. Recent studies indicate a significantly elevated risk for leukemias among farmers handling famphur (Brown et al. 1990), but this needs verification.

Abstract. Acrolein (CH_2=CHCHO) is the simplest member of the unsaturated aldehydes and enters the environment from incomplete combustion of fossil fuels, industrial discharges, herbicides, chemical control agents of fouling organisms, and normal metabolic processes of animals. Acrolein is volatile, flammable, and explosive. Biochemical and toxic effects of acrolein are caused by its reaction with sulfhydryl compounds to form a stable thiol ether. Acrolein metabolites under certain conditions are reportedly mutagenic, teratogenic, or carcinogenic. Acrolein degrades quickly in soils and in plant tissues; in water the half-time persistence is usually less than 50 h and in the atmosphere, less than 3 h. In treated irrigation canals, acrolein probably eliminates or seriously depletes all populations of aquatic fauna. Recommended herbicidal concentrations of acrolein for the control of submerged aquatic weeds usually exceed 1,000 µg/L; however, short-term tests with various species show that frog tadpoles die at 7 µg/L, representative fish are killed at 14 to 62 µg/L, and sensitive crustaceans are immobilized or die at 34 to 80 µg/L. Terrestrial plants and insects are comparatively resistant to acrolein; terrestrial plants tolerated 500 µg acrolein/L air and 25,000 µg/L in irrigation water, and adult fruitflies (*Drosophila melanogaster*), 3,700,000 µg acrolein/L culture medium. Birds are adversely affected by concentrations greater than 51 µg acrolein/kg whole egg by injection of eggs, greater than 9,100 µg/kg body weight (BW) by single oral doses, and greater than 50,000 µg/L (greater than 113 mg/m^3) by air concentrations. Mammals were affected by 50 µg acrolein/L air for 1 min, by 300 µg/L air for 10 min, and by intravenous injections of 850-6,000 µg/kg BW. Acrolein was fatal to mammals after exposure to 660 µg/L air for 24 days, 8,000-11,000 µg/L air for 4 h, 875,000 µg/L air for 1 min, and 4,000-28,000 µg/kg BW by single oral doses, or when fed diets equivalent to 500 µg/kg BW for 102 weeks. Proposed acrolein criteria for the protection of various resources include less than 15,000 µg/L in irrigation water of agricultural crops, less than 68 µg/L for aquatic fauna in acute exposures and less than 21 µg/L in chronic exposures, and less than 44 µg/L (less than 0.1 mg/m^3) in air for rats. No acrolein criteria are now available for the protection of avian and terrestrial wildlife. Acrolein criteria for the protection of human health include less than 320 µg/L in drinking water, less than 110 µg/L in air (less than 0.25 mg/m^3), and less than 0.68 µg/kg BW daily intake from all sources. More research is needed on acrolein and its metabolites.

Key words: Acrolein, aldehyde, herbicide, ecotoxicology, fish, aquatic plants, invertebrates, criteria.

Acrolein (CH_2=CHCHO) is an aldehyde that was first isolated in 1843 from the dry distillation of fats and glycerol (Beauchamp et al. 1985). It is now known that acrolein is ubiquitous in the environment; it is often present in trace amounts in foods and as a component of smog, fuel combustion products such as wood smoke, exhaust emissions from internal combustion engines, and cigarette smoke (Smith 1962; U.S. Environmental Protection Agency [EPA] 1980; Beauchamp et al. 1985). Atmospheric concentrations of acrolein over urban areas are between 2 and 7 µg/L; cigarette smoke, however contains about 10,000 µg of acrolein/L (Beauchamp et al. 1985). Acrolein is classified as a hazardous chemical because of its reactivity and flammability (EPA 1980). At low sublethal concentrations, acrolein is widely known for its acrid pungent odor and strong irritating effects on mucous membranes of the eyes and of the upper respiratory tract, its toxicity to cilia in all organisms, and its interference with nucleic acid synthesis in bacteria (Marano and Puiseux-Dao 1982; Beauchamp et al. 1985). In bulk, acrolein during storage or transfer is potentially hazardous if it becomes overheated or contaminated with water. For example, in 1982, 17,000 residents from Toft, Louisiana, were evacuated when two large tanks of acrolein began to burn (Bowmer and Smith 1984).

Acrolein enters the aquatic environment from its use as an aquatic herbicide, from industrial discharges, and as a byproduct of the chlorination of organic compounds in wastewater and drinking water treatment (EPA 1980). Dilute solutions of acrolein kill undesirable plant life in irrigation streams and ditches (National Research Council [NRC] 1977) and have been used routinely in about 4,000 km of irrigation canals in southeastern Australia to control submerged weeds, including *Potamogeton tricarinatus, Elodea canadensis,* and *Vallisneria gigantea* (Bowmer and Smith 1984). Acrolein has also been used for many years in channel maintenance in the United States (especially in western states), Canada, Egypt, Argentina, Mexico, and Turkey (Bowmer and Smith 1984). Unlike most other aquatic herbicides, acrolein rapidly dissipates from the water by volatilization and degradation without leaving phytotoxic residues (Bowmer and Smith 1984; Parent et al. 1992). However, acrolein provides only temporary control of submerged weeds and also kills fish and other aquatic life at recommended treatment concentrations (Bowmer and Smith 1984). In one Montana stream, acrolein killed all fish in a 4-km stretch after application to control submerged weeds; some fish deaths were recorded as far as 6.4 km downstream (Fritz-Sheridan 1982). Useful reviews on ecological and toxicological aspects of acrolein are presented by Smith (1962), EPA (1980), Beauchamp et al. (1985), and the Agency for Toxic Substances and Disease Registry [ATSDR] (1990).

This report is part of a continuing series of brief reviews of environmental contaminants and their effects on living organisms with special emphasis on fishery and wildlife resources. It was prepared in response to requests for information on acrolein from environmental specialists of the U.S. Fish and Wildlife Service.

Sources and Uses

General

Acrolein enters the environment as a result of normal metabolic processes; incomplete combustion of coal, wood, plastics, tobacco, and oil fuels; and industrial emissions. Acrolein has been detected in smog, foods, and water. It is used extensively in chemical manufacture, for control of fouling organisms, and as an herbicide to control submerged weeds in irrigation canals.

Sources

Acrolein is ubiquitous in the environment as a result of natural and anthropogenic sources. Sources of atmospheric acrolein include smog; incomplete combustion of coal, wood, gasoline, plastics and fats; tobacco smoke; and industrial emissions. The total amount of acrolein released into the atmosphere is unknown. In 1978, production losses of acrolein by emission from the four main U.S. plant locations were estimated at 34,682 kg; however, the gaseous emission streams are now either burned on emergence from the exhaust stack or sent to a furnace to destroy residual material (Beauchamp et al. 1985). Acrolein is found in photochemical smog and contributes to the smog's irritant capacity to the eye and respiratory pathways (Beauchamp et al. 1985; Leikauf et al. 1989). Recorded maximum acrolein concentrations in smog ranged from 12 to 14 µg/L (0.025 to 0.032 mg/m^3) in Los Angeles between 1961 and 1963 and were 13 µg/L in Hudson County, New Jersey (EPA 1980). For humans, exposure to atmospheric acrolein is greatest in the vicinity of incompletely combusted organic materials such as coal, wood, and petrol; highest acrolein concentrations are reported near forest fires and urban area fires (Beauchamp et al. 1985; Srivastava et al. 1992). The burning of southern pine (*Pinus* sp.), for example, generates 22 to 121 mg of acrolein/kg of burned wood (EPA 1980).

Acrolein is also in the smoke of burning plastic materials. Air samples from more than 200 fires in Boston, Massachusetts, contained greater than 3,000 µg acrolein/L (greater than 6.8 mg/m^3) in more than 10% of all samples; greater than 3,000 µg acrolein/L air is an immediately hazardous concentration for human life and health (Beauchamp et al. 1985). Cigarette smoke in some enclosed areas may account for as much as 12,400 µg of acrolein/L air (Feron et al. 1978; Astry and Jakab 1983; Beauchamp et al. 1985; Leikauf et al. 1989; Cohen et al. 1992). In the case of an enclosed room of 30 m^3 capacity, smoking 5 cigarettes raises the air concentration to about 50 µg acrolein/L and smoking 30 cigarettes, to 380 µg/L (EPA 1980).

Acrolein is also generated when animal or vegetable fats are subjected to high temperatures (Feron et al. 1978; EPA 1980). Acrolein was detected aboard submarines in trace concentrations as a degradation product during the heating of lubrication oils and edible fats (Lyon et al. 1970). Large amounts of acrolein are generated from exhausts of internal combustion engines (Astry and Jakab 1983; Heck et al. 1986; Ballantyne et al. 1989). Acrolein concentrations of 10,000 µg/L (23 mg/m^3) have been measured in nondiesel automobile exhausts, 2,900 µg/L in diesel engine emissions, and 2,600-9,600 µg/L in other internal combustion engines (EPA 1980). Acrolein concentrations in air from several urban areas in the United States ranged from a maximum of 10 µg/L in 1960 to 1.8-3.4 µg/L in 1968; air in Tokyo during this period had an average acrolein concentration of 7.2 µg/L (Beauchamp et al. 1985). Urban acrolein pollution is derived mainly from automobile exhaust and incomplete burning of refuse (Beauchamp et al. 1985). Acrolein is formed during normal metabolic degradation of spermine and spermidine, glycerol, allyl formate, allyl alcohol, and cyclophosphamide (EPA 1980; Marano and Puiseux-Dao 1982; Leach et al. 1987). Acrolein was also in spores from the wheat stem fungus (*Puccinia graminis*) of infected wheat (*Triticum aestivum*); acrolein was the major chemical factor that normally induced infection structure formation in Puccinia (Macko et al. 1978).

Acrolein has been detected in effluent-water streams from industrial and municipal sources. Municipal effluents from Dayton, Ohio, for example, contained between 20 and 200 µg acrolein/L in 6 of 11 analyzed samples (EPA 1980; Beauchamp et al. 1985). Acrolein is also a component of many foods, and processing may increase the acrolein content (EPA 1980). Acrolein has been identified in raw turkey, potatoes, onions, coffee grounds, raw cocoa beans, alcoholic beverages, hops (EPA 1980), white bread, sugarcane molasses, souring salted pork, and cooked bluefin tuna (*Thunnus thynnus*; Beauchamp et al. 1985).

Occupational exposure to acrolein may occur during its production and isolation as a chemical intermediate or during the manufacture of acrylic acid, acrylic acid esters, and methionine (Beauchamp et al. 1985). Other sources of acrolein in the workplace include emissions from rubber vulcanization plants, from welding of metals treated with anticorrosion primers, and from pitch-cooking plants and skin contact with herbicides during applications for aquatic weed control and with paper and paperboard, the manufacture of which includes acrolein as a slimicide. Acute acrolein poisoning from occupational exposure is improbable. However, the risks of poisoning are significant in certain industries including welding of fat and oil cauldrons, smelting work and foundry operations, printing plants, linoleum and oil cloth factories, manufacture of insulators, tin plating of sheet iron, and processing of linseed oil (Beauchamp et al. 1985).

Uses

Since its discovery in 1843, acrolein has been known to polymerize readily in the presence of many chemicals, and since 1947 it has been used safely in a wide variety of commercial applications (Albin 1962; Fischer 1962). Acrolein is presently produced by the catalytic oxidation of propylene for the manufacture of methionine, glutaraldehyde, 1,2,6-hexane thiol, and other chemicals. The largest quantity of acrolein produced by this process is converted directly to acrylic acid and acrylic acid esters (Beauchamp et al. 1985). In 1975, global production of acrolein was 59,000 metric tons; in 1980, this value was 102,000 tons--including 47,600 tons produced by the United States (EPA 1980). In 1983, about 250,000 tons (about 550 million pounds) of acrolein were produced; 92% was converted to acrylic acid and 5% to methionine; 3% was used as an aquatic herbicide (Beauchamp et al. 1985; Heck et al. 1986). Acrolein copolymers are used in photography, in textile treatment, in the paper industry, as builders in laundry and dishwater detergents, and as coatings for aluminum and steel panels (EPA 1980). Acrolein is used to scavenge sulfides from oil-field floodwater systems (Kissel et al. 1981), to crosslink protein collagen in the leather tanning industry, and to fixate tissue of histological samples (EPA 1980). The use of acrolein as a military poison gas has been advocated because of its lacrimatory and blistering properties; during World War I the French used acrolein under the name of Papite in hand grenades because of its irritating effect on the respiratory airways and the ocular mucosa (Beauchamp et al. 1985).

Acrolein has been used since 1960 to control submerged aquatic weeds in irrigation systems in the United States, Australia, and other countries where open channels distribute water for crop production (Hill 1960; Bartley and Hattrup 1975; Bowmer and Higgins 1976; EPA 1980; Reinert and Rodgers 1987). Acrolein is preferable to sodium arsenite for herbicidal control of submerged weeds because arsenicals are persistent (as long as for 1 year) and the high arsenic concentrations that are attained in water may be hazardous to humans and livestock (Hill 1960). Acrolein is extremely effective in killing submerged weeds that are difficult to control with other herbicides (Hill 1960). Acrolein has also been used as an herbicide in ponds, drains, and other bodies of water (Donohue et al. 1966). In Australia, the concentration of acrolein in irrigation canals to control various species of *Elodea, Potamogeton,* and *Vallisneria* is usually less than 15,000 µg/L (Bowmer and Higgins 1976). In general, acrolein has a low order of toxicity to terrestrial plants (Donohue et al. 1966). Most field and garden crops can tolerate water with as much as 15,000 µg acrolein/L without serious adverse effects (Bartley and Hattrup 1975). Acrolein, as discussed later, has comparatively low persistence and low accumulation in aquatic ecosystems. One disadvantage to its use as an herbicide is its pungent, irritating odor (Hill 1960). At recommended treatment concentrations, however, acrolein kills fish and other aquatic organisms; therefore, acrolein should be used only in aquatic systems where these resources are considered expendable (Reinert and Rodgers 1987).

Acrolein has been used to control bacteria, fungi, algae, and molluscs in cooling-water systems: 1,500 µg/L killed as much as 95% of the target species in a once-through treatment (Donohue et al. 1966). Acrolein has been applied directly to the marine environment to control the growth and settlement of mussels (*Mytilus edulis*) and other fouling organisms in cooling-water systems of coastal steam-electric-station power plants (EPA 1980; Rijstenbil and van Galen 1981). Mussels in marine cooling-water systems are controlled with 600 µg acrolein/L for 8 h daily for 3 days or with 700 µg/L for 3 h daily for 2 weeks (Rijstenbil and van Galen 1981). Acrolein prevents the growth of microorganisms in liquid fuels such as jet fuels, in feed lines of subsurface wastewater injectors, and in water conduits of paper manufacturing plants (EPA 1980; Beauchamp et al. 1985).

Environmental Chemistry

General

Acrolein, the simplest member of the class of unsaturated aldehydes, has a pungent, irritating odor. It is volatile, flammable, and explosive and requires elaborate and specific conditions for storage and use. The half-time persistence of acrolein in freshwater is usually less than 50 h; in seawater it is less than 20 h and in the atmosphere less than 3 h. Biochemical and toxic effects of acrolein are caused by its rapid and essentially irreversible reaction with sulfhydryl compounds to form a stable thiol ether; however, many compounds can mitigate or block its toxicity. Acrolein is eventually metabolized to acrylic acid and glyceraldehyde; glycidaldehyde--an intermediate metabolite with mutagenic and carcinogenic properties--has been produced in vitro but not in vivo.

Chemical Properties

Acrolein is soluble in water and in many organic solvents including ethanol, acetone, and ether (Table 1; Beauchamp et al. 1985). Acrolein is a highly reactive molecule with two reactive centers: one at the carbon-carbon double bond and the other at the aldehydic group. Typical reactions involving acrolein are shown in detailed figures in Beauchamp et al. (1985). Acrolein is extremely volatile, flammable, and explosive (Table 1; Reinert and Rodgers 1987), especially in sunlight or in the presence of alkali or strong acid (Albin 1962; EPA 1980). A potential hazard in handling acrolein is its rapid exothermic polymerization caused by the use of insufficient hydroquinone inhibitor or lack of strict control of pH (Beauchamp et al. 1985). Commercial acrolein should be maintained at pH 6.0 and contain less than 3% water and 0.1-0.25% hydroquinone as a polymerization inhibitor. Atypical commercial sample contains about 97% acrolein, 0.5% other carbonyls, and 2.5% water. The addition of hydroquinone (0.1-0.25%) prevents the vinyl polymerization of acrolein, and controlling the pH between 5 and 6 by acetic acid increases stability of commercial acrolein by preventing aldol condensation. Elaborate and specific conditions are now prescribed for the storage of acrolein and include vents and safety valves, construction materials, fire control, spills, and waste disposal (Beauchamp et al. 1985). Commercial acrolein is stored and shipped under a blanket of oxygen-free inert gas (Albin 1962).

Table 1. Chemical and other properties of acrolein.[a]

Variable	Data
Chemical name	2-Propenal
Alternate names	Acraaldehyde, acraldehyde, acrolein, acryladehyde, acrylaldehyde, acrylic aldehyde, allyl aldehyde, aqualin, aquilin, Magnacide H, propenal
CAS Number	107-02-8
Structural formula	CH_2=CHCHO
Molecular weight	56.06
Specific gravity	0.8427-0.8442
Physical state	Colorless or yellow liquid at 25° C
Odor	Pungent, irritating
Boiling point	52.5-53.5° C
Melting point	-86.95° C
Solubility	
Water	206-208 g/L
Organic solvents	Miscible
Log K_{ow}	0.01
Vapor pressure	215-220 mm Hg at 20° C
Explosive limits of vapor and air	
Upper limit	31% acrolein
Lower limit	2.8% acrolein

[a] Hill (1960), Anderson and Hood (1962), Folmar (1977), EPA (1980), Hudson et al. (1984), Beauchamp et al. (1985), Mayer (1987), Reinert and Rodgers (1987), Ballantyne et al. (1989), Sine (1991), Agency for Toxic Substances and Disease Registry [ATSDR] (1990), National Institute for Safety and Health [NIOSH] (1990).

Spectrophotometric determination with 4-hexylresorcinol and a fluorometric method with m-aminophenol are the most commonly used procedures for the determination of acrolein; however, gas chromatography and high performance liquid chromatography procedures are also used (EPA 1980; Kissel et al. 1981; Nishikawa and Hayakawa 1986). Acrolein concentrations in rainwater between 4 and 200 µg/L can be measured rapidly (in less than 80 min) without interference from related compounds; the method involves acrolein bromination and analysis by gas chromatography with electron capture detection (Nishikawa and Hayakawa 1986). Kissel et al. (1981) emphasize that water samples from potential acrolein treatment systems require the use of water from that system in preparing blanks, controls, and standards and that acrolein measurements should be made at the anticipated use concentrations.

Persistence

Degradation and evaporation seem to be the major pathways for acrolein loss in water; smaller amounts are lost through absorption and uptake by aquatic organisms and sediments (EPA 1980; Reinert and Rodgers 1987). The half-time persistence of acrolein in freshwater is 38 h at pH 8.6 and 50 h at pH 6.6; degradation is more rapid when initial acrolein concentrations are less than 3,000 µg/L (Bowmer and Higgins 1976). At pH 5, acrolein reacts by reversible hydrolysis to produce an equilibrium mixture with 92% beta-hydroxypropionaldehyde and 8% acrolein; in alkali, the primary reaction is consistent with a polycondensation reaction (EPA 1980). In natural waters, acrolein degradation proceeds to carboxylic acid via a microbial pathway (EPA 1980); beta-hydropropionaldehyde is readily biotransformed in about 17.4 days (Reinert and Rodgers 1987).

Acrolein is applied to irrigation canals to control submerged aquatic weeds at greatly different time-concentration treatments. Regardless of time-concentration regimens--which vary from 100 µg/L for 48 h in the United States to 15,000 µg/L for several hours in Australia--the daily decay rate constants are remarkably

similar, ranging from 0.14 to 0.21, and are probably affected by variations in weed density (O'Loughlin and Bowmer 1975; Parent et al. 1992). In one case, acrolein applied to the Columbia River at an average initial concentration of 125 µg/L degraded to 25 µg/L after 48 h in samples greater than 65 km from the application point--a loss of 80% (EPA 1980). High initial concentrations (50,000 - 160,000 µg/L) of acrolein in natural waters degraded 57 to 80% in 192 h, suggesting that high concentrations can alter the rate of hydrolysis (Kissel et al. 1981). In seawater, the half-time persistence of acrolein was less than 20 h (Rijstenbil and van Galen 1981). In photochemical smog, acrolein is comparatively unstable and not likely to persist; the dominant removal mechanism involves hydroxide attack on acrolein, and the atmospheric half-life persistence is 2-3 h under these conditions (Beauchamp et al. 1985).

Metabolism

Biochemical and toxic effects of acrolein are probably caused by its reaction with critical protein and nonprotein sulfhydryl groups (EPA 1980; Beauchamp et al. 1985; Heck et al. 1986). The reaction of acrolein with sulfhydryl compounds is rapid and essentially irreversible, resulting in the formation of a stable thiol ether (Beauchamp et al. 1985; Heck et al. 1986). Metabolism of acrolein is believed to result in the formation of acrylic acid and glyceraldehyde (Figure). The postulated metabolites of acrolein can be oxidized to carbon dioxide (Beauchamp et al. 1985). Acrylic acid does not seem to represent a significant toxic hazard when compared with the parent acrolein because at low airborne concentrations of less than 1,000 acrolein/L, the quantity of acrylic acid produced by metabolism is negligible. Thus, metabolism to acrylic acid after inhalation should be regarded as a detoxification pathway. Conjugation of acrylic acid with glutathione represents another elimination and detoxification pathway (Beauchamp et al. 1985). In-vitro studies of acrolein metabolism in mammals suggested that acrolein exposures may result in exposure to glycidaldehyde, an intermediate in acrolein metabolism (Figure). The major toxic effects of acrolein exposure--including irritation, ciliastasis, and hypersensitivity--are probably due either to the parent acrolein or to the reaction of glycidaldehyde with cell proteins. Glycidaldehyde is a potent mutagen and carcinogen; however, no evidence is available showing that acrolein can produce glycidaldehyde in vivo (Beauchamp et al. 1985). Acrolein is more toxic when inhaled than when taken orally (EPA 1980). Inhalation of acrolein decreased the concentrations of protein and nonprotein sulfhydryl groups in nasal mucosal tissue (Heck et al. 1986). Acrolein is highly reactive towards thiol groups and rapidly conjugates with glutathione and cysteine (EPA 1980). When glutathione is depleted, acrolein potentiates the nasal toxicity of formaldehyde to rats (Heck et al. 1986).

Acrolein is a metabolite of allyl alcohol and cyclophosphamide, and these compounds should be considered in acrolein metabolism schemes (Beauchamp et al. 1985; Cohen et al. 1992). Allyl alcohol in the presence of NADPH and liver or lung microsomes degrades to acrolein, acrylic acid, and glycidol (Figure).

When added to water as an aquatic herbicide, acrolein undergoes rapid decomposition, especially in the sunlight. At the same time, it reacts rapidly with amines, alcohols, and mercaptans of aquatic plants, destroying cell structure and killing the plants (Parent et al. 1992). Mammals drinking acrolein-contaminated water rapidly convert acrolein to saturated alcohol compounds because of the low pH in the upper portion of their GI tracts; the primary breakdown product is beta-propionaldehyde (EPA 1980).

Many compounds including glutathione, 2-mercaptoethanol, beta-dimethylcysteamine, penicillamide, gamma-mercaptopropionylglycine, and N-acetylcysteine mitigate or block the toxic effects of acrolein (EPA 1980; Beauchamp et al. 1985; Heck et al. 1986). In frogs (*Rana japonica*), sulfhydryl compounds reduce the effects of acrolein on excitation-contraction uncoupling in skeletal muscle (Fujino et al. 1985). In mice, cysteine reduced the cytotoxic effects of acrolein on tumor cells; in rabbits, cysteine mitigated acrolein-induced alveolar macrophage calcium-dependent ATP-ase, phagocytosis, and adhesiveness (EPA 1980). In male rats, cysteine and ascorbic acid antagonized the acute lethal effects of orally-administered acrolein, and 2-mercaptoethanol antagonized the inhibitory effect of acrolein on liver DNA-polymerase (EPA 1980).

Lethal and Sublethal Effects

General

Acrolein degrades quickly in soils and in plant tissues regardless of mode of administration. Most terrestrial crop plants easily tolerate 25,000 µg of acrolein/L of irrigation water and some can tolerate 70,000-80,000 µg/L without adverse effects. Terrestrial plants were adversely affected at atmospheric concentrations of 500 µg

acrolein/L air, but this concentration exceeds the recommended value of 110 µg/L (0.25 mg/m^3) air for protection of human health in occupational settings.

Adult fruitflies (*Drosophila melanogaster*) were comparatively resistant to acrolein and had lowered survival when reared in culture media with greater than 3,700,000 µg acrolein/L. At recommended concentrations for the control of nuisance submerged aquatic weeds (frequently 100-1,000 µg/L, often greater than 9,600 µg/L), acrolein was lethal or harmful to almost all aquatic vertebrates and invertebrates tested in short-term exposures. The most sensitive groups of tested aquatic organisms in short-term assays were frog tadpoles (dead at 7 µg/L) and representative species of fish (reduced survival at 14-62 µg/L) and crustaceans (death or immobilization at 34-80 µg/L). Adverse effects of acrolein on birds were observed at acute oral doses of 9,100 µg/kg BW (reduced survival), at concentrations greater than 51 µg/kg egg for egg injection (abnormal development and reduced survival), and at greater than 50,000 µg/L air (respiratory tract histopathology): In mammals, acrolein is a strong cytotoxic and ciliostatic agent that is irritating to mucous membranes of dermal, ocular, gastrointestinal, and respiratory systems and is systemically toxic by all routes of exposure. Adverse effects of acrolein are documented in sensitive species of mammals under the following regimens: 50 µg/L air for 1 min (increased blood pressure and heart rate); 300 µg/L air for 10 min (ocular and nasal irritation); 500 to 1,000 µg/L air (repelled by odor); 660 µg/L air for 24 days (reduced survival); 8,000 to 11,000 µg/L air for 4-6 h or 875,000 µg/L air for 1 min (death); dietary concentrations equivalent to 500 µg/kg BW for 102 weeks (decreased survival); 850-6,000 µg/kg BW by intravenous injection (liver necrosis, embryo resorption); and single oral doses between 4,000 and 28,000 µg/kg BW (death).

Acrolein was mutagenic to certain microorganisms and to the fruitfly; mutagenicity may be due, in part, to glycidaldehyde, an acrolein metabolite. Injected into the amniotic fluid, acrolein is teratogenic to rats; teratogenicity may be due to acrylic acid, an acrolein metabolite. There is limited evidence that acrolein acts as a weak carcinogen and tumor promoter. Acrolein interacts with other chemicals, sometimes synergistically, additively, or antagonistically. Also, some chemicals normally contain acrolein as an impurity or yield acrolein as a metabolite.

Terrestrial Plants and Invertebrates

Most crop plants easily tolerate irrigation water with 25,000 µg of acrolein/L and many tolerate 70,000 to 80,000 µg/L without adverse effects--including corn (*Zea mays*), cotton (*Gossypium hirsutum*), milo (*Sorghum spp*.), squash *(Cucurbita* spp.), castor bean (*Ricinus communis*), tomato (*Lycopersicon esculentum*), alfalfa (*Medicago sativa*), and sugarcane (*Saccharum officinarum*; Ferguson et al. 1961). Acrolein degrades quickly in soils and plant tissues regardless of mode of administration (Ferguson et al. 1961). Atmospheric concentrations of 500 µg acrolein/L and higher were harmful to certain plants (Beauchamp et al. 1985). Leaves of the pinto bean (*Phaseolus* spp.) and the morning glory (*Ipomoea* spp.) developed brown foliar lesions after exposure to 500 µg/L air for 4-7 h; damage was more severe if the plants were moist during exposure. Leaves of the radish (*Raphanus* spp.) developed lesions after exposure to 1,500 µg acrolein/L air for 6-7 h; however, leaves of the geranium (*Geranium* spp.) and the tomato showed no adverse effects after exposure to 1,500 µg/L air for 7 h (Beauchamp et al. 1985).

Acrolein inhibits DNA, RNA, and protein synthesis in the bacterium *Escherichia coli*, and this inhibition probably accounts for its cytotoxic and inhibitory effects on *E. coli* cell division (EPA 1980; Beauchamp et al. 1985). Acrolein is demonstrably mutagenic to microorganisms and to larvae of the fruitfly (*Drosophila melanogaster*). Acrolein-induced mutagenicity--including point mutations, sister chromatid exchanges, and chromosome breakages--has been observed in selected strains of bacteria (*E. coli, Salmonella typhimurium*), yeast (*Saccharomyces cerevisiae*), fruitfly larvae, and cultured Chinese hamster ovary cells (EPA 1980; Beauchamp et al. 1985; Sierra et al. 1991; Cohen et al. 1992). Acrolein's mutagenicity may be due to the metabolite glycidaldehyde; glycidaldehyde was mutagenic to bacteria and yeast under controlled conditions (Beauchamp et al. 1985; Sierra et al. 1991). Studies with *D. melanogaster* show that acrolein is mutagenic in the sex-linked recessive lethal test when injected but not when fed (Sierra et al. 1991). Acrolein caused 2.2% sexlinked mutations in *D. melanogaster*--the highest percentage recorded among several tested aldehydes (EPA 1980). In studies by Comendador (1984), early embryonic stages of fruitflies were most sensitive to the mutagenic properties of acrolein and sensitivity decreased with increasing development to the point that adults showed negligible mutagenic responses. Adults of the fruitfly were generally resistant to acrolein; mortality was

25% when the culture medium contained 3,700,000 µg of acrolein/L, 50% at 8,600,000 µg/L, and 75% at 22,100,000 µg/L (Comendador 1984).

Aquatic Organisms

Adverse effects of acrolein on sensitive groups of aquatic organisms are documented (Table 2) at concentrations--in µg acrolein/L medium--as low as 7 for frog tadpoles (death), 14-62 for fish (death), 34-80 for crustaceans (death, immobilization), 50 for oysters (reduction in shell growth rate), 100-200 for freshwater algae (DNA and RNA reduction, photosynthesis inhibition), 151 for gastropods (death), >151 for insects (death), 500-2,000 for macrophytes (leaf cell deterioration, death), 1,250 for trematodes (death of miracidia in 20 min), and 62,000 for bacteria (growth reduction). Aquatic vertebrates were more sensitive than invertebrates (Holcombe et al. 1987), and younger fish were more sensitive than older fish (Burdick et al. 1964). Aquatic insects do not avoid acrolein at concentrations that repel fish (Folmar 1978).

As an herbicide, acrolein is most effective in controlling dense accumulations of submerged weeds in habitats where waterflow is rapid and uniform, such as irrigation canals and rapidly-flowing streams (Ferguson et al. 1961). Acrolein is lethal to various genera of submerged plants (*Hydrodictyon, Spirogyra, Potamogeton, Zannichellia, Cladophora, Ceratophyllum, Elodea, Chara, Najas*) at 1,500 to 7,500 µg/L (Ferguson et al. 1961; Beauchamp et al. 1985). But some floating plants (*Pistia, Eichhornia, Jussiaea*) are more resistant to acrolein than submerged plants and require concentrations that are at least double those necessary for submerged forms (Ferguson et al. 1961). Acrolein has little effect on emergent aquatic macrophytes and should not be used to control emergents (Ferguson et al. 1961). In Australia, acrolein is the only herbicide now used for control of submerged aquatic weeds in larger irrigation canals (Bowmer et al. 1979); effective plant control was obtained at 9.6-28.8 mg/L for 3 h (Bowmer and Smith 1984). In the United States, the U.S. Bureau of Reclamation controls aquatic algae and weeds at lower concentrations (0.1 mg/L) and longer exposures (48 h; Folmar 1980). In the Columbia River basin in the state of Washington, acrolein is used to control submerged aquatic macrophytes at concentrations of 0.1 mg/L for 48 h or 1.0 mg/L for 4 to 8 h with applications every 3 to 5 weeks (Bartley and Hattrup 1975). Vegetation destruction by acrolein is maximal 1 week after application, and green filamentous algae are usually the first plants to return after 1 month (Ferguson et al. 1961). Biomass and species diversity were altered in acrolein-treated phytoplankton populations in Egyptian irrigation canals 1 year after treatment (Kobbia 1982). Although acrolein is a powerful cytotoxic agent, its inhibitory effects at sublethal concentrations on plant mitosis, nucleic acid synthesis, and protein synthesis are considered completely reversible (Marano and Puiseux-Dao 1982).

Table 2. Acrolein effects on representative aquatic organisms.

Taxonomic group, organism, concentration, and other variables	Effect	Reference[a]
Bacteria, Algae, and Macrophytes		
Fresh water algae, *Anabaena* sp.; 690 µg/L; 24-h exposure	50% reduction in photosynthesis at 25° C	1
Aquatic bacteria, 3 species		
62,000 µg/L; 48-h exposure	Some growth reduction, but recovery by 120 h	2
125,000 µg/L; 120-h exposure	LC100	2
500,000 µg/L; 2-h exposure	LC100	2
Freshwater alga, *Cladophora glomerata*		
100 µg/L	Onset of photosynthesis inhibition at 30° C	1
760 µg/L; 24-h exposure	50% reduction in photosynthesis at 30° C	1

1,000 µg/L;24-h exposure	50% reduction in photosynthesis at 25° C	1
Alga, *Dunaliella bioculata*		
100 µg/L; 48-h exposure	DNA concentration reduced 28%	3
200 µg/L; 48-h exposure	DAN concentration reduced 36% and RNA 28%	3
400 µg/L; 48-h exposure	DNA reduced 93%, RNA 68%, and proteins 74%	3
1,000 µg/L; 48-h exposure	No development in 48 h	3
8,000 µg/L; 3-h exposure	Ultrastructural anomalies, and cytoplasmic inclusions	4
Elodea, *Elodea canadensis*		
Sublethal (actual exposure concentration and duration unknown)	Growth stimulation (from reduced competition by aufwuchs, bacteria, and epiphytic algae)	5
500 µg/L; 24-h exposure	Leaf cell deterioration	6,7
2,800 µg/L; 3-h exposure in irrigation canal	80% reduction in density; recovery began in 17 days	5
15,000 µg/L; 2-6 h exposure in Australian canals	Effective control for up to 21 km in flowing-water irrigation canals	8
18,000 µg/l; 2 to 12 h exposure in smaller channels and up to 72 h in major canals; New South Wales	Effective control	5
22,000 µg/L; 3-h exposure in irrigation canal	94% reduction in biomass after 14 days	5
Filamentous algae, unidentified		
500 µg/L; 5-months exposure; petroleum-refinery recirculating cooling-water system	Effective control	9
1,000 µg/L; 20-h exposure in Arizona irrigation canal	Effective control for 2 weeks	10
3,500 µg/L; 2-weeks exposure in petroleum refinery cooling water	Lethal	9
5,000 µg/L; 1-week exposure in petroleum refinery cooling water	Lethal	9
Freshwater alga, *Enteromorpha intestinalis*		
1,800 µg/L; 24-h exposure	50% reduction in photosynthesis at 25° C	1
2,500 µg/L for 24 h	50% reduction in photosynthesis at 20° C	1
>5,000 µg/L for 24 h	50% reduction in photosynthesis at 15° C	1
Freshwater plants; 6 species of submerged plants, 2 species of floating plants, 4 groups of phytoplankton; irrigation drains, Egypt; 15,000-25,000 µg/L for 45 min, repeated 4 times;	Effective control of all plants within 2-7 days, Phytoplankton recovery over 1-year period was most rapid for the Cyanophyceae, followed by the Bacilliarophyceae, Chlorophycae, and Euglenophyceae, and resulting in altered biodiversity when compared with a control canal	11

Submerged macrophytes, 3 species (*Najas* sp., *Ceratophyllum* sp., and *Ipomoea* sp.); 25,000 µg/L	All dead 1 week after application	6
Floating pondweed, *Potamogeton carinatus*		
2,000 µg/L for 12 h	LC50	12
10,000-15,000 µg/L for >1 h (actual exposure time unknown)	LC50	12
15,000 µg/L for 1.7 h	LC50	12
22,000-26,000 µg/L for >1 h (actual exposure time unknown)	LC80	12
Pondweed, *Potamogeton crispus;* 20,000 µg/L for 5 h	All dead in 8 days	6
Pondweed, *Potamogeton tricarinatus;* 4,000 µg/L; 1-h exposure in irrigation canal	Minimum effective concentration	5
Submerged macrophyte, *Vallisneria gigantea*; 26,000 µg/L for 1 h in irrigation canal	Minimum effective concentration	5
Ribbonweed, *Vallisneria spiralis*		
1,600 (95% confidence interval [CI] of 1,300-2,000) µg/L	50% reduction in biomass	12
3,700 (95% CI of 3,200-4,600) µg/L for 1 h	80% reduction in biomass	12
Invertebrates		
Snail, *Aplexa hypnorum*; 151 µg/L for 96 h	Less than 50% mortality	13
Snail, *Australorbis glabratus*		
1,250 µg/L for 24 h	All adults and 90% of embryos survived	7
2,500 µg/L for 24 h	35% of adults and 40% of embryos died	7
10,000 µg/L for 24 h	90% of adults and 100% of embryos died	6,7
Barnacle, *Balanus ebarneus*; 1,600-2,100 µg/L for 48 h	LC50	6
American oyster, *Crassostrea virginica*; 50-55 µg/L for 96 h	50% reduction in shell growth rate	6,14,15
Daphnid, *Daphnia magna*		
17-34 µg/L	MATC[b]	6,16
51 (95% CI of 43 to 62) µg/L for 48 h	50% immobilized	13
57-80 µg/L for 48 h	LC50	6
Mayfly, *Ephemerella walkeri*; 100 µg/L for 1 h	No avoidance of acrolein by nymphs	17
Freshwater snails, 3 species	All dead	14

(*Physa, Biomphalaria*, *Bulinus*); 25,000 µg/L for 3.5-4 h		
Common mussel, *Mytilus edulis*		
200-1,000 µg/L; exposed for as much as 8 h daily for 3 days	Valves closed immediately after start of exposure to acrolein regardless of concentration or duration; effect in 45% of mussels at 200 µg/L, 80% at 400 µg/L, and 90% at 600 µg/L	8
600 µg/L; single 8-h exposure followed by 48-h of uncontaminated seawater	70% of the mussels (1-2.5 mm shell length) in the cooling water systems of power plants became detached in 3 days vs. 13% of controls	18
600 µg/L; 8-h exposure daily for 3 days	97% of mussels became detached	18
600 µg/L; 29-h continuous exposure	100% detachment	18
Brown shrimp, *Penaeus aztecus*		
100 µg/L for 48 h	LC50	14
100 µg/L for 48 h	50% loss in equilibrium	6,15
Trematode, *Schistosoma mansoni*		
1,250 µg/L for 20 min	Killed all miracidia	7
2,500 µg/L	Killed all miracidia in 10 min, and all cercariae in 18 min	7
Midge, *Tanytarsus dissimilis*; 151 µg/L for 48 h	Less than 50% mortality	13
Vertebrates		
Bowfin, *Amia calva*; 62 µg/L for 24 h	LC50, fry	14
Goldfish, *Carassius auratus*		
80 µg/L for 24 h	LC50	6
1,000-2,000 µg/L for 3 h	Fatal	14
White sucker, *Catostomus commersoni*; 14 (95% CI of 8-25) µg/L for 96 h	LC50	13
Longnose killifish, *Fundulus similis*; 240 µg/L for 48 h	LC50	6,15
Western mosquitofish, *Gambusia affinis*		
61 µg/L for 48 h	LC50	6,14
149 µg/L for 24 h	LC50	14
Bluegill, *Lepomis macrochirus*		
13 µg/L for 28 days	Whole fish, bioconcentration factor of 344	6
33 (95% CI of 27-40) µg/L for 96 h	LC5	13
79 µg/L for 24 h	LC50	6,19
90-100 µg/L for 96 h	LC50	6,14

Largemouth bass, *Micropterus salmoides*		
160 µg/L for 96 h	LC50	6,14
183 µg/L for 24 h	LC50	14
Rainbow trout, *Oncorhynchus mykiss*		
8 µg/L for 48 h	None dead	20
16 (95% CI of 14-19) µg/L for 96 h	LC50	13
20, 50, or 100 µg/L; exposure for 4 h; trout collected 1, 4 and 7 days postexposure; cooked fillets evaluated for odor and taste by human panel	Unacceptable organoleptic qualities were recorded for fillets 1 and 4 days (P = 0.05) after treatment with 100 µg/L; some unacceptable qualities were detected 1 and 4 days after treatment with 50 µg/L, and at 7 days after treatment with 100 µg/L	17
29 (95% CI of 22-37) µg/L for 96 h	LC50	21
48 µg/L for 48 h	LC32	6, 20
65 µg/L for 24 h	LC50, fingerlings	6
77 µg/L for 20.5 h	LC50	21
90 µg/L for 4.8 h	No deaths	20
96 µg/L for 48 h	All dead	20
100 µg/L for 1 h	Avoidance by fry	6, 14, 23
150 µg/L	Lethal	22
240 µg/L for 4.8 h	LC10	20
410 µg/L for 4.8 h	LC70	20
>500 µg/L for 4.8 h	All dead	20
Chinook salmon, *Oncorhynchus tshawytscha*; 80 µg/L for 24 h	LC50	6, 19
Fathead minnow, *Pimephales promelas*		
11.4-41.7 µg/L	MATC[b]	6, 16
14 (95% CI of 8-25) µg/L for 96 h	LC50	13
84 µg/L for 6 days	LC50	6
115 µg/L for 48 h	LC50	6, 14
150 µg/L for 24 h	LC50	14
Harlequin fish, *Rasbora heteromorpha*; 130 µg/L for 48 h	LC50	14
Brown trout, *Salmo trutta*		
46 µg/L for 24 h	LC50	6, 14, 19
1,500 µg/L for 76-138 min	All dead	19
6,000 µg/L for 28-61 min	All dead	19
16,000 µg/L for 15-39 min	All dead	19
Frog, *Xenopus laevis*, tadpoles; 7 (95% CI of 6-8) µg/L for 96 h	LC50	13

[b] Maximum acceptable toxicant concentration. Lower value in each pair indicates highest concentration tested producing no measurable effect on growth, survival, reproduction, or metabolism during chronic exposure; higher value indicates lowest concentration tested producing a measurable effect.

Acrolein in concentrations sufficient to control nuisance submerged aquatic weeds may also kill snails, crayfish, shrimp, fish, and toads (Ferguson et al. 1961). In one case, acrolein was used to control *Potamogeton* and *Chara* in an Ohio farm pond during June 1960 (Hill 1960). Acrolein was applied at 16,100 µg/L to a 0.1 ha portion of the 0.7 ha pond. Within 1 h of application, many dead amphibian tadpoles and small bluegills (*Lepomis macrochirus*) were recovered. In 24 h, *Chara* had turned white and *Potamogeton* brown; both plant species seemed dead; fish were swimming in the treated area. In 72-96 h, several large dead walleyes (*Stizostedion vitreum vitreum*) were found. One week posttreatment, all algae and weeds in the treated area were dead; weeds were present in the untreated areas. The treated section remained weed-free for 4-6 weeks; after 8 weeks, the treated area was heavily infested with *Chara*. Hill (1960) concluded that tadpoles, walleyes, and small bluegills were more susceptible to acrolein toxicity than larger bluegills and bass (*Micropterus* spp.) in the pond. Acrolein is also effective in controlling trematodes that cause schistosomiasis wherein snails are the intermediate host, especially in irrigation systems. For example, native species of snails (*Lymnaea, Helisoma*), along with *Potamogeton* weeds, were destroyed within 12 km in the main irrigation canal of Kern County, California, after a single application of acrolein (Ferguson et al. 1961).

Acrolein was the most toxic of 15 herbicides tested for toxicity to fish (EPA 1980). Responses by rainbow trout (*Oncorhynchus mykiss*) surviving 77 µg acrolein/L, a concentration that killed 50% in about 21 h, were characteristic of respiratory irritants (McKim et al. 1987). These responses included a steady increase in cough rate; decreases in ventilation rate, oxygen utilization, and heart rate; increases in hematocrit; and decreases in total arterial oxygen, carbon dioxide, and pH (McKim et al. 1987). In studies by Bartley and Hattrup (1975), no-observable-effect concentrations of acrolein for rainbow trout were 240 µg/L for exposures of 4.8 h and 48 µg/L for exposures of 48 h; these values are below the concentrations that control aquatic weeds. In the same study, rainbow trout that survived exposure to high sublethal concentrations for 48 h were unable to recover completely after acrolein treatments were ended. Trout and other teleosts are poorly adapted to detoxify acrolein and other xenobiotic aldehydes (Parker et al. 1990). The low metabolic capacity of fish liver aldehyde dehydrogenase for aldehydes, in general, suggests that these compounds may be hazardous to fish populations (Parker et al. 1990). Applications of acrolein to waters where fish may be taken for human consumption should be made with caution; rainbow trout surviving exposure to acrolein in reservoirs or connecting canals frequently presented odor and taste problems to human consumers (Folmar 1980).

Acrolein is used also to control fouling organisms in cooling water systems. Effective control was established in a once-through cooling system of a steel mill with continuous application of 200 µg acrolein/L (Donohue et al. 1966). Acrolein controlled bacteria in condenser pipes of a powerplant cooling system but only at extremely high concentrations of 125,000 µg/L for 120 h or 500,000 µg/L for 2 h (Starzecka 1975). Acrolein reduced settlement of young mussels (*Mytilus* sp.) in cooling seawater systems of power plants (Rijstenbil and van Galen 1981). In recirculating cooling water systems, algae and bacteria can be controlled at 500 µg/L for 5 months or at 5,000 µg/L for 1 week (Table 2).

Birds

Acrolein was lethal to birds at single oral doses of 9,100 µg/kg BW (Table 3). Observed signs of acrolein poisoning in subadult mallards (*Anas platyrhynchos*) after oral administration included regurgitation, a reluctance to leave the swimming area, slow responses, muscular incoordination, heavy-footed walking, phonation, wing tremors, running and falling, weakness, and withdrawal (Hudson et al. 1984). Treatment concentrations as low as 3,300 µg/kg BW have produced signs of acrolein poisoning. These signs appeared as soon as 10 min after administration and persisted for as long as 36 days. At lethal oral concentrations, deaths occurred as soon as 32 min posttreatment and continued for several days (Hudson et al. 1984). Acrolein was lethal to developing avian embryos when whole eggs were injected with 51 to 182 µg/kg FW; in descending order, embryos were most sensitive when acrolein was administered by way of the yolk sac (51 µg/kg), by the inner shell (82 µg/kg), and by the air sac (182 µg/kg; Table 3). Acrolein is 50 times more toxic to embryos of the domestic chicken (*Gallus* sp.) than acrylonitrile and 100 times more toxic than acrylamide (Kankaanpaa et al. 1979). Acrolein inhibits mucus transport in the trachea of the domestic chicken (Denine et al. 1971), probably

through ciliostatic action (EPA 1980). Adverse effects of acrolein were observed on chicken respiratory tract physiology and pathology at greater than 50,000 µg/L air (Table 3).

Table 3. Acrolein effects on birds.

Organism, route of administration, dose, and other variables	Effect	Reference[a]
Mallard, *Anas platyrhynchos*; oral route; 9,100 µg/kg body weight (BW), 95% confidence interval [CI] of 6,300-13,100 µg/kg BW	LD50, age 3-5 months	1
Domestic chicken, *Gallus sp.*		
Inhalation route		
Adults subjected to 50,000 or 200,000 µg acrolein/L (113 or 454 mg/m^3) air via an endotracheal cannula for up to 27 days	Decreases in trachea complement of ciliated and goblet cells; inhibited mucus transport activity in trachea; lymphocytic inflammatory lesions in the tracheal mucosa. Changes were more pronounced at the higher dose and with increasing exposure	2
Air sac injection route. Embryos, 2-3 days old; examined at day 13		
>127 µg/kg fresh weight (FW) whole egg	Dose-dependent decrease in survival	3
182 µg/kg FW whole egg	LD50	3
1,818 µg/kg FW whole eff	LD80	3
Air sac injection route. Embryos, 3-days old		
1 µg/kg FW whole egg	20% developmental abnormalities vs. 5% in controls	4
10 µg/kg FW whole egg	No malformations	4
1,000 µg/kg FW whole egg	Lethal	
Inner shell injection of membrane on heart route. Embryos, 72-76 h old; examined on day 14 of incubation		
25 µg/kg FW whole egg	No deaths or malformations	5
51 µg/kg FW whole egg	50% dead or malformed	5
82 µg/kg FW whole egg	LD50	5
102 µg/kg FW whole egg	71% dead, 6% malformed	5
203 µg/kg FW whole egg	97% dead, 3% malformed	5
Yolk-sac injection route. Embryos 3-days old, examined at day 14		
51 µg/kg FW whole egg	LD50	6
1,018 µg/kg FW whole egg	LD90; no evidence of increased teratogenicity over controls	6

[a] 1, Hudson et al. 1984; 2, Denine et al. 1971; 3, Chhibber and Gilani 1986; 4, Beauchamp et al. 1985; 5, Korhonen et al. 1983; 6, Kankaanpaa et al. 1979.

Malformations of the eye, coelom, neck, back, wings, and legs were observed in surviving acrolein-treated chicken embryos (Korhonen et al. 1983) after whole eggs were injected with greater than 51 µg acrolein/kg FW (Table 3). In other studies, acrolein showed no clear evidence of teratogenicity in chicken embryos, although there is a dose-dependent embryotoxic effect (Beauchamp et al. 1985; Chhibber and Gilani 1986). Acrolein-treated chicken embryos had a higher frequency of abnormal limbs, abnormal neck, and everted viscera than the controls, but the frequency was not dose-related. The overall incidence of abnormal embryos when treated at age 48 h was 24% but only 4% in controls; in embryos given acrolein at age 72 h, these values were 26% and 12% in controls (Chhibber and Gilani 1986).

Mammals

Acrolein is a strong cytotoxic and ciliostatic agent; its irritating effects on mucous membranes and its acute inhalation toxicity in mammals are well documented (Feron and Kruysse 1977; Feron et al. 1978; EPA 1980; Astry and Jakab 1983; Beauchamp et al. 1985; Leach et al. 1987; Leikauf et al. 1989). A characteristic of acrolein is its pungent, offensive, and acrid smell that is highly irritating to ocular and upper respiratory-tract mucosae (Beauchamp et al. 1985). Acrolein is toxic by all routes of exposure, and many of its toxic and biochemical effects are produced by interfering with critical sulfhydryl groups (Srivastava et al. 1992). In isolated rat-liver fractions, acrolein is a potent inhibitor of the high-affinity aldehyde dehydrogenase isozymes in mitochondrial and cytosolic fractions (Mitchell and Petersen 1988). Acrolein impairs DNA replication in vitro and inhibits certain mitochondrial functions (Feron et al. 1978). Studies with isolated rat livermembrane proteins revealed that acrolein inhibits plasma membrane enzymes and alters the membrane protein profile; this may be due to acrolein-induced polymerization of plasma-membrane proteins (Srivastava et al. 1992).

Measurable adverse effects of acrolein have been documented in representative species of mammals, but the severity of the effects are contingent on the mode of administration, concentration, dose, and duration of exposure (Table 4). Single oral doses of 4,000 µg/kg BW were lethal to guinea pigs and 28,000 µg/kg BW to mice; diets containing the equivalent of 500 µg/kg BW and more decreased survival in rats after 102 weeks (Table 4). Concentrations of 60,000 µg acrolein/L in drinking water had no measurable adverse effects on cows (*Bos* sp.) after 24 h; rats initially rejected drinking water containing 200,000 µg/L but eventually tolerated this concentration (Table 4). Dermal toxicity seems low; rabbits that were immersed up to their necks in water containing 20,000 µg acrolein/L for 60 min showed no adverse effects (Table 4). No dermal sensitization occurred in healthy female guinea pigs (*Cavia* spp.) after repeated skin exposures to acrolein (Susten and Breitenstein 1990). In undiluted liquid or pungent vapor form, however, acrolein produces intense irritation of the eye and mucous membranes of the respiratory tract, and direct contact with the liquid can produce skin or eye necrosis (Beauchamp et al. 1985). A single intravenous injection of 850 µg acrolein/kg BW produced liver necrosis in rats; 6,000 µg/kg BW caused increased embryo resorption in mice (Table 4). Rats receiving near-lethal doses of acrolein by subcutaneous injection had liver and kidney damage and lung pathology (EPA 1980). Although subcutaneous injections revealed LD50 values between 164,000 and 1,022,000 µg/kg BW in rabbits, these results are questionable because acrolein may be sequestered at the injection site and delay delivery to the systemic circulation (Beauchamp et al. 1985). A single intraperitoneal injection of 1,000 µg/kg BW caused peritonitis in rats, and 7,000 µg/kg BW was lethal to mice; daily injections of 1,000 µg/kg BW were eventually lethal to rats (Table 4). Sublethal intraperitoneal injections of acrolein induced ascites, increased hematocrit, and prolonged sleeping times (Beauchamp et al. 1985). Acquired tolerance to acrolein in mice given repeated intraperitoneal injections suggests that an increased metabolism can partially explain the acquired tolerance (Warholm et al. 1984).

The largest number of studies of the toxicity of acrolein in animals was conducted by way of inhalation, probably because acrolein has an appreciable vapor pressure under ambient conditions and inhalation is the principal exposure for humans (Beauchamp et al. 1985). Because of their intolerance to sharp and offensive odor and to intense irritation of conjunctiva and the upper respiratory tract, humans have not suffered serious intoxication from acrolein. The strong lacrimatory effect of acrolein usually is a warning to occupational workers. Physiological perception of acrolein by humans begins at about 500 to 1,000 µg/L air with eye and nasal irritation; the irritating effects compel afflicted individuals to immediately leave the polluted area (Beauchamp et

al. 1985). Laboratory animals died from inhalation of 8,000-11,000 µg/L after 4-6 h, mice from 875,000 µg/L after 1 min and rats from 660 µg/L after 24 days (Table 4). Animals dying from acute and subacute exposure to acrolein vapor had lung injury with hemorrhagic areas and edema (Albin 1962). Repeated exposures of hamsters, rats, and rabbits to high sublethal concentrations of acrolein caused ocular and nasal irritation, growth depression, and respiratory tract histopathology in all species (Feron and Kruysse 1977; Table 4). However, repeated exposures to low, tolerated concentrations of acrolein did not produce toxicological effects (Albin 1962), suggesting that acrolein effects are not cumulative and that minimal damage is quickly repaired.

Table 4. Acrolein effects on selected mammals

Organism, route of administration, dose, and other variables	Effect	References[a]
Cow, *Bos* sp.; drinking water route; lactating dairy cows given 60,000 µg acrolein/L for 24 h	No change in feed or water intake or milk production; acrolein residues in milk <500 µg/L	1
Dog, *Canis familiaris*; inhalation route		
220, 1,000 or 1,800 µg/L air (0.5, 2.3, or 4.1 mg/m^3); continuous exposure for 90 days	Low concentration group appeared normal and gained weight. At 1,000 µg/L, ocular and nasal discharges. At the high concentration, severe irritation evident plus nonspecific inflammation of brain, heart, lung, liver, and kidney; no deaths	2
400-600 µg/L air for 1-3 min	81-84% of acrolein retained; accumulations greater in upper respiratory tract than lower respiratory tract	3,4
700 or 3,700 µg/L air (1.6 or 8.4 mg/m^3); exposure for 8 h daily, 5 days	Low concentration group appeared normal and gained weight. High concentration group visibly affected with weight loss, excessive salivation, ocular discharges, labored breathing, and histopathology of lung, liver, and kidney; blood and serum chemistry normal	2
150,000 µg/L air (340 mg/m^3) for 30 min	LC50	3, 5, 6
Guinea pig, *Cavia* spp.; inhalation route		
200, 1,000 or 1,800 µg/L continuously for 90 days	The low concentration group appeared normal. At 1,000 µg/L, pulmonary inflammation and liver necrosis. At high concentration, all had nonspecific inflammation of brain, heart, lung, liver, and kidney	2
400-1,000 µg/L for 2 h	Decreased respiratory rate; effects reversed after exposure stopped	6,7

400-1,000 µg/L for as long as 12 h	Concentration-related increases in respiratory resistance together with prolonged and deepened respiratory cycles	3
700 or 3,700 µg/L; 8 h daily, 5 days weekly for 6 weeks	Low concentration group seemed normal. At high concentration, histopathology of lung, liver, and kidney	2
10,500 µg/L for 6 h	LC50	6
20,000 µg/L for 10 min	Bronchioconstriction	6
Cat, *Felis domesticus*; inhalation route		
650,000 µg/L air for 2.25 h	Died within 18 h	6
870,000 µg/L air for 2.5 h	Died during exposure	6
Human, *Homo sapiens*; inhalation route		
20 µg/L air	Threshold for affecting electrocortical activity	6
30-40 µg/L air	Odor threshold for the most acrolein-sensitive people	6
90-300 µg/L air	Increasing concentration and increasing exposure caused increasing eye blinking, irritation, and decreasing respiratory frequency	8
140-150 µg/L air for 2 min	Eye irritation in 30% of subjects	6
250 µg/L air for 5 min	Moderate irritation of sensory organs	3, 5
300 µg/L air for 10 min	Considerable acute irritation	8
300-500 µg/L air	Odor threshold for most people	3, 6
1,000 µg/L air for 1 min	Slight nasal irritation	3, 5
1,000 µg/L for 5 min	Moderate nasal irritation; intolerable eye irritation	3,5
1,800 µg/L air for 1 min	Slight eye irritation	3
5,500 µg/L air for 20 sec	Painful eye and nasal irritation	3, 5
21,800 µg/L air for 1 sec	Intolerable	3, 5
Syrian golden hamster, *Mesocricetus auratus*		
Gavage route; 1,000 µg/animal, equivalent to about 4,000 µg/kg BW	Fatal within a few hours	11, 12
Inhalation route		
400 or 1,400 µg/L air, exposure for 6 h daily, 5 days weekly for 13 weeks	No adverse effects at low concentrations nasal histopathology at high concentration	9
4,000 µg/L air (9.2 mg/m^3); 7 h daily, 5 days weekly for 52 weeks	No effect on survival; no indication of cancer. Abnormal behavior, growth retardation, increased lung weight, decreased liver weight, nasal histopathology	10
6,000 µg/L air (13.8 mg/m^3) for 4 h	Cytotoxic to airway cells	3
25,400 µg/L air for 4 h	LC50	6, 10
Mouse, *Mus* sp.		
Drinking water route; 24,000 µg/L for 18 months	Death	29

Inhalation route		
10 µg/L air continuously for 5 weeks	Some reduction in pulmonary compliance	4
1,000-2,000 µg/L (2.3-4.6 mg/m^3) air for 24 h	Decreased pulmonary ability to kill bacteria *Staphylococcus aureus* and *Proteus mirabilis*	3
1,700 µg/L air for 10 min	50% reduction in respiratory rate	6, 14
3,000 or 6,000 µg/L air for 8 h	Concentration-dependent impairment of pulmonary antibacterial responses	15
6,000-15,000 µg/L air; 6 h daily, 5 days weekly for 6 weeks	Decreased body weight (6%) in all test groups, but not concentration-related	3
66,000 µg/L for 6 h	LC50, 24 h post-exposure	6
175,000 µg/L air for 10 min	LC50	3, 5, 6
875,000 µg/L air for 1 min	LC50	3, 5, 6
Intraperitoneal injection route		
4,000 µg/kg BW; single injection	Plasma total lactic dehydrogenase activity (LDH) increased 5 times, with peak after 10 h	16
4,000 µg/kg BW; multiple daily or weekly injections	Progressively less pronounced effect on LDH activity	16
7,000 µg/kg BW; single injection	LD50	16
12,000 µg/kg BW; preceded by daily injections of 4,000 µg/kg BW for 5 days	50% mortality	16
Oral route; 28,000 µg/kg BW	Acute oral LD50	3, 4, 5, 6
Rabbit, *Oryctolagus* sp.		
Dermal route; immersed up to necks for 60 min in water with 20,000 µg/L	No adverse effects	1
Drinking water route		
9,000 µg/L for 13 days	Miscarriages	29
36,000 µg/L for 13 days	Stomach ulcers	29
Inhalation route		
400 or 1,400 µg/L; 6 h daily, 5 days weekly for 13 weeks	No adverse effects at low concentration; some signs of distress at 1,400 µg/L	9
600 µg/L; 4 h daily for 30 days	No ocular effects	2
1,700-2,400 µg/L for 10 min; with or without 1,000 µg ozone/L	Acrolein alone had no effect on respiratory rate. Ozone-acrolein mixtures produced a marked decrease in respiratory rate	6
4,900 µg/L air, 6 h daily, 5 days weekly for 13 weeks	Ocular and nasal irritation, growth depression, respiratory tract histopathology	10
6,500-10,500 µg/L; exposure duration unknown	Emphysema, tracheobronchitis, some deaths	2
10,500 µg/L air for 6 h	LC50	6
Intravenous injection route; 3,000, 4,500 or 6,000 ug acrolein/kg BW on day 9 of	Embryo resorption was significantly higher in 6,000 µg/kg group vs. controls, but was the same as	6

gestation; killed on day 28 of gestation	controls in lower concentration groups	
Percutaneous injection route		
164,000 µg/kg BW	LD50 for 20% acrolein in mineral spirits	3, 5
238,000 µg/kg BW	LD50 for 10% acrolein in mineral spirits	3, 5
335,000 µg/kg BW	LD50 for 20% acrolein in water	3, 5
562,000 µg/kg BW	LD50 for undiluted acrolein	3, 5
1,022,000 µg/kg BW	LD50 for 10% acrolein in water	3, 5
Domestic sheep, *Ovis aries*; inhalation route via cervical trachea; ewes, 3-4 years old; exposed to smoke containing high (but unknown) concentrations of acrolein for 20 min; killed 1-22 days after exposure	Within 24 h of exposure there was sloughing of total cervical tracheal epithelium and a 35% reduction in tracheal basal cells; trachea was normal 18-22 days after exposure	13
Baboon, *Papio anubis*; inhalation route. Juveniles exposed to air concentrations of 12,000-2,780,000 µg acrolein/L (272-63,100 mg/m^3) for 5 min, then tested for learned avoidance/escape response	Avoidance/escape response enhanced in all animals at all concentration tested. The group exposed to 1,025,000 µg/L air died with respiratory complications within 24 h post-exposure. The group exposed to the highest concentration of 2,780,000 µg/L for 5 min died within 90 min postexposure with severe respiratory complications	17
Laboratory white rat, *Rattus* sp.		
Dermal route; exposure duration and dose unknown	Skin burns; severe ocular effects	18
Drinking water route		
5,000, 13,000, 32,000, 80,000 or 200,000 µg/L for 12 weeks	Water consumption in the 200,000 µg/L group was reduced by about 33% for the first 3 weeks; by week 12, all groups appeared normal and had apparently adapted to the odor and taste of acrolein	4
80,000 µg/L for 3 days	Some deaths	29
100,000 or 250,000 µg/L for 124 weeks	No increase in tumors over controls; no decrease in survival	11
100,000, 250,000 or 625,000 µg/L for 120 weeks	No significant decrease in survival when compared to controls. The 100,000 µg/L group had a 30% frequency of liver neoplasms and a 5% frequency of adrenal cortex neoplasms; however, no neoplasms were found in the 250,000 µg/L group. The 625,000 µg/L group had a 10% frequency of liver neoplasms vs. 25% in controls	12
200,000 µg/L for 90 days	No adverse effects	1
600,000, 1,200,000 or 1,800,000 µg/L for 60 days	Rats in the two high-concentration groups refused to drink and all died, apparently from dehydration. In the low-concentration group 20% died, but survivors were not dehydrated and had no tissue pathology	4
625,000 µg/L for 100 weeks	No decrease in survival; 20% of females developed adrenal cortical ademonas and 10% had neoplastic	6

	nodules in the adrenal cortex vs. 0% in controls	
625,000 µg/L for 104 weeks	No decrease in survival. Increased frequency of adrenal cortex adenomas in females; 25% vs. 1.3% in controls	11
Inhalation route		
10 or 50 µg/L air for 1 min	Increased blood pressure and heart beat rate	19
10,500, 1,000, or 2,400 µg/L air for 3 h	At 500 µg/L and higher, effects on respiratory mucosa included depletion of nonprotein sulfhydryl (NPSH) concentration and slight decrease in protein sulfhydryl (PSH) concentration. Effects on olfactory mucosa showed no changes in PSH at all test concentrations, but significant depletion of NPSH in the two high-concentration groups	20
100, 1,000, or 3,000 µg/L air, exposed 6 h daily, 5 days weekly for 3 weeks	No adverse effects in the two low-concentration groups. The high concentration group had depressed spleen weight and body weight and extensive nasal histopathology	14
150, 510, or 1,520 µg/L air; continuous exposure for 61 days	At low concentration, no respiratory tract lesions or deaths. At 510 µg/L, bronchial epithelium abnormalities but all survived. At high concentration, reduced survival; bronchopneumonia and bronchial abnormalities in survivors	6
220 or 660 µg/L air; exposed continuously for 60 days	No deaths at 220 µg/L; 70% died within 24 days at 660 µg/L	2
220, 1,000 or 1,800 µg/L air; exposed continuously for 90 days	The low concentration group appeared normal and gained weight. At 1,000 µg/L, liver necrosis and pulmonary hemorrhage. At 1,800 µg/L, all had nonspecific inflammation of brain, heart, lung, liver, and kidney	2
400 µg/L air; exposed 6 h daily, 5 days weekly for 13 weeks	Nasal histopathology	9
400, 1,400, or 4,000 µg/L air; exposed 6 h daily, 5 days weekly for 62 days	Some bronchial histopathology at 1,400 µg/L; some deaths among males at 4,000 µg/L	6
520 µg/L (1.2 mg/m^3); continuous exposure for 30 days	Decreased growth, altered liver enzyme activity	3
550 ug/L air; continuous exposure for up to 77 days	Upper respiratory irritation, reduced resistance to infection by *Salmonella*, and increased pulmonary macrophages; all effects disappeared by day 63	6
700 or 3,700 µg/L air; exposed 8 h daily, 5 days weekly for 6 weeks	No adverse effects noted at low concentration. At 3,700 µg/L histopathology of lung, liver,	2

	and kidney	
2,000 µg/L air for 40 h	Increased hepatic alkaline phosphatase activity; increased liver and adrenal weight	3
2,500-5,000 µg/L air for 1 min	Cardioinhibitory effect that was reversed within 10 sec after inhalation of acrolein ceased	19
4,900 µg/L air; exposed 6 h daily, 5 days weekly for 13 weeks	50% mortality during first 4 weeks with no deaths thereafter. Survivors had depressed growth and respiratory tract histopathology	9
6,000-8,888 µg/L air; exposed 6 h daily, 5 days weekly for 3 weeks	Most died within 5 exposure days	14
8,000-8,300 µg/L air for 4 h	LC50 within 14 days; death due to lung injury	5, 6, 21
26,000 µg/L air for 1 h	LC50	21
43,500-304,000 µg/L air for 30 min	Respiratory distress; nasal and ocular irritation; some deaths in 4-5 days; pulmonary edema; bronchial degeneration; excess blood in heart, liver, and kidney	2, 6
131,000 µg/L air for 30 min	50% dead; tracheobronchial pathology	6
283,000 µg/L air; daily 10-min exposures for 6 months	No deaths; some bronchial pathology	6
326,000 µg/L air; daily 10-min exposures for 6 months	50% dead; tracheobronchial pathology	6
435,000 µg/L air; daily 10-min exposures for 6 months	All dead; severe histopathology of respiratory tract	6
5,00,000-10,000,000 µg/L air for 5 min	Rats on a motor-driven exercise wheel were incapacitated within 5-7 min and died shortly thereafter	17
Intraamniotic injection route		
Embryos given 0.1, 1, 10, or 100 µg of acrolein on day 13 of gestation; examined on day 20 of gestation	98-100% dead at 10 and 100 µg; 85% of live fetuses receiving 1 µg were malformed (edema, hydrocephaly, cleft palate, defects of limbs and tail); no teratogenic effects at 0.1 µg	6
Intraperitoneal injection route		
1,000 µg/kg BW, single injection	Peritonitis	22
1,000 µg/kg BW daily for at least 5 days	Lethal	22
2,000 µg/kg BW twice a week for 6 weeks followed by uracil as 3% of the diet for 20 weeks, then control diet for 6 weeks	Acrolein followed by uracil produced a 60% incidence of papilloma in urinary bladder in treated group (acrolein plus uracil) vs. 27% in water control (uracil only). No tumors in either group	22
2,500 µg/kg BW daily	All dead after second dose	3
3,360 µg/kg BW; single injections; tissues analyzed after 24 h	Most (89%) of the acrolein recovered was in the acid-soluble fraction of	3

	the liver, 3% in the liver lipids, and minor amounts (0.4-1.7%) in liver proteins RNA and DNA fractions	
Intravenous injection route		
50-500 µg/kg BW to spontaneously hypersensitive rats	At 50-200 µg/kg BW, blood pressure increased; at 300-500 µg/kg BW, blood pressure decreased	23
250-1,000 µg/kg BW	Increased blood pressure within 5 sec which peaked at 20-30 sec and lasted about 1 min	19
850 or 1,700 µg/kg BW	Liver necrosis	3
10,000 µg/kg BW	Cardioinhibitory effects	19
In vitro studies		
Cultured embryos		
4,500 µg/L serum medium	Growth retardation; 50% malformation frequency among survivors	24, 25
6,700 µg/L serum medium	Mortality of 64%; all surviving embryos malformed	24, 25
7,800-9,000 µg/L serum medium	All dead	24, 25
160 µg/L serum-free medium	50% frequency of malformations in brain, facial area, and heart	25
300-1,100 µg/L serum-free medium	50%-100% lethal	25
Cultured myocytes and fibroblasts from neonatal heart		
600 µg/L culture medium for 4 h	Myocyte ATP levels reduced	26
2,800 µg/L culture medium for 4 h	Irreversible cell lysis and ciliostasis	26
Isolated liver fractions		
1,700 µg/L medium	Mitochondrial aldehyde dehydrogenase (ALDH) activity inhibited 91%; cytosolic ALDH activity inhibited 33%	27
2,700 µg/L medium; 5 sec preincubation in aldehyde substrate	Inhibition of mitochondrial and cytosolic ALDH	27
Oral route		
Daily gavage of 50, 500, or 2,500 µg/kg BW for 102 weeks	Dose-related mortality in males during first year and in females during entire study; significant lethality in the 500 and 2,500 µg/kg groups. No increased incidence of microscopic neoplastic or nonneoplastic lesions in treated rats; decreased creatinine phosphokinase levels in treated rats	28
Two treatments of 4,000-10,000 µg/kg BW (estimated), 2-3 days apart; total dose of 8,000-20,000 µg/kg BW	All died shortly after the second dose	12

5,000 µg/kg BW daily for 9 days via stomach intubation	No deaths	3
10,000 µg/kg BW, single stomach intubation	Fatal	3
25,000 µg/kg BW, single gastric dose	LD50 within 48 h	22
42,000-46,000 µg/kg BW, single dose	LD50 within 14 days	3, 4, 5, 6, 18,22
Squirrel monkey, *Saimiri sciurea*; Inhalation route		
220, 1,000, or 1,800 µg/L air; continuous exposure for 90 days	Low concentration group appeared normal and gained weight; 1,000 µg/L monkeys were visibly affected with ocular and nasal discharges. No deaths at 1,800 µg/L, but excessive salivation, ocular discharges, and hyperplasia of trachea	2
700 or 3,700 µg/L air; 8 h daily, 5 days weekly for 6 weeks	Low concentration group appeared normal. High dose group had weight loss; histopathology of lung, liver, and kidney; 22% mortality (2 of 9 died on days 6 and 9 of exposure) excessive salivation, and frequent blinking	2

Inhaled acrolein--in µg acrolein/L air--had sublethal effects at 10-50 for 1 min on rats (increased blood pressure and heart rate); at 10 for 5 weeks on mice (reduction in pulmonary compliance); at 140-150 for 2 min on humans (eye irritation in 30%); at 300-500 on humans (odor threshold); at 300 for 10 min on humans (acute irritation); at 400 for 13 weeks on rats (nasal histopathology); at 400-600 for 1-3 min on dogs (accumulations in upper respiratory tract); and at 1,000 for 90 days on dogs, monkeys, and guinea pigs (ocular and nasal discharges; Table 4). Sublethal effects of inhaled acrolein in representative small laboratory mammals were greatest on the upper respiratory tract and bronchial airways and included edema, ciliastasis, inflammation, degenerative loss of epithelia, altered ventilatory function, and bronchoconstriction (Feron and Kruysse 1977; Feron et al. 1978; EPA 1980; Astry and Jakab 1983; Beauchamp et al. 1985; Barkin et al. 1986; Leach et al. 1987; Leikauf et al. 1989; Table 4). Typical signs of toxicity from inhaled acrolein in small mammals include ocular and nasal irritation; growth depression; shortness of breath; lesions in the urinary tract, respiratory tract, trachea, and nasal passages; laryngeal edema; reduced resistance to bacterial infection; enlarged liver and heart; elevated blood pressure and heart rate; altered enzyme activities; and protein synthesis inhibition (EPA 1980; Beauchamp et al. 1985; Leach et al. 1987; Table 4). Signs of inhaled acrolein toxicity varied significantly with dose and species. For example, acrolein toxicity in rats at environmental concentrations was confined to local pathologic nasal changes, including metaplastic, hyperplastic, and dysplastic changes in the mucous, respiratory, and olfactory epithelium of the nasal cavity (Leach et al. 1987). Some inhaled toxicants, including acrolein, can prolong bacterial viability in the lung and thus enhance severeness of the disease. Mice convalescing from viral pneumonia became severely deficient in antibacterial defenses when exposed to acrolein (Astry and Jakab 1983). But acrolein-treated mice subjected to 100 µg/L air (5 consecutive daily 3-h

exposures) were not significantly sensitive to pulmonary bacteria *Klebsiella pneumoniae* or *Streptococcus zooepidemicus* (Aranyi et al. 1986).

Acrolein may be a carcinogen, cocarcinogen, or tumor initiator. As an aldehyde with strong affinity to sulfhydryl groups, acrolein is theoretically expected to remove free tissue thiols--compounds that protect bronchial epithelia against attack by carcinogens (Feron and Kruysse 1977; Feron et al. 1978). Carcinogenicity from inhalation of acrolein has not been reported (Lijinsky and Reuber 1987), and acrolein was not an evident cofactor in studies of respiratory-tract carcinogenesis with hamsters (*Cricetus* spp.) exposed to benzo(a)pyrene or diethylnitrosamine (Feron and Kruysse 1977). Moreover, long-term studies with rodents given acrolein by gavage did not increase incidences of neoplastic or nonneoplastic lesions (Parent et al. 1992). Other studies, however, suggest that acrolein is carcinogenic. Compounds closely related to acrolein are carcinogenic to rodents and humans and include acrylonitrile (vinyl cyanide) and vinyl acetate (Lijinsky 1988). Glycidaldehyde--an acrolein intermediate metabolite--is classified as an animal carcinogen by The International Agency for Research on Cancer; however, no convincing data are available on the carcinogenic potential of acrylic acid and other acrolein metabolites (Beauchamp et al. 1985). Acrolein at least partially can account for the initiating activity of cyclophosphamide carcinogenesis (Cohen et al. 1992). Cyclophosphamide and its analogs are a group of chemotherapeutic and immunosuppressive drugs; toxic side effects of this drug group are attributed to its metabolites, especially acrolein (Cohen et al. 1992). Acrolein is a suspected carcinogen because of its 2,3-epoxy metabolite and its weak mutagenic activity in the *Salmonella* screen (Leach et al. 1987). Acrolein may be a weak carcinogen, as judged by the increased frequency of adrenal adenomas in female rats after exposure for 2 years to drinking water with 625,000 µg acrolein/L (Lijinsky and Reuber 1987). Acrolein has cancer-initiating activity in the rat urinary bladder, but studies with N-[4-(5-nitro-2-furyl)-2 thiazoyl] formamide precluded evaluation of acrolein as promoting a complete carcinogenic activity from low rodent survival (Cohen et al. 1992). Additional studies seem needed to evaluate the carcinogenic potential of acrolein.

After intraamniotic injection, acrolein is teratogenic to rats in vivo but not in vitro. When administered intraamniotically to the whole embryo culture system of the rat on day 13 of gestation, acrolein caused edema, hydrocephaly, open eyes, cleft palate, abnormal umbilical cord, and defects of the limbs and face (Slott and Hales 1986). Beauchamp et al. (1985) suggest that acrolein-associated teratogenicity is caused by acrylic acid, an acrolein metabolite. Acrylic acid injected into amniotic fluid of rats on day 13 of gestation produced a dose-dependent increase in the percentage of fetuses with skeletal and other abnormalities (Beauchamp et al. 1985).

Acrolein can react synergistically, additively, or antagonistically with other chemicals (Beauchamp et al. 1985). Rat embryos were protected by glutathione against acrolein-induced mortality, growth retardation, and developmental abnormalities-provided that glutathione was concurrently present with acrolein. When rat embryos were cultured in the presence of acrolein for 2 h prior to glutathione exposure, there was no protection against acrolein-induced embryolethality, teratogenicity, and growth retardation (Slott and Hales 1987). Acrolein effects--including altered liver enzyme activity in rats--were reduced by pretreatment of animals with chemicals that inhibited protein synthesis (NRC 1977). Exposure to acrolein is sometimes accompanied by exposure to formaldehyde and other short-chain saturated aliphatic aldehydes, which in combination cause allergic contact dermatitis (Susten and Breitenstein 1990). A 40-mL puff of cigarette smoke contains 8.2 µg of acrolein and 4.1 µg of formaldehyde; irritation, ciliastasis, and pathologic changes of the respiratory tract from both compounds have been widely studied (Egle and Hudgins 1974). The toxicities of acrolein and formaldehyde seem similar; both exert their principal effects in the nasal passages (Leach et al. 1987). Acrolein in combination with formaldehyde was synergistic in reducing respiratory rates in mice; however, mixtures of sulfur dioxide and acrolein were antagonistic (Beauchamp et al. 1985). Formaldehyde pretreatment (15,000 µg/L, 6 h daily for 9 days) of rats protects against respiratory-rate depression by acrolein. Rats pretreated with formaldehyde had a 50% respiratory-rate depression at 29,600 µg acrolein/L versus 6,000 µg/L from acrolein alone (Babiuk et al. 1985), suggesting cross tolerance. Effects of interaction of acrolein with other toxicants are not comparable between rodents and humans. In rodents, the presence of irritant gases in smoke--such as acrolein--may delay the effects of other toxicants. In humans, however, the inhalation of acrolein and other irritant gases may cause a hypoxemic effect that can enhance the effects of hypoxia-producing gases (Kaplan 1987).

Some chemicals normally contain acrolein as a metabolite or impurity. For example, allylamine toxicity to the rat cardiovascular system is believed to involve metabolism of allylamine to the highly reactive acrolein (Toraason et al. 1989). Certain mercapturic acids can be used as biological markers of exposure for chemicals that are metabolized to acrolein and excreted as mercapturic acid in the urine (Sanduja et al. 1989). In one

case, rats given 13,000 µg acrolein/kg BW by gavage excreted 79% of the acrolein and 3-hydroxypropylmercapturic acid (3-OHPrMCA) in urine within 24 h. These data suggest that 3OHPrMCA can be used as a marker of exposure to allylic and other compounds that lead to the formation of acrolein (Sanduja et al. 1989). The common industrial chemical MDP (2-methoxy-3,4-dihydro-2PH-pyran) is frequently contaminated with acrolein during its synthesis; MDP causes severe irritancy and death of rats from accumulation of acrolein vapor (Ballantyne et al. 1989). Sparging acrolein-contaminated MDP with nitrogen gas before atmospheric release significantly reduced or abolished lethal toxicity to rats (Ballantyne et al. 1989).

Recommendations

Agricultural crops can usually tolerate as much as 15,000 µg of acrolein/L of irrigation water; however, aquatic invertebrates and fish die in acute exposures to 55-68 µg/L or in chronic exposures to greater than 21 µg/L (Table 5). Those who use acrolein to control submerged aquatic macrophytes are strongly advised that acrolein treatment at recommended application concentrations also eliminates nontarget fish and aquatic invertebrates. No acrolein criteria are now available or promulgated by regulatory agencies for the protection of avian and terrestrial wildlife; this seems to be a high-priority research need. Beauchamp et al. (1985) recommend additional research in several areas: long-term effects of acrolein inhalation on carcinogenicity and respiratory histology with rodent models; biochemical mechanisms of acrolein toxicity; genotoxic potential with chromosome breakage and exchange systems; acute and chronic toxicity from interaction effects of acrolein with other gases; and fate of accumulated acrolein in animals.

Table 5. Proposed acrolein criteria for the protection of living resources and human health.

Resource, criterion, and other variables	Concentration	Reference[a]
Agricultural Crops		
Irrigation water, tolerated level	<15,000 µg/L	1
Aquatic life		
Freshwater organisms		
Sensitive species, tolerated level		
Acute exposures	<68 µg/L	2
Chronic exposures	<21 µg/L	2
Rainbow trout, safe level	20 µg/L for <48 h or 200 µg/L for <4.8 h	3
Marine organisms; acute exposures, tolerated level	<55 µg/L	2
Laboratory white rat		
Air		
Maximum daily average	<13 µg/L (<0.03 mg/m^3)	7
Maximum daily	<44 µg/L (<0.1 mg/m^3)	7
Human health		
Air		
Maximum allowable emission concentration in populated areas of former Soviet Union	132 µg/L (0.3 mg/m^3)	4
No observable effect level	<22 µg/L (<0.05 mg/m^3)	4
90-day confined space (i.e., submarines) guideline	22 µg/L (0.05 mg/m^3)	5
Odor threshold	<44 µg/L (<0.1 mg/m^3)	4
Maximum acceptable concentration in room air of former Soviet Union	44 µg/L (0.1 mg/m^3)	2,4

Irritation threshold mg/m^3)	44-88 µg/L (0.1-0.2 mg/m^3)	4
Occupational exposure standard (8 h daily, 40 h work week) in United States; not to exceed in most European countries, Australia, and Japan	100-110 µg/L (0.25 mg/m^3)	2, 4, 5, 6, 8
Occupational exposure standard in Hungary and former Soviet Union	308 µg/L (0.7 mg/m^3)	4
Maximum 15-min exposure limit in USA workplace	300-352 µg/L (0.8 mg/m^3)	4, 8
Ceiling standard for occupational exposure in the former Czechoslovakia	440 µg/L (1.0 mg/m^3)	4
Acceptable ambient air concentrations		
New York	0.83 µg/m^3 for 1 year	9
Florida	2.5 µg/m^3 for 8 hr	9
North Dakota	8.0 µg/m^3 for 1 hr	9
North Carolina	80 µg/m^3 for 15 min	9
Diet		
Water plus consumption of contaminated aquatic organisms from that water body	<320 µg/L medium	2
Consumption of contaminated aquatic organisms alone	<780 µg/L medium	2
Food packaging materials; food starch	<0.6%	2
Total daily intake	<47.8 µg = <0.68 µg/kg body weight daily for a 70-kg person	2

[a] 1, Ferguson et al. 1961; 2, EPA 1980; 3, Bartley and Hattrup 1975; 4, Beauchamp et al. 1985; 5, Lyon et al. 1970; 6, Leach et al. 1987; 7, NRC 1977; 8, NIOSH 1990; 9, ATSDR 1990.

The human threshold concentration of acrolein in the United States for an 8-h workday and 40-h workweek is 110 µg/L (0.25 mg/m^3) air; the shortterm exposure limit is 350 µg/L (0.8 mg/m^3) air and is predicated on continuous exposure of workers for short intervals (Table 5; Beauchamp et al. 1985). Humans can tolerate a total daily intake of 47.8 µg of acrolein, equivalent to 0.68 µg/kg BW by a 70-kg individual (Table 5).

For handling acrolein, gloves, vapor-proof goggles or a full-face mask, and other protective clothing are mandatory (Albin 1962; Beauchamp et al. 1985; NIOSH 1990). Acrolein spills should be neutralized with 10% sodium bisulfite solutions (Albin 1962). Air packs or fresh-air breathing masks, safety showers, and eye baths should be available wherever acrolein is handled (Beauchamp et al. 1985). Purging confined areas with nitrogen is recommended prior to entering a suspected acrolein-contaminated enclosure. The eyes are particularly susceptible to liquid acrolein and, if exposed, should receive prompt treatment, although severe residual injury is probable regardless of treatment; dilute solutions of acrolein may also cause residual eye injury. Acrolein represents a serious fire hazard because of its high flammability and potential for vapors to form explosive mixtures with air. Flame-proof electrical equipment and proper grounding is required to prevent acrolein ignition. Individuals exposed to acrolein by inhalation should be removed from the area and given oxygen; subsequent

treatment by physicians of pulmonary inflammation with corticosteroids and hydroxocobalamin is recommended even if there are no symptoms (Beauchamp et al. 1985) because adverse effects from acrolein exposure may not become apparent until 4-24 h after exposure (Albin 1962). Oxygen therapy should be continued and analgesics given for relief of other symptoms as necessary (Beauchamp et al. 1985). There are many synthetic and natural sources of acrolein; however, special precautions are recommended when acrolein occurs as a contaminant in the synthesis of widely used chemicals such as 2-methyoxy-3,4-dihydro-2H pyran (Ballantyne et al. 1989).

Abstract

This account is a selective review and synthesis of the voluminous technical literature on radiation and radionuclides in the environment and their effects on notably fishes, wildlife, invertebrates, and other natural resources. The subtopics include the physical and biological properties of the electromagnetic spectrum and of charged particles; radiation sources and uses; concentrations of radionuclides in field collections of abiotic materials and living organisms; lethal and sublethal effects, including effects on survival, growth, reproduction, behavior, metabolism, carcinogenicity, and mutagenicity; a synopsis of two case histories of massive releases of radionuclides into the biosphere (military weapons tests at the Pacific Proving Grounds and the Chernobyl nuclear reactor accident); currently proposed radiological criteria for the protection of human health and natural resources; and recommendations for additional research. A glossary is included.

Key words: Radioactivity, radionuclides, radioecology, Chernobyl, Pacific Proving Grounds, wildlife, aquatic organisms, invertebrates, flora, radiological protection criteria.

Life on earth has evolved under the ubiquitous presence of environmental solar, X-ray, gamma, and charged-particle radiation. On a global basis, radiation from natural sources is a far more important contributor to radiation dose to living organisms than radiation from anthropogenic sources (Aarkrog 1990). However, ionizing radiation can harm biological systems (Aarkrog 1990; Nozaki 1991; Severa. and Bar 1991), and this harm can be expressed (1) in a range of syndromes from prompt lethality to reduced vigor, shortened life span, and diminished reproductive rate by the irradiated organism and (2) by the genetic transmission of radiation-altered genes that are most commonly recessive and almost always disadvantageous to their carriers (Bowen et al. 1971). Direct effects of radiation were documented in lampreys in 1896-soon after H. Becquerel discovered radioactivity-and in brine shrimp (*Artemia sp*.) in 1923 (Whicker and Schultz 1982a). Genetic effects of ionizing radiation and thus X-rays as a mutagenic agent were first documented in 1927 in fruit flies, *Drosophila melanogaster* (Evans 1990). The discovery of radioactivity of nuclear particles and the discovery of uranium fission resulted in a great upsurge of nuclear research. During and shortly after World War II, nuclear reactors, nuclear weapons, and radionuclides as tracers in almost all scientific and technical fields were developed rapidly (Severa and Bar 1991). In the early 1940's when fission of uranium and transuranic nuclei became possible in reactors and in explosions of nuclear weapons, environmental radiation from anthropogenic sources began to cause serious concerns (Aarkrog 1990). The first nuclear explosion resulted from a 19-kiloton (TNT-equivalent) source in New Mexico in July 1945 (Whicker and Schultz 1982a). On 6 August 1945, about 75,000 people were killed when the United States Army Air Corps dropped a uranium nuclear bomb on Hiroshima, Japan; on 9 August 1945, about 78,000 Japanese were killed and more than 100,000 injured when a plutonium nuclear bomb was detonated at Nagasaki (Kudo et al. 1991). The former Soviet Union detonated its first nuclear device in August 1949, and in 1952 the United Kingdom exploded a device in Australia (Whicker and Schultz 1982a). Since 1960, nuclear devices have also been detonated by France, India, and The People's Republic of China. Nuclear devices have been developed that can release energy in the megaton range. The first such device was detonated by the United States in 1954 at Bikini Atoll and accidentally contaminated Japanese fishermen and Marshall Island natives. Between 1945 and 1973, an estimated 963 nuclear tests were conducted by The People's Republic of China, France, the former Soviet Union, the United Kingdom, and the United States; 47% of them were atmospheric, and 53% subterraneous (Whicker and Schultz 1982a). Today, the most important environmentally damaging anthropogenic radiation comes from atmospheric testing of nuclear weapons that was conducted 20 to 30 years ago, authorized discharges to the sea from nuclear reprocessing plants, and the Chernobyl accident in 1986 (Aarkrog 1990). By the year 2000, the United States will have an estimated 40,000 tons of spent nuclear fuel that will be stored at some 70 sites and await disposal; by 2035, after all existing nuclear plants have completed 40 years of operation, about 85,000 metric tons will be awaiting disposal (Slovic et al. 1991).

This report was initiated in response to a request for information on radiation from environmental contaminant specialists of the U.S. Fish and Wildlife Service. Specifically, general information was requested on radiation nomenclature, sources and uses, fate, effects, concentrations in field collections, and protection criteria. More detailed information was requested on radiation hazards to living organisms, especially fishes and wildlife. The report is an introduction to the broader fields of radioecology and radiation risk assessment and is intended primarily for use by service personnel, I emphasize that the published literature in these subject areas is particularly voluminous and that I selected for synthesis a comparatively small and highly selective portion of the available information. For more detailed information on various aspects of radiation in the environment, readers are strongly advised to consult at least several of the many reviews [1] that I found particularly useful.

Physical Properties of Radiation

General

Radiation is usually defined as the emission and propagation of energy through space in the form of waves and subatomic particles (Weast 1985; Kiefer 1990). For regulatory purposes in the United States, radiation is narrowly defined as α, β, , or X-rays; neutrons; and high-energy electrons, protons, or other atomic particles; but not radio-waves or visible, infrared, or ultraviolet light (U.S. Code of Federal Regulations [CFR] 1990). Readers may wish to consult the glossary at this time.

In current atomic theory, all elementary forms of matter consist of small units called *atoms*. All atoms of the same element have the same size and weight; atoms of different elements differ in size and weight. Atoms of the same element or of different elements may unite to form compound substances called *molecules*. Each atom consists of a central nucleus and several negatively charged electrons in a cloud around the nucleus. The nucleus is composed of positively charged particles called *protons*, and particles without charge are called *neutrons*. Electrons are arranged in successive energy levels around the nucleus, and the extranuclear electronic structure of the atom is characteristic of the element. Electrons in the inner shells are tightly bound to the nucleus but can be altered by high energy waves and particles (Weast 1985). Based on the number of protons in their nucleus (= the atomic number), atoms are classified chemically into 92 naturally occurring elements and another dozen or so artificial elements (Rose et al. 1990; Severa and Bar 1991). Atoms of the same element may occur as isotopes that differ in the number of neutrons that accompany the protons in the nucleus. The sum of the number of protons and neutrons in the nucleus is called the *mass number* (see Glossary) and is indicated by a superscript that precedes the chemical symbol of the element. For example, three isotopes of hydrogen (one proton) are denoted as ^{1}H (no neutrons), ^{2}H (1 neutron, also known as deuterium), and ^{3}H (2 neutrons, also known as tritium). A nuclide is an elemental form that is distinguished from others by its atomic and mass numbers. Some nuclides, such as ^{238}U and ^{137}Cs, are radioactive and spontaneously decay to a different nuclide with the emission of characteristic energy particles or electromagnetic waves; isomers of a given nuclide that differ in energy content are metastable (i.e., ^{115m}Cd) and characterized in part by the half-life of the isomer (Rose et al. 1990; Severa and Bar 1991).

Chemical forms with at least one radioactive atomic nucleus are radioactive substances. The capability of atomic nuclei to undergo spontaneous nuclear transformation is called *radioactivity*. Nuclear transformations are accompanied by emissions of nuclear radiation (Severa and Bar 1991). The average number of nuclei that disintegrates per unit time (= activity) is directly proportional to the total number of radioactive nuclei; the time for 50% of the original nuclei to disintegrate (= half-life or Tb ½) is equal to ln 2/decay constant for that element (Kiefer 1990). Radiations with sufficient energy to interact with matter to produce charged particles are called *ionizing radiations* (Hobbs and McClellan 1986; UNSCEAR 1988). Radiation injury is related to the production of ions inside the cell. Ionizing radiations include electromagnetic radiation such as gamma ( ) and X-rays and particulate or corpuscular radiation such as alpha (α) particles, beta (β) particles, electrons, positrons, and neutrons. Ionizing radiation may be produced from manufactured devices such as X-ray tubes or from the disintegration of radioactive nuclides. Some nuclides occur naturally, but others may be produced artificially, for example, in nuclear reactors. The basic reaction of ionizing radiation with molecules is either ionization or excitation. In ionization, an orbital electron is ejected from the molecule and forms an ion pair. Directly ionizing particles are charged and possess the energy to produce ionizations along their paths from impulses imparted to orbital electrons by electrical forces between the charged particles and electrons. In excitation, an electron is raised to a higher energy level. Indirectly ionizing radiations are not charged and penetrate a medium until they collide with elements of the atom and liberate energetically charged ionizing particles.

Electromagnetic Spectrum

The electromagnetic spectrum is defined as the ordered array of known electromagnetic radiations including cosmic rays; gamma rays; X-rays; ultraviolet, visible, and infrared radiations; and radiowaves (Weast 1985). The energy transfer by electromagnetic waves can be described by discrete processes with elementary units called *photons* (Kiefer 1990). Their energy, E, is given by E = hv, where h is Planck's constant and v is the frequency. Because velocity C, wavelength , and frequency v are related (C = v), E = hc/ (Kiefer 1990). The relations between E, v, and for parts of the total spectrum of the electromagnetic waves are shown in Figure 1. The high energy radiation that enters the earth's atmosphere from outer space is known as primary cosmic rays. On

interaction with the nuclei of atoms in the air, secondary cosmic rays and a variety of reaction products (cosmogenic nuclides) such as ^{3}H, ^{7}Be, ^{10}Be, ^{14}C, ^{22}Na, and ^{24}Na are produced (UNSCEAR 1988).

Radionuclides

Radioactive nuclides contain atoms that disintegrate by emission of subatomic particles and gamma or X-ray photons (Weast 1985; Hobbs and McClellan 1986; Kiefer 1990; Rose et al. 1990). In alpha decay, a helium nucleus of 2 protons and 2 neutrons is emitted and reduces the mass number by 4 and the atomic number by 2. In beta decay, an electron--produced by the disintegration of a neutron into a proton, an electron, and an antineutrino--is emitted from the nucleus and increases the atomic number by 1 without changing the mass number. Sometimes a positron together with a neutrino is emitted. And sometimes an electron may be captured from the K (outermost) shell of the atom; the resultant electron hole in the K shell is filled by electrons from outer orbits and causes the emission of X-rays. Alpha and beta decay generally leave the resultant daughter nuclei in an excited state that is deactivated by emission of photons. Although emission accompanies most decays, it is not always detected, especially not with light β emitters such as ^{3}H, ^{14}C, ^{32}P, and ^{35}S. The half-life of individual radionuclides can be measured (i.e., the time during which half the atoms of the radionuclide spontaneously decay to a daughter nuclide). Another form of nuclear breakdown is fission in which the nucleus breaks into two nuclides of approximately half the parent's size (Rose et al. 1990). The symbol, mass number, atomic number, half-life, and decay mode of all radionuclides mentioned herein are listed in Table 1.

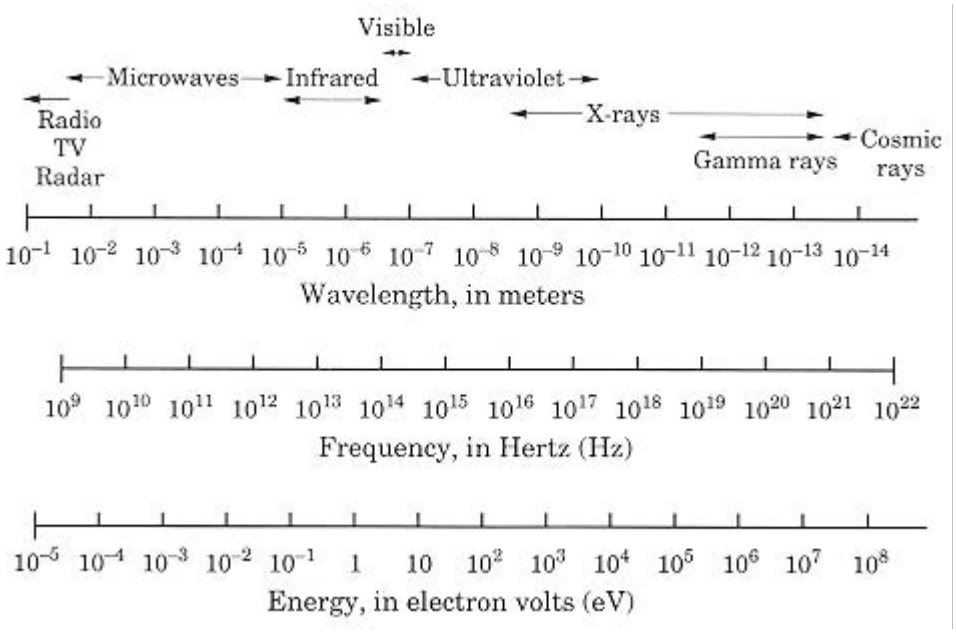

Fig. 1. The spectrum of electromagnetic waves, showing relation between wavelength, frequency, and energy (modified from Kiefer 1990).

Four general groups of radionuclides are distinguished: (1) a long half-life group (i.e., Tb ½ >10^{9} years) of elements including ^{238}U, ^{235}U, ^{232}Th, ^{40}K, ^{87}Rb, and ^{143}Sm that were formed about 4.5 billion years ago; (2) shorter-lived daughters of U and Th such as Ra and Rn that form as a result of the decay of their long-lived parents; (3) nuclides (i.e., ^{14}C and ^{3}H) formed by continuing natural nuclear transformations that are driven by cosmic rays, natural sources of neutrons, or energetic particles that are formed in the upper atmosphere by cosmic rays; and (4) nuclides that are formed as a result of nuclear weapons tests, nuclear reactor operations, and other human activities. Important members of this group include ^{90}Sr, ^{137}Cs, ^{14}C, and ^{3}H; note that many members of the third group such as ^{14}C and ^{3}H are also formed in this fourth fashion (Rose et al. 1990).

Radioactive decay usually does not immediately lead to a stable end product but to other unstable nuclei that form a decay series (Kiefer 1990). The most important examples of unstable nuclei are started by heavy, naturally occurring nuclei. Because the mass number changes only with α-decay, all members of a series may be classified according to their mass numbers (see the uranium-238 decay series in Figure 2). A total of three natural decay series--formed at the birth of our planet--are named after their parent isotope: ^{232}Th, ^{235}U, and ^{238}U (Fig. 3). Several shorter decay series also exist. For example, ^{90}Sr decays with a Tb ½ of 28 years by β emission to ^{90}Y, which in turn disintegrates (β emission) with a Tb ½ of 64 h to the stable ^{90}Zr (Kiefer 1990). Other examples of known radionuclides since the earth's origin include ^{40}K and ^{87}Rb. In hazard assessments, all members of a decay series must be considered.

Linear Energy Transfer

The deposition of energy in an exposed body is mediated almost exclusively by charged particles. These particles cause ionizations but lose energy with each ionization until they reach the end of their ranges. Depending on the type of particle, the ionizations are more or less closely spaced and described by the energy loss of a traversing particle. The linear energy transfer (LET) is defined as the amount of locally absorbed energy per unit length, that is, only the energy fraction that leads to ionizations or excitations in the considered site is counted (Kiefer 1990; ICRP 1991a). Because radiation effects are dependent on the nature of the radiation, a weighting factor is used to modify the absorbed dose and to define the dose equivalent; this factor--now called the Radiation Weighting Factor--is a function of LET. Approximate weighting values range from 1 (X-rays, electrons, gamma rays) to 10 (neutrons, protons, singly charged particles of rest mass greater than one atomic mass of unknown energy) and to 20 (alpha particles and multiply-charged particles of unknown energy; ICRP 1977; Whicker and Schultz 1982a; Hobbs and McClellan 1986; Severa and Bar 1991). The relation between radiation type and energy to weighting factors is shown in Table 2.

Table 1. Selected radionuclides: symbol, mass number, atomic number, half-life, and decay mode (modified from Whicker and Schultz 1982a, 1982b; Weast 1985; Kiefer 1990; Severa and Bar 1991).

Table 1. Nuclide	Symbol	Mass number	Atomic number	Half-life	Major decay mode [a]

[a] Observed modes of decay for all radioactive species: α = particle emission; β = beta emission, β^+ = positron emission; EC = electron capture resulting in X-ray emission; IT = isomeric transition from higher to lower energy state; SF = spontaneous fission.

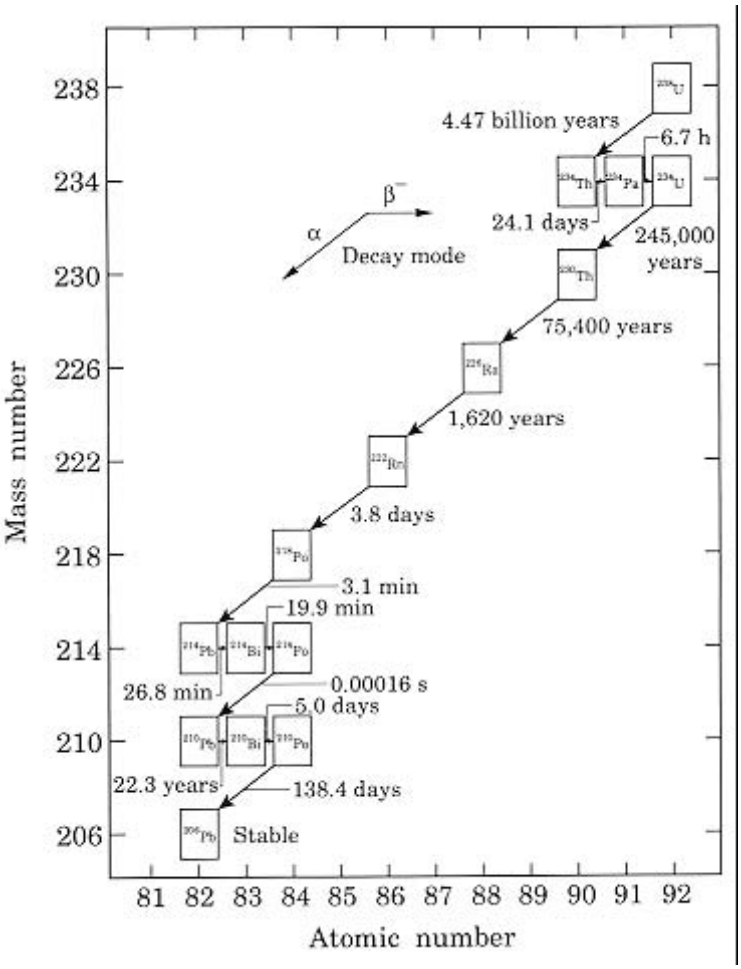

Fig. 2. The principal uranium-238 decay series, indicating major decay mode and physical half-time of persistence (modified from Cecil and Gessell 1992).

New Units of Measurement

A variety of units have been used for the assessment of exposures to ionizing radiation. The current international standard terminology is shown in Table 3. In this report, I use only the new terminology; this frequently necessitated data transformation of units from early published accounts into the currently accepted international terminology.

Table 2. Radiation weighting factors for various types of ionizing radiations (International Commission on Radiological Protection 1991a).

Radiation type and energy range	Radiation weighting factor
X-rays, gamma rays, beta particles, electrons, muons; all energies	1
Neutrons	
10 keV	5
10 keV-100 keV	10
>100 keV-2 MeV	20
>2 MeV-20 MeV	10
>20 MeV	5
Protons	5
Alpha particles, fission fragments, heavy nuclei	20

Table 3. New units[a] for use with radiation and radioactivity (International Commission on Radiological Protection 1977, 1991a; Hobbs and McClellan 1986; United Nations Scientific Committee on the Effects of Atomic Radiation 1988).

Variable	Old unit	New unit	Old unit in terms of new unit
Activity	Curie (Ci) = 3.7 x 10^{10} disintegrations /s (dps)	Becquerel (Bq) = 1 dps	1 Ci = 3.7 x 10^{10} Bq
Exposure	Roentgen (R) = 2.58 x 10^{-4} Coulombs/kg	Coulomb/kg (C/kg)	1 R = 2.58 x 10^{-4} C/kg
Absorbeddose	Rad 100 erg/g	Gray (GY) = 1 J/kg	1 Rad = 0.01 Gy
Dose equivalent	Rem = damage effects of 1 R	Sievert (Sv) = 1 J/kg	1 Rem = 0.01 Sv

[a] See Glossary.

Sources and Uses

General

Most external exposure of living organisms to radiation is from naturally occurring electromagnetic waves, and most internal exposure is from naturally occurring radionuclides such as potassium-40. Natural radiation doses vary significantly with altitude, radionuclide concentrations in the biogeophysical environment, and uptake kinetics. The major source of global anthropogenic radioactivity is fallout from military atmospheric-weapons testing; locally, radiation levels tend to be elevated near nuclear power-production facilities, nuclear-fuel reprocessing plants, and nuclear-waste disposal sites. Dispersion of radioactive materials is governed by a variety of physical chemical, and biological vectors, including winds, water currents, plankton, and avian and terrestrial wildlife.

Natural Radioactivity

Exposure to natural sources of radiation is unavoidable. Externally, individuals receive cosmic rays, terrestrial X-rays, and gamma radiation. Internally, naturally occurring radionuclides of Pb, Po, Bi, Ra, Rn, K, C, H, U, and Th contribute to the natural radiation dose from inhalation and ingestion. Potassium-40 is the most abundant radionuclide in foods and in all tissues. The mean effective human dose equivalent from natural radiations is 2.4 milliSieverts (mSv); this value includes the lung dose from radon-daughter products and is about 20% higher than a 1982 estimate that did not take lung dose into account (Table 4).

Table 4. Annual effective dose equivalent to humans from natural sources of ionizing radiation (Whicker and Schultz 1982a; Hobbs and McClellan 1986; United Nations Scientific Committee on the Effects of Atomic Radiation 1988; Aarkrog 1990).

Source of radiation	Dose equivalents (mSv)
Cosmic rays	
Ionizing component	0.30
Neutron component	0.06
Cosmogenic radionuclides (mainly ^{3}H and ^{14}C)	0.02
Primordial radionuclides	
Potassium-40	0.33
Rubidium-87	0.01
Uranium-238 series	1.34
Thorium-232 series	0.34
Total	2.4

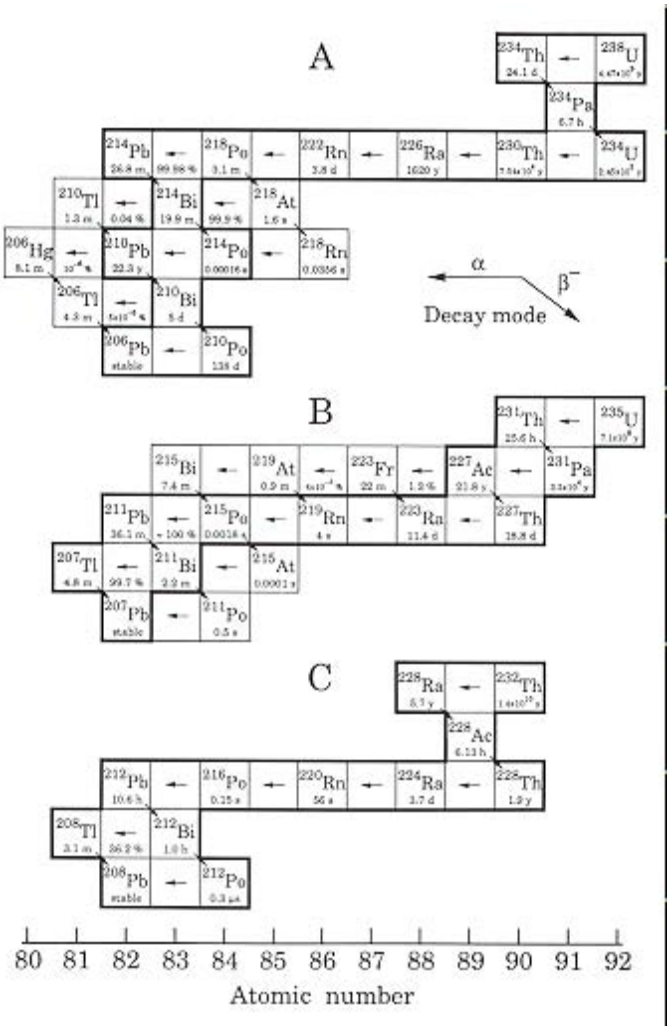

Fig. 3. The three, still-existing natural decay series. A. Uranium-238; B. Uranium-235; and C. Thorium-232 (modified from Holtzman 1969; LWV 1985; UNSCEAR 1988; Kiefer 1990; Rose et al. 1990). Principal decay products occur inside the heavy borders.

Table 5. Annual whole-body radiation doses to humans from various sources (Gray et al. 1989).

Source of radiation	Dose (mSv)
Natural external background	
Denver, Colorado	1.65
Washington State, mean	0.88
United States, average	0.84
Hanford, Washington	0.59
Average medical dose per capita, United States	0.36
Average internal dose from natural radioactivity, United States	0.25
Global weapons fallout	0.05
Consumer product radiation (TV, smoke detector, and other sources)	0.02
Total	1.27-2.33

The dose of natural radiation that an organism receives depends on height above sea level, amount and type of radionuclides in the soil of its neighborhood, and the amount taken up from air, water, and food (ICRP 1977; Whicker and Schultz 1982a; Hobbs and McClellan 1986; UNSCEAR 1988; Aarkrog 1990; Kiefer 1990; Nozaki 1991). Natural radiations in various ecosystems result in radiation dose equivalents that usually are between <0.005 and 2.07 mSv annually (Fig. 4). Radiation doses are substantially higher at atypically elevated local sites (Table 5), such as Denver, and sometimes exceed 17 mSv annually in mountainous regions of Brazil and the former Soviet Union (Whicker and Schultz 1982a).

Anthropogenic Radioactivity

Nuclear explosions and nuclear power production are the major sources of anthropogenic activity in the environment. But radionuclide use in medicine, industry, agriculture, education, production and transport, and disposal from these activities present opportunities for wastes to enter the environment (Whicker and Schultz 1982a; Table 6). Radiation was used as early as 1902 in the treatment of diseases such as an enlarged thymus, tinea capitis, acne, and cancers of childhood and adolescence (Bowden et al. 1990). The use of X-rays by physicians and dentists represents the largest source of annual dose equivalent of the U.S. population to artificial radiation: 0.78-1.01 mSv to bone marrow and 0.016 mSv to the upper GI tract; radiopharmaceuticals contribute an additional 0. 14 mSv or a yearly total mean dose of 0.94-1.17 mSv to bone marrow (Hobbs and McClellan 1986).

Table 6. Sources and applications of atomic energy (Joseph et al. 1971).

Source and output	Application
Nuclear reactor	Electric power (stationary or portable plants), desalination,
Steam, electricity	propulsion of submarines and surface ships
Heat, electricity, neutrons	Spacecraft and satellite power, spacecraft propulsion, research and special materials production
Nuclear explosives, kinetic energy	Military and civilian applications: large-scale earth moving, subsurface excavation, mineral extraction from underground
Encapsulated radioisotopes	Marine navigation aids, unmanned weather stations,
Electricity	spacecraft project power, artificial human organs
Beta and gamma radiation	Food preservation, polymerization, sterilization of medical supplies, thickness gauges
Radionuclides, beta and gamma radiation	Medical uses, tracers in scientific research, measures of manufacturing processes

Atmospheric testing of nuclear weapons is an important human source of environmental radiation (Hobbs and McClellan 1986; UNSCEAR 1988; Aarkrog 1990; Table 7). The first test explosion of a nuclear weapon took place in 1945. Atmospheric tests by the United States, the former Soviet Union, and the United Kingdom continued until they were banned in 1963. France and the People's Republic of China continued to conduct limited atmospheric tests, although no atmospheric nuclear explosions have taken place since 1980. Large nuclear explosions in the atmosphere carry most of the radioactive material into the stratosphere where it remains for 1 to 5 years, depending on the altitude and the latitude; fallout can occur years after an explosion injected material into the atmosphere. Smaller explosions carry the radioactive material only into the troposphere, and fallout occurs within days or weeks. Fallout was highest in the temperate regions and in the northern hemisphere where most of the testing was done. The most abundant radionuclides from atmospheric tests to date are $^{14}C > {}^{137}Cs > {}^{95}Zr > {}^{90}Sr > {}^{106}Ru > {}^{144}Ce > {}^{3}H$. Of the many radionuclides produced in nuclear and thermonuclear explosions, the primary contributors to human radiation exposure include ^{14}C, $^{89+90}Sr$, ^{95}Zr, ^{106}Ru, ^{131}I, ^{137}Cs, ^{141}Ce, and ^{144}Ce; isotopes of plutonium and americium--although present in quantity--are not significant contributors because of their low solubility. The primary dose from fallout radiation is through external gamma radiation, assimilation through the food chain, or beta radiation of the skin.

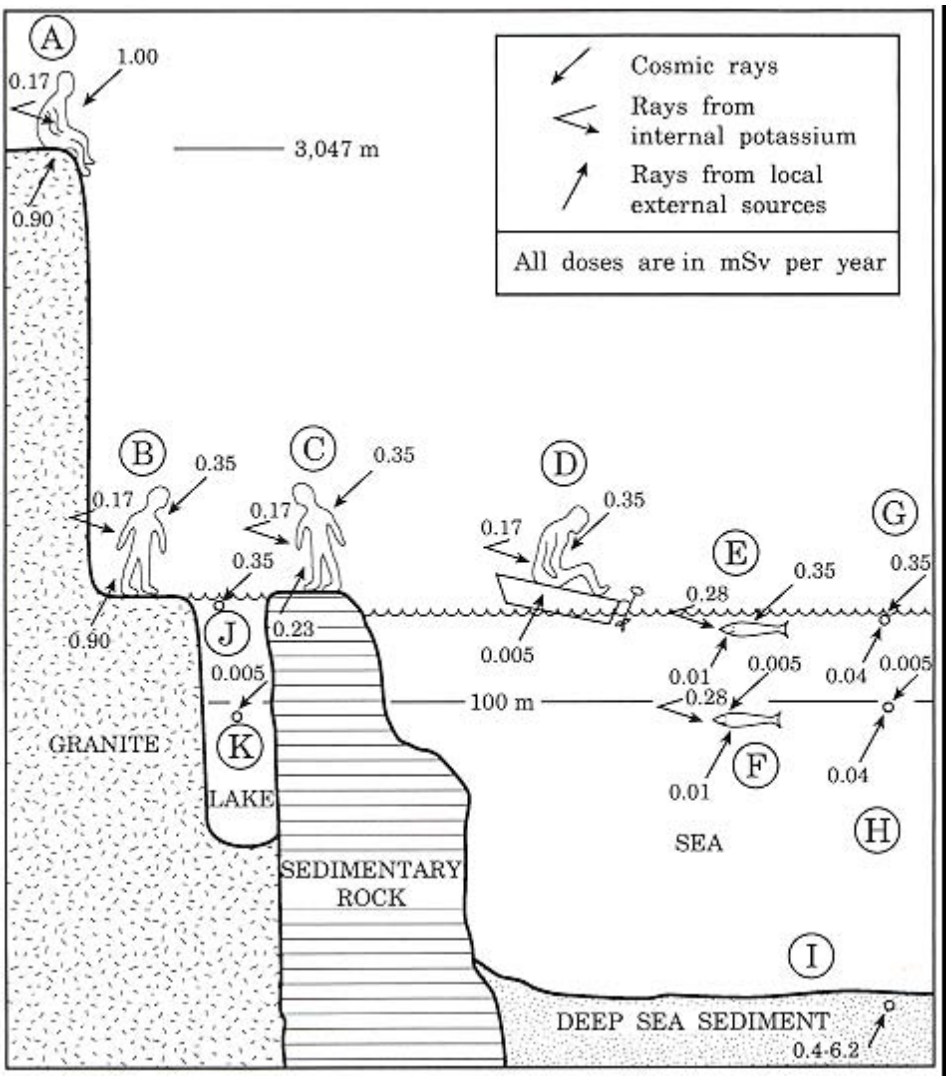

Fig. 4. Natural radiations in selected radiological domains (modified from Folsom and Harley 1957). A. Human over granite at 3,047 m (10,000 feet) elevation above sea level; total annual dose equivalent of 2.07 mSv (cosmic rays 1.00, granite 0.90, internal emitters 0.17); B. Human over granite at sea surface; total annual dose of 1.42 mSv; C. Human over sedimentary rock at sea level; total annual dose of 0.75 mSv; D. Human over sea; total annual dose of 0.525 mSv; E. Large fish in sea near surface; total annual dose of 0.64 mSv; F. Large fish in sea at depth of 100 m; total annual dose of 0.295 mSv; G. Microorganism in water near sea surface; total annual dose of 0.39 mSv, H. Microorganism in water >100 m deep in sea; total annual dose of 0.045 mSv; I. Microorganism buried in deep sea sediments; total annual dose between 0.4 and 6.2 mSv, J. Microorganism near freshwater surface; total annual dose of 0.35 mSv; K. Microorganism 100 m deep in a fresh-water lake; total annual dose of 0.005 mSv.

Radioisotope thermoelectric generators (RTG) are sometimes used as power sources for space systems. In April 1964, a United States RTG navigational satellite, SNAP 9A, reentered the atmosphere and burned up at high altitude over the Mozambique Channel, releasing 629 trillion becquerels (TBq), equivalent to 17,000 Ci of ^{238}Pu and 0.48 TBq of ^{239}Pu (Whicker and Schultz 1982a; Richmond 1989). In January 1978, a Soviet RTG satellite, Kosmos 954, reentered the atmosphere over Canada and spread radiouranium across parts of that country (Richmond 1989). The amount of radioactive materials in space applications is expected to increase (Richmond 1989).

Significant amounts of radioactivity are present in the Great Lakes basin, which has numerous nuclear reactors and uranium-mine waste areas (Joshi 1991). The prevailing low levels of artificially produced radionuclides, arising largely from previous fallout (Table 8), provide small doses of radiation to residents who consume lake water. Radionuclides enter the Great Lakes ecosystem from natural and anthropogenic processes. The main natural processes that introduce radioactivity are the weathering of rocks, which contain uranium-and thorium-series radionuclides, and fallout of cosmic ray-produced radionuclides such as ^{3}H, ^{7}Be, and ^{14}C. Anthropogenic radioactivity is created, for example, by uranium mining, milling, and fuel fabrication; releases of artificially produced radionuclides by nuclear power reactors and nuclear fuel processing plants; medical uses of radioisotopes; and coal-fired electrical generating plants (Joshi 1991).

Table 7. Annual effective dose equivalent from nuclear-weapons testing to humans in the north temperate zone (Aarkrog 1990).

Nuclide	Dose (mSv[a])
^{3}H	0.05
^{14}C	2.6
^{90}Sr	0.18
^{95}Zr	0.29
^{106}Ru	0.14
^{131}I	0.05
^{137}Cs	0.88
^{144}Ce	0.09
Pu and Am nuclides	0.09
Other nuclides	0.08
Total	4.45[b]

[a] External, 24%; inhalation, 5%; ingestion, 71%.

[b] Equivalent to 1.85 times the natural background dose.

Production of power from nuclear reactors involves uranium mining, fuel fabrication, the reactor operations, and storage of wastes. All of these processes may expose humans and the environment to radiation (Hobbs and McClellan 1986). Uranium production in the United States was 12,300 tons of U_3O_8 in 1977, primarily from western states, Texas, and Florida (Whicker and Schultz 1982a). Mining from deep shafts or open pits is the preferred method of uranium extraction, although in Florida it is produced as a byproduct of phosphate mining. Mines disperse radionuclides of uranium, thorium, and radium, which are associated with dust particles, and radon, which emanates from ore as a gas and decays to create a series of radioactive daughters. Groundwater also contains radionuclides of the uranium series. As many as 18 operating uranium mills were close to major mining centers in the western states. Collectively, these mills process or processed about 30,000 tons of ore daily and use acid or alkali leach methods to extract 90% to 95% of the uranium from ore. Uranium is barreled at the mill for shipment as uranium oxide or as salt concentrates (yellowcake) that contain 70-90% U_3O_8 by weight. Residues of the uranium extraction process are usually pumped as a slurry to liquid-retention impoundments; about 0.55 TBq of ^{230}Th and ^{226}Ra enter tailings each day from milling operations. Radium-226 produces gaseous ^{222} Rn; daughters of ^{222} Rn, such as ^{210}Pb, expose the surrounding biota to measurable radiation. Purification of yellowcake to UF_6 (uranium hexafluoride) and its enrichment to ^{235}U causes a loss of about 0.55 TBq annually. Nuclear reactor fuel contains about 3% ^{235}U. A nuclear explosion in a nuclear reactor is highly unlikely because the nuclear fuel that is suitable for weapons must contain more than

90% ^{235}U. Following enrichment, UF_6 is hydrolyzed to uranyl fluoride, converted to ammonium diuranate, and calcined to the dioxide UO_2. Uranium dioxide pellets at one time were prepared by as many as 10 commercial fuel fabrication plants and subsequently transported to nuclear reactors (Whicker and Schultz 1982a). In the current light-water cooled reactors the most abundant radionuclides in the reactor effluents under normal conditions are ^{3}H, ^{58}Co, ^{60}Co, ^{85}Kr, ^{85}Sr, ^{90}Sr, ^{130}I, ^{131}I, ^{131}Xe, ^{133}Xe, ^{134}Cs, ^{137}Cs, and ^{140}Ba (Hobbs and McClellan 1986). Gaseous and volatile radionuclides such as ^{85}Kr, ^{131}Xe, and ^{133}Xe contribute to the external gamma dose, whereas the others contribute to the dose externally by surface deposition and internally by way of the food chain. The mean dose from environmental releases of all radionuclides from nuclear reactors in the United States is less than 0.01 mSv/year (Hobbs and McClellan 1986). Nuclear fission follows the capture of a neutron by an atom of fissionable material such as ^{235}U or ^{239}Pu. The fission releases 1 to 3 neutrons and, if additional fissionable material is present in sufficient quantity and in the right configuration, a chain reaction occurs (Hobbs and McClellan 1986). Radionuclides formed per megaton of fission include fission products (^{89}Sr, ^{90}Sr, ^{95}Zr, ^{103}Ru, ^{106}Ru, ^{131}I, ^{137}Cs, ^{144}Ce), and activation products in air (^{3}H, ^{14}C, ^{39}Ar) and soil (^{24}Na, ^{32}P, ^{42}K ^{45}Ca, ^{55}Fe, ^{59}Fe; Whicker and Schultz 1982a). Fission-product radionuclides of potential biological importance include ^{90}Sr, ^{137}Cs, ^{131}I, ^{129}I, ^{144}Ce, ^{103}Ru, ^{106}Ru, ^{95}Zr, ^{140}Ba, ^{91}Y, ^{143}Ce, ^{147}Nd (Kahn 1971; Whicker and Schultz 1982a), and others (Table 9).

Table 8. Estimated fallout of ^{90}Sr and ^{137}Cs over the Great Lakes, 1954-83, in cumulative millions of Bq/km^2 (Joshi 1991).

Great Lake	Cesium-137	Strontium-90	**Total**
Superior	2,429	1,491	3,920
Michigan	2,738	1,680	4,418
Huron	2,670	1,638	4,308
Erie	2,859	1,754	4,613
Ontario	2,773	1,701	4,474
Total	13,469	8,264	21,733

Table 9. Fission products per kg ^{235}U reactor charge at 100 days cooling (modified from Renn 1957).

		Trillions of becquerels/kg^{235}U	
Product	Grams	Beta	Gamma
Short-lived[a]	15.93	7,217	6,002
Long-lived[b]	16.61	698	755
Inactive fission products	230.00	—	—
Total	262.54	8,045	6,757

a ^{90}Y, ^{106}Rh, ^{144}Ce, ^{95}Zr, ^{95}Nb, ^{91}Y, ^{89}Sr, ^{103}Ru, ^{141}Ce, ^{137}Ba, ^{106}Ru, ^{143}Pr, ^{140}Ba, ^{140}La, ^{131}I.

b ^{137}Cs, ^{90}Sr, ^{144}Pr, ^{129}Te.

Most of the world's supply of uranium consists of about 0.7% ^{235}U and 99% ^{238}U. In theory, about 2.27 kg of ^{235}U can release energy equivalent to 20,000 tons of TNT (Hobbs and McClellan 1986). Uranium-238 and ^{232}Th can be converted into fissionable material after neutron capture. Radionuclides of biological significance that are produced by neutron activation in nuclear reactors include ^{3}H, ^{14}C, ^{24}Na, ^{32}P, ^{35}S, ^{45}Ca, ^{54}Mn, ^{55}Fe, $^{57+58+60}Co$, ^{65}Zn, ^{239}Pu, ^{239}Np, ^{241}Am, and ^{242}Cm (Whicker and Schultz 1982a). Nuclear energy can also be released by fusion of smaller nuclei into larger nuclei that is accompanied by a decrease in mass

(Hobbs and McClellan 1986). Fusion reactors—which do not yet exist—require very high temperatures of several million degrees; no fission products are produced in the fusion process (Whicker and Schultz 1982a).

[c] Effluent composition primarily ^{106}Ru and ^{125}Sb.

Radioactive wastes are currently stored in underground tanks or in temporary storage at reactor sites for recycling or disposal (Whicker and Schultz 1982a). For low level wastes, containment and isolation are the preferred disposal options, including burial, hydraulic injection into deep geological strata, and ocean disposal (Table 10). Options for the disposal of high-level wastes include retrievable surface storage and entombment in deep geological strata; many risks are associated with these options, and more suitable alternative disposals are needed. Spent nuclear fuel elements are usually stored for about 3 months to allow the decay of shorter-lived radionuclides before reprocessing or disposal. Reprocessing involves extractions to separate uranium and plutonium from the fission products into UF_6 and plutonium dioxide. Longer-lived fission products such as ^{90}Sr and ^{137}Cs are sometimes chemically separated and encapsulated for storage or disposal. Fuel reprocessing tends to release measurable quantities of various radionuclides that are detected in fishes, wildlife, and food for humans (Whicker and Schultz 1982a). Liquid discharges from the Sellafield reprocessing plant (Table 10) have been reduced by a factor of more than 100 since the mid-1970's (Aarkrog 1990). Human populations that consume higher than average quantities of marine fish and shellfish from the Sellafield area theoretically receive about 3.5 mSv annually from radioactivity associated with nuclear power production. Human populations in the vicinity of nuclear-power production with discharges directly into the marine environment--except Sellafield--generally receive less than 0.05 mSv annually from this source (Aarkrog 1990).

Radioactive transuranic elements with atomic numbers that are greater than 92 have been introduced into the environment since the 1940's from atmospheric testing of nuclear weapons, discharges of nuclear wastes, and nuclear fuel reprocessing (Noshkin et al. 1971; Hetherington et al. 1976; Sibley and Stohr 1990; Morse and Choppin 1991). Transuranic isotopes with half-lives of more than 10,000 years (i.e., ^{247}Cm, ^{248}Cm, ^{239}Pu, ^{242}Pu, ^{244}Pu, ^{237}Np) will persist over geologically significant time periods. Transuranics at detectable but considered nonhazardous levels to biota are now widely dispersed throughout the environment in most waters, soils, sediments, and living organisms including humans. Of current primary concern are ^{244}Cm, ^{241}Am, $^{238+239+240+241}Pu$, and ^{237}Np—especially americium-241, which is increasing globally as a result of ^{242}Pu decay (Sibley and Stohr 1990; Morse and Choppin 1991). However, the estimated peak dose received from Pu and Am radioisotopes seems to be decreasing in the vicinity of the Sellafield nuclear-fuel reprocessor (Table 11). Miscellaneous exposures include radiations from television sets, luminous dial watches, smoke detectors, electron microscopes, building materials, and air travel (Hobbs and McClellan 1986). Most of the exposure in building materials is due to naturally occurring radionuclides; similarly, air travel increases radiation exposure of travellers from increased exposure to cosmic radiations. Dose equivalent rates can be as much as 3 times higher for cigarette smokers than for nonsmokers because of inhalation of ^{210}Po and ^{210}Pb from the cigarette. Some of the lung dose is also received from radionuclides that are released during combustion of fossil fuels, which contain small quantities of naturally occurring radionuclides (Hobbs and McClellan 1986).

Dispersion

Radioactive materials are cycled throughout the environment by a variety of physical, chemical, and biological vectors. Dispersion through the atmosphere is governed by the magnitude, frequency, and direction of the wind; in the hydrosphere, transport is modified by water depth, motion, temperature, winds, tides, and groundwater (Whicker and Schultz 1982b). Deposition from the atmosphere is a function of particle size, precipitation, and dry deposition. Small radioactive particles may be elevated into the airstream from the ground surface; resuspension is a function of disturbances by wind at the soil surface, atmospheric variables (i.e., velocity, turbulence, density, viscosity), and soil-ground variables such as texture, cohesiveness, moisture content, density, vegetation cover, ground surface roughness, and topography (Whicker and Schultz 1982b). Only 1 kg of the original 15 kg of Pu was fissioned from the dropping of the plutonium nuclear bomb on Nagasaki, Japan, on 9 August 1945 (Kudo et al. 1991). The remaining 14 kg of Pu escaped into the environment. Local fallout accounted for about 37 g or 0.26% of the total global fallout; the highest measured $^{239+240}Pu$ concentration was 64 Bq/kg soil about 2.8 km from ground zero (Kudo et al. 1991).

Table 11. Theoretical peak dose, in microsieverts per year, received from plutonium and americium by three human populations (McKay and Pattenden 1990).

	Year		
Population	1973	1987	2000
Average person near Sellafield nuclear fuel reprocessor	24	4	2
Critical group, mainly agricultural workers	35	20	16
Heavy consumers of Irish Sea fish and shellfish in local fishing communities	—	250	55-90

Biological agents can also transport radioactive wastes. Birds, especially waterfowl, disperse accumulated radiocesium and other radionuclides along their migratory flyways (Brisbin 1991). Native mammalian herbivores and their predators that have come in contact with radioactivity in food or soils disperse the material in their feces, urine, or regurgitated pellets (O'Farrell and Gilbert 1975). For example, the black-tailed jackrabbit (*Lepus californicus*) in the vicinity of radioactive waste-disposal trenches dispersed radioactive fecal pellets over an area of 15 km^2; elevated radioactivity readings were recorded in jackrabbits and in their predators, including feces of coyotes (*Canis latrans*) and bones of hawks (O'Farrell and Gilbert 1975).

Biological transport of trace elements and radionuclides in the sea is provided mainly by phytoplankton and zooplankton because of their (1) ability to accumulate these elements to high levels, (2) diurnal vertical migration, and (3) production of detritus in the form of fecal pellets, molts, and carcasses (Lowman et al. 1971). Considerations related to biomass, feeding rates, conversion efficiencies, migratory habits of zooplankton, and the chemical properties of trace elements suggest that the major downward transport of these elements and radionuclides is through gravitational action on fecal pellets, molts, and carcasses; direct biological transport accounts for less than 10% of the total downward movement. In estuarine and near-shore regions, the bottom sediments and their associated epiphyton often significantly influence the distribution of added radionuclides. Large populations of sessile filter feeders may drastically increase the rate of sedimentation of added trace elements and radionuclides (Table 12).

In some coastal areas, some of the radionuclides that are discharged into coastal waters from industrial establishments are recycled by the air-sea interface back onto land (McKay and Pattenden 1990). At the sea surface, aerosol is generated by bubble bursting and wave shearing. The aerosol is advected to land by onshore winds and deposited in coastal regions. Sea-to-land transfer has been documented from the vicinity of nuclear-fuel reprocessing facilities in England, Scotland, and France; however, the sea-to-land transfer pathway was only about 8% of that from the seafood pathway (McKay and Pattenden 1990). The solubility of different radionuclides at the sediment-seawater interface is variable. Plutonium solubility, for example, depends on pH, Eh, ionic strength, complexing ions, organic chelators, living accumulator organisms, and oxidation state (Mo and Lowman 1976). The oceanic distributions of many nuclides are strongly controlled by interactions with particulate matter (Nozaki 1991). Thorium is an extreme case; the high reactivity of this element accounts for its residence of only a few decades in the ocean from where it is removed largely by vertical transport in association with settling particulate matter. Lead-210 and ^{231}Pa are also particle-reactive but to a lesser extent than Th. Their oceanic mean residence time is about 100 years. The mean oceanic residence time of ^{227}Ac and Ra isotopes is about 1,000 years because of particulate scavenging; these nuclides are supplied by insoluble parents in underlying sediments and are released to overlying waters by porewater diffusion. Radium-228 can serve as a novel tracer in ocean circulation for about 30 years; ^{227}Ac can be used for about 100 years. The distribution of ^{226}Ra is largely governed by biogeochemical cycling, much like dissolved silica (Nozaki 1991).

Table 12. Time required to transport selected radionuclides added into marine waters at surface from the upper mixed layer by biological transport. Processes include diurnal vertical migration, fecal pellets, and sinking of dead matter (Lowman et al. 1971).

	Time required to transport radionuclides (in years)		
Radionuclide	Eastern North Pacific	Coastal areas	Upwelling areas
^{54}Mn	74	7	3
$^{55+59}Fe$	7.2	0.7	0.3
$^{57+58+60}Co$	220	20	8.8
^{65}Zn	12	1.1	0.5
^{95}Zr	5.4	0.5	0.2
^{210}Pb	7.3	0.7	0.3

Radionuclide Concentrations in Field Collections

General

The wide dispersion of anthropogenic radiocontaminants has significantly altered natural background levels of radioactivity in many parts of the globe. Radionuclide concentrations in selected abiotic materials and living organisms were usually elevated in samples from the vicinity of human nuclear activities, especially atmospheric military tests. Radionuclide concentrations in organisms were significantly modified by age, sex, diet, metabolism, trophic level, proximity to point source, and many other biological, chemical, and physical variables,

as discussed later. Additional and more detailed data on environmental radionuclide concentrations and isotopic composition and levels of radioactive wastes discharged into the biosphere from nuclear plants and other anthropogenic activities are given in Schultz and Klement (1963), Nelson and Evans (1969), Nelson (1971), IAEA (1976), Whicker and Schultz (1982a, 1982b), and UNSCEAR (1988).

Abiotic Materials

Radionuclide concentrations in selected nonliving materials (Table 13) show that concentrations are elevated in samples from the site of repeated nuclear detonations, near nuclear-fuel reprocessing and waste facilities, and from locations that receive radioactive fallout from atmospheric military tests. Rocks, especially granite, had high levels of naturally occurring radionuclides such as ^{40}K. Concentrations were usually low or negligible in drinking water and in cow's milk for human consumption. Nuclear-weapons testing has released large amounts of radionuclides into the environment. Between 1961 and 1966, for example, the Republic of Korea received fallout from nuclear tests by the former Soviet Union in 1961 and by the United States in 1962 and from 3 explosions by the People's Republic of China (Bai 1969). The highest levels of total combined β and activity in various Korean samples during 1962-64, in Bq/L or Bq/kg, were 0.0002 in air, 133 in water, 1,572 in milk, 2,023 in rain, 16,428 in plants, and 99,345 in soils (Bai 1969).

Table 13. Radionuclide concentrations in field collections of selected materials. Concentrations are in becquerels per kilogram fresh weight (FW) or dry weight (DW).

Table 13 Material, radionuclide, and other variables	Concentration (in Bq/kg or Bq/L)	Reference [a]
Common rock types		
Shale, limestone, sandstone, basalt

[b] — = no data.

[c] ND = not detectable.

Water in the Great Lakes in 1981 contained measurable concentrations of ^{137}Cs, ^{3}H, and ^{90}Sr and detectable but extremely low concentrations of ^{241}Am, ^{113m}Cd, ^{144}Ce, ^{210}Pb, $^{239+240}Pu$, ^{226}Ra, ^{125}Sb, and ^{228}Th (Joshi 1991). Radiocesium-137 in water from the Hudson River estuary, New York, decreased tenfold between 1964 and 1970, but the ^{137}Cs content in fishes and in sediments remained relatively constant (Wrenn et al. 1971). The effluent from the United Kingdom's Atomic Energy Agency Sellafield facility on the Cumberland Coast of the Irish Sea contained ^{90}Sr and ^{137}Cs, which are soluble in seawater and tend to remain in solution, and ^{106}Ru, ^{144}Ce, and $^{95}Zr/^{95}Nb$, which are relatively insoluble in seawater and coprecipitate or adsorb on free inorganic and organic surfaces (Pentreath et al. 1971).

Soils in the vicinity of an English nuclear-fuel reprocessing facility in 1979-85 contained as much as 42 times more ^{241}Am, 12 times more ^{137}Cs, 13 times more ^{90}Sr, and 87 times more $^{239+240}Pu$ than soils from a reference site (Curtis et al. 1991). In the United States, radiological trends in abiotic materials were difficult to interpret. For example, one nationwide monitoring program for radionuclide concentrations in air, drinking water, milk, groundwater, and precipitation (Table 13) was not consistent in the selection of measured radionuclides, frequency of sampling, and types of analyzed samples.

Aquatic Ecosystems

Field studies indicated that effects of radiation on marine ecosystems cannot be demonstrated at prevailing dose rates (Templeton et al. 1971).Two major periods of worldwide fallout occurred in Arctic ecosystems. The first and most sustained occurred during 1953-59 and the second during 1961-64, reflecting the atmospheric nuclear-weapons test regimes of Great Britain, the former Soviet Union, and the United States (Hanson 1976). Military accidents created localized radiocontamination of the Arctic environment. In one case, a B-52 aircraft from the U.S. Air Force crashed on the ice in northwestern Greenland in January 1968. Plutonium from the nuclear weapons on board contaminated the benthos (Fig. 5). The $^{239+240}Pu$ concentrations in various environmental samples declined at a much faster rate than the physical half-life of ^{239}Pu (24,000 years), suggesting that Pu becomes increasingly unavailable to the benthos over time as a result of dispersion from the epicenter and a dilution effect (Aarkrog 1990).

In marine environments, the major portion of the background dose rate in plankton and fishes arises from the incorporated activity of natural alpha emitters, such as ^{210}Po , and from ^{40}K; in molluscs, crustaceans, and benthos, the gamma radiation from the seabed provides the major background dose (IAEA 1976). The situation is similar in freshwater environments, although water that contains appreciable levels of ^{222}Rn and its daughter radionuclides may exert an additional burden, especially to phytoplankton. Artificial radionucludes that contribute significantly to background concentrations of marine organisms include ^{239}Pu and ^{90}Sr; of freshwater organisms, ^{137}Cs and ^{90}Sr (IAEA 1976). The total natural radiation received by a marine flounder (*Pleuronectes platessa*) in the Irish Sea consisted of 63% from radiations from seabed sediments, 16% from ^{40}K in seawater, 15% from internal ^{40}K and 6% from cosmic radiation (Templeton et al. 1971). The estimated dose rates in aquatic environments from natural background are as high as 3.5 mGy annually and of the same order as those in most terrestrial environments. By 1976, the estimated dose rates from global fallout had declined to the same range as natural dose rates, although environments that receive radioactive wastes had variable responses (IAEA 1976).

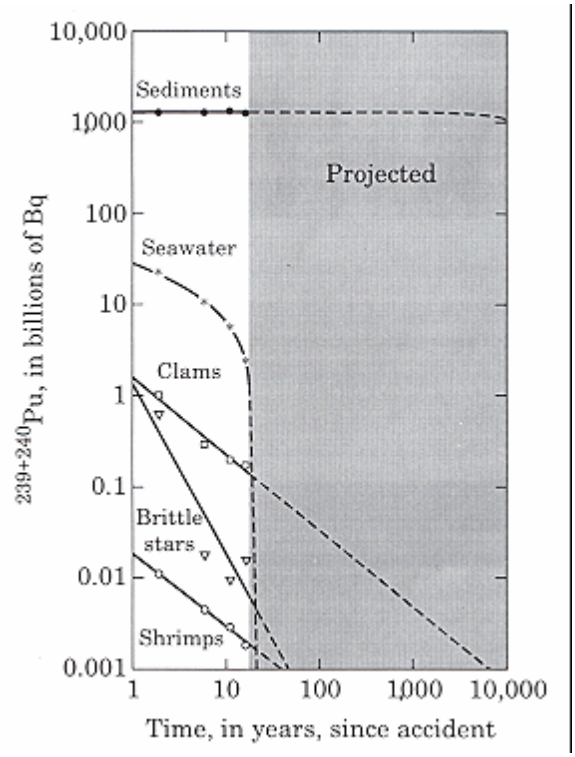

Fig. 5. Plutonium-239 + 240 in environmental samples at Thule, Greenland, between 1970 and 1984, after a military accident in 1968 (modified from Aarkrog 1990). In the contaminated area of 3.2 x 10^9 m^2, the fresh

weight biomass of shrimps was 0.11 x 10^9 kg, of brittle star echinoderms 0.06 x 10^9 kg, and of clam (*Macoma balthica*) soft parts 0.32 x 10^9 kg. The seawater mass was 3 x 10^{14} kg, and the dry weight of the upper 15 cm sediment layer was 3 x 10^{11} kg.

Increasing levels of ^{137}Cs in fish muscles in Minnesota between 1954 and 1966 reflect fallout from atmospheric nuclear testing. The effective half-life of ^{137}Cs in these lakes, as judged from small fishes, is about 30 months (Gustafson 1969). In game fish from Colorado, ^{137}Cs in muscle was as much as 7 times higher in 1968 than in 1965; higher in fishes in mountain lakes than in fishes from reservoirs in the plains, foothills, lakes, and rivers; and highest in trout from alpine lakes and reservoirs (Nelson and Whicker 1969). In 1966, ^{137}Cs levels in trout from Colorado alpine lakes were 8 to 18 times higher than mean levels in muscle of deer from Colorado during the same period and 20 to 300 times higher than in domestic meat products (Nelson and Whicker 1969). Radionuclides in livers of tunas from southern California during 1964-70 originated mainly from weapons tests in 1961-62, although ^{65}Zn may have reached southern California waters from nuclear reactors in Hanford (Washington) and from French or Chinese nuclear tests (Folsom et al. 1971).

Many variables modify radionuclide concentrations in biota. In general, lower trophic levels of aquatic organisms usually have greater concentrations of radionuclides than higher trophic levels (Bowen et al. 1971). However, radionuclide concentrations in biota are modified significantly by the organism's age, size, sex, tissue, season of collection, and other variables--and these have to be acknowledged when integrating radiological analyses. For example, older *Fucus vesiculosus* had higher radioactivity concentrations than younger algae; concentrations of ^{60}Co and ^{54}Mn were highest in older parts of plants during spring and summer; and ^{137}Cs and ^{40}K were highest in receptacles and new vegetative fronds (Carlson and Erlandsson 1991). Changes in concentrations of ^{60}Co and ^{137}Cs in freshwater plankton from the discharge canal of an Italian nuclear power station seem to reflect changes in water concentrations of these isotopes; changes were lowest in winter and highest in summer (Smedile and Queirazza 1976). Marine bivalve molluscs and algae from Connecticut in 1960 and 1961 had the highest levels of gross beta radioactivity in spring and summer and the lowest in winter (Table 14; Hatfield et al. 1963); natural ^{40}K probably accounted for most of the beta radioactivity. Similar seasonal variations in gross beta radioactivity in other species of marine algae and molluscs were documented, suggesting a correspondence with periods of dormancy and activity (Hatfield et al. 1963). Although fat in the livers of crabs accounted for 47% of the fresh weight (74% on a dry weight basis), the gross beta activity of the fat fraction amounted to less than 0.5% of the total radioactivity, suggesting that radiological liver analyses be conducted on the basis of nonfat solids (Chakravarti and Eisler 1961). In some locations of a ^{137}Cs-contaminated reservoir, males of the mosquitofish (*Gambusia holbrooki*) contained higher ^{137}Cs concentrations than females and smaller females contained more ^{137}Cs than larger females (Newman and Brisbin 1990). Strontium-90 concentrations in the carapace bone of turtles from 5 southwestern states in 1970 were used as indicators of ^{90}Sr fallout. However, older turtles tended to have lower concentrations of ^{90}Sr, and concentrations differed geographically; concentrations were highest in Georgia and increasingly lower in Tennessee, Mississippi, Arkansas, and Florida (Table 14; Holcomb et al. 1971).

Table 14. Radionuclide concentrations in field collections of selected living organisms. Concentrations are in becquerels per kilogram fresh weight (FW), dry weight (DW), or ash weight (AW).

Table 14. Ecosystem, organism, radionuclide, and other variables	Concentration (in Bq/kg[a])	Reference[b]
Terrestrial plants		
Sweet potato, *Ipomoea batatas*, Nagasaki, Japan, 1945, postatomic detonation		
^{137}Cs	0.09 DW	1
$^{239+240}Pu$	0.01 DW	1
Lichens, various species, Alaska and Greenland

[c]ND = non detectable.

Consumption of shellfish represents a negligible radiological risk to humans (Crowley et al. 1990), although bivalve molluscs seem to be effective accumulators of radioisotopes. After the Chinese nuclear tests in May and December 1966, concentrations of ^{144}Ce, ^{103}Ru, ^{95}Zr, ^{95}Nb, ^{140}Ba, and ^{140}La in three species of bivalves in the Neuse River, North Carolina, increased suddenly (Wolfe and Schelske 1969). In 1973, Pacific oysters (*Crassostrea gigas*) from the discharge canal of a nuclear power plant in Humboldt Bay, California, rapidly accumulated ^{54}Mn, ^{60}Co, ^{65}Zn, and ^{137}Cs within 30 min of release. Isotope uptake correlated positively with particulates in the water, including living microorganisms, organic detritus, inorganic materials, and especially resuspended bottom sediments (Harrison et al. 1976). Although concentrations of cesium and plutonium in mussels (*Mytilus edulis*) from most Irish estuaries are essentially the same as global fallout levels, concentrations were elevated in mussels from the northeast coast (Crowley et al. 1990).

Birds

Television and newspaper reporters attributed radionuclides to a decline in bird numbers at the Ravenglass estuary, England, particularly of the common black-headed gull (*Larus ridibundus*), although the concentrations of radionuclides in the avian diet, body tissues, and general environment were at least 1,000 times too low to have had any effect (Table 14; Lowe 1991). Although Eurasian oystercatchers (*Haematopus ostralegus*) and shelducks (*Tadorna tadorna*) had the highest concentrations of ^{137}Cs in their tissues, the breeding success and population sizes of these birds were not affected. Black-headed gulls had less radiocontamination than other

birds at Ravenglass, but their population continued to decline. The most probable cause was a combination of an uncontrolled fox population, a severe outbreak of myomatosis in rabbits (normal fox prey), and a drought--all in the same year (Lowe 1991). Nesting success of birds was unaffected in the vicinity of nuclear power plants. For example, nesting barn swallows (*Hirundo rustica*) near radioactive leaching ponds had normal nesting success despite their consumption of arthropods from the pond and use of contaminated mud for nest construction (Millard and Whicker 1990; Table 14). Adult swallows received a total internal dose rate of 219 uGy/day, mostly (72%) from ^{24}Na; daily dose rates to eggs and nestlings during the nesting season were 840 uGy and 2,200 uGy. The total dose to eggs and nestlings (54 mGy) and adults (450 mGy) had no measurable effect on survival and was below accumulated doses reported to cause death of passerines (Millard and Whicker 1990).

Strontium-90 behaves much like calcium in the biological environment. In birds, ^{90}Sr is expected to occur in bone and in the calcium-rich eggshell. In one case, a positive relation was demonstrated between reactor releases of ^{90}Sr to the Columbia River and ^{90}Sr concentrations in reed canary grass (*Phalaris arundinacea*) and eggshells of the Canada goose (*Branta canadensis moffitti*; Rickard and Price 1990).

No human health problem is anticipated from consumption of ruffed grouse (*Bonasa umbellus*) that are contaminated with ^{226}Ra in Canada or of American coots (*Fulica americana*) contaminated with ^{137}Cs in Washington state. Tissues of ruffed grouse that were collected near discharged uranium tailings in Canada in 1987-88 did not contain grossly elevated levels of ^{226}Ra over controls; consumption of grouse by humans did not present a radiological health problem (Clulow et al. 1992). Based on ^{137}Cs alone, humans who consume a single contaminated American coot captured at Hanford, Washington, would receive about 1.1% of the annual radiation protection dose of 1.70 mSv by individuals and populations in uncontrolled areas (Cadwell et al. 1979).

Mammals

Diets in Denmark contained elevated loadings of ^{137}Cs in 1964 because of the intensive atmospheric nuclear-test series by the United States and the former Soviet Union in 1961 and 1962. Total ^{137}Cs intake declined in the Danish population from 72 Bq/kg BW in 1964 to less than 2 in 1985 but rose to about 13 in 1986 from the effects of debris from Chernobyl on dietary ^{137}Cs during the first year after the accident (Aarkrog 1990). The estimated dose equivalent from ^{137}Cs to human consumers of fish from the Great Lakes is about 0.01 uSv/kg fresh weight (FW) muscle of fish from Lakes Erie and Ontario and 0.06-0.07 uSv/kg from fish in Lakes Superior and Huron (Joshi 1991). The guide for the protection of the general public from radiation is less than 5 mSv annually, and consumption of fish that contains a dose equivalent greater than 0.02 uSv/kg fish flesh is not recommended (Joshi 1991). Some Scandinavians now receive a dose equivalent of about 5 mSv/year from intake of radiocesium in the diet (Johanson 1990). In Finland, uptake of radionuclides by humans in Finnish Lapland and in other areas with an arctic climate is attributed to ecological factors and to a high amount of local fallout. For example, reindeer-herding Finnish Lapps contained about 50 times more ^{137}Cs and 10 times more ^{55}Fe than other Finns during 1961-67. For ^{137}Cs, this disparity is attributed mainly to the reliance by Finns on reindeer meat--which contains high levels of ^{137}Cs as a result of reindeer feeding on lichens--and secondarily, on freshwater fish and cow's milk (Miettinen 1969).

In the United States, the estimated annual whole body human radiation dose equivalent is 1.61 mSv, mostly from natural sources (0.85 mSv) and medical sources (0.70 mSv) but also from fallout (0.03 mSv), miscellaneous sources (0.02 mSv), occupational hazards (0.008 mSv), and nuclear power (0.0001 mSv; League of Women Voters [LWV] 1985). Radiation doses to people who live near the Hanford nuclear industrial and research site in the state of Washington are well below existing regulatory standards. Only trace amounts of radionuclides from Hanford have been detected in the offsite environment (Gray et al. 1989). In December 1984, radon levels as much as 130 times greater than considered safe under the current guideline for underground uranium miners were discovered in human residences in eastern Pennsylvania, New Jersey, and New York. About 25% of all residences in 10 states exceeded the action level for radon of 0.185 Bq/L air (Cross 1990; Oge and Dickson 1990). The significance of this observation to avian and terrestrial wildlife merits investigation.

As a result of nuclear weapons testing, mandibles of Columbian black-tailed deer (*Odocoileus hemionus columbianus*) from California increased from less than 9 Bq ^{90}Sr/kg ash weight (AW) to more than 204 Bq/kg AW between 1952 and 1960 (Table 14; Schultz and Longhurst 1963). Age and season affected strontium kinetics in male mule deer (*Odocoileus hemionus hemionus*) during the period of antler growth; these variables did not affect strontium kinetics in females (Schreckhise and Whicker 1976). The concentrations of ^{90}Sr in forage of mule deer were higher in summer than in winter and the differences were of sufficient magnitude to account for the ^{90}Sr variations in mule deer antlers (Farris et al. 1969); ^{137}Cs concentrations were similar in the forage and flesh of the white-tailed deer (*Odocoileus virginicanus*; Cummings et al. 1971). Levels of iodine-129 in thyroids of mule deer and pronghorns (*Antilocapra americana*) increased with proximity to nuclear-fuel reprocessing plants in Colorado, Idaho, New Mexico, and Wyoming during 1972-76, although levels were considered of no consequence to the health of the animals (Markham et al. 1983).

Radium-226, a bone-seeking α-emitter with a half-life of 1,600 years, may cause tissue damage and possibly subsequent osteosarcoma. Elevated ^{226}Ra concentrations have been reported in tissues of the beaver (*Castor canadensis*) from the Serpent River watershed, Canada, the recipient of uranium tailings during 1984-87 (Table 14). Measurable levels of ^{226}Ra were also found in feces of snowshoe hares (*Lepus americanus*) from this area and in black cutworms (*Agrotis ipsilon*) eaten by herring gulls (*Larus argentatus*) on the tailings (Clulow et al. 1991). Maximum levels in tissues of beavers from this watershed were less than 5 Bq ^{232}Th/kg dry weight (DW) in all tissues, 15 Bq ^{228}Th/kg DW bone, less than 5 Bq ^{228}Th/kg DW muscle and liver, 70-160 Bq ^{210}Po/kg DW bone, 11-75 Bq ^{210}Po/kg DW muscle, and 35-65 Bq ^{210}Po/kg DW liver. Consumption of these beavers would not be hazardous to human health. In the worst case, humans who consume substantial (71 kg) amounts of flesh of beavers from the Serpent River drainage system would receive less than 10% of the annual limits set by Canadian regulatory authorities (Clulow et al. 1991).

Cesium-137 levels in gray seals (*Halichoerus grypus*) in 1987 seem to reflect ^{137}Cs levels in their fish diet, but there is no biomagnification of ^{137}Cs and other radionuclides. An estimated 29% of the ^{137}Cs in the diets of gray seals is from the Chernobyl accident and 71% from the nuclear facility at Sellafield, United Kingdom. The dose to gray seals from their diet is about 36 mSv annually and higher than the permissible dose limit of 5 mSv/year allowed the general public but below the current limit for radiation workers of 50 mSv/year (S.S. Anderson et al. 1990).

The weekly dose rates from internal radionuclides were markedly different in muskrats (*Ondatra zibethicus*) and cotton rats (*Sigmodon hispidus*) collected at Oak Ridge, Tennessee, in August 1960 (20-1,112 mSv in muskrats vs. 3 mSv in cotton rats); the difference is probably due to differences in diets and habitats (Kaye and Dunaway 1963). Foxes and wildcats contain 2 to 16 times more ^{137}Cs than their prey organisms such as rats and rabbits (Jenkins et al. 1969), suggesting food-chain magnification. The biological half-life of ^{137}Cs is about 30 days in foxes, dogs, and pigs but about 60 days in humans (Jenkins et al. 1969). Black-tailed jackrabbits (*Lepus californicus*) in 1958, 1 year after contamination at the Nevada test site, averaged 1,908 Bq ^{90}Sr/kg AW bone within a 160-km radius from ground zero; in 1961, the average in the same population was only 984 Bq ^{90}Sr/kg AW bone, and the few higher values were restricted to older animals (Neel and Larson 1963). The authors concluded that ^{90}Sr from fallout in jackrabbits is at its maximum at an early time after contamination and that biological availability is later reduced by natural (unspecified) mechanisms. Jackrabbits at the Nevada test site also contained certain neutron activation products, including isotopes of Co, Mn, and W (Romney et al. 1971).

Radionuclide concentrations in sheep and cattle that grazed near a nuclear-fuel reprocessing facility amounted to a small fraction of the recommended limits. Americium-241, ^{137}Cs, and $^{239+240}$Pu in bone, liver, lung, and muscle of beef cattle from the vicinity of a nuclear-fuel reprocessing facility in England were quite low between September and December 1986 and practically indistinguishable from control samples. Maximum concentrations, in Bq/kg FW, were 0.0015 $^{239+240}$Pu in lung, 0.019 ^{241}Am in liver, and 3.1 ^{137}Cs in muscle (Curtis et al. 1991). Levels of ^{129}I were elevated in thyroids of cows near Mol, Belgium, in 1978 in the vicinity of a nuclear reprocessing plant closed in 1974 (Table 14; Handl et al. 1990).

Case Histories

Military weapons tests on the Pacific Proving Grounds in the 1940's and 1950's greatly elevated local concentrations of radionuclides, and an accident at the Chernobyl nuclear power plant in the former Soviet Union in 1986 dispersed comparatively low concentrations of radionuclides over a wide geographical area. Both cases are briefly reviewed.

Pacific Proving Grounds

The first artificial, large-scale introduction of radionuclides into a marine environment was at Bikini Atoll in 1946. In succeeding years through 1958, Bikini and Eniwetok became the Pacific Proving Grounds where 59 nuclear and thermonuclear devices were detonated between 1946 and 1958 (Welander 1969; Templeton et al. 1971; Bair et al. 1979; Table 15). Gross radiation injury to marine organisms has not been documented, possibly because seriously injured individuals do not survive and the more subtle injuries are difficult to detect. On land, the roof rat (*Rattus rattus*) survived heavy initial radiation by remaining in deep burrows. Terrestrial vegetation was heavily damaged by heat and blast but generated regrowth in 6 months. The land-dwelling hermit crab (*Coenobita* sp.) and coconut crab (*Birgus latro*) were subjected to higher levels of chronic radiation from internally deposited radionuclides than any other studied Atoll organism; levels remained constant in *Coenobita* at 166,000 Bq of ^{90}Sr/kg skeleton and 16,835 Bq ^{137}Cs/kg muscle for 2 years; *Birgus* contained 25,900 Bq ^{90}Sr/kg skeleton and 3,700 Bq ^{137}Cs/kg muscle for 10 years (Templeton et al. 1971). A survey in August 1964 at Eniwetok and Bikini Atolls (Welander 1969; Table 15) showed that general levels of radioactivity were comparatively elevated and highest in soils and increasingly lower in aquatic invertebrates, groundwater, shorebirds, plants, rats, zooplankton, algae, fishes, sediments, seawater, and seabirds. Cobalt-60 was in all samples of animals, plants, water, sediments, and soils and was the major radionuclide in the marine environment; on land, cesium-137 and ^{90}Sr predominated. All samples contained traces of ^{54}Mn; ^{106}Ru and ^{125}Sb were in groundwater, and soil and trace concentrations were in animals and plants. Trace amounts of ^{207}Bi and ^{144}Ce were usually detected in algae, soils, and land plants. Iron-55 was comparatively high in vertebrates, and ^{239}Pu was found in the soil and in the skin of rats and birds (Welander 1969).

Table 15. Radionuclide concentrations in selected samples from the Pacific Proving Ground. Concentrations are in becquerels/kg fresh weight (FW) or dry weight (DW).

Table 15 Location, sample, radionuclide, and other variables	Concentration, in Bq/kg or Bq/L	Reference[a]
Bikini Atoll		
Samples with highest concentrations, August 1964

Chernobyl

General

Several accidents in nuclear facilities have been extensively analyzed and reported. The three most widely publicized accidents were at Windscale (now known as Sellafield), United Kingdom, in 1957; Three Mile Island, Pennsylvania, in 1979; and Chernobyl, Ukraine, in 1986 (UNSCEAR 1988; Severa and Bar 1991). The accident at Windscale released about 750 trillion (T)Bq of ^{131}I, 22 TBq of ^{137}Cs, 3 TBq of ^{89}Sr, 0.33 TBq of ^{90}Sr, and twice the amount of noble gases that were released at Chernobyl but 2,000 times less ^{131}I and ^{137}Cs. The Three Mile Island accident released about 2% as much noble gases and 50,000 times less ^{131}I than the Chernobyl accident. The most abundant released radionuclides at Three Mile Island were ^{133}Xe, ^{135}Xe, and ^{131}I, but the collective dose equivalent to the population during the first post-accident days was less than 1% of the dose accumulated from natural background radiation in 1 year.

The most serious accident of a nuclear reactor occurred on 26 April 1986 at one of the four units at Chernobyl when at least 3,000,000 TBq were released from the fuel during the accident (Table 16). The accident happened while a test was conducted during a normal scheduled shutdown and is attributed mainly to human error: "...the operators deliberately and in violation of rules, withdrew most control rods from the core and switched off some important safety systems..." (UNSCEAR 1988). The first power peak reached 100 times the nominal power within 4 s. Energy released in the fuel by the power excursion suddenly ruptured part of the fuel into minute pieces. Small, hot fuel particles caused a steam explosion. After 2 or 3 s, another explosion occurred, and hot pieces of the reactor were ejected. The damage to the reactor allowed air to enter, causing combustion of the graphite. About 25% of the released radioactive materials escaped during the first day of the accident; the rest, during the next 9 days (UNSCEAR 1988). The initial explosions and heat from the fire carried some of the radioactive materials to an altitude of 1,500 m where they were transported by prevailing winds (Fig. 6) and caused widespread radioactive contamination of Europe and the former Soviet Union, initially with ^{131}I, ^{134}Cs, and ^{137}Cs (Smith and Clark 1986; Anspaugh et al. 1988; Clark and Smith 1988; UNSCEAR 1988; Aarkrog 1990; Johanson 1990; Brittain et al. 1991; Palo et al. 1991). Long-range atmospheric transport spread the radioactive materials through the northern hemisphere where it was first detected in Japan on 2 May, in China on 4 May, in India on 5 May, and in Canada and the United States on 5-6 May 1986 (UNSCEAR 1988). Airborne activity was also detected in Turkey, Kuwait, Monaco, and Israel in early May. No airborne activity from Chernobyl has been reported south of the equator (UNSCEAR 1988). Among the reactors now operating in the former Soviet Union, 13 are identical to the one in Chernobyl, Ukraine, including units in Chernobyl, Leningrad, Kursk, and Smolensk (Mufson 1992).

Table 16. Selected fission products in the Chernobyl reactor core and their estimated escape into the environment (Severa and Bar 1991).

	Trillions of becquerels (TBq)	
Radionuclide	In core	Escaped[a]
^{85}Kr	33,000	33,000
^{133}Xe	1,700,000	1,700,000
^{131}I	1,300,000	260,000
^{132}Te	320,000	48,000
^{134}Cs	190,000	19,000
^{137}Cs	290,000	37,700
^{99}Mo	4,800,000	110,400
^{95}Zr	4,400,000	140,800
^{103}Ru	4,100,000	118,900
^{106}Ru	2,000,000	58,000
^{140}Ba	2,900,000	162,400
^{141}Ce	4,400,000	101,200
^{144}Ce	3,200,000	89,600
^{89}Sr	2,000,000	80,000
^{90}Sr	200,000	8,000
^{239}Np	140,000	4,200
^{238}Pu	1,000	30
^{239}Pu	850	25
^{240}Pu	1,200	36
^{241}Pu	170,000	5,100
^{242}Cm	26,000	780

[a] Aarkrog (1990) estimates escapement of 100,000 TBq of ^{137}Cs; 50,000 TBq of ^{134}Cs; and 35,000 TBq of ^{106}Ru. Aarkrog (1990) also includes the following radionuclides in the Chernobyl escapement: 1,500 TBq of ^{110}Ag, 3,000 TBq of ^{125}Sb, 6 TBq of ^{241}Am, and 6 TBq of $^{243+244}Cm$.

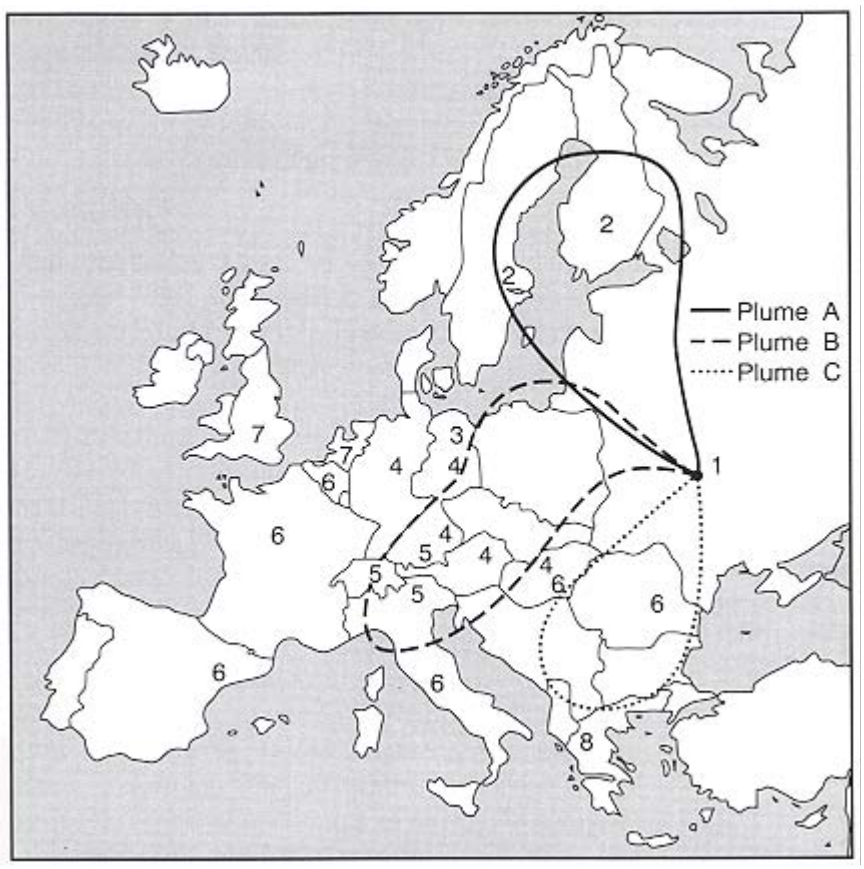

Fig. 6. Chernobyl air plume behavior and reported initial arrival times of detectable radioactivity. Plume A originated from Chernobyl on 26 April 1986, Plume B on 27-28 April, and Plume C on 29-30 April. The *numbers* indicate initial arrival times: 1, 26 April; 2, 27 April; 3, 28 April; 4, 29 April; 5, 30 April; 6, 1 May; 7, 2 May; and 8,3 May (UNSCEAR 1988; country boundaries in 1986).

Effective dose equivalents from the Chernobyl accident in various regions of the world were highest in southeastern Europe (1.2 mSv), northern Europe (0.97 mSv), and Central Europe (0.93 mSv; Table 17). In the first year after the accident, whole-body effective dose equivalents were highest in Bulgaria, Austria, Greece, and Romania (0.5-0.8 mSv); Finland, Yugoslavia, Czechoslovakia, Italy (0.3-0.5 mSv); Switzerland, Poland, USSR, Hungary, Norway, Germany, and Turkey (0.2-0.3 mSv); and elsewhere (<0.2 mSv; UNSCEAR 1988). Thyroid dose equivalents were significantly higher than whole-body effective dose equivalents because of significant amounts of ^{131}I in the released materials. Thyroid dose equivalents were as high as 25 mSv to infants in Bulgaria, 20 mSv in Greece, and 20 mSv in Romania; the adult thyroid dose equivalents were usually 80% lower than the infant dose equivalents (UNSCEAR 1988).

Table 17. Regional total effective human dose-equivalent commitment from the Chernobyl accident (UNSCEAR 1988; Aarkrog 1990).

Region	Effective dose equivalent (mSv)
Southeastern Europe	1.2
Northern Europe	0.97
Central Europe	0.93
Former Soviet Union	0.81
Southwest Asia, West Europe	>0.1-<0.2
North Africa, Greenland, East Africa, Central Africa, South Asia, West Africa	>0.01-<0.l
East Asia, Southwest Europe, Southeast Asia, North America, Caribbean, South America, Central America	<0.01

Local Effects

At Chernobyl, at least 115 humans received acute bone-marrow doses of greater than 1 Gy, as judged by lymphocyte aberrations (UNSCEAR 1988). The death toll within 3 months of the accident was at least 30 individuals, usually from groups that received more than 4 Gy, including the reactor's operating staff and the fire-fighting crew. Local residents were evacuated from a 30-km exclusion zone around the reactor because of increasing radiation levels; more than 115,000 people, including 27,000 children, were evacuated from the Kiev region, Byelorussia, and the Ukraine. Tens of thousands of cattle were also removed from the contaminated area, and consumption of locally produced milk and other foods was banned. Agricultural activities were halted and a large-scale decontamination effort was made (UNSCEAR 1988). The radiological effect of the accident to individual risk was insignificant outside a limited local region, either because contamination levels were generally low or because remedial actions to ban the consumption of highly contaminated foodstuffs prevented high exposures (UNSCEAR 1988).

Biological effects of the Chernobyl accident on local natural resources were documented by Sokolov et al. (1990). They concluded that the most sensitive affected ecosystems at Chernobyl were the soil fauna and pine forest communities and that the bulk of the terrestrial vertebrate community was not adversely affected by released ionizing radiation. Pine forests seemed to be the most sensitive ecosystem. One stand of 400 ha of *Pinus silvestris* died and probably received a dose of 80-100 Gy; other stands experienced heavy mortality of 10-12 year old trees and as much as 95% necrotization of young shoots; these pines received an estimated dose of 8-10 Gy. Abnormal top shoots developed in some *Pinus*, and these probably received 3-4 Gy. In contrast, leafed trees such as birch (*Betula* sp.), oak (*Quercus sp.*), and aspen (*Populus* sp.) in the Chernobyl Atomic Power Station zone survived undamaged, probably because they are about 10 times more radioresistant than pines. There was no increase in the mutation rate of the spiderwort *Arabidopsis thaliana*, a radiosensitive plant, suggesting that the dose rate was less than 0.05 Gy/h in the Chernobyl locale. Populations of soil mites were reduced in the Chernobyl area, but no population showed a catastrophic drop in numbers. By 1987, soil microfauna--even in the most heavily contaminated plots--was comparable to controls. Flies (*Drosophila* spp.) from various distances from the accident site and bred in the laboratory had higher incidences of dominant lethal mutations (14.7%, estimated dose of 0.8 m Gy/h) at sites nearest the accident than controls (4.3%). Fish populations seemed unaffected in July-August 1987, and no grossly-deformed individuals were found; however, $^{134+137}$Cs levels were elevated in young fishes. The most heavily contaminated teleost in May 1987 was the carp (*Carassius carassius*). But carp showed no evidence of mutagenesis, as judged by chromosomal aberrations in cells from the corneal epithelium of some carp as far as 60 km from Chernobyl (Sokolov et al. 1990).

Several rodent species compose the most widely distributed and numerous mammals in the Chernobyl vicinity. It was estimated that about 90% of rodents died in an area that received 60 Gy and 50% in areas that received 6-60 Gy. Rodent populations seemed normal in spring 1987, and this was attributed to migration from adjacent nonpolluted areas. The most sensitive small mammal was the bank vole (*Clethrionomys glareolus*),

which experienced embryonic mortality of 34%. The house mouse (*Mus musculus*) was one of the more radioresistant species. *Mus* from plots receiving 0.6-1 mG/h did not show signs of radiation sickness, were fertile with normal sperm, bred, and produced normal young. Some chromosomal aberrations were evident, namely, an increased frequency of reciprocal translocations (Sokolov et al. 1990). During the early period after the accident, there was no evidence of increasing mortality, decline in fecundity, or migration of vertebrates as a result of the direct action of ionizing radiation. The numbers and distributions of wildlife species were somewhat affected by the death of the pine stand, the evacuation of people, the termination of cultivation of soils (the crop of 1986 remained standing), and the evacuation of domestic livestock. No changes in survival or species composition of game animals and birds were recorded. In fact, because humans had evacuated and hunting pressure was negligible, many game species, including foxes, hares, deer, moose, wolves, and waterfowl moved into the zone in fall 1986-winter 1987 from the adjacent areas in a 50-60 km radius (Sokolov et al. 1990).

Nonlocal Effects

The partial meltdown of the 1,000-megawatt reactor at Chernobyl on 26 April 1986 released large amounts of radionuclides into the environment--especially ^{131}I, ^{137}Cs, and ^{134}Cs--and widely dispersed and deposited radioactive material in Europe and throughout the northern hemisphere (UNSCEAR 1988; Palo et al. 1991; Table 18). Transuranics and to some extent ^{90}Sr were deposited closer to the accident site than more volatile radionuclides such as radiocesium; accordingly, radiological problems changed quantitatively and qualitatively with increasing distance from the accident site (Aarkrog 1990).

Table 18. Radionuclide concentrations in biotic and abiotic materials from various geographic locales before or after the Chernobyl nuclear accident on 26 April 1986. All concentrations are in Bq/kg fresh weight (FW) or dry weight (DW), unless noted otherwise.

Soil and Vegetation. The radiocesium fallout in Sweden was among the highest in western Europe--exceeding 60,000 Bq/m^2 on Sweden's Baltic coast--and involved mainly upland pastures and forests (Johanson 1990; Brittain et al. 1991; Palo et al. 1991). In Norway, radiocesium deposition from the Chernobyl accident ranged from less than 5,000 to more than 200,000 Bq/m^2 and greatly exceeded the deposition from prior nuclear weapons tests (Hove et al. 1990a). In Italy, heavy rainfall coincident with the passage of the Chernobyl radioactive cloud caused high local deposition of radionuclides in soil, grass, and plants (Battiston et al. 1991). The Chernobyl plume reached Greece on 1 May 1986. A total of 14 gamma emitters were identified in the soil and vegetation in May 1986, and three (^{134}Cs, ^{137}Cs, ^{131}I) were also detected in the milk of free-grazing animals in the area (Assimakopoulos et al. 1989). Radiocesium-134 and ^{137}Cs intake by humans in Germany during 1986-87 was mainly from rye, wheat, milk, and beef (Clooth and Aumann 1990). In the United Kingdom, elevated concentrations of radionuclides of iodine, cesium, ruthenium, and others were measured in the air and in rainwater during 2-5 May 1986 (Smith and Clark 1986). The background-activity concentrations were about three times normal levels in early May, and those of ^{131}I approached the derived emergency reference level (DERL) of drinking water of 5 mSv ^{131}I (equivalent to a thyroid dose of 50 mSv); however, ^{131}I levels were not elevated in foodstuffs or cow's milk (Smith and Clark 1986). Syria--1,800 km from Chernobyl--had measurable atmospheric concentrations of ^{137}Cs and ^{131}I and near-detection limit concentrations of ^{144}Ce, ^{134}Cs, ^{140}La, and ^{106}Ru (Othman 1990). The maximum ^{131}I thyroid dose equivalent received by Syrians was 116 uSv in adults and ^{210} uSv in children; 1 year later, these values were 25 uSv in adults and 70 uSv in a 10-year-old.

The amount of fallout radioactivity deposited on plant surfaces depends on the exposed surface area, the developmental season of the plants, and the external morphology. Mosses, which have a relatively large surface area, showed the highest concentrations of radiocesium. (Table 18). In northern Sweden, most of the radiocesium fallout was deposited on plant surfaces in the forest ecosystem and was readily incorporated into living systems because of browsing by herbivores and cesium's chemical similarity to potassium (Palo et al. 1991). Forest plants seemed to show less decrease than agricultural crops in ^{137}Cs activity over time (Bothmer et al. 1990). For example, the effective retention half-life of ^{137}Cs from Chernobyl was 10-20 days in

herbaceous plants and 180 days in chestnuts, *Castanea* spp. (Tonelli et al. 1990). The radioactive fallout from the Chernobyl accident also resulted in high ^{137}Cs levels in Swedish pasture grass and other forage, although levels in grain were relatively low (Andersson et al. 1990). Radiocesium isotopes were still easily measurable in grass silage that was harvested in June 1986 and used as fodder for dairy cows in 1988 (Voors and Van Weers 1991). The rejection of the first harvests of radiocesium-contaminated perennial pasture and in particular of rye grass (*Lolium perenne*) does not constitute a safe practice because later harvests--even 1 year after the contamination of the field--may contain very high values as in Greece (Douka and Xenoulis 1991).

Aquatic Life. After Chernobyl, the consumption of freshwater fishes by Europeans declined, fish-license sales dropped by 25%, and the sale of fish from radiocesium-contaminated lakes was prohibited (Brittain et al. 1991). Many remedial measures have been attempted to reduce radiocesium loadings in fishes, but none has been effective to date (Hakanson and Andersson 1992). Radiocesium concentrations in muscle of fishes from the southern Baltic Sea increased 3 to 4 times after Chernobyl (Grzybowska 1989), and $^{134+137}Cs$ and ^{106}Ru in fishes from the Danube River increased by a factor of 5; however, these levels posed negligible risk to human consumers (Conkic et al. 1990). Chernobyl radioactivity, in particular ^{141}Ce and ^{144}Ce, that entered the Mediterranean as a single pulse, was rapidly removed from surface waters and transported to 200 m in a few days primarily in fecal pellets of grazing zooplankton (Fowler et al. 1987). Bioconcentration factors (BCF) of ^{137}Cs in fishes from Lake Paijanne, Finland--a comparatively contaminated area--ranged from 1,250 to 3,800; the highest BCF values were measured in the predatory northern pike (*Esox lucius*) 3 years after the Chernobyl accident; consumption of these fishes was prohibited (Korhonen 1990).

After the Chernobyl accident, radiocesium. isotopes were also elevated in trees and lichens that bordered an alpine lake in Scandinavia and in lake sediments, invertebrates, and fishes (Table 18). Radiocesium levels in muscle of resident brown trout (*Salmo trutta*) remained elevated for at least 2 years (Brittain et al. 1991). People who consumed food near this alpine lake derived about 90% of their effective dose equivalent from the consumption of freshwater fish, reindeer meat, and milk. The average effective dose equivalent of this group during the next 50 years is estimated at 6-9 mSv with a changed diet and 8-12 mSv without dietary changes (Brittain et al. 1991).

Wildlife. Reindeer (*Rangifer tarandus*)--*also* known as caribou in North America--are recognized as a key species in the transfer of radioactivity from the environment to humans because (1) the transfer factor of radioactivity from reindeer feed to reindeer muscle is high, (2) lichens--which constitute a substantial portion of the reindeer diet--are efficient accumulators of Sr, Cs, and actinide radioisotopes and, (3) reindeer feed is not significantly supplemented with grain or other feeds of low contamination (Jones et al. 1989; Rissanen and Rahola 1989; 1990; Eikelman et al. 1990; Skogland and Espelien 1990). During 1986-87, about 75% of all reindeer meat from Sweden was unfit for human consumption because ^{137}Cs exceeded 300 Bq/kg FW. In May 1987, the maximum permissible level of ^{137}Cs in Swedish reindeer, game, and freshwater fish was raised to 1,500 Bq/kg FW; however, about 25% of slaughtered reindeer in 1987-89 still exceeded this limit (Ahman et al. 1990b). Concentrations in excess of 100,000 Bq $^{134+137}Cs$/kg FW lichens have been recorded in the most contaminated areas and in the 1986-87 season was reflected in reindeer muscle concentrations of greater than 50,000 Bq/kg FW from the most contaminated areas of central Norway (Roed et al. 1991). Norwegian reindeer with 60,000-70,000 Bq ^{137}Cs/kg FW in muscle receive an estimated yearly dose of 500 mSv (Jones 1990). The maximum radiation dose to reindeer in Sweden after the Chernobyl accident was about 200 mSv/year with a daily dose rate of about 1 mSv during the winter period of maximum tissue concentrations (Jones et al. 1989). In general, reindeer calves had higher ^{131}Cs levels in muscle than adult females (4,700 vs. 2,700 Bq/kg FW) during September 1988, suggesting translocation to the fetus (Eikelmann et al. 1990). Two reindeer herds in Norway that were heavily contaminated with radiocesium had a 25% decline in survival of calves; survival was normal in a herd with low exposure (Skogland and Espelien 1990). Several compounds inhibit uptake and reduce retention of ^{137}Cs in reindeer muscle from contaminated diets, but the mechanisms of the action are largely unknown. These compounds include zeolite--a group of tectosilicate minerals--when fed at 25-50 g daily (Ahman et al. 1990a); ammonium hexacyanoferrate--also known as Prussian Blue or Giese salt--at 0.3-1.5 g daily (Hove et al. 1990b; Mathiesen et al. 1990; Staaland et al. 1990); bentonite--a montmorillonite clay--when fed at 2% of diet (Ahman et al. 1990a); and high intakes of potassium (Ahman et al. 1990a). Much additional work seems needed on chemical and other processes that hasten excretion and prevent uptake and

accumulation of radionuclides in livestock and wildlife. Reindeer herding is the most important occupation in Finnish Lapland and in portions of Sweden (Rissanen and Rahola 1989). Swedish Lapland reindeer herders have experienced a variety of sociocultural problems as a result of the Chernobyl accident. The variability of contamination has been compounded by the variability of expert statements about risk, the change in national limits of Bq concentrations set for meat marketability, and the variability of the compensation policy for slaughtered reindeer. These concerns may result in fewer Lapps becoming herders and a general decline in reindeer husbandry (Beach 1990).

Caribou in northern Quebec contained as much as 1,129 Bq ^{137}Cs/kg muscle FW in 1986-87, but only 10-15% of this amount originated from Chernobyl; the remainder is attributed to fallout from earlier atmospheric nuclear tests (Crete et al. 1990). The maximum concentration of ^{137}Cs in meat of caribou (*Rangifer tarandus granti*) from the Alaskan Porcupine herd after the Chernobyl accident did not exceed 232 Bq/kg FW, and this is substantially below the recommended level of 2,260 Bq ^{137}Cs/kg FW (Allaye-Chan et al. 1990). Radiocesium transfer in an Alaskan lichen-reindeer-wolf (*Canis 1upus*) food chain has been estimated. If reindeer forage contained 100 Bq/kg DW in lichens and 5 Bq/kg DW in vascular plants, the maximum winter concentrations--at an effective half-life of 8.2 years in lichens and 2.0 years in vascular plants--was an estimated 20 Bq/kg FW in reindeer-caribou skeletal muscle and 24 Bq/kg FW in wolf muscle (Holleman et al. 1990).

The radioactive body burden of exposed reindeer and the character of chromosomal aberrations--which was different in exposed and nonexposed reindeer--indicated a genetic effect of radiation from the Chernobyl accident (Roed et al. 1991). Chromosomal aberrations in Norwegian female reindeer positively correlated with increasing radiocesium concentrations in flesh (Skogland and Espelien 1990). The frequency of chromosomal aberrations in reindeer calves from central Norway were greatest in those born in 1987 when tissue loadings were equivalent to fetal doses of 70-80 mSv and lower in 1988 (50-60 mSv) and 1989 (40-50 mSv), strongly suggesting a dose-dependent induction (Roed et al. 1991). Mutagenicity tests with feral rodents have also been used successfully to evaluate the biological effects of the radiation exposure from the Chernobyl accident. Increased mutagenicity in mice (*Mus musculus domesticus*) was evident as judged by tests of the bone-marrow micronucleus at 6 months and 1 year after the accident. Rodents with increased chromosomal aberrations also had ^{137}Cs burdens that were 70% higher 6 months after the accident and 55% higher after 1 year, but elevated radiocesium body burdens alone were not sufficient to account for the increase in mutagenicity (Cristaldi et al. 1990). In bank voles, however, mutagenicity (micronucleated polychromatic erythrocytes) correlated well with the ^{137}Cs content in muscle and in the soil of the collection locale (Cristaldi et al. 1991). The estimated daily absorbed doses (4.2-39.4 uGy) were far lower than those required to produce the same effect in the laboratory (Cristaldi et al. 1991).

For many households in Sweden, moose (*Alces alces*) are an important source of meat (Palo et al. 1991). Radiocesium concentrations in the foreleg muscle of moose in Sweden during 1987-88 were highest in fall when the daily dietary intake of the animals was about 25,000 Bq ^{137}Cs and lowest during the rest of the year when the mean daily intake was about 800 Bq (Bothmer et al. 1990). Cesium-137 levels in moose flesh did not decrease significantly for about 2 years after the Chernobyl accident (Johanson 1990). The selection of food by moose is paramount to the uptake of environmental contaminants and the changes in tissue levels over time. Increased foraging on highly contaminated plant species, such as bilberry (*Vaccinium myrtillus*), aquatic plants, and mushrooms, may account for the increased ^{137}Cs radioactivity in moose (Palo et al. 1991). For reasons that are not yet clear, transfer coefficients of ^{137}Cs from diet to muscle were about the same in moose (0.03) and beef cattle (0.02) but were significantly higher in sheep (0.24) (Bothmer et al. 1990).

The song thrush (*Turdus philomelas*) collected in Spain in November 1986 had elevated concentrations of ^{134}Cs, ^{137}Cs , and ^{90}Sr; the contamination probably occurred in central and northern Europe before the bird's migration to Spain (Baeza et al. 1991). Spaniards who ate songthrushes that were contaminated with radiocesium isotopes usually received about 58 uSv/year, which is well below the current international guidelines (Baeza et al. 1991). Consumption of game or wildlife in Great Britain after the Chernobyl accident probably also do not exceed the annual limits of intake (ALI) based on $^{134+137}$Cs concentrations in game and the numbers of animals that can be eaten in 1 year before ALI is exceeded (Lowe and Horrill 1991). For example, a person that eats hares with 3,114 Bq $^{134+137}$Cs/kg FW in muscle would have to consume 99 hares

before exceeding the ALI; for the consumption of red grouse (3,022 Bq/kg), this number is 441 grouse; and for the consumption of woodcock (55 Bq/kg), it is 45,455 woodcocks (Lowe and Horrill 1991). Rabbits (*Oryctolagus* sp.) from northeastern Italy that were fed Chernobyl-contaminated alfalfa meal (1,215 Bq $^{134+137}$Cs/kg diet) had a maximum of 156 Bq/kg muscle FW of $^{134+137}$Cs, a value much lower than the current Italian guideline of 370 Bq/kg FW for milk and children's food and 600 Bq/kg FW for other food (Battiston et al. 1991). More than 85% of the ingested radiocesium was excreted by rabbits in feces and urine; about 3% was retained (Battiston et al. 1991).

Cesium radioactivity in tissues and organs of the wolverine (*Gulo gulo*), lynx (*Felis lynx*), and Arctic fox (*Alopex logopus*) in central Norway after the Chernobyl accident was highly variable. In general, cesium-137 levels were substantially lower in these carnivores than in lower trophic levels (Ekker et al. 1990), suggesting little or no food-chain biomagnification, and at variance with results of studies of the omnivore and herbivore food chain.

Domestic Animals. Radiocesium isotopes from the Chernobyl accident transferred easily to grazing farm animals (Hove et al. 1990a). Both ^{134}Cs and ^{137}Cs were rapidly distributed throughout the soft tissues after dietary ingestion and were most highly concentrated in muscle (Book 1969; Van Den Hoek 1989). Radiocesium activity in milk and flesh of Norwegian sheep and goats increased 3 to 5 fold 2 years after the accident and coincided with an abundant growth and availability of fungal fruit bodies in which $^{134+137}$Cs levels were as much as 100 times greater than green vegetation (Hove et al. 1990a). In cattle, coefficients of radiocesium transfer from diet to muscle were about 2.5% in adults and 16% in calves; the higher value in calves was probably due to a high availability of cesium from the gastrointestinal tract and to daily uptake of potassium in growing animal muscle (Daburon et al. 1989). There was no correlation between the retention of ^{137}Cs and the pregnancy stage in cattle (Calamosca et al. 1990). Radiocesium concentrations in pork in Czechoslovakia did not decline between 1986 and 1987 because the feed of pigs during this period contained milk byproducts contaminated with $^{134+137}$Cs (Kliment 1991).

Sheep farming is the main form of husbandry in the uplands of western Cumbria and northern Wales, a region that received high levels of radiocesium fallout during the Chernobyl accident. Afterwards, typical vegetation activity concentrations were about 6,000 Bq/kg (down to about 1,000 Bq/kg in January 1989). But concentrations in sheep muscle exceeded 1,000 Bq ^{137}Cs/kg FW, which is the United Kingdom's dietary limit for human-health protection (Crout et al. 1991). Contaminated lambs--which usually had higher concentrations of ^{137}Cs than ewes--that were removed to lowland pastures (<50 Bq/kg vegetation) rapidly excreted radiocesium in feces and urine, and cesium body burdens had an effective half-life of 11 days. This practice should not significantly increase radiocesium levels in the soil and vegetation of lowland pastures (Crout et al. 1991). The absorption and retention of radiocesium by suckling lambs is highly efficient, about 66%. Fecal excretion was an important pathway after the termination of ^{137}Cs ingestion. In weaned animals, the absorption of added ionic cesium was about twice that of cesium fallout after the accident at Chernobyl (Moss et al. 1989). Silver-110m was also detected in the brains and livers of ewes and lambs in the United Kingdom. The transfer of ^{110m}Ag was associated with perennial rye grass that was harvested soon after deposition in 1986. Silver-110m was taken up to a greater extent than ^{137}Cs in liver, but unlike ^{137}Cs, ^{110m}Ag was not readily translocated to other tissues. Other than cesium isotopes and ^{131}I, ^{110m}Ag was the only detected nuclide in sheep tissues (Beresford 1989).

Atmospheric deposition of ^{137}Cs from Chernobyl to vegetation and eventually to the milk of sheep, cows, and goats on contaminated silage was reported in Italy, the Netherlands, Japan, and the United Kingdom (Book 1969; Belli et al. 1989; Pearce et al. 1989; Voors and Van Weers 1989; Aii et al. 1990; Monte 1990). The effective half-life of ^{137}Cs was 6.7 days in pasture grass and 13.6 days in milk (Spezzano and Giacomelli 1991). The average transfer coefficient of $^{134+137}$Cs from Chernobyl from a 70% grass-silage diet to milk of Dutch dairy cows was about 0.250%/liter/day (Voors and Van Weers 1991). In goats (*Capra* sp.), about 12% of orally administered ^{137}Cs was collected in milk within 7 days after dosing (Book 1969).

Iodine-131 was one of the most hazardous radionuclides released in the Chernobyl accident because it is easily transferred through the pasture-animal-milk pathway and rapidly concentrated in the thyroid gland to an extent unparalleled in any other organ. Because of its high specific activity, ^{131}I can transmit a high dose of radiation to the thyroid (Ionannides and Pakou 1991). Iodine-131 levels of 618,000 Bq/kg FW in sheep thyroids from northwestern Greece on 3 July 1986 are similar to maximal ^{131}I concentrations in sheep thyroids in Tennessee in 1957 after global atmospheric fallout from military weapons tests and in London after the Windscale accident (Ionannides and Pakou 1991). Iodine-131 has an effective whole-body half-life of about 24 h and is rapidly excreted from sheep and cows (Assimakopoulos et al. 1989). The effective half-life of ^{131}I was 3.9 days in pasture grass and 5 days in cow's milk (Spezzano and Giacomelli 1991). The transfer coefficients of ^{131}I from vegetation to cow's milk was 0.007% day/L milk; this value was 57 times higher (0.4) in sheep (Monte 1990), but the mechanism to account for this large interspecies difference is not clear.

Effects: Nonionizing Radiations

Living organisms are constantly exposed to nonionizing electromagnetic radiations, including ultraviolet, visible, infrared, radio, and other low energy radiations that form an integral part of the biosphere. Emissions from anthropogenic sources such as radios, microwave ovens, television communications, and radar significantly altered the character of our natural electromagnetic field (Garaj-Vrhovac et al. 1990). Although the primary focus of my review is on ionizing radiations, an assumption that low energy electromagnetic waves cannot elicit significant biological responses would be misleading. For example, behavioral and biochemical changes are reported in rats, monkeys, rabbits, and other laboratory animals after exposure to nonionizing electromagnetic radiations; the severity of the effect is associated with the type and duration of the radiation and with various physicochemical variables (Ghandi 1990). Selected examples follow.

Ultraviolet radiation in mammals causes the aging of skin, making it wrinkled and leathery (Kligman and Kligman 1990). Dermatologists of the late nineteenth century described the devastating effects of sunlight on the skin of farmers and sailors when compared with indoor workers. Photoaged skin has a variety of neoplasms, deep furrows, extensive sagging, and profound structural alterations that are quite different from those in protected, intrinsically aged skin (Kligman and Kligman 1990). Similar results were documented of skin of guinea pigs (Davidson et al. 1991) and rodents (Ananthaswamy and Pierceall 1990; Ronai et al. 1990) after exposure to ultraviolet radiation. Ultraviolet radiation causes eye cancer in cattle (Anderson and Badzioch 1991), interferes with wound healing in guinea pig skin (Davidson et al. 1991), is a potent damaging agent of DNA and a known inducer of skin cancer in experimental animals (Ronai et al. 1990), and interferes with an immune defense mechanism that normally protects against skin cancer (Ananthaswamy and Pierceall 1990). Aquatic organisms exposed to ultraviolet radiation show disrupted orientation, decreased motility, and reduced pigmentation in *Peridinium gatunense*, a freshwater alga (Hader et al. 1990); effects were similar in several species of marine algae (Lesser and Shick 1990; Hader and Hader 1991; Shick et al. 1991). Increased lipid peroxidation rates and a shortening of the life span after ultraviolet exposure were reported in the rotifer *Asplanchna brightwelli* (Sawada et al. 1990). Cells of the goldfish (*Carassius auratus*) were damaged, presumably by DNA impairment, from UV exposure (Yasuhira et al. 1991).

Visible radiation adversely affected survival and growth of embryos of the chinook salmon (*Oncorhynchus tshawytscha*; Eisler 1961), chloroplast structure in the symbiotic marine dinoflagellate *Symiodinium sp*. (Lesser and Shick 1990), and in-vitro growth of cultured mammalian cells (Karu 1990). Infrared radiation contributes significantly to skin photoaging, producing severe elastosis; the epidermis and the dermis were capable of self-restoration when the exogenous injury ceased (Kligman and Kligman 1990).

Investigations of the cellular effects of radiofrequency radiation provide evidence of damage to various types of avian and mammalian cells. These effects involve radiofrequency interactions with cell membranes, especially the plasma membrane. Effects include alterations in membrane cation transport, Na^+/K^+-ATPase activity, protein kinase activity, neutrophil precursor membrane receptors, firing rates and resting potentials of neurons, brain cell metabolism, DNA and RNA syntheses in glioma cells, and mitogenic effects on human lymphocytes (Cleary 1990). Microwaves inhibit thymidine incorporation by DNA blockage in cultured cells of the Chinese hamster; irradiated cells had a higher frequency of chromosome lesions (Garaj-Vrhovac et al. 1990). Microwaves induce teratogenic effects in mice when the intensity of exposure places a thermal burden on the dams and fetuses, reducing fetal body mass and increasing number of resorptions (O'Connor 1990).

Extremely low frequency (ELF) electromagnetic fields--similar to fields that emanate from electrical appliances and the electrical power distribution network, usually less than 300 Hz--are used therapeutically in the healing of human nonunion bone fractures, in the promotion of nerve regeneration, and in acceleration of wound healing (Anderson 1990). ELF electric and magnetic fields produce biological effects, usually subtle, and of low hazard in short-term exposure. These effects include altered neuronal excitability, neurochemical changes, altered hormone levels, and changes in behavioral responses. For example, electric-field perception has been reported in humans, mice, pigs, monkeys, pigeons, chickens, and insects; altered cardiovascular responses in dogs and chickens; and altered growth rate of chicks. No deleterious effects of ELF fields on mammalian reproduction and development or on carcinogenesis and mutagenesis have been documented (Anderson 1990). ELF fields had no effect on the growth of bone in chicks (Coulton and Barker 1991). However, adult eastern newts (*Notophthalmus viridescens*), regenerating amputated forelimbs, had grossly abnormal forelimbs 12% of the time when exposed for 30 days to ELF fields of the type reported to facilitate healing of human bone fractures (Landesman and Douglas 1990). Additional studies are recommended on the biological effects of nonionizing radiations on fishes and wildlife, especially ELF radiations.

Effects: Ionizing Radiations

General

High acute doses of ionizing radiation produce adverse biological effects at every organizational level: molecule, cell, tissue-organ, whole animal, population, community, and ecosystem (ICRP 1977; Whicker and Schultz 1982b; LWV 1985; Hobbs and McClellan 1986; UNSCEAR 1988; Kiefer 1990; Severa and Bar 1991). Typical adverse effects of ionizing radiation include cell death (McLean 1973; LWV 1985; Kiefer 1990), decreased life expectancy (Lorenz et al. 1954; Brown 1966; Hobbs and McClellan 1986; Kiefer 1990; Rose 1992), increased frequency of malignant tumors (Lorenz et al. 1954; ICRP 1977; Hobbs and McClellan 1986; UNSCEAR 1988; Hopewell 1990; Kim et al. 1990; Little 1990; Nagasawa et al. 1990; Raabe et al. 1990; Fry 1991), inhibited reproduction (ICRP 1977; Barendson 1990; Kiefer 1990; Rose 1992), increased frequency of gene mutations ICRP 1977; Whicker and Schultz 1982b; Hobbs and McClellan 1986; Abrahamson 1990; Evans 1990; Kiefer 1990; Thacker 1990; Sankaranarayanan 1991a; 1991b; Rose 1992), leukemia (ICRP 1977; Kiefer 1990), altered blood-brain barrier function (Trnovec et al. 1990), and reduced growth and altered behavior (Rose 1992). Species in kingdoms have a wide variation in sensitivity, and sometimes at low radiation exposures the response is considered beneficial (Luckey 1980; Rose 1992). Overall, the lowest dose rate at which harmful effects of chronic irradiation have been reliably observed in sensitive species is about 1 Gy/year; this value for acute radiation exposures is about 0.01 Gy (Rose 1992).

In general, the primitive organisms are the most radioresistant taxonomic groups and the more advanced complex organisms--such as mammals--are the most radiosensitive (Fig. 7). The early effects of exposure to ionizing radiation result primarily from cell death; cells that frequently undergo mitosis are the most radiosensitive, and cells that do not divide are the most radioresistant. Thus, embryos and fetuses are particularly susceptible to ionizing radiation, and very young animals are consistently more radiosensitive than adults (McLean 1973; Hobbs and McClellan 1986). In addition to the evolutionary position and cell mitotic index, many extrinsic and intrinsic factors modify the response of a living organism to a given dose of radiation. Abiotic variables include the type and energy of radiation, exposure rate, length of exposure, total exposure and absorbed dose, dose rate, spatial distribution of dose, season, temperature, day length, and environmental chemicals; biotic variables include the species, type of cell or tissue, metabolism, sex, nutritional status, sensitizing or protective substances, competition, parasitism, and predation (Whicker and Schultz 1982b; Hobbs and McClellan 1986; UNSCEAR 1988; Kiefer 1990).

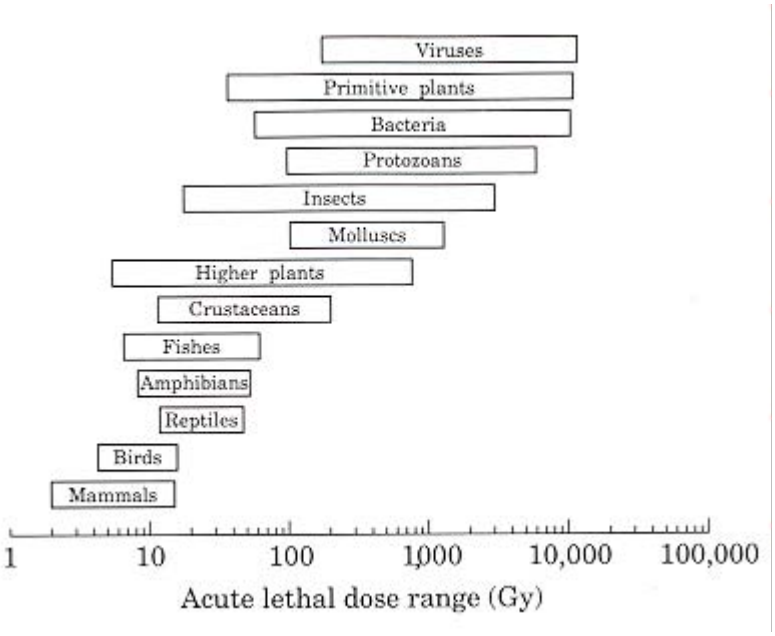

Fig. 7. Acute radiation dose range fatal to 50% (30 days postexposure) of various taxonomic groups (modified from Whicker and Schultz 1982b; Hinton and Scott 1990).

Radiosensitivity of cells is related directly to their reproductive capacity and indirectly to their degree of differentiation (Hobbs and McClellan 1986). Early adverse effects of exposure to ionizing radiation are due mainly to the killing of cells. Cell death may result from the loss of reproductive integrity, that is, when after irradiation a cell fails to pass through more than one or two mitoses. Reproductive death is important in rapidly dividing tissues such as bone marrow, skin, gut lining, and germinal epithelium. When the whole animal is exposed to a large dose of ionizing radiation, some tissues are more prone to damage than others. Death rates of mammalian reproductive cells from ionizing radiations is modified by variations in the linear energy transfer of the radiation, the stage in the cell cycle, cell culture conditions, and sensitizing and protecting compounds (Barendsen 1990). The chemical form of the main stage of the acute radiation syndrome depends on the size and distribution of the absorbed dose. It is determined mainly by damage to blood platelets and other blood-forming organs at 4-5 Gy, to epithelial cells lining the small intestine at 5-30 Gy, and to brain damage at more than 30 Gy; death usually occurs within 48 h at more than 30 Gy (McLean 1973).

Cellular DNA is extremely sensitive to ionizing radiation, although other cell constituents may approach DNA in sensitivity (IAEA 1976; Billen 1990; Kiefer 1990; Lett 1990; Lucke-Huhle et al. 1990; Woloschak et al. 1990a; Shadley et al. 1991). Radiation-induced mutations are explainable on the basis of chromatin and DNA organization in cells and the biophysical properties of ionizing radiation (Sankaranarayanan 1991b). Based on studies of spontaneous and radiation-induced mutations in the mouse (Sankaranarayanan 1991a), more than 67% of the ionizing radiation-induced mutations are lethal and almost all mutations, including enzyme activity variants, dominant visibles, and dominant skeletal mutations, are lethal. These findings are consistent with the view that most radiation-induced mutations in germ cells of mice are due to DNA deletions (Sankaranarayanan 1991a).

Experimental animal data clearly demonstrate that ionizing radiation at relatively high doses and delivered at high dose rates is mutagenic (Hobbs and McClellan 1986). However, radiation-induced genetic damage in the offspring of exposed parents has not been credibly established in any study with humans (Abrahamson 1990). In one human population--the ethnically isolated Swedish reindeer breeding Lapps--elevated concentrations of fallout products have been ingested via the lichen-reindeer-human food chain since the 1950's. However, during 1961-84, incidences of genetic damage did not increase in Lapps (Wiklund et al. 1990).

Radiation is carcinogenic. The frequency of death from cancer of the thyroid, breast, lung, esophagus, stomach, and bladder was higher in Japanese survivors of the atomic bomb than in nonexposed individuals, and carcinogenesis seems to be the primary latent effect of ionizing radiation. The minimal latent period of most

cancers was less than 15 years and depended on an individual's age at exposure and site of cancer. The relation of radiation-induced cancers to low doses and the shape of the dose-response curve (linear or non-linear), the existence of a threshold, and the influence of dose rate and exposure period must be determined (Hobbs and McClellan 1986).

Radioactive materials that gain entry to the body, typically through ingestion or inhalation, exert effects that are governed by their physical and chemical characteristics which, in turn, influence their distributions and retention inside the body. The effective half-life includes physical and biologic half-times. In addition, the type of radiation (i.e., αβ) and its retention and distribution kinetics govern the radiation-dose pattern. In general, the radiation dose from internal emitters is a function of the effective half-life, energy released in the tissue, initial amount of introduced radioactivity, and mass of the organ (Hobbs and McClellan 1986). Retention of radionuclides by living organisms is quite variable and modified by numerous biologic and abiotic variables. For example, ^{137}Cs retention in selected animals varies significantly with the body weight, diet, and metabolism of an organism (Fig. 8). The time for 50% persistence of ^{137}Cs is between 30 and 430 days in ectotherms and was longer at lower temperatures and shortest in summer and under conditions of inadequate nutrition (Hinton and Scott 1990). In mammals, the ^{137}Cs biological half-life was between 6 and 43 days in rodents, dogs, mule deer, reindeer, and monkeys; in humans, this value ranged from 60 to 160 days. The biological half-life of ^{90}Sr ranges from 122 to 6,000 days in ectotherms and is longer at colder temperatures and under laboratory conditions. In mammals and under conditions of chronic intake, the ^{90}Sr biological half-life was 533 days in rats, 750 days in humans, and at least 848 days in beagles (Hinton and Scott 1990).

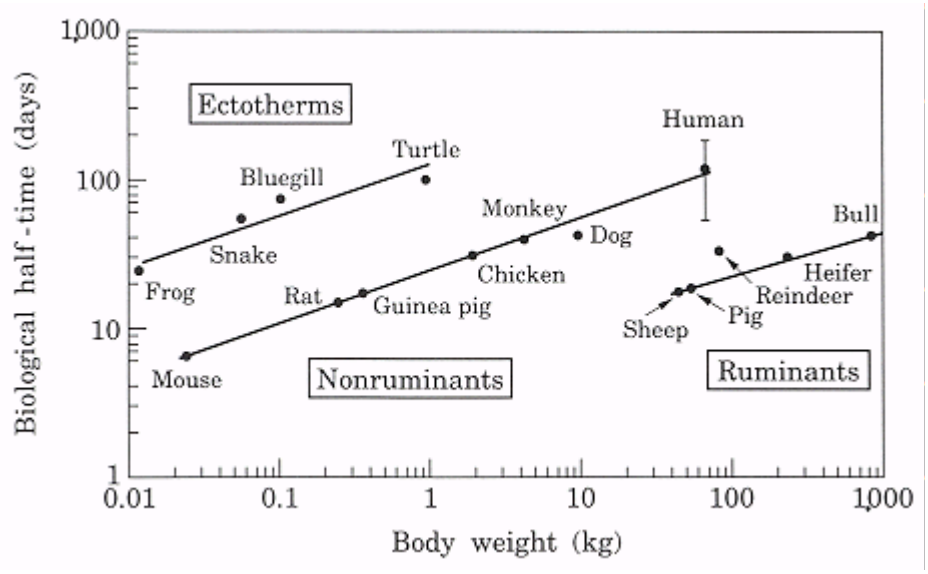

Fig. 8. Relation between diet, metabolism, and body weight with half-life retention of longest-lived component of cesium-137. Data are from selected ruminant and nonruminant mammals (Richmond 1989) and ectotherms (Hinton and Scott 1990).

Terrestrial Plants and Invertebrates

Radiosensitive terrestrial plants exposed to single doses of ionizing radiation had reduced growth at 0.5-1.0 Gy and reduced survival at 3.0-4.1 Gy (Table 19); chronic exposures of 0.2-0.65 Gy/day adversely affected sensitive forest ecosystems (Table 19). Chronic gamma irradiation of 131 Gy/year and higher of mixed forest ecosystems caused the disappearance of trees and shrubs and subsequent erosion of the soil (Poinsot-Balaguer et al. 1991). The radiation sensitivity of five plant communities suggested that pine (*Pinus* spp.) forests were the most sensitive and that deciduous evergreen forests, tropical rain forests, herbaceous rock-outcrop communities, and abandoned cropland were increasingly less sensitive (McCormick 1969). Neutrons were 3 to 4 times more effective than gamma rays in root growth inhibition (Witherspoon 1969). Altitude affects the response of vegetation to ionizing radiation. Peas (*Pisum sativum*) in gardens at 2,225-3,750 m above mean

sea level and exposed to 0, 5, 10, or 50 Gy had reduced growth from all treatments at increasing altitudes; however, a dose-response growth curve was evident only at less than 3,049-m altitude (Osburn 1963). Seeds of tobacco (*Nicotiana tabacum*) exposed to cosmic rays aboard a spacecraft had a higher mutation rate than controls; effects occurred at total doses as low as 0.1-0.2 Gy (Gaubin et al. 1990), but this needs verification.

Table 19. Radiation effects on selected terrestrial plants.

Table 19. Species, dose, and other variables	Effect	Reference[a]
Tropical rainforest tree, *Dacryodes excelsa*, 4 to 280 Gy/year	Growth stimulation	1
Deciduous evergreen forest		
40 Gy yearly	Minor effects	2
100 Gy yearly	Severe sublethal effects	2
350 Gy yearly	Lethal	2
Deciduous plants, 13 species		
4 to 15 Gy, single fast neutron doses	Shoot growth inhibited by >85%	3
60 to 85 Gy, single gamma radiation dose	Shoot growth inhibited by >85%	3
Forest ecosystem, northern Wisconsin, experimentally exposed to a ^{137}Cs point source for 5 months during a growing season. Distance from source (meters) and daily exposure (Gy)		
5 m, 15 Gy	No vegetation	4
5-10 m, 5-15 Gy	Lower plants present	4
10-15 m, 1.5 Gy	Resistant trees and shrubs present	4
10-15 m, 2.5-5.0 Gy	Some growth	4
20-30 m, 0.65-1.5 Gy	Resistant angiosperm trees	4
30-50 m, 0.2-0.65 Gy	Angiosperm trees present	4
50 m, 0.2 Gy	Original northern forest	4
Herbaceous rock outcrop community		
90 Gy yearly	Minor effects	2
400 Gy yearly	Severe sublethal effects	2
1,000 Gy yearly	Lethal	2
Mango, Queensland *Mangifera indica,* fruit irradiated postharvest, single dose, 250 or 750 Gy	At 250 Gy, skin and pulp color inhibited 50% due to irradiation-induced suppression of chlorphyll breakdown and reduction in carotenoid production. At 750 Gy, fruit respiration increased for 3-5 days, but no effect on fruit firmness	5
Mixed oak forest, southern France, experimentally irradiated for 18 years by a ^{137}Cs source at dose rates between 0.3 and 116 mGy/h, equivalent to a yearly rate between 2.6 and 1,016 Gy	At 60-100 mGy/h (525-876 Gy yearly), all trees, shrubs, and litter were absent; low overall insect density; soil deficient in carbon, nitrogen, and water. At 15 mGy/h (131 Gy yearly), woody	6

Table 19. Species, dose, and other variables	Effect	Reference[a]
	plants were present, but visibly abnormal	
Tobacco, *Nicotiana tabacum,* 55 Gy/year	Growth stimulation	1
Pine forest		
1-10 Gy yearly	Minor effects	2
20 Gy yearly	Severe sublethal effects	2
30 Gy yearly	Lethal	2
Slash pine, *Pinus elliottii,* acute single exposure of 3 Gy	50% dead 1-4 months after exposure; no other deaths in 2 years	2
Sugar pine, *Pinus lambertiana,* acute single exposure of 4.1 Gy	LD50 (30 days postexposure)	1
Longleaf pine, *Pinus palustris*		
0.5 Gy, single dose	Growth inhibition	1
8 Gy, acute single exposure	50% of trees <5 years old died in 1-4 months; others survived for at least 2 years	2
>28 Gy, acute single exposure	Fatal to 50% of trees >5 years old in 1-4 months; no other deaths in 2 years	2
Winter wheat, *Triticum aestivum,* acute single exposure of 1.0 Gy	Growth inhibition	1
Tropical rainforest		
70 Gy yearly	Minor effects	2
350 Gy yearly	Severe sublethal effects	2
400 Gy yearly	Lethal	2
Vegetation, abandoned crop land		
50 Gy yearly	Minor effects	2
450 Gy yearly	Severe sublethal effects	2
1,500 Gy yearly	Lethal	2
Bean, *Vicia faba,* 58-100 Gy/year	Growth stimulation	1

[a]1, Rose 1992; 2, McCormick 1969; 3, Witherspoon 1969; 4, Zavitokovski and Rudolph 1971; 5, Boag et al. 1990; 6, Poinsat-Balaguer et al. 1991.

Sometimes, irradiation prevents the usual colonizing vegetation from becoming established (Poinsot-Balaguer et al. 1991). Germination and survival of shrub seedlings have been much slower in nuclear test sites than in undisturbed sites (Romney et al. 1971). The return to its original state of the perennial shrub vegetation takes decades on a radiation-disturbed site, although native annual species and grasses have grown abundantly within 12 months. Transplanting of shrubs into radiation-disturbed areas has been largely unsuccessful because of intense browsing by rabbits and other small mammals (Romney et al. 1971). A nuclear detonation damages terrestrial vegetation by heat, blast, or radiation. Plant injury from thermal or ionizing radiation at an above-ground detonation site varied with stem rigidity and stability of the substratum, although radiation effects are ordinarily masked by damage from blasts. A typical nuclear detonation at the Nevada test site--an airburst of a 20- to 40-kiloton yield--denuded a zone of desert within a 0.8-km radius of shrub vegetation. Recovery at the Nevada site seemed complete within 4 years, suggesting little relation between fatal

injury, morphological aberration in vegetation, and ionizing radiation from nuclear detonations (Shields and Wells 1963). A northern Wisconsin forest experimentally subjected to a ^{137}Cs radiation source for 5 months showed several trends: (1) herbaceous and shrub species with a spreading form of growth are more radioresistant than upright forms; (2) larger pines and oaks are more radioresistant than smaller trees; (3) perennial plants with shielded buds and vigorous asexual reproduction are relatively radioresistant; (4) plants that are adapted to extreme habitats such as old fields and granite rock outcrops and plants that are typical of early successional stages are relatively radioresistant; (5) all plants are more radiosensitive during the growing season than during the dormant season; and (6) reproductive stages are always more radiosensitive than vegetative stages (Zavitokovski and Rudolph 1971). The recovery of vegetation in a tropical rain forest in Puerto Rico--after plants were deliberately subjected to lethal doses of gamma radiation--closely resembled secondary succession after other types of disturbances such as mechanical stripping and treatment with the Picloran herbicide (Jordan 1969).

Hormesis--the beneficial physiological stimulation by low doses of a potentially harmful agent--is documented of ionizing radiation and many species of terrestrial plants and invertebrates (Luckey 1980). Radiation hormesis in plants includes increased germination, growth, survival, and yield. Some species of terrestrial invertebrates had increased fecundity, growth, survival, disease resistance, and longevity after exposure to low sublethal doses of ionizing radiation (Luckey 1980).The growth and development of some terrestrial invertebrates are stimulated at comparatively high sublethal acute doses (i.e., 2 Gy in silkworm [*Bombyx mori*]), but survival is reduced at 10 Gy; in all cases, younger stages were the most sensitive (Table 20). Cockroaches (*Blaberus giganteus*) adapted to the dark reportedly can visually detect radiation sources as low as 0.001 mGy (Rose 1992), however, the mechanisms are not understood.

Table 20. Radiation effects on selected terrestrial invertebrates.

Species, dose, and other variables	Effect	Reference[a]
Caribbean fruit fly, *Anastrepha suspensa*; larvae, heavily parasitized by the hymenopteron *Diachasmimorpha longicaudata*, exposed to single acute exposures of 10 to 70 Gy	50% of control flies developed into adults vs. 25% at 10 Gy, and <1% at 30 Gy. At 40 Gy and higher, no adults were recovered but parasite development was the same at all doses	1
Silkworm, *Bombyx mori*; eggs, acute single exposure of 2, 5, or 10 Gy	At 2 Gy, an average increase of 23% in larval mass, cocoon shell weight, and silk production; no stimulatory effect at 5 Gy; at 10 Gy, larval development inhibited	2
Mediterranean fruit fly, *Ceratitis capitata*; females, acute single exposure of 150-155 Gy	Inhibited oviposition	3
Moth, *Ectomyelois ceratoniae*; male pupae, age 3 or 5 days, acute single exposure of 50 to 500 Gy	Younger pupae were more sensitive than older pupae. Only 3% of pupae developed into adults at 500 Gy. At >250 Gy, progeny development reduced 50%. Normal fecundity at 100-250 Gy when mated with control females	4
Leafmining fly, *Liriomyza trifolii*; immature stages, on artificially infested bean	All dead at >750 Gy; 80% dead at 250 Gy; eggs and prepupae were the most sensitive	5

Species, dose, and other variables	Effect	Reference[a]
seedlings; acute single exposure of 25 to 2,000 Gy	stage; no phytotoxic effects	

[a] 1, Sivinski and Smittle 1990; 2, Yusifov et al. 1990; 3, McInnes and Wong 1990; 4, Al-Izzi et al. 1990; 5, Yathom et al. 1990.

Following the successful application of radiation to sterilize male screw-worm flies (*Cochliomyia hominivorax*), various insect pests became the target of similar techniques throughout the world (Al-Izzi et al. 1990). The technique has suppressed populations of the Mediterranean fruit fly (*Ceratitis capitata*), a major pest of fruits, although results have not been as spectacular as with the screw-worm fly (McInnes and Wong 1990). The pestiferous Caribbean fruit fly (*Anastrepha suspensa*), heavily parasitized by a beetle, became sterile after acute exposures to ionizing radiation, although beetles remained fecund. Mass rearing and inundative release of the radioresistant beetle parasite is now considered an option for control of the Caribbean fruit fly (Table 20).

Aquatic Organisms

Among aquatic organisms, it is generally acknowledged that primitive forms are more radioresistant than complex vertebrates and that older organisms are more resistant than the young (Donaldson and Foster 1957; Bonham and Welander 1963; Templeton et al. 1971; Table 21). Developing eggs and young of some species of freshwater fishes are among the most sensitive tested aquatic organisms; death was observed at acute doses of 0.3-0.6 Gy, and minor effects on physiology or metabolism were observed at chronic daily dose rates of 0.01 Gy (Bonham and Welander 1963; Templeton et al. 1971; IAEA 1976; Table 21). Radiosensitivity correlated positively with the metabolic rate of the dividing cell, which accounts for the radioresistance of dormant eggs of aquatic invertebrates and the general sensitivity of early embryonic stages of all aquatic species (Donaldson and Foster 1957; Table 21).

Table 21. Radiation effects on selected aquatic organisms.

Table 21. Taxonomic group, organism, dose, and other variables	Effect	Reference[a]
Algae		
Diatom, *Nitzchia closterium*; acute single exposure of 100 Gy	Lethal	1
Euglena, *Euglena gracilis*; acute single exposure of 550 Gy	Tolerated	1
Freshwater algae, seven species, held in water containing 1,110 Bq ^{226}Ra/L for as long as 14 days	After 24 h, four species (*Ankistrodesmus falcatus*, *Chlorella vulgaris*, *Coelastrium cambricum*, *Scenedesmus obliquus*) had decreased oxygen production by 22-37%; after 14 days, no effect on growth or protein content	2
Various species, single acute exposure		
80-1,000 Gy	LD50, 45 days, postexposure	3
250-6,000 Gy	LD100, 45 days after single exposure	3
Protozoans, various species, acute single exposure		

Table 21. Taxonomic group, organism, dose, and other variables	Effect	Reference[a]
100-300 Gy	LD50, up to 40 days postexposure	3
180-12,500 Gy	LD100, up to 40 days postexposure	3
Coelenterates		
Sea anemone, *Anthopleura xanthogrammica*; 0.2 Gy, acute single exposure	Tentacles withdrawn	1
Jellyfish, *Aurelia aurita*; acute single exposure		
50-150 Gy	No deaths in 60 days	4
50-400 Gy	Dose-dependent increase in developmental abnormalities and abnormal budding rates and patterns	4
100 Gy	Metamorphosis and budding inhibited; reduction in pulsation rate	4
150 Gy	Inhibited reproduction	4
200 Gy	60% died in 60 days	4
400 Gy	90% died in 30 days	4
Molluscs		
Water snail, *Physa heterostropha*; exposure of 2.4-5.5 Gy daily for 1 year	Increased growth rate	1
Various species, acute single exposure		
50-200 Gy	LD50, up to 2 years postexposure	3
100-500 Gy	LD100, up to 2 years postexposure	3
Crustaceans		
Brine Shrimp, *Artemia salina*; acute single exposure		
0.004 Gy	No adverse effects on development of cysts	5
0. 1-9 Gy	Decreased development when exposed as cysts	5
4.5-9 Gy	LD50, nauplii, 20-25 days postexposure	6
130 Gy	LD50, adults, 25 days after exposure	6
486-2,084 Gy	Dose-dependent delay in development of eggs	7
3,000 Gy	LD50, cysts	5
Blue crab, *Callinectes sapidus*; continuous exposure to 0.76 Gy daily for 1 year	Increased growth rate	1
Shore crab, *Carcinus maenus*		
Americium-241, dose unknown	After 8 days, bioconcentration factors (BCF) were 145 in whole crab, 960 in gills, and 240 in exoskeleton; 50% elimination in 45 days	8
Plutonium-237, dose unknown	After 8 days, BCF values were	8

Table 21. Taxonomic group, organism, dose, and other variables	Effect	Reference[a]
	75 in whole crab, 340 in gills, and 70 in exoskeleton; 50% elimination in 55 days	
Daphnid, *Daphnia pulex*; daily exposure to 8.2-17.8 Gy for 1 year	Increased growth rate	1
Various species, single acute exposure		
5-900 Gy	LD50, up to 80 days postexposure	3
50-800 Gy	LD100, up to 80 days postexposure	3
Annelids		
Polychaete, *Neanthes arenaceodentata*; acute single exposure		
1-4 Gy	Adverse effects on reproduction	9
2-100 Gy	Significant increase in frequency of chromosomal aberrations	9
>100 Gy	Decreased life span	9
>500 Gy	Death	9
Fishes		
Common carp, *Cyprinus carpio*		
Adults, 3 Gy, acute single exposure	No effect on growth	1
Fertilized eggs, exposed through hatch		
144 million Bq ^{238}Pu/L	Increased abnormalities	10
277 million Bq ^{238}Pu/L	Decreased hatch	10
44 million Bq ^{232}U/L	Increased abnormalities	10
815 million Bq ^{232}U/L	Decreased hatch	10
Anchovy, *Engraulis* sp.; fertilized eggs, ^{90}Sr-^{90}Y, continuous exposure		
7.4 Bq/L	Increased developmental abnormalities	10
740 Bq/L	Decreased hatch, retarded growth rate	10
Fishes, various species, acute single exposure		
6-30 Gy	LD50, up to 460 days postexposure	3
3.7-200 Gy	LD100, up to 460 days postexposure	3
Pinfish, *Lagodon rhomboides*; exposure to 0.197 Gy daily for 1 year	Increased growth rate	1
Bluegill, *Lepomis macrochirus*; acute single exposure of 10, 20, or 30 Gy	At 20 and 30 Gy, serum proteins were reduced more than 50% within 24 h; damage to the GI capillary system and injury to the gastroepithelium accounted for the excessive protein loss	12
Marine teleosts, 6 species,	LD50	11

Table 21. Taxonomic group, organism, dose, and other variables	Effect	Reference[a]
10-55 Gy, acute single exposure		
Silver salmon, *Oncorhynchus kisutch*; acute single exposure		
Early embryonic stages, 0.3-0.6 Gy	LD50 at hatch	13
Later embryonic stages, 9.2-18.7 Gy	LD50 at hatch	13
Rainbow trout, *Oncorhynchus mykiss*		
Embryos, acute single exposure		
0.6 Gy, 1-cell stage	LD50 by end of yolk resorption	10
0.8 Gy, 1-cell stage	LD50 at hatch	3
3.1 Gy, 32-cell stage	LD50 by end of yolk resorption	10
4.1 Gy, early eyed stage	LD50 by end of yolk resorption	3
4.6 Gy, 32-cell stage	LD50 by hatch	3
9.0 Gy, late eyed stage	LD50 by end of yolk resorption	3
Embryos held in water containing 370 million Bq/L of ^{3}H from immediately after fertilization through hatching	No effect on hatching abnormalities	10
Embryos held in water containing 37 million Bq/L of ^{3}H from 6 h after fertilization through hatch	Suppressed immune response of fry	10
Immatures, single acute exposure of 0.2 Gy	Growth stimulation	1
Juveniles exposed for 27 days to radioneptunium isotopes and analyzed 2-15 days postexposure	Maximum BCF values were 8.7 for whole fish, 1.1 for skin, and 0.34 for muscle	14
Yearlings, force-fed 185,000, 1.85 million, or 18.5 million Bq ^{90}Sr-^{90}Y/kg BW daily for 21 weeks	At highest dose, adverse effects on growth (week 12) and survival (week 15); survivors had leucopenia and gut histopathology, and concentrations of 9.2 billion Bq/kg FW in bone and 9.99 million Bq/kg FW in muscle. Residues in the 1.85 million group were 1.04 billion Bq/kg in bone and 2.96 million Bq/kg in muscle. For the 185,000 group, these values were 77.7 million Bq/kg in bone and 74,000 Bq/kg in muscle	11,15
Yearlings force-fed 370,000, 3.7 million, or 37 million Bq ^{65}Zn/kg BW daily for 17 weeks, or 370 million Bq ^{65}Zn/kg BW daily	Adverse effects on growth, survival, or gut histology at any dose; leucopenia evident at week 10 at the highest dose. Residues, in Bq/kg FW,	11,15

Table 21. Taxonomic group, organism, dose, and other variables	Effect	Reference[a]
for 10 weeks	in the 37 million group at 17 weeks were 148 million in bone and 12.9 million in muscle	
Yearlings force-fed 222,000, 2.2 million, or 22.2 million Bq ^{32}P/kg BW daily for as long as 25 weeks	At highest dose tested, adverse effects on growth, survival, and gut histology between day 17 and 77. In the intermediate 2.2 million group, adverse effects on growth at 17 weeks; residues (Bq/kg FW) were 66.6 million in bone and 8.5 million in muscle. The 220,000 group had no adverse effects in 25 weeks on growth, survival, or tissue alterations	11
Gametes of adults, single acute exposure of 0.5-1.0 Gy	50% reduction in fecundity	3
Adults, single acute exposure of 15 Gy	LD50	3
Chinook salmon, *Oncorhynchus tshawytscha*		
0.0004 Gy/h, eggs, 81-day exposure, total dose of 0.78 Gy	Significant adverse effects on survival and development	21
0.005 Gy daily, continuous exposure from egg fertilization through yolk sac absorption; total dose of 0.35 Gy	No adverse effects on growth and survival or on numbers of returning adults after seaward migration	22
0.028 Gy daily, continuous exposure from egg fertilization through yolk sac absorption; total dose of 1.99 Gy	No adverse effects observed prior to seaward migration	22
0.2 Gy, single acute exposure	Growth increase	1
10 Gy, eyed eggs, single acute exposure	LD50	3
12.5-25 Gy, fingerlings, single acute exposure	LD50	3
Medaka, *Oryzias latipes*; adult males receiving single acute exposure of 0.64,4.75, or 9.5 Gy	Dose-dependent increase in total mutations in sperm, spermatids, and spermatogonia	16
Sea lamprey, *Petromyzon marinus*; males captured during spawning run, single acute exposure		
20 Gy	LD50, 45 days postexposure; survivors sterile	17

Table 21. Taxonomic group, organism, dose, and other variables	Effect	Reference[a]
30 Gy	All died before spawning,	17
Fathead minnow, *Pimephales promelas*; developing eggs, continuous exposure		
4,440 Bq ^{144}Ce-^{144}Pr/L	No effect on embryonic development or hatch	10
9.6 million Bq ^{238}Pu/L	Increased abnormalities	10
48.1 million Bq ^{238}Pu/L	Decreased hatch	10
7.4 million Bq ^{232}U/L	Increased abnormalities	10
18.5 million Bq ^{232}U/L	Decreased hatch	10
Atlantic salmon, *Salmo salar*; fertilized eggs, continuous immersion in 92.5 Bq ^{137}Cs/L or 185 Bq ^{90}Sr/L	Increased mortality of embryos and fry	10
Brown trout, *Salmo trutta*		
Fertilized eggs continuously immersed in water containing 3.7 million Bq/L of ^{90}Sr-^{90}Y through hatch	No effect on hatch or developmental abnormalities	10
Juveniles held in water containing 30,000 Bq ^{110m}Ag/L for 57 days, then transferred to uncontaminated media for 28 days	At day 57, whole trout contained 105,000 Bq ^{110m}Ag/kg FW; about 70% was in liver. No detectable radioactivity after depuration for 28 days	18
Juveniles fed diet containing 3,343,000 Bq ^{110m}Ag/kg for 1 week (5 times weekly), then 269,000-296,000 Bq ^{110m}Ag/kg diet between weeks 2 and 5. Depuration for 28 days	At end of exposure, whole trout contained 27,400 Bq ^{110m}Ag/kg, equivalent to 11.7% of ingested radioactivity; liver accounted for 63%. No detectable radioactivity after depuration for 28 days	19
Integrated study		
Artificial stream simulating outfall from Czechoslovakian nuclear power plant, 28-day exposure, strontium-90		
Water	894 Bq/L	20
Sediments	1,589-2,288 Bq/kg FW	20
Alga, *Cladophora glomerate*	Max. 22,106 Bq/kg FW	20
Snail, *Planorbis corneus*, shell vs. soft parts	760,588 Bq/kg FW vs. 27,468 Bq/kg FW	20
Common carp, *Cyprinus carpio*		
Bone	29,144 Bq/kg FW	20
Muscle	580 Bq/kg FW	20

Table 21. Taxonomic group, organism, dose, and other variables	Effect	Reference[a]
Scales	13,101 Bq/kg FW	20
Uncontaminated site		
Water	0.002-0.005 Bq/L	20
Common carp, internal organs vs. scales	0.1-0.5 Bq/kg FW vs. 1.5-9.3 Bq/kg FW	20

[a] l, Rose 1992; 2, Havlik and Robertson 1971; 3, Donaldson and Foster 1957; 4, Prokopchak et al. 1990; 5, Gaubin et al. 1990; 6, Engel and Davis 1976; 7, Su et al. 1990; 8, Guary and Fowler 1990; 9, S. L. Anderson et al. 1990; 10, Whicker and Schultz 1982b; 11, Templeton et al. 1971; 12, Ulrickson 1971; 13, Bonham and Welander 1963; 14, Poston et al. 1990; 15, IAEA 1976; 16, Shima and Shimada 1991; 17, Hanson 1990; 18, Garnier et al. 1990; 19, Garnier and Baudin 1990; 20, Stanek et al. 1990; 21, National Council on Radiation Protection and Measurements (NCRP) 1991; 22, Donaldson and Bonham 1970.

Adverse effects on the fecundity of sensitive aquatic vertebrates were detected at dose rates as low as 0.4 mGy/h; adverse effects on fecundity were measured only at dose rates of greater than 1.0 mGy/h. Thus, deleterious effects in populations of aquatic vertebrates are probably not detected until the 0.4-1.0 mGy/h dose rate is exceeded (NCRP 1991). Organisms such as estuarine organisms that are exposed to variable physicochemical conditions are more radioresistant than those in buffered environments, and this may be due to a higher degree of genetic polymorphism in species of fluctuating environments (IAEA 1976). Estimated dose effects from the induction of chromosomal aberrations in polychaete annelid worms were dependent on cell stage at time of irradiation (S.L. Anderson et al. 1990). For reproduction, the estimated dose effects were dependent on the potential regeneration of gonadal tissue (S.L. Anderson et al. 1990). Radiation causes dominant lethal mutations in the medaka (*Oryzias latipes*; Shima and Shimada 1991). Ionizing radiation at low-level chronic exposure reportedly has no deleterious genetic effects on aquatic populations because exposure is compensated by density-dependent responses in fecundity (IAEA 1976); however, this needs verification.

Accumulation of radionuclides from water by aquatic organisms varies substantially with ecosystem, radionuclide, and trophic level (Tables 22-24); with numerous biological, chemical, and physical variables; and with proximity to sources of radiation (Bowen et al. 1971; Lowman et al. 1971; Templeton et al. 1971; Mo and Lowman 1976; Shure and Gottschalk 1976; Whicker and Schultz 1982b; Becker 1990; Poston et al. 1990; Joshi 1991). Accumulated radionuclides inside embryos of the scorpionfish (*Scorpaena porcus*) and the turbot (*Scopthalmus maeoticus maeoticus*) increased the frequency of nuclear disruptions in these species; ^{90}Sr-^{90}Y and ^{91}Y had greater cytogenetic effects than other tested radionuclides (Polikarpov 1973). In the absence of site-specific data, the U.S. Nuclear Regulatory Commission recommends the use of listed concentration ratios--the concentration of the element in the organism (in mg/kg FW) divided by the concentration in the medium (in mg/L)—for various elements in marine and freshwater fishes and invertebrates (Whicker and Schultz 1982b). However, the commission clearly indicates that these values are only approximations.

Table 22. Concentration factors[a] for cesium-137 and strontium-90 in aquatic organisms (Whicker and Schultz 1982a).

Radionuclide and ecosystem	Molluscs, whole	Crustaceans, whole	Fishes, muscle
Cesium-137			
Freshwater	600	4,000	3,000
Marine	8	23	15
Strontium-90			
Freshwater	600	200	200
Marine	1	3	0.1

[a] Bq per gram fresh weight sample/Bq per mL medium.

Table 23. Maximum concentration factors[a] reported for selected elements in marine organisms at various trophic levels (Bowen et al. 1971).

Element	Algae	Grazers	Predators
Ag	1,000	20,000	3,000
Cd	6,000	2,000,000	10,000
Ce	4,500	300	12
Co	1,000	10,000	50,000
Cr	600	300,000	3,900
Cs	50	15	10
Fe	70,000	300,000	30,000
I	7,000	70	10
Mo	200	175	200
Mn	20,000	60,000	100,000
Ni	1,000	10,000	80
Pb	3,000,000	2,000,000	200,000
Ru	1,000	16	10
Sr	90	85	5
Ti	30,000	20,000	3,000
Zn	3,000	100,000	20,000
Zr	20,000	30,000	40,000

[a] Bq per gram fresh weight tissue/ Bq per mL seawater.

Table 24. Approximate maximum concentration factors[a] for selected transuranics in marine sediments, macroalgae, and fishes (Morse and Choppin 1991).

	Concentration factor		
Transuranic nuclide	Sediments	Macroalgae	Fish
Neptunium	1,000	5,000	10
Plutonium	100,000	2,000	40
Americium, curium, berkelium, californium	2,000,000	8,000	50

[a] Bq per gram fresh weight sample/Bq per mL water.

After more than 400 atmospheric nuclear test explosions and the fallout from Chernobyl, ^{137}Cs became the most frequently released nuclear fission product throughout central Europe (Jandl et al. 1991). Cesium behaves like potassium; it has a ubiquitous distribution inside the body, especially in soft tissues. In the common snail *Helix pomatia*, the biological half-time after a single 24-h dietary dose was 2.5 days by the short-lived component and 28.5 days by the long-lived component (Jandl et al. 1991). Concentration factors (CF) of ^{137}Cs in muscle (ratio of Bq/kg FW muscle:Bq/L filtered seawater) of marine fishes from the North Sea between 1978 and 1985 ranged from a low of 39 in the plaice (*Pleuronectes platessa*) to a high of 150 in the whiting (*Merlangius merlangius*); CF values were intermediate in the haddock (*Merlanogrammus aeglifinus*; CF of 58) and in the Atlantic cod (*Gadus morhua*; CF of 92). These data seem to support the use of a CF of 100 for ^{137}Cs in muscle of marine fishes in generalized assessments, although some adjustment is necessary when particular species, such as whiting, form the bulk of a consumer's diet (Steele 1990). In the Great Lakes, the maximum CF values of ^{137}Cs range from 1,000 to 10,000 in algae, amphipods, and fishes and from 100 to 1,000 in zooplankton (Joshi 1991). Maximum concentration factors of ^{137}Cs in a contaminated creek in South Carolina were 4,243 in suspended particulates, 938 in detritus, 4,496 in algae and macrophytes, 997 in omnivores, 1,292 in primary carnivores, and 1,334 to 2,595 in top carnivores such as the redbreast sunfish (*Lepomis auritis*), largemouth bass (Mi*cropterus salmoides*), and water snakes (*Natrix* spp.; Shure and Gottschalk 1976). Cesium

uptake by oligochaete worms (*Limnodrilus hoffmeisteri*) *is* inhibited by low temperatures, potassium concentrations of greater than 1 mg/L and the presence of bacteria (*Escherichia coli*) that compete with the worms for ^{137}Cs (Steger and Goodnight 1976).

Atmospheric fallout from nuclear testing is the main pathway by which transuranic nuclides such as Np, Pu, Cm, and Am enter the aquatic environment (Guary and Fowler 1990). In general, transuranics are strongly partitioned onto particulates. Living organisms are less enriched than particulate matter by as much as 1,000 times, and concentration factors by marine biota are similar for transuranics beyond neptunium (Morse and Choppin 1991). The uptake of ^{241}Am and ^{244}Cm from contaminated sediments by a freshwater amphipod (*Hyalella* sp.) and oligochaete (*Tubifex* sp.) is reported, presumably by way of adsorption, and this is considered the principal uptake pathway by benthic organisms in freshwater and in marine ecosystems (Sibley and Stohr 1990). Transuranics that were ingested with food by various crabs were initially excreted with feces; the remaining transuranics entered a soluble radionuclide pool inside the animal that was slowly excreted. Decapod crustaceans assimilate and retain 10-40% of the tranuranic nuclides in their diets. Initially, absorbed radionuclides accumulate in the hepatopancreas but are then translocated to other tissues, particularly to tissues of the exoskeleton; accordingly, molting strongly influences elimination in crustaceans (Guary and Fowler 1990). Neptunium isotopes have a higher potential for environmental transport in aquatic systems and in groundwater than other tested actinides. Laboratory studies with ^{235}Np and ^{237}Np, for example, showed concentration factors between 275 and 973 in a green alga (*Selenastrum capricornutum*), 32 and 72 in a daphnid (*Daphnia magna*), 2 in an amphipod (*Gammarus* sp.) and in juvenile rainbow trout, 8.7 in carcass, 1.1 in skin, and 0.3 in muscle during a 96-h period (Poston et al. 1990). When the much higher biological effectiveness of alpha than of beta or gamma radiation is considered, plutonium isotopes may contribute more artificial radiation dose equivalent to marine invertebrates than either ^{90}Sr or ^{137}Cs. Concentration factors of ^{239}Pu and marine organisms ranged from 300 to 100,000 in seaweeds, 250 to 690 in molluscs, 760 to 1,020 in echinoderms, 2,100 in sponges, and as much as 4,100 in worms (Noshkin et al. 1971). Concentration factors of $^{239+240}Pu$ in Lake Michigan were between 1 and 10 in predatory salmonids, 10 and 300 in nonpredatory fishes, 900 and 1,200 in amphipods and shrimp, about 200 in zooplankton, and about 6,000 in algae (Joshi 1991).

Iodine-131 (half-life of 8 days) may cause deleterious effects in marine teleosts--although ^{131}I concentrations in tissues were not detectable. In one case, coral reef fishes from Eniwetok Atoll collected as long as 8 months after a nuclear explosion had thyroid necroalteration, suggesting a thryotoxic level of ^{131}I in the environment. Laboratory studies with teleosts injected with ^{131}I showed similar signs of histopathology. Herbivorous fishes and species that habitually consumed bivalve molluscs were most severely affected (Gorbman and James 1963).

Strontium-90 is an anthropogenic radionuclide in liquid effluents from some European nuclear power plants. Algae and sediments are the most important accumulators of ^{90}Sr, although levels in gastropods and fish bone and scales are also elevated, suggesting piscine uptake through gills and skin (Stanek et al. 1990). Fishes tend to accumulate calcium more than strontium, even when Ca levels in food and water were low. Gill tissue was the most and gut the least discriminatory against Sr. Strontium assimilation was linked to the Sr:Ca ratio in food and water, amounts of Ca derived from each source, and biological discrimination against Sr relative to Ca (Ophel and Judd 1976). The ability of organisms to discriminate between strontium radioisotopes is also documented. In one case, ^{85}Sr was taken up rapidly in bluegill (*Lepomis macrochirus*) muscle and blood and quickly exchanged with stable strontium; however, ^{90}Sr was retained longer than 35 days in these tissues (Reed and Nelson 1969).

Ruthenium-106 appeared in clams from North Carolina within 2 weeks after the third and fifth Chinese nuclear tests in 1965-67. Its retention was resolved into two rate functions with apparent effective half-lives of 40 days and 7 days (Wolfe and Jennings 1971). Iron-55 is a neutron-activation product produced in large quantities from ferrous materials in the immediate vicinity of a nuclear detonation. Concentration factors of ^{55}Fe and plankton in Bikini Atoll ranged from 15,000 to 25,000 (Schell 1976). Silver-110m has been detected in marine organisms after atmospheric weapon tests in the Pacific, in fishes from the Rhone River after the Chernobyl

accident, and in fishes near reactor-waste outfalls (Gamier et al. 1990). Silver-110m is depurated rapidly by brown trout (*Salmo trutta*) after high intake exposures in the water or diet (Gamier et al. 1990; Gamier and Baudin 1990). Radiotungsten is produced in quantity by certain types of nuclear devices. In one case tungsten was the most abundant radionuclide in the environment, accounting for about 90% of the total fallout activity 167 days after the detonation (Reed and Martinedes 1971). Tungsten-181 tended to concentrate in the hepatopancreas and gut of the crayfish (*Cambarus longulus longerostris*); whole body elimination consisted of two components: a rapid 1-day component and a second slower component with a biological half-time of 12.2 days (Reed and Martinedes 1971). Benthic organisms take up limited amounts of heavy metals and radionuclides from bottom sediments and recycle them to benthic and pelagic food webs. For example, polychaete worms (*Nereis diversicolor*) in contact with ^{65}Zn-contaminated sediments for 5 days lost 50% of accumulated ^{65}Zn in about 19 days on transfer to uncontaminated sediments (Renfro and Benayoun 1976).

Amphibians and Reptiles

Radiation adversely affects limb regeneration of amphibians, alters DNA metabolism, and increases the frequency of chromosomal aberrations and liver lesions (Table 25). In some species of amphibians and reptiles as in many mammals, mortality rates after acute exposure to radiation do not stabilize within 30 days--effectively invalidating the conventional LD50 (30-day postexposure) value. In the rough-skinned newt (*Taricha granulosa*), for example, the minimal LD50 dose was 2.5 Gy at 200 days after irradiation but 350 Gy at 30 days (Willis and Lappenbusch 1976). Low temperatures seem to prolong the survival of amphibians that are exposed to ionizing radiation. The survival was greater of leopard frogs (*Rana pipiens*) held at low temperatures (5-6° C) after total-body exposure to lethal doses of X-rays than of frogs held at higher temperatures. Prolonged survival at low temperatures was due to a prolongation of the latent period rather than to appreciable recovery (Patt and Swift 1948).

Table 25. Radiation effects on selected amphibians and reptiles.

Table 25. Species, dose, and other variables	Effect	Reference[a]
Leopard lizard, *Crotaphytus wislizenii*; chronic field exposure of 0.04-0.06 Gy daily (4-5 Sv yearly) for 3 to 6 years	No female reproduction in years 3 and 4. In year 5, males were sterile and females had complete regression of ovaries, undeveloped oviducal walls, and hypertrophied fat bodies. In year 6, 75% of females lacked ovaries and 25% had normal ovaries with signs of recent egg deposition; males appeared normal	1
Mud puppy, *Necturus maculosus*; 1.1 Gy, single acute exposure	LD50, 30 days postexposure	2
Salamander, *Necturus sp*.; 0.8 Gy, single acute exposure	LD50, 200 days postexposure	3
Eastern newt, *Notophthalmus viridescens*; adults, single acute exposure of 20Gy, one limb shielded; or 22 Gy, whole body, no limbs shielded	Forelimb regeneration completely suppressed when limbs to be amputated were irradiated directly. Irradiated limbs had severe and protracted inflammation, with total resorption of the affected limbs in 85% of the cases. Shielded limbs subsequently amputated had	4

Table 25. Species, dose, and other variables	Effect	Reference[a]
	delays-but not suppression-in rate of forelimb regeneration and skin graft rejection	
Frog, *Rana sp*., single acute exposure		
7.0-7.2 Gy	LD50, 730 days after exposure	3
7.8 Gy	LD50, 150 days after exposure	3
Snakes, 2 species, 3 to 4 Gy, single acute exposure	LD50, 90 days after exposure	3
Rough-skinned newt, *Taricha granulosa*; single acute exposure		
2.5 Gy	LD50, 200 days after exposure; skin lesions and depigmentation	5
>6.5 Gy	Progressive anemia over 6-week postirradiation period; reduction in erythrocyte numbers and weight of spleen	5
80 Gy	LD50, 100 days after exposure	5
350 Gy	LD50, 30 days after exposure	5
Turtles, 4 species, <8 to 15 Sv, single acute exposure	LD50, 120 days postexposure	3
Common slider, *Trachemys scripta*; inhabiting a radioactive reservoir, in Aiken, South Carolina. Radionuclide concentrations, in Bq/kg, whole body fresh weight, (FW) were 1,002 for ^{137}Cs and 550 for ^{90}Sr. For controls, these values were 2 for ^{137}Cs and 260 for ^{90}Sr	Contaminated turtles, when compared with controls, had greater variation in DNA content of red blood cell nuclei, suggesting genetic damage. The biological half-life of ^{137}Cs in soft tissues was 64 days; for ^{90}Sr in shell and bone, it was 364 days	6
Spiny tailed lizard, *Urornastix hardwickii*; single acute exposure, held for up to 14 days after irradiation		
2.25 Gy	No lesions in liver	7
4.5 Gy	No liver lesions, but swollen hepatocytes, increases in bile pigmentation, and altered cytoplasmic degranulation; normal after 14 days	7
9.0 Gy	Some liver lesions, but all livers normal 14 days postexposure	7
Side-blotched lizard, *Uta stansburiana*; 10-22 Gy, single acute exposure	LD50, 30 days postexposure	3

[a] 1,Turner et al. 1971; 2, Rose 1992; 3, Hinton and Scott 1990; 4, Sicard and Lombard 1990; 5, Willis and Lappenbusch 1976; 6, Lamb et al. 1991; 7, Gupta and Umadevi 1990.

The South African clawed frog (*Xenopus laevis*) was a suggested bioindicator of radioactive contamination because of the greater radiosensitivity of amphibians than fishes, the ease of maintaining *Xenopus* in the laboratory, and the sensitivity of the *Xenopus* liver to radioactive contamination--including ^{45}Ca, which does not accumulate in the liver (Giannetti et al. 1990). *Xenopus* oocytes exposed to X-rays showed single- and double-strand breaks in DNA and oxidative-type base lesions at a frequency between 85% and 95%. *Xenopus* oocytes repaired X-ray induced damage in plasmid DNA; however, some X-ray lesions can stimulate homologous recombination in these cells (Sweigert and Carroll 1990). Common slider turtles (*Trachemys scripta*) in a radioactive reservoir show evidence of genetic damage, and this was attributed to long-term exposure of low concentrations of long-lived radionuclides, including ^{137}Cs and ^{90}Sr (Lamb et al. 1991). Natural populations of gulf coast toads (*Bufo valliceps*) reportedly can survive genetically damaging doses of ionizing radiation without impairment of population integrity (Whicker and Schultz 1982b). Toads and many other species share a high attrition on the large numbers of young produced each generation, and this provides an agency for intensive selection. Also under this regime, recessive mutants are eliminated as they are exposed through inbreeding in future generations (Whicker and Schultz 1982b). Sterility in field collections of the leopard lizard (*Crotaphytus wislizenii*) and the western whiptail lizard (*Cnemidophorus tigris*) was reported after long-term exposure of 3 to 5 years to various doses of gamma radiation, that is, 4-5 Sv annually in *Crotaphytus* and 2.0-2.5 Sv annually in *Cnemidophorus* (Turner et al. 1971). However, a third species of lizard in the study area (side-blotched lizard, *Uta stansburiana*) reproduced normally (Turner et al. 1971).

The retention of selected isotopes by amphibians and reptiles is quite variable. For example, whole-body retention of ^{131}I after intraperitoneal injection in the rough-skinned newt showed 2 distinct loss components with biological half-lives of 2 and 210 days; the slower component accounted for 26% of the administered activity; thyroid contained 78% of the total ^{131}I and clearly accounted for the long-term component (Willis and Valett 1971). However, similar studies with ^{131}I and the leopard frog showed three distinct loss components (0.1 day; 1.4-2.9 days; 44.3-69.4 days); loss of each component was greater at 25° C than at 10° C; also, the fast component probably represented plasma clearance through urinary excretion (Willis and Valett 1971).

Birds

Among birds, as in most other tested species, there is a direct relation between dose and mortality at single high doses of ionizing radiations (Whicker and Schultz 1982b; Table 26). For any given total dose, the survival of a bird is higher if the dose is delivered at a lower rate or over a longer period of time and suggests that biological repair processes compensate for radiation-induced cellular and tissue damage over a prolonged period or at a comparatively low dose rate (Brisbin 1991). Nestling bluebirds (*Sialia sialis*) were more resistant to gamma radiation than young domestic chickens (*Gallus* sp.), and nestling greatcrested flycatchers (*Myiarchus crinitus*) were more sensitive than bluebirds (Willard 1963). Passerine nestlings are more resistant to radiation stress than adults of larger-bodied precocial species (Brisbin 1991). But the comparatively resistant passerine nestlings frequently show a disproportional disturbance in radiation-induced growth, resulting in a reduction of overall survival. For example, if feather growth is stunted, death results from the inability to escape predators because of impaired flight (Brisbin 1991).

Table 26. Radiation effects on selected birds.

Table 26. Species, dose, and other variables	Effect	Reference[a]
Green-winged teal, *Anas carolinensis*; 4.8 Gy, single acute exposure	LD50, 30 days postexposure	1
Northern shoveler, *Anas clypeata*; 8.9 Gy, single acute exposure	LD50, 30 days postexposure	1
Blue-winged teal, *Anas discors*; 7.2 Gy, single acute exposure	LD50, 30 days postexposure	1

Table 26. Species, dose, and other variables	Effect	Reference[a]
Birds		
Eggs, passerine species, single acute exposure, 5-10 Gy	LD100	2
Nestlings, various species, 1 Gy daily	Growth retardation	3
Common quail, *Coturnix coturnix*; fertilized eggs, exposed first 9 days of incubation, single acute exposure		
5 Gy	Negligible effect on survival	4
7 Gy	Mortality >50%	4
9 Gy	All dead before hatch	4
Domestic chicken, *Gallus sp*.		
Single acute exposure		
Eggs of broilers exposed to 0.05-2.1 Gy before incubation	No adverse effects on embryonic development at 1.6 Gy and lower; at 2.1 Gy, adverse effects on development, survival, and body weight of hatched chicks	5
Chicks, age 15 days		
2.1 Gy	Reversible changes in blood chemistry within 60 days; no deaths	6
6.6 Gy	Irreversible and permanent damage to red blood cells, hemoglobin, and hematocrit; all dead within 7 days	6
Dietary exposure		
Laying hens fed diet containing 400 Bq ^{137}Cs/kg ration for 4 weeks	Of total ^{137}Cs ingested, 3% was distributed in egg contents (29-33 Bq/kg egg; 2 Bq egg); 9% in muscle (171 Bq/kg FW); and 81% in excreta	7
Broiler chickens fed diets containing 400 Bq ^{137}Cs/kg ration for 40 days; some diets contained up to 5% bentonite	Feeding with bentonite reduced ^{137}Cs concentration in muscle by 32% from 155 to 105 Bq/kg FW	7
Common black-headed gull, *Larus ridibundus ridibundus*; eggs, 9.6 Gy over 20 days	LD50	3
Great crested flycatcher, *Myiarchus crinitus*; nestlings, single acute exposure >8 Gy	All dead by fledging	8
Eastern bluebird, *Sialia sialis*, single acute exposure		
Nestlings, age 2 days		
3 Gy	Reduced growth after 16 days	8
3-5 Gy	Reduced growth and shorter primary feathers at fledging	8
4-12 Gy	Developed normally and	2

Table 26. Species, dose, and other variables	Effect	Reference[a]
	fledged successfully	
5-6 Gy	LD50, nestling to fledgling	8
25 Gy	LD50, 16 days postexposure	8
30 Gy	All dead 4 days postexposure	2,8
Fertilized eggs, 6 Gy	All dead before hatch	2
European starling, *Sturnus vulgaris*; >2 Gy, single exposure	Fatal	9
Tree swallow, *Tachycineta bicolor*		
0.006 mGy/h during breeding season, equivalent to annual dose of about 50 mSv	No adverse effects on breeding performance of adults or growth performance of nestlings	10
0.9-4.5 Gy, single acute exposure, nestlings	Adverse effects on growth, survival or both	2
1.0 Gy daily, chronic	Reduced hatch, depressed growth	2
House wren, *Troglodytes aedon*; fledglings, 0.9 Gy, single acute exposure	Growth reduction	9

a 1, Hinton and Scott 1990; 2, Millard and Whicker 1990; 3, Lowe 1991; 4, Wetherbee 1966; 5, Zakaria 1991; 6, Malhotra et al. 1990; 7, Andersson et al. 1990; 8, Willard 1963; 9, Rose 1992; 10, Zach et al. 1993.

Free-living, resident bird populations in the vicinity of sites contaminated with low levels of ionizing radiations generally have negligible genotoxic effects (George et al. 1991). However, 14% of mallards (*Anas platyrhynchos*) from an abandoned South Carolina reactor cooling reservoir heavily contaminated with ^{137}Cs (mallards contained an average of 2,520 Bq ^{137}Cs/kg whole body FW) had abnormal chromosome numbers and unusual variability in the concentration of erythrocyte DNA (George et al. 1991). Contaminated waterfowl rapidly eliminate accumulated radionuclides, suggesting inconsequential long-term damage to the birds and little hazard to human consumers of waterfowl flesh (Halford et al. 1983). This conclusion was from a study of mallards that were held for 68 to 145 days on liquid radioactive waste ponds in southeastern Idaho before they were transferred to an uncontaminated environment for 51 days. The biological half-life in mallards under these conditions was 10 days at ^{131}I and ^{134}Cs, 11 days at ^{137}Cs, 22 days at ^{140}Ba, 26 days at ^{75}Se, 32 days at ^{58}Co, 67 days at ^{6O}Co and ^{65}Zn, and 86 days at ^{51}Cr. At the time of removal from the waste ponds, radionuclide concentrations were highest in gut, then in feather, liver, and muscle, in that order. After 51 days in a radionuclide-free environment, the decreasing order of radionuclide concentrations was feather, liver, muscle, and gut (Halford et al. 1983).

Zinc-65 in trace amounts is accumulated by migratory waterfowl in the Pacific Flyway of North America from ^{65}Zn discharged into the Columbia River from water-cooled reactors at Hanford, Washington (Curnow 1971). The retention of ^{65}Zn in mallards was affected by sex and season but not by the age of the duck. Biological retention of ^{65}Zn was greater in males (Tb½ of 34.7 days) than in females (29.8 days) and greater in October (38 days) than in spring (32 days). Egg production accounted for the elimination of 25% of the ^{65}Zn and feather molt of 2-8% (Curnow 1971). Retention of ^{60}Co and ^{137}Cs--but not ^{109}Cd--in the Northern bobwhite (*Colinus virginianus*) after either acute or chronic exposure to contaminated food is similar. The biological half-life in bobwhites during exposure for 21 days was 8 days at ^{109}Cd, 11 days at ^{137}Cs, and 13 days at ^{60}Co. When radioisotopes were administered during a single 4-h feeding, Tb½ values were 3 days at ^{109}Cd, 10 days at ^{137}Cs, and 15 days at ^{60}Co (Anderson et al. 1976). The biological half-life of ^{137}Cs in avian tissues is about 6.0 days in the domestic chicken (Andersson et al. 1990), 6.7 days in the blue jay (*Cyanocitta cristata*); Levy et al. 1976), 5.6 days in the American wood duck (*Aix sponsa*) and 11.7 days in the mallard (Cadwell et al. 1979). Domestic poultry seem to accumulate a higher fraction of the daily ingested ^{137}Cs/kg muscle than mammals, but levels were effectively reduced by feeding an uncontaminated ration for at least 10 days prior to slaughter

(Andersson et al. 1990).

Mammals

The mammalian sensitivity to acute and chronic exposures of ionizing radiation, ability to retain selected radionuclides, and effect of biological and abiotic variables on these parameters are briefly summarized in Table 27. These data clearly indicate a dose-dependent effect of radiation on growth, survival, organ development, mutagenicity, fatal neoplasms, kidney failure, skeletal development, behavior, and all other investigated parameters. In general, fetuses and embryos were most sensitive to ionizing radiation, and acute or chronic exposures between 0.011 and 0.022 Gy were demonstrably harmful to mice, rats, and guinea pigs.

Table 27. Radiation effects on selected mammals.

Table 27. Species, dose, and other variables	Effect	Reference[a]
Short-tailed shrew, *Blarina brevicauda*; 7.8 Gy, single acute exposure	LD50, 30 days postexposure	1
Cow, *Bos sp*.		
Oral intake of 0.89 Bq ^{129}I, whole animal	Thyroid contained 0.97 Bq ^{129}I/kg fresh weight (FW) vs. <0.0012 Bq/kg FW for all other tissues	2
Fed 6.4 Bq ^{129}I daily for 8 days	After 8 days, 22% of total dose of 51.2 Bq was in thyroid; after 63 days, thyroid contained 1 Bq/kg FW and other tissues <0.01 Bq/kg FW	3
Dog, *Canis familiaris*		
Beagle embryos age 55 days, or pups 2 days old, given single acute exposure of 0.16, 0.83, or 1.25 Gy	Dose-dependent increase in immature dysplastic glomeruli and other signs of progressive renal failure	4
Beagles, prenatal and early neonatal stages, given single acute dose of 0.2-1.0 Gy, then observed over 11-year life span	Irradiation at all ages was associated with increased risk: decreased fertility; inhibited growth and development; lower brain weight; and increase in fatal neoplasms	5
Beagle embryos or pups As above, 2.24-3.57 Gy	Reduction in total number of nephrons and progressive renal failure	4
Beagles, 17-20 months old, single intravenous injection of 200-440,000 Bq ^{226}Ra/kg body weight (BW)	Dose-dependent increase in skeletal malignancies in 36% of dogs during lifetime	6
Beagles, age 5 years, given single injection of ^{226}Ra, in Bq/kg BW, of 39,000, 116,000, or 329,000. Injected ^{226}Ra solutions also contained ^{210}Po, ^{210}Pb, and ^{210}Bi	At lowest dose of 39 kBq/kg BW, kidney was normal, death after 2,032 days. At intermediate dose, death in 1, 210 days; at high dose, death in 581 days. Tubular degeneration and necrosis of kidney at 116 and 329 kBq	7
Beagles, age 7 years, single	No kidney damage with ^{226}Ra, but	7

Table 27. Species, dose, and other variables	Effect	Reference[a]
injection of ^{226}Ra (no contaminating ^{210}Po, ^{210}Pb, or ^{210}Bi) at 45,000 Bq/kg BW, or 122,000 Bq ^{210}Po/kg BW	kidney damage with ^{210}Po	
Beagles, age 7 years given single injection of 1,629,000 Bq ^{226}Ra/kg BW, equivalent to 1.89 Gy (from ^{210}Po contaminants), or 4,831,000 Bq ^{226}Ra/kg BW = 5.15 Gy from ^{210}Po	At low dose, all dead after 516 days; at high dose, all dead in 266 days. Death was from renal failure	7
Guinea pig, *Cavia* sp.; chronically irradiated daily during 8-h exposure. Daily dose, in Gy		
0.000	Mean survival time of 1,372 days	8
0.001	50% dead in 1,457 days	8
0.011	50% dead in 1,224 days	8
0.022	50% dead in 978 days; anemia	8
0.044	50% dead in 653 days; anemia	8
0.088	50% dead in 187 days; anemia	8
Monkey, *Cebus apella*; 1 Gy, whole body, single acute exposure	Leucocyte reduction in 6 days; blood chemistry normal after 90 days	9
Chinese hamster, *Cricetus* sp.; ovary cells, single acute dose ranging between 0.005 and 0.06 Gy	Increased frequency of sister chromatid exchange at 0.005 Gy; increased numbers of chromosomal aberrations at >0.02 Gy; no significant increase in cell death	10
Syrian hamster, *Cricetus* sp.; 0.12-2 Gy, single acute exposure	Genes modifying cytoskeletal development adversely affected at all doses within 3 h by both high LET (neutrons) and low LET (gamma rays, X-rays) radiations	11
Human, *Homo sapiens*		
Developing forebrain, 0.18-0.55 Gy (estimated dose to prenatally exposed Japanese atomic bomb survivors)	Seizures in childhood; reduced school performance at least through age 11 years; some cases of severe mental retardation by age 17 years	12
Fetus, 1 Sv, 8-15 weeks of gestation	40% probability of severe mental retardation; IQ score lowered 30 points	13
Sperm chromosomes, 0.23, 0.45, 0.91, or 1.82 Gy, single acute exposure	Chromosomal aberrations increased linearly from 6.1% at 0.23 Gy to 62% at 1.82 Gy	14
Thyroid, single acute exposure 0.065 Gy	Minimum dose for induction of thyroid carcinoma	15

Table 27. Species, dose, and other variables	Effect	Reference[a]
3-5 Gy	5% increase in thyroid malignancies 20 years after exposure, with tumors appearing 4-5 years after exposure	16
7-10 Gy	Linear dose relation to thyroid cancer, and pathology in adjacent parathyroid and salivary glands	16
Whole body		
Single brief exposure		
0.05-0.11 Sv	Doubles rate of cancers	17
0.15 Sv	Temporary sterility, males	13
0.18-0.29 Sv	Doubles rate of pregnancy complications	17
0.5-2.0 Sv	Opacity of lens; depression of hematopoiesis	13
0.68-1.10 Sv	Doubles rate of F1 generation mortality	17
1 Sv, adults	1% probability of hereditary effects; 4% probability of fatal cancer in occupational workers	13
2.5-6.0 Sv	Sterility, females	13
3.5-6.0 Sv	Permanent sterility, males	13
5.0 Sv	Cataracts	13
<1 Gy	Survival almost certain	18
1-2 Gy	Survival probable	18
1-2 Gy	About 5% mortality in several months from infection and hemorrhage	19
2-5 Gy	Survival possible	18
2-7.5 Gy	Hematopoietic syndrome characterized by bone marrow damage, anemia, lowered immune response, hemorrhage, and sometimes death	20
3-5 Gy	Death in 30-60 days, bone marrow damage	13
5-10 Gy	100% adversely affected within weeks with bone marrow abnormalities; about 45% mortality	19
5-15 Gy	Death in 10-20 days; GI tract and lung damage	13
5-20 Gy	Survival improbable	18
7.5-30 Gy	Gastrointestinal damage: nausea, vomiting, anorexia, diarrhea, lethargy, weight loss, dehydration, exhaustion, and death	20
10-15 Gy	All adversely affected with intestinal problems within 30 min; 95% dead in 2 weeks from enterocolitis shock	19
>15 Gy	Death in 1-5 days, nervous	13

Table 27. Species, dose, and other variables	Effect	Reference[a]
	system damage	
>50 Gy	All dead in 48 h, usually from cerebral edema	19
Annual dose rate or protracted annual exposure for many years		
>0.1 Sv	Lens opacity	13
>0.15 Sv	Cataracts	13
>0.2 Sv	Sterility, females	13
0.4 Sv	Temporary sterility, males; hematopoiesis depression	13
2.0 Sv	Permanent sterility, males	13
Rhesus monkey, *Macaca mulatta*		
Females, single acute dose of 0.25 to 6.5 Gy, observed over a 17-year postexposure period	At doses >2 Gy, 53% developed endometriosis (abnormal uterine growth) vs. 26% in controls; irradiated monkeys weighed 43% less than controls, 35% were anorexic, 89% had abnormal uterine anatomy, and histopathology in most tissues exceed 50% frequency	21
Exposed to single brief whole body proton irradiation (protons in the energy range encountered by astronauts) ranging between 0.25 and 12 Gy and observed for 24 years until death	Dose-dependent life shortening of at least 40 months at doses >4.5 Gy; mean life shortening was 200-500 monkey days per Gy, equivalent to 500-1,250 human days. Brain cancer first observed in 8 Gy group after 13 months. Monkeys receiving between 3 and 8 Gy had a significantly higher proportion of cancer deaths than those receiving 0.25-2.8 Gy. Latent period for cancer in animals receiving 4-8 Gy ranged between 13 months and 20 years	22
Mammals		
10 species, 2.8-8.05 Gy, single acute exposure	LD50, 30 days after exposure	23
Various species, bioconcentration factors (BCF) of selected radionuclides		
^{60}Co		
Herbivores	Whole body BCF of 0.3	24
Caribou, *Rangifer tarandus*		
Bone vs. kidney	BCF of 0.5 vs. 0.4	24
Liver vs. muscle	BCF of 0.9 vs. 0.02	24
$^{134+137}Cs$		
Herbivores	Whole body BCF of 0.3-2.0	24
Omnivores	Whole body BCF of 1.2-2.0	24

Table 27. Species, dose, and other variables	Effect	Reference[a]
Carnivores	Whole body BCF of 3.8-7.0	24
^{131}I		
Herbivores	Whole body BCF of 0.05	24
Omnivores	Whole body BCF of 0.2	24
Carnivores	Whole body BCF of 0.1	24
^{90}Sr, caribou, muscle vs. bone	BCF of 0.02 vs. 7.0	24
Various species, biological half-life of selected radionuclides		
^{241}Am		
Bone	27.4 years	25
Gonads	>27.4 years	25
Kidney, liver	11 years	25
Muscle	4 years	25
Serum	5 days	25
^{137}Cs, kidney, liver, and muscle	30 to 50 days	25
$^{238+239+240}Pu$		
Bone	49 years	25
Gonads	>49 years	25
Kidney, liver	19 years	25
Muscle	5.5 years	25
Serum	5 days	25
Singing vole, *Microtus miurus*; 8.46 Gy, single acute dose	LD50, 30 days after exposure	26
Creeping vole, *Microtus oregoni*; 6.51 Gy, single acute dose	LD50, 30 days after exposure; sensitivity may be associated with low chromosome complement	26
Meadow vole, *Microtus pennsylvanicus*; single brief exposure		
7.04 (6.35-7.98) Gy, irradiated in November	LD50, 30 days after exposure; irradiated voles released into environment	27
7.67 (7.01-8.39) Gy, irradiated in May	LD50, 30 days after exposure; irradiated voles released into environment	27
8.44 (8.17-8.77) Gy	LD50, 30 days after exposure; irradiated voles held in laboratory	7
Pine vole, *Microtus pinetorum*; single brief exposure		
7 Gy	None dead 30 days after exposure; weight normal	28
8.8 Gy, males	LD50, 30 days after exposure; weight loss in survivors	28
10.0 Gy, females	LD50, 30 days postexposure; weight loss in survivors	28
House mouse, *Mus museulus*;		

Table 27. Species, dose, and other variables	Effect	Reference[a]
single brief exposure		
7.5-8.8 Gy	LD50, 30 days postexposure	26,29
7.8, 8.1, 8.3, and 9.8 Gy	LD50, 30 days after exposure; four different strains	1
Mouse, *Mus* sp.		
Intraperitoneal injection		
Single injection of 850 Bq ^{227}Ac/kg BW alone or in combination with ^{227}Th at 18,500, 74,000, or 185,000 Bq/kg BW	The highest bone cancer incidence was observed at the highest doses of ^{227}Th. The addition of ^{227}Ac resulted in an additional osteosarcoma incidence only at 18,500 Bq ^{227} Th/kg BW	30
Single injection of ^{241}Am at concentrations-in Bq/kg BW-of 0.02, 0.06, 0.19, 0.37, or 1.2	Survival time decreased from 594 days for controls and 0.02 group to 135 days in the 1.2 group; increased frequency of tumors in bone, liver and lymph	31
Adult males, 84 days old, given 2 to 64 Bq ^{224}Ra/mouse, either as single injection, or 8 injections at 3.5 day intervals over 4 weeks; observed for 24 months	No difference in single or multiple injection effects. No effect at 16 Bq and lower, At 32 and 64 Bq, reduction in bone growth and osteonecrosis of mandible ("radium jaw")	32
Oocytes given single exposures of 0.1, 0.15, or 0.25 Gy; immature oocytes examined 8-12 weeks later	Controls had 100% survival and zero chromosome aberrations; the 0.1 Gy group had 30% survival and 2% chromosome aberrations; 0.15 Gy had 17% survival and 6% chromosome aberrations; 0.25 Gy had 5% survival and 23% chromosomal aberrations	33
Whole body, single brief exposure		
1 Gy	Acute exposure may extend life span	34
1.35 Gy	Doubles mutation rate of spermatogonia	17
7.6 Gy	LD50, 30 days postexposure	35
9.5 Gy	LD100, 30 days postexposure	35
10.0 Gy, adult males, 16-20 weeks old, observed for 7 days	At 90 min after irradiation, locomotor activity was suppressed and remained depressed; at 4 days, body weight decreased; at day 7, offensive aggressive behavior	20
12.5 Gy	LD100, days 3-7 postexposure	35
0.12-2.5 Sv	Doubles rate of heritable translocations in males	17
0.25-2.5 Sv	Doubles rate of congenital malformations in females	17
0.4-1.0 Sv	Doubles frequency of dominant	17

Table 27. Species, dose, and other variables	Effect	Reference[a]
	lethal mutations	
0.5-1.0 Sv	Doubles rate of heritable translocations in females	17
0.8-2.5 Sv	Doubles rate of congenital malformations in males	17
1.5-3.0 Sv	Doubles rate of recessive lethal mutations	17
Chronic exposure, daily dose over 8-h period, in Gy		
0.0	Mean survival time of 703 days	8
0.001	Mean survival of 761 days	8
0.011	Mean survival time of 684 days; 50% weight gain over controls	8
0.022	50% dead in 630 days	8
0.044	50% dead in 591 days	8
0.088	50% dead in 488 days	8
Total yearly dose, chronic exposure, 16 Gy (about 0.044 Gy daily)	Tolerated	34
Domestic ferret, *Mustela putorius*; 2, 4, or 6 Gy; single brief exposure; adult males	All doses depressed locomotion; vomiting in 22 min at 2 Gy, 13 min at 4 Gy, and 11 min at 6 Gy. Various substituted benzamides reduced vomiting	36
Marsh rice rat, *Oryzomus palustris*; 5.25 Gy, single acute exposure	LD50, 30 days after exposure; this species was the most sensitive of 10 rodent species tested	1
Domestic sheep, *Ovis aries*		
Ewes fed hay containing 9,000 Bq ^{137}Cs/kg DW for 50-60 days, then 40 days on uncontaminated hay; some diets contained 30 or 60 g of vermiculite daily, or 2 g of ammonium ferricyanoferrate (AFCF) daily	Maximum levels of ^{137}Cs were reached in 10 days in milk and 35-40 days in muscle. Radionuclide transfer to milk and meat was reduced 2.5 times at daily intakes of 30 g vermiculite, and 8 times at 60 g vermiculite or 2 g AFCF	37
Ewes given oral dose of 74,000 Bq ^{137}Cs, observed for 76 days	At 76 days, only 26% of ^{137}Cs remained; tissue concentrations, in Bq ^{137}Cs/kg FW, were 77,000 in salivary gland; 42,000 in muscle; 24,000-36,000 in pancreas, liver, and kidney; 14,000-17,000 in spleen and lung; and <8,000 in other tissues	38
Lambs fed 21 kg of vegetation containing 16,600 Bq of	Of the Pu ingested, 46% was in liver, 30% in bone, 12% in muscle, and 2% in	39

Table 27. Species, dose, and other variables	Effect	Reference[a]
$^{238+239+240}Pu$ and 14,400 Bq of ^{241}Am over a 14-day period, followed by 4 days on uncontaminated hay	lung; for ^{241}Am, these values were 19% in liver, 15% in bone, bone, 6% in meat, and 0.5% in lungs	
Lamb given single intravenous injection of 23 Bq ^{238}Pu plus 27 Bq ^{241}Am and held for 11 days	Liver retained up to 44% of the injected ^{238}Pu and 28% of the ^{241}Am; bone had 21% of the ^{238}Pu and 20% of the ^{241}Am	39
Great Basin pocket mouse, *Perognathus parvus*; 8.56 Gy, single exposure	LD50, 30 days after exposure; hair loss within 7 days	26
White-footed mouse, *Permoyscus leucopus*; whole body, single brief exposure		
9.5 Gy, both sexes irradiated	No reproduction	40
9.5 Gy, males only irradiated	91% of pairs successful in producing young	40
9.5 Gy, females only irradiated	40% of pairs reproduced successfully	40
10.7 Gy	LD50, 30 days postexposure; this species was the most radioresistant of 10 species of rodents tested	1
Deer mouse, *Peromyscus maniculatus*; 9.19 Gy, single brief exposure	LD50, 30 days after irradiation	26
Oldfield mouse, *Peromyscus polionotus*; 11.25 Gy, single exposure	LD50, 30 days after exposure	29
Norway rat, *Rattus norvegicus*; 8.67 Gy, single exposure	LD50, 30 days postexposure	1
Laboratory white rat, *Rattus* spp.		
0.001, 0.01, or 0.1 Gy; single acute whole body exposure; adult males; killed up to 180 days after exposure	Fertility reduction was zero in the low-dose group, 25% at 0.01 Gy, and 66% at 0.1 Gy. Primary sites of damage were tubuh of the testes and spermatogonia. The high-dose group also had altered serum hormone chemistry after 30 days that persisted for 180 days	41
Pregnant rats given single brief exposure to 0.25, 0.5, 0.75, or 1 Gy on gestational day 15; fetuses examined 24 h after irradiation	No effect at 0.5 Gy and lower on cerebral mantle of developing brain; however, dose- related increase in pyknotic cells and macrophages in cortical mantle of fetus for all doses	42
Pregnant females exposed on day 15 of gestation	Rats irradiated in utero had impaired gait, slower motor	43

Table 27. Species, dose, and other variables	Effect	Reference[a]
to 0.75 Gy; fetuses examined 1-3 months after birth	behavior, difficulty in learning motor tasks, reduced growth rate, and reduced thickness of the cerebral cortex	
<1 Gy, whole body, single exposure	No brain pathology	44
2 Gy, whole body, single exposure	Brain pathology	44
Adult males conditioned to avoid electric shock by pressing a lever were subjected to various whole body acute exposures		
1.5 Gy daily for 5 consecutive days (total 7.5 Gy)	No significant change in performance over 8 weeks	45
4.5 Gy, single exposure	No effect on performance for at least 6 weeks	45
7.5 Gy, single exposure	Significantly decreased response rate over the first 4 weeks; performance normal during weeks 5-6; 9% reduction in body weight	45
9.5 Gy, single exposure	LD100, 30 days postexposure	45
Single local dose of 5 to 20 Gy to various salivary glands	Dose-dependent decrease in salivary flow rate and sodium composition of saliva; at 10 Gy and higher, changes were irreversible	46
25 Gy, single whole body exposure	50% dead 30-60 days postirradiation from fatal stomach damage; significant liver damage in survivors	47
Eastern harvest mouse, *Reithrodontomys humulis*; 9.5 Gy, single exposure	LD50, 30 days after exposure	1
Rodents, single brief exposure		
3.8-13.3 Gy, 13 species	LD50, 30 days postexposure; females more sensitive than males	48
4-8 Gy, 5 species	Dead rodents had histopathology of lymph nodes, thymus, bone marrow, liver, lung, and gonads; male survivors had atrophied testes	26
5.3-10.7 Gy, 10 species	Range of LD50 values (30 days after exposure); survivors showed conjunctivitis, ataxia, diarrhea, passiveness, cessation of feeding, aggressiveness, and graying of pelage	1
Squirrel monkey, *Saimiri* spp.; fetuses, 80-90 days postconception; given 0.1 or 1.0 Gy, single acute	No effect on behavior at 0.1 Gy. At 1 Gy, emotional stability and vision impaired at age 30 days,	44

Table 27. Species, dose, and other variables	Effect	Reference[a]
exposure; young observed from birth to age 2 years	learning impaired at 1 year; normal at 2 years	
Cotton rat, *Sigmodon hispidus*		
Females given 5, 7.5, 9, 10.5, or 12 Gy whole body once a month for 4 months, then released into a 0.4 ha-impoundment with unirradiated males and females for 15 days	Survival was 91% at 5 Gy and 25% at 12 Gy; intermediate doses had intermediate survival	49
9.58 Gy, single brief exposure	LD50, 30 days after exposure	1
11.2 Gy, single acute exposure, adult females	LD50, 30 days after exposure	49
11.3 Gy, single exposure, adult females	LD50, 15 days postexposure	49
Eastern chipmunk, *Tamias striatus*		
2-4 Gy, single exposure	Irreversible injury throughout life, but lifespan was increased	50
Given single exposure of 2 or 4 Gy, then released into environment	Irradiated chipmunks had consistently smaller home ranges and moved shorter distances than did controls	51
Iodine-131, half-time release rate from thyroid; females vs. males		
Summer	2.3 h vs. 263 h	52
Spring	156 h vs. 217 h	52
Autumn	126 h vs. 129 h	52

Survival

Survival time is inversely related to dose in whole-body, acute exposures to ionizing radiation (Fig. 9). In general, hematopoietic organs are most sensitive and gastrointestinal tract and central nervous system are next most sensitive (UNSCEAR 1988). Body weight is an important modifier, and heavier mammals are usually most sensitive to radiation (Fig. 10). Feral rodent populations are at risk from ionizing radiation through the reduction in numbers from direct kill and indirectly from the radiation-caused diminution of reproduction (Di Gregorio et al. 1971).

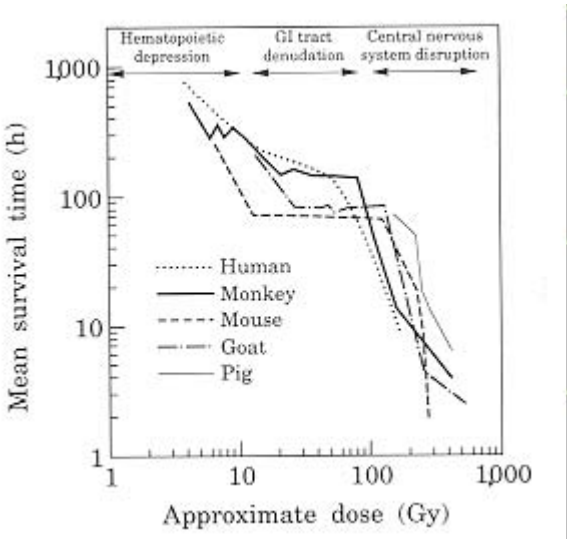

Fig. 9. Survival time and associated mode of death of selected mammals after whole-body doses of gamma radiation (modified from Hobbs and McClellan 1986; UNSCEAR 1988).

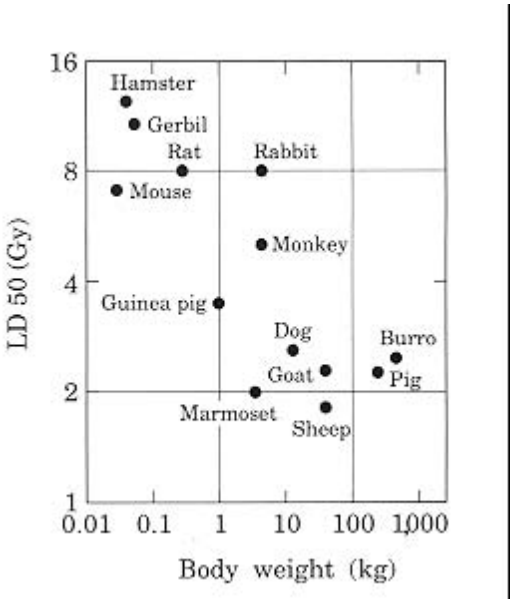

Fig. 10. Relation between body weight and radiation-induced LD50 (30 days postexposure) for selected mammals (modified from UNSCEAR 1988).

Low doses of ionizing radiation are beneficial to many species of mammals; effects of radiation hormesis include increased survival and longevity, lowered sterility, increased fecundity, and accelerated wound healing (Luckey 1980). Low doses of gamma irradiation cause irreversible injury to the eastern chipmunk (*Tamias striatus*), although the life span was significantly longer (Thompson et al. 1990). Acquired radioresistance after exposure to a low dose of ionizing radiation has been described in rats, mice, and yeast (Yonezawa et al. 1990). In mice, for example, low doses of X-irradiation (not higher than 0.15 Gy) enhanced 30-day survival if given 2-months prior to a dose of 7.5 Gy. The low-dose exposure seems to stimulate the recovery of blood-forming stem cells after the second irradiation and favors a decrease in the incidence of bonemarrow death. The exact mechanisms of radiation hormesis are unknown because effects are not related to and not predictable from the high-dose exposure (Yonezawa et al. 1990).

Irradiated small mammals that were released into the environment had a lower survival rate than laboratory populations, suggesting that the extrapolation from laboratory results may overestimate the radioresistance of free-ranging voles and other small animals because of the general level of stress in the population (Iverson and Turner 1976). The opposite was observed in eastern chipmunks after high sublethal doses of X-rays. Chipmunks had an overall reduction in mobility when they were released into the environment and a higher survival rate than controls (Snyder et al. 1976), possibly because of increased predation on the more mobile controls.

Carcinogenicity

The risk of the induction of cancer is a recognized somatic effect of low doses of ionizing radiation, as judged by epidemiological studies of Japanese survivors of the U.S. nuclear bombs (Coggle and Williams 1990) and of Marshall Islanders, underground miners, and radium watchdial workers (Bowden et al. 1990). Yoshimoto et al. (1990), however, conducted a study on the occurrence of malignant tumors in Japanese children that were older than 10 years and born between 1946 and 1982 to survivors of the atomic bombings in 1945 and in a suitable control group. They found no statistically significant increase in malignant tumors in the children of parents who had been exposed to more than 0.01 Sv whole-body radiation (mean gonadal exposure of 0.43 Sv) at the time of the atomic bombings. Nutritional status is important when treating malignant tumors. Unlike tumors of nonanemic individuals, tumors in anemic mice and humans frequently do not satisfactorily respond to radiotheraphy (McCormack et al. 1990).

Ionizing radiation induces basal-cell carcinomas in skin and is active in the initiation of malignant tumors and in the progression of benign to malignant tumors (Bowden et al. 1990). Skin has been widely used in studies of carcinogens because of its accessibility and the visibility of its tumors. All data on experimental radiogenic skin cancer in mice are on a relatively narrow and well defined response curve; however, mouse skin is about 100 times more sensitive than human skin (Coggle and Williams 1990), strongly suggesting that appropriate animal models are necessary in the extrapolation of results to another species.

Thyroidal cancer in dogs and sheep has been induced with repeated administrations of ^{131}I, although single injections of ^{131}I failed to induce thyroid cancer in adult animals except in some strains of laboratory rodents (Walinder 1990). Humans with a prior history of ^{131}I and other radiation exposure in childhood are at a significantly higher risk of thyroid carcinogenesis, and females are at higher risk than males. The minimum latent period in humans is about 4 years, and neoplastic lesions may develop as late as 40 years after irradiation (Kim et al. 1990). Historically, the human thyroid received radiation from irradiation of the scalp for epilation (as much as 0.5 Gy), thymus (as much as 5 Gy), tonsils and adenoids (8 Gy), and facial acne (15 Gy). Higher doses of external irradiation (as much as 50 Gy) were used during 1920-40 for the treatment of hyperthyroidism in adults and are still used for the treatment of cervical malignancies in people of all ages (Refetoff 1990).

Radium-induced bone malignancies after exposure to ^{226}Ra are similar in beagles and humans, and the tibia in dogs is especially sensitive (Lloyd et al. 1991). *Radium jaw* has been described in humans as a late effect of accidental ingestion or therapeutic administration of long-lived radium isotopes such as ^{216}Ra and ^{228}Ra and is characterized by bone tumors, spontaneous fractures, and osteosclerosis (Robins 1990). However, the short-lived ^{224}Ra (Tb½ of 3.6 days) produces similar effects in mice, suggesting that the events that trigger radium-induced bone disorders occur within days of incorporation, even though the consequence is a late effect (Robins 1990).

Aerosol exposures of mice, rats, dogs, and hamsters to radon and its decay products resulted in lifetime shortening, pulmonary emphysema, pulmonary fibrosis, and respiratory tract carcinoma; damages to the skin and kidney were also reported, but the lung seems to be the primary organ that is affected (Cross 1990). Radon and ^{222}Rn daughters have caused problems to miners who work underground in uranium mines. These miners had an excessive incidence of disease of the respiratory system, including lung cancer. The problem is related to the emanation of radon into the mines and the decay of the radon, the short-lived radioactive daughters (^{216}Po, ^{214}Pb, ^{214}Bi, ^{214}Po), which attach to dust particles, eventually resulting in alpha-radiation exposure of the respiratory airways (Hobbs and McClellan 1986). A similar pattern was evident in rats exposed to ^{239}Pu.

Rats exposed to $^{239}PuO_2$ aerosol of about 3,700 Bq/lungs and examined 8 to 18 months after exposure had a high frequency (as much as 80%) of malignant pulmonary neoplasms; genetic mutations were evident in 46% of the radiation-induced tumors (Stegelmeier et al. 1991).

The incidence of ovarian tumors in mice, guinea pigs, and rabbits increased after 3 years of chronic irradiation at doses as low as 1.1 mGy daily (Lorenz et al. 1954). Unlike other tumors, the induction of ovarian tumors depended on a minimum total dose and seemed to be independent of a daily dose (Lorenz et al. 1954). Radiation-induced neoplastic transformation of hamster cells may be associated initially with changes in expression of the genes modifying cytoskeletal elements (Woloschak et al. 1990b).

Mutagenicity

In general, ionizing radiation has produced mutations in every studied plant and animal species. Some genetic risks are associated with exposures, but the risk of inducing a dominant genetic disease is small because radiation-induced mutations are primarily recessive and usually lethal (Sankaranarayanan 1991c).The genetic doubling dose of radiation is the amount of acute or chronic radiation that doubles the naturally occurring spontaneous mutation rate in each generation. For mice, the estimated genetic doubling-dose equivalent is 1.35 Sv from acute exposures and 4.0 Sv from chronic exposures to radiation (Neel and Lewis 1990). For protection from radiation, the estimated genetic risks to humans have largely been based on data from mice (Straume et al. 1991). Studies of children of Japanese survivors of nuclear bomb explosions revealed that the genetic doubling dose equivalent of acute gonadal radiation is about 2.0 Sv (1.69-2.23); from chronic radiation, this value is about 4.0 Sv (Neel and Lewis 1990). Based on results of the study of Japanese survivors of the nuclear explosions, Yoshimoto et al. (1990) and Sankaranarayanan (1991c) concluded that the spontaneous mutation rate did not increase after parents were exposed. The high doubling dose of about 4 Sv estimated from these data is another way of stating that, relative to the assumed spontaneous rates, the rate of induction of mutations that leads to the measured effects is too small (Sankaranarayanan 1991c). The transmission of radiation-induced genetic effects to offspring has not yet been demonstrated in any human population (Straume et al. 1991).

Specific point mutations were identified in ^{239}Pu-induced preneoplastic lesions and in malignant neoplasms in the lungs of rats (Stegelmeier et al. 1991). Mice exposed to a single whole-body dose of 3 Gy produced a radiation-induced mutation that simultaneously generated distinct alleles of the limb deformity and agouti (grizzled fur color) loci, 2 developmentally important--but not adjoining--regions on a single chromosome. This phenomenon was probably associated with DNA breaks that were caused by inversion of a segment in another chromosome (Woychik et al. 1990). The plasma membrane in immature oocytes of mice is the hypersensitive lethal target in producing radiation-induced genetic damage (Straume et al. 1991).

Organ and Tissue Damage

In the abdomen, the kidneys are one of the most sensitive organs to serious or fatal radiation-induced damage (Jaenke and Angleton 1990). The relatively high incidence of kidney disease among mature beagles that were injected with ^{226}Ra and its accompanying ^{210}Bi and ^{210}Po were from alpha irradiation of the kidneys by the substantial amount of ^{210}Po that was in the injected solution (Bruenger et al. 1990). Hepatic injury that was induced by ionizing radiation can be a life-threatening complication. The main responses of the liver to acute radiation exposure include enlargement, dilation of blood vessels, fluid accumulation, and histopathology (Geraci et al. 1991). Damaging effects of ionizing radiation on the fetal cerebral cortex has been recognized for many years (Norton and Kimler 1990). The deleterious effects of ionizing radiation on the developing-brain are prolonged and progressive. Less than 2-Gy doses of gamma radiation are harmful to the developing brain, and mental retardation in humans may occur from doses as low as 0.2 Gy between week 8 and 15 of gestation (Norton et al. 1991).

Irradiated white-footed mice (*Peromyscus leucopus*) frequently had atrophied gonads, degenerating fetuses in the uterus, and greying hair (Di Gregorio et al. 1971). High sublethal doses (7 Gy) of radiation to the pine vole (*Microtus pinetorum*) caused pelage graying wherein unpigmented hair from damaged follicles replaces molted pigmented hair. Pelage graying may decrease survival from increased predation (Dunaway et al 1971), although this needs verification.

Human sperm chromosomes retain a high fertilizing ability after a high dose of X-irradiation, although mammalian spermatozoa have little capacity to repair DNA damage that is induced by radiation (Kamiguchi et al. 1990). Radiation-induced deaths of lymphoid cells in rats are associated with damage to the cell itself but may also be due to secretions from irradiation-activated natural killer cells, which induce pycnosis and interphase death in lymphoid cells (Eidus et al. 1990).

Behavior

Numerous behavioral measures have been evaluated for their usefulness as sensitive indexes of exposure to ionizing radiation. Radiation-related mental retardation is the most likely type of behavioral abnormality in humans; sensitivity peaked between 8 and 15 weeks of conception and doses that were greater than 0.4 Gy (UNSCEAR 1988). No specific mechanism for the production of mental retardation has been established, although proposed mechanisms include the loss of cells, migration of neurons, and failure of synaptogenesis (Norton and Kimler 1990). In studies with rats, operant responses decreased (maintained by positive reinforcement such as food or water) at sublethal radiation doses (3.0-6.75 Gy) under various schedules of reinforcement (Mele et al. 1990). Disrupted operant responses under shock avoidance at greater than LD100 levels are reported in pigs and rhesus monkeys (Mele et al. 1990).

Absorption and Assimilation

The absorption, bioavailability, and retention of radionuclides in mammals are modified by age, sex, species, and diet of the organism; season of collection; the chemical form of the radionuclide in tissue and blood; residence time in the digestive tract; preferential accumulation by selected organs and tissues; and many other variables (Kitchings et al. 1976; Whicker and Schultz 1982a, 1982b; Richmond 1989; Desmet et al. 1991; Harrison 1991). Recommended assimilation fractions of various elements by the International Commission on Radiological Protection are presented in detail by Whicker and Schultz (1982b).

Many radionuclides preferentially accumulate in certain organs or tissues, but the critical organ is different for different radionuclides: liver for ^{54}Mn, erythrocytes and spleen for ^{55}Fe, liver and kidney for cobalt nuclides, liver and prostate for ^{65}Zn, skeletal muscle for ^{137}Cs, and GI tract for ^{95}Zr (Whicker and Schultz 1982a). The persistence of radionuclides in mammals varies with the chemical form, kinetics, species, and other variables. For example, the time for 50% persistence of selected radionuclides in whole-animal studies ranged from 19 h to 14 days at ^{134}Cs; 4 to 35 days at ^{137}Cs; 5 to 12 h at the short-lived component of ^{60}Co, and 5 to 21 days at the long-lived component; 25 to 593 days at ^{90}Sr; and 4 to 26 days at ^{131}I (Kitchings et al. 1976; Whicker and Scultz 1982b).

Some radionuclides act antagonistically when administered together. The combined incorporation of ^{227}Ac and ^{227}Th at tested levels in mice showed a lower biological effect than the sums of the effects of the components administered singly. The less-than-additive effect is in good agreement with experiments with the incorporation of a mixture of β emitters, in which the effects are also less than additive (Muller et al. 1990). Uptake and retention characteristics of essential biological nutrients (i.e., H, C, P, I, K, Ca, Mn, Fe, Co, Zn) are largely controlled by biological processes (Whicker and Schultz 1982a). For example, ^{131}I regardless of route of administration is rapidly absorbed into the bloodstream and concentrated in the thyroid. Ionizing radiation from high levels of ^{131}I destroys the thyroid and affects the thyroid hormone production (Hobbs and McClellan 1986).

Alkali metals (K, Rb, Cs) behave similarly and sometimes one is accumulated preferentially when another is deficient; a similar case is made for Sr and Ca (Whicker and Schultz 1982a). The most important alkali-metal isotope is ^{137}Cs because of its long physical half-life (30 years) and its abundance as a fission product in fallout from nuclear weapons and in the inventory of a nuclear reactor or a fuel-reprocessing plant. Cesium behaves much like potassium. It is rapidly absorbed into the bloodstream and distributes throughout the active tissues of the body, especially muscle. The β and radiation from the decay of ^{137}Cs and its daughter, ^{137}Ba, result in essentially whole-body irradiation that harms bone marrow (Hobbs and McClellan 1986).

Because ^{226}Ra and ^{90}Sr are metabolic analogs of calcium, they are deposited in the skeleton; both isotopes are associated with bone cancers (Hobbs and McClellan 1986). In pregnant rats, the total amount of

^{226}Ra that is transferred from the dam to the 8-10 fetuses in a litter was low after a single injection and did not exceed 0.3% of the maternal content; the retained whole-body burden in dams was 53% at the first, 48% at the second, and 44% at the third pregnancy, mostly in the skeletal system (Kshirsagar 1990). The rare earths (i.e., ^{144}Ce, ^{152}Eu, ^{140}La, ^{147}Pr, ^{151}Sm) are usually not absorbed from the GI tract, and elimination is rapid (Palumbo 1963). Cerium-144 is one of the more biologically hazardous radionuclides in this group because of its half-life (285 days) and the energetic β emissions from it and its daughter, ^{144}Pr (Hobbs and McClellan 1986).

The greatest uncertainty in dose estimates from the ingestion of long-lived alpha emitters is the values used for their fractional absorption from the GI tract (Harrison 1991). For transuranic elements, the fraction of the ingested material that was assimilated by the whole organism was always less than 0.01% and usually nearer 0.003% (Whicker and Schultz 1982b). The major hazard of plutonium nuclides to terrestrial organisms comes from inhalation; uptake by plants is low, and further uptake by humans through the gut is low (Noshkin et al. 1971). Americium-241 is an artificial, toxic bone-seeking radionuclide produced by beta decay of ^{241}Pu (Schoeters et al. 1991). Because of its long half-life, its high-energy alpha irradiation, and its accumulation in the liver and skeleton, consideration should be given to ^{241}Am in risk estimates of latent effects such as induction of liver cancers, bone cancers, and leukemias. In comparison with ^{226}Ra, ^{241}Am is 20 times more effective in reducing the life-span in mice and 13 times more effective in the rate of death from bone cancer (Schoeters et al. 1991).

Although radon has long been known as a health hazard to miners in the uranium industry, global radon contamination of buildings was not recognized before the 1980's; however, years of exposure are required before a health problem develops (Majumdar et al. 1990). Exposure to radon-decay products can be expressed in two different ways: the amount of inhaled decay products (taking into account their potential emission of radiation energy) or the product of the time during which the decay products were inhaled and their concentration in the inhaled air. The potential alpha energy of the inhaled decay products may be expressed in joules (J). The potential alpha energy concentration in air is expressed in joules per cubic meter; for radon in equilibrium with its decay product, this corresponds to 3,700 Bq/m^3 (UNSCEAR 1988).

Rodents that were dosed with tungsten-185 excreted 80% in 24 h; bone was the major retention site; the half-time persistence ranged from 5.7 days in femurs of mice to 86 days in femurs of rats; some components in the bone of rats persisted with a half-time of longer than 3 years (Reed and Martinedes 1971). Niobium-95 is produced directly by nuclear fission and indirectly by decay of ^{95}Zr. Routine discharges of ^{95}Nb from a nuclear fuel-reprocessing plant in the United Kingdom in 1970 contributed about 5% of the bone-marrow dose to a 10-year-old child that resided in the vicinity (Harrison et al. 1990). Gastrointestinal absorption of ^{95}Nb by adult guinea pigs was about 1.1% and supports the now-used values of 1% absorption in adults and 2% in infants to calculate percentage absorption of niobium isotopes by humans (Harrison et al. 1990).

Proposed Criteria and Recommendations

For the protection from radiation, effects of radiation have been characterized as stochastic or nonstochastic. The probability of a stochastic effect--and not its severity--varies as a function of dose in the absence of a threshold, that is, hereditary effects or carcinogenesis. The probability and severity of nonstochastic effects vary with dose, and a threshold for the dose exists, that is, cataract of lens, nonmalignant damage to the skin, cell depletion in the bone marrow that causes hematological deficiencies, gonadal cell damage that leads to impairment of fertility, or pneumotis and pulmonary fibrosis after lung irradiation (ICRP 1977; Hobbs and McClellan 1986; UNSCEAR 1988). Nonstochastic effects can be prevented by setting dose-equivalent limits at sufficiently low levels so that no threshold dose is reached, not even after exposure for the whole of a lifetime or for the total period of a working life (ICRP 1977, 1991a, 1991b). Guides for the protection from radiation are also predicated on the effective half-life of each isotope, the critical organ, the fraction that reaches the critical organ by ingestion and inhalation, and the maximum tolerable whole-body burdens, as judged by radionuclide concentrations in air, water, and diet (Palumbo 1963).

At present, no radiological criteria or standards have been recommended or established for the protection of fishes, wildlife, or other natural resources. All radiological promulgated or proposed criteria are directed towards the protection of human health. It is generally assumed that humans are comparatively radiosensitive and that

guides probably also protect sensitive natural resources (UNSCEAR 1988; ICRP 1991a, 1991b; NCRP 1991; IAEA 1992; Zach et al. 1993), although this needs verification. Numerous radiological criteria exist for the protection of human health (Table 28). Most authorities agree that some adverse effects to humans are probable under the following conditions: more than 5 mSv whole-body exposure of women during the first 2 months of pregnancy; more than 50 mSv whole-body exposure in any single year or more than 2,000 mSv in a lifetime; an annual inhalation intake by a 60 kg individual--in Bq/kg BW--that exceeds 0.67 ^{232}Th, 3.3 ^{241}Am, 3.3 ^{239}Pu, 16 ^{252}Cf, 33 ^{235}U, 1,666 ^{90}Sr, 16,666 ^{60}Co, or 166,666 ^{32}P; an annual ingestion intake by a 60 kg individual--in Bq/kg BW--that exceeds 3,333 ^{129}I, 16,666 ^{125}I, 16,666 ^{131}I, or 66,666 ^{137}Cs; or a total annual intake from all sources--in Bq/kg BW by a 60 kg person--that exceeds 66 ^{210}Pb, 166 ^{210}Po, 333 ^{226}Ra, 666 ^{230}Th, 833 ^{228}Th, or 1,333 ^{238}U (Table 28).

Table 28. Criterion and other variables	Concentration or dose	Reference[a]
Air		
United States; radon-222		
Average	<0.0555 Bq (<1.5 pCi)/L or <55 Bq/m^3	1
Acceptable	<0. 148 Bq (<4.0 pCi)/L	1,2
Allowable emission discharge	<0.74 Bq (<20 pCi)/m^2/s; should not increase the radon 222 concentration in air at or above any location outside the disposal site by >0.0185 Bq (>0.5 pCi)/L or >18 Bq (>500 pCi)/m^3	3
Unacceptable	>0.185 Bq (>5 pCi)/L	2
Astronauts		
Age 25-55 years; expected whole body career dose; females vs. males	1.0-3.0 Sv (100-300 rem) vs. 1.5-4.0 Sv (150-400 rem)	4
Adverse effects expected; lifetime exposure	>2.0 Sv (>200 rem)	4
Cancer risk and birth defects		
Projected 0.04% increase in cancers; 0.01% increase in birth defects	0.11 mSv (0.011 rem) whole body maximum /year; 0.69 mSv (0.069 rem) whole body over 30 years; or 1.00 mSv (0.1 rem) bone marrow over 30 years	5
Projected 0.18% increase in cancers; 0.07% increase in birth defects	0.51 mSv (0.05 rem) whole body maximum/year; 3.30 mSv (0.33 rem) whole body over 30 years; or 4.60 mSv (0.46 rem) bone marrow over 30 years	5
Projected 0.92% increase in cancers; 0.38% increase in birth defects	3.03 mSv (0.3 rem) whole body maximum/year; 19.0 mSv (1.9 rem) whole body over 30 years; or 23.0 mSv (2.3 rem) bone marrow over 30 years	5
Projected 4.4% increase in cancers; 1.8% increase in birth defects	20.1 mSv (2.0 rem) whole body maximum/year; 91.0 mSv (9.1 rem) whole body over 30 years; or 110.0 mSv (11 rem)	5

Diet		
All foods; maximum recommended values		
Adults, Italy	600 Bq (16,200 pCi) cesium-134 + 137/kg fresh weight (FW)	6
Children, Italy	370 Bq (10,000 pCi) cesium-134 + 137/kg FW	6
Sweden, pre-Chernobyl	300 Bq (8,100 pCi) cesium-134 + 137/kg FW	6
Caribou; muscle; North America	<2,260 Bq (<61,000 pCi) cesium-137/kg FW	8
Fish; Great Lakes; muscle	Dose of <0.02 Sv (0.00002 rem)/kg FW fish flesh equivalent to consumers	9
Fish; Sweden	<1,500 Bq (<40,500 pCi) cesium-137/kg FW	10
Fraction of ingested dose absorbed; recommended maximum; selected isotopes		
Americium, curium, neptunium, plutonium, thorium	<0.05%	11
Americium, plutonium	<0.1%	12
Californium, and higher mass radionuclides	<0.1%	11
Uranium	<5.0%	11
Milk; maximum values		
Italy	370 Bq (10,000 pCi) cesium-134 + 137/L	6
Japan	370 Bq (10,000 pCi) cesium-137/L	13
Sweden	300 Bq (8,100 pCi) cesium-137/L	14
Meat and fish; Sweden; maximum values	1,500 Bq (40,500 pCi) cesium-137/kg FW	14
Reindeer meat, game, animal meat, fish, berries, mushrooms; Sweden; post-Chernobyl; maximum values	1,500 Bq (40,500 pCi) cesium-137/kg FW	15
Sheep, muscle	<1,000 Bq (<27,000 pCi) cesium 134 + 137/kg FW	16
Sheep, muscle	<1,000 Bq (<27,000 pCi) cesium-137/kg FW	17
Drinking water		
Natural radioactivity; maximum allowed		
Radium-226 + 228	0.185 Bq (5 pCi)/L	18
Gross alpha	0.555 Bq (15 pCi)/L	18
Artificial radioactivity; maximum		

Table 28. Criterion and other variables	Concentration or dose	Reference[a]
allowed		
Gross beta	1.85 Bq (50 pCi)/L	18
Tritium (Hydrogen-3)	740 Bq (20,000 pCi)/L	18
Strontium-90	0.296 Bq (8 pCi)/L	18
Great Lakes; maximum dose to consumers	10 mSv (0.001 rem)/year	9
General public		
Annual effective dose[b]	<1 mSv (<0.1 rem)	19,29
Cesium-137; total intake		
Sweden	<50,000 Bq (<1,350,000 pCi)/year, equivalent to <1 mSv (<0.l rem)	15
North America	<300,666 Bq (<8,100,000 pCi)/year	8
United Kingdom	<400,000 Bq (<10,800,000 pCi)/year, equivalent to 5 mSv (0.5 rem)	20
Maximum permissible dose		
Eye lens	<15 mSv (<1.5 rem)/year	19
Skin	<50 mSv (<5 rem)/year	19
Whole body		
Individual, except students and pregnant women	<5 mSv (<0.5 rem)/year	9,21,22,23
Students	<1 mSv (<0.1 rem)/year	21
Pregnant women	<5 mSv (<0.5 rem) during the first 2 months of pregnancy	22
Population dose limits, genetic or somatic	<1.7 mSv (<0.17 rem) yearly average	21
Groundwater, maximum allowed		
Radium-226 + 228	0.185 Bq (5 pCi)/L	3
Alpha-emitting radionuclides-including radium-226 + 228, but excluding radon isotopes	0.555 Bq (15 pCi)/L	3
Total beta and gamma radiation	Total annual whole body dose equivalent, or dose to any internal organ, <0.04 mSv (<0.004 rem), based on individual consumption of 2 L daily of drinking water from a groundwater source	3
Radioactive wastes		
Dose limits from spent nuclear fuel or transuranic radioactive wastes		
Whole body	<0.25 mSv (<0.025 rem)/year	3,24
Thyroid	<0.75 mSv (<0.075 rem)/year	3,24
Any other critical organ	<0.25 mSv (<0.025 rem)/year	3,24
Stored for 10,000 years; maximum cumulative release allowed to the accessible environment per 1,000 metric tons of heavy metal during storage		
Americium-241	3.7 trillion (T) Bq (100 TpCi)	3
Americium-243	3.7 TBq (100 TpCi)	3

Table 28. Criterion and other variables	Concentration or dose	Reference[a]
Any alpha emitter with physical half-life >20 years	3.7 TBq (100 TpCi)	3
Any non-alpha emitter radionuclide with physical half-life >20 years	37.0 TBq (1,000 TpCi)	3
Carbon-14	3.7 TBq (100 TpCi)	3
Cesium-135	37.0 TBq (1,000 TpCi)	3
Cesium-137	37.0 TBq (1,000 TpCi)	3

[b] The Annual Limit of Intake (ALI) for any radionuclide is obtained by dividing the annual average effective dose limit (20 mSv) by the committed effective dose (E) resulting from the intake of 1 Bq of that radionuclide. ALI data for individual radionuclides are given in ICRP (1991b).

Astronauts between 25 and 55 years of age usually receive an average career dose of 2.0 Sv (1.0-3.0 Sv in females; 1.5-4.0 Sv in males), and this theoretically may cause a life shortening of 2,000 to 3,000 days (Wood 1991). Other environmental variables also shorten lives and include cigarette smoking (2,250 days), coal mining (1,100 days), and being 30% overweight (1,300 days); thus, models that assess the harm of a single variable such as radiation on life expectancy have to incorporate all known data and their interacting effects (Wood 1991).

Environmental dose-response models and animal epidemiological data are most frequently used to assess the risk from ionizing radiation. In its ideal form, a risk assessment should clearly present the rationale for an estimate of risk and should include the recognition of the roles of assumptions, approximations, data, theories, models, and deductions in arriving at an inference and a discussion of the involved uncertainties (Cothern et al. 1990). Current risk assessments of ionizing radiation hazards to all living organisms--not just humans--clearly require additional data and reinterpretation of existing data. Specifically, more effort is needed in the following areas: (1) measurement of concentrations of naturally occurring radionuclides and natural background doses in the environment as a baseline for studies of radiation effects (Templeton et al. 1971); (2) refinement of models of radionuclide transfer in food chains to aid in the assessment of radioactive releases from nuclear reactors and other point sources--including possible biomagnification by trophic components and turnover rates by receptor organisms (Kitchings et al. 1976); (3) continuance of protracted exposure studies to measure carcinogenesis in animal and human cell lines and the role of secondary factors--especially chemical agents--in radiation carcinogenesis (Little 1990); (4) research on radiation-induced recessive lethal mutations--the predominant type of radiation-induced mutation--and dominant mutation systems (Sankaranarayanan 1991c); (5) long-term studies to establish sensitive indicators of radiation stress on individuals and communities, including effects on growth and reproduction (Templeton et al. 1971); (6) clarification of the role of enzymes and proteins in repair of radiation-damaged cellular DNA and of mechanisms of enzymatic reactions leading to altered nucleotide sequences (Hagen 1990); (7) reinterpretation of low-level chronic irradiation effects on developing embryos under rigorously controlled conditions (Templeton et al. 1971); and (8) resolution of mathematical shape(s) of radiation dose-response curve(s; Hobbs and McClellan 1986).

Conclusions

Nuclear explosions and nuclear power production are the major sources of human radioactivity in the environment. Other sources include radionuclide use in medicine, industry, agriculture, education, and production; transport and disposal from these activities present opportunities for wastes to enter the environment. Dispersion of radioactive materials is governed by a variety of biogeochemical factors including winds, water currents, and biological vectors. Living organisms normally receive most of their external exposure to radiation from naturally occurring electromagnetic waves and their internal exposure from naturally occurring radionuclides such as potassium-40. Radiation exposure doses from natural sources of radiation are significantly modified by altitude, amount and type of radionuclides in the immediate vicinity, and route of exposure.

Radionuclide concentrations in representative field collections of biota tend to be elevated in the vicinity of nuclear fuel reprocessing, nuclear power production, and nuclear waste facilities; in locations that receive radioactive fallout from nuclear accidents and atmospheric nuclear tests; and near sites of repeated nuclear detonations. Radionuclide concentrations in field collections of living organisms vary significantly with organism age, size, sex, tissue, diet, and metabolism; season of collection; proximity to point source; and other biological, chemical, and physical variables. To date, no extinction of any animal population has been linked to high background concentrations of radioactivity.

The accident at the Chernobyl, Ukraine, nuclear reactor on 26 April 1986 contaminated much of the northern hemisphere, especially Europe, by releasing large amounts of radiocesium-137 and other radionuclides into the environment. In the immediate vicinity of Chernobyl, at least 30 people died, more than 115,000 others were evacuated, and the consumption of locally produced milk and other foods was banned because of radiocontamination. The most sensitive local ecosystems were the soil fauna and pine forest communities. Elsewhere, fallout from Chernobyl measurably contaminated freshwater, marine, and terrestrial ecosystems, including flesh and milk of domestic livestock. Reindeer (*Rangifer tarandus*) calves in Norway showed an increasing frequency of chromosomal aberrations that seemed to correlate with cesium-137 tissue concentrations; tissue concentrations in turn were related to cesium-137 in lichens, an efficient absorber of airborne particles that contain radiocesium and the main food source of reindeer during winter. A pattern similar to that of reindeer was documented in moose (*Alces alces*) in Scandinavia.

A dose and dose-rate dependent radiation effect on growth, survival, organ development, mutagenicity, fatal neoplasms, and other parameters exists for almost all organisms that were tested under laboratory conditions. Some discoveries suggest that low acute exposures of ionizing radiation may extend the life-span of certain species, although adverse genetic effects may occur under these conditions. In living organisms, the sensitivity to radiation is governed by ontogeny and phylogeny. Thus, rapidly dividing cells that are characteristic of embryos and fetuses are most radiosensitive, and evolutionarily advanced organisms such as mammals are more radiosensitive than primitive organisms. Between species in each taxonomic grouping are large variations in sensitivity to acute and chronic exposures of ionizing radiation and in ability to retain selected radionuclides; these processes are modified by many biological and abiotic variables.

Radiosensitive terrestrial plants are adversely affected at single exposures of 0.5-1.0 gray (Gy) and at chronic daily exposures of 0.2-0.65 Gy. Terrestrial insects are comparatively resistant to ionizing radiation; some species show growth stimulation and development at acute doses of 2 Gy--a demonstrably harmful dose for many species of vertebrates. Among aquatic organisms, the developing eggs and young of freshwater fishes are among the most sensitive tested organisms; death was observed at acute doses of 0.3-0.6 Gy and adverse effects on physiology and metabolism at chronic daily exposure rates of 0.01 Gy. The ability of aquatic organisms to concentrate radionuclides from the medium varies substantially with ecosystem, trophic level, radionuclide, proximity to radiation point source, and many other biological, chemical, and physical modifiers. In amphibians, radiation adversely affects limb regeneration, alters DNA metabolism, causes sterility, and increases the frequency of chromosomal aberrations.

Mortality patterns in some species of amphibians begin to stabilize about 200 days after exposure to a single acute dose of ionizing radiation and cannot be evaluated satisfactorily in the typical 30-day postexposure period. In birds, adverse effects on growth were noted at chronic daily exposures as low as 0.9-1.0 Gy and on survival and metabolism at single exposures to 2.1 Gy. Genotoxic effects were associated with whole-body loadings of 2,520 becquerels (Bq) of cesium-137/kg in mallards (*Anas platyrhynchos*). The radionuclide

retention in birds was modified by sex, season, and reproductive state. In mammals, embryos and fetuses of sensitive species were adversely affected at acute doses of 0.011-0.022 Gy. Humans exposed as fetuses to 0.18-0.55 Gy scored significantly lower on tests of intelligence.

No radiological criteria now exist for the protection of fishes, wildlife, or sensitive other natural resources. All current guides for protection from radiation target human health and are predicated on the assumption that protection of comparatively radiosensitive humans confers a high degree of protection to other life forms. Most authorities agree that significant harmful effects on humans occur under the following conditions: exposure of the whole body of women during the first 2 months of pregnancy to more than 5 millisieverts (mSv); exposure of the whole body to more than 50 mSv in any single year or to more than 2,000 mSv in a lifetime; annual inhalation intake by a 60-kg individual, in Bq/kg body weight (BW), of more than 0.7 of thorium-232, 3.3 of americium-241, 3.3 of plutonium-239, 16 of californium-252, 33 of uranium-235, 1,670 of strontium-90, 16,670 of cobalt-60, or 166,670 of phosphorus-32; annual ingestion intake by a 60-kg individual, in Bq/kg BW, of more than 3,330 of iodine-129, 16,670 of iodine-125, 16,670 of iodine-131, or 66,670 of cesium-137; or total annual intake, in Bq/kg BW, from all sources by a 60-kg person exceeds 66 of lead-210, 166 of polonium-210, 333 of radium-226, 670 of thorium-230, 830 of thorium-228, or 1,330 of uranium-238.

Current risk assessments of ionizing radiation hazards to living organisms require additional data and reinterpretation of existing data. Specifically, more effort seems needed in eight areas: (1) establishing a baseline for studies of radiation through measurement of naturally occurring radionuclides and natural background radiation doses; (2) refining radionuclide food-chain transfer models; (3) measuring the role of chemical agents in radiation-induced carcinogenesis; (4) accelerating research on radiation-induced lethal mutations; (5) initiating long-term studies to establish sensitive indicators of radiation stress on individuals and ecosystems; (6) clarifying the role of enzymes and proteins in repair of radiation-damaged cellular DNA; (7) reinterpreting embryotoxic effects of low-level chronic irradiation; and (8) resolving the mathematical shapes of radiation dose-response curves.

Acknowledgments

I greatly appreciate the scientific and technical input of E. K. Block, I. L. Brisbin, Jr., S. W. Fowler, J. B. Hunn, J. F. Moore, S. N. Wiemeyer, and several anonymous reviewers. I also thank L. J. Garrett and P. W. Manning for library services, M. G. Holmes for secretarial assistance, J. Hamilton for illustrations, and E. D. Rockwell for editorial services.

Glossary[1]

Actinides Elements of atomic numbers 89 to 103 (Ac, Th, Pa, U, Np, Pu, Am, Cm, Bk, Cf, Es, Fm, Md, No, Lw).

Activity The activity of a radioactive material is the number of nuclear disintegrations per unit time. Until 1977, the accepted unit of activity was the curie (Ci), equivalent to 37 billion disintegrations/s—a number that approximated the activity of 1 g of radium-226. The present unit of activity is the becquerel (Bq), equivalent to 1 disintegration/s.

Alpha (α) particles An α particle is composed of 2 protons and 2 neutrons and has a charge of +2; essentially, it is a helium nucleus without orbital electrons. Alpha particles usually originate from the nuclear decay of radionuclides of atomic number >82 and are detected in samples that contain U, Th, or Ra. Alpha particles react strongly with matter and consequently produce large numbers of ions per unit length of their paths; as a result, they are not very penetrating and traverse only a few centimeters of air. Alpha particles are unable to penetrate clothing or the outer layer of skin; however, when internally deposited, α particles are often more damaging than most other types of radiations because comparatively large amounts of energy are transferred in a small volume of tissue. Alpha particle absorption involves ionization and orbital electron excitation. Ionization occurs whenever the particle is sufficiently close to an electron to pull it from its orbit. The α also loses kinetic energy by exciting orbital electrons with interactions that are insufficient to cause ionization.

Atom The smallest part of an element that has all the properties of that element. An atom consists of one or more protons and neutrons (in the nucleus) and of one or more electrons.

Atomic number The number of electrons outside the nucleus of a neutral (nonionized) atom plus the number of protons in the nucleus.

Becquerel (Bq) The present accepted unit of activity is the becquerel, equivalent to 1 disintegration/s. About 0.037 Bq = 1 picocurie.

Beta (β) particles Beta particles are electrons that are spontaneously ejected from the nuclei of radioactive atoms during the decay process. They may be either positively or negatively charged. A positively charged beta (β), called a *positron, is* less frequently encountered than its negative counterpart, the *negatron* (β). The *neutrino,* a small particle, accompanies beta emission. The neutrino has little mass and is electrically neutral. But neutrinos conduct a variable part of the energy of transformation and account for the variability in kinetic energies of beta particles that are emitted from a given radionuclide. Positrons (β^+) are emitted by many of the naturally and artificially produced radionuclides; they are considerably more penetrating than α particles but less penetrating than X-rays and rays. Beta particles interact with other electrons and with nuclei in the travel medium. The ultimate fate of a beta particle depends on its charge. Negatrons, after their kinetic energy is spent, combine with a positively charged ion or become free electrons. Positrons also dissipate kinetic energy through ionization and excitation; the collision of positrons and electrons causes annihilation and release of energy that is equal to the sums of their particle masses.

Breeder reactor A nuclear chain reactor in which transmutation produces a greater number of fissionable atoms than the number of consumed parent atoms.

Cosmic rays Highly penetrating radiations that originate in outer space.

Curie (Ci) The Curie is equal to that quantity of radioactive material that produces 37 billion nuclear transformations/s. One millicurie (Ci) = 0.001 Ci; 1 microcurie (Ci) = 1 millionth of a Ci; 1 picocurie (pCi) = 1 millionth of a millionth Ci = 0.037 disintegrations/s. About 27 pCi = 1 becquerel (Bq).

Decay Diminution of a radioactive substance because of nuclear emission of α or β particles or of rays.

Decay product A nuclide resulting from the radioactive disintegration of a radionuclide and found as the result of successive transformations in a radioactive series. A decay product may be either radioactive or stable.

Effective dose equivalent The weighted sum, in sieverts, of the radiation dose equivalents in the most radiosensitive organs and tissues, including gonads, active bone marrow, bone surface cells, and the lung.

Electron An electron is a negatively charged particle with a diameter of 10^{-12} cm. Every atom consists of one nucleus and one or more electrons. Cathode rays and negatrons are electrons.

Electron-volt (eV) Energy acquired by any charged particle that carries unit electronic charge when it falls through a potential difference of 1 volt. One eV = 1.602×10^{-19} joule.

Fission The splitting of an atomic nucleus into two fragments that usually releases neutrons and rays. Fission may occur spontaneously or may be induced by capture of bombarding particles. Primary fission products usually decay by β particle emission to radioactive daughter products. The chain reaction that may result in controlled burning of nuclear fuel or in an uncontrolled nuclear weapons explosion results from the release of 2 or 3 neutrons/fission. Neutrons cause additional fissile nuclei in the vicinity to fission, which produces still more neutrons that in turn produce still more fissions. The speed of the chain reaction is governed by the density and geometry of fissile nuclei and of materials that slow or capture the neutrons. In nuclear reactors, neutron-absorbing rods are inserted to various depths into the reactor core. A nuclear explosion is not physically possible in a reactor because of fuel density, geometry, and other factors.

Fusion A nuclear reaction in which smaller atomic nuclei or particles combine to form larger nuclei or particles with the release of energy from mass transformation.

Gamma ( ) rays Gamma rays have electromagnetic wave energy that is similar to but higher than the energy of X-rays. Gamma rays are highly penetrating and able to traverse several centimeters of lead. See *Photons.*

Genetically significant dose (GSD) A radiation dose that, if received by every member of the population, would produce the same total genetic injury to the population as the actual doses that are received by the various individuals.

Grey(Gy) 1 Gy = 1 Joule/kg = 100 rad.

Half-life The average time in which half the atoms in a sample of radioactive element decay.

Hertz (Hz) A measure of frequency equal to 1 cycle/s.

Indirectly ionizing particles Uncharged particles such as neutrons or protons that directly liberate ionizing particles or initiate nuclear transformations.

Ion An atomic particle, atom, or chemical radical with an either negative or positive electric charge.

Ionization The process by which neutral atoms become either positively or negatively electrically charged by the loss or by the gain of electrons.

Isomer One of two or more radionuclides with the same mass number and the same atomic number but with different energies and radioactive properties for measurable durations.

Isotope One of several radionuclides of the same element (i.e., with the same number of protons in their nuclei) with different numbers of neutrons and different energy contents. A single element may have many isotopes. Uranium, for example, may appear naturally as ^{234}U (142 neutrons), ^{235}U (143 neutrons), or ^{238}U (148 neutrons); however, each uranium isotope has 92 protons.

Joule (J) 1 J = 10^7 ergs.

Latent period Period of seeming inactivity between time of exposure of tissue to an acute radiation dose and the onset of the final stage of radiation sickness.

Linear energy transfer (LET) A function of the capacity of the radiation to produce ionization. LET is the rate at which charged particles transfer their energies to the atoms in a medium and a function of the energy and velocity of the charged particle. See *Radiation dose.*

Linear hypothesis The assumption that any radiation causes biological damage in the direct proportion of dose to effect.

Mass number The total number of neutrons and protons in the nucleus of the element, which is equal to the sum of the atomic number and the number of neutrons.

Meson Particles of mass that are intermediate between the masses of the electron and proton.

Neutrinos Neutrinos and antineutrinos are formed whenever a positron particle is created in a radioactive decay; they are highly penetrating.

Neutrons Neutrons are electrically neutral particles that consist of an electron and a proton and are not affected by the electrostatic forces of the atom's nucleus or orbital electrons. Because they have no charge, neutrons readily penetrate the atom and may cause a nuclear transformation. Neutrons are produced in the atmosphere by cosmic ray interactions and combine with nitrogen and other gases to form carbon-14, tritium and other radionuclides. A free neutron has a life time of about 19 minutes, after which it spontaneously decays to a proton, a β particle, and a neutrino. A high energy neutron that encounters biological material is apt to collide with a proton with sufficient force to dislodge the proton from the molecule. The recoil proton may then have sufficient energy to cause secondary damage through ionization and excitation of atoms and molecules along its path.

Nucleus The dense central core of the atom in which most of the mass and all of the positive charge is concentrated. The charge on the nucleus distinguishes one element from another.

Photons X-rays and gamma ( ) rays, collectively termed photons, are electromagnetic waves with shorter wavelengths than other members of the electromagnetic spectrum such as visible radiation, infrared radiation, and radiowaves. X- and photons have identical properties, behavior, and effects. Gamma rays originate from atomic nuclei, but X-rays arise from the electron shells. All photons travel at the speed of light, but energy is inversely proportional to wavelength. The energy of a photon directly influences its ability to penetrate matter. Many types of nuclear transformations are accompanied by ray emission. For example, α and β decay of many radionuclides is frequently accompanied by photons. When a parent radionuclide decays to a daughter nuclide, the nucleus of the daughter frequently contains excess energy and is unstable; stability is usually achieved through release of one or more photons, a process called isometric transition. The daughter nucleus decays from one energy state to another without a change in atomic number or weight. The most probable fate of a photon with an energy higher than the binding energy of an encountered electron is photoelectric absorption, in which the photon transfers its energy to the electron and photon existence ends. As with ionization from any process, secondary radiations that are initiated by the photoelectron produce additional excitation of orbital electrons.

Planck's constant (h) A universal constant of nature that relates the energy of a photon of radiation to the frequency of the emitting oscillator. Its numerical value is about 6.626 X 10^{-27} ergs/s.

Positron A positively charged particle of equal mass to an electron. Positrons are created either by the radioactive decay of unstable nuclei or by collision with photons.

Proton A positively charged subatomic particle with a mass of 1.67252×10^{-24} g that is slightly less than the mass of a neutron but about 1,836 times greater than the mass of an electron. Protons are identical to hydrogen nuclei; their charge and mass make them potent ionizers.

Radiation The emission and propagation of energy through space or through a material medium in the form of waves. The term also includes subatomic particles such as α, β, and cosmic rays and electromagnetic radiation.

Radiation absorbed dose (rad) Radiation-induced damage to biological tissue results from the absorption of energy in or around the tissue. The amount of energy absorbed in a given volume of tissue is related to the types and numbers of radiations and the interactions between radiations and tissue atoms and molecules. The fundamental unit of the radiation absorbed dose is the rad; 1 rad = 100 erg (absorbed)/g material. In the latest nomenclature, 100 rad = 1 grey (Gy).

Radiation dose The term radiation dose can mean several things, including absorbed dose, dose equivalent, or effective dose equivalent. The absorbed dose of radiation is the imparted energy per unit mass of the irradiated material. Until 1977, the *rad* was the unit of absorbed dose, wherein 1 rad = 0.01 joule/kg. The present unit of absorbed dose is the grey (Gy), equivalent to 1 joule/kg. Thus, 1 rad = 0.01 joule/kg = 0.01 Gy. Different types of radiation have different Relative Biological Effectiveness (RBE). The RBE of one type of radiation in relation to a reference type of radiation (usually X or) is the inverse ratio of the absorbed doses of the two radiations needed to cause the same degree of the biological effect for which the RBE is given. Regulatory agencies have recommended certain values of RBE for radiation protection and absorbed doses of various radiations are multiplied by these values to arrive at radioprotective doses. The unit of this weighted absorbed dose is the roentgen equivalent man (rem). The dose equivalent is the product of the absorbed dose and a quality factor (Q), and its unit is the rem. The quality factor is a function of the capacity to produce ionization, expressed as the linear energy transfer (LET). A Q value is assigned to each type of radiation: 1 to X-rays, rays, and β particles; 10 to fast neutrons; and 20 to α particles and heavy particles. The new unit of the effective dose equivalent is the sievert (Sv), replacing rem, where 1 Sv = 100 rem. In addition to absorbed dose and dose equivalent, there is also the exposure. Exposure is the total electrical charge of ions of one sign produced in air by electrons liberated by X or gamma rays per unit mass of irradiated air. The unit of exposure is Coulomb/kg, but the old unit, the roentgen (R) is still in use. One roentgen = 2.58×10^{-4} Coulomb/kg.

Radioactivity The process of spontaneous disintegration by a parent radionuclide, which releases one or more radiations and forms a daughter nuclide. When half the radioactivity remains, that time interval is designated the half-life (Tb ½). The Tb ½ value gives some insight into the behavior of a radionuclide and into its potential hazards.

Radionuclide An atom that is distinguished by its nucleus composition (number of protons, number of neutrons, energy content), atomic number, mass number, and atomic mass.

Relative biological effectiveness (RBE) The biological effectiveness of any type of ionizing radiation in producing a specific damage (i.e., leukemia, anemia, carcinogenicity). See *Radiation dose.*

Roentgen (R) 1 R = 2.58×10^{-4} Coulombs/kg air = production by X or rays of 1 electrostatic unit of charge/cm^3 of dry air at 0° C and 760 mm Hg = 0.87 rad in air.

Roentgen equivalent man (rem) The amount of ionizing radiation of any type that produces the same damage to humans as 1 roentgen of radiation. One rem = 1 roentgen equivalent physical (rep)/ relative biological effectiveness (RBE). In the latest nomenclature, 100 rem = 1 Sievert (Sv).

Roentgen equivalent physical (rep) One rep is equivalent to the amount of ionizing radiation of any type that results in the absorption of energy of 93 ergs/g and is approximately equal to 1 roentgen of X-radiation in soft tissue.

Shell Extranuclear electrons are arranged in orbits at various distances from the nucleus in a series of concentric spheres called shells. In order of increasing distance from the nucleus the shells are designated the K, L, M, N, O, P, and Q shells; the number of electrons that each shell can contain is limited.

Sievert (Sv) New unit of dose equivalent. One Sv = 100 rem = 1 J/kg. See *Radiation dose.*

Specific activity The ratio between activity (in number of disintegrations/m) and the mass (in grams) of material giving rise to the activity. Biological hazards of radionuclides are directly related to their specific activity and are expressed in Bq/kg mass.

Threshold hypothesis A radiation-dose-consequence hypothesis that holds that biological radiation effects occur only above some minimum dose.

Transmutation A nuclear change that produces a new element from an old one.

Transuranic elements Elements of atomic number >92. All are radioactive and produced artificially; all are members of the actinide group.

X-rays See *Photons.*

Abstract. Sodium monofluoroacetate ($CH_2FCOONa$), also known as 1080, was first used in the United States to control gophers (*Geomys* spp.), squirrels (*Sciurus* spp., *Spermophilus* spp.), prairie dogs (*Cynomys* spp.), other rodents (Rodentia), and coyotes (*Canis latrans*); 1080 domestic use is currently restricted to livestock-protection collars on sheep and goats to selectively kill depredating coyotes. However, Australia, New Zealand, and some other nations continue to use 1080 to control rabbits, possums, deer, foxes, feral pigs and cats, wild dogs, wallabies, rodents, and other mammals. The chemical is readily absorbed by ingestion or inhalation. At lethal doses, metabolic conversion of fluoroacetate to fluorocitrate results in the accumulation of citrate in the tissues and death within 24 h from ventricular fibrillation or from respiratory failure; no antidote is available. At sublethal doses, the toxic effects of 1080 are reversible. Primary and secondary poisoning of nontarget vertebrates may accompany the use of 1080. Sensitive mammals including representative species of livestock, marsupials, felids, rodents, and canids died after receiving single doses of 0.05-0.2 mg 1080/kg body weight (BW); most tested species died after a single dose of 1-3 mg/kg BW. High residues were measured in some poisoned target mammals, and this contributed to secondary poisoning of carnivores that ingested poisoned prey. Sublethal effects occurred in sensitive mammals at greater than 2.2 mg 1080/L in drinking water or at 0.8-1.1 mg 1080/kg in the diet. Sensitive species of birds died after a single 1080 dose of 0.6-2.5 mg/kg BW, after daily doses of 0.5 mg/kg BW for 30 days, after 47 mg/kg in diets for 5 days, or after 18 mg/L in drinking water for 5 days. Adverse effects occurred in birds at dietary loadings as low as 10-13 mg 1080/kg ration. Amphibians and reptiles were more resistant to 1080 than birds and mammals. LD50 values were greater than 44 mg/kg BW in tested amphibians and greater than 54 mg/kg BW in tested reptiles; resistance to 1080 was attributed to their reduced ability to convert fluoroacetate to fluorocitrate and their increased ability to detoxify fluoroacetate by defluorination. Mosquito larvae reportedly died at 0.025-0.05 mg 1080/L, but fishes seemed unaffected at 13 mg/L; however, data on 1080 in aquatic ecosystems are incomplete. Acute LD50 values in terrestrial insects ranged from 1.1-3.9 mg/kg BW to 130.0 mg/kg BW in larvae feeding on fluoroacetate-bearing vegetation. Residues of 1080 in exposed insects were usually low (<4 mg 1080/kg fresh weight) or negligible and were usually eliminated completely within 6 days, suggesting low risk to insectivorous birds. Loss of 1080 from baits occurs primarily from microbial defluorination and secondarily from leaching by rainfall and consumption by insect larvae; leachates from 1080 baits are probably held in the upper soil layers. The use of 1080 seems warranted in the absence of suitable alternative control methods.

Key words: Sodium monofluoroacetate, 1080, organofluorines, pesticide, predacide, toxicity, wildlife, livestock, invertebrates.

Sodium monofluoroacetate ($CH_2FCOONa$), also known as 1080 or Compound 1080, belongs to the class of chemicals known as fluoroacetates (Pattison 1959). It is a tasteless and odorless, water-soluble poison of extraordinary potency that has been used widely against rodents and other mammalian pests (Anonymous 1946; Negherbon 1959; Rammell and Fleming 1978; McIlroy 1981a; Hornshaw et al. 1986; Aulerich et al. 1987; Connoly and Bums 1990). The widespread use of 1080 in pest control has caused accidental deaths of livestock, wildlife, pets (cats and dogs), and humans (Anonymous 1946; Chenoweth 1949; Sayama and Brunetti 1952; Negherbon 1959; U.S. Environmental Protection Agency [EPA] 1976; McIlroy 1982a), and several suicides in Asia from drinking 1080 rat poison solutions (Howard 1983). There is no effective antidote to 1080 (Mead et al. 1991). When consumed, fluoroacetate is converted to fluorocitrate that inhibits the enzymes aconitase and succinate dehydrogenase; the accumulated citrate interferes with energy production and cellular function (Aulerich et al. 1987).

Monofluoroacetic acid (CH_2FCOOH) was first synthesized in Belgium in 1896 but attracted little attention from chemists and pharmacologists at that time (Chenoweth 1949; Atzert 1971). In 1927, sodium monofluoroacetate was patented as a preservative against moths (Sayama and Brunetti 1952). The toxic nature of monofluoroacetate compounds was first noted in Germany in 1934 (Atzert 1971). In the late 1930's and early 1940's, Polish scientists conducted additional research on the toxic properties of fluoroacetate compounds, especially the methyl ester of fluoroacetic acid that they had synthesized (Anonymous 1946; Chenoweth 1949). In 1942, British scientists further refined this compound to the sodium salt that became known as 1080 (Anonymous 1946). In 1944, potassium monofluoroacetate (CH_2FCOOK) was isolated from *Dichapetalum cymosium*, a South African plant, and was the first known example of a naturally occurring organic fluoride; the plant, known locally as Gifblaar, caused many deaths of livestock (Chenoweth 1949) and was recognized by Europeans as poisonous as early as 1890 (Peacock 1964). Fluoroacetate compounds have since been isolated from poisonous plants in Australia (*Acacia georginae*, *Gastrolobium* spp.), in Brazil (rat weed, *Palicourea marcgravii*), and in Africa (*Dichapetalum* spp; Atzert 1971). Ratsbane (*Dichapetalum toxicarium*), an African plant, was known to contain a poison--subsequently identified as a fluoroacetate--that was lethal to rats, livestock, and humans and reportedly was used by African natives during the 1800's to poison the wells and water supplies of hostile tribes (Anonymous 1946).

During World War II (1939-45), as a result of acute domestic shortages of common rodenticides such as thallium, strychnine, and red squill, testing for alternative chemicals was initiated (Anonymous 1946). In June 1944, the U.S. Office of Scientific Research and Development supplied the Patuxent Wildlife Research Center--then a laboratory of the U.S. Fish and Wildlife Service--with sodium monofluoroacetate and other chemicals for testing as rodenticides (Atzert 1971). The center gave sodium monofluoroacetate the acquisition number 1080, which subsequently was adopted as its name by the chemical's manufacturer. Samples of 1080 were also shipped to the Denver Wildlife Research Center, another former laboratory of the U.S. Fish and Wildlife Service, for testing on additional species. Results of these tests gave evidence of the value of 1080 as an effective control of animal predators of livestock and other animal pests (Atzert 1971). During World War II, 1080 protected allied troops in the Pacific Theater against scrub typhus, also known as tsut sugamushi, a louse-borne rickettsial disease with rodents as vectors (Peacock 1964). In the United States, 1080 was first used in 1945 to control rodents, and later coyotes (*Canis latrans*) and rabbits (*Lepus* spp.; *Sylvilagus* spp.; Hornshaw et al. 1986; Aulerich et al. 1987). Between 1946 and 1949, at least 12 humans died accidentally in the United States from 1080 poisoning when used as a rodenticide; a child became ill but recovered after eating the cooked flesh of a 1080-poisoned squirrel (EPA 1976). Since 1955, 1080 has been used extensively in a variety of baits--especially in Australia and New Zealand--to control European rabbits (*Oryctolagus cuniculus*), dingoes (*Canis familiaris dingo*), feral pigs (*Sus scrofa*), brush-tailed possums (*Trichosurus vulpecula*), and various species of wallabies (McIlroy 1981a, 1981b, 1982a, 1984; Twigg and King 1991). In Australia, vegetable baits are sometimes eaten by nontarget herbivores such as sheep (*Ovis aries*), cattle (*Bos taurus*), and various species of wildlife and cause primary and secondary poisoning of nontarget animals (McIlroy 1982a). In the United States, most uses of 1080 were canceled in 1972 because, in part, of deaths of nontarget animals (Balcomb et al. 1983). At present, the use of 1080 in the United States is restricted to livestock-protection collars on sheep and goats (*Capra hircus*) against predation by coyotes (Palmateer 1989,1990).

Useful reviews of ecotoxicological aspects of 1080 include those by Chenoweth (1949), Peacock (1964), Atzert (1971), Kun (1982), Twigg and King (1991), and Seawright and Eason (1994). I prepared my account in response to requests for information on 1080 from environmental contaminant specialists of the U.S. Fish and

Wildlife Service. It is part of a continuing series of brief reviews of chemicals in the environment with an emphasis on hazards to plants and animals.

Uses of 1080

The use of 1080 in the United States is now restricted to the protection of livestock--collars on sheep and goats--from predation by coyotes. Other countries, most notably Australia and New Zealand, use 1080 extensively in a variety of baits to control many species of vertebrate pests.

Domestic Use

Compound 1080 is highly poisonous to all tested mammals and to humans (Green 1946). There is no known antidote to 1080, and it has been impossible to resuscitate any animal or human during the final stages of 1080 poisoning (Kalbach 1945; Green 1946; Connolly 1989, 1993a). In the United States, 4 suicides and at least 12 accidental human deaths occurred in 25 years of use of 1080 between 1959 and 1969 and 37 known incidents of domestic animal poisoning resulted from federal use of 1080 (Atzert 1971). Compound 1080 is not recommended for use in residential areas or for distribution where the public may be exposed (Green 1946); only licensed pest control operators can use 1080 (Green 1946; Peacock 1964; EPA 1985; Murphy 1986). Tull Chemical in Oxford, Alabama, is the sole domestic producer of 1080; none is imported (EPA 1985). Operators who handle 1080 should wear protective clothing, including gloves and a respirator; extreme caution is recommended at all times (Green 1946). During attaching, removing, or disposing of livestock-protection collars, each applicator must carry syrup of ipecac to induce vomiting in case of accidental poisoning (Connolly 1989, 1993a).

Compound 1080 was first used in the United States in the late 1940's to control gophers (*Geomys* spp.), ground squirrels (*Spermophilus* spp.), prairie dogs (*Cynomys* spp.), field mice (Muridae), commensal rodents, and coyotes (Chenoweth 1949; Fry et al. 1986). Annual damage from coyotes to livestock in California alone is an estimated $75 million (Howard 1983). Yearly amounts of 1080 used in the United States for predator control were 23 kg in the early 1960's, 7,727 kg in the late 1960's, and only 8 kg in 1971 (Connolly 1982). The total annual production of 1080 in the United States between 1968 and 1970 averaged about 1,182 kg (Atzert 1971). In 1977, 277,545 kg of 1080-containing baits (272 kg of 1080) were used to control ground squirrels (76%), prairie dogs (7%), and mice, rats, chipmunks (*Tamias* spp.), and other rodents (17%); California used 83% of all 1080 baits, Colorado 12%, and Nevada and Oregon 5% (EPA 1985). About 0.3 kg of 1080/year are used in the livestock-protection collars but only about 35 g/year is released into the environment (Connolly 1993b). In March 1972, the use of 1080 for predator control was prohibited on federal lands. Later that year, all uses of 1080 for predator control were banned in the United States because of adverse effects on nontarget organisms including endangered species (Palmateer 1989, 1990). Since 1080 was banned, the number of grazing livestock reported lost to predation in western national forests has increased. Between 1960 and 1971, 1.42% (range 1.0-1.9%) of all grazed sheep and goats were lost to predators versus 2.17% (1.7-2.5%) in 1970-78 (Lynch and Nass 1981). Until it was banned in 1972, the use of 1080 as a control agent of predators in the United States was strictly controlled. The chemical was registered under the Federal Insecticide, Fungicide and Rodenticide Act (61 Stat 163; 7 U.S.C. 135-135K) for use only by governmental agencies and experienced pest-control operators (Atzert 1971). The use of 1080 as a rodenticide was disallowed in 1985 for three reasons; (1) lack of emergency treatment, namely a viable medical antidote; (2) high acute toxicity to nontarget mammals and birds; and (3) a significant reduction in populations of nontarget organisms and fatalities to endangered species (EPA 1985). In 1985, 1080 use was conditionally permitted in livestock-protection collars and in single lethal dose baits; a registration of the livestock-protection collar was issued to the U.S. Department of the Interior on 18 July 1985 (EPA 1985). On 21 February 1989, the registration of 1080 was cancelled, prohibiting all uses. In June 1989, however, technical 1080 was conditionally approved for use only in the livestock-protection collar. The 30-mL collar is registered for use by the U.S. Department of Agriculture; by the states of Montana, Wyoming, South Dakota, and New Mexico; and by Rancher's Supply, Alpine, Texas (Palmateer 1989, 1990).

Compound 1080 was highly effective against all species of rats, prairie dogs, and ground squirrels and satisfactory for the control of mice (Peacock 1964). The chemical was formulated in grain baits or chopped greens for crop and range rodents and in water bait stations to control rats (EPA 1985). The concentration of 1080 in baits was lowered to 0.02% in the range of the California condor (*Gymnogyps californianus*) and for prairie dog control because of possible harm to the endangered black-footed ferret (*Mustela nigripes*; EPA 1985). Commercial 1080 was commonly colored with 0.5% nigrosine and sold as a compound containing

greater than 90% sodium monofluoroacetate, to be mixed with foods at 2,226 mg/kg in preparing baits or to be dissolved in water at 3,756 mg/L for poisoning drinking water in indoor control of rodents (Anonymous 1946; Green 1946; Negherbon 1959). Bait acceptance by rats was not significantly reduced by the dye (Peacock 1964). Compound 1080 was adequately accepted by rats and mice when present in water; solid food baits poisoned with 1080 were not always accepted as readily and sometimes required special preparation to insure the ingestion of lethal amounts (Green 1946). A water solution of 1080 was the most effective tested rodenticide for rat control in southern states, and 1080-grain baits were the most effective field rodenticides against ground squirrels, prairie dogs, and mice in California, South Dakota, and Colorado (Kalmach 1945). Seeds and cereal grains were the most effective baits for small rodents: 1 kg of 1080 was sufficient to kill 3.96 million squirrels (Peacock 1964). Grain baits were colored brilliantly yellow or green to heighten the repellency of birds; coloring did not affect the acceptance of baits by rodents (Peacock 1964; Atzert 1971). Rats did not develop a significant tolerance to 1080 from ingestion of sublethal doses; although rats that survived poisoning may develop an aversion to 1080 (Green 1946; Peacock 1964).

To kill coyotes and gray wolves (*Canis lupus*) in the United States and in Canada, meat baits containing 35 mg 1080/kg were recommended--usually an injected water solution of 1080 into horsemeat baits; only 28-56 g of a poisoned bait was sufficient to kill (Peacock 1964). Meat baits were usually placed in fall in areas with maximum coyote use and minimum use by most nontarget carnivores (Atzert 1971). The most widely publicized technique for poisoning predators was the 1080 large bait station: a 22-45 kg livestock meat bait injected with 35 mg 1080/kg bait (Connolly 1982). The use of 1080 stations peaked in the early 1960's, at which time 15 to 16 thousand stations were placed each winter in the western United States. After 1964, the number of stations declined annually to 7,289 stations in 1971 (Connolly 1982). Against canine predators of livestock, 1080 was more selective and less hazardous than strychnine or traps to nontarget species (Peacock 1964). Meat baits for the control of coyotes were seldom fatal to hawks, owls, and eagles (Falconiformes), even when these birds gorged themselves on the poisoned baits (Peacock 1964). In addition to the large bait stations, an unknown number of U.S. Government hunters used 1080 in smaller baits at various stations (Connolly 1982).

The introduction of 1080-livestock-protection collars to protect goats and sheep against coyote depredation was initiated in 1985; its use was limited to certified applicators (Burns et al. 1991). The 1080-filled rubber collars are attached to the throats of sheep and goats; 1080 is released when coyotes attack collared livestock with characteristic bites to the throat (Walton 1990; Burns et al. 1991). The livestock-protection collars contain 30 mL of a 1% 1080 solution (Walton 1990) and tartrazine (Burns and Savarie 1989; Connolly 1993a) as a marker. The livestock-protection collar may not be used in areas known to be frequented by endangered species of wildlife, and these include various geographic areas in California, Michigan, Minnesota, Montana, Washington, Wisconsin, and Wyoming (Connolly 1989, 1993a). In livestock-protection collars, Compound 1080 is reportedly more effective and safer than sodium cyanide, diphacinone, or methomyl (Connolly 1982). Pen tests with compound 1080 in livestock-protection collars began late in 1976 and field tests in 1978 (Connolly and Burns 1990). In the field, 1080 livestock-protection collars on sheep seem to protect selectively against predation by coyotes; no adverse effects on humans, domestic animals, and nontarget wildlife were recorded (Connolly and Burns 1990). The decision to permit limited use of 1080 in livestock-protection collars is now being contested by at least 14 conservation groups because of its alleged hazard to nontarget organisms (bears, *Ursus* spp.; badgers, *Taxidea taxus*; dogs, *Canis* spp.; eagles, *Aquila chrysaetos*, *Haliaeetus leucocephalus*) and to human health, and to the availability of alternate and more successful methods of coyote control (Sibbison 1984). In Texas, for example, the annual cost from losses of sheep and goats to coyotes are an estimated $5 million. But few Texas ranchers have taken advantage of the opportunity to use livestock-protection collars, and only 23 coyotes were killed in 1989 by the collars versus 473 by cyanide, snares, aerial gunning, and other measures (Walton 1990). Toxic livestock-protection collars in full operation would probably kill fewer than 1,000 coyotes annually versus 1 million coyotes killed annually from hunting and other measures (Sibbison 1984).

Compound 1080 was also effective against jackrabbits, foxes, and moles. Baits containing 0.05-0.1% of 1080 on vegetables were used in California to kill jackrabbits (*Lepus* spp.) and various rodents (Schitoskey 1975). The Arctic fox (*Alopex lagopus*), intentionally introduced onto the Aleutian Islands in 1835 (Bailey 1993), almost eliminated the Aleutian Canada goose (*Branta canadensis leucopariea*) by 1967; 1080-tallow baits were successfully used to control fox populations (Byrd et al. 1988; Tietjen et al. 1988; Bailey 1993). Earthworm baits are used to kill moles (Talpidae). The earthworms are soaked for 45 min in a 2.5% solution of 1080 and placed

in mole burrows. The solution can be used several times for additional lots of worms; however, the use of the manure worm (*Eisenia foetida*) should be avoided because it is seldom eaten by moles (Peacock 1964).

Secondary poisoning of domestic cats and dogs from consumption of 1080-poisoned rodents was frequently noted (Anonymous 1946). Cats and dogs are highly susceptible to 1080 and may die after eating freshly poisoned rodents, dried carcasses, or 1080-baits or after drinking 1080-poisoned water (Green 1946). All pets should be confined or removed from the area to be poisoned and released after the entire control is completed. Pigs and carnivorous wildlife are also at risk from consumption of 1080-poisoned rodents (Peacock 1964). Secondary poisoning of kit foxes (*Vulpes macrotis*) is theoretically possible after eating a single kangaroo rat (*Dipodomys* sp.) that swallowed or stuffed its cheeks with 1 g of a 0.1% vegetable/cereal bait and contained a total whole-body burden of about 1 mg of 1080/rat (Schitoskey 1975). To prevent secondary poisoning, all uneaten baits and carcasses of poisoned rodents should be recovered and incinerated (Green 1946), and no 1080-contaminated animal should be eaten by humans or be fed to animals (Connolly 1989, 1993a).

Nondomestic Use

Compound 1080 has had limited use as a vertebrate pesticide in Canada, India, Mexico, and South Africa and extensive use in Australia (Calver et al. 1989b) and New Zealand (Rammell and Fleming 1978). In Canada, 1080 was first used in 1950-51 in British Columbia to control wolves and coyotes preying on livestock (Peacock 1964). Poisoned 1080 baits were used in India to control (67-100% effective) populations of the Indian crested porcupine (*Hystrix indica*) throughout its range because of porcupine-caused damage and losses to agricultural crops; however, control of this species with 1080 baits was not as effective as fumigants (Khan et al. 1992). In Mexico, 1080 was used against rabid coyotes, although many domestic dogs were also killed (Peacock 1964). Beginning in 1961 in South Africa, 1080 was used to control the black-backed jackal (*Canis mesomelas*) that preyed on livestock, and baboons (*Papio anubis*) and moles that consumed agricultural crops (Peacock 1964). Livestock-protection collars containing 30 mL of a 1% solution of 1080 are now used in South Africa to combat predation by the Asiatic jackal (*Canis aureus*; Walton 1990).

Compound 1080 was first used in Australia in the 1950's to kill the introduced European rabbit (*Oryctolagus cuniculus*). Principal target species in Australia now include other introductions such as dingoes, red foxes (*Vulpes vulpes*), feral pigs (*Sus scrofa*), feral cats (*Felis cattus*) as well as native brush-tailed possums (*Trichosurus vulpecula*), red-necked wallabies (*Macropus rufogriseus*), and pademelons (*Thylogale billardierii*; McIlroy 1981a, 1981b, 1982,1984; Calver et al. 1989a, 1989b; Wong et al. 1991). In Australia, different baits contained different concentrations of 1080; meat baits contained 144 mg/kg, grain baits 288-300 mg/kg, fruits and vegetables 330 mg/kg, and pellets 500 mg/kg (McIlroy 1983a).

One method of killing rabbits in many areas of Australia is to apply 1080-poisoned bait (carrots, oat grains, pellets of bran or pollard) to furrows made in the earth or to broadcast baits across the area from the air or on the ground (McIlroy 1984; McIlroy and Gifford 1991). Aerial dropping of diced carrots treated with 1080 was almost 100% effective against rabbits (Anonymous 1964). In Victoria, more than 6.5 million ha were treated with 1080 poisoned carrots. To attract rabbits to the kill area, nonpoisoned carrots were applied to rabbit trails at more than 8.3 kg/km; nonpoisoned baits were offered twice, 3 days apart, before 1080-poisoned carrots were offered 1 week later (Woodfield et al. 1964). Bait avoidance is reported in some populations of European rabbits exposed repeatedly to 1080 baits during sustained control. Behavioral resistance may reduce the effectiveness of sustained control and should be considered in pest management (Hickling 1994). Individuals--but not populations--of some native species of Australian animals and birds face a greater risk of poisoning by 1080 during rabbit-poisoning campaigns than rabbits, particularly herbivorous macropodids, rodents, and bird species with no prior exposure to naturally occurring fluoroacetates (McIlroy 1992). Foxes, dingoes, dogs, and cats seem to be at greater risk of secondary poisoning than native birds and mammals, particularly from eating muscle from poisoned rabbits that contained as much as 5 mg of 1080/rabbit (McIlroy 1992).

The injection of fresh meat baits for the control of dingoes produced more uniform amounts of 1080 in the baits than tumbling mixed baits in 1080 solutions. Both techniques, however, produced baits containing variable quantities of 1080 (Kramer et al. 1987). Use of 1080-poisoned baits to control wild dogs (*Canis familiaris familiaris*) and dingoes were not as successful as traps: 22% control from 1080 versus 56% control with traps. Factors that reduced the success of poisoned baits included rapid loss in toxicity after distribution of the baits; the rapid rate at which they were removed by other animals, particularly foxes and birds; and the dogs' apparent preference for natural prey (McIlroy et al. 1986a).

Feral pigs in Australia damage crops, degrade pastures, kill and eat lambs, and are potential vectors and reservoirs of exotic pathogens (O'Brien et al. 1986; O'Brien 1988). Control of feral pigs with poisoned baits, including 1080 bait, is difficult because most pigs regurgitate these baits shortly after ingestion (O'Brien et al. 1986). The vomitus may cause secondary poisoning of nontarget species, and pigs surviving sublethal exposure to 1080 from vomiting may develop an aversion to 1080 and thus decrease their susceptibility to subsequent poisoning programs. The incorporation of antiemetics into 1080 baits should reduce or prevent vomiting, but those tested were not completely successful (O'Brien et al. 1986). Feral cats altered ecosystems and depleted populations of indigenous lizards and birds in Australia and in New Zealand and in numerous island habitats throughout the world. Fresh fish baits injected with 2 mg of 1080 per bait are used as a humane and lethal poison for feral cats (Eason and Frampton 1991).

The use of 1080 in New Zealand is restricted to licensed operators of pest-destruction boards and government departments (Temple and Edwards 1985). In Australia and in other locations, the addition of dye to identify toxic baits is standard practice (Temple and Edwards 1985; Statham 1989). The main purpose of such addition is to reduce the unintentional poisoning of birds; birds eat significantly less blue- or green-dyed feed than undyed feed (Statham 1989). Although birds prefer undyed baits to those dyed green, Canada geese (*Branta canadensis*) when feeding at night are unable to distinguish between dyed and undyed baits and consume both with equal frequency (Temple and Edwards 1985). Carrots used as wallaby baits in New Zealand are dyed with special green or blue pigments: however, the red-necked wallaby (*Macropus rufogriseus*) equally accepted dyed and undyed carrots (Statham 1989). Mice (*Mus* spp.) readily consumed dyed wheat (Twigg and Kay 1992). Compound 1080 is used in jam-type baits to control brush-tailed possums. These baits contained 1080 at concentrations as high as 1,500 mg 1080/kg FW bait and were dyed green to protect birds. Cinnamon was added to mask the flavor of the 1080 poison, and 800 mg potassium sorbate/kg was added as an antifungal preservative (Goodwin and Ten Houten 1991).

The Norway rat (*Rattus norvegicus*) had a severe effect on island populations of birds, reptiles, and invertebrates in New Zealand (Moors 1985). In one case, rats on the Big South Island exterminated five species of native forest birds within 3 years, including the last known population of the bush wren (*Xenicus longipes*). A paste containing petroleum jelly, soya oil, sugar, green dye, and 800 mg 1080/kg remained toxic for 6 to 9 months to rats that prey on grey-faced petrels (*Pterodroma macroptera*) and on other birds. Because 1080 produces a poison-shyness in any Norway rat that eats a sublethal dose, complete eradication of this species by 1080 is improbable (Moors 1985). The use of anticoagulants--such as warfarin (multiple doses needed), brodifacoum. (single dose) or coumatetralyl--seems more promising than 1080 for the control of rats (Moors 1985), although secondary poisoning of owls and hawks may occur (Hegdal and Colvin 1988).

In New Zealand, compound 1080 in a gel carrier is sometimes applied to the leaves of broadleaf (*Griselinia littoralis*) to poison red deer (*Cervus elephus*), feral goats, white-tailed deer (*Odocoileus virginianus*) and red-necked wallabies (Batcheler and Challies 1988). Use of 1080-gel baits reduced feral goat populations by 90% (Parkes 1983). Wallaby populations were reduced 87-91% with a 1080 gel applied to the foliage of palatable plants, and this compares favorably to reductions with aerially sown baits (Warburton 1990). The gel carrier was an effective phytotoxin, causing withering, death, or loss of chlorophyll from leaves within 10 days and sometimes within 24 h (Parkes 1983).

Feral pigs are sometimes poisoned by inserting as many as 10 gelatin capsules (each containing 100 mg of 1080) into carcasses or offal baits. Poisoned carcasses may remain edible for more than 2 months during fall and winter when poisoning campaigns are conducted; the 1080 is leached out when the carcass disintegrated (McIlroy 1983a). Other techniques to control feral pigs include injection of 1080 gel into beef-lung baits or insertion of capsules containing 1080 into apple, potato, or other fruit and vegetable baits. However, these techniques are potentially the most dangerous to applicators because 1080 powder, rather than a diluted solution, is used; also, the baits are lethal to nontarget scavengers (McIlroy 1983a).

Environmental Chemistry

General

Sodium monofluoroacetate is a whitish powder that is soluble in water to at least 263 mg/L but relatively insoluble in organic solvents. Some aqueous solutions of 1080 retain their rodenticidal properties for at least 12 months, but others lose as much as 54% of their toxicity after 24 days. Compound 1080 is unstable at more than 110° C and decomposes at more than 200° C, although 1080 in baits or poisoned carcasses is comparatively stable. Losses of 1080 from meat baits are due primarily to microbial defluorination and also to leaching from rainfall and consumption by maggots. Leachates from 1080 baits are probably not transported long distances by groundwater because they tend to be held in the upper soil layers. Compound 1080 can be measured in water at concentrations as low as 0.6 m/L and in biological samples at 10-15 m/kg. As discussed later, 1080 is readily absorbed through the gastrointestinal tract, mucous membranes, and pulmonary epithelia; once absorbed, it is uniformly distributed in the tissues. Metabolic conversion of high concentrations of fluoroacetate to fluorocitrate results in large accumulations of citrate in the tissues and eventual death from ventricular fibrillation or respiratory failure. Regardless of dose and tested species, no signs or symptoms of 1080 poisoning were evident during a latent period of 30 min to 2 h; however, death usually occurred within 24 h of exposure. Repeated sublethal doses of 1080 have increased the tolerance of some species of tested birds and mammals to lethal 1080 doses. Because of their low facility to convert fluoroacetate to fluorocitrate and their high defluorination capability, reptiles are more resistant to 1080 than mammals. No effective antidote is now available to treat advanced cases of fluoroacetate poisoning; accidental poisoning of livestock and dogs by 1080 is probably fatal. Partial protection against 1080 poisoning in mammals has been demonstrated with glycerol monoacetate, a sodium acetate-ethanol mixture, and with a calcium glutonate-sodium succinate mixture.

Chemical Properties

Compound 1080 is relatively soluble in water but not in organic solvents (Table 1). In water, trace amounts (0.6 m/L) of 1080 were detected during gas chromatography (GC) with electron capture detection; recoveries from environmental water spiked at 5-10 mg/L ranged from 93 to 97% (Ozawa and Tsukioka 1987). Recent advances make it possible to measure 1080 in solutions at concentrations as low as 0.2 mg/L (Kimball and Mishalanie 1993). In biological tissues, various methods have been used to determine fluoroacetic acid, including colorimetry, fluoride-ion electrodes, gas-liquid chromatography, and high-pressure chromatography; however, these methods involve lengthy extraction procedures, have low recoveries, or show lack of selectivity (Allender 1990). A sensitive gas chromatographic technique was developed and used successfully to determine fluoroacetate levels in organs from a magpie (*Gymnorhina tibicen*) that had ingested a bait containing 1080 poison. The procedure involved extraction of 1080 with acetone:water (8:1) followed by derivatization with pentafluorobenzyl bromide. Bait samples were initially screened by thin-layer chromatography, and identification of derivatized extracts was confirmed by gas chromatography/mass spectrometry = GC/MS (Allender 1990). A new method for fluoroacetate determination in biological samples requires the isolation of fluoroacetate as its potassium salt by ion-exchange chromatography and conversion to its dodecyl ester. The ester is quantified by capillary GC with a flame ionization detector for the range 1-10 mg/kg and by selected ion monitoring with GC/MS for the range 0.01-1.00 mg/kg (Burke et al. 1989). The detection limit for 1080 in tissues and baits is 15 mg/kg by a reaction-capillary GC procedure with photo-ionization detection; the detection limit is 100 mg/kg with flame-ionization procedures. The detection limit with these procedures is less sensitive than GC/MS; however, GC/MS is not normally available in veterinary diagnostic laboratories (Hoogenboom and Rammell 1987).

Table 1. Some properties of sodium monofluoroacetate.[a]

Variable	Datum
Alternate names	1080; Compound 1080; fratol; monosodium fluoroacetate; sodium fluoacetate; sodium fluoroacetate; ten-eighty
Chemical formula	$CH_2FCOONa$
Molecular weight	100.03
Physical state	White, odorless, almost tasteless, hygroscopic powdery salt, resembling powdered sugar or baking powder
Primary use	Rodenticide; mammal control agent
Purity	96.0-98.6%
Solubility	
Water	263 mg/L
Acetone, alcohol, animal and vegetable fats, kerosene, oils	Relatively insoluble
Stability	Unstable at > 110 and decomposes at >200° C. Hydrogen fluoride (20% by weight) is a decomposition product that readily reacts with metals or metal compounds to form stable inorganic fluoride compounds

[a]Chenoweth 1949; Negherbon 1959; Peacock 1964; Tucker and Crabtree 1970; Atzert 1971; Hudson et al. 1984.

Persistence

Significant water contamination is unlikely after aerial distribution of 1080 baits (Eason et al. 1993a). In one field trial in New Zealand in which more than 20 metric tons of 1080 baits were aerially sown over a 2,300-ha island to control brushtail possums (*Trichosurus vulpecula*) and rock wallabies (*Petrogale penicillata*), no 1080 was detected in surface or ground water of the island for at least 6 months after baits were dropped. A similar case was made for streams and rivers after 100 metric tons of 1080 baits were sown by airplane over 17,000 ha of forest (Eason et al. 1992, 1993b). Laboratory studies on 1080 persistence in solutions suggested that degradation to nontoxic metabolites is most rapid at elevated temperatures and in biologically conditioned media but is highly variable. In general, aqueous solutions of the salt or esters decrease in toxicity over time through spontaneous decarboxylation to sodium bicarbonate and to the highly volatile, relatively nontoxic methyl fluoride. Solutions refrigerated at 5° C lost about 54% of their initial toxicity to laboratory rats after 24 days and about 40% after 7 days at room temperature, but 1080 solutions remained toxic to yeast for at least 1 month after storage at 3-5° C (Chenoweth 1949). In an aquarium with plants and invertebrates and 0.1 mg 1080/L, the water concentration of 1080 declined 70% in 24 h and was not detectable after 100 h; residues in plants were not detectable after 330 h (Eason et al. 1993b). In a distilled water aquarium without biota, 1080 residues declined only 16% in 170 h (Eason et al. 1993b). In another study, 1080 solutions prepared in distilled water and stored at room temperature for 10 years showed no significant breakdown; moreover, solutions of 1080 prepared in stagnant algal-laden water did not lose biocidal properties during 12 months (McIlroy 1981a). More research on 1080 persistence in aquatic environments seems needed.

In soils, 1080 is degraded to nontoxic metabolites by soil bacteria and fungi, usually through cleavage of the carbon-fluoride bond (Eason et al. 1991, 1993a). Soil microorganisms capable of defluorinating 1080 include *Aspergillus fumigatus*, *Fusarium oxysporum*, at least 3 species of *Pseudomonas*, *Nocardia* spp., and 2 species of *Penicillium* (Wong et al. 1992a). When grown in solution with 1080 as the sole carbon source and in autoclaved soil, these microorganisms can defluorinate 1080; the amount of defluorination ranged from 2 to 89% in soils and from 2 to 85% in 1080 solutions. Some indigenous soil microflora were able to defluorinate 50-87% of the 1080 within 5-9 days in soil at 10% moisture and 15-28° C. The most effective defluorinaters in solution and in soils were certain strains of *Pseudomonas*, *Fusarium*, and *Penicillium* (Wong et al. 1991, 1992a; Walker 1994). *Pseudomonas cepacia*, for example, isolated from the seeds of various fluoroacetate-accumulating plants can grow and degrade fluoroacetate in fluoroacetate concentrations as high as 10,000

mg/kg (Meyer 1994). Biodefluorination of 1080 by soil bacteria was maximal under conditions of neutral to alkaline pH, at fluctuating temperatures between 11 and 24° C, and at soil moisture contents of 8-15%; biodefluorination of 1080 by soil fungi was maximal at pH 5 (Wong et al. 1992b).

Losses of 1080 from meat baits were probably due to consumption of the bait by blowfly maggots, leaching by rainfall, defluorination by microorganisms, and leakage from baits during decomposition (McIlroy et al. 1988), The 1080 in baits will persist under hot and dry conditions where leaching from rain is unlikely (Wong et al. 1992a). Baits remained toxic to dogs for more than 32 days during winter when maggots were absent and for 6-31 days during summer when maggots were present. Baits contained an average LD50 dose to tiger quolls (*Dasyurus maculatus*)—a raccoon-like marsupial--for 4-15 days in winter and for 2-4 days in summer (McIlroy et al. 1988). Meat baits that initially contained 4.6 mg of 1080 retained 62% after 3 days, 29% after 6 days, and 28% after 8 days (McIlroy et al. 1986a). The persistence of 1080 in fatty meat baits for control of wild dogs in Australia was measured during 226 days (Fleming and Parker 1991). Baits that initially contained 5.4 mg of 1080 retained 73% at day 7, 64% at day 20, 25% at day 48, and 15% at day 226. These baits retained LD50 kill values after 52 days to wild dogs, 93 days to cattle dogs, and 171 days to sheep dogs. In that study, loss of 1080 from the baits did not correlate with rainfall, temperature, or humidity. Losses were attributed to metabolism of 1080 bound to the fatty meat bait, leaching, consumption by maggots, and bacterial defluorination (Fleming and Parker 1991). When it is desirable for baits to remain toxic for long periods, the defluorination activity and microbial growth can be reduced significantly by incorporating bacteriostats and fungistats; conversely, inoculations with suitable defluorinating microbes rapidly detoxify 1080-poisoned baits (Wong et al. 1991).

Compound 1080 was highly persistent in diets formulated for the mink (*Mustela vison*). Mink diets analyzed 30 months after formulation lost 19-29% of the 1080 when the initial concentration was between 0.9 and 5.25 mg 1080/kg; loss was negligible at 0.5 mg 1080/kg ration (Hornshaw et al. 1986). A paste containing 0.08% 1080 and petroleum jelly, soya oil, sugar, and green dye retained its rodenticidal properties for 6 to 9 months. But a rolled oats-cat food 1080 bait, because of its moistness, became fly-infested in warm weather, tended to rot, and lost its rodenticidal properties in a few days (Moors 1985). Gel baits set to kill deer were sampled after 45 days of weathering; only 10% of the 1080-treated leaves retained toxic gel after 45 days (Batcheler and Challies 1988). About 1.4% of 1080/mm rainfall was lost from the leaves; about 90% was lost in 2 trials in which 81 and 207 mm of rainfall were recorded. Compound 1080 decreased from 604 mg/bait at the start to 76 mg/bait after 30 days and to 5 mg/bait after 45 days. Significant losses of compound 1080 also resulted from biodegradation in storage. *Penicillium* spp. from broadleaf samples degraded 1080 at pH 5.4 and 23° C and grew vigorously on 1080-poisoned gels; other species of microorganisms can also degrade 1080 (Batcheler and Challies 1988).

Leachates from 1080-poisoned baits are probably not transported long distances by the leaching water because they are held in the upper soil layers (Atzert 1971). This statement is predicated on the facts that (1) salts of monofluoroacetic acid rapidly adsorb to plant tissues and other cellulosic materials; (2) some plants can decompose 29% of the adsorbed 1080 in 48 h; and (3) 1080 in soils is decomposed by soil microorganisms (Atzert 1971). The percent of 1080 defluorinated from various bait materials after 30 days as a result of microbial action ranged from 0.0 to 7.2% in cereals, eggs, horse meat, and beef and was 14% in kangaroo meat and 71% in oats (Wong et al. 1991). The defluorinating ability of fungi and bacteria was low when 1080 was the sole carbon source and high when alternative carbon sources such as peptone-meat extracts were present. The extent of defluorination varied among the different types of organisms in the baits. Microorganisms isolated from oats and kangaroo meat had the highest defluorinating activity and those from cereals and eggs, the lowest (Wong et al. 1991).

Metabolism

Sodium monofluoroacetate is absorbed through the gastrointestinal tract, open wounds, mucous membranes, and the pulmonary epithelium; it is not readily absorbed through intact skin (Negherbon 1959; Atzert 1971). Once absorbed, it seems to be uniformly distributed in the tissues including the brain, heart, liver, and kidney (Peacock 1964). All tested routes of 1080 administration are equally toxic; there is no noteworthy difference in the acute toxicity of 1080 when administered orally, subcutaneously, intramuscularly, intraperitoneally, or intravenously (Chenoweth 1949; Peacock 1964; Atzert 1971). Moreover, the oral toxicity of

1080 is independent of the carrier, including water, meat, grain, oil, gum acacia suspension, or gelatin capsule carriers (Atzert 1971).

All students of the action of fluoroacetate have been impressed with the unusually long and variable latent period between administration and response. This latent period occurred in all studied species regardless of route of administration (Chenoweth 1949; Negherbon 1959; Peacock 1964; Tucker and Crabtree 1970; Atzert 1971; Hudson et al. 1984). With few exceptions, the latent period ranges from 30 min to 2 h and massive doses—such as 50 times an LD95 dose—do not elicit immediate responses. The time between 1080 treatment and death was relatively constant in all tested species and usually ranged from 1 h to 1 day. The latent period associated with 1080 may result from 3 major factors: (1) the time required for hydrolysis of monofluoroacetate to monofluoroacetic acid and its subsequent translocation and cell penetration; (2) the time required for biochemical synthesis of a lethal quantity of fluorocitrate; and (3) the time required for the fluorocitrate to disrupt intracellular functions on a large enough scale to induce gross signs of poisoning (Chenoweth 1949; Atzert 1971).

Many authorities agree that the toxicity of 1080 to mammals is due to its conversion to fluorocitrate, a fluorotricarboxylic acid (Gal et al. 1961; Atzert 1971; Roy et al. 1980; McIlroy 1981b; Kun 1982; Mead et al. 1985a, 1985b; Hornshaw et al. 1986; Twigg et al. 1986, 1988a, 1988b; Murphy 1986). These authorities concur that enzymatic conversion of fluoroacetate via fluoroacetyl coenzyme A plus oxalacetate in mitochondria is the metabolic pathway that converts the nontoxic fluoroacetate to fluorocitrate. Fluorocitrate blocks the Krebs cycle, also known as the tricarboxylic acid cycle, which is the major mechanism for realizing energy from food. Fluorocitrate inhibits the enzyme aconitase and thereby inhibits the conversion of citrate to isocitrate. Fluorocitrate also inhibits succinate dehydrogenase, which plays a key role in succinate metabolism. The inhibition of these two enzymes results in large accumulations of citrate in the tissues, blocking glucose metabolism through phosphofructokinase inhibition, and eventually destroys cellular permeability, cell function, and finally the cell itself. The classical explanation of fluorocitrate toxicity through aconitase inhibition has been questioned (Kun 1982; Savarie 1984). A more recent explanation is that fluorocitrate binds with mitochondrial protein, thereby preventing citrate transport and its utilization by cells for energy production, although the underlying biochemical mechanisms are not completely understood (Kun 1982). Based on calculated metabolic rates of fluorocarboxylic acids, secondary poisoning of animals that have consumed 1080-poisoned prey is probably due to unmetabolized fluoroacetate rather than to fluorocitric acid (Kun 1982).

Dogs, rats, and rabbits metabolize fluoroacetate compounds to nontoxic metabolites and excrete fluoroacetate and fluorocitrate compounds; the rate of excretion peaks during the first day after dosing and drops shortly thereafter. Rats dosed with radiolabeled 1080 at 5 mg/kg BW had 7 different radioactive compounds in their urine. Monofluoroacetate comprised only 13% of the urinary radioactive material, fluorocitrate only 11%, and an unidentified toxic metabolite, 3%; 2 nontoxic metabolites accounted for almost 73% of the urinary radioactivity (Atzert 1971). Animal muscle usually contained nondetectable residues of any 1080 component within 1 to 5 days of treatment (Marsh et al. 1987; Eason et al. 1993c). Defluorination occurred in the liver by way of an enzymic glutathione-dependent mechanism, which in the brush-tailed opossum resulted in the formation of S-carboxymethylcysteine and free fluoride ion (Twigg et al. 1986). A rapid rate of defluorination together with a low reliance on aerobic respiration favored detoxification of fluoroacetate rather than its conversion into fluorocitrate and may account for the greater resistance of 1080 by reptiles than by mammals (Twigg et al. 1986).

Sublethal doses of 1080 led to a tolerance to subsequent challenging doses in certain animals; in other species, however, lethal concentrations accumulated after repeated sublethal doses (Atzert 1971). Repeated sublethal doses of 1080 increased the tolerance of some eagles, rats, mice, and monkeys but not of dogs. Conversely, repeated sublethal doses of 1080 accumulated to lethal levels in dogs, guinea pigs, rabbits, and mallards. Continued sublethal doses of 1080 to rats caused regressive changes in the germinal epithelium of the seminiferous tubules (Atzert 1971). Altered behavior in mice after high sublethal doses of 1080 were probably caused by neuronal damage from concurrent energy deficiency that was further accentuated by the CNS stimulant action of fluoroacetate/fluorocitrate and the brain anoxia that occurred during 1080-induced intermittent convulsions; a similar pattern was observed in two human patients (Omara and Sisodia 1990). Anuria in some 1080-dosed mice were probably caused by renal shutdown from hypocalcemic tension (Omara and Sisodia 1990). Tolerance to 1080 is a time-related phenomenon (Atzert 1971). Laboratory rats that were pretreated with 0.5 mg 1080/kg BW 4-24 h prior to a dose of 5.0 mg/kg BW were more resistant than rats that

were not similarly pretreated (Atzert 1971). Accumulation of 1080 is also a time-related phenomenon (Chenoweth 1949; Atzert 1971). Domestic dogs given 25 mg 1080/kg BW daily were unaffected until the fifth dose, when they went into convulsions and died. Also, larger sublethal doses could be administered to dogs on alternate days without adverse effects (Atzert 1971).

Fishes, amphibians, and reptiles are usually less sensitive to 1080 than warm-blooded animals (Atzert 1971). Reptiles, for example, are more resistant to 1080 than mammals (Twigg et al. 1986). The relatively small elevation of plasma citrate levels in skinks (*Tiliqua rugosa*) given 100 mg 1080/kg BW reflects the exceptional tolerance of this lizard species. The minimal effect of fluoroacetate on aerobic respiration in *T*. *rugosa* could be explained by a low conversion of fluoroacetate into fluorocitrate or by a low susceptibility of aconitase to the fluorocitrate formed. Although defluorination in skinks helped to minimize the immediate effects of fluoroacetate in aerobic respiration, it resulted in rapid depletion of liver glutathione levels (Twigg et al. 1986).

The breakdown in intracellular processes from fluorocitrate or from decreased energy production may cause death from gradual cardiac failure or ventricular fibrillation, death from progressive depression of the CNS with either cardiac or respiratory failure, or death from respiratory arrest after severe convulsions; signs of 1080 intoxication included labored breathing, vomiting, lethargy, muscular incoordination, weakness, and tremors (Chenoweth 1949; Negherbon 1959; Tucker and Crabtree 1970; Atzert 1971; Hudson et al. 1984; Murphy 1986; Eason and Frampton 1991). Among herbivores, 1080-induced deaths were due primarily to cardiac disorders; among carnivores, deaths were from CNS disorders; and among omnivores, deaths were from both cardiac and CNS disorders (Atzert 1971). Other signs of 1080 intoxication included kidney and testicular damage (Savarie 1984) and altered blood chemistry, specifically, elevated concentrations of citrate (Twigg et al. 1986), glucose, lactic acid, pyruvic acid, acetate, inorganic phosphate, potassium, and fluorine (Negherbon 1959). Some mammals also displayed parasympathetic nervous system effects including increased salivation, urination, and defecation and eventual cardiac failure (Hudson et al. 1984).

Vomiting probably evolved among carrion eaters as a natural protective mechanism, but it does not necessarily ensure survival from 1080 poisoning (McIlroy 1981b). For example, even though 90% of eastern native quolls (*Dasyurus viverrinus*) and 95% of tasmanian devils (*Sarcophilus harrisii*) vomited within 26-55 min after ingesting 1080, this time was still sufficient for many to absorb a lethal dose. Loud sounds, sudden movements of an observer, or convulsions by another animal nearby sometimes stimulated convulsions; however, intraspecific and interspecific variability was great. Signs preceding convulsions usually included restlessness; hyperexcitability or increased response to stimuli; trembling; rapid, shallow breathing; incontinence or diarrhea; excessive salivation; twitching of facial muscles; abnormal eye movements; incoordination; vocalization; and sudden bursts of violent activity. All affected animals subsequently fall to the ground in a tetanic seizure; their hind limbs or all four limbs and sometimes the tail extend rigidly from their arched bodies. This tonic phase is followed by a clonic phase in which the animals kick with the front legs and eventually begin to relax. After this phase, animals either recover gradually, die shortly afterwards, experience additional seizures and then die or recover, or remain comatose until death as many as 6 days later (McIlroy 1981b).

Antidotes

No highly effective treatment of well established fluoroacetate poisoning is available (Chenoweth 1949; Peacock 1964; Atzert 1971), and accidental poisoning of livestock and domestic dogs is probably fatal (Mead et al. 1991). The following compounds were tested and had no effect on ameliorating 1080 intoxication: salts of fatty acids, anticonvulsants, vitamins, metabolic intermediates (Chenoweth 1949), and nonphysiological sulfhydryl compounds such as N-acetylcysteine and cysteamine (Mead et al. 1985a). As discussed later, sodium-acetate/ethanol mixtures, barbituates, glycerol monoacetate, calcium glutonate/sodium succinate mixtures, and 4-methylpyrazole offer partial protection to 1080-poisoned mammals, possibly because they compete with fluoroacetate in the Krebs cycle.

Sodium acetate and ethanol partially protect mice against 1080. Ethanol and sodium acetate administered together are twice as effective as either alone, suggesting a synergistic effect (Chenoweth 1949). Mixtures of acetate and ethanol reduced mortality of 1080-poisoned mice (given 2 times an LD50 dose) from 80% to 30% (Tourtellotte and Coon 1950). Mortality was reduced by 90% in mice given 170 mg 1080/kg BW (about 10 times an LD50 dose) and an intraperitoneal injection of sodium acetate (2-3 g/kg BW) dissolved in ethanol (1.6 g/kg BW). But the beneficial effect of the acetate-ethanol treatment to mice decreased rapidly with increasing time after the administration of 1080. Ethanol-acetate mixtures had some antidotal effect on 1080-poisoned dogs

provided that treatment was administered within 30 min of poisoning (Tourtellette and Coon 1950). A mixture of 2 g sodium acetate/kg BW and 2 g ethanol/kg BW is recommended for treatment of 1080-poisoned monkeys (Peacock 1964).

Barbituates were marginally effective in protecting domestic dogs but not laboratory mice against fluoroacetate poisoning (Chenoweth 1949; Peacock 1964). Barbituates administered to dogs within 30 min of 1080 poisoning (4 times an LD50 dose) resulted in 80% survival; when therapy was given 3 h after poisoning, survival was 17% (Tourtellette and Coon 1950). At higher 1080 doses (i.e., 6 times the LD50 value), barbiturates were ineffective. Repeated intravenous injections of 20 mg pentobarbital/kg BW to a 1080-poisoned dog (0.3 mg 1080/kg BW) prevented death when administered within 8.5 h of poisoning (Tourtellette and Coon 1950).

Glycerol monoacetate at 2 to 4 g/kg BW partially protects 1080-poisoned rats, rabbits, dogs, and rhesus monkeys (Chenoweth 1949; Peacock 1964; Murphy 1986). But its effectiveness is apparent only when administered intramuscularly in large amounts immediately after 1080-ingestion (Mead et al. 1991). A single dose of magnesium sulphate at 800 mg/kg BW given intramuscularly as a 50% solution shortly after 1080 exposure prevented death of rats dosed with marginally lethal amounts of 1080 (Peacock 1964).

A reduced level of blood calcium is one explanation for the toxic effects of fluoroacetate and may account for the gap between chemical manifestations and the biochemistry of 1080 poisoning (Roy et al. 1980). Cats poisoned with 1080 showed a 27% drop in blood calcium levels within 40 min; intravenous administration of calcium chloride prolonged the life of treated cats from 94 min to 167 min (Roy et al. 1980). In a search for effective antidotes to fluoroacetate poisoning, calcium gluconate was chosen to antagonize hypocalcemia, and sodium alpha ketoglutarate and sodium succinate were selected to revive the TCA cycle (Omara and Sisodia 1990). Effectiveness of each of these antidotes individually and in certain combinations was tested in laboratory mice exposed to lethal doses (15 mg/kg BW, intraperitoneal injection) of 1080. Antidotal treatments were administered from 15 min to 36 h after dosing. All three of the antidotes alone, and a combination of calcium glutonate with sodium alpha ketoglutarate were ineffective in reducing mortality in treated mice. However, a combination of calcium glutonate (130 mg/kg BW) and sodium succinate (240 mg/kg BW) was effective if the two solutions were either injected at separate sites or mixed in the same syringe just prior to injection. Increasing the dose of sodium succinate to 360 or 480 mg/kg BW with calcium glutonate (130 mg/kg BW) was unrewarding. Additional studies are needed to confirm the efficacy and mechanisms of action of this combination (Omara and Sisodia 1990).

Intraperitoneal injection of 4-methylpyrazole to rats at 90 mg/kg BW, given 2 h prior to 1080 administration, offered partial protection against accumulations of citrate or fluorocitrate in the kidney (Feldwick et al. 1994). The antidotal effects of 4-methylpyrazole are attributed to its inhibition of NAD^+-dependent alcohol dehydrogenase that converts 1,3-difluoro-2-propanol to difluoroacetone, an intermediate in the pathway of erythrofluorocitrate metabolism (Feldwick et al. 1994). A disadvantage of 4-methylpyrazole is that it needs to be administered before significant exposure to fluoroacetate.

First-aid treatment of humans accidentally poisoned with 1080 includes immediate emesis and gastric lavage followed by an oral dose of magnesium sulfate or sodium sulfate to remove the poison from the alimentary tract before absorption of lethal quantities can occur (Peacock 1964; Atzert 1971). When the stomach is emptied, oral administration of ethanol may be beneficial (Temple and Edwards 1985). The patient should be put at complete rest and given barbituates with moderate duration of action, such as sodium amytol, to control convulsions (Anonymous 1964; Atzert 1971). Intramuscular injections of undiluted glycerol monoacetate at 0.5 mg/kg BW are recommended every 30 min for several hours and then at a reduced level for at least 12 h (Atzert 1971; Temple and Edwards 1985). If intramuscular administration is not feasible, a mixture of 100 mL of undiluted glycerol monoacetate in 500 mL of water can be given orally and repeated in an hour (Atzert 1971). If glycerol monoacetate is not available, acetamide or a combination of sodium acetate and ethanol may be given in the same dose (Atzert 1971). If ventricular fibrillation occurs, the heroic treatment of 5 mL of a 1% procaine hydrochloride by intracardiac puncture is justified (Anonymous 1964). Intravenous administration of procainamide is also effective in the restoration of normal rhythm in ventricular fibrillations (Atzert 1971). Symptoms of 1080 poisoning usually subside in 12 to 24 h, but the patient should be kept in bed for at least 3 days (Anonymous 1946).

Lethal and Sublethal Effects

General

Mammals were the least resistant tested group against 1080; individuals of sensitive species died after receiving a single dose of 0.05-0.2 mg/kg BW. As discussed later, adverse sublethal effects included testicular damage in rats (*Rattus* spp.) after drinking water containing 2.2-20.0 mg 1080/L for 7 days (0.07-0.71 mg/kg BW daily), impaired reproduction in the mink on diets containing 0.8 mg 1080/kg ration for 60 days, and altered blood chemistry in European ferrets on diets containing 1.1 mg 1080/kg feed for 28 days. Elevated fluoroacetate residues of 34 mg/kg DW muscle and 423 mg/kg DW liver were measured in some 1080-poisoned mammals, notably in European rabbits. Sensitive species of birds died after a single 1080 dose of 0.6-2.5 mg/kg BW, daily doses of 0.5 mg/kg BW for 30 days, 47 mg/kg diet for 5 days, or 18 mg/L drinking water for 5 days.

Accumulation and adverse sublethal effects in birds occurred at dietary loadings of 10-13 mg 1080/kg ration. The risk to human consumers of cooked meat from 1080-poisoned waterfowl seems negligible. Amphibians and reptiles were more resistant to 1080 than mammals and birds because of their greater ability to detoxify fluoroacetate by defluorination, a reduced ability to convert fluoroacetate to fluorocitrate, and an aconitase hydratase enzyme that is comparatively insensitive to fluorocitrate inhibition. LD50 values in amphibians were greater than 44 mg 1080/kg BW; in reptiles, this value was greater than 54 mg 1080/kg BW. Other studies with 1080 and sensitive species showed death of mosquito larvae at water concentrations of 0.025-0.05 mg/L, death of terrestrial beetle and lepidopteran larvae at 1.1-3.9 mg/kg BW, no phytotoxicity to terrestrial flora at water concentrations of 10 mg/L, and--based on limited data--no adverse effects on freshwater fishes at 370 mg/L.

Terrestrial Plants and Invertebrates

Fluoroacetate was first isolated in South Africa in 1944 from the gifblaar plant (*Dichapetalum cymosum*; Negherbon 1959). Seeds of the South African *D*. *braunii* may contain as much as 8,000 mg fluoroacetate/kg DW (Meyer 1994). Several other species of *Dichapetalum* and *Palicourea marcgravii*, a South American poisonous species, produce fluoroacetate (Twigg et al. 1986; Twigg and King 1991). In Australia, fluoroacetate occurs naturally in the leaves, flowers, and seeds of more than 35 species of leguminous plants of the genera *Gastrolobium* and *Acacia* (Mead et al. 1985; Twigg et al. 1986, 1988, 1990; Twigg and King 1991; McIlroy 1992). All but two of these species are confined to the southwestern corner of Western Australia; the other two species occur in northern and central Australia. Fluoroacetate concentrations varied regionally, seasonally, among species, and among parts of the plants. The fluoroacetate content of these plants is usually greatest in flowers, seeds, and young leaves, and this is consistent with chemically mediated defense strategies in which plants use poisonous compounds to protect their most essential parts (Twigg and King 1991). In Australia, the highest measured fluoroacetate concentrations were in air-dried leaves and seeds of two species from Western Australia: concentrations reached 2,650 mg/kg in leaves and 6,500 mg/kg in seeds of *Gastrolobium* spp. Air-dried samples of the two species from northern and central Australia, *Acacia georginae* and *Gastrolobium grandiflorum*, contained as much as 25 mg fluoroacetate/kg leaf and 185 mg/kg seed (Twigg and King 1991).

Economic losses of domestic livestock were significant in Africa and Australia after ingestion of fluoroacetate-bearing vegetation (Twigg and King 1991). Herbivores that have had evolutionary exposure to this vegetation are much less susceptible to fluoroacetate intoxication than geographically separate, unchallenged species (Mead et al. 1985; Twigg et al. 1986). The development of tolerance to fluoroacetate by insects, reptiles, birds, and mammals has evolved on at least three continents where indigenous plants produce fluoroacetate that protects them against herbivory (Twigg and King 1991). In Australia, for example, animal populations that have coexisted with fluoroacetate-bearing vegetation for at least several thousands of years have developed varying degrees of tolerance to this potent toxin. Tolerance depends on their diets and habitats, sizes of their home ranges, mobility, and length of evolutionary exposure to fluoroacetate-bearing vegetation. Once developed, this tolerance is retained by animal populations even after isolation from the toxic vegetation for 70 to 100 centuries. Biochemical mechanisms responsible for the large toxicity differential between conspecifics with and without exposure to fluoroacetate-bearing vegetation are poorly understood (Twigg and King 1991).

Fluoroacetate and fluorocitrate have also been isolated from forage crops grown in an environment that is rich in atmospheric or inorganic fluoride (Lovelace et al. 1968; Ward and Huskisson 1969; Atzert 1971; Savarie 1984; Twigg and King 1991). For example, soybeans (*Glycine max*) can synthesize fluoroacetic acid when

grown in an atmosphere with elevated levels of hydrogen fluoride or in media containing high levels of sodium fluoride. Forage crops, including alfalfa (*Medicago sativa*) and crested wheat grass (*Agropyron cristatum*) grew near a phosphate plant that discharged inorganic fluoride with as much as 179 mg fluoroacetate/kg DW, 896 mg fluorocitrate/kg DW, and 1,000 mg total fluoride/kg. The plants were not adversely affected, but horses (*Equus caballus*) that grazed on these crops showed signs of fluoride poisoning, suggesting that the toxic effect of inorganic fluoride adsorbed or absorbed by plants and not incorporated into monofluoroacetic acid was greater than the toxic effect of monofluoroacetic acid synthesized by the plants (Lovelace et al. 1968; Atzert 1971). Lettuce (*Lactuca sativa*) that absorbed radiolabeled 1080 through its roots or leaves had elevated citrate concentrations and retained radioactivity (Ward and Huskisson 1969). Plants can degrade 1080 by cleaving the carbon-fluorine bond, as judged by studies with germinating seeds of the peanut *Arachis hypogea* (Atzert 1971).

Compound 1080 in gels, pastes, or grease carriers and smeared on leaves of palatable plants has been used to control ungulate and marsupial pests in New Zealand, including feral goats (*Capra* sp.), red deer (*Cervus elephus*), and white-tailed deer (*Odocoileus virginianus*; Parkes 1991). The effectiveness of 1080 in carbopol gel or in petrolatum grease on leaves of the mahoe (*Melicytus ramiflorus*) was significantly modified by the phytotoxicity of these carriers. Both carriers caused baited leaves to absciss, and the rate of abscission increased when 1080 was included. Petrolatum was one-third as phytotoxic as carbopol and retained 1080 for longer periods--at least 1 year. Carbopol lost about 95% of its 1080 after 64 days of exposure and 100 mm of rain but only 22% in petrolatum under similar conditions. Carbopol with 1080 is recommended for use where its distribution is sufficient to place goats and other target species at immediate risk; petrolatum can be used where a long-lasting bait is needed (Parkes 1991).

Compound 1080 has systemic insecticidal properties against insects feeding on treated plants. Cabbage (*Brassica oleracea capitata*) that had accumulated 1080 through its roots from solution or from soil cultures after application on leaves was toxic by contact to eggs and larvae of the large white butterfly (*Pieris brassicae*) and to various species of aphids (Negherbon 1959). Compound 1080 was not phytotoxic at 10 mg/L or at several times the concentration necessary for insecticidal action, but its use as an insecticide is not recommended because of its high toxicity in mammals (Negherbon 1959; Spurr 1991).

At least nine groups of terrestrial invertebrates are adversely affected by 1080-poisoned baits, by contaminated habitats with residues that leach from 1080 baits, or by the consumption of animal byproducts and carcasses contaminated with 1080 (Chenoweth 1949; Notman 1989). Lethal effects are reported in houseflies, moths, aphids, ants, bees, and mites that ate 1080-poisoned baits and in fleas that ingested 1080-poisoned rats (Notman 1989). Cockroaches, collembolids, and slugs that ate poisoned baits experienced adverse effects. Egg production in wasps was disrupted after a single sublethal dose of 1080, and mortality of larvae from butterfly eggs treated with 1080 was 98% (Notman 1989). Harvester ants (*Pogonomyrtnex* sp.) and darkling ground beetles (Tentyridae) removed and consumed 1080 bait, leaving bait and dead ants concentrated on the ground near the nest (Hegdal et al. 1986). In a control program, German wasps (*Vespula germanica*) and common wasps (*Vespula vulgaris*) fed 1080-poisoned canned sardines in aspic jelly were not affected at concentrations of less than 100 mg 1080/kg bait (Spurr 1991). At 1,000 mg/kg, however, wasp traffic at nest entrances was reduced by 17%; at 5,000-10,000 mg/kg, traffic was reduced by 78-89%, and almost all wasps died within 100 m of bait stations after 6 h (Spurr 1991). Honeybees (*Apis mellifera*) feed readily on 1080-jam baits that are used to control opossums (*Trichosurus vulpecula*) in New Zealand (Goodwin and Ten Houten 1991). Bee kills have been documented in the vicinity of jam baits, and dead bees contained 3.1 to 10.0 mg 1080/kg whole bee. The oral LD50 in the honey bee is 0.8 mg/bee. Because no deaths occur within 2 h after feeding, poisoned bees may make several foraging trips before dying. Molasses or oxalic acid is now added to 1080-jam baits to repel bees (Goodwin and Ten Houten 1991). Poisoned insects may cause secondary poisoning of insectivores. Accordingly, 1080 should not be used in the vicinities of susceptible nontarget invertebrates or endangered insectivores (Notman 1989).

Variability in sensitivity to 1080 after abdominal injection in tested insect larvae was great (Twigg 1990). The LD50 value in mg 1080/kg BW--administered by fluoroacetate-bearing vegetation--was 1.05 in *Perga dorsalis* (Hymenoptera); in Lepidoptera, these values were 3.9 in *Mnesampla privata*, 42.7 in *Spilosoma* sp., and about 130.0 in *Ochrogaster lunifer*. In all tested species, death occurred within 2 to 48 h after injection, and total body citrate concentrations were significantly higher in the poisoned than in the unpoisoned conspecifics. Tolerance to 1080 was enhanced in larvae of Western Australian insects that consumed fluoroacetate-bearing vegetation (Twigg 1990).

Populations of terrestrial invertebrates including populations of amphipods, ants, beetles, collembolids, millipedes, mites, weevils, slugs, spiders, and snails were not adversely affected by 1080 poisoning in operations to control brushtail possums in New Zealand (Spurr 1994). Residues of 1080 in nontarget terrestrial invertebrates were low or negligible after aerial applications (Eason et al. 1993b). Residues of 1080 were measured in various species of terrestrial invertebrates in New Zealand before and after aerial application of possum baits with 800 mg 1080/kg and sown at 5 kg/ha. No residues of 1080 were found in spiders, beetles, millipedes, centipedes, or earthworms at any stage. Residues of 1080 were detectable in some orthopteran insects (2 mg/kg FW) and in some cockroaches (4 mg/kg FW). Laboratory studies indicated that 90% of all 1080 was eliminated from insects within 4-6 days after dosing, suggesting a low risk to insectivorous birds (Eason et al. 1993b).

Aquatic Organisms

Despite an intensive literature search, very little data were found on the toxicity of 1080 to aquatic life. King and Penfound (1946) reported that fingerling bream and bass (species unidentified) tolerated 370 mg of 1080/L without apparent discomfort for an indefinite period. Deonier et al. (1946) aver that fourth-instar larvae of the mosquito *Anopheles quadrimaculatas* were comparatively sensitive to 1080 and that 1080 was among the most toxic 3% of 6,000 organic compounds screened against this life stage. In 48 h, concentrations of 0.025 mg 1080/L were fatal to 15% of these larvae, 0.05 mg 1080/L to 40%, and 0.1 mg 1080/L to 65%. The common duckweed (*Spirodela oligorrhiza*) seems to be unusually sensitive to 1080. Growth of duckweed was inhibited at 0.5 mg/L (Walker 1994), but this needs verification.

Recent unpublished data (as quoted in Fagerstone et al. 1994) on the acute toxicity of 1080 to rainbow trout (*Oncorhynchus mykiss*), bluegills (*Lepomis macrochirus*), and daphnids (*Daphnia magna*) suggested that these organisms are comparatively tolerant to 1080. For example, bluegills exposed to 970 mg 1080/L for 96 h showed no observable adverse effects; in rainbow trout, the no-observable-effect concentration during a 96-h exposure was 13 mg 1080/L, and the LC50 (96 h) value was 54 mg/L with a 95% confidence interval of 39-74 mg/L; in *Daphnia*, no adverse effects were noted at 130 mg 1080/L during an exposure for 48 h, although 50% were immobilized at 350 mg/L in 48 h (Fagerstone et al. 1994). No data were available on effects of 1080 to aquatic biota during a life cycle or during long-term exposures. The effects of chronic exposure to 1080 on nontarget species of aquatic arthropods and macrophytes require study.

Amphibians and Reptiles

In general, the onset of action and time to death or to recovery was slowest in amphibians and reptiles, which were among the most resistant to 1080 of all tested vertebrate animals (McIlroy et al. 1985; McIlroy 1986). LD50 values in representative species of amphibians ranged from 54 to 2,000 mg 1080/kg BW and in reptiles from 44 to 800 mg/kg BW (Table 2). Frogs and lizards given a lethal oral dose of 1080 did not show signs of poisoning for 22 to 56 h and survived for 78 to 131 h (McIlroy et al. 1985). Frogs seem to be more sensitive to 1080 in summer than in winter (Chenowith 1949). Unlike mammals, amphibians and reptiles possess an innate tolerance to 1080 because of their greater ability to detoxify fluoroacetate by defluorination, a reduced ability to convert fluoroacetate to fluorocitrate, and an aconitase hydratase enzyme system that is less sensitive to inhibition by fluorocitrate (Twigg and Mead 1990).

One of the most tolerant tested reptiles was the shingle-back lizard (*Tiliqua rugosa*; McIlroy 1986), but populations of *T. rugosa* from Western Australia that coexist with fluoroacetate-bearing vegetation were much less sensitive to 1080 intoxication than conspecifics from South Australia not exposed to the toxic plants (Table 2; McIlroy et al. 1985; Twigg et al. 1988a; Twigg and Mead 1990). The shingle-back lizard is an omnivore that feeds on flowers, leaves, and seeds and probably evolved an increased tolerance to fluoroacetate through feeding on toxic plants such as *Gastrolobium* and *Oxylobium* that are abundant in southern Western Australia (McIlroy et al. 1985).

Reptiles are probably not affected by either primary or secondary poisoning during 1080-poisoning campaigns (McIlroy 1992). In Australia, 1080-poisoned baits contained 330 mg 1080/kg in carrot baits for rabbits and in oat baits for pigs, 400 mg 1080/kg in oat baits for rabbits, 500 mg 1080/kg in pellet baits for rabbits and pigs, 14 mg 1080/kg in meat baits for dingoes, and 144 mg/kg in meat baits for pigs (McIlroy et al. 1985). These data indicate that most species of tested reptiles must ingest unrealistic quantities of bait to be adversely affected by 1080. Most lizards, for example, must eat 43-172% of their body weight of poisoned rabbit

baits and 143 to 393% of their body weight of meat baits intended for pigs. However, Gould's monitor (*Varanus gouldi*) may ingest lethal amounts of meat baits intended for pigs after eating 31% of its body weight of poisoned baits. By comparison, a large pig (130 kg) must eat about 2 kg of meat baits (1.6% of its body weight) for an LD99 dose (McIlroy et al. 1985).

Birds

Laboratory studies with birds (Table 3) revealed several trends: (1) death occurred in orally dosed sensitive species after a single dose of 0.6-2.5 mg 1080/kg BW, after daily doses of 0.5 mg 1080/kg BW for 30 days, after 47 mg/kg diet for 5 days, or after 18 mg/L drinking water for 5 days; (2) single doses of more than 10 mg/kg BW were usually fatal; (3) 1080 toxicity was enhanced at lower temperatures; (4) younger birds were more sensitive than older birds; (5) birds tended to avoid diets and drinking water with high sublethal concentrations of 1080; (6) accumulations and adverse effects were noted at dietary concentrations of 10-13 mg 1080/kg feed; and (7) birds with prior or continuing exposures to naturally occurring fluoroacetates were more resistant to 1080 than conspecifics without such exposures. Drinking-water-LC50 values were about 10 times higher (i.e., 10 times less toxic) than dietary LC50s in mallards (*Anas platyrhynchos*) and in northern bobwhites (*Colinus virginianus*); however, both species of birds consumed 5 to 10 times more water than food on a daily mg/kg BW basis (Kononen et al. 1991). The minimum repeated daily oral dosage that was lethal to mallards in 30-day tests was 0.5 mg/kg BW, suggesting a high degree of cumulative action by this species (Tucker and Crabtree 1970). But European starlings (*Sturnus vulgaris*) tolerated 13.5 mg 1080/kg diet for extended periods without significant adverse effects (Balcomb et al. 1983). Studies with the galah (*Cacatua roseicapilla*) showed that 1080 lethality was not affected by the age or sex of the bird or by the route of administration (McIlroy 1981a). But breeding adult female Pacific black ducks (*Anas superciliosa*) were more sensitive to 1080 than either males or nonbreeding females (McIlroy 1984).

The most common external signs of 1080 poisoning in birds included depression, fluffed feathers, a reluctance to move, and convulsions (McIlroy 1984). Signs of 1080 poisoning first appeared 1 to 60 h after dosing, and deaths occurred 1 h to almost 11 days after dosing (McIlroy 1984). Death of 1080-poisoned California quail (*Callipepla californica*) usually occurred within 3 h, although birds were inactive within 2 h of dosing and comatose until death (Sayama and Brunetti 1952). The most common internal sign of 1080 poisoning was a dose-related increase in plasma citrate concentration, and this was a useful indicator of fluoroacetate sensitivity among birds of similar metabolic rates and phylogenetic affinities (Twigg and King 1989).

Table 2. Effects of 1080 on representative amphibians and reptiles.

Table 2. Group, species, dose, And other variables	Effects	Reference[a]
Amphibians		
Spotted grass frog, *Limnodynastes tasmaniensis*; 60 mg/kg body weight (BW); single dose	LD50, adults	1
Bullfrog, *Rana catesbeiana*; 54.4 (95% confidence interval [=CI] of 25.6-115.0) mg/kg BW; single dose	LD50	2, 6
Frogs, various; 1,000-2,000 mg/kg BW; single dose	LD50	7, 8
Leopard frog, *Rana pipiens*; 150 mg/kg BW; single dose	LD50	2, 9
South African clawed frog, *Xenopus laevis*; >500 mg/kg BW; single dose	LD50	2, 9

Table 2.

Group, species, dose, And other variables	Effects	Reference[a]
Reptiles		
Australian reptiles 163 (44-336) mg/kg BW	LD50 mean and range for five species with no previous exposure to naturally occurring fluoroacetates	10
250 and 800 mg/kg BW	LD50 for two species with prior or continuing exposure to naturally occuring fluoroacetates	10
Gopher snake, *Pituophis catenifer*; fed dead or moribund rodents poisoned with high concentrations of 1080	In 21 separate trials, 14 snakes regurgitated rodents and 7 had no significant effects within 5 days of ingestion	11
Bearded dragon, *Pogona barbatus*; <110 mg/kg BW; single dose	LD50	1
Blotched blue-tongued lizard, *Tiliqua nigrolutea*; 336 (95% CI of 232-487) mg/kg BW; single dose	LD50	1, 5
Shingle-back lizard, *Tiliqua rugosa*; single dose 25 mg/kg BW	No effect on plasma testosterone concentration	3
100 mg/kg BW	Plasma testosterone concentration decreased 52%	3
100 mg/kg BW	Plasma citrate levels increased 3.4 times after 48 h	4
206 (95% CI of 147-289) mg/kg BW	LD50; nontolerant populations from South Australia	1,5
300 mg/kg BW	Oxygen consumption reduced 2.5-11.0% over a 22-h postdosing observation period	4
525 (95% CI of 487-589 mg/kg BW)	LD50; tolerant populations from Western Australia	1
Gould's monitor, *Varanus gouldi* 43.6 (95% CI of 27.5-69.2) mg/kg BW; single dose	LD50	1,5
Lace monitor, *Varanus varius*; <119 mg/kg BW; single dose	LD50	1

Table 3. Effects of 1080 on representative birds.

Table 3. Species, dose, and other variables	Effects	Reference[a]
Chukar, *Alectoris graeca*; 3.5 (95% confidence interval [=CI] of 2.6-4.8) mg/kg body weight (BW); single dose	LD50	1, 2, 3, 4
Northern pintail, *Anas acuta*; 8-10 mg/kg BW; single dose	50-100% dead	2, 5
American wigeon, *Anas americana*; single dose		
4.0 mg/kg BW; males	LD100	5
11.0 mg/kg BW; females	LD100	5
Mallard, *Anas platyrhynchos*		
0.5 mg/kg BW; daily oral dose for 30 days	Some deaths in 30 days, but less than 50%	3, 4
3.7 (95% CI of 21.5-5.5) mg/kg BW; single dose; age 7 days	LD50	6
4.8 (95% CI of 2.6-9.0) mg/kg BW; single dose; age 6 months	LD50	6
6.0 (95% CI of 4.2-8.4) mg/kg BW; single dose; ducklings	LD50	3, 4
7.0-7.5 mg/kg BW; single dose	LD75-LD100	5
8.0 mg/kg BW; adult females; single dose	LD50	2
9.1 (95% CI of 5.6-14.6) mg/kg BW; single dose; adults	LD50	1, 3, 4
10.0 mg/kg BW; adult males; single dose	LD50	2
13-24 mg/L drinking water for 5 days plus 3-day observation period; age 10 days	Avoidance of water containing 1080 when given choice	7
18-24 mg/L drinking water for 5 days plus 3-day observation period; age 10 days	50-90% dead	7
≥236 mg/kg diet fresh weight (FW) for 5 days plus 3-day observation period; age 10 days	Avoidance of diets containing 1080 when given choice	7
527 mg/kg diet FW for 5 days plus 3-day observation period; age 10 days	50% dead	7
Pacific black duck, *Anas superciliosa*; single dose		
10.0 (95% CI of 7.4-13.5) mg/kg BW;	LD50	8

Table 3. Species, dose, and other variables	Effects	Reference[a]
adult breeding females		
18.9 (95% CI of 16.3-219) mg/kg BW; adult males	LD50	8, 9
23.8 (95% CI of 15.3- 37.0) mg/kg BW; adult nonbreeding females	LD50	8
Wedge-tailed eagle *Aquila audax*; 9.5 (95% CI of 7.2-12.5) mg/kg BW; single dose	LD50	8, 10
Golden eagle, *Aquila chrysaetos*; single dose		
1.25-5.00 mg/kg BW	LD50	2, 3, 5, 26
3.5 (95% CI of 0.5-25.1) mg/kg BW	LD50	4, 11
Australian birds; various species; single dose		
7.8 (0.6-25.0) mg/kg BW	LD50 mean and range for 45 species with no known past exposure to naturally occurring fluoroacetates	27
28.4 (1.8-102.0) mg/kg BW	LD50 mean and range for 14 species with prior or continuing exposure to naturally occurring fluoroacetates	27
Australian birds, 41 species; single dose		
0.6-0.99 mg/kg BW	LD50, 2 species	8
1.0-9.9 mg/kg BW	LD50, 27 species	8
20.0-49.9 mg/kg BW	LD50, 11 species	8
>200 mg/kg BW	LD50, 1 species	8
Port Lincoln parrot, *Barnardius zonarius*; 11.5 (95% CI of 9.6-13.7) mg/kg BW; single dose	LD50	9, 12
Great horned owl, *Bubo virginianus*; 20 mg/kg BW; single dose	LD50	5
Rough-legged hawk, *Buteo lagopus*; 10 mg/kg BW; single dose	LD50	5
Ferruginous hawk, *Buteo regalis*; 10 mg/kg BW; single dose	LD50	5
Sulphur-crested cockatoo, *Cacatua galerita*; 3.5 (95% CI of 2.9-4. 1) mg/kg BW; single dose	LD50	8, 13
Galah, *Cacatua roseicapilla*; ~5.6 (95% CI of 3.1-10.5) mg/kg BW; single dose	LD50	8, 14
California quail, *Callipepla californica*		
0.5 or 1.0 mg/kg BW; single dose	No deaths	15
0.5 or 1.0 mg/kg BW on day 1; 2.5 mg/kg BW on days 2, 3, and 4	All dead	15

Table 3. Species, dose, and other variables	Effects	Reference[a]
4.6 (95% CI of 2.7-8.1) mg/kg BW; single dose	LD50	4
>5.0 mg/kg BW; single dose	All dead	15
Turkey vulture, *Cathartes aura*; single dose		
20 mg/kg BW	Lethargy and wing-drooping at 13° C	24
30 mg/kg BW	Tremors, lethargy, ataxia, incoordination at 11-17° C	24
40 mg/kg BW	Lethal at 7-9° C; lethargy, ataxia, and incoordination at 15° C	24
60 mg/kg BW	Tremors, lethargy, and wing-droop at 15-20° C	24
80 mg/kg BW	All dead within 4 h at 20° C; no regurgitation	24
100 mg/kg BW	75% dead at 23-28° C	24
Maned duck, *Chenonetta jubatta*; 12.6 (95% CI of 10.1-15.7 mg 1080/kg BW); single dose	LD50	8, 9
Northern harrier, *Circus cyaneus*; 10 mg/kg BW; single dose	LD50	5
Northern bobwhite, *Colinus virginianus*		
>9 mg/L drinking water daily for 5 days plus 3-day observation period	Avoidance of water containing 1080 when given choice	7
31 mg/L drinking water daily for 5 days plus 3-day observation period	50% dead	7
93 mg/L drinking water daily for 5 days plus 3-day observation period	All dead	7
>95 mg/kg diet daily for 5 days plus 3-day observation period	Avoidance of 1080 diets when given choice	7
385 mg/kg diet daily for 5 days plus 3-day observation period	50% dead	7
Grey shrike thrush, *Colluricincla harmonica*; ~ 12.0 mg/kg BW; single dose	LD50	13
Rock dove, *Columba livia*; 4.2 (95% CI of 3.4-5.3) mg/kg BW; single dose	LD50	1, 2, 3
Black vulture, *Coragyps atratus*; 15 mg/kg BW; single dose	LD50	2, 5
Little crow, *Corvus bennetti*; 13.4 (95% CI of 11.7-15.2) mg/kg BW; single dose	LD50	8, 10, 13

Table 3. Species, dose, and other variables	Effects	Reference[a]
Australian raven, *Corvus coronoides*; 5.1 mg/kg BW; single dose	LD50	10, 13
Little raven, *Corvus mellori*; 3.1 (95% CI of 2.7-3.6) mg/kg BW; single dose	LD50	8
Japanese quail, *Coturnix japonica*; 16.2 (95% CI of 7.2-28.7) mg/kg BW; single dose	LD50	2, 4
Laughing kookaburra, *Dacelo novaeguineae*;~6.0 mg/kg BW; single dose	LD50	10, 13
Emu, *Dromaius novaehollandiae*; 102-278 mg/kg BW; single dose	LD50	8, 12, 13
Red-browed firetail, *Emblema temporalis*; 0.6 (95% CI of 0.4-1.0) mg/kg BW; single dose	LD50	8
Brewer's blackbird, *Euphagus cyanocephalus*; 2.5-3.0 mg/kg BW; single dose	LD33-LD50	2,5
Finches, 7 species; 2.7 (95% CI of 0.8-4.6) mg/kg BW; single dose	LD50	16
Flycatchers, 4 species; 13.2 (95% CI of 8.7-20.0) mg/kg BW; single dose	LD50	16
Domestic chicken, *Gallus* spp.; 5.0-18.0 mg/kg BW; single dose	LD50-LD100	2, 5, 15, 17, 18, 19, 25, 26
Gamebirds, 8 species; 7.3 (95% CI of 0.0-16.4) mg/kg BW; single dose	LD50	16
Australian magpie-lark, *Grallina cyanoleuca*; 8.8 (95% CI of 4.0-13.5) mg/kg BW; single dose	LD50	8, 13
Australian magpie, *Gymnorhina tibicen*; 9.9 (95% CI of 7.6 12.9) mg/kg BW; single dose	LD50	8, 10, 13
Honeyeaters, 5 species; 8.1 (95% CI of 6.9-9.5) mg/kg BW; single dose	LD50	16
Gambel's quail, *Callipepla gambeli*; 20 mg/kg BW; single dose	LD50-LD57	2, 5, 26
Turkey, *Meleagris gallopavo*; 4.8 (95% CI of 1.2-19.0) mg/kg BW; single dose	LD50	4
Black kite, *Milvus migrans*; 18.5 (95% CI of 15.0-23.2) mg/kg BW; single dose	LD50	8, 10, 13
Parrots, single dose 8 species; 4.0 (95% CI of 0.0-9.3) mg/kg BW	LD50	16

Table 3. Species, dose, and other variables	Effects	Reference[a]
5 species; 5-75 mg/kg BW	LD50	9
House sparrow, *Passer domesticus*; single dose		
2.5 mg/kg BW	LD43	5
3.0 (95% CI of 2.4-3.8) mg/kg BW	LD50-LD100	1, 2, 3, 4, 20, 26
Zebra finch, *Peophila guttata*; fed diet containing 10 mg 1080/kg; equivalent to 11-15 mg/kg BW daily	Maximum fluoroacetate concentrations, in mg/kg FW, were 12.6 in crop, 2.0 in stomach, 2.0 in liver, 6.0 in heart, 3.9 in intestine, and 1.2 in muscle; mean concentrations were about 1 mg/kg FW for all tissues except heart (2.0 mg/kg FW)	21
Ring-necked pheasant, *Phasianus colchicus*; 6.5 (95% CI of 3.9-10.8) mg/kg BW; single dose	LD50	1, 2, 3, 4
Black-billed magpie, *Pica pica*; single dose		
0.67 mg/kg BW	No deaths	5
1.3 mg/kg BW	LD100	5
1.6 mg/kg BW; survivors sacrificed at 24 h	Residues of 1080, in mg/kg FW, in survivors were 0.05-0.34 in muscle and 0.07-0.49 In stomach. Dead birds contained 0.2 mg/kg FW in muscle and 0.25 in stomach	22
2.0, 2.5, or 3.2 mg/kg BW	All dead within 24 h. Mean (max.) 1080 residue concentrations, in mg/kg FW, were 0.4 (0.6),0.7 (1.0) and 0.9 (1.4) in muscle, respectively; for stomach, these values were 0.4 (0.9), 0.7 (1.1), and 1.0 (1.5), respectively	22
Pigeons and doves, single dose		
3 species; 10.6 (6-40) mg/kg BW	LD50	9
5 species; 10.6 (95% CI of 1.9-60.9) mg/kg BW	LD50	8, 16, 26
Red-rumped parrot, *Psephotus haematonotus*; ~5.3 mg/kg BW; single dose	LD50	13
Raptors, 5 species; 9.1 (95% CI of 5.1-13. 1) mg/kg BW; single dose	LD50	16
Seed-eating birds; 4 species; single dose; from Western Australia, exposed to fluoroacetate-bearing vegetation; 25-75 mg/kg BW	LD50	12
Pied currawong, *Strepera graculina*; 13.1 (95% CI of 10.9-15.7)	LD50	8

Table 3. Species, dose, and other variables	Effects	Reference[a]
mg/kg BW; single dose		
Laughing dove, *Streptopelea senegalensis*; 5.9 (95% CI of 4.2-8.2) mg/kg BW; single dose	LD50	9
European starling, *Sturnus vulgaris*		
13.5 mg 1080/kg diet for 4 weeks	Treated birds had slightly lower body weight and testes weight than controls, but differences were not statistically significant	23
27 mg 1080/kg diet	No deaths in 5 days	23
47 (95% CI of 27-108) mg 1080/kg diet for 5 days	50% dead	23
54 mg 1080/kg diet for 5 days	67% dead	23
108 mg 1080/kg diet for 3 days	50% dead	23
198 (95% CI of 119-400) mg 1080/kg diet for 24 h	50% dead	23
432 mg 1080/kg diet for 48 h	All dead	23
Waterfowl, 7 species; 7.1 (95% CI of 1.9-25.6) mg/kg BW; single dose	LD50	16
Mourning dove, *Zenaida macroura*; 8.6-14.6 mg/kg BW; single dose	LD25-LD50	1, 2, 4, 5, 20

[a] 1, Tucker and Haegele 1971; 2, Atzert 1971; 3, Tucker and Crabtree 1970; 4, Hudson et al. 1984; 5, Peacock 1964; 6, Hudson et al. 1972; 7, Kononen et al. 1991; 8, McIlroy 1984; 9, Twigg and King 1989; 10, McIlroy and Gifford 1992; 11, Burns et al. 1991; 12, Twigg et al. 1988b; 13, McIlroy 1983a; 14, McIlroy 1981a; 15, Sayama and Brunetti 1952; 16, McIlroy 1986; 17, Anonymous 1946; 18, Kalmbach 1945; 19, Negherbon 1959; 20, Green 1946; 21, Burke et al. 1989; 22, Okuno et al. 1984; 23, Balcomb et al. 1983; 24, Fry et al. 1986; 25, Robison 1970; 26, Chenoweth 1949; 27, McIlroy 1992.

Some birds poisoned with 1080 either vomited (little crow, *Corvus bennetti*; emu, *Dromaius novaehollandiae*; wedge-tailed eagle, *Aquila audax*; sulphur-crested cockatoo, *Cacatua galerita*) or had saliva or fluid dripping from their beaks (Pacific black duck, *Anas superciliosa*; McIlroy 1984). Early signs of poisoning, such as vomiting, were seen at oral doses of 10 mg/kg BW in various raptors including the rough-legged hawk (*Buteo lagopus*), the ferruginous hawk (*Buteo regalis*), the northern harrier (*Circus cyaneus*), and the great horned owl (*Bubo virginianus*; Atzert 1971). The onset of convulsions was preceded by rapid panting, squawking, shrieking or other vocalizations and then a brief period (5-120s) of violent wing flapping, loss of balance, or paddling or running motions with the feet. Birds then fell to the ground while undergoing tetanic seizures, breathing slowly and laboriously, and having wings and tail outstretched (McIlroy 1984). Turkey vultures (*Cathartes aura*) fatally poisoned by 1080 died 4-32 h after dosing; prior to death, birds displayed tremors, ataxia, lethargy, wing drooping and emesis. Turkey vultures were more sensitive to 1080 at colder temperatures of 8-9° C than at 23-28° C; this may be due to inhibition by 1080 of mitchondrial oxidative phosphorylation at colder temperatures that make animals more sensitive at times of increased metabolic demand (Fry et al. 1986).

Some bird species probably developed a tolerance to 1080 from eating plants that contain fluoroacetate or insects and other organisms that fed on such plants (McIlroy 1984). Birds indigenous to geographic areas of Australia where fluoroacetate-bearing vegetation is abundant were more tolerant to 1080 than birds distributed outside the range of the toxic plants. Fluoroacetate tolerance in birds is postulated to increase with increasing evolutionary exposure to the toxic plants and decreasing mobility (Twigg and King 1989). In the low-nutrient environment of Western Australia, fluoroacetate-tolerant herbivores clearly have a potential advantage over nontolerant herbivores in their broadened choice of fluoroacetate-bearing vegetation in the diet (Twigg et al.

1988b). The most sensitive tested Australian bird was the red-browed firetail (*Emblema temporalis*) with an LD50 of 0.63 mg 1080/kg BW (0.007 mg/whole bird); the most resistant tested bird was the emu with an LD50 of about 250 mg 1080/kg BW or about 8,000 mg/whole bird (McIlroy 1983a, 1984, 1986). Emus in the southwestern portion of Western Australia with evolutionary exposure to fluoroacetate-bearing vegetation unusually have a high tolerance to 1080. The tolerance in emus was attributed to (1) their ability to detoxify fluoroacetate by defluorination; (2) a limited ability to convert fluoroacetate into fluorocitrate; and (3) possession of an aconitase hydratase enzyme that is relatively insensitive to fluorocitrate (Twigg et al. 1988b).

Nontarget species of birds have died after eating 1080-poisoned baits (Spurr 1979; McIlroy 1984; Fry et al. 1986; Hegdal et al. 1986; McIlroy et al. 1986a), although population effects have not yet been demonstrated. Dead birds of several species were found after 1080 baits were applied to kill California ground squirrels (*Spermophilus beecheyi*), but only Brewer's blackbirds (*Euphagus cyanocephalus*) contained measurable 1080 residues. Nontarget seed-eating birds that died after eating 1080-poisoned baits included sparrows, blackbirds, towhees (*Pipilo* spp.), horned larks (*Eremophila alpestris*), McCown's longspurs (*Calcarius mccownii*), chestnut-collared longspurs (*Calcarius ornatus*), and western meadowlarks (*Sturnella neglecta*; Hegdal et al. 1986). Individuals of at least 20 species of Australian birds are at risk from dingo and pig poisoning campaigns with meat baits that contain 14-140 mg 1080/kg bait, and 39 species are at risk from rabbit and pig poisoning campaigns with vegetable baits that contain 330-500 mg 1080/kg bait. The extent of bird mortality and possible population effects depend on several factors: bait palatability to each species; availability of other foods; the amount of ingested 1080; the number of birds in each population that consumes baits before the target species or other nontarget groups; and the rate of 1080 leaching from baits by dew or rainfall (McIlroy 1984). Birds that fed on 1080-poisoned baits for control of wild dogs included the pied currawong (*Strepera graculina*), the Australian raven (*Corvus coronoides*), the Australian magpie, (*Gymnorhina tibicen*), and the wedge-tailed eagle (*Aquila audax*; McIlroy 1981b; McIlroy et al. 1986a). Avian scavengers such as vultures, condors, hawks, and ravens probably find poisoned food items as they search for carcasses (Fry et al. 1986).

Secondary 1080 poisoning of birds is documented. Australian birds that died after eating 1080-poisoned carcasses of pigs (*Sus* sp.) included kites (whistling kite, *Haliastur sphenurus*; black kite, *Milvus migrans*), eagles (Australian little eagle, *Hieraaetus morphnoides*; wedge-tailed eagle), the brown falcon (*Falco bevigora*), the Australian kestrel (*Falco cenchroides*), the brown goshawk (*Accipiter fasciatus*), the Australian magpielark (*Grallina cyanoleuca*), the Australian raven, and crows (Australian crow, *Corvus orru*; little crow, *Corvus bennetti*; McIlroy 1983a). Insectivorous birds that may have died after eating 1080-poisoned ants (*Veromessor andrei*, *Liometopum occidentale*) in the United States included acorn woodpeckers (*Melanerpes formicivorus*), the white-breasted nuthatch (*Sitta carolinensis*), and the ash-throated flycatcher (*Myiarchus cinerascens*; Hegdal et al. 1986).

Little or no secondary hazards were evident--as judged by the absence of carcasses--to raptors (hawks, harriers, eagles, ravens, vultures, and condors) from 1080 poisoning of ground squirrels. However, some species of owls including burrowing owls (*Athene cunicularia*) and barn-owls (*Tyto alba*; Hegdal et al. 1986) were comparatively susceptible to 1080. Raptors are less susceptible to secondary poisoning from 1080 than mammalian predators because birds have higher LD50 values, refuse to eat large amounts of 1080-poisoned meats, and sometimes regurgitate poisoned baits (Hegdal et al. 1986). The reduced hazard of acute 1080 poisoning of raptors from secondary sources is illustrated by the golden eagle (*Aquila chrysaetos*), a bird that normally consumes the internal organs of its prey before consuming other portions of the carcass (Atzert 1971). All golden eagles on diets with 7.7 mg 1080/kg diet--about 3 times the highest concentration of 1080 detected in carcasses of coyotes killed by 1080 in livestock-protection collars--survived, although some eagles showed signs of 1080 intoxication such as loss of strength and coordination, lethargy, and tremors (Bums et al. 1991). A 3.2 kg golden eagle must consume the internal organs of 7 to 30 coyotes killed by 1080 to obtain an LD50 dose (1.25-5.00 mg 1080/kg BW), assuming that each coyote ingested 0.1 mg 1080/kg BW and did not excrete, detoxify, or regurgitate any of the toxicant and that, as in rats, about 40% of the dose is present in the internal organs at death (Atzert 1971). Because the internal organs of a coyote account for 20-25% of its live weight or 2.7-3.2 kg/coyote, and a golden eagle's daily consumption of food is about 30% of its live weight or 0.9 kg (Atzert 1971), raptors are probably not at great risk from consuming coyotes killed by 1080 in livestock-protection collars (Burns et al. 1991).

Human consumers of meat from 1080-killed ducks would probably not be adversely affected after eating an average cooked portion (Temple and Edwards 1985). Moreover, oven-baking or grilling at temperatures of

greater than 200° C causes breakdown of 1080. For example, if a mallard received a triple lethal dose of 1080, then a 1-kg mallard would contain an estimated 14.4 mg of 1080. A 70-kg human must consume 25.4 kg of poisoned duck flesh to receive a lethal dose, as judged by LD50 values of 4.8 mg/kg BW in mallards and 5 mg/kg BW in humans; theoretically, consumption of only two whole ducks poisoned by 1080 may cause transient toxicity (Temple and Edwards 1985).

Bird populations that were reduced in numbers during 1080 poisoning of possums usually recovered quickly if they had a high potential for reproduction and dispersal (Spurr 1979). Birds from Australia or New Zealand with poor reproductive potential and poor dispersal had a high risk of nonrecovery; this group includes the three species of kiwi (*Apteryx* spp.), the takake (*Notornis mantelli*), kakapo (*Strigops habroptilus*), laughing owl (*Sceloglaux albifacies*), bush wren (*Xenicus longipes*), rock wren (*Xenicus gilviventris*), fernbird (*Bowdleria punctata*), yellowhead (*Mohoua ochrocephala*), stitchbird (*Notiomystis cincta*), saddleback (*Philesturnus carunculatus*), kokako (*Callaeas cinera*), and New Zealand thrush (*Turnagra capensis*; Spurr 1979, 1993). Control of wild dogs, dingoes, and their hybrids with 1080 meat baits did not significantly affect nontarget populations of birds in the treated areas (McIlroy et al, 1986b). Baiting with 1080 to control rabbits and foxes in Australia usually had no significant permanent adverse effects on nontarget birds, although the abundances of 15 of the 30 bird species in the treated areas tended to decline during the poisoning campaign, especially welcome swallows (*Hirundo neoxena*), tree martins (*Hirundo nigricans*), and crimson rosellas (*Platycercus elegans*; McIlroy and Gifford 1991). Aerial drops of 1080-laced pellets (11.8 kg/ha) to control brushtail possums and rock wallabies (*Petrogale penicillata*) on Rangitoto Island, New Zealand, had no observed effect on island bird populations during the next 12 months (Miller and Anderson 1992). No species of bird showed a population decline and several showed significant increases in numbers, including the greenfinch (*Carduelis chloris*), Australian harrier hawk (*Circus approximans*), and tui (*Prosthemadera novae-seelandiae*). Increases were attributed to the reduction in numbers of mammalian browsers that increased vegetation and improved habitat for nontarget bird species (Miller and Anderson 1992).

The mortalities of nontarget birds from 1080 poisonings may be underreported because many die in their nests or roosts and are never found (Koenig and Reynolds 1987). Dead raptors of several species were found shortly after application of 1080 baits; however, no 1080 residues were detected in any of these birds and the causes of death were not established (Hegdal et al. 1986). Application of 1080 baits to control California ground squirrels was associated with deaths of yellow-billed magpies (*Pica nuttalli*) that contained about 1.02 mg 1080/kg FW of internal organs (Koenig and Reynolds 1987) in contrast to 0.6-0.7 mg 1080/kg FW in stomachs of black-billed magpies (*Pica pica*) that were treated with lethal doses of 1.6-3.2 mg 1080/kg BW (Okuno et al. 1984). Whether *P. nutalli* ingested the 1080 bait directly, ate other poisoned animals, or both is not known (Koenig and Reynolds 1987). Risks of 1080 poisoning to birds can be reduced by (1) setting meat baits out just before sunset and removing them early next morning; (2) burying baits for pigs below ground; (3) using baits that only the target animals prefer; (4) reducing the number of available small bait fragments; and (5) masking the appearance of baits and enhancing their specificity with dyes--although some birds in Australia seem to prefer green-dyed meat baits (McIlroy 1984; McIlroy et al. 1986a).

Mammals

Studies with mammals (Table 4) showed several trends: (1) individuals of sensitive species including species of livestock, marsupials, felids, rodents, and canids died after receiving a single dose between 0.05 and 0.2 mg/kg BW; (2) most individuals of tested species died after a single dose between 1 and 3 mg/kg BW; (3) a latent period was evident between exposure and signs of intoxication; (4) mortality patterns usually stabilized within 24 h after exposure; (5) species from fluoroacetate-bearing vegetation areas were more resistant than conspecifics from nonfluoroacetate vegetation areas; (6) the route of administration had little effect on survival patterns; (7) younger animals were more sensitive than adults; (8) high residues were in some 1080-poisoned animals, notably rabbits with 34 mg/kg DW muscle and 423 mg/kg DW liver; (9) secondary poisoning was evident among carnivores after eating 1080-poisoned mammals; and (10) sublethal effects included testicular damage in rats after drinking water containing 2.2-20.0 mg 1080/L for 7 days (0.07-0.71 mg/kg BW daily), impaired reproduction in mink on diets containing 0.8 mg 1080/kg ration for 60 days, and altered blood chemistry in ferrets on diets containing 1.1 mg 1080/kg ration for 28 days.

Table 4. Effects of 1080 on representative mammals.

Table 4. Species, dose, and other variables	Effects	Reference[a]
Arctic fox, *Alopex lagopus*		
Fed a single bait containing 4 mg of 1080	Muscle contained 0.39 (0.24-0.65) mg 1080/kg fresh weight (FW)	1
Muscle from 66 foxes found dead on Kiska Island, Alaska, after 1080 poisoning. Analysis 60 days after collection	Muscle from males contained 0.7 (0.12-2.2) mg 1080/kg FW; for females, it was 0.81 (0.09-2.8) mg/kg FW	1
Brown antechinus, *Antechinus stuartii*		
1.1-3.5 mg/kg body weight (BW)	LD50, from nonfluoroacetate-bearing vegetation area	2, 3, 4
11.0 mg/kg BW	LD50, from fluoroacetate vegetation area	4
Dusky antechinus, *Antechinus swainsonii*; 3.2 (95% confidence interval [=CI] of 2.4-4.2) mg/kg BW	LD50	3
Black-handed spider monkey, *Ateles geoffroyi*; 10.0-15.0 mg/kg BW	LD50	5, 6, 7, 8
Australian mammals, various; 1.6-20.0 mg/kg BW	Lethal to 8 species of marsupials and 5 species of rodents	9
Australian rodents		
3.1 (0.7-9.0) mg/kg BW	LD50 mean (range) for 10 species with no known exposure to naturally occurring fluoroacetates	10
21.6 (3.5-80.0) mg/kg BW	LD50 mean (range) for 10 species with known past or continuing exposure to naturally occurring fluoroacetates	10
Burrowing bettong, *Bettongia*. *leseuer*; 10-20 mg/kg BW	LD50	11
Cow, *Bos* spp; single dose		
0.078 mg/kg BW	Not fatal to calves and adults	12
0.156 mg/kg BW	Not fatal to cows; LD20 for calves	12
0.22 (95% CI of 0.15-0.33) mg/kg BW	LD50 for steers and calves	5, 11, 12
0.312 mg/kg BW	LD67 for cows; LD80 for calves	12
0.39 (95% CI of 0.25-0.63) mg/kg BW	LD50 for Hereford cows	5, 11
0.624 mg/kg BW	LD100 for cows and calves	12
Canids, 6 species; 0.15 (95% CI of <0.1-0.3) mg/kg BW	LD50	13
Dog, *Canis familiaris*		
0.06 mg/kg BW, single oral dose	LD50; death in 5-9 h	6, 14
0.1-0.35 mg/kg BW, single oral dose	LD100; death in 4-6 h	6, 7, 14, 15, 16
Ingested about 1.96 mg of 1080 (56 g of a 1080-poisoned bait containing 35 mg 1080/kg horse meat)	Vomiting at 1.75 h postingestion; seizure and a short yip 20 min later; seizures and exhaustion for the next 50 min; death at about	16

Table 4. Species, dose, and other variables	Effects	Reference[a]
	3 h after ingestion	
Dingo, *Canis familiaris dingo*		
0.11 (95% CI of 0.09-0.15) mg/kg BW	LD50	3
0.123 (95% CI of 0.110-0.137) mg/kg BW	LD99	13
Coyote, *Canis latrans*		
Fed 1080-poisoned ground squirrels (*Spermophilus* sp.); that contained 0.01-0.09 mg fluoroacetate/kg FW	Maximum residues in dead coyotes, in mg 1080/kg FW, were 0.14 in large intestine, 0.09 in kidney, 0.07 in brain, 0.05 in stomach, and 0.03 in liver	17
0.1-0.2 mg/kg BW	LD50	5, 6, 7, 8, 16
0.13-0.16 mg/kg BW by gavage	Muscle residues were 0.10-0.11 mg/kg FW	18
0.23-0.5 mg/kg BW; poisoned bait	Muscle residues of 0.08-0. 15 mg/kg FW	18
0.5-1.0 mg/kg BW by gavage	Muscle residue of 0.08-0.15 mg/kg FW	18
1 mg/kg BW; poisoned bait	Muscle residue of 0.21 mg/kg FW	18
Ingestion of bait containing 5 mg 1080 (about 2.28 mg 1080/kg BW)	Signs of poisoning noted in 17-18 min after bait ingestion; death in 243 to 313 min after ingestion	19
Single lethal oral dose of 5 mg/kg BW		
Nonrefrigerated muscle tissue	Muscle contained 2.3 mg/kg FW <3 h after death; 1.5 mg/kg FW at 7 days	18
Frozen muscle tissue	Residue of 2.3 mg/kg FW after 30 days, 2.1 mg/kg FW after 60 days	18
Room temperature, muscle tissue	Residues ranged from 1.8-2.0 mg/kg FW between <3 h and 28 days	18
<3 h after death	Residues, in mg/kg FW, were 11.0 in stomach; 2.1-2.4 in heart, muscle, kidney and intestine; and 1.2 in liver	18
30.0 mg/kg BW by gavage	19.5 mg/kg FW in muscle	18
In pen tests, 25 coyotes were offered lambs with collars containing 5 or 10 mg 1080/mL	A total of 23 coyotes attacked and 21 died after collars were punctured in their first (n = 17), second (n = 3), or fifth (n = 1) tests. The average time to death was 217 min (range 115-436 min)	20
Goat, *Capra* sp.		
0.1 mg/kg BW; single oral dose	Half-time persistence of 5.4 h in plasma	21
0.3-0.7 mg/kg BW	LD50	5, 6, 7, 8, 11, 16
Guinea pig, *Cavia* spp.		
0.18 mg/kg BW	LD50 at 4° C	22

Table 4. Species, dose, and other variables	Effects	Reference[a]
0.23 mg/kg BW	LD50 at 32° C	22
0.38 mg/kg BW	LD50 at 17° C	22
0.39 mg/kg BW	LD50 at 24° C	22
Ground squirrels, *Citellus* spp.; 0.3-0.9 mg/kg BW	LD50	5, 6, 7, 15, 16
Hamsters, *Cricetus* spp.; 3.0 mg/kg BW	LD50	6
Black-tailed prairie dog, *Cynomys ludovicianus*		
0.125 mg/kg BW	No deaths	7, 23
0.17-0.3 mg/kg BW	LD50	5, 8, 23, 50
0.4-2.5 mg/kg BW	LD50-LD100	15, 16, 50
Dasyurids, 11 species; 3-12 mg/kg BW	LD50	24
Kowari, *Dasyuroides byrnei*; ~2.8 mg/kg BW	LD50	3
Northern native cat, *Dasyurus hallucatus*; 5.7 (95% CI of 3.9- 8.2) mg/kg BW	LD50	3
Tiger cat, *Dasyurus* *maculatus*; 1.8 (95% CI of 1.3-2.7) mg/kg BW	LD50	3
Quolls, *Dasyurus* spp.		
1.5 mg/kg BW	LD50, nontolerant population from southeastern Australia	4
7.5 mg/kg BW	LD50, tolerant populations from Western Australia	4
Eastern native cat, *Dasyurus viverrinus*; 3.7 (95% CI of 3.2- 4.4) mg/kg BW	LD50	3
Opposum, *Didelphis* *virginana*; 60.0 mg/kg BW	LD50	5
Kangaroo rats, *Dipodomys* spp.		
0.1-0.2 mg/kg BW	LD47-LD85	5, 6, 16
0.2-1.0 mg/kg BW	LD100	16
Mule, *Equus asinus* X *E. caballus*; 0.22-0.44 mg/kg BW	LD50	5, 11, 25
Horse, *Equus caballus*; 0.32-1.00 mg/kg BW	LD50	5, 6, 7, 8, 11, 12, 16, 25
North American porcupine, *Erethizon dorsatum*; ~1.0 mg/kg BW	LD50	5
Eutherian mammals, Australia		
0.36 (95% CI of 0.04- 3.5) mg/kg BW	LD50, 13 species of carnivores	13
0.44 (95% CI of 0.21- 0.60) mg/kg BW	LD50, 7 species of herbivores	13
Feral cat, *Felis cattus*		
0.1-0.19 mg/kg BW	No deaths using poisoned fish baits	26

Table 4. Species, dose, and other variables	Effects	Reference[a]
0.2-0.3 mg/kg BW	LD50, intravenous injection	26
0.28 (95% CI of 0.07-0.49) mg/kg BW	LD50, poisoned fish baits	26
0.35 mg/kg BW	LD50, acute oral route	26
0.35 mg/kg BW	LD90, poisoned fish baits	26
0.4 (95% CI of 0.31-0.52) mg/kg BW	LD50, oral intubation	3
1.3 mg/kg BW	All dead within 24 h when ingested as a fish bait	26
Domestic cat, *Felis cattus*		
0.2-0.3 mg/kg BW	LD50	5, 6, 7, 8, 16
0.5 mg/kg BW	LD100	16
Breviceps pocket gopher, *Geomys breviceps*		
<0.05 mg/kg BW	LD50	5, 6
0.05 mg/kg BW	LD100	16
Tuza pocket gopher, *Geomys floridanus*		
0.2 mg/kg BW	LD50	5, 6
0.25-0.5 mg/kg BW	LD60-LD100	16
Human, *Homo sapiens*		
0.7-2.1 mg/kg BW	LD50 (estimated)	5
2.0 mg/kg BW	LD100 (estimated) for children	16
2.0-10.0 mg/kg BW	LD50 (estimated) for adults	6, 27
Water-rat, *Hydromys chrysogaster*, 2.9 mg/kg BW	LD50	28, 29
Golden bandicoot, *Isoodon auratus barrowensis*; 8.9 (95% CI of 7.2-11.0) mg/kg BW	LD50	30
Northern brown bandicoot, *Isoodon macrourus*; 3.5 mg/kg BW	LD50	30, 31
Southern brown bandicoot, *Isoodon obesulus*		
7.0-8.0 mg/kg BW	LD50; maximum latent period, 183 h; time until death, 7-206 h; time for survivors to recover, 27 h	30, 31
20.0 mg/kg BW; from area of fluoroacetate-bearing vegetation	Tolerated	30
Southern hairy-nosed wombat, *Lasiorhinus latifrons*; 0.21 (95% CI of 0.15-0.29) mg/kg BW	LD50	11
Black-tailed jack rabbit, *Lepus californicus*; 5.6 mg/kg BW	LD50	5, 11
Bobcat, *Lynx rufus*; 0.67 mg/kg BW	LD50-LD100	7, 8, 16
Rhesus monkey, *Macaca mulatta*; 4-12 mg/kg BW	LD50	5, 6, 7, 16
Macropodids, 7 species; 0.23 (95% CI of 0.1-0.6) mg/kg BW	LD50	13
Agile wallaby, *Macropus agilis*; 0.22 mg/kg BW	LD50	11

Table 4. Species, dose, and other variables	Effects	Reference[a]
Tammar wallaby, *Macropus eugenii*		
0.15 mg/kg BW	LD50, pouch young	11
0.27 mg/kg BW vs. 2.0-10.0 mg/kg BW	LD50, adults from nonfluoroacetate- vs. fluoroacetate-vegetation areas	11
Gel containing 12.5 mg 1080 applied to a single leaf of edible foliage	Population reduced 91% in North Island, New Zealand field trial	32
Marsupials		
Various species; fatally poisoned with 1080 under laboratory conditions	Mean residue concentrations, in mg 1080/kg FW, were 0.2 in muscle, 6.1 in viscera, and 29.7 in stomach and contents	33
0.25 (95% CI of 0.1-0.7) mg/kg BW; 10 species of herbivores	LD50, eastern Australia (nonfluoroacetate-vegetation area)	10, 13
2.6 (95% CI of 0.9-7.6) mg/kg BW; 9 species of carnivores	LD50	13
24.2-42.0 (95% CI of 1.5-389.4) mg/kg BW; 10 species of herbivores	LD50, Western Australia (fluoroacetate-vegetation area)	10, 13
From area of fluoroacetate-bearing vegetation		
Red kangaroo, *Macropus rufus*; 2.0-4.4 mg/kg BW	LD50	11
Western brush wallaby, *Macropus irma*; 5-10 mg/kg BW	LD50	11
Western gray kangaroo, *Macropus fuliginosus*; 40-60 mg/kg BW	LD50	11
Brush-tailed bettong, *Bettongia penicillata* and banded hare-wallaby, *Lagostrophus fasciatus*; 100-200 mg/kg BW	LD50	11
Eastern gray kangaroo, *Macropus giganteus*; 0.1-0.4 mg/kg BW	LD50	11
Bennett's wallaby, *Macropus rufogriseus*		
0.2 mg/kg BW	LD50	11
Gel containing about 25 mg 1080 applied to single leaf of edible foliage	Population reduced 87% in South Island, New Zealand, field trial	32
Greater bilby (bandicoot), *Macrotus lagotis*; 15 mg/kg BW; from area of fluoroacetate-bearing vegetation	Tolerated	30
Marten, *Martes martes*; ~1.0 mg/kg BW	LD50	5
Grassland melomys rat, *Melomys burtoni*; 2.6 (95% CI of 2.2-3.1) mg/kg BW	LD50	28

Table 4. Species, dose, and other variables	Effects	Reference[a]
Striped skunk, *Mephitis mephitis*		
Diet		
Fed diet containing 4.1 mg 1080 kg/ration for 5 days (about 2 times level found in 1080-poisoned coyotes)	No deaths or signs of poisoning other than reduced feeding and loss in body weight	35
Fed coyote muscle for 14 to 35 days; coyote had been poisoned with massive (400 mg) dose of 1080	Fatal to all 3 skunks tested	19
Single dose		
0.125 mg/kg BW	No deaths in 7 days	34
0.25 mg/kg BW	LD40	34
0.35 (95% CI of 0.21-0.54) mg/kg BW	LD50	34
0.75 mg/kg BW	LD100	34
Tristram jird, *Meriones tristrami*; fed wheat grain baits		
0.38-0.47 mg/kg BW	50% dead in 3 days	36
1.7-2.5 mg/kg BW	All dead within 24 h	36
Levant vole, *Microtus guentheri*; fed wheat grain baits		
0.24-0.43 mg/kg BW	LD50	36
0.44 mg/kg BW	LD73	36
2.0-2.5 mg/kg BW	All dead within 24 h	36
Meadow mouse, *Microtus haydeni*; 0.3-0.5 mg/kg BW	LD33-LD100	16
Meadow vole, *Microtus pennsylvanicus*; 0.92 mg/kg BW	LD50	5
House mouse, *Mus musculus*		
2.6 mg/kg BW	LD50 at 12.2° C	22
4.5 mg/kg BW	LD50 at 33° C	22
5.8 mg/kg BW	LD50 at 17.9° C	22
7.4 mg/kg BW	LD50 at 30° C	22
8.3 (95% CI of 6.3-11.0) mg/kg BW	LD50	28
10.0 mg/kg BW	LD66	16
12.8 mg/kg BW	LD50 at 24° C	22
Mice, *Mus* spp.		
5.0-19.3 mg/kg BW	LD50	6, 14
13.5 (95% CI of 11.0-16.6) mg/kg BW	LD50; survivors exhibited persistent abnormal behavior ranging from circling to resting with their heads tucked under the abdomen or brisket	37
15 mg 1080/kg BW alone, or followed by intraperitoneal injection of mixture of 130 mg calcium glutonate/kg BW plus 240 mg sodium succinate/kg BW	Alone, 1080 resulted in 80% dead in 48 h and 100% in 120 h. If antidote is administered within 15 min of 1080 exposure, survival increased to 70% at 48 h and 50% at 120 h after 1080 treatment; antidote survivors	37

Table 4. Species, dose, and other variables	Effects	Reference[a]
	recovered much earlier and resumed feeding within 3 days of 1080 injection	
150 mg 1080/kg bait	In pen tests, population numbers were reduced 88% in 20 days	38
Domestic ferret, *Mustela putorius*		
1.41 (95% CI of 1.00-2.00) mg/kg BW	LD50	39
Fed one 1080-poisoned white-footed mouse (*Peromyscus leucopus*) equivalent to 1, 2, 4, or 8 mg/kg BW ferret	All died at all doses except 1 ferret at 2 mg/kg BW	39
European ferret, *Mustela putorius furo*		
Fed internal organs for 3 days of 1080-killed black-tailed prairie dogs	1 of 10 ferrets died and 5 others showed signs of 1080 poisoning; all affected ferrets recovered 24-48 h after exposure	50
Fed ground whole carcasses (less skin, skull, and feet) of black-tailed prairie dogs that died of 1080 poisoning. Carcasses contained 0.05-0.1 mg fluoroacetate/kg FW and composed 90% of diet	No adverse effects after 28 days	23
1.1 mg/kg diet for 28 days	Reduction in red and white blood cell numbers	40
1.2-1.4 mg/kg BW, single dose	LD50	5, 25, 40, 50
9.4 mg/kg diet for 28 days	LD50	40
Mink, *Mustela vison*		
0.1 mg/kg BW	No deaths in 3 days	40
0.25 mg/kg BW	50% dead in 3 days	40
0.5 mg/kg BW	2.5 to 2.8 h to death	40
0.8 mg/kg diet for 2 months prior to breeding	Impaired reproduction	40
1.0 mg/kg BW	1.5 h to death	40
2.9 mg/kg diet for 28 days	40% dead	40
3.2 (95% CI of 2.4-4.5) mg/kg diet for 28 days	50% dead	40
5.25 mg/kg diet for 28 days	Partial paralysis of hind limbs and reduced feed intake by day 5; 90% dead at 28 days	40
Nutria, *Myocastor coypus*; 0.6 mg/kg BW	LD50	5
White-throated wood rat, *Neotoma albigula*		
<0.8 mg/kg BW	LD50	5
0.8 mg/kg BW	LD100	16
Wood rat, *Neotoma intermedia*		
1.0 mg/kg BW	LD20	16
1.5 mg/kg BW	LD50	5
2.0 mg/kg BW	LD100	16

Table 4. Species, dose, and other variables	Effects	Reference[a]
Spinifex hopping mouse, *Notomys alexis*; 32.7 (95% CI of 27.4-39.3) mg/kg BW	LD50	28
Mitchell's hopping mouse, *Notomys mitchelli*; 19.4 (95% CI of 15.8-23.9) mg/kg BW	LD50	28
Mule deer, *Odocoileus hemionus hemionus*; 0.3-1.0 mg/kg BW	LD50, 8-11 months of age	5, 11, 25, 39
European rabbit, *Oryctolagus cuniculus*		
Found dead after consuming 1080-treated carrots; New South Wales, Australia; February 1986	Maximum concentrations of 1080, in mg/kg DW, were 263 in kidney, 423 in liver, 151 in heart, 34 in muscle, 136 in stomach, and 243 in stomach contents. Total 1080 content was 7.04 mg whole body and 4.87 mg in whole body less stomach and contents	33
0.36 (95% CI of 0.30-0.42) mg/kg BW	LD50, immatures	
0.42 (95% CI of 0.26-0.58) mg/kg BW	LD50, adults	
0.51 (95% CI of 0.44-0.58) mg/kg BW	LD90	
Fed pellets containing 10 mg 1080/kg pellet	All dead within 6 h	41
Sheep, *Ovis aries*		
0.1 mg/kg BW; single oral dose	Residues after 2.5 h, in mg/kg, were 0.1 in plasma and 0.02-0.06 in other tissues; after 96 h the maximum value in any tissue was 0.003 mg/kg. Half-time persistence of 1080 in plasma was 10.8 h	21
0.25-0.64 mg/kg BW	LD50	5, 11
2.0 mg/kg BW	LD50	6, 12
Gunn's bandicoot, *Perameles gunni*; 5.4 mg/kg BW	LD50; latent period, 2-6 h; time until death, 4-86 h	31
Long-nosed bandicoot, *Perameles nasuta*; 7.7 (95% CI of 5.3-11.2) mg/kg BW	LD50; maximum latent period, 6.4 h; time until death 4-56 h; time for survivors to recover, 26-42 h	3, 31
Pocket mouse, *Perognathus inornatus*; 1.0 mg/kg BW	LD100	16
Deer mouse, *Peromyscus sp*.		
2.0-4.0 mg/kg BW	LD39-LD50	16
4.0-5.0 mg/kg BW	LD50	5, 6, 15
Raccoon, *Procyon lotor*; single oral dose		
Ambient air temperature of 23-27° C vs. 13-23° C		
0.5 mg/kg BW	LD40 vs. none dead	42

Table 4. Species, dose, and other variables	Effects	Reference[a]
1.0-1.85 mg/kg BW	LD60 vs. LD20	42
2.45 mg/kg BW	LD80 vs. LD60	42
2.82 mg/kg BW	LD100 vs. LD75	42
3.24 mg/kg BW	All dead	42
Plains mouse, *Pseudomys australis*; 1.2 (95% CI of 1.1-1.4) mg/kg BW	LD50	28
Sandy inland mouse, *Pseudomys hermannsburgensis*		
1.6 (95% CI of 1.3-2.0) mg/kg BW	LD50, New Zealand	9
39.3 (95% CI of 23.6-65.4) mg/kg BW	LD50, Australia	28
Long-tailed mouse, *Pseudomys higginsi*; 9.0 (95% CI of 6.2-13.1) mg/kg BW	LD50	28
Western chestnut mouse, *Pseudomys nanus*; 14.7 (95% CI of 13.7-15.9) mg/kg BW	LD50	28
Alexandrine rat, *Rattus alexandricus*		
0.5 mg/kg BW	LD50	5, 6
1.0-2.0 mg/kg BW	LD92-LD100	16
Bush rat, *Rattus fuscipes*; 1.1 (95% CI of 0.9-1.5) mg/kg BW	LD50	28, 29
Swamp rat, *Rattus lutreolus*; 1.7 (95% CI of 1.4-2.1) mg/kg BW	LD50	28
Norway rat, *Rattus norvegicus*		
0.22-3.0 mg/kg BW	LD50, wild strains	6, 43
2.0 mg/kg BW	Oxygen consumption reduced 28-57% in 24 h	43
2.1-2.2 mg/kg BW	LD50, laboratory strains	5
3.0 mg/kg BW	5-fold increase in plasma citrate levels in 4 h	43
4.0-8.0 mg/kg BW	LD72-LD100	16
Black rat, *Rattus rattus*; 1.7 (95% CI of 1.2-2.4) mg/kg BW	LD50	28
Canefield rat, *Rattus sordidus*; 1.3 (95% CI of 1.0-1.6) mg/kg BW	LD50	28, 29
Laboratory white rat, *Rattus* sp.		
Single dose		
0.2 mg/kg BW	LD50	27
4.0 mg/kg BW	LD60	16
7.5 mg/kg BW	LD100	16
10.53 mg radiolabelled 1080/kg BW	After 4 h, radioactivity was highest in carcass (60%), liver (12%), intestine and stomach (10%) and brain, kidney, testes, and spleen (2-3% each)	5
Multiple doses		
Males given drinking water containing 2.2, 6.6, or 20 mg	No overt signs of acute toxicity in any group. However, all groups	44

Table 4. Species, dose, and other variables	Effects	Reference[a]
1080/L for 7 days then observed for 21 days. Daily dose rates, in mg/kg BW, were 0.07 (2.2 mg/L), 0.18 and 0.71 (20 mg/L), respectively	had testes damage (altered appearance, decreased number of spermatids, formation of spermatid and spermatocyte giant cells). The two high dose groups had reduction in testicular weight and seminiferious tubule atrophy; regeneration of tubules was incomplete at day 21 postexposure	
Tunney's rat, *Rattus tunneyi*; 2.6 (95% CI of 2.2-2.9) mg/kg BW	LD50	9
Rodents, 32 species		
<0.1 mg/kg BW	LD50, 4 species	28
0.1-0.25 mg/kg BW	LD50, 6 species	28
0.26-1.0 mg/kg BW	LD50, 15 species	28
>1.0 mg/kg BW	LD50, 7 species	28
Rodents, various, single dose		
0.83 (95% CI of 0.1-6.3) mg/kg BW	LD50, 11 species of cricetids	13
1.05 (95% CI 0.02-2.1) mg/kg BW	LD50, 5 species of *Rattus*	13
2.0-20.0 mg/kg BW	Lethal, 8 species	24
19.4 (95% CI <0.05-48.1) mg/kg BW	LD50, 6 species of pseudo-mice	13
Tasmanian devil, *Sarcophilus harrisii*; 4.2 (95% CI of 2.8-6.6) mg/kg BW	LD50	3
Quokka (kangaroo), *Setonix brachyurus*		
3.5 mg/kg BW	Nontolerant populations had significantly increased plasma citrate levels in 12 h, but none died	45
10-40 mg/kg BW	10 mg/kg BW killed 50% of a nontolerant population; tolerant populations survived	45
60 mg/kg BW	All populations dead within 12 h; plasma citrate levels elevated	45
Cotton rat, *Sigmodon hispidus*		
0.1 mg/kg BW	LD50	5, 6, 16
5.0 mg/kg BW	LD100	16
Fat-tailed dunnart, *Sminthopsis crassicaudata*; 2.1 (95% CI of 1.6-2.7) mg/kg BW	LD50	3
Stripe-faced dunnart, *Sminthopsis macroura*; 0.9 (95% CI of 0.6-1.6) mg/kg BW	LD50	3
Ground squirrel, *Spermophilus beecheyi*; fatally poisoned with 1080		
0.8 mg/kg BW	Tissue residues, in mg fluoroacetate/kg FW, were	17

Table 4. Species, dose, and other variables	Effects	Reference[a]
	0.2-0.7 in brain, kidney, liver, muscle, and lung; 1.0 in caecum; 1.3 in spleen; and 11.8 in stomach	
4.8 mg/kg BW	Tissue residues, in mg fluoroacetate/kg FW, were 0.5-0.7 in brain and muscle; 1.1-1.8 in caecum, kidney, liver, and lung; 9.7 in spleen; and 55.9 in stomach	17
Feral pig, *Sus scrofa*		
0.4 mg/kg BW	LD50, juveniles	46
<1.0 mg/kg BW	LD50, adults	46
1.0 (95% CI of 0.8-1.3) mg/kg BW	LD50	29
1.8 (95% CI of 1.3-185.9) mg/kg BW	LD95	29
2.3 (95% CI of 1.6-3,381) mg/kg BW	LD99	29
4.3 mg/kg BW	LD28 with pellet baits; LD60 with wheat baits	47
21.3 mg/kg BW	LD100; median time to death of 244 min (range 131-7,200 min)	47
Domestic pig, *Sus* sp.		
0.3-0.4 mg/kg BW	LD50, juveniles	5, 7, 8, 16
<1.0 mg/kg BW	LD50, adults	5
Badger, *Taxidea taxus*; 1.0-1.5 mg/kg BW	LD50-LD100	5, 16
Red-bellied pademelon, *Thylogale billardierii*; 0.13 (95% CI of 0.09-0.19) mg/kg BW	LD50	11, 31
Brush-tailed possum, *Trichosurus vulpecula*		
0.3-1.0 mg/kg BW	LD50, from nonfluoroacetate vegetation area	2, 11
16.9 (95% CI of 11.6-24.7) mg/kg BW	LD50 at 10.5° C	22
41.2 (95% CI of 30.2-56.1) mg/kg BW	LD50 at 23.5° C	22
>100->125 mg/kg BW	LD50, from fluoroacetate-bearing vegetation area	11, 45
Gray fox, *Urocyon cinereoargenteus*; 0.3 mg/kg BW	Lethal	5, 16
Bears, *Ursus* spp.; 0.5-1.0 mg/kg BW	LD50	5
Common wombat, *Vombatus ursinus*		
0.15 (95% CI of 0.12-0.19) mg/kg BW	LD50, free-ranging	11
0.22 (95% CI of 0.18-0.27) mg/kg BW	LD50, captive wombats	11
Desert kit fox, *Vulpes*		

Table 4. Species, dose, and other variables	Effects	Reference[a]
macrotis arsipus		
0.22 (95% CI of 0.15-0.34) mg/kg BW; single dose	LD50	48
Fed a 1080-poisoned kangaroo rat (*Dipodomys* sp.). Approximate dose to fox of 0.434 mg/kg BW	Death within 12 h	48
Red fox, *Vulpes vulpes*		
0.08-0.10 mg/kg BW	No deaths	49
0.125-0.15 mg/kg BW	All dead	49
Thick-tailed rat, *Zyzomys argurus*; 3.2-5.8 mg/kg BW	LD50	9
